Antioxidant-Restricted Diet Reduces Plasma Nonesterified Fatty Acids in Trained Athletes

Trent A. Watson[a], Robert J. Blake[a], Robin Callister[b], and Manohar L. Garg[a],*

[a]Nutrition & Dietetics, School of Health Sciences, and [b]Human Physiology, School of Biomedical Science, University of Newcastle, New South Wales, 2308, Australia

ABSTRACT: Nonesterified FA (NEFA) are a major fuel source for humans at rest and during moderate exercise. The effect of dietary antioxidant restriction on plasma NEFA levels and exercise performance in trained athletes was examined. Seventeen athletes followed a 2-wk restricted-antioxidant (R-AO) diet, which resulted in a threefold reduction in antioxidant intake (ascorbic acid, 139 to 49 mg; β-carotene, 5093 to 1142 μg) and a significant ($P = 0.001$) reduction in the plasma NEFA. The amount and types of fat consumed were not different between the R-AO and habitual diets. Exercise time to exhaustion was not affected by the R-AO diet, but rating of perceived exertion (RPE) was significantly ($P = 0.03$) elevated. The increase in RPE may have occurred as a result of the R-AO diet and subsequent reduction in plasma NEFA; however, further research is required to confirm this conclusion.

Paper no. L9675 in *Lipids* 40, 433–435 (April 2005).

Nonesterified FA (NEFA) are a major fuel source for humans at rest and during exercise (1–4). Thus, a reduced availability of NEFA may influence exercise performance (5). A number of factors are known to influence an individual's available FA and ability to oxidize them as a fuel. These include exercise intensity and duration (4,6), training status (7,8), total and lean body weight (9), and diet.

Dietary intakes of fat and carbohydrate are known to influence plasma NEFA (10) and fat oxidation rates (11), which is where most researchers have focused their attention.

We previously reported that a restricted-antioxidant (R-AO) diet increases oxidative stress and increases the rating of perceived exertion (RPE) of athletes completing a 30 min submaximal run (12). Since NEFA has a significant role in exercise metabolism, the present study examined the effects of an R-AO diet and subsequent increase in oxidative stress on plasma NEFA levels and exercise performance in trained athletes.

EXPERIMENTAL PROCEDURES

Subjects. Healthy, well-trained male endurance-running athletes ($n = 17$) were recruited to participate in the study. All subjects were between 18 and 35 yr, were nonsmokers, and for at least 3 mon before the study had not taken any vitamin or mineral supplements or medication. The study was approved by the Human Research Ethics Committee of the University of Newcastle.

Study design. The study design has been described in detail previously (12). Briefly, subjects were required to attend the laboratory on three occasions. During the first visit, height, weight, skinfold thickness, and maximal oxygen uptake (VO$_2$max) were measured. The VO$_2$max was conducted using an incremental treadmill test to exhaustion. Before visits two and three, subjects completed a 4-d weighed-food record. Subjects followed their habitual (H-AO) diets prior to visit two and a restricted-antioxidant (R-AO) diet for 2 wk between visits two and three. During visits two and three, subjects were required to undertake a running test to exhaustion (30 min 60% VO$_2$ max, incremental to exhaustion) and provided blood samples for analysis of plasma NEFA. Four blood samples were collected: (i) at rest, (ii) after 30 min of submaximal exercise, (iii) immediately post high-intensity exhaustive exercise, and (iv) after 1 h of recovery. Time to exhaustion and Borgs RPE (13) were also measured.

The R-AO diet required participants to limit fruit and vegetables to one and two servings per day, respectively, and to avoid other foods high in antioxidants including tea, offal meat, wheat germ oil, and cod liver oil. Record *et al.* (14) used this protocol and reduced plasma concentrations of antioxidants in a 2-wk period. Participants in the present study were also encouraged to replace whole-grain breads and cereals with more processed varieties and to avoid antioxidant additives in processed foods.

NEFA analysis. NEFA were determined using the method established by Welz *et al.* (15). To 75 μL of plasma was added 2.5 mL of methanol/toluene (50:1 vol/vol) along with 75 μL of 21:0 free acid (0.04 mg/mL) as an internal standard, and then vortexed vigorously. To promote methylation, samples were incubated at 25°C for 45 min; this mixture was vortexed vigorously for 5 min, and then 1.25 mL of 6% K$_2$CO$_3$ was slowly added to stop the reaction. Hexane (75 μL) was added to the sample, which was then vortexed for 2 min and centrifuged at $3000 \times g$ at 4°C for 10 min to facilitate separation of layers. The latter two processes were conducted a second time to ensure the separation of layers. The upper hexane layer (approximately 100 μL) containing the FAME was then transferred to a 2-mL glass vial, containing a 200-μL high-recovery insert, and crimp-sealed with a Teflon-lined cap for subsequent analysis by GC using a 30 m × 0.25 mm (DB-225) fused carbon-silica

column, coated with cyanopropylphenyl (J&W Scientific, Folsom, CA).

Statistical analysis. FA data were analyzed by repeated-measures analysis using the PROC MIXED model of SAS (1996; SAS Institute, Cary, NC). The MIXED model procedure was used to account for covariation within and between subjects over time (16). The MIXED model procedure of SAS provides a range of covariance structures to model for covariation. Once the covariance structure was modeled, inferences about fixed effects were established as generalized least squares (LS) means and SE estimates for intervention and time differences (16). The study has a power of 80% to detect differences in means. Statistical significance was set at $P \leq 0.05$.

RESULTS

Seventeen subjects completed the study; one athlete withdrew prior to the second visit because of injury. Subject physical characteristics, dietary intake, F_2-isoprostane levels, antioxidant biomarkers, and physical performance indicators have been reported previously (12).

Plasma concentrations of NEFA and the saturated, n-6, and n-3 PUFA components of the NEFA fractions were all significantly lower following the 2-wk R-AO diet when compared with the H-AO diet (Fig. 1) and were inversely correlated with plasma free F_2-isoprostanes (Table 1). Monunsaturated FA in the NEFA fraction tended to be lower on the R-AO diet but did not reach significance, nor were they significantly correlated with plasma free F_2-isoprostane. Plasma concentrations of NEFA tended to increase following the 30-min submaximal exercise period, then fall toward resting levels after exhaustive exercise, and increase again after 1 h of recovery. Although many individual FA in the NEFA fraction changed significantly as a result of exercise, this was not enough for exercise to affect the total plasma NEFA fraction significantly.

TABLE 1
Correlation Between Plasma Free F_2-Isoprostanes and Nonesterified FA (NEFA) Fractions

NEFA	r value	P-value
Total	−0.196	0.022
Saturated	−0.226	0.009
Monounsaturated	−0.043	0.621
Polyunsaturated		
n-6	−0.313	0.000
n-3	−0.210	0.015

DISCUSSION

The aim of this study was to examine the effect of an R-AO diet on plasma FA at rest and during exercise. The reduction in intake of antioxidant-rich foods resulted in a significant reduction in plasma NEFA concentration at rest, following 30 min of submaximal exercise, at exhaustion, and following 1 h of recovery when compared with the H-AO diet. The exercise protocol alone did not appear to have any significant effect on plasma NEFA concentrations, and no interaction effects were observed. Time-to-exhaustion was not affected by the reduction in NEFA, but the RPE was significantly increased during the exercise test when following the R-AO diet compared with the H-AO diet.

As previously reported (12), the R-AO diet resulted in a threefold reduction in ascorbic acid and β-carotene intakes. Energy, protein, carbohydrate, and fat intakes remained unchanged between the R-AO and H-AO diet, which excludes total carbohydrate and fat (type and amount) intakes of athletes that are known to influence plasma NEFA (17). Fasting, caffeine ingestion, and various supplements including L-carnitine, medium-chain TG, and long-chain TG have been shown to influence plasma NEFA (5). None of the subjects were taking these supplements, and the caffeine intake was not affected by the R-AO protocol. This leaves the reduction in dietary antioxidants on the R-AO diet as a single variable that could influence NEFA.

It is often thought that any intervention that increases FA availability in circulation has the potential to increase fat oxidation, slow the rate of glycogen use, and improve endurance exercise performance (5). On the contrary, reduced FA availability would be expected to have the opposite effect. FA availability is not the only factor to affect fat oxidation, which could explain why the majority of studies that have manipulated FA availability in plasma, including the present study, have not observed variations in exercise time to exhaustion (for review, see Ref. 5). Other factors that alter NEFA availability include NEFA movement across the muscle membrane, regulation of muscle TG lipase activity, and regulation of NEFA across the mitochondrial membranes (2). Exercise time-to-exhaustion as a performance measure also may lack the sensitivity to determine performance changes, which may explain why significant changes are not observed, particularly in a short-duration exercise protocol such as that used in the present study.

The present study does not explain the mechanism for the reduction in plasma NEFA following consumption of the

FIG. 1. Plasma nonesterified FA (NEFA) fractions following consumption of a restricted antioxidant diet in athletes at rest. Values reported as least squares means (SE of LS means). *$P < 0.001$. SFA, saturated FA; MUFA, monounsaturated FA; LS, least squares.

R-AO diet for 2 wk. However, we previously showed that the R-AO diet increased plasma concentrations of F_2-isoprostanes indicating that the balance of antioxidants and pro-oxidants had tipped in favor of the latter, which leaves the pro-oxidants to react with plasma molecules such as NEFA, consequently reducing their concentration (12). This is supported by the finding that the F_2-isoprostane value is inversely correlated with plasma NEFA. NEFA has previously been suggested to inhibit peroxidation of lipid membranes, thus acting like an antioxidant (18). In the presence of the reduction in antioxidant intake when consuming the R-AO diet, NEFA itself may have functioned as an antioxidant.

There is also a possibility that the inverse correlation between F_2-isoprostanes and NEFA could be explained by an indirect mechanism. Insulin levels (and insulin-mediated glucose uptake) are positively correlated ($r = 0.51$, $P < 0.004$) with free radical generation (19). Insulin is known to be a primary regulator of adipose tissue lipolysis and also FA re-esterification by reducing lipolysis and increasing re-esterification (17). Plasma NEFA concentrations may be reduced as a consequence of the increase in oxidative stress, which could in turn increase circulating insulin, a potent inhibitor of NEFA release from adipose tissue. Indeed, in the absence of insulin level measurements, there is not enough evidence in the present study to suggest that the proposed mechanism above is valid and thus merits further investigation.

It is also more likely that altered FA availability only has application in long-duration endurance-based exercise because of its substantial abundance when compared with carbohydrate, and the relative contribution of fat as a fuel is highest during low to moderate exercise intensities. The significantly elevated RPE score when subjects followed the R-AO diet in the present study indicates that their perception of effort to complete the 30-min submaximal run was increased on the R-AO diet compared with the H-AO diet protocol. It may be argued that an athlete with a heightened perception of effort is more likely to suffer performance detriment as the duration of exercise is increased.

The findings from this study suggest that the R-AO diet reduces plasma NEFA concentrations. However, further investigations are required to confirm the findings and further elucidate whether our proposed mechanisms are plausible. This will provide answers to the questions of whether antioxidants have a significant effect on fat oxidation and whether a reduction in plasma NEFA concentration has the potential to reduce the use of FA as a fuel for exercise to subsequently affect exercise performance.

Triacylglycerol Oxidation in Pig Lipoproteins After a Diet Rich in Oxidized Sunflower Seed Oil

Jukka-Pekka Suomela[a,*], Markku Ahotupa[b], and Heikki Kallio[a]

Departments of [a]Biochemistry and Food Chemistry and [b]Biomedicine, University of Turku, FI-20014 Turku, Finland

ABSTRACT: The effects of two sunflower seed oil diets differing in oxidation levels (PV in oils 1 and 190 mequiv O_2/kg) on lipoprotein TAG and total lipid oxidation were investigated in growing pigs. For 2 wk, two groups of 10 pigs were fed either of the diets, after which blood samples were collected. A method based on RP-HPLC and electrospray ionization-MS was used for the analysis of oxidized TAG molecules in chylomicrons and VLDL. The baseline diene conjugation method was used for the estimation of *in vivo* levels of lipoprotein lipid oxidation. TAG molecules with a hydroxy, an epoxy, or a keto group attached to a FA, as well as TAG core aldehydes were detected in the samples. Typically, lipoprotein TAG and total lipids were more oxidized in the pigs fed on the oxidized oil compared with those fed on nonoxidized oil. Oxidation of dietary fat was thus reflected in the lipoprotein oxidation, which confirmed our earlier findings.

Paper no. L9695 in *Lipids* 40, 437–444 (May 2005).

Studies suggest that oxidized dietary lipids increase the oxidation level of chylomicrons and VLDL (1–3). In addition to oxidized LDL, which has a central role in atherogenesis, oxidized chylomicrons and their remnants also seem to be potentially atherogenic (4–7). Oxidation of chylomicrons results in particles that may serve as a substrate for scavenger receptors (7). Chylomicrons and their remnants may associate with arterial tissue with even greater efficiency than LDL (8).

Thus far, studies of the dietary effects on lipoprotein oxidation at the molecular level have been scarce. Also, there are only a few methods for direct measurement of lipoprotein oxidation (9). In our previous studies (3,10), we used a novel approach based on HPLC-electrospray ionization (ESI)-MS and baseline diene conjugation (BDC) methods to investigate lipid oxidation in human LDL (10) and in different pig lipoproteins (3). HPLC-ESI-MS was applied to the analysis of the oxidized TAG molecules. The BDC method was used to evaluate the oxidation levels of the samples. New information on the oxidized TAG molecules of lipoproteins was obtained. The results of the pig study (3) also suggested that oxidized dietary fat, in comparison with nonoxidized dietary fat, has an increasing effect on lipoprotein total lipid and TAG oxidation.

In the present study, we applied the approach described above to investigate the effects of oxidized dietary sunflower seed oil on the oxidation of pig lipoproteins. The group sizes were larger compared with the earlier pig study (3), and only two diet groups were compared with each other. Detailed information on lipoprotein total lipid and TAG oxidation as well as on the molecular structures of oxidized chylomicron and VLDL TAG was obtained. The results confirmed the conclusions drawn in the earlier pig study (3) and also gave more detailed information on the level of lipoprotein lipid oxidation.

MATERIALS AND METHODS

Chemicals and reagents. 3-Chloroperoxybenzoic acid, triphenyl phosphine and activated manganese dioxide (MnO_2) were obtained from Aldrich Chemical Co. (Milwaukee, WI). Reagents were of reagent grade or better quality. All solvents were of chromatography or reagent grade and were purchased from local suppliers. HPLC standard (G-1) containing synthetic monoacid TAG was obtained from Nu-Chek-Prep, Inc. (Elysian, MN). Synthetic 1,3-distearoyl-2-oleoyl-*sn*-glycerol was obtained from Sigma Chemical Co. (St. Louis, MO). 1,3-Didocosanoyl-2-oleoyl-*sn*-glycerol and 1-linoleoyl-2-oleoyl-3-palmitoyl-*sn*-glycerol were obtained from Larodan Fine Chemicals AB (Malmö, Sweden).

Preparation of reference compounds. The oxidized derivatives of synthetic TAG were prepared as described earlier (3,10) and purified by TLC as described below.

Animals and diets. The study plan was approved by the Test Animal Committee of MTT Agrifood Research Finland.

[a]Results expressed as percentage of total FA.
[b]PV 1 mequiv O_2/kg oil.
[c]PV 190 mequiv O_2/kg oil.

Twenty growing pigs (castrated boars) were used in the study. For 2 wk, two groups of 10 pigs (groups 1 and 2) were fed a diet (Table 1) containing 16% sunflower seed oil varying in oxidation levels. The average weight of the animals was 25.3 ± 1.9 kg (mean ± SD) at the beginning of the feeding period and 39.1 ± 4.1 kg at the end of the period. The oil of group 1 was not oxidized (PV 1 mequiv O_2/kg), whereas the oil of group 2 was oxidized in convection ovens at 60°C until the PV of 190 mequiv O_2/kg was reached. The PV determinations were made according to the AOCS official method Cd 8-53 (11) and could be expressed as millimoles of FA hydroperoxide groups per kilogram of oil. This method does not assay oxidized FA other than hydroperoxides. The vitamin E contents of the oils were as follows: group 1, 550 mg/kg; group 2, 103 mg/kg. The vitamin E determinations were made according to IUPAC 2.432 method (12). FA compositions of the oils (Table 2) were determined as described below.

The pigs were fed twice a day. During the first week, the pigs were fed 200 g oil/d and during the second week 230 g oil/d. Because of the high fat load, the pigs were fed in total 161 mg vitamin E/kg feed, not including vitamin E from the oils (Table 1). The level of vitamin E supplementation was based on the guidelines of MTT Agrifood Research Finland.

Sample preparation. Chylomicrons and VLDL were assumed to reach their highest levels during the first 4 h after a meal. Blood samples were obtained by venipuncture from the jugular vein at 3 and 4 h (time points 1 and 2, respectively) after the last meal (half of the daily dose). The blood was collected into tubes containing EDTA as an anticoagulant. Plasma was separated from cells by centrifugation at 3000 × *g* for 15 min. Chylomicrons and VLDL were separated from plasma by ultracentrifugation, and LDL were directly precipitated from EDTA plasma by buffered heparin as described (9,13). Lipids were extracted from plasma and lipoproteins using chloroform/methanol.

Purification of TAG and their oxidation products. For FA analysis, the TAG of chylomicrons and VLDL were purified using Sep-Pak® prepacked silica columns (Waters, Milford, MA) (14). Normal-phase TLC without added antioxidants was used to purify the reference compounds and the oxida-

tion products of chylomicron and VLDL TAG (15). Heptane/di-isopropyl ether/acetic acid (60:40:4, by vol) solution was used as the mobile eluent. Samples were applied to silica G plates. Resolved components were scraped off the plates and were recovered from the silica gel by extraction with chloroform/methanol (2:1, vol/vol). When TLC was applied to the lipoprotein lipid samples, two fractions below the TAG band were scraped from the plate (TAG band, R_f = 0.59; fraction 1, R_f = 0.30–0.50; fraction 2, R_f = 0.10–0.30). The fractions contained the oxidized TAG molecules (3). The extracts were washed with distilled water. TAG and their hydroxy, hydroperoxy, oxo, and epoxy derivatives were detected in UV light after spraying with 2,7-dichlorofluorescein (15).

FA analysis. The FAME of TAG were prepared by sodium methoxide-catalyzed transesterification (16). Methyl esters were dissolved in hexane and analyzed by GC (PerkinElmer AutoSystem, Norwalk, CT) using a DB-23 column (30 m × 0.32 mm i.d., 0.25 µm film thickness; Agilent Technologies, Palo Alto, CA). The instrument was equipped with an FID.

Analysis of samples by HPLC-ELSD and HPLC-ESI-MS. TAG and their oxidation products were separated by RP-HPLC. The HPLC system consisted of a Hitachi (Tokyo, Japan) L-6200 Intelligent Pump with a Discovery® HS C18 column (250 mm × 4.6 mm i.d.; Supelco Inc., Bellefonte, PA). The column was eluted at 0.85 mL/min and a linear gradient was used: 20% 2-propanol in methanol was changed to 80% 2-propanol in 20 min. The final composition was held for 10 min. Eighty-five percent of the effluent (0.72 mL/min) was led to a Sedex 75 (S.E.D.E.R.E., Alfortville, France) ELSD. An evaporation temperature of 70°C and nebulizer gas (air) pressure of 2.7 bar were used in the ELSD. Fifteen percent of the effluent (0.13 mL/min) was led to a Finnigan MAT TSQ 700 triple quadrupole mass spectrometer (Finnigan, San Jose, CA) equipped with a nebulizer-assisted electrospray interface. Full-scan MS spectra were collected in positive (*m/z* 450–1100) ionization mode. The electrospray voltage used was +4.5 kV.

Determination of the oxidation level of plasma and lipoproteins. For the estimation of total lipid oxidation by the baseline level of diene conjugation in plasma and lipoproteins, extracted lipids of plasma, chylomicrons, VLDL, and LDL were dissolved in cyclohexane and analyzed spectrophotometrically at 234 nm. Absorbance units were converted to molar units using the molar extinction coefficient $2.95 × 10^4$ M^{-1} cm^{-1}. The results were expressed as micromoles conjugated dienes in a liter of plasma to have an estimation of the actual level of oxidized lipoproteins in circulation (17). The proportions of oxidized TAG molecules were estimated by HPLC using the conditions described above. The estimations were based on the ELSD chromatograms of the HPLC runs in which an internal standard was used. The response of ELSD to the injected amount of a reference compound (10) was tested before the estimations were made.

Statistical analysis. SPSS 12.0 for Windows (Chicago, IL) was used for data analysis. Independent samples *t*-test and

Mann–Whitney U-test were used to compare the BDC values and FA compositions of the different pig groups.

RESULTS

FA compositions of the TAG of chylomicrons and VLDL are listed in Tables 3 and 4, respectively. As in our earlier study (3), the lipoproteins reflected to a large degree the FA compositions of the test oils. However, chylomicron and VLDL TAG contained more 16:0 (palmitic acid) and 18:3n-3 (α-linolenic acid), and less 18:1n-9 (oleic acid) than the corresponding test oils. Fat derived from soy at least partly explains these differences. VLDL TAG also seemed to contain less 18:2n-6 (linoleic acid) than the test oils. In chylomicron and VLDL TAG of group 2, the relative amount of 18:1n-9 appeared to be higher and that of 18:2n-6 lower compared with the TAG of group 1, as could be expected based on the FA compositions of the test oils. In VLDL TAG, 18:3n-6 (γ-linolenic acid) was present in notable amounts, which indicated incorporation of endogenous γ-linolenic acid into VLDL.

Elution factors determined by Sjövall *et al.* (18) and our group (10) for HPLC were used in the identification of TAG oxidation products after their applicability was confirmed for the present HPLC column. Several oxidation products of TAG were detected in the TLC fractions of chylomicron and VLDL lipids. The oxidized structures were found by extracting peaks of specific *m/z* values from the MS chromatograms of HPLC runs (Fig. 1) (10). Only sodium adduct ions were formed from the molecules in positive ion mode.

The postulated molecular structures of the oxidized TAG of chylomicrons and VLDL are listed in Table 5. In most oxidation products detected, oxidation had occurred in only one of the FA of a TAG molecule. These products consisted of TAG molecules with a hydroxy, an epoxy, or a keto group attached to a FA, and of TAG core aldehydes. Typically, the oxidation products were formed from TAG with ACN:DB (acyl carbon number:number of double bonds) 52:2, 52:3, 52:4, 54:3, 54:4, 54:5, and 54:6. In the present study, TAG core aldehydes were identified as such, not derivatives, in positive ion mode. The aldehydic [M + Na]$^+$ ions were observed to be

partly transformed to $[M + Na + 32]^+$ adduct ions in our ion source, possibly indicating formation of hemiacetal structures within the molecules (Sjövall, O., personal communication). The phenomenon helped in the detection and identification of the core aldehydes.

Most of the oxidized TAG molecular structures were found in all samples at both time points. However, the peaks representing the TAG hydroxides/epoxides/ketones of 54 or 56 acyl carbons and the peaks representing the TAG core aldehydes of 45 carbons with a hydroxy/epoxy/keto group attached to the molecule were stronger in group 2 compared with group 1 (Table 5, Fig. 1). An exception was the ion representing the structure 18:2 OH/18:1/18:1 (postulated), which was stronger in group 1. The ratio of the structure 18:2 keto/18:2/18:2 (ACN:DB 54:6) to the structures 18:2 keto/18:2/18:1 + 18:1 keto/18:2/18:2 (ACN:DB 54:5) seemed to be higher in group 2 compared with group 1 (Fig. 1).

TAG epoxides and ketones may have formed so that the number of double bonds did not change (e.g., conversion of hydroperoxide to a ketone by dehydration) or so that one double bond was lost (formation of an epoxide or a ketone at a site of unsaturation) (19). In the epoxides formed from TAG

with ACN:DB 54:6 or 52:4, oxygen seems to have been added mainly at the site of a double bond, leading to the loss of the double bond. The assumption is based on the intensities of the extracted peaks in the MS chromatograms (Fig. 1) and the FA composition of the TAG (Tables 3 and 4).

In the oxidized test oil, TAG monohydroperoxides were the major class of oxidized TAG. Monohydroperoxides detected were formed from TAG with ACN:DB 52:2, 52:3, 52:4, 54:3, 54:4, 54:5, and 54:6. Dihydroperoxides were formed from TAG with ACN:DB 52:4, 54:6, and 54:5. The hydroperoxy TAG molecules were partly fragmented in the ion source (cleavage of H_2O), which helped in the identification of such molecules.

However, TAG hydroperoxides could not be detected in the lipoprotein samples, neither as such nor as a combination of hydroperoxy and oxo/epoxy groups. This is in accordance with our earlier studies (3,10), and indicates an absence of these molecules in the lipoprotein TAG, or a considerable decrease in the level of them compared with the oxidized sunflower seed oil.

Figure 2 shows the BDC values of plasma (total lipid BDC) and separate lipoproteins. The BDC method is sensi-

[c]PV of the sunflower seed oil used in feed: 190 mequiv O_2/kg.

tive, the normal level of conjugated dienes in lipoproteins being at least 10 times higher than the detection limit of the method. The amount of conjugated dienes appeared to be somewhat higher in plasma, chylomicrons, and LDL of group 2 compared with group 1. The differences were statistically significant in the plasma of time point 1 and in the chylomicrons of time point 2. In the VLDL of group 1, the amount of conjugated dienes seemed to be higher compared with group 2. However, these differences were not statistically significant.

The estimated proportions of oxidized TAG molecules in the total lipids of the test oils, chylomicrons, and VLDL are listed in Table 6. The oxidized molecules include all the oxidized TAG species that were detectable in HPLC-ELSD chromatograms. In the oxidized test oil, the TAG hydroperoxides could not be distinguished from secondary oxidation products because of overlapping peaks. However, based on MS chromatograms, the amount of the other oxidation products seemed to be small compared with TAG hydroperoxides.

Some samples could not be analyzed by HPLC owing to a small amount of sample provided. The results show that the proportion of oxidized TAG molecules was remarkably higher in the chylomicrons of group 2 compared with group 1. The proportion of the molecules in the VLDL of group 2 also seemed to be higher compared with group 1.

DISCUSSION

Our results demonstrate an effect of dietary lipid oxidation on lipoprotein oxidation level. Thus, it seems that the oxidized TAG are absorbed in the small intestine, and/or they initiate a cascade of subsequent oxidation reactions that result in the increased oxidation of lipoproteins and their TAG molecules.

It is noteworthy that the oxidized test oil contained less vitamin E than the nonoxidized oil, resulting in lower total vitamin E content in the feed containing the oxidized oil compared with the feed containing the nonoxidized oil (177 vs. 249 mg/kg feed, respectively).

TAG make a contribution of almost 30% to the diene conjugation of LDL (Ahotupa, M., and Viikari, J., unpublished results), a lipoprotein class containing considerably less TAG than chylomicrons and VLDL. Thus, oxidized TAG molecules are expected to have a major contribution to the total lipid oxidation of lipoproteins, particularly chylomicrons and VLDL. This is supported by the present results (Table 6).

TAG hydroperoxides could be detected in neither the chylomicron nor the VLDL samples. This is in accordance with our earlier pig study (3) and the observation that only small amounts of unmodified hydroperoxy lipids are found in tissue and blood samples (20,21). Studies by Kanazawa *et al.* (22,23) and by our group (24) suggest that dietary FA hydroperoxides ingested in moderate amounts may not survive in the gastrointestinal tract. If so, unmodified dietary TAG hydroperoxides are not transported into lipoproteins. Oxidation of formerly unmodified TAG molecules takes place in plasma to some extent (10), but we hypothesize that the TAG oxidation products found in plasma lipoproteins are partly formed from hydroperoxides in the gastrointestinal tract and possibly further modified in plasma.

The possibility that some decomposition of hydroperoxy structures had occurred during sample preparation cannot be excluded. However, in our studies, TAG hydroperoxides have been relatively stable during extraction procedures, TLC, and HPLC runs.

Lipoproteins rich in TAG seem to be important factors in the induction of atherogenesis (25), which could at least partly be explained by oxidized TAG molecules. As in our previous study (3), TAG hydroxides were present in the chylomicrons and VLDL. Linoleic acid hydroxides are found in atherosclerotic plaques, and they have been found to be endogenous activators and ligands of peroxisome proliferator activated receptor protein γ, which promotes monocyte/macrophage differentiation and uptake of oxidized LDL (20,26,27). Thus, lipoprotein TAG hydroxides could have an influence on atherogenesis (20).

The present results give further evidence on the effect of dietary fat oxidation on lipoprotein oxidation. Most of the results were in line with our earlier study (3) in which smaller pig groups were used. The results obtained by the BDC method suggest that plasma, chylomicron, and LDL lipids of group 2 were more oxidized compared with group 1. It was also shown that the chylomicron and VLDL samples of group 2 contained more oxidized TAG molecules than the samples of group 1. Our results suggest that the level of dietary fat oxidation is reflected in the level of lipoprotein oxidation.

Changes in the Milk and Cheese Fat Composition of Ewes Fed Commercial Supplements Containing Linseed with Special Reference to the CLA Content and Isomer Composition

Pilar Luna, Javier Fontecha, Manuela Juárez, and Miguel Angel de la Fuente*

Instituto del Frío (Consejo Superior de Investigaciónes Científicas), José Antonio Novais 10, 28040 Madrid, Spain

ABSTRACT: A study was carried out to increase the CLA contents in ewes' milk fat under field conditions by dietary means and to investigate the extent of the changes and consequences for milk processing and cheese quality. During a 3-mon period, ewes' bulk milk samples were collected every week from two different herds. For the first 4 wk the ewes were fed a conventional diet. Then the following 6 wk a supplement enriched in α-linolenate (whole linseed) was incorporated into the ovine diet. Finally, in the last 3 wk the feeding was the same as in the first 4 wk. The FA profile in milk fat was monitored by GC, and the distribution of CLA isomers was thoroughly tested by combining GC–MS of 4,4-dimethyloxazoline derivatives (DMOX) with silver ion-HPLC (Ag$^+$-HPLC) of FAME. Reconstructed mass spectral profiles of CLA characteristic ions from DMOX were used to identify positional isomers, and Ag$^+$-HPLC was used to quantify them. An increase in total CLA in milk fat was observed, and total CLA remained elevated during the weeks of enriched α-linolenate feeding. In our experimental conditions there was a linear relationship between *trans*-vaccenic acid (*trans*-11-octadecenoic acid; *trans*-11 18:1) and 9-*cis*,11-*trans* CLA in ewes' milk fat. Concerning the CLA isomer profile, increases in the 11,13- and 12,14-18:2 positional isomers were considerable when linseed was included in the diet. Organoleptic characteristics of cheeses made with CLA-enriched milk did not substantially differ from those made with nonsupplemented ewes' milk. CLA total content and isomer profile did not change during ripening.

Paper no. L9567 in *Lipids 40*, 445–454 (May 2005).

CLA is a mixture of positional and geometric isomers of linoleic acid (18:2), which contains a conjugated double-bond system. In animal models, CLA exhibits several health-promoting attributes, including anticarcinogenic and antiatherogenic activities. Natural dietary sources of CLA are mainly milk fat contained in foods, such as whole milk, butter, and cheese. The quantitatively predominant CLA isomer in milk is the 9-*cis*,11-*trans* isomer, also called rumenic acid (RA), and it has been implicated as the most important isomer in terms of biological activity. The 10-*trans*,12-*cis* isomer seems to be the isomer responsible for reducing body fat content and might be the most active one, but its natural occurrence is low. More recently, other isomers have been found to be even more powerful than RA against human breast cancer cells (9-*cis*,11-*cis*) (1) or to exhibit greater cytotoxicity against gastric cancer cells (9-*trans*,11-*trans*) (2). However, their presence in lipids from ruminant products is reported less.

The CLA content in dairy products is affected by many factors during every stage from the field to the table, including raw material production, processing, aging, storage, and food preparation (3,4). Animal feeding strategies for CLA enrichment of milk have been reviewed, and diets with seed/oil supplements rich in PUFA that provide lipid substrates for the production of RA or *trans*-11 18:1 (*trans*-vaccenic acid, TVA) have proved to be effective (3,4). A number of studies have reported the effects of linseed or linseed oil on milk FA composition in dairy cows (5–12). In addition to enhancing CLA content, the dietary changes with linseed also result in milk fat containing a lower proportion of saturated FA and greater amounts of monounsaturated FA and PUFA.

The most significant changes in milk fat quality relate to rheological properties, which influence numerous aspects of the nature and quality of cheeses and other manufactured dairy products (13). The effects of processing conditions, storage, and aging on the CLA content of various types of dairy products are not very clear. As regards cheeses, reports and reviews present results for individual varieties, often in the belief that CLA levels may vary as a result of different processing conditions. These effects are likely to be small, and variations in CLA levels are similar to the levels in the starting milk (14–16). However, other studies have detected changes in the CLA levels or new isomers in ripened cheeses (17–20), and it is hypothesized that biohydrogenation of linolenic acid in cheese could lead to the formation of CLA isomers as intermediates.

Production of ewes' milk is of economic importance in a number of countries, especially those in the Mediterranean region and Middle East, where it is mainly used to produce a variety of cheeses. While it is accepted that hardly any studies have reported the effects of seed/oil supplements on ovine milk FA composition, and with one exception (21) a detailed characterization of the CLA isomer profile has been supplied, the evidence to support differences in lipid metabolism between ruminants is rather limited. Thus, changes in FA pro-

---

file of ovine milk fat should not substantially differ from the pattern previously described for cows' milk. If there are differences between ruminants, then goats appear to be the exception rather than ewes or cows (22).

Most of the works on ovine dairy products are limited to quantifying the most prominent peak assigned to CLA as FAME by means of GC. However, the CLA isomer mixtures in milk are complex, and no single technique can resolve all isomers. In recent years, different procedures have been used to elucidate CLA isomers. The majority of them have been quantified by silver-ion HPLC (Ag[+]-HPLC) (18,23–25). GC–MS has been shown to be the most powerful tool for identifying them (18,26). A more complete qualitative and quantitative analysis involves applying both techniques, especially when GC is coupled to MS to provide structural information. A detailed positional analysis of the double bonds of FA subsequently can be performed using one of several FA derivatives other than FAME, such as 4,4-dimethyloxazoline (DMOX), that already are applied in different food materials. High-resolution MS with a selected ion-recording technique makes it possible to distinguish CLA from interfering FA and discriminate among the different isomers.

This experiment was carried out to enhance CLA levels in ewes' milk fat under field conditions by dietary means (commercial supplement enriched in linseed, SEL) and to investigate the extent of the changes and consequences for milk processing and cheese quality. The dietary intervention chosen could lead to changes in the FA composition in ewes' milk fat, and it would be useful to know how this could affect the characteristics of the cheese produced from this milk. Furthermore, it would mean that it was possible to see how the FA composition, particularly the amount and proportion of specific CLA isomers, would develop during the processing and aging of the cheese. Research on this topic, assisted by the analytical tools already mentioned, could lead to the development of natural, consumer-acceptable strategies and processing systems to produce CLA and dairy foods of proven quality with enhanced healthful properties.

MATERIALS AND METHODS

Feeding experiments. Briefly the study dealt with the impact of a diet supplemented with α-linolenate on the FA composition of the ewes' bulk milk fat. The experiment was performed from December to March with two representative herds of 330 and 300 lactating ewes of Assaf breed located in two different places in the Madrid region (Spain). All ewes were housed in dairy barns, and they had free access to water and appropriate bedding.

The study was conducted over a 13-wk period. Bulk milk samples were collected at weekly intervals during the milking period from both herds. Samples were taken from the storage tanks containing milk from the whole herd. During the first 4 wk both herds were offered a mixture *ad libitum* consisting of dehydrated alfalfa (45% of dry matter), corn (15% of dry matter), beet pulp (10% of dry matter), cotton seed

(13% of dry matter), and Lactovejina 100 (17% of dry matter), a commercial supplement from Cargill España S.A (Madrid, Spain). After 4 wk, Lactovejina 100 was replaced with Lactovejina 100 Tech (Cargill España S.A.), a supplement enriched in whole linseed. From weeks 5 to10 both herds were fed *ad libitum*, and their diets included Lactovejina 100 Tech (17% of dry matter). Finally, in the last 3 wk, the feeding was the same as in the first 4 wk. The chemical composition of both supplements is shown in Table 1, and total lipid contents were 4.7 and 5.8% in diets with Lactovejina 100 and Lactovejina 100 Tech, respectively.

Cheese-making experiments. The bulk milk of both herds, collected separately in the last weeks of both feeding periods, at 4 wk (control diet) and at 10 wk (SEL diets) from the starting point, was used for cheese making. Cheeses from each batch were made in a pilot plant as follows: 50 L of raw milk was heated to 32°C, and rennet was added to curdle the milk. No starter culture was added for cheese making because raw milk was used. After the milk had clotted (30 min), the curd was cut to the size of a hazelnut and then the vat temperature was gradually increased to 36–37°C at a rate of 1°C/3 min. At the same time, the curd was stirred to remove the whey and favor grain aggregation. Curds were placed into 3-kg molds and pressed in a horizontal pneumatic press until the pH was about 5.5. Cheeses were salted in brine (20° Baume) at 10°C for 12 h and then transferred to a ripening room where they remained at a temperature of approximately 13–14°C and ~85% RH for 120 d. Samples at 30, 60, and 120 d were taken from each batch for chemical analysis. A total of 5 cheeses were obtained from each batch.

Milk and cheese chemical analyses. Fat, protein, and total solids in milk were measured with a MilkoScan FT-6000 (Foss Electric, Barcelona, Spain). Total solids and fat in cheeses were determined according to the International Dairy Federation (IDF) standards (27,28).

(i) Lipid extraction and FA derivatization. Milk and cheese fat extraction was carried out according to the International Standards Organization (ISO; 29). The fat residue extracted was stored in amber vials, exposed to a stream of N_2 and

TABLE 1
Chemical Composition of Lactovejina 100 and Lactovejina 100 Tech[a]

Component	(weight %)

frozen at −20°C until analysis. FAME were prepared by base-catalyzed methanolysis of the glycerides (KOH in methanol) as described in ISO (30). The preparation of DMOX derivatives from FAME was based on the Fay and Richli (31) procedure.

(ii) Ag⁺-HPLC. Ag⁺-HPLC separation of CLA methyl esters was carried out using a high-performance liquid chromatograph (Series 1100; Agilent Technologies, Palo Alto, CA) equipped with a photodiode array detector operated at 234 and 205 nm. Three ChromSpher 5 Lipid analytical columns (4.6 mm i.d. × 250 mm stainless steel; 5 μm particle size; Varian) were connected in series. The mobile phase was 0.1% acetonitrile in hexane and operated isocratically at a flow rate of 1.0 mL/min. The flow was initiated 0.5 h prior to the sample injection and the injection volume was 10 μL. To identify positional isomers a mixture (*cis*-9 *trans*-11, *trans*-8 *cis*-10, *cis-11 trans*-13, *trans*-10 *cis*-12 18:2 and small amounts of a variety of *cis-cis* and *trans-trans* 18:2 isomers) and pure CLA methyl ester isomers (*cis*-9 *trans*-11 and *trans*-10 *cis*-12 18:2) were purchased from Nu-Chek-Prep. Inc. (Elysian, MN).

(iii) GC–FID and GC–MS analyses. Milk and cheese FA contents were determined by GC–FID after conversion to FAME. FAME were analyzed on a PerkinElmer chromatograph (model 8420; Beaconsfield, United Kingdom) with an FID. FA were separated by using a CP-Sil 88 fused-silica capillary column (100 m × 0.25 mm i.d. × 0.2 μm film thickness; Chrompack, Middelburg, The Netherlands). The column was held at 70°C for 4 min after injection, temperature-programmed at 13°C/min to 175°C, held there for 27 min, and then temperature-programmed at 4°C/min to 215°C and held there for 36 min. Helium was the carrier gas with a column inlet pressure set at 214 KPa and a split ratio of 1:20. Injection volume was 0.2 μL. To obtain response factors, an anhydrous milk fat (reference material CRM-164) obtained from the European Commission (Brussels, Belgium), consisting of known amounts of FA, was used.

CLA DMOX derivatives were separated with the same column on an Agilent GC chromatograph (model 6890N) connected to an Agilent mass spectrometer detector (MS 5973N). The filament trap current was 400 μA at 70 eV. A 1-μL solution of DMOX derivatives was injected under the following conditions: initial oven temperature was 75°C for 2 min after injection, then temperature-programmed at 5°C/min to 180°C, held there for 30 min, and then temperature-programmed at 5°C to 220°C and held there for 30 min. The column inlet pressure was set at 197 KPa in a splitless injection system. To create other CLA isomers, standards from Nu-Chek-Prep described above were isomerized using I_2 (23), then converted to DMOX derivatives and used to identify CLA isomers by GC–MS.

Cheese sensory analysis. The sensory test was carried out following IDF recommendations (32) by a trained group of panelists (accustomed to consuming this type of cheese), consisting of staff from our Institute (15 tasters minimum). Cheeses were sampled and tested at 60 and 90 d of ripening.

A wedge (1-cm thick) was cut from the block of cheese and the rind was removed. All analyses were rated on a 10-point scale. The attributes analyzed were appearance, aroma strength, taste strength, texture, and general acceptability. The possible presence of certain features responsible for negative aspects in flavor and aroma were also evaluated. The SPSS package (SPSS 11.0 for Windows; SPSS Inc., Chicago, IL) was used for statistical analysis of these results. Variance analysis was performed to establish the effectiveness and significance level for $P \leq 0.05$.

RESULTS AND DISCUSSION

Milk yield and composition. To draw conclusions about the effects of diet on animal performance would require data from individual animals. However, descriptive data on average milk yield and composition can also be important for studies if the bulk raw milk is going to be used to manufacture cheese and other dairy products. Milk yields from both ewe herds were recorded daily during the entire period of the study. The mean daily milk yields per ewe were 2.5 and 2 L in herds 1 and 2, respectively. These volumes remained constant and did not decrease during the 3 mon that were monitored. Figure 1 shows the development of fat and protein concentration measured weekly for 3 mon in both herds. As can be seen, fat percentages decreased slightly during the period monitored, whereas the protein content remained stable.

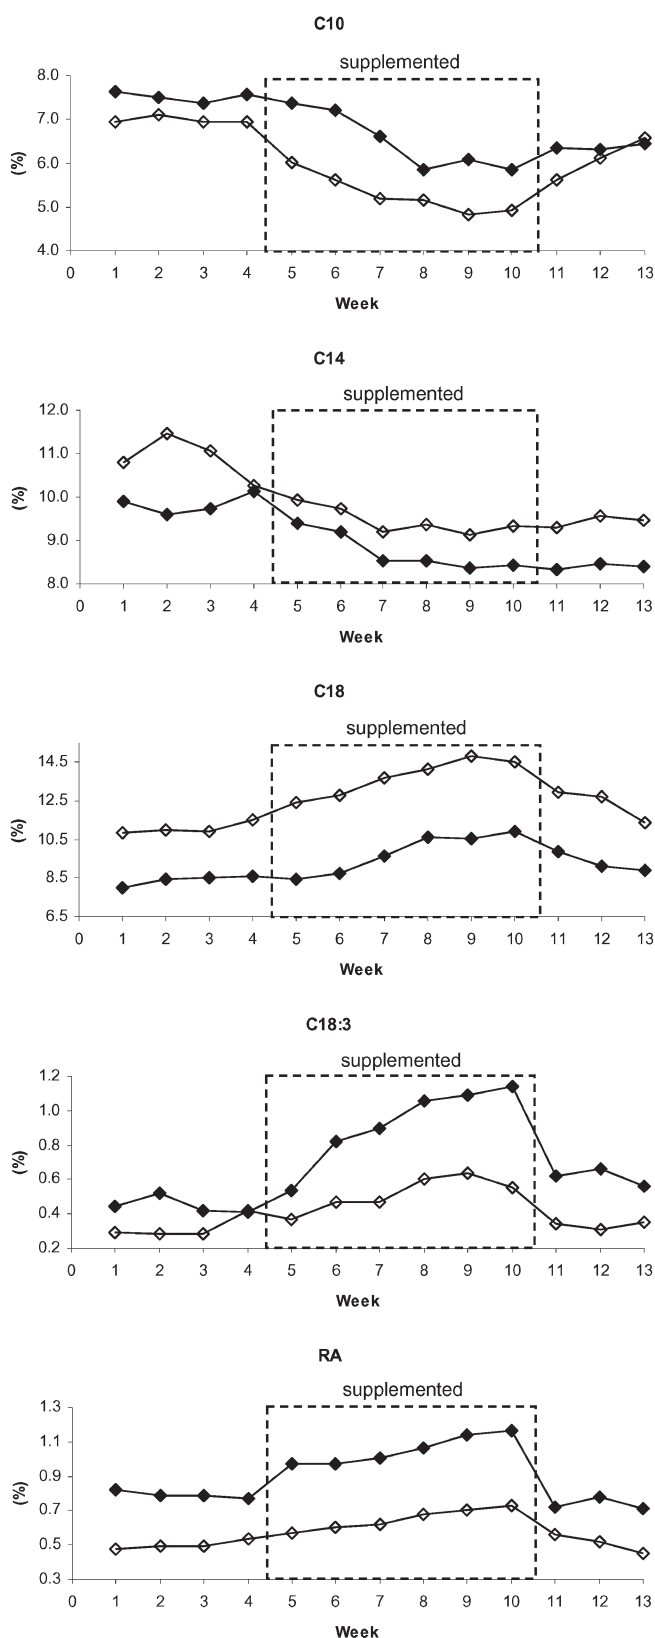
FA composition of milk. The FA profile of ewes' milk fat was altered by the feed, and the development of the major FA content was similar for both herds during the period monitored (Fig. 2, Table 2). The proportions of saturated FA from 8:0 to 16:0 decreased with the SEL diet, whereas 4:0 and 6:0 hardly varied. Lipid supplementation with α-linolenic acid increased the 18:0 and 18:3 percentage as well as most of the 18:1 and 18:2 and isomers (Fig. 2, Table 2). Ewes' milk fat contained very small amounts of C_{20} and C_{22} PUFA, which were identified by using GC–MS. The most prominent PUFA
FIG. 1. Temporal pattern (% of total milk) of fat and protein content of bulk milk in two ewe herds fed a diet enriched in α-linolenic acid. During the treatment period (broken lines) a supplement enriched in linseed was added.


FIG. 2. Temporal pattern (% of total FA) of 10:0, 14:0, 18:0, α-linolenic acid (18:3), and rumenic acid (RA) of milk fat from ewes fed a diet enriched in α-linolenic acid. During the treatment period (broken lines), a supplement enriched in linseed was added. Herd 1 (♦), herd 2 (◇).

present were 20:4, 20:5 (EPA), and 22:5 (Table 2), whereas 22:6 (DHA) was absent. These percentages did not change when the diet was enriched in α-linolenic acid.

Although it is not possible to draw conclusions from bulk milk samples from 300 animals, since individual variability should be studied, these results seem to confirm the established theories developed from research studies with cows' milk when the livestock were fed different dietary supplements enriched in oilseed (3,4). The inclusion of long-chain FA in the diet reduces the concentration of medium-chain saturated FA in the milk mainly by inhibiting mammary *de novo* FA synthesis. Increases in the proportion of 18:0, 18:1, and 18:2 isomers would be associated with biohydrogenation activity in the rumen, which is stimulated by feeding with PUFA-enriched lipids. Nevertheless, the process of biohydrogenation in the rumen seemed to be limited, because noticeable amounts of α-linolenic acid contents escaped hydrogenation and increased the amounts of this FA in the milk fat of herds fed SEL. The proportion of α-linolenic acid in ewes' milk shifted from an average of 0.45 and 0.29% in the first weeks to 1.10 and 0.63% in both herds, respectively, at the end of the period of feeding with the supplement. The fact that there was a higher proportion of α-linolenic acid in milk when linseeds were added than when linseed oil was used could be due to partial protection by whole linseed against biohydrogenation because of the localization of oil in the seed. Oil is released slowly from seeds in the rumen and has relatively less probability of biohydrogenating than free oil (8,10).

Particularly remarkable was the rise in the *trans*-11 *cis*-15 18:2 level in the milk fat of ewes fed SEL (Table 2). *Trans*-11 *cis*-15 18:2 was first recognized as the main intermediate in the ruminal hydrogenation of α-linolenic acid *in vitro* and has also been confirmed recently in studies *in vivo* (33) as the major 18:2 isomer produced during hydrogenation of α-linolenic acid in the rumen. This pathway involves an initial isomerization to a conjugated triene (*cis*-9 *trans*-11 *cis*-15 18:3), followed by reductions in the double bonds at carbons 9, 15, and 11 to yield *trans*-11 *cis*-15 18:2, *trans*-11 18:1, then 18:0, respectively.

The analysis of PUFA is important considering present-day efforts to increase the n-3 FA content in milk fat. Two of the most important n-3 PUFA (EPA and DHA) usually have a very low level in traditional dairy diets (<0.1% of total FAME). DHA, for instance, is present only in trace amounts in milk fat unless the ruminant diet contains marine products. Consequently, the very low amounts of n-3 PUFA found in the present study came as no surprise.

RA and TVA relationship. RA content in milk fat was greater in ewes fed SEL than when they were fed the control diet (Fig. 2). Mean levels of RA in the first 4 wk were stable (0.80 and 0.50% in herds 1 and 2, respectively). With the new diet, levels rose in both herds. Finally, after SEL was eliminated from the diet, RA content dropped to its original values. In our experimental conditions, a high correlation of RA with TVA ($R^2 = 0.93$) was found in ewes' milk fat (Fig. 3). A

product–precursor relationship of CLA with TVA in the ewes' rumen was suggested by Noble *et al*. (34), indicating that the TVA accumulated in the ewes' rumen could be used for postruminal synthesis of CLA, which might be more important quantitatively than CLA ruminal synthesis. Investigations to establish the importance of endogenous synthesis of CLA in ewes' body fat (35) found a correlation between TVA and RA concentrations in different tissues, and the accumulation of RA appeared to be far greater in the liver. Daniel *et al*. (35) highlighted the predominance of endogenous synthesis as the source of RA in ewes and also stressed the critical role of Δ-9 desaturase in the biology of CLA in this ruminant. However, information on the mammary gland or milk fat was not supplied.

The results of this study support the idea that dietary α-linolenic acid could also be a valuable means for increasing RA in ewes' milk. Although ewes and cows' response to lipid feeding might not be exactly the same, the effects of α-linolenic acid supplementation should not be very different between these species. Nonetheless, increases in CLA contents were modest in comparison with some previous studies on cows' milk, in which other types of seeds were used. The reasons could be the predominant pathways of biohydrogenation of dietary α-linolenic and linoleic acids in the rumen. Supplementation of linoleic acid appears to have an advantage over supplementation of α-linolenic acid, probably because it contributes to increased production of both CLA and TVA in the rumen, the latter of which ultimately becomes the
FIG. 3. Relationship between rumenic acid (9-*cis* 11-*trans* 18:2) and *trans*-vaccenic acid (11-*trans* 18:1, TVA) in ewes' milk fat from two herds (g/100 g of total FAME). Herd 1 (◆), herd 2 (◇).

substrate for CLA synthesis by Δ-9 desaturase in the mammary gland, whereas α-linolenic acid contributes to TVA only during its biohydrogenations (4). Feeding linseed results in great production of ruminal TVA, which could be subsequently used by the mammary gland for RA synthesis (33).

CLA isomer profile. The effect of diet on milk fat CLA is largely accounted for by a change in the concentration of RA, but other isomers can play an important role. The major positional isomer determined by Ag⁺-HPLC was 9,11 (*cis/trans* plus *trans/cis*), and 7,9 (*cis/trans* plus *trans/cis*) was the second most relevant peak with percentages about 80–85 and 6–8% of total CLA, respectively. RA abundance would be consistent with the relative importance of the endogenous synthesis of *cis*-9 *trans*-11 CLA from TVA by Δ-9 desaturase. Similarly, *trans*-7 *cis*-9 CLA would be produced from *trans*-7 18:1 by the same enzyme (36–38).

Figure 4 represents the relative concentration determined by Ag⁺-HPLC of minor CLA isomers and their development during the period of study. Noticeable increases in 12,14 and 11,13 (*cis-trans/trans-cis* and *trans-trans*) CLA were observed when linseed was added to the diet. Analysis by GC–MS of DMOX derivatives confirmed the increases in some of these isomers (Fig. 5). Three peaks emerged in the time of elution corresponding to *trans*-12 *trans*-14, *trans*-11 *trans*-13, and *trans*-11 *cis*-13 18:2, and their mass spectra (Fig. 6) were similar to the 11,13 and 12,14 positional isomer spectra previously described (26).

Only limited data are available on the effects of diet on the distribution of individual CLA isomers, but it seems that dietary supplements high in α-linolenic acid may increase the relative proportion of 11,13 and 12,14 positional isomers (21,39,40). Kraft *et al.* (24) hypothesized that the CLA isomers *trans*-11 *cis*-13 and *trans*-11 *trans*-13 18:2 are formed in large quantities as a result of grazing mountain pasture, which is rich in α-linolenic acid. As explained earlier, the pathway for the hydrogenation of α-linolenic acid in the rumen involves an initial isomerization in which the double bond at the carbon-12 position is transferred to the carbon-11 position to form *cis*-9 *trans*-11 *cis*-15 18:3, which is then reduced at both *cis* bonds to produce TVA through *trans*-11 *cis*-
FIG. 4. Development of CLA isomer contents (% of total CLA) determined by silver-ion HPLC in milk fat of ewes fed a diet enriched in α-linolenic acid. The treatment period (broken lines) involved a 6-wk addition of a supplement enriched in linseed.
FIG. 5. Profiles by GC–MS of CLA dimethyloxazoline derivatives of milk fat from ewes fed a control diet (solid line) and a diet enriched in α-linolenic acid (dotted line) obtained by high-resolution selected-ion recording at *m/z* 333. **1:** 9-*cis* 11-*trans* 18:2 + 7,9 18:2. **2:** 9-*trans* 11-*cis* 18:2. **3:** 10-*trans* 12-*cis* 18:2. **4:** 9-*cis* 11-*cis* 18:2. **5:** 10-*trans* 12-*trans* 18:2 + 9-*trans* 11-*trans* 18:2.

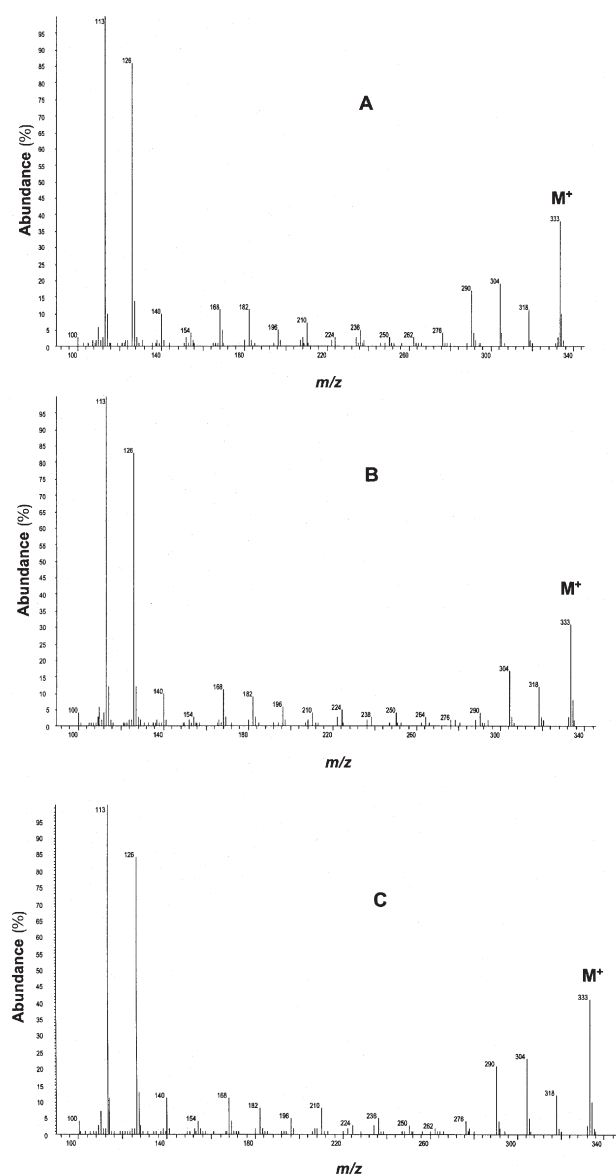
15 18:2 as an intermediate (33,41). Kraft *et al.* (24) argued that the *trans*-11 double bond was the most stable *trans*-bond found among the 18:1 isomers and among the CLA isomers in ruminal fermentation. They proposed the existence of three different CLA isomers having a *trans*-11 double bond in milk: *cis*-9 *trans*-11 from bacterial synthesis in the rumen (*via* linoleic acid) plus mammary gland desaturation, and *trans*-11 *trans*-13 and *trans*-11 *cis*-13, both of bacterial origin in the rumen from α-linolenic acid as an indirect precursor. Thus, the increases in *trans*-11 *trans*-13 and *trans*-11 *cis*-13 18:2


FIG. 6. Mass spectra of the peak labeled in Figure 5 as 11-*trans* 13-*cis* 18:2 (A), 12-*trans* 14-*trans* 18:2 (B), and 11-*trans* 13-*trans* 18:2 (C) corresponding to dimethyloxazoline derivatives of the milk fat of ewes fed a diet enriched in α-linolenic acid.

isomers found in the present study would be consistent with the results reported for the milk fat of cows grazed in alpine conditions (21,24). Nevertheless, the pathway from the *trans*-11 *cis*-15 18:2 to *trans*-11 *cis*-13 and *trans*-11 *trans*-13 18:2 isomers and the biological significance of these isomers are unclear and still have not been established.

With regard to other minor isomers, amounts of *trans*-10 *cis*-12 18:2 in the samples studied were low, less than 0.75% of total CLA isomers (Fig. 4, Table 3), and values did not change throughout the 3 mon of monitoring. As explanation, *trans*-10 *cis*-12 18:2 in the rumen would be formed from a linoleic but not from an α-linolenic acid pathway, as occurred for the *cis*-9 *trans*-11 isomer of CLA (41). Furthermore, since *cis*-12 desaturase activity has not been detected in the mam-

mary gland or other ruminant tissues, *trans*-10 18:1, formed in the rumen by biohydrogenation of different PUFA and absorbed from the intestine, would not be transformed endogenously to *trans*-10 *cis*-12 18:2.

With respect to *cis/cis* isomers, which are undetectable by UV-HPLC, small amounts were found in the ewe sample. The mass spectrum of the 9,11 positional isomer was detected just at the elution time of 9-*cis* 11-*cis* 18:2 when FA were derivatized to DMOX and analyzed by GC–MS. However, traces of other *cis/cis* isomers were not so clear. Concerning the rest of the CLA isomers found at low levels, no changes were observed when the supplement was added to the diet. These minor isomers seem to originate in the rumen (38). It has been suggested that ruminal bacteria possess several specific *cis*, *trans* isomerases that cause a wide range of these isomers and subsequently help produce a wide range of *trans*-18:1 FA in milk (36,41). Nonetheless, the biological significance of minor *trans*-18:1 isomers is still not well known and the pathways to their formation must be elucidated.

Development of CLA composition during cheese ripening. Mean fat content in cheeses made from the milk of ewes fed SEL was 58% (referring to total solid) and did not change during the ripening period. Nor were there alterations in proportions of major FA and total CLA after 4 mon. As can be seen in Table 2, FA profile hardly changed during the ripening period. After 4 mon, the levels of total CLA and other potentially healthful FA were steady. The effect on CLA content of converting milk to cheese and the subsequent aging and/or storage is controversial. Oxidative reactions could cause destruction of double bond systems, thus potentially reducing CLA levels. It could be argued that because CLA contains a conjugated double bond system, it would be more sensitive to oxidation or isomerization than linoleic or α-linolenic acid, and longer ripening times should show lower CLA content owing to the longer period of air exposure and fermenta-

tion time, which increases radical-mediated oxidation. The fact that no changes were observed in the PUFA profile during ripening (Table 2) seems to indicate that oxidation processes would not take place in these cheeses and that the original raw milk FA profile would not be altered.

The results of the present study coincide with previous research on different kinds of cheeses. No detrimental changes in the CLA content were observed during Mozzarella (14), Emmental (15), or Edam manufacture (16). However, other studies reported modifications in the FA profile and CLA content of Cheddar-type cheeses as a result of the processing (20). These changes were attributed to differences in lipid metabolism of the starter cultures, reflecting the activity of certain bacterial strains, such as lactic acid bacteria and propionibacteria, that are capable of converting linoleic acid to CLA *in vitro* (42,43).

The development of individual CLA isomers during cheese aging as determined by Ag^+-HPLC is shown in Table 3. Most of these isomers were previously reported in different types of cheeses (18,19,25). Considerable changes as a consequence of ripening were not observed, and only slight increases in some *trans/trans* isomers were noticed. Gnädig *et al.* (15) also showed a small increase in the content of the total *trans/trans* CLA isomers during Emmental cheese ripening. By carrying out studies of DMOX derivatives with GC–MS, it was possible to detect variable amounts of the different 9,11 18:2 geometric isomers (*trans/cis, cis/cis*, and *trans/trans*). However, it was not possible to do a reliable quantification and monitor the development of these isomers during the ripening period. The *cis*-9 *cis*-11 isomer co-elutes with C_{21} by GC and in the same area as oleic acid by Ag^+-HPLC, whereas *trans*-9 *cis*-11 18:2 was only resolved from RA when DMOX GC–MS was used. Werner *et al.* (17) also found that concentrations of individual CLA isomers (*cis*-9 *trans*-11, *cis*-9 *cis*-11, *trans*-9 *trans*-11/*trans*-10 *trans*-12) were different among cheeses with different ages. These authors attributed such differences in cheese to cultures and processing conditions. However, monitoring of CLA isomers from raw milk to aged cheese was not carried out.

Overall, the changes in CLA content and FA profile during cheese processing were small under the conditions studied. Such minor changes may not be of great significance. Since the processing of milk into cheese did not substantially alter the CLA content, the ideal solution for achieving cheeses with high concentrations of CLA would be to produce ewes' milk with a high CLA content.

Cheese sensory analysis. Table 4 shows the results of the sensory analysis of the cheeses, made with ewes' milk from the herds fed and not fed the supplement, at 2 and 3 mon of ripening. Scores for the sensory attributes—appearance, taste, and acceptability—did not differ among the samples, and there were no significant differences ($P \leq 0.05$) for cheeses made from the milk of ewes fed SEL. Although aroma and texture scores for cheeses manufactured from CLA-enriched milk at 2 mon of ripening were slightly lower than for cheeses prepared with bulk milk from ewe herds fed without SEL,

TABLE 4
Mean Scores of Sensory Attributes (on a 10-point scale) for Two Batches of Cheeses Made from Ewes' Raw Milk Fat from Animals Fed a Control Diet (CD) and a Diet Enriched in α-Linolenic Acid (LIN) at 2 and 3 mon of Ripening[a]

	2 mon		3 mon	
	CD	LIN	CD	LIN
Appearance	6.5 ± 0.7^a	6.7 ± 1.2^a	6.7 ± 1.2^a	6.0 ± 0.8^a
Aroma	6.7 ± 1.1^a	5.6 ± 1.3^a	5.6 ± 1.4^a	5.6 ± 1.0^a
Taste	5.4 ± 1.5^a	5.6 ± 1.3^a	4.8 ± 1.8^a	6.0 ± 0.9^a
Texture	6.5 ± 0.9^a	5.5 ± 1.0^a	5.7 ± 1.3^a	5.9 ± 0.9^a
General acceptability	5.7 ± 1.3^a	5.6 ± 1.2^a	5.6 ± 1.6^a	5.7 ± 0.9^a

[a]Values in the same row without a common superscript letter were significantly different: $P \leq 0.05$.

such differences were not significant. Furthermore, at 3 mon of ripening both values were similar. Finally, no strange flavors or odors were detected in the study.

Previous descriptive sensory analyses in dairy products high in PUFA and/or CLA do not supply definitive evidence. The impact of fortification with CLA on the properties of fluid milk and butter revealed that these products could exhibit different organoleptic characteristics (44,45), and their acceptance by consumers could be affected. However, in a more recent study (46), untrained panelists were unable to detect flavor differences initially and over time in milk with high CLA and TVA levels. For cheese, there are fewer studies. CLA-enriched milk was used successfully to manufacture Edam cheese with a softer texture and with acceptable organoleptic properties (16). Although in the current study no gritty characteristics were observed in cheeses made with milk from ewe herds fed SEL, increases in CLA and PUFA were small in comparison with amounts reported by Ryhänen *et al.* (16). Thus more research would be needed in this field to confirm the present findings and provide a full picture.

Commercial SEL addition to ovine diet under field conditions could be one way of increasing CLA content in milk fat. In the conditions assayed, minimum effects on the bulk milk yield and composition were observed. An additional advantage is the new FA profile. Other FA, potentially beneficial for human health, apart from RA, such as TVA and 18:3, increased in the milk fat of ewes fed supplemented diets. A decrease in the proportion of medium-chain saturated FA would also enhance the nutritional value of the milk. The changes observed in the CLA isomer profile do not apparently affect the nutritional properties of milk fat.

Overall, FA profile did not change during cheese making. The CLA content in ripened cheeses was comparable with the starting material, and no losses of potentially healthful FA were detected during processing. Finally, cheeses made with milk from linseed-supplemented diets exhibited sensory properties similar to the control products. Thus feeding with these supplements would not represent a hurdle for consumer acceptance of the final product. This could be an alternative way of obtaining dairy products from ewes' milk with added nutritional value.

Dietary Fatty Acids Regulate Cholesterol Induction of Liver CYP7α1 Expression and Bile Acid Production

ABSTRACT: In the present study we investigated the effects of dietary fats containing predominantly PUFA, monounsaturated FA (MUFA), or saturated FA (SFA) on lipid profile and liver cholesterol 7α-hydroxylase (CYP7α1) mRNA expression and bile acid production in C57BL/6J mice. The animals ($n = 75$) were randomly divided into five groups and fed a basic chow diet (AIN-93G) (BC diet), a chow diet with 1 g/100 g of cholesterol (Chol diet), a chow diet with 1 g/100 g of cholesterol and 14 g/100 g of safflower oil (Chol + PUFA diet), a chow diet with 1 g/100 g of cholesterol and olive oil (Chol + MUFA diet), or a chow diet with 1 g/100 g of cholesterol and myristic acid (Chol + SFA diet) for 6 wk. The results showed that the Chol + SFA diet decreased CYP7α1 gene expression and bile acid pool size, resulting in increased blood and liver cholesterol levels. Addition of PUFA and MUFA to a 1% cholesterol diet increased the bile acid pool production or bile acid excretion and simultaneously decreased liver cholesterol accumulation despite decreased CYP7α1 mRNA expression. The results indicate that the decreased bile acid pool size induced by the SFA diet is related to inhibition of the liver CYP7α1 gene expression, but an increased bile acid pool size and improved cholesterol homeostasis are disassociated from the liver CYP7α1 gene expression.

Paper no. L9639 in *Lipids 40*, 455–462 (May 2005).

The role of high blood cholesterol as an important factor in advancing atherosclerosis is now widely accepted. The role of diet in modifying blood cholesterol concentrations is also generally recognized. Dietary cholesterol and saturated FA (SFA) increase total cholesterol (TC) concentrations in circulation, whereas PUFA generally reduce and monounsaturated FA (MUFA) have a little or no effect on plasma cholesterol concentrations. Whole-body cholesterol homeostasis is controlled by many factors including absorption of dietary cholesterol, metabolism of plasma cholesterol, *de novo* cholesterol synthe-

sis, cellular uptake of cholesterol, and excretion of cholesterol into bile acids. The mechanisms by which dietary FA influence blood cholesterol are not fully defined.

Removal of excess cholesterol from the body by the formation of bile acids in the liver is very important for maintaining cholesterol homeostasis. Cholesterol 7α-hydroxylase (CYP7α1) is the first and rate-limiting enzyme of bile acid synthesis in the liver (1). Thus, the activity of CYP7α1 can have a major impact on the overall catabolism of excess cholesterol. Epidemiological studies and animal experiments suggest that lower CYP7α1 activity or CYP7α1 gene deficiency is related to hypercholesterolemia and the accumulation of cholesterol in liver. Mutation in the CYP7α1 gene may lead to high LDL-cholesterol (LDL-C) level and cardiovascular disease, and enhancement of CYP7α1 activity may decrease serum LDL-C effectively (2–6).

The level of CYP7α1 is regulated by various factors including nutrients, bile acid back to the liver from the intestine *via* the enterohepatic circulation process, and others. The regulation usually occurs at the level of transcription. Recently, some of the factors that regulate transcription of this gene have been described (7). Hydrophobic bile acids have a relatively strong inhibitory effect on this enzyme. Among dietary nutrients, cholesterol increases the expression of CYP7α1 mRNA (8–10), and other dietary fats or FA also play a role in modulation of CYP7α1 activity and mRNA expression. Cheema *et al.* in 1997 (11) reported that cholesterol status does not necessarily determine the amount of CYP7α1 mRNA, suggesting that other dietary fats are important factors in the regulatory potential of dietary cholesterol on CYP7α1 gene expression. The role of different FA in the ability of dietary cholesterol to stimulate liver CYP7α1 mRNA abundance and protein content and to regulate total bile acid synthesis has not been fully investigated.

The mechanisms by which dietary fat or FA affect cholesterol-induced bile acid synthesis and CYP7α1 activity or gene expression are complex and have not been elucidated so far. Evidence from some studies indicates that FA does not directly bind to CYP7α1 (12,13); the pathway of different FA that regulate CYP7α1 is worthy of further investigation.

The present study investigated the effects of dietary fats containing predominantly PUFA, MUFA, or SFA on the ability

of dietary cholesterol to regulate liver CYP7α1 mRNA abundance and bile acid synthesis.

MATERIALS AND METHODS

Animals and diets. Seventy-five female mice (C57BL/6J) from the animal center of Sun Yat-sen University were used in the experiments. The animals were bred and maintained under conventional housing conditions, and all procedures were followed in accordance with the approved protocol for use of experimental animals set by the standing committee on animal care at Sun Yet-sen University. The animals were randomly divided into five groups of 15 animals and fed for 6 wk with one of the following: a normal chow diet (AIN-93G formulation) (14) (BC group); a chow diet containing 1 g/100 g cholesterol (Chol diet); a chow diet with 1 g/100 g of cholesterol and 14 g/100 g of safflower oil (Chol + PUFA diet); a chow diet with 1 g/100 g of cholesterol and olive oil (Chol + MUFA diet); or a chow diet with 1 g/100 g of cholesterol and myristic acid (Chol + SFA diet). Linseed oil (1 g/100 g) was also added to Chol + PUFA, Chol + MUFA and Chol + SFA diets to ensure an adequate source of n-3 FA (15). The composition of the diets is shown in Table 1. The nutritional ingredients including casein, mineral mixture, and vitamin mixture were all purchased from Harlan Teklad (Madison, WI). Myristic acid and linseed oil were purchased from Sigma (St. Louis, MO). The FA composition was determined by GLC (Table 2). The animals were given free access to food and water. Samples of serum, liver, small intestine and its whole content were collected after 6 wk. Serum was frozen at −20°C, and the tissue samples were kept in liquid nitrogen. The total energy intake in food or body weight gained in the animals of the BC group was less than that of four test groups; however, no differences in the intake of energy or body weight gained among the four test groups was observed throughout the duration of the study (data not shown).

Serum lipids. Blood samples were obtained by retro-orbital bleeding under ether anesthesia, and serum was separated by centrifugation. Serum TC, LDL-C, and HDL-cholesterol (HDL-C) were measured using a Hitachi Automatic Analyzer (Tokyo, Japan). Serum TC was determined by a cholesterol esterase and cholesterol oxidase assay (16), and the concentrations of HDL-C were assayed by the same method after removing LDL-C and VLDL cholesterol with magnesium dextran sulfate. Serum LDL concentrations were calculated according to the Friedwald *et al.* formula (17), which assumes that circulating VLDL consists of 80% TG and 20% cholesterol.

Serum FA. The levels of serum FA were determined by capillary GC after extraction by methanol and hexane (4:1, vol/vol) and transesterification directly in a one-step reaction (18). The relative amount of each FA (g/100 g) was quantified. Serum levels of SFA, MUFA, and PUFA were calculated.

Hepatic cholesterol level. Liver was removed immediately and rinsed with cold PBS after the animal had been sacrificed, then dried, minced, and weighed before extracting the lipids by the method of Folch *et al.* (19). The TC content in liver was determined by using an enzymatic fluorometric assay based on a modification of the previously described methods (20). The samples were run in duplicate. All values are expressed as µmol/g tissue per animal.

Bile acid pool. The entire small intestine and its contents, along with the bulk of the liver and the gallbladder, were homogenized and combined, then extracted with isopropanol. The total bile acid content of the extract was taken to dryness and resuspended in an appropriate volume of methanol. Bile acids were quantified using the method of Bianchini *et al.* (21).

Preparation of liver microsomes. Liver microsomes were obtained using a modification of the method of Cheema *et al.* (11). Samples of frozen livers (100–500 mg) were minced in 1 mL of ice-cold buffer containing 0.3 mol/L sucrose, 1 mmol/L EDTA, 50 mmol/L KF, 50 mmol/L KC1, 5 mmol/L DTT, 0.1

mol/L K_2HPO_4 (pH 7.4), and then disrupted in a 2-mL Potter-Elvehjem homogenizer. Homogenates were centrifuged at 9,000 × g at 4°C. The supernatant was centrifuged for 70 min at 110,000 × g in a SW-60 rotor (Beckman Instruments) at 4°C. The microsomal pellet from the second spin was resuspended in 1 mL of buffer containing 0.1 mol/L K_2HPO_4 (pH 7.4), 1 mmol/L EDTA, 50 mmol/L KF, 5 mmol/L DTT, and 50 mmol/L KCl. Aliquots of liver microsomes (60–70 mg/mL) were then rapidly frozen in liquid nitrogen and stored at −80°C until assayed.

Assay for CYP7α1 mRNA by RT-PCR. Total RNA was extracted from liver by using a reagent kit according to the manufacturer's instructions (Sangon, Shanghai, China). RNA was reverse-transcribed from 5 µg of total RNA in a final volume of 20 µL using the kit RT-PCR (Sangon). The reaction was stopped by heating the samples at 70°C for 10 min. cDNA was subjected to DNA amplification by PCR (22) using 2 units of Tag DNA polymerase and both primer pairs complementary to murine CYP7α1 cDNA, PPARα cDNA, and actin cDNA, at a final concentration of 0.4 µmol/L of each primer. The reaction was predenaturated at 94°C for 4 min. The amplification cycle (denaturing at 94°C for 30 s, annealing at 56°C for 45 s, and extending at 72°C for 45 min) was repeated 35 times and followed by a final extension for 10 min at 72°C. The primers for CYP7α1 were 5′-CCTTGGGACGTTTTCCTGCT-3′ (sense) and 5′-GCGCTCTTTGATTTAGGAAG-3′ (antisense). The expected product length was 515 bp. The primers for the "housekeeping gene" β-actin were 5′-GGACTCCTATGTGGGTGACGAGG-3′ (sense) and 5′-GGGAGAGCATAGCCCTCGTAGAT-3′ (antisense). The expected product length was 366 bp. Final PCR products were separated on 2% agarose gel and detected by ethidium bromide staining. Semiquantitative estimation was done by com-paring the amount of mRNA expression of CYP7α1 with β-actin.

Assay for CYP7α1 protein by Western blot. CYP7α1 protein was analyzed by immunoblotting with the anti-CYP7α1 antibody. Protein extracts of the liver microsome were prepared, and protein concentration was determined by using a Bio-Rad kit. Immunoblot analysis was performed using a modification of the method described by *Liang et al.* (23). Briefly, microsomal polypeptides (50 µg of protein) were loaded on 10% SDS-PAGE (Bio-Rad Laboratories, Hercules, CA), and the separated proteins were electrophoretically transferred to polyvinylidene difluoride membranes at 100 V for 90 min. The membrane was blocked in Tris-buffered saline with 0.1% Tween 20 and 5% nonfat milk and probed with the goat polyclonal antibody to CYP7α1 (1:800) (Santa Cruz Biotechnology, Santa Cruz, CA) overnight at 4°C, followed by a rabbit anti-goat conjugated horseradish peroxidase IgG (1:10,000) (Santa Cruz Biotechnology). Specific protein bands were revealed by enhanced chemiluminescence and visualized by the exposure to autoradiographic film.

Statistical analysis. Results are expressed as means ± SD. Data were analyzed by one-way ANOVA coupled with the Student–Newman–Keuls multiple comparison test. Differences were considered significant if $P < 0.05$. SPSS 11.0 software (Chicago, IL) was used for all statistical analyses.

RESULTS

Body weights and food intake. The amount of food consumption by the mice was recorded daily and did not significantly differ between the diet groups throughout the 6-wk feeding period. The

TABLE 3
Serum Lipid Concentrations in Mice Fed Different Diets[a]

Groups	TC (mmol/L)	LDL-C (mmol/L)	HDL-C (mmol/L)	LDL-C/HDL-C

[a]Results shown are means ± SD, $n = 10$. ○, $P < 0.001$ vs. BC group; △, $P < 0.05$ vs. Chol group; ☆, $P < 0.001$ vs. Chol + SFA group. TC, total cholesterol; LDL-C, LDL-cholesterol; HDL-C, HDL-cholesterol; BC, basic chow; for other abbreviations see Tables 1 and 2.

body weights of the animals did not significantly differ among the different dietary groups at the beginning. At the end of the feeding period, the body weight of mice fed BC diet was significantly lower than that of mice fed other diets, and there were no significant differences among Chol, SFA + Chol, PUFA + Chol, and MUFA + Chol dietary groups (data not shown).

Serum lipid profile. Addition of 1% cholesterol to the chow diet induced hypercholesterolemia, and addition of different types of FA with cholesterol further modified the plasma cholesterol levels (Table 3). As compared with the 1% cholesterol diet, supplementation of PUFA significantly decreased the serum levels of LDL-C and the LDL-C/HDL-C ratio, but increased the serum level of TC by 27% ($P < 0.001$) and that of HDL-C by 44% ($P < 0.001$). MUFA reduced serum HDL-C by 6.7% ($P < 0.05$) and elevated LDL-C by 12% ($P < 0.001$) and

the LDL-C/HDL-C ratio by 21% ($P < 0.001$), but had no influence on serum TC. SFA increased serum TC, LDL-C, and the LDL-C/HDL-C ratio by 56 ($P < 0.001$), 150 ($P < 0.001$), and 120% ($P < 0.001$), respectively. The mice fed the Chol + SFA diet had the highest LDL-C level and LDL-C/HDL-C ratio as compared with the other groups ($P < 0.001$) (Table 3).

Cholesterol accumulation in liver. Addition of cholesterol to diets increased the hepatic TC accumulation in all diet groups as compared with the BC diet ($P < 0.001$) (Fig. 1). Supplementation with SFA doubled the liver cholesterol content as compared with the 1% cholesterol diet alone ($P < 0.001$) and resulted in the highest level of liver cholesterol among the diet groups ($P < 0.001$). Accumulation of cholesterol in livers of mice fed Chol + PUFA and Chol + MUFA diets was reduced by 40 ($P < 0.001$) and 25% ($P < 0.001$), respectively, as compared with the mice fed cholesterol alone ($P < 0.001$). There was a significant difference in liver cholesterol levels between the Chol + PUFA and the Chol + MUFA groups ($P < 0.001$).

Bile acid pool. Addition of 1% cholesterol to the BC diet increased the bile acid pool size by 52% as compared with that of the BC diet ($P < 0.001$) (Fig. 2). When different FA were added to a cholesterol-supplemented diet, the response in bile acid pool size was variable. The bile acid pool size of mice fed the Chol + SFA diet decreased by 54% ($P < 0.001$) compared with mice fed the Chol diet; animals consuming the Chol + SFA diet had the lowest bile acid pool size among the different dietary groups ($P < 0.001$). The bile acid pool size in mice fed Chol + PUFA and Chol + MUFA diets increased by 26 ($P < 0.001$) and 48%, respectively, compared with mice fed a cholesterol diet alone ($P < 0.001$).

CYP7α1 mRNA expression and CYP7α1 protein content in liver. To investigate whether different diets cause an alteration of CYP7α1 mRNA, a reverse transcriptase-PCR analysis for total mRNA samples extracted from the liver was performed, and β-actin was used as housekeeping gene. The results showed that the highest level of CYP7α1 mRNA was expressed in the liver of mice fed Chol diet ($P < 0.001$). Consumption of Chol + PUFA or Chol + MUFA diets decreased the expression of CYP7α1 mRNA by 43 and 50%, respectively, compared with mice fed cholesterol alone ($P < 0.001$ and $P < 0.001$, respectively). The expression of CYP7α1 mRNA of the liver in mice fed Chol + SFA was only 16% ($P < 0.001$) of that of mice fed the Chol diet, and it was the lowest among the groups ($P < 0.001$) (Fig. 3A).
FIG. 1. Hepatic cholesterol concentrations in mice fed diets containing cholesterol and different fats. Cholesterol accumulation in livers was quantified as described in the Materials and Methods section. The differences among the groups were analyzed by one-way ANOVA coupled with LSD-*t* multiple comparison test. Values are expressed as means ± SD, $n = 8$. ○, $P < 0.001$ vs. BC group; △, $P < 0.001$ vs. Chol group; ☆, $P < 0.001$ vs. Chol + SFA group. BC, basic chow; MUFA, monounsaturated FA; SFA, saturated FA.
FIG. 2. Bile acid pool size in mice fed diets containing cholesterol and different fats. The bile acid pool size in mice was assayed as described in the Materials and Methods section. The differences among the groups were analyzed by one-way ANOVA coupled with LSD-t multiple comparison test. Values are means ± SD, $n = 7$. ○, $P < 0.001$ vs. BC group; △, $P < 0.001$ vs, Chol group; ☆, $P < 0.001$ vs. Chol + SFA group. For abbreviations see Figure 1.

Figure 3B shows that feeding of the cholesterol diet elevated liver CYP7α1 protein content by 48% compared with the BC group ($P < 0.001$), whereas feeding of the Chol + PUFA, Chol + MUFA, or Chol + SFA diets decreased CYP7α1 protein content by 29 ($P < 0.001$), 31 ($P < 0.001$), and 45% ($P < 0.001$), respectively, as compared with mice fed cholesterol alone. The mice fed Chol + SFA diet had the lowest content among the groups ($P < 0.001$).

DISCUSSION

All diets containing cholesterol in the present study induced hypercholesterolemia, but the response of blood lipids to the addition of different dietary FA to 1% cholesterol diet varied. The striking aspect in these results was that when PUFA was added to the Chol diet, the serum TC was significantly increased, although the increased fraction was mainly in the HDL-C. The effects of MUFA or SFA on serum cholesterol levels were similar to those found previously (24–28). Compared with cholesterol diet feeding, the Chol + MUFA diet produced the same serum TC, but significantly increased the LDLC/HDL-C ratio, meaning that MUFA does not affect the total serum cholesterol level but increases the distribution of cholesterol in LDL-C. The Chol + SFA diet resulted in higher ($P < 0.001$) serum TC and LDL-C/HDL-C (Table 3). In addition, the dietary cholesterol plus FA changed the accumulation of cholesterol in the liver. Liver cholesterol in mice fed the Chol + SFA diet was the highest among the groups, and was three, four, and five times more than that in mice fed Chol, Chol + MUFA, and Chol + PUFA diets, respectively (Fig. 1). Together, the changes of lipid profile in blood and cholesterol accumula-

tion in the liver following addition of SFA to the diet increased the risk of atherosclerosis. Dietary PUFA showed a beneficial effect, indicated by the increasing HDL concentration. MUFA did not cause a beneficial change by improving the lipid profile, as has been reported by others (29,30) because it increased serum LDL concentration.

In the present study, feeding a diet containing SFA and cholesterol for 6 wk reduced the bile acid pool size; consumption of diets containing MUFA and PUFA increased the pool size as compared with cholesterol alone. In previous study by Cheema *et al.* (11), feeding the SFA diet for 3 wk to mice induced the highest level of bile acids in gallbladder bile as compared with PUFA and MUFA diets. The different lengths of the feeding period could explain the discrepancy in results between our study and the report of Cheema *et al*. Synthesis of bile acid is affected by many factors, such as blood lipid profile, CYP7α1 activity, and bile acid feedback. It is possible that bile acid synthesis during a period of 3 wk of feeding of FA is different from that for 6 wk. A longer feeding period may better reflect the real impact of FA on bile acid synthesis. Secondly, Cheema *et al*. measured bile acid level in gallbladder bile, which does not represent the bile acid pool size that we measured.

Cholesterol degradation to bile acids occurs *via* "classic" (or neutral) and "alternative" (or acidic) bile acid biosynthetic pathways. The classic or neutral pathway, common to all mammals, is initiated by CYP7α1, an enzyme located in the endoplasmic reticulum. The rate of cholesterol degradation to bile acids is controlled in part by the enzyme CYP7α1, which catalyzes the initial step in the pathway of bile acid synthesis that is responsible for more than 50% of bile acid formation (31,32). CYP7α1 activity is controlled by a variety of hormonal and nutritional factors. On the basis of the fact that a positive correlation between CYP7α1 mRNA and CYP7α1 activity has been illustrated by many studies (11,33), we assayed the CYP7α1 mRNA expression to examine the influence of different dietary FA on the liver CYP7α1 activity. The stimulation of murine CYP7α1 gene expression by dietary cholesterol is well documented (34,35). In the present study we also confirm that CYP7α1 mRNA and protein abundance increased in response to a 1% cholesterol supplementation of the diet.

Dietary fats are known to modify the whole-body cholesterol homeostasis; the mechanism proposed is related to the regulation on CYP7α1 (1,24–28). Feeding 1% cholesterol increased CYP7α1 gene expression; however, addition of dietary FA to the cholesterol-enriched semipurified diets did not result in a further increase of CYP7α1 mRNA and protein abundance. The addition of PUFA, MUFA, and SFA to a 1% cholesterol diet all caused a significant reduction in both CYP7α1 mRNA and protein abundance as compared with a 1% cholesterol diet. The Chol + SFA diet caused the lowest expression of CYP7α1 mRNA among the groups (Fig. 3). Although the majority of studies have documented induction of CYP7α1 mRNA in response to dietary PUFA and suppression in response to dietary SFA, the reports on CYP7α1 mRNA in response to MUFA have not been unanimous (11,36). It has been

A

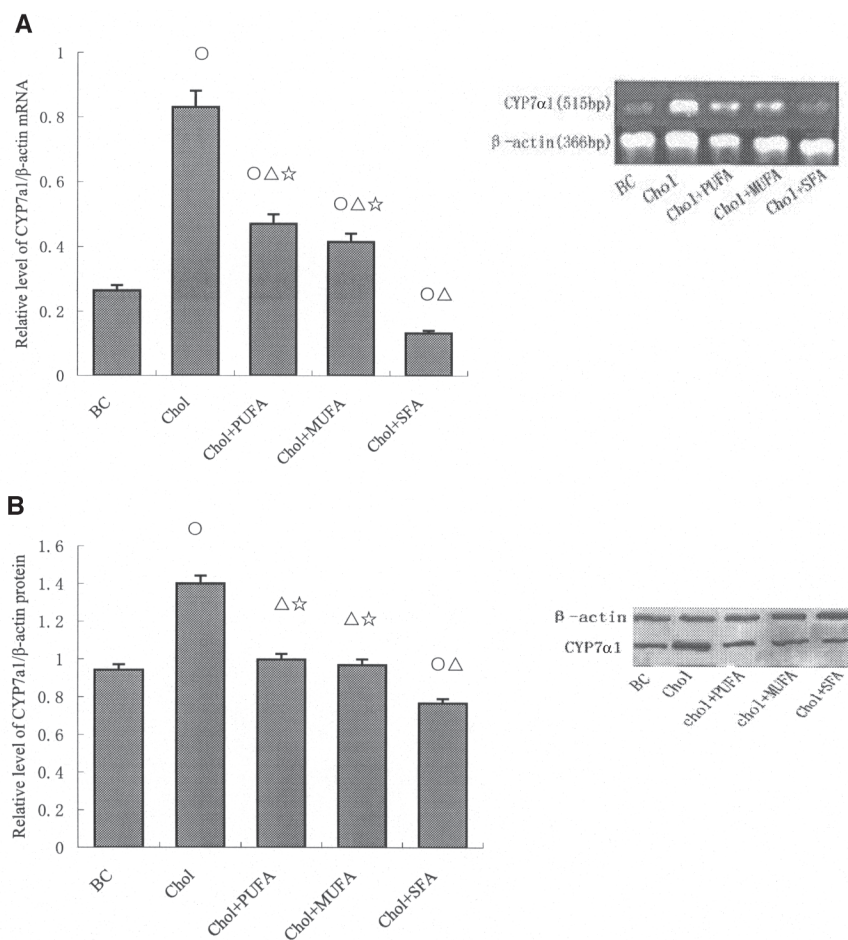
B


FIG. 3. Cholesterol 7α-hydroxylase (CYP7α1) mRNA (A) and protein (B) abundance in the liver microsome of mice fed diets containing cholesterol and different fats. The CYP7α1 mRNA and protein abundance were quantified as described in the Materials and Methods section. The levels of CYP7α1 mRNA (protein) were calculated as the ratio of CYP7α1 to β-actin mRNA (protein). The differences among the groups were analyzed by one-way ANOVA coupled with LSD-*t* multiple comparison test. Values are means ± SD, *n* = 5. ○, $P < 0.001$ vs. BC group; △, $P < 0.001$ vs. Chol group; ☆, $P < 0.001$ vs. Chol + SFA group. For other abbreviations see Figure 1.

reported that SFA directly inhibit CYP7α1 activity, which is related to the decrease of bile acid synthesis and smaller bile acid pool size (11). The alteration of pool size of bile acid induced by SFA diet is associated with the level of CYP7α1 mRNA. The SFA diet significantly decreased both the bile acid pool size and CYP7α1 mRNA expression (Fig. 2). The most striking aspect of the present results is that levels of CYP7α1 mRNA expression did not correlate with the variation of bile acid pool size in mice fed PUFA and MUFA diets. Addition of PUFA or MUFA to 1% cholesterol-supplemented diet led to a significant increase in the bile acid pool but decreased CYP7α1 mRNA expression.

Although several recent studies challenge the notion that the regulation of CYP7α1 is a major determinant of plasma cholesterol responsiveness, the regulation of bile acid biosynthesis by CYP7α1 behavior is quite different between mouse and human (33,37). The human CYP7α1 gene is not stimulated by dietary cholesterol in transgenic mice. In contrast, CYP7α1 gene expression is responsive to dietary cholesterol in the mouse (33). Bile acid synthesis exhibits negative feedback regulation *via* inhibition of the transcription of the CYP7α1 gene and a decrease in the enzymatic activity of CYP7α1 (38–40). The mechanism includes: "bile acid response element (BARE)" (41); activation of protein kinase C (42), which in turn activates farnesoid X receptor (FXR) (43,44); and cytokines (45). The fact that the SFA diet caused the lowest CYP7α1 mRNA expression and bile acid pool size among the groups suggested that SFA may directly inhibit the liver CYP7α1 through the BARE pathway. This result is consistent with a study (45) that suggested that dietary saturated fats retard excretion of dietary cholesterol as compared with PUFA and MUFA. However, the levels of CYP7α1 mRNA and protein decreased, whereas, contrary to expectation, the bile acid pool size increased in the mice fed Chol + PUFA or Chol +

MUFA diet. The effects of PUFA and MUFA on bile acid biosynthesis may consist of positive and negative pathways. PUFA and MUFA may directly exert stimulatory influence on CYP7α1 expression (11,36), which in turn promotes bile acid formation. However, bile acids back to the liver via the process of enterohepatic circulation inhibit CYP7α1 expression. It has been proposed that the bile acid pool size is the major regulator of CYP7α1 activity (46). When the feedback inhibition effect by bile acid overrides the induction by cholesterol and FA, the integrated outcome is the decrease of CYP7α1 mRNA expression. Tiemann *et al.* (46) demonstrated that long-term feeding of dietary cholesterol increases bile acid pool size despite decreased enzyme activity in mice. Thus, in the present study, the lower CYP7α1 mRNA expression in mice fed Chol + PUFA or Chol + MUFA may result mostly from the feedback inhibition of bile acids back to the liver rather than direct inhibition from PUFA or MUFA.

As already mentioned, the alternative (acidic) bile acid biosynthesis is also an important mechanism for maintenance of cholesterol homeostasis in animals (31). The acidic pathway initiated by CYP27α1 converts cholesterol to 27-hydroxycholesterol and cholestenoic acid. The acidic pathway may be considered as a reverse cholesterol transport process for removing excess cholesterol from the peripheral tissue to the liver for conversion to bile acids and thus may protect humans from developing atherosclerosis (47). It is possible that the high blood cholesterol concentration induced by dietary cholesterol and FA may promote the pathway of acidic bile acid biosynthesis, thus enlarging the bile acid pool size. Consequently, the increase of bile acid going back to the liver *via* the enterohepatic circulation process exerts an inhibitory role on CYP7α1 mRNA expression. However, it was reported that the alternate pathway of bile acid synthesis is not regulated by dietary cholesterol (35). How the high plasma lipid profile stimulates acidic bile acid biosynthesis remains unclear and needs further elucidation.

In conclusion, the present study found that diets containing SFA in addition to cholesterol decreased CYP7α1 gene expression and bile acid pool size, resulting in increased blood cholesterol and LDL concentrations. The addition of PUFA and MUFA to a cholesterol-supplemented diet increased bile acid pool production or bile acid excretion despite decreased CYP7α1 mRNA expression, which is beneficial in maintaining cholesterol homeostasis. The different dietary FA may play different roles in cholesterol removal or bile acid production *via* CYP7α1 or other pathways.

Regulation of Palmitoyl-CoA Chain Elongation by Clofibric Acid in the Liver of Zucker fa/fa Rats

Tomoaki Toyama[a], Naomi Kudo[a,*], Atsushi Mitsumoto[b], and Yoichi Kawashima[a]

[a]Faculty of Pharmaceutical Sciences, Josai University, Saitama 350-0295, Japan, and [b]Faculty of Pharmaceutical Sciences, Josai International University, Chiba 283-8555, Japan

ABSTRACT: The regulation of palmitoyl-CoA chain elongation (PCE) by clofibric acid [2-(4-chlorophenoxy)-2-methylpropionic acid] was investigated in comparison with stearoyl-CoA desaturase (SCD) in the liver of obese Zucker fa/fa rats. The proportion of oleic acid in the hepatic lipids of Zucker obese rats is 2.7 times higher than that of lean littermates. The activities of PCE and SCD in the liver of Zucker obese rats were markedly higher than in lean rats, and the hepatic uptake of 2-deoxyglucose (2-DG) was also higher in Zucker obese rats compared with lean rats. The increased activities of SCD and PCE in Zucker obese rats were due to the enhanced expression of mRNA of both SCD1 and rat FA elongase 2 (rELO2), but not SCD2 or rELO1. The proportion of oleic acid in the liver was significantly increased by the administration of clofibric acid to Zucker obese rats, and the hepatic PCE activity and rELO2 mRNA expression, but not the SCD activity or SCD1 mRNA expression, were increased in response to clofibric acid treatment. By contrast, the activities of both PCE and SCD and the mRNA expression of SCD1 and rELO2 in the liver were increased by the treatment of Zucker lean rats with clofibric acid. Multiple regression analysis, which was performed to determine the relationships involving PCE activity, SCD activity, and the proportion of oleic acid, revealed that the three parameters were significantly correlated and that the standardized partial regression coefficient of PCE was higher than that of SCD. These results indicate that oleic acid is synthesized by the concerted action of PCE and SCD and that PCE plays a crucial role in the formation of oleic acid when Zucker fa/fa rats are given clofibric acid.

Paper no. L9702 in *Lipids 40*, 463–470 (May 2005).

Oleic acid is a major component of TG for storing energy and an important constituent of phospholipids for maintaining membrane function in mammals. Recently, the secretion of VLDL has been shown to be highly dependent on oleic acid production in the liver (1). Moreover, oleic acid is involved in the differentiation of neurons (2,3), regulation of appetite (4), and the development of obesity (5) and metabolic diseases such as atherosclerosis (6). The biosynthesis of oleic acid from palmitic acid involves sequential reactions catalyzed by palmitoyl-CoA chain elongase (PCE) and stearoyl-CoA desaturase (SCD) (7). PCE and SCD are induced by carbohydrates (8), refeeding after fasting (9,10), and peroxisome proliferators, such as clofibric acid [2-(4-chlorophenoxy)-2-methylpropionic acid], diethylhexylphthalate, and perfluorooctanoic acid (7,11,12). Based on these findings, it has been postulated that PCE is regulated by mechanisms similar to SCD. However, on the basis of an experiment in which the effects of carbohydrate and clofibric acid on PCE and SCD were examined in the liver of Wistar rats, we concluded that PCE is regulated in a manner different from that of SCD. Thus, the effects of clofibric acid on the activities of PCE and SCD in oleic acid formation in animals under a variety of physiological conditions are of interest.

Lipogenesis in the liver of genetically obese Zucker fa/fa rats is enhanced, resulting in excessive fat accretion and elevated plasma levels of TG compared with their nonobese littermates (13,14). The proportion of oleic acid in the hepatic lipids of obese Zucker rats is much higher than that of lean rats (15). It seems likely therefore that the formation of oleic acid is not governed by normal regulation in the liver of obese Zucker rats. However, no information is available on the activity of PCE and its regulation in the liver of obese and lean Zucker rats. Treatment of obese Zucker rats with fenofibrate, a clofibric acid analog, has been demonstrated to increase the proportion of oleic acid in hepatic lipids (13) but there is little information about the response of PCE and SCD to fibrates.

The aims of the present work are (i) to identify the genes responsible for PCE and SCD expression in the liver of lean and obese Zucker rats, (ii) to study the effects of clofibric acid on the expression of the genes responsible for PCE and SCD in the liver of Zucker rats, and (iii) to investigate the role of PCE, in comparison with SCD, in oleic acid formation in the liver of Zucker rats.

MATERIALS AND METHODS

Materials. [2-^{14}C]Malonyl-CoA (55 Ci/mol) and 2-deoxy-[1-^{14}C]glucose (2-[^{14}C]DG, 55 Ci/mol) were purchased from American Radiolabeled Chemicals, Inc. (St. Louis, MO); D-[2-^{3}H]mannitol (20 Ci/mmol) was from MP Biochemicals Inc. (Irvine, CA). Stearoyl-CoA, palmitoyl-CoA, malonyl-CoA, clofibric acid, and BSA were purchased from Sigma (St. Louis, MO); NADH and NADPH were from Oriental Yeast

Abbreviations: AOX, acyl-CoA oxidase; clofibric acid, 2-(4-chlorophenoxy)-2-methylpropionic acid; 2-DG, 2-deoxyglucose; rELO, rat FA elongase; PCE, palmitoyl-CoA chain elongase; SA, specific radioactivity; SCD, stearoyl-CoA desaturase.

Co. (Tokyo, Japan); nonadecanoic acid was from Nu-Chek-Prep Inc. (Elysian, MN). All other chemicals used were of analytical grade.

Animals. Male obese Zucker fa/fa rats and their lean littermates aged 11 wk were purchased from Charles River Japan (Tokyo, Japan). Rats were fed on a standard chow (CE-2) (Clea Japan, Tokyo, Japan) *ad libitum* and allowed free access to water. Rats aged 15 wk were given a subcutaneous injection of clofibric acid at a dose of 100 mg/kg body weight twice a day for 7 d. Blood was obtained from the descending vena cava under diethylether anesthesia, and then their livers were removed and perfused with ice-cold 0.9% (wt/vol) aqueous NaCl. Part of the livers was frozen in liquid nitrogen and stored at -80°C for preparation of total RNA while another part of the livers was homogenized with 4 vol of 0.25 M sucrose/1.0 mM EDTA/10 mM Tris-HCl (pH 7.4) in a Potter glass-Teflon homogenizer. An aliquot of the homogenates was frozen in liquid nitrogen and stored at –80°C for lipid analysis and assay for peroxisomal acyl-CoA oxidase (AOX). The remaining homogenates were centrifuged at $18,000 \times g$ for 20 min, and the supernatant was recentrifuged under the same conditions. The supernatant was centrifuged at $105,000 \times g$ for 60 min. The pellet was resuspended in 0.25 M sucrose/0.1 mM EDTA/10 mM Tris-HCl (pH 7.4) and recentrifuged under the same conditions. The resulting pellet was resuspended in a small volume of 0.25 M sucrose/0.1 mM EDTA/10 mM Tris-HCl (pH 7.4) and used as an enzyme source (microsomes). All of these operations were carried out at 0–4°C. Protein concentrations were determined by the method of Lowry *et al.* (16) using BSA as a standard. All animal studies complied with the institutional board for animal studies, Josai University.

Enzyme assays. SCD activity was estimated spectrophotometrically as the stearoyl-CoA-stimulated re-oxidation of NADH-reduced cytochrome b_5 (17). The assay for the microsomal chain elongation of palmitoyl-CoA was performed by measuring the incorporation of [2-^{14}C]malonyl-CoA into palmitoyl-CoA (8). AOX was assayed by measuring palmitoyl-CoA-dependent H_2O_2 production according to the method of Small *et al.* (18) as previously described (8).

RNA extraction and real-time quantitative PCR. Total RNA was prepared from the livers of rats using an RNeasy kit (Qiagen, Hilden, Germany). RNA was quantified spectrophotometrically based on the absorption at 260 nm. Complementary DNA was prepared from the total RNA with avian myeloblastosis virus (AMV) reverse transcriptase (Takara, Tokyo, Japan). The specific primer sets for SCD1, SCD2, rat FA elongase 1 (rELO1), and rELO2 were designed using Primer Express 2.0 software (Applied Biosystems, Foster City, CA) (Table 1). The specific primer set for β-actin was used as described by Zhang *et al.* (19). PCR amplification was carried out using QuantiTect SYBR Green PCR master mix (Qiagen) with 300 nM primers. The amplification and detection were performed with an iCycler IQ real-time detection system (Bio-Rad, Richmond, CA). PCR conditions were a 15-min denaturation step at 95°C followed by 40 cycles of 15 s denaturation at 94°C, 30 s annealing at 57°C, and 30 s extension at 72°C. Reverse transcriptase-PCR products were analyzed by electrophoresis on ethidium bromide-stained agarose to ensure that a single amplicon of the expected size was indeed obtained. To measure PCR efficiency, serial dilutions of reverse transcribed RNA (0.1 to 100 ng) were amplified, and a line was obtained by plotting cycle threshold (C_T) values as a function of the starting reverse-transcribed RNA, the slope of which was used for an efficiency calculation using the formula $E = 10^{|(1/\text{slope})| - 1}$ (20). The quantity of any given gene, expressed as the value relative to the amount in the lean rats, was calculated after determination of the difference between the C_T of the given gene A and that of the calibrator gene B (β-actin) in the obese rats or clofibric acid-treated rats ($\Delta C_{T1} = C_{T1A} - C_{T1B}$) and lean rats ($\Delta C_{T0} = C_{T0A} - C_{T0B}$) using the $2^{-\Delta\Delta CT(1-0)}$ formula (20).

2-Deoxyglucose (2-DG) uptake. 2-DG uptake was measured according to Rajkumar *et al.* (21). In this procedure, rats were fasted for 12 h and then anesthetized by an intraperitoneal injection of pentobarbital (50 mg/kg body weight). A polyethylene catheter was placed in the right jugular vein, and then 2-[^{14}C]DG (9 μCi/rat) and D-[2-^{3}H]mannitol (90 mCi/rat) were injected through the catheter. D-[2-^{3}H]Mannitol was used to measure the extracellular spaces. For the determination of the decay of the specific radioactivity of 2-DG in blood, 200-mL blood samples were collected at 3, 5, 10, 20, 30, and 40 min after the injection of 2-[^{14}C]DG. The radioactivity in plasma was determined with a liquid scintillation

counter (LSC-5100; Aloka, Tokyo, Japan), and the glucose concentration was measured with a glucometer (Glucocard; Aventis Pharma Japan, Tokyo, Japan). On completion of blood sampling, rats were killed and the livers rapidly removed. A small portion (about 200 μg) of each tissue was removed, frozen in liquid nitrogen, and kept frozen at –80°C for subsequent analysis. These tissues were digested at 70°C for 30 min in 0.5 mL of 1 M NaOH, followed by the addition of 0.5 mL 1 M HCl. Then 1 mL of 6% HClO$_4$ was added to the neutralized solution (200 mL) and, after centrifugation, an aliquot of the supernatant was used for the determination of radioactivity after the addition of 10 mL scintillation cocktail (EcoLite; ICN Biomedicals, Irvine, CA) in a scintillation counter. Protein concentrations were determined by BCA protein assay (Pierce, Rockford, IL). Calculation of 2-DG uptakerate was carried out using Equation 1:

$$2-\text{DG uptake} = \frac{(2-[^{14}C]DG)_t}{\int_0^{40} \text{SA } dt} \qquad [1]$$

where 2-[^{14}C]DG is the radioactivity (expressed as dpm per mg protein) taken up by the liver; t is time (min); and SA is the specific radioactivity of the glucose pool expressed as dpm per nmol of plasma glucose. The 2-[^{14}C]DG uptake derived from these data reflects the net glucose uptake over the 40 min period. Extracellular spaces were calculated using the formula: Extracellular spaces = (D-[2-^{3}H]mannitol)$_{liver}$/(D-[2-^{3}H]mannitol)$_{plasma}$, where (D-[2-^{3}H]mannitol)$_{liver}$ and (D-[2-^{3}H]mannitol)$_{plasma}$ represent mannitol concentrations in tissue and plasma, respectively (22).

Lipid analyses. For quantification of FA, a known amount of nonadecanoic acid was added to liver homogenates as an internal standard. Total lipid was extracted from the liver homogenates by the method of Bligh and Dyer (23). After the extract was taken to dryness in a stream of nitrogen, 1 mL of 10% KOH/90% methanol was added, and then the mixture was heated at 80°C for 60 min to allow saponification to take place. Nonsaponified lipids were removed by extracting three times with 3 mL hexane. After the addition of 1 mL of 6 M HCl, FFA were extracted three times with 3 mL of hexane. The combined extracts were taken to dryness, and methanolic BF$_3$ (15%, wt/vol) was added to the residue and the mixture heated at 100°C for 10 min. The FAME formed were extracted with hexane and subjected to GLC analysis as previously described (8).

Statistical analyses. Statistical significance between clofibric acid-treated and untreated rats or between Zucker lean and obese rats was analyzed by Student's *t*-test or Welch's test after applying the *F*-test for two means. Linear or multiple regression analyses were performed to evaluate the correlation between two or three parameters, respectively (24).

RESULTS

Activities and mRNA expression of both PCE and SCD in the liver of Zucker lean and obese rats. The activities of PCE and SCD in hepatic microsomes were measured in Zucker lean and obese rats. The activities of PCE and SCD were approximately 3 and 5 times higher, respectively, in the obese rats than in their lean littermates (Fig. 1). The mRNA expression of two rELO genes, rELO1 and rELO2 (25), and two SCD genes, SCD1 (26) and SCD2 (27), were determined in the liver of Zucker lean and obese rats. The hepatic mRNA expression of rELO2 and SCD1 in the liver of Zucker obese rats was markedly higher than that of lean littermates, whereas no significant difference was observed in the mRNA expression of either rELO1 or SCD2 between lean and obese rats (Fig. 2).
FIG. 1. Palmitoyl-CoA chain elongase (PCE) and stearoyl-CoA desaturase (SCD) activities in the liver of Zucker lean and obese rats, with or without clofibric acid. Rats were given subcutaneous injections of clofibric acid twice a day for 7 d. Microsomes were prepared from the rats, and the activities of PCE (A) and SCD (B) were determined. In (B), k^+ is the rate constant for steroyl-CoA-dependent reoxidation of NADH-reduced cytochrome b_5. Open bars and solid bars represent clofibric acid untreated rats and clofibric acid-treated rats, respectively. Values are means ± SD for four rats. *Differences from clofibric acid-untreated rats were statistically significant (*P* < 0.05). #Differences between lean and obese rats were statistically significant (*P* < 0.05).

Effects of clofibric acid on PCE and SCD activities and mRNA expression in the liver of Zucker lean and obese rats. The administration of clofibric acid to the lean rats increased the activities of PCE and SCD 3.0 and 4.9 times, respectively (Fig. 1). The treatment of the obese rats with clofibric acid further increased PCE activity, whereas SCD activity did not increase in response to clofibric acid treatment (Fig. 1). The administration of clofibric acid to Zucker lean rats increased the levels of mRNA for rELO2 and SCD1 5.1 and 2.8 times, respectively (Fig. 2B,C). However, there were no significant changes in the expression of either rELO1 or SCD 2 in lean rats following administration of clofibric acid (Fig. 2A,D). The treatments of Zucker obese rats with clofibric acid further increased the expression of rELO2 mRNA (Fig. 2B), as was observed with PCE activity (Fig. 1A), but the expression of SCD1 mRNA was unaffected (Fig. 2C). To confirm that the effect of clofibric acid on the liver of Zucker obese rats was sufficient to induce peroxisome proliferator-responsive enzymes, the effects of clofibric acid on liver weight and

AOX activity were determined (Table 2). In response to clofibric acid administration, there was a marked increase in AOX activity in both lean and obese rats. No significant difference was observed in AOX activity between lean and obese rats following treatment with clofibric acid. The liver weight of Zucker obese rats was 2.3 times greater than that of lean rats, and treatment with clofibric acid increased the liver weight of lean rats but not obese rats.

Proportion of hepatic oleic acid in Zucker lean and obese rats, with or without treatment with clofibric acid. Figure 3 shows the effects of clofibric acid administration on the proportion of oleic acid in hepatic lipids. The proportion of oleic acid in the hepatic lipids of Zucker obese rats was 2.7 times higher than that of the lean rats. The treatments of lean and obese rats with clofibric acid increased the proportion of oleic acid 2.0 and 1.4 times, respectively.

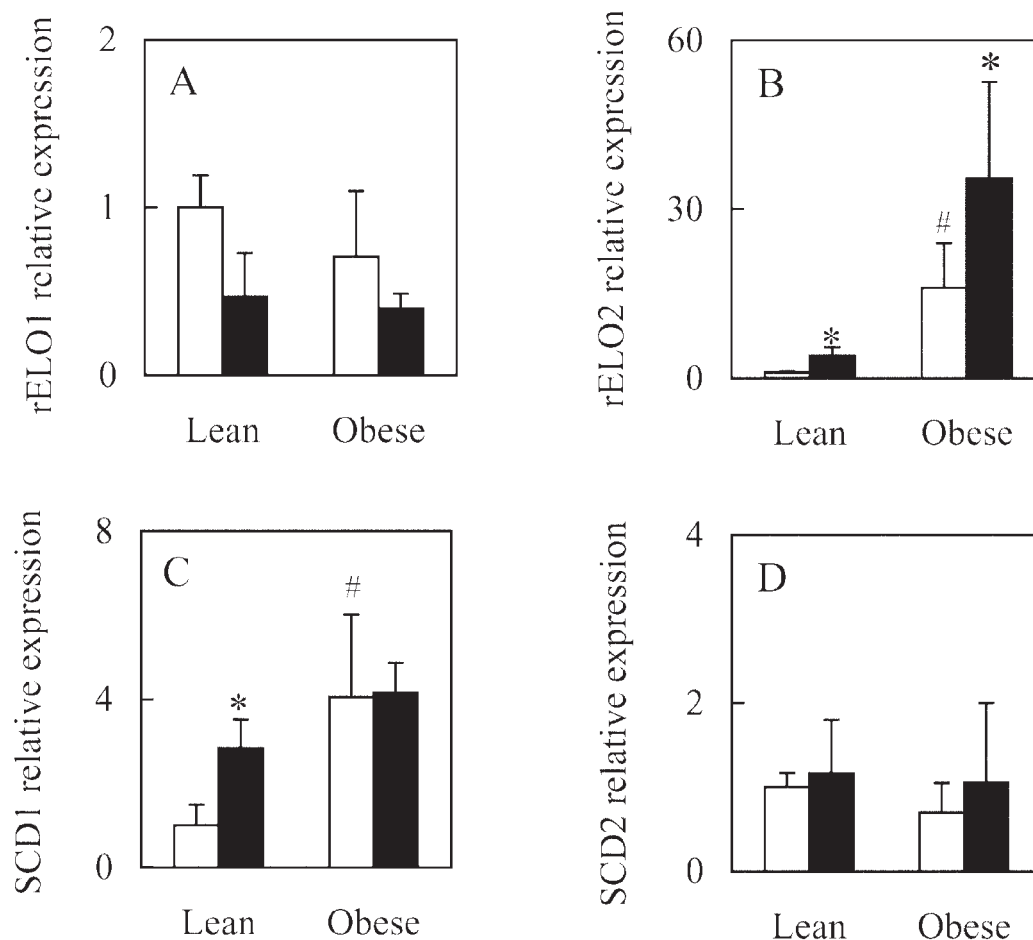
Effects of clofibric acid treatment on hepatic glucose uptake in vivo. Table 3 shows the effects of clofibric acid treatment on hepatic 2-DG uptake and the extracellular spaces in


FIG. 2. mRNA expression of PCE and SCD in the liver of Zucker lean and obese rats, with or without clofibric acid. mRNA levels of rat FA elongase 1 (rELO1) (A), rELO2 (B), SCD1 (C), and SCD2 (D) were determined in the liver of Zucker lean and obese rats with or without clofibric acid treatment, using real-time reverse transcriptase-PCR and normalized by the expression of β-actin. The data are expressed as the relative mRNA level compared with the average expression level in Zucker lean rats (=1). Open bars and solid bars represent clofibric acid-unreated rats and clofibric acid-treated rats, respectively. Values are means ± SD for four rats. *Differences from clofibric acid-untreated rats were statistically significant ($P < 0.05$). #Differences between lean and obese rats were statistically significant ($P < 0.05$). For other abbreviations see Figure 1.

TABLE 2
Effects of Clofibric Acid on Liver Weight and AOX Activity in the Liver of Zucker Rats[a]

Phenotype	Clofibric acid	Body weight (g)	Liver weight (g)	AOX activity (nmol/min/mg)
Lean	–	390 ± 15	14.4 ± 0.7	3.7 ± 0.1
	+	370 ± 5.5*	18.1 ± 0.5	32.8 ± 2.0*
Obese	–	590 ± 8.8[#]	33.5 ± 2.4[#]	4.9 ± 0.6
	+	601 ± 12[#]	39.5 ± 5.2[#]	33.7 ± 2.8*

[a]Rats were given a subcutaneous injection of clofibric acid twice a day for 7 d at a dose of 100 mg/kg body weight. Values are means ± SD for four rats. *Differences from clofibric acid-untreated rats were statistically significant ($P < 0.05$). [#]Differences between lean and obese rats were statistically significant ($P < 0.05$). AOX, acyl-CoA oxidase; clofibric acid, 2-(4-chlorophenoxy)-2-methylpropionic acid.

Zucker rats. The blood glucose levels of the animals in the fed state were not significantly different between lean and obese rats, irrespective of clofibric acid treatment (data not shown). The decay in the specific radioactivity of 2-[^{14}C]DG in plasma was similar in all the experimental groups (data not shown), and the hepatic extracellular spaces were unaffected by the treatment with clofibric acid. The uptake of 2-DG by the liver in obese rats was 1.8 times higher than that in lean rats. Clofibric acid treatment did not affect the hepatic uptake of 2-DG in either lean or obese rats.

Relationship between the activity of PCE or SCD and the proportion of oleic acid in the liver. Linear regression analyses were carried out to examine the relationship between the proportion of oleic acid and the activity of either PCE or SCD in the liver. One regression line between the proportion of oleic acid and PCE activity was obtained for 16 sets of data from Figures 1 and 3, with a high correlation being seen be-

tween the two parameters ($r^2 = 0.728$, $P < 0.001$). Similarly, a high correlation was observed between the proportion of oleic acid and SCD activity ($r^2 = 0.647$, $P < 0.001$). The relative contribution of PCE and SCD to the proportion of oleic acid was determined by multiple linear regression analysis. The 16 sets of data from Figures 1 and 3 revealed a significant correlation among the three parameters ($r^2 = 0.748$, $P < 0.001$) (Table 4). The standardized partial regression coefficient between the proportion of oleic acid and PCE activity was 0.60 ($P < 0.05$), whereas that between the proportion of oleic acid and SCD activity was 0.29, with a partial correlation not achieving statistical significance ($P = 0.298$).

DISCUSSION

Increased activity of PCE and increased proportion of oleic acid in the liver of Zucker obese rats. In agreement with previous findings (13), the present study confirmed that the proportion of oleic acid in hepatic lipids of Zucker obese rats is much greater than that of their lean littermates. So far, an elevated activity of hepatic SCD is believed to be responsible for the increased proportion of oleic acid in the liver of Zucker obese rats (28); we also demonstrated the enhanced hepatic activity of SCD in obese rats. The biosynthesis of oleic acid from palmitic acid involves sequential reactions catalyzed by PCE and then SCD (7). Moreover, our recent study came to the conclusion that PCE plays a more important role than SCD in the physiological regulation of oleic acid biosynthesis in the liver of Wistar rats (8). No information, however, is available about the role of PCE in oleic acid formation in Zucker obese rats. The present study shows that the activity of not only SCD but also PCE in the liver is markedly higher in Zucker obese rats compared with lean rats. The possibility that the increased proportion of oleic acid following clofibric acid treatment is due to degradation of erucic acid (22:1n-9) is ruled out since the hepatic level of erucic acid was less than the detection limit in the liver of any animals tested. To our knowledge, this is the first evidence showing that Zucker obese rats exhibit an elevated PCE activity in the liver. Recently, two FA elongases, which catalyze the chain elongation of palmitoyl-CoA, rELO1, and rELO2, were cloned in rat liver (25). Moreover, four isoforms of SCD (SCD1, SCD2, SCD3, and SCD4) have been identified (26,27,29,30), and
FIG. 3. Effects of clofibric acid administration on the proportion of oleic acid in hepatic lipids of Zucker lean and obese rats. Rats were given a subcutaneous injection of clofibric acid twice a day for 7 d. The FA composition of hepatic lipids of Zucker obese and lean rats was analyzed. Open bars and solid bars represent clofibric acid-untreated rats and clofibric acid-treated rats, respectively. Values are means ± SD for four rats. *Differences from clofibric acid-untreated rats were statistically significant ($P < 0.05$). [#]Differences between lean and obese rats were statistically significant ($P < 0.05$).

TABLE 3
Effects of Clofibric Acid on Hepatic 2-DG Uptake and Extracellular Spaces in Zucker Rats[a]

Phenotype	Clofibric acid	2-DG uptake (nmol/min/mg protein)	Extracellular spaces (mL/mg protein)
Lean	−	0.24 ± 0.01	1.8 ± 0.15
	+	0.21 ± 0.03	2.1 ± 0.67
Obese	−	0.43 ± 0.09[#]	2.0 ± 0.53
	+	0.39 ± 0.09[#]	1.5 ± 0.13

[a]Rats were given a subcutaneous injection of clofibric acid twice a day for 7 d at a dose of 100 mg/kg body weight. Values are means ± SD for four to five rats. [#]Differences between lean and obese rats were statistically significant ($P < 0.05$). 2-DG, 2-deoxyglucose; for other abbreviation see Table 2.

SCD1 and SCD2 were shown to be expressed in the liver of rats (26,31). The present study shows a considerable increase in the mRNA expression of rELO2 and SCD1, but not rELO1 or SCD2, in the liver of Zucker obese rats. It seems likely therefore that the elevated expression of rELO2 and SCD1 is responsible for the enhanced activities of PCE and SCD in the liver of Zucker obese rats, respectively, leading to the higher proportion of oleic acid. The present results strongly suggest that, compared with rELO2 and SCD1, neither rELO1 nor SCD2 plays a physiologically important role in the increased formation of oleic acid in the liver of Zucker obese rats.

Both PCE and SCD are considered to be regulated by transcriptional factors, such as peroxisome proliferator-activated receptor-α (32, 33) and sterol regulatory element binding protein-1 (34,35). However, recent studies have shown that carbohydrate induces PCE and SCD activity *via* a pathway that is independent of peroxisome proliferator-activated receptor-α (8) and that fructose increases the expression of SCD1 mRNA in the liver of sterol regulatory element binding protein-1c knockout mice (36). In addition to these facts, our previous study showed that carbohydrate regulates PCE activity in the liver of Wistar rats (8). These findings, taken together, suggest the possible involvement of carbohydrate in the regulation of PCE and SCD in the liver of Zucker obese rats. In fact, the present study shows that the hepatic uptake of 2-DG in Zucker obese rats is significantly greater than that in lean rats. It seems plausible therefore that the elevated hepatic uptake of glucose is responsible for the increase in the activities of PCE and SCD in the liver of Zucker obese rats. The Zucker obese rat has been shown to be deficient in leptin receptors (37), and the leptin-mediated signal is considered to produce

down-regulation of SCD expression (5). It seems likely therefore that the higher expression of PCE and SCD in Zucker obese rats is due to the loss of leptin signals in the liver. However, the relationship between glucose uptake and leptin remains to be clarified.

Induction of PCE by clofibric acid. Treatment of Wistar rats with clofibric acid markedly induces both PCE and SCD in the liver (8). However, in Zucker obese rats, there is no information about how clofibric acid affects the activity and gene expression of both PCE and SCD. The present study demonstrated that the proportion of oleic acid in the liver was significantly increased by the administration of clofibric acid to Zucker obese rats and that treatment with clofibric acid increased hepatic PCE activity and rELO2 mRNA expression, but not SCD activity or SCD1 mRNA expression. By contrast, the activities of both PCE and SCD are increased in response to clofibric acid treatment in the liver of Zucker lean rats. The increase in the activities of SCD and PCE is due to the elevated levels of mRNA expression of both rELO2 and SCD1. Both rELO1 and SCD2 exhibit no response to clofibric acid in the liver of both Zucker lean and obese rats. It should also be noted that PCE activity was additively induced by treating Zucker obese rats with clofibric acid, whereas SCD was not induced. Since clofibric acid induces AOX and SCD activity *via* peroxisome proliferator-activated receptor-α activation (32,38) and AOX is induced to the same extent in the liver of both Zucker lean and obese rats, the lack of induction of SCD by clofibric acid in Zucker obese rats seems not to be due to a peroxisome proliferator-activated receptor--α defect in the liver. To date, PCE and SCD have been considered to be regulated through common factors, such as carbohydrates (8), refeeding after fasting (9,10), and peroxisome proliferators (11,39,40). Our present results indicate the possibility that the mechanism of PCE regulation differs somewhat from that of SCD (8). Since hepatic glucose uptake is not changed by treating Zucker lean and obese rats with clofibric acid, it seems unlikely that clofibric acid regulates PCE activity *via* a change in the hepatic uptake of glucose.

Role of PCE in the formation of oleic acid. Our previous study suggested that PCE plays an important role in the formation of oleic acid in the liver of Wistar rats (8). In the present study, multiple regression analysis, which was performed to determine the relationship among the activities of PCE, SCD and the proportion of oleic acid, revealed that the stan-

TABLE 4
Relative Contribution of PCE and SCD to the Proportion of Oleic Acid in the Liver of Zucker Rats[a]

Independent variable	Standardized partial correlation coefficient	P
PCE	0.604	<0.05
SCD	0.290	0.298

[a]Multiple linear regression analysis was performed on the 16 sets of mean data from Figures 1 and 3. From the PCE activity, the SCD activity, and the proportion of oleic acid, a single linear regression line was obtained: $Y = 0.60X_1 + 0.29X_2$; Y, proportion of oleic acid; X_1, PCE activity; X_2, SCD activity; $r^2 = 0.748$; $P < 0.001$. PCE, palmitoyl-CoA chain elongase; for other abbreviation see Table 1.

dardized partial regression coefficient of PCE was higher than that of SCD. This result strongly suggests that the contribution of PCE to the regulation of the proportion of oleic acid is greater than that of SCD in the liver of Zucker rats treated with clofibric acid. The conclusion, which the present study has reached, is the same as the conclusion of our previous study using Wistar rats as experimental animals (8).

Thus, oleic acid is synthesized by the concerted action of PCE and SCD, and PCE plays an important role in the formation of oleic acid in the liver. Clofibric acid increases oleic acid formation *via* the induction of rELO2 in the liver of Zucker obese rats.

ABSTRACT: Paraoxonase 1 (PON 1) is an esterase with antioxidant properties that is present in HDL. Gln192Arg polymorphism (also named Q192R or Q/R) of the PON 1 gene that encodes this protein defines two alleles (Q and R). The R allele has been associated with higher cardiovascular risk. LDL size and susceptibility to oxidation also have been identified as cardiovascular risk factors. Our objective was to determine whether genetic variations in the Gln192Arg polymorphism influence LDL size and susceptibility to oxidation after the consumption of diets with different fat content. In our experiments, the participants ($n = 98$) underwent three 4-wk diets—one, saturated fat-enriched (SAT); another, monounsaturated fat-enriched (MONO); and a third, carbohydrate-enriched (CHO). We observed that LDL were smaller in the QQ group after the CHO diet vs. the SAT ($P < 0.01$) and MONO diets ($P < 0.03$). No differences in LDL size were found in QR/RR subjects. When we analyzed lag time of oxidation of LDL, we found that when carriers of the R allele (QR/RR) received the MONO diet, the lag period of LDL oxidation was longer as compared with the CHO diet. Otherwise, we found no differences in QQ homozygotes when we evaluated the lag time of oxidation of LDL after the three diets. These results suggest that the Gln192Arg polymorphism of the paraoxonase gene influences LDL size and susceptibility to oxidation in response to diet.

Paper no. L9680 in *Lipids 40*, 471–476 (May 2005).

The pathogenesis of atherosclerosis is multifactorial and is a result of the interaction of various environmental and genetic factors. Among these, genes encoding proteins related to lipid metabolism may play a significant role. One of these genes is responsible for encoding paraoxonase 1(PON 1), an HDL-associated esterase. It reduces the accumulation of lipoperoxides and destroys biologically active lipids that are present in minimally oxidized LDL, which is why an antiatherogenic role has been attributed to it (1,2). Recent data suggest the importance of nutritional factors in the regulation of its enzymatic activity (3). Among these, saturated FA (SAFA) or food rich in oxidized products decreases postprandial paraoxonase activity (4,5), whereas oleic acid increases it (6). In the PON 1 gene there are several polymorphisms related to changes in the activity of the enzyme. One of them is PON 1 Gln192Arg, which has two genetic variations (Q and R alleles). Q is the more prevalent form. The frequency of R varies among different populations, but an average frequency of 0.70 for Q and 0.30 for R alleles can be estimated. This frequency of alleles conforms to 55% QQ, 45% QR, and10% RR genotypes (7); Q allele (the more prevalent form) carriers produce an enzyme with a greater antioxidant capacity and a lower risk of coronary heart disease (CHD); on the other hand, the mutation that changes glutamine to arginine (R allele) has been identified as a possible independent risk factor for CHD in certain populations (8–10). A recent meta-analysis that included 43 case–control studies and 23,998 participants estimated the relative risk per allele of R allele for CHD as 1.12 (95% confidence interval 1.07–1.16). Nevertheless, the authors of that work (11) found a high variability in their results. A possible explanation of this variation could be the existence of environmental factors (such as diet) that would interfere with their results.

Diet plays an important role in the development of atherosclerosis. Saturated diets, high in SAFA, increase the formation of atherosclerotic plaques. Two diets have been proposed to slow the progress of this entity. One of them is a low-fat, high-carbohydrate (CHO) Diet. The other is the so-called Mediterranean diet, characterized by 33–40% energy intake as fat, mainly from monounsaturated FA (MUFA) from olive oil (16–29% energy), and a high intake of fruit, vegetables, grain, and fish and low consumption of meat, most of it in the form of poultry (12–14).

Small, dense LDL particles have an increased susceptibility to oxidative modification and elevated atherogenic properties (15). Because HDL prevents LDL oxidation, mainly by the effect of the PON 1 enzyme, we wanted to establish whether the existence of polymorphisms in the PON gene interacts with diet to influence two interrelated features of LDL: the size of the particles and their susceptibility to oxidative modifications.

MATERIALS AND METHODS

Subjects of the study. Both the study protocol and the subjects have been described previously (16). The volunteers (*n* = 98), 30 women and 68 men, ranged between 18 and 49 yr of age. All supplied a clinical history and underwent a medical examination, with no evidence of any chronic illness (such as cardiac, hepatic, renal, or thyroid dysfunction), obesity [defined as body mass index (BMI) ≥30 kg/m^2] or unusually high levels of physical activity. None had a family history of early onset coronary disease or had consumed substances that might interfere with plasma lipid levels in the 6 mon before the start of the study. Mean initial BMI remained constant at 22.6 ± 3.2 kg/m^2 throughout the study, with oscillations of less than 1%. To calculate individual daily energy requirements, the participants were asked, before the start of the experimental periods, to record in a diary their physical activity and diet for a full week. They were also encouraged to maintain their lifestyle and normal levels of physical activity and to note any event that could affect the outcome of the study, such as stress, any changes in smoking habits, or changes in the consumption of alcohol or foods not included in the experimental design. All the studies were carried out at the Lipids Research Unit of the Reina Sofía University Hospital (Córdoba, Spain), following the approval of the study protocol by the Human Investigation Review Committee of this institution.

Design and diets in the study. The study design included an initial 28-d period, during which all the subjects consumed a diet rich in SAFA (SAT phase), and whose composition as percentages of energy was: 15 protein, 47 carbohydrates, and 38 fats (of which 20% were SAFA, 6% PUFA, and 12% MUFA). During the next 28-d phase, and under a randomized crossover design, 49 subjects were given a Mediterranean MUFA-enriched diet (MONO phase), composed of: 15% protein, 47% carbohydrates, and 38% fat (<10% SAFA, 6% PUFA, 22% MUFA). During the third 4-wk period, they consumed a low-fat, high-carbohydrate diet (CHO) diet (17), which contained 15% protein, 55% carbohydrates and less than 30% fat (<10% SAFA, 6% PUFA, 12% MUFA). The remaining participants were given the carbohydrate diet (CHO) followed by the Mediterranean diet (MONO). The assignment of volunteers to this sequence was randomized, following a 1:1 ratio. Dietary cholesterol content remained constant throughout all three phases. Eighty percent of the MUFA in the MONO diet was obtained from extra virgin olive oil (*Olea europea* species). Carbohydrate consumption in the CHO period consisted of biscuits, bread, and jam. The source of saturated fat during the SAT phase was butter and palm oil.

Body weight was measured twice weekly.

Tables of food values from the United States and Europe (18,19) were used to calculate food composition and to design the menus for each dietary phase. During each experimental period 14 menus, prepared with regular solid foods, were used in rotation. All the meals, under the direct supervision of a qualified dietitian, were prepared and served in the

hospital. Dietary compliance was evaluated by examining the food diaries. Duplicate samples from each menu were collected and stored at −70°C. Protein, fat, and carbohydrate contents of each diet were analyzed using standard methods.

Blood sampling and biochemical determinations. Venous blood was collected from the subjects in EDTA-containing tubes (1 g/L) after a 12-h overnight fast, both at the beginning of the study and at the end of each dietary period. Plasma was then isolated from the samples obtained by centrifugation (2500 × *g* for 10 min at 4°C). All analyses, except the one for TG, were performed at the end of the study on samples stored at −70°C, to minimize assay variability. Plasma TG and cholesterol concentrations were measured using standard enzymatic methods (20,21). HDL cholesterol was measured using phosphotungstic acid-MgCl$_2$, after precipitation of apolipoprotein B (apo B)-containing lipoproteins (22). Quality controls were applied to every measurement using commercial kits (Precinorm; Precilip; Boehringer Mannheim, Mannheim, Germany). LDL cholesterol levels were calculated using the Friedewald formula (23). Apo A-I and apo B were determined by turbidimetry (24).

LDL isolation. LDL was isolated from fresh plasma samples by sequential ultracentrifugation with a Beckman model LE-70 ultracentrifuge with a type NVT65 rotor (Beckman, Palo Alto, CA) for 2 h at 405,000 × *g* and 4°C.

Determination of LDL particle size. The predominant peak particle diameter (LDL size) was measured in serum samples with polyacrylamide gradient gel electrophoresis (2 to 16% gradient) as previously described (25). The resulting gels were scanned and analyzed with the Scion Image for Windows (Scion Corporation, Frederick, MD) program. The LDL size of the subjects was determined by interpolating LDL migration on a regression curve of pattern size (in nm) vs. migration.

LDL particle oxidation. LDL oxidation was performed *in vitro* by adding Cu^{2+} (to a final concentration of 10 μmol/L) to 50 μg of LDL in 500 μL of PBS. Oxidation kinetics was analyzed by monitoring diene absorbance changes at 234 nm at 37°C for 200 min at 5-min intervals, in a UV/vis spectrophotometer (Beckman DU 640), following the technique described by Esterbauer *et al.* (26). The lag time (time before onset of the exponential phase of the LDL oxidation curve, expressed in minutes) was calculated as an indirect marker of the onset of LDL particle lipoperoxidation.

Genotype determination of the PON-1 polymorphism. DNA was extracted from the samples stored at −20°C in 10 mL Na-EDTA tubes. Codon 192 genotypes in the PON 1 gene were identified by a combination of PCR followed by digestion of the Alw-1 enzyme, as described by Humbert *et al.* (27). The PCR reactive mixture contained not only the genomic DNA but also MgCl$_2$, 4 dNTP (deoxy nucleotide 5′-triphosphate), buffer solution, DNA Taq polymerase, and the following oligonucleotide primer sequence: E1, 5′-TATTGTTGCTGTGGGAC-CTGAG-3′; and E2, 5′-CACGCTAAACCCAAATACATCTC-3′. The denaturation phase of the DNA sequence was achieved after 4 min at 95°C, followed by 30 denaturation cycles (30 s

at 95°C), annealing (30 s at 59°C), and extension (45 s at 72°C). Ten microliters of the 99 bp PCR product as mixed with the restrictive endonuclease *Alw-1* in a total volume of 15 μL for its enzymatic digestion. After incubating the mixture for over 4 h at 37°C, the digested DNA was isolated by electrophoresis onto an 8% nondenaturing polyacrylamide gel (2 h at 150 V). Bands were visualized using silver staining. The R genotype (Arginine) contains a unique restriction site, which results in 66 and 33 bp products, whereas the Q genotype (glutamine) does not cut, and its bands are located 99 bp away.

Statistical analysis. We made a stratified analysis based on the PON 1 Gln192Arg polymorphism. Population was distributed into two groups (QQ homozygotes, $n = 58$; QR/RR, $n = 40$). QR and RR were studied together owing to the small size of the RR group. Data were tested for statistical significance by ANOVA for repeated measures. When statistical significance was found, the Tukey's *post hoc* comparison test was used to identify group differences. A probability value less than 0.05 was considered significant. All data presented in text and tables are expressed as means ± S.E. The Statistical Package for the Social Sciences (SPSS) 11.0 (Chicago, IL) was used for the statistical comparisons.

RESULTS

Relative frequency of QQ homozygotes and QR/RR subjects, as well as participants' baseline characteristics according to genotype, are shown in Table 1. No differences were found between the two groups, QQ and QR/RR, in terms of age, BMI, or lipid and apo levels.

When evaluating the effect of the PON 1 Gln192Arg polymorphism on LDL particle size, we found no differences between different genotypes following the same diet. Nevertheless, we found that LDL were smaller in size in the QQ group after the consumption of CHO-rich diet as compared with the SAT- and MONO-rich diet (Table 2). In contrast, no differences in LDL size were found in QR/RR subjects after the three diets.

When studying LDL resistance to oxidation, we saw no differences between subjects when analyzing QQ vs. QR/RR groups for the same diet. Otherwise, we observed that replacing the SAT-enriched diet with the MONO-enriched diet improved resistance to oxidation, regardless of the Gln192Arg genotype. Likewise, QR/RR subjects presented a higher resistance to LDL oxidation after the MONO-enriched diet than after the CHO-enriched diet. This result was not observed with QQ homozygotes (Table 3).

With respect to plasma lipid levels after the consumption of the three diets, we observed that the Q/R polymorphism exerted no effect on the lipid level changes induced by the different diets. According to previous knowledge, consumption of the SAT-enriched diet increased levels of total cholesterol, LDL, and HDL in comparison with the CHO-enriched diet; similarly, consumption of the SAT-enriched diet increased levels of total cholesterol and LDL but not HDL in comparison with consumption of the MONO-enriched diet (Table 4).

[a]Values with different superscript letters are statistically different. Differences between SAT and CHO in QQ are at a level of $P = 0.01$ and between MONO and CHO in QQ are $P = 0.025$). G, genotype; SAT, saturated FA-enriched diet; CHO, carbohydrate-enriched diet; MONO, monounsaturated FA-enriched diet.

DISCUSSION

Our results show that a high-CHO diet induces the formation of smaller LDL than high-fat diets in carriers of the QQ genotype for the Q192R polymorphism (also called Gln192Arg) of the PON 1 gene, but not in carriers of the QR/RR genotypes. The presence of an R allele (genotypes QR/RR) increases LDL resistance to oxidation when a high-CHO diet is replaced isocalorically by MONO. Furthermore, R carriers,

although they show no difference in LDL size in the CHO diet, benefit from changing from this diet to MONO, as it increases the resistance of their LDL to oxidation.

Data were obtained from an intervention study based on a baseline diet, followed by two diets administered using a randomized crossover design, in young normolipemic subjects. The rigorous control of the dietary protocol makes these data particularly significant. As described earlier, we observed an increase in LDL *in vitro* oxidation lag time during the consumption of a MONO-enriched diet as compared with SAT- and CHO-enriched diets, regardless of the PON genotype.

We previously reported other gene–diet interactions in lipid metabolism-related genes. Apo E has an important role in the metabolism of TG-rich lipoproteins. Genetic variations in the promoter region of apo E defines three alleles: E3, E4, and E2. It is known that people who carry E4 and E2 alleles in their apo E genotype show different lipid responses to diet from persons who are homozygous for the most prevalent form, E3. We have recently shown a direct relation between apo E genetic alleles and LDL size response to diet (28). To avoid confusing factors, we selected only E3E3 homozygotes in this study (29–32).

The relationship between the Q192R polymorphism and lipid response to different types of diets in humans is little known. In experiments with animals atherogenic diets have been found to decrease PON 1 activity, whereas a MONO-enriched diet or polyphenols increase it (33). In a study carried out on healthy women, a low-vegetable diet decreased PON 1 activity. The presence of the R allele in the Q192R polymorphism was thought to be responsible for a more marked decrease in this activity and in HDL reduction (34). However, as noted above, we observed no difference in the lipid response of the different genotypes to changes in dietary fat composition.

The Q192R polymorphism of PON 1 gene has two alleles, the Q allele, which carries a glutamine molecule at position 192, and the R allele, which carries arginine. The presence of the R allele previously has been associated with a higher cardiovascular risk, although evidence to support this view remains incomplete (8,11,35,36). This allele determines the production of PON, conferring it with a greater ability to metabolize paraoxon; this artificial substrate, which is not naturally present in humans, has been used in experimental studies to evaluate enzyme activity, although the clinical importance of

this ability is not clear. The enzyme activity metabolizing paraoxon seems to increase according to the following pattern: QQ < QR < RR (37).

On the other hand, several studies have shown that the Q allele has a greater antioxidant ability than the R allele, owing to its higher esterase and peroxidase activities (38,39).

Earlier work indicated that a low-fat diet induced a decrease in LDL particle size in the general population (15). In our study, QQ subjects followed this trend, but not QR/RR. On the other hand, R carriers showed a greater resistance of LDL to oxidation after consumption of the MONO-enriched diet compared with SAT- and CHO-enriched diets. No data about the polymorphism of PON 1 or LDL lag time in response to diet have been reported, but a study by Tomás *et al*. (40) revealed that a high oleic oil diet improves HDL cholesterol levels and PON 1 activity in carriers of the R allele (39). Furthermore Kuremoto *et al*. (41) recently associated the R/R genotype in Japanese (another population typically consuming a highly unsaturated fat diet) with lower LDL and HDL oxidation and lower risk of coronary disease. Our findings support the idea that carriers of QQ and QR do not have the same response to diet with respect to LDL. QQ subjects decreased their LDL particle size when exposed to a CHO-enriched diet. This effect has been previously shown in a general population not genotyped for PON 1. Nevertheless, QR/RR did not show this decrease in the present study. On the other hand, we found a more prolonged LDL oxidation lag time after consumption of the MONO diet compared with CHO diet only for QR/RR, and not for QQ. Although further research is needed, we hypothesize that PON 1 increases its function in R carriers following consumption of a MONO-enriched diet, and so LDL resistance to oxidation increases in these persons. In agreement with this hypothesis, it has been proposed before that an oleic acid-rich diet gives protection against lipoprotein oxidation, particularly in men carrying one or two R alleles and that increasing the amount of oleic acid in the diet of R carriers should reduce the risk of atherosclerosis (40).

The influence of the Q192R polymorphism as an isolated factor for absolute coronary disease risk is thought to be slight, although it could become clinically significant when combined with other environmental risk factors, such as diet (42).

ABSTRACT: We have studied the effects of dietary FA on the accumulation and secretion of [³H]glycerolipids by salmon hepatocytes in culture. Atlantic salmon were fed diets supplemented with either 100% soybean oil (SO) or 100% fish oil (FO), and grew from an initial weight of 113 ± 5 g to a final weight of 338 ± 19 g. Hepatocytes were isolated from both dietary groups and incubated with [³H]glycerol in an FA-free medium; a medium supplemented with 0.75 mM of one of three FA—18:1n-9, 20:5n-3, or 22:6n-3—or a medium supplemented with 0.75 mM of the sulfur-substituted FA analog tetradecylthioacetic acid (TTA), which cannot undergo β-oxidation. Incubations were allowed to proceed for 1, 2, 6, or 24 h. The rate of the secretion of radioactive glycerolipids with no FA added was 36% lower from hepatocytes isolated from fish fed the FO diet than it was from hepatocytes isolated from fish fed the SO diet. Hepatocytes incubated with 18:1n-9 secreted more [³H]TAG than when incubated with no FA, whereas hepatocytes incubated with 20:5n-3 or TTA secreted less labeled TAG than when incubated with no FA. This observation was independent of the feeding group. Hepatocytes incubated with 22:6n-3 secreted the highest amounts of total [³H]glycerolipids compared with the other treatments, owing to increased secretion of phospholipids and mono- and diacylglycerols (MDG). In contrast, the same amounts of [³H]TAG were secreted from these cells as from cells incubated in an FA-free medium. The lipid-lowering effect of FO is thus independent of 22:6n-3, showing that 20:5n-3 is the FA that is responsible for the lipid-lowering effect. The ratio of TAG to MDG in lipids secreted from hepatocytes to which 20:5n-3 or TTA had been added was lower than that in lipids secreted from hepatocytes incubated with 18:1n-9 or 22:6n-3, suggesting that the last step in TAG synthesis was inhibited. Morphometric measurements revealed that hepatocytes incubated with 20:5n-3 accumulated significantly more cellular lipid than cells treated with 18:1n-9, 22:6n-3, TTA, or no treatment. The area occupied by mitochondria was also greater in these cells. The present study shows that dietary FO reduces TAG secretion from salmon hepatocytes and that 20:5n-3 mediates this effect.

Paper no. L9540 in *Lipids* 40, 477–486 (May 2005).

Fish oil (FO), which is particularly rich in the PUFA 20:5n-3 and 22:6n-3, has traditionally been used as the predominant lipid component of salmon feed. However, the uncertain supply and variable price of FO have led to an interest in using the more readily available plant oils rich in 18-carbon n-6 [soybean oil (SO) and sunflower oil] and n-9 (rapeseed oil) FA in salmon diets. Little information is available, however, concerning how these plant oils affect lipid deposition in salmon hepatocytes and how they affect the secretion of TAG-rich VLDL from these cells. There is considerable evidence that consumption of FO lowers plasma TAG concentrations in humans (1,2) and protects against coronary heart diseases (1,3,4). It is particularly important to study these processes in salmonids, since they are more predisposed to coronary arteriosclerosis than other fish species (5). Several mechanisms are probably involved in the inhibiting effect of FO on the secretion of TAG-rich VLDL particles in mammals, and the detailed mechanisms have not been completely elucidated. The effect has been attributed to the content of n-3 FA in the feed (6,7). Studies using primary hepatocytes from rats have shown that n-3 PUFA inhibit the secretion of TAG-rich VLDL (8–11). The PUFA inhibit diacylglycerol acyltransferase (DGAT, EC 2.3.1.20) (12–15), which is the rate-limiting enzyme in TAG synthesis, and they inhibit the assembly process of the VLDL particles (9,10,16). Furthermore, several studies in mammals have shown that the lipid-lowering effect of FO is mediated by 20:5n-3 and not by 22:6n-3 (13–15,17,18).

We have investigated the effects of several FA on lipid accumulation and on the secretion of glycerolipids in Atlantic salmon. We isolated hepatocytes from salmon fed diets supplemented with either FO or SO and then added the two main PUFA in FO (20:5n-3 and 22:6n-3) separately to the hepatocyte cultures. We incubated other cultures with 18:1n-9, which is a common FA in vegetable oils and which stimulates lipid secretion by cultivated rat hepatocytes (9,13,19). Finally, we compared the effects of these FA with the effects of a sulfur-substituted FA analog, tetradecylthioacetic acid (CH$_3$–(CH$_2$)$_{13}$–S–CH$_2$–COOH) (TTA), on glycerolipid secretion. TTA is unable to undergo β-oxidation (for review see Ref. 20), and it inhibits TAG secretion in mammals (14,21).

MATERIALS AND METHODS

Materials. TTA was produced at Dr. R. Berge's laboratory (Haukeland Hospital, University of Bergen, Norway). The radioactive isotope [1,2,3-³H]glycerol (30–60 Ci/mmol) was ob-

---

tained from American Radiolabeled Chemicals, Inc. (St. Louis, MO). Nonlabeled glycerol, Leibowitz-15 medium, FBS, antibiotics, HEPES, L-glutamine, collagenase, trypsin, FA, essential FA-free BSA, collagenase type 1, and 2′,7′-dichlorofluorescein were all supplied by Sigma-Aldrich (St. Louis, MO). Tissue culture plastic ware was obtained from NalgeNunc International (Naperville, IL). Acetic acid, chloroform, petroleum ether, diethyl ether, and methanol were purchased from Merck (Darmstadt, Germany). Benzene was obtained from Rathburn Chemicals, Ltd. (Walkerburn, Scotland). Methanolic HCl and 2,2-dimethoxypropane were purchased from Supelco Inc. (Bellefonte, PA). Glass-baked silica gel K6 plates were obtained from Whatman International, Ltd. (Maidstone, England). Glutaraldehyde, epon resin, copper grids, and lead citrate were supplied by Electron Microscopy Sciences (Fort Washington, PA).

Fish and experimental design. The feeding study was performed as described by Grisdale-Helland *et al.* (22). Briefly, Atlantic salmon in tanks containing seawater at 12°C were fed for approximately 950 day-degrees with one of two test diets. There were three tanks per diet. The diets, containing 30% fat, were based on fish meal and differed only in the type of supplementary oil that they contained [see Grisdale-Helland *et al.* (22) for a detailed description of the diets]. The fish were fed *ad libitum* using automatic band-feeders every 10 min, 24 h/d. Supplementary lipid in one diet, called "FO," came solely from fish oil (capelin oil), whereas the supplementary lipid in the other diet, called "SO," came solely from crude soybean oil. The salmon grew from an initial weight of 113 ± 5 g to a final weight of 338 ± 19 g.

Isolation of hepatocytes. Three fish from each tank were used for isolation of hepatocytes at the end of the growth period. The fish were anesthetized with metacain. The abdominal cavity was exposed and the vena porta cannulated. The liver was perfused following a two-step collagenase procedure developed by Seglen (23) and modified by Dannevig and Berg (24), to isolate hepatocytes. The hepatocytes were easily isolated after the collagenase digestion by gentle shaking of the digested liver in Leibowitz-15 medium. The suspension of parenchymal cells was filtered through a 100 μm nylon filter. Hepatocytes were isolated from this suspension by three sedimentations each of 2 min at $50 \times g$. The hepatocytes were resuspended in Leibowitz-15 culture medium containing 2% FBS, 2 mM L-glutamine, and 0.1 mg mL^{-1} gentamycin. Cell viability was assessed by staining with Trypan blue (0.4%). The protein content of the cell suspension was determined using the method described by Lowry *et al.* (25). Approximately 5×10^6 hepatocytes (approximately 8 mg of protein) were plated onto 75-mL Nunc flasks and left to attach overnight at 12°C.

Incubation with FA and [^{3}H]glycerol. The hepatocytes were thoroughly washed with Leibowitz-15 medium without serum supplementation, before the incubation with FA and [^{3}H]glycerol. Each cell flask with hepatocytes was incubated with 0.5 Ci/mmol [^{3}H]glycerol (final glycerol concentration 25 μM), 10 mM lactate, and either no FA (Ctr), 18:1n-9, 20:5n-3, 22:6n-3, or TTA in a total volume of 5 mL Leibowitz-15 medium. A

final FA concentration of 0.75 mM was used, a concentration often used in similar studies with mammalian cells (13,19). The FA were added to the medium in the form of their potassium salts bound to BSA (the molar ratio between an FA and BSA was 2.5). The cells were incubated for 1, 2, 6, or 24 h at 12°C, and then the medium from each culture flask was transferred to vials and centrifuged for 5 min at $50 \times g$. The supernatant (culture medium) from a flask was either immediately frozen at −70°C and stored until the analysis of radiolabeled lipids or directly used for the isolation of VLDL as described next. Hepatocytes were washed twice with 0.1 M PBS (pH 7.4), followed by preparation for electron microscopy.

Isolation and analysis of VLDL. To determine the most representative method for investigating the secretion of glycerolipids from cultivated hepatocytes, we compared the lipid analysis of secreted VLDL fractions with the analysis of total esterified lipids secreted to the culture media. Hepatocytes from SO-fed fish that had been incubated for 1, 2, 6, or 24 h in a medium without FA supplementation, but with [^{3}H]glycerol, were used for the comparison of the two methods. The culture media were divided in two halves at each time point; one for VLDL separation and one for determination of total secreted esterified lipids. A discontinuous NaCl/KBr gradient was formed by filling Bell-top Quick-Seal tubes with two layers with different densities, using a peristaltic pump. A layer of aqueous NaCl solution (10 mL, 0.9%) was pumped into the bottom of the tube, and then culture medium (5 mL), the density of which had been adjusted to 1.30 g mL^{-1} with KBr, was pumped underneath. The tubes were sealed with a cordless tube stopper and then ultracentrifuged (4 h, 4°C, average acceleration $167,153 \times g$) in a vertical rotor, using slow acceleration and deceleration below 160 rpm. The procedure was a modified version of the procedure developed by Chung *et al.* (26). Rotor shut-down added approximately 20 min to the total runtime. The top of the tube was gently sliced off using a scalpel, and the gradient was unloaded into 30 fractions (each of volume 0.5 mL) from the bottom of the tube using a peristaltic pump. The fractions covered the density range from 1.01 to 1.28 g mL^{-1}. The density of a fraction was determined by measuring its refractive index (n) in a refractometer, and calculating the density according to:

$$d = 3.298n - 3.396G \qquad [1]$$

where d is the density of the fraction and G is the density of the NaCl/KBr gradient at which this fraction was collected.

VLDL was recovered from the surface of the gradient with density lower than 1.015 g mL^{-1}. The VLDL fraction was frozen at −70°C and stored until the analysis of radiolabeled lipid classes and protein composition. Protein samples (0.5 μg protein) from the fraction associated with VLDL were added to a buffer containing SDS and boiled for 5 min. They were then loaded onto a 7% polyacrylamide gel for further analyses by SDS-PAGE as described by Burnette (27).

Lipid extraction and analysis of lipid classes and FA composition. Total lipids were extracted from culture media and

from VLDL by the method described by Folch *et al.* (28). The chloroform phase was dried under N_2, and the residual lipid extract was redissolved in hexane. Phospholipids (PL), mono- and diacylglycerols (MDG), and TAG were separated by TLC using a mixture of petroleum ether, diethyl ether, and acetic acid (113:20:2, by vol) as the mobile phase. The lipids were visualized by spraying the TLC plates with 0.2% (wt/vol) 2′,7′-dichlorofluorescein in methanol, and they were identified by comparison with known standards under UV light. The spots corresponding to PL, MDG, and TAG were scraped off into vials containing liquid scintillation fluid (InstaGel II Plus; Packard Instrument, Downers Grove, IL), and the radioactivity was measured in a liquid scintillation counter (TRI-CARB 1900 TR; Packard Instrument). There are certain limitations to the method used, and what is actually measured is the recovery of tritium (derived from tritiated glycerol) in the different lipid class fractions. The total FA profiles in the diets were determined by GC as described by Grisdale-Helland *et al.* (22). The total endogenous FA composition of hepatocytes was determined essentially as described by Ruyter *et al.* (29).

Preparation of hepatocytes for electron microscopy. After being washed in 0.1 M PBS, cells were scraped from the flask into 2 mL of 0.1 M PBS (pH 7.4), gently centrifuged, and then resuspended and fixed in 2% glutaraldehyde in 0.1 M cacodylate buffer (pH 7.4) at 4°C for 24 h. The cells were rinsed in the same buffer and post-fixed for 60 min in 2% OsO_4 containing 1.5% potassium ferrocyanide, followed by *en bloc* staining with 1.5% uranyl acetate. Cells were dehydrated in a series of ethanol solutions (70, 90, 96, and 100%) and propylene oxide, and then embedded in epon resin, which was polymerized at 60°C for 12 h. Ultrathin sections (approximately 50 nm) were cut on a Reichert Ultracut E ultramicrotome using a diamond knife. The sections were placed onto formvar/carbon-coated 75-mesh copper grids, post-stained for 2 min with 0.2% lead citrate solution in 0.1 M NaOH, and examined in a Philips CM 100 transmission electron microscope at an accelerating voltage of 80 kV.

Morphometry. Hepatocytes isolated from three fish in each feeding group were incubated for 24 h in medium containing either no FA (Ctr), 18:1n-9, 20:5n-3, 22:6n-3, or TTA. Lipid droplets and mitochondria in these samples were then analyzed by morphometry. Micrographs for morphometry were taken from 20 cells per treatment at a magnification of 2950×, at random positions in the sample. A square lattice grid was superimposed onto the micrographs, and the number of intersections falling on lipid droplets or on mitochondria was counted. We determined the total area of the mitochondria and of the lipid droplets in the cells relative to the total area of the cells (excluding the nuclei), as described by Hexeberg *et al.* (30). In brief, the percent area, A, of the cells constituting lipid droplets or mitochondria was calculated from:

$$A = (P_{lip}/P_{cell}) \times 100 \qquad [2]$$

where P_{lip} is the number of intersections falling on the lipid droplets and P_{cell} is the number of intersections falling on the cells (excluding the nuclei).

Statistical analysis. ANOVA was carried out using a model that included effects of diet, incubation time, and exogenous FA, and all interactions between these factors, to analyze the effect of endogenous FA composition on the secretion of total radiolabeled lipids. A reduced model in which only main effects were included was used where the interactions included in the full model gave nonsignificant results. Treatment differences were ranked using Duncan's multiple range test for the main effects. Pearson's correlation coefficient was calculated and used to analyze the correlation between the mitochondrial area and the lipid area.

One-way ANOVA (general linear model) was used to test the significance of the analysis of the level of [³H]glycerolipids secreted at different time points and at different additions of exogenous FA. Significant differences between means were analyzed using Duncan's test. Differences were considered to be significant at a 5% level. SAS computer software was used for all the statistical analyses (31).

RESULTS

FA composition. The SO diet contained more than eight times more n-6 FA (45.4%) than the FO diet (5.3%). The FO diet, on the other hand, contained almost twice as much n-3 FA (21.3%) as the SO diet (10.9%). The percentage of total monounsaturated FA was twice as high in the FO diet (49.3%) than in the SO diet (25.3%). The FA composition of hepatocytes isolated from fish fed either the SO or the FO diets was substantially affected by the dietary FA composition (Table 1). The percentage of n-3 FA in the hepatocyte lipids was 1.6 times greater in cells from fish fed the FO diet (39.3%) than in cells from fish fed the SO diet (24.5%). The percentage of n-6 FA was approximately seven times greater in cells from fish fed the SO diet (31%) than in cells from fish fed the FO diet (4.5%). There was an enrichment of 22:6 n-3 in hepatocytes isolated from both SO-fed (17%) and FO-fed fish (27%) compared with the corresponding percentages in the two diets (3 and 7%, respectively).

There were no major differences in the percentages of total saturated FA between cells in the two dietary groups.

[³H]Glycerolipids in the total extracted lipid fractions from culture media and from isolated VLDL particles. There was a lower recovery of secreted radiolabeled glycerolipids in the VLDL fraction than in the total culture media (Table 2). Lipid class analysis showed that whereas TAG dominated at all time points in the VLDL fractions, it constituted only 13% of the glycerolipid fraction in the total culture media at the early time points (1 and 2 h) and increased thereafter to 87% at the later time points (Table 2). The discrepancy between the results obtained by these two analytical methods can most probably be explained by the fact that exogenously added radiolabeled glycerol exhibits a natural time lag in its appearance in secreted glycerolipids. In addition, the procedure used for VLDL isolation (density gradient centrifugation) also may influence the results. In this method, the most TAG-rich VLDL particles will be more buoyant than the VLDL particles that are less TAG-rich. Only the TAG-rich VLDL particles will therefore be col-

[a]Data are shown as means ± SEM ($n = 3$). Values marked with different roman letters indicate significant differences ($P \leq 0.05$) between lipid classes. VLDL recovery was calculated as the amounts of [³H]glycerolipids recovered in the isolated VLDL fraction as a percentage of the amounts of total [³H]glycerolipids recovered in the culture medium. Isolated VLDL and total media were from hepatocyte cultures isolated from SO-fed fish. MDG, mono- + diacylglycerols; PL, phospholipids; for other abbreviations see Table 1.

lected on the top of the gradient. Based on these results, the total recovery of glycerolipids in the culture media, and not the recovery of glycerolipids in isolated VLDL fraction, was used for the further analysis of glycerolipid secretion from hepatocytes.

Effect of endogenous FA composition on the secretion of total [³H]glycerolipids. The rate of secretion of total [³H]glycerolipids (the sum of PL, MDG, and TAG) was 36% lower in hepatocytes from fish fed the FO diet than in hepatocytes from fish fed the SO diet ($P = 0.003$) (Fig. 1).

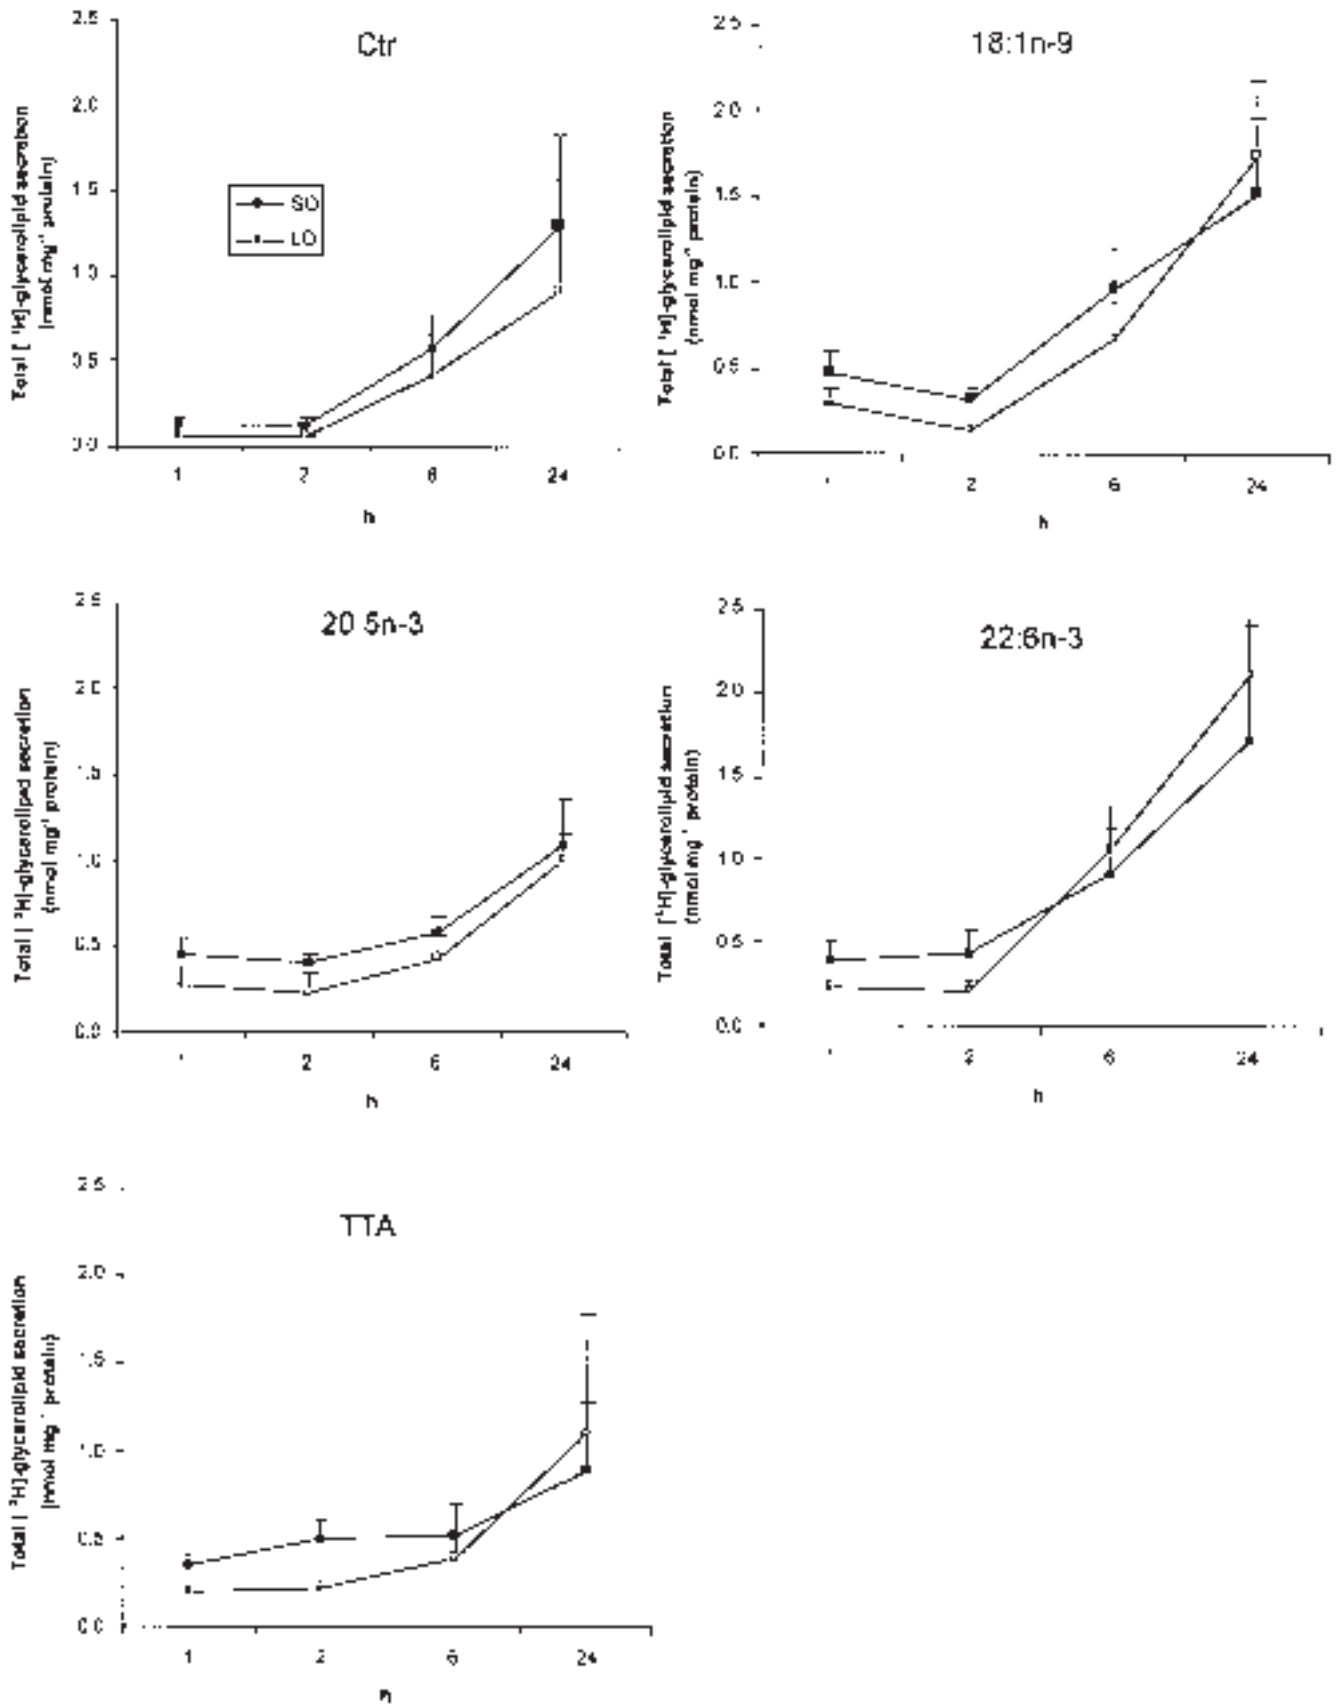
Effects of time and exogenously added FA on the secretion of [³H]glycerolipids. Figure 2 shows the secretion of total [³H]glycerolipids (the sum of PL, MDG, and TAG) after 1-, 2-, 6-, and 24-h incubations with either no FA (Ctr), 18:1n-9, 20:5n-3, 22:6n-3, or TTA. Hepatocytes from SO-fed fish secreted more esterified lipids than cells from FO-fed fish at the early time-points (1 and 2 h) irrespective of FA supplementation. Incubation of the hepatocytes with a relatively high concentration (0.75
FIG. 1. Secretion rate of [³H]glycerolipids by hepatocytes from fish fed soybean oil (SO) or fish oil (FO) [the sum of TAG, mono- and diacylglyerols (MDG) and phospholipids (PL)]. The secretion rate is calculated as nmol [³H]glycerolipids secreted per min per mg protein. Data are means ± SEM ($n = 3$). The difference is significant at $P = 0.003$. Each data point (n) is the average of 20 individual measurements.


FIG. 2. Effect of exogenously added FA on the secretion of [³H]glycerolipids (the sum of TAG, MDG and PL) from fish fed SO or FO after incubations with an FA-free medium (Ctr) or media supplemented with 0.75 mM of either 18:1n-9, 20:5n-3, 22:6n-3, or tetradecylthioacetic acid (TTA) for 1, 2, 6, or 24 h. Data are means ± SEM (*n* = 3). For other abbreviations see Figure 1.
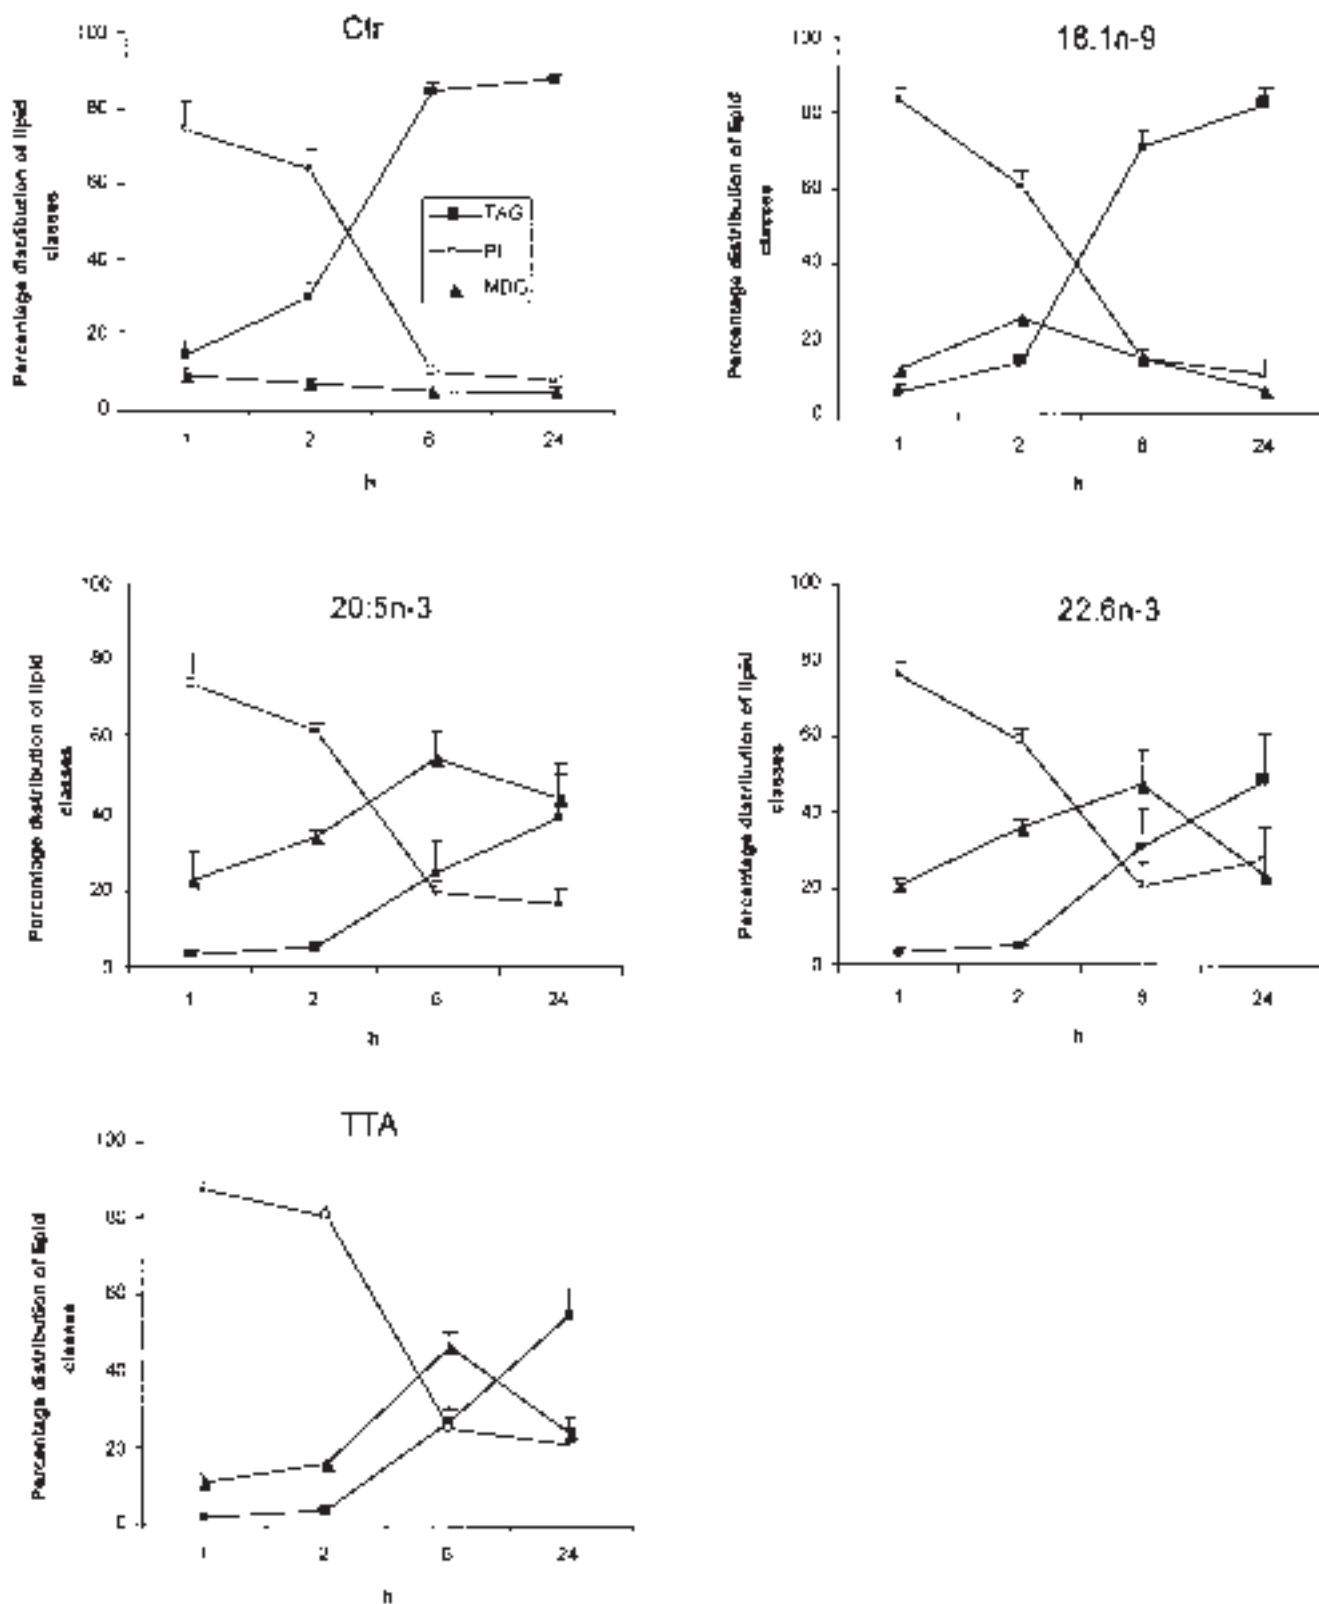

FIG. 3. Percentage distribution between the different [³H]glycerolipids (TAG, MDG, and PL) after incubations with an FA-free medium (Ctr) or media supplemented with 0.75 mM of either 18:1n-9, 20:5n-3, 22:6n-3, or TTA for 1, 2, 6, or 24 h. Each data point shown is a mean value of the two dietary groups ± SEM (*n* = 6). For abbreviations see Figures 1 and 2.

mM) of exogenously added FA for a longer period of time, however, reduced the effect of the feeding group that had been observed at 1 and 2 h. Approximately 6–7 times more [3H]glycerolipids were secreted at 24 h than at 1 h from hepatocytes incubated with 22:6n-3 or 18:1n-9, irrespective of dietary group. In comparison, there were only approximately 2–3 times more [3H]glycerolipids secreted at 24 h than at 1 h from control cells or cells incubated with 20:5n-3 or TTA. This shows that hepatocytes to which 18:1n-9 or 22:6n-3 had been added secreted [3H]glycerolipids more than twice as rapidly as control cells or cells to which 20:5n-3 or TTA had been added.

Figure 3 shows the effect of exogenously added FA on the secretion of different [3H]glycerolipid classes (TAG, MDG, and PL). No significant differences in percent distribution of glycerolipid classes were found between the two feeding groups at any time point. The results are therefore presented as mean values of the two feeding groups.

The majority of the [3H]glycerolipids secreted from all cell incubations after 24 h were in the form of TAG, except from hepatocytes incubated with 20:5n-3. The percentage of MDG secreted from the cells incubated with 20:5n-3 increased during the time period, giving a ratio of TAG to MDG of approximately 1 after 24 h of incubation. In comparison, this ratio was 23.5 in control cells after 24 h of incubation. The ratios of TAG to MDG after 24 h were approximately 10, 3, and 2.5, for cells incubated with 18:1n-9, 22:6n-3, and TTA, respectively. The secretion patterns for the different lipid classes from cells incubated with TTA were similar to those for cells incubated with 20:5n-3.

TAG secretion from 20:5n-3-treated cells was approximately 70% lower after 24 h of incubation than it was for control cells (Fig. 4). The FA 22:6n-3, in contrast to 20:5n-3, had

no major effect on the amount of TAG secreted. The only exogenously added FA that stimulated TAG secretion compared with control cells during the experiment was 18:1n-9. The amount of TAG secreted from cells incubated with TTA for 24 h was approximately 40% lower than that of control cells.

Morphometric quantification of lipid and mitochondrial area. The mitochondrial area of the hepatocytes was not affected by the composition of FA in the feed. There was a slightly higher intracellular lipid area in cells from the FO-fed fish than in cells from the SO-fed fish. Owing to a relatively high SD between the analyzed samples, the differences were, however, not significant. This allows us to present the morphometric results as mean values from all observed cells, irrespective of feeding group. The FA added to the cells in culture, on the other hand, affected the lipid area and the mitochondrial area more profoundly.

Figure 5 shows the percent area of lipid droplets and mitochondria after incubation with either no FA (Ctr), 18:1n-9, 20:5n-3, 22:6n-3, or TTA for 24 h, and Figure 6 shows representative micrographs of hepatocytes after each incubation. Lipid accumulations were observed as light and/or black droplets in the cytoplasm of hepatocytes. Cells incubated with 20:5n-3 had the largest lipid area (12.0%) (Figs. 5, 6C), whereas cells incubated with 18:1n-9 or 22:6n-3 had a significantly smaller lipid area: 4.8 and 6.7%, respectively (Figs. 5, 6B, 6D). Cells incubated with TTA had the lowest lipid area, 2%, a level similar to that of control cells (Figs. 5, 6A, 6E). The lipid area and the mitochondrial area were highly correlated (*P* = 0.002). The mitochondrial area was highest in cells incubated with 20:5n-3 (13.5%) and was significantly higher than in cells incubated with TTA (10.7%) and in control cells (9.7%), which had the lowest mitochondrial area.
FIG. 4. Relative TAG secretion after incubations with an FA-free medium (Ctr) or media supplemented with 0.75 mM of either 18:1n-9, 20:5n-3, 22:6n-3, or TTA for 24 h. The control TAG levels are set to 100% in each incubation for both dietary groups, and the mean values of the two dietary groups are presented. The mean values of the TAG levels of the different FA incubations are presented relative to the control TAG levels. Data are means ± SEM (*n* = 6). Different letters indicate significant (*P* < 0.05) differences. For abbreviations see Figures 1 and 2.
FIG. 5. Morphometrical estimates of lipid area and mitochondrial area of hepatocytes incubated for 24 h in an FA-free medium (Ctr) or media supplemented with 0.75 mM of either 18:1n-9, 20:5n-3, 22:6n-3, or TTA. Data are the relative areas of lipid droplets or mitochondria of total cell area (exclusive of the nuclei) and are shown as the mean values of the two dietary groups ± SEM (*n* = 6). Different letters indicate significant (*P* < 0.05) differences between the different FA-incubations. For abbreviation see Figure 2.
FIG. 6. Electron micrographs of hepatocytes incubated for 24 h in (A) an FA-free medium, or a medium supplemented with 0.75 mM of either (B) 18:1n-9, (C) 20:5n-3, (D) 22:6n-3, or (E) TTA. The micrographs shown are representative cells for each of the five treatments. Lipid accumulations (arrows) were observed as light and/or black droplets in the cytoplasm. The highest accumulation of lipid droplets was observed in hepatocytes incubated with 20:5n-3, whereas hepatocytes incubated with 18:1n-9 or 22:6n-3 showed a significantly lower lipid droplet area. No or only a few lipid droplets were observed in hepatocytes incubated with TTA or an FA-free medium. Bars = 5 μm. For abbreviation see Figure 2.

DISCUSSION

The endogenous FA composition of hepatocytes was influenced by the identity of the oil used as lipid source in the diet. This agrees with several studies using different types of vegetable oil in salmonid diets. Generally, the replacement of FO by SO results in higher levels of n-6 FA and lower levels of n-3 FA in the tissues of Atlantic salmon and rainbow trout (29,32–35). The marked differences in FA composition due to the diets had a pronounced effect on the secretion of glycerolipids. Lipid secretion from hepatocytes from fish fed the FO diet was 36% lower than the secretion from hepatocytes from fish fed the SO diet. A number of *in vivo* studies in mammals during the past few decades have shown that FO diets inhibit lipid secretion by hepatocytes (2,16,36). Our results from fish hepatocytes agree with the findings from mammals and show that an endogenous FA composition with a high n-6/n-3 ratio promotes lipid secretion to a level that is higher than that with a lower n-6/n-3 ratio. Other components in diets however,

may also influence the TAG-rich lipoprotein secretion from hepatocytes. SO may contain significant quantities of lecithin (37), whereas FO may contain relatively high levels of cholesterol (38), both of which are known to modify lipoprotein metabolism in mammals (39–41). We do not know whether dietary lecithin and cholesterol affect these processes in fish, but this topic will be important for further studies.

The mechanisms by which FO in the diet reduces TAG secretion in fish are not known, nor have they been completely elucidated in mammals. However, several mechanisms and regulatory sites may be involved. The present study demonstrates that 20:5n-3, and not 22:6n-3, inhibits TAG secretion in salmon hepatocytes, in accordance with the results of many studies in rat hepatocytes (13–15,17,19,42,43). Studies in mammals have shown that dietary FO interferes with the assembly of the initial VLDL precursor particles in hepatocytes and inhibits VLDL secretion in this way (9,10,16,44,45). Whether VLDL secretion in fish is regulated in the same manner is not known.

Several studies in mammals have shown that 20:5n-3 reduces the availability of intracellular TAG for incorporation into VLDL by inhibiting the activity of DGAT (13,14), that is, the enzyme catalyzing the conversion of 1,2DAG into TAG (13–15,19). In contrast, 22:6n-3 does not affect DGAT activity in rat hepatocytes (14). Although we did not measure the activity of DGAT, the reduced lipid secretion from hepatocytes incubated with 20:5 n-3 has led us to suggest that DGAT also may be a regulated step in fish. The inhibition of TAG synthesis should occur before or at the DGAT step, since the ratio of TAG to MDG secreted from these cells is lower than that secreted from control cells. The seemingly contradictory results of a reduced DGAT activity and the observed increase in intracellular lipid level in 20:5n-3 treated cells may be explained by an inhibiting effect of 20:5n-3 on the VLDL assembly step, leading to a net increase in cytosolic lipid droplets. Many factors seem to affect the different steps of the lipid secretion process and its regulation, and we cannot on the basis of our results draw conclusions about which regulatory mechanisms are most important for the lowering effect of 20:5n-3 on TAG secretion. However, lipid class composition of cellular lipids may give valuable additional information about the DGAT activity and TAG synthesis.

Furthermore, several studies in mammals have shown that 20:5n-3 reduces TAG secretion by stimulating mitochondrial β-oxidation, thus reducing the availability of FA for TAG synthesis (15,18,42), whereas 22:6n-3 is a poor substrate for mitochondrial β-oxidation in rats (14,15). Frøyland *et al.* (18) showed that the plasma TAG level decreased in rats fed 20:5n-3, but not in rats fed 22:6n-3. The decrease was caused by an increase in the number of mitochondria and an increase in the level of mitochondrial β-oxidation. We have not measured the activities of enzymes involved in β-oxidation. However, we have shown that incubation with 20:5n-3 leads to an increased mitochondrial area and that it reduces the secretion of glycerolipids. These results suggest that 20:5n-3 also stimulates the capacity of mitochondria to β-oxidize FA in salmon.

The microscopy study revealed only normal-sized mitochondria in all hepatocyte samples, without any observations of megamitochondria. Other investigators have found more dramatic effects on mitochondrial number and size after feeding trials in rats. It has been shown that EPA may initiate a signal for megamitochondria formation and subsequent proliferation (30,46). We suggest that a 24-h incubation is too short a time to achieve megamitochondria formation and high mitochondrial proliferative activity in our cell culture experiment. The observed increase in mitochondrial area in EPA-treated cells can therefore be a result of a moderate increase in the number of mitochondria.

The relative area of lipid droplets was highly correlated ($P = 0.002$) with the relative area of mitochondria, and both were significantly higher in cells incubated with 20:5n-3 than they were in control cells. It may be that the amount of accumulated lipid *per se* induces mitochondrial proliferation directly by an unknown mechanism, and that the potency of 20:5n-3 as a mitochondrial proliferator in salmon hepatocytes is related to the increased intracellular lipid level estimated in the cells through lipid droplet areas.

Although 22:6n-3 had no effect on TAG secretion, this FA resulted in the highest secretion of total glycerolipids. This was mainly due to a higher incorporation of 22:6n-3 into secreted PL. Previous results from salmon hepatocytes showed that 22:6n-3 was preferentially incorporated and conserved in PL (47,48).

Cells incubated with TTA secreted less TAG than control cells, in accordance with studies in mammals showing that TTA inhibits TAG secretion (14,21). This FA analog directs FA away from esterification and toward FA oxidation in rats (14,17,21) through regulations resulting in increased activities of enzymes involved in mitochondrial and peroxisomal β-oxidation (18,30), and by inhibiting DGAT (14).

We have shown that 18:1n-9 stimulates TAG secretion, which is in accordance with results from rat hepatocytes (13,19,43). However, the observed stimulating effect of SO and 18:1n-9 on lipid secretion, and the reported negative effects of some vegetable oils on fish heart histology (49,50), should be considered. These effects may give rise to problems that are similar to problems related to coronary heart diseases in humans. Such problems have been linked to a diet low in n-3 FA (1–4).

In conclusion, we have shown that lipids are secreted from cultivated salmon hepatocytes at a rate that is significantly lower in fish fed a diet containing FO as the only lipid source than in fish given a diet that has been supplemented with SO. Further, we have shown that 20:5n-3, and not 22:6n-3, somehow mediates this effect, whereas 18:1n-9 stimulates TAG secretion to levels that are higher than those in control cells. Our results indicate that in dietary FO, 20:5n-3 is the FA that reduces TAG secretion in fish and may be responsible for the hypotriglyceridemic effect of FO observed in fish and humans.

Instituto de Investigaciones Bioquímicas de La Plata (INIBIOLP), Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET)–Cátedra de Bioquímica, Universidad Nacional de La Plata (UNLP), (1900) La Plata, Argentina

ABSTRACT: The effect of the water-soluble fraction (WSF) of crude oil on lipid contents, lipid classes, FA, and PC molecular species was studied in high-phospholipid (hepatopancreas) and low-phospholipid (egg) tissues of a freshwater crustacean. After a 21-d exposure to a sublethal concentration of WSF, a significant decrease in shrimp total lipids was observed, although no alterations could be detected in the hepatopancreas or egg lipid contents. TAG/phospholipid ratios increased in the hepatopancreas and decreased in the eggs, suggesting alterations either in the mobilization of TAG to phospholipid pools or in the energy balance. The FA composition of phosphoglycerides in the hepatopancreas and eggs was dominated by PUFA, whereas the n-3/n-6 ratio was not affected by WSF exposure, although there was a significant increase in hepatopancreas 18:1n-9. Analysis of the PC molecular species by HPLC-ELSD showed the presence of 15 species, with 16:0/18:1, 18:1/18:2, 16:0/20:5, and 16:1/20:5 being the major species in the hepatopancreas. The PC molecular species in the eggs showed a different pattern, dominated by 16:0/18:1 and 18:1/18:2. Of the PC molecular species, 10 contained 22:6n-3, 20:5n-3, and 20:4n-6. Small amounts of di-PUFA species were also found. Exposure to WSF altered the PC molecular species in both tissues. The four major hepatopancreas molecular species and most of the ones containing PUFA decreased. This was compensated for by an increase in 16:1/18:1 (152%) and 18:1/18:1 (50%). The two major egg PC molecular species decreased, whereas the PUFA-containing ones increased. The contrasting responses of both tissues to WSF contamination suggests the presence of different homeostatic mechanisms.

Paper no. L9587 in *Lipids 40*, 487–494 (May 2005).

The freshwater shrimp *Macrobrachium borellii* is a decapod crustacean widespread in South America that lives in turbid, tepid waters such as the ones in the Río de La Plata estuary (1,2). In several past studies the lipid composition and metabolism of *M. borellii* were investigated. Phospholipids (PL) and TAG were identified as the main lipid classes in adult tissues and eggs, respectively (3–5). Monounsaturated FA were the major group in egg TAG, whereas PUFA were the major group in PL after embryo organogenesis and in the total lipids of adult

tissues (4,5). PL classes and their FA composition play a key role in the structure and function of most cellular membranes, including *M. borellii* membranes, whose main PL class is PC (6,7). Knowledge of the molecular species of PL is important for understanding the membrane properties and functions (8). However, unlike vertebrates, few reports are available on the molecular species of PL in invertebrates (9–13), and none are available on the effect of the water-soluble fraction (WSF) of petroleum hydrocarbons (HC) on them.

When lipophilic contaminants such as petroleum HC are taken up by organisms, they partition at some equilibrium level between water and the lipids of the organism and become bioconcentrated in lipid compartments such as membranes, lipoproteins, and lipid storage tissues (14). Benthic organisms are known to accumulate HC directly from the water column or from the interstitial water in the sediment (15). Thus, *M. borellii* was chosen because it is a species with ecological relevance in the Río de La Plata estuary in which we had previously studied the bioaccumulation and biodepuration rates of WSF; we had observed that lipid compartments retain polyaromatic HC for long periods of time (16). Oil spills occur periodically in the Río de La Plata estuary, which has become the most contaminated region in the country in terms of HC (17). In the present study, we investigated the use of molecular species of PL as a potential biochemical marker for HC pollution. The effect of WSF on the lipid content and lipid class composition of *M. borellii* was examined. Changes in the pattern of PC molecular species after exposure to a sublethal concentration of HC are described.

EXPERIMENTAL PROCEDURES

Sample collection. Adult *M. borellii* were sampled during the spring and summer (October to February) in a watercourse free of petrogenic contamination close to the Rio de La Plata River in Argentina (20 km southwest of La Plata city), with temperatures ranging from 21 to 28°C. Ovigerous females with eggs were collected for the experiments in early summer, and adults were collected in the spring for another set of experiments. They were taken to the laboratory and kept in dechlorinated tap water at 24 ± 2°C and a 14-h light/10-h dark photoperiod for at least a week before the experiments (18). The eggs were removed from the pleopods of the ovigerous females and

Abbreviations: HC, hydrocarbon(s); HP-TLC, high-performance thin-layer chromatography; PL, phospholipids; WSF, water-soluble fraction.

checked under a stereoscopic microscope to determine the stage of development (19).

Preparation of the WSF of crude oil. Light crude oil obtained from Punta Loyola (Santa Cruz, Argentina), stored at 4°C, was used to prepare the WSF. The oil was stirred in a 10-L stainless-steel mixing vessel equipped with a mechanical stirrer and a bottom drain, and was kept in a cold room at 4°C. Crude oil and fresh water in a ratio of 1:100 (vol/vol) were stirred at a low speed for 24 h and allowed to settle for an additional 48 h (shorter settling times produced a fraction with dispersed oil droplets). The WSF was collected daily using the bottom drain. During the experiments, fresh batches of WSF were prepared every 2 d, and a sample was extracted and analyzed by GLC following the method described by Lavarías *et al.* (16).

Exposure to WSF. Groups of 10 adults or 4 ovigerous females carrying eggs at developmental stage 3 (19) were placed into 750-mL glass flasks with air-tight screw-capped lids to avoid the loss of HC. The number of individuals per flask was selected to ensure the appropriate concentration of dissolved oxygen, which was checked daily. To evaluate the effect of WSF exposure on lipids in either the whole organism, hepatopancreas, or eggs, three groups were used as a control and another three were exposed to a sublethal concentration of WSF (0.6 ppm, chosen from the results of a previous study) (16). Shrimp were exposed for 21 d without being fed, and the WSF was replaced daily. After exposure, the eggs were removed from the female pleopods, the hepatopancreas was dissected from the adults, and the total weight of the samples was recorded. All animals per group were pooled at the end of the experiment. Individuals were dried on an absorbant tissue, weighed on a semi-analytical balance with 0.01-mg accuracy, and dissected; the size of the animals was homogeneous. Weight differences among the samples were minor, and mortality was always less than 10% of animals in the control and exposed groups.

Lipid extraction and analysis. Tissues were immediately homogenized in a Potter-type homogenizer (Thomas Scientific, Swedesboro, NJ) using 0.02 M Tris-HCl buffer, pH 7.5, and a subsample was taken for protein analysis for another experiment. For the analysis of whole organisms, homogenization was performed using an UltraTurrax tissue disrupter (Janke and Kunkel, Ika Werk, Germany). Lipids were extracted with a chloroform/methanol mixture following the method of Bligh and Dyer (20). Each group was analyzed separately.

The total lipid concentration was determined gravimetrically in an aliquot of chloroform, and the rest was kept in hexane under a nitrogen atmosphere at −70°C until further analysis.

A lipid class analysis was performed by TLC on silica gel Chromarods (type S-III) with quantification by FID using an Iatroscan TH-10, Mark III (Iatron Laboratories Inc., Tokyo, Japan), as described by Parrish and Ackman (21). The separation was conducted with a sequence of three different solvent systems according to Ackman *et al.* (22). The first development was carried out for 45 min in hexane/ethyl acetate/diethyl

ether/formic acid (91:6:3:1, by vol). The Chromarods were dried, partially scanned to analyze the neutral lipids, and then developed in acetone for 15 min to quantify the carotenoid peak. Finally, the Chromarods were developed in chloroform/methanol/formic acid/water (50:30:4:2, by vol) for 60 min and completely scanned to reveal the different PL. Tetracosanol was used as an internal standard, and quantification was performed using the calibration curves of authentic standards run under the same conditions. Carotenoids from the shrimp were purified for use as standards to avoid error caused by differing responses of the FID to different carotenoids. The lipids were identified as described previously (5).

FA analysis. Preparative high-performance TLC (HP-TLC) (Merck, Darmstadt, Germany) was used to isolate the neutral lipids from the polar lipids, as described previously (5). FAME from PL were prepared using a base-catalyzed transesterification microscale procedure according to Christie (23). Amidebound FA, like those in sphingomyelin, are not affected by alkaline transesterification; therefore, the PL FA analyzed came mainly from the PC and PE in this species. FAME were analyzed by GLC on an Omegawax 250 (30 m × 0.25 mm, 0.25 μm film; Supelco, Bellefonte, PA) capillary column in a Hewlett-Packard HP-6890 equipped with a FID. The column temperature was programmed for a linear increase of 3°C/min from 175 to 230°C. FA were identified by their characteristic retention times and by co-injecting the sample with authentic standards (Supelco, St. Louis, MO) or a FAME mixture of established composition run under the same conditions.

PC molecular species. PL fractions were isolated from lipid extracts by HPLC using a Merck-Hitachi L-6200 Intelligent pump (Hitachi Ltd., Tokyo, Japan). An Evaporative Light-Scattering Detector 500 (Alltech Associates Inc., Deerfield, IL) operating at a nitrogen flow rate of 2.2 mL/min and a drift tube temperature of 90°C was used for detection. To purify the PC, an Econosil Silica column (250 × 4.6 mm × 10 μm; Alltech Associates Inc.) and a guard column packed with the same material were used. Elution was performed as described elsewhere (24). PC was collected manually, the eluate was evaporated to dryness under a stream of nitrogen, and the PC was redissolved in chloroform/methanol (1:1, vol/vol).

Resolution of the PC molecular species was performed on two end-capped Lichrosphere 100 RP18 columns in series (250 × 4 mm; Merck, Darmstadt, Germany). Isocratic elution was applied with a mobile phase composed of acetonitrile/methanol/triethylamine (40:58:2, by vol) (25). Detection and quantification were done by ELSD using nitrogen as the nebulizer gas at a flow of 1.8 L/min and a temperature of 100°C (24).

The column eluate was collected every 30 s using an LKB 2212 Helirac fraction collector (Bromma, Sweden). The individual PC molecular species were identified by determining the FA composition of each peak by GLC as described, and its relative abundance was calculated from the areas of the peaks.

Statistical analyses. Data collected from all experiments were analyzed by ANOVA using Instat, v. 2.0 (GraphPad, San Diego, CA). Data were transformed prior to performing the statistical procedures. Results were considered significant at a level of 5%.

Total Lipid Concentration of Whole Organisms, Hepatopancreas, and Eggs of *Macrobrachium borellii* from Control and Water-Soluble Fraction (WSF)-Exposed Organisms[a]

	Control	WSF-exposed
Whole	11.2 ± 0.5	9.5 ± 0.2*
Hepatopancreas	11.3 ± 1.8	13.5 ± 4.2
Eggs	83.0 ± 5.1	90.3 ± 10.4

[a]Values are the means of triplicate analyses ± 1 SD and are expressed as mg/g wet weight. *$P < 0.05$.

RESULTS

Changes in lipid content and composition by WSF exposure. After a 21-d exposure to WSF, the total lipid concentrations of exposed animals decreased significantly compared with control organisms; however, the total lipid concentrations of the hepatopancreas and eggs did not vary significantly (Table 1).

To determine the effect of WSF on the lipids, each lipid class was studied separately in the adult hepatopancreas and eggs of control and exposed organisms. We also checked the muscle, but no changes were observed; therefore, it was not included in the present study. PL were the major lipids in the hepatopancreas, accounting for 74.4%, by weight of the total lipids, whereas egg lipids were dominated by TAG, representing 69.5% of the total lipids. This markedly different lipid composition provided us with two contrasting models within the same species to study the effect of HC contamination. After a 21-day exposure to WSF, both the hepatopancreas and eggs showed significant changes in their lipid class composition. The hepatopancreas showed a significant decrease in PL as well as a decrease in the carotenoid pigment (Table 2). PC in particular, representing the major lipid class in this tissue, showed a significant reduction from 62 to 53% by wet weight ($P < 0.05$) in WSF-exposed animals. However, the average sphingomyelin concentration in the WSF-exposed hepatopancreas was almost two times higher than the hepatopancreas control (Table 2). The eggs, in contrast, showed a significant decrease (more than 11%) in TAG reserves in WSF-exposed embryos compared with the percentage in controls. In addition, there was an overall increase in PL, whereas the carotenoid pig-

ment did not change significantly in WSF-exposed eggs (Table 2). The PL/TAG ratio decreased in the hepatopancreas of WSF-exposed animals because of the decrease in PL, whereas in the eggs the ratio increased from 0.4 to 0.6, reflecting both the decrease in TAG and the increase in PL (Table 2).

FA. Table 3 shows the FA profiles of phosphoglycerides from the hepatopancreas and eggs of control and WSF-exposed organisms. Regardless of treatment, EPA (20:5n-3) was the major FA in the hepatopancreas, followed by arachidonic (20:4n-6) and oleic acids (18:1n-9). The exposure of shrimp to WSF did not significantly change the FA profile of the PL, except for an increase in 18:1, which made it the second most important FA in the PL. The FA profile of the eggs was also dominated by 20:5n-3, followed by similar amounts of 18:1n-9, 16:0, and 18:0. After exposure to WSF, there were no statistically significant differences in the relative FA composition between the WSF and control groups. PUFA was the major group in the PL, regardless of the tissue or treatment analyzed.

PC molecular species. After studying the effect of WSF on total lipids, the lipid composition, and PL FA, we identified PC as the only PL whose concentration was significantly altered by the contaminant in both the hepatopancreas and eggs (Table 2). We therefore studied PC in detail, analyzing its molecular species. The eggs and hepatopancreas were chosen, as in preliminary experiments these tissues were found to be the ones most sensitive to HC pollution.

Using HPLC-ELSD, we were able to resolve 15 molecular species of PC in both the hepatopancreas and eggs of *M. borellii* (Fig. 1). The major molecular species of the hepatopancreas were 16:0/18:1, 18:1/18:2, 16:0/20:5, and 16:1/20:5, which represented more than 60% of the total (Fig. 2). Remarkably, 10 of the 15 PC species resolved contained 20-carbon PUFA, particularly 20:5n-3 and 20:4n-6, and some minor species were di-PUFA. On the other hand, PC molecular species in the eggs showed a different pattern, dominated by 16:0/18:1 and 18:1/18:2 (Fig. 3). These two species accounted for more than 55% of the total. When we exposed adult shrimp to WSF for 3 wk, the PC molecular species showed changes in both tissues. Except for 18:1/18:2, the major molecular species of the he-

patopancreas decreased significantly, together with most PUFA-containing molecular species. This was paralleled by an increase in molecular species containing monounsaturated FA

(mean increase 152% in 16:1/18:1 and 50% in 18:1/18:1) and increases in the minor species 18:0/18:2 and 18:0/20:4.

The two major egg PC molecular species showed a significant decrease after a 3-wk exposure to WSF, totaling 55% in the control and 45% in the exposed organisms. Unlike in the hepatopancreas, the proportions of several PUFA-containing molecular species in the exposed eggs (16:0/20:5, 16:0/22:6, 18:1/22:6, and 16:0/20:4) increased significantly.

DISCUSSION

Total lipid content as a pollution indicator. In this work, we analyzed the effect of a sublethal exposure to WSF on lipid contents, lipid classes, and the PL FA composition of adult *M. borellii* tissues and eggs and characterized the PC molecular species as well as the variations triggered by this contaminant.

When we analyzed the total lipid contents, we observed a significant decrease in the exposed adults, probably because the shrimp catabolized more of their lipid reserves to obtain energy for the detoxification processes triggered by the contaminant. Wang and Stickle (26), studying the crab *Callinectes sapidus*, also observed a decrease in the total lipid concentration after a 15-d exposure to crude oil. Nevertheless, when we determined total lipids in the hepatopancreas and eggs of *M. borellii*—tissues metabolically active in biosynthesis, degradation, and depuration—we found no differences between exposed and control organisms. Nowadays, it has become clear that the traditional use of total lipid content or lipid-normalized pollutant data as a pollution indicator is not always a safe approach because of variations in lipid extraction and analysis, differences in contaminant partitioning among lipid pools, and seasonal/physiological changes in the lipid concentration and composition (27). In addition, the homeostatic mechanisms of the organisms may not be overcome, thus avoiding the appearance of significant changes in lipid concentration. It is therefore important to consider the variations in lipid classes or, like the novel approach explored in the present study, changes in the PL molecular species induced by exposure to WSF.

Variations in lipid and FA classes in response to WSF. We

observed a significant decrease in PC concentration in the hepatopancreas of exposed shrimp, whereas the sphingomyelin increased significantly and the TAG showed an increasing trend. Similar changes in PC and TAG were also found in crabs (28) and mussels (29) in response to other pollutants. Those authors suggested this might result from membrane damage, a fact that could also be the case with *M. borellii*, whose membranes contain PC as the major component (30); PC changes could be affecting the structure and properties of *M. borellii* membranes (4). Moreover, there are indications that xenobiotics increase membrane lipid peroxidation (31), and because the hepatopancreas is in charge of xenobiotic detoxification in adult crustaceans (32), it was not surprising to observe that the concentration of astaxanthin, a very potent antioxidant, decreased in WSF-exposed organisms, suggesting its consumption to prevent oxidative damage.

The significant decrease in the PL/TAG ratio of the hepatopancreas of exposed organisms would also be reflective of a mechanism to raise TAG levels, either by increasing TAG synthesis or by decreasing TAG mobilization into PL pools, thereby raising the number of hydrophobic reservoirs for WSF and diminishing the contaminant bioavailability by dilution. This mechanism also has been observed in other aquatic organisms (29). Previous studies in *M. borellii* have shown that the bioconcentration of aromatic HC from the environment and their subsequent depuration rate is related to the lipid contents (16). Capuzzo and Lancaster (33) demonstrated the impairment of lipid utilization in lobsters exposed to oil and suggested that the disruption in energetics was caused by alterations in their lipid metabolism.

Macrobrachium borellii egg lipids are composed primarily of TAG, which serve as the main source of energy during development (5). In this model we observed a significant decrease of this reserve in embryos exposed to WSF. This contrasting effect, compared with the hepatopancreas, is probably related to the fact that, being a closed system, egg embryos are faced with a different pressure: They have no source of energy other than the vitellus and must expend more energy coping with the increase in free radicals and detoxification mechanisms induced by WSF, as shown by the highly significant increase in the PL/TAG ratio. Although the concentration of the antioxidant astaxanthin did not change, the enzymatic defense systems are well developed in these shrimp embryos (see ensuing discussion). We have previously shown that developing embryos have a high metabolic rate and an important consumption of lipids from the vitellus at later stages (5); thus, an alteration of the major energy source attributable to the presence of WSF was expected.

The FA profile of PL from the hepatopancreas of *M. borellii* did not differ much from the one previously reported for egg PL (5), the major FA being 20:5n-3, followed by 20:4n-6, the 18:1 isomers, 16:0, and 18:0. The n-3/n-6 ratio was below one, as is usual in freshwater environments. In both the hepatopancreas and eggs, this FA composition was not greatly affected by the WSF. Nevertheless, the significant increase in 18:1 in the hepatopancreas after WSF exposure is noteworthy, as it became the second most important FA in the tissue, and this in-

crease was coincident with the increase in PC molecular species containing this FA (see ensuing discussion). Embryos are enclosed in the eggshell, and as closed systems, they cannot afford to lose the PUFA they need for the active membrane synthesis that takes place during organogenesis. The embryos of the crustacean *Gammarus locusta* are known to have a more developed antioxidant defense system than that of adults (34). A study in progress shows that *M. borellii* embryos have background levels of antioxidant defense enzymes such as catalase and glutathion transferase over twice as high as levels in the adult hepatopancreas. This probably allows the embryos to reduce oxidative damage, thus accounting for the unchanged PUFA concentration in embryos caused by the stressor. In contrast to results for the hepatopancreas, the astaxanthin concentration did not change by WSF exposure, suggesting that this antioxidant pigment is conserved by the embryo, as was shown in a previous study (5).

Variations in PC molecular species in response to WSF. After studying the effect of WSF on total lipids, lipid classes, and the phosphoglyceride FA composition, we identified PC as the only lipid in both the hepatopancreas and eggs whose concentration was varied significantly by the contaminant. We therefore focused on this lipid class and analyzed its molecular species to investigate whether there was a remodeling of the PC molecular species in response to WSF. In the hepatopancreas and eggs, we were able to identify 15 PC molecular species, dominated by 16:0/18:1 (24 and 31% of the total, respectively). Currently, very few reports are available on the PC molecular species of aquatic arthropods. The PC molecular species of the amphipod *Gammarus* sp. were also dominated by this molecular species (12). Unlike those results and the ones reported for *Limulus polyphemus* amebocytes (13), no fully saturated species were detected in the caridean decapod *M. borellii* (present results), *Pandulus* sp., or *Parapandulus* sp. (9). Moreover, we found minor amounts of di-polyunsaturated molecular species. Nevertheless, the vast majority of PC molecular species in these species consisted of *sn*-1 saturated or monoenoic 16- or 18-carbon FA and *sn*-2 monoenoic and polyenoic PC molecular species. This was expected, as it is a feature also found in the composition of most PC molecular species of freshwater (35,36) and terrestrial (37–39) vertebrates. In general, the molecular species composition reflected the high level of PUFA found in the PL FA profile of *M. borellii*.

After 3 wk of exposure to WSF, the composition of the molecular species of hepatopancreatic PC was modified such that it probably compensated for any changes triggered by the stressor. Tissues with a lower TAG/PL ratio were more greatly affected by the WSF, as suggested by Bergen *et al.* (27) for mussels; with the hepatopancreas there was a significant decrease in most of the PUFA-containing PC molecular species, probably due to the high susceptibility of PUFA to lipoperoxidation induced by aromatic HC detoxification (32).

One inherent property of the cells in poikilothermic animals is their ability to adjust the physicochemical characteristics of their membranes to the prevailing temperatures. Saturated FA produce less fluid PL with increasing chain lengths (38), but PUFA make the membranes only slightly more fluid than do monounsaturated FA. Therefore, the decrease in the fluidizing highly PUFA-containing species triggered by WSF exposure could be compensated for by the increase in di-monounsaturated 18:1-containing PC species as well as the decrease in 16:0/18:1. Interestingly, these results are similar to those found for shrimp exposed to different temperatures in which changes in the PC molecular species were produced in such a way that the fluidity was roughly maintained (35). Reshuffling and restructuring of the molecular species might be an important factor in lipid membrane adaptation, minimizing alterations caused by exposure to the WSF, although the present data do not allow us to differentiate between an adaptation to the WSF or a direct effect of WSF on the membranes.

The lack of change caused by WSF in the FA composition of the eggs, together with significant changes in the PC molecular species (Fig. 2), indicates that the type and proportion of the FA at both the *sn*-1 and *sn*-2 positions had altered. This could be a consequence of the availability of different FA (for example, from the TAG pool), but also of changes found in the specific activity of enzymes involved in PC synthesis. A retailoring process was evidently induced, and a deacylation–reacylation at carbons *sn*-1 and *sn*-2 was also manifest, although not much information is available on these processes in crustaceans. The profile of the PC molecular species might also have been influenced by different types of pathways, such as PE N-methylation, which has been found to be very active in crustaceans (40), although this was not checked on these shrimp.

In contrast to the hepatopancreas, the eggs showed a significant decrease in molecular species containing oleic acid and an increase in the PUFA-containing molecular species in WSF-exposed embryos. The increase in PUFA-containing molecular species may be related to the fact that the embryos must conserve these EFA for proper development, and in this sense, we previously observed that developing time and hatching are not significantly altered in WSF-exposed embryos (16). Ongoing experiments are focusing on the changes in membrane properties, e.g., chemical reactivity, fluidity, and interaction with proteins, induced by WSF.

The PC species 16:0/18:1 was the most affected by exposure to WSF, and its marked decrease in the hepatopancreas or eggs could be used as a complementary early biochemical biomarker, indicating the presence of HC pollution. Nevertheless, work is needed to validate the suitability of PC species as biomarkers in the environment. The shift in molecular composition of PC is noteworthy since it illustrates that relatively small changes on a total scale (lipids and FA composition) are translated into major changes in the PUFA- and monounsaturated FA-containing PC fractions. The different responses observed in the adults and eggs of PC species reinforce the need to include different life history stages of species in toxicological tests, as well as an appropriate biomarker that integrates chemical data with biological responses, when aiming for a better evaluation of hazardous compounds.

Lipid Composition Influences the Shape of Human Low Density Lipoprotein in Vitreous Ice

Andrea Coronado-Gray and Rik van Antwerpen*

Department of Biochemistry, Medical College of Virginia Campus,
Virginia Commonwealth University, Richmond, Virginia 23298

ABSTRACT: Earlier cryo-electron microscopic studies have indicated that the normal low density lipoprotein (N-LDL) has a discoid shape when its core is in the liquid-crystalline state. In the present study, we investigated whether the shape of LDL depends on the physical state and/or the lipid composition of the lipoprotein core. Using a custom-built freezing device, we vitrified N-LDL samples from either above or below the phase-transition temperature of the core (42 and 24°C, respectively). Cryo-electron microscopy revealed no differences between these samples and indicated a discoid shape of the N-LDL particle. In contrast, TG-enriched LDL (T-LDL) did not have discoid features and appeared to be quasi-spherical in preparations that were vitrified from either 42 or 24°C. These results suggest that the shape of N-LDL is discoid, regardless of the physical state of its core, whereas T-LDL is more spherical. Aspects that may influence the shape of LDL are discussed.

Paper no. L9583 in *Lipids 40*, 495–500 (May 2005).

Low density lipoprotein (LDL) transports cholesterol throughout the human body, and elevated levels of this lipoprotein in the blood correlate with increased risk of atherosclerosis and coronary heart disease. LDL is a quasi-spherical particle that contains a core of mainly cholesteryl esters and a surface monolayer of phospholipids, free cholesterol, and a single molecule of apolipoprotein B-100 (apoB; M_r ~550,000) (1,2). ApoB is a ligand for the apoB/E-receptor, allowing for receptor-mediated endocytosis of LDL by cells that express the receptor (3,4). In addition, apoB binds to proteoglycans in the vascular wall (5,6), which is one of the critical first steps in atherosclerosis (7,8). Thus, both the normal metabolism of LDL and the pathogenic properties of the lipoprotein particle depend on the structure of apoB.

Studies have shown that the lipid composition and size of the LDL core influence the conformation of apoB on the lipoprotein surface. Structural parameters, such as the relative amount of α-helical and β-sheet structure (9,10), the exposure of lysine amino groups on the LDL surface (11), the exposure of epitopes on the LDL surface (10–12), the susceptibility of apoB to protease digestion (9), and the affinity of apoB for the LDL receptor (9–14), all depend on the size of the LDL core. As a result, small, dense LDL particles appear to be more atherogenic than larger and more buoyant LDL (15,16).

Recent experiments have shown that the conformation of apoB on the LDL surface also depends on the physical state of the LDL core (17,18). The main components of the core, cholesteryl esters, are normally in a disordered liquid state at physiological temperature and in a more ordered liquid-crystalline state at room temperature (19–25). The temperature at which the transition between these two states occurs, i.e., the phase-transtion temperature, is usually around 30°C. However, animal studies have shown that diets with a high content of cholesterol and saturated fat can change the composition of the LDL core, and as a result elevate the phase-transition temperature to 40–45°C (26–28). Temperature-dependent IR spectroscopy and circular dichroism studies (17,18) indicate that these diet-induced changes in the physical state of the core may affect the conformation of apoB on the LDL surface, which in turn may influence the metabolic and pathogenic properties of the lipoprotein particle.

Recent cryo-electron microscopy (cryo-EM) studies have shown quite unexpectedly that LDL particles with a liquid-crystalline core may have an oblate ellipsoid or "discoid" shape (29–34). Low-resolution X-ray crystallography and high-performance gel-filtration chromatography appear to confirm the discoid nature of the LDL complex (35,36). Based on these observations, we have recently speculated that the liquid to liquid-crystalline transition of the LDL core may be associated with a spherical to discoid change in the shape of the lipoprotein particle, and that this shape change may be responsible for the observed change in the conformation of apoB on the LDL surface (18,33). A recent cryo-EM study seems to confirm this suggestion (34); however, high-performance gel-filtration chromatography indicates that LDL has a discoid shape regardless of the physical state of its core (36).

To address this issue further, we analyzed two LDL species with different core properties using cryo-EM. Our results suggest that the shape of normal LDL (N-LDL) is discoid, regardless of the physical state of its core, and that TG-rich LDL (T-LDL) is more spherical.

MATERIALS AND METHODS

LDL samples. N-LDL, $d = 1.019$–1.064 g/mL, was isolated from the blood of a healthy, nonsmoking, normolipidemic donor,

using sequential flotation ultracentrifugation as described earlier (18). T-LDL was produced by an *in vitro* lipid transfer procedure, using N-LDL, Intralipid (Sigma Chemical Company, St. Louis, MO), and lipoprotein-deficient plasma as a source for the cholesteryl ester transfer protein (18). The integrity of apoB in N-LDL and T-LDL was confirmed using SDS polyacrylamide gel electrophoresis according to Laemmli (37). Protein concentrations were determined with a modified Lowry assay, using BSA as a standard (38). Total cholesterol concentrations were determined using assay kit 439-17501 from Wako Chemicals (Richmond, VA). TG concentrations were determined using assay kit TR22421 from Thermo Trace (Melbourne, Australia).

Differential scanning calorimetry (DSC). DSC was performed using a Nano II Differential Scanning Calorimeter (Calorimetry Sciences Corporation, American Fork, UT). Before analysis, LDL samples were dialyzed into 10 mM sodium phosphate buffer (pH 7.4). Buffer and LDL samples were degassed under vacuum, after which 0.6 mL of each was loaded into the reference and sample cells of the calorimeter, respectively. LDL samples were analyzed at protein concentrations of 0.75–1.5 mg/mL. Thermograms were recorded over a temperature range of 0–45°C at heating and cooling rates of 60°C/h. Three sequential up-and-down scans were performed to verify reversibility of the phase transition.

Preparation of LDL for cryo-EM. Cryo-EM samples were prepared with a custom-built freezing device as described in Figure 1. Using this device, LDL samples were vitrified from either 24 or 42°C. Before loading samples into the freezing device, they were incubated for at least 15 min in a temperature-controlled water bath to bring the preparations to the desired temperature (either 24 or 42°C). Once the samples were loaded into the freezing device, they were equilibrated at the desired temperature for an additional 5 min before being plunge-frozen. These loading procedures assured that the LDL sample was at either 24 or 42°C immediately prior to vitrification.

Vitrification, i.e., freezing at rates that are high enough to prevent the formation of ice crystals, is commonly achieved when thin cryo-EM samples are plunged into liquid propane or ethane (29–31,39). Earlier studies have shown that the vitrification process is fast enough to capture membrane fusion intermediates and characteristic features of lipid phases that exist above the phase-transition temperature of the system (40–42). The present study, therefore, assumed that structural features related to the physical state of the LDL core were likewise preserved during vitrification.

Cryo-EM. N-LDL and T-LDL samples were analyzed under low-dose conditions, at 120 kV and –170°C, using a JEOL 1200EX electron microscope (JEOL, Ltd., Peabody, MA) and a Gatan model 626 cryo-transfer device (Gatan, Inc., Warrendale, PA) as described earlier (29–31). The following areas of the preparation were exluded from analysis: (i) Areas in which the ice was too thick for penetration of the electron beam. (ii) Areas with cubic or hexagonal ice crystals. These ice crystals, which prevent proper structural analysis, are easily recognized in electron diffraction patterns (in the electron microscope) and in the final cryo-EM image (photographic negative). (iii) Areas in
FIG. 1. Custom-built freezing device for the vitrification of samples of different temperatures. A pair of forceps (A), holding an electron microscopy (EM) grid with a lacy substrate (white arrow), is attached to a plunger (B). This plunger is connected to tubing that is pressurized with air. Air pressure in the tubing is adjusted with a control valve (not shown), usually set at 20 psi. Release of the pressure with a control switch (C) forces the plunger and the attached forceps down with high speed. The environment in the Plexiglas box (D) can be warmed by a heating pad in the back of the box (rectangle, E). The temperature near the EM sample is measured with a thermocouple (F) that is connected to a thermostat (not shown). In the bottom of the box are two small containers (G) that are filled with water. Filter paper soaked with water is guided from the water containers to the top of the heating pad to allow efficient distribution of water vapor throughout the box. The front panel of the box hinges on the left (black arrows) and can be opened to allow the forceps to be attached to the plunger and the sample to be applied to the EM grid (white arrow). After application of the sample, the front panel is closed and the environment is equilibrated at the desired temperature and high humidity. Subsequently, the bulk of the lipoprotein sample is blotted from the EM grid through a side entrance of the box (H), using a spatula covered with filter paper. Blotting of the sample results in the formation of thin films of lipoprotein solution in the holes of the lacy substrate on the EM grid. On formation of the thin films, the preparation is equilibrated at the set temperature for an additional 5 min. Subsequently, the control switch (C) pressurizes the plunger (B), which forces the attached forceps through the opened shutter into the container of liquid propane (I). Propane in the central compartment of the container (I) is kept in a liquid state by liquid nitrogen, present in the outer compartment of the container (I).

which the ice was too thin for random orientation of the LDL particles. These areas did not appear very often, and could be recognized by a steep gradient of background ice combined with an altered distribution of various projections (43). All other areas of the cryo-EM preparation were photographed and included in the analysis. At least 500 projections of each sample were measured. Images were recorded on Kodak 4489 film (Eastman Kodak Company, Rochester, NY) at a magnification of 30,000×. Photographic negatives were digitized at an optical resolution of 4800 dpi using a FlexTight Precision II Scanner (Imacon, Inc., Redmond, WA). Dimensions of the various LDL projections were determined using the measuring tool of Adobe Photoshop, software version 5.0 (Adobe Systems, Inc., San Jose, CA).
FIG. 2. DSC of normal low density lipoprotein (N-LDL) and TG-rich low density lipoprotein (T-LDL). Representative thermograms of N-LDL with a high phase-transition temperature (T_m = 31°C) and T-LDL with a low phase-transition temperature (T_m = 12°C) are shown.

RESULTS

The influence of the physical state and lipid composition of the LDL core on the overall shape and substructure of the lipoprotein particle was analyzed with two different LDL species: N-LDL, with a core phase-transition temperature of 31.1 ± 0.96°C, and *in-vitro*-produced T-LDL, with a core phase-transition temperature of 15.0 ± 1.79°C (Fig. 2, Table 1). The cholesterol and TG content, as well as some of the physical properties of these two LDL species, are shown in Table 1.

N-LDL samples vitrified from 24 or 42°C. Figure 3A shows a typical N-LDL preparation that was vitrified from 24°C (which is ~7°C below the phase-transition temperature of the N-LDL core). Various types of projections of the LDL structure were observed, including circular projections with a high-density ring and rectangular projections with two high-density bands. Earlier studies have shown that these projections represent face-on and edge-on views of a discoid structure, respectively (29–31). The projection most indicative of the discoid shape of N-LDL is the rectangular projection, resulting from an edge-on view of the structure. However, as the lipoprotein particles were free to rotate in solution immediately prior to vitrification, only a limited number of particles provided an edge-on view. In N-LDL preparations vitrified from 24°C, 12.8% of

all measured projections were unambiguously rectangular with two high-density bands (Fig. 4). This result is in good agreement with the number of rectangular projections observed in previous studies (29–31).

Figure 3B shows a typical N-LDL preparation that was vitrified from 42°C (which is ~11°C above the phase-transition temperature of the N-LDL core). As in preparations vitrified from 24°C, various types of projections of the LDL structure were observed, including circular projections with a high-density ring and rectangular projections with two high-density bands. The various projections observed in preparations frozen from 42°C were indistinguishable from those observed in preparations frozen from 24°C. In N-LDL preparations vitrified from 42°C, 10.2% of all measured projections were unambiguously rectangular with two high-density bands (Fig. 4). This percentage was not significantly different from the percentage of rectangular projections seen in N-LDL preparations frozen from 24°C (Fig. 4), indicating that, as at 24°C, N-LDL had a discoid shape at 42°C.

T-LDL samples vitrified from 24 or 42°C. T-LDL samples were vitrified from 24 and 42°C to further assess whether LDL particles with a liquid core have discoid features. Because the phase-transition temperature of the T-LDL core is ~15°C, T-LDL has a liquid core at both experimental temperatures. Figures 3C and 3D show typical cryo-EM preparations of T-LDL, vitrified from 24 and 42°C, respectively. In both types of T-LDL preparations, very few rectangular projections with two high-density bands were observed. In T-LDL preparations frozen from 24°C, only 0.8% of the measured projections were rectangular, whereas in preparations frozen from 42°C, 0.5% of the measured projections were rectangular (Fig. 4). These observations indicate that T-LDL particles are not discoid, but instead have a more spherical shape. The fact that N-LDL with a liquid core, vitrified from 42°C, had a discoid shape (see preceding discussion), suggests that the high TG content of the T-LDL core, and not the physical state of the core, is responsible for the quasi-spherical features of T-LDL (Table 2).

DISCUSSION

Molecular models of LDL generally depict the lipoprotein particle as a sphere. In these models, the liquid-crystalline LDL core is organized in concentric, spherical layers of cholesteryl

TABLE 1
Properties of Normal LDL (N-LDL) and TG-Rich LDL (T-LDL)[a]

	Chol/protein[b] (w/w)	TG/protein (w/w)	Chol/TG[b] (w/w)	T_m (°C)	Size (nm)
N-LDL	1.34 ± 0.08	0.15 ± 0.05	9.81 ± 2.57	31.1 ± 0.96	19.8 ± 1.85
T-LDL	1.08 ± 0.19	0.30 ± 0.08	3.81 ± 0.73	15.0 ± 1.79	18.5 ± 1.92

[a]Chol, total cholesterol; T_m, midpoint of the phase-transition of the low density lipoprotein (LDL) core, determined using differential scanning calorimetry (DSC). Size of the lipoprotein particles is indicated as the diameter of circular LDL projections in cryo-electron microscopy (cryo-EM) preparations frozen from 24°C. Values are the means of analyses on three different LDL preparations ± SE.
[b]Separate experiments showed that the *in vitro* conversion of N-LDL to T-LDL does not influence the free cholesterol and total phospholipid contents of the lipoprotein particle: The free cholesterol content of N-LDL and T-LDL was 0.35 ± 0.08 mg/mg protein (n = 5) and 0.30 ± 0.03 mg/mg protein (n = 5), respectively (P = 0.128), whereas the total phospholipid content of N-LDL and T-LDL was 0.82 ± 0.17 mg/mg protein (n = 5) and 0.75 ± 0.06 mg/mg protein (n = 5), respectively (P = 0.379).
FIG. 3. Cryo-electron micrographs of N-LDL (A, B) and T-LDL (C, D), ultra-rapidly frozen from 24 (A, C) and 42°C (B, D). Arrowheads indicate rectangular projections with two high-density bands, representing edge-on views of the LDL disc (29–31). For abbreviations see Figure 2.

FIG. 4. Frequency distribution of rectangular projections with two high-density bands in cryo-EM preparations of N-LDL and T-LDL, vitrified from 24 or 42°C. The occurrence of rectangular projections in N-LDL preparations vitrified from 24 or 42°C is not significantly different (t-test; $P = 0.105$); n refers to the number of separate LDL preparations analyzed using cryo-EM. For abbreviations see Figure 2.

esters (19–25) (Fig. 5A). However, recent cryo-EM studies suggest that LDL has an oblate ellipsoid or discoid shape when its core is in the liquid-crystalline state (29–34). This suggestion has recently been supported by low-resolution X-ray crystallography (35) and high-performance gel-filtration chromatography (36). New LDL models therefore propose that the liquid-crystalline core is organized into flat layers of cholesteryl esters (32,35,36) (Fig. 5B), which is consistent with the crystallization of neat cholesteryl esters in flat sheets (44).

The present study was designed to test the hypothesis that the phase-transition of the LDL core is associated with a spherical to discoid change in the shape of the lipoprotein particle. Quite unexpectedly, projections of N-LDL in preparations vitrified from 42°C (i.e., ~11°C above the phase-transition of the LDL core) (Fig. 3B) were similar to those observed in preparations vitrified from 24°C (i.e., ~7°C below the phase-transition of the LDL core) (Fig. 3A). In addition, roughly equal numbers of rectangular projections, representing edge-on views of the discoid structure (29–31), were observed in preparations vitrified from 42 or 24°C (Fig. 4). These results suggest that the N-LDL particle has a discoid shape regardless of the physical state of its core.

Our present results are in agreement with a recent study by Teerlink *et al.* (36), who used compositional analyses in combination with high-performance gel-filtration chromatography to investigate the shape of LDL. Their results fit a discoid model of LDL better than a spherical model both at 24°C, when the core was liquid-crystalline, and at 37°C, when the core was liquid. Interestingly, however, our results seem to disagree with

a recent cryo-EM study by Sherman *et al.* (34) suggesting that LDL particles with a liquid core are spherical. The reason for this discrepancy is not clear. However, we have recently observed that discoid LDL particles may assume preferred face-on orientations in extremely thin aqueous films, resulting in a predominance of circular projections on the microscope screen (43). This predominance of circular projections may create the impression that the LDL particle has a spherical shape, while in fact only face-on orientations of a discoid structure are observed.

The present study shows that T-LDL does not have discoid features, indicating that the TG content of the LDL core plays a role in determining the shape of LDL. Consistent with this suggestion is the cryo-EM observation that TG-rich VLDL and intermediate density lipoproteins are spherical, whereas intermediate density lipoprotein particles with a lower TG content are discoid in preparations that are vitrified from room temperature (31). In addition, similar to T-LDL in the present study, TG-rich small, dense LDL from hypertriglyceridemic subjects lack discoid features (30). A possible explanation for the absence of discoid features in TG-rich lipoprotein particles may be found in a recent study by Pregetter *et al.* (45). The authors of this study propose that, below the phase transition temperature, the core of T-LDL contains two concentric compartments:

TABLE 2
Core Properties and Overall Shape of N-LDL and T-LDL[a]

	T_m (°C)	Physical state/shape at 24°C	Physical state/shape at 42°C
N-LDL	31.1 ± 0.96	Liquid crystalline/disc	Liquid/disc
T-LDL	15.0 ± 1.79	Liquid/sphere	Liquid/sphere

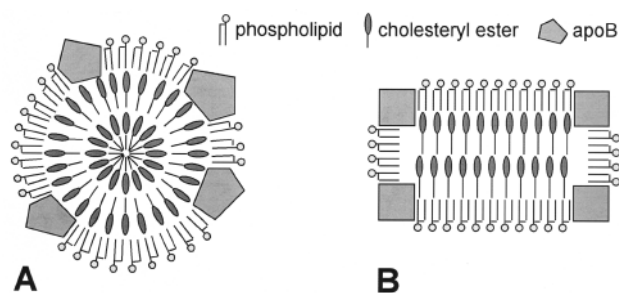
[a]Indicated are the physical state of the LDL core and the overall shape of the lipoprotein particle, as observed in cryo-electron micrographs. For abbreviations see Table 1.


FIG. 5. Highly schematic representations of the liquid-crystalline LDL core (cross-sectional views). Free cholesterol and TG have been omitted from the drawings for clarity. (A) Generalized representation of earlier models (19–25). In these models, the LDL particle is spherical and the liquid-crystalline core is organized in concentric shells of cholesteryl esters. (B) Generalized representation of new models (32,35,36), in which the liquid-crystalline core contains flat layers of cholesteryl esters. For abbreviation see Figure 2.

a fluid inner core containing mostly TG, surrounded by a shell of cholesteryl esters in the liquid-crystalline state. Thus, the presence of a relatively large TG inner core may prevent the arrangement of cholesteryl esters in flat layers.

Presently, we cannot exclude the possibility that the discoid shape of normal LDL, observed with cryo-EM (29–34), X-ray crystallography (35), and high-performance gel-filtration chromatography (36), is generated during isolation or storage of the lipoprotein complex at nonphysiological temperatures, i.e., below the phase transition of the cholesteryl ester core. These conditions may irreversibly deform the shape of LDL, which, in the native state, may still be spherical. It will be important to resolve this issue while attempts are made to reconstruct the 3-D structure of LDL at a higher resolution.

ABSTRACT: The effects of droplet size and emulsifiers on oxidative stability of polyunsaturated TAG in oil-in-water (o/w) emulsions with droplet sizes of 0.806 ± 0.0690, 3.28 ± 0.0660, or 10.7 ± 0.106 μm (mean ± SD) were investigated. Hydroperoxide contents in the emulsion with a mean droplet size of 0.831 μm were significantly lower than those in the emulsion with a mean droplet size of 12.8 μm for up to 120 h of oxidation time. Residual oxygen contents in the headspace air of the vials containing an o/w emulsion with a mean droplet size of 0.831 μm were lower compared with those of the emulsion with a mean droplet size of 12.8 μm. Hexanal developed from soybean oil TAG o/w emulsions with smaller droplet size showed significantly lower residual oxygen contents than those of the larger droplet size emulsions. Consequently, oxidative stability of TAG in o/w emulsions could be controlled by the size of oil droplet even though the origins of TAG were different. Spin-spin relaxation time of protons of acyl residues on TAG in o/w emulsions measured by ^{1}H NMR suggested that motional frequency of some acyl residues was shorter in o/w emulsions with a smaller droplet size. The effect of the wedge associated with hydrophobic acyl residues of emulsifiers was proposed as a possible mechanism to explain differences in oxidative stability between o/w emulsions with different droplet sizes.

Paper no. L9705 in *Lipids 40*, 501–507 (May 2005).

Human epidemiological and experimental animal studies have suggested that regular consumption of fish oil reduces morbidity as well as mortality due to cardiovascular diseases (1). n-3 PUFA in marine oils are known to possess several kinds of physiological functions (2,3). Most foods contain oil droplets in a range of sizes varying from less than 0.2 μm to greater than 100 μm, depending on the product (4). The oxidation rate of PUFA-containing oils in a bulk system increases with their degree of unsaturation (5,6). Numerous factors influence the susceptibility of PUFA to lipid oxidation when it proceeds in a heterogeneous emulsion system consisting of an oil interior, interfacial region, and aqueous phase. With regard to the interfacial characteristics of emulsions, the electrical charge of the oil droplet deriving from surface-active components is one of the factors influencing the rate of lipid oxidation (7,8). In addition, the interfacial membrane may act as a physical barrier that separates lipid molecules from pro-oxidants in the aqueous phase (9). With regard to physical characteristics of droplets in emulsions, the physical state (10), concentration (11), and droplet size (12,13) influence the rate of lipid oxidation. Other factors influencing oxidative susceptibility of emulsions include transition metal ions (14), types of emulsifiers (15–18), pH (19,20), and pro-oxidative and antioxidative compounds (9,21–24).

The oxidative stability of PUFA in aqueous micelles decreases with increasing number of double bonds (1,25). Nevertheless, there have been few systematic studies on the influence of droplet size on the oxidative stability of oil-in-water (o/w) emulsions. Under fixed oil concentrations, the surface area of droplets increases with decreasing droplet diameter (26). Therefore, one would expect the rate of lipid oxidation to increase with decreasing droplet size. Recently, Lethuaut *et al.* (27) reported that the oxidative stability of a sunflower oil o/w emulsion became worse by increasing the diameter of the oil droplets. Coupland *et al.* (28) reported, however, that droplet size did not affect oxidation rate of o/w emulsions. In most previous studies on the influences of droplet sizes on oxidative stabilities of lipids in emulsion systems, the emulsions were prepared using traditional techniques such as ultrasonic agitation or high-speed mechanical blending. Those traditional techniques, however, usually provided undesirable oxidative stress to unsaturated lipids during preparation of emulsions prior to subjecting the emulsions to the oxidation process. An oxidative stress-free technique is therefore necessary when unsaturated oil emulsions are prepared for the purpose of evaluating the effects of droplet size on oxidative stability.

The present study was conducted to evaluate the effects of droplet sizes on the oxidative stability of cod liver oil and soybean oil TAG o/w emulsions prepared by an oxidative stress-free technique. To explain the differences in oxidative stabilities between o/w emulsions with different droplet sizes, the spin-spin relaxation times of protons (^{1}H T_2) of the acyl residues on TAG molecules in o/w emulsions were measured by ^{1}H NMR.

MATERIALS AND METHODS

Materials and chemicals. Partially purified and refined cod liver oil and soybean oil were obtained from Toho Co., Ltd. (Tokyo, Japan) and Miyazawa Yakuhin Co. Ltd. (Tokyo, Japan), respectively. Sucrose lauryl ester and decaglycerol lauryl ester, both of which had HLB values of 16, were kindly donated by Mitsubishi-Kagaku Foods Co. (Tokyo, Japan). Diphenyl-1-pyrenylphosphine (DPPP) was purchased from Dojindo Laboratories Co. Ltd. (Kumamoto, Japan). 1-Myristoyl-2[12-(7-nitro-2-1,3-benzoxadiazol-4-yl)amino dodecanoyl]-*sn*-glycero-3-phosphocholine (NBD-labeled PC) was purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). Shirasu porous glass (SPG) membranes were purchased from SPG Technology Co. Ltd. (Miyazaki, Japan).

Purification of cod liver oil and soybean TAG. Both cod liver oil and soybean oil were further purified by column chromatography on silica gel 60 (6 cm i.d. × 72 cm, Spherical, 40–50 µm; Kanto Chemical Co. Inc., Tokyo, Japan). Oils (35 g) were loaded on the top of the column, and the TAG fraction was eluted using *n*-hexane, followed by 5% (vol/vol) diethyl ether in *n*-hexane to remove polar compounds and tocopherol analogs.

Preparation of o/w emulsion. A solution containing 10% (w/w) TAG, 1% (w/w) sucrose lauryl ester or decaglycerol lauryl ester, 100 µM EDTA tripotassium salt dihydrate (EDTA·3K), and 25 mM citrate-phosphate buffer (pH 6.6) was prepared using ultrapure water. Components were pre-mixed gently in a glass beaker with a Teflon-coated magnetic stir bar. The singly dispersed o/w emulsions with different droplet sizes were prepared using a membrane filtration technique with an external pressure-type membrane emulsification instrument (SPG Technology Co. Ltd.) equipped with an SPG membrane with a mean pore size of 0.8, 1, 3, or 10 µm (29).

Measurement of droplet size. Droplet sizes of o/w emulsions were measured with a laser diffraction particle size analyzer model SALD-300V (Shimadzu Co., Kyoto, Japan).

Oxidation of o/w emulsions. To determine hydroperoxide (HPO) contents in the o/w emulsions, 50 mL of control or test emulsion was transferred into an Erlenmeyer flask. For determination of oxygen absorption, 10 mL of emulsion was placed in a glass vial of 61 mL in volume and subsequently sealed tightly with an aluminum cap with polytetrafluoroethylene/silicone liner (Supelco, Bellefonte, PA). Flasks and vials were shaken gently and horizontally in an oven at 40°C in the dark.

Determination of oxygen absorption. One-tenth of a milliliter of headspace air in the vial was withdrawn with a gas-tight microsyringe attached to a 24 G needle and immediately injected into a Shimadzu gas chromatograph model GC3BT equipped with a glass column (2.5 mm i.d. × 2.1 m) packed with molecular sieve 5A (80–100 mesh; Nihon Chromato Co. Ltd., Tokyo, Japan) and a thermal conductivity detector. The column oven, injection port, and detector temperatures were controlled at 67°C. Helium was used as a carrier gas at an inlet pressure of 1.2 kg/cm^2.

Determination of HPO. HPO content was determined by a flow-injection analysis (FIA) system with a DPPP fluorescent post-column detection system as reported previously (30). For the preparation of sample solution, 0.1 mL o/w emulsion was mixed with 1 mL DPPP solution (21.6 nmol/mL in methanol) in a 10 mL-volumetric flask, and then the mixture was made up to 10 mL using butanol. Next, 20 µL of the butanol solution was injected into the FIA system.

Determination of hexanal. Hexanal in headspace was determined following a method slightly modified from Frankel *et al.* (31). Volatiles were collected with a Hewlett-Packard model 19395A headspace sampler (Avondale, PA) and separated on a Shimadzu model GC-15A gas chromatograph (Kyoto, Japan) equipped with a Simplicity-5 capillary column (0.25 mm i.d. × 30 m, 0.25 µm in film thickness; Supelco), and the sample signals were integrated with a Shimadzu Chromatopac C-R4A. Sampling conditions of the headspace gas were as follows: sample loop and transfer line temperature of 100°C, sample temperature of 65°C, venting period of 10 s, and injection time of 1 min.

^{1}H NMR measurement. ^{1}H T_2 measurements for cod liver oil TAG molecules in the o/w emulsion were carried out with a Bruker Avance DRX-300 spectrometer operating at 300.15 MHz for ^{1}H. Acquisition time was 0.683 s, corresponding to 4048 points in the time domain. Dead time of the spectrometer was 4.5 µm. The temperature was continuously monitored with an optical fiber thermometer (Takaoka Electric Mfg. Co., Tokyo, Japan) placed in the sample tube and was maintained at 40 ± 0.5°C with a variable temperature unit (Bruker model VT-2000). The standard Carr–Purcell–Meiboom–Gill (CPMG) method with the pulse sequence of $\{\pi/2_x–(t–\pi_y–\tau– \text{echo}–)_n\}$ was used. The pulse spacing τ was 1 ms and the $\pi/2$ was 8.6 µs. Echo signals were measured varying the echo time $2\tau n$ from 4 to 1760 ms and Fourier-transformed to give spectra. Peak intensities were plotted against the echo time for each peak. ^{1}H T_2 was obtained from a least-squares fitting to the experimental data using Equation 1 for single-component decay and Equation 2 for two-component decay.

$$I/I_0 = \exp(- t/T_2) \qquad [1]$$
$$I/I_0 = f_1 \exp(- t/T_2,1) + f_2 \exp(- t/T_2,2) \qquad [2]$$

where I is peak intensity at echo time, I_0 is peak intensity at $t = 0$, and f_1 and f_2 are fractions of components 1 and 2, respectively.

Statistical analyses. Contents of HPO, residual oxygen, and hexanal were given as means ± SD. Student's *t*-test (32) was used to distinguish significant differences among the mean values. ANOVA was performed by a one-way procedure. Significant differences were determined at $P < 0.05$.

RESULTS

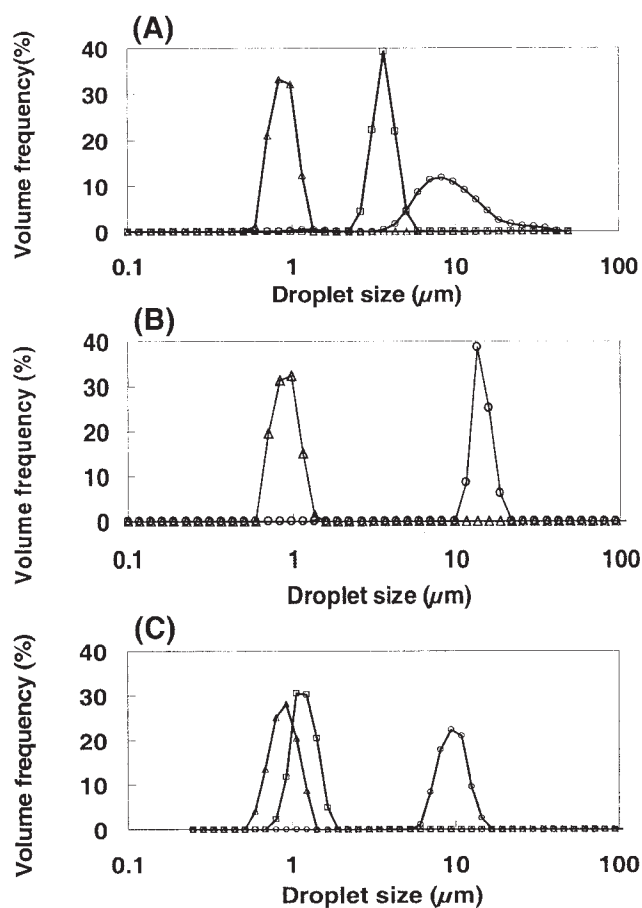
Droplet sizes of o/w emulsions. Droplet size distributions of cod liver oil TAG o/w emulsions stabilized by decaglycerol lauryl ester are shown in Figure 1A. The mean values of droplet sizes and SD of o/w emulsions prepared with an SPG membrane with a mean pore size of 0.8, 3.1, or 10 µm were 0.806 ±


FIG. 1. Droplet size distributions of (A) cod liver oil-in-water emulsions (10% TAG in water) stabilized by 1% decaglycerol lauryl ester, (B) cod liver oil-in-water emulsions (10% TAG in water) stabilized by 1% sucrose lauryl ester, and (C) soybean oil TAG (10% oil-in-water emulsions) stabilized by 1% decaglycerol lauryl ester. The mean droplet sizes for (A) were: △, 0.806 μm; □, 3.28 μm; ○, 10.7 μm; for (B), △, 0.831 μm; ○, 12.8 μm; for (C), △, 0.828 μm; □, 1.09 μm; ○, 9.38 μm.

FIG. 2. Changes in total hydroperoxide contents (A) and in residual oxygen contents in the headspace air of vials (B) during oxidation of cod liver oil TAG 10% oil-in-water emulsions stabilized by 1% decaglycerol lauryl ester with mean droplet sizes of 0.806 (△), 3.28 (□), and 10.7 μm (○) at 40°C in the dark. Values represent the mean of replicate determinations ($n = 5$) ± SD at each time point. For each sample for the same oxidation period, values with different superscripts (a–c) are significantly different ($P < 0.05$).

0.0690, 3.28 ± 0.0660, and 10.7 ± 0.106 μm (mean ± SD), respectively. The use of sucrose lauryl ester as the emulsifier also provided single-dispersed emulsions with droplet sizes of 0.831 ± 0.0760 and 12.8 ± 0.0610 μm as shown in Figure 1B. When soybean oil TAG o/w emulsions were prepared by using decaglycerol lauryl ester as the emulsifier, the single-dispersed emulsions with mean droplet sizes of 0.828 ± 0.0850, 1.09 ± 0.0760, or 9.38 ± 0.276 μm were again obtained successfully as shown in Figure 1C.

Although the single-dispersed o/w emulsions were prepared successfully for TAG of both fish and vegetable oils as well as for both emulsifiers, emulsions with mean droplet sizes of over 3.28 μm showed creaming during standing without any shaking. Oil droplets of o/w emulsions were, however, physically stable over the period of oxidation, and droplet sizes of the emulsions remained unchanged at 40°C in the dark for up to 120 h of oxidation time (data not shown).

Oxidative stability of TAG in o/w emulsions. Changes in total HPO contents generated in cod liver oil TAG o/w emulsions

stabilized by decaglycerol lauryl ester are shown in Figure 2A. With decreasing droplet size of o/w emulsions from 10.7 to 0.806 μm, HPO contents in the vials became significantly less during oxidation for up to 120 h. Changes in residual oxygen contents in cod liver oil TAG o/w emulsions stabilized by 1% decaglycerol lauryl ester are shown in Figure 2B. Residual oxygen contents in the headspace air of the vials containing the o/w emulsion showed a trend similar to the case when sucrose lauryl ester was used as an emulsifier; with decreasing droplet sizes of the emulsions, the amount of absorbed oxygen became lower after 96 h of oxidation.

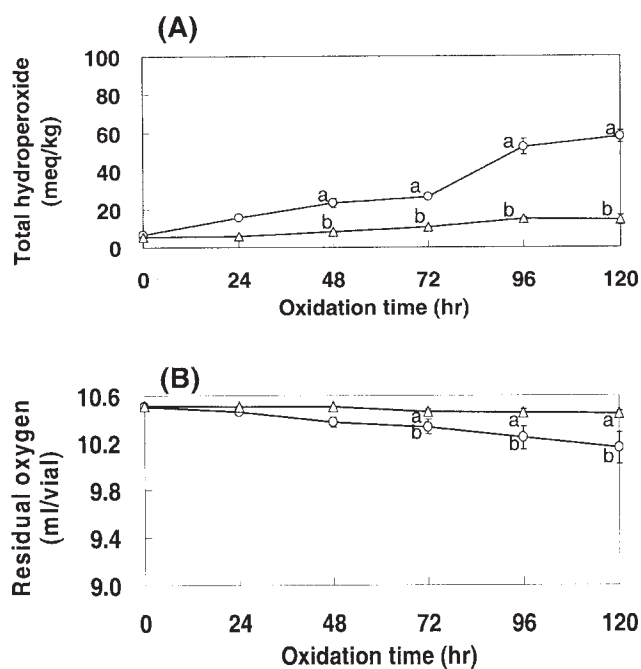
Changes in the contents of total HPO generated in cod liver oil TAG o/w emulsions stabilized by sucrose lauryl ester are shown in Figure 3A. Total HPO contents in emulsions with a mean droplet size of 0.831 μm were significantly lower than those in emulsions with a mean droplet size of 12.8 μm for 120 h of oxidation time. HPO contents in emulsions with a mean droplet size of 12.8 μm increased up to 58.1 mequiv/kg lipid. On the contrary, for the same oxidation period, the HPO contents in the emulsion with a mean droplet size of 0.831 μm was 14.3 mequiv/kg lipids. Decreases in residual oxygen contents in the headspace air of the vials containing the o/w emulsion that had a mean droplet size of 0.831 μm were significantly lower than that with the emulsion that had a mean droplet size


FIG. 3. Changes in total hydroperoxide contents (A) and in residual oxygen contents in the headspace air of vials (B) during oxidation of cod liver oil TAG 10% oil-in-water emulsions stabilized by 1% sucrose lauryl ester with mean droplet sizes of 0.831 (△) and 12.8 μm (○) at 40°C in the dark. Values represent the mean of replicate determinations (*n* = 5) ± SD at each time point. For each sample for the same oxidation period, values with different superscripts (a, b) are significantly different (*P* < 0.05).

of 12.8 μm after 72 h of oxidation as shown in Figure 3B. After 120 h oxidation, the residual oxygen content in the vial containing the emulsion with a mean droplet size of 0.831 μm amounted to 10.4 mL/vial; however, that in the vial containing the emulsion with a mean droplet size of 12.8 μm was significantly lower, amounting to 10.1 mL/vial.

Changes in total HPO contents of soybean oil TAG o/w emulsions stabilized by decaglycerol lauryl ester are shown in Figure 4A. With decreasing droplet size of o/w emulsions from 9.38 to 0.828 μm, HPO contents in the vials became significantly lower during oxidation for up to 72 h. Changes in residual oxygen contents in the o/w emulsion of the soybean oil TAG stabilized by 1% decaglycerol lauryl ester are shown in Figure 4B. Residual oxygen contents in the headspace air of the vials containing the emulsions showed a similar trend; with decreasing droplet size of the emulsions, the amount of absorbed oxygen became lower after 72 h of oxidation. The amounts of hexanal formed from the 9.38 μm emulsion were significantly higher than those of the 0.828 and 1.09 μm emulsions after 72 h of oxidation (Fig. 4C).

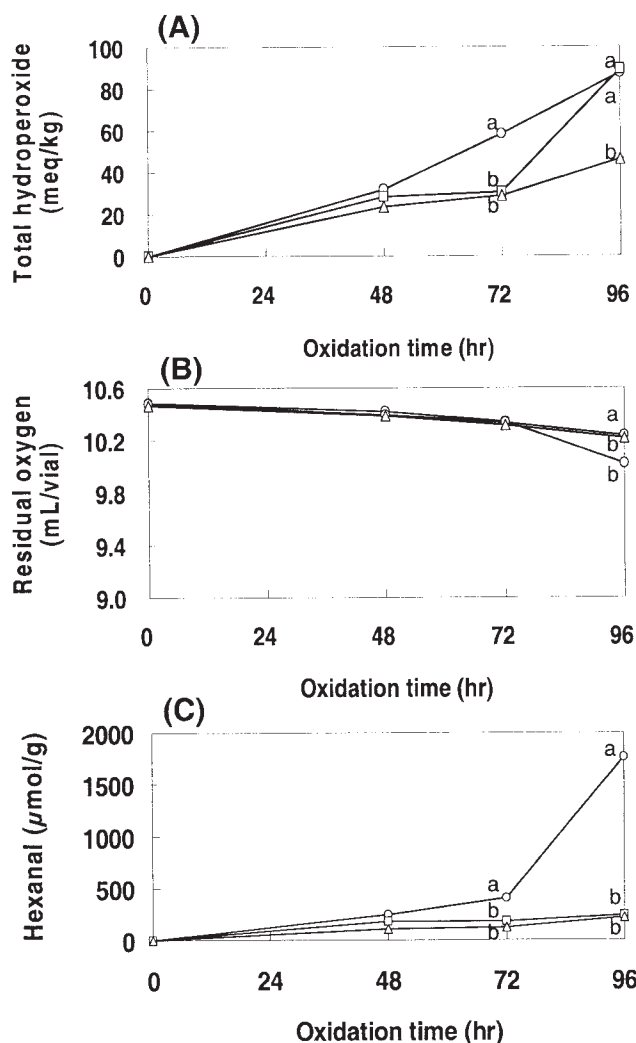
Spin–spin relaxation time of protons. ^{1}H NMR spectra of cod liver oil TAG o/w emulsions with a mean droplet size of 0.815 and 6.54 μm, which were stabilized by 1% decaglycerol lauryl ester, are summarized in Figure 5. Peaks at 0.94, 1.34, 1.63, 2.07, 2.29, and 2.87 ppm are assigned to methyl protons (a), alkyl protons (b), carboxyl terminal (c), olefin proton (d),


FIG. 4. Changes in total hydroperoxide contents (A), in residual oxygen contents in the headspace air of vials (B), and in hexanal contents in the headspace air of vials (C) during oxidation of soybean oil TAG 10% oil-in-water emulsions stabilized by 1% decaglycerol lauryl ester with mean droplet sizes of 0.828 (△), 1.09 (□), and 9.8 μm (○) at 50°C in the dark. Values represent the mean of replicated determinations (*n* = 5) ± SD at each time point. For each sample for the same oxidation period, values with different superscripts (a, b) are significantly different (*P* < 0.05).

and bisallylic proton (f), respectively. Figure 6A shows logarithmic plots of peak intensities against echo time. Plots for peaks at 0.94, 1.63, 2.07, 2.29, and 2.87 ppm regressed following a straight line, and ^{1}H T_2 values were calculated by using Equation 1. On the other hand, the plot for the peak at 1.34 ppm had a bend, indicating that each methylene proton has different ^{1}H T_2 depending on the position in the alkyl group. We assumed that these methylene protons can be divided into two groups with large and small ^{1}H T_2 and analyzed the decays by using Equation 2. The obtained ^{1}H T_2 values are summarized in Figure 6B.

For peaks at 0.94, 1.63, 2.07, 2.29, and 2.87 ppm, ^{1}H T_2 differed from peak to peak reflecting the chemical structure;
FIG. 5. Typical ^{1}H NMR spectra of cod liver oil TAG 10% oil-in-water emulsions stabilized by 1% decaglycerol lauryl ester with a mean droplet size of 0.815 μm.

however, it is difficult to discuss the small differences of ^{1}H T_2 between the o/w emulsions with different droplet sizes because small intensities for these peaks led to lower accuracy. For the large peak at 1.34 ppm, the ^{1}H T_2 of the slow decay component for the emulsion with smaller droplet size was smaller than that for the emulsion with larger droplet size.

DISCUSSION

The present study clearly showed that droplet size of an o/w emulsion influenced oxidative stability, and oxidative stability increased with decreasing droplet size. Additionally, differences between nonionic types of emulsifier were not an important factor in influencing the oxidative stability of the emulsions. Numerous reports have evaluated the effects of droplet size on oxidative stability of o/w emulsions. Gohtani *et al.* (13) compared the oxidative stability of free DHA o/w emulsions with droplet sizes of 3.4 and 6.4 μm and reported that the oxidative stability of the emulsion with the smaller droplet size was inferior to that of larger droplet size. They pointed out that the close-packed droplets gathered by creaming at the surface of emulsions and resulted in acccelerating a chain reaction in the oxidation step of DHA when the emulsion was kept standing without shaking. In the present study, however, emulsions were shaken gently and continuously during the oxidation process and therefore the density of droplets in the emulsion system should be similar between the emulsions with different droplet sizes.

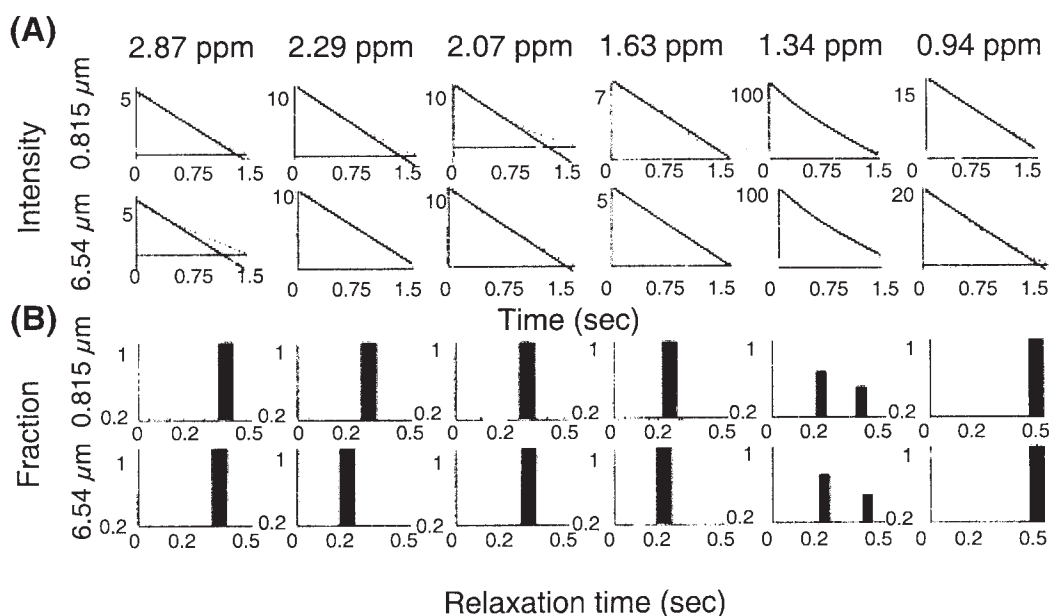
As one possible mechanism to explain improvements in oxidative stability found in o/w emulsions with smaller droplet sizes, we propose the following hypothesis: The location of emulsifier molecules at the interface between oil and water phases may affect the mobility of TAG molecules existing at the surface of the oil phase and may participate in the improvement of oxidative stability of TAG. The ratio of the surface area of a sphere to its volume is inversely proportional to the radius. When the total interface areas as well as the total volumes of droplets of equal volume of two o/w emulsions differing in oil


FIG. 6. ^{1}H NMR based on chemical shifts of cod liver oil TAG 10% oil-in-water emulsions stabilized by 1% decaglycerol lauryl ester with mean droplet sizes of 6.54 and of 0.815 μm. Logarithmic plots of peak intensities against echo time (A) and distributions of spin-spin relaxation times of protons (B).
FIG. 7. Hypothesis on the effect of wedges due to hydrophobic acyl residues of sucrose lauryl ester or decaglycerol lauryl ester used as emulsifiers. The wedge driven in the oil phase of smaller-sized oil droplets suppresses the mobility of TAG molecules migrating in the oil phase of the droplet. In a larger droplet, however, the TAG molecules migrating in the core of the oil phase are not influenced by the wedge.

droplet diameter by 10 times from each other are compared, the relative concentration of the lauryl ester in the oil phase is inversely proportional to the radius of the oil droplet. Thus, the concentration of lauric acid residues of the emulsifier in the oil phase of the smaller droplet becomes 10 times higher than that of the larger droplet. On the other hand, the number of emulsifier molecules located at the interface of the smaller droplet is one-hundredth of that of the larger droplet, resulting in the actual concentration of lauric acid residues in smaller droplet becoming about 10 times higher than that in the larger droplet. Consequently, the concentration of unsaturated TAG in a smaller droplet becomes lower and thus lipids in the emulsion become more stable against oxidation.

Recently, Osborn and Akoh (11) investigated the oxidative stability of caprylic acid/canola oil o/w emulsion and reported that the droplet size of the emulsion did not affect oxidative stability. The emulsion system used in those studies contained no chelating agent, suggesting that HPO decompositions occurred easily to form secondary oxidation products in the early stages of the oxidation period. In our study, the added EDTA suppressed the decomposition of HPO and resulted in the differences in oxidative stabilities between emulsions with different droplet sizes.

As a possible mechanism to explain the different oxidative stabilities between o/w emulsions with different droplet sizes, another hypothesis on the wedge effect due to hydrophobic lauryl residues of a sugar ester or polyglycerol ester has been proposed and is illustrated in Figure 7. Emulsifier molecules located at the interface between the oil and water phases may influence the mobility of TAG molecules existing in the oil phase and may result in the improvement of oxidative stability of TAG. The wedge driven in the oil phase of a droplet with a small size suppresses the mobility of TAG molecules. In a larger droplet, however, the wedge does not influence TAG molecules located in the core of the droplet.

Yazu *et al.* (33,34) compared oxidation stabilities of methyl eicosapentaenoate (methyl EPA) and methyl linoleate in micelles and found that methyl EPA was more stable than methyl linoleate. They explained the mechanism of this phenomenon

as follows: HPO generated by oxidation of methyl EPA is polar, and HPO molecules located in the core of micelles move to the interface area. Consequently, the propagation rate of radicals becomes slower with increasing concentration of methyl EPA HPO at the surface compared with the micelle core. In the present study, oxidized TAG molecules with higher polarity distribute in the interface area of an oil droplet, and their mobility is restricted by wedges of emulsifier residues. The rate of radical propagation will therefore become slower and result in reduction of the oxidation rate. Since the distance from the core of the oil droplet to the interface is short in a small droplet, it will take less time to decrease the concentration of HPO molecules in the core of droplets compared with the case of larger droplets. Additionally, mobilities of polar HPO molecules moving to the interface will be restricted by the wedge effect of the emulsifier molecules.

The relaxation times of protons measured by ^{1}H NMR strongly support the foregoing hypothesis on wedge effect. The TAG has higher molecular mobility when located at the core than in the vicinity of the surface. When TAG migrates between the surface and the core of droplets in a shorter time than ^{1}H T_2, the observed ^{1}H T_2 ($T_{2,\mathrm{obs}}$) is expressed as follows:

$$1/T_{2,\mathrm{obs}} = F_{\mathrm{core}}/T_{2,\mathrm{core}} + F_{\mathrm{surf}}/T_{2,\mathrm{surf}} \qquad [3]$$

where F_{core} and F_{surf} are fractions of TAG migrating at the core of the droplet and in the vicinity of the surface, respectively, and $F_{\mathrm{core}} + F_{\mathrm{surf}} = 1$. $T_{2,\mathrm{core}}$ and $T_{2,\mathrm{surf}}$ are inherent T_2 values for TAG at the core and vicinity of the surface, respectively, and $T_{2,\mathrm{surf}} \ll T_{2,\mathrm{core}}$ because of the low molecular mobility at the vicinity of the surface. Smaller droplets have smaller F_{core}; therefore, $T_{2,\mathrm{obs}}$ becomes smaller. Thus, these observations support the preceding hypothesis on the wedge effect due to the hydrophobic residues of emulsifiers. The rates of chain oxidation reactions consequently become smaller in smaller droplet size emulsions due to the restriction of vibration frequency of the acyl chains of TAG molecules in the smaller oil droplet.

Our findings provide clear evidence that droplet size in o/w emulsions influences oxidative stability of oils. Decreasing emulsion droplet size directly improves oxidative stability of oils. These observations will provide useful knowledge in developing food with stable oxidative characteristics.

ABSTRACT: CLA, defined as one or more octadecadienoic acids (18:2) with conjugated double bonds, has been reported to be active in a number of biological systems. GC and silver ion HPLC (Ag⁺-HPLC) have been the primary techniques for identifying specific CLA isomers in both foods and biological extracts. Recently, GC relative retention times were reported for all *c,c, c/t* (*c,t* and *t,c*), and *t,t* CLA FAME from the 6,8- to the 13,15-positions in octadecadienoic acid (18:2). Presented here is the relative retention order of the same CLA FAME using Ag⁺-HPLC with two different elution systems. The first elution system, consisting of 0.1% acetonitrile/0.5% diethyl ether (DE) /hexane, has been used previously to monitor CLA composition in foods. Also presented here is the retention order of CLA FAME using 2% acetic acid/hexane elution solvent, which has advantages of more stable retention volumes and a complementary elution order of CLA FAME isomers. The data are reported using retention volumes (RV) adjusted for toluene, an estimator for dead volume, and relative to *c*9,*t*11-18:2. Measurement of relative RV in the analysis of 88 samples of cow plasma, milk, and rumen fluids using Ag⁺-HPLC is also presented here. The % CV ranged from 1.04 to 1.62 for *t,t* isomers and from 0 to 0.48 for *c/t* isomers.

Paper no. L9281 in *Lipids 40*, 509–514 (May 2005).

Conjugated linoleic acid and CLA are terms used to describe octadecadienoic (18:2) fatty acid(s) or ester(s) with two conjugated double bonds. Different double bond positions and geometric configurations can create a large set of compounds with similar structure but not necessarily similar chemical or biological properties. Twenty CLA isomers already have been reported in food (1). GC separation, using the best capillary columns that are currently available, typically elutes the CLA-18:2 FAME in a small interval, ~3.5 min, of a 70-min run. Insufficient resolution is obtained by GC to identify or quantify individual isomers. A typical Ag⁺-HPLC run of ~60 min will spread the area of elution for CLA isomers to >30 min. The two techniques, GC and Ag⁺-HPLC, are complementary and can be used successfully for separation of virtually all the isomers present in a test portion of a sample.

A major problem with Ag⁺-HPLC is the retention volume (RV) drift that occurs over time (2). This Ag⁺-HPLC technique, which provides a wide separation of CLA isomers, is gaining more acceptance but it is not yet in common use because the nonreproducibility of RV makes the identification of peaks difficult. To simplify the interpretation of Ag⁺-HPLC chromatograms, we present here the application of relative retention volumes (RRV) to the identification of CLA isomers. The mean (μ), standard deviation (σ), and % CV (100 × σ/μ) are presented for the RRV of 88 sample extracts from cow plasma, milk, and rumen fluid. Lack of knowledge concerning the chromatography of CLA FAME has been a point of concern in the accurate identification of specific isomers. In many reports, responses occurring at the retention time of *c*9,*t*11-CLA have been reported only as *c*9,*t*11-CLA even though, depending on the relative quantities present, the isomers *c*6,*t*8-, *t*7,*c*9-, and both *c/t* (*c,t* and *t,c*) 8,10-CLA give responses at this retention time (3). The use of relative retention times (GC) or RRV (HPLC), combined with the availability of reference materials for all CLA isomers from 6,8 to 13,15, allows the development of a basis for a more conservative approach to identification.

EXPERIMENTAL PROCEDURES

A mixture of CLA FFA, CLA FAME, γ-linolenic acid (*cis*-6, *cis*-9, *cis*-12-octadecatrienoic acid) and α-linolenic (*cis*-9, *cis*-12, *cis*-15-octadecatrienoic acid) FAME were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). CLA isomers of known purity (*c*9,*t*11-, *t*10,*c*12-, *c*9,*c*11-, *c*11,*t*13-, and *t*9,*t*11-18:2) were obtained as FFA from Matreya, Inc. (Pleasant Gap, PA). The CLA isomers that were not commercially available were synthesized as previously reported (4). FAME were prepared from fat extracted from milk, plasma, and rumen fluid of dairy cows as previously described (5). Acetonitrile (MeCN) and hexane were UV grade. Diethyl ether (DE) was anhydrous. BF₃ in methanol was obtained from Supelco (Bellefonte, PA). Test portions of FAME were dissolved in 0.5% toluene/hexane (or isooctane) prior to chromatographic analysis. Normalization of the chromatograms shown in this work was accomplished using default functions of Microsoft® Excel (9.0 3821 SR-1) (Microsoft Corp., Redmond, WA). Chromatograms were ex-

ported from the acquisition software as the raw signals vs. time. HPLC data were exported from Millenium (Waters Associates, Milford, MA) as ASCII (ARW) files to Microsoft Excel. The new chromatograms, in the relative scale, were obtained as X-Y scatter plots of the signal vs. RRV. Column values were recalculated in the RRV scale using the following formula:

$$RRV_a = (RV_a - RV_{tol})/(RV_{c9,t11} - RV_{tol}) \qquad [1]$$

where RRV_a is the relative retention volume of a CLA isomer, RV_a is the retention volume of a CLA isomer, RV_{tol} is the retention volume of toluene, and $RV_{c9,t11}$ is the retention volume of the $c9,t11$-CLA.

Analytical Ag⁺-HPLC. Ag⁺-HPLC separation of the CLA FAME was carried out using a Waters 2960 chromatographic system (Waters Associates), equipped with a photodiode array detector (Waters 996) operating between 200 and 300 nm, and a Millenium 3.20 chromatography manager. Three Chrom-Spher 5 Lipids analytical silver-impregnated columns (each 4.6 mm i.d. × 250 mm stainless steel; 5 µm particle size; Chrompack, Bridgewater, NJ) were used in series. The temperature was maintained at 30°C. The first mobile phase, 0.1% MeCN/0.5% DE/hexane, was prepared fresh daily and introduced isocratically at a flow rate of 1.0 mL/min. The columns were conditioned with 1% MeCN/hexane then equilibrated with the elution solvent for 60 min each day prior to starting test portion analysis. Typical injections, 1–10 µL, for milk, plasma, or reference materials resulted in <100 µg FAME being loaded onto the columns. For test portions of rumen

FAME, column loads of >>100 µg were used. Single chromatograms of CLA isomers were extracted at 233 nm. To obtain the RRV values of all CLA isomers, iodine-isomerized mixtures of positional CLA isomers (4) were co-injected with a small amount of $c9,t11$-18:2 FAME and toluene. The second mobile phase used was 2% acetic acid/hexane eluted at 1 mL/min. HPLC chromatograms were obtained using the same three ChromSpher 5 Lipids analytical silver-impregnated columns described above. Responses were measured using UV detection at 233 nm.

RESULTS AND DISCUSSION

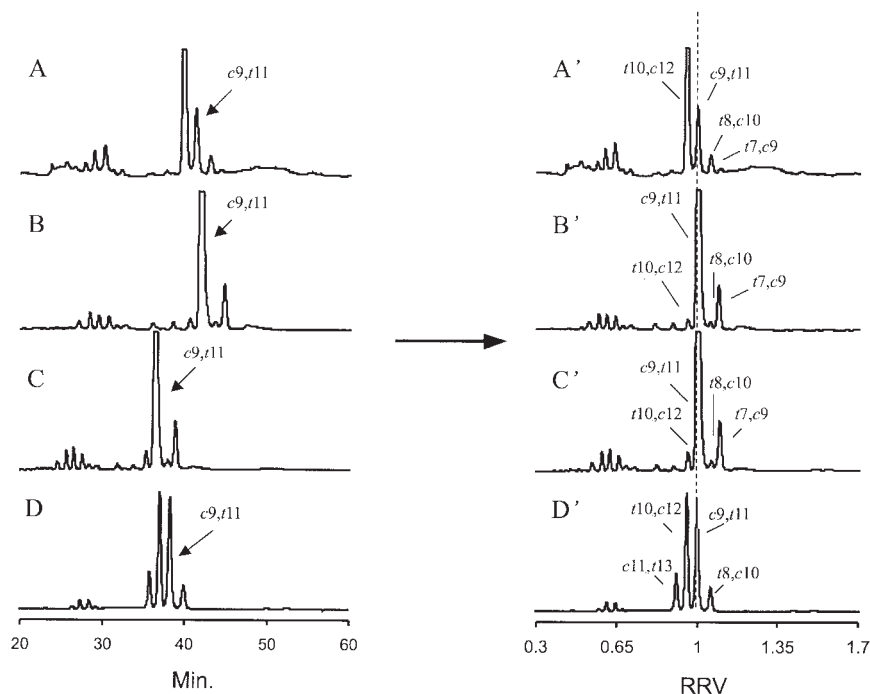
We recently completed an exhaustive analysis of CLA isomers in 88 samples of plasma, milk, and rumen fluid from dairy cows (5). Ag⁺-HPLC chromatograms from that study, from plasma, two samples of cow's milk and CLA reference material (Nu-Chek-Prep) are shown in Figure 1A–D, left side. As can be seen in the figure, the retention volumes (shown as retention times in the figures) shift for the elution of each isomer. The $c9,t11$ isomer elutes over a range of several minutes. In most of the cases, the rule that the $c9,t11$-isomer is the most abundant may be applied to CLA analysis by Ag⁺-HPLC, but in several other cases, as shown in Figure 1, this rule does not apply. Chromatogram A was obtained by injection of a plasma sample from a cow that had been fed a diet supplemented with $t10,c12$-CLA. Our original analysis of these samples involved many co-injections of standard with samples to verify the identities. We discovered that by using toluene as a reference to approximate the dead volume


FIG. 1. Ag⁺-HPLC chromatograms. Time vs. response (233 nm) of FAME obtained from plasma (A), milk fat (B, C), and Nu-Chek-Prep CLA (D). The corresponding graphs A′–D′ of the same sample test portions plotting response vs. relative retention volumes (RRV) are shown on the right.

[a]Not applicable.

in the HPLC system, and *c*9,*t*11 as a retention reference, the chromatographic data could be recalculated into a reproducible format using a formula derived from standard chromatography theory. The RRV was calculated as shown in the Experimental Procedures section. By using this format, the chromatograms were regenerated using Excel as shown in Figure 1A′–D′, but these chromatograms are plotted as response vs. RRV. This application of the RRV theory is based on the assumption that, for the small variation in MeCN in hexane concentration occurring during the analysis of a sample set, the change in composition of the mobile phase will affect the elution of all of the CLA isomers in the same way.

The reproducibility of RRV in sample data using a specific chromatography system was established as shown in Table 1. The % CV measured for the 88 samples was 1.04–1.62 for the *t,t* isomers, and 0–0.47 for the *c/t* isomers. The precision was

better for the plasma and milk samples, as is seen from the lower SD for these sample types in Table 1. A factor that leads to higher RRV SD of CLA isomers in rumen samples is related to critical (sample overload) chromatography conditions. CLA FAME isomers were present at trace levels in all the methylated rumen samples we analyzed, and test portions loaded onto the columns were increased to reach the detection limits of as many CLA isomers as possible. Co-eluting *cis* monoenoic FAME interfered with the CLA analysis of rumen test portions under these extreme conditions, requiring UV (232 nm) confirmation for every identification.

Ag[+]-HPLC chromatograms, transformed using Equation 1, are presented in Figure 2. A small amount of *c*9,*t*11-CLA FAME was added to every sample shown in Figure 2 to aid in translating chromatograms to the RRV scale. A graphical representation in Figure 3 further elucidates the RRV pattern. The
FIG. 2. Ag[+]-HPLC chromatograms using 0.1% acetonitrile (MeCN)/0.5% diethyl ether (DE)/hexane elution, RRV vs. response (233 nm) of all geometric CLA isomers from the 6,8 to the 13,15 carbon–carbon double bond positions. A small quantity of *c*9,*t*11 was added to each positional mixture for reference.
FIG. 3. Plot of RRV vs carbon-carbon double bond position for all geometric CLA isomers from the 6,8 to the 13,15 carbon–carbon double bond positions (using 0.1% MeCN/0.5% DE/hexane elution). For abbreviations see Figures 1 and 2.

RRV values of the *t,t*, *c,t*, and *t,c* isomers fit third-degree curves with R^2 greater than 0.99. The RRV values of the *c,c* isomers fit a third-degree equation with R^2 greater than 0.985. All four curves show a similar pattern, with a maximum corresponding to the 7,9 positional isomer, and an inflection point close to the 10,12 position. Isomers *c10,t12* and *t10,c12* have the same RRV, and the *c,t* and *t,c* curves intersect at the 10,12 position. For a given position, from 6,8 to 9,11 (all of these isomers elute

after the 10,12 *c/t* isomer), the RRV of the *t,c* isomer will be higher than that of the corresponding positional *c,t* isomer. For *c/t* isomers eluting before the *c/t* isomers of 10,12 (from 11,13 to 13,15), the *c,t* isomer will elute after the *t,c* isomer.

Chromatograms obtained using the second solvent system presented here are shown in Figure 4. The set of the iodine-isomerized solutions (4) containing all the positional isomers from 6,8- to 13,15-18:2 are presented. Under these operating
FIG. 4. Partial Ag$^+$-HPLC chromatograms (RRV) of the iodine-isomerized solutions from each CLA positional isomer from 6,8- to 13,15-18:2 as FAME. Chromatographic conditions: three ChromSpher 5 Lipids columns in series maintained at 25°C, 2% HOAc in hexane mobile phase at 1.0 mL/min, UV detection at 233 nm.
FIG. 5. Plot of RRV vs. double bond positions of CLA isomers. Three ChromSpher 5 Lipids columns maintained at 25°C were used in series, with 2% HOAc in the hexane mobile phase at 1.0 mL/min.

conditions there is no appreciable drift in RV, but the data are presented as RRV for a direct comparison of the retention order of CLA isomers eluted using either elution system. In Figure 5, the RRV of all the CLA isomers shown in Figure 4 are plotted as a function of double bond position. The plot in Figure 5 is similar to the plot in Figure 3 in that the *c,t* isomers of positional compounds near the carbonyl moiety elute before the corresponding *t,c* isomers. The plots differ in that for the 2% acetic acid/hexane mobile phase (Fig. 5) the position at which *c,t* and *t,c* isomers have the same RV is near the 7,9 position compared with the 10,12 position for the mobile phase containing MeCN (Fig. 3). The importance of this difference is emphasized by the separation of *t*10,*c*12- from *c*10,*t*12-18:2 and the partial separation of the *c*6,*t*8 from the *c/t* 7,9 isomers.

RRT are commonly used in GC analysis, but the use of RRV in HPLC analysis is less common. We believe that it is advantageous to use both in the instance of CLA analysis. The use of the *c*9,*t*11-CLA as a chromatographic reference in chromatographic analysis makes the identification of other peaks considerably easier, i.e., the analyst will know all the isomers that elute at a given RRV. The precision obtained, shown in Table 1, suggests that the drift in RV is only due to a loss of MeCN in the elution reservoir, and this is very consistent with the observation that adding more MeCN to the reservoir will re-establish the original RV. Column effects, particularly column temperature, age, and the amount of silver loaded, may, however, affect consistencies of RRV between different columns. Use of RRT (4) and RRV (presented herein) data also allows a substantially improved understanding of the GC and Ag⁺-HPLC chromatographic patterns of elution. The reproducibility of

RRV on a given column is excellent despite drifts in absolute RV.

The 2% acetic acid/hexane mobile phase produces a slightly different but complementary pattern of elution for CLA FAME. Its advantages include resolution of the two *c/t* 10,12 isomers and partial resolution for the *c*6,*t*8 isomer from the *t*7,*c*9 isomer. The disadvantages of this procedure are that it takes longer for a chromatographic run, 100 vs 60 min, and that in using this elution system it is not possible to use lower wavelengths, e.g., 205 nm, to monitor the chromatogram for interfering monoenoic (18:1) FAME that can interfere with CLA responses when present at a greatly elevated level.

The two Ag⁺-HPLC chromatographic techniques presented here, along with GC data (4), complement each other quite well, and these data demonstrate that use of relative retention parameters allows for a more rapid initial identification.

One observation that is clear from the Ag⁺-HPLC and GC (4) chromatographic patterns is that the identification of the *c*6,*t*8-18:2 CLA isomer, which is known (6) to be produced by the desaturation of *t*8-18:1 by Δ^6-desaturase, has been missed by every laboratory that depended on only GC (equipped with an FID) and Ag⁺-HPLC using an MeCN/hexane system for their analysis.

ABSTRACT: We have developed a sensitive reversed-phase chemiluminescence HPLC approach for simultaneous quantitative and qualitative analyses of hydroperoxides of cholesteryl ester and TG in human plasma. Standard hydroperoxides of cholesteryl ester and TG and a novel internal standard (1-tetradecanyl 3-octadecenoyloxy-5β-cholan-24-oate monohydroperoxide) (I.S.) were chemically synthesized and the standard curves confirmed to be linear throughout the calibration range (1–1000 pmol). Within-day and between-day CV were less than 7%, and the recoveries were within the range of 84–93%. With sample size minimized to 0.1 mL of plasma for each run, plasma cholesteryl ester hydroperoxide levels were 189 ± 87 nM (mean ± SD) in healthy young (22–25 yr old; $n = 15$, male/female = 6:9) and 210 ± 69 nM in healthy elderly (39–60 yr old; $n = 6$, male/female = 3:3). TG hydroperoxide was not detected in healthy subjects. In patients with advanced liver failure (36–67 yr old; $n = 4$, male/female = 2:2), hydroperoxide levels of plasma cholesteryl ester and TG were 11,903 ± 9,553 nM and 3,318 ± 1,590 nM, respectively, indicating an involvement of lipid oxidation. Sensitive and specific monitoring of plasma lipid peroxides using the present chemiluminescence HPLC approach with the synthesized I.S. may help our understanding of chemical and pathophysiological aspects of lipid peroxidation.

Paper no. L9714 in *Lipids 40*, 515–522 (May 2005).

Lipid peroxidation has been linked to atherosclerosis (1), inflammation (2), carcinogenesis (3), diabetes (4,5), aging (6), and to a variety of other diseases, including nonalcoholic steatohepatitis (7) and alcoholic fatty liver (8). Several HPLC methods have been reported for the measurement of hydroperoxides of cholesteryl ester and TG in human plasma as lipid peroxidation products, generally using fluorimetry (9–11) or chemiluminescence methods with isoluminol (12–14). How-

ever, the cholesteryl ester hydroperoxide or TG hydroperoxide used as standards in previous chemiluminescence or fluorimetric methods was not well characterized in terms of their chemical structures (9–14). For instance, ^{1}H NMR or ^{13}C NMR spectra were not provided. Although previous studies reported the presence of cholesteryl ester hydroperoxides or TG hydroperoxides in plasma, only limited chemical information was given (9–14). Further, storage conditions for standard hydroperoxides and sample plasma were not optimized (9–11) or clearly described (12–14). We have in fact shown that a previously reported storage condition for standard monohydroperoxide cholesteryl linoleate at −25°C results in decomposition within a few months (9). Furthermore, a matter of the greatest importance is that previous measurements were performed without using any hydroperoxides as internal standard (12–14), and the wide discrepancies found in plasma lipid peroxide levels can be partly explained on this basis. It is widely recognized that lipid hydroperoxides are chemically unstable and consequently may be lost during analytical procedures. Moreover, detection that is based on chemiluminescence can gradually deteriorate during runs because of adhesion of unspecified plasma substances to the detector. The only solution for these problems is to use an internal standard, which must be similar to plasma lipid hydroperoxides in terms of not only extraction efficiency and retention time but also chemical stability and chemiluminescence efficiency.

Here we report sensitive and specific reversed-phase chemiluminescence HPLC with luminol for simultaneous measurement of hydroperoxides of cholesteryl ester and TG in human plasma. The internal standard of hydroperoxide was synthesized and its structure confirmed with reference to ^{1}H NMR and ^{13}C NMR spectra and elemental analysis as well as chromatographic behavior. Validation of the assay and its application to normal plasma and pathological plasma from patients with liver failure are also described here.

MATERIALS AND METHODS

Materials. Oleic acid was purchased from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). N,N′-Dicyclohexylcarbodiimide (DCC), 4-dimethylaminopyridine (4-DMAP), lithocholic acid, oxalyl chloride, and cytochrome C (from horse heart) were from Wako Pure Chemical Industry, Ltd. (Osaka, Japan). Ethyl

acetate, *n*-hexane, and 2-propanol were also purchased from Wako Pure Chemical Industry, Ltd. (Osaka, Japan). Dehydrated dichloromethane (CH_2Cl_2), 2,6-di-*tert*-butyl-*p*-cresol (BHT), *tert*-butyl alcohol, methanol, ethanol, luminol, and sodium borohydride ($NaBH_4$) were from Kanto Chemical Co., Inc. (Tokyo, Japan). The solvents used for HPLC were all analytical grade. For column chromatography, Silica gel 60N (100–120 µm, Kanto Chemical Co.) was used, with aluminum sheets (Silica gel 60 F_{254}; Merck Co., Darmstadt, Germany) applied for TLC. ^{1}H NMR spectra were taken with a JEOL ECA 500 at 500 MHz with tetramethylsilane as an internal standard (abbreviations used are *s* for singlet, *d* for doublet, *dd* for doublets of doublet, *t* for triplet, *sext* for sextet, and *m* for multiplet).

Blood samples. For the measurements of hydroperoxides of cholesteryl ester and TG, blood was drawn into vacuum tubes containing disodium EDTA (1.5 mg/mL) after an overnight fast from healthy young subjects (22–25, 23 ± 1.0, yr old; *n* = 15, male/female = 6:9), healthy elderly (39–60, 50 ± 9.0, yr old; *n* = 6, male/female = 3:3), and patients (36–67, 54 ± 14, yr old; *n* = 4, male/female = 2:2) with liver failure due to cholangiocarcinoma (Cases 1 and 2), autoimmune liver cirrhosis (Case 3), and metastatic hepatoma (Case 4). Plasma was separated by centrifugation (2000 × *g*, 10 min, 4°C), and then stored at −80°C for no longer than 3 mon. Serum was also obtained from each blood sample and subjected to measurement of other lipids. These samples were used under the approval of the institute and after obtaining informed consent from the volunteers and patients.

HPLC analysis. A normal-phase HPLC was performed with the LC-10AD pump system equipped with an SCL-10A system controller (Shimadzu Co., Kyoto, Japan), including a CTO-10A injector and an SPD-10A UV-vis detector (Shimadzu Co.). The analytical column used for normal-phase HPLC was a Mightysil Si 60 (4.6 × 250 mm, 5 µm; Kanto Chemical Co.). The mobile phase was a mixture of *n*-hexane/2-propanol (250:1, vol/vol). The flow rate was 1 mL/min, and the temperature was ambient. The detection wavelength was 210 nm.

Reversed-phase HPLC with detection at 210 nm and with post-column chemiluminescence detection was also performed using a system equipped with an SCL-6A system controller (Shimadzu Co.), three LC-9A pumps (Shimadzu Co.), a CTO-10A injector, the SPD-10A UV-vis detector, and a CLD-10A chemiluminescence detector (Shimadzu Co.). The column used was an Inertsil ODS-2 (4.6 × 250 mm, 5 µm; GL Sciences Inc., Tokyo, Japan). The mobile phase was a mixture of ethanol/water (50:1, vol/vol), and the flow rate was 0.5 mL/min. The column eluant was mixed with luminescent reagent solution (0.5 mL/min) in a post-column mixing joint at 40°C.

Mobile solutions for both normal-phase HPLC and chemiluminescence HPLC were degassed by sonication under reduced pressure before use.The luminescent reagent consisted of cytochrome C (10 µg/mL) and luminol (2 µg/mL) in 50 mM borate buffer (H_3BO_3/KCl-Na_2CO_3, pH 10), and was also degassed (15). The solutions were prepared daily.

Preparation of standard hydroperoxides. (i) Monohydroperoxides of cholesteryl linoleate and cholesteryl oleate. Cholesteryl linoleate monohydroperoxide (CL-OOH) was chemically synthesized by our method as previously reported (16). Simply, cholesteryl linoleate (4 mmol) and hematoporphyrin (6 mg) were dissolved in pyridine (20 mL) and irradiated with a tungsten lamp (200 W) as O_2 gas was bubbled through a glass-ball filter for 1.0 h. The reaction mixture was extracted with diethyl ether and the extract was washed with cold water, 2 M HCl, and then dried over Na_2SO_4. The crude product was purified by a SiO_2 column chromatography (hexane/ethyl acetate, 10:1, vol/vol) to give pure CL-OOH as a colorless viscous liquid (a mixture of regioisomers). The structure of CL-OOH was elucidated by ^{1}H NMR, MS, and normal-phase HPLC (16).

With this method, cholesteryl oleate monohydroperoxide (CO-OOH) was also synthesized, and the structure was similarly elucidated.

(ii) TG monohydroperoxides. For measurement of TG hydroperoxides in human plasma, we synthesized three TG hydroperoxides: 1,2-dioleoyl-3-palmitoylglycerol monohydroperoxide (OOP-OOH), 2-linoleoyl-1-oleoyl-3-palmitoylglycerol monohydroperoxide (OLP-OOH), and triolein monohydroperoxide (OOO-OOH) by our previously described method (17). Briefly, the three TG were prepared by using a convenient, simple condensation of glycerol and corresponding acid chlorides in pyridine, then converting them into their monohydroperoxides by photosensitized peroxidation. The structures of these three TG hydroperoxides were confirmed by their ^{1}H NMR and ^{13}C NMR spectra and analyzed by normal and reversed-phase HPLC (17).

(iii) Synthesis of the internal standard (I.S.). Synthesis of the I.S. for the HPLC analysis of lipid peroxides was carried out as shown in Figure 1. DCC (24 mmol) was added to an ice-cooled, stirred solution of oleic acid (35 mmol) and 4-DMAP (40 mg) in dichloromethane (50 mL) at 0°C, and the whole was stirred for 10 min. Then lithocholic acid (**1**, 20 mmol) was added to the solution in several portions. The reaction mixture was stirred for 30 min at 0°C and then for 24 h at room temperature. Precipitates were filtered off, and the filtrate was concentrated in a vacuum evaporator. The crude products were subjected to SiO_2 column chromatography by eluting with *n*-hexane/ethyl acetate (8:1, vol/vol) to give 3-(9-*cis*-octadecenoyloxy)-5β-cholan-24-oic acid (**2**) at a yield of about 80%. The obtained compound (**2**) was used for the next reaction step without further purification. Compound **2** (10 mmol) was dissolved in dichloromethane (50 mL) containing 1-tetradecanol (10 mmol) and 4-DMAP (20 mg). Then DCC (12 mmol) was added to the ice-cooled, stirred solution followed by stirring for 30 min at 0°C and then for 24 h at room temperature. Precipitates were again filtered off, and the filtrate was concentrated by vacuum evaporation. The oily residue was then subjected to SiO_2 column chromatography by eluting with *n*-hexane/ethyl acetate (80:1, vol/vol) to give pure 1-tetradecanyl 3-(9-*cis*-octadecenoyloxy)-5β-cholan-24-oate (**3**) at a yield of 80%. ^{1}H NMR (CDC_3), δ: 0.64 (3H, *s*, 18-CH_3), 0.85 (3H, *d*, *J* = 6 Hz, 21-CH_3), 0.90 (6H, *t*, *J* = 6.4 Hz, –CH_2–CH_3),
FIG. 1. Synthesis of internal standard (I.S.) (1-tetradecanyl 3-octade-cenoyloxy-5β-cholan-24-oate monohydroperoxide). DCC, *N,N′*-dicy-clohexylcarbodiimide.

0.93 (3H, *s*, 19-C*H*$_3$), 2.26 (4H, *m*, –C=C–C*H*$_2$–), 4.05, (4H, *t*, *J* = 6.7Hz, –OCO–C*H*$_2$–), 4.73 (1H, *m*, 3-*H*), 5.34 (2H, *m*, –C*H*=C*H*–). Then the solution of compound **3** (2 mmol) in pyridine (10 mL) containing hematoporphyrin (3 mg) was irradiated with a 200 W tungsten lamp for 1.5 h with bubbling of O$_2$ gas through a glass ball filter at 15°C. The reaction mixture was poured into ice-water, acidified with 2 mol/L HCl, and extracted with peroxide-free diethyl ether twice. The combined organic phase was washed with water and saturated sodium chloride solution and then dried over Na$_2$SO$_4$. After evaporating the solvent, the residue was subjected to SiO$_2$ column chromatography eluted with *n*-hexane/ethyl acetate (10:1, vol/vol) to give monohydroperoxide (**4**) as a colorless, viscous liquid at a yield of 30%. ^{1}H NMR (CDC$_3$), δ: 0.64 (3H, *s*, 18-C*H*$_3$), 0.85 (3H, *d*, *J* = 6.4Hz, 21-C*H*$_3$), 0.90 (6H, *t*, *J* = 6.4Hz, –CH$_2$–C*H*$_3$), 0.93 (3H, *s*, 19-C*H*$_3$), 2.26 (4H, *m*, –C=C–C*H*$_2$–), 4.05, (4H, *t*, *J* = 6.7Hz, –OCO–C*H*$_2$–), 4.26 (1H, *m*, –C=C–C*H*OOH), 4.73 (1H, *m*, 3-*H*), 5.36 (1H, *sext*, *J* = 15.6 and 6.4 Hz, –CH$_2$–C*H*=C–COOH), 5.76 (1H, *dd*, *J* = 15.6 and 8.4 Hz, –C=C*H*–CHOOH–). Anal. C: 77.37%, H: 11.60%; Found, C: 77.27%, H: 11.42%. The purity of the compound **4** was checked by TLC and HPLC. In the TLC, no contamination was detected after development with several solvent systems (*n*-hexane/ethyl acetate, 8:1; *n*-hexane/acetone, 6:1; benzene/acetone, 40:1, vol/vol), and spraying several color-producing reagents (20% sulfuric acid, 10% phosphomolybdic acid in ethanol, anisaldehyde-H$_2$SO$_4$ in acetic acid) and UV detection (254 and 365 nm). The three R_f values of TLC for these solvent systems were 0.375, 0.286. and 0.429, respectively.

Extraction of plasma. For extraction, 0.1 mL of plasma from a healthy human (0.01 mL plasma of subjects with liver failure) was mixed with 0.05 mL of I.S. solution (1 μM in ethanol), 0.2 mL of freshly prepared 0.2% BHT solution (as antioxidant, in methanol), and 2 mL of *n*-hexane. The mixture was

vigorously mixed with a vortex mixer for 1 min and then centrifuged at 2,000 × *g* for 1 min at 4°C. The methanol layer was discarded, while the upper phase (hexane layer) was collected and evaporated under vacuum in a rotary evaporator at room temperature. The residue was dissolved in 0.1mL of *n*-hexane/ethyl acetate (6:1, by vol) containing 2.2×10^{-3}% BHT and then subjected to short refining column (8 × 50 mm, 1.3 g of SiO$_2$) chromatography and eluted with *n*-hexane/ethyl acetate (6:1, vol/vol) containing 2.2×10^{-3}% BHT. The column was pre-washed with 20 mL of the above hexane/ethyl acetate before applying the sample solution. The first 0.8 mL of solution eluted from the column was thrown away, and the following 2.0 mL was collected and evaporated under vacuum. The residue was dissolved in 0.05 mL of CH$_2$Cl$_2$/ethanol (1:1, vol/vol), and the sample (0.02 mL) was injected into the chemiluminescence HPLC system. The chromatogram showed peak counts for the known quantities of I.S. and unknown initial plasma peroxides. In accordance with these data, the initial plasma peroxide concentrations were calculated.

Serum lipid measurements. Serum lipids were measured by automated enzymatic methods, using commercial kits: Determiner TC (Kyowa Medex Co., Tokyo, Japan) for total cholesterol (TC); AutoSera S TG-N (Daiichi Pure Chemicals, Tokyo, Japan) for TG; Determiner HDL-C (Kyowa Medex) for HDL-cholesterol; Cholestest LDL (Daiichi Pure Chemicals) for LDL-cholesterol.

Statistical analyses. All data are presented as means ± SD. Differences between groups, namely, liver failure vs. healthy elderly group (LF vs. Elder), liver failure vs. healthy young group (LF vs. Young), and healthy young group vs. healthy elderly group (Young vs. Elder) were assessed using the Mann–Whitney *U* test. Statistical significance was concluded at *P* < 0.05.

RESULTS

Synthesis of the I.S. To achieve a simultaneous quantitative determination of cholesteryl ester hydroperoxides and TG, a suitable I.S. is necessary. We synthesized 1-tetradecanyl 3-octadecenoyloxy-5β-cholan-24-oate monohydroperoxide as a convenient I.S. because of its stability and its desirable chromatographic behavior. Figure 1 shows the synthetic pathway. The ester, **3**, was prepared from lithocholic acid by the initial esterification of oleic acid and the subsequent esterification with tetradecanol using the well-known DCC method. The monohydroperoxide, **4**, was then derived by the method previously reported (16) and its chemical structure confirmed with reference to the ^{1}H NMR spectrum and elemental analysis.

Purity of the I.S. was checked by normal-phase HPLC, reversed-phase HPLC, and reversed-phase HPLC with chemiluminescence detection. All peaks observed with the three chromatograms for I.S. were single and symmetric, and no contamination was detected. The retention times were 7.9 min for normal-phase HPLC, 19.9 min for reversed-phase HPLC, and 20.4 min for reversed-HPLC with chemiluminescence detection (data not shown).
FIG. 2. Chromatograms of a mixture of OLP-OOH (50 pmol), CL-OOH (50 pmol), and I.S. (50 pmol) by reversed-phase HPLC with chemiluminescence detection. The mobile phase was ethanol/water (50:1, vol/vol) for (A), ethanol for (B), and *tert*-butyl alcohol/methanol (1:1, vol/vol) for (C). The mobile phase flow rate and the luminescent reagent rate were both 0.5 mL/min. OLP-OOH, 2-linoleoyl-1-oleoyl-3-palmitoylglycerol monohydroperoxide; CL-OOH, cholesteryl linoleate monohydroperoxide; for other abbreviation see Figure 1.

HPLC analysis of synthesized standard monohydroperoxides. Figure 2A shows a typical chromatogram in chemiluminescence HPLC detection for a mixture of chemically synthesized standard OLP-OOH, CL-OOH, and the I.S. (each 50 pmol). All peaks were symmetric and sufficiently resolved. The retention times were 15.5 min for OLP-OOH, 18.2 min for CL-OOH, and 20.9 min for the I.S. The peak areas for CL-OOH and OLP-OOH were larger than that for I.S. with the chemiluminescence system, although the same amounts (50 pmol) were injected. The relative sensitivities were 1.33 for CL-OOH to I.S., and 1.37 for the OLP-OOH to I.S., and these were used to calculate the amounts of CL-OOH and OLP-OOH in plasma.

Effects of the mobile phase. The effects of the solvent in the mobile phase on the peak area of synthesized CL-OOH, OLP-OOH, and I.S. (each 50 pmol) in the chemiluminescence HPLC system were investigated with the flow rate of the mobile phase set at 0.5 mL/min. Ethanol/water (50:1, vol/vol) gave the high-

est peak (Fig. 2A), but ethanol (Fig. 2B) and *tert*-butyl alcohol/methanol (1:1, vol/vol, Fig. 2C) gave 62 and 60% of the peaks in Figure 2A, respectively. Hence we selected ethanol/water (50:1, vol/vol) as the column eluant for the chemiluminescence HPLC system.

Effects of the flow rate of the mobile phase rate. The effects of flow rate of mobile phase (ethanol/water, 50:1, vol/vol) on the chemiluminescence counts for 50 pmol of chemically synthesized OLP-OOH, CL-OOH, and I.S. were studied. We set the reagent flow rate at 0.5 mL/min, and changed the flow rate of ethanol/water (50:1, vol/vol). The flow rates of mobile phase in the range 0.2–0.5 mL/min show gradually increasing chemiluminescence counts, but in the range 0.5–1.0 mL/min, show gradually decreasing chemiluminescence counts. At the flow rate of 0.5 mL/min, OLP-OOH, CL-OOH, and I.S. showed the maximum chemiluminescence response. Therefore, the flow rate of the mobile phase was set at 0.5 mL/min (data not shown).

Calibration curves of CL-OOH and OLP-OOH. Two calibration curves of CL-OOH and OLP-OOH were obtained by combination with the I.S. using the chemiluminescence HPLC system. They were plotted as the peak area ratios of CL-OOH and OLP-OOH to that of I.S. vs. the amounts of CL-OOH and OLP-OOH and showed good linearity throughout the range 1–1000 pmol (CL-OOH, $y = 0.1726x - 0.0958$, $r^2 = 0.999$; OLP-OOH, $y = 0.1778x - 0.0988$, $r^2 = 0.9995$; $x =$ amounts of hydroperoxide; $y =$ peak area ratio to I.S.). Each datum is the average of three determinations. These results allowed us to use the calibration curves of either CL-OOH or OLP-OOH in these ranges for the determination of hydroperoxides in human plasma. The detection limit for both CL-OOH and OLP-OOH was 0.5 pmol at a signal-to-noise ratio of 6 (calibration curves not shown).

Precision and relative recoveries for CL-OOH and OLP-OOH. For the determination of within-day and between-day precision, two defined, different amounts of CL-OOH and OLP-OOH (50 and 200 nM) were analyzed five times on the same day and once each on 10 different days, respectively. The results of the precision experiments are summarized in Table 1. All within-day and between-day CV were less than 7%. Table 1 also shows

TABLE 1
Precision and Recoveries of Hydroperoxides Determination in Plasma

Hydroperoxides	Found (nM)[a] (endogenous) Mean	SD	Added (nM)	Found (nM)[b] (total) Mean	SD	CV (%)	Recoveries (%)

FIG. 3. Chromatograms of human plasma extracts with chemiluminescence detection. (A) From a healthy subject; (B) from a healthy subject, spiked with CL-OOH; (C) after reduction of the sample yielding (B) with NaBH$_4$; (D) from a case of liver failure; (E) from a case of liver failure, spiked with CL-OOH and OLP-OOH; (F) after reduction of the sample yielding (E) with NaBH$_4$. The mobile phase was a mixture of ethanol/water (50:1, vol/vol), and the flow rate was 0.5 mL/min. The luminescent reagent rate was also 0.5 mL/min. For other abbreviations, see Figure 2.

$-25°C$, which was reported for storage of standard monohydroperoxide cholesteryl linoleate in the literature (9). We confirmed by TLC and normal-phase HPLC that this condition resulted in decomposition, possibly owing to autoxidation, of the standard monohydroperoxides into unspecified substances within a few months (data not shown).

Qualitative analyses for hydroperoxides of cholesteryl ester and TG in human plasma. Figure 3A shows the typical chemiluminescence HPLC chromatogram of a plasma sample from a healthy volunteer, with two peaks observed. Peak 1 was assigned to the added I.S. and peak 2 was presumed to be CL-OOH from its retention time. Figure 3B shows the chemiluminescence HPLC chromatogram of the plasma sample from the same healthy volunteer spiked with synthesized CL-OOH. The height and area of peak 2 on Figure 3B were enhanced compared with that in Figure 3A, so peak 2 was assigned to CL-OOH. Furthermore, the above plasma sample was treated with NaBH$_4$ and reanalyzed by HPLC. As shown in Figure 3C, the peaks then completely disappeared, so that peak 2 in human plasma actually possesses a hydroperoxyl group in the molecule and can be identified as CL-OOH. We did not observe any peaks for TG hydroperoxide in the plasma from healthy subjects.

Figure 3D shows a chemiluminescence HPLC chromatogram of a plasma sample from a patient with liver failure, in which peaks 2 and 3 are evident. For their identification, we added synthetic CL-OOH and OLP-OOH to the sample. As shown in Figure 3E, the peaks 2 and 3 completely overlapped those of the added standards. These peaks also disappeared after treatment with NaBH$_4$ as above, as shown in Figure 3F. These results indicated that they were also the derivatives of hydroperoxide. Other lipid hydroperoxides, CO-OOH, OOP-OOH and OOO-OOH, that were synthesized in our laboratory were also added to the plasma sample from the patient with liver failure; however, the retention times of the peaks of these synthetic hydroperoxides did not agree with those of peaks 2 and 3.

Plasma lipid profiles of normal and liver failure subjects. As shown in Table 2, significantly lower TC and higher TG

recoveries relative to I.S. of CL-OOH and OLP-OOH added into 0.1 mL of plasma prior to extraction. At the concentrations of 50 and 200 nM of CL-OOH, they were within the range of 84–93%. The recoveries at the concentration of 50 and 200 nM of OLP-OOH were within the range of 86–93%.

Storage condition. The I.S. and standard hydroperoxides of cholesteryl ester and TG synthesized were found to be stable for at least 3 mon at $-80°C$. We tested a storage condition of

[a]Values are means ± SD. *$P < 0.05$; **ND: not detected, and the values were considered under detection limit. TC, total cholesterol; LDL-C, LDL-cholesterol; HDL-C, HDL-cholesterol; CE-OOH, cholesteryl ester monohydroperoxides; TG-OOH, triglyceride monohydroperoxides.

concentrations in serum were observed in the patients with liver failure in comparison with both healthy young and elderly groups. The very low HDL-cholesterol concentrations in the patients with liver failure well reflected their severe loss of liver functions. Serum TC concentrations in the healthy elderly group were significantly higher than those in the healthy young group. Serum LDL-cholesterol concentrations did not significantly differ among the three groups.

All four patients with liver failure showed a striking increase of cholesteryl ester monohydroperoxides in plasma (11,903 ± 9,553 nM, mean ± SD, range: 1,912–24,900 nM) in comparison with the two healthy groups (210 ± 69 nM, 107–289 nM for the elderly, and 189 ± 87 nM, 63–332 nM for the young). No statistically significant difference was observed in plasma concentrations of cholesteryl ester monohydroperoxide between the healthy elderly and young groups. TG monohydroperoxide was undetectable in plasma from all subjects in the healthy elder and healthy young groups. On the other hand, marked increase (3,318 ± 1,590 nM, 1,970–5,600 nM) was observed in all patients with liver failure.

DISCUSSION

In the present study we chemically synthesized CL-OOH and CO-OOH as standard cholesteryl ester hydroperoxides, since their precursors (CL, CO) are reported to be major cholesteryl esters in human plasma, accounting for 51 and 23%, respectively, of the total (18,19). In our previous report, synthetic CL-OOH was shown to be composed of regioisomers with the hydroperoxy group at 9-, 10-, 12-, and 13-positions of the FA chain, and these four isomers could be separated by normal-phase HPLC (16). However, in the present reversed-phase HPLC system with chemiluminescence detection, all four isomers eluted in a single peak, facilitating comparisons. Peak 2 in Figure 3A was assigned to CL-OOH, since its retention time was identical to that of the synthetic CL-OOH but not to that of the synthetic CO-OOH (16). This strongly suggests that CL-OOH is a predominant hydroperoxide of cholesteryl ester in human plasma.

For the measurement of plasma TG hydroperoxides, previous studies used trilinolein hydroperoxide as the standard (9,10,12). However, since trilinolein was reported to be absent in human plasma by Kuksis *et al.* (18,19) and by Ruíz-Gutiérrez *et al.* (20), the observed hydroperoxide peak by an HPLC study may not have been trilinolein hydroperoxide. To be able to assign each TG hydroperoxide in plasma, we need TG hydroperoxide standards and an HPLC system to separate them effectively. The major TG in human VLDL, which is the major plasma lipoprotein species containing TG as the preponderant lipid, are reported to be 1,2-dioleoyl-3-palmitoylglycerol (OOP, 32.8%), 2-linoleoyl-1-oleoyl-3-palmitoylglycerol (OLP, 22.3%,) and triolein (OOO, 12.2%) in healthy young men (20). Ruíz-Gutiérrez *et al.* (21) have reported a similar TG composition for human adipose tissue. From these studies, monohydroperoxides of the three major TG might be expected to be suitable standards and thus were initially synthesized in our

previous study (17) and their structures confirmed with reference to chromatographic behavior, ^{1}H NMR, ^{13}C NMR, and mass spectra. The results of normal-phase HPLC analysis showed the monohydroperoxides to be mixtures of regioisomers. Six peaks in the chromatogram of OLP-OOH corresponded to the isomers with a hydroperoxy group at 9-, 10-, 12-, or 13-position on the linoleoyl side chain and at 9- or 10-position on the oleoyl side chain. In the reversed-phase HPLC, however, the regioisomers of synthetic OLP-OOH eluted in a single peak, again advantageous for sensitive and simple measurement of TG hydroperoxides (17).

The presence of TG hydroperoxides in plasma has not been confirmed in previous studies. Akasaka *et al.* (9) reported detection in normal plasma stored at −30°C but not in fresh plasma, suggesting accumulation of TG hydroperoxides during storage. In a recent report of a structural analysis of oxidized TG in human and porcine lipoproteins by an HPLC-electrospray ionization-MS method, no hydroperoxides were detected, whereas the presence of ketones, epoxides, aldehydes, and hydroxides was confirmed (22,23).

In our present study, peak 3 (Fig. 3D) for a patient with liver failure was assigned to OLP-OOH based on the retention time. On the other hand, synthetic OOO-OOH and POO-OOH were confirmed to have retention times distinct from that for peak 3 (data not shown). Further, no peak comparable to the peak 3 was detectable in normal plasma (Fig. 3A), strongly suggesting that selective accumulation of OLP-OOH in plasma occurs with liver failure. OLP, reported to account for 22.3% of total TG in plasma, was lower than the 32.8% for OOP (20), which favors an interpretation of higher susceptibility to oxidation of linoleic acid than oleic acid. To our knowledge, this is the first report to identify TG hydroperoxides in human plasma as OLP-OOH.

Using the present method, we found plasma levels of cholesteryl ester hydroperoxide to be 210 ± 69 nM (mean ± SD, *n* = 6) in healthy elderly and 189 ± 87 (*n* = 15) in healthy young. In previous chemiluminescence HPLC methods, variable cholesteryl ester hydroperoxide levels were reported. For instance, Yamamoto *et al.* described the level of cholesteryl ester hydroperoxides in healthy human plasma to be 317 ± 2.0 (*n* = 3), 3.4 ± 2.0 (*n* = 23), and 8.0 ± 4.5 nM (*n* = 9) in their three different studies (12,14,24) with chemiluminescence assays. Although the reason for the discrepancy was not specified by the authors (24), it is likely that the lack of an I.S. contributed. We have observed significantly decreased detection counts during sequential sample injections in our HPLC system, which can be best explained by adhesion of unspecified substances in plasma to the flow cell, since the detection can be restored after washing the flow system.

Akasaka *et al.* (9) reported the level of cholesteryl ester hydroperoxides in fresh human plasma to be 24.5 ± 9.6 nM (*n* = 15) by a fluorometric HPLC method, a value lower than ours. They used a nonhydroperoxide compound as I.S. and then detected this and cholesteryl ester hydroperoxides, respectively, using UV and fluorimetric detectors. Here, we used a hydroperoxide, and detected both our I.S. and lipid hydroperoxides by

chemiluminescence. Moreover, as anticoagulant, they used heparin, which has no antioxidant action, whereas the EDTA used in our method is an effective antioxidant. Thus, the theoretical superiority of our method appears clear.

In the present study, we chemically synthesized the novel hydroperoxide of the ester composed of oleic acid, lithocholic acid, and tetradecanol, namely, 1-tetradecanyl 3-octadecenoyloxy-5β-cholan-24-oate monohydroperoxide for use as the I.S. for the first time. This compound has a number of virtues for the measurement of lipid hydroperoxides by chemiluminescence HPLC. First, it is relatively stable, which presumably is attributable to the stability of the monohydroperoxide of oleic acid, in line with our previous observation that CO-OOH is more stable than CL-OOH (16). Furthermore, the ratio of chemiluminescence intensities of the targeted lipid hydroperoxides and the I.S. is about 1.3 and constant throughout the range, which also contributes to good accuracy and precision with our HPLC system. Finally, two regioisomers (the 9- and 10-isomers) are included in the I.S., but they elute in a single peak on chemiluminescence HPLC, preventing interference with other substances and increasing sensitivity. The validation data showed good within-day and between-day reproducibility for the tested two hydroperoxides, with CV of less than 7% and recoveries between 84 and 93%. Thus, our chemiluminescence HPLC system allowed simultaneous measurements at picomolar to nanomolar levels of hydroperoxides of cholesteryl ester and TG in human plasma (Fig. 3A, B, D, E).

Since TG hydroperoxide was not detectable in plasma from normal persons, as previously reported by Yamamoto *et al*. (12), we tested whether any pathological condition might be associated with the appearance of TG hydroperoxide in plasma. For the first time, a striking increase of TG hydroperoxide was confirmed in all four patients with liver failure, without exception, whereas the compound was not detectable in any of 21 normal subjects (Table 2). Although the number of studied patients has not reached a statistically significant level, this finding not only indicates that our method for measuring lipid hydroperoxides is reliable but also suggests that a severe lipid oxidation process is involved in advanced liver disease. Accordingly, elevation of phospholipid hydroperoxides in plasma of patients with cirrhosis and hepatocellular carcinoma has been reported in the literature, suggesting the presence of increased oxidative stress in advanced liver disease (4). In our method, phospholipid hydroperoxides did not appear in the chromatogram, because they are more polar than the hydroperoxides of cholesteryl ester and TG and therefore should be extracted in the methanol phase to be discarded.

Additionally, cholesterol hydroperoxides have been reported to increase in lipid extracts from alcoholic fatty liver (8). In our previous study, we reported the occurrence of hydroperoxidation not only in the olefinic parts of FA chains but also in the sterol ring during the photosensitization of synthetic cholesteryl esters (16). The structures of the hydroperoxides were identified as 5-hydroperoxy- and 7-hydroperoxy-cholest-6-en-3-ol esters, according to their ^{1}H NMR spectra. In our reversed-phase system, these hydroperoxides showed retention times distinct from those of cholesteryl ester hydroperoxides carrying the hydroperoxy group in the FA chain (data not shown). Further, the formation of hydroperoxides at the sterol moiety was much slower than that at the FA chains, when synthetic cholesteryl esters were photosensitized (16). Hence, cholesteryl ester hydroperoxides carrying a hydroperoxy group only at the sterol ring are unlikely to occupy a major component in plasma.

As for a mechanism leading to the accumulation of oxidized lipids in plasma from patients with liver failure, some explanations seem possible. HDL is known to carry cholesteryl ester hydroperoxides to the liver where such oxidized lipids are detoxified effectively. Interestingly, LDL-associated cholesteryl ester hydroperoxides are neither removed nor detoxified in the liver (25). In this context, the extremely low levels of HDL in our patients might play a central role in the disruption of this salvaging system. Regarding the accumulation of TG hydroperoxides, Nagasaka *et al*. (26) have reported that in patients with progressive familial intrahepatic cholestasis, LDL particles were enriched with TG and were highly capable of transforming macrophages into foam cells, indicating the nature of this lipoprotein as an oxidized LDL species. Retarded hepatic clearance of LDL, predicted from both the suppressed LDL receptor expression and the modified physicochemical nature of LDL, has been proposed as a possible explanation by the authors. Further, we would like to stress a potential role of the failed bile excretion system in the accumulation of TG-rich oxidized LDL species in severe cholestasis. It is well known that free cholesterol and phospholipids are major components of bile. Supposing that oxidized lipids also are excreted into bile, the lack of bile formation and excretion commonly seen in the liver failure may result in the accumulation of oxidized lipids in the liver and blood. Additionally, ischemia, inflammation, and the loss of antioxidants in the failing liver could also be involved in this process.

Finally, the striking elevation of TG hydroperoxides in liver failure might suggest its potential as a specific clinical marker that could help in diagnosis, evaluation of severity, and monitoring of the effects of treatments in liver diseases.

ABSTRACT: This paper discusses a rapid GC-FID technique for the simultaneous quantitative analysis of FFA, MAG, DAG, TAG, sterols, and squalene in vegetable oils, with special reference to palm oil. The FFA content determined had a lower SE compared with a conventional titrimetric method. Squalene and individual sterols, consisting of β-sitosterol, stigmasterol, campesterol, and cholesterol, were accurately quantified without any losses. This was achieved through elimination of tedious conventional sample pretreatments, such as saponification and preparative TLC. With this technique, the separation of individual MAG, consisting of 16:0, 18:0, and 18:1 FA, and the DAG species, consisting of the 1,2(2,3)- and 1,3-positions, was sufficient to enable their quantification. This technique enabled the TAG to be determined according to their carbon numbers in the range of C_{44} to C_{56}. Comparisons were made with conventional methods, and the results were in good agreement with those reported in the literature.

Paper no. L9664 in *Lipids* **40**, 523–528 (May 2005).

Palm oil is one of the major oils consumed worldwide. Commercial palm oil is derived from the mesocarp of the *Elaeis guineensis*. Crude palm oil (CPO) consists of >90% TAG, 5.3–7.7% DAG, 0.21–0.34% MAG, 2.4–4.5% FFA, and 1% minor components such as carotenes, tocopherols and tocotrienols, sterols, and squalene (1,2). Analyzing these components using a single method is a challenging task as the components have a wide range of M.W., ranging from 200 to 1000 amu (e.g., FFA <300 amu, and TAG >800 amu). The analysis and quantification of these components generally require some pretreatment, which involves extensive work and the use of chemicals, as each component must be treated differently. A separate analytical method is required for each compound class.

The amount of FFA is an indicator of the quality of oils and fats. In practice, the FFA content in palm oil and its products is determined using an established method reported in *Palm Oil Research Institute of Malaysia* (*PORIM*) *Test Methods* (3). The method involves titration with the use of phenolphthalein as the indicator. However, CPO contains 500–700 ppm (2) of carotenes, which impart an orange-red color that obscures the color change of the indicator.

Sterols are the major portion of unsaponifiable matter in vegetable oils. The official method proposed by European Union legislation is based on the separation of the sterols fraction by silica gel chromatography (4). This method for the quantification of sterols also has been reported previously (5). The prevalent technique for quantifying squalene is also carried out using this method, followed by chromatographic separation. As reported by Moreda *et al.* (6), these methods are laborious and time-consuming, with a significant loss of squalene.

Partial acylglycerols (MAG and DAG) are important constituents in palm oil. They are the hydrolysis products of TAG in the oil, which will affect the physical properties of the oil. The presence of partial acylglycerols (MAG and DAG) in edible oils can cause cloudiness in the oil even though its total concentration is <10%. The DAG profile, i.e., the nature and concentration of DAG in the oil, enables the nucleation process in palm oil to be predicted (7). The nucleation process is the precursor to crystallization and the precipitation of DAG in the oil. Thus, the content of acylglycerols is an important determinant of oil quality.

The MAG, DAG, and TAG are typically determined using AOCS Recommended Practice Cd 11c–93 (8) with the extensive use of chemicals and solvents. The technique is time-consuming and requires a verification step using TLC. The only drawback to the method is the co-elution of FFA in the TAG and DAG fractions, which is not ideal for samples with a high FFA content. Other reported methods include the determination of TAG using GC-FID (9,10), silver-ion HPLC with FID (11), HPLC coupled with ELSD, UV-vis spectrophotometry, and refractive index detectors (12).

Three other AOCS Official Methods that use high-temperature GC to analyze MAG and DAG (Cd-11b-91) (13), tocopherols and sterols (Ce 3-74) (14), and TAG (Ce 5-86) (15) are widely accepted, with their own specificities of the targeted

compounds. Thus, efforts have been made to determine the acyglycerols that are normally present in bulk quantity and the minor components, such as sterols and squalene, simultaneously at the ppm level in a single GC injection.

In recent years, supercritical fluid chromatography (SFC) has been exploited in the analysis of lipids especially to quantify high-M.W. TAG (16–18). Although SFC has relatively few practical applications, this technique has unique advantages where relatively low column temperatures will prevent the degradation of heat-sensitive components and using carbon dioxide will permit the use of an FID.

This paper reports a rapid technique for the quantitative determination of a mixture of FFA, acylglycerols, sterols, and squalene in a single GC-FID injection of vegetable oils, with special reference to palm oil. It is a simplified method for analyzing sterols and squalene that has the possibility of replacing conventional sample preparation steps for routine sample analysis. This method has been tested for about 3 years in the Palm Diesel Quality Control Laboratory of the MPOB for numerous analyses of oil samples.

EXPERIMENTAL PROCEDURES

Materials. CPO was obtained from the MPOB Experimental Palm Oil Mill in Labu, Negeri Sembilan, Malaysia.

Standard and chemical reagents. Myristic acid (14:0), palmitic acid (16:0), stearic acid (18:0), and oleic acid (18:1); monopalmitin, monostearin, and monoolein; 1,2- and 1,3-dipalmitin, 1,2- and 1,3-distearin, and 1,2- and 1,3-diolein; tripalmitin and squalene, with a purity of 99%; and β-sitosterol (95%), campesterol (98%), stigmasterol (95%), and cholesterol (99%) were purchased from Sigma Aldrich Inc. (St. Louis, MO). The silylating reagent *N,O*-bis(trimethylsilyl) trifluoroacetamide with 1% trimethylchlorosilane (BSTFA) was purchased from Fluka Chemicals (Buchs, Switzerland). A TLC plate coated with silica gel 60 F_{254} (20 × 20 cm; Merck 1.05715.0001) was purchased from Merck (Darmstadt, Germany). All solvents were purchased from Merck and were of chromatographic or analytical grade.

FFA titration. The titration of FFA was carried out using a PORIM Test Method (3). A 5.0-g quantity of oil was weighed accurately into a 250-mL conical flask. Then 50 mL of neutralized 2-propanol was added. The flask was placed on a hot plate and the temperature was regulated to about 40°C. The sample was swirled gently while titrating with a standardized sodium hydroxide solution, using phenolphthalein as the indicator to the first permanent pink color. The color had to persist for 30 s.

Saponification (19). Oil (5.0 g) was saponified with 30 mL of absolute ethanol and 5 mL of aqueous potassium hydroxide (50%) for 1 h. The unsaponifiable matter was extracted five times with 30 mL of *n*-hexane. The combined extract was washed repeatedly with 100 mL of distilled water/ethanol (90:10, vol/vol) to neutralize the excess hydroxide. The solution was dried with anhydrous sodium sulfate. The solvent was removed by evaporation under reduced pressure.

TLC (20). The unsaponifiable fraction was subjected to preparative TLC with an eluting solvent system of chloro-

form/diethyl ether/acetic acid (99:5:1, by vol). After the plate was dried, the components were identified by iodine vapor using cholesterol and squalene as standard reference materials. The components were scraped off and extracted three times with 30 mL of *n*-hexane. The solvent was removed by evaporation under reduced pressure. The samples were injected into the gas chromatograph-FID (6).

GC. A 0.02 g quantity of sample was weighed accurately into a 2-mL GC vial. Then 1.2 mL of dichloromethane and 0.3 mL of the silylating reagent BSTFA were pipetted into the vial. The vial was capped tightly and heated at 60°C for 2 h. The instrument used was a Hewlett-Packard Series II gas chromatograph, model 5890 (Hewlett-Packard, Avondale, PA), equipped with an FID and an on-column injector. A BPX 5 fused-silica capillary column (15 m × 0.32 mm), coated with 5% phenyl/95% polysilphenyl-siloxane, with a film thickness of 0.25 μm (SGE, Austin, TX), was used. GC conditions were as follows: injector temperature, 45°C; detector temperature, 370°C; initial oven temperature, 100°C; initial holding time, 1 min; ramping rate, 10°C/min; final temperature, 360°C; final holding time, 16 min; carrier gas (He) flow rate, 2 cm^3/min; column pressure, 14.5 psi; injection volume, 1 mL. Quantification of the components was performed using a 5-point external standard calibration assay, with R^2 values of >0.9900.

RESULTS AND DISCUSSION

A typical gas chromatogram of derivatized CPO obtained using the rapid GC-FID technique is shown in Figure 1. The derivatization procedure prior to GC injection is an essential step in oils and fats analysis as it reduces the elution temperature of MAG, DAG, and especially TAG. It also enhances the response signal of the derivatized compound, which indirectly increases the sensitivity of the FID detector. The elution order of the components begins with FFA (9.0–15.0 min), MAG (15.5–17.0 min), squalene (17.2 min), free sterols (19.0–20.5 min), DAG (22.5–25.5 min), and TAG (28.0–38.0 min). Good resolutions of FFA, MAG, and DAG were achieved, as shown in enlargements of the chromatogram in Figure 2.

Determination of FFA. Table 1 depicts the percentage of FFA in CPO determined using the GC technique and the conventional titration method. Each determination was carried out in triplicate. We found that both techniques gave comparable results of about 4% FFA in the CPO samples. However, the SE of <1.0% calculated using this rapid technique was much smaller than that of the conventional titration technique of 3.0–5.0%. The smaller SE shows the increased precision in quantifying FFA in CPO. The GC technique overcomes the problem of determining the end point in the titration method, especially for palm oil, which has a high amount of red color pigments such as carotenes. In addition, this method provides a detailed analysis of individual FA.

Determination of sterols. With the use of the rapid GC technique, the individual sterols were separated and detected in the oil matrix without subjecting the oil to the conventional sample preparation method of (i) saponification of the sample (ii) isolation of the sterols fraction *via* TLC, (iii) derivatization of
FIG. 1. A typical chromatogram of crude palm oil using the rapid GC-FID method.
FIG. 2. Enlarged chromatogram of FFA, MAG, and DAG of Crude Palm Oil using the rapid GC-FID method. (a) Monopalmitin at the 1- or 2-position; (a′) monostearin at the 1- or 2-position; (a″) monoolein at the 1- or 2-position; (b) 1,2(2,3)-C_{32} DAG; (b′) 1,3-C_{32} DAG; (c) 1,2(2,3)-C_{34} DAG; (c′) 1,3-C_{34} DAG; (d) 1,2(2,3)-C_{36} DAG; (d′) 1,3-C_{36} DAG.

the recovered sterols, and (iv) GC analysis (20). The enlarged chromatogram (Fig. 3) shows a good separation of free sterols with little interference from the tocopherols and tocotrienols. However, a consistent repeatability of results was not obtained for the tocopherols and tocotrienols because these heat-sensitive compounds degraded during derivatization and because of the high-temperature oven programming. Other minor sterols such as Δ^5-avenasterol, Δ^7-stigmasterol, Δ^7-avenasterol, dimethylsterols, and methylsterols contributed to less than 10% of the total sterols (2). Table 2 shows the comparison of results obtained for selected individual sterols (%) in CPO using the rapid GC technique and the conventional method. The total concentration of sterols determined in the present study is consistent with the results reported by Tang (21). In addition, the percentage of individual sterols found is supported by data reported by Jalani and Rajanaidu (22). We observed that both techniques gave similar percentages of individual sterols. The absolute concentration of sterols found using the rapid GC-FID

method was slightly higher, which may be attributed to some losses during conventional sample preparation steps, such as saponification and TLC isolation.

Determination of squalene. The plant sources that contain squalene are palm oil and olive oil. Palm oil has been reported to contain 200–500 ppm squalene (2). The rapid GC technique was able to detect squalene in both crude and refined palm oil. The squalene content in CPO was determined to be 433 ± 3

TABLE 1
Comparison of FFA in Crude Palm Oil (CPO) by the Rapid GC and Conventional Titration Methods

Sample	FFA (%)	
	Rapid GC method	Conventional titration
CPO 1	4.47 ± 0.01	4.00 ± 0.12
CPO 2	4.32 ± 0.02	4.00 ± 0.17
CPO 3	4.29 ± 0.04	4.28 ± 0.12
CPO 4	4.49 ± 0.02	4.35 ± 0.22
FIG. 3. Enlarged chromatogram of free sterols, tocopherols, and tocotrienols in crude palm oil using the rapid GC-FID method.

TABLE 2
Comparison of Selected Sterols in Crude Palm Oil by the Rapid GC and Conventional Methods

Component	Retention time (min)	Composition (%)	
		Rapid GC method	Conventional method
β-Sitosterol	20.453	60.93 ± 0.22	60.51 ± 0.78
Campesterol	20.095	24.50 ± 0.18	24.25 ± 0.33
Stigmasterol	19.955	12.56 ± 0.43	11.50 ± 0.55
Cholesterol	19.390	2.01 ± 0.13	3.74 ± 0.10

ppm using the rapid technique and 410 ± 4 ppm using the conventional method. The squalene content in refined, bleached, and deodorized palm olein was found to be 415 ± 5 ppm using the rapid technique and 395 ± 3 ppm using the conventional method. The results fell within the concentration range reported earlier (23). Squalene, a highly unsaturated hydrocarbon, may have been partially destroyed during the saponification step, and losses may have occurred during sample isolation by TLC, thus reducing the overall concentration of the compound as compared with the rapid GC technique. The higher recovery ensured greater accuracy in the analysis.

Determination of acylglycerols. The content of MAG was relatively low in CPO, <0.3% (1). However, the level of DAG is known to be exceptionally high in CPO compared with other oils (24). Table 3 shows the content of acylglycerols in CPO determined using the rapid GC-FID method. The content of

partial acylglycerols found in the present study is in agreement with that observed by Goh and Timms (1), with average concentrations of 0.10 and 3.90% for MAG and DAG, respectively. The FA composition of the MAG obtained in the present study showed a slight deviation for 18:0 as compared with that found by George and Arumughan (25) (Table 4). The ratio of saturated to unsaturated FA in MAG was 1:1, which was close to data reported previously (25). A detailed analysis of 1,2(2,3)- and 1,3-DAG could also be performed using the rapid method. We found from the present study that the 1,3-isomer predominated over the 1,2(2,3)-isomers at a ratio of 1.7:1 (Table 5). These results support those of Goh and Timms (1), who found a ratio of about 2:1, as well as those of Siew and Ng (7), who found a ratio of 2.3:1.

The successful separation and identification of the TAG composition in CPO by carbon number was demonstrated

TABLE 3
Composition of MAG, DAG, and TAG in Crude Palm Oil (CPO) by the Rapid GC Method

Sample	Composition (%)		
	MAG	DAG	TAG
CPO 1	0.10 ± 0.011	3.72 ± 0.13	91.72 ± 0.18

using the rapid GC method in the present study (Table 6). The composition of TAG in terms of carbon number is one of the important parameters that characterizes palm oil, with the major TAG being C_{50} and C_{52}. TAG defines some physical characteristics of palm oil such as its m.p. and crystallization properties. As can be seen, the data obtained in the present study are similar to those reported previously (21). The composition of TAG in palm olein and palm stearin obtained by dry fractionation was distinctive and differed significantly by the C_{48} TAG (26). With the rapid GC technique, compositional changes in TAG during the fractionation process can be monitored.

The rapid GC-FID method described in this report provided valuable information about the composition of oils; it required minimal analysis time and eliminated the need for saponification and TLC isolation of the minor components. The repeatability of the developed method for analyzing a mixture of FFA, sterols, squalene, and acylglycerols illustrates its use as a fast, quantitative technique for the analysis of vegetable oils.

and [d]Ministère de l'Agriculture, des Pêcheries et de l'Alimentation du Québec (MAPAQ), Québec G1R4X6 Canada

ABSTRACT: The goal of this study was to examine the FA composition of wild and farmed Atlantic salmon (AS) and rainbow trout (RT). FA profiles were obtained by GC/FID. Results showed that lipid and n-3 highly unsaturated FA contents of farmed and wild AS were similar. Total n-3 and n-6 PUFA were significantly higher in farmed AS than in wild AS. Farmed RT contained more fat and less n-3 PUFA than wild RT. Our results show that farmed salmonids provide high levels of n-3 HUFA to consumers.

Paper no. L9633 in *Lipids 40*, 529–531 (May 2005).

Public interest in the health benefits of long-chain n-3 FA is increasing because numerous studies report that a diet rich in fish protects against chronic diseases such as coronary heart disease (CHD) (1). Hence, it is recommended to consume at least two meals of fish, preferably oily, per week (1).

However, wild fish is a finite resource. The increase in demand for fish products over the past two decades has been met by aquaculture production. Given the increasing role of aquaculture in ensuring future per capita fish supplies as world population grows, farmed fish has a significant role to play in providing n-3 FA sources to consumers (2). Atlantic salmon (AS; *Salmo salar*) and rainbow trout (RT; *Oncorhynchus mykiss*) are the major farmed fish consumed by Quebecers, because of their great availability and accessibility in food markets. The goal of the present study was to examine and compare the FA composition of wild and farmed AS and RT.

MATERIAL AND METHODS

In 2003, Ministère de l'Agriculture, des Pêcheries et de l'Alimentation du Québec (MAPAQ) collected farmed AS ($n = 46$) and RT ($n = 37$) in Québec food markets. Wild AS samples ($n = 10$) were obtained from anglers of the Gaspésie area, the Centre Interuniversitaire de Recherche sur le Saumon Atlantique (CIRSA), and the Ministère des Ressources Naturelles, de la

Faune et des Parcs du Québec (FAPAQ). Wild RT samples ($n = 10$) were obtained from the Freshwater Fisheries Society of British Columbia and FAPAQ. Fish fillets were packaged in plastic bags and stored at $-20°C$ until laboratory analyses (within 2 months following sampling).

FA analyses. Analyses were conducted on raw, skinless fillets, excluding other types of fat such as subcutaneous or mesenteric fat. In the presence of PC containing 15:0 FA used as an internal standard, 300 mg of tissues was extracted three times with chloroform/methanol (2:1 vol/vol) (3). Lipid extract solvents were then evaporated under a stream of nitrogen, weighed, and methylated (4). FA profiles were obtained by capillary GC (Hewlett-Packard 5890 gas chromatograph, equipped with an automated injector 7673A and an FID injector). Injector and detector temperatures were 200 and 260°C, respectively. A capillary column (DB-23: 30 m × 0.25 mm i.d. × 0.25 µm film thickness; Agilent Technologies, Palo Alto, CA) was used with nitrogen as the carrier gas. The FA were identified with a standard mixture of 37 different FA (FAME 37; Supelco, Bellefonte, PA).

The arithmetic mean of total lipids and FA concentrations was calculated for each species. For each FA, comparison of the concentrations between the wild and farmed fish was assessed with the nonparametric Wilcoxon test. Statistical significance was set at $P < 0.05$.

RESULTS

Table 1 shows the FA compositions of wild and farmed AS and RT. The average total lipid contents of wild and farmed AS were similar. However, the range of lipid values was quite large for both types of AS, varying between 1.3 and 16.1 g/100 g of fish flesh. Total n-6 PUFA, n-6 HUFA (highly unsaturated FA), and linoleic acid in farmed AS were four-, two-, and sixfold higher, respectively, than in wild AS. Total n-3 PUFA, α-linolenic acid, and EPA were significantly higher in farmed AS than in wild AS, whereas concentrations of DHA and n-3 HUFA were similar. The ratio of n-3 to n-6 PUFA was 11.0 in wild AS compared with 3.6 in farmed AS. PUFA were the major FA in farmed AS compared with wild AS. Saturated FA (SFA) were 35% higher in farmed AS than in wild AS. In contrast, monounsaturated FA (MUFA) were 60% higher in wild AS than in farmed AS.

The total lipid content in farmed RT was 5.6-fold higher than that of wild RT. Total n-6 PUFA and n-6 HUFA in wild

RT were significantly higher than in farmed RT, whereas linoleic acid was higher in farmed RT. Total n-3 PUFA, n-3 HUFA, α-linolenic acid, and DHA were higher in wild RT than in farmed RT whereas the ratio of n-3 to n-6 PUFA was similar in all trout samples. However, absolute concentrations showed that farmed RT provided threefold higher amounts of n-3 PUFA than wild RT (931 vs. 268 mg/100 g). PUFA were present in higher proportion in wild RT than in farmed RT. In contrast, SFA and MUFA were higher in farmed RT than in wild RT.

DISCUSSION

Although farmed salmonids generally display higher amount of lipids than wild fish (5,6), our results showed that the lipid content of farmed AS was lower than expected and similar to that of wild AS. Moreover, linoleic, α-linolenic, and arachidonic acids were, respectively, six-, three-, and twofold higher in farmed AS than in wild AS. The recent use of vegetable oils in feeds of farmed AS may explain these differences. It is well known that the FA composition of farmed fish greatly varies depending upon their diet (5,7). In the present study, the composition of the diets for the farmed fish was unknown, as they are mainly produced in Chile (Morin, R., unpublished data). Unexpectedly, the flesh of wild and farmed RT displayed a similar ratio of n-3/n-6 PUFA even though farmed RT contained

more lipid and less n-3 and n-6 PUFA than wild RT. Moreover, the concentration of arachidonic acid was sixfold higher in wild RT than in farmed RT, probably reflecting the greater consumption of terrestrial insects by wild RT (8).

In 2004, for primary prevention of CHD, nutrition experts of the International Society for the Study of Fatty Acids and Lipids recommended 500 mg of EPA + DHA per day (1). Fortunately, our results show that the consumption of farmed salmonids provides high levels of n-3 HUFA and consequently may have beneficial health effects for consumers.

REVIEW

Astonishing Diversity of Natural Surfactants: 3. Carotenoid Glycosides and Isoprenoid Glycolipids

Valery M. Dembitsky*

Department of Organic Chemistry and School of Pharmacy, Hebrew University, Jerusalem, Israel

ABSTRACT: Carotenoid glycosides and isoprenoid glycolipids are of great interest, especially for the medicinal, pharmaceutical, food, cosmetic, flavor, and fragrance industries. These biologically active natural surfactants have good prospects for the future chemical preparation of compounds useful as antimicrobial, antibacterial, and antitumor agents, or in industry. More than 300 unusual natural surfactants are described in this review article, including their chemical structures and biological activities.

Paper no. L9708 in *Lipids 40*, 535–557 (June 2005).

Carotenoids and related compounds are an important group of natural pigments in both the prokaryote and eukaryote kingdoms, exhibiting colors from dark red to bright yellow. Carotenoids are important in human nutrition as a source of β-carotene (vitamin A) and possibly as preventive agents against cancer and heart disease. In addition, carotenoids add color to foods and beverages. Carotenoids are the precursors of many important chemicals responsible for the flavors of foods and the fragrances of flowers. Carotenoids are a class of isoprenoid hydrocarbons (carotenes) and their oxygenated derivatives (xanthophylls). About 700 carotenoids have been isolated from natural sources, and about 160 of these pigments contain a carbohydrate moiety and belong either to the carotenoid glycosides or to the carotenoid glycosyl esters. This article describes the basic principles of the structure, stereochemistry, and nomenclature of carotenoids. The relationships between the structure and the chemical and physical properties on which all the varied biological functions and actions of the carotenoids depend have been observed in some review articles and books (3–9). The conjugated polyene chromophore determines not only the light-absorption properties, and hence color, but also the photochemical properties of the molecule and consequent light-harvesting and photoprotective action. The polyene chain is also the feature mainly responsible for the chemical reactivity of carotenoids toward oxidizing agents and free radicals, and hence for any antioxidant role. *In vivo*, carotenoids are found in specific locations and orientations in subcellular structures, and their chemical and physical properties are strongly influenced by other molecules in their vicinity, especially proteins and membrane lipids. In turn, the carotenoids influence the properties of these subcellular structures. Structural features such as size, shape, and polarity are essential determinants of the ability of a carotenoid to fit correctly into its molecular environment to allow it to function. A role for carotenoids in modifying the structure, properties, and stability of cell membranes, and thus affecting the molecular processes associated with these membranes, may be an important aspect of their possible beneficial effects on human health (5–7,10).

Archaebacteria, the third primary kingdom of cells in addition to eukaryotes and eubacteria, are all characterized by unusual isoprenoid ether lipids (11–17). Archaebacteria, or Archaea, have been discovered in extreme environments such as hot springs and salt lakes (11–13). Lipids of these microorganisms always possess saturated C_{20}-, C_{25}-, and C_{40}-polyisoprenoid chains in the hydrophobic moiety. Many studies have indicated that the membranes of the polyisoprenoid lipids are stable at high temperatures and high salt concentrations. The prior reviews of membrane lipids in archaebacteria have revealed a remarkable variety of polar lipids classes, including phospholipids, glycolipids, phosphoglycolipids, and sulfolipids, all derived from the one basic core structure, diphytanylglycerol, and an equally remarkable set of novel pathways for their biosynthesis (15). These ether lipids normally account for 80–95% of the membrane lipids, with the remaining 5–20% being neutral squalenes and other isoprenoids. Specific combinations of various lipid core structures found in methanogens include diether-tetraether, diether-hydroxy diether, or diether-macrocyclic diether-tetraether lipid moieties (16). The unusual molecular architecture gives rise to substantial modifications in the organization of the lipidic layer of their membranes, which still retains the typical trilaminar structure (11–17).

CAROTENOID GLYCOSIDES

Acyclic Carotenoid Glycosides

The first carotenoid glycoside was isolated from saffron and described in 1818 (18). Crocin **1**, as the major carotenoid, was isolated from *Crocus sativus* by Karrer and Miki in 1929 (19), and was later isolated from *Nyctanthes arbortristis* (20). Saffron, the dried stigmas of *C. sativus* L. (Iridaceae), is a very expensive spice that is used mainly as an herbal medicine or food

Abbreviations: DMPC, dimyristoylphosphatidycholine; ED_{50} (effective dose$_{50}$), the amount of material required to produce a specified effect in 50% of an animal population; InhA, a mycobacterial long-chain enoyl acyl carrier protein reductase (RV1484, EC 1.3.1.9); SQDG, sulfoquinovosyldiacylglycerol; TPA, 12-*O*-tetradecanoyl-phorbol-13-acetate.

coloring and flavoring agent in different parts of the world (21). Saffron originally grew in India, Iran, Spain, Greece, and other countries and has been successfully cultivated in various places in China, especially Tibet (21). It has historically been used in Chinese traditional medicine as an anti-anginal agent. Among the four crocins, crocin **1** is the most abundant in saffron and has been studied extensively for its pharmacological effects (22–24). The major biologically active ingredients of saffron (*C. sativus*) are crocin analogs, including crocins **1–4**, which are all glycosides of *trans*-crocetin **5–8**, a *cis*-carotenoid derivative **9** (25–27). The major yellow colorant, crocin **1**, has been isolated from the fruit of *Gardenia jasminoides* (28–31). Yellow colorants from *G. jasminoides* that are suitable for foodstuffs and natural dye preparations have been postulated to be crocetin glycosyl esters. The utility of carotenoid glycosyl esters as colorants for textiles (32) and food (33), as antioxidant quenchers for free radicals (34–36), and as antitumor agents (37) also has been reported. The unusual and adaptogenic xanthone carotenoid glycosidic conjugate termed mangicrocin **10** was isolated from Indian saffron *C. sativus* (38). A major new pigment isolated from *C. sativus* has been identified as the crocetin dineapolitanosyl ester **11** (39).
A series of dihydroxylycopene diglucoside diesters as a novel class of carotenoids, **12–18**, have been isolated from the phototrophic purple sulfur bacteria *Halorhodospira abdelmalekii* and *H. halochloris* (40). Diglucoside esters and diesters were esterified by two FA only: 12:0 (48% of total) and 14:1 (52%).

β-D-Glucosyl of the 4,4″-diapocarotene-6,6′-dioic acid **19** has been isolated from *Pseudomonas rhodos* and red-strain *Rhizobium lupini*, both isolated from *Lotononis bainesii* Baker (41–44). An apo-lycopenoate mannosyl ester, **20**, was found as a minor component in the yellow halophilic cocci strains H5B-2 and SE20-4 (45).

The carotenoid composition of the myxobacterium *Chondromyces apiculatus* was reported previously (46); a new acyclic carotenoid glucoside ester was isolated, and its structure was determined as the 1′-glucosyloxy-3′,4′-didehydro-1′,2′-dihydro-ψ,ψ-carotene monoesters **21–25**.
Staphylococcus aureus, a major human pathogen causing a wide spectrum of diseases, is able to survive under a variety of extreme conditions and produces staphyloxanthin **26** as a major pigment (47). Pigments of three species of alkaliphilic heliobacteria of the genus *Heliorestis*—*H. daurensis*, *H. baculata*, and an undescribed species, *Heliorestis* strain HH—produced two novel carotenoid glycosides, **27** and **28** (48). In these species, as in other heliobacteria, bacteriochlorophyll G esterified with farnesol was present. In addition, trace amounts of the biosynthetic intermediates OH-diaponeurosporene and OH-diaponeurosporene glucoside **29** were found. Trace amounts of a carotenoid with 20 carbon atoms, 8,8′-diapo-ζ-carotene, also were found in these species as well as in the non-alkaliphilic heliobacteria. The non-alkaliphilic species *Heliophilum fasciatum* also contained trace amounts of the two OH-diaponeurosporene glucoside esters. The results were used to predict the pathway of carotenoid biosynthesis in heliobacteria (47).

Mannosyl apo-lycopene alcohol **34** was a minor compound, as was apo-lycopenoate mannosyl **20** isolated from the yellow halophilic cocci strains H5B-2 and SE-20-4 (45). The mono-β-D-glucosyl ester **35** and the di-β-D-glucosyl ester **36** of 4,4′-diapocarotene-6,6′-dionic acid have been isolated both from a red strain of *Rhizobium* sp. isolated from the roots of *Lotononis bainesii* and from *Pseudomonas rhodos* (42,43,53–55). They represent the C$_{30}$ homologs of the glycosyl esters **1**–**8** and **11** occurring in *C. sativus* and *G. jasminoides*. Triterpenoid mono-β-D-glucosyl of 4,4′-diaponeurosporene **37** was produced by *Streptococcus faecium* UNH-564P (56). α-L-Rhamnopyranosyl, of the acyclic carotenoid named as oscillaxanthin **38**, is produced by the cyanobacterium *Oscillatoria rubescens* and represents the most important carotenoid glycoside in this group of cyanobacteria (57,58).

Neurosporene fucoside **39** and some other mono- and bicyclic carotenoid glycosides produced by the unicellular cyanobacterium *Synechocystis* sp. strain PCC 6803, which were isolated during myxoxanthophyll biosynthesis, have been studied (59).

Bacterioruberin mono- and diglycosides containing glycose **40** and **41** and mannose **42** and **43** sugars belonging to the C$_{50}$ carotenoid group have been isolated from the halophilic bacterial strain BOS 66 from glacial mud (60). The presence of C$_{50}$ carotenoids in halophilic bacteria is an interesting finding, and it has been suggested that the molecular length of C$_{50}$ carotenoids with two polar end groups is suitable in membrane architecture. It has been reported briefly that bacterioruberin reinforces the reconstituted lipid membrane of *Halobacterium* (61).

Monocyclic Carotenoid Glycosides

Monocyclic carotenoids are a large group of pigments that are produced by bacteria, lower fungi, and invertebrates (5,7,8,10). Some monocyclic carotenoids contain sugar moieties. Two carotenoid esters, salinixanthin **44** and **45**, have been isolated from the extremely halophilic eubacterium *Salinibacter ruber* (62). The same carotenoid glucoside in the acylated form in *Rhodothermus marinus* was isolated from marine hot springs (63). The FA ester of pheixanthophyll **46** was found in *Nocardia kirovani* (64). *Rhodococcus rhodochrous* RNMS1 (IAM 13988) contains a series of carotenoid glycoside esters with different FA residues, **47**–**55** (65). The same keto-myxoxanthin glycoside esters were isolated from a thermophilic filamentous photosynthetic bacterium *Roseiflexus castenholzii* (66). The FA composition was determined and included the acids 14:0 (24.1%), *iso*-15:0 (12.5%), 15:0 (6.2%), *iso*-16:0 (1%), 16:0 (29.8%), branched 17:0 (12.8%), *iso*-17:0 (10.3%), 17:0 (2.6%), and 18:0 (0.6%).

Dihydrochlorobactene glycoside laurate, **56**, was identified from the thermophilic green sulfur bacterium *Chlorobium tepidum* (67). Two new carotenoid glucoside mycolic acid esters, **57** and **58**, have been isolated from the nocardioform actinomycetes *R. rhodochrous* (68). Monocyclic carotenoid glucoside esters **59a–n**, which are major carotenoids, have been isolated from the green filamentous bacterium *Chloroflexus aurantiacus* (69). The major FA were hexadecanoic (16:0) and hexadecenoic (16:1) acids, whereas those of the cellular lipids were hexadecanoic, octadecanoic (18:0), and octadecenoic (18:1) acids. [Percentages included with **59a–n** represent the range of each FA in lipid extracts, calculated from total FA (100%)].

The thermophilic bacterium *Meiothermus ruber* produces a series of carotenoid glycoside esters. The major carotenoid has been identified as 1′-β-glucopyranosyl-3,4,3′,4′-tetradehydro-1′,2′-dihydro-β,ψ-caroten-2-one **68** (83). Acylated carotenoid glycoside esters at the 6″-position of the glucose unit contain a series of C_{10}–C_{17} FA **69–74**. Twelve FA from *M. ruber* carotenoids were characterized by GC–MS. The major component was a 10:1 FAME (37%). Other minor components were identified, ranging from 11 to 17 carbon atoms in length. Two branched-chain C_{15} FA esters also were identified. A similar substitution was found in the carotenoid glycosides of *Thermus thermophilus* (84). The major FA of the total cellular FA of *M. ruber* have been identified as branched-chain compounds, and 2-hydroxy FA were found to be produced in moderate amounts.

Some carotenoids, their glycosides **75** and **44** (with other FA residues), and their esters **76–91** have recently been detected in the thermophilic bacterium *Rhodothermus marinus* from submarine Icelandic hot springs (85). The FA profiles derived from the two acylated carotenoid glucosides **44** and **75** were found to be similar. The composition established with odd-carbon *iso*-13:0 (13%), *anteiso*-13:0 (16%), *iso*-15:0 (10%), and *anteiso*-15:0 (19%) as major FA in two carotenoid glucoside esters of **44** and **75** was reported. The minor even-carbon FA were found to be a mixture of the *n*- and *iso*-isomers, whereas the odd-carbon FA were a mixture of *iso*- and *anteiso*-isomers.

Lipophilic Vitamins

Among the lipophilic vitamins, which are derivatives of the carotenoids known as true retinoids, are retinyl-β-D-glucoside **103**, retinyl-β-D-glucuronide **104**, and retinoyl-β-D-glucuronide **105** (91; see Fig. 1). They are naturally occurring biologically active metabolites of vitamin A and are found in freshwater and marine fish and in mammals (92–94). Retinoyl-β-glucuronide **105** has been characterized as a metabolite of vitamin A in the plasma of humans (95) and in the plasma and tissues of several animals, such as the monkey (96), mouse (97), and rabbit (98).

Olson and co-workers (94,99,100) studied the metabolites of radioactive retinal and all-*trans* retinoic acid in the bile of bile-duct-cannulated rats and showed that the water-soluble metabolites were glucuronide derivatives of retinol and retinoic acid.
FIG. 1. Chemical structures of retinoid glucuronides and the pathways of their formation.

Thus, Olson's group discovered retinyl-β-glucuronide, the glucuronic acid derivative of retinol, and retinoyl-β-glucuronide, the glucuronic acid derivative of retinoic acid. Retinoyl-β-glucuronide was found to be an interesting retinoid that possessed the biological activity of retinoic acid but without pronounced toxicity. Retinoyl-β-glucuronide was also found to be as effective as retinoic acid in inhibiting LA-N-5 human neuroblastoma cell growth and might also serve as a less toxic alternative to 13-*cis* retinoic acid in the treatment of this tumor disease. Many reports have indicated that the biological activity of all-*trans* retinoyl-β-glucuronide is similar to that of all-*trans*-retinoic acid, but without the toxic side effects of retinoic acid (91,92).

The semisynthetic retinoyl-β-glucuronides **106–109**, as well as **105**, have been isolated from urine of the human, monkey, mouse, and rat (101–107).

Bicyclic Carotenoid Glycosides

Zeaxanthin mono- and diglucosides and rhamnosides, **110–113**, represent an important group of natural pigments and occur

mostly in bacterial species (8–10,108). They are found in *Corynebacterium autrophicum* (109–111) and are produced by *Erwinia herbicola* and *Rhodobacter sphaeroides* (112). Seven zeaxanthin glycosides, **110–123**, including the Z-isomers **114–117**, have been isolated from the extreme thermoacidophilic archeabacterium *Sulfolobus shibatae* (113).

Zeaxanthin glucoside esters (called thermocryptoxanthins) with branched FA, **118–123**, were isolated from the thermophilic eubacterium *T. thermophilis* (114,115). The structures of the carotenoids were identified as symmetrical bis-FA esters of zeaxanthin-β-glucosides.

155b
NORISOPRENOID GLYCOSIDES

Natural norisoprenoids structurally derived from carotenoids are widely distributed in the plant kingdom. Because they often have low flavor thresholds, many of them are highly potent aroma compounds and are thus of great interest for the flavor and fragrance industries (130,131). Norisoprenoids, as carotenoid degradation products (131), are the preferable cleavage of (6,7), (7,8), (8,9), and (9,10) bonds leading to flavor components with 9, 10, 11, and 13 carbon atoms, respectively. In the intact plant, carotenoid degradation is likely to be affected by oxygenase systems and by photo-oxygenation and other types of nonenzymatic oxidation (132). The sensory-active C_9-, C_{10}-, C_{11}-, and C_{13}-norisoprenoids naturally emerge from the oxidative cleavage of tetraterpenoid precursor carotenoids (130,133). Nonselective fission of the polyene chain induced by abiotic factors such as heat or light results in a broad spectrum of oxidized breakdown products (134,135). A smaller range of products, which often display biological activities, is released by enzymatic cleavage reactions. Enzymes catalyzing the centric or eccentric fission of specific carotenoids *in vivo* have been isolated from plants and characterized in recent years (136).

Recently, the chemical, photochemical, and oxidase-coupled degradation of carotenoids to norisoprenoids has been studied (137). The proposed biogenetic pathway in grapes that leads from carotenoids to C_{13}-norisoprenoids has been reported as involving the enzymatic degradation of carotenoids by regiospecific oxygenases (137). These findings include the preponderance of norisoprenoids possessing 13 carbon atoms, thereby indicating the specificity of cleavage; the configuration of the asymmetric centers and axes common to C_{13}-norisoprenoids and the corresponding carotenoids; the negative correlations observed between the levels of norisoprenoids and carotenoids during berry development; and the *in vivo* transfer of C_{13} markers from carotenoids to norisoprenoids in berries

between véraison (color change stage) and berry maturity. All of these findings are major arguments in favor of the hypothesis that glycosylated C_{13}-norisoprenoids are derived from carotenoids in the grapes. Carotenoids are mostly synthesized from the first stage of fruit formation until véraison, and then degrade between véraison and maturity to produce glycosylated C_{13}-norisoprenoids and other compounds. The formation of some norisoprenoid glycoside species is shown in Figure 2. Volatile C_{13}-norisoprenoids are thought to be the breakdown products of neoxanthin, a xanthophyll of the carotenoid group. In grapes, tobacco, tea, flower scents, and tropical fruits, norisoprenoids occur mainly as glycosidically bound precursors that can contribute considerably to the aroma. Carotenoid-derived aroma compounds are important carotenoid metabolites in the flavor and fragrance industries (138).

More than 50 filamentous fungi and yeasts, known for the *de novo* synthesis or biotransformation of mono-, sesqui-, tri-, or tetraterpenes, were screened for their ability to cleave β,β-carotene into flavor compounds, including norisoprenoids (139). Carotenoid-derived volatile products were detected in the media of *Ischnoderma benzoinum, Marasmius scorodonius*, and *Trametes versicolor*; β-ionone proved to be the main metabolite, whereas β-cyclocitral, dihydroactinidiolide, and 2-hydroxy-2,6,6-trimethylcyclohexanone were formed in minor quantities.

Many norisoprenoid glycosides, **156–253**, mostly belonging to megastigmane-type derivatives of cyclohexane (or cyclohexene), have been isolated from plant leaves (or roots) grown in different places, e.g., France, Italy, Turkey, China, Korea, Japan, Egypt, Thailand, Jordan, and other countries; and some of the glycosidic compounds isolated and tested have shown biological activities.

The norisoprenoid glycosides **156**, **157**, **228**, and **244–247** were isolated from the aerial parts of the Turkish medicinal plant *Salvia nemorosa* (140). Otsuka and co-workers (141–146) have studied Japanese plants belonging to several genera and have isolated many different norisoprenoid compounds. The megastigmane (ionol-type) glycosides **158–163**, **164–166**, **215**, **218–221**, **226–228**, and **252** were identified from the butanol-soluble fraction of the leaves of *Alangium platanifolium* var. *platanifolium* (Fukuoka Prefecture, Japan) (141,142). The leaves of *Alangium premnifolium* (Japanese name: Shima-urinoki) from Nakagami-gun (Okinawa Prefecture) were found to contain **191**, **194–196**, **241–243** (143), and **212–217** (144) glycosides. *Myrsine seguinii* (syn. *Rapanea neriifolia*), which is found in temperate and subtropical areas of Japan, contains the compounds **167–173** and **251** (145). The leaves of *Turpinia ternata* contains the glycosides **181–186** and **225–227** (146). Lasianthionosides A–C **236–238** were isolated from the leaves of *Lasianthus fordii* (147). Compounds of **175–177**, **231**, and **232** were isolated from the Turkish tree *Stachys byzantina* (Tokat, Turkey) (148), and **234** and **235** were isolated from the leaves of *Lonicera gracilipes* var. *glandulosa* (Sendai, Japan) (149).

The megastigmane glycosides **221–224**, **230**, and **244–247**
FIG. 2. Biodegradation of some carotenoid species and formation of C_{13}-norisoprenoids.

and their polyphenolic constituents isolated from the leaves of *Eriobotrya japonica* (Rosaceae) were found to inhibit the 12-*O*-tetradecanoyl-phorbol-13-acetate (TPA)-induced activation of the Epstein–Barr virus early antigen in Raji cells (150,151). Roseoside **230** significantly delayed carcinogenesis induced by peroxynitrite (the initiator) and TPA (the promoter), and its potency was comparable to that of a green tea polyphenol, (−)-epigallocatechin 3-*O*-gallate. The loquat, *E. japonica* (Rosaceae), is a small tree native to Japan and China that is widely cultivated for its succulent fruit. Its leaves have been used as a folk medicine for the treatment of chronic bronchitis, coughs, phlegm, high fever, and ulcers in Japan and other Asian countries (152). A traditional therapy using the leaves in a compress also has been used to treat cancers in Japan.

Five megastigmane glycosides, **230** and **244–247**, have been isolated from the seeds of *Trifolium alexandrinum* (153). The seeds of *T. alexandrinum* are popularly used in Egypt as an antidiabetic agent (154). Compounds of **172** and **191** were found in the glycosidic fraction of sloe tree *(Prunus spinosa)* leaves (155); **193**, **202**, **204**, and **228** were isolated from South American lulo (*Solanum quitoense*) leaves (156); **178** and **229** were isolated from *Caralluma negevensis* (157); an extract

from the tropical Chinese tree *Laggera alata* containing **179** is usually used for anti-inflammatory and antibacterial treatments (158); **180** was obtained from tea leaves (cv. Yabukita) (159); **187** and **188** were isolated from the aerial part of *Clerodendrum inerme* (160); **241**–**243** were isolated from *Acanthus ebracteatus* (161); **190** was isolated from the leaves of *Phlomis aurea* (162); and **198** was isolated from the leaves of *Carallia brachiata* (Rhizophoraceae), collected near Kuala Lumpur (Malaysia). The leaves of *C. brachiata* are used to prepare tea or, taken together with a mixture of turmeric, benzoin, and rice dust, are used for the treatment of gangrenous toxicity, whereas the bark is used to treat itching (163). **199** was isolated from grapevines (137); **195** and **237** were isolated from daylily (*Hemerocallis fulva*) leaves (164); **200** was isolated from the aerial part of *Taraxacum obovatum* (165); **156**, **174**, and **245** were isolated from barley (*Hordeum vulgare*) roots (166); and **229** and **230** were isolated from *Sauropus androgynus* (167).

Glycoside **194** was isolated from *Scurrula atropurpurea* (called "benalu teh" in Indonesia) belonging to the family Loranthaceae, a parasitic plant of the tea plant *Thea sinensis* (Theaceae). It showed 19.4% inhibitory activity against cancer cell invasion (inhibitory rate at 10 µg/mL) (168).

From the leaves of the poisonous perennial shrub *Breynia officinalis* (Euphorbiaceae), collected on Okinawa Island (Japan), were isolated the megastigmane glycosides **197**, **198**, **226**, and **248**–**251** (169); **194**, **201**, and **202** were isolated from the water-soluble fraction of the methanol extract of coriander (the fruit of *Coriandrum sativum*), which has historically been used as a spice and medicine (170).

Bay laurel (*Laurus nobilis*, Lauraceae) is a pyramid-shaped tree or large shrub with aromatic evergreen leaves and shiny gray bark; the popular culinary seasoning, bay leaf, is used extensively in French, Italian, Spanish, and Creole cooking and also in folk medicine. The extract of leaves from this shrub collected in Campania (Avellino, Italy) contained the megastigmane glycosides **199**, **202**, and **204**–**211** (171). An inhibitory effect was reported on nitric oxide production in lipopolysaccharide-activated murine macrophages. Compounds **227** and **228** and the acylated glycoside **253** were isolated from the aerial part of *Baccharis dracunculifolia* (Compositae) (172).

Biological activities of some C_{13}-norisoprenoids (not glycosides) have been reported. An inhibitory effect on mammary carcinoma cells induced by β-ionone was observed (173): β-ionone could inhibit the cell growth of MCF-7 cells (IC_{50} value, 104 µmol/L). Putative antiproliferative and cell-cycle inhibitory effects of β-ionone and geraniol were found on MCF-7 human breast cancer cells in a culture mediated by mevalonate depletion resulting from the inhibition of HMG-CoA activity (174). The effect of β-ionone on the proliferation of the human gastric adenocarcinoma cell line SGC-7901 and the inhibition of metalloproteinase was also studied (175). β-Ionone had an inhibitory effect on the growth of SGC-7901 cells; the IC_{50} value of β-ionone for SGC-7901 cells was estimated to be 89 µmol/L. Norisoprenoids that were isolated from

the leaves of *Cestrum parqui* (Solanaceae) showed phytotoxic effects on the germination and growth of *Lactuca sativa* (176).
ISOPRENOID GLYCOLIPIDS

Organisms that are able to live in environments that exhibit extraordinary conditions, such as very high temperatures (50–110°C and/or up to 400°C in deep-sea thermal vents), very high salt conditions (20 to 25% of NaCl), or very low or very high pH values (from 1.0 to 5.5, and from 8.5 to 11.0), are extremophiles or Archaea (Archaebacteria) (177,178). Hyperthermophiles are found mainly in the water near places with volcanic activity. The magma of the volcanoes heats the water to very high temperatures (up to 400°C). Acidophiles and alkaliphiles are able to grow at low pH (below 5.5) and high pH (above 8.5). Barophiles can survive only at the high pressures (above 300 atm) mainly found in the deep sea. Halophiles live in salt lakes and cannot survive without these very high salt concentrations. Also, combinations of these features are possible, e.g., *Sulfolobus* is an acidophilic hyperthermophile. Extremophilic organisms are found in both the Bacteria and the Archaea.

Archaea and Bacteria are prokaryotes, and both are single-cell organisms. There are, however, distinct features that place Archaea and Bacteria each in their own domain. This distinction is mainly based on studies of 16sRNA. Also, the composition of the cytoplasmic membrane is different in Bacteria and Archaea. Bacteria have glycerol diester lipids with FA as the hydrophobic backbone (1,2-diacyl-*sn*-glycerol), whereas Archaea have glycerol diether and diglycerol tetraether lipids with a phytanoyl chain as the backbone (2,3-di-*O*-phytanyl-*sn*-glycerol, or 2,3,2′,3′-tetra-*O*-dibiphytanyl-di-*sn*-glycerol). The tetraether lipids do form a membrane-spanning monolayer, and diethers and diesters do form a bilayer. All Archaea, including the halotolerant species, are characterized by the presence of isopranyl glycerol ether lipids in their membranes, and more than 150 polar lipids from Archaea have now been structurally characterized (11–17,179,180).

DIETHER AND TETRAETHER GLYCOLIPIDS

The extremely halophilic bacteria classified as Archaea generally require saturated or nearly saturated (3.0–5.0 M) NaCl for optimal growth and survival, although some species are capable of growth in as low as 2.5 M NaCl (14). The diether glycolipids **254**–**260** have been isolated from halophilic bacteria (13). More than 40 years ago unusual lipids were found in an extreme halophile, *Halobacterium cutirubrum*, which differed considerably from moderate halophiles and nonhalophilic bacteria (181,182). The major glycolipid in *H. cutirubrum* is the sulfated triglycosylarchaeol S-TGA-1 **256** (183,184), but minor amounts of the sulfated tetraglycosylarchaeol S-TeGA **258** are also present, as are two unsulfated glycolipids, **257** and **259** (185). The lipids of an extremely halophilic bacterium, *Halobacterium marismortui*, isolated from the Dead Sea, were found to contain 86% polar lipids and 14% nonpolar lipids. The major glycolipid detected was **257** (186). Species of the genera *Haloarcula* and *Haloferax* contain **257** and **257a**, and **255**, respectively (186,187).

The lipids of the halophilic eubacteria *Planococcus* H8 (NRCC 14037) and *Haloferax volcanii* were studied and found to be remarkably simple in their polar lipid content, with 49% phosphatidylglycerol and cardiolipin, and surprisingly, 51% of the anionic lipid sulfoquinovosyldiacylglycerol (SQDG) (188). SQDG is a sulfonolipid associated with plants, algae, and other photosynthetic organisms (13). *Haloferax volcanii* and *Planococcus* H8 produce the same classes of polar lipids, consisting of phosphoglycerols, sulfoglycolipids, and cardiolipins. Because the glycolipids of both microbes contain sulfur, they may have the potential to exhibit the properties of certain other sulfoglyco ligands in inducing phagocytosis by binding to the mannose receptor (189). The new sulfated diglycosyl lipid S-

GL-1 **260** was isolated from *H. volcanii* (188). A novel bis-sulfated glycolipid, **261**, has been isolated in Japan from a nonalkaliphilic extremely halophilic Archaebacterium, strain 172 (190).

260

261
The lipids of methanogenic bacteria consist of di- and tetraether glycerol. More than 40 complete structures of ether polar lipids from seven methanogenic species have been determined to date. The isoprenoid glycolipids **262–281** have been isolated from methanogens and their structures have been elucidated. The glycolipid **262** is common to all methanogenic species (191,192). Compounds of **262**, **263**, and **268** are major lipids in *Methanococcus voltae* (193). The caldarchaeol core was predominant in the total lipids of *Methanobacterium thermoautotrophicum* (up to 83%), and the structures of 15 lipids from *M. thermoautotrophicum* have been determined in this species (193–196). Thirteen of the 15 lipids are as follows: a bare archaeol (type **262**), a bare caldarchaeol (tetraether type), two glycolipids [gentiobiosyl (β-Glc(1-6)-β-Glc), archaeol **263**, and gentiobiosyl caldarchaeol], six phospholipids, and three phosphoglycolipids.

Methanococcus jannaschii is one of the extremely thermophilic methanogens that can grow at temperatures up to 86°C (197); it was isolated from the deep-sea hydrothermal vent in the East Pacific Rise (depth, 2,600 m). Because of the extreme thermophilicity of this bacterium, its lipids are very interesting. Besides the usual archaeol and caldarchaeol, a unique glycerol ether core lipid was identified in this organism. It was identified as a macrocyclic archaeol, in which a 40-carbon bifunctional 1,32-biphytanediyl (3,7,11,15,18,22,26,30-octamethyldotriacontamethylene) group was etherified at the *sn*-2 and *sn*-3 positions of the glycerol, forming a 36-member macrocyclic diether compound, **270**; lipids **271**–**274** also were isolated from this species (198).

The lipids of GP1 *(Methanospirillum hungateii),* GP6 *(Methanothrix soehngenii = Methanosaeta concilii),* and MS *(Methanosarcina barkeri),* all bacteria belonging to the Methanomicrobiales, have been isolated and their structures deter-

mined by physical and chemical methods. Kates and co-workers (199) reported the structures of polar lipids from *M. hungateii* GP1 in 1981 as the first methanogenic polar lipids. These lipids consist of two phosphoglycolipids (both tetraether type) and four glycolipids (two tetraether and two diether types). The glycosyl residues of the six lipids comprise only two species: β-glucopyranosyl(1→2)β-galactofuranosyl **282** and β-galactofuranosyl-(1→6)β-galactofuranosyl **283**. The occurrence of galactofuranose residues in glycolipids is uncommon, and the phosphate ester group of the phosphoglycolipids is *sn*-glycerol-3-phosphate. More recently, Sprott and co-workers (200) isolated **266**, **267**, and **282**–**290** glycolipids from *M. hungatei*. A new acid-labile glycerol ether lipid, **274**, was identified in *M. soehngenii* GP6 (also known as *Methanothrix concilii* and *Methanosaeta concilii*) (201). The cause of the lability of the lipid is the presence of a hydroxyl group bound at the 3′ position of the phytanyl chain linked to the *sn*-3 position of the core glycerol moiety. The hydroxyarchaeol core made up 30% of the total lipids. The structures of eight polar lipids, **263** and **274**–**280**, of *M. soehngenii* were determined (202,203). The major lipids were two diglycosylated lipids, **263** and **274** (which made up 59% of the polar lipids), and archaetidylinositol (which made up 24%). Glycolipids of this organism contained three kinds of hexose residues: glucose, galactose, and mannose.

De Rosa and co-workers (17) reported that the lipid core of *M. barkeri* DSM800 consists of diphytanyltetritol, caldarchaeol with various numbers of cyclopentane rings, glyceroarchaeol with hydrocarbon chains with 20 and 25 carbons, and a typical archaeol. The hydroxyarchaeol of *M. barkeri* resembles the hydroxyarchaeol from *M. soehngenii* but differs in the position of glycerol on which the hydroxyphytanyl group is linked. The 3′-hydroxyphytanyl chain is etherified at the *sn*-2 position of glycerol in *M. barkeri* **274** and at the *sn*-3 position in *M. soehngenii* **279**. Six phospholipids, seven amino phospholipids, and one glycolipid of *M. barkeri* MS have been identified, including the unusual "hybrid lipid" **304** (204).

Several strains of extremely halophilic Archaebacteria, both nonalkaliphilic and alkaliphilic, including *Halobacterium*, *Haloferax*, and *Natronobacterium* species, were isolated from salt locales in India, and their lipids have been studied (205). The *Halobacterium* strains possessed the characteristic glycolipids, sulfated triglycosyl diether **254** and tetraglycosyl diether **254a**, and the unsulfated triglycosyl diether **257**; the *Haloferax* strains had the characteristic sulfated and unsulfated diglycosyl glycerol diethers **255** and **263**.

Lipid **293** and its analog, R₁ = PO₂(OH)-glycerol, have been isolated from cells of the acidophilic, autotrophic, mesophilic, ferrous compound-oxidizing archaeon *Ferroplasma acidiphilum* strain YT (206).

Thermoplasma acidophilum, a wall-less mycoplasma-like thermoacidophilic archaeon, grows at 59°C and pH 2.0 as its optimal conditions. The membrane lipids consist of derivatives of a tetra-*O*-di(biphytanyl) diglycerol and a 2,3-di-*O*-phytanyl-*sn*-glycerol similar to the usual archaea. Three types of polar ether lipids were found in *T. acidophilum* HO-62: phospholipids, glycolipids, and phosphoglycolipids (207). The seven glycolipids had different combinations of gulose, mannose, and

glucose, which formed the mono- or oligosaccharides **291a–e; 292a,b;** and **293–303.** Although gulose is an unusual sugar in nature, several glyco- and phosphoglycolipids in *T. acidophilum* contained gulose as one of the sugar moieties. All the ether lipids had isopranoid chains of C_{40} or C_{20} with zero to three cyclopentane rings (207). In *T. acidophilum,* the main polar lipid is phosphoglycolipid, composed of caldarchaeol, gulose, and *sn*-3 glycerophosphate at a molecular ratio of 1 to 1 to 1 and comprising about 46% of the total lipids. The structures of other neutral glycolipids, **291a**, **291d**, **292b**, and **294–296**, all of which contain gulose and/or glucose, have been detected by Uda and co-workers (208,209).

All *Sulfolobus* are hyperthermophilic organisms and belong to the subkingdom of Crenarchaeotes. The first member of this group to be described was *Sulfolobus acidocaldarius* and was found by Brock and co-workers in 1972 in Yellowstone National Park (210). Many *Sulfolobus* strains have been found in terrestrial hydrothermal situations, mainly solfataric fields, in different parts of the world, for example, in the United States, Italy, Japan, Iceland, and New Zealand. They have been isolated from hot waters, mud pots, and the upper layers of soils with temperatures from 60 to 95°C and a pH of 1 to 5, and contain two major tetraether glycophospholipids, **305** and **306** (13,17,211,212).

Diglycerol tetraether lipids **306–312**, from thermoacidophilic Archaebacteria of the *Caldariella acidophila*, which grow in the temperature range of 75–89°C, with differently cyclized biphytanyl components have been detected (213–215).

ISOPRENOID ETHER BOLAFORM AMPHIPHILES

Over the past several years, various archaebacterial symmetrical or asymmetrical, acyclic or macrocyclic bipolar lipid analogs have been synthesized to investigate, from well-defined molecules, the membrane organizing and packing properties of some new classes of amphiphiles and the results obtained have been reported and partly reviewed (15–17,216,217).

Archaeal natural tetraether bipolar lipids are thought to span the membrane to form monolayers and allow the microorganisms to maintain their membrane integrity in harsh environments (15,17,212). These bipolar membrane-spanning lipids give rise to several model systems with advantageous properties, such as mechanically and thermally stable monolayers, artificial black membranes, and highly thermostable liposomes (212,218). The archaeal 36-membered macrocyclic diether (e.g., type **270**) phospholipid was studied by measuring its membrane fluidity, liposomal proton permeability, and liposomal thermostability in comparison with its acyclic counterpart, diphytanyl-PC, its glycolipid derivatives, egg yolk lecithin, and a mixed lipid of dimyristoylphosphatidylcholine (DMPC)–cholesterol (220). Fluorescence anisotropy measurements indicated that the macrocyclic structure led to a greater decrease in the fluidity of the intermembrane hydrophobic part than in the membrane surface by limiting the motional freedom of the

alkyl chains. The proton permeability was also significantly reduced by introducing a macrocyclic structure. Liposomal thermostability measurements using 6-carboxyfluorescein suggested that the 36-membered diether formed liposomes with greater thermal stability than those of diphytanyl-PC. The data obtained suggested that the cyclic structure contributed to the formation of stable liposomes, especially at higher temperatures. These findings clearly demonstrate that the 36-membered macrocyclic lipid membrane plays an important role for the thermophilic Archaea in adapting to extreme environments.

Symmetrical and unsymmetrical archaeal tetraether glycolipid analogs **313–317** have been synthesized, and these compounds represent the first examples of tetraether-type analogs containing a phosphate unit and/or glycosyl moieties (221–223). The self-assembling properties of a new series of archaeal tetraether glycolipid analogs, **313–317**, were studied and were characterized by a bipolar architecture with two similar or different glycosidic and/or phosphate polar heads and a lipid core possessing a cyclopentane unit and/or branched chains (222). Supramolecular aggregates of the neutral glycolipids **313**, **314**, and **317** were found to depend on both the saccharidic polar heads and the chain composition. The presence of one glycosidic residue with rather marked hydrophilic properties, such as the lactosyl moiety, was required to allow the formation of multilamellar vesicles. Surprisingly, the introduction of a cyclopentane unit in the bridging chain was able to induce an apparent two-by-two membrane association; this unusual behavior might be the result of unsymmetrical interfacial properties of the lipid layer caused by the presence of the cyclopentane unit. Asymmetrical phosphate derivatives spontaneously formed thermostable monolayered vesicles, but neutral glycolipids **317**, which contain a cyclopentane ring in the middle of the bridging chain, did not form monolayer associations. Bipolar surfactants possessing a single polymethylene bridging chain were found to self-organize into bilayered or monolayered vesicles, disks, or fibers depending on the symmetrical or asymmetrical structure of the lipids, the bridging chain length, the nature of the polar groups and also the structure of the spacers (223).

Liposomes obtained from archaebacterial ether lipids (or synthetic analogs) named archaeosomes demonstrate relatively higher stabilities to oxidative stress, high temperature, alkaline pH, and the action of phospholipases, bile salts, and serum proteins. Some archaeosome formulations can be sterilized by autoclaving, without problems such as the fusion or aggregation of vesicles. The uptake of archaeosomes by phagocytic cells can be up to 50-fold greater than that of conventional liposome formulations. Studies in mice have indicated that systemic administration of several test antigens entrapped within certain archaeosome compositions gives humoral immune responses that are comparable to those obtained with the potent but toxic Freund's adjuvant. Archaeosome compositions can be selected to give a prolonged, sustained immune response and to generate a memory response. Tissue distribution studies of archaeosomes administered *via* various systemic and peroral routes indicate the potential for targeting specific organs. All *in vitro*

and *in vivo* studies performed to date have indicated that archaeosomes are safe and do not invoke any noticeable toxicity in mice. The stability, tissue distribution profiles, and adjuvant activity of archaeosome formulations indicate that they may offer a superior alternative to the use of conventional liposomes, at least for some biotechnology applications (224,225).

PHENOLIC GLYCOLIPIDS

Phenolic glycolipids were discovered more than 50 years ago (226) and exhibit a fascinating diversity in their structures and biological activities (227). Smith and co-workers (226) studied lipid extracts of bovine and human tubercle bacilli by IR spectrometry and found aromatic substituents, named glycolipids G. More recently, these aromatic glycolipids were detected in *Mycobacterium bovis* and *Mycobacterium kansasii*. These glycolipids attracted great interest at first for the unusual structure of their lipid part, and then as potential tools to detect infections by *Mycobacterium tuberculosis*. The structure of the lipid aglycone moiety (phenolphthiocerol) was studied by Gastambide-Odier and co-workers (228,229). It is unusual because of its terminal phenol moiety, derived biosynthetically from tyrosine, which bears a long chain with two hydroxyl groups acylated by multimethyl-branched FA. Although some phenolglycolipids bear only one methyl rhamnoside residue (in *M. bovis* and *M. marinum*), others have oligosaccharides, one of them with a labile dideoxyhexose at its nonreducing end (in *M. kansasii*) (230).

In 1961, MacLennan and co-workers (231) reported the occurrence of 2-*O*-Me-fucose, 2-*O*-Me-rhamnose, and 2,4-di-*O*-Me-rhamnose in a specific glycolipid from a photochromogenic atypical mycobacterium (now called *M. kansasii*). Structural reinvestigation in 1970 by Gastambide-Odier and co-workers (229,232) and in 1981 by Hunter and Brennan (233) confirmed the oligosaccharide composition; however, the presence of 3-*O*-Me-fucose and 3-*O*-Me-rhamnose was also noticed by the former group. Finally, in 1984 the following

trisaccharide was proposed (234) as the tentative structure for the oligosaccharide moiety of the phenolic glycolipid: 2,4-di-*O*-Me-L-Rha*p*(l→4)2-*O*-Me-L-Fuc*p*(l→4)2-*O*-Me-L-Rha*p*1-R. The aglycon R residue was identified by Gastambide-Odier and co-workers (229,232) as a phthiocerol molecule mainly esterified by mycocerosic FA. *Mycobacterium kansasii,* the "yellow" bacillus, is an important etiologic agent of chronic pulmonary infections indistinguishable from tuberculosis. This disease is the most important clinical problem arising from nontuberculous mycobacteria (235). A recent study has demonstrated that the species-specific phenolic glycolipid of *M. leprae* triggers uptake into Schwann cells by interaction with laminin-2 and the α-dystroglycan receptor. This finding emphasizes the importance of lipids in the biology of mycobacterial infections and suggests possible strategies to combat nerve damage in leprosy (236).

The major phenolic glycolipids **318–331**, with different aliphatic chains and sugar moieties, have been isolated from *M. kansasii* and *M. gastri* (**318–321**), *M. bovis* (**320**), *M. leprae* (**322–324**), *M. tuberculosis* (Canetti strain, **325–327**), *M. marium*, *M. ulcerans* (**328**), and *M. haemophilum* (**329–331**) (237,238).

318 R = 2,6-dideoxy-4-O-Me-Ara	**325** R = 2,3,4-tri-O-tri-Me-Fuc
319 R = 2-O-Me-Fuc	**326** R = Rha
320 R = 2-O-Me-Rha	**327** R = 2-O-Me-Rha
321 R = 2,4-O-di-Me-Rha	**328** R = 3-O-Me-Rha
322 R = 3,6-O-di-Me-Glc	**329** R = 2,3-O-di-Me-Rha
323 R = 2,3-O-di-Me-Rha	**330** R = 2-O-Me-Rha
324 R = 3-O-Me-Rha	**331** R = 2,3-O-di-Me-Rha
Phenolic glycolipids **332** and **333**, acylated in the 19 and 21 positions by multimethyl-branched FA, have been isolated from *M. kansasii*, and also found in *M. gastri* (239–241). The novel phenolic glycolipids **334–338** were isolated from *M. tuberculosis*, as were their deacylated analogs (242).

332 R = A. R₁ = B
333 R = A. R₁ = C

334 R = Me, R₁ = H
335 R = R₁ = H
336 R = R₁ = Me

337 R = Me
338 R = H
MYCOLIC GLYCOLIPIDS WITH MULTIMETHYL-BRANCHED FA

Mycolic acids of mycobacterial glycolipids are complex hydroxylated branched-chain FA with elevated (from 60 to 90) carbon numbers, and they may also contain diverse functional groups such as an epoxy ester group or keto, methoxy, and/or cyclopropane ring(s) (243). These FA were isolated and named by Stodola and co-workers in 1938 (244) from a waxy extract of the human tubercle bacillus (*M. tuberculosis*). Their common structure was elucidated in 1950 by Asselineau and co-workers (245,246) and was shown to be formed of a β-hydroxy-α-alkyl branched chain. Both *M. tuberculosis* and *M. leprae*, the causative agent of leprosy, have been shown to add unique cyclopropyl groups to their mycolic acids (243). Mutations that affect cyclopropane groups of mycolic acids have been shown to render *M. tuberculosis* unable both to core and to cause a persistent infection in mice. The cyclopropane lipids appear to represent a unique virulence factor that protects pathogenic mycobacteria against an effective immune response. Also, some glycolipids based on trehalose containing the multimethyl-branched FA **339** and **340** have been isolated from *M. tuberculosis* (247,248).

Mycobacterium tuberculosis, the tubercule bacillus, was originally described by Robert Koch (249) and, characterized by its unusual staining properties, was proved to be the causative agent of tuberculosis. These acid-fast staining properties have been found to result from the unique lipid surface, which is predominantly long-chain mycolic acids. These FA are common to the entire genus of *Mycobacterium*, thus providing a unique signature for the species. The tuberculosis-specific drugs isoniazid and ethionamide have been shown to target the synthesis of these mycolic acids. Using a combination of genetic, biochemical, and X-ray crystallographic analyses, the target, InhA (long-chain enoyl acyl carrier protein reductase, an enzyme involved in the biosynthesis of mycolic acids),

has been identified and characterized. Specific inhibition of InhA induces the lysis of mycobacterial cells, thus defining a key Achilles heel for the mycobacterial species that has led to novel drug development. Furthermore, it is noticeable that mycolic acids were the first known CD1-presented antigen (250); also, mammalian T-cells can recognize a foreign lipid structure by a CD1-dependent mechanism (251,252). It is now recognized that mycolic acids are localized in the inner leaflet of the mycobacterial cell wall, either covalently bound or loosely associated with arabino-galactan polymers (253). Mycolic acids have been involved in maintaining a rigid cell shape, but they also contribute to the resistance to chemical injury and to the protection of cells against hydrophobic antibiotics.

340 PAT
SUMMARY

Carotenoids and their glycosides are important factors in human health and are essential for vision. The role of β-carotene and other carotenoids as the main dietary source of vitamin A is well known. Protective effects of carotenoids and their glycosides against serious disorders such as cancer, heart disease, and degenerative eye disease have been recognized and have stimulated intensive research into the role of carotenoids as antioxidants and as regulators of the immune response system.

Archaeal lipids are based on ether links, and their aliphatic components are isoprenic in nature. These molecules are the structural components of a new model of biological membrane in which a monolayer of bipolar lipids replaces the conventional bilayer of monopolar lipids universally present in the biological membranes. Archaeal bolaform lipids can be obtained from the membranes of microorganisms grown at optimal temperature and pH conditions. Diether archaeal lipids and/or their synthetic analogs behave quite similarly to the ester analogs, whereas tetraether lipids behave in a more complex way. In fact, a bolaform lipid can have a U-shaped disposition, with both heads in contact with the aqueous subphase, or it may assume a stretched configuration, with only one polar interface in contact with water. Some interesting properties of these bolaform lipids make them attractive candidates as drug or antigen delivery systems and as stable S-layer supported lipid films for functional membrane protein reconstitutions or supported membrane biosensor devices.

Mycobacteria, members of which cause tuberculosis and leprosy, produce cell walls of unusually low permeability, which contribute to their resistance to therapeutic agents. Phenolic glycolipids are unusual surface-active lipid surfactants found only in pathogenic mycobacteria. They are extremely hydrophobic, having a high portion of long-chain moieties and relatively hydrophobic sugars. Most of the hydrocarbon chains of these lipids assemble to produce an asymmetrical bilayer of exceptional thickness. Structural considerations suggest that the fluidity is exceptionally low in the innermost part of the bilayer and that it gradually increases toward the outer surface. Differences in mycolic acid structure may affect the fluidity and permeability of the bilayer and may explain the different sensitivity levels of various mycobacterial species to lipophilic inhibitors. Phenolic glycolipids play an important key role as an antigenic probe for the serodiagnosis of some human pathogen mycobacterial infections.

ABSTRACT: Although long-chain fatty acyl-coenzyme A (LCFA-CoA) thioesters are specific high-affinity ligands for hepatocyte nuclear factor-4α (HNF-4α) and peroxisome proliferator-activated receptor-α (PPARα), X-ray crystals of the respective purified recombinant ligand-binding domains (LBD) do not contain LCFA-CoA, but instead exhibit bound LCFA or have lost all ligands during the purification process, respectively. As shown herein: (i) The acyl chain composition of LCFA bound to recombinant HNF-4α reflected that of the bacterial LCFA-CoA pool, rather than the bacterial LCFA pool. (ii) Bacteria used to produce the respective HNF-4α and PPARα contained nearly 100-fold less LCFA-CoA than LCFA. (iii) Under conditions used to crystallize LBD (at least 3 wk at room temperature in aqueous buffer), 16:1-CoA was very unstable in buffer alone. (iv) In the presence of the respective nuclear receptor (i.e., HNF-4α and PPARα), LBD 70–75% of 16:1-CoA was degraded after 1 d at room temperature in the crystallization buffer, whereas as much as 94–97% of 16:1-CoA was degraded by 3 wk. (v) Cytoplasmic LCFA-CoA binding proteins such as acyl-CoA binding protein, sterol carrier protein-2, and liver-FA binding protein slowed the process of 16:1-CoA degradation proportional to their respective affinities for this ligand. Taken together, these data for the first time indicated that the absence of LCFA-CoA in the crystallized HNF-4α and PPARα was due to the paucity of LCFA-CoA in bacteria as well as to the instability of LCFA-CoA in aqueous buffers and the conditions used for LBD crystallization. Furthermore, instead of protecting bound LCFA-CoA from autohydrolysis like several cytoplasmic LCFA-CoA binding proteins, these nuclear receptors facilitated LCFA-CoA degradation.

Paper no. L9730 in *Lipids 40*, 559–568 (June 2005).

Abbreviations: 16:1-CoA, palmitoleoyl-coenzyme A; 17:0-CoA, *n*-heptadecanoyl-coenzyme A; aa, amino acid; ACBP, acyl CoA-binding protein; CoA, coenzyme A; HNF-4α (aa 1–455), full-length hepatocyte nuclear factor 4α; HNF-4α-E (aa 132–370), N- and C-terminal truncation mutant of HNF-4α comprising aa 132–410 (i.e., ligand-binding domain E, but missing the negative regulatory domain F and the DNA-binding domain); HNF-4α-E-F (aa 132–455), N-terminal truncation mutant of HNF-4α comprising aa 132–455 (i.e., ligand-binding domain E and negative-regulatory domain F, but missing the DNA-binding domain); HNF-4α-E-0.5F (aa 132–410), N- and C-terminal truncation mutant of HNF-4α comprising aa 132–410 (i.e., ligand-binding domain E, but missing half of the negative-regulatory domain F and all of the DNA-binding domain); LBD, ligand-binding domain; LCFA, long-chain fatty acid; LCFA-CoA, long-chain fatty acyl CoA; L-FABP, liver fatty acid-binding protein; MPD, 2-methyl-2,4-pentanediol; PPARα, peroxisome proliferator-activated receptor-α, RARα, retinoic acid receptor-α; RXRα, retinoid X receptor α; SCP-2, sterol carrier protein-2.

Two members of the nuclear receptor superfamily, hepatocyte nuclear factor-4α (HNF-4α) and peroxisome proliferator-activated receptor-α (PPARα), bind coenzyme A (CoA) thioesters of long-chain FA (LCFA, C_{14}–C_{22}) in *in vitro* binding assays (1–7). Although early radioligand competition binding assays showed these proteins exhibiting only weak affinities (i.e., μM K_i) for LCFA-CoA (1,6), subsequent direct fluorescence binding assays demonstrated that both HNF-4α (2–4) and PPARα (7) exhibited high affinities (i.e., low nM K_d) for LCFA-CoA. Furthermore, in the case of HNF-4α this high affinity for LCFA-CoA was dependent on the presence of an intact F domain C-terminal to the ligand-binding domain (LBD). Deletion of the F domain abolished LCFA-CoA binding and enhanced that of LCFA (4). The molecular basis for the discrepancy reported in affinities obtained between radioligand competition and fluorescence binding assays is based on the fact that radioligand competition assays are known to significantly underestimate the affinities of ligand-binding proteins for LCFA-CoA and LCFA (8,9). For example, cytoplasmic LCFA-CoA-binding proteins such as acyl-CoA-binding protein (ACBP), sterol carrier protein-2 (SCP-2), and liver FA-binding protein (L-FABP) exhibit M K_d in radioligand binding assays (reviewed in Refs. 8 and 10), whereas those obtained with fluorescence and titration calorimetry binding assays display a 100- to 1000-fold stronger affinity (10–13).

Although PPARα is widely recognized as a ligand-inducible nuclear receptor that is activated only when specific ligands (e.g., peroxisome proliferators, LCFA, nonhydrolyzable LCFA-CoA, etc.) are present in cells (reviewed in Refs. 5, 7, 14, and 15), the transcriptional activity of HNF-4α in the liver, intestine, or pancreas as a function of specific ligands has been highly debated. For instance, some authors considered HNF-4α to be a constitutively active and ligand-independent nuclear receptor, even though its modular structure includes the LBD (16). In contrast, other groups demonstrated that various LCFA (C_{14}–C_{22}) were able to modulate the transcriptional activity of HNF-4α by reporter gene assays in transfected COS-7 cells in culture (1,3). In addition, overexpression of fatty acyl CoA synthase enhanced the ability of LCFA to modulate the transcriptional activity of HNF-4α, whereas overexpression of fatty acyl CoA hydrolase inhibited the ability of LCFA to modulate the transcriptional activity of HNF-4α (1). Furthermore, it was shown that purified full-length HNF-4α and truncation mutants

with an intact LBD and C-terminal F domain had an affinity for the CoA thioesters of LCFA several orders of magnitude higher than for the corresponding free LCFA *in vitro* (1–4).

Despite the above data indicating that both PPARα and HNF-4α bind LCFA-CoA with high affinity, the crystal structures of the LBD of PPARα (17) and HNF-4α (18,19) do not contain endogenously bound LCFA-CoA. Instead, these truncated proteins contain either no endogenously bound ligand, as for the PPARα LBD (17), or, in the case of the HNF-4α LBD, contain constitutively bound LCFA that do not influence the open vs. closed conformational state of the HNF-4α LBD. However, LCFA-CoA is known to alter PPARα conformation, as demonstrated by circular dichroism (7), and a nonhydrolyzable LCFA-CoA analog is known to alter PPAR LBD conformation, as evidenced by sensitivity to protease digestion and the ability to bind to co-activators (7,20). Likewise, LCFA-CoA and nonhydrolyzable LCFA-CoA analogs (but not LCFA) alter the conformation of full-length HNF-4α as well the HNF-4α LBD containing the C-terminal F domain (2,4,21). Such ligand-induced conformational changes are a hallmark of ligand-activated nuclear receptors (reviewed in Refs. 2 and 22–25).

Although the molecular basis for the above discrepancies is not yet known, at least three possibilities may be considered: First, the level of endogenous LCFA-CoA may be very small as compared with that of LCFA in the bacteria used to produce the recombinant truncated PPARα and HNF-4α constructs. Second, the FFA detected within the binding site of HNF-4α LBD by X-ray crystallography may arise from residual LCFA formed by degradation of CoA thioesters during the crystallization process. Third, truncation of the C-terminal F domain, especially long in HNF-4α, significantly alters the ligand specificity of the recombinant N- and C-terminal truncation proteins used for crystallography (4). The purpose of the present work was: (i) to examine the relative proportions of LCFA-CoA and LCFA in the recombinant bacteria, (ii) to show the stability of LCFA-CoA in the context of protein crystallization conditions; (iii) to show the effect of nuclear receptors that bind LCFA-CoA, i.e., HNF-4α and PPARα, on LCFA-CoA stability; and (iv) to determine the stability of LCFA-CoA in the context of the cytoplasmic LCFA-CoA-binding proteins ACBP, SCP-2, and L-FABP.

MATERIALS AND METHODS

Materials. Palmitoleoyl-CoA (16:1-CoA) and *n*-heptadecanoyl-CoA (17:0-CoA) were purchased from Sigma Chemical Co. (St. Louis, MO). Protease inhibitor cocktail, ultralow range color markers for SDS-PAGE, gel filtration M.W. markers (range 6,500–66,000 Da), alkaline phosphatase conjugated goat anti-rabbit IgG, alkaline phosphatase conjugated rabbit anti-goat IgG, and 5-bromo-4-chloro-3-indolyl-phosphate/nitroblue tetrazolium (BCIP/NBT) for Western analysis were purchased from Sigma-Aldrich (St. Louis, MO). Protein concentration was determined by the Bradford method using Protein Assay Dye Reagent Concentrate purchased from Bio-Rad Laboratories (Richmond, CA).

Rabbit polyclonal anti-rat HNF-4-LBD antisera were prepared according to Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC) guidelines and further purified by affinity chromatography on protein-A-sepharose as described earlier (26). Rabbit polyclonal anti-mouse PPARα antibodies were from Affinity BioReagents (Golden, CO). Polyclonal antisera to murine recombinant L-FABP, human recombinant SCP-2 (12), and murine recombinant ACBP (28,29) were prepared as described (29) in the cited papers. The specificity of appropriate dilutions of the purified antibodies was determined as described earlier (30). None of the antisera cross-reacted with proteins other than the one against which the antisera were raised.

Expression and purification of recombinant full-length and deletion mutant forms of rat HNF-4α. The full-length rat HNF-4α [amino acids (aa) 1–455] and the N-terminal deletion mutant HNF-4α-E-F (aa 132–455) recombinant proteins were obtained as described previously (1,2). The cDNA of the rat C-terminal truncation mutant lacking the entire F domain, HNF-4α-E (aa 132–455) was obtained by PCR using the sense 5′-CATGC-CATGGGCAGCCATCATCATCATCATCACAGGTCAAGC-TACGAG and antisense 5′-GAAGATCTCTAGGCAGACC-CTCCAAG primers. Rat N-terminal His-tagged HNF-4α1 (aa 132–410) recombinant was prepared by PCR using the sense 5′-CATGCCATGGGCAGCCATCATCATCATCATCACAGGT-CAAGCTACGAG and antisense 5′-GAAGATCTCTAGGTG-GACATCTGTCC primers. The PCR products were cloned into pET11d plasmid. The recombinants plasmids were expressed in the *Escherichia coli* BL21(DE3)pLyS strain, and the His-tagged proteins were purified by affinity chromatography on nickel nitrilotriacetic resin (Qiagen, Chatsworth, CA) and stored at −70°C. Purity of the recombinant proteins was assessed by SDS-PAGE and Western blotting as described earlier (2–4).

Expression and purification of recombinant PPARα-ΔAB (aa 101–468). The cDNA encoding mouse PPARα with a deletion of the amino-terminal A/B domain (i.e., encoding PPARα aa 101–468) cloned into a $(His)_6$-tagged bacterial expression vector (pET-PPARα-ΔAB) was a gift from Dr. Noa Noy (Cornell University, Ithaca, NY) (31). Recombinant PPARα-ΔAB protein was expressed in BL21(DE3)pLysS strain of *E. coli* and purified by affinity chromatography with cobalt resin (BD Biosciences, Clontech, Palo Alto, CA) as described earlier (7). The purified recombinant PPARα-ΔAB protein eluting from the column was dialyzed against a buffer containing 10 mM Hepes (pH 8.0), 0.1 mM EDTA, 1 mM DTT, 400 mM KCl, and 10% glycerol, and stored in 25% glycerol at −80°C. Protein purity was assessed by SDS-PAGE and Western blotting as described earlier (7,31).

Expression and purification of recombinant ACBP, SCP-2, and L-FABP. Murine recombinant L-FABP (27), human recombinant SCP-2 (12), and murine recombinant ACBP (28,29) were purified as described in the cited papers. Protein purity was also determined by SDS-PAGE, silver staining, and Western blotting as described therein.

Analysis of LCFA-CoA content and distribution in purified recombinant HNF-4α and in E. coli cells expressing HNF-4α. After a known amount of 17:0-CoA internal standard was added

to each sample, total LCFA-CoA were extracted from purified full-length HNF-4α (aa 1–455), HNF-4α truncation mutants (i.e., HNF-4α-E, aa 132–370, and HNF-4α-E-F, aa 132–455), and cell homogenate of *E. coli* expressing full-length HNF-4α, by a solid-phase extraction procedure (32). The LCFA-CoA were then converted to fluorescent etheno CoA esters and resolved by HPLC with fluorescence detection (33). Comparison with the known standard LCFA-CoA in this procedure allowed determination of the total mass of LCFA-CoA/mg protein, mass of the individual LCFA-CoA species/mg protein, and relative percentage distribution of individual LCFA-CoA species basically as described earlier (34).

Analysis of free LCFA content of purified recombinant HNF-4α and E. coli expressing HNF-4. Purified full-length HNF-4α and bacterial cell homogenate were analyzed for total FFA using a Waco NEFA C test kit (Waco Chemicals USA, Inc., Richmond, VA) following the procedures provided by the manufacturer. A reagent blank, specimen blank, and standard curve with a known amount of FA were run as suggested.

Determination of HNF-4α protein concentration in E. coli expressing HNF-4α. *E. coli* cells expressing HNF-4α were lysed by sonication in the presence of protease inhibitor cocktail used for purification of His-tagged proteins from Sigma. The unbroken cells and debris were removed by centrifugation at $50,000 \times g$ for 10 min at 4°C. The supernatant was used to determine: (i) total protein by the BCA Protein Assay kit from Pierce (Rockford, IL) and (ii) HNF-4α protein by SDS-PAGE and Western blot analysis as described previously (2,26). Quantitative estimation of HNF-4α protein in Western blots was performed by densitometric analysis after image acquisition using a single-chip CCD (charge-coupled device) video camera and a computer workstation (IS-500 system; Alpha Innotech, San Leandro, CA). Image files were analyzed (mean 8-bit gray-scale density) using NIH Image (available by anonymous FTP). To obtain the HNF-4α protein concentration in the bacterial lysate supernatant samples, the HNF-4α pixel density in Western blots of bacterial lysate supernatant samples was compared with that of known amounts of pure recombinant His-tagged HNF-4α protein run as standards on the same blot.

Stability of LCFA-CoA under conditions used to crystallize N- and C-terminal truncation mutants of HNF-4α: Effect of ACBP. Equal concentrations of the three most prevalent cytosolic acyl-CoA binding proteins (ACBP, SCP-2, L-FABP), full-length HNF-4α (aa 1–455), HNF-4α-E-F (aa 132–455), HNF-4α-E-F (aa 132–410), and HNF-4α-E (aa 132–370) were individually incubated with 16:1-CoA (1:1 molar ratio of protein to 16:1-CoA) at room temperature in a buffer system previously described for HNF-4α-E (aa 132–382) crystallization [0.1 M sodium citrate, pH 8.0, 0.7 M ammonium acetate, 16% 2-methyl-2,4-pentanediol (MPD), and 10 mM DTT] (18). 16:1-CoA in buffer only was used as a blank for autohydrolysis in the absence of protein under the same conditions. After 1 d, 1 wk, and 3 wk, aliquots of the mixtures were taken and a known amount of 17:0-CoA internal standard was added to each sample as well as to a fresh aliquot of 16:1-CoA in buffer

without protein and without incubation. The amount of remaining 16:1-CoA was determined by extracting the 16:1-CoA using a solid-phase extraction procedure (32), converting the 16:1-CoA to fluorescent etheno CoA esters (33), and analyzing by HPLC with a fluorescence detector (33) as described earlier (34).

Stability of LCFA-CoA in the crystallization buffer used in PPARα LBD X-ray studies. PPARα-ΔAB or ACBP, both at 0.5 µM, were incubated with equimolar 16:1-CoA at room temperature in each of the following buffers previously used for PPARα LBD protein crystallization: (i) buffer 1 (5.5–9.6% PEG 35K, 50 mM di-ammonium hydrogen citrate, pH 4.9, 50 mM 1,3-bis-tris-propane (BTP), pH 7.0, 10% MPD (35); (ii) buffer 2 (10 mM Tris, pH 8.0, 75 mM sodium chloride, 5% glycerol, 0.5 mM tris-2-carboxyethyl)-phosphine hydrochloride, 1.6 M sodium formate, 50 mM Hepes, pH 7.5) (17). 16:1-CoA alone without added protein was used in each buffer for comparison. After 1 d, 1 wk, and 3 wk, aliquots of the mixtures were analyzed for remaining 16:1-CoA as compared with fresh 16:1-CoA controls and fresh 17:0-CoA that was added to each sample as an internal control. To determine the amount of each fatty acyl-CoA remaining, the fatty acyl-CoA were extracted by solid-phase extraction (33), converted to fluorescent etheno CoA esters, and analyzed by HPLC (33).

RESULTS

LCFA-CoA content of purified recombinant HNF-4α proteins. *In vitro* ligand-binding assays have clearly shown that recombinant full-length HNF-4α exhibits affinity for LCFA-CoA several orders of magnitude higher than LCFA in solution (1–4). Basically similar data are obtained with N-terminal truncation mutants containing the complete E and F domains (1–4). However, heretofore there have been no reports examining the presence of endogenously bound LCFA-CoA in purified recombinant full-length HNF-4α or in N-terminal truncation mutants of HNF-4α containing the complete E and F domains. Therefore, the content of LCFA-CoA in recombinant full-length HNF-4α (aa 1–455), as well as in its truncation mutants HNF-4α-EF (aa 132–455) and HNF-4α-E (aa 132–370), in solution was determined as described in the Materials and Methods section. However, no LCFA-CoA were detected in either the full-length HNF-4α (aa 1–455) or its truncation mutants containing the complete ligand-binding E and negative-regulatory F domains, i.e., HNF-4α-E-F (aa 132–455). Interestingly, the N-terminal and C-terminal truncation mutant HNF-4α-E (aa 132–370) also did not contain any detectable endogenously bound LCFA-CoA. The latter observation confirmed earlier data from X-ray crystals of such N- and C-terminal HNF-4α truncation mutants that contained bound LCFA, but not LCFA-CoA (18,19).

LCFA-CoA and free LCFA content of E. coli expressing the full-length HNF-4α. It is important to consider that not only the affinity for LCFA-CoA vs. LCFA but also the relative availability of the respective ligands in *E. coli* will contribute to the

type of endogenous ligand associated with HNF-4α and its mutants. Therefore, this possibility was examined in *E. coli* overexpressing the full-length HNF-4α. The contents of LCFA, LCFA-CoA, and HNF-4α were determined as described in the Materials and Methods section. As shown in Table 1, bacterial cells expressing the full-length HNF-4α contained 4.95 ± 0.62 nmol LCFA/mg total protein, equivalent to 396 ± 50 nmol LCFA/mg HNF-4α. When expressed on a molar basis, the molar ratio of LCFA/HNF-4α was 20:1. In contrast, *E. coli* contained much less LCFA-CoA, only 54.5 ± 4.5 pmol/mg total bacterial protein (Table 2). When expressed on the basis of HNF-4α content, this was equivalent to 4.36 ± 0.36 nmol LCFA-CoA/mg HNF-4α (Table 1). Thus, the molar ratio of LCFA-CoA/HNF-4α in bacterial extract was only 0.22:1.

LCFA-CoA composition of E. coli cells expressing HNF-4α. The acyl chain length and level of saturation of endogenous LCFA associated with HNF-4α constructs isolated from bacterial extracts differ substantially from that present in bacteria (3,18). For example, even though 16:0 and 18:1 are the most abundant LCFA present in *E. coli*, full-length HNF-4α (Hertz, R., personal communication), HNF-4α-E-F (aa 132–455) (3), or HNF-4α (aa 132–383) (19) contain 50–65% of 16:1, an LCFA barely detectable in bacteria (3,36). This finding cannot be explained simply on the basis of differences in affinities of the HNF-4α constructs (1–4). Instead, high endogenous 16:1 bound to HNF-4α constructs might reflect that in the bacterial LCFA-CoA pool, rather than in the LCFA pool. Hydrolysis of the bound LCFA-CoA during recombinant protein isolation could then account for the high endogenous 16:1 associated with the HNF-4α constructs. To examine this possibility, the acyl chain composition of bacterial LCFA-CoA was determined by HPLC analysis after solid-phase extraction of bacterial LCFA-CoA. The results showed that the most abundant LCFA-CoA was 16:1-CoA (34.9 ± 1.1%), followed by significantly less 16:0-CoA (13.8 ± 0.4%) and 18:1-CoA (25.8 ± 1.0%) (Table 2). Thus, the acyl chain composition of the bacterial LCFA-CoA pool, rather than that of the LCFA pool, re-

flected the acyl chain distribution of endogenously bound LCFA in recombinant HNF-4α constructs.

Stability of LCFA-CoA under protein crystallization conditions. Since X-ray crystallography detects only endogenous LCFA bound in N- and C-terminal truncation mutants of HNF-4α and HNF-4γ (19), it was concluded that only LCFA are endogenous ligands of HNF-4α and HNF-4γ (18,19). However, no data were provided supporting the assumption that LCFA-CoA were stable under the stringent crystallization conditions used therein. To begin to resolve this issue, the stability of 16:1-CoA under crystallization conditions (19) was tested, as described in the Materials and Methods section. In the crystallization buffer at 24°C, 16:1-CoA quickly decomposed. As quickly as 1 d at room temperature, 75% of the 16:1-CoA was degraded (Fig. 1A). Since crystals were typically formed over periods ranging in weeks, the stability was also examined after 1 and 3 wk. Only 13 and 6.6% of the 16:1-CoA remained intact after 1 and 3 wk, respectively (Fig. 1A). Thus, nearly 94% of 16:1-CoA was degraded by 3 wk, the time used for crystallizing the HNF-4α N- and C-terminal F domain truncation mutant (19). Thus, the instability of LCFA-CoA in solution, together with the lengthy isolation procedure required for isolating the recombinant proteins and, even more so, the 3 or more weeks at room temperature required for crystallization of such proteins, likely contributed to the lack of detectable endogenously bound LCFA-CoA therein.

Effect of HNF-4α (full-length and truncation mutants) on LCFA-CoA stability as compared with other LCFA-CoA-binding proteins under protein crystallization conditions. Although it has been hypothesized that cytosolic LCFA-CoA-binding proteins may protect LCFA-CoA from being hydrolyzed by intracellular esterases (reviewed in Refs. 8, 27, and 37), nothing is known regarding the effect of either cytosolic or nuclear LCFA-CoA-binding proteins on the autohydrolysis of LCFA-CoA in buffer alone, especially under protein crystallization conditions. To assess whether LCFA-CoA are protected from autodegradation in the buffer by association with a binding protein, the effects of several LCFA-CoA-binding proteins were examined.

First, the effect of intracellular LCFA-CoA-binding proteins such as ACBP, SCP-2, and L-FABP was examined. These cytosolic proteins bind LCFA-CoA with affinities in the order ACBP ≥ SCP-2 > L-FABP (reviewed in Refs. 8, 9, 11, and 12). When these proteins were individually incubated at 1:1 molar ratio with 16:1-CoA under conditions used to crystallize HNF-4α (i.e., crystallization buffer at room temperature), only the

TABLE 2
Composition of LCFA-CoA Thioesters of *E. coli* Cells Expressing Recombinant Rat HNF-4α[a]

LCFA-CoA	%	LCFA-CoA	%
16:0	13.8 ± 0.4	18:1	25.8 ± 1.0
16:1	34.9 ± 1.1	20:0	12.1 ± 1.4
18:0	5.8 ± 0.9		

[a]For abbreviations see Table 1.

highest-affinity proteins (ACBP, SCP-2) significantly reduced, but did not completely prevent, 16:1-CoA hydrolysis (Fig. 1B). The lower-affinity protein L-FABP was without effect (Fig. 1B). After 1 d in the presence of ACBP, SCP-2, or L-FABP, the majority of LCFA-CoA was degraded: 63, 65, and 80%, respectively (Fig. 1B). Thereafter, at longer incubation times only ACBP significantly protected 16:1-CoA from hydrolysis, albeit 81% of available 16:1-CoA was still hydrolyzed after 3 wk (Fig. 1B).

Second, the effects of the nuclear receptor HNF-4α (full-length) and HNF-4α deletion mutants on LCFA-CoA stability were similarly tested. Although full-length HNF-4α (aa 1–455) exhibits high affinity (i.e., nM K_d) for LCFA-CoA in *in vitro* binding assays (2–4), this did not protect LCFA-CoA from degradation. Instead, full-length HNF-4α (aa 1–455) enhanced hydrolysis as compared with incubation in the buffer alone: nearly 10-fold accelerated conversion of LCFA-CoA to free LCFA within 1 d of incubation and total degradation at longer incubation times (Fig. 1A). Similarly, the N-terminal DNA-binding domain deletion construct, i.e., HNF-4α-E-F (aa 132–455), also exhibits high affinity (i.e., nM K_d) for LCFA-CoA in *in vitro* binding assays (2–4), but it did not protect LCFA-CoA from degradation. Instead, 16:1-CoA hydrolysis was enhanced ninefold within 1 d of incubation, followed by total degradation at longer time points (Fig. 1A). Surprisingly, the N-terminal and partial C-terminal F domain deletion construct, HNF-4α-E-0.5F (aa 132–410), showed some protection against 16:1-CoA hydrolysis during the first day of incubation but not thereafter, since 16:1-CoA was degraded to the same high extent as in the crystallization buffer only at longer incubation times (Fig. 1A). The N-terminal and C-terminal F domain deletion construct, HNF-4α-E (aa 132–370), comprising only the LBD, only weakly binds LCFA-CoA in *in vitro* binding assays (4) and had no or little effect on LCFA-CoA degradation. At 1 d and 1 wk of incubation, 16:1-CoA hydrolysis was the same in the presence of HNF-4α-E (aa 132–370) as for buffer alone. Only at 3 wk incubation did HNF-4α-E (aa 132–370) slightly enhance 16:1-CoA hydrolysis as compared with buffer alone.

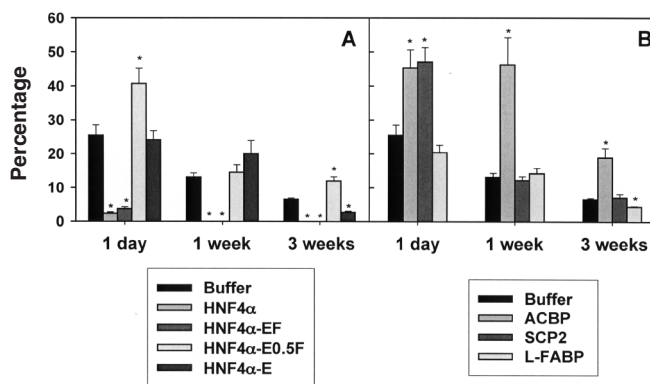
Stability of LCFA-CoA in the presence of PPARα vs. ACBP. To determine whether the unusual effect of HNF-4α to enhance LCFA-CoA degradation was a unique feature of this nuclear regulatory protein, the effect of another nuclear receptor that binds LCFA-CoA, i.e., PPARα (7,20), on LCFA-CoA stability was examined. Despite the high affinity (very low nM K_d) PPARα displays for LCFA-CoA, endogenously bound LCFA-CoA have also not been detected in X-ray crystal structures of PPARα LBD (17,35). To begin to address this issue, the possibility that LCFA-CoA are unstable under PPARα crystallization conditions was considered. To test the stability of LCFA-CoA under crystallization conditions, aliquots of 16:1-CoA were incubated in the absence or presence of added LCFA-CoA binding protein (i.e., PPARα or ACBP) in two types of buffers previously used to crystallize recombinant PPARα-LBD protein as described in the Materials and Methods section (17,35).


FIG. 1. Long-chain fatty acyl-coenzyme A (LCFA-CoA) stability under hepatocyte nuclear factor 4α (HNF-4α) crystallization conditions. 16:1-CoA was incubated in HNF-4α crystallization buffer (as described in the Materials and Methods section) in the absence or presence of proteins known to have affinity for LCFA-CoA, in a molar ratio of 1:1, for various time periods (1 d to 3 wk). (A) Percentage of 16:1-CoA recovered after incubation with full-length HNF-4α or truncated forms of HNF-4α, such as HNF-4α-E-F [amino acids (aa) 132–455; ligand-binding domain (LBD) E and negative-regulatory domain F, but missing the DNA-binding domain], HNF-4α-E-0.5F (aa 132–410; LBD E, but missing half of the negative-regulatory domain F and all of the DNA-binding domain), and HNF-4α-E (aa 132–370; LBD E, but missing the negative regulatory domain F and the DNA-binding domain). (B) Percentage 16:1-CoA recovered after incubation with acyl CoA-binding protein (ACBP), sterol carrier protein-2 (SCP-2), or liver FA-binding protein (L-FABP).

Solid-phase extraction was then used to determine the proportion of intact vs. hydrolyzed 16:1-CoA, as described in the Materials and Methods section.

In the absence of added LCFA-CoA binding protein (i.e., PPARα or ACBP), LCFA-CoA was very unstable in the incubation buffers and conditions (room temperature) used to crystallize PPARα LBD. Within 1 d of incubation, 70–75% of the 16:1-CoA was degraded (Figs. 2A,B). By 1 wk, 85–88% of the 16:1-CoA was degraded, and by 3 wk 86–97% was hydrolyzed (Fig. 2B). These data suggest that by the end of 3–6 wk, typical conditions used to crystallize the PPARα LBD protein, almost no LCFA-CoA would remain intact. However, it must be considered that protein-bound ligands are typically thought to be more stable in solution than free ligands. Therefore, the aforementioned experiments with the two crystallization buffers were repeated in the presence of LCFA-CoA binding proteins (i.e., PPARα or ACBP).

Recently, it was shown that PPAR is a nuclear receptor that binds LCFA-CoA (15) with very high affinity (low nM K_d) (7). However, the data indicate that in the presence of the LCFA-CoA binding protein PPARα, 16:1-CoA was not protected from degradation (Fig. 2). Instead, depending on the buffer used and the time period examined, PPAR enhanced 16:1-CoA degradation by 2- to 10-fold (Fig. 2). In any case, by 3 wk of incubation all of the 16:1-CoA was degraded in the presence of PPARα, regardless of the buffer used.

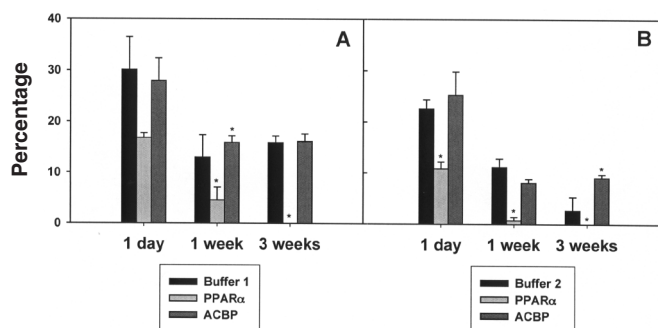
Although ACBP is primarily a cytosolic protein, low


FIG. 2. LCFA-CoA stability under peroxisome proliferator-activated receptor-α (PPARα) crystallization conditions. 16:1-CoA was incubated in two different buffers that were previously used to crystallize the PPARα LBD (as described in the Materials and Methods section) in the absence or presence of PPARα and ACBP. (A) Buffer 1, as described in the Materials and Methods section. (B) Buffer 2, as described in the Materials and Methods section. For other abbreviations see Figure 1.

amounts of ACBP are detected in nuclei, where it interacts with nuclear receptors to influence transcriptional activity (26). Similar to PPARα, ACBP exhibits very high affinity (very low nM K_d) for LCFA-CoA (8,11,38). In contrast to PPARα, however, ACBP did not accelerate LCFA-CoA degradation but, depending on the buffer used, actually protected 16:1-CoA from hydrolysis. In buffer 2 (Fig. 2B), but not buffer 1 (Fig. 2A), ACBP protected 16:1-CoA from degradation at long time points, i.e., 3 wk, but not at short time points. As shown above, ACBP was even more protective of 16:1-CoA degradation in another buffer (i.e., 0.75 M ammonium phosphate, pH 5.0, and 10 mM DTT) used to crystallize HNF-4α truncation mutants (Fig. 1B).

DISCUSSION

Despite the importance of nuclear receptors such as HNF-4α and PPARα in glucose and FA metabolism, relatively little is known regarding the nature of the endogenous ligands, and in particular LCFA-CoA associated with these proteins.

A wide body of evidence is consistent with LCFA-CoA as putative endogenous, physiologically significant ligands of these nuclear receptors: (i) *In vitro* ligand-binding assays performed with the respective full-length proteins (or their N-terminal truncation constructs containing intact C-terminal F domains) clearly demonstrate that these nuclear receptors bind LCFA-CoA in aqueous buffers with equal (PPARα) (7,20) or considerably higher (HNF-4α) (2–4) affinities than exhibited for LCFA. (ii) The nM K_d obtained for LCFA-CoA binding by direct fluorescence binding assays (2–4,7) are in the same range as the concentration of LCFA-CoA in the nucleus of living cells (34). (iii) LCFA-CoA, but not LCFA, alter the conformation of HNF-4α (1–4,21) and PPARα (7,20). However, under other *in vitro* conditions only slight (39) or no (16) effects on conformation of HNF-4α were observed. (iv) Normal LCFA-CoA and nonhydrolyzable LCFA-CoA modulate the transactivation of HNF-4α in living cells (3,4,38). (v) Several investigators used purified recombinant HNF-4α to show that LCFA-CoA,

but not LCFA, regulate HNF-4α homodimer formation and DNA binding (gel mobility shift) *in vitro* (1,40). This action is analogous to LCFA-CoA regulating the binding of Fad-R (an *E. coli* DNA-binding protein) to its cognate DNA response element *in vitro* (41). However, the finding that LCFA-CoA regulates HNF-4α homodimer formation and DNA binding may depend on the exact conditions used for this *in vitro* assay (16,39). (vi) Recombinant purified PPARα has been used to show that LCFA-CoA or nonhydrolyzable LCFA-CoA analog binding increases PPARα co-activator recruitment (7). (vii) Manipulation of cellular LCFA-CoA levels affects HNF-4α transcriptional activity consistent with LCFA-CoA being endogenous HNF-4α ligands: Fatty acyl-CoA synthase overexpression enhances HNF-4α-mediated transactivation, whereas overexpression of fatty acyl-CoA hydrolase inhibits HNF-4α-mediated transactivation in living cells (1). Also, treatment with the fatty acyl-CoA synthase inhibitor triacsin C prevents suppression of HNF-4α transcriptional activity by inhibitory proligands (3).

In contrast to these findings, X-ray crystallographic analysis does not detect the presence of LCFA-CoA as endogenously bound ligands in HNF-4α and PPARα. Unfortunately, the X-ray crystallographic studies are limited by the inability to crystallize the full-length HNF-4α and PPARα. Thus, all available data were obtained with truncation mutants missing the DNA-binding domain and all or most of the C-terminal F domain. For example, X-ray analysis of crystalline recombinant LBD of both PPARα (17,35) and HNF-4α (18,19) does not contain any endogenously bound LCFA-CoA. In the case of PPARα, it is not yet completely clear whether the absence is due to the fact that the truncated nuclear receptors used for X-ray crystallography do not reflect the properties of the full-length PPARα or whether other factors contribute to the loss of LCFA-CoA. With regard to crystals of HNF-4α-E (i.e., the LBD) missing both the N-terminal DNA-binding domain and most of the C-terminal F negative regulatory domain, these crystals contain bound LCFA but not LCFA-CoA (18,19). *In vitro* binding assays performed in solution show that the truncated HNF-4α-E only binds LCFA with high affinity, but not LCFA-CoA (4), opposite to what was observed with the full-length HNF-4α or constructs containing the intact C-terminal F negative regulatory domain (2–4). In summary, the X-ray crystallographic findings with truncated proteins in the absence of water may not necessarily accurately reflect the endogenously bound ligand distribution of the respective full-length proteins in solution. As shown in the present investigation, several additional properties of LCFA-CoA and the nuclear receptors themselves also contribute to the inability to detect endogenously bound LCFA-CoA in these proteins.

First, the acyl chain distribution of the endogenously bound LCFA (3,18,19) reflected that of the bacterial LCFA-CoA pool (Table 2) rather than that of bacterial LCFA (3,18,19). Analysis of the LCFA associated with a variety of HNF-4α constructs revealed that 16:1 accounted for 50–65% of the total acyl chains of wild type HNF-4α (3,18,19). Although bacterial LCFA are enriched in 16:0 and 18:1, the level of 16:1 is barely

detectable in bacterial LCFA (3,18,19). In contrast, within the bacterial LCFA-CoA pool the 16:1-CoA was the single most prevalent LCFA-CoA (present data).

Second, the relative proportions of LCFA-CoA and LCFA in the recombinant bacteria heavily favored the availability of LCFA over LCFA-CoA for binding to the recombinant nuclear receptor proteins and their truncation mutants. The bacteria contained nearly 100-fold more LCFA than LCFA-CoA. Furthermore, the total concentration of LCFA-CoA was so low as to be sufficient for binding to only 20% of the available HNF-4α. Thus, even if the endogenous LCFA-CoA was not degraded during isolation of the respective recombinant proteins or by the nuclear receptors themselves, the vast majority of available nuclear receptor ligand-binding sites would be expected to be occupied by LCFA rather than LCFA-CoA.

Third, LCFA-CoA were unstable in the aqueous buffers used to isolate HNF-4α and PPARα or to crystallize the respective N- and C-terminal truncation mutants of HNF-4α and PPARα. Nearly 75–80% of LCFA-CoA was degraded by 1 d incubation in buffer alone. By 3 wk or longer, the incubation typically required to obtain crystalline protein, more than 97% of LCFA-CoA was degraded. Thus, the intrinsic instability of LCFA-CoA thioesters in aqueous buffers alone can significantly contribute to the inability to detect endogenously bound LCFA-CoA in the full-length nuclear receptors in solution or in crystals of truncation mutant proteins.

Fourth, although it is commonly assumed that bound ligands are more stable than in solution, this was the case for cytoplasmic LCFA-CoA binding proteins, but not the nuclear LCFA-CoA binding proteins. For example, the cytoplasmic LCFA-CoA-binding proteins ACBP, SCP-2, and L-FABP bound and protected LCFA-CoA from degradation directly in proportion to their relative affinities for this ligand. ACBP exhibits not only the highest affinity for LCFA-CoA in this group (reviewed in Refs. 8, 11, and 38), but was the most protective of LCFA-CoA hydrolysis. In fact, freshly isolated recombinant ACBP contains some detectable endogenously bound LCFA-CoA (42). In contrast, neither HNF-4α nor PPARα protected LCFA-CoA from degradation, but instead significantly accelerated LCFA-CoA hydrolysis by nearly 10- and 2-fold, respectively, within 1 d of incubation. Longer incubation periods reduced LCFA-CoA levels to almost nothing. Therefore, it is not surprising that despite the high affinities of full-length HNF-4α (aa 1–455) for LCFA-CoA, lipid extraction of full-length HNF-4α (aa 1–455) or HNF-4α truncation mutants and subsequent analysis did not detect the presence of endogenously bound LCFA-CoA (3,4,18,19). Instead, endogenously bound LCFA was detected even though LCFA is a much lower-affinity ligand for the respective proteins.

Together, the latter findings suggest that this enzymatic activity of nuclear receptors could operate to shut down LCFA-CoA-induced transcription activation/inhibition by LCFA-CoA processing such that it would not further affect the transcription activation function. Most models of molecular mechanisms underlying the ligand-induced activation function of nuclear receptors do not explain how the ligand effect is dimin-

ished and eliminated after the fact of modulation. Several possibilities could be considered: (i) The ligand is chemically modified (esterified, hydrolyzed, etc.) so that its binding in the LBD is reduced. In this case, the enzymatic activity required to modify the bound ligand could either be the nuclear receptor itself (as shown herein for HNF-4α and PPARα) or an entirely different protein proximal to it; (ii) complex formation of nuclear receptor molecules with co-activators/co-repressors may induce further conformational changes of the nuclear receptor, resulting in reduced affinity for the ligand and even its release from the binding site. Our data demonstrated that, like HNF-4α, PPARα hydrolyzed LCFA-CoA to free LCFA, and the effect of the catalytic activity of these nuclear receptors on the ligand-induced transcriptional activation function deserves further study. Taken together, these findings may help to explain the absence of endogenously bound LCFA-CoA, the presence of endogenously bound LCFA, and the acyl composition of the endogenously bound LCFA detected in a variety of recombinant HNF-4α proteins (3,19).

Finally, although the exact identity and structure of the esterase sites in HNF-4α and PPARα remain to be determined, comparisons with known long-chain acyl-CoA hydrolases/thioesterases may provide some insights. Long-chain acyl-CoA hydrolases/thioesterases are enzymes that catalyze the hydrolysis of fatty acyl-CoA to the corresponding FFA and CoA. Long-chain acyl-CoA hydrolases from rat liver microsomes (43,44), from rat liver and brain cytosol (45,46), and from rat liver mitochondria and peroxisomes (47,48) have been purified and characterized, demonstrating a wide variety of structures and mechanisms of catalysis. The long-chain acyl-CoA hydrolases from liver and brain cytosol are serine or cysteine-dependent esterases with a catalytic triad consisting of a nucleophile (serine or cysteine), an acidic group (aspartic or glutamic acid), and a histidine (43,46). Other forms of acyl-CoA hydrolases like those found in mitochondria and peroxisomes have an active site serine motif (Gly-X-Ser-X-Gly) common to carboxyl esterases and lipases in general (47,48). Although the existing X-ray crystal structures do not provide structural data on the F domain in HNF-4α (19,49) or in HNF-4γ (coded by a completely different gene and sharing only 37% sequence homology in the F domain with that of HNF-4α) (18), structural and sequence comparison with other long-chain acyl-CoA hydrolases/thioesterases suggests several possibilities comprising a potential hydrolytic/esterasic site. With regard to the catalytic motif of typical esterases containing a Gly-X-Ser-X-Gly motif, analysis of the full-length HNF-4α aa sequence indicated that there was no Gly-X-Ser-X-Gly motif within the LBD E (aa 132–370), the negative regulatory domain F (aa 371–455), or in any other parts of the protein. However, several residues of Ser, Cys, Glu/Gln, Asp/Asn, and His were present within the LBD E (aa 132–370) and the negative regulatory domain F (aa 371–455), suggesting that the acyl-CoA hydrolytic activity of HNF-4α may be explained by a coordinated action of Ser/Cys, Glu/Gln (or Asp/Asn), and His residues forming a 3-D triad positioned around the acyl-CoA thioester linkage. These aa can be separated by a variable number of aa, as long as the active

head groups are in the proper orientation to form a triad. The data presented herein demonstrated that only full-length HNF-4α (aa 1–455) and the truncation mutant containing the entire F domain (aa 132–455) exhibited acyl-CoA hydrolysis. In contrast, the truncation mutants containing a small part of the F domain (i.e., aa 132–410) or no F domain at all (i.e., aa 132–370) had no hydrolytic activity. Examination of the X-ray crystal structure of a truncated HNF-4α comprising the LBD (aa 132–382) (19,49) suggests that Cys246 and Glu184 are close to the carboxylic end of the FFA within the FA binding site. Only one histidine residue (His218) is present in the LBD (aa 132–382), but this residue is not close to the bound FA or FA carboxylate. Instead, the His involved in the catalytic activity could be provided by a histidine-rich sequence within the F domain (i.e., aa 371–455 containing His375, His377, His378, His381, His383, His388, and His402). The fact that the HNF-4α truncation mutant consisting of aa 132–410 did not exhibit acyl-CoA hydrolysis indicated that at least one of the three amino acids of the catalytic triad was missing. The HNF-4α F domain contains six serine residues (Ser427, Ser430, Ser432, Ser434, Ser436, and Ser452) and two Glu residues (Glu422 and Glu435) in the region between aa 411 to 455. These considerations would suggest that one or more of these Ser and/or His residues in the F domain, together with a Glu residue in the LBD E, could form a 3-D catalytic triad that accounts for the esterasic activity of HNF-4α.

Analysis of the PPARα aa sequence and structure (17) also suggests several possible esterasic motifs: (i) Analysis of the aa sequence of the LBD of PPARα reveals a potential SerX-HisXAsp motif (i.e., aa 414–418). However, as for the HNF-4α LBD, the crystal structure shows that these amino acids are not in the proper orientation/proximity to form an active esterase triad. (ii) Another potential esterase motif comprising Cys, Glu, His, and Asp is found at aa 191–194 of the PPARα (within the DNA-binding domain). However, since this region has not been crystallized, it is impossible to determine the orientation of the amino acids. Further, the presence of this region within the DNA-binding domain would suggest that it is not responsible for the acyl-CoA hydrolysis noted with the PPARα. (iii) Another potential esterase motif that may account for PPARα hydrolytic activity is composed of Gly, Ser, and Gly with one to two aa between them (50). Although a similar glycine- and serine-rich motif is present in the A/B domain of PPARα, comprising aa 42–50 (GlyXXSerSerGlySerXGly), this region is outside the area used for the crystallization studies and the recombinant protein used for the experiments described herein. Therefore, it is unlikely that this region was responsible for the acyl-CoA hydrolysis demonstrated in the Results section. (iv) Finally, a conserved motif of Cys, His, and Cys (formed by orientation rather than sequence order) has been suggested to serve as the catalytic site for thiolases (51). Examination of the X-ray crystal structure of PPARα reveals the presence of such a motif comprised of C278 folding in to interact with H274 and C275. The orientation of this motif and its location within the ligand-binding site suggests that this may represent an active thiolytic site. In summary, although the exact structure and location of the esterase sites in HNF-4α and PPARα are not known, examination of the respective aa sequences and available structures of truncation mutants of these proteins suggests several possible motifs consistent with those of known fatty acyl-CoA hydrolase/esterase enzymes.

ABSTRACT: We investigated the changes in human LDL primary and secondary lipid oxidation products and modification of the apolipoprotein B-100 (apoB-100) secondary structures during Cu^{2+}-mediated oxidation by FTIR spectroscopy in the presence of catechin, quercetin, and α-tocopherol at physiological concentrations. Catechin- and quercetin-containing samples had slower rates and longer lag phases for conjugated diene hydroperoxide (CD) formation than α-tocopherol-containing samples; however, all antioxidant-treated LDL samples generated similar CD levels ($P < 0.05$). A lower maximum (98.4 nmol/mg LDL protein) of carbonyl compounds was produced in the quercetin- and catechin-treated samples than in α-tocopherol samples. Modification of the apoB-100 secondary structures corresponded closely to the formation of carbonyls and was hampered by the presence of antioxidants. Physiological concentrations of catechin and quercetin offered similar levels of protection against modification by carbonyls of the apoB-100 at advanced stages (carbonyls ~96.0 nmol/mg LDL protein) but not at the intermediate stages (carbonyls ~58.0 nmol/mg LDL protein) of LDL oxidation probably owing to differences in the protein-binding mechanisms of catechin and quercetin. Relationships between peroxide formation, carbonyl products, and LDL protein denaturation were shown by the FTIR approach. The FTIR technique provided a simple new tool for a comprehensive evaluation of antioxidant performance in protecting LDL during *in vitro* oxidation.

Paper no. L9776 in *Lipids 40*, 569–574 (June 2005).

Oxidation of human LDL occurs *in vivo*, and oxidatively modified LDL seem to play a crucial role in several degenerative diseases, including atherosclerosis (1). One possible oxidative mechanism involves LDL PUFA peroxidation initiated by free radicals (2). The lipid hydroperoxides so formed cleave to form highly reactive aldehydes that react with lysine residues on the LDL apolipoprotein B-100 (apoB-100). These apoB-100 changes, and possibly other LDL oxidation-related changes, increase LDL recognition and uptake by the scavenger receptors on macrophages and decrease LDL uptake by the hepatic

apoB/E receptor (LDL receptor), which is primarily responsible for removing LDL from the circulation. These alterations are believed to be associated with the development of atherosclerosis (2).

Dietary intake of antioxidants such as vitamin E and flavonoids influences lipoprotein metabolism (3). Dietary flavonoids of significance include the flavonol quercetin, which is found in apples, onions, tea, and red wine, and the flavan-3-ol catechin, which is one of the most abundant flavonoids in foods especially in green tea and red wine (4). Epidemiological studies show an inverse relationship between dietary or plasma levels of naturally occurring antioxidants such as vitamin E (5), catechin, and quercetin (6) and the incidence of stroke or coronary artery disease. Vitamin E, catechin, and quercetin are chain-breaking free radical scavengers and prevent lipid peroxidation and modification of LDL proteins both *in vitro* and *in vivo* (7).

The progression of LDL oxidation and the influence of antioxidants on LDL oxidation have previously been followed by measuring the formation of either hydroperoxide or carbonyl groups. IR spectroscopy has also been used to investigate apoB-100 modifications during LDL oxidation and provide insight into the changes in the α-helix, β-sheet, and β-turn structures (8). This technique is rapid, requires only a small sample, and provides information on functional group composition. We have demonstrated that FTIR can be used to quantify LDL lipid primary and secondary oxidation products as well as changes in LDL protein conformations (9). Studies that simultaneously measure the primary and secondary oxidation products of lipoprotein lipids and of apoB-100 conformational changes and their interrelation are rare. Given that the apoproteins are recognition factors for LDL uptake, protection of their integrity may be of paramount concern in ameliorating arteriosclerosis. Therefore, the relative efficacy of a given antioxidant in protecting apoB conformation against lipid oxidation needs investigation. It is unknown how changes in LDL lipids and apoB-100 structural conformations proceed during LDL oxidation in the presence of antioxidants such as vitamin E and flavonoids.

In the present study, we used the FTIR techniques developed in our laboratories (9) in combination with band-fitting procedures to simultaneously evaluate the production of primary and

secondary oxidation products and apoB-100 modifications in the presence of the antioxidants quercetin, catechin, and α-tocopherol during LDL oxidation. Integrated intensities of the fitted component of LDL spectral bands were measured and analyzed to obtain the relative concentrations of the LDL lipid components and protein conformational structures.

The objective of this study was to measure by FTIR the formation of lipid hydroperoxides and carbonyls, the modification of apoB-100, and the effectiveness of α-tocopherol, quercetin, and catechin on the rate of *in vitro* LDL oxidation at reported physiologic concentrations.

EXPERIMENTAL PROCEDURES

Materials. Quercetin (3,3′,4′,5,7-pentahydroxyflavone) dihydrate, (+)-catechin hydrate, and (±)-α-tocopherol were obtained from Sigma-Aldrich (St. Louis, MO).

LDL isolation. Blood samples from five fasting human males were obtained in vacutainers containing 1 mg/mL EDTA and centrifuged for 10 min at $2000 \times g$ and 4°C to separate the plasma. Human LDL were isolated from the fresh human plasma by sequential floating ultracentrifugation, according to the method described by Lam *et al.* (9). The protein content of LDL was determined according to Lowry *et al.* (10) with BSA as a standard. LDL samples were desalted to remove EDTA using 3.5-mL PD-10 gel filtration columns (Supelco, Bellefonte, PA) pre-equilibrated with phosphate buffer (pH 7.4) immediately before the oxidation study.

In vitro LDL oxidation. Prior to oxidation, all LDL samples were diluted to a final concentration of 50 μg of protein/mL with EDTA-free phosphate buffer (pH 7.4). The *in vitro* oxidation of LDL was performed in the absence (control) or presence of 0.5 μM quercetin, 2.0 μM catechin, and 0.05 μM α-tocopherol (in ethanol) per mg LDL protein, as previously described (9). The concentrations of quercetin, catechin, and α-tocopherol used in this study corresponded to those reported in human plasma (4,11,12) and will from here on also be referred to as their physiological concentrations. Oxidation was initiated by adding freshly prepared $CuCl_2 \cdot 2H_2O$ solution (final concentration 5 μmol/L) in duplicate samples at 37°C. The LDL samples from the five donors were incubated individually.

IR spectroscopy. Duplicate 30-μL aliquots, taken every 5 min for 6 h from LDL incubated at 37°C, were evenly spread on one side of a multi-bounce attenuated total reflectance (ATR) window (Thermo Electron Corp., Madison, WI). The aliquots were allowed to dry under a steady stream of nitrogen to produce films (9). The spectra of the phosphate buffer containing the antioxidants were collected under the same conditions as the LDL sample spectra. FTIR spectra of the films were recorded at 22°C using a Nexus 670 spectrometer (Thermo Electron Corp.) equipped with a deuterated triglycine sulfate detector scanning over the frequency range of 4000–400 cm^{-1} at a resolution of 4 cm^{-1}. Spectra were collected by using rapid-scan software running under OMNIC (Nicolet, Madison, WI), and the spectrum for each sample was calculated from the average of 100 repetitive scans. The internal reflection element

was a Spectra-Tech ZnSe ATR trough plate crystal with an aperture angle of 45° generating seven bounces. A reference background absorbance spectrum was taken by scanning the clean and dry ATR crystal.

LDL conjugated diene and total carbonyls determinations. The primary and secondary products of LDL lipid oxidation were determined by predicting the conjugated diene hydroperoxide (CD) and total carbonyl contents from a calibration model obtained by partial least squares (PLS) regressions using the LDL spectral regions 1800–1500 cm^{-1} as described previously (9). Six LDL spectra from each of the four treatments (control, catechin, quercetin, and α-tocopherol) were selected to constitute a calibration set of 24 spectra of varying CD contents. The spectra (1800–1500 cm^{-1}) of the four LDL treatments at similar CD and total carbonyl contents were not significantly different (data not shown).

LDL protein secondary structures analysis. Quantitative information on the protein structure was obtained by decomposing the amide I band into its constituents. Spectral resolution enhancement was performed according to Byler and Susi (13) and the decomposition of amide I band conducted using the peak-fitting routine under Grams/AI (Thermo Galactic, Salem, NH). The frequencies of the overlapping amide I band components were obtained by calculating the second-derivative spectra. Band shapes were fitted with weighted sums of Gaussian-Lorentzian functions as described previously (14). The deconvolution parameters used for the amide I band were set with half-bandwidth at half-height at 10 cm^{-1} and a resolution enhancement factor, *K*, of 1.0. The intensities of the amide I band components were obtained and expressed as the area under the curve.

Data analysis and statistics. The area percentages of the amide I band components were reported as the mean of the duplicate samples. Differences between antioxidant experimental groups were determined by the Student's *t*-test.

RESULTS AND DISCUSSION

LDL CD. Figure 1 shows the FTIR/PLS-predicted primary LDL oxidation products expressed as CD content in the presence or absence of antioxidants at physiological antioxidant concentrations. The classic three phases of lipid oxidation, namely, the lag, propagation, and decomposition, were evident. However, a second propagation phase then developed after the decomposition phase, probably due to formation of unsaturated aldehyde oxidation products (15). The second propagation phase proceeded with similar patterns but attained higher levels in the control and α-tocopherol samples than in the quercetin and catechin samples, suggesting that the presence of flavonoids interfered with the release of the unsaturated aldehyde oxidation products.

Table 1 summarizes the effect of the presence of antioxidants on the formation of conjugated dienes as predicted by FTIR/PLS and shown in Figure 1. The presence of 0.5 μM quercetin, 2.0 μM catechin, and 0.05 μM α-tocopherol resulted in peak CD values of 8.0, 7.8, and 8.3 nM/mg LDL
FIG. 1. Inhibition of production of lipoprotein lipids primary oxidation products by 2.0 µM catechin, 0.5 µM quercetin, and 0.05 µM α-tocopherol predicted by FTIR spectra as conjugated diene hydroperoxide content. Control has no antioxidant.

FIG. 2. Formation of lipoprotein lipids carbonyl oxidation products predicted by FTIR spectra in LDL incubated without (control) or with catechin, quercetin, and α-tocopherol.

protein, respectively, after the first propagation phase. The control samples produced higher contents of CD (9.8 nM/mg) than those produced in the presence of antioxidants. The decomposition phase, representing a decline in concentrations after the peak values, was longest in the control samples, followed by samples treated with 0.5 µM quercetin and 2.0 µM catechin, which had similar duration, and shorter in samples containing 0.05 µM α-tocopherol. The decomposition rates of the hydroperoxides were, however, similar probably owing to the fact that chain-breaking antioxidants influence the autocatalytic phase of lipid peroxidation rather than the peroxide decomposition phase (7).

LDL carbonyl compounds. Figure 2 presents the time course of FTIR/PLS-predicted generation of carbonyls as secondary oxidation compounds from the decomposition of lipoprotein lipid hydroperoxides. Carbonyl formation progressed through a gradual, exponential, and stabilized phase for all samples incubated with or without antioxidants. The carbonyls formed stabilized after the exponential phase even though CD was still

being produced, probably as a result of the binding of carbonyls to the lipoprotein residues (2). The period of gradual increase corresponded to the respective propagation phase of predicted CD formation whereas the exponential increase in carbonyls corresponded to the respective decomposition phase of the predicted CD formation profiles (Fig. 1). Predicted total carbonyl formation rates were slower and the gradual phase of carbonyl formation longer in the presence of the antioxidants as compared with those of the control. The predicted total levels of carbonyl compounds formed were similar in the 0.5 µM quercetin- and 2.0 µM catechin-treated samples but lower than those in the control and samples containing 0.05 µM α-tocopherol. This may be attributed to the inhibiting effect of the flavonoids on the hydroperoxide formation in LDL (16).

LDL protein secondary structures. Figure 3 is a typical FTIR spectrum of an LDL sample for the band region between 4000 and 800 cm^{-1}. The absorption bands include a 3280 cm^{-1} N–H stretch, 2930 and 2850 cm^{-1} methylene C–H stretches, and 1735 cm^{-1} C=O stretch. The band between 1700 and 1600

FIG. 3. Representative mid-IR spectrum of an LDL film showing the band assignment of observed bands including the amide I band (1700–1600 cm^{-1}) that was decomposed into its components.

FIG. 4. Percentage composition of the amide I band components (mean ± SD, $n = 2$), centered at different band frequencies, of LDL samples drawn at 10 min of incubation. Amide I band components at each wavenumber for LDL samples with or without antioxidants are not significantly different ($P < 0.05$).

cm^{-1} represents the amide I band arising mainly (>80%) from the stretching vibrations of the apoB-100 peptide bond C=O (8). The amide II band is centered at 1550 cm^{-1}, C–H scissoring at 1460 cm^{-1}, P=O stretching at 1250 cm^{-1}, and C–O vibrations in the bands between 1200 and 800 cm^{-1}. The protein of LDL accounts for the NH bands, the lipids mainly account for the methylene C–H and carbonyl bands, and the phospholipids are responsible for the band at 1250 cm^{-1}. The band at 1735 cm^{-1} increased in intensity with longer LDL incubation (data not shown), suggesting that it was due to the C=O groups from hydroperoxide decomposition.

Figure 4 shows a typical composition of the components of apoB-100 secondary structures obtained after amide I band decomposition for LDL samples with or without antioxidants. The compositions of the apoB-100 secondary structures were similar ($P < 0.05$) in LDL samples incubated in the presence or absence of antioxidants. This indicates that the presence of antioxidants or antioxidant type did not affect the quantification of the apoB-100 components. The apoB-100 secondary structures have previously been assigned (8,17,18). The band at 1616 cm^{-1} was assigned to β-strands, a structure that extends from the monolayer on the LDL outer shell to the inner core. Bands centered at 1680, 1670, and 1663 cm^{-1} arise from β-turns, and bands at 1697, 1631, and 1625 cm^{-1} are due to β-sheet. The band at 1643 cm^{-1} is due to the random (unordered) structure and that at 1651 cm^{-1} is due to the α-helix structure of the apoB-100.

Figure 5 represents a profile of changes in the ratio of random structure to α-helix structures of apoB-100 during LDL incubation with or without antioxidants, as an indicator of protein denaturation. The ratio of random to α-helical structures exhibited an initial gradual increase, followed by an exponential increase and a subsequent stabilization. The changes reflected the gradual, exponential, and stabilized phases of the carbonyl formation profile (Fig. 2). The similarity in pattern may be due to the modification of the amino acid residues of
apoB-100 by the carbonyls generated during oxidation (19). The highest rate of apoB-100 denaturation corresponded to the exponential phase of carbonyl formation, reinforcing the fact that the random structures are formed during carbonyl modification of the apoB-100 α-helix structure (8). The control sample produced the highest ratios, followed by samples containing 0.05 µM
FIG. 5. The modification of apolipoprotein B-100 secondary structures, expressed as the ratio of random to α-helix structures during LDL oxidation, in the presence of catechin, quercetin, and α-tocopherol. Control has no antioxidant.

TABLE 2
Relative Intensity Ratios of Bands at 1735 (aldehydes C=O) to 1632 (β-sheet C=O) and 1735 to 1651 cm^{-1} (α-helix C=O) of Oxidized LDL in the Presence/Absence of Antioxidant

Total carbonyls		Intensity ratios[a]	
(nmol/mg protein)	Antioxidant	1735/1651	1735/1632
58	Control	0.79[d]	0.74[d]
	α-Tocopherol	0.62[c]	0.50[c]
	Quercetin	0.49[b]	0.42[b]
	Catechin	0.38[a]	0.33[a]
96	Control	1.13[c]	1.05[c]
	α-Tocopherol	0.92[b]	0.89[b]
	Quercetin	0.82[a]	0.70[a]
	Catechin	0.78[a]	0.68[a]

[a]Ratios in a column followed by same letter, at each total carbonyls concentration, are not significantly different at $P < 0.05$.

α-tocopherol, and samples with 0.5 μM quercetin and 2.0 μM catechin produced the lowest ratios. The pattern and rates of denaturation in the presence or absence of antioxidants reflected the pattern of carbonyl formation. However, differences observed between antioxidants, other than those due to concentration difference, probably reflected their solubilities and partitioning behavior between the aqueous and lipid phases in the LDL system and the α-helix structure location within the apoB-100 particle. The α-helix structures are located close to the surface of the apoB-100 particle, and the LDL molecule is surrounded by a monolayer of hydrophilic phospholipids (8). This implies that the more hydrophilic flavonoids would partition into the aqueous buffer layer surrounding the LDL molecule and provide better protection to the α-helix against carbonyl modification than the more lipophilic α-tocopherol as observed in this study. The α-tocopherol might also form micelles in the LDL-containing buffer solution that would render them less available for antioxidant activities on the LDL particles. It has previously been pointed out that the effectiveness of an antioxidant is influenced by its location within the system (20).

Effect of antioxidants on LDL protein secondary structure. Table 2 shows a comparison of the relationship between FTIR band intensities of carbonyls (1735 cm^{-1}) and of apoB-100 α-helix (1651 cm^{-1}) and β-sheet (1632 cm^{-1}) structures at the 58.0 and 96.0 nmol/mg total carbonyls stages of LDL oxidation in the presence or absence of antioxidants. The stages of carbonyl formation selected for each treatment were the intermediate carbonyl level (58.0 nmol/mg protein) and the high carbonyl level (96.0 nmol/mg protein). The band ratios 1735/1651 and 1735/1632 cm^{-1} may be considered as an indirect measurement of the amount of aldehydes C=O groups relative to α-helix and β-sheet structures, respectively, in oxidized LDL. These band ratios could therefore indirectly represent the extent of modification of the α-helix and β-sheet structures by the aldehydes.

The 1735/1651 and 1735/1632 cm^{-1} band ratios at the 58.0 nmol/mg LDL protein of total carbonyl stage were highest in the control samples, followed by samples containing α-tocopherol, quercetin, and catechin. At the total carbonyls of 96.0 nmol/mg LDL protein stage, the 1735/1651 and 1735/1632

cm^{-1} band ratios increased but remained highest in the control samples, followed by α-tocopherol-containing samples. The ratios were not significantly different between the quercetin- and catechin-containing samples but lower than those in α-tocopherol-treated samples. This may be attributed to the flavonoids binding to the apoB-100 and prohibiting LDL oxidative modification (21). It indicates that flavonoids, in addition to prohibiting the propagation phase of LDL oxidation, may also protect the apoB-100 protein from modification by the lipid secondary oxidation products.

This study included α-tocopherol, quercetin, and catechin only at physiological concentrations that represent the actual quantities reported *in vivo*; however, differences in concentrations may constrain the objective comparison of their activities *in vitro*. The concentrations of catechin in this study were 4 and 40 times higher than those of quercetin and α-tocopherol, respectively, and definitely contributed to the higher antioxidant activity of catechin observed. The mechanism of action of the flavonoids and α-tocopherol *in vivo* may not be just through direct action as implied in this study but probably through synergistic activities involving other LDL endogenous antioxidants such as carotenoids. Further studies would be needed with the antioxidants to clarify their possible effects on LDL oxidation *in vivo*. However, the findings of this study may be relevant and applicable to other flavonoids and lipophilic antioxidants owing to similarities in their structures and chemical properties.

In conclusion, the presence of antioxidants increased the induction period of hydroperoxide generation, and the presence of flavonoids significantly affected carbonyl formation more than α-tocopherol in oxidized LDL. The denaturation of apoB-100 was commensurate with the formation of carbonyls but alleviated by the presence of flavonoids. Our data showed that the presence of the antioxidants catechin, quercetin, and the α-tocopherol, at physiological concentrations, impeded the formation of primary and secondary oxidation products of lipoprotein lipids and the modification of apoB-100 *in vitro*. This suggests that levels of catechin and quercetin normally found in plasma may influence disease risks associated with LDL oxidation, as does α-tocopherol,

but their relative quantitative importance needs further study. The present study also demonstrated that FTIR in combination with chemometrics provided a comprehensive anaysis of LDL oxidation and antioxidant performance and is a potential tool for dynamic monitoring of LDL oxidation using multiple indicators such as CD, total carbonyls, and changes in the apoB-100 secondary structures.

ABSTRACT: The effect of supplementing 200 mg/kg body weight palm vitamin E (PVE) and 200 mg/kg body weight α-tocopherol (α-Toc) on the healing of wounds in streptozotocin-induced diabetic rats was evaluated. The antioxidant potencies of these two preparations of vitamin E were also evaluated by determining the antioxidant enzyme activities, namely, glutathione peroxidase (GPx) and superoxide dismutase (SOD), and malondialdehyde (MDA) levels in the healing of dermal wounds. Healing was evaluated by measuring wound contractions and protein contents in the healing wounds. Cellular redistribution and collagen deposition were assessed morphologically using cross-sections of paraffin-embedded day-10 wounds stained according to the Van Gieson method. GPx and SOD activities as well as MDA levels were determined in homogenates of day-10 dermal wounds. Results showed that PVE had a greater potency to enhance wound repair and induce the increase in free radical-scavenging enzyme activities than α-Toc. Both PVE and α-Toc, however, were potent antioxidants and significantly reduced the lipid peroxidation levels in the wounds as measured by the reduction in MDA levels.

Paper no. L9408 in *Lipids 40*, 575–580 (June 2005).

Vitamin E consists of two subfamilies, namely, tocopherols and tocotrienols, each of which comprises four forms: α, β, γ, and δ (1). Although their structures are similar, the presence of three double bonds in the isoprenoid side chain of tocotrienols confers different potencies and biological activities between them (2–6). Some studies reported that tocotrienol possessed higher antioxidant activity than tocopherols (2,3). α-Tocotrienol was reported to exhibit greater peroxyl radical-scavenging potency than α-tocopherol (α-Toc) in liposomal membranes (2) and to possess greater anticancer activity (4). More recently, tocotrienols were reported to be more effective than α-Toc in preventing glutamate-induced neuronal cell death (5). On the other hand, the study by Suarna *et al.* (6) in 1993 did not show a significant difference in antioxidant activities between corresponding tocopherol and tocotrienol isomers.

Palm oil is the richest natural source of tocotrienols. Palm oil vitamin E extract consists largely of tocotrienols (70%) and only 30% tocopherols (7). In contrast, the vitamin E in most other vegetable oils consists of only tocopherols. In this study we compared the potency of palm vitamin E (PVE) extract and α-Toc, the most abundant form of vitamin E *in vivo*, on wound healing in diabetic rats. Delayed wound healing is one of the complications of diabetes, and free radicals have been postulated as one of the causes (8–10). In a clinical sense, delayed wound healing in persons with diabetes may lead to severe complications requiring extended hospitalization and amputation. Thus, it is of interest to determine the use of antioxidants in accelerating wound healing, not only in diabetes but also in other conditions of impaired healing.

The beneficial effects of antioxidant vitamins on the healing of wounds have mainly been studied using animal models. Only vitamin C has been shown to accelerate healing in human subjects (11). Oral and topical application of vitamin A has been shown to enhance healing in animals compromised by the administration of corticosteroids (12,13), the presence of a malignant tumor (14), and chemically induced diabetes mellitus (15). The benefit of vitamin E in wound healing has been reported by Martin (16) on guinea pigs. Vitamin E also was reported to accelerate the treatment of wounds resulting from exposure to radiation, including sunlight (17–19). Altavilla *et al*. (20) and Galeano *et al*. (21) have treated genetically diabetic rats with raxofelast, a hydrophilic vitamin E-like antioxidant compound and found accelerated healing of linear wounds. We have also studied the effects of oral vitamin E supplementation on 6-cm skin lesions in normal and chemically induced diabetic rats and found accelerated healing only in diabetic rats (22).

In this study, the effects of PVE and α-Toc on chemically induced diabetic rats were determined in an excision wound model. Full-skin punch biopsies were used, as they allow wound contraction, wound protein, lipid peroxidation, and antioxidant enzyme activities to be measured in the healing wounds.

MATERIALS AND METHODS

Materials. Streptozotocin was purchased from Sigma (St. Louis, MO). PVE and α-Toc were gifts from the Malaysian Palm Oil Board (Bangi, Malaysia).

Animals. This study was approved by the Universiti Ke-

---

bangsaan Malaysia Animal Ethics Committee. Male Sprague-Dawley rats weighing 250–300 g were used and were made diabetic with an intramuscular injection of streptozotocin (50 mg/kg body weight). Rats were considered diabetic when their fasting blood glucose levels were greater than 8 mmol/L using a glucose reagent strip and glucometer (Advantage, Boehringer Mannheim, Mannheim, Germany). The animals were allowed to rest for 10 d before the start of the experiment.

Diabetic rats were divided into groups of 6 animals each, according to the supplementation given: control, PVE, or α-Toc.

Study design. On the day of the experiment (day 1), the animals were anesthetized with Zoletil 50® (Virbac Labs, Carros Cedex, France). The back of each animal was then partially shaved, and the skin was cleaned with a 70% alcohol and iodine solution. Four 6-mm-diameter excision wounds were made to create full-thickness dorsal cutaneous wounds using a punch biopsy needle (Stiefel Laboratories, Dublin, Ireland). The animals were then force-fed (oral feeder; Popper and Sons Inc., New Hyde Park, NY) with either 200 mg/kg body weight PVE, 200 mg/kg body weight α-Toc, or an equal volume of olive oil (control). Animals were not fasted before being force-fed. The administration of olive oil or the vitamins was carried out daily by oral gavage until the animals were sacrificed on day 10. The animals were kept individually in separate cages and fed a standard diet (Gold Coin, Malaysia) and water *ad libitum.*

The progress of healing was monitored by determining the wound areas, total protein content in the full-skin punch biopsy wounds, and histological changes as examined after staining with Van Gieson stain.

Blood samples also were taken and were analyzed for fasting blood glucose (to ensure the diabetic status of the rats). Wound tissues were collected on day 10 for measurement of antioxidant enzyme activities, namely, glutathione peroxidase (GPx) and superoxide dismutase (SOD). Lipid peroxidation was determined as malondialdehyde (MDA) in the day-10 wound tissues.

Determination of wound closure. Wound areas were determined as the in-growth of epithelial cells by measuring wound areas on days 1, 6, and 10. Wound areas were traced onto a tracing paper and then calculated using an image analyzer (Axiovert S 100; Zeiss, Oberkochen, Germany) according to the method described by Baie and Sheikh (23).

Wound collection. Wounds were collected on day 10 after wounding. Briefly, the animals were anesthetized with Zoletil 50 (diethyl ether) before the procedure. The lesion and the surrounding areas were cut using a punch biopsy needle of the same diameter used earlier in the creation of wounds.

Protein determination. The total protein content was determined using one punch biopsy wound from each animal according to the method of Bradford (24). Briefly, wound tissues were homogenized in 1.15% calcium chloride at a ratio of 1:5 (wt/vol). A 0.1-mL quantity of the homogenate was added to 5 mL of Bradford reagent, mixed, and the absorbance read at 595 nm wavelength against a 0.1 M phosphate buffer, pH 7.4. Standards were treated similarly using BSA at concentrations of 0, 20, 40, 60, 80, and 100 μg/mL in 0.1 M phosphate buffer, pH 7.4.

Histological examination. Wound tissues were fixed by immersion in formalin for routine histology. The tissues were dehydrated in ascending concentrations of alcohol, cleaned in xylene, and impregnated in paraffin according to standard procedures. Just before staining, the lesions were sliced along a longitudinal plane and embedded on-edge. Sections of 5-μm thickness were treated with the Van Gieson stain (25).

GPx activity. For the determination of GPx activity in the wound tissue, day-10 wound tissues were prepared by homogenizing in 1.15% potassium chloride at a ratio of 1:5 (wt/vol). They were then centrifuged at 8,000 rpm for 20 min at 4°C. The resultant supernatant was again centrifuged at 35,000 rpm for 1 h at 4°C.

Erythrocyte GPx activity was determined according to the method described by Paglia and Valentine (26). The hemolysate was diluted with distilled water (1:5). A 0.5-mL quantity of Drabkin reagent (cyanmethemoglobin) was then added to 0.5 mL of the diluted hemolysate. Then 2.88 mL of substrate mixture was added to 0.02 mL of the resulting mixture. The substrate mixture consisted of 8.4 mM NADPH, 1.125 M sodium azide, 5 mM GSH, and 34.5 IU reduced GSH in 0.05 M phosphate buffer, pH 7.0. The reaction was started by adding 0.1 mL of hydrogen peroxide. The solutions in the test tubes were then mixed and the absorbance read at 340 nm wavelength for 5 min.

SOD activity. Hemolysates of the day-10 wound tissues were prepared as for GPx and were analyzed for SOD activity.

SOD was determined according to the method of Beyer and Fridovich (27). Hemolysate was mixed with a substrate mixture consisting of 50 mM phosphate buffer containing 0.1 mM EDTA, pH 7.8, prepared fresh on the day of analysis; L-methionine (0.03g/mL); nitroblue tetrazolium chloride (NBT·2HCl) (1.41 mg/mL); and 1% Triton X-100® (vol/vol). The reaction was started by adding 10 μL riboflavin (4.4 mg/100 mL). The mixtures were mixed, then left in an aluminum box illuminated with two fluorescent lamps of 20 W for 7 min, and the absorbance was read at 560 nm wavelength. The whole procedure was carried out in the dark because both riboflavin and NBT are sensitive to light.

MDA levels. MDA levels in the day-10 wound tissue homogenate were also determined to reflect the level of lipid peroxidation using the TBARS method, as described by Ledwozyw *et al.* (28). Briefly, the tissues were homogenized as just described in 1.15% potassium chloride and diluted 1:5 with distilled water before analysis. A 2.5-mL quantity of TCA solution was then added to the hemolysate and left at room temperature for 15 min. Thiobarbituric acid (1.5 mL) was then added to the mixture, mixed, and the solution incubated in a water bath at 100°C for 30 min. The tubes were then cooled and shaken vigorously for 30 min before adding 4 mL of *n*-butanol solution. The tubes were then centrifuged at 3000 rpm for 10 min at room temperature. The absorbance of the resulting upper layer was then read using a spectrofluorometer (Shimadzu, Kyoto, Japan).

Statistical calculation. The percent wound areas were calculated using ANOVA with repeated measures, followed by *post hoc* Student's *t*-test with correction for multiple comparisons. For the other parameters, ANOVA with multiple comparisons was used.

RESULTS

Wound healing was evaluated from the morphological changes observed with stained preparations of cross-sections of wounds taken on day 10 of healing using the Van Gieson techniques. We also measured the wound surface areas and total protein in the wounds during healing. The amount of protein in the wound reflects the synthesis of new cells and cellular redistribution (29).

Wound closure. Figure 1 shows that supplementation of PVE and α-Toc resulted in smaller wounds on day 10 postwounding compared with the control. Supplemented rats had significantly less wound area on day 10 of healing ($P < 0.05$) compared with the control, but the wound areas of rats supplemented with PVE were significantly smaller than those of the α-Toc-supplemented group.

Total protein content. Figure 2 shows the total protein (mean ± SEM) in the full-skin punch biopsy taken from each of the animals on day 10. Significant increases in the total protein content were observed in all supplemented groups compared with the control ($P < 0.01$). However, higher levels were observed with diabetic rats supplemented with PVE.

Morphological studies. Observations of stained paraffin sections of the wound sites on day 10 in full-skin punch biopsy wounds of diabetic rats showed little epidermal regeneration in the control rats (Fig. 3A). The underlying dermis showed an ill-formed granulation tissue and sparse collagen. PVE supplementation resulted in a well-formed and differentiated epidermis (Fig. 3B). There were complete re-epithelization and thick bundles of well-aligned collagen showing the advanced state of healing compared with the control. α-Toc supplementation resulted in a more dense infiltration of the wound bed and a
FIG. 2. Means ± SEM of total protein in day 10 full-skin punch biopsies of control, PVE-, and α-Toc-supplemented diabetic rats ($n = 6$). The letters a and b denote a significant difference from the control and α-Toc groups, respectively ($P < 0.01$). For abbreviations see Figure 1.

greater collagen content than the control (Fig. 3C) but at an earlier state of healing when compared with PVE supplementation.

Antioxidant enzymes and MDA levels in wound tissues. GPx and SOD activities and MDA levels were calculated, taking into account the amount of protein present in the healing wound, as this indicates the number of living cells present. Results showed that both enzymes were significantly elevated in rats receiving PVE ($P < 0.001$) compared with controls and the group treated with α-Toc (Table 1). There were significant reductions in MDA levels observed in the tissues taken from the rats supplemented with PVE and α-Toc ($P < 0.001$).

DISCUSSION

Wound healing is a complex but ordered process involving three overlapping phases: inflammation, granulation tissue formation, and remodeling of the extracellular matrix. These events include cellular migration, proliferation, adhesion, and phenotypic differentiation (30).

The present data demonstrate that PVE supplementation resulted in significantly smaller wound areas on day-10 postwounding compared with controls. Although α-Toc supplementation also resulted in smaller wound areas, the difference was not significant compared with controls. These data were further substantiated by the quantification of protein in the wounds. The amount of protein in wounds taken from the rats supplemented with PVE was significantly increased compared with controls and higher than those of α-Toc. Since the amount of wound protein reflects the rate of cellular proliferation, we deduced that PVE accelerates the synthesis and migration of new cells into the wound areas. Results of Van Gieson staining of cross-sections of paraffin-embedded day-10 wounds were also in agreement with these findings. There was a greater rate of proliferation and infiltration of cells at the wound sites taken from rats supplemented with PVE. These cells play an important role in matrix deposition and the restoration of tissue integrity, as shown

FIG. 1. Means ± SEM of percent wound areas during healing of excision dermal wounds of control, palm vitamin E (PVE)-, and α-tocopherol- (α-Toc-) supplemented diabetic rats ($n = 6$). The letters a and b denote a significant difference from the control and α-Toc groups, respectively ($P < 0.05$).
FIG. 3. Van Gieson stained paraffin sections of day-10 dermal wounds of control (A), PVE-supplemented (B), and α-Toc-supplemented (C) diabetic rats. Slides A and C are shown under 40× magnification, whereas slide B is shown under 100× magnification to better illustrate cellular growth and the formation of the different cell layers. Healing was most advanced in the PVE-supplemented group where there were complete re-epithelization, well-differentiated cells, and thick collagen bundles (B). α-Toc supplementation resulted in more epithelial cell migration to the wound bed with some collagen deposition (C). The wound bed of the control group (A) had a sparse number of epithelial cells with little collagen, showing that healing was at an earlier stage compared with the PVE- and α-Toc-supplemented groups. For abbreviations see Figure 1.

by the increased collagen content at the wound sites. Collagen is a major determinant of increased tensile strength of the healing wound (31).

We also performed a similar experiment on nondiabetic rats and found that supplementation with either PVE or α-Toc did not improve the rate of healing of excision wounds (results not shown). This result agrees with our earlier finding in which we used the linear incision model of wound healing and found no acceleration of wound closure with α-tocopherol supplementation (22).

In our earlier work, supplementation of the same dose of α-Toc resulted in significantly accelerated linear wound closure in diabetic rats, in contrast to what we observed here using the excision wound model (22). This probably reflects the complexity of healing in excision wounds compared with the incision model. Incision wounds cause only minimal damage to epithelial basement membrane continuity and the death of relatively few epithelial and connective tissue cells. The repair process involves primarily epithelial regeneration. The repair process for excision wounds, by contrast, is more complex, in-

volving the regeneration of parenchymal cells, extensive ingrowth of granulation tissue, and an accumulation of the extracellular matrix (32). Therefore, the dose of α-Toc needed to elicit a positive response may be much higher than that used in the present study.

The differences in the potencies of the vitamin preparations may be due to the fact that PVE is a mixture containing a high

percentage of tocotrienols, which in some conditions have been shown to be more potent antioxidants than tocopherols (2–4). Their effectiveness in wound healing may be because orally administered tocotrienols have been reported to accumulate in the skin (33). Traber *et al.* (33) reported that in mice, nearly 15% of tocotrienols given orally were distributed to the skin compared with only 1% of the tocopherols. This may be attributed to the unsaturated isoprenoid side chain of the tocotrienols, which had been suggested to provide higher mobility, allowing more efficient and uniform distribution into the bilayer cell membranes (34). This unique distribution of tocotrienols in the skin may give it superior properties in aiding wound repair. In contrast, topical application of a tocotrienol-rich fraction from palm oil on hairless mice was reported to result in a preferential increase in α-Toc in the skin, and no difference was observed in the potential to afford antioxidant protection against UV radiation or ozone (34). Weber *et al.* (36) suggested that the skin may have a specific mechanism for enrichment with α-Toc rather than tocotrienols.

Apart from the possible differences in distribution kinetics, studies have reported that tocotrienols exert a greater protective effect than tocopherols (37–41). Thus, Serbinova *et al.* (2) reported that α-tocotrienol was 40 to 60 times more potent in reducing lipid peroxidation in rat liver microsomal membrane and 6.5 times more potent against oxidative damage to cytochrome P-450 than was α-Toc (2). Tocotrienols showed a significant inhibition of human and mouse tumor cell growth compared with tocopherols (37–39). In a study on serum biliary enzyme, Ong *et al.* (41) reported that a higher concentration of α-Toc was needed to elicit the same level of reduction of hepatocyte γ-glutamyltranspeptidase release after rats were treated with a carcinogen. Perhaps in the case of wound healing in persons with diabetes, a higher dose of α-Toc is needed to elicit the same response as that of PVE, or perhaps the effect is best seen when a mixture of vitamin E (as in PVE) is supplemented, as was reported by Ong *et al.* (41) in their study on chemically induced hepatitis.

The present study also shows that rats supplemented with PVE had significantly higher levels of antioxidant enzyme activities than controls and those supplemented with α-Toc. SOD and GPx act as scavengers for free radicals: SOD turns superoxide radicals into hydrogen peroxide (42), and GPx neutralizes hydrogen peroxides to water (26). The reduction in free radical damage can be assessed by MDA as an index of lipid peroxidation. Results showed that both PVE and α-Toc were effective in significantly reducing the MDA levels. Although the present study was done on oral vitamin E supplementation, topical vitamin E also has been reported by other researchers to result in up-regulation of a network of enzymatic and nonenzymatic antioxidants such as SOD, reduced GSH, and ascorbate (35).

In conclusion, this study shows that PVE, a vitamin E mixture with a high tocotrienol content, was more potent at enhancing wound healing and inducing increased antioxidant enzyme levels in the wounds of diabetic rats than was α-Toc. However, both vitamins were able to reduce lipid peroxidation in the healing wounds.

Maternal Dietary Alpine Butter Intake Affects Human Milk: Fatty Acids and Conjugated Linoleic Acid Isomers

ABSTRACT: Consumption of CLA by lactating women affects the composition of their milk, but the pattern of the different CLA isomers is still unknown. We determined the effects of short maternal supplementation with CLA-rich Alpine butter on the occurrence of FA and CLA isomers in human milk. In an open randomized controlled study with a two-period cross-over design, milk FA and CLA isomer concentrations were measured on postpartum days ≥20 in two parallel groups of lactating women before, during, and after consumption of defined quantities of Alpine butter or margarine with comparable fat content (10 d of butter followed by 10 d of margarine for one group, and vice versa in the other). In the 16 women who completed the study (8/group), Alpine butter supplementation increased the C_{16} and C_{18} FA, the sum of saturated FA, the 18:1 *trans* FA, and the *trans* FA with CLA. The CLA isomer 18:2 *c*9,*t*11 increased by 49.7%. Significant increases were also found for the isomers *t*9,*t*11, *t*7,*c*9, *t*11,*c*13, and *t*8,*c*10 18:2. The remaining nine of the total 14 detectable isomers showed no changes, and concentrations were <5 mg/100 g fat. A breastfeeding mother can therefore modulate the FA/CLA supply of her child by consuming Alpine butter. Further studies will show whether human milk containing this FA and CLA isomer pattern acts as a functional food for newborns.

Paper no. L9632 in *Lipids 40*, 581–587 (June 2005).

Human milk (from German women) contains more long-chain FA, with chain lengths of C_{20} to C_{24} including several double bonds, than bovine milk fat. It contains a high proportion of palmitic acid (16:0, 25.3%) and the isomeric groups of 18:1 and 18:2, their main components being oleic acid (*c*9, 29.0%) and linoleic acid (*c*9,*c*12, 9.5%) (8).

The major CLA isomer is *c*9,*t*11-octadecadienoic acid (*c*9,*t*11 18:2) (1), also called rumenic acid (2). Although linoleic acid is isomerized by the enzymatic conversion of the *c*12 to the *t*11 bond by the anaerobe *Butyrivibrio fibrisolvens* in the rumen (3), an estimated 64% of dairy milk fat CLA is of endogenous origin (4). Total CLA and isomer concentrations in dairy milk fat depend on feeding (i.e., pasture, oilseeds), the effects of altitude and season, as well as the age and breed of the cow (5–7). Total CLA and isomer concentrations in human milk depend on maternal diet, stage of lactation, and *de novo* synthesis (8–12). As humans do not synthesize PUFA, concentrations depend exclusively on dietary fat intake (13). A study reporting CLA concentrations (*c*9,*t*11 isomer) of 5.8 mg/g fat in milk from mothers on conventional diets vs. 11.2 mg/g fat in Hare Krishna mothers hypothesized that the difference was due to the large amounts of butter, ghee, and cheese consumed by the latter (9). Chronic dietary *c*9,*t*11 18:2 intake is thought to increase milk 18:2 *c*9,*t*11 concentrations (10). The proportions of partially hydrogenated oils and ruminant fats in the diet also determine *trans* 18:1 isomeric distribution (8), whereas maternal diet, i.e.. consumption of different products or amounts of milk and meat, has been shown to correlate with differences in the CLA content of human milk (11).

Several effects of a high-CLA diet in animals and humans have been described. However, for the effect of most interest to us, that on neonatal development, only animal data are available: in rats, increased milk CLA concentrations in dams on a high-CLA diet are associated with enhanced pup weight gain (14). Recent studies have also shown that individual isomers have different effects.

The aim of the present investigation as an essential preliminary to an efficacy study was to quantify CLA isomers and FA concentrations in human milk from mothers consuming defined quantities of CLA-rich Alpine butter.

SUBJECTS, MATERIALS, AND METHODS

Subjects. Following approval from the Institutional Review Board of the Departments of Obstetrics and Urology at Zurich University Hospital, healthy lactating women (*n* = 20) from the Obstetrics Department were recruited on day (D) 2–4 postpartum with their written informed consent. The noninclusion criteria were pre-existing disease, medication other than vitamins or minerals, HIV, mastitis, vegan or similar extreme diet, substance abuse (including alcohol), smoking, and inability to understand conversational German. Subjects started the study from D20 postpartum when at home and healthy in lactation stage III.

Protocol. Dietary treatment was randomized in sealed opaque envelopes according to an open controlled two-period cross-over design in two parallel groups. Group 1 followed a normal diet at home to day 20 postpartum (= study D1). From D1 through D10 (period 1), women were invited to supplement their diet with 40 g/d (4 packages of 10 g per 24 h) margarine (M) (Becel®;

www.unilever.com) containing 24 g fat and 16 g water. From D11 through D20 (period 2), the diet was supplemented with 30 g/d (3 packages of 10 g per 24 h) Alpine butter (AB) containing 25.7 g fat, 4.3 g water, and an average of 2.09 g CLA/100 g milk fat (equivalent to approximately 0.5 g CLA/d). The difference between the daily amount of M (30 g) and AB (40 g), respectively, should result in an equal daily fat intake from the study products. Group 2 women followed the same dietary schedule in reverse order (period 1: AB; period 2: M).

The Alpine butter originated from Alp Mutten (Graubünden, Switzerland, 2100 m altitude) and consisted of a blend of five 2-kg portions that was produced between July 1 and 25, 2003, and stored at −20°C until use. The 10-g portions of this blend contained 8.6 g fat, 1.4 g water, and 180.0 mg total CLA (corresponding to 2.09 g total CLA/100 g milk fat). The predominant CLA isomers were *c*9,*t*11, *t*11,*c*13, *t*7,*c*9, and *t*8,*c*10 18:2. The FA and CLA composition of the two supplements is shown in Table 1.

The women had to record the real daily intake of study products (weight). No additional Alpine milk or ruminant meat products were allowed during the study.

Dietary diary. The subjects documented potential additional sources of CLA by recording every day the estimated intake (volume or weight) of milk and dairy products (yogurt, sour cream, cream, cheese, etc.) and meat (type). The amount of a consumed product was given in the database of the EBIS program (15), which transforms the consumed volume or weight of a product in consumed grams fat by considering the product's specific percent fat. From the daily fat intake, the daily CLA intake (milligrams) was calculated using the values of Fritsche and Steinhart (16,17) for CLA amounts (grams CLA per gram fat) in different foods (German and others); for chicken or turkey the CLA values of Chin *et al.* (1) were used.

Milk sampling. On D1, D5, D10, D15, and D20, the subjects took milk samples at home according to a standardized procedure assisted by the principal investigator (IB): between 8:00 and 11:00 A.M. and 1–3 h after a continental breakfast, the breast that was not actually used for infant feeding at the last feed was emptied completely using an electric pump (Lactina™ Electric plus; Medela AG, Baar, Switzerland) and the volume measured; 2 × 10-mL aliquots were transferred to plastic tubes, cooled at +4°C (cold box), and stored at −20°C until analysis. The remainder was fed to the baby.

Lipid extraction and analysis of FA. (i) Lipid extraction. Milk fat was obtained gravimetrically using the Roese-Gottlieb method, i.e., the fat globule membranes were disrupted with ammonia and ethanol, the fat was extracted with diethyl ether and petroleum ether, and the pure fat was stored at −20°C until analysis (18).

(ii) FA. The milk fat was dissolved in hexane, and the glycerides were transesterified to the corresponding FAME using a solution of potassium hydroxide in methanol (2 mol/L) as per ISO standard 15885. FA composition was determined using a gas chromatograph (GC; Agilent 6890, www.agilent.com) equipped with an on-column injector and FID (19). Nearly 70 FA were separated on a capillary column (100 m × 0.25 mm ×

FIG. 1. Silver-ion HPLC (Ag⁺-HPLC) separation of CLA methyl esters of human milk using three columns in series (peak *t*6,*t*8 tentatively assigned according to Ref. 20).

0.20 μm, CP-Sil 88; www.varianinc.com) and quantified in absolute values (g FA/100 g fat) using nonanoic acid as internal standard.

(iii) CLA isomers. CLA isomers were analyzed by silver-ion (Ag⁺) HPLC according to Rickert *et al.* (20), modified by Kraft *et al.* (21). The analysis was performed on an Agilent LC series 1100 equipped with a photodiode array detector (234 nm) using three ChromSpher Lipids columns in series (stainless steel, 250 × 4.6 mm, 5 μm particle size; Chrompack, Middleburg, The Netherlands). The solvent consisted of UV-grade hexane with 0.1% acetonitrile and 0.5% ethyl ether (flow rate 1 mL min⁻¹), prepared fresh daily. Injection volumes were 10 μL, representing <250 μg lipid. The identification of CLA isomers was based on co-injection with commercial reference material and synthesized CLA. The methyl esters of *c*9,*t*11 (98%), *t*10,*c*12 (98%), and *c*9,*t*11 18:2 (75–78%) were obtained from Matreya Inc. (Pleasant Gap, PA). Other CLA isomers were synthesized by isomerization of the commercially available reference (technical grade) with I_2 (22). The results were expressed as absolute values in mg per 100 g fat. Fourteen different CLA isomers were separated by this HPLC method (Fig. 1).

Statistical analysis. A power calculation was performed based on an expected difference in CLA human milk content of 30% between the two phases, Alpine butter (AB) and margarine (M). The power was 80% for *n* = 8/group (α = 0.5).

Data were entered into Excel, analyzed in Systat for Windows, version 10.2 (www.uic.edu/depts/accc/software), and expressed as means ± SD. The Kolmogorov–Smirnov test was used for normality. Mean values were compared using the unpaired two-tailed *t*-test for cross-over design and a *P* value of <0.05. "Effect" refers to the differences between the two phases AB vs. M of group-pooled data, and "period" to the period effect, i.e., the differences between the two phases AB and M of group 1 vs. group 2.

RESULTS

Subjects. Three women withdrew because of lactation failure and one developed diarrhea in response to Alpine butter, leaving eight subjects per group. The groups did not differ statistically in age (27.8 ± 3.5 vs. 29.5 ± 5.6 yr, respectively), parity, gravidity, gestational age at delivery, or body mass index (BMI) during the study (Table 2).

Two group 2 women were excluded from the statistical analysis of the CLA isomers because of technical problems in the isomer analysis.

Study product intake and dietary diaries (Table 3). The mean daily intake of margarine was 29.75 g (group 1) and 30.25 g (group 2) and that of Alpine butter 22.0 g (group 1) and 23.75 g (group 2). Study product intake was thus below the requested level (margarine: up to 40.0 g; Alpine butter: up to 30.0 g). The higher intake of margarine than butter (*P* = 0.003) resulted in an equal daily fat intake in both groups (*P* = 0.25 differences between M and AB [effect] and differences between the groups [period]). Fat intake was calculated from 60 g fat/100 g (margarine) and 85.8 g fat/100 g (Alpine butter) as specified in the Subjects, Materials, and Methods section.

Dietary nonsupplement CLA intake, calculated from the daily dietary records, also did not differ statistically (*P* = 0.52) between phases or groups. Extremely small or zero amounts of ruminant meat (beef) were recorded in both groups, as requested (data not shown).

Human milk. (i) Fat content. In neither group did fat content of human milk differ significantly between margarine and butter phases (group 1: 3.3 ± 0.6 vs. 3.4 ± 1.6 g/100 mL milk; group 2: 2.9 ± 1.3 vs. 3.4 ± 1.1 g/100 mL milk) corresponding to a mean fat yield (g) per breast of 1.94 in the margarine and 1.90 in the butter phase (NS).

(ii) FA. The sum of saturated FA increased by 2.057 g/100 g fat during the pooled butter phases (*P* = 0.03), 18:1 *trans* FA by 0.428 g/100 g fat (*P* = 0.001), and *trans* FA with CLA by 0.178 g/100 g fat (*P* = 0.005) (all without period effects). There were significant pooled-group decreases in the butter phases in the sum of PUFA (3.502 g/100 g fat), 18:2 (3.252 g/100 g fat), n-6 FA (3.571 g/100 g fat) (all *P* = 0.001), and the sum of unsaturated FA (3.389 g/100 g fat; *P* = 0.02) (Table 4). The ratio of n-6/n-3 FA was lower in the butter than in the margarine phases (mean: 13.7 vs. 17.9, *P* < 0.01), but the dif-

ference was only minimal if we consider a ratio of 1 vs. 50 in the corresponding study products (see Table 1).

The butter phases showed highly significant pooled-group differences (g/100 g fat; all *P* < 0.001) vs. margarine in the following individual FA (Table 4): increases in C_{15} (0.116 g), C_{16} (1.507 g), C_{17} (0.072 g), C_{18} (0.960 g), and *t*9,*c*12 + *t*11,*c*15 18:2 (0.043 g); decreases in *c*9,*c*12 18:2 (3.632 g), *c*,*c*20:2n-6 (0.056 g), and 20:3n-6 (0.062 g) FA.

CLA isomers. (i) At baseline. The overall baseline concentration (D1, after normal nonstandardized diet, *n* = 14) showed a predominance of the *c*9,*t*11 (277 ± 195 mg/100 g fat, range 77–800), *t*9,*t*11 (13 ± 7 mg/100 g fat, range 4–31), and *t*11,*c*13 (12 ± 10 mg/100 g fat, range 2–37) 18:2 isomers, and a total CLA concentration of 352 ± 229 mg/100 g fat (range 103–956).

(ii) During the study. Analysis of the mean pooled study day values (D5 + D10 and D15 + D20, respectively), showed significant increases in *t*12,*t*14, *t*11,*t*13, *t*6,*t*8, *c*11,*t*13, *t*11,*c*13, *c*9,*t*11, and *t*8,*c*10 18:2 as well as in the sum of CLA isomers during Alpine butter intake of both groups (Table 4). There were no significant period effects. Pooled-group increases of the individual isomers, expressed per 100 g fat, are shown in Figure 2. The sum of CLA isomers increased by 129.4 mg (45.0%, *P* = 0.005) and the ratio of *t*11,*c*13 and *t*7,*c*9 18:2 isomers by 70.8% (*P* < 0.0001).

DISCUSSION

This study demonstrated that 10-d supplementation with Alpine butter, a natural CLA-rich product, affects the FA and CLA isomer content of human milk.

Butter significantly increased the concentrations of saturated FA. At study start (after a normal nonstandardized diet), 18 *c*9,*t*11 18:2 and total CLA concentrations in human milk were 277 ± 195 (range 7–800) and 352 ± 229 (range 103–956) mg/100 g fat, respectively. The isomers showing the highest increases in milk were *t*11,*c*13 (100.5%), *t*6,*t*8 (67.3 %), *t*12,*t*14 (61.3%), *c*9,*t*11 (49.7%), *c*11,*t*13 (39.6%), *t*11,*t*13 (34.0%), and *t*8,*c*10 (28.2%) (all *P* < 0.05).

Ethical limitations in standardization and compliance, which was not 100% in our study (Table 3), make human data inevitably more variable than their dairy counterparts. The women were allowed to consume their total supplement per 24 h in as many portions as they wished, and we could not control for the well-known differences in absorption relating to the amount of fat per portion (23). However, our study has certain advantages compared with others with human milk (9,10). The cross-over design excluded interindividual differences and differences due to lactation duration; all subjects consumed the same supplements with defined fat content and FA composition; milk sampling was standardized (volume, time of day) to minimize the effect of differential fat absorption (23) and milk volume (24); dietary intake of other dairy and beef products was recorded daily throughout the study; BMI was calculated throughout; milk analysis was longitudinal, with two time points per period. Since no significant differences were found in compliance, BMI, dietary (nonsupplement) CLA intake, or total milk fat content between periods or groups, these factors can be excluded as accounting for the differential milk content of FA or CLA isomers in response to butter supplementation.

Our basal value in human milk for the predominant isomer (*c*9,*t*11 18:2) (0.25 g/100 g fat) is similar to those reported by Jensen *et al.* (0.19 and 0.18 g/100 g fat) (25,26), Park *et al.* (0.21 g/100 g fat) (10), and Ritzenthaler *et al.* (0.28 g/100 g total FA) (12) in lactating American mothers during the low-dairy periods (10,25,26) or in baseline (12). However, McGuire *et al.* (27) and Innis and King (28) recorded higher basal values (0.4 g/100 g fat) in American mothers, matching those in German mothers (0.39 and 0.40 g/100 g fat) (29).

The increase in the predominant *c*9,*t*11 isomer in our study by 109.8 mg/100 g fat (49.7%) approximates that reported by Park *et al.* (10) (64.6%) from the low to the high CLA dairy period of their study and is higher than that reported by Ritzenthaler *et al.* (12) (29.0%) from baseline to 4 wk of consumption of high-CLA cheese. Unlike us, earlier investigators into human milk CLA content could identify, in addition to the predominant *c*9,*t*11 18:2 isomer, only *t*9,*t*11 (29), *t*10,*c*12 (12,27,29), *t*7,*c*9 (30), and *t*9,*t*11/*t*10,*t*12 18:2 (12). In milk

TABLE 4
FA and CLA Isomers in Human Milk (per 100 g human milk fat) During Maternal Supplementation with Margarine and Alpine Butter (pooled study days)

from German women, *c*9,*t*11 18:2 accounted for no more than 0.39%, *t*9,*t*11 18:2 at most 0.04%, and *t*10,*c*12 18:2 at most 0.08% of total FA (29). For Yurawecz *et al.* (30), the *t*7,*c*9 18:2 isomer accounted for 5.5–9.9% of total CLA. In our study, the *c*9,*t*11, *t*9,*t*11, *t*7,*c*9, and *t*10,*c*12 isomers accounted for 0.380, 0.019, 0.018, and 0.002% of total FA and for 79, 3.9, 3.6, and 0.3% of total CLA; these values are consistent with those indicated above.

The distribution of other FA in milk during the study periods reflects some but not all of the differences between supplements (Table 1). The 18:1 *trans* FA other than *trans*10-11, which occur in low concentrations in both study products, also show low concentrations in human milk during both phases. This aspect could be of interest because in recent years attention has been given to the potential impairment of EFA metabolism to their long-chain metabolites by the *trans*-isomers in humans (31). It is therefore unlikely that the small amounts found in human milk in our study have any important negative effect on the newborn. The higher amounts of C_{15}, C_{16}, C_{17}, and C_{18} acids and the *trans* unsaturated octadecadienoic acids (*t*9,*c*12 + *t*11,*c*15 18:2) are likely to have resulted from their higher content in Alpine butter. C_{15} and C_{17} acids are synthe-
FIG. 2. Mean increase (%) of CLA isomers in human milk during pooled Alpine butter intake (*n* = 14).

sized by ruminant flora but not in humans owing to the uneven number of carbon atoms (32). They thus act as markers of a dairy fat diet (33,34). The highly significant decrease (3.63 g/100 g milk fat = 26.3%) in octadecadienoic acid (*c*9,*c*12 18:2) on butter vs. margarine is also probably due to its much lower content in butter than in margarine (1.53 g vs. 46.70 g/100 g fat). The n-6 FA that occur at high concentrations in margarine have an extremely low transfer into human milk.

Mothers can rapidly and easy modulate the fat composition of their milk by consuming Alpine butter (or related natural dairy products). This could have positive implications for the newborn. Several studies, most of them in animals, have indicated the potential impact of CLA-rich milk on the development of the newborn. One point could be the potential effect on body weight. In rats, the *c*9,*t*11 18:2 isomer increases body weight (14,35), whereas the *t*10,*c*12 18:2 isomer decreases it in both mice (35,36) and humans [loss of body fat in diabetics (37)]. Another point could be the protection of CLA-rich milk against development of atopy. In rats and mice, oral supplementation with 100 mg/kg CLA (isomer profile unknown) reduces allergic anaphylaxis (by decreasing blood pressure), vasodilatation, and scratching behavior in response to egg-white lysozyme (38). However, further studies in humans are necessary to confirm these effects and to show whether human milk with a special pattern of FA and CLA could be a functional food for newborns.

ABSTRACT: This study examined the effects of feeding pasture vs. concentrate on the distribution of CLA isomers in the lipids of *longissimus* and *semitendinosus* muscle, liver and heart muscle, and subcutaneous fat in beef bulls. Sixty-four German Holstein and German Simmental bulls were randomly allocated to either an indoor concentrate system or periods of pasture feeding followed by a finishing period on a concentrate containing linseed to enhance their beef content of n-3 PUFA and CLA. The concentrations of CLA isomers in the different tissues were determined by GC and silver ion HPLC. The diet affected the distribution of individual CLA isomers in the lipids of the different tissues. The concentration (mg/100 g fresh tissue) of the most prominent isomer, *cis*-9,*trans*-11 18:2, was increased up to 1.5 times in liver and heart tissue of bulls fed on pasture as compared with concentrate. However, no diet effect was observed for *cis*-9,*trans*-11 18:2 in the lipids of *longissimus* muscle and subcutaneous fat. In all tissues, the second-most abundant CLA isomer in concentrate-fed bulls was *trans*-7,*cis*-9 18:2. In contrast, *trans*-11,*cis*-13 18:2 was the second-most abundant CLA isomer in all investigated tissue lipids of pasture-fed bulls. The concentration of the *trans*-11,*cis*-13 18:2 isomer was up to 15 times higher in tissues of pasture-fed bulls as compared with concentrate-fed animals. Furthermore, diet affected the concentrations of the CLA *trans,trans* 18:2 isomers. Pasture feeding significantly increased the concentrations of some *trans,trans* 18:2 isomers as compared with concentrate, predominantly *trans*-12,*trans*-14 18:2 and *trans*-11,*trans*-13 18:2. Overall, pasture feeding resulted in significantly increased concentrations of the sum of CLA isomers in the lipids of *longissimus* muscle, subcutaneous fat, heart and liver muscle of German Holstein and German Simmental bulls, but not in *semitendinosus* muscle.

Paper no. L9674 in *Lipids* **40**, 589–598 (June 2005).

CLA consists of a collection of positional and geometric isomers of octadecadienoic acid, with conjugated double bonds ranging from positions 6,8- to 12,14-. For each positional isomer there are four possible geometric pairs of isomers (e.g., *cis,trans*; *trans,cis*; *trans,trans*; *cis,cis*). Ruminant meats and milk and their products are the main source of CLA in the human diet. CLA has been linked to a multitude of potential health benefits, including inhibition of carcinogenesis, reduced rate of fat deposition, altered immune response, reduced serum lipids, and antidiabetic and antiatherogenic effects (1–4). Most of the research has focused on two isomers: *cis*-9,*trans*-11 18:2 and *trans*-10,*cis*-12 18:2 (2–4). Studies on pure single isomers showed that they differ in biological activities as reported in recent reviews by Banni *et al.* (5), Khanal (6), and Martin and Valeille (7). In addition, current studies show that a mixture of *trans,trans* 18:2 isomers exhibited stronger cytotoxicity against NCI-N87 gastric cancer cells than *cis,trans/trans,cis* isomers (8). Therefore, the biological activities of all individual CLA isomers must be verified.

In ruminants, dietary PUFA undergo biohydrogenation in the rumen. *cis*-9,*trans*-11 18:2 is formed during biohydrogenation of linoleic acid in the rumen, and it was assumed that this was the source of *cis*-9,*trans*-11 18:2 in milk and intramuscular fat (9). Griinari *et al.* (10) and Palmquist (11) showed that the primary source of *cis*-9,*trans*-11 18:2 is the endogenous synthesis involving Δ^9-desaturase and *trans* vacccenic acid (18:1 *trans*-11), another intermediate in ruminal biohydrogenation. Recently, Kay *et al.* (12) demonstrated that a minimum estimate of 91% of *cis*-9,*trans*-11 18:2 in milk fat was produced endogenously in cows fed fresh pasture. The lipids in pasture are high in linolenic acid (18:3n-3), and in the rumen biohydrogenation of 18:3n-3 does not result in the production of *cis*-9,*trans*-11 18:2 as an intermediate. The processes of biosynthesis for the formation of CLA and its incorporation into ruminant products were described recently in reviews by Song and Kenelly (13) and Khanal and Dhiman (14). *cis*-9,*trans*-11 18:2 is the major CLA isomer in ruminant milk and meat products (15,16). *trans*-7,*cis*-9 CLA is the second-most abundant CLA isomer in ruminant fat and represents approximately 10% of total CLA in *longissimus* muscle of bulls (16). The CLA content of the ruminant fat can be increased by dietary modifications.

Several investigations demonstrated that feeding pasture to dairy cows doubles the CLA content of milk fat (17,18). Recently, Kraft *et al.* (19) and Collomb *et al.* (20) showed differences between the CLA isomer distribution in milk lipids of cows fed indoors with diets having high levels of unsaturated FA concentrate and of cows grazing in the Alps (Switzerland). The concentrations of many CLA isomers were highest in

the milk fat of cows fed on pasture in the Alps. In addition to the main isomer, *cis*-9,*trans*-11 18:2, there was a difference in the second-most abundant CLA isomer. *trans*-11,*cis*-13 18:2, in milk fat of pasture-fed cows CLA represented more than a fourth of the total CLA present in milk fat (19,20). However, overall there is only limited information about the effect of pasture on the concentration of individual CLA isomers in beef fat. Until now, the effects of pasture feeding on the CLA isomer distribution were predominantly investigated in milk products. Only a few publications deal with the CLA isomer distribution in different beef tissues. Nuernberg *et al.* (21) and Dannenberger *et al.* (22) described the effects of CLA isomer distribution in *longissimus* muscle of German Simmental and German Holstein bulls fed pasture compared with concentrates indoors. Pasture feeding compared with concentrate feeding decreased the proportion of *trans*-7,*cis*-9 18:2 to 4.1% of total CLA in the muscle and increased *trans*-11,*cis*-13 18:2 up to 18.5% of total CLA. Furthermore, pasture feeding resulted in significantly higher concentrations of *trans*-12,*trans*-14 18:2 and *trans*-11,*trans*-13 18:2 among the CLA *trans*,*trans* 18:2 isomers in the muscle lipids of both breeds (21,22).

In measuring CLA, it is important to separate the individual CLA isomers because of the different effects of some CLA isomers in biological systems. This is particularly important because the CLA distribution pattern in the tissue lipids will be affected by different diet systems. The silver-ion HPLC (Ag$^+$-HPLC) method has proven very useful for the separation of geometrical and positional CLA isomers (23–25).

A large study was established to investigate the effect of feeding pasture vs. concentrate to two different breeds (German Holstein and German Simmental) on the meat quality and the FA composition of intramuscular fat in muscles of bulls. The results regarding aspects of meat quality and FA composition in different lipid fractions (total lipids, TG, and phospholipids) have been reported recently by Nuernberg *et al.* (26) and Dannenberger *et al.* (22, 27). This paper reports the effects of pasture vs. concentrate diet on the concentration (mg/100 g fresh tissue) of individual CLA isomers in *longissimus* muscle, *semitendinosus* muscle, subcutaneous fat, and heart muscle and liver of German Holstein and German Simmental bulls.

EXPERIMENTAL PROCEDURES

Materials. Sixty-four bulls of two breeds (5–6 mon old), German Simmental (*n* = 31) and German Holstein (*n* = 33), were randomly assigned to two dietary treatments, concentrate or pasture. German Simmental (*n* = 16) and German Holstein bulls (*n* = 17) fed on concentrate were kept in a stable and fed using single-fodder workstations. The concentrate ration consisted of winter barley, molasses particles, soybean extraction particles, calcium carbonate, sodium chloride, and a mixture of minerals and vitamins. The forage component of the diet consisted of maize silage (13.8 kg/d), concentrated feed (3.2 kg/d), soybean extraction particles (0.15 kg/d), hay (0.1 kg/d), and straw (0.09 kg/d). German Simmental (*n*-15) and German Holstein bulls (*n*-16) were kept on pasture during two summer

periods (approximately 160 d) followed by indoor periods (approximately 190 d) when animals received semi-*ad libitum* a high-energy diet. The latter consisted of wilted silage (15 kg/d), hay (0.7 kg/d), a mixture of minerals and a mixture of vitamins, and a special concentrate diet containing 12% barley, 10% coarsely cracked linseed, and a mixture of minerals and vitamins. The chemical composition including the FA composition of the diets has been reported by Nuernberg *et al.* (26). All bulls were slaughtered at 620 kg live weight in the abattoir of the Research Institute for the Biology of Farm Animals Dummerstorf (Germany) and the carcasses were chilled (4°C) before muscle samples were removed. The heart and liver samples were taken immediately (35 min) after slaughter. Samples of the *longissimus* and *semitendinosus* muscles and of the subcutaneous fat were taken at the sixth rib of the left carcass side 24 h after slaughter and stored frozen at −70°C until lipid extraction and assessment of the FA composition of the muscle lipids.

A reference standard, Sigma-FAME mixture, and a mixture of methyl esters of CLA were obtained from Sigma-Aldrich (Deisenhofen, Germany). Individual isomers of CLA methyl esters (CLA-ME), *cis*-9,*trans*-11 18:2, *trans*-9,*trans*-11 18:2, *trans*-10,*cis*-12 18:2, and *cis*-9,*cis*-11 18:2, were purchased from Matreya (Pleasant Gap, PA). All solvents used were HPLC grade from Lab-Scan (Dublin, Ireland).

Methods. (i) Extraction of tissue lipids. The intramuscular fat from 1 to 2 g of tissue was extracted with chloroform/methanol (2:1, vol/vol) according to Folch *et al.* (28) by homogenization (UltraTurrax, 3 × 15 s, 12,000 rpm) at room temperature. The details of muscle lipid extraction were described previously (21). Nonadecanoic acid methyl ester, used as an internal standard, was added to the lipids prior to saponification and methylation.

(ii) GC analysis. The FA composition of tissue lipids was determined by capillary GC using a CP SIL 88 CB column (100 m × 0.25 mm; Chrompack-Varian, Bridgwater, NJ) installed in a PerkinElmer gas chromatograph Autosys XL with an FID and split injection (PerkinElmer Instruments, Shelton, CT). Initial oven temperature was 150°C, held for 5 min, subsequently increased to 175°C at a rate of 2°C min^{-1}, held for 15 min, then to 200°C at 7°C min^{-1}, held for 20 min, then to 220°C at 5°C min^{-1} and held for 25 min. Hydrogen was used as the carrier gas at a flow rate of 1 mL min^{-1}. The split ratio was 20:1, the injector was set at 260°C, and the detector at 280°C. The amounts were calculated using the internal standard method of Turbochrom workstation software. The calculation for the index of stearoyl CoA desaturase (Δ^9-desaturase) activity was calculated according Malau-Aduli *et al.* (29) [Δ^9-Desaturase index = 100 × (14:1 + 16:1 + 18:1)/(14:1 + 16:1 + 18:1 + 14:0 + 16:0 + 18:0)].

(iii) Ag$^+$-HPLC. The distribution of CLA isomers was determined using an HPLC system (LC10A; Shimadzu, Tokyo, Japan) equipped with a 50 μL injection loop, a photodiode array detector (SPD-M10Avp; Shimadzu) operated at 233 nm, and an operating system (Shimadzu CLASS-VP version 6.12 sp4). Two ChromSpher 5 Lipids silver-impregnated columns (4.6 mm i.d. × 250 mm stainless steel; 5 μm particle size; Varian, Palo Alto, CA) were used in series. The mobile phase (0.1% acetonitrile,

0.5% diethyl ether in *n*-hexane) was prepared fresh daily and pumped at a flow rate of 1.0 mL/min. The injection volume depended on the total amounts of CLA and ranged between 20 and 40 µL. The Ag⁺-HPLC quantification of CLA isomers is based on the measurement of the integrated area under the 233 nm peaks attributed to conjugated dienes. The identification of the CLA isomers was made by the retention times of the standard compounds (*cis*-9,*trans*-11 18:2, *trans*-9,*trans*-11 18:2, *trans*-10,*cis*-12 18:2, and *cis*-9,*cis*-11 18:2). Starting from these compounds, the other isomers were identified from the known elution order. The elution order of the CLA isomers in beef was reported previously by Fritsche *et al.* (16) and Rickert *et al.* (23) and recently reviewed by Cruz-Hernandez *et al.* (25). Additionally, the identity of each isomer was controlled by the typical UV spectra of CLA isomers from the photodiode array detector in the range from 190 to 360 nm. The external calibration plots of the standard solutions were adapted to the different concentration levels of the individual CLA isomers in the lipid extracts. The external calibration plot of area vs. µg *cis*-9,*trans*-11 18:2 was prepared for a standard mixture in a range of 9.0 to 700 µg/mL. The external calibration plots of area vs. µg *trans*-9,*trans*-11 18:2, µg *trans*-10,*cis*-12 18:2, and µg *cis*-9,*cis*-11 18:2 were made for a standard mixture in the range of 0.5 to 20 µg/mL. The calibration of *trans*-9,*trans*-11 18:2 was used for the other *trans,trans* 18:2 isomers; the calibration of *trans*-10,*cis*-12 18:2 for the *cis,trans– trans, cis* isomers; and the *cis*-9,*cis*-11 18:2 calibration for the other *cis,cis* 18:2 isomers. Fritsche *et al.* (16) already have described this procedure for quantification of CLA isomers, which is not commercially available, in beef fat. Because of possible formation of artifacts during the sample preparation procedure, the very low concentrations of CLA isomers (<0.02 mg/100 g fresh tissue) were indicated as ND (not detectable). The detection limit of CLA isomers was calculated from the fivefold signal/noise ratio.

Statistical analysis. All data were analyzed by the least-squares method using the GLM procedures of the Statistical Analysis System (SAS© Systems, Release 8.2, SAS Institute Inc., Cary, NC). All tables contain the least squares mean (LSM) and the standard error (SEM) of the LSM. All statistical tests of LSM were performed for a significance level of $P = 0.05$.

RESULTS

The distribution pattern of CLA isomers in the intramuscular fat of the *longissimus* muscle, *semitendinosus* muscle, heart, and liver were very similar to that in the subcutaneous fat of both breeds. The predominant CLA isomer in all samples was *cis*-9,*trans*-11 18:2. The concentration of *cis*-9,*trans*-11 18:2 (mg/100 g fresh muscle) was highest in subcutaneous fat, up to 325 mg/100 g muscle, followed by the intramuscular fat of the *longissimus* and liver muscle, 14.4 and 10.2 mg/100 g muscle, respectively. The lowest values of *cis*-9,*trans*-11 18:2 occurred in the intramuscular fat of *semitendinosus* and heart muscle, ranging from 1.7 to 4.8 mg/100 g fresh muscle (Tables 1 to 5). The concentration of *cis*-9,*trans*-11 18:2 in the lipids of heart, liver, and *semitendinosus* muscle of both breeds was significantly affected by the diet. Pasture feeding as compared with concentrate feeding significantly increased the concentration of *cis*-9,*trans*-11 18:2 in heart and liver muscle by a factor of

approximately 1.4. No diet effect was detected for the *cis*-9,*trans*-11 18:2 content in *longissimus* muscle and subcutaneous fat (Tables 1, 3). However, a pasture diet significantly decreased the *cis*-9,*trans*-11 18:2 concentration in *semitendinosus* muscle (Table 2).

No diet effect was observed for the *trans*-7,*cis*-9 18:2 isomer in the muscle lipids of tissues, except *semitendinosus* and heart muscle. This isomer was identified by Fritsche *et al.* (16) and Yurawecz *et al.* (30) and reported to be the second-most abundant CLA isomer in commercial milk fat and beef muscle. However, this study has found that the second-most abundant CLA isomer in muscle lipids and subcutaneous fat of pasture-fed bulls was *trans*-11,*cis*-13 18:2. The highest concentration of *trans*-11,*cis*-13 18:2 was measured in subcutaneous fat of pasture-fed German

Simmental bulls (110 mg/100 g muscle). A pasture diet resulted in a very high accumulation rate of trans-11,cis-13 18:2 up to a factor of 14.5 as well as in muscle tissues and subcutaneous fat as compared with concentrate fed bulls (Tables 1–5). Furthermore, the concentration of trans-11,cis-13 18:2 was significantly affected by breed. The intramuscular fat in the muscles and the subcutaneous fat of the German Simmental bulls had a significantly higher concentration of trans-11,cis-13 18:2 as compared with the German Holstein bulls, except for the longissimus muscle (Tables 1–5). The concentration of trans-10,cis-12 18:2 was affected by diet, except in the heart muscle. Pasture feeding increased the concentration of trans-10,cis-12 18:2 in the lipids of longissimus muscle and liver and decreased the values in semitendinosus muscle and subcutaneous fat. Overall, the level of trans-10,cis-12 18:2 was generally low in all samples and ranged between 0.02 and 0.35 mg/100 g fresh tissue (Tables 1–5). Among the trans,trans isomers of CLA, trans-12,trans-14 18:2 and trans-11,trans-13 18:2 were significantly affected by the diet in all tissues. Pasture feeding resulted in an increase in the concentration of trans-12,trans-14 18:2 by a factor of approximately 5 in the

muscle tissues and subcutaneous fat (Tables 1–5). Furthermore, pasture feeding resulted in a significantly higher concentration of *trans*-11,*trans*-13 18:2 in all tissues. The concentrations of *trans*-10,*trans*-12 18:2, *trans*-9,*trans*-11 18:2, *trans*-8,*trans*-10 18:2, and *trans*-7,*trans*-9 18:2 were lower than the two other *trans,trans* isomers, described above. In the *semitendinosus* and heart muscles these *trans,trans* 18:2 isomers were mostly not detected. Additionally, the *cis,cis* 18:2 isomers were below the detection limit in all samples investigated. The peaks detected in the region of the CLA *cis,cis* isomers of the Ag⁺-HPLC chromatograms did not show UV spectra (photodiode array detector from 190 to 360 nm) typical of CLA isomers and were not identified as CLA *cis,cis* isomers. The geometrical isomer pairs of *cis,trans/trans,cis* 18:2 could not be separated by using a double-Ag⁺-HPLC column system. The concentrations of *cis,trans* or *trans,cis*18:2 in Tables 1 to 5 are the sum of both geometrical isomers. The use of six Ag⁺-HPLC columns in series clearly resolved (Fig. 1) the two 11,13 geometric isomers (32).

The total FA composition of the *longissimus* and *semitendinosus* muscle and subcutaneous fat was reported before (26,33). The total FA concentration (mg/100 g fresh muscle) of the heart muscle and liver is summarized in Tables 6 and 7.

Pasture feeding resulted in a significantly higher concentration of *cis*-9,*trans*-11 18:2 (determined by GC), up to 15.9 mg/100 g fresh muscle in the lipids of liver as compared with concentrate-fed bulls of both breeds (Tables 6, 7). The level of *cis*-9,*trans*-11 18:2 in the lipids of liver was approximately 2.5 times higher as compared with the concentration in the heart muscle (Tables 6, 7). Comparison of the *cis*-9,*trans*-11 18:2 concentration showed higher values measured by GC as compared with Ag⁺-HPLC. The values measured by GC included *cis*-9,*trans*-11 18:2, *trans*-7,*cis*-9 18:2, and *trans*-8,*cis*-10 18:2 (16). However, the sum of *cis*-9,*trans*-11 18:2, *trans*-7,*cis*-9 18:2, and *trans*-8,*cis*-10 18:2 values measured by Ag⁺-HPLC is lower than the concentration of *cis*-9,*trans*-11 18:2 measured by GC. One reason could be the occurrence of coeluting compounds detected with GC/FID, also described by Fritsche *et al.* (16) and Cruz-Hernandez *et al.* (25). Pasture-fed bulls had significantly increased total and individual n-3 FA concentrations in liver and heart muscle lipids of both breeds. The highest accumulation was detected for linolenic acid (18:3n-3) in the heart muscle of pasture-fed German Holstein bulls (concentrate: 13.2 mg/100 g vs. pasture: 59.4 mg/100 g, Table 7). In contrast, pasture feeding resulted in a significant decrease of total and individual n-6 FA concentrations in liver and heart muscle lipids of both breeds. Consequently, the n-6/n-3 ratio was beneficially low in pasture-fed bulls, ranging between 1.3 and 1.4 in the lipids of liver and 3.2 and 3.6 in the lipids of heart muscle (Tables 6, 7). However, no diet effect was detected for the concentration of saturated FA.

DISCUSSION

The occurrence of the main CLA isomer, *cis*-9,*trans*-11 18:2, in the lipids of beef muscles as affected by feeding pasture compared with concentrate has been extensively investigated (34–39). Diets containing proportionally high levels of linolenic acid in the fat, such as fresh grass, grass silage, concentrates containing linseed, and pasture feeding with finishing periods, resulted in increased deposition of *cis*-9,*trans*-11 18:2 in the muscles (22,34,37,38). French *et al.* (34) reported a significant increase in *cis*-9,*trans*-11 18:2 in muscle of crossbred steers grazed for 85 d on pasture compared with concentrate, averag-

ing 1.08 and 0.37% of total FA, respectively. Steen and Porter (37) reported that the content of *cis*-9,*trans*-11 18:2 in muscle and subcutaneous fat from steers finished on pasture was three times higher than in those on concentrate. Similarly, Poulson *et al.* (38) observed a significant increase of *cis*-9,*trans*-11 18:2 in muscle of crossbred steers on forage and pasture without grain supplementation. Our results regarding CLA isomers analyzed by Ag[+]-HPLC showed that the highest accumulation rates of the main isomer, *cis*-9,*trans*-11 18:2 (based on mg/100 g fresh tissue), occurred in the lipids of heart and liver tissue of pasture-fed bulls as compared with concentrate-fed bulls (Tables 4, 5). However, no effect of pasture feeding as compared

with concentrate was found for *cis*-9,*trans*-11 18:2 in the lipids of *longissimus* muscle and the subcutaneous fat as well as of German Holstein and German Simmental bulls. Furthermore, pasture feeding significantly decreased the *cis*-9,*trans*-11 18:2 concentration in the *semitendinosus* muscle (Table 2).

Most of the studies of biosynthetic formation of CLA, predominantly *cis*-9,*trans*-11, involving animals that were pasture-fed were carried out with milk fat (10–12,19,20). The lipids in pasture are high in linolenic acid (18:3n-3), and the biohydrogenation by rumen microorganisms does not include *cis*-9,*trans*-11 18:2 as an intermediate (9). *Trans* vaccenic acid (18:1 *trans*-11) is formed during the biohydrogenation of linolenic acid and linoleic acid to stearic acid, and therefore *trans* vaccenic acid is a common intermediate in the metabolic pathway of linoleic and linolenic acids (9). Griinari and Bauman (40) concluded that a relatively small proportion of the *cis*-9,*trans*-11 18:2 formed in the rumen escapes and is available for deposition in the muscles. Griinari *et al.* (10) showed that the primary source of *cis*-9,*trans*-11 18:2 was from the endogenous synthesis involving Δ^9-desaturase and *trans* vaccenic acid. Recently, Kay *et al.* (12) confirmed these results and demonstrated that approximately 90% of *cis*-9,*trans*-11 18:2 in milk fat was produced endogenously in cows fed fresh pasture. Furthermore, Piperova *et al.* (41) investigated duodenal samples and estimated that rumen synthesis of CLA was 4 to 7% and the rest derived through endogenous synthesis. No similar studies have been reported to investigate the importance of endogenous synthesis of CLA isomers in the adipose tissue of ruminant muscles. However, Δ^9-desaturase also occurs in the small intestine and adipose tissue of ruminants (42), suggesting some endogenous synthesis may occur in these tissues as well. Very recently, Khanal and Dhiman (14) speculated that the contribution from the endogenous synthesis in muscle tissues is similar to that reported for milk because *trans* vaccenic acid and Δ^9-desaturase are the two primary prerequisites for the synthesis of *cis*-9,*trans*-11 18:2. The Δ^9-desaturase enzyme is active in ruminant adipose tissue (43), and their mRNA is well expressed (44).

Pasture feeding increased the concentration of *cis*-9,*trans*-11 18:2 in the lipids of liver and heart muscle by a factor of approximately 2.0 as compared with concentrate feeding (Tables 4, 5). Also, the *trans* vaccenic acid concentrations were increased in the lipids of liver and heart muscle of pasture-fed bulls (Tables 6, 7). However, the other important parameter for the endogenous synthesis of *cis*-9,*trans*-11 18:2, the Δ^9-desaturase activity, calculated as a Δ^9-desaturase index according to Malau-Aduli (29), was significantly decreased by pasture feeding in the liver tissue (German Holstein bulls, concentrate: 24.7, pasture: 21.2, Table 4). No diet effect was found for the Δ^9-desaturase index in heart muscle (Table 5). The *cis*-9,*trans*-11 18:2 concentrations in the *longissimus* muscle tended to be higher in pasture compared with concentrate-fed bulls (significance at $P = 0.58$). The concentration of *cis*-9,*trans*-11 18:2 in the *longissimus* muscle was strongly correlated ($P < 0.001$) with *trans*-11 18:1 ($r = 0.80$, confidence interval 0.50–0.93) and also with *trans*-9 18:1 ($r = 0.75$, confidence interval 0.40–0.91), and *trans*-10 18:1 ($r = 0.86$, confidence interval

0.63–0.95) in pasture-fed compared with concentrate-fed bulls as described earlier (22).

Kay *et al.* (12) presented the first study to examine the importance of endogenous synthesis of *cis*-9,*trans*-11 18:2 in milk fat of pasture-fed cows. Pasture diets have a number of differences that are important considerations in the biology of *cis*-9,*trans*-11 18:2 in milk. First, pasture results in a milk fat with a higher content of *cis*-9,*trans*-11 18:2 than observed with typical totally mixed ration diets. Second, the FA present in concentrates and most plant oils that are used in dairy cow diets are high in linoleic acid (12). On the contrary, pasture lipids are high in linolenic acid, and its biohydrogenation produces *trans* vaccenic acid, but not *cis*-9,*trans*-11 18:2, as an intermediate (9). These differences suggest that endogenous synthesis may be a relatively more important source of CLA in milk from cows consuming pasture (12). Recently, different studies have shown the diet effect of pasture feeding on the distribution of all CLA isomers in lipids of milk fat analyzed by Ag$^+$-HPLC (19,20). However, the knowledge of the distribution of Ag$^+$-HPLC-analyzed CLA isomers in the lipids of beef products affected by pasture feeding is limited (21,22). Our study showed that, besides *cis*-9,*trans*-11 18:2, pasture feeding affected the concentration of *trans*-11,*cis*-13 18:2, *trans*-11,*trans*-13 18:2, and *trans*-12,*trans*-14 18:2 in the lipids of *longissimus*, liver, heart muscle and subcutaneous fat in German Holstein and German Simmental bulls, (Tables 1, 3, 4, 5). Pasture compared with concentrate feeding led to a very high accumulation of the isomer *trans*-11,*cis*-13 18:2, up to a factor of 14.5, as well as in muscle tissues and subcutaneous fat. The second- and third-highest accumulations in tissues and subcutaneous fat of pasture-fed bulls were observed for the *trans*-11,*trans*-13 and *trans*-12,*trans*-14 18:2 isomers, up to a factor of 7.1, respectively. These results confirmed the investigations of Kraft *et al.* (19) and Collomb *et al.* (20) in lipids of milk fat from cows fed high levels of unsaturated FA. The concentration of the *trans*-11,*cis*-13 18:2 isomer was about four times higher in milk fat from grazing cows in the Alps (Switzerland) as compared with indoor-fed cows (19,20). It is well known that the pathway for the biohydrogenation in the rumen of linolenic acid (*cis*-9,*cis*-12,*cis*-15 18:3), up to 65% in the lipids of pasture diets, involves an initial isomerization to a conjugated triene (*cis*-9,*trans*-11,*cis*-15 18:3). The next step is the hydrogenation to *trans*-11,*cis*-15 18:2, which undergoes further hydrogenation, depending on the bacteria involved, leaving *trans*-vaccenic acid. The final product is stearic acid (9). But the metabolic pathway from the intermediate *trans*-11,*cis*-15 18:2 to *trans*-11,*cis*-13 18:2 is unknown until now. Collomb *et al.* (20) inferred that the *trans*-11,*cis*-13 18:2 isomer could be a useful indicator of milk products of Alpine origin. Kraft *et al.* (19) hypothesized that linolenic acid is an indirect precursor of *trans*-11,*cis*-13 18:2 in milk fat. Furthermore, Kraft *et al.* (19) discussed that the *trans*-11 double bond seems to be the most stable *trans*-bond among the 18:1 and CLA isomers during the ruminal fermentation, and they observed the formation of larger amounts of CLA isomers with a *trans*-11 double bond—*cis*-9,*trans*-11, *trans*-11,*cis*-13, and *trans*-11,*trans*-13 18:2 isomers—in milk from grazing cows in the Alps. Also, we found that, among the CLA *trans*,*trans* isomers

in the lipids of muscle tissues and subcutaneous fat of both breeds, the *trans*-11,*trans*-13 18:2 was the most abundant compound, followed by the *trans*-12,*trans*-14 18:2 (Tables 1–5).

Previous studies showed that the *trans*-7,*cis*-9 18:2 isomer is the second-most abundant CLA isomer in beef meat and milk products (16,30,45–48). In the muscle lipids and subcutaneous fat of concentrate-fed German Holstein and German Simmental bulls, *trans*-7,*cis*-9 18:2 was also the second-most abundant CLA isomer. However, a pasture diet had no effect on the *trans*-7,*cis*-9 18:2 concentration in lipids of *longissimus* muscle, liver, and subcutaneous fat. The *trans*-7,*cis*-9 18:2 concentration in the lipids of heart and *semitendinosus* muscle was slightly increased and decreased, respectively, in pasture-fed bulls as compared with concentrate. Because of the significantly higher concentrations of *trans*-11,*cis*-13 18:2, *trans*-7,*cis*-9 18:2 is the third-most abundant isomer in the tissue lipids of pasture-fed bulls. Corl *et al.* (49) studied the metabolic pathway for the formation of *trans*-7,*cis*-9 18:2 in the rumen of dairy cows and showed that this CLA isomer is synthesized endogenously almost exclusively by Δ^9-desaturase using rumen-derived *trans*-7 18:1 as the substrate. Piperova *et al.* (46) also concluded that almost all *trans*-7,*cis*-9 18:2 present in milk fat was produced postruminally. The endogenous synthesis of *trans*-7,*cis*-9 18:2 in intramuscular and subcutaneous fat was not investigated until now, but it could be expected to be analogous to that of *cis*-9,*trans*-11 18:2 since both of them use the activity of the same enzyme. As mentioned earlier, in our study pasture feeding decreased the Δ^9-desaturase activity, calculated as a Δ^9-desaturase index according to Malau-Aduli (29). That could be one reason why the CLA *trans*-7,*cis*-9 were not affected by pasture compared with concentrate diet in most of the investigated tissues.

The concentration of *trans*-10,*cis*-12 18:2 was affected by diet, except in the heart muscle. Pasture feeding resulted in an increased *trans*-10,*cis*-12 18:2 concentration in the lipids of *longissimus* and liver muscle and in decreased concentration in the lipids of *semitendinosus* muscle and subcutaneous fat as compared with concentrate feeding. Though important physiologically, the proportion of *trans*-10,*cis*-12 18:2 to the sum of all isomers in the lipids of pasture- and concentrate-fed bulls was quite low (0.3–1.8%). Because mammals do not have Δ^{12}-desaturase, *trans*-10,*cis*-12 18:2 cannot be endogenously produced. *trans*-10,*cis*-12 18:2 reported in the lipids of milk and tissue originates from the absorption processes in the intestine (19).

Thus, pasture feeding resulted in a variation in the distribution pattern and concentration level of individual CLA isomers in all investigated tissues. Overall, pasture feeding enhanced the concentration of the sum of CLA isomers in the tissue lipids. Further studies will clarify the high accumulation rates and the metabolic pathways of CLA *trans*-11,*cis*-13 and some isomers of CLA *trans*, *trans* in the tissues of pasture-fed bulls.

Daphnia magna Can Tolerate Short-Term Starvation Without Major Changes in Lipid Metabolism

E.A. Bychek[a], G.A. Dobson[b], J.L. Harwood[c],*, and I.A. Guschina[c]

[a]Institute of Ecology of the Volga River Basin RAS, Togliatti 445003, Russia, [b]Scottish Crop Research Institute, Invergowrie, Dundee DD2 5DA, United Kingdom, and [c]School of Biosciences, Cardiff University, Cardiff CF10 3US, United Kingdom

ABSTRACT: *Daphnia magna* is a common crustacean that is adapted to brief spells of fasting. Lipids are naturally a major component of their diet and are stored as energy reserves. However, there has been some controversy in the literature on the extent to which dietary lipids are used directly for complex lipid formation in *Daphnia*. We examined lipid metabolism in *D. magna* by labeling the animals using [1-^{14}C]acetate and then followed the turnover of radiolabeled lipids during a pulse chase. *Daphnia* were either fed or maintained without food during the chase period. The decrease in radioactivity during the chase was relatively unaffected by feeding, although there were some differences in the distribution of radioactivity between lipid classes or individual FA. The polar lipids, which were four times better labeled than nonpolar lipids, contained the most radioactivity in the zwitterionic phosphoglycerides, PE and PC. Under the experimental conditions, the turnover of the polar membrane lipids was unaffected by feeding. Within nonpolar lipids, TAG accounted for up to about 80% of the label, followed by DAG. Overall, our data show that *D. magna* is capable of high rates of lipid radiolabeling *de novo* and, in addition, is able to use—and indeed may be dependent on—some dietary components such as the PUFA linoleate and α-linolenate. The results also clearly show that *Daphnia* is able to tolerate brief spells of fasting (24 h) with very little change to its lipid metabolism.

Paper no. L9689 in *Lipids 40*, 599–608 (June 2005).

Crustaceans, like other animals, need a balanced supply of nutrients for development, growth, reproduction, and survival. Lipids, together with proteins and carbohydrates, are important dietary components for crustaceans, in which they function as both a general energy source and as essential nutrients. Crustaceans are considered to be unable to synthesize, and may consequently require an exogenous source of, linoleic (18:2n-6) and α-linolenic (18:3n-3) acids as examples of essential PUFA. However, it should be emphasized that an essential FA requirement has been unequivocally demonstrated only in mammals (1). In other organisms they may be better called essential nutrients, as defined by Lauritzen and Hansen (2). In addition, specific aspects of crus-

tacean lipid nutrition are the requirement for sterols (3) and possibly some phospholipids (4). Sterols are metabolic precursors of steroid hormones and molting hormones and cannot be synthesized by crustaceans *de novo* (5,6). Dietary phospholipids, such as PC and/or PI, have been suggested to accelerate the transport of dietary lipids, especially cholesterol, in some crustaceans (5). The major lipid classes of most aquatic animals are phosphoglycerides, TAG, wax esters, and sterols (7). The phosphoglycerides and sterols are structural and functional elements of cell membranes, whereas TAG and wax esters are storage biomolecules that provide metabolic energy through oxidative catabolic reactions. TAG contents are often highly variable and depend on the nutritional and physiological states of organisms. Moreover, they are influenced by environmental factors (8,9). In contrast, the phosphoglycerides of a given species are considered to be much less variable and essentially independent of their nutritional state (10).

Although lipids are important for zooplankton (11,12), little, in general, is known about lipid metabolic pathways in freshwater crustaceans. Nevertheless, it has been shown that zooplankton can accumulate large amounts of lipids (up to 40–70% of their dry body mass) (13,14), and Goulden and Place (15) were the first researchers who tried to answer the question "What proportion of accumulated lipids originate from the diet and how much is synthesized by animals *de novo*?" In a series of tracer experiments using ^{14}C-acetate or ^{3}H-water, incorporation of radioactivity into FA was studied and the rates of *de novo* FA synthesis were calculated in two species of daphniids, *Daphnia magna* and *D. pulicaria*. Goulden and Place (16) concluded that no more than 1.6 or 0.16% of the accumulated FA could be biosynthesized by either species under high-food and low-food conditions, respectively. According to their results, at least 98% of the total lipids, and virtually all of the storage lipids, were derived from the diet. Incorporated radioactivity was largely found in phosphoglycerides and was not present in storage lipids. In fact, they concluded that most of the incorporation was a result of the chain elongation of dietary acids. Thus, they suggested that storage lipid accumulation rates in daphniids were strongly regulated by the availability of dietary lipids (15,16).

In contrast, Farkas *et al*. (17) showed that some copepods, namely, *Cyclops strenuus* and *D. magna*, showed substantial FA synthesis rates. Their calculations indicated that 0.9% of

---

the total FA were renewed in 1 h in *D. magna*, and they suggested that the bulk of FA accumulated in both species could be synthesized by the animals. They also showed that incorporation of radioactivity from labeled acetate into total lipids was greatly affected by temperature, with large changes in the pattern of FA labeled in *D. magna* (17). Various other external (e.g., UV light, salinity, dissolved oxygen concentration, pH, water transparency, stressors) and internal (e.g., reproductive condition) factors may also influence zooplankton lipid composition and biosynthesis (13,18–20). *De novo* lipogenesis has also been measured in the euphausiids *Thysanoessa inermis* and *T. raschii,* where *de novo* lipogenesis was shown to be capable of accounting for much of the lipids accumulated by these animals in the field (21). Moreover, extensive lipid synthesis in the presence of a substantial input of dietary lipids has been noted when studying the importance of *de novo* lipid biosynthetic activity in the accumulation of wax esters by marine zooplankton (21). This finding is relatively unusual for animals, where the activity of FA synthase itself is often repressed by a substantial input of dietary FA (especially polyunsaturated ones) so that *de novo* FA biosynthesis no longer proceeds at significant rates (22,23). It is not known whether such repression takes place in freshwater copepods, which do not possess active wax ester synthesis and accumulation. Furthermore, according to Goulden and Place (15,16), in poorly fed daphniids, the rate of *de novo* synthesized FA was 10-fold slower than in well-fed animals. Thus, answers to the question, "How may food availability modify basic lipid metabolism in copepods?" are contradictory, and more experimental work is obviously needed to clarify the topic.

In the present work we studied lipid metabolism in the important freshwater crustacean *D. magna* by following the incorporation of radiolabel from [1-14C]acetate in pulse-chase experiments and its response to either starvation or feeding using the alga *Coccomyxa peltigeracea* as a food source. We used this radiolabeled precursor because it is regarded as a good compound with which to examine *de novo* FA biosynthesis and to allow comparison with the previous work referred to above (15–17). *Daphnia magna* represents freshwater cladocerans, which are important in the structure of the zooplankton community. *Daphnia* spp. are one of the most important live foods for fish, and *D. magna* is the largest of these species. Moreover, although this species has been widely used as a model animal in ecological, toxicological, and physiological studies (24,25), experimental data on changes in the lipid biochemistry of daphniids in response to altering feeding conditions are limited. Nevertheless, a number of publications have reported aspects of lipid composition (26,27), including those for other *Daphnia* species, which include examination of the possible physiological role of the diet (28–35). These provide a good background to our re-examination of the ability of *Daphnia* to synthesize FA *de novo* and incorporate them into lipids, and whether these processes are affected by their nutritional status.

EXPERIMENTAL PROCEDURES

Chemicals and reagents. FA standards were obtained from Nu-Chek-Prep. Inc. (Elysian, MN) and silica gel G plates were from Merck (Darmstadt, Germany). Complex lipid standards were from Sigma (Poole, Dorset, United Kingdom). [1-14C]Acetate, Na salt (sp. act. 1.85–2.29 GBq mmol^{-1}) was from Amersham Life Sciences Ltd. (Bucks, United Kingdom). Other reagents were of the best available grades and were from Sigma or from BDH (Poole).

Incubations. Stock cultures of *D. magna* Straus (Crustacea, Cladocera) were maintained in the laboratory in 0.45-μm filtered lake water at 24–25°C and fed with the green microalga *C. peltigeracea* grown in Bold's mineral medium (36). New hatchlings were used, and these were fed for 10 d prior to their use in the experiments. For pulse-chase experiments, immature parthenogenic females of *D. magna* with a body size of 1.7–2.0 mm were selected with a microscope, washed three times with 0.45-μm membrane filtered water, and 50 individuals transferred into 100-mL flasks containing 50 mL of filtered (0.45 μm) lake water at 24–25°C. This filter treatment of water is consistent with many previous studies using *Daphnia* spp. (28,32,34,35,37). For lipid labeling, 185 KBq of [1-14C]acetate was added to these flasks, and animals were incubated without algal food with radiolabel for 22 h (pulse period). At the end of the pulse period, the animals were rinsed three times with distilled water and transferred into the new 100-mL flasks containing 50 mL of filtered lake water. (This methodology did not impair the animal's ability for active movement or, in longer-term control experiments, to grow and reproduce. Furthermore, it did not result in any loss in detectable unlabeled or radiolabeled lipids compared with using filtered lake water.) Two feeding treatments were used. Animals in the first group were kept with no food until the end of the chase period, whereas the animals in the second group were fed with algae (1 mL, about 10 mg wet wt of the algal suspension to each flask). Sampling of the animals for lipid extraction was performed at 0, 4, 8, 12, and 24 h into the chase period. Experiments with each group were replicated at least three times.

Lipid analysis. Lipids were extracted by a modified method of Folch *et al.* (38) as described by Garbus *et al.* (39). FAME were prepared by transmethylation with 2.5% H_2SO_4 in dry methanol. Nonpolar lipids were separated by 1-D TLC on 20 × 20 cm silica gel G plates with double development, first with 140:60:1 (by vol) toluene/hexane/formic acid for the whole plate height, followed by 60:40:1 (by vol) hexane/diethyl ether/formic acid to half height. Polar lipids (PL) were separated by 2-D TLC on 10 × 10 cm silica gel G plates using 65:25:4 (by vol) chloroform/methanol/water in the first dimension and then 50:20:10:10:5 (by vol) chloroform/acetone/methanol/acetic acid/water in the second direction. Plates were sprayed with 0.05% (wt/vol) 8-anilino-4-naphthosulfonic acid in methanol and viewed under UV light to reveal lipids or were visualized under iodine vapor. Identification was made by reference to authentic standards and was confirmed using specific color reagents (40).

FA identification and analysis. Radiolabeled FAME were analyzed by radio-GLC using a Unicam GCD gas chromatograph connected *via* an effluent splitter to a LabLogic RAGA (LabLogic, Sheffield, United Kingdom) gas flow proportional counter. Glass columns (1.5 m × 4 mm i.d.) were packed with 10% SP-2330 on a 100/120 Supelcoport (Supelco, Bellefonte, PA). The SP-2330 column was run isothermally at 180°C. Routine identification was by reference to standards, and quantification (Rachel Software, LabLogic) was made by reference to an internal standard of pentadecanoate. Identification of FA was made by comparison with standards using GLC on a capillary column. GC of FAME was performed using a Hewlett-Packard model 5890 series II gas chromatograph equipped with a split/splitless injector, autosampler, and FID. A capillary column of fused silica coated with CP-Wax 52CB^{TM} (0.25 mm i.d. × 25 m in length, 0.2 µm film thickness; Chrompack UK Ltd., London, United Kingdom) was used, and hydrogen was the carrier gas at an initial flow rate of 1 mL min^{-1}. After holding the temperature at 170°C for 3 min, the column was temperature-programmed at 4°C min^{-1} to 220°C and then held at this point for an additional 15 min. In all analyses, the detector was set at 300°C, the injector at 230°C, and a split ratio of 50:1 was used. An HP 3365 Chemstation (Hewlett-Packard Ltd., Stockport, United Kingdom) was used for data acquisition.

Preparation of 4,4-dimethyloxazoline (DMOX) derivatives. The FAME were hydrolyzed with 0.1 mol L^{-1} KOH in 90% aqueous ethanol (0.25 mL per mg of sample) at 50°C for 3 h. After acidification with acetic acid and addition of water (2 mL), the FFA were extracted twice with 1:1 (vol/vol) diethyl ether/isohexane (6 mL, then 3 mL). The combined organic layers were passed through a short (3-cm) column of anhydrous sodium sulfate prepared in a Pasteur pipette, and were taken to dryness under nitrogen at 30°C on a heating block. The FFA were converted to DMOX derivatives by heating with 2-amino-2-methyl-1-propanol (0.25 mL) at 190°C for 16 h. These DMOX derivatives were made in order to have stable components for positional double-bond analysis without migration. On cooling, water (5 mL) was added and the DMOX derivatives were extracted with 1:1 (vol/vol) diethyl ether/isohexane (5 mL). The aqueous layer was re-extracted with fresh solvent (2 mL), and the combined solvent extracts were washed with water (3 mL) and dried over anhydrous sodium sulfate. Finally, the solvent extract was passed through a short (3-cm) column of anhydrous sodium sulfate prepared in a Pasteur pipette. The column was washed with isohexane and the sample containing the DMOX derivatives was taken to dryness under nitrogen at 30°C on a heating block. The DMOX derivatives were dissolved in isohexane containing BHT (50 ppm) and kept at −20°C until they were analyzed.

The positions of double bonds in the hexadecenoic and octadecenoic acid fractions were determined by GC–MS of their DMOX derivatives using a Hewlett-Packard 5890 Series II Plus gas chromatograph fitted with an on-column injector and a SUPELCOWAX^{TM} 10 (0.25 mm × 30 m, 0.25 µm film thickness; Supelco) capillary column, connected to a Hewlett-Packard 5989B MS Engine quadrupole mass spectrometer. The column temperature was held at 80°C for 3 min, temperature-programmed to 170°C at 20°C min^{-1}, then to 240°C at 2°C min^{-1} and to 280°C at 5°C min^{-1}, and was finally held at 280°C for 15 min. Helium was the carrier gas, at a flow rate of 1.4 mL min^{-1}, and pressure-programming was used in constant flow mode. The mass spectrometer was operated in EI mode at an ionization energy of 70 eV.

Radioactive counting was made using dried lipid or aqueous samples and Opti-Fluor (Packard Bioscience B.V., Groningen, The Netherlands) scintillant and a Beckman 1209 Rackbeta liquid scintillation counter. Quench correction was by the external standard channels ratio method.

Statistical analysis. Analysis was carried out using at least three independent samples in triplicate and a one-way ANOVA using Tukey's test comparing fed vs. starved animals.

RESULTS

Figure 1 shows the total lipid labeling in *D. magna* during a pulse-chase experiment. The label was significantly reduced (30–40%) in the first 4 h of chase, was relatively stable for the following 8 h of chase, and halved in the next 12 h of the chase period. The data also show that there were no statistically significant differences in the labeling of total lipids from [1-^{14}C]acetate in *D. magna* as a response to food supply during the chase period (Fig. 1). Among nonpolar lipids, DAG, sterols, nonesterified FA, TAG, waxes, and steryl esters were identified in *D. magna* (data not shown). TAG were the main labeled class, accounting for 50–80% of the total nonpolar lipid labeling.

For the nonpolar lipid fraction, some differences were noted in response to feeding (Fig. 2). Thus, the labeling in starved animals followed, to some extent, the labeling of total lipids noted above (Fig. 1) with a decrease in the first 4 h, less change in the next 8 h, and a decrease again in the period 12–24 h (Figs. 1,2). The final level of radiolabeling of total nonpolar lipids (Fig. 2) and its major component, TAG (Fig. 3), was significantly less for starved than for fed *Daphnia*. In contrast to the time-course of the total nonpolar lipid labeling in starved *Daphnia*, that of fed animals showed an increase between 4 and 12 h. As expected (given that TAG represented up to 80% of the labeling of the total nonpolar lipids), the time-courses of TAG labeling in fed vs. starved *Daphnia* were similar (Fig. 3B) to those for the total nonpolar lipids (Fig. 2). Thus, because of the increase in TAG labeling in the 4–12 h chase period for fed *Daphnia*, the amount of radioactivity in this lipid at the end of the chase period was about 75% of the starting value, whereas in starved animals the value was about 25%. Unexpectedly, DAG (which is a direct precursor of TAG) showed a different time-course of labeling (Fig. 3A). For both fed and starved *Daphnia*, there was a rapid decrease in labeling in the initial 4-h chase period, with the decrease more marked for fed animals. In the intermediate period
FIG. 1. Effect of starvation and feeding on the radiolabeling of total lipids in *Daphnia magna* from [1-^{14}C]acetate during a pulse-chase experiment. The radiolabel pulse was for 22 h. The results show means ± SD of three independent experiments. dpm, disintegration per minute.

(4–12 h), the alterations in fed *Daphnia* were less marked than for TAG and the decrease in the final 12–24 h period meant there was no significant difference between fed or starved animals in the radioactivity in DAG (Fig. 3A).

Our results showed that PL were much better labeled (3600 dpm individual^{-1}; 77% of total labeling) than nonpolar lipids (1030 dpm individual^{-1}). This agreed excellently with previous data for this species (15–17). The radiolabel in these polar membrane components decreased significantly for the first 4 h of chase and then decreased only slightly in the remainder of the chase period (Fig. 4). Essentially, there was little difference in the labeling of total PL between the fed or starved *Daphnia* (Fig. 4). Of course, since PL (mainly phos-

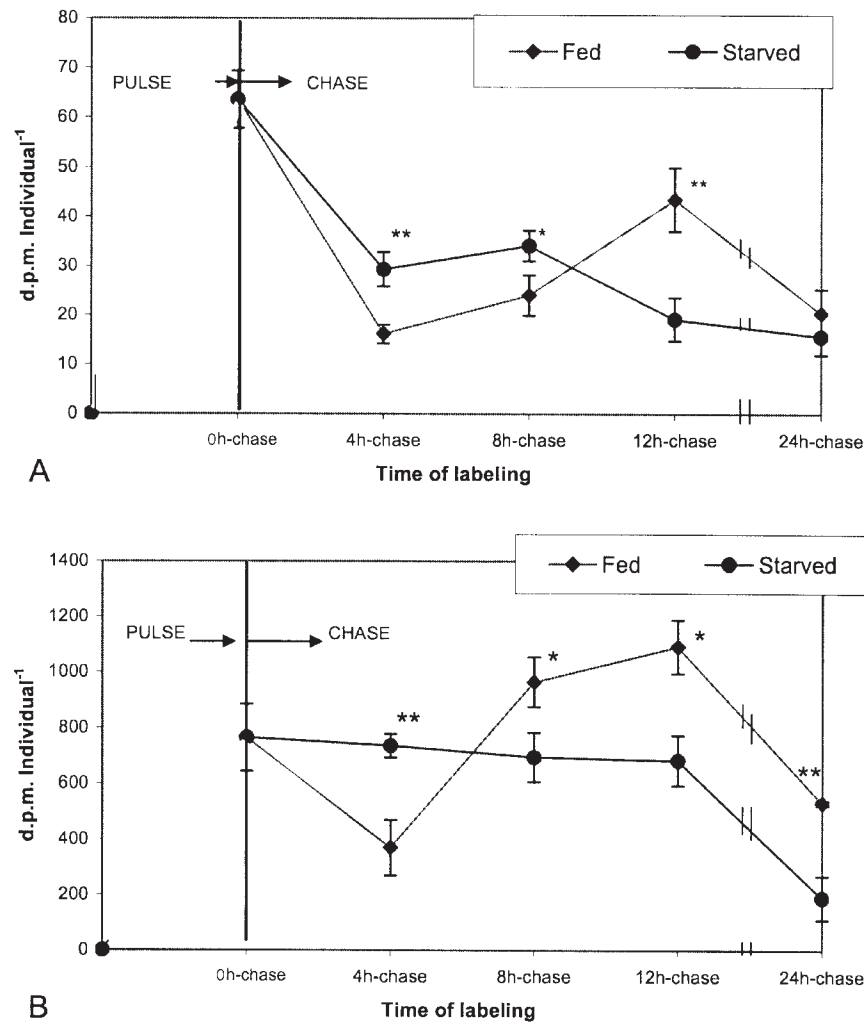
phoglycerides) represented over 75% of the total lipid labeling, the lack of effect of feeding was also reflected in the total labeling patterns (Fig. 1). In our study, PE was the best-labeled compound and accounted for about 50% of the total phospholipid labeling after the initial pulse, followed by PC (25%), PS, and PI (each about 10%). Phosphatidylglycerol (PG) was a minor labeled phosphoglyceride, representing only 5% of the total PL labeling (Fig. 5). Our results showed that the radiolabeled phospholipid patterns in *D. magna* were similar for both fed and starved animals (Figs. 5A, 5B). The labeling of PE and PS both reduced by about half or more within the first 4 h of chase. By 24 h, the radioactivity in these phosphoglycerides was of the order of one-fifth the starting
FIG. 2. Effect of starvation and feeding on the radiolabeling of total nonpolar lipids in *D. magna* during a pulse-chase experiment. The radiolabel pulse was for 22 h. The results show means ± SD of three independent experiments. Asterisks show statistically different values at $P < 0.005$ (**) and $P < 0.05$ (*) on statistical analysis by one-way ANOVA using a Tukey test for comparison of fed and starved *Daphnia*. For abbreviation see Figure 1.


FIG. 3. Radiolabeling of DAG (A) and TAG (B) from [1-^{14}C]acetate in fed or starved *D. magna* during a pulse-chase experiment. The radiolabel pulse was for 22 h. The results show means ± SD of three independent experiments. Asterisks show statistically different values at $P < 0.005$ (**) and $P < 0.05$ (*) on statistical analysis by one-way ANOVA using a Tukey test comparing fed and starved animals. For abbreviation see Figure 1.

amount, regardless of the feeding regime. For the other phosphoglycerides (PC, PG, PI), the reductions were more gradual and caused about a halving in the starting radioactivity during the chase period (Fig. 5).

The main FA identified in *D. magna* were palmitic, linoleic, and α-linolenic acids. In addition, 16:1, 16:2, 16:3, and 18:1 were found in significant amounts. GC–MS was used to identify the double bond positions of the hexadecenoic and octodecenoic acid fractions, which were the main unsaturated FA radiolabeled during our experiments (see following discussion). There were two octadecenoic acid isomers, of which oleic acid (18:1n-9) represented 5.4% of the total FA and *cis*-vaccenic acid (18:1n-7) was 2.4%. Palmitoleic acid (16:1n-7) was a significant component (1.4% of total FA) but palmitvaccenic acid (16:1n-9) was not detected. The relative content of FA was consistent with data previously reported for *D. magna* (26,29) and was not changed sig-

nificantly during the experiment. Moreover, no significant differences were found in endogenous FA percentage compositions between starved and fed *Daphnia* (data not shown).

Figure 6 presents the data on FA labeling. The main FA labeled during the course of the experiment were palmitate (16:0), hexadecenoate (16:1), and octadecenoate (18:1). No radiolabel was detected in odd-chain or branched-chain FA, which are considered markers of bacterial FA (34). The proportional labeling of palmitate was stable and did not change during the chase under both food regimes, whereas the relative labeling of 16:1 and 18:1 was altered by the end of the chase, especially in fed animals (Fig. 6A). Thus, a significant increase in the percentage labeling of octadecenoate was seen at the expense of hexadecenoate between 12 and 24 h of chase. Because of the probability that palmitoleic acid is converted into the vaccenic acid by elongation, we also calculated the total amounts of radioactivity in the 16:0, 16:1, and 18:1 fractions
FIG. 4. Radiolabeling of total polar lipids from [1-^{14}C]acetate in fed or starved *D. magna* during a pulse-chase experiment. The results show means ± SD of three independent experiments. Asterisks show statistically different points at *P* < 0.05 on statistical analysis by one-way ANOVA using a Tukey test comparing fed and starved animals. For abbreviation see Figure 1.

during the total duration of the experiment. In both fed and starved *Daphnia*, there was a large decrease in the total amount of radioactivity during the first 4 h of chase (Fig. 1). However, because the percentage labeling of 18:1 increased (especially for starved animals), the total radioactivity in this fraction decreased less than, say, for palmitate. Between 4 and 12 h of chase, there was little change in total radioactivity (Fig. 1); therefore, all FA fractions remained labeled to a constant amount. Between 12 and 24 h of chase, there were significant losses of total radioactivity for both fed and starved animals (Fig. 1), and in the latter case, because of the altered percentage of labeling (Fig. 6), the loss in radioactivity was in the order 16:1 > 16:0 > 18:1.

DISCUSSION

It is well known that the ability of an animal to survive starvation depends on the amount of energy reserves and the way this energy is allocated to survival, growth, and reproduction (41). In a study of growth and mortality of fed and starved *D. magna* over 22 d, starved animals grew significantly less than fed animals (41). All animals survived at least 5 d of starvation. However, after a period of 3 d of starvation, energy reserves were not sufficient to allow further growth and reproduction (41). In fact, it appeared that lipid reserves were especially crucial because, although total carbohydrate and glycogen were reduced by 1 d of starvation, it was not until day 3 that the TAG stores were significantly depleted (41). In another daphnid, *D. galeata*, it was also shown that the animal was able to adapt quickly to short periods of starvation and to variations in food supply (42). Thus, it is perhaps not surprising that there were not large differences in the response of *D. magna* to feeding, rather than starva-

tion, during the time course of our experiments (Figs. 1–4).

Among individual phosphoglycerides, PE, PC, PS, PG, and PI were identified (see the Experimental Procedures section). A similar phospholipid composition with an abundance of PC (52.6% of total PL) and PE (31.9%) has been reported previously for *D. magna*, and their amounts are known to be significantly affected by growth temperature (43). The domination of PC and PE also has been found in three developmental stages of *D. magna*, with PC/PE ratios of 1.57, 2.22, and 1.26 from newborn, 3-d-old immature females, and mature females, respectively (44).

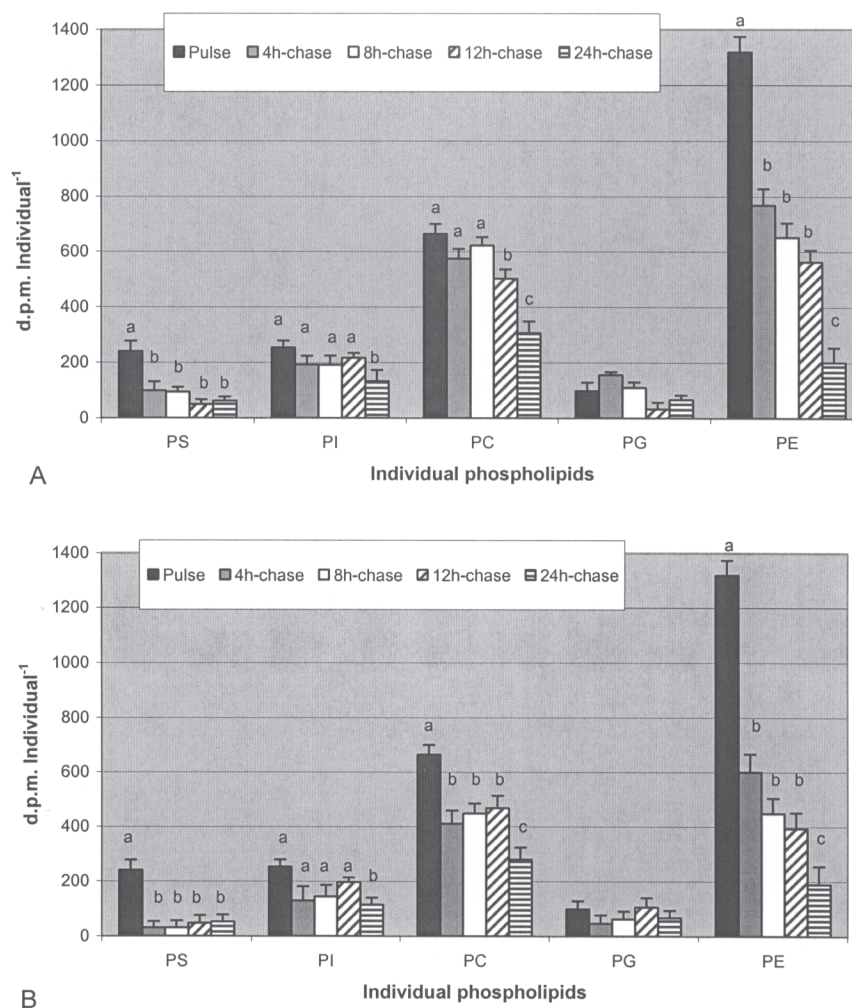
The preferential labeling of PL (mainly phosphoglycerides) compared with nonpolar lipids from ^{14}C-acetate (Figs. 2, 3) agrees with other studies with *D. magna* (17). In addition, these workers also found, as we did, that TAG was by far the highest labeled nonpolar lipid (Figs. 1, 2). The rapid decrease in total lipid radioactivity during the first 4 h of chase implies a rapid turnover of some acyl groups. In quantitative terms, this change is mainly located in the phospholipids, and indeed it is well known that many PL (including phosphoglycerides) show a rapid turnover of their acyl groups (23). After a 4-h chase, the decrease in both total lipid (Fig. 1) and PL (Fig. 4) radioactivity was slower but was approximately similar in both fed and starved animals. We interpret this to reflect the normal replacement of membrane phosphoglycerides that takes place in different organisms. Presumably, the replacement carbon in the starved *Daphnia* came from storage compounds, which could have been carbohydrates as well as TAG, whereas the fed animals could also have used dietary sources. Indeed, over the 24-h chase, the starved *Daphnia* appeared to turn over more of their TAG (Figs. 2, 3B), although they seemed to make some effort to conserve these reserves, as reflected in the constant amounts of radioactivity over the


FIG. 5. Radiolabeling of individual phosphoglycerides from [1-^{14}C]acetate in fed (A) or starved (B) *D. magna* during a pulse-chase experiment. The results show means ± SD of three independent experiments. Different letters indicate statistically significant differences at $P < 0.01$ on statistical analysis by one-way ANOVA using a Tukey test comparing fed or starved animals with the initial pulse values. PG, phosphatidylglycerol; for other abbreviation see Figure 1.

first 12 h of chase (Fig. 3B). This would probably correspond to the period when carbohydrate reserves were being used (41). Fed *Daphnia* had no need to husband food reserves, so a dramatic drop in TAG radioactivity in the first 4 h of chase would not have been serious physiologically and TAG synthesis could continue to take place, with radiolabeled FA also possibly coming from membrane lipids, as these were replaced from food sources. The quicker labeling of TAG during the 4- to 12-h chase period compared with DAG (Fig. 3A) suggests that a major part of the DAG total pool may be formed from TAG during catabolism by the latter rather than *via* the role of DAG as an intermediate in the Kennedy pathway (23). In agreement with this, like Farkas *et al.* (17), we (data not shown) found 1,3-DAG to be more abundant than 1,2-DAG.

According to our results, both lipid fractions, PL and nonpolar lipids, were efficiently labeled from [1-^{14}C]acetate. About

25% of the label incorporated was found in nonpolar lipids, with TAG as their main constituent. In a previous study using *Daphnia*, Goulden and Place (15) found that "accumulation" of TAG was greater than that of phospholipids in fed *D. magna* and *D. pulex*. Even in *D. pulex* acclimated to a low food level (4,000 algal cells mL^{-1} d^{-1} vs. 100,000 algal cells mL^{-1} d^{-1} in control) for several generations (experiment for more than 20 d), the accumulation of TAG was still five times that of phospholipids. However, it is not clear from their results whether accumulation was really being measured, since no starting values were given. Moreover, although these authors also measured radiolabeling from both [U-^{14}C]acetate and [^{3}H]$_2$O, they did not separate labeling into different lipid classes. They did show, however, much less labeling of starved *D. pulex* from either radiolabeled precursor than of fed animals.

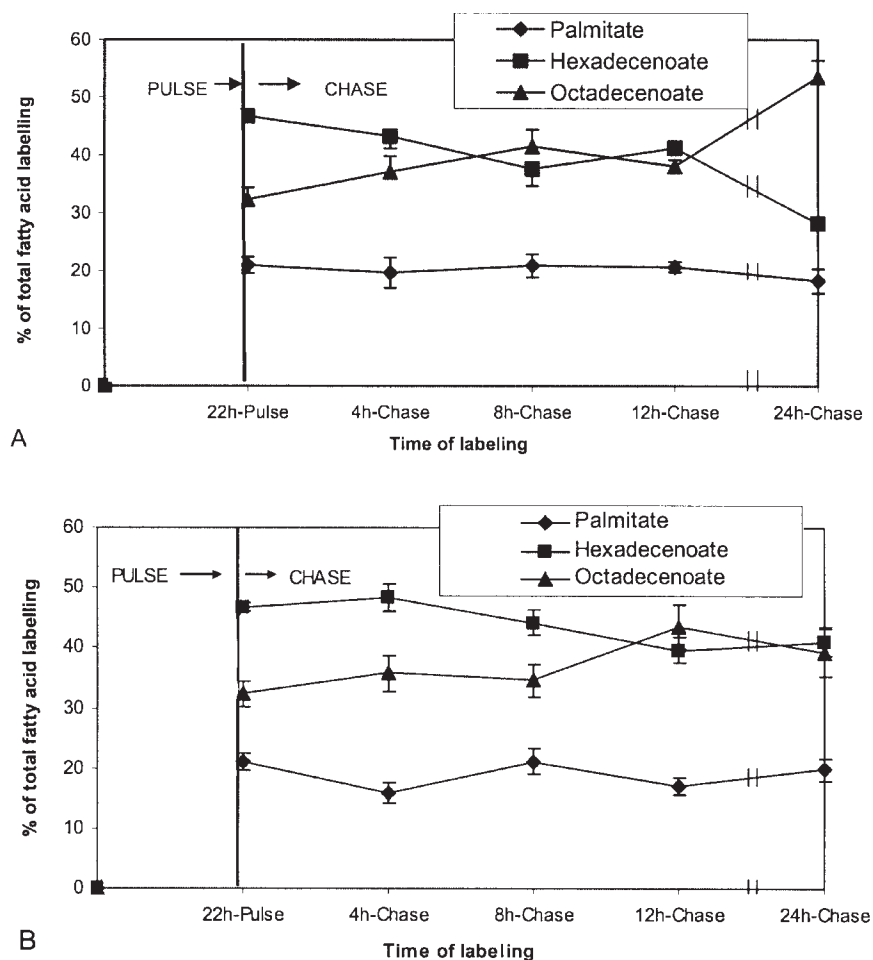
In general, the loss of label (30–40%) in total lipids in the first 4 h of chase may reflect the rapid turnover of some lipids


FIG. 6. Labeling of FA from the total lipids of *D. magna* that were fed (A) or starved (B) during a pulse-chase experiment. The results show means ± SD of three independent experiments. For abbreviation see Figure 1.

(e.g., PS, PE, DAG), whereas after 12 h, when the labeling of all lipids decreased, a general turnover was seen.

The labeling of phospholipids was not affected by food supply as much as that of nonpolar lipids, probably reflecting the relative independence of phospholipid synthesis on the nutritional state of the organisms (10). In contrast, Elendt (41) reported that the amount of these lipids diminished from about 6.3% of dry weight to 4.8% over a longer experimental period (6 d) of starvation in *D. magna*. We found that the turnover of the membrane compounds in *D. magna* was significant in that approximately 70% of the label previously incorporated into phosphoglycerides disappeared during the 24-h chase period. Although the experimental protocol is not directly comparable, Farkas *et al.* (17) also revealed a rapid turnover of lipids in *Daphnia*.

It was interesting that PE and PS lost half of their radioactivity in the first 4 h of the chase, whereas other phospholipids (PC, PI, and PG) lost half of their radioactivity only after 24 h (Fig. 5). This might indicate that PE and PS are important as (precursors of) signaling molecules or, alternately, that they play a significant role in metabolism.

Although the PUFA, linoleic and linolenic acids, accumulated in *D. magna* as two of the three main FA (a typical total FA composition was 23.2% palmitate, 23.2% linoleic, and 19.2% α-linolenic acids), no labeling of these molecules was noted during our experiments, probably indicating their dietary origin as suggested by various studies (28–33,35,37). This observation is in agreement with the accepted dogma that no animals (except a few insects, noninsect invertebrates, and protozoa) (45–48) can biosynthesize linoleic or α-linolenic acids. However, it must be borne in mind that sometimes the labeling of PUFA during radiolabeling experiments takes some time; therefore, the duration of the experiment is important. Nevertheless, we incubated *Daphnia* for 22 h, so we are confident that if there is any capacity for the synthesis of linoleic or α-linolenic acids, it is very small.

Because the radio-gas chromatograph used a packed column, we were unable to distinguish individual isomers of the two monoenoate peaks with any certainty. The endogenous octadecenoate contained oleate (5.4% total FA) and *cis*-vaccenate (2.4%), whereas the hexadecenoate fraction contained palmitoleate (1.4%) as a significant fraction. The presence of

vaccinate suggests that elongation of palmitoleate to this FA is a significant metabolic reaction (23). Indeed, the changes in total radioactivity that occurred during the chase period for the three FA fractions would be consistent with such elongation. Thus, for the starved *Daphnia* (Figs. 1, 6), the decrease in radioactivity in the 16:1 fraction was the highest (355 down to 100 dpm individual^{-1} between 12 and 24 h of chase), whereas that in 18:1 changed much less (327 to 197 dpm individual^{-1}). If elongation of palmitoleate to vaccinate was occurring, then that would explain the results.

One issue in interpreting the data that needs to be considered is how much bacterial contamination could affect the radiolabeling results. The filtered culture water was clearly not sterile, although the use of a 0.45-μm filter is a standard method in use for *Daphnia* (28,32,34,35,37). However, we took care in washing *D. magna* at the end of the experiment to exclude bacteria in the water, although consumption of radiolabeled organisms by the copepods cannot be excluded. Nevertheless, similar FA and acyl lipids were labeled by both fed and starved *Daphnia* (Figs. 5, 6), which would not be expected if (radiolabeled) bacteria were a major source of food for the starved *Daphnia*. Farkas *et al.* (17), in considering the question of bacterial contamination, thought that the gut was the main potential source but concluded that any contamination of radiolabeled products was negligible. Furthermore, the pattern of FA labeling in our experiments did not include significant amounts of typical "bacterial markers" (34) such as odd-chain or branched-chain acids; moreover, the pattern of labeling of the phospholipids (Fig. 5) was typical of a eukaryotic organism with high PC labeling and a low amount of PG. Therefore, we conclude that bacterial contribution to the overall lipid labeling in our experiments was not significant.

In summary, our data clearly show that *D. magna* is able to tolerate short-term starvation well and that the latter does not result in major changes in lipid metabolism. In addition, the results indicate that the animal is capable of good rates of lipid synthesis *de novo* in addition to being able to make direct use of dietary components, such as PUFA. Therefore, lipid metabolism can be said to be well-adapted to the normal lifestyle of *Daphnia*.

Dietary Phospholipids Are More Efficient Than Neutral Lipids for Long-Chain Polyunsaturated Fatty Acid Supply in European Sea Bass *Dicentrarchus labrax* Larval Development

ABSTRACT: We evaluated the effects of dietary lipid class (phospholipid vs. neutral lipid) and level of n-3 long-chain PUFA (LC-PUFA) on the growth, digestive enzymatic activity, and histological organization of the intestine and liver in European sea bass larvae. Fish were fed from the onset of exogenous feeding at 7 to 37 d post-hatch with five isoproteic and isolipidic compound diets with different levels of EPA and DHA. Diet names indicated the percentage of EPA and DHA contained in the phospholipids (PL) and neutral lipids (NL), as follows: PL5, PL3, PL1, NL1, and NL3. Histological observations showed different patterns of lipid absorption and accumulation in the intestinal mucosa depending on the level and nature of the dietary lipid fraction. Fish fed high levels of neutral lipids (11%, NL3 diet: 2.6% of EPA + DHA in the NL fraction) showed large intracellular and intercellular lipid deposits in the anterior intestine, but no such lipid accumulation was detected when larvae were fed with low and moderate levels of EPA and DHA in the phospholipid and neutral lipid fractions of the diet (PL and NL1 diets). PL were preferentially absorbed in the postvalvular intestine, and the accumulation of marine PL was inversely correlated to their dietary level. The postvalvular intestinal mucosa and liver showed signs of steatosis; large lipid vacuoles were observed in this region of the intestine and in the liver and were inversely correlated with the level of dietary neutral lipids. The best results in terms of growth, survival, and development (maturation of the digestive system and histological organization of the liver and intestinal mucosa) were obtained in the group fed with 2.3% of EPA and DHA in the PL fraction of the diet (PL3 diet), revealing that European sea bass larvae use the LC-PUFA contained in the PL fraction more efficiently than those from the NL fraction of the diet.

Paper no. L9685 in *Lipids 40*, 609–618 (June 2005).

Dietary lipids are the main energy source in developing fish larvae and serve as a source of the FA needed for the synthesis of new cellular structures that are required for normal larval growth and development (1). Lipid requirements of marine fish larvae have been extensively studied during the last two decades (1–3), and particular attention has been paid to long-

chain PUFA (LC-PUFA) and phospholipids (PL) (4–7). Like most marine fish, European sea bass is considered to have an absolute requirement for LC-PUFA, such as EPA (20:5n-3), DHA (22:6n-3), and arachidonic acid (20:4n-6), being unable to produce these FA from their precursors 18:3n-3 and 18:2n-6 (1). In this sense, the deficiency in LC-PUFA delays fish growth, induces mortality, reduces resistance to stress, and results in anatomical alterations associated with nutritional disorders (6). The EFA requirements of marine fish vary both qualitatively and quantitatively, and the optimal level of dietary components for marine fish is known to be around 3% of dry matter for EPA + DHA (1). However, most studies dealing with the determination of LC-PUFA requirements for first-feeding marine larvae were conducted using live prey to deliver different levels of LC-PUFA (3), but these studies did not evaluate the effect of the class of lipids [neutral lipids (NL) vs. PL] incorporated into the diet, since in most cases lipids and LC-PUFA are generally provided in the diet by fish oils, which are constituted mainly of neutral lipids (6,7).

Although it is generally accepted that there are beneficial effects from adding PL to microdiets (microparticulated diets having particle sizes of 200–400 µm) or live-prey enrichment emulsions on the larval growth, survival, stress tolerance, and larval quality (reduction of skeletal deformities) (2–4,6–8), their exact role in fish digestive physiology and development has not been completely characterized. Fish larvae are extremely sensitive to dietary PL deficiency and require higher levels of dietary PL than juveniles (see review in Ref. 8). Feeding gilthead sea bream larvae with microdiets containing marine PL instead of marine TAG resulted in better growth even if larvae were fed PL at lower levels than TAG (10). Recently, it has been shown that a diet containing 19% lipids including almost 9% PL induced good growth in European sea bass first-feeding larvae, demonstrating that the development of skeletal deformities in European sea bass during early development was more linked to the proportions of dietary PL and NL than to the total dietary lipid content (7). Dietary PL seem to have a marked effect on lipid absorption and transport (6,8,9,11,12). An accumulation of lipid droplets in enterocytes has been associated with PL deficiency (13–15) that may result in intestinal steatosis (16,17), suggesting that PL have a specific role in the synthesis and secretion of chylomicrons and VLDL from the intestinal mucosa into the circulatory system.

Different segments of the gastrointestinal tract in vertebrates have been shown to employ different cellular mechanisms in

response to diet quality (18). Thus, the use of the intestine and liver as indicator organs of the nutritional and physiological status in fish is well known (19–22). As the primary site of food digestion and nutrient uptake, the intestine is involved in important physiological digestive functions (23), whereas the liver is the central metabolic organ of the body, taking a predominant role in intermediary metabolism and having important functions in lipid storage and in digestive and detoxification processes (23). The optimal use of dietary nutrients ultimately depends on the effectiveness of functions in the intestine and liver (22). Consequently, the structural alteration of the histomorphological organization of the liver and intestine can provide useful information about the quality of the diet, the metabolism, and the nutritional status of the fish (18,20,21,24,25).

The present study evaluates the effect of the lipid class (PL vs. NL) and the level of n-3 LC-PUFA in the diet on the growth, the digestive enzymatic activities, and the histological organization of the intestine and liver in European sea bass larvae.

MATERIALS AND METHODS

Animals and diets. Three-day-old European sea bass (*Dicentrarchus labrax* L.) larvae were obtained from the Ecloserie

Marine de Gravelines (Gravelines, France) and shipped to the Fish Nutrition Laboratory at the IFREMER (Centre de Brest). Fish were acclimated and divided into fifteen 35-L cylindroconical fiberglass tanks (2100 larvae/tank) at an initial density of 60 larvae/L. Tanks were supplied with running sea water (35‰), which had previously been filtered through a sand filter, then passed successively through a tungsten heater and a degassing column packed with plastic rings. Throughout the experiment, the water temperature and salinity were 20°C and 35‰, respectively, and the oxygen level was maintained above 6 mg/L by setting the water exchange of the tank up to 30% per hour (flow rate: 0.18 L/min). Photoperiod was 24L:0D, and light intensity was 9 W/m^2 (900 lux) maximum at the water surface. All animal procedures and handling were conducted in compliance with the Guide for the Care and Use of Laboratory Animals (26).

At 4 d post-hatch (dph), European sea bass larvae were divided into 5 experimental groups (4 replicates per group) that were fed from the onset of exogenous feeding at 7 dph until 37 dph with experimental compounded microdiets. Five isonitrogenous and isolipidic diets (Table 1) were formulated to incorporate different levels of LC-PUFA (Table 2) and differed in their lipid class composition, PL vs. NL. Fish meal, normally

containing 17% lipids, was rigorously defatted to control the experimental dietary lipid composition only by the addition of PL and NL. Lipid was extracted from fish meal using dichloromethane (5 mL/g fish meal) for 20 min at 40°C, rinsed, and dried until completely free of solvent. Diet names indicate the total percentage of EPA and DHA contained in the PL and NL fractions of the diet: PL5, PL3, PL1, NL1 and NL3 (Tables 1 and 2). The marine phospholipid fraction in PL diets varied in an inverse relation to soybean lecithin, whereas NL diets contained soybean lecithin in an inverse proportion to the marine TAG (cod liver oil). The composition of diet PL1 was close to the diet previously used (7) that had supported good growth and survival in European sea bass larvae; for comparative purposes it was considered in this study as the control diet. Microdiets were prepared as follows: fish meal, fish meal hydrolysate, betaine, and mineral mixture were first mixed. The oil, PL, and vitamin mixture were added as an emulsion to the dry mixture. Then water was added; and the mixture was thoroughly blended mechanically, pelleted, and dried at 50°C for 20 min (6). This procedure prevents undesirable reactions between ingredients (particularly between minerals and vitamins). The pellets were sieved to obtain two sizes of particles: 125–200 μm, used during the first 5 d, and 200—400 μm, used during the rest of the experiment. At this stage, a sample of each experimental diet was taken for analysis. Diets were then vacuum-packed and stored at 4°C until use. During the entire experimental period, larvae were continuously fed *ad libitum* 24 hours per day using an automatic belt feeder. Food inges-

tion was monitored by observing the larval digestive tract under a binocular microscope; dietary microparticles were visible by their transparency against tissue.

Sampling. To evaluate growth, 10 specimens were randomly sampled from each experimental tank (30 larvae per experimental diet) at 12, 16, 23, 30, and 37 dph and euthanized with an overdose of anesthetic (tricaine methanesulfonate, MS 222); their wet body weights were measured to the nearest 0.1 mg. To evaluate the level of maturation of the digestive system, larvae (20–50 larvae, depending on wet body weight) were sampled from each tank and kept at −20°C until analysis. Samples for measuring lipase (EC 3.1.1.3), and brush border intestinal enzymes (alkaline phosphatase, EC 3.1.3.1; and aminopeptidase N, EC 3.4.11.2) were taken at 30 and 37 dph, whereas trypsin (EC 3.4.21.4) and amylase (EC 3.2.1.1) secretions were only measured at 37 dph. For light microscopy purposes, 10 specimens were randomly sampled from rearing tanks at 30 and 37 dph, preserved in 10% buffered formalin (pH 7.2), and stored in the dark at 6–8°C. Repetitive sampling did not allow the determination of real survival (percentage of surviving individuals in relation to the initial number of larvae); however, relative survival, expressed as the percentage of surviving fish fed on a diet (i.e., NL1) in relation to the surviving specimens fed on the control diet (PL1), could be calculated.

Analytical methods. A minimum of 30 larvae per replicate and treatment were dissected on a glass cutting board kept on ice (0°C) under a binocular microscope. Individuals were cut into 4 parts: head, pancreatic segment (PS), intestinal segment

(IS), and tail, to limit the assay of enzymes to specific segments. This dissection inevitably produced a mixture of organs in each segment. Besides the pancreas, the pancreatic segment contained the liver, heart, muscle, and spine. The intestinal segment contained the intestine, muscle, and spine (27). Once dissected, pancreatic segments were homogenized in 5 vol (vol/wt) of ice-cold distilled water. Amylase and trypsin activities were measured using sodium benzoyl-DL-arginine-*p*-nitroaniline and starch as substrates (28,29), respectively, in both pancreatic and intestinal segments. Lipase was measured in the pancreatic segment using *p*-nitrophenyl myristate as substrate (30). Purified brush border membranes from the intestinal segment were obtained according to a method developed for intestinal scraping (31). The degree of purification of the brush border membrane, considering alkaline phosphatase and aminopeptidase N as markers of cell membrane fraction, was close to that reported in the literature (31), i.e., 11.0- and 10.8-fold, respectively. Alkaline phosphatase and aminopeptidase N, two enzymes of the intestinal brush border membrane, were quantified using *p*-nitrophenylphosphate (32) and L-leucine-*p*-nitroaniline (33) as substrates, respectively. Specific enzyme activities were expressed as mmol of substrate hydrolyzed per min and mg of protein (mU/mg protein), and protein was determined using the Bradford method (34). Secretions of trypsin and amylase were calculated as the ratio of the activity in the intestinal segment, related to total activity (PS + IS) considering that enzyme activity in PS can be used as an index of the synthesis function of pancreas and in IS as an index of pancreatic secretory function (35).

Dietary total lipid content was determined using a procedure slightly modified from Folch *et al.* (36), with chloroform being replaced by dichloromethane. The separation of NL and PL was carried out as described by Juaneda and Rocquelin (37). FA were saponified by a 2 M KOH/methanol solution, recovered, and then esterified in a 0.7 M HCl/methanol solution. FAME were separated by GC in an Auto-system PerkinElmer instrument with an FID on a BPX 70 capillary column (25 m × 0.22 mm i.d. × 0.25 μm film thickness; J&W Scientific, Folsom, CA), with a split-splitless injector and with helium as carrier gas (flow rate 1.4 mL/min). The injector and detector temperatures were, respectively, 220 and 260°C. The initial temperature of the oven was 50°C, increasing to 180°C by increments of 15°C/min, maintained for 5 min, and finally increased to 220°C by increments of 3°C/min. Data acquisition and handling were carried out by connecting the gas chromatograph to a Nelson computer. Each FAME was identified by comparison with the retention time of authentic standard mixtures of FAME, and the results of individual FA composition were expressed as area percentages of total identified FAME in the PL and NL fractions.

Light microscopy. Larvae were dehydrated in a graded series of aqueous ethanol mixtures, embedded in paraffin wax, and cut in serial longitudinal sections (5–7 μm thick). Slides were stained by hematoxylin and eosin for topographic observations of the liver, intestine (prevalvular and postvalvular regions), and swim bladder. The term steatosis was applied, without pathological connotation, when clear vacuoles with a diameter greater than 5 μm were observed in the enterocytes (13).

Statistical analyses. Results are given as mean ± SD. All data were checked for variance homogeneity using the Barlett's test (38). Growth, enzymatic specific activity, and arcsin ($x^{1/2}$)-transformed trypsin and amylase secretions were compared by means of a one-way ANOVA followed by Newman–Keuls multiple range test when significant differences were detected ($P < 0.05$).

RESULTS

Growth and survival. At the end of the rearing period (37 dph), statistically significant differences in larval growth were observed between experimental groups (ANOVA, $P < 0.05$, Fig. 1). Larvae fed PL3 exhibited the best growth performance. Larvae fed PL1 and PL5 were similar in weight, being 21 and 26% smaller than PL3 larvae, respectively. Larvae from the NL3 dietary group were smaller than all the other groups (e.g., 50% smaller than PL3 larvae). Because the NL3 group died before 37 dph, the larval body weight could not be compared with those of the other experimental groups, although it was significantly lower at early stages of development (23 and 30 dph).

The best survival, i.e., the largest number of fish at the end of the experiment, was observed in groups fed PL3 and NL 1 diets ($n = 710$ and 404, respectively). The relative survival of groups PL3, NL1, and PL5 was 226.1, 128.7, and 31.5% higher, respectively, than the control (PL1, $n = 314$).

Enzyme activities. At the end of the study, total EPA and DHA content in diets significantly affected trypsin and amylase secretion (ANOVA, $P < 0.05$; Fig. 2). Fish fed diets containing low levels of EPA and DHA (PL1 and NL1) exhibited
FIG. 1. Growth of European sea bass larvae fed isonitrogenous and isolipidic diets containing different levels of EPA and DHA. Diets are named according to the percentage of dietary EPA and DHA contained in the phospholipid (PL) and neutral lipid (NL) fraction of the diet: PL5 (○), PL3 (■), PL1 (△), NL1 (●), and NL3 (□). Results are shown as mean ± SD ($n = 4$). Different superscripts for the same day indicate significant differences ($P < 0.05$).
FIG. 2. Trypsin (□) and amylase (■) secretion in 37 days post-hatch (dph) European sea bass larvae fed isonitrogenous and isolipidic diets containing different levels of EPA and DHA. Means ± SD (*n* = 4) with different superscript letters were significantly different (*P* < 0.05). For other abbreviations see Figure 1.

the highest trypsin secretion rates, whereas those reared with PL3 and PL5 showed lower secretion values. Amylase secretion was negatively affected by a high dietary content of EPA and DHA (group PL5, Fig. 2), being 8.2% lower than in those groups fed low or medium levels of these two FA (PL3, PL1, and NL1 diets). Similarly, the specific activity of lipase was affected by the experimental diets (ANOVA, *P* < 0.05; Fig. 3). At 30 dph, lipase specific activity was two times higher in fish fed NL1 than in PL5 group. In 37-d-old larvae, the lipase activity in PL5 group was 55 and 45% higher than in fish fed PL3 and NL1, respectively.

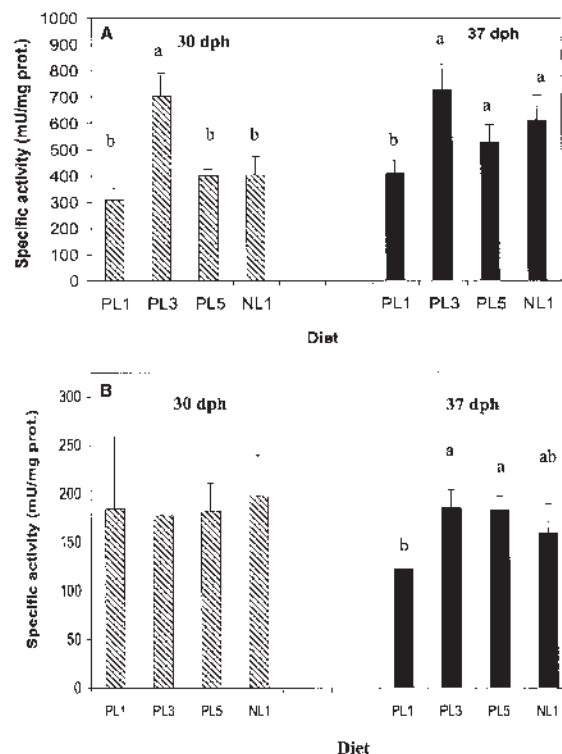
The same effect was observed in the specific activities of brush border enzymes (ANOVA, *P* < 0.05; Fig. 4). At 30 dph, the highest alkaline phosphatase specific activity was observed in fish fed PL3; no differences in activity were observed between the other experimental groups (PL1, PL5, and NL1), which were significantly lower than in fish fed PL3. At day 37, the lowest alkaline phosphatase activity was detected in larvae
FIG. 3. Lipase specific activity in 30 and 37 dph European sea bass larvae fed isonitrogenous and isolipidic diets containing different levels of EPA and DHA. Means ± SD (*n* = 4) with different superscript letters were significantly different (*P* < 0.05). For abbreviations see Figures 1 and 2.


FIG. 4. Specific activity of alkaline phosphatase (A) and aminopeptidase N (B) of the intestinal brush border in European sea bass at 30 and 37 days dph fed isonitrogenous and isolipidic diets containing different levels of EPA and DHA. Means ± SD (*n* = 4) with different superscript letters were significantly different (*P* < 0.05). For abbreviations see Figures 1 and 2.

fed PL1, no differences being evidenced between the other dietary groups. No statistically significant differences at 30 dph were observed in aminopeptidase N specific activity of larvae fed different diets. At the end of the larval rearing period, aminopeptidase N specific activity was 30% lower in larvae fed PL1 (control group) compared with the rest of the dietary treatments.

Light microscopy. The liver of European sea bass larvae is organized in polygonal-shaped hepatocytes arranged along hepatic sinusoids. Nuclei position and lipid deposition depended on dietary levels of marine and vegetable PL (Fig. 5). Large central nuclei were observed in livers containing few lipid inclusions (PL1, PL3, PL5, and NL1), whereas peripheral nuclei were detected in livers of larvae showing high levels of lipid deposition (NL3).

The mucosa of the intestine (prevalvular and postvalvular regions) is lined by a simple columnar epithelium with prominent acidophilic brush borders and centrally located nuclei (Figs. 6a, 6b, 7). The only morphological differences observed between both regions are the number and size of mucosal folds, which are longer and more numerous in the anterior region. Changes in the histological organization of the prevalvular intestine were observed only in fish fed the NL3 diet, which showed a large accumulation of small lipid droplets, resulting in the displacement of nuclei to a basal position (Fig. 6c). Large intercellular lipid vacuoles were also observed (Fig. 6d). The mucosa of the postvalvular intestine exhibited remarkable signs
FIG. 5. Longitudinal paraffin sections of the liver in European sea bass larvae fed isonitrogenous and isolipidic diets containing different levels of EPA and DHA. Liver from fish fed control diet (PL1) and NL1 showing regular-shaped hepatocytes with very few lipid inclusions (a, d). Livers from fish fed PL3 and PL5 with a high (b) and intermediate (c) degree of cytoplasmatic lipid accumulation in hepatocytes. Liver from fish fed NL3 showing the displacement of the nucleus to the periphery of the hepatocytes and the presence of numerous varying-size cytoplasmatic lipid vacuoles (e). Histological sections from larvae fed PL and NL1 diets were from fish aged 37 dph, whereas those from the NL3 group were obtained from 30 dph. For abbreviations see Figures 1 and 2. Scale bar: 25 μm.

of steatosis in fish fed diets containing EPA and DHA derived mainly from the phospholipid fraction (PL diets) (Fig. 7a-d). Fish fed NL diets exhibited a lower lipid accumulation in this region than in the other experimental groups (Figs. 7e, 7f).

Fish fed on PL and NL1 diets had normally inflated swim bladders, which were organized in a stratified cuboidal epithelium and rete mirabile (Fig. 6e). Most of the larvae (90%) fed the NL3 diet did not inflate their swim bladders and showed hyperplasia of the gas gland cells, with hypertrophied cells occupying the swim bladder's lumen (Fig. 6f).

DISCUSSION

In a previous study, good growth and survival were obtained using a compound microdiet containing 11% phospholipids (7). We have used this PL dietary level in the current study to formulate experimental diets with an appropriate level of PL (PL5, PL3, PL1, and NL1 diets). However, even though the NL3 diet contained only 8% of PL, this content was acceptable in terms of growth and larval survival rates (7). In the present study, diets were efficiently ingested by European sea bass larvae. Thus, the differences observed in growth and survival rates in this study were not related to dietary PL level and/or larval food intake of compound diets.

In the present study, total DHA/EPA ratios in PL diets and in NL diets were close to 2 (i.e., higher than 1), which is considered as a suboptimal ratio for fish larvae, either by not providing sufficient DHA or by providing an undesirable excess of EPA (1). Therefore, the observed differences in growth and

survival of European sea bass in the present study could not be attributed to inappropriate DHA/EPA ratios. The tested diets, mainly differing by their LC-PUFA source included in the PL or NL fraction, induced large differences in growth and survival of European sea bass larvae. The diet containing a moderate level of EPA and DHA in the PL fraction (PL3) induced the best growth, survival, and intestinal maturation in comparison with the rest of the experimental diets, including the control (PL1), whereas the diet with a similar level of EPA and DHA in the neutral lipid fraction (NL3) was lethal for European sea bass larvae. A high content of EPA and DHA in the PL fraction (PL5) negatively affected growth, survival, and maturation of the digestive tract in larvae. The differences observed in growth between larvae feeding on a low dietary level of EPA and DHA depended on the form in which both EFA were supplied; if they were included in the PL fraction (PL1), good growth was observed, whereas it was significantly lower when they were included in the NL fraction. The more efficient use of EPA and DHA supplied in the PL class of the diet might be related to the ability of young larvae to better modulate phospholipase A2 expression than that of lipase, suggesting a more efficient capacity to use PL than TG (7).

PUFA, and especially DHA and EPA, which are vital constituents for cell membrane structure and function, are very susceptible to oxidation by oxygen and other radicals. The resultant PUFA oxidation of membrane PL can have dramatic consequences for cell membrane structure and fluidity, with a potential pathological effect on cells and tissues, and can result in a reduction in fish growth, loss of appetite, decreased feeding
FIG. 6. Longitudinal paraffin sections of the prevalvular intestine and swim bladder in European sea bass larvae fed isonitrogenous and isolipidic diets containing different levels of EPA and DHA. Prevalvular intestine from 37-d-old larvae fed PL1 showing the mucosa lined by a simple columnar epithelium with centrally located nuclei and not containing lipid accumulations in cytoplasmatic vacuoles (a, b). Prevalvular intestinal mucosa from larvae aged 30 dph fed PL3 showing the presence of small apical lipid droplets (asterisk), the displacement of nuclei to a basal position (arrowhead), and large intercellular lipid vacuoles between enterocytes (arrow) (c, d). Normal inflated swim bladder from larvae fed PL1 (e). Noninflated swim bladder with hyperplasic gas gland cells (asterisk) from fish fed NL3 (f). gg, gas gland; pi, prevalvular intestine; rm, rete mirabile; for other abbreviations see Figures 1 and 2. Scale bar: 100 µm.

efficiency, and increased mortality (2). In the present study, differences in growth, survival, and histological organization of the intestine and liver in the European sea bass larvae were not attributed to *in vivo* lipid peroxidation, since any of the histological lesions commonly associated with this phenomenon, such as myopathy of skeletal muscle, lipoid liver degeneration, and accumulation of ceroid pigments (2), was not observed in the larvae fed high dietary levels of LC-PUFA. Moreover, diets were formulated using stable forms of vitamins, α-tocopherol acetate for vitamin E and ascorbate polyphosphate for vitamin C, at concentrations recommended by the National Research Council (26), to prevent the oxidation of unsaturated FA in the microparticles.

The level of secretion of the pancreatic enzymes (amylase, trypsin, and lipase) has been used as an indicator of intestinal maturation during European sea bass development (7,27,43). It is generally accepted that at a similar stage of development, pancreatic enzyme secretion is higher in fish exhibiting a good growth and normal development than in those showing a delay in these processes. In the present study, all the experimental
FIG. 7. Longitudinal paraffin sections of the postvalvular intestine in European sea bass larvae fed isonitrogenous and isolipidic diets containing different levels of EPA and DHA showing different levels of intestinal steatosis depending on the experimental diet [PL1 (a), PL3 (b), PL5 (c-d), NL1 (e) and NL3 (F)]. Note the lower accumulation of lipids in the enterocytes of fish fed NL3 in comparison with those fed PL3 diets (b, f). Scale bar: 100 µm.

groups exhibited a good level of trypsin secretion, but the fish fed the highest levels of EPA and DHA in the PL and NL fractions (PL5 and NL3 diets) showed lower values of amylase secretion than the rest of the experimental groups. It should be noted that although larvae fed PL1 and NL1 diets exhibited the highest values of trypsin and amylase secretion among all dietary treatments, these values should not be attributed to a major maturation of the digestive system and normal development of larvae, since the specific activity of intestinal brush border enzymes (particularly alkaline phosphatase) was lower in these groups in comparison with fish fed the PL3 diet. High secretion of pancreatic enzymes observed in the larvae fed PL1 and NL1 diets might be correlated with the high dietary content of linoleic acid, since C_{18} FA, such as linoleic and oleic acids, play an important role in the regulation of the pancreatic secretion (44). *In vitro* experiments have shown that these FA increased the intracellular calcium levels in enterocytes, stimulating the release of two gastrointestinal hormones, cholecystokinin (CCK) and secretin, which regulate the pancreatic secretion of amylase, trypsin, and lipase (12,44).

Despite major advances in our understanding of lipid digestion in juvenile or adult fish, knowledge of lipolytic enzymes in young larvae is scarce, particularly in terms of luminal digestion of dietary lipids (6). The capacity to digest fats is related to lipase secretion by the pancreas and the production of

bile salts in the liver, processes regulated by the levels of dietary TAG and the rate of intestinal absorption of lipids (12). In this sense, although it was not possible to determine the specific activity of pancreatic lipase in fish fed high levels of neutral lipids (NL3), since most of larvae died during the study, we observed that the specific activity of lipase in fish fed intermediate levels of neutral lipids (6.2%, NL1 diet) tended to be higher than that of fish fed PL diets at 30 dph. At the end of the experiment, this tendency in lipase activity was not observed. Such changes in specific activity might be related to the high accumulation of lipids observed in the enterocytes rather than to a lesser maturation of the digestive system, since lipids accumulated in the intestinal mucosa might have disrupted the metabolic capacity of the intestine to digest, absorb, and export lipids into the circulatory system. These observations strongly suggested that large quantities of accumulated lipids in the intestinal mucosa might have resulted in a reduction of the CCK secretion by intestinal endocrine cells in order to diminish lipase release by the pancreas and thus regulate lipid digestion and accumulation in enterocytes (44). The dramatic change in lipase activity in the PL5 group at day 37 compared with day 30 could not be attributed to a stimulation of lipase by its substrate, i.e., NL. This change probably reflected an indirect consequence of intraluminal FA concentration resulting from the hydrolysis of dietary PL, which in turn stimulated a hormonal mechanism involving secretin (45).

Generally, nutritional studies evaluating lipid digestion and absorption processes in fish are limited to the anterior region of the intestine, which is considered the region involved in the absorption of these nutrients (14,46). Nevertheless, lipid absorption still continues in the posterior and rectal regions of the intestine, particularly in carnivorous fish with short digestive tracts, such as European sea bass (47). The enterocytes of the pre- and postvalvular intestinal regions showed a larger degree of lipid accumulation than that observed by other authors (48). Such differences were due to the different level and nature of the lipid fraction contained in diets (compounded feeds vs. live preys). The results of the present study showed that European sea bass larvae have different patterns of lipid absorption and accumulation in the intestinal mucosa depending on the level and class of lipid used in the diet. Thus, we observed an important intracellular and intercellular accumulation of lipid in the anterior intestine of fish fed diets containing high levels of NL (11%, NL3 diet), whereas no such accumulation was detected when larvae were fed with low and moderate levels of NL (PL and NL1 diets). Similarly, the deposition of large lipid vacuoles in the postvalvular intestinal mucosa of larvae fed different experimental diets seemed to be inversely correlated with the level of dietary NL, since PL levels were almost the same among the diets, with the exception of NL3. The different n-6/n-3 ratio in the diets could have also influenced the accumulation of lipids in the enterocytes (14,49). Some authors have reported the use of unbalanced feeds in terms of lipid class composition as the cause of high, pathological level of intestinal accumulation of lipids (steato-

sis) (16,17). However, diet formulation and histological observations in the present study seemed to contradict this hypothesis; even though high levels of lipid deposition were observed in the postvalvular intestine of European sea bass larvae, they cannot be considered to be the cause of any pathological damage, since no signs of epithelial abrasion, cellular necrosis, and/or inflammatory reactions were detected along the intestinal mucosa.

The use of the liver as an indicator of the nutritional condition in fish is well known. Different studies have shown that structural alterations of the liver due to nutritional imbalances can provide useful information on diet quality and metabolism, complementing the information obtained with growth studies to evaluate the nutritional status of the fish. In the present study, levels of lipid accumulation in the liver of the larvae fed high levels of LC-PUFA in the neutral lipid fraction (NL3) were higher than those in fish fed similar or even higher levels of LC-PUFA contained in the diet as PPL (PL3 and PL5). These observations indicated that the form of dietary LC-PUFA supplied has a direct effect on fat storage in the liver, which could be related to a higher influx of chylomicrons and/or VLDL from the intestine due to the differences in lipid exportation capacities of the intestinal mucosa.

The comparative histological study carried out on 37-d-old larvae revealed the existence of a "dietary regime effect" on swim bladder inflation during early stages of development in European sea bass. The high frequency of occurrence of larvae without a functional swim bladder in the NL3 group (90%) contrasted with the rest of the experimental groups (PL and NL1). It is well recognized that inflation of the swim bladder is temporally limited and can only take place during a short window of larval morphogenesis, during which access to the air–water interface is critical for the normal inflation and development of the swim bladder (50). In the present study, the similar rearing conditions and procedures used for culturing larvae from different experimental groups, coupled with the low incidence of fish with non-inflated swim bladder in larvae fed PL and NL1 diets, suggested that anomalies in swim bladder inflation observed among larvae fed the NL3 diet might be related to diet quality rather than to problems of larvae in gulping air from the air–water interface. Thus, the high percentage of neutral lipids in the diet might be responsible for a disruption (retardation) of normal fish development, as growth results indicated, resulting in the failure to dilate the swim bladder lumen and the atrophy of this organ (51).

In conclusion, data on larval growth, survival, histological organization of the liver and intestine, and digestive enzyme activities showed that the quantity and form of EPA and DHA (NL or PL) supplied in the diet were determining for European sea bass larval development; fish used EPA and DHA more efficiently when these EFA were present in the PL rather than in the NL fraction of the diet. These results must be taken into account in the formulation of compound diet for larvae. Indeed, lipid and LC-PUFA are generally provided by fish oil, which is a neutral lipid, but marine PL would be a nutritionally better source of LC-PUFA.

Docosahexaenoic Acid- and Eicosapentaenoic Acid-Enriched Cardiolipin in the Manila Clam *Ruditapes philippinarum*

Edouard Kraffe[a], Philippe Soudant[b], Yanic Marty[a],*, and Nelly Kervarec[c]

[a]Unité mixte Centre National de la Recherche Scientifique (CNRS) 6521, Université de Bretagne Occidentale, 29238 Brest cedex, France, [b]Unité mixte CNRS 6539, Institut Universitaire Européen de la Mer (IUEM), Université de Bretagne Occidentale, 29280 Plouzané, France, and [c]Laboratoire de Résonance Magnétique Nucléaire (RMN), Université de Bretagne Occidentale, 29285 Brest cedex, France

ABSTRACT: The FA composition of cardiolipin (CL) from the Manila clam *Ruditapes philippinarum* was investigated in whole body and individual organs. CL was isolated by HPLC and its chemical structure characterized using NMR spectroscopy. Two prominent FA, EPA and DHA, were found in approximately equal proportions, contributing together up to 73 mol% of the total FA. The FA composition of CL is presumed to reflect a specific synthesis pathway independent of diet and of total glycerophospholipid FA composition. To the best of our knowledge, this is the first time that a CL dominated by the two PUFA 22:6n-3 and 20:5n-3 has been characterized and described. This EPA + DHA specificity of the CL in the Manila clam is thought to reflect a functional and structural modification of mitochondrial membranes of this bivalve species compared with scallops, oysters, and mussels that possess a CL dominated by DHA. The FA composition and levels of CL differed little between separated organs, and the large pool of DHA and EPA was found fairly equally distributed in gills, mantle, foot, siphon, and muscle. However, whereas DHA and PUFA levels were most stable between organs, EPA and arachidonic acid were significantly more variable and seemed to be interrelated.

Paper no. L9694 in *Lipids 40*, 619–625 (June 2005).

Cardiolipin, a phospholipid carrying four acyl chains, is considered to occur exclusively in bacterial and mitochondrial membranes. It is recognized to be of great importance in the maintenance of optimal activity of a number of key mitochondrial membrane enzymes involved in cellular energy metabolism such as cytochrome *c* oxidase, ADP-ATP carrier, and the oligomycin-sensitive ATPase complex (1–5). Generally, the unique FA patterns of eukaryotic cardiolipins, particularly in the C_{18} chains, have been emphasized. In mammals these CL acyl chains are dominated by linoleic acid (18:2n-6), constituting up to 85 mol% of total FA of CL (2,4). This specific FA hydrophobic part appeared to be an important structural requirement for the high protein-binding affinity of CL (6). Dietary modification significantly affects the composition of FA in mammalian CL (2,7) and was shown to alter cytochrome *c* oxidase (8,9) and F_1F_0-ATP synthase activities (8). Thus, in addition to CL content, the molecular composition of CL may be critical for optimal mitochondrial respiratory performance.

Few studies have investigated whether the CL content and FA composition of CL vary between organs. CL content is assumed to reflect mitochondrial content and oxidative capacity of the organ (10,11). In terms of FA composition, the CL from rat kidney, heart, and liver are markedly enriched in linoleic acid (from 60 to 85%) whereas CL from rat brain, lung, and testis only contains from 8 to 15% linoleic acid (10,12,13). Nevertheless, mechanisms able to explain these variations of CL FA composition are still lacking (4).

In a previous study, we provided the first evidence for CL containing more than 80 mol% DHA (22:6n-3). This occurred in three marine bivalves, the scallop *Pecten maximus*, the mussel *Mytilus edulis,* and the oyster *Crassostrea gigas* (14). The predominance of 22:6n-3 acyl chains in CL of these bivalves goes against the concept that FA of eukaryotic CL are mostly constituted of C_{18} acyl chains with one or two double bonds. This may reflect the paucity of data about FA compositions of marine bivalve phospholipids (15) and in particular of minor phospholipid classes such as CL (16–18).

In the present study, a DHA–EPA-enriched CL found in the Manila clam *Ruditapes philippinarum* was isolated by HPLC and characterized by NMR. The potential of inter-organ variations in the CL content and its FA composition were also investigated. The possible functional significances of this CL structure composition are discussed.

MATERIALS AND METHODS

Materials. Boron trifluoride [BF_3, 10% (by wt) in methanol] was obtained from Supelco (St. Quentin Fallavier, France). Others reagents and solvents were purchased from Merck (Darmstadt, Germany).

Sample preparation and lipid extraction. Adult *R. philippinarum* Manila clams were collected from the Bay of Brest during spring and summer 2001. After removing the digestive

Abbreviations: CL, cardiolipin, common name of diphosphatidylglycerol; DQF-COSY, double-quantum filter correlated spectroscopy; GPL, glycerophospholipid(s); HMBC, heteronuclear multiple bond coherence HMQC, heteronuclear multiple quantum coherence; NL, neutral lipids; NMI, non-methylene interrupted..

tract, whole animals were pooled and homogenized with a Dangoumeau homogenizer at −180°C. Samples were taken in triplicate, each of three pooled individuals. Mantle, foot, siphon, gills, and adductor muscle of *R. philippinarum* clams were excised, pooled, weighed, and homogenized as above (triplicates of three pooled individuals). Lipids were extracted from tissue homogenates according to the method of Folch *et al.* (19). To ensure complete extraction of tissue lipids, a solvent-to-tissue ratio of 70:1 was used as described by Nelson (20). After removing the organic phase, the residue was washed with a mixture of $CHCl_3$/MeOH (2:1, vol/vol) to exclude any solvent retention. The final extract was stored at −20°C under nitrogen after 0.01 wt% BHT (antioxidant) was added.

Separation of polar lipids and CL by silica gel LC microcolumn. An aliquot of the lipid extracts was evaporated to dryness, and lipids were recovered with three washings of 500 µL of $CHCl_3$/MeOH (98:2, vol/vol) and deposited at the top of a silica gel microcolumn [30 × 5 mm i.d., packed with Kieselgel 60 (70–230 mesh; Merck)] previously heated at 450°C and deactivated with 6 wt% H_2O (21). Neutral lipids were eluted with 10 mL of $CHCl_3$/MeOH (98:2, vol/vol). CL was isolated from the rest of the glycerophospholipid (GPL) classes by rinsing the column with 15 mL of $CHCl_3$/MeOH (90:10, vol/vol) as described previously (14). An aliquot of the isolated fraction was taken for later confirmation of the presence of the CL class by HPLC. The rest of the polar lipids was recovered with 20 mL of MeOH and stored at −20°C for later GPL class separation by HPLC or FA composition analysis by GC. To obtain high quantities of CL for NMR analysis, the lipid extract of *R. philippinarum* was separated on a silica gel column [40 × 25 mm i.d, packed with Kieselgel 60 (70–230 mesh; Merck)] as described elsewhere (14).

Separation of phospholipid classes and FA analysis. Separation of the phospholipid classes followed the method previously described (14), using a Waters (Milford, MA) HPLC system (UV detection at 206 nm). Briefly, separation was performed on a Lichrosorb Diol column (OH-bound silica gel column, Lichrosorb Diol 5 µm, 250 × 4 mm i.d.; Merck) using a binary mobile phase. A linear gradient of 15 min was performed from 100% solvent A (acetonitrile) to an 8:2 ratio of solvent A and solvent B (acetonitrile/methanol/phosphoric acid, 93:5:1.5, by vol). This solvent ratio was maintained for 5 min, followed by a linear gradient to 100% solvent B in 10 min. Solvent B was maintained for another 30 min, and then switched to 100% solvent A for 15 min to reactivate the column. The solvent flow rate was 1 mL/min. The CL fraction as well as the other GPL classes was identified, collected, and analyzed for FA composition using GC after transesterification (MeOH/BF_3) (22).

NMR spectroscopy. All NMR spectra were recorded on Bruker DRX-500 Avance Spectrometers (Wissembourg, France) equipped with an indirect 5-mm TBI gradient $^1H/\{BB\}/^{13}C$ and an indirect 5-mm TXI gradient $^1H/^{13}C/^{31}P$ probeheads. The probe temperature was 25°C. Prior to analysis, lipid samples (CL from *R. philippinarum*) were dissolved into $CDCl_3$/CD_3OD (1:2.5, vol/vol). To promote solubilization

of the smallest lipid entities for a good resolution of resonances, samples were warmed and sonicated at about 30°C for about 5 min. 2-D NMR spectra were acquired with nonspinning samples with deuterium frequency locking. ^1H-^1H double-quantum filter correlated spectroscopy (DQF-COSY), heteronuclear multiple quantum coherence (HMQC), and heteronuclear multiple bond coherence (HMBC) were employed to assign signals. DQF-COSY and HMQC were performed according to standard pulse sequences, whereas HMBC was performed with 60 ms of delay. Measurements were recorded by collecting 1K (F2) × 200 (F1) data points zero filled to 1K (F1) using a spectral width of 500 Hz (500.13 MHz) with a repetition time of 2 s. ^1H and ^{13}C NMR chemical shifts were expressed in ppm by reference to tetramethylsilane as external standard.

Statistical analysis. To compare the differences between organs, *t*-tests and one-way ANOVA were performed using Statview (SAS Institute Inc., Cary, NC). Percentage data were transformed (arcsin of the square root) before ANOVA and *t*-test, but are presented in figure and table as untransformed percentage values. Differences were considered statistically significant if $P \le 0.05$.

RESULTS

FA composition of CL in whole animals. GC analysis of FAME derived from the isolated CL fraction of *R. philippinarum* showed a FA profile with 84.6 mol% of PUFA (Table 1). Interestingly, two predominant PUFA, 22:6n-3 and 20:5n-3, were found in similar proportions (34.9 and 37.9 mol% of the total FA of CL, respectively). The minor components included 20:4n-6, 16:0, and 18:0 (<6.8% individually). The CL class represented 0.9 mol% of the total GPL whereas 4.3 and 10.6 mol% of the total GPL content of DHA and EPA, respectively, were located in the CL fraction.

FA composition of GPL and neutral lipids (NL) in whole animals. The FA composition of GPL showed that DHA was found in higher proportions than EPA in *R. philippinarum* membranes (20.3 vs. 8.1%, respectively) (Table 1). On the contrary, NL (mainly TG) presented a higher level of EPA than DHA (12.7 vs. 6.5%, respectively).

NMR spectroscopy. Unsaturated acyl chains esterified to the glycerol backbone of a CL were characterized by the ^1H and ^{13}C resonances of olefinic –CH=CH–, bis-allylic methylene, allylic methylene, and $C_\alpha H_2$, $C_\beta H_2$ protons (where α and β positions are relative to the carbonyl group) (Fig. 1). The integral ratio of the characteristic multiplets at 0.85 (from 20:4n-6 and saturated acyl chains) and 0.95 ppm (from unsaturated n-3 acyl chains) confirmed that 75% of the FA are n-3 PUFA. As described in detail in an earlier study (14), the high-field single proton of C-2 outer glycerols resonated typically at 5.21 ppm whereas ^1H resonances between 3.7 and 4.5 ppm were characteristic of the glycerol protons of the two quasi-equivalent outer glycerols and of the central glycerol of a polyunsaturated CL.

From the HMBC spectrum it can be inferred that DHA chains are bound to the *sn*-2 position whereas EPA chains and others (mainly 20:4n-6 and saturated acyl chains) are bound to

FIG. 1. [1]H resonance spectrum of *Ruditapes philippinarum* cardiolipin. The insert shows the expanded ^{1}H glycerol backbone region. [a]$C_\alpha H_2$– protons of 20:5n-3, 20:4n-6, and saturated acyl chains. [b]$C_\beta H_2$– protons of 20:5n-3, 20:4n-6, and saturated acyl chains. Enlargement: [1]C-1 protons of the two outer glycerols (*sn*-1 *O*-acyl chain). [2,3]Outer glycerols C-3 (phosphate group) and central glycerol protons. For details of assignments see Reference 1.

the *sn*-1 position (Fig. 2). Indeed, when considering ^{13}C chemical shifts of the carbonyl carbon resonances in the 173–175 ppm region, the signal from *sn*-2 carbonyl carbons appeared at 173.45 ppm, typically shifted by about 0.85 ppm to a lower frequency than those of *sn*-1 carbonyls (174.3 ppm) (23). This is confirmed by the correlation between carbonyls at 174.3 ppm and part of the eight-line multiplet at 4.15 ppm assigned to the magnetically inequivalent methylene protons (C-1-H_1, C-1-H_1') of outer *sn*-1-glycerol. On the other hand, protons from both C_α and C_β carbons of DHA chains (multiplet at 2.37 ppm in relation with the Δ4 unsaturation) were clearly resolved from

those of C_α and C_β carbons of EPA chains, 20:4n-6, and saturated acyl chains (2.35 and 1.75 ppm, respectively). The former (DHA chains, multiplet at 2.37 ppm) appeared to be specifically correlated to *sn*-2 carbonyl carbons whereas the latter (mainly EPA chains, multiplet at 2.35 and 1.75 ppm) were correlated to *sn*-1 carbonyls (Fig. 2).

Content and FA composition of CL of different organs. In *R. philippinarum*, CL accounted for 0.6% of the total GPL in muscle, which was significantly different from the 1.3% in foot, while CL contents in mantle, siphon, and gills were very similar and were not significantly different from those in muscle and foot (Table 2). Although the same general FA composition as in the whole animals was observed in the different organs isolated from the Manila clam *R. philippinarum* with a predominant preference for 22:6n-3 and 20:5n-3, small but significant differences of EPA contents were observed between organs. In muscle and foot, 20:5n-3 was present at similar levels as 22:6n-3, but in gills, mantle, and siphon 20:5n-3 was less abundant than 22:6n-3. Interestingly, in these organs, significantly higher levels of 20:4n-6 (9.2, 7.8, and 7.4 mol% in gills, mantle, and

[a]C$_\alpha$H$_2$– protons of 20:5n-3, 20:4n-6, and saturated acyl chains. [b]C$_\beta$H$_2$– protons of 20:5n-3, 20:4n-6, and saturated acyl chains.

siphon, respectively) seemed to be interrelated to the lower levels of 20:5n-3 found.

FA composition of total GPL. The FA patterns of total GPL of gills, mantle, foot, siphon, and muscle from *R. philippinarum* are presented in Table 3. Major FA were 22:6n-3 > 16:0, 18:0 > 20:5n-3, non-methylene-interrupted (NMI) FA, and 20:4n-6. In each organ DHA was uniformly found in higher proportion than EPA.

DISCUSSION

A CL containing up to 73 mol% of EPA + DHA has been isolated from the Manila clam *R. philippinarum*. Interestingly, EPA and DHA were found in almost equimolar proportions. This polar lipid class showed the same HPLC retention time value as the DHA-enriched CL previously isolated and characterized in the three bivalves *P. maximus*, *M. edulis,* and *C. gigas* (14). The chemical structure of this EPA + DHA-enriched polar lipid class isolated from the clam *R. philippinarum* was analyzed using

NMR in the 3.9–4.5 ppm (^{1}H) region (14,24) and was demonstrated to be exclusively constituted of CL molecules.

In mammals, it is well documented that CL molecules present the same marked enrichment in PUFA with low amounts of saturated FA. This apparent selectivity encountered in CL of most mammalian tissues is associated with linoleic acid, 18:2n-6 (2,4,25). In contrast, there is little knowledge concerning the FA composition of CL in marine animals. As reviewed in a previous study (14), although high amounts of both n-3 and n-6 PUFA were reported in some CL from marine animals, no specific PUFA was found to be predominant. Our demonstration of the existence of a DHA-dominant (22:6n-3 > 80 mol%) CL in the scallop *P. maximus*, the mussel *M. edulis,* and the oyster *C. gigas* (14) revealed the importance of long-chain PUFA in CL of mollusk bivalves. In the present study, the evidence of a CL enriched with EPA and DHA in almost equimolar proportions in the Manila clam *R. philippinarum* provided a new example of highly polyunsaturated CL.

The difference between Manila clam CL (DHA + EPA) and the DHA-enriched CL of the three bivalve species cited above can be hypothesized to reflect FA dietary variations between these species. Indeed, it was shown that diet significantly affects the composition of FA in mammalian CL (2). Then, it is conceivable that clam CL was not specifically enriched with DHA compared with the other bivalve species because of a DHA deficiency and/or an EPA enrichment of its diet. However, considering that the FA composition of *R. philippinarum* NL provided a good sig-

nature of the diet intake (26), the fact that NL contain 12.7% of DHA indicated that the diet was not deficient in DHA. Moreover, the fact that DHA represented up to 20.3% of the total FA of GPL (vs. 8.1% for EPA) showed that *R. philippinarum* is able to selectively incorporate and maintain DHA vs. EPA in its membranes. Obviously, these observations refute the possibility of a dietary imbalance for the Manila clam. Hence, the selective incorporation in equal amounts of EPA and DHA in *R. philippinarum* CL is likely to be metabolically controlled and to be involved in CL structural functions. CL, specifically located in mitochondria, was shown to be a key factor in the maintenance and modification of activity of major membrane proteins such as cytochrome *c* oxidase, ADP-ATP carrier, and pyruvate carrier or of other large complexes of oxidative phosphorylation including complex I (NADH-CoQ reductase), III (ubiquinol:ferricytochrome *c* oxidase), and V (F_0F_1-ATP synthase) (1–5,8,9,27,28). The FA hydrophobic part appeared to be an important structural requirement for this high protein-binding affinity of CL (6). Thus, the equal amounts of EPA and DHA in *R. philippinarum* CL may be critical for optimal mitochondrial respiratory performance of the Manila clam.

It was shown that increasing dietary levels of 22:6n-3 in the CL of rats reduced cytochrome *c* oxidase activity (8,9) and increased the activity of F_1F_0-ATP synthase (8). Although there are not enough literature data to support the idea that specific PUFA compositions (i.e., 18:2n-6 vs. 20:5n-3, or 20:5n-3 vs. 22:6n-3) have distinct effects on mitochondrial enzymes, it

[a]Results are expressed in mol% of the total FA of GPL. Different lowercase roman letters indicate significant difference between organs (ANOVA, *P* < 0.05). Values are presented as mean ± SD (*n* = triplicate of three pooled individuals). For abbreviations see Table 1.
[b]Main characteristic FA are represented. FA also detected but not represented are 14:0, 15:0, 17:0, 16:1n-7, 16:1n-5, 18:1n-5, 18:2n-4, 18:3n-6, 18:3n-4, 18:4n-3, 20:2n-6, 20:3n-6, 20:4n-3, 21:4n-6, none of which was more than 1.0 mol%. "Totals" refer to all analyzed FA.
[c]22:2 NMI (7,15), 22:2 NMI (7,13), 20:2 NMI (5,13), 20:2 NMI (5,11), and 22:3 NMI (7,13,16) FA.

could be supposed that the typical DHA + EPA-enriched CL (Manila clam) and the DHA-dominant CL (scallop, oyster, and mussel) may affect differentially the packing and the interaction of the CL with key metabolic enzymes. It can also be advanced that the specific positional distribution of EPA and DHA, respectively, on the *sn*-1 and *sn*-2 glycerol positions, deduced by the detailed examination of NMR data, would account in such functions.

Inter-organ variations. FA composition of CL varied little between separated organs, and the large pool of DHA and EPA was fairly equally distributed in gills, mantle, foot, siphon, and muscle. As for the whole body, the total GPL FA composition of each organ indicated that DHA is more efficiently incorporated and maintained than EPA in the membranes of *R. philippinarum*. In addition, although the CL represented less than 1.3% of total GPL classes, an important part of total EPA of GPL was located in the CL (up to 17 mol% in foot), indicating a specific incorporation of this FA into the CL class. Almost nothing is known about the inter-organ variability of bivalve CL. Only studies from Soudant *et al.* (16–18) have investigated the FA composition of male and female gonad CL from the scallop *P. maximus*. In both gonads, the composition of the DHA-dominant CL was unchanged. In mammals, CL FA composition can vary much more between organs. Indeed, even if linoleic acid is generally the predominant FA found in similar percentages in the CL from rat heart, liver, and kidney (up to 85% of total CL FA) (12,13), 18:2n-6 accounts for only 8–15% in rat brain, lung, testis, and spleen whereas 16:0 and 18:0 together represent 51–71% of total CL FA (10,13). In rabbit skeletal muscles, CL from the oxidative muscles contains less 18:2n-6 than CL from glycolytic muscles (76.3 and 84.5%, respectively) (29). The functional significance of such differences in mammals is not known. As CL contained almost equal amounts of DHA and EPA in the different organs of *R. philippinarum*, it can be inferred that the metabolic functions of CL requiring such a specific acyl composition are quite ubiquitous in these organs. However, in regard to mammals, the possibility of some variations between organs due to the small but significant differences of EPA contents, along with arachidonic acid, cannot be excluded.

The CL content differed little according to the organs of the clam *R. philippinarum*. In mammals, the organ concentration of CL is much more variable and is assumed to reflect mitochondrial content and oxidative capacity (10,11). CL constitutes 14.7, 12.6, and 9% of total GPL in rat, bovine, and human heart, respectively, whereas other muscle tissues that are not so highly specialized for oxidative phosphorylation have much smaller amounts of CL, ranging from 1.4–2.1% in the rat to 6.6 and 8.9% in human and bovine skeletal muscle, respectively. The CL content was also reported to be very low in the lung and spleen (less than 3%) (10). We hypothesize that the nearly constant proportions of CL in *R. philippinarum* may reflect the mitochondrial oxyconformity of marine bivalve invertebrates (30,31), contrary to mammals. which are oxyregulating organisms.

A DHA + EPA-enriched CL has been isolated from the Manila clam *R. philippinarum* that is different from the DHA-enriched CL found in the scallop *P. maximus*, the mussel *M. edulis,* and the oyster *C. gigas*. The differences were speculated to reflect means of modifications in oxidative phosphorylation between these species. It is unclear whether these differences could be related to the phylogeny of species. Further studies should investigate more bivalve species to determine whether other FA patterns of CL exist and the importance of these highly unsaturated PUFA CL differences in mitochondrial functioning.

Unusual Minor Nonmethylene-Interrupted Di-, Tri-, and Tetraenoic Fatty Acids in Limpet Gonads

Hideki Kawashima

Bioscience Laboratory, Miyako College Division, Iwate Prefectural University, Iwate 027-0039, Japan

ABSTRACT: Unusual minor nonmethylene-interrupted (NMI) FA have been identified in the lipids of gonads from the limpets *Cellana grata* and *Collisella dorsuosa* by using GC–MS of the combination of their 4,4-dimethyloxazoline derivatives and picolinyl esters. Among 23 NMI unsaturated FA from C_{18} to C_{22} and C_{24} identified in this study, 5,11-nonadecadienoic (5,11-19:2), 7,16-heneicosadienoic (7,16-21:2), 9,15-tetracosadienoic (9,15-24:2), 5,9,15-docosatrienoic (5,9,15-22:3), and 5,9,15-tetracosatrienoic (5,9,15-24:3) acids may not have been reported previously from living organisms. The presence of 5,11,14,17-eicosatetraenonoic (5,11,14,17-20:4) and 7,13,16,19-docosatetraraenenoic (7,13,16,19-22:4) acids as FA components in marine mollusks may be reported here for the first time. In this study, the male and female gonads of both species showed distinct differences in both their composition and proportions of NMI FA. Most NMI FA identified were mainly present in the female gonads of both species, especially in TAG that contained 21 NMI FA.

Paper no. L9732 in *Lipids 40*, 627–630 (June 2005).

Although nonmethylene-interrupted (NMI) FA, especially C_{20} and C_{22} dienoic acids, are frequently present in small amounts in marine gastropods (1,2), only a few studies have been conducted on the occurrence of NMI FA in the gonads of marine gastropods, especially of both male and female gonad lipids, which are attracting increasing interest in the fields of cell development and the reproductive cycle. The FA composition has been compared in male and female gonads of the limpets *Cellana grata* and *Collisella dorsuosa*, which are widely distributed on tidal rocks (3), but the NMI FA were found in only small or trace amounts and so were not identified in the previous study. This paper describes the identification and occurrence of minor NMI FA, including unusual diene and triene isomers in the gonads of these limpets, which may not have been described previously.

EXPERIMENTAL PROCEDURES

Materials, lipid extraction, and preparation of FAME. Cellana grata (shell length = 30 mm) and *C. dorsuosa* (shell length = 30 mm) were obtained in August 2001 from Miyako Bay, Iwate

Prefecture, northern Japan, and were frozen at −20°C. These limpets were transported to our laboratory, where the gonads were immediately removed and placed on ice. The sex was determined by microscopic examination, and the gonads were distinguished as female or male. The gonads of males and females of each species were dissected, suspended in chloroform–methanol (2:1, vol/vol), and then homogenized for 30 s at $891 \times g$ by using an IKA UltraTurrax® T25 Basic (IKA Japan KK, Nara, Japan) to disrupt the cells. Lipids were extracted by using the method of Bligh and Dyer (4). The extracted total lipids were methylated in 14% BF_3/methanol (5).

Argentation TLC and preparation of 4,4-dimethyloxazoline (DMOX) derivatives and picolinyl esters. FAME were fractionated according to the degree of unsaturation by using argentation TLC on 5% (w/w) silver nitrate-impregnated layers of Kieselgel 60G. Derivatives of DMOX were prepared by adding 200 μL of 2-amino-2-methyl-1-propanol to the fractionated FAME in screw-capped tubes. The tubes were flushed for 1 min with N_2, capped, and heated at 185°C overnight. The reaction mixture was cooled and then dissolved in 2 mL of dichloromethane, which was washed three times with 2 mL of distilled water. After drying the organic phase with anhydrous Na_2SO_4, the dichloromethane phase was removed under a steam of N_2. The samples were dissolved in *n*-hexane for analysis by GC–MS. Picolinyl ester derivatives were prepared as described previously (6).

GLC and GC–MS. FAME, DMOX derivatives, and picolinyl esters were analyzed by using GLC with a Shimadzu GC-8A instrument (Shimadzu Seisakusho Co., Kyoto, Japan) equipped with an FID and a SUPELOWAX™-10 capillary column (30 m × 0.25 mm i.d., 0.25 μm film thickness; Supelco Inc., Bellefonte, PA). The column temperature was isothermal at 210°C or at 230°C. The injector and detector temperatures were 250 and 260°C, respectively. GC–MS analyses were recorded at an ionization energy of 70 eV (EI ionization) using a Hewlett-Packard Agilent 5973N MS ChemStation equipped with an OMEGAWAX™-320 capillary column (30 m × 0.32 mm i.d., 0.25 μm film thickness; Supelco Inc.). The carrier gas was helium at a flow rate of 1.5 mL/min. The column temperature was programmed as follows: isothermal at 200°C for 2 min, increased from 200 to 210°C (1°C/min), and maintained at 210°C for 30 min.

Statistical analysis. The procedures were repeated three times for three different male and female sets of gonads and samples for statistical analysis. All samples were analyzed in

triplicate. Data are means ± SD (n = 3). Statistical comparisons among NMI FA were made using Student's t-test. Differences were considered significant at $P < 0.05$.

RESULTS AND DISCUSSION

Table 1 lists 23 NMI FA of *C. grata* and *C. dorsuosa* gonads identified by using GC–MS of their DMOX derivatives. The most interesting characteristic was the presence of NMI dienes and trienes with a 5,9-double bond system; 5,11-nonadeca-dienoic (5,11-19:2), 7,16-heneicosadienoic (7,16-21:2), 9,15-tetracosadienoic (9,15-24:2), 5,9,15-docosatrienoic (5,9,15-22:3), and 5,9,15-tetracosatrienoic (5,9,15-24:3) acids may not have been reported previously from living organisms.

In the diene fraction, the mass spectrum (MS) of the DMOX derivative 5,11-19:2 had a molecular ion at m/z 347. The double bond positions at 5 and 11 were confirmed by a diagnostic ion at m/z 153, a gap of 12 amu between m/z 222 and 234. The structure of 5,11-19:2 was also confirmed by the MS of its picolinyl ester, which had a molecular ion at m/z 385, and the double bond positions were definitely assigned by a gap of 26 amu

between m/z 178 and 204 and between m/z 260 and 286. The MS of the DMOX derivative 7,16-21:2 had a molecular ion at m/z 375 and diagnostic peaks at m/z 168 and 180 for double bond 7, and 292 and 304 for double bond 16. The MS of the DMOX derivative 9,15-24:2 had a molecular ion at m/z 417 and diagnostic peaks at m/z 196 and 208 for double bond 9, and 278 and 290 for double bond 15. GC–MS data for the picolinyl esters confirmed the structure of 7,16-21:2 at m/z 413 [M$^+$] and 206, 232, 330, and 356, and of 9,15-24:2 at m/z 455 [M$^+$] and 234, 260, 316, and 342.

In the triene fraction (Table 1), the MS of DMOX derivatives 5,9,15-22:3 and 5,9,15-24:3 had diagnostic ions at m/z 153, 166, and 180 for a 5,9-double bond system and an interval of 12 amu between ions m/z 276 and 288, indicating a double bond at position 15. The mass spectra of the picolinyl esters 5,9,15-22:3 and 5,9,15-24:3 had a molecular ion at m/z 425 and 453, respectively, the ion at m/z 219 for a 5,9-double bond system, and a peak with a gap of 26 amu between m/z 314 and 340, confirming a double bond at position 15. Similarly, 5,9,17-24:3 was also characterized by using its DMOX derivative and picolinyl ester.

7,13,16,19-22:4	21.14	126 (100), 168 (9), 180 (27), 250 (3), 262 (4), 290 (9), 302 (6), 330 (7), 342 (9), 385 (M$^+$, 11)

^{a}Retention times: OMEGAWAX^{TM}-320 capillary column (Supelco, Bellefonte, PA); column temperature, isothermal at 200°C for 2 min, programmed at 1°C/min to 210°C and maintained for an additional 30 min.
^{b}Picolinyl ester: 93 (100), 164 (35), 178 (4), 204 (7), 260 (5), 286 (9), 385 (M$^+$, 22).
^{c}Picolinyl ester: 92 (100), 164 (70), 206 (7), 232 (5), 330 (4), 356 (6), 413 (M$^+$, 39).
^{d}Picolinyl ester: 92 (100), 164 (66), 234 (8), 260 (6), 316 (4), 342 (12), 455 (M$^+$, 30).
^{e}Picolinyl ester: 92 (100), 164 (35), 178 (4), 204 (2), 219 (49), 232 (7), 258 (4), 314 (6), 340 (4), 425 (M$^+$, 24).
^{f}Picolinyl ester: 92 (100), 164 (64), 178 (3), 204 (1), 219 (45), 232 (6), 258 (5), 314 (3), 340 (3), 453 (M$^+$, 20).
^{g}Picolinyl ester: 92 (100), 164 (44), 178 (4), 204 (2), 219 (41), 232 (4), 258 (6), 342 (5), 368 (4), 453 (M$^+$, 23).

In the tetraene fraction (Table 1), the MS of the DMOX derivatives 5,11,14,17-20:4 and 7,13,16,19-22:4 showed characteristic fragments; their spectra agreed with the data from other studies (7). Although 5,11,14,17-20:4 has usually been found in some marine bivalves (8) and seed oils from gymnosperms (9), 7,13,16,19-22:4 has been found only in mammalian cells (10,11).

To clarify the distribution of NMI FA in the male and female gonads of *C. grata* and *C. dorsuosa*, the FA and their positional isomers in TAG and polar lipids (PL) were analyzed to compare these gonads (Table 2). The positional isomers of NMI dienes C_{18} to C_{22} and trienes C_{22} and C_{24} were widely present in both species. Most NMI FA identified were mainly detected in the female gonads of both species, especially in the TAG of both species that contained 21 NMI FA. Among these NMI FA, the positional isomers of 24:3 were found only in the female gonads of both species. In this study the male and female gonads of both species showed distinct differences in both their composition and proportions of NMI FA. The proportions of 5,9-24:2 and 5,9,17-24:3 showed a statistically significant difference between the male and female gonads of both species. An interesting result was that the proportions of 5,9-18:2, 5,9-22:2, 5,9-24:2, 5,9,15-24:3, and 5,9,17-24:3 were higher in the PL of the female gonad of both species than in the female TAG,

and that both female gonads had the highest content of 5,9-22:2. These differences between the TAG and PL of female gonads of both species were statistical significant. The findings of this study suggest that the occurrence of 5,9-24:2 and 5,9,17-24:3 is a sexual difference and that female gonads have more specific NMI FA components of structural lipids (PL) than storage lipids (TAG). However, the NMI FA composition results in limpet gonads also might be related to the effects of seasonal variations or the reproductive cycle or both. Some NMI FA with a 5,9-double bond system could play an important role in female reproductive physiology because of their exclusive presence in the PL of female gonads and their unique structure. A clarification of the physiological role of NMI FA in limpet gonads will be the subject of future study.

Although both 5,9-24:2 and 5,9,17-24:3 are found in each of the two sponges *Hymeniacidon sanguinea* and *Dysidea fragilis* (12,13), the presence of 5,9,15-24:3 may not have been reported previously from any living organism. The NMI diene FA 5,9-18:2, 5,9-22:2, and 5,9-24:22 are found in the phospholipids of the Caribbean sponges *Plakortis halichondroides* and *Calyx podatypa* (14,15) and in the phospholipids of the anemone *Condylactis gigantea* and the zoanthid *Palythoa caribaeorum* (16). In contrast, 5,9-18:2 is also found in terrestrial seed lipids as well as in some marine sponge lipids

[a]Values are expressed as mean ± SD ($n = 3$). For statistical analysis, "Trace" and "not detected" (—) were set as 0.01 and 0, respectively. Means with the same lowercase superscript letters are significantly different between sexes (Student's *t*-test, $P < 0.05$), those with the same capital letters are significantly different (Student's *t*-test, $P < 0.05$) between the TAG and polar lipid fractions of female gonads, and those with the same lowercase Greek superscript letters are significantly different (Student's *t*-test, $P < 0.05$) between the TAG and polar lipid fractions of male gonads. Trace, <0.01%; —, not detected.

(9,15,16). Therefore, the long-chain NMI FA 5,9-22:2, 5,9-24:2, 5,9,15-24:3, and 5,9,17-24:3 detected in this study might be biosynthesized by the limpet itself or by some of its symbiotic organisms. These dienes with 5,9 double bonds might be derived from the corresponding 9-monoenoic FA by $\Delta 5$ desaturation. On the other hand, the unusual isomers 5,9,15-24:3 and 5,9,17-24:3 might be derived from the typical NMI dienes 7,13-22:2 and 7,15-22:2, respectively, by chain elongation and subsequent $\Delta 5$ desaturation. In contrast, some NMI FA detected in these gonads might be derived from the diet or the result of marine food web effects, or both, because of their very small amounts. Thus, further research is needed to confirm whether the occurrence of NMI FA in limpet gonads is a consequence of intake from the marine food chain or *de novo* synthesis or both.

Dietary Nucleotides Do Not Alter Erythrocyte Long-Chain Polyunsaturated Fatty Acids in Formula-Fed Term Infants

Robert A. Gibson[a,b], Joanna S. Hawkes[a], and Maria Makrides[b,*]

[a]Child Health Research Institute, Flinders Medical Centre and Flinders University, Bedford Park, South Australia 5042, and [b]Child Health Research Institute and University of Adelaide Department of Paediatrics, Women's and Children's Hospital (WCH), North Adelaide, South Australia 5006, Australia

ABSTRACT: There have been conflicting reports regarding the effectiveness of dietary nucleotides (NT) to regulate tissue desaturases and hence stimulate accumulation of both n-6 and n-3 long-chain polyunsaturated fatty acids (LCPUFA). The aim of this study was to examine the effect of NT-supplemented cow's milk-based formula on erythrocyte phospholipid FA status in a large randomized controlled trial involving a well-nourished infant population born at term. Formula-fed infants were allocated to control formula with an innate level of NT at 10 mg/L ($n = 102$), or formula fortified with NT at 34 mg/L ($n = 98$). A parallel group of breastfed infants was included as a reference. Peripheral blood samples were collected by venipuncture at 7 mon of age and erythrocyte phospholipid FA determined by capillary GC. Erythrocyte LCPUFA levels did not differ between the NT-supplemented and control formula groups and were reduced in both groups compared with breastfed infants. We conclude that there is no induction of LCPUFA accumulation in erythrocyte phospholipids of term, formula-fed infants following 7 mon of NT supplementation.

Paper no. L9748 in *Lipids 40*, 631–634 (June 2005).

Human milk contains higher amounts of nonprotein nitrogen as nucleotides (NT), nucleosides, and nucleic acids compared with bovine milk from which most infant formulas are manufactured (1,2). NT in human milk are thought to play an important role in aspects of cellular function and metabolism, including growth and maturation of the gastrointestinal tract and the development of infant immunity (1,3). Recent changes in the composition of some infant formulas marketed throughout the world have resulted in the addition of NT in an attempt to mimic the typical composition of human milk. Some randomized controlled trials (RCT) involving formula-fed infants have reported beneficial effects of NT supplementation on various components of the immune system (4–6), the incidence of diarrhea (7), intestinal microflora (8), and growth in infants born small for gestational age (9). An area of controversy in NT nutrition relates to their ability to modulate the accumulation of long-chain PUFA (LCPUFA), such as DHA (22:6n-3) and arachidonic acid (20:4n-6) (10,11). Whereas reports from one laboratory suggest beneficial effects, subsequent studies involving preterm (12) or low-birth-weight infants (13) have been unable to confirm the LCPUFA-enhancing effects of supplemental NT compared with unsupplemented formula. In a more recent study designed primarily to examine the effect of added NT on iron status of term infants, there was also no significant difference between the NT-supplemented group and other formula groups in erythrocyte FA composition at both time points following commencement of feeding (4 and 6 mon of age) (14).

LCPUFA have been implicated as factors affecting growth and development of term infants (15). Healthy term infants randomly allocated to LCPUFA-supplemented formula have been shown to have better LCPUFA tissue status, and in some cases, improved indices of neural function compared with unsupplemented infants (16–18). Therefore, any interaction between NT and LCPUFA may be of importance in the nutrition of infants.

The purpose of this study was to investigate the effect of term infant formula supplemented with NT as marketed in Australia and Europe (33.5 mg/L 5'-monophosphates; 5 mg/100 kcal) on erythrocyte phospholipid LCPUFA status in comparison with unsupplemented formula. Infants were enrolled in a large RCT conducted with primary outcome measures focused on growth and biochemical indices of immune function (19). Secondary outcomes included erythrocyte phospholipid FA at 7 mon, which are reported here.

EXPERIMENTAL PROCEDURES

Subjects. Mothers with eligible infants were recruited from the postnatal ward at the Women's and Children's Hospital (WCH), Adelaide according to the protocol approved by the WCH Research Ethics Committee. Infants were eligible if they were born at term (≥37 wk gestation) and had a birth weight ≥2500 g and were excluded if they had major congenital deformities or illnesses, confirmed infection in the neonatal period requiring antibiotic therapy, or if their mother had diabetes requiring insulin during pregnancy. Infants allocated to the formula feeding groups had mothers who had decided

Abbreviations: ALA, α-linolenic acid; LA, linoleic acid; LCPUFA, long-chain PUFA; NT, nucleotide; RCT, randomized controlled trial.

to exclusively formula-feed from birth. Mothers who intended to breastfeed for at least 7 mon were approached for enrollment into the reference breastfed group.

Randomization and blinding. Formula-fed infants were randomly assigned to one of four masked formula codes corresponding to two different formulas. Assignment to the infant's feeding regimen was by sequentially numbered, opaque, sealed envelopes. Trial participants and study personnel had no knowledge of the next assignment prior to obtaining consent.

Treatments. Infants in the control group received standard whey-adapted, cow's-milk protein-based S26 (Wyeth Nutrition) in powder form to provide 67 kcal/100 mL and an innate level of NT at 10 mg/L (1.5 mg/100 kcal). Infants in the treatment group (NT+) received the same whey-adapted, cow's-milk protein-based S26 in powder form to provide 67 kcal/100 mL and fortified with cytidine monophosphate (CMP) at 17.3 mg/L (2.58 mg/100 kcal), uridine monophosphate (UMP) at 6.6 mg/L (0.99 mg/100 kcal), adenosine monophosphate (AMP) at 4.4 mg/L (0.66 mg/100 kcal), inosine monophosphate (IMP) at 3.1 mg/L (0.46 mg/100 kcal), and guanosine monophosphate (GMP) at 2.2 mg/L (0.33 mg/100 kcal). The composition of fat blends used to manufacture both the control and NT+ formulas was randomized palm olein (36% of total blend), high-oleic sunflower (21%), coconut (21%), soy (21%), and lecithin (0.98%). Both test formulas contained linoleic acid (LA, 16.2% of total FA) and α-linolenic acid (ALA, 1.5% of total FA) but no added LCPUFA (Wyeth Nutrition).

Mothers were asked to feed their infant their assigned study formula as the only milk source until 7 mon of age. For breastfed infants, breastfeeding was strongly encouraged for the entire 7-mon feeding period. The use of solid foods was strongly discouraged during the first 4 mon of the study. Intake of non-study milks, juice, or solid foods was recorded for all infants as part of monthly telephone contact throughout the study. Egg, meat, chicken, and fish were considered likely to contribute some LCPUFA to the diet.

Laboratory assessments. Blood samples were taken by venipuncture at 31.9 ± 1.6 wk of age for measurement of erythrocyte FA composition. Plasma and erythrocytes were separated by centrifugation at $690 \times g$ for 5 min at room temperature. Plasma samples were used for measurement of immune responses as reported elsewhere (19). Erythrocyte FAME were prepared, separated, and analyzed as described previously (20). Briefly, erythrocyte lipids were extracted with chloroform/propanol on the day of blood collection. The phospholipid fractions were separated by TLC, methylated, and quantified using a Hewlett-Packard 6890 gas chromatograph and identified based on the retention time of authentic lipid standards (Nu-Chek-Prep Inc., Elysian, MN).

Sample size and statistics. To cover all sample size estimates required for the primary outcome measures associated with this RCT, we aimed for 70 infants per group to complete the trial (19). We therefore enrolled approximately 100 infants per group. This allowed for 30% loss due to withdrawals, low compliance, and incomplete blood collections. Seventy infants per formula group enabled us to detect a minimum difference of 0.15% total phospholipid DHA (SD 0.3) between NT-supplemented and control formula-fed infants with 84% power and an α of 0.05. This level of difference is unlikely to be of any clinical relevance (21), and a statistical analysis supporting the null hypothesis would indicate equivalence of NT-supplemented and control formula in terms of LCPUFA status.

The effect of feeding formula with or without NT on erythrocyte FA composition was assessed on an intention-to-treat basis. Differences between the randomized dietary groups were analyzed by Independent Samples T Test. Secondary analyses included the comparison between the two formula-fed groups and the breastfed reference group using one-way ANOVA with *post hoc* analysis using Bonferroni corrections and analysis including only the infants who complied with the feeding protocol (≥80% of all milk feeds were study formula or breast milk). All analyses were completed using SPSS for Windows 10.0 (SPSS Inc., Chicago, IL).

RESULTS

Characteristics of trial participants. Two hundred mothers of formula-fed infants agreed to participate in the study and were allocated either to the control group ($n = 102$) or to the NT+ group ($n = 98$). Blood samples suitable for analysis of FA status were collected from 136 of 200 (68%) formula-fed infants at 7 mon of age. More than 90% (66 of 69 in the control group and 63 of 67 NT+ group) of all infants were receiving at least 80% of their milk feeds as study formula at the time of blood collection. One hundred twenty-five infants were enrolled in the breastfed reference group, and analysis of erythrocyte FA was completed on 96 (77%) infants at 7 mon of age. As expected, the number of infants receiving ≥80% of milk feeds as breast milk decreased throughout the study to 59% (57 of 96) at the end of the 7-mon feeding period.

Introduction of solids. Solids were introduced into the diet of 71% (97 of 136) of formula-fed infants by 4 mon of age. Only 6% of foods were likely to contribute to the LCPUFA intake of those infants receiving solids, and there was no difference in the rate of introduction of weaning foods or type of weaning foods between the treatment groups. Fewer infants in the breastfed reference group had received solids by 4 mon of age (56 of 96, 58%), and the proportion of foods likely to contribute some LCPUFA to the diet was 7% (7 of 96). By 7 mon of age, all infants in the study were receiving weaning foods and there was no difference between the groups regarding the proportion of foods likely to contribute LCPUFA to the diet (Control, 44 of 69; NT+, 41 of 67; breastfed, 62 of 96).

FA composition. Dietary NT had no effect on the LCPUFA status of erythrocyte membranes of formula-fed infants regardless of whether the comparison was on an intention-to-treat basis (Table 1) or only included the infants who were compliant with the feeding protocol (data not shown). The level of n-3 LCPUFA present in erythrocyte membrane phospholipids was higher in the breastfed group whereas monounsaturated FA and total n-6 FA were lower compared with both groups of infants receiving formula.

TABLE 1
Comparison of Erythrocyte Phospholipid FA from Control and NT-Supplemented Formula-Fed Infants at 7 mon of Age[a,b]

FA	Control formula (*n* = 69)	NT+ formula (*n* = 67)	Reference breastfed group[b] (*n* = 96)
Total saturates	42.0 ± 0.1	42.0 ± 0.1	42.4 ± 0.1
Total monounsaturates	18.2 ± 0.1	18.2 ± 0.1	17.2 ± 0.1
18:2n-6 (LA)	12.8 ± 0.1	12.8 ± 0.1	10.1 ± 0.2
20:3n-6 (DGLA)	1.9 ± 0.04	1.9 ± 0.1	1.6 ± 0.03

Total n-3	3.9 ± 0.07	4.0 ± 0.07	7.8 ± 0.2

[a]Mean ± SEM, % of total FA. LA, linoleic acid; DGLA, di-homo-γ-linoleic acid; AA, arachidonic acid; DPA, docosapentaenoic acid. Control, unsupplemented formula; NT+, nucleotide-supplemented formula.
[b]Differences between the randomized treatment groups were analyzed by Independent Samples T Test. There were no significant differences between the two randomized groups for any of the variables described. Data were also analyzed by ANOVA with *post hoc* analysis using Bonferroni corrections on an intention-to-treat basis. Breastfed infants were different from both formula-fed groups for all of the FA variables described ($P < 0.01$).

DISCUSSION

This is the largest RCT to rigorously test the effect of dietary NT on FA status in term infants. Our trial showed that supplementation of infant formula with 33.5 mg/L (5 mg/100 kcal) free NT did not influence the FA status of term infants at 7 mon of age. Our results support the findings of Hernell and Lönnerdal (14), Woltil *et al.* (13), and Axelsson *et al.* (12) but contrast with the frequently cited studies from Spain suggesting that dietary NT may play a role in enhancing enzymes involved in the conversion of 18-carbon PUFA precursors to their longer-chain derivatives (10,11,22). The Spanish studies report higher levels of LCPUFA in erythrocyte phospholipids, plasma lipids, and plasma phospholipids in the NT-supplemented group of infants compared with unsupplemented infants in the first months of life. In addition, DeLucchi *et al.* and Gil *et al.* reported that, in general, the pattern of LCPUFA in tissues from NT-supplemented infants was more like those of breastfed infants, as dietary NT appeared to stimulate accumulation of both n-6 and n-3 LCPUFA (10,11). Infants in our study were supplemented with a higher dose of NT (33.5 mg/L compared with 11.7 mg/L) for a longer period of time (7 mon compared with 1 mon), and group sizes were considerably larger (67–69 per group compared with 19 per group). Furthermore, the values seen in our current trial concur with those reported for formula-fed and breastfed infants in other studies (21,23). It would seem likely that the conditions under which our study was conducted would lead to measurable effects on LCPUFA status if dietary NT contribute to augmentation of LCPUFA synthesis.

There are no food composition tables that document NT content of Australian foods. Therefore, we have considered the age of introduction of solid foods and the proportion likely to contribute some LCPUFA and NT to the diet. There were no differences between the treatment groups in the timing or type of weaning foods introduced, thus it is unlikely that dietary intake of weaning foods is a confounding factor in this study. In fact, it appears that even against a background of increasing amounts of foods containing NT and LCPUFA, breastfed infants still maintain significantly higher levels of LCPUFA. Although we cannot exclude the possibility that NT supplementation may have an effect on the FA status of formula-fed infants at an earlier age, such an effect would be transitory in nature and may be of little clinical benefit.

We have shown in another study that infants in this age group have the capacity to alter their erythrocyte LCPUFA status in response to diet (21). In that study we showed that reducing the LA/ALA ratio from 10:1 to 5:1 (but keeping other constituents equal) resulted in an enhancement of EPA, docosapentaenoic acid, and DHA levels although not to the levels seen in breastfed infants. Thus, we are confident that we have the ability to detect small changes in erythrocyte LCPUFA status when they are present. The current study was larger than our earlier report (21).

In summary, in a pragmatic trial that considers usual and recommended feeding practices regarding the introduction of solids, the use of NT-supplemented formula does not change erythrocyte LCPUFA levels in late infancy.

ABSTRACT: Treatment of animals or cells with the amphipathic tertiary amine U18666A {3β-[2-(diethylamino) ethoxy]androst-5-en-17-one} provides models for several human diseases (e.g., cataracts, Niemann–Pick disease, and epilepsy). Although U18666A can inhibit several enzymes in the cholesterol synthesis pathway, we hypothesized that induction of these varied conditions was due to physical effects of the amine rather than to inhibition of specific proteins. To test this possibility we compared the capacity of U18666A and its enantiomer, *ent*-U18666A, to inhibit net sterol synthesis and induce apoptosis in cultured bovine lens epithelial cells. Nonenantiospecific actions dependent on the physical properties of these mirror image molecules would be identical, but effects dependent upon enantiospecific interactions would be different for the enantiomers. At the same concentrations, both forms of the compound equally inhibited sterol synthesis and induced apoptosis. These observations supported a generalized mechanism of enzyme inhibition such as perturbation of the microenvironment of endoplasmic enzymes and alteration of membrane order, perhaps of the mitochondrial membrane, to explain induction of apoptosis.

Paper no. L9707 in *Lipids 40*, 635–640 (June 2005).

The steroid 3β-[2-(diethylamino) ethoxy]androst-5-en-17-one (U18666A) is a widely-studied inhibitor of sterol synthesis because, when given to intact animals or cells, it generates models of at least three human diseases: atypical absence (petit mal) epilepsy (1,2), cataracts (3,4), and Niemann–Pick type C disease (NPC) (5–7). U18666A has recently also been shown to induce apoptosis in cultured lens cells (4) and neurons (8). Understanding how a single inhibitor of sterol metabolism can induce such varied disorders is a long-term goal of these investigations. Although multiple mechanisms may underlie induction of these diverse conditions [U18666A can decrease the cholesterol content of membranes (1,3), alter sterol composition of cells (2,3), and increase cellular free cholesterol levels (8)], we hypothesized that its broad toxic actions are more related to general perturbation of membrane structure through direct intercalation of this molecule (4). Part of the complexity in understanding the effects of U18666A on cells may be due to its multiple effects on sterol biosynthesis.

Although U18666A is considered to be an inhibitor of oxidosqualene cyclase (OSC) (9), it can also inhibit sterol Δ8-isomerase (SI) (10) and desmosterol reductase (1l). The mechanism of enzyme inhibition is unclear. Catalysis by both OSC and SI proceeds through a high-energy carbocationic intermediate (12,13). Structural mimics of the intermediate that inhibit the enzyme include amphipathic molecules containing a suitable positive charge, often provided by an ammonium group. Examples of mimics include the azasqualene series of compounds (12), the 8-azadecalin series of compounds (13), as well as U18666A. Inhibition of OSC by the azasqualenes was shown to be noncompetitive (12), and both noncompetitive and competitive mechanisms of inhibition were seen for the azadecalins depending upon the specific compound (13).

U18666A and other Class 2 amphiphiles can also interfere with the intracellular movement of cholesterol and cause accumulation of unesterified cholesterol, mimicking NPC lipid storage disease (14), a genetic condition characterized by the deficiency of an integral membrane protein, NPC1 protein, which is important for the intracellular transport of cholesterol (15). The apoptosis induced in cultured neurons by U18666A was also believed due to intracellular accumulation of toxic levels of unesterified cholesterol (8). Although U18666A could directly interact with the NPC1 protein, the block in cholesterol trafficking could occur through a more general effect on membranes due to the structural diversity of the hydrophobic amines that induce NPC (6).

As part of our studies into the mechanism of the U18666A-induced cataract, we observed that the induction of apoptosis in cultured lens epithelial cells appeared unrelated to inhibition of cholesterol synthesis (4). In addition, because U18666A was shown to intercalate into lens lipid membranes and alter their structure, we hypothesized that the toxic actions of U18666A were due to direct perturbation of membrane structure. To further test this possibility in the current study, we compared the capacity of U18666A and its enantiomer (*ent*-U18666A) to inhibit sterol synthesis and induce apoptosis in cultured lens epithelial cells. U18666A and *ent*-U18666A differ in configuration at all stereocenters and are mirror images of one another (Fig. 1). Because enantiomers have the same chemical and physical properties, their effects on membrane structure should

FIG. 1. (A) 2-D structures of the nonprotonated amine forms of U18666A {3β-[2-(diethylamino) ethoxy]androst-5-en-17-one} and the enantiomer of U18666A (*ent*-U18666A). (B) 3-D models of the two enantiomers (hydrogens not shown). Notice that the 3-substituent has the equatorial configuration in both enantiomers (see text for additional details). (C) An edge and top view of the superimposed enantiomers. The *ent*-U18666A has been turned upside down and the carbon atoms of the steroid A-rings have been superimposed.

be identical (16). On the other hand, enantiomers should demonstrate different actions on processes that are enantioselective, such as binding to an enzyme's active site (16). Thus, if U18666A inhibition of sterol synthesis and induction of apoptosis is due to interaction with specific proteins, the capacity of U18666A and *ent*-U18666A to cause these effects should markedly differ. Identical capacities would argue in favor of a more general mechanism, such as drug-induced changes in membrane structure. To conduct this study, we developed a method to synthesize the enantiomer of U18666A. This organic synthesis and the proof of structure are described.

MATERIALS AND METHODS

Synthesis of the ent-U18666A. The *ent*-U18666A was prepared by the same literature method used to prepare U18666A except that *ent*-dehydroepiandrosterone was used instead of dehydroepiandrosterone (17). A mixture of *ent*-dehydroepiandrosterone acetate (460 mg, 1.39 mmol) prepared according to the literature (18), ethylene glycol (1 mL), and *p*-toluenesulfonic acid (50 mg) in benzene (100 mL) was heated at reflux in a Dean–Stark distillation apparatus for 16 h. The reaction was cooled. The reaction mixture was made basic by adding a few drops of aqueous NaHCO₃ and stirred for a few minutes. Ethyl acetate (150 mL) was added, and the biphasic mixture was transferred to a separatory funnel and washed with aqueous saturated NaHCO₃ (3 × 100 mL), dried (anhydrous sodium sulfate), and concentrated to give a white solid, (500 mg). A mixture of the crude 17-ketal product (500 mg), methanolic KOH (85%, 200 mg dissolved in 25 mL), and THF (10 mL) was stirred at room temperature for 16 h to remove the 3-acetate

group. The solvents were removed to give a white solid that was partitioned between methylene chloride (100 mL) and water (100 mL). The methylene chloride layer was separated, and the aqueous layer was extracted with methylene chloride (40 mL × 3). The combined methylene chloride extracts were dried and concentrated to give the 17-ketal/3-alcohol as a colorless solid (290 mg, 63%) that was used in the next step without any further purification.

To a cold (0°C) solution of the 17-ketal/3-alcohol (280 mg, 0.84 mmol) in toluene (5 mL) was added 2.5 M butyl lithium in hexanes (0.37 mL, 0.92 mmol), and the resulting mixture was stirred at 0°C for 15 min. To that solution was added chloroethyldiethylamine (342 mg, 2.52 mmol, prepared by neutralization of the hydrochloride salt purchased from Aldrich Chemical Co., Milwaukee, WI) in toluene (2 mL), and the mixture was heated at reflux for 40 h under a nitrogen atmosphere. The reaction mixture was cooled, diethyl ether (200 mL) was added, and the organic layer was extracted with aqueous 1 N HCl (50 mL × 4). The organic layer was discarded. The combined aqueous extracts were further extracted with methylene chloride (50 mL × 4). The combined methylene chloride extracts were dried and concentrated to yield an oil, which was dried under high vacuum for 16 h. This material was purified by flash chromatography on 32–63 µm silica gel (Scientific Adsorbents, Atlanta, GA) using 10–25% methanol in ethyl acetate as eluents to give a solid. Ethereal HCl (5 mL, which was prepared by bubbling dry HCl into the cold ether solution) was added into a solution of the above-obtained solid (~200 mg) in anhydrous methylene chloride (6 mL), and the mixture was stirred for a few minutes. The solvents then were removed by distillation on a water bath to give an off-white solid. This material was dissolved in methanol to which was added 200 mg of decolorizing charcoal, and the resulting suspension was swirled at room temperature, then filtered through a J.T.Baker, Inc. (Phillipsburg. NJ) 6 mL Octadecyl (C₁₈) disposable extraction column (cat. # 7020-06). The filtrate was concentrated to give an off-white solid (180 mg, 51%) m.p. 200–202°C, [α]_D = −24 (methanol, c = 0.20); ¹³C NMR (CDCl₃) δ 220.99, 140.17, 121.44, 79.55, 62.47, 51.64, 51.21, 50.10, 47.45, 47.28 (2 × C), 38.70, 36.82 (2 × C), 35.77, 31.39, 31.34, 30.69, 28.06, 21.80, 20.78, 19.32, 13.48, 8.65 (2 × C). ¹H NMR (CDCl₃) δ 5.37 (1H, *b s*), 3.99 (2H, *b s*), 3.22 (*b s*, 7H), 2.60–0.90 (*m*, 19H), 1.42 (*t*, 6H, *J* = 7.1 Hz), 1.02 (*s*, 3H), 0.89 (*s*, 3H). Analysis calculated for C₂₅H₄₂ClNO₂: C, 70.81; H, 9.98; N, 3.30. Found: C, 70.60; H, 9.70; N, 3.34.

U18666A, prepared by the same procedure, had a m.p. of 196–199°C, identical ¹H and ¹³C NMR spectra, and [α]_D = +18.6 (methanol, c = 0.20). The reported literature values (17) for the m.p. and optical rotation of U18666A are 197–201°C and [α]_D = +17 (methanol).

Cell culture and measurement of sterol synthesis. Routine chemicals and reagents were from Sigma Chemical Co. (St. Louis, MO). Bovine lenses were obtained from cattle slaughtered for human food by local abattoirs. Bovine lens epithelial cells (BLEC) were cultured in 60-mm (diameter) dishes in Dulbecco's modified Eagle's medium (DMEM) containing 10%

calf serum as previously described in detail (19). Dishes of BLEC near confluence (about 1.3×10^6 cells and 1.0 mg protein/dish) were washed twice in serum-free DMEM and then incubated for 4 h at 37°C in 2.5 mL of serum-free DMEM containing 5.7 µCi/mL of sodium 1-^{14}C-acetate (56.5 mCi/mmol; PerkinElmer, Boston, MA). Media contained no compounds (controls) or U18666A or *ent*-U18666A at 0.1 or 1.0 µM, added in ethanol. The concentration of ethanol in all media was 0.14%. Simvastatin acid at 10 µM was examined as a positive control, i.e., an established inhibitor of HMG CoA reductase that should almost completely block the cholesterol synthesis pathway at this concentration. The magnitude of the ^{14}C-acetate incorporation into lens cell sterols may have been decreased due to adding the compounds in a metabolizable solvent vehicle, ethanol. However, since all incubations contained the same concentration of ethanol (0.14%, vol/vol), the relative effects of the compounds should be independent of a possible solvent effect.

Recovery of radiolabed sterols. Following incubation, cell layers were washed in ice cold PBS and PBS containing 15 mM sodium acetate and then dissolved in 1.6 mL of 1.0 M KOH, which was transferred to preweighed 125-mm screw-capped test tubes containing 100 µg of cholesterol added as carrier. The volume of KOH solution in each tube was determined by weighing and 40 µL was taken for protein assay. The mass of protein per tube (dish) was calculated. One milliliter of ethanol was added to each tube, the tubes were capped, and the samples saponified at 100°C for 1 h. Water (0.5 mL) was added, and the nonsaponifiable (NS) lipids were extracted into hexane (twice with 6 mL). The pooled hexane extracts were evaporated and the lipids separated by TLC on silica gel G plates using a solvent of hexane/diethyl ether/glacial acetic acid (73:25:2, by vol). The air-dried plates were briefly exposed to iodine vapor to locate the cholesterol (sterol) band. The R_f was about 0.25. The sterol band was recovered by scraping and transferred to a 20-mL scintillation counting vial. After adding 1.0 mL of methanol and 15 mL of scintillation solution, the dpm per sample were measured to generally 1% counting error. Results were expressed as dpm $\times 10^{-3}$ incorporated into sterols per mg of protein. Results were expressed as means of replicate dishes ± SEM, and differences from controls were statistically evaluated by the unpaired Student's *t*-test. We did not examine the media for labeled sterols potentially released from the cultured cells but assume that any release would have been proportional to that synthesized.

Apoptosis in lens epithelial cells treated with U18666A or ent-U19666A. BLEC grown to subconfluence on well-slides were incubated with either no inhibitors (controls) or 40 to 200 nM U18666A or *ent*-U18666A for 48 h at 37°C in an atmosphere of 6% carbon dioxide. Slides were washed twice with PBS and fixed for 25 min in 10% buffered formalin. Apoptosis was detected using the DeadEnd Colorimetric Apoptosis Detection System (Promega, Madison, WI) as done before (4). Briefly, cells were permeablized by exposure to Triton X-100, and biotinylated nucleotides were incorporated into the 3′OH ends of the DNA using terminal deoxynucleotidyl transferase.

Horseradish peroxidase-labeled streptavidin was then bound to the biotinylated nucleotides, and color development was detected using the substrate diaminobenzidine plus hydrogen peroxide. Positive control slides were exposed to DNase I to induce apoptosis.

RESULTS AND DISCUSSION

Comparison of the structure of U18666A and ent-U18666A. At first glance, the 2-D drawings of Figure 1A convey the impression that changing the configuration of the oxygen atom attached to C-3 changes an equatorial 3β-substituent to an axial 3α-substitutent. While it is true that the substituent is 3α, it is not true that the substituent has the axial configuration. Instead, the substituent remains in an equatorial configuration (see Fig. 1B). This results from the fact that the remaining chiral centers in the molecule (C-8, C-9, C-10, C-13, and C-14, i.e., the carbons at the ring fusions) are also inverted, thereby flipping the ring conformations in the molecule and placing the 3α-substituent back in an equatorial configuration. The inverted chair conformations for the steroid A ring are readily apparent in Figure 1B.

In Figure 1C, the A rings of U18666A and *ent*-U18666A have been superimposed to emphasize similarities and differences in the shapes of the enantiomers. The 3-substituents, steroid A and C rings, the 18- and 19-methyl groups, and the 17-keto groups can be placed in identical or nearly identical positions in 3-D space when the molecules are compared in this way. However, the steroid B rings, and the double bond contained therein, as well as the steroid D rings, lie in different positions. The different positions of these rings would form a steric basis for chiral discrimination by an enzyme if the molecules were aligned in this manner in the active site. However, the way that U18666A and *ent*-U18666A might be bound in the OSC active site is unknown, and it remains possible that each enantiomer might bind in a very different orientation to inhibit OCS activity.

Comparison of inhibition of sterol synthesis by U18666A and ent-U18666A. Sterols were separated by TLC from the NS fraction of BLEC incubated with 1-^{14}C-acetate. The sterol band would contain cholesterol and precursor sterols such as desmosterol and 7-dehydrocholesterol (11). Exposure of cells to 10 µM simvastatin acid decreased incorporation of ^{14}C-acetate into sterols by more than 98% (Table 1). Sterol synthesis by cells exposed to either 1 µM U18666A or *ent*-U18666A was decreased by 88–89%. U18666A and *ent*-U18666A at 0.1 µM similarly decreased sterol synthesis by 55–65% (Table 1). We did not examine the media for labeled sterols potentially released from the cultured cells but assume that any released would have been proportional to that synthesized.

The results of these incorporation studies clearly show that U18666A and *ent*-U18666A have essentially identical effects on total sterol synthesis and presumably OSC. Although this observation may suggest that the inhibition of OSC by U18666A is not competitive, the mechanism of catalysis by OSC and its interaction with inhibitors can be complex. Squa-

lene-hopene cyclase (SHC) is the prokaryotic equivalent of eukaryotic OSC. Using X-ray diffraction analysis of recombinant SHC, Lenhart *et al.* (20,21) demonstrated that SHC, and presumably OSC, is a monotopic membrane protein with a deep hydrophobic pocket that extends from the protein surface to the plasma membrane surface from which the enzyme extracts its substrate. Kinetic analysis of OSC inhibition by Ro48-8071 (22) and similar compounds suggested noncompetitive or mixed noncompetitive mechanisms (20,21); however, binding of the inhibitors at the active site favors competitive inhibition. The inhibitors examined contained a tertiary amine cationic group at one end of the molecule and a ketone carbon separated from the amine by a hydrophobic domain at the other end of the molecule, as in U18666A and *ent*-U18666A. The inhibitor compounds insert into the active site cavity with the tertiary amine near the surface located close to Asp376, and the ketone carbon toward the membrane interface is near Phe601 and Phe606. The apparent paradox of noncompetitive inhibition kinetics and the OSC inhibitors binding at the active site is explained by "the inhibitors (being) kinetically captured in the sequestered cavity, feigning a noncompetitive case" (21).

Although we cannot exclude the possibility that U18666A and *ent*-U18666A could inhibit OSC equally well by binding in the active site of this enzyme, more generalized mechanisms of inhibition are also suggested by our results. Either inhibition resulting from perturbation of the microenvironment of the enzyme secondary to U18666A intercalation into membrane (4) or nonenantioselective binding of the inhibitor to sites other than the active site of the enzyme is a reasonable possibility. These more generalized mechanisms of inhibition may explain the capacity of U18666A to inhibit multiple endoplasmic late-stage enzymes of cholesterol biosynthesis (OSC, SI, and desmosterol reductase).

Comparison of induction of apoptosis by U18666A and ent-U18666A. U18666A and *ent*-U18666A both induced apoptosis in cultured BLEC in a highly concentration-dependent manner (Fig. 2). Neither induced apoptosis at 40 nM, but both did at 100 and 200 nM. At the lower concentrations (30–40 nM), U18666A can block proliferation of cultured BLEC due to inhibition of cholesterol synthesis, because adding cholesterol to the cholesterol-free media restored proliferation (4). However, adding cholesterol could not overcome the inhibition of cell proliferation or apoptosis caused by higher levels (100–200 nM) of U18666A

(4) (Fig. 2). These observations suggest that the induction of apoptosis in BLEC by U18666A and *ent*-U18666A is independent of cellular cholesterol levels. But Cheung *et al.* (8) reported that induction of apoptosis in cultured mouse neurons was related to accumulation of toxic levels of free cholesterol in U18666A-treated cells. The difference between the two sets of findings could be related to differences in the response of cell types to U18666A. Neither elevation of free cholesterol nor induction of significant apoptosis was seen in the neurons exposed to 236 nM U18666A (0.1 μg/mL media) (8), a concentration that was clearly apoptotic in the cultured lens epithelial cells. It is well documented that the sensitivity to induction of apoptosis by specific agents can greatly differ from one cell type to another (23). In fact, Cheung *et al.* (8) stated that U18666A did not induce apoptosis in other neuronal cell lines.

Although it appears unlikely that the apoptosis induced by U18666A and *ent*-U18666A in lens epithelial cells at the concentrations studied was due to raising intracellular cholesterol levels, the mechanism is unknown. Lovastatin, an inhibitor of the rate-limiting enzyme (HMG-CoA reductase) in the cholesterol synthesis pathway, can induce apoptosis in various tumor cell lines (24,25). The apoptosis was prevented by providing cells with geranylgeranyl pyrophosphate, an isoprene with anti-inflammatory roles formed prior to squalene, but not by providing squalene, sterol precursors of cholesterol, or cholesterol (25). U18666A does not appear to inhibit isoprene formation (26). The turnover of HMG-CoA reductase by proteolysis in BLEC is dependent on isoprene formation, and when HMG-CoA reductase is inhibited by lovastatin the half-life of this enzyme is prolonged by 10-fold (26). When mevalonic acid and U18666A were added to the lovastatin-exposed cells, the short half-life was restored. In light of these observations, it seems possible that the apoptotic activity of U18666A is unrelated to inhibition of the cholesterol synthesis pathway, i.e., it is independent of isoprene or cholesterol. The equivalent apoptotic activity of U18666A and *ent*-U18666A also argues against these molecules interacting with a specific apoptotic signaling protein. Rather, a more generalized mechanism of apoptosis dependent on the equal physical properties of the molecules is suggested. Radiolabeled U18666A became highly associated with mitochondria and membrane fractions when injected into rats (27). Mitochondrial destabilization precedes caspase activation in some types of apoptosis (28). Induction of apoptosis
FIG. 2. Apoptosis in cultured bovine lens epithelial cells caused by U18666A and *ent*-U18666A. Bovine lens epithelial cells were cultured in Dulbecco's modified Eagle's medium plus 10% calf serum containing 40 (C), 100 (E), or 200 nM (G) of U18666A or 40 (D), 100 (F), or 200 nM (H) of *ent*-U18666A. Control (A) contained neither compound. Positive control (B) is a cell layer exposed to DNase I to induce DNA fragmentation. The arrows displayed in panels E, F, G, and H identify cells positive for DNA fragmentation as evaluated by the TUNEL assay. For full chemical name see Figure 1.

in cultured hepatocytes by hydrophobic bile salts was related to direct perturbation of mitochondrial structure as reflected by increased membrane lipid order (29). Such a mechanism might explain the induction of apoptosis by U18666A and *ent*-U18666A. Additionally, U18666A intercalated into lens membranes increased lipid order (4).

REVIEW

Astonishing Diversity of Natural Surfactants: 4. Fatty Acid Amide Glycosides, Their Analogs and Derivatives

Valery M. Dembitsky*

Department of Organic Chemistry and School of Pharmacy, Hebrew University, Jerusalem, Israel

ABSTRACT: FA amide glycosides are of great interest, especially for the medicinal and pharmaceutical industries. These biologically active natural surfactants are good prospects for future chemical preparation of compounds useful as antibiotics, anticancer agents, or for industry. More than 200 unusual and interesting natural surfactants, including their chemical structures and biological activities, are described in this review article.

Paper no. L9744 in *Lipids 40*, 641–660 (July 2005).

Fatty (carboxylic) acid amides, their analogs and derivatives are widespread in nature, although the occurrence of their glycosides is more limited (2). They are incorporated into ceramides (3), glycosphingolipids (4,5), gangliosides (6,7), N-acylated lipids (8), bacterial lipoproteins (9), and other natural complex compounds. The best known FA amides, such as anandamide, oleamide, *N*-arachidonoyldopamine, and *N*-acylethanolamines, as well as aminoglycosides have a high biological activity. They and primary amines attracted attention as bioregulators for the first time in 1957 when Meisinger and co-workers (10) demonstrated that *N*-palmitoylethanolamine is an anti-inflammatory factor contained in the lipid fraction of soybean, peanut oil, and egg yolk. More interest in FA amides with primary amines was associated with the discovery of potent neuromodulatory effects of natural *N*-arachidonyl-ethanolamide (anandamide) (11) and oleoylamine (oleamide) (12).

Anandamide has attracted special interest because of its marked biological activities (11). Like the pharmacologically active compounds in marijuana (from *Cannabis sativa*), it exerts its effects through binding to and activation of specific cannabinoid receptors, designated CB1 and CB2, both of which are membrane-bound G-proteins. CB1 is found in the central nervous system and in some other organs, including the heart, uterus, testis, and small intestine, whereas the CB2 receptor is found in the periphery of the spleen and other cells as-

sociated with immunochemical functions, but not in brain (13). Recently, it has been shown that anandamide and presumably other polyunsaturated *N*-acylethanolamines bind to and activate both the central (CB1) and peripheral (CB2) cannabinoid receptors and elicit virtually all of the known effects of cannabis. Anandamide is believed to have important anti-inflammatory and anticarcinogenic properties, and it affects the cardiovascular system by inducing profound decreases in blood pressure and heart rate (14).

cis-9,10-Octadecenamide is a primary FA amide. It was first isolated from the cerebrospinal fluid of sleep-deprived cats, and has been characterized and identified as the signaling molecule responsible for causing sleep. It induces physiological sleep when injected directly into the brain of rats. Although other FA primary amides in addition to *cis*-9,10-octadecenamide are present naturally in the cerebrospinal fluid of animals, no others exhibit similar physiological activity (15). The biological effects of the other fatty acyl-ethanolamine derivatives are less clear, although they are by far the most abundant components of this lipid class.

FA amide glycosides such as ceramides, gangliosides, aminoglycosides, their analogs and derivatives also show high biological activity (3–7,16–18). FA (carboxylic) amides are produced synthetically in industry in large amounts (more than 400,000 tons per annum) for use as ingredients of detergents, lubricants, inks, and many other products (19–22). However, in this review article, we are concerned with those as simple, complex of fatty (carboxylic) acid amide glycosides, which are found in nature, and some of which have profound biological functions.

AMINOGLYCOSIDES AND DERIVATIVES

Since Florey and co-workers (23) reported in 1940 that penicillin, a microbial product, is active against pathogenic microorganisms, many investigations have focused on the screening of natural compounds with antibiotic properties (24). A great number of antibiotics, termed aminoglycosides, have been discovered from cultures of bacteria and actinomycetes such as *Bacillus, Nocardia, Micromonospora*, and *Streptomyces*. The aminoglycoside antibiotics show broad spectra against both Gram-positive and Gram-negative bacteria. The term "aminoglycoside" refers to their structural aspects. These compounds are a large and diverse class of antibiotics that characteristically contain two or more aminosugars linked by glycosidic bonds to an aminocyclitol component (24,25).

A few FA amide glycosides have been found. Amikacin **1** inhibits the growth of resistant bacteria producing APH(3′)-1

(3′-aminoglycoside phosphotransferase) and AAD(2′) (2′-amino acid decarboxylase). Amikacin **1** was biologically transformed from kanamycin by a mutant of butirosin-producing *Bacillus circulans* (26). Arbekacin **2** showed strong activity against resistant bacteria including *Pseudomonas*. It was launched into the clinical market in Japan in 1990 as a chemotherapeutic agent for the treatment of infections caused by methicillin-resistant *Staphylococcus aureus* (27). 2″-Amino-2″-deoxyarbekacin **3** demonstrated potent activity against *S. aureus* (28). Isepamicin **4** showed activity against resistant bacteria with lower toxicity than gentamicin B and has been useful in the clinical treatment of infection (24).

Fortimicins A **5** and B are bicyclic aminoglycoside antibiotics that contain a fortamine moiety instead of the deoxystreptamine; both are produced by strain *Micromonospora* sp. MK-7 (29,30), and fortimicin A also is produced by *M. olivoasterospora* KY 1151 (31). Fortimicin A showed excellent activity against 352 strains of Enterobacteriaceae (a concentration of 6.2 µg/mL inhibited the greatest number of strains, 92.6%) and other medically significant organisms, and weak activity against *Pseudomonas aeruginosa* strains (32,33). The marine bacterium *Streptomyces tenjimariensis* produced the antibiotics istamycin A **6** and B **7** under select laboratory culture conditions (34). Butirosin A **8** and B **9**, which are aminoglycosidic antibiotics produced by a mutant of *Bacillus circulans,* showed antibacterial activity *in vitro* in mice (35,36).

Simple amides of uronic acids **10–12** were isolated by mild acid degradation of the lipopolysaccharides of the marine bacterium *Shewanella fidelis* type strain KMM 3582T (37). Originally, this bacterial strain was isolated from a sipunculan (*Phascolosoma japonicum*), a common inhabitant of Troitsa Bay in the Gulf of Peter the Great (Sea of Japan, Russia) (38). Mycothiol **13** has been identified from the bacterial pathogen *Mycobacterium tuberculosis* and *M. bovis* (39).

NUCLEOSIDE FATTY AMIDE GLYCOSIDES

Nucleosides are glycosylamines made by attaching a nucleobase to a ribose ring. Examples of these include cytidine, uridine, adenoside, guanosine, thymidine, and inosine. Nucleosides can be acylated and/or phosphorylated by specific kinases in the cell, producing bioactive compounds that are the molecular building blocks of DNA and RNA (40).

Many nucleosides are categorized as antibiotics and have nonspecific antibacterial activities (41–43). Three classes of nucleotide antibiotics are targeted against translocase I. The first class is represented by tunicamycin, which was identified from the fermentation broth of *Streptomyces lysosuperficus nov*. as having antiviral activity (44–46). Series of nucleoside fatty amide glycosides named tunicamycins I–X, **14–23**, respectively, containing uracil, have been isolated from *S. lysosuperficus nov.* (44–46). Tunicamycins showed antibacterial activities against Gram-positive bacteria, especially those of the genus *Bacillus* [minimal inhibitory concentration of antibiotic that inhibits a bacterium (MIC), from 0.1 to 20 µg/mL]. The related compounds of tunicamycins named streptovirudins (series II) **24–28** (47–49), corynetoxins **29–42** (50,51), and streptovirudins (series I, where uracil is replaced by dihydrouracil) **43–47** (52) have been isolated from *Streptomyces griseoflavus* subsp. *thuringiensis* (47–49), and from *Corynebacterium rathayi* (51), respectively. Streptovirudins (series II) **24–28** have potent antibacterial activities against the genus *Bacillus* (MIC, 0.31–10 µg/mL). All corynetoxins **29–42** exhibit toxicity against ryegrass (*Lolium rigidum*) (50). Sheep were very sensitive to corynetoxins (the lethal dose was about 35 µg/kg bodyweight) (53).
FATTY AMIDE OLIGOSACCHARIDES

Among natural surfactants there are some groups of high-molecular-mass bioemulsifiers, including amphipathic polysaccharides, proteins, lipopolysaccharides, lipoproteins, and complex mixtures of these biopolymers, that are more effective at stabilizing oil-in-water emulsions than the low-molecular-mass bioemulsifiers such as glycolipids, trehalose lipids, sophoro-

lipids, and rhamnolipids (2,54,55). Bioemulsifiers have several advantages over chemical surfactants, such as (i) low toxicity, (ii) biodegradability, (iii) high specificity and biocompatibility, (iv) molecular masses ranging from 500 to 1,500 Da, (v) solubility and surface-active properties that are dependent on the orientation of residues, and (vi) occurrence in a wide variety of microorganisms. These advantages should allow these compounds to become important in industrial and environmental applications. The potential commercial applications of bioemulsifiers include bioremediation of oil-polluted soil and water; enhanced oil recovery; replacement of chlorinated solvents used in cleaning up oil-contaminated pipes, vessels, and machinery; use in the detergent industry; formulations of herbicides and pesticides; and formation of stable oil-in-water emulsions for the food and cosmetic industries.

Bacterial lipopolysaccharides are the major components of the outer surface of Gram-negative bacteria (56). They are often of interest in medicine for their immunomodulatory properties. In small amounts they can be beneficial, but in larger amounts they may cause endotoxic shock. Although they share a common architecture (see structures **48**–**53**), their structural details exert a strong influence on their activity. These molecules comprise (i) a lipid moiety, called lipid A, which is considered to be the endotoxic component, (ii) a glycosidic part, consisting of a core of approximately 10 monosaccharides, and (iii) in "smooth-type" lipopolysaccharides, a third region, named O-chain, consisting of repetitive subunits of one to eight monosaccharides responsible for much of the immunospecificity of the bacterial cell.

The most common FA in lipid A have 10–16 carbon atoms although longer chains exist, i.e., C_{18} FA in *Helicobacter pylori* lipid A, and C_{18} and C_{21} in *Chlamydia trachomatis* (57–60). Hydroxylated FA are usually found in direct acylation of the sugar except in a few cases (see below) where they appear in secondary acylation. Some *Bordetella* strains have unhydroxylated FA at the C-3 position (61). In *Chlamydia* lipid A, hydroxylated FA occur only as amide-linked substituents whereas positions C-3 and C-3′ are both substituted by C_{14} FA (62,63). Another kind of FA, which has been described for a few species, is the 3-oxo FA, e.g., the 3-oxotetradecanoic acid found in *Rhodobacter capsulatus* and the 27-oxooctacosanoic and heptacosane-1,27-dioic acids found in *Legionella pneumophila* (64,65). The number of acyl groups present in a molecule has a direct effect on its toxicity: Six acyl groups constitute the optimum for many isolated lipopolysaccharides. FA chain length is also critical for lipid A toxicity since C_{12}, $C_{12}OH$, C_{14}, and $C_{14}OH$ FA are the moieties found in the most toxic lipids A (66). Unsaturated FA are rarely present in lipid A, but examples were found in *Rhodopseudomonas sphaeroides* and other species of this genus as well as in *Rhodobacter capsulatus* (67). Another kind of unusual FA, with a methyl branch at C_{n-1}, is found in some *Legionella* and *Porphyromonas* strains (68). Selected structures of lipid A isolated from bacteria are **48** (*Escherichia coli*), **49** (*Yersinia enterocolitica*, both species belonging to the Enterobacteriaceae; **50** isolated from *Bordetella pertussis*, **51** isolated from *Neisse-*

ria meningitidis, **52** from *Chlamydia trachomatis*, and **53** from *Rhizobium etli* (56).

GUANIDINE GLYCOSIDE DERIVATIVES

A large number of biologically active molecules, including peptides, peptide mimetics, and guanidine-containing natural compounds, possess a guanidine group as an important structural element (69). Guanidine-containing bioactive molecules, particularly the analogs or derivatives of natural products, are notable targets for drug design and discovery (70–73). Because of the strongly basic character of the guanidine group, this group is protonated under physiological conditions. As a result of the positive charge thus imposed on the molecule, specific interactions between ligand and receptor or enzyme and substrate can be formed. With the current evolution in drug discovery whereby combinatorial chemistry plays an increasingly important role, the need for building blocks is rising as well (69).

Erylusamines A–E **54–58** are interleukin (IL)-6 receptor antagonists that were isolated from the Japanese sponge *Erylus placenta* (74,75). The cytotoxic glycolipids erylusamine TA **59**, erylusine **60**, and erylusidine **61,** similar to erylusamines, have been isolated from Red Sea sponge *Erylus cf. lendenfeldi* (76). Pachymoside A **62** has been isolated from crude extract of the North Sea marine sponge *Pachymatisma johnstonia* (77).

62 Pachymoside A
Streptothricins are a group of related basic antibiotics produced by a soil actinomycete (*Streptomyces* species) (78), and they show antibacterial, antimicrobial, antiviral, antiphage, and antifungal activities (79–81). Streptothricins F **63**, E **64**, D **65**, and C **66** have been isolated from *Streptomyces noursei* (78). A new member of the streptothricin family of antibiotics, *N*-methyl-streptothricin D **67**, has been isolated from an unidentified *Streptomyces* strain (82). This compound has a broad range of antimicrobial activity against fungi, Gram-positive and Gram-negative bacteria. Three streptothricin derivatives A-53930A **68**, A-53930B **69**, and A-53930C **70** (which was identical to streptothricin B) have been isolated from *Streptomyces vinausdrappus* SANK-62394 (83). These compounds showed inhibitory activity against N-type Ca^{2+} channels. Although A-53930C had antimicrobial activity against Gram-negative and Gram-positive bacteria and fungi, A-53930A and B showed weak activity only against Gram-negative bacteria. Streptothricins also are potent inhibitors of prokaryotic protein biosynthesis, but they are not used therapeutically because of their nephrotoxicity (84).
The nourseothricins **71**–**77** belong to the family of the streptothricin antibiotics that are produced by various streptomycete strains such as *Streptomyces noursei* (85). These compounds are nucleoside peptides containing a carbamido-D-gulosamine core, to which a poly-β-lysine chain and the unusual amino acid streptolydine are attached in amide and N-glycosidic linkages, respectively. The various members of the group differ in the length of their poly-β-lysine chains. Nourseothricin is currently being used under the name cloNAT (Werner Bioagents, Germany), and is an effective selective agent for molecular cloning technologies in fungi and plants (86–89).

TETRAMIC ACID GLYCOSIDE DERIVATIVES

A culture of a marine strain of the fungus *Epicoccum purpurascens*, isolated from the inner tissue of the jellyfish *Aurelia aurita*, produced a novel tetramic acid derivative, epicoccamide **78** (90). Ancorinosides A **79**, B **80**, C **81**, and D **82**, inhibitors of membrane type 1 matrix metalloproteinase (MT1-MMP), were identified from the marine sponge *Penares sollasi* (91). Ancorinosides B–D inhibited MT1-MMP with IC$_{50}$ values of 180–500 µg/mL.
Aurantosides A **83** and B **84**, cytotoxic tetramic acid amine glycosides, have been isolated from the marine sponge *Theonella* sp. (92). The structures of these chlorinated metabolites were elucidated by chemical and physical methods. Aurantoside C **85,** which is lethal to brine shrimp, was found in the sponge *Homophymia conferta* (93). Other aurantosides D **86**, E **87** and F **88,** which exhibit potent antifungal activity against *Aspergillus fumigatus* and *Candida albicans,* were isolated from the marine sponge *Siliquariaspongia japonica* (94).
Rubroside A **89**, B **90**, C **93**, D **91**, G **92**, E **94**, F **95**, H **96**, and also hexadecahydrorubroside D **97**, aurantoside A **98**, and aurantoside B **99** have also been found in *Siliquariaspongia japonica* (95). The rubrosides induced numerous large intracellular vacuoles in 3Y1 rat fibroblasts at concentrations of 0.5–1.0 µg/mL, and rubrosides A, C, D, and E were cytotoxic against P388 murine leukemia cells with IC$_{50}$ (concentration at which growth or activity is inhibited by 50%) values of 0.046–0.21 µg/mL. Most rubrosides show antifungal activity against *Aspergillus fumigatus* and *Candida albicans.*
Aurantosides G–I **100**–**102** have been isolated from the lithistid sponge *Theonella swinhoei* from Papua New Guinea (96). Compounds **100**–**102** represent new monochloropentaenoyl tetramic acids with mono-, di-, and tri-N-saccharide substituents, respectively. Aurantosides G–I failed to show any significant cytotoxicity against the human colon tumor cell line HCT-116.
CEREBROSIDES

Cerebrosides are a group of glycosphingolipids composed of a hexose, a long-chain aminoalcohol (sphingoid), and an amide-linked long-chain FA. Galactocerebrosides were first isolated from brain tissue in the late 1800s (97). The "sphingosin" backbone of sphingolipids was so named by J.L.W. Thudichum in 1884 for its enigmatic ("Sphinx-like") properties. These mammalian cerebrosides include a mix of saturated and monoenoic *n*-alkyl and 2-hydroxy-FA, with sphingosine (4-*trans*-sphingenine, a 1,3-dihydroxy-2-aminoalcohol) as the major sphingoid (97). Over 30 years ago, glucocerebrosides were identified as a minor (<1%) lipid class in plant tissues (98). Perhaps because they constitute such a small portion of the total tissue lipids, plant glucocerebrosides received little attention prior to the recent finding (following development of the two-phase membrane partitioning method) that they can represent a major fraction of the total lipids in both the plasma membrane and tonoplast (99–102). Several reports have also implicated glucocerebrosides as playing a role in chilling injury (101) and in acclimation to cold and water-deficit stress in different plant species (99,103).

Many FA amides as well as their glycosides that have been isolated from marine microorganisms and invertebrates show high biological activity (104–106). Placosides A **103** and B **104** have been isolated from Bahamian sponge *Plakortis simplex* (107). These compounds exhibit immunosuppressive properties. Glycosyl ceramides **105**–**110** have been isolated from marine sponges *Agelas dispar* (108), *A. clathrodes* (109), *A. conifera* (110), and *A. longissima* (111,112). All the isolated compounds were tested using the mixed leucocyte reaction assay, and only **106**, **107**, and **110** were shown to be immunoactivating agents, suggesting a possible structure–activity relationship. It was also reported that glycosyl ceramides isolated from sponges belonging to the genus *Agelas* show antitumor activity (108,109).
Another sponge species, *Agelas mauritianus*, from Okinawa Island contained a series of glycosphingolipids termed agelasphins: AGL-10 **111** and AGL-12 **112** (two major components), AGL-7A **113**, AGL-7B (mixture), AGL-9A **114**, AGL-9B **115**, AGL-11 **116**, and AGL-13 **117** (113). Three glycosphingolipids, regulosides A-C **118**–**120,** were obtained from extracts of the starfish *Pentaceraster regulus* (114), and two related compounds, temnosides A **121** and B **122**, were isolated from the sea urchin *Temnopleurus toreumaticus*; both specimens were collected from the Mandapam coast of India (115).

Six cerebrosides, acanthacerebrosides D–F **123**–**125** and A–C **126**–**128,** have been isolated from the starfish *Acanthaster planci* (116,117), along with two ceramide lactosides, acanthalactosides A **131** and B **132** (118). Ophidiacerebrosides A–F **133**–**137**, the cytotoxic cerebrosides, have been isolated from the Mediterranean starfish *Ophidiaster ophidiamus* (119). Cerebrosides CE-2b **138**, CE-2c **139,** and CE-2d **140** were found in the sea cucumber *Cucumaria echinata* (120); and cerebrosides PA-0–1 **129**, PA-0–5 **130**, PA-2–5 **141,** and PA-2–6 **142** were isolated from *Pentacta austalis* (121).

GANGLIOSIDES

Gangliosides are a family of glycosphingolipids containing one or more *N*-acetyl-neuraminic acid (sialic acid) residues in their structure. They are found in the plasma membrane of eukaryotic cells and confer a net negative charge on most animal cells. Localized mainly on the outer surface of cells, they are involved in various cellular functions including growth, differentiation, cell-to-cell interactions, and signal transduction (130). Gangliosides are also antigenic and participate in the pathogenesis of certain autoimmune diseases (131,132). The expression of gangliosides is tissue- and cell-specific and also development- and stage-specific. The species of animals is another determinant for ganglioside expression. Thus, it is suggested that gangliosides may carry a specific function(s) in a certain cell type of individual animal species (133).

The biological significance of the phylogenetic patterns of lenticular gangliosides is not known. Regarding brain gangliosides, it has been claimed that their remarkable changes in composition and concentration may be required for the development of brain structure and function and environmental adaptation during evolution (134–136). Lenticular gangliosides may perform specific function(s) in the formation and function of eye lenses (137).

According to the National Library of Medicine (Bethesda, MD), more than 11,000 original and review articles have been published on gangliosides since 1950. The structures of more than 500 gangliosides isolated from animals, invertebrates, and microorganisms have been elucidated, and many novel biologically active gangliosides were synthesized. This review article will cover the structures of only some novel gangliosides that were isolated from natural sources.

Two new ganglioside molecular species, named acanthaganglioside I **158** and acanthaganglioside J **159,** have been isolated from the whole body of the crown-of-thorns starfish *Acanthaster planci* (138). The *N*-acyl groups on residue are C22:0 and C24:0 FA, whereas the fatty alcohol is straight (C16:0) in both gangliosides. Two monomethylated GM3-type ganglioside molecular species, **160** and **161**, have been obtained from the polar lipid fraction of the chloroform/methanol extract of the starfish *Luidia maculata* (139). The ceramide moieties were composed of heterogeneous unsubstituted FA, 2-hydroxy FA, sphingosine, and phytosphingosine units. Compound **160**, designated as LMG-3, represented a new ganglioside molecular species, and compound **161** was a known ganglioside species.
Three ganglioside molecular species, SCG-1 **162**, SCG-2 **163**, and SCG-3 **164**, were obtained from the lipid fraction of the sea cucumber *Stichopus chloronotus* (140). The ceramide moieties were composed of heterogeneous long-chain base and FA units. SCG-3 is the first type of ganglioside shown to contain a fucopyranose in the sialosyl trisaccharide moiety. Moreover, these three gangliosides exhibited neuritogenic activity toward the rat pheochromocytoma PC12 cells in the presence of nerve growth factor. The proportions of the neurite-bearing cells of SCG-1, SCG-2, and SCG-3 at a concentration of 3.3 mg/mL were 34.1, 24.4, and 24.5%, respectively. These effects were compared with that of the mammalian ganglioside GM1 (22.1% at a concentration of 3.3 mg/mL). Gangliosides with the same sugar moiety as that of SCG-1 have been identified from some marine invertebrates: *Cucumaria japonica* (141), *Holothuria atra*, *Telenota ananas* (142), *Stichopus japonicus* (143), *Holothuria leucospilota* (144), *Ophiura sarsi* (145), *Ophiocoma echinata*, *Ophiomastix annulosa* (146), *Ophiocoma scolopendrina* (147), and *Anthocidaris crassispina* (148). SCG-1 differs from them in the structure of the ceramide moiety. Gangliosides with the same sugar moiety as that of the major component of SCG-2 also have been obtained from *O. sarsi* (145), *O. scolopendrina* (147), and *Hemicentrotus pulcherrimus* (149), although the major component of SCG-2 is different from them in the ceramide structure.

On the other hand, to the best of our knowledge, SCG-3 is a new ganglioside with a unique sialosyl trisaccharide moiety, **164**. The major species of gangliosides **165–167** were isolated from the Japanese sea cucumber *Stichopus chloronotus* (140). All three species displayed neuritogenic activity against PC12 cells in the presence of nerve growth factor. Structurally more complex ganglioside molecular species SJG-2 **168–170**, isolated from a Japanese collection of *S. japonicus*, also exhibited neuritogenic activity.

MACROLACTONE FATTY AMIDE GLYCOSIDES

Vicenistatin **171** is an antitumor antibiotic produced by *Streptomyces halstedii* HC-34. Its structure is unique in that it comprises a 20-membered lactam aglycon having an aminosugar vicenisamine. Its biological activity is also intriguing since antitumor activity has been particularly shown against xenographed models of certain human colon cancers. **171** and **172** have been isolated as minor congeners of vicenistatin **171** in the culture filtrate of the producing microorganism, and named as vicenistatin M **172**, because the minor congener is substituted by D-mycarose in place of vicenisamine of **171** (150,151). A novel ansamitocin amide N-glycoside, *N*-demethyl-*N*-β-D-glucopyranosyl ansamitocin P-2, named ansamitocinoside P-2 **173**, was isolated from *Actinosynnema pretiosum* (152).

172 R = OH

173
Fluvirucins A1 **174**, A2 **175**, B1 **176**, B2 **177**, and B3 **178** are macrolactam antibiotics produced by the actinomycete *Microtetraspora tyrrhenii* sp. nov. (*Actinomadura pusilla* group) strains Q464-31, L407-5, R-359-5, and R516-16 (153,154). All isolated compounds are active against the influenza A virus; B1 **176** is also active against *Candida* sp. (MIC, 0.91 µg/mL), and dermatophytes (MIC > 80.6 µg/mL) (154). Fluvirucin B2 **177** from the culture broth of *Streptomyces* inhibited PI-specific phospholipase C in cultured A431 cell cytosol with an IC$_{50}$ of 1.6 µg/mL (155).

178
Semisynthetically produced 3-keto-substituted macrolide antibiotics (ketolides) **179** and **180** were compared for concentration-dependent inhibitory effects on growth rate, viable cell numbers, and protein synthesis rates in *Staphylococcus aureus* cells. Inhibitory effects on 50S ribosomal subunit formation were also examined, as this is a second target for these antibiotics. A concentration range of 0.01–0.1 µg/mL was tested. Compound **179** was the most effective from tested compounds with an IC$_{50}$ = 0.035 mg/mL. Telithromycin **180** had an IC$_{50}$ of 0.08 mg/mL (156). The authors concluded that these results indicate specific structural features of these antimicrobial agents contribute to defined inhibitory activities against susceptible organisms.

179

180
MISCELLANEOUS COMPOUNDS

A series of biologically active chlorinated metabolites that are derivatives of 7-methoxytetradec-4-enoic acid are produced by marine cyanobacteria belonging to the genus *Lyngbia* and by some marine invertebrates. The malyngamides, which are present in extracts of *L. majuscula*, consist typically of a FA side chain and a polar head group containing the unusual vinyl chloride functionality. The first malyngamide was isolated by Moore and co-workers in 1979 from Hawaiian *L. majuscula* (157). The (non-chlorine-containing) FA amide glycoside malyngamide J **181** isolated from Curaçao collections of *Lyngbia majuscula* (158) was toxic to both brine shrimp (LC$_{50}$ 18 µg/mL) and fish (goldfish LC$_{50}$ 40 µg/mL) (158). Malyngamide A **182** was found in a methanolic extract of *L. majuscula* (157) and isolated from the sea hare *Stylocheilus longicauda* (159). The sea hares (Opisthobranchia, Anaspidea) generally consume seaweeds that are chemically rich in secondary metabolites and concentrate these secondary metabolites in their digestive glands. The lipid extract of a Madagascan *L. majuscula* yielded malyngamides Q **183** and R **184** (160). Malyngamide R **184** was modestly toxic to brine shrimp (LD$_{50}$ 18 µg/mL). Isomalyngamides A (isomer **182**) and B **185** and the isomer of the latter, **186,** were isolated from *L. majuscula* collected from Hawaiian waters (161).

196
Simocyclinones are novel natural hybrid antibiotics isolated from the fermentation broth of *Streptomyces antibioticus* Tü 6040 that combine structural elements from various groups of known antibiotics such as aquayamycin, fumagillin, and novobiocin (163,164). So far, 14 different angucyclinone antibiotics have been isolated and classified in four series, A–D. The simocyclinones of the A-series consist solely of an angucycline ring. The components of series B are glycosylated. Compounds of the C-series have a tetraene side-chain, and those of the D-series **190–193** also have a coumarin ring system. A novel family of angucyclinone antibiotics demonstrated antibiotic activity against Gram-positive bacteria, as well as cytostatic effects against human tumor cell lines and antibacterial and antitumor activities (163–167). The 3-amino-4,7-dihydroxy-coumarin moiety is also found in the antibiotics novobiocin **194**, clorobiocin **195**, and coumermycin A1 **196**, which are very potent inhibitors of DNA gyrase (168). The aminocoumarin ring is of central importance for the binding of these compounds to the B subunit of gyrase (169–171). Recent experiments have suggested that simocyclinone D8 **193** is even more potent as a DNA gyrase inhibitor than novobiocin (171). The aminocoumarin antibiotics novobiocin **194**, clorobiocin **195,** and coumermycin A1 **196** are produced by different *Streptomyces* strains.

Ten different derivatives of glycine-containing glycolipids **197–206** have been isolated from a Gram-negative, biosurfactant-producing, *n*-alkane-degrading marine bacterium *Alcanivorax borkumensis* (172). This Gram-negative, aerobic, rod-shaped bacterium uses a limited number of organic compounds, including aliphatic hydrocarbons, volatile FA, and pyruvate and its methyl ether. During cultivation on *n*-alkanes as sole source of carbon and energy, all strains produced both extracellular and cell-bound surface-active glucose lipids **197–206** (173). This novel class of glucolipids was produced only by these strains, which were isolated from sediment samples collected near the Isle of Borkum (North Sea). The mixed active biosurfactants produced are characterized as glucose lipids, one of which consists of four 3-hydroxydecanoic acids linked together by ester bonds and coupled glycosidically with the C-1 of glucose. Other FA were found, namely, 16:0, 16:1, and 18:1, in the phospholipid fraction (173).

The bengamides **207–225,** isolated from marine sponges belonging to the genus *Jaspidae*, comprise a large family of natural metabolites. In 1986, a group from the University of California–Santa Cruz reported the first examples of this class, (+) bengamide A **207** and (+) B **208**, as an easily separable mixture from a small sponge collection, subsequently identified as *Jaspis* cf. *coriacea* (Family Coppatiidae, Order Choristida) (174). These compounds display a wide and interesting range of biological activities, including antitumor, antibiotic, and antihelmintic properties. Bengamides A **207** and B **208** were more potent than bengamide P, with average IC_{50} values of 0.046, 0.011, and 2.70 fM, respectively (175). The *in vitro* antitumor activity against MDA-MB-435 human mammary carcinoma was also determined for natural bengamides A, B, E, F, P, M, O, and Z and for synthetic samples of B and O. The best activity was observed for the natural bengamides A (IC_{50} = 1 nM) and O (IC_{50} = 0.3 nM) (175).

Several unusual α-glucosidase inhibitors **232–237** containing sulfated FA have been isolated from some marine sponge species. Penasulfate A **232**, a new α-glucosidase inhibitor, was isolated from a marine sponge *Penares* sp. (178); this compound included a novel sulfated FA (2-piperidine-carboxylic acid). Three similar α-glucosidase inhibitors named schulzeines A **233**, B **234**, and C **235** were isolated from the marine sponge *P. schulzei* (179). Schulzeines A–C showed inhibitory activity against α-glucosidase, with IC_{50} values of 48–170 nM. Unique 30- and 31-membered macrolides encompassing a proline residue and three sulfate groups, named penarolide sulfates A1 **236** and A2 **237**, have been isolated from a marine sponge *Penares* sp. (180). These metabolites inhibited α-glucosidase, with IC_{50} values of 1.2 and 1.5 mg/mL.

UNUSUAL AMIDE GLYCOSIDES

Amide surfactants are widely used as functional chemicals and are indispensable for various industrial fields (181–183). Synthetic detergents have molecular structures and properties that are similar to soap. Detergent molecular structures consist of a long hydrocarbon chain and a water-soluble ionic group. Most detergents have a negative ionic group and are called anionic detergents. Surfactants have a major impact on the performance of modern-day cleaning systems. In addition to performance, however, there is a growing appreciation for surfactants that are also environmentally friendly and produced from renewable resources. Sugar-based surfactants fit these requirements, and glucosamides (183–186) are one form that is experiencing rapid growth rates. In recent years, much attention has been paid from the ecologial and industrial viewpoints to sugar-based surfactants such as alkyl glucoside (187–189). Some interesting surfactants based on amide bond(s) that have biological activities have been synthesized (183).

Some diseases are initiated by the adherence of viruses, bacteria, or bacterial toxins to cell surface carbohydrates, a number of which are components of glycosphingolipids. Studies of the binding of lectins indicated that many adhered weakly to monomeric carbohydrate ligands (183,184). In addition to more completely defining ligand specificity of the carbohy-

drate-binding pathogen, identification of multivalent carbohydrate ligands has led to studies of their efficacy as pathogen inhibitors. This commentary focuses on pathogens that recognize the carbohydrate portion of glycosphingolipids. Because many glycosphingolipid-binding pathogens have been shown to bind multivalent saccharides, approaches for identifying and preparing them as well as methods for characterizing their effectiveness as ligands were reviewed (183,184). Several multivalent saccharide ligands were reported in the past 10 years.

Synthesis of amide glycoside derivatives of multivalent ligands that cross-link concanavalin A dimers of saccharides **238** and **239** and a biophysical evaluation of their interaction with the plant lectin concanavalin A have been reported (190). To the best of our knowledge, these structures are the first reported of their kind. Results obtained by Dimick *et al.* (190) indicate that hemagglutination assays evaluate the ability of ligands to inhibit the formation of cross-linked lattices, a process only tangentially related to reversible ligand binding. Cluster glycoside effects observed in agglutination assays must therefore be viewed with caution. Such effects may be relevant to the design of therapeutically useful amide saccharides.

238

239
Several convergent glycodendrimer syntheses based on aromatic cores have been reported (183). Stoddart and co-workers reported convergent synthesis of polyvalent dendritic compound **240** (191). Thus, carbohydrate-centered ligands are terminated with a total of 12 glucose residues, although the microscopic environment of each is somewhat different. A related group of ligands, again derived from a convergent synthetic route and centered on an aromatic core, present terminal glucose residues in nominally equivalent microenvironments. Burke and co-workers synthesized three mannosyl residues around a macrocyclic core **241** to produce a rigid trivalent ligand (192).
A group of so-called two-component toxins are responsible for the pathology of the world's most severe enterotoxic diseases; these toxins include the *Escherichia coli* heat-labile toxin, the shiga toxin, and the cholera toxin. The toxins are structurally and mechanistically related to the tetanus, diphtheria, and pertussis toxins and to the plant toxins abrin and ricin. Fan and co-workers (193) synthesized a pentavalent galactoside ligand for the *E. coli* heat-labile toxin based on a macrocyclic core **242–245**. Multivalent cyclo-oligosaccharides **246–250**, versatile carbohydrate clusters with dual roles as molecular receptors and lectin ligands, have recently been synthesized (194).

SUMMARY

FA amides are commonly used as foaming and wetting agents in hand dish-washing detergents, shampoos, and bar soaps, particu-larly the diethanollauryl amide. Amphoteric or zwitterionic surfactants have two functional group, one anionic and one cationic. In most cases it is the pH that determines which of the groups will dominate, by favoring one or the other ionization: anionic at alkaline pH and cationic at acid pH. Near the isoelectric point, these surfactants display both charges and are truly amphoteric, often with a minimum of interfacial activity and a concomitant maximum of water solubility. Amphoteric surfactants, particularly the amino acid ones, are quite biocompatible and are used in pharmaceuticals and cosmetics. Besides their excellent surfactant properties, i.e., wetting power, cleaning performance, foaming power, hard water tolerance, and lime soap dispersibility, particular emphasis is placed on the mildness of amphoteric surfactants and on their low toxicity toward the skin and eyes and, in particular, on the improvement in dermatological and mucous membrane compatibility in mixtures with anionic surfactants in shampoos. In addition, their zwitterionic character makes them compatible with both anionic and cationic surfactants. Amphoteric surfactants are a minor, but important ingredient of cosmetic products. Beside their activity as a surfactant, they contribute in combination with anionics toward the particular mildness and low toxicity of the products.

ABSTRACT: The formation of *trans* FA residues in membrane phospholipids may be due to a free radical-catalyzed isomerization process occurring to the *cis* unsaturated FA moieties. Radical stress is well documented in inflammatory processes of atopic diseases, but no data are yet available about a possible association with *trans* FA detected in these patients. We investigated the presence of *trans* lipid isomers in the erythrocyte and T-lymphocyte membranes of 26 children affected by atopic eczema/dermatitis syndrome (AEDS). *Trans* lipid isomers were found in both cell membranes, up to a total content of 2.7 and 4.9% of the FA composition, respectively. By using the geometrical *trans* lipid library derived from *in vitro* models of thiyl radical-catalyzed isomerization, oleic and arachidonic acid isomers were detected. The statistical significance was evaluated by comparison with an age-matched control group. These results suggest the role of an endogenous free radical isomerization path occurring to membrane unsaturated lipids, complementary to the dietary contribution, which can be involved in the lipid impairment in AEDS. This study contributes to lipidomic research regarding the double bond structure and the influence of a geometrical change of membrane lipids in physiology and diseases.

Paper no. L9738 in *Lipids* 40, 661–667 (July 2005).

Several studies reviewed by Horrobin (1) have demonstrated abnormalities of EFA metabolism and altered PUFA profiles in atopic patients. This alteration can influence the physiological roles played by PUFA, as, for example, the T-cell receptor (TCR) signaling with suppression of the immune response (2). Moreover, the levels of PUFA and in particular of arachidonic acid can be correlated to functions other than structure, since they are precursors for a number of key mediators of inflammation, including prostaglandins, leukotrienes, and thromboxanes. These mediators alter T-helper (Th) lymphocyte activity by suppressing Th1-type (Th1) cytokine production and favoring a Th2-type (Th2) response characteristic of atopic disease.

Reports by us and other authors suggested using PUFA serum level as a potential marker for the risk of developing atopic disease, and considering the deficiency of a key enzyme, such as Δ^6-desaturase, as a favorable condition for developing allergy (3–5). However, in lipid analyses related to atopic diseases, attention was given only to FA with double bonds in the natural *cis* configuration.

As far as the geometry of the FA double bonds is concerned, several studies show the role of *trans* isomers in the perturbation of membrane properties (6,7), as well as in the functioning of embedded proteins and ion channels (8,9). Since humans do not synthesize *trans* FA (TFA), nutritional studies have focused on *trans* isomers contained in meat or milk and on partially hydrogenated fats (10). Dietary TFA are incorporated into both adult and, *via* placental transfer, fetal tissues (11–14). Although still debated, epidemiological studies have suggested the involvement of TFA intake in human diseases such as cardiovascular diseases (15) and allergy in children (16,17).

Studies on the *cis-trans* isomerization of unsaturated lipids catalyzed by free radicals that support the hypothesis of a different origin of TFA detected in tissues are now available (18). In fact, TFA can arise from the isomerization of natural *cis* lipids, a process studied under different conditions of radical stress (19–22), and recently also described during the normal incubation of human leukemia cell lines (THP-1) under physiological conditions (23). Interestingly, biomimetic models as well as *in vitro* studies showed that in the membranes the FA residue most affected by radical attack is arachidonic acid (18,20,22). It is worth recalling that the *trans* compounds formed by free radical processes are exclusively the geometrical isomers, that is, with the double bond in the same position of the naturally occurring *cis* FA but with the opposite configuration. This fact highlights the need for a more careful monitoring of lipid isomers during the analysis of biological samples, to distinguish between the isomers produced by a radical stress and the dietary *trans* isomers, which are mostly positional isomers with the *trans* double bond shifted to adjacent positions.

Atopic/eczema dermatitis syndrome (AEDS) is a disease in which radical stress and inflammatory conditions are realized (24). We hypothesized that the formation of *trans* phospholipids in cell membranes might occur by radical-based isomerizing species derived from chronic inflammation in AEDS, and

Abbreviations: AEDS, atopic eczema/dermatitis syndrome; CD, cluster of differentiation; DGLA, dihomo-g-linolenic acid; MUFA, monounsaturated FA; PBMC, peripheral blood mononuclear cell; RAST, RadioAllergoSorbentTest; SCORAD, skin clinical score; SFA, saturated FA; TCR, T-cell receptor; TFA, trans FA; Th, T-helper; THP-1, a human leukemia cell line.

the effects could parallel those of dietary *trans* lipids. Indeed, the effect of TFA on lipid enzymatic pathways is well assessed (25–27).

Based on these premises, we approached the study of subjects affected by atopic diseases such as AEDS by investigating the alteration of membrane FA profiles due to the presence of TFA. To address specifically the presence of geometrical *trans* isomers in biological samples, TFA characterization was performed by comparison with a *trans* lipid library prepared by a radical-based protocol carried out on naturally occurring compounds (19–21,28). Examining all main FA residues, we could also address the interference of TFA with lipid enzymatic pathways.

Herein we report the results obtained for a group of children affected by AEDS. Red blood cell and T-lymphocyte membrane lipids were examined and, for the first time in the case of T-lymphocytes, TFA were detected. TFA levels were also correlated to other FA levels and to clinical data, such as the presence of IgE.

This study aims at contributing to lipidomic research regarding the double bond structure and the influence of FA geometrical change on cell membranes in physiological conditions and diseases.

MATERIALS AND METHODS

Subjects. Twenty-six Caucasian children, 18 females and 8 males, aged 6 mon–12 yr (mean age 5 yr), who were affected by AEDS were recruited in the Pediatric Department of the Policlinico Tor Vergata, Rome. The duration of the disease ranged from 3 mon to 7 yr. The skin clinical score (SCORAD) combines subjective and objective criteria, giving a global quantitative score that represents the intensity of the disease at a given time, and it was assessed according to the European task force on atopic dermatitis (29). The patients had SCORAD values ranging from 0 to 35. In 13 out of 26 AEDS patients, atopic dermatitis was not IgE-mediated [prick tests/RadioAllergoSorbent Test (RAST) negative]; 8 out of 13 IgE-mediated AEDS patients had prick tests/RAST positive for inhalants, and 8 out of 13 had positive prick tests and RAST for cow milk and were on a diet without milk proteins. None of the patients had a history of cardiovascular disease or a family history for hyperlipidemia and diabetes, and all of them had normal laboratory tests for liver and renal function. They were receiving antihistaminic treatment at the time of the investigation. A group of 10 age-matched normal subjects was included in the study as controls. Informed parental consent was obtained.

Cell isolation. Blood samples were taken by sterile venipuncture of the antecubital vein. Blood samples were collected with the addition of 1 mM EDTA and kept refrigerated at 4°C until processed for the separation. One aliquot was processed for the separation of erythrocytes and isolation of erythrocyte membranes (30). Another aliquot was used for separation of peripheral blood mononuclear cells (PBMC) and erythrocytes from whole blood by gradient centrifugation over Ficoll-Hypaque (Pharmacia Biotech, Uppsala, Sweden).

Monocytes and B-lymphocytes were isolated from PBMC by positive selection, using anti-CD14 and anti-CD19-conjugated magnetic Microbeads, respectively (MACS magnetic cell sorting system; Miltenyi Biotec, Belgish Gladbach, Germany), according to the manufacturer's instructions. T-lymphocytes were obtained by negative selection as a result of the above separation. Analysis of cell surface phenotype was performed by flow cytometry and routinely resulted in 95% purity of the three populations. Briefly, cells were stained for 20 min on ice, with monoclonal antibodies conjugated to fluorescein isothiocyanate or PE, specific for CD14, CD19, CD3, CD56, as well as with isotype controls (all from Pharmingen, San Diego, CA). A minimum of 1×10^4 events for each sample was acquired on a FACSCalibur (Becton Dickinson, San Jose, CA) using Cellquest software (Becton Dickinson).

Phospholipid extraction and analysis. Phospholipid extraction from cell membranes was performed according to Bligh and Dyer (31). The total phospholipid fraction was treated with 0.5 M KOH/MeOH (32) for 10 min at room temperature, and the corresponding FAME were formed and extracted with *n*-hexane. Geometrical TFA were recognized by comparison with a *trans* lipid library obtained by thiyl radical-catalyzed reaction of naturally occurring lipids, as already described (19,23,28). The GC protocol consisted of two injections of the same sample under previously described conditions (23): the first analysis gives the separation of C_{16} and C_{18} saturated FA (SFA) and unsaturated FA, and the second analysis gives separation of arachidonic acid and other eicosenoic FA. Representative GC runs performed under the two conditions are reported in Figures
FIG. 1. Partial GC runs representing C_{16} and C_{18} FA residues of membrane phospholipids isolated from (A) erythrocyte of normal donor, (B) erythrocyte of normal donor treated under radical stress conditions, i.e., γ-irradiation in the presence of 2.8 μM mercaptoethanol (Ref. 20). (C) T-lymphocyte of atopic eczema/dermatitis syndrome (AEDS) children, and (D) erythrocyte of AEDS children. Peak labels: (1) methyl palmitate (16:0); (2) methyl palmitoleate (9*c*-16:1); (3) methyl stearate (18:0); (4) methyl elaidate (9*t*-18:1); (5) methyl *trans*-vaccenate (11*t*-18:1), (6) methyl oleate (9*c*-18:1), (7) methyl vaccenate (11*c*-18:1). Chromatograms are normalized to the methyl palmitate peak (100%).
FIG. 2. Partial GC runs representing (A) C_{20} FA residues of erythrocyte membrane phospholipids isolated from normal donor, (B) C_{20} FA residues of erythrocyte membrane phospholipids isolated from AEDS children; (C) methyl arachidonate model isomerization, containing a mixture of *cis* and mono- and di-*trans* isomers (Ref. 20); (D) profile resulting from the subtraction of run A from the run obtained after treatment under radical stress conditions, i.e., γ-irradiation of the blood in the presence of 2.8 μM mercaptoethanol. The preferential formation of two isomers in the erythrocyte membrane is visible (Refs. 20,23). Peak labels: (1) methyl arachidonate (5*c*,8*c*,11*c*,14*c*-20:4); (2) methyl eicosatrienoate (8*c*,11*c*,14*c*-20:3); (3) methyl eicosenoate (11*c*-20:1). Chromatograms are normalized to methyl arachidonate (100%). For abbreviation see Figure 1.

1 and 2. In the separation of the arachidonate isomers of Figure 2, we could not completely resolve the peaks, and the 20:3 FA eluted together with other isomers (peak 2 in Fig. 2). In normal subjects (profile A) the most abundant C_{20} FA is arachidonic acid (peak 1), with 20:3 (peak 2) and 20:1 (peak 3) being the minor residues recognized by GC/MS analyses (*m/z* = 320 and 324, respectively). The isomer identity also was investigated by GC/MS analyses and, when the mass fragmentation was compatible with the structure of 20:4 isomers, the sum of the peak areas matching the isomer references was reported as *trans*-20:4 in Table 1. A more detailed description of the isomer analyses has been previously given (23).

Statistical analysis. FA levels are expressed as mean ± SD of the percentage of the total FA peak areas, as detected in the GC chromatograms. The results are listed in Table 1. Differences between the AEDS patients and controls were assessed by Kolmogorov–Smirnov test, and the statistical significance level *P* is given in the text for the relevant cases. A value of *P* < 0.05 was considered statistically significant for all analyses. All statistical analyses were performed using SPSS software (version 10 for PC; Chicago, IL).

RESULTS

GC analysis. In this study, erythrocyte and T-lymphocyte membrane phospholipids isolated from AEDS patients were analyzed by a protocol consisting of two parallel GC injections of

the same sample. Representative GC runs are shown in Figures 1 and 2, referred to the subjects and the reference isomeric mixtures obtained from the isomerization of naturally occurring lipids by thiyl radicals, as already described (19,23,28).

In particular, in Figure 1 the reference mixture of *cis/trans* isomers was obtained from erythrocyte membranes treated under radical stress condition (profile B), i.e., γ-irradiation in the presence of a certain amount of thiol (20). In this condition, geometrical C_{18} monounsaturated FA (MUFA) isomers can be formed, and they elute in a region of the GC chromatogram immediately before the corresponding *cis* isomers, which is indicated between two dashed lines in Figure 1 (peaks 4 and 5) (23). Profile A shows an example of erythrocyte membrane lipids from controls having <0.1% of *trans*- octadecenoic acid isomers. Profiles C and D show examples of T-lymphocyte and erythrocyte membranes from AEDS patients containing *trans* isomers as 0.7 and 0.3% of the total FA content, respectively.

In Figure 2, the regions of GC runs relative to eicosenoic FA residues of different samples are shown. In the atopic patients, arachidonic acid was still the most abundant residue, but the run was complicated by the presence of other components. The similarity of the altered FA in atopic patients, with the transformation of arachidonic acid under *in vitro* radical stress conditions, can be appreciated by comparison of profile B with profiles C and D (20,23). The analytical procedure and isomer analysis have been described in detail recently (23). It was gratifying to see that the components detected in atopic patients match the *trans* isomers of the references. In our cohort, different percentages of *trans* components were detected, and the alterations were reproduced similarly in erythrocyte and T-lymphocyte membranes of the same patient.

FA composition. Studies of FA composition have been reported in several cases of atopic dermatitis, one of the commonest chronic inflammatory diseases in childhood (33–35). In particular, disorders of EFA metabolism have been evidenced, with a possible inhibition of the enzymatic activity of desaturases (3,5,33–35). Although changes of less than 1% of the total FA were reported, they were considered to influence the normal prostaglandin production significantly (36).

In our study, we evaluated FA residues of erythrocyte and T-lymphocyte membrane phospholipids up to a total of 12 components, including geometric *cis* and *trans* isomers, identified as previously discussed in the GC analysis section. The values are reported in Table 1 and are expressed as percentages of the peak areas relative to the sum of the main FA residues detected by GC. Control values were obtained from a group of 10 children, age-matched with AEDS patients, and these were in agreement with data reported for normal subjects in the recent literature (37–40). It is known that lipid composition of erythrocytes and lymphocytes in the elderly can vary (41) whereas it does not change consistently in young subjects (42).

Examination of the naturally occurring FA led to the following results: (i) 16:0 values were significantly higher in AEDS patients compared with controls (*P* < 0.001), and this increase occurred both in erythrocyte and T-lymphocyte membranes. (ii) 18:0 levels were similar between patients and controls. (iii) The increase of 16:1 in both erythrocyte and T-lymphocyte

[a]FAME are obtained from total lipid extraction, derivatization, and GC analysis.
[b]These values are mean ± SD and are expressed as percentage of the peak areas as detected in the GC chromatogram.
[c]Values higher than normal in erythrocyte ($P < 0.001$) and lymphocyte ($P < 0.001$) membranes.
[d]Values higher than normal in erythrocyte ($P < 0.02$) and lymphocyte ($P < 0.01$) membranes.
[e]Values lower than normal in erythrocyte ($P < 0.493$) and lymphocyte ($P < 0.001$) membranes.
[f]Values lower than normal in erythrocyte ($P < 0.303$) and lymphocyte ($P < 0.001$) membranes.
[g]Detected in all samples and assigned to 8c,11c,14c-20:3 (dihomo-g-linolenic acid DGLA) by comparison with an authentic sample. In five samples of erythrocyte and lymphocyte membranes DGLA was > 10%.
[h]Values lower than normal in erythrocyte ($P < 0.001$) and lymphocyte ($P < 0.001$) membranes
[i]EFA deficiency index.
[l]Highest value detected in controls. AEDS, atopic eczema/dermatitis syndrome; SFA, saturated FA; MUFA, monounsaturated FA.

membranes was also significant ($P < 0.001$) compared with controls. (iv) No significant differences of linoleic and arachidonic acid levels were detected in erythrocytes compared with controls, whereas for lymphocytes low values of both FA were significant ($P < 0.001$). (v) The SFA/MUFA ratio was higher than in controls ($P < 0.001$).

Significant correlations were found in the case of palmitic acid, which had an inverse correlation with the levels of arachidonic acid ($r = -0.622$; $P = 0.001$) and a positive correlation with linoleic acid ($r = 0.432$; $P = 0.03$). For stearic acid, an inverse correlation was found with linoleic acid ($r = -0.555$; $P = 0.005$).

With respect to *trans* isomers, octadecenoic acid isomers were detected and, compared with controls belonging to the same geographical area, the values were significantly higher in AEDS patients both in erythrocyte ($P < 0.02$) and T-lymphocyte ($P < 0.01$) membranes. *Trans* isomers of arachidonic acid were found both in erythrocyte and T-lymphocyte membrane phospholipids of all patients (1.2 ± 1 and 1.1 ± 0.6, respectively), as well as in controls (0.3 ± 0.1 and 0.4 ± 0.2, respectively). Since the occurrence of these *trans* isomers is not yet well known even in control subjects, the statistical significance of the subjects compared with controls had a particular meaning, and it was found to be high ($P < 0.001$).

The sum of *trans* 18:1 and 20:4 isomers is reported in Table 1 as the total *trans*-FA (TFA) content. It is worth noting that the highest values of total TFA found in the erythrocyte and T-lymphocyte membranes were 2.7 and 4.9% of the FA composition, respectively, whereas controls did not exceed the value of 0.5–0.6%. Correlation between the total TFA contents and the other FA values in erythrocyte membranes was also evaluated. Significant correlations were found with SFA, such as palmitic acid ($r = 0.446$; $P = 0.03$) and inversely, stearic acid ($r = -0.618$; $P = 0.001$).

In five subjects, the arachidonic acid precursor, dihomo-γ-linolenic acid (DGLA; 8*c*,11*c*,14*c*-20:3), was found in high amounts compared with the normal values.

Generally, low levels of the long-chain PUFA 22:6n-3 (DHA) were found in almost all erythrocyte and T-lymphocyte membranes compared with controls ($P < 0.001$ in both cases).

Finally, we divided the 26 patients in two groups, based on the skin prick/RAST test for detecting the non-IgE-mediated dermatitis. Table 2 reports the total TFA levels found in erythrocyte and T-lymphocyte membranes of the two groups. The highest values were found in lymphocyte membranes from 10 out of the 13 patients with non-IgE-mediated dermatitis. However, the differences were not significant ($P = 0.169$).

DISCUSSION

Although the results of different studies are not in agreement, the balance of evidence indicates that lipid metabolism is abnormal in atopic eczema (1). Data of the present study, as found in previous reports, show that in children affected by AEDS the FA membrane composition of red blood cells is altered. Control values obtained from a group of 10 children, age-matched with AEDS patients, were also found to be in agreement with data reported in the recent literature for normal subjects (36–40).

Moreover, here we report that the lipid composition in erythrocyte membranes had modifications that were reflected in membranes of T-lymphocytes, which are key effector cells in immunopathology of AEDS (compare with Table 1). The impairment consisted of an alteration of normal lipid ratios and, for the first time we report the presence of TFA isomers. In particular, with the help of a *trans* lipid library for GC analysis, not only octadecenoic acid isomers but also arachidonic acid isomers were detected in erythrocyte and T-lymphocyte membranes. The comparison of model radical-based isomerization of MUFA and PUFA, with the lipid trends of our patients shown in Figures 1 and 2, is gratifying.

In our model studies of arachidonate isomerization (20,21) and in the more recent work on the endogenous formation of TFA in THP-1 cells (23), we highlighted the relevance of the double bonds of arachidonic acid residues, which are the most affected by a radical-catalyzed isomerization process directly occurring in the biological membranes. Except for the presence of *trans* octadecenoic acids, which also can be expected from the diet, the *trans* 20:4n-6 isomers are not common in the diet, since their production from the *trans* 18:2 isomers is minimal. The four mono-*trans* isomers of arachidonic acid have been previously detected in human blood plasma and correlated to the presence of isomerizing radical species in smokers (22). Radical stress is also deeply involved in skin inflammation and atopic disease and, owing to a reduction of antioxidant defenses reported in these cases (24,43), it could affect membrane lipids, in particular polyunsaturated components. It must also be taken into account that lipid isomerization is inhibited by some antioxidants (44).

Considering other possible factors, in Europe TFA intake from the diet was correlated with childhood asthma and allergy (16). Our cohort had a diet balanced and normal for age as ascertained by the pediatrician, with no increased intakes of foods containing TFA isomers and olive oil as the main condiment, as ascertained during an interview with the parents. Eight children were on a diet free of cow's milk proteins and dairy prod-

ucts. Moreover, as discussed above, the presence of arachidonic acid isomers suggests that contributions from sources other than diet must be involved.

Once formed in the biological environment, TFA are active molecules known to inhibit desaturase and elongase enzymes and cause interruption of lipid pathways at different levels (25–27). The effects of *trans* arachidonic acid isomers are not yet fully disclosed, although some evidence for their interaction with lipid enzymes has been gathered (45–48).

In this study, significance was found for the correlation between total TFA levels and the high 16:0 and low 18:0 levels (*P* = 0.03 and *P* = 0.001, respectively). Together with the observation that high levels of 16:0 are inversely correlated with 20:4 levels (*P* = 0.001), a scenario results in which the inhibition of elongase enzyme can be suggested. Moreover, the reduced polyunsaturated content could couple with the high content of SFA and TFA, which are known to reduce the fluidity and permeability of cell membranes (6–9,44) as well as to affect membrane functions, including protein activities (7,8). The presence of higher amounts of palmitoleic acid residues could be explained from the activity of desaturase enzymes on the excess palmitic acid, and this MUFA residue could increase membrane fluidity. Therefore, activation of desaturase enzymes working with SFA could be a compensative mechanism in response to a general diminution of PUFA levels and lack of unsaturation observed in patients.

Cases of increased 20:3n-6 (DGLA), in particular in T-lymphocyte membranes, which is normally processed to arachidonic acid by Δ^5 desaturase activity, seem to indicate an inhibition of this pathway. It is also worth noting that a high amount of 20:3n-6 occurs in hematopoietic cells at an immature stage of development, which is also due to the absence of other cofactors (49). Generally, in our patients, low DHA contents were found in erythrocyte and lymphocyte membranes (*P* < 0.001, respectively). The low levels of arachidonic and linoleic acids compared with controls were significant only in T-lymphocytes (*P* < 0.001), thus showing some differences between the two cell populations in the same group of subjects. More recently, defects of PUFA have been related to a lack in the gene expression for FA enzymes (50).

The above-described correlation between the high content of 16:0 and the low content of 20:4 in erythrocytes could also indicate a possible relationship with desaturase enzymatic inhibition given by TFA. A clear correlation between high 18:1 *trans* isomers with low amounts of arachidonic acid and DHA in infant development has been described (51) although in our patients this correlation was not statistically significant.

Finally, we examined the relationship between TFA levels in erythrocyte and T-lymphocyte membranes and the presence of IgE (Table 2). In 13 out of 26 children where atopic disease was not IgE-mediated, the highest levels of TFA were detected in lymphocytes (1.8 ± 0.9%). However, the statistical significance of this parameter between the two groups appears not to be meaningful (*P* = 0.169), and a larger survey of patients is needed to address this point properly.

These data point out the need for a more comprehensive

picture of diseases involving lipid impairment, which has to include *cis* and *trans* isomer detection along with elucidation of their exogenous or endogenous origin. Indeed, the connection of diseases based on inflammation and free radical production with an *in vivo cis-trans* isomerization is an interesting hypothesis that is also connected with the concomitant unbalance of antioxidant defenses reported in these cases. In view of the radical-based mechanism of lipid alteration, the suggested supplementation of PUFA in skin disorders should be combined with compounds having a radical-repair activity (52).

Owing to the types and amounts of TFA detected in our AEDS patients, the contribution of radical-based isomerization to the presence of FA isomers in skin inflammatory diseases is proposed here for the first time. We speculate that the formation of TFA isomers in T-cell membranes of AEDS patients might affect membrane fluidity and produce consequences on the location and behavior of membrane-bound receptors and therefore might alter the activities of T cell signaling.

Fish Oil Supplementation of Lactating Mothers Affects Cytokine Production in 2½-Year-Old Children

[a]Center for Advanced Food Studies, Department of Human Nutrition, The Royal Veterinary & Agricultural University, 1958 Frederiksberg, Denmark, and [b]BioCentrum, Biochemistry & Nutrition Group, Technical University of Denmark, 2800 Lyngby, Denmark

ABSTRACT: n-3 PUFA influence immune functioning and may affect the cytokine phenotype during development. To examine whether maternal fish oil supplementation during lactation could modify later immune responses in children, 122 lactating Danish mothers with a fish intake below the population median were randomized to groups supplemented for the first 4 mon of lactation with 4.5 g/d of fish oil (equivalent to 1.5 g/d of n-3 long-chain PUFA) or olive oil. Fifty-three mothers with a fish intake in the highest quartile of the population were also included. The FA composition of erythrocyte membranes was measured at 4 mon and at 2½ yr. Plasma immunoglobulin E (IgE) levels and cytokine production in lipopolysaccharide-stimulated whole-blood cultures were determined at 2½ yr. Erythrocyte n-3 PUFA at 4 mon were higher in infants from the fish oil group compared with the olive oil group ($P < 0.001$) but were no longer different at 2½ yr. The median production of lipopolysaccharide-induced interferon γ (IFN-γ) in the fish oil group was fourfold higher than that in the olive oil group ($P = 0.034$), whereas interleukin-10 (IL-10) production was similar. The IFN-γ/IL-10 ratio was twofold higher in the fish oil group ($P = 0.019$) and was positively correlated with 20:5n-3/20:4n-6 in erythrocytes at 4 mon ($P = 0.050$). The percentages of atopic children and plasma IgE were not different in the two groups, but the study was not designed to look at atopy. Cytokine responses and erythrocyte FA composition in children of mothers with a high fish intake were intermediate in comparison with those in the randomized groups. Fish oil supplementation during lactation resulted in increased *in vitro* IFN-γ production in the children 2 yr after the supplementation was given, which may reflect a faster maturation of the immune system.

Paper no. L9666 in *Lipids 40,* 669–676 (July 2005).

Because of the immunosuppressive action of n-3 PUFA, there has been some concern about the safety of an increased intake of n-3 long-chain PUFA (LCPUFA) in infancy (1). However, it has also been hypothesized that an increased intake of n-3 PUFA may protect against atopy (2). There has been an in-crease in the prevalence of atopic diseases in the last decades, which could be due to environmental factors. Atopic sensitization occurs early in life and may therefore be specifically sensitive to environmental factors, e.g., diet, that are introduced in this period. It is therefore possible that some "nutritional programming" of the immune system may occur.

Infants are born with an immature immune system characterized by a polarization of T helper lymphocytes (Th) toward a proallergic Th2-type response. The capacity to induce protective Th1 immune responses is impaired in early childhood, and immune maturation in childhood is characterized by a Th1 polarization. Breast milk contains numerous components that may promote the development of the infant's immune system (3), including PUFA. The maternal diet is the most important determinant of infant PUFA accretion in membranes of breast-fed children (4). Thus, variations in maternal intake of PUFA may influence the maturation and polarization of the infant immune system.

Immune maturation occurs faster in breast-fed than in formula-fed infants and is enhanced by the addition of LCPUFA to infant formula (1,5). Fish oil (FO) supplementation of pregnant women has been shown to affect immune function in the neonate and atopic sensitization during early life (6,7). Some longitudinal studies found that a higher n-3 PUFA content in breast milk was associated with a decreased likelihood of atopy in infants (8–10), whereas another study found contrasting results (11). Supplementation with n-3 PUFA during lactation has been found to reduce the prevalence of wheezing during the first 18 mon of life (12). The effect of maternal FO supplementation during lactation on later immune function in the offspring has not been investigated.

We performed a randomized trial in which the n-3 LCPUFA intake of breast-fed infants was raised *via* FO supplementation to the mother during the first 4 mon of lactation. The trial was designed to investigate the effects on breast-milk FA composition, n-3 PUFA levels in infant erythrocytes (RBC), and development during the first year of life (13). The long-term effect on immune function was investigated at a follow-up visit, when the children were 2½ yr old. The aim of this study was to see whether maternal FO supplementation during lactation would affect later immune function, determined by the cytokine phenotype and assessed by the *in vitro* production of interferon γ (IFN-γ) and interleukin 10 (IL-10) and plasma immunoglobulin E (IgE). The study did not have the power to look at atopic sensitization.

SUBJECTS AND METHODS

The study hypothesis was tested in a parallel-group randomized trial. A diagram of the trial profile, with special focus on the present follow-up study, is shown in Figure 1. The details of the study design, recruitment procedure, and subjects, which have been reported elsewhere (13), are described briefly here.

During 1999, participants were selected from among pregnant women recruited for the Danish National Birth Cohort (14) based on their intake of n-3 LCPUFA. Women with a fish intake below the population median (<0.4 g n-3 LCPUFA/d) were recruited for the randomized intervention trial, and women with a fish intake in the upper quartile (>0.8 g n-3 LC-PUFA/d) as a high-fish-intake reference group (HFI group). The inclusion criteria were: an uncomplicated pregnancy, pre-pregnancy body mass index < 30 kg/m^2, no metabolic disorders, and the intention to breast-feed for at least 4 mon. Furthermore, the newborns had to be healthy, term, singleton infants with normal weight for gestation (15) and an Apgar score > 7, and the mothers were to begin taking the supplements within 2 wk after birth. One hundred twenty-two and 53 of the women with a low and high fish intake, respectively, fulfilled all criteria.

The protocols for the intervention trial and follow-up study were approved by the local scientific ethical committee (KF 01-300/98 and KF 01-183/01). Both parents of all participating children gave written consent to participate after the study had been explained to them orally as well as in writing.

Trial and supplements. After birth, women with a fish intake below the median were randomly allocated to daily supplementation for the first 4 mon of lactation with microencapsulated FO or olive oil (OO) given in müesli bars (Halo Foods Ltd., Tywyn Gwynedd, Wales, United Kingdom). The FO supplement (Dry n-3^{TM}; BASF Health and Nutrition A/S, Ballerup, Denmark) provided 1.5 g/d of n-3 LCPUFA (equivalent to 4.5 g/d of fish oil). As an alternative, the supplements were offered in homemade cookies or oil capsules (a gift from Lupe/ProNova Biocare, Lysaker, Norway). The overall self-reported compliance in both groups was, on average, 91% (range 67–100%, n = 64). Investigators and families were blinded to the randomization throughout the first year of life.

One hundred seven mothers complied with the criterion for exclusive breast-feeding for 4 mon. Mothers who did not fulfill this criterion were not excluded from the trial, but we estimated to which extent breast milk covered the energy needs of the infants from their intake of formula and complementary food. Breast milk was estimated to be the dominant source in all but 15 of the infants, most of whom were from the FO group [but the overall degree of breast-feeding did not differ between the two randomized groups (P = 0.059)]. The typical infant formulas on the Danish market at the time had an n-6/n-3 PUFA ratio of around 10 and contained no LCPUFA. One hundred mothers completed the intervention, and 50 mothers from the HFI group remained in the study for the initial 4-mon period. The biochemical effect of the intervention was assessed from the FA composition of breast milk and RBC from mothers and infants at the end of the intervention (13).

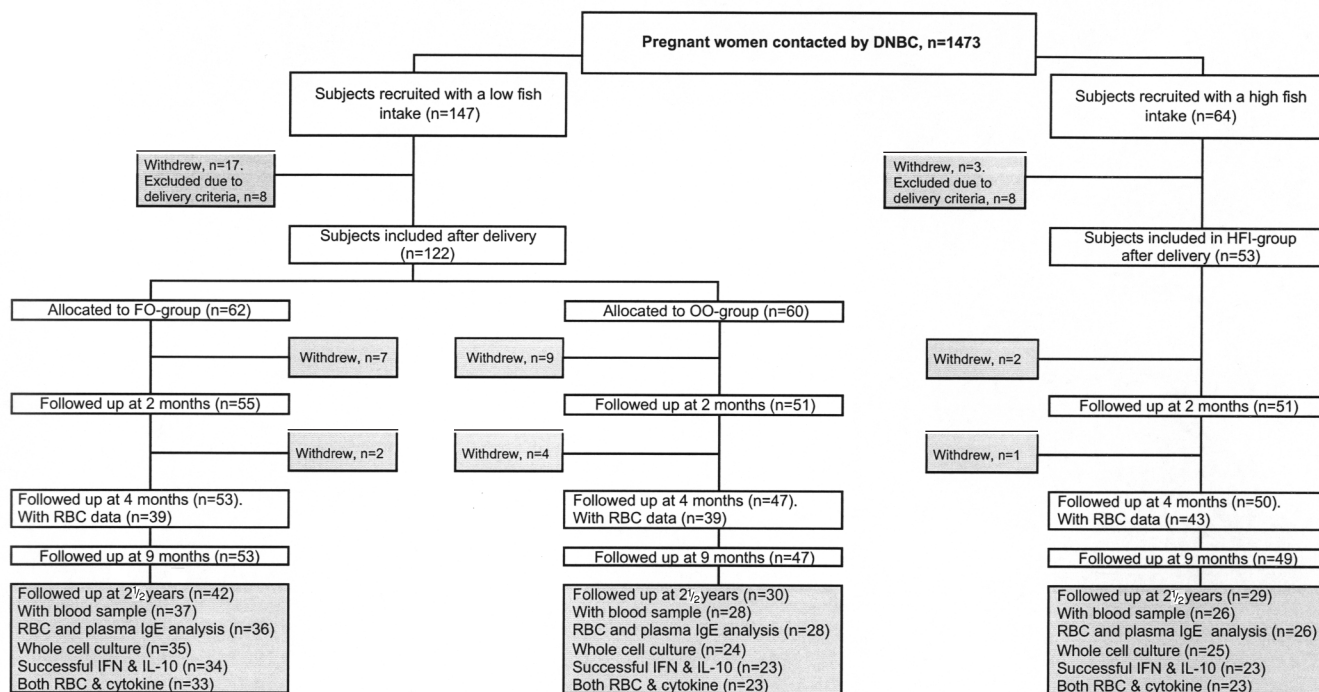
Follow-up study. When the children were 2½ yr old, all 150 families were invited to participate in the follow-up examination


FIG. 1. Trial profile summarizing participant flow, number of randomization assignments, and follow-up examinations for all groups, with special focus on the assessment of immune function at 2½ years of age. DNBC, Danish National Birth Cohort; FO, fish oil; IFN, interferon; IL, interleukin; OO, olive oil; HFI-group, group of mothers with a high fish intake; RBC, red blood cell.

TABLE 1
Characteristics of the 91 Children in the Follow-up Study on Immune Function[a]

	HFI	Olive oil	Fish oil
n	26	28	37
Sex (% boys)	61.5	57.1	62.2
Parity (% with no siblings)	50	39	59
Birth weight (kg)	3.64 ± 0.08	3.56 ± 0.08	3.68 ± 0.07
Mean duration of breast-feeding (mon)	10.0 ± 0.9	9.9 ± 0.9	8.2 ± 0.8
Degree of breast-feeding (% 100 and <50)[b]	80.8 & 7.7	78.6 & 3.6	59.5 & 24.3
Age at follow-up (mon)	31.7 ± 0.2	31.9 ± 0.2	31.7 ± 0.1
Height at $2\frac{1}{2}$ yr (cm)	93.4 ± 0.6	92.6 ± 0.6	92.8 ± 0.5
Weight at $2\frac{1}{2}$ yr (kg)	14.0 ± 0.3	13.7 ± 0.2	14.2 ± 0.2
Family history of atopy (% with 1 and >1)[c]	36.0 & 20.0	42.9 & 21.4	33.3 & 16.7

[a]Data given as mean ± SE or percentage of all children of mothers with a habitual high fish intake (HFI) or mothers supplemented during lactation with olive oil or fish oil. There were no statistically significant differences between groups. IgE, immunoglobulin E.
[b]Children exclusively breast-fed in the first 4 mon of lactation and those estimated to have had less than 50% of their energy intake covered by breast milk.
[c]1 and >1 atopic family members (parents or siblings).
[d]Only children with an atopic diagnosis made by a physician.

at the Department of Human Nutrition, as previously described (16). The follow-up rates in the randomized groups and in the HFI group were 72 and 58%, respectively. At the time of the follow-up study, the children were healthy, i.e., they were not given continuous medication and did not suffer from chronic disease (except for some having allergies). The parents were interviewed about allergy diagnoses in the child, signs of allergic tendencies, and family history of allergy using questions that has been validated with respect to atopic dermatitis (17). Only allergic tendencies (itchy rash, wheezing, or food allergy) reported that had been verified by a doctor were used for categorization.

At the end of the follow-up examination, a 1-mL blood sample was collected from the children in ice-cold heparin-conditioned tubes by venipuncture. The study group in the present study consisted only of children with successful blood sampling; their characteristics are shown in Table 1.

Within 30 min after sampling, 30-μL aliquots of heparinized whole blood were cultured with lipopolysaccharide (LPS) for measurement of cytokine production. Within 1 h after sampling, RBC were separated from plasma and leukocytes by centrifugation and washed three times in physiological saline. The plasma samples were frozen at −80°C. The isolated, packed RBC were reconstituted 1:1 in physiological saline with 1 mM EDTA and 0.005% BHT (Sigma, St. Louis, MO) and kept at −80°C until the FA composition was determined (maximum storage time 8 mon).

Measurement of cytokine production by whole-blood cultures. Heparinized blood was diluted 1 in 7 with RPMI 1640 medium supplemented with 0.1% FCS and 30 IU/mL Na-heparin. Diluted whole-blood cultures were set up in 96-well culture plates, with 8 wells for each child. In 4 wells, LPS (from *Escherichia coli* O26:B6; Sigma) was added to give a final concentration of 1 μg/mL, and 4 wells with control cultures were the added medium alone. Cultures were incubated at 37°C in a 5% CO_2 atmosphere for 22.5 ± 1.5 h, the supernatant was carefully removed, and aliquots were frozen at −20°C.

Cytokine concentrations in the culture supernatants were measured by ELISA. IFN-γ, IL-12 p70, and IL-4 were measured with commercial kits (Duosets DY285, DY1270, and DY204; R&D Systems Europe, Abington, United Kingdom) in accordance with the manufacturer's instructions. The IL-10 concentration was determined with paired antibodies (BD Pharmingen, San Diego, CA) using anti-human IL-10 (clone JES3-19F1, 2 μg/mL) as the coating antibody and biotinylated anti-human IL-10 (clone JES3-12G8, 1 μg/mL) as the detector antibody. Cytokine concentrations were quantified relative to standard curves representing a range of dilutions of recombinant cytokine using a four-parameter curve-fit analysis (KinetiCalc software, version KC4 Rev 29; Bio-Tek Instruments). Limits of detection for these assays were 62 pg/mL (IFN-γ), 33 pg/mL (IL-10), 33 pg/mL (IL-12), and 31 pg/mL (IL-4). Nondetected values were set to 0.5× the limit of detection in calculating the ratios of IFN-γ to IL-10. IFN-γ IL-10, and IL-12 were determined in most of the children, whereas the IL-4 analysis was carried out only with the supernatants from 10 of the children. The were no correlations between the determined levels of cytokines in the supernatants and storage time (data not shown).

Measurement of IgE in plasma. IgE was measured in plasma from heparinized blood samples with paired antibodies (BD Pharmingen) in a sandwich ELISA. It was performed as described above, but with antibodies against human IgE. Anti-human IgE (clone G7-18) was used as the capture antibody at 2 μg/mL, and biotin-coupled anti-human IgE (clone G7-26) at 2 μg/mL was used as the detector antibody. Plasma from high-IgE producers (a kind gift from ALK-Abello, Hørsholm, Denmark) was used as a reference to control for plate-to-plate variation. Samples were serially diluted and antibody titers were expressed as $\log_2$ titers and defined as the dilution (four-parameter analysis, KinetiCalc software; Bio-Tek Instruments) of a blood sample leading to an absorbance at 0.2 above background.

RBC FA analysis. Thawed RBC from the heparin blood samples were hemolyzed in redistilled water, and the lipids were extracted by the procedure of Folch *et al.* (18). Lipids were methylated with BF_3 in methanolic NaOH (19), and the

resulting FAME were extracted and separated by GLC as previously described (13). All peaks from lauric acid (12:0) to docosahexaenoic acid (22:6n-3) were identified from the retention times of commercial standards (Nu-Chek-Prep Inc., Elysian, MN) as previously described (20). On average, 96.9 ± 0.1% (mean ± SE) of the chromatogram areas were identified (excluding BHT). The FA compositions of all RBC samples were determined in duplicate. Results are expressed as the area percentage of each FA relative to that of all FA peaks together.

Statistical analysis. The results are given as average ± SE for normally distributed variables (RBC FA composition) and as the median (10th and 90th percentiles) for other variables (all immune variables). RBC FA composition and immune responses in the two randomized groups and in atopic and nonatopic children were compared by Student's *t*-test and the Mann–Whitney U-test, respectively. The distribution of LPS-induced IL-10 production in the two randomized groups was performed by Levene's test for equal variances. Paired comparisons of the LPS stimulation in cytokine production were performed using a Wilcoxon signed ranks test. Associations between immune variables and between RBC FA composition and cytokine production were calculated by Kendall ι. A Pearson correlation analysis was used to analyze the correlation between RBC FA compositions in mothers and children. All data were analyzed using SPSS for Windows 11.0 (Chicago, IL).

RESULTS

FO supplementation had a pronounced effect on the FA composition of breast milk (13) and on that of RBC from infants in month 4 of lactation (Table 2). The ratio of 20:5n-3 to 20:4n-6

in the RBC of infants was significantly higher in the FO group than in the OO-group at the end of the 4-mon intervention period. The 91 children with follow-up blood samples at $2\frac{1}{2}$ yr of age were similar to the children with no follow-up blood sample with respect to gestational age, weight, length at birth, degree of breast-feeding, dietary group, and RBC FA composition at 4 mon (data not shown). However, the follow-up group had significantly better compliance in the intervention trial (89 vs. 85%), and the follow-up rate for boys was higher ($P = 0.020$). At $2\frac{1}{2}$ yr of age, no differences were apparent in RBC FA compositions between children from the two randomized groups (Table 2).

At $2\frac{1}{2}$ yr of age, no group difference was observed in plasma IgE levels (Table 1). Cytokine production was not detectable in the supernatants of unstimulated cultures, except in a few children (Fig. 2). LPS induced a marked increase in IL-10 production to levels approximately 18 times above the detection limit (Fig. 2). Median LPS-induced IL-10 level did not differ between the FO and OO groups ($P = 0.367$), but the distribution of IL-10 in the two groups did ($P = 0.003$). LPS-induced IFN-γ production was significantly increased compared with the control in both the OO and FO groups ($P = 0.008$ and $P < 0.001$, respectively). LPS induced detectable levels of IFN-γ in 62% of the children in the FO group and 39% in the OO group (chi-square, $P = 0.093$). The median IFN-γ production was still undetectable in the OO group, but was 2.2 times above the limit of detection in the FO group and significantly higher than in the OO group ($P = 0.034$, Fig. 2). This difference was also significant when the child with detectable control levels of IFN-γ was excluded ($P = 0.049$), and there was a trend in the same direction when all children who were breast-fed <50% during the

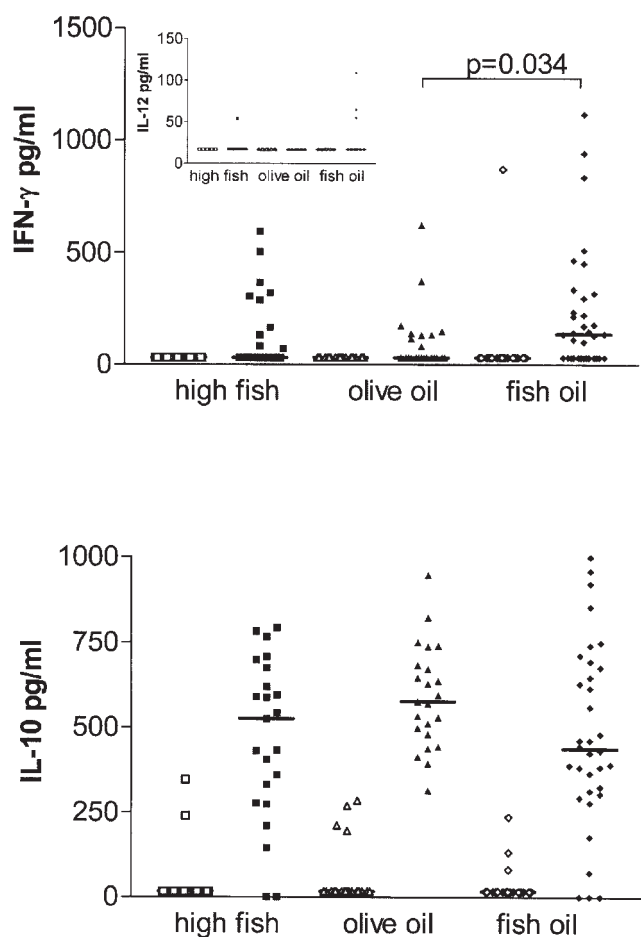
[a]The values are given as area% of all FA in the chromatogram − mean ± SE. Individual FA are named by the number of carbon atoms:number of double bonds and the position of the last double bond. SFA, saturated FA; MUFA, monounsaturated FA. Statistical differences between groups are indicated by superscript letters: [a]$P < 0.05$, [b]$P < 0.01$, and [c]$P < 0.001$ compared with the olive oil group, and [d]$P < 0.05$, [e]$P < 0.01$, and [f]$P < 0.001$ compared with the HFI group.


FIG. 2. *In vitro* lipopolysaccharide-stimulated cytokine production in 2½-year-old children in the maternal dietary groups (high fish intake and olive oil- or fish oil-supplemented). Cytokine production (pg/mL) for each child is given as the mean of three to four values. Open and filled symbols give control and lipopolysaccharide-stimulated values, respectively. The solid lines indicate median values in each group (*n* = 23 in the high fish intake group, 23 in the olive oil group, and 34 in the fish oil group).

intervention were excluded from this analysis (*P* = 0.063). The HFI group was intermediate with respect to LPS-induced IFN-γ production, which was detectable in 44% of the children. LPS-induced IL-12 production was detectable in only three children from the FO group and one from the HFI group (Fig. 2, insert). LPS stimulation did not result in detectable levels of IL-4 (data not shown). The ratio of IFN-γ/IL-10 was significantly higher in the FO group compared with that in the OO group [being 0.27 (0.04–1.11) and 0.07 (0.04–0.56), respectively (*P* = 0.019)]. The ratio was also significantly different in the two randomized groups when those children who were breast-fed <50% during the intervention period were excluded from the analysis (*P* = 0.033, *n* = 47). The HFI group had an intermediate ratio (data not shown).

Thirty-six percent of the children were reported to have a diagnosis of eczema, wheezing, or food allergy, and these children were equally distributed between the three groups (Table 1). Total plasma IgE was not significantly higher in children

with a diagnosis of eczema, wheezing, or food allergy compared with nondiagnosed children, although there was a trend in that direction (*P* = 0.071). LPS induced detectable levels of IFN-γ in 37% of the whole-blood cultures from diagnosed children and 58% from nondiagnosed children (*P* = 0.084). There was no significant difference between atopic and nonatopic children with respect to LPS-stimulated production of IFN-γ (*P* = 0.378), IL-10 (*P* = 0.782), or IFN-γ/IL-10 (*P* = 0.435). Also, there was no significant association between plasma IgE and LPS-induced IFN-γ or IL-10 production (*r* = 0.011, *P* = 0.895 and *r* = 0.142, *P* = 0.075, respectively). No differences were observed in the FA composition of RBC from atopic and nonatopic children at either 4 mon or 2½ yr of age (data not shown).

In children from the randomized groups, LPS-induced IFN-γ production and the ratio of IFN-γ to IL-10 correlated with the ratio of 20:5n-3 to 20:4n-6 in infant RBC (*r* = 0.220 and *r* = 0.205, respectively; *P* = 0.050 and *n* = 44 for both). The correlations between LPS-induced IFN-γ production and IFN-γ/IL-10 and maternal RBC 20:5n-3/20:4n-6 were more prominent, probably due to the higher power (*n* = 56; *r* = 0.249, *P* = 0.011 and *r* = 0.222, *P* = 0.016, respectively). IFN-γ/IL-10 was also correlated with the levels of 22:6n-3 in the RBC of mothers at the end of the intervention and of the randomized children at 2½ yr of age (data not shown). However, these correlations were weaker (lower *r*-values and less significant), and the RBC 22:6n-3 of both mothers and 2½-yr-old children was associated with RBC 20:5n-3/20:4n-6 at the end of the intervention (data not shown). No correlation was observed between LPS-induced IL-10 production and any PUFA in the RBC of the mother, infant, or child.

DISCUSSION

FO is known to be immunosuppressive and to suppress the production of inflammatory cytokines (2). Because of such immunomodulatory actions of n-3 PUFA, several FO intervention studies have been conducted in atopic patients. Atopy is characterized by increased B-lymphocyte IgE-production, which is regulated by cytokines produced by Th cells according to the Th1/Th2 hypothesis (21). FO-supplementation studies show conflicting results regarding the effect on Th1/Th2 cytokines and tend to show a limited efficacy once the allergic immune responses are established (2). However, atopic sensitization occurs early in life; therefore, perinatal n-3 PUFA exposure may affect immune maturation in infants and the risk of subsequent disease. Several studies indicate that the development of allergies may be associated with breast-milk PUFA (8–10). FO-supplementation of lactating atopic mothers has been found to reduce the prevalence of wheezing in the child (12). To our knowledge, no other studies have assessed the potential immunomodulatory function of FO supplementation in breast-feeding mothers.

Maturation of the immune system during infancy is characterized by an increase in IFN-γ production and a shift from Th2 to Th1 polarization in the immune response (1). In the present

study, maternal FO supplementation increased LPS-induced IFN-γ production. Furthermore, IL-12 was found only in children of FO-supplemented mothers or mothers with a high fish intake, which strengthens the IFN-γ result. No effect of FO was observed on IL-10 production, although this had a significantly broader distribution, but the IFN-γ to IL-10 ratio was higher after maternal FO supplementation during lactation. Our data indicate that an increased n-3 LCPUFA intake early in life gives rise to faster immune maturation and is able to polarize the immune response later in childhood toward Th1. These results are in agreement with other observations. Field *et al.* (5) observed a slower maturation of the immune response in formula-fed infants compared with breast-fed infants, which disappeared with the addition of LCPUFA (22:6n-3 and 20:4n-6) to the formula. Maternal FO supplementation during pregnancy has been shown to reduce levels of IL-13 in cord plasma (6) and to reduce the allergen-induced production of IL-10 (7).

In vitro cytokine production in whole-blood cultures of the children in the present study was on the limit of detection, which is a general problem in studies of young children (6,22). We were able to detect only IL-12 in a few of the children, although this may have been improved if we had primed the cells with IFN-γ. Instead, we measured the concentration of IFN-γ, as we had demonstrated that IFN-γ production in stimulated whole-blood could be inhibited by the addition of anti-IL-12 antibodies (Jensen, M., Christensen, H.R., and Frøkiær, H., unpublished manuscript). Moreover, we used only one toll-like receptor ligand to stimulate cytokine production; hence, we explored only a small potential of the immune response, and LPS is primarily a Th1 polarizing agent. We were not able to detect IL-4 in LPS-stimulated whole-blood samples and therefore used IL-10, which was detectable in almost all samples, as a Th2 marker. However, IL-10 is secreted by a wide variety of cell types, including Th cells, monocytes, macrophages, dendritic cells, and mast cells. IL-10 possesses potent immune-suppressive functions and is currently believed to drive the differentiation of regulatory T cells. However, we found that IL-10 tended to correlate positively with plasma IgE, which, although not significant, may indicate that IL-10 in young children may be a marker of Th2 response. The LPS-induced responses in IL-10 and IFN-γ production were variable. This variability could be due to differences in cell counts of mononuclear cells between samples, as we did not assess this. However, it is not likely to give rise to a bias between the groups that could explain the observations. Unfortunately, the power of the study was not sufficient to show any difference in the number of high and low responders between the groups, although there was a trend. To overcome the differences in response level, we focused on the ratio between the production of IFN-γ and IL-10. In the study we used OO as a control supplement. However, OO also has been suggested to have some immunomodulatory actions and anti-inflammatory effects, and many of the effects observed for FO are also shown for OO (23). Accordingly, the difference between the FO group and the control group may have been larger if we had used a more neutral control oil.

A fast immune maturation and Th1 polarization could result in better immune functioning and a decreased risk of atopic sensitization. The study was not powered to look at atopic sensitization, and no differences in atopy and plasma IgE were observed between the groups. The children were not selected to have a high risk of atopy, but the prevalence of self-reported eczema, wheezing, or food allergy was high. Furthermore, the study is limited by a low rate of follow-up (around 70%). Plasma IgE is a very crude measure of atopy and does not give an indication of allergen sensitization. Allergen-specific immune responses provide information on cytokine production by allergen-reactive cells influenced by prior antigen exposure, whereas cytokine production after polyclonal stimulation, as in the present study, examines the underlying predisposition of cytokine production. This is especially important in light of the findings that both Th1 and Th2 allergen-induced cytokine responses are increased in children with atopic disease concomitant with a reduced polyclonal Th1 response (22). No association was found between *in vitro* cytokine production and plasma IgE levels; also, there was no association between IgE and eczema, wheezing, or food allergy, although both associations tended to be positive. A weak association may not be surprising considering the self-reported diagnosis and the low power of the study with respect to atopy. Supplementation with n-3 PUFA during pregnancy and in the first year of life has been shown to reduce the prevalence of self-reported wheeze symptoms, which were not associated with a decrease in serum IgE or atopy (12). Allergic diseases may be related to a dysfunction of various IL-10-producing regulatory cells, and allergen-specific IL-10 is known to be down-regulated in atopic children (24). Low levels of IL-12 in cord blood have been associated with later IgE sensitization (25), and high-risk children who developed clinical allergy tended to have lower neonatal Th1 responses (26,27). It has been suggested that a relative absence of IL-12 favors the development of a default Th2 cytokine profile (28). Maturation of antigen-presenting cells, and thus increased IL-12 production, is a key rate-limiting step in the postnatal development of Th1 function.

The present data show that n-3 LCPUFA intake in early infancy appears to be able to increase the polyclonal Th1 response. The FO-induced changes in RBC FA composition during the intervention were no longer evident at $2\frac{1}{2}$ yr of age. RBC were used as a proxy for the FA composition of body tissue membranes in general. Therefore, the effect of FO supplements on immune function during lactation does not appear to be mediated *via* membrane n-3 LCPUFA in whole-blood cultures. We speculate that a long-term effect may be caused by a shift in immune polarization during infancy, which, because of a mutual inhibition between the Th1 and Th2 responses, is maintained or even attenuated throughout early childhood. The mechanism behind the immune-modulating effect of n-3 PUFA could be mediated through changes in prostaglandin E_2 (PGE_2) synthesis (2), but other mechanisms cannot be excluded. PGE_2 enhances Th2 differentiation and suppresses the differentiation of Th1 cells. *In vitro* studies have shown that all PGE subtypes equipotently inhibit Th1 cytokine production (29,30), but they

may influence the ratio of Th1 to Th2 cytokines and T cell proliferation differently (29). We found an association between IFN-γ/IL-10 and RBC 20:5n-3/20:4n-6 in RBC, thus suggesting that n-3 PUFA may exert the effect on cytokine production by competition in eicosanoid synthesis and action.

In summary, we found an increased LPS-induced *in vitro* IFN-γ production and higher IFN-γ to IL-10 ratio in 2$\frac{1}{2}$-year-old children after maternal FO supplementation in lactation. These results indicate that early n-3 PUFA intake may result in faster maturation of the immune system and/or a TH1 polarization. An important finding of this present study is the observation that the immunomodulating effect is present 2 yr after the supplements were given.

Christina H. Hansen, and Carl-Erik Høy[†]

Biochemistry and Nutrition Group, BioCentrum-DTU, Technical University of Denmark, DK-2800 Lyngby, Denmark

ABSTRACT: In this study we examined the lymphatic transport in rats of FA after administration of interesterified oils containing CLA, with emphasis on the location of CLA and octanoic acid in the TAG. The oils were produced by enzymatic interesterification. Eight oils with different structures or FA profiles were examined in this study: MCM, CMC, OCO, and COC, where M was expected to be octanoic acid and O oleic acid. In group 1, C was CLA as a mixture of the two CLA isomers $c9,t11$ or $t10,c12$, and in group 2, C was mainly the isomer $t10,c12$. Rats were subjected to cannulation of the mesenteric lymph duct, and the following day they were intragastrically administered one of the oils and lymph samples were collected for 24 h. The lymphatic transport of total FA from 0 to 8 h in group 1 was significantly ($P < 0.05$) higher for the OCO-1 and the COC-1 oils than for the CMC-1 oil. Similarly, in group 2 the transport was higher for the OCO-2 oil than for the CMC-2 oil. The recovery of both of the CLA isomers examined was similar (50–70%) and independent of the isomer, oil structure, and FA profile, whereas more octanoic acid was recovered from the CMC oils than from the MCM oils. The results indicated that the FA profiles and the position of octanoic acid had only a minor influence on the absorption of CLA.

Paper no. L9717 in *Lipids 40*, 677–684 (July 2005).

CLA is a collective term for several conjugated isomers of linoleic acid that differ in the geometry and position of the double bonds. The CLA isomer $c9,t11$ is the major isomer occurring naturally in food, mainly in milk fat and meat from ruminants (1), whereas the $t10,c12$ isomer is naturally present in much lower amounts in food products. Furthermore, CLA is produced by alkaline isomerization of linoleic acid (e.g., safflower, sunflower, or soybean oil). The resulting oil contains 60–80% CLA, dominated by the two isomers $c9,t11$ and

$t10,c12$ (50:50) (2). These isomers have been reported to have various health-related benefits (3), including anticarcinogenic, antiatherosclerotic, lean body mass enhancing-, and immune function-enhancing effects, while also reducing inflammation and reducing body fat and diabetic symptoms in some animal models (4).

Dietary TAG are hydrolyzed in humans by gastric (5) and pancreatic lipases (6) in the stomach and duodenum, respectively, by specific hydrolysis of the sn-1/3 ester bonds. The hydrolysis results in the formation of sn-2-MAG and FFA. The nature of the FA in the TAG molecule determines the hydrolysis rate, and some experiments have shown that medium-chain FA (MCFA) are hydrolyzed faster than highly unsaturated long-chain FA (LCFA) (7–9). The sn-2-MAG is absorbed intact into the enterocytes (10,11), whereas the FFA are absorbed either directly into the portal blood (mostly short-chain FA and MCFA) or, together with the sn-2-MAG, into the enterocytes. In the enterocytes, sn-2-MAG are reesterified with exogenous as well as endogenous FA to form a new pool of TAG, packed into chylomicrons, and secreted into the lymphatic duct (12). Therefore, the intramolecular TAG structures play important roles in the absorption of fat. Studies have shown that CLA $c9,t11$ is absorbed better from the sn-1/3-positions than from the sn-2-position of the TAG molecules (13). In milk (14) and meat from ruminants (15,16), CLA $c9,t11$ is primarily located in the outer positions, indicating that the CLA in these products is well absorbed.

Structured lipids are synthesized either by chemical or enzymatic interesterification (17). The advantage of enzymatic interesterification is the specificity of the enzyme to generate TAG molecules with a well-defined structure. Structured TAG containing MCFA in the outer positions and LCFA in the sn-2-position combine the advantages of rapid intestinal hydrolysis of MCFA as well as being a source of LCFA. Oils with this kind of structure were shown to be absorbed faster and to a higher degree than oils containing only LCFA in normal-, but especially in malabsorbing, rats (18–20). Furthermore, the absorption of the FA located in the sn-2-position of the structured oil was also increased. This may be explained by a faster hydrolysis in the intestine of MCFA when located in the sn-1/3-positions compared with LCFA (7,9). The advantage of specific structured oils with MCFA in the sn-1/3-positions was used to improve the fat uptake, and thereby energy intake, and to increase nitrogen digestibility in weaning piglets (21).

Because of the reported health-related benefits of CLA, it is

---

of major interest to maximize the uptake of the CLA ingested. We examined the possibility of enhancing the absorption by incorporating CLA into oils with different structures and FA profiles, including MCFA. The study was carried out in rats with normal absorption, mainly with emphasis on investigating the absorption of the two CLA isomers *c*9,*t*11 and *t*10,*c*12, but also that of other FA. Dietary fats were produced by enzymatic interesterification of either an oil containing a mixture of the two isomers *c*9,*t*11 and *t*10,*c*12 or one with *t*10,*c*12 as the major CLA isomer.

MATERIALS AND METHODS

Interesterified oils. The conjugated trilinoleylglycerol (CLA), a mix of *c*9,*t*11 and *t*10,*c*12 (75% TAG), and *t*10,*c*12 (75% TAG), as well as a mix of *c*9,*t*11 and *t*10,*c*12 (80% FFA) and a product enriched with *t*10,*c*12 (80% FFA) were kindly donated by Natural Lipids Ltd. A/S (Hovdebygda, Ålesund, Norway). Octanoic acid (8:0) was purchased from Brøste A/S (Lyngby, Denmark), trioctanoin (Myritol 888) was from Cognis Japan Ltd. (Shinagawaku, Tokyo, Japan), oleic acid (95%) was from AppliChem GmbH (Darmstadt, Germany), and high-oleic sunflower oil was from Aarhus United A/S (Aarhus, Denmark). Novo Nordisk A/S (Bagsværd, Denmark) donated the Lipozyme IM, in which an *sn*-1/3-specific lipase from *Rhizomucor miehei* was immobilized on a macroporous ion resin.

For the survey, eight dietary groups were divided into two groups: group 1—MCM-1, CMC-1, OCO-1, COC-1; and group 2—MCM-2, CMC-2, OCO-2, and COC-2. C was CLA, O was oleic acid (18:1n-9), and M was 8:0. Group 1 contained both the CLA isomers *c*9,*t*11 and *t*10,*c*12, whereas the CLA in group 2 was primarily the *t*10,*c*12 isomer.

The four different oils containing CLA as a mix of *c*9,*t*11 and *t*10,*c*12 were produced by enzymatic interesterification in a packed-bed reactor (22). The substrate mixture had a molar ratio of 6:1 (FFA/TAG) and a water content adjusted to 0.09%. A constant reactor temperature of 60°C was maintained by circulating water between the inner and outer tube of the reactor. CLA, as a mix of *c*9,*t*11 and *t*10,*c*12, was used as a substrate in the production of the MCM-1 and OCO-1 oils. Trioctanoin and sunflower oil were used to produce the CMC and COC oils (O was 18:1n-9), respectively. The FFA, either as the CLA mix, 8:0, or 18:1n-9, was spontaneously esterified in the *sn*-1/3-positions because of their abundance in the reaction mixture. A two-step short-path distillation process was used to separate FFA from TAG in the interesterification products.

The four different oils containing CLA as *t*10,*c*12 were produced by enzymatic interesterification in a batch reactor (23). CLA *t*10,*c*12, as TAG and FFA, was not available in quantities necessary for packed-bed reactor interesterification. The substrate molar ratio and water content were as described for the packed-bed reactor interesterification. The enzyme Lipozyme IM was added to the reaction flask as 15% (wt) on a total substrate basis. The reaction proceeded for 10 h with magnetic stirring in a 55°C water bath. The enzyme resin was removed by filtration through sterile, degreased cotton wool, and the prod-

ucts were sparged with nitrogen and stored at −20°C until distillation.

The interesterified products were distilled to separate the FFA from the TAG. Interesterification products with a mixture of 8:0, CLA, and 18:1n-9 FFA were distilled by a two-step short-path distillation process. The 8:0 evaporated at 90–100°C and the LCFA at 190°C under vacuum (10^{-3} mbar).

Lipid analysis. FAME were prepared from oil dissolved in heptane by transesterification catalyzed by KOH in methanol (24). To determine the FA profiles, lipids from lymph samples were extracted according to the method of Folch *et al.* (25) and transmethylated to FAME as described above. FAME were analyzed by GLC using a Hewlett-Packard 5890 series II chromatograph with an FID (Hewlett-Packard GmbH, Ingelsheim, Germany), and a fused-silica capillary column (SP-2380, 60 m, i.d. 0.25 mm, 0.2 µm film thickness; Supelco Inc., Bellefonte, PA). The temperature of the injector and FID was 270°C. A split (1:11) injection mode was used. The carrier gas was helium with a column flow of 1.2 mL/min. The initial oven temperature was 70°C for 0.5 min, and the temperature programming was as follows: a rate of 15°C/min to 160°C; 1.5°C/min to 200°C, which was maintained for 15 min; and finally 30°C/min to 225°C, which was maintained for 5 min.

Regiospecific analysis of the structured oils was performed by degradation with allylmagnesium bromide as Grignard reagent (26). The *sn*-2-MAG fraction was isolated by TLC on boric acid-impregnated plates developed twice (2 × 60 min) in chloroform/acetone (90:10 vol/vol), transesterified into FAME, and analyzed by GLC as described above. The FA profiles of TAG and *sn*-2-MAG are listed in Table 1.

TAG species of the oils were analyzed by RP-HPLC. A high-performance liquid chromatograph (JASCO Corporation, Tokyo, Japan) was used with two pumps, a solvent-mixing module, an autosampler, and an ELSD (Sedere, Alfortville, France) operated at 40°C at a gas pressure of 2.2 bar. The separation was performed on a Supelcosil LC-C$_{18}$ column (l = 25 cm, i.d. = 4.6 mm, particle size = 5 µm; Supelco Inc., Bellefonte, PA) with a binary solvent system of acetonitrile (solvent A) and isopropanol/hexane (solvent B, 2:1 vol/vol) (27). A linear gradient of solvent B from 25 to 40% for 15 min, followed by an increase to 45% for another 25 min was applied at a flow rate of 1 mL/min. The structured lipid samples were dissolved in chloroform, and 10-µL aliquots were injected for analysis. The TAG species were expressed in terms of relative percentages of the total TAG after normalization to 100.

TAG species were identified by their equivalent carbon numbers (ECN) and confirmed by LC-MS (HP 1100 Series LC/MSD system; Hewlett-Packard, Waldbronn, Germany) as described by Mu and Høy (28). The column and solvents were as described above. Separation occurred according to chain length and saturation of the acyl chains; for example, it was impossible to distinguish between linoleic acid and CLA. However, only a small amount of linoleic acid was present in the substrates and products as determined by GLC (Table 1). The TAG species are listed in Table 2.

Animals. The experiment was performed with male Wistar

[b]A dash (—) indicates "not detected."

rats (Taconic M&B, Ll. Skensved, Denmark). The animals were acclimatized for a minimum of 10 d. They were housed in polyethylene cages, each with 2 rats, and fed a commercial pelleted rat diet (Altromin no. 1324; Chr. Petersen A/S, Ringsted, Denmark) containing approximately 4 wt% fat. The feed was removed just prior to surgery. The room was illuminated to give a cycle of 12 h light and 12 h darkness, and the temperature control was $21 \pm 3°C$ and RH $55 \pm 15\%$. At the time of surgery, the rats weighed 292 ± 2.3 g (mean ± SEM).

Collection of lymph. The Danish National Committee for Animal Experiments approved the experiment.

Rats were anesthetized intramuscularly with a combination of zolazepam, xylaxin, and butorphanol (Zoletil solution 0.06 mL/100 g; Royal Veterinary and Agricultural University, Frederiksberg, Denmark), and were subjected to cannulation of the main mesenteric lymph duct (29) with clear vinyl tubing (i.d. 0.5 mm, o.d. 0.8 mm; Dural Plastics and Engineering, Crictley Electrical Products Pty. Ltd., NSW, Australia). A gastrostomy tube (silicone tubing i.d. 1.0 mm, o.d. 3.0 mm; Polystan, Værløse, Denmark) was inserted 2 cm into the fundus region of the stomach and fixed with a purse-string suture. After surgery the rats were placed in individual restraining cages (30) and given 0.05 mL of a 5 mg/mL atipamezol solution (Antisedan, Orion, Espoo, Finland). They were kept hydrated by infusion of 2 mL/h of a saline–glucose solution (0.15 M NaCl + 4 mM KCl + 0.28 M glucose) administered through the gastrostomy tube and with free access to drinking water. Six hours after surgery and during the experiment, the rats received 0.3 mL of a 5 mg/mL carprofen solution (Rimadyl® Vet; Vericore Ltd, Dundee, Scotland) and 0.2 mL of a 5 mg/mL diazepam solu-

tion (Stesolid; Dumex-Alpharma A/S, Copenhagen, Denmark) to reduce pain and stress.

The rats recovered from surgery overnight. The following day, 270 mg of test oil was administered as a bolus through the gastrostomy tube followed by 0.5 mL of saline. One-hour lymph samples were collected from –1 h (i.e., 1 h prior to fat administration) to 8 h, one sample was collected from 8 to 23 h, and a 23- to 24-h sample was collected. The lymph was collected at room temperature in nontransparent tubes containing 100 μL (700 μL for overnight fractions) 10% (wt/vol) $Na_2EDTA \cdot 2H_2O$ solution. The samples were stored at $-20°C$ until analyzed.

Statistical analysis. Results are expressed as mean ± SEM. The incremental area under the curve from 0 to 8 h [IAUC, using the trapezoidal rule (31)] was used to compare lymphatic transport among the groups.

Recoveries of total and individual FA were calculated using an internal standard (TAG 15:0, added to lymph samples before extraction). The recovery was calculated as the amount of a FA found in lymph divided by the amount of the same FA in the oil, multiplied by 100. By doing this, differences in CLA and 8:0 contents between the oils were eliminated. The recovery calculations included a contribution of endogenous FA transported in the lymph; thus, recoveries could exceed 100%. Significant differences among groups of IAUC and recoveries were determined using one-way ANOVA. A Newmann–Keuls multiple comparison test was used to determine the exact nature of the differences. The computer program, GraphPad PRISM (version 3.02; GraphPad Software, San Diego, CA) was used for all calculations. The level of statistical significance was $P < 0.05$.

[a]TAG species of the eight enzymatically interesterified oils: C in group 1 is a mixture of CLA c9,t11 and CLA t10,c12, and C in group 2 is mainly CLA t10,c12; M is 8:0 and O, 18:1n-9. ECN, equivalent carbon number.
[b]A dash (—) indicates "not detected."

RESULTS

FA profiles of interesterified oils. FA compositions of TAG and *sn*-2-MAG of the interesterified oils are shown in Table 1. CLA in four of the oils was a mixture of the two isomers *c*9,*t*11 and *t*10,*c*12 (MCM-1, CMC-1, OCO-1, and COC-1; group 1), whereas in the other four oils CLA was primarily the isomer *t*10,*c*12 (MCM-2, CMC-2, OCO-2, and COC-2; group 2). The total content of CLA in the oils containing both CLA and MCFA was 57.7, 43.0, 70.3, and 60.5 mol% in MCM-1, CMC-1, MCM-2, and CMC-2, respectively, and the content of CLA in the *sn*-2 position was 70.4, 6.9, 96.0, and 8.0 mol%, respectively. Similarly, for the oils containing CLA and 18:1n-9, total CLA was 45.4, 35.0, 52.7, and 43.3 mol% for OCO-1, COC-1, OCO-2, and COC-2, respectively, and in the *sn*-2-position the content was 67.3, 4.1, 86.5, and 4.8 mol%, respectively. These were not the expected results for the oils, but the compositions of the *sn*-2-FA show that a large part of the CLA in the MCM and OCO oils was located in this position, whereas this was 8 mol% or less in the CMC and COC oils. However, owing to a high (MCM and OCO oils) and respectively low (CMC and COC oils) total CLA incorporation, the content of CLA in the outer positions of the MCM and OCO oils was higher and those of CMC and COC were lower than expected.

TAG species. The TAG species of the oils are listed in Table 2, and a chromatogram of the TAG species in the CMC-2 oil is shown in Figure 1. The original TAG, which was CCC for the OCO-1 and OCO-2 oils and OOO for the COC-1 and COC-2 oils, represented 3–17% of the product highest in COC-1 and lowest in COC-2, whereas MMM, the original TAG of the CMC

oils, constituted only 0.8%. In the OCO-1 oil, 31% was the desired TAG species (COO), and 38% was the CCO species. Similarly, for the COC-1 oil 30% was the desired product (CCO) and 30% was the COO species. The MCM-1 production resulted in a wide range of TAG species, with 12% MMC. The analyses of
FIG. 1. Chromatogram of TAG species of the CMC-2 oil analyzed by reversed-phase HPLC. CMC, structured TAG with CLA primarily in the *sn*-1/3-positions and 8:0 in the *sn*-2-position.

the oils in group 2 showed that the desired TAG species in the MCM-2, CMC-2, OCO-2, and COC-2 oils constituted, respectively, 24 (MMC), 51 (MCC), 27 (COO), and 34% (CCO) of the total species.

Lymphatic transport. The lymphatic transport of total FA showed a slow increase from the time of oil administration to 1 h after oil administration (Fig. 2). The increase continued at a higher rate from 1–2 h, with the maximum transport appearing between 2 and 6 h for group 1 and between 2 and 3 h for group 2, followed by a slower decrease toward baseline in both groups. The lymphatic transport of total FA measured as the IAUC in group 1 was significantly higher in rats fed OCO-1 and COC-1 compared with rats fed CMC-1 ($P < 0.05$), and tended to be higher in rats fed MCM-1 than rats fed CMC-1 ($P = 0.08$, Fig. 2A). In group 2 the total FA transport was similar except for OCO-2, which had a higher transport of total FA than CMC-2 ($P < 0.05$, Fig. 2B). After 24 h,

the lymphatic transport of total FA in all groups had returned to baseline.

Recoveries. In group 1 the recovery of total FA tended to be lower in the lymph fractions after 6 and 7 h ($P < 0.1$) and was significantly lower at 8 h ($P < 0.05$) in the CMC-1 group than in the OCO-1 and COC-1 groups. In the other lymph fractions and among the other groups, the recoveries of total FA were similar (Fig. 3A). The recoveries of the individual CLA isomers ($c9,t11$ and $t10,c12$) were similar in all groups at 24 h. At 8 h, however, the recovery of each of the two isomers tended to be lower in the CMC-1 than in the COC-1 ($P < 0.1$).

In group 2 the recoveries of total FA were significantly different from 4 to 8 h ($P < 0.05$) between the CMC-2 and OCO-2 groups, whereas the recoveries of both CLA $c9,t11$ and CLA $t10,c12$ tended to be different between the CMC-2 and OCO-2 groups ($P < 0.09$) after 4 h. At 24 h the recoveries of CLA $c9,t11$, CLA $t10,c12$, and total FA were similar both in group 1 and group 2—between 50 and 70% for CLA and 70 and 115% for total FA (Fig. 3).

The recovery of 8:0 differed among groups depending on the TAG structure (Fig. 4). The recovery of 8:0 was similar in all four groups until 5 h after oil administration, after which the curves diverged; CMC-1 and CMC-2 continued to increase slowly, whereas the curves for MCM-1 and MCM-2 did not increase further from 4 h after oil administration. The highest recovery was observed when CMC was administered to the rats, which was about 12–13% compared with only about 4–5% in the MCM groups after 24 h. Already after 6 h, significant differences appeared among groups fed the two oil types ($P < 0.05$).

FIG. 2. Lymphatic transport of total FA over 24 h in rats administered enzymatically interesterified oils: MCM, CMC, OCO, and COC, with M as 8:0 and O as 18:1n-9. In group 1, C was CLA as a mixture of the two CLA isomers $c9,t11$ or $t10,c12$, and in group 2, C was mainly the isomer $t10,c12$. (A) Incremental area under the curve (IAUC) for 0–8 h was significantly higher in the OCO-1 and COC-1 groups than in the CMC-1 group ($P < 0.05$), $n = 4$–5. (B) IAUC for 0–8 h was significantly higher in the OCO-2 group compared with the CMC-2 group ($P < 0.05$), $n = 5$–6. MCM, structured TAG with the major proportion of CLA in the sn-2-position and 8:0 in the sn-1/3-positions; OCO, structured TAG with CLA primarily in the sn-2-position and 18:1n-9 in the sn-1/3-positions; COC, structured TAG with the major proportion of CLA in the sn-1/3-positions and 18:1n-9 in the sn-2-position; for other abbreviation see Figure 1.

DISCUSSION

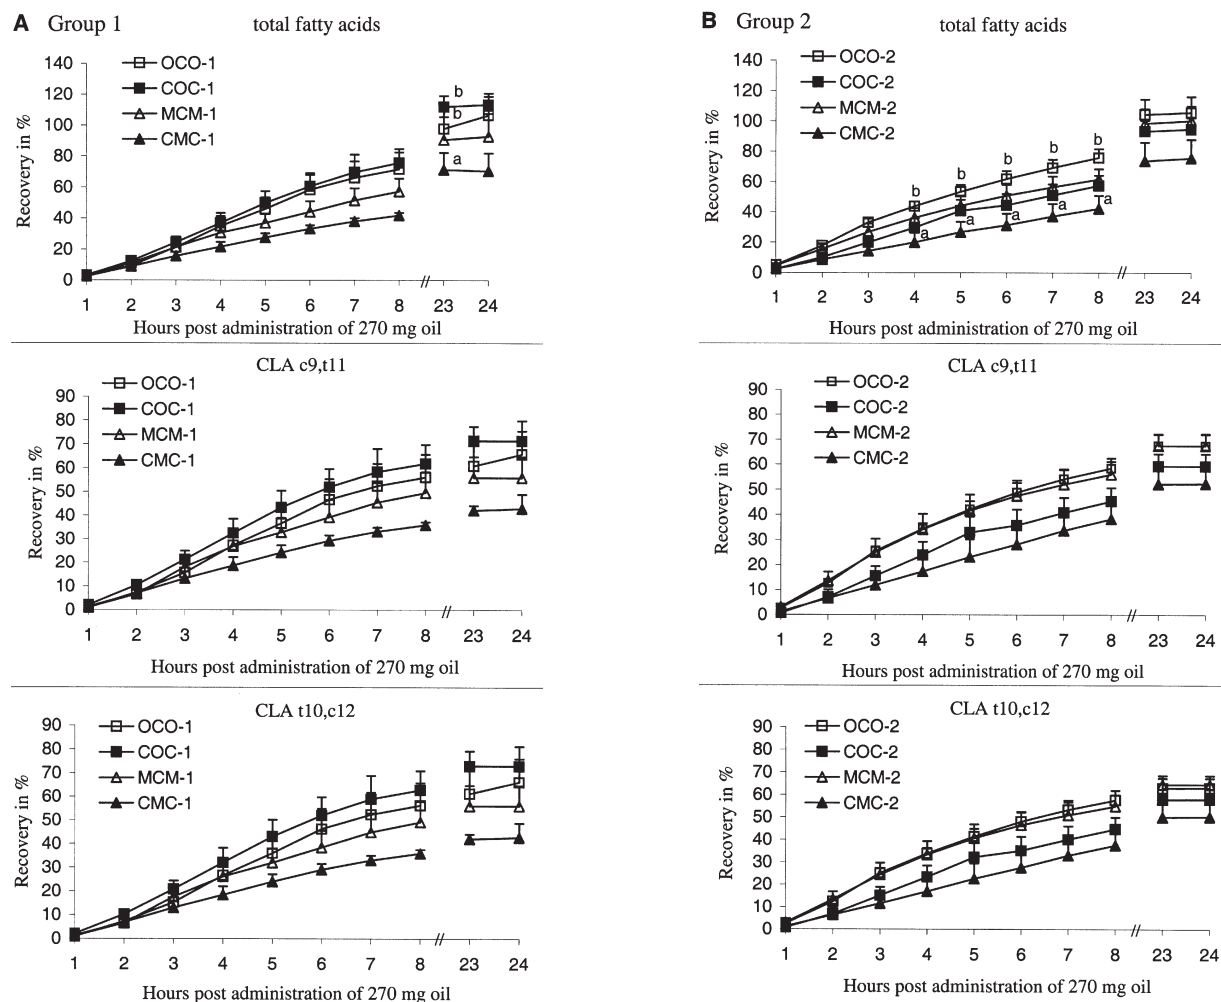
The recoveries of the two CLA isomers, $c9,t11$ and $t10,c12$, were similar during 24 h, independent of the FA profile of the TAG, demonstrating that TAG containing CLA were well hydrolyzed and absorbed in the intestines of rats with normal absorption. However, there was a tendency for CLA from an oil containing MCFA primarily in the sn-2-position (CMC oils) to be transported more slowly than CLA from an oil containing only LCFA (OCO-1, COC-1, and OCO-2 oils). This difference in the recovery of FA was significant for total FA, especially after 4 h, as observed in group 2, and was probably not due to the hydrolysis rate of the TAG, because the difference did not occur until after 4 h. In the intestine, the TAG are hydrolyzed to sn-2-MAG and FFA. In LML oils (where L is LCFA) the MCFA in the sn-2-position tends to migrate to the sn-1/3 positions of the TAG (32,33) and then is substrate for the pancreatic lipase. The products of hydrolysis will be three FFA and glycerol instead of 2-MAG and two FFA. This results in a lack of 2-MAG for the resynthesis of TAG in the enterocytes and a delayed or lower absorption of the fat, a tendency we saw in our study for the CMC oils both in lymphatic transport and recoveries. Jensen *et al.* (34) reported that the conservation of MCFA in the sn-2-MAG after absorption was about 40%, whereas Åkesson *et al.* (35) reported that this was 75% for


FIG. 3. Lymphatic recovery of total FA, CLA *c*9,*t*11, and CLA *t*10,*c*12 from oils containing M as 8:0 and O as 18:1n-9. (A) C was a mixture of CLA *c*9,*t*11 and CLA *t*10,*c*12, and (B) C was primarily CLA *t*10,*c*12. Curves with different letters at similar time points are significantly different ($P < 0.05$), and curves without letters are similar to the other curves. $n = 4$–6. For abbreviations see Figures 1 and 2.

LCFA. Jensen *et al.* (34) used a mixture of MCFA containing twice as much 8:0 as 10:0, and Mu and Høy showed that 10:0 was transported by the lymph in rats to a higher degree than 8:0 (36). In the present study the conservation of the *sn*-2-MAG FA from CMC oils may therefore be less than 40%. This was supported by the 12% recovery of 8:0 in the lymph after 24 h. When *sn*-2-MAG is lacking for the resynthesis of TAG, the pathway shifts from the *sn*-2-MAG pathway to the glycero-3-phosphate pathway, which uses glycerol and three FFA to synthesize TAG in the intestine (37). This pathway, however, has to be up-regulated before resynthesis can occur, resulting in slower formation of TAG and therefore a slower secretion of chylomicrons into the bloodstream.

In agreement with our results, Ikeda *et al.* (20) observed a higher lymphatic transport of 8:0 when it was present in the *sn*-2-position of the TAG than when it was located in the outer positions. Furthermore, they observed a similar absorption of linoleic acid following administration of MLM, LML, or LLL oils to rats with normal absorption.

Because MCFA (as 8:0 and 10:0) as FFA are transported pri-

marily *via* the portal vein (38) to the liver, structured fats containing MCFA in the outer positions of the TAG molecules will be short of FFA for TAG resynthesis after hydrolysis. This results in an increased utilization of endogenous FA for TAG resynthesis in the enterocytes, and may delay the lymphatic transport of exogenous fat (18). These observations were emphasized by the present study, since we recovered only 4–5% 8:0 in the lymph after administration of the MCM oil. A recent study by Porsgaard *et al.* (39) showed a faster *in vitro* pancreatic lipase hydrolysis of fish oil compared with MLM and LML oils containing n-3 long-chain PUFA. This correlated well with a faster absorption of the fish oil compared with the two structured oils, and the authors concluded that the absorption was highly influenced by the lipase hydrolysis rate. These results are partly in agreement with the present results; however, we observed similar recovery of the different oils after 4 and 8 h, with a tendency toward lower recovery of the CMC oil. These discrepancies may be due to all our oils being interesterified, whereas the LLL oil in the experiment by Porsgaard *et al.* used natural fish oil.
FIG. 4. Lymphatic recovery of 8:0 from the enzymatically interesterified oils MCM-1, MCM-2, CMC-1, and CMC-2, with M as 8:00 and C as a CLA mix in group 1 and as CLA $t10,c12$ in group 2. Recoveries of 8:0 were calculated as 8:0 gained in the lymph relative to that in the oil. An asterisk (*) shows significant differences ($P < 0.05$) between the curves for the MCM groups and those for the CMC groups, $n = 4–6$. For abbreviations see Figures 1 and 2.

A previous study (13) showed that CLA $c9,t11$ is absorbed better from the sn-1/3-positions than from the sn-2-position. Our results cannot confirm these observations, probably because our oils with the majority of CLA in the sn-2-position had a relatively high content of CLA in the sn-1/3-positions compared with CLA in the sn-2-position. However, the oils with CLA located in the sn-1/3-positions (CMC and COC oils) contained only small amounts of CLA in the sn-2-position. Furthermore, in the study by Chardigny *et al.* (13), absorption and excretion were measured as radioactivity, which is a very sensitive method.

We observed recoveries of CLA of 50–70%, which is lower than the recovery of oleic acid (86.5%) observed by Yanagita *et al.* (40) in thoracic lymph duct-cannulated rats. However, the recovery of 50–70% of the two CLA isomers after 24 h was similar to the recovery of linoleic acid (41,42) and was similar in all groups. Therefore, the FA and the position of CLA in the TAG did not seem to influence the absorption and transport of CLA on a long-term basis (24 h) in rats with normal absorption. Furthermore, these results showed no discrimination in the absorption of the two CLA isomers. The incorporation of the two CLA isomers into tissues has been shown to be selective, with a preference for the incorporation of CLA $c9,t11$ compared with CLA $t10,c12$, but this discrimination was not observed in enterocytes of rats fed a butter-rich diet and therefore probably did not appear before the absorption was finished and when FA had reached the blood circulation (Lund, P., Sejrsen, K. and Straarup, E.M., unpublished results). Our observation is in accordance with that of Martin *et al.* (40), who found that the two main CLA isomers ($c9,t11$ and $t10,c12$) were equally well transported through the lymphatic pathway when administered as TAG.

On the other hand, the position of 8:0 in the TAG influenced the lymphatic transport of 8:0, as shown by the higher recovery of this FA when administered as CMC oils compared with

MCM oils. In agreement with the foregoing discussion, this shows that the sn-2-MAG MCFA was preserved to some extent and not fully hydrolyzed in the CMC oils.

A specific structure of the TAG with MCFA in the outer positions and LCFA in the sn-2-position has previously been shown to improve the absorption of fat in malabsorbing and, to some degree, in normal rats (18,19). However, the specificity of the oil is very important for absorption; the best results were obtained with most of, or preferably all, the MCFA located in the sn-1/3-positions and the LCFA in the sn-2-position. Furthermore, the effect of structure was mainly observed in malabsorption, where the sn-3-specific gastric lipase with a preference for short and MCFA may play an important role (5). As previous studies (20,43) show, the structure of TAG is almost without importance for the absorption of specific FA (e.g., CLA, n-3) under normal absorption conditions when MCFA are present in the outer positions of the TAG molecules, whereas when they are present in the sn-2-position, the tendency was for the absorption to be slowed or even decreased. We observed no differences in the absorption of CLA from our oils, although the CMC and COC, compared with the OCO, had different structures regarding the position of CLA in the TAG, with very little CLA in the sn-2-position of the former oils. However, structured TAG containing MCFA in the outer position may increase the uptake of FA, e.g., as in LCFA as EFA, in malabsorption conditions, and could therefore be of great importance in the clinical treatment of these patients.

Preferential Effect of Lead Exposure During Lactation on Non-Essential Fatty Acids in Maternal Organs

Sun-Young Lim[a], James Loewke[b], John D. Doherty[c], and Norman Salem, Jr.[b,*]

[a]Division of Marine Environment & Bioscience, Korea Maritime University, Busan, Republic of Korea, [b]Laboratory of Membrane Biochemistry and Biophysics, National Institute on Alcohol Abuse and Alcoholism (NIAAA), National Institutes of Health (NIH), Rockville, Maryland, and [c]U.S. Environmental Protection Agency, Office of Pesticide Programs, Health Effects Division, Washington, D.C.

ABSTRACT: This study determined the effects of lead exposure during the lactational period on maternal organ FA compositions in rat dams that were fed either an n-3 adequate (n-3 Adq) or deficient (n-3 Def) diet prior to conception. On giving birth, dams were subdivided into four groups in a 2×2 design with n-3 FA supply and Pb exposure as the dependent variables. Pb acetate (0.2 wt%) was administered in the drinking water from the time they gave birth to weaning 3 wk later. Following weaning, the dams were decapitated. and the liver, plasma, kidney, brain, and retina analyzed for FA composition. The n-3 deficient diets markedly decreased the percentages of total n-3 FA, including docosahexaenoic acid (DHA), and increased total n-6 FA including both arachidonic (AA) and n-6 docosapentaenoic acids in all tissues ($P < 0.05$). The principal effects of Pb occurred in the liver and plasma, where 20–32% losses in total FA concentration concurrent with increased relative percentages of AA ($P < 0.05$) were observed. In kidney, the percentages of AA and DHA also increased after Pb exposure ($P < 0.05$) with lesser effects in the nervous system. There was a diet × Pb interaction for liver, plasma, and retinal 20-C n-6 PUFA ($P < 0.05$). Generally, shorter-chain saturated and monounsaturated FA concentrations were decreased after Pb exposure. An analysis of the changes in the tissue concentrations induced by Pb indicated that the increases in the percentages of PUFA likely reflected a preferential loss of non-EFA. The mechanisms by which Pb affects saturated and monounsaturated FA concentration are unknown.

Paper no. L9720 in *Lipids 40*, 685–693 (July 2005).

Recent experiments from our laboratory have tested the hypothesis that dietary deficiency in n-3 FA may worsen the impact of other developmental challenges. More specifically, the hypothesis tested was that low dietary intakes of n-3 FA during fetal and postnatal growth would worsen performance on behavioral tasks in animals exposed to high levels of lead (Pb)

Abbreviations: AA, arachidonic acid, 20:4n-6; DGLA, dihomo-γ-linolenic acid, 20:3n-6; DHA, docosahexaenoic acid, 22:6n-3; DMA, dimethyl acetal derivative; DPAn-3, n-3 docosapentaenoic acid, 22:5n-3; DPAn-6, n-6 docosapentaenoic acid, 22:5n-6; DTA, docosatetraenoic acid, 22:4n-6; EFA, essential fatty acid; EPA, eicosapentaenoic acid, 20:5n-3; FA, fatty acid, GLA, γ-linolenic acid, 18:3n-6; LA, linoleic acid, 18:2n-6; LNA, α-linolenic acid, 18:3n-3; n-3 Adq-Na, n-3 adequate and Na control group; n-3 Adq-Pb, n-3 adequate and Pb exposure group; n-3 Def-Na, n-3 deficient and Na control group; n-3 Def-Pb, n-3 deficient and Pb exposure group; NIAAA, National Institute on Alcohol Abuse and Alcoholism; NIH, National Institutes of Health.

via lactation (1). Both Pb exposure (2) and a lower n-3 intake (3,4) are developmental risks that frequently occur together in lower income, urban populations, and so a lower n-3 FA status may exacerbate adverse effects of Pb. Or, from a different perspective, higher n-3 status may serve to counteract some of the adverse effects of Pb on neurodevelopment. A deficit in n-3 FA intake during the fetal or early postnatal period leads to a loss of brain DHA and suboptimal nervous system development as reflected by poorer performance in a variety of behavioral tasks (5–7). Similarly, Pb exposure during early development leads to a variety of neurodevelopmental abnormalities (8–10).

In the experiments of Lim and colleagues, rat pups lactating to dams receiving Pb in their drinking water were examined both for performance on spatial tasks and olfactory discriminations (1) and for the FA compositions of various organs (11). Although both Pb exposure and DHA deficiency led to poorer performance in the probe trial of the Morris water maze and in the olfactory reversal task, no protective effect of higher n-3 FA intake was apparent. It was also observed, in the acquisition of two-odor olfactory discriminations, that Pb exposure and n-3 FA deficiency led to behavioral deficits and produced additive effects. Even though Pb exposure was discontinued at 3 wk of age, some of the effects on organ FA compositions noted at weaning persisted until adulthood. At weaning, the liver was the most affected organ: total FA concentrations were decreased by 56% after Pb exposure. The percentages of liver arachidonic acid (AA, 20:4n-6) and DHA (22:6n-3) were increased but the tissue concentrations were not different after Pb exposure as non-EFA were lost.

In these previous experiments, pups were exposed to Pb indirectly, as Pb was administered to the dams in drinking water during the lactational period. In the present study, our aim is to examine the direct effects of both dietary deficiency in n-3 FA and Pb exposure on the dam tissues with respect to their FA compositions. A 2×2 study design was implemented with Pb and n-3 FA as the dependent variables and with FA analyses performed for plasma, brain, retina, liver, and kidney.

MATERIALS AND METHODS

Animals and study design. Animals were bred and raised as previously described (1). Briefly, 120 Long-Evans female rats (F1) were raised from 3 wk of age on either an n-3 FA adequate (n-3 Adq) or n-3 FA deficient (n-3 Def) diet (see the following

[d]DHASCO is a trademark of Martek Biosciences Corp. (Columbia, MD) and contains approximately 45% of FA as DHA.
[e]Only trace quantities of long-chain polyunsaturates including 20:4n-6, 20:5n-3, and 22:5n-3 were detected (ND), i.e., less than 0.01%. Other minor peaks were not included.

section). At birth, half of the dams (F1) in each dietary group were given either a 0.2% by weight lead acetate trihydrate solution or a 0.2% by weight solution of sodium acetate (Aldrich Chemical Company, Milwaukee, WI) for their drinking water. This dose was similar to that given in previous studies (12–14). These solutions were maintained for their drinking water until the pups (F2) were weaned at postnatal day 21. The four groups of dams were designated as n-3 Adq-Na, n-3 Adq-Pb, n-3 Def-Na, and n-3 Def-Pb to identify the n-3 FA intake in the diet (n-3 Adq or n-3 Def) and treatment with either Pb acetate (Pb) or sodium acetate (Na). Pb exposure was discontinued after weaning (day 21), and the dams were sacrificed 4 d later on postnatal day 25. Generally, 6 dams were used per group. This experimental protocol was approved by the Animal Care and Use Committee of the NIAAA, NIH.

Experimental diet. The experimental diets (Table 1), n-3 Adq and n-3 Def, were based on the AIN-93G formulation (15) with several modifications to obtain the extremely low n-3 FA level required in this study. Custom pelleted diets were commercially prepared using a cold-pressing process to preserve PUFA (Dyets, Bethlehem, PA). The critical difference between the n-3 Adq and n-3 Def diets was the presence of the n-3 FA, α-linolenic acid (LNA) and DHA. The total fat content in both

diets was 10 wt%, and the amount of LNA in the n-3 Def and n-3 Adq diets was 0.09 and 3.0% of total FA, respectively, with the n-3 Adq diet also containing 1.45% DHA. There was no difference in linoleic acid (LA) content between the two diets.

Lipid composition. Shortly after weaning, the dams (now 18 wk of age) were decapitated, and their organs (brain, liver, and kidney) were weighed and quickly frozen (−80°C) for subsequent analyses for lipid composition. Blood was collected into centrifuge tubes containing EDTA (10.8 mg/tube) and immediately centrifuged at $1000 \times g$ at 4°C, and the plasma was removed for analysis. The Pb concentration was measured by a commercial laboratory (Antech Diagnostics, Farmingdale, NY), using atomic absorption spectrometry on whole blood samples. Lipid extraction (16), FA transmethylation (17), and GC analysis (18) of FA profiles were performed as previously described.

Statistical analysis All data were expressed as the mean percentage or concentration of total FA ± SEM, and significance was determined by two-way ANOVA with interactions for diet and Pb exposure effects using Statistica (StatSoft, Tulsa, OK). When the *F*-test was significant ($P < 0.05$), comparisons among groups were performed using Tukey's HSD (Honest Significant Difference) test.

RESULTS

Body and organ weight. Lead exposure affected the dam body, brain, and liver but not kidney weights (Table 2). After weaning, dams fed either the n-3 Adq-Pb or n-3 Def-Pb diets were 17 or 18% smaller based on body weight, respectively ($P < 0.05$), with 18 or 14% lower liver weights, respectively ($P < 0.05$), in comparison with those in the respective Na groups. There was a main effect of Pb on brain weight with the mean values showing a 5% difference between the two n-3 Adq groups and a 14% difference between the two n-3 Def groups ($P < 0.05$). Pb exposure led to a significantly increased ratio of kidney to body weight particularly in the n-3 Adq group ($P < 0.05$). The kidney weights were similar in the Pb-exposed groups to the control groups in spite of the decrease in body weight in those exposed to Pb. There was also a main effect of diet on body and liver weight, but not brain and kidney weight. Body and liver weights in the n-3 Def groups were lower than in the n-3 Adq groups ($P < 0.05$).

At weaning (3 wk), the brains of pups exposed to Pb during lactation exhibited Pb concentrations of 7.17 ± 0.47 in the n-3 Adq and 6.49 ± 0.63 nmol Pb/g wet weight in the n-3 Def diets, and Pb was at background levels in the Na groups. Brain Pb concentrations were not available for the dams; however, the mean whole blood Pb concentration for dams was 14.9 ± 2.7 μmol/L for the two Pb groups combined and the Na groups were at the background level of 0.005 μmol/L.

Effects of diet on FA compositions. The total FA concentrations of the liver, plasma, kidney, or retina did not differ between the n-3 Def and the n-3 Adq groups, but the brain total FA concentrations were significantly greater in the n-3 Adq groups. As expected, the percentages of total and many individual n-3 FA were reduced in all tissues studied for both groups given the n-3

TABLE 2
Effect of Pb Exposure and n-3 FA Deficiency on Body and Organ Weights in 18-wk-old Dams[a]

[b]Percentage of FA
[c]Concentration of FA.

Def diets (Tables 3–7). In the n-3 Def groups, a very marked effect was observed with much lower percentages of total n-3 FA in the livers (≥90%, Tables 3), plasma (≥94%, Table 4), or kidney (≥91%, Table 5) relative to the n-3 Adq groups ($P < 0.05$). However, although the brain (Table 6) and retina (Table 7) also showed significantly lower percentages of total n-3 FA in the n-3 Def groups (18–26% lower for brain and 31–39% lower for retina, $P < 0.05$), these effects were of a lower magnitude than the peripheral tissues. Most of the decrease in total n-3 FA percentages could be accounted for by a lower percentage of DHA. In liver, plasma, and kidney, LNA, EPA (20:5n-3), and n-3 docosapentaenoic acid (DPAn-3, 22:5n-3) were also markedly lower in the n-3 Def group ($P < 0.05$).

Replacing the n-3 FA in the n-3 Def group was a higher percentage of n-6 FA. Within the n-6 FA family, there were large increases in the n-6 docosapentaenoic acid (DPAn-6, 22:5n-6) percentage in all tissues in the n-3 Def group ($P < 0.05$). For example, the DPAn-6 content was 3.47 and 9.08% in brain and retina, respectively, in the n-3 Def-Na group but was 0.28% for brain (Table 6) and 0.18% for retina (Table 7) in the n-3 Adq-Na group. A 38-fold difference between the n-3 Adq and n-3 Def groups in the concentration of DPAn-6 was evident in the liver (Table 3). Also, there were several significant changes in the major n-6 species AA and LA ($P < 0.05$). The AA percentages were higher in the liver (92%), plasma (61%), kidney (38%), brain (18%), and retina (30%) in the n-3 Def groups.

[a]Values are mean ± SEM, $n = 6$. *Significant effect of diet, $P < 0.05$; [†]significant effect of Pb exposure, $P < 0.05$; significant diet × Pb exposure interaction. Means with different alphabetical superscripts are significantly different by Tukey's HSD test at $P < 0.05$.
[b]Percentage of FA.
[c]Concentration of FA. ND, not detected.

The docosatetraenoic acid (DTA, 22:4n-6) percentage was also higher in all tissues in the n-3 Def group, with the brain exhibiting a 38% and retina an 87% higher content ($P < 0.05$). However, an exception to the generally higher tissue percentage of n-6 FA in the n-3 Def groups was LA, for which a lower percentage was found in the liver (24%), plasma (22%), kidney (19%), and brain (27%) ($P < 0.05$). In most cases, with the exception of liver and retina, there was also a lower concentration of dihomo-γ-linolenic acid (DGLA, 20:3n-6) in the n-3 Def group ($P < 0.05$). In general, there were no main effects of diet on the tissue concentrations of saturated and monounsaturated FA. However, the percentages of liver total saturated FA

for the n-3 Adq groups were lower than those of the n-3 Def groups ($P < 0.05$).

Pb effects on liver FA composition. The effects of Pb on the FA composition were most pronounced in the liver (Table 3) where Pb exposure resulted in increased percentages of total n-6 (67% in the n-3 Adq-Pb and 28% in the n-3 Def-Pb group) and total n-3 (39% in the n-3 Adq-Pb and 49% in the n-3 Def-Pb group) FA ($P < 0.05$). Within the n-6 FA family, γ-linolenic acid (GLA, 18:3n-6), AA, and DTA were increased by Pb exposure. Liver DHA was 37% higher in the n-3 Adq-Pb and 52% higher in the n-3 Def-Pb relative to their respective Na-control groups. A significant decline in saturated FA after Pb

[a]Values are mean $\pm$ SEM, $n = 6$. *Significant effect of diet, $P < 0.05$; [†]significant effect of Pb exposure, $P < 0.05$; Significant diet $\times$ Pb exposure interaction. Means with different alphabetical superscripts are significantly different by Tukey's HSD test at $P < 0.05$.
[b]Percentage of FA.
[c]Concentration of FA.

exposure occurred for 12:0, 14:0, and 16:0, however, the percentages of 20:0, 22:0 and 24:0 were increased by Pb exposure ($P < 0.05$). Among monounsaturated FA, Pb exposure resulted in a significant decline in the percentages of 14:1 and 16:1 but increases in 24:1n-9 ($P < 0.05$). There were interactions between Pb $\times$ diet for several n-6 and n-3 FA in the liver with significant interactions of Pb $\times$ diet for DGLA, DPAn-6, and DPAn-3 ($P < 0.05$).

The concentration of total FA was significantly decreased by 32% in the livers of the n-3 Adq-Pb group in comparison with the n-3 Adq-Na group and, in the n-3 Def groups, Pb exposure led to a 30% loss in total FA concentration ($P < 0.05$). When the data were expressed in terms of concentration, there were significant losses of total saturates, monounsaturates, and DGLA in the Pb-exposed groups. As for the percentage data, there were Pb $\times$ diet interactions for the DPAn-3 and DPAn-6 FA. In addition, there was an interaction for the DGLA as Pb exposure led to a decrease in the n-3 Def group but an increase in the n-3 Adq group. Besides those just noted, no other polyunsaturate concentration was significantly altered by Pb exposure.

Pb effects on plasma FA composition. There were no main effects of Pb in the plasma on either the total saturated or the total n-3 FA in plasma (Tables 4). However, Pb exposure decreased total monounsaturated (32% decline for n-3 Adq-Pb and 21% decline for n-3 Def-Pb) and total FA concentrations (29% decline for n-3 Adq-Pb and 20% decline for n-3 Def-Pb) but increased total n-6 FA (25% for n-3 Adq-Pb and 11% for n-3 Def-Pb) ($P < 0.05$). Within the n-6 FA family, GLA and AA were increased by Pb exposure but DGLA was decreased. Plasma AA was 34% higher in n-3 Adq-Pb and 15% higher in n-3 Def-Pb relative to the Na-control groups. With respect to the saturated FA after Pb exposure, the 16:0 percentage was decreased but 20:0, 22:0 and 24:0 were increased ($P < 0.05$). Among monounsaturated FA, Pb exposure decreased the percentages of 16:1,

[a]Values are mean ± SEM, $n = 6$. *Significant effect of diet, $P < 0.05$; [†]significant effect of Pb exposure, $P < 0.05$; significant diet × Pb exposure interaction. Means with different alphabetical superscripts are significantly different by Tukey's HSD test at $P < 0.05$.
[b]Percentage of FA.
[c]Concentration of FA.

18:1n-9, 18:1n-7, and 20:1n-9 but increased the level of 24:1n-9 ($P < 0.05$).

When examined in terms of concentration, Pb exposure led to decreases in monounsaturates and total FA, but the decreased levels of saturates did not reach statistical significance. There were also significant decreases in LA, DGLA, and EPA concentrations due to Pb. There were interactive effects of Pb × diet for LNA and DHA.

Pb effects on kidney FA composition. In the kidney, there were main effects of Pb on total monounsaturated (9% decline for n-3 Adq-Pb and 12% decline for n-3 Def-Pb) and total n-6 (14% increase for n-3 Adq-Pb and 21% increase for n-3 Def-Pb) FA ($P < 0.05$) (Table 5). Pb exposure resulted in increased percentages of LA, docosadienoic acid (20:2n-6), and AA. For the monounsaturated FA, Pb exposure decreased the percentage of 16:1 but increased the percentage of 18:1-DMA (dimethyl acetal derivative) and 20:1n-9 ($P < 0.05$). Pb exposure

did not affect the percentages of total saturated or total n-3 FA or the total FA concentration. However, kidney DHA was increased by 21% in the n-3 Adq-Pb group and by 50% in the n-3 Def-Pb after Pb exposure ($P < 0.05$). Among the saturated FA, the percentages of 16:0-DMA, 18:0-DMA, 18:0, 20:0, and 22:0 after Pb exposure were increased, but the percentages of 10:0 and 16:0 were decreased by Pb exposure ($P < 0.05$). There was significant interaction between Pb × diet for the percentage of DPAn-6 in the kidney ($P < 0.05$).

When expressed in terms of concentration, Pb exposure led to a significant loss of monounsaturates, docosadienoic acid, and DGLA. The lower levels of saturates and total FA did not reach significance.

Pb effects on brain FA composition. There were no main effects of Pb exposure on total FA concentration, or the percentages of total monounsaturated, total n-6, or total n-3 FA in brain (Table 6). However, there was a diet × Pb exposure interaction for total

saturated FA and for 24:1n-9 ($P < 0.05$). The percentages of 12:0 and DGLA were decreased by Pb exposure, but 16:1 was increased ($P < 0.05$). In terms of concentration, both AA and DHA were increased by Pb exposure. In contrast to the responses observed in peripheral tissues, both saturated and monounsaturated FA concentration increased in Pb-exposed groups, but not significantly so.

Pb effects on retina FA composition. There were no main effects of Pb exposure on total FA, total saturated, total monounsaturated, or total n-6 FA in the retina either when expressed as a percentage or as a concentration (Table 7). However, there was a diet × Pb exposure interaction for 12:0 and several n-6 FA including 20:2n-6, DGLA, AA, and DTA ($P < 0.05$). The percentage of 20:1n-9 was decreased by Pb exposure ($P < 0.05$). As was observed in the brain, the DHA concentration was significantly increased after Pb exposure, and this led to a significant increase in total n-3 FA as well.

DISCUSSION

Lead exposure solely during the lactational period significantly altered the dam liver, plasma, and kidney FA composition but produced weaker effects on the nervous system tissues. In particular, the percentages of 20-C PUFA were increased by Pb exposure, with AA being most affected. As expected, the n-3 Def diets markedly decreased the percentages of total n-3 FA including DHA, and increased total n-6 FA including both arachidonic (AA) and DPAn-6 in all tissues.

It has been known that Pb exposure resulted in increased percentages of AA in rats (19), chickens (12,13,20,21), and humans (22). However, in a previous study of lactational Pb exposure (11), Lim *et al.* observed that pup liver AA and DHA at weaning were increased in terms of the percentages but that the organ concentrations of AA and DHA were not in fact different. In many of the previous studies of FA composition after Pb exposure, although only the percentage of FA was measured and no internal standard was used, the data are often discussed in terms of concentration (12,13,20–22), leading to much confusion. This is an especially unfortunate error since there are in fact both percentage changes in many FA subsequent to Pb exposure and changes in total FA absolute concentrations. Our tables are constructed to facilitate the comparisons of various PUFA expressed in both manners. Since Pb generally decreases the tissue total FA concentration, even those FA that appear to be increased when expressed as a percentage may in fact exhibit little or no change when the organ concentration is determined. The large increases in the percentages of polyunsaturates may then simply reflect a preferential decrease in non-EFA concentration.

In fact, when the concentration data are examined, our results show that there is no significant difference in AA concentration in maternal liver and plasma. More specifically, the percentage of liver AA was increased by 37% in the n-3 Adq-Pb group compared with the n-3 Adq-Na group, but the actual concentrations were 2.92 and 2.97 µg/mg, respectively. Similarly, the liver DHA concentrations in the two n-3 Adq groups were

unchanged, as they were 3.02 (Na) and 2.94 µg/mg (Pb). However, the concentrations of 16:0 and 18:0 fell rather precipitously in liver as did the monounsaturates 16:1 and 18:1 in the Pb-exposed groups. Qualitatively similar results were observed in the plasma and kidney. The nervous system was an exception to this. In both the brain and retina, DHA concentration was significantly increased by Pb exposure. Pb-induced increases in AA were also observed in both retina and brain, but only those in the brain were statistically significant. The nervous system was also distinct from the peripheral tissues in that non-EFA were not decreased and even rose somewhat subsequent to Pb exposure. It is apparent that Pb alters the FA profile in the nervous system in a different manner from that for peripheral tissues.

The mechanisms underlying these changes in essential and non-EFA composition are unclear. Previous discussions of Pb effects on FA have centered on lipid peroxidation as a result of the observation that high levels of Pb exposure in chicks led to increased production of malondialdehyde (20). However, peroxidative reactions would be expected to selectively remove PUFA species in preference to saturates and monounsaturates. In general, the opposite pattern is observed here in the dams and to an even greater extent in pups exposed to Pb through lactation (11), as non-EFA are lost in Pb-exposed animals in preference to EFA. Such a FA profile is also inconsistent with a hypothesis that Pb alters FA desaturation. A more straightforward interpretation of these results would be that the increased percentages of the highly unsaturated FA reflect preferential sparing of these lipids with respect to non-essential species. The loss of body weight in the Pb-exposed groups indicates that there may have been a decrease in food intake (although not measured here) associated with the high level of Pb in the drinking water. It is likely that non-EFA were then preferentially metabolized for energy as a consequence of Pb exposure.

One hypothesis to be tested was to determine whether an n-3 Def diet would lead to greater effects of Pb exposure on FA composition, or, alternatively, whether an n-3 Adq diet would lead to "protective" effects on FA composition of various tissues. Several interactions of the two key variables of this study, diet and Pb exposure, occurred mainly in the 20- and 22-carbon PUFA. For example, Pb exposure increased liver DPAn-6 and 22:5n-3 and kidney DHA concentrations in the n-3 Adq group, but not in the n-3 Def group. In plasma, Pb exposure reduced 18:3n-3, DHA, and total n-3 FA concentrations only in the n-3 Adq group. There were interactions between diet and Pb exposure for several of the n-6 PUFA in the retina including DGLA, AA, and 22:4n-6.

Another manner in which to examine protective effects of diet is to compare the magnitude of the principal changes in FA concentrations with or without Pb for the two diets (i.e., compare the FA concentrations for the groups as follows: $100 - $ [(Adq-Pb)/(Adq-Na) × 100] vs. $100 - $ [(Def-Pb/Def-Na) × 100]). In the dam liver, Pb exposure in the n-3 Def groups led to significant decreases in saturates, monounsaturates, DGLA, and total FA. The n-3 Adq diet led to a smaller Pb-induced loss for the monounsaturates and DGLA. Similarly, in the plasma,

the n-3 Adq diet led to a smaller Pb-induced loss of DGLA and EPA concentrations. Also, in the kidney, the n-3 Adq diet led to a smaller Pb-induced loss in monounsaturates and DGLA.

It is of interest to compare responses of the dam exposed to Pb through drinking water to that of her pups exposed *via* lactation (11). The main effect of Pb in the weanling pup liver was losses in saturates, monounsaturates, and total FA concentrations. In all three cases, the losses in the n-3 Adq group were considerably greater than those in the n-3 Def group. In the pups given the n-3 Adq diet, there was a significant interaction with Pb exposure for liver DHA and a 37% loss in the n-3 Adq group but a 60% increase in the n-3 Def group. In the dams, there was no effect of Pb exposure on DHA concentrations in either dietary group. Thus, the protective effects noted above for the n-3 Adq diet in the dam appeared to be lost for the pups exposed to Pb during lactation.

Fish Oil Fatty Acid Esters of Phytosterols Alter Plasma Lipids but Not Red Blood Cell Fragility in Hamsters

Isabelle Demonty, Naoyuki Ebine, Xiaoming Jia, and Peter J.H. Jones*

School of Dietetics and Human Nutrition, McGill University, Sainte-Anne-de-Bellevue, Québec, Canada, H9X 3V9

ABSTRACT: In an attempt to combine the hypocholesterolemic properties of plant sterols with the hypotriglyceridemic action of fish oil FA, plant sterols have recently been esterified to fish oil n-3 PUFA. The objective of this study was to determine the effects of plant sterols esterified to n-3 PUFA on plasma lipid levels and erythrocyte fragility. For 5 wk, male Golden Syrian hamsters were fed diets varying in cholesterol and plant sterol content: (i) Non-cholesterol (semipurified diet with no added cholesterol or plant sterols) (ii), Cholesterol (0.25% cholesterol) (iii), Sterols (0.25% cholesterol plus 1% nonesterified plant sterols), or (iv) Fish oil esters of plant sterols (0.25% cholesterol plus 1.76% EPA and DHA sterol esters, providing 1% plant sterols). The addition of fish oil esters of plant sterols to the cholesterol diet decreased ($P = 0.001$) plasma total cholesterol levels by 20%, but nonesterified plant sterols did not have such a beneficial impact. In addition, non-HDL cholesterol concentrations were 29% lower in hamsters fed fish oil esters of plant sterols than in hamsters fed nonesterified plant sterols ($P < 0.0001$). Despite higher ($P < 0.0001$) plant sterol levels in whole erythrocytes of hamsters fed nonesterified plant sterols and fish oil esters of plant sterols compared with hamsters fed no plant sterols, no difference was observed in erythrocyte fragility. The present results show that EPA and DHA esters of plant sterols have a hypocholesterolemic effect in hamsters, and that these new esters of plant sterols exert no detrimental effect on erythrocyte fragility.

Paper no. L9712 in *Lipids 40*, 695–702 (July 2005).

Elevated blood lipid concentrations, including increased levels of total and LDL cholesterol, as well as high TG concentrations, are among the major risk factors for cardiovascular disease (CVD) (1). In patients who do not respond to dietary changes by a significant decrease in cholesterolemia, an alternative approach to pharmaceutical intervention is supplementation with plant sterols. Recently, the National Cholesterol Education Program included the consumption of 2 g of plant sterols/stanols in its recommendations to lower elevated LDL cholesterol levels (2). Indeed, the lowering effect of plant sterols on plasma total and LDL cholesterol in humans is well documented (3). However, plant sterols do not have any beneficial impact on circulating TG levels (3,4). Thus, in patients presenting both elevated cholesterol and TG concentrations, plant sterols do not offer an optimal reduction in CVD risk.

Dietary components that do have a hypotriglyceridemic effect in humans and animal models are n-3 PUFA from fish oil (5,6). In an attempt to combine the hypocholesterolemic proper-

ties of plant sterols with the hypotriglyceridemic action of fish oil FA, plant sterols have recently been esterified to fish oil n-3 PUFA. Plant sterols are usually esterified to unsaturated FA from vegetable oils, which increases their solubility and allows their incorporation into fat-containing foods such as margarines. Whether the esterification of plant sterols with FA improves their hypocholesterolemic effect is still unclear (7). Preliminary studies in guinea pigs (8) and obese, insulin-resistant rats (9) suggest that fish oil–plant sterol esters may decrease both plasma cholesterol and TG concentrations. In those experiments, however, plant sterol esters were not compared with free forms of plant sterols, and the possible contribution of esterification to the lowering effect on cholesterolemia could not be evaluated.

Plant sterols are considered to be relatively safe for human health (3). However, results obtained in spontaneously hypertensive rats, showing that plant sterols may decrease red blood cell deformability and life span in these animals (10), have raised the question of the effects of plant sterols on blood rheological properties. Whether the detrimental effects of plant sterols on spontaneously hypertensive rats can be extrapolated to healthy animals and other animal species still remains to be determined. On the other hand, fish oil FA, *via* their incorporation in red blood cell membrane phospholipids, may improve erythrocyte lipid fluidity and deformability, and consequently reduce their fragility (11–15). It can be hypothesized that the esterification of plant sterols to fish oil FA may protect red blood cells against the increased fragility potentially associated with plant sterol consumption.

Our working hypothesis was that fish oil esters of phytosterols would have a beneficial impact on both plasma cholesterol and TG concentrations, as well as on red blood cell fragility. The present study was therefore undertaken to compare the effects of nonesterified plant sterols and fish oil FA esters of plant sterols on plasma lipids and red blood cell fragility. The Golden Syrian hamster was chosen as an animal model because of its well-established similarities with human cholesterol and bile metabolism (16–18).

MATERIALS AND METHODS

Animals. Male Golden Syrian hamsters (Charles River Laboratories, Montreal, Quebec, Canada) initially weighing 80–100 g and 35–45 d old were housed individually in stainless-steel wire-bottomed mesh cages. The temperature ($20 \pm 1°C$) of the animal room was constant and the hamsters were kept under a 12-h light–dark cycle (light: 7:00–19:00). During an adaptation period of 2 wk, hamsters were fed a plain, pelleted chow diet (Charles River Laboratories). They were then randomly assigned to one of four dietary groups ($n = 10$ per group). Semi-

purified diets and water were provided on an *ad libitum* basis for 5 wk. Records of food intake were taken every 3 d, with corrections made for spillage. Body weight was monitored once a week. The protocol was approved by the Animal Care and Research Ethics Committee of McGill University according to the guidelines of the Canadian Council on Animal Care.

Experimental diets. The semipurified diets were prepared every 2 wk and stored at –20°C. Diets were similar except for the cholesterol and phytosterol content (Table 1), consisting of either (i) no added cholesterol or plant sterols (Noncholesterol diet), (ii) 0.25% cholesterol and no added plant sterols (Cholesterol diet), (iii) 0.25% cholesterol plus 1% nonesterified plant sterols (Sterols diet), or (iv) 0.25% cholesterol plus 1.76% EPA and DHA sterol esters furnishing 1% of plant sterols (Fish oil esters of plant sterols diet). All diets contained 5% fat provided by a mix of beef tallow and safflower oil yielding a polyunsaturated-to-saturated FA ratio of 0.4. Nonesterified plant sterols (Forbes Medi-Tech Inc., Vancouver, British Columbia, Canada) consisted mostly of β-sitosterol (37.9% w/w), campesterol, (23.1% w/w), stigmasterol (17.5% w/w), and brassicasterol (5.12% w/w). Traces of sitostanol (2.78% w/w) were detected. Other minor phytosterols were present at a concentration of 9.82% (w/w), and minor chemical components represented 0.23%. For the preparation of fish oil esters of plant sterols, free plant sterols from the same batch as those used for the plant sterol diet were esterified to fish oil FA. The fish oil used for esterification to plant sterols was stabilized with ascorbylpalmitate, citric acid, and mixed tocopherols. The resulting fish oil FA esters of plant sterols (Forbes Medi-Tech Inc.) contained 37.4% (w/w) β-sitosterol and a total of 62.5% (w/w) plant sterols. The remaining components (37.5% w/w) consisted in 41.1% (w/w) EPA and 19.8% (w/w) DHA. The energy content of the diets was measured in an automatic adiabatic calorimeter (Model 1241; Parr Instruments, Moline, IL) and the diets were found to be isoenergetic, with values ranging from 18.7 to 19.1 kJ/g. After 5 wk of feeding with the semipurified diets, hamsters were deprived of food overnight. Animals

were then anesthetized with halothane and decapitated, and blood samples were collected immediately.

Plasma lipid analyses. Blood samples were collected in vacutainer tubes containing EDTA (Becton Dickinson, Missisauga, Ontario, Canada) and centrifuged at 1,300 rpm for 15 min to isolate plasma. Plasma samples were stored at –80°C until lipid determination. Part of the whole red blood cell samples, collected from the bottom of the vacutainer tubes after centrifugation, was stored at –80°C for plant sterol determination, and the remainder was used immediately at room temperature for red cell fragility determination. Analyses were done in duplicate. Plasma total cholesterol and HDL cholesterol concentrations were measured by an enzymatic method using the CHOD-PAP kit from Roche Diagnostics (Laval, Québec, Canada). HDL cholesterol concentrations were measured after the precipitation of apoB-containing lipoproteins with phosphotungstic acid and magnesium ions as described by Burstein *et al.* (19). Because the Friedewald *et al.* equation (20) may not be applicable in hamsters, results are expressed as non-HDL cholesterol levels. Non-HDL cholesterol was determined by subtracting HDL cholesterol from total cholesterol. Plasma total TG were determined enzymatically (21) using Triglyceride/GB kits from Roche Diagnostics. The procedure includes a preliminary step to eliminate free glycerol prior to the enzymatic dosage of TG.

Plant sterol measurement in red blood cells. Plant sterols (campesterol and β-sitosterol) and a cholesterol precursor (lathosterol), as well as cholesterol concentrations in whole red blood cells, were determined by GLC as reported previously (22). Briefly, an internal standard of 5α-cholestane (Sigma-Aldrich Canada Ltd., Oakville, Ontario, Canada) was added to each sample of red blood cells (100 μg/0.5 g red blood cells). Samples were saponified for 2 h at 100°C with 0.5 M methanolic KOH. Nonsaponified materials were then extracted two times with petroleum ether and dried under nitrogen flux. The extracts were derivatized using 1.5 mL of TMS reagent (pyridine-hexamethyldisilazane-trimethylchlorosilane 9:3:1, by vol) (Sigma-Aldrich Canada Ltd.) (23). After evaporation under nitrogen, the samples were dissolved

in 750 μL of hexane and injected into a gas–liquid chromatograph (HP 5890 Series II; Hewlett-Packard, Palo Alto, CA) equipped with an FID and an auto-injector system. Separation was achieved on a 30-m capillary column with an i.d. of 0.25 mm and film thickness of 0.25 μm (SAC-5; Supelco, Sigma-Aldrich Canada Ltd.). A 2-μL quantity of sample was used for a split injection. The carrier gas (helium) flow rate was 7.5 psi. Samples were injected at 300°C. The oven temperature remained at 160°C for 1 min after injection, was increased to 245°C at a rate of 15°C/min, and was then kept constant for 5 min. This was followed by a rise to 285°C at a rate of 15°C/min. Afterward, the temperature was kept constant at 285°C for 20 min. The detector was set at 310°C. Plant sterols (campesterol, β-sitosterol) and lathosterol were identified using authentic standards (Sigma-Aldrich Canada Ltd.).

Red blood cell fragility determination. Red cell fragility was assessed on fresh red blood cells by an osmolar tolerance test. Red blood cells were collected at the bottom of vacutainer tubes containing EDTA after centrifugation and the collection of plasma. The intermediate layer, containing white blood cells, was discarded. A 0.2-mL sample of red cells was added to 2 mL of unbuffered saline containing graded concentrations of sodium chloride (0.2–0.6%). Samples were mixed gently for 30 s. After 1 h, the cells were centrifuged at $1000 \times g$ for 5 min and the supernatant O.D. was read at 520 nm (24–27). Data are presented as O.D. readings. The saline concentration required to obtain 50% hemolysis was determined using O.D. readings adjusted as a percentage of the maximal density obtained and assuming a linear response between 0.55 and 0.4% sodium chloride.

Statistical analyses. Results are expressed as mean ± SEM, and a *P* value of 0.05 was considered significant. Data were subjected to ANOVA procedures using the general linear model approach of the Statistical Analysis System (SAS Institute, Cary, NC) to determine the main diet effects. When statistically significant effects were detected, a *post hoc* Tukey test was performed to identify differences among the diet groups.

RESULTS

Food consumption and body weight gain. Food consumption, initial and final weight, and body weight gain of hamsters fed the various diets are presented in Table 2. Average food consumption did not differ among the treatment groups. Initial body weights were similar in all diet groups. All animals gained weight during the experiment. After 5 wk of experimental feeding, diets had no significant effect on final body weight or weight gain.

Plasma lipids and lipoproteins. Effects of the experimental diets on plasma total cholesterol, HDL cholesterol, non-HDL cholesterol, and the HDL cholesterol/total cholesterol ratio are shown in Figure 1. Plasma total cholesterol concentrations were higher ($P < 0.005$) in hamsters fed various cholesterol-containing diets than in hamsters fed the noncholesterol diet. The addition of fish oil esters of plant sterols to the cholesterol diet partially prevented the increase in total cholesterolemia ($P = 0.001$). However, such a beneficial impact on total cholesterolemia was not observed when hamsters were fed the nonesterified plant sterols. Consequently, plasma total cholesterol concentrations were lower ($P < 0.0001$) in hamsters fed fish oil esters of plant sterols than in hamsters fed nonesterified sterols. Similar to plasma total cholesterol levels, HDL cholesterol concentrations were lower ($P = 0.002$) in fish oil ester-fed hamsters than in cholesterol-fed animals. However, the HDL cholesterol/total cholesterol ratio remained unchanged in hamsters fed fish oil esters of plant sterols. Nonesterified plant sterols resulted in HDL cholesterol levels intermediate to, and not significantly different from, those observed with cholesterol and fish oil FA esters of plant sterols. In hamsters fed the fish oil ester diet, non-HDL cholesterol levels were not significantly decreased compared with hamsters fed the cholesterol diet. When compared with the nonesterified sterol diet, however, plant sterols esterified with fish oil FA significantly decreased ($P = 0.0016$) the non-HDL cholesterol concentrations.

Plasma total TG concentrations in hamsters fed the experimental diets are presented in Figure 2. TG levels were higher in cholesterol-fed hamsters than in hamsters fed the cholesterol-free diet, but the difference was significant only between sterol- and noncholesterol-fed animals ($P = 0.03$). Fish oil esters of plant sterols did not significantly lower plasma TG levels in comparison with nonesterified sterols and diets containing no plant sterols.

Plant sterol concentrations in whole red blood cells. No significant impact of diets was observed on the cholesterol content in whole red blood cells, with values of 5.56 ± 0.14, 6.38 ± 0.14, 6.00 ± 0.32, and 6.41 ± 0.42 mmol/g in hamsters fed the noncholesterol, cholesterol, sterols, and fish oil esters of plant sterols diets, respectively. The concentrations of lathosterol, campesterol, and β-sitosterol, as well as the phytosterol/cholesterol ratios in whole red blood cells are displayed in Figure 3. No significant effect of diet was observed on cholesterol and lathosterol concentrations. There was a trend toward lower lathosterol/cholesterol ratios in the red blood cells of hamsters fed cholesterol-containing diets compared with hamsters fed the noncholesterol diet, but this was statistically significant only in comparison with the fish oil ester group ($P = 0.0468$). Compared with the cholesterol diet, nonesterified plant sterols and fish oil esters of plant sterols did not affect the lathosterol/cholesterol ratios in red

TABLE 2
Food Consumption and Body Weight of Golden Syrian Hamsters (*n* = 10 per group) Fed Experimental Diets Varying in Cholesterol and Plant Sterol Content

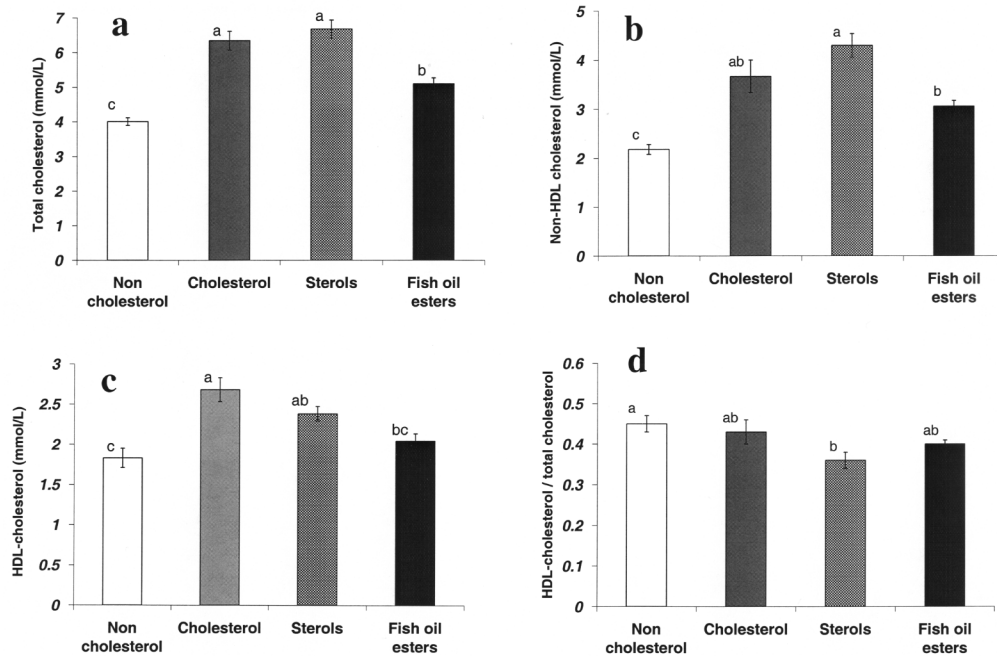
Dietary group	Food consumption (g/d)	Initial body weight (g)	Final body weight (g)	Body weight gain (g/35 d)
Noncholesterol	7.15 ± 0.16	117.97 ± 2.28	134.67 ± 2.19	16.70 ± 1.86
Cholesterol	6.92 ± 0.19	118.05 ± 2.39	130.92 ± 3.41	12.87 ± 2.30
Sterols	7.11 ± 0.14	118.20 ± 2.40	131.69 ± 2.35	13.49 ± 2.06
Fish oil esters of plant sterols	7.09 ± 0.21	118.30 ± 2.43	134.34 ± 3.31	16.04 ± 1.40


FIG. 1. Total plasma cholesterol (a), non-HDL cholesterol (b), HDL-cholesterol (c), and HDL cholesterol/total cholesterol ratio (d) in Golden Syrian hamsters ($n = 10$ per group) fed experimental diets varying in cholesterol and plant sterol content for 5 wk. Values are means ± SEM. Noncholesterol, semipurified diet with no added cholesterol or plant sterols; Cholesterol, diet with 0.25% cholesterol; Sterols, diet with 0.25% cholesterol plus 1% nonesterified plant sterols; Fish oil esters, diet with 0.25% cholesterol plus 1.76% EPA and DHA sterol esters, providing 1% plant sterols. Different letters represent significant differences between treatment groups ($P < 0.05$). For details on diet composition, see Table 1.

blood cells. Animals fed nonesterified sterols and fish oil esters of plant sterols had higher campesterol concentrations and campesterol/cholesterol ratios in red blood cells than animals fed diets containing no added sterols ($P < 0.0001$). Sitosterol and sitosterol/cholesterol ratios were higher ($P < 0.0001$) in the red blood cells of hamsters fed fish oil esters of plant sterols than in hamsters fed nonesterified sterols or no plant sterols.

Red blood cell fragility. O.D. did not differ between groups after the red blood cells of hamsters fed the various diets were added to eight different saline concentrations (data not shown). Mean saline concentrations associated with 50% hemolysis were similar among the dietary groups (0.48 ± 0.01%, 0.49 ± 0.01%, 0.49 ± 0.01%, and 0.48 ± 0.01% in hamsters fed the noncholesterol, cholesterol, nonesterified sterols, and fish oil esters of plant sterols diets, respectively).

DISCUSSION

In the present study, plant sterols esterified to fish oil FA lowered plasma total cholesterol concentrations in hamsters, whereas nonesterified plant sterols did not have such a beneficial impact. No detrimental effect of plant sterols was observed on red blood cell fragility, whether they were esterified with n-3 PUFA or not.

A lowering effect of plant sterols on total and LDL cholesterol levels is a common observation in humans (3). Plant sterols are thought to interfere with the intestinal absorption of cholesterol by displacing cholesterol from micelles (4,28). An

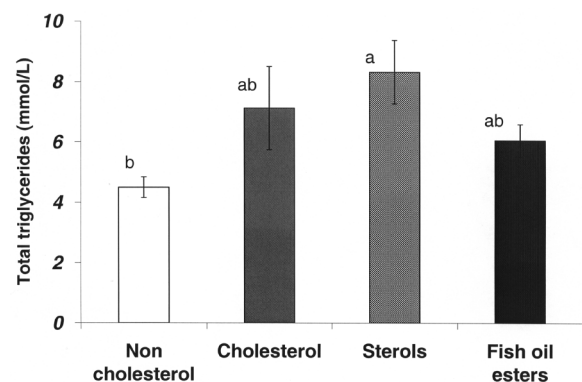
up-regulation of the expression of ATP-binding cassette transporters in intestinal cells, resulting in an increased excretion of cholesterol by the enterocyte back into the lumen, may also be implicated (29). Cholesterol metabolism in the hamster model presents many similarities with that in humans, such as a low rate of hepatic cholesterol synthesis (30) and a significant proportion of cholesterol associated with the LDL fraction (31,32). However, the impact of plant sterols on plasma cholesterol concentrations in hamsters is less consistent than in humans. In a


FIG. 2. Plasma total TG concentrations in Golden Syrian hamsters ($n = 10$ per group) fed experimental diets varying in cholesterol and plant sterol content for 5 wk. Values are means ± SEM. Different letters represent significant differences between treatment groups ($P < 0.05$). For diet descriptions see Figure 1; for details on diet composition see Table 1.
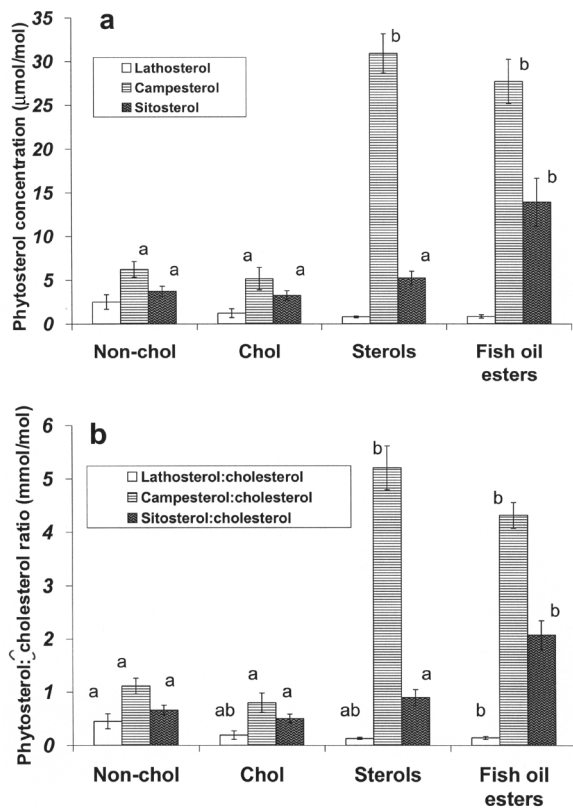

FIG. 3. Plant sterol concentrations (a) and plant sterol/cholesterol ratios (b) in whole red blood cells of Golden Syrian hamsters (*n* = 10 per group) fed experimental diets varying in cholesterol and plant sterol content for 5 wk. Values are means ± SEM. Non-chol, noncholesterol diet; Chol, cholesterol diet; Sterols, nonesterified plant sterol diet; Fish oil esters, diet with fish oil esters of plant sterols. Different letters represent significant differences between treatment groups (*P* < 0.05). For diet descriptions see Figure 1; for details on diet composition see Table 1.

few studies, nonesterified plant sterols have been shown to decrease plasma cholesterol (33,34) and cholesterol absorption (34). In other studies in hamsters, feeding plant sterol esters has resulted in decreased total cholesterol concentrations (34–36). However, in most of these studies showing a beneficial impact of free or esterified plant sterols in hamsters, the amount of cholesterol in the diet was lower (0.08–0.09%) (34,35) than in the present experiment (0.25%). It is therefore possible that the hypercholesterolemic impact of a greater intake of cholesterol in the present study may not have been counteracted completely by plant sterol consumption. Other results are in accordance with the absence of a beneficial impact of nonesterified plant sterols, as observed in the present study (22,37,38). Indeed, feeding a diet containing 1% of a plant sterol mixture supplying almost no sitostanol for 45 d did not affect plasma cholesterol concentrations in hamsters (22). In rats, a sitostanol-free phytosterol mixture had no significant effect on total and LDL cholesterol concentrations (37). However, when the rats were fed a phytosterol mixture containing sitostanol, total and LDL cholesterol levels were decreased (37). Similar results have been obtained in rabbits fed increasing amounts of sitostanol (38). A diet supplemented with a 1% phytosterol mixture furnishing 0.01% sitostanol had no impact on total cholesterol

concentrations, whereas a higher concentration (0.8%) of sitostanol was associated with a significant decrease in plasma cholesterol levels (38). These data, along with those observed in rats by Ling and Jones (37) and in hamsters by Ntanios and Jones (22) as well as in the present study, suggest that plant stanols may be more efficient in lowering cholesterolemia in rodents than plant sterols.

In the present study, plasma total cholesterol concentrations were significantly decreased in animals fed fish oil esters of plant sterols compared with animals fed no plant sterols or nonesterified plant sterols. Lower plasma cholesterol concentrations have been reported previously in guinea pigs after consumption of a phytosterol–fish oil conjugate (8). Phytosterols esterified with EPA and DHA also have been shown to decrease total plasma cholesterol in obese, insulin-resistant rats (9). In those studies in guinea pigs and obese rats, however, the control diets did not contain nonesterified plant sterols. The results of the present study, where fish oil–phytosterol esters were compared with nonesterified plant sterols, suggest that plant sterols esterified with EPA and DHA may result in lower plasma cholesterol concentrations than free sterols. On the other hand, the hypocholesterolemic impact of fish oil esters of plant sterols was accompanied by a decrease in HDL cholesterol levels, but the HDL cholesterol/total cholesterol ratio remained unchanged. This may be due in part to the fact that in hamsters, HDL transport a larger proportion of cholesterol than other lipoproteins (39). It is difficult to determine to which extent the decrease in total cholesterol in hamsters fed fish oil–plant sterols in the present experiment may be due to a possible reducing effect of fish oil on total and HDL cholesterol. Studies on the effect of fish oil on lipoprotein metabolism in hamsters have led to inconsistent results, probably because of the great variability in diet composition from one study to another. Whereas decreased total and HDL cholesterol have been reported in hamsters fed relatively high amounts of fish oil (40–42), some studies have shown no lowering effect on total and HDL cholesterol (41,43,44). Other results suggest that a small amount of fish oil, similar to the one supplemented in the present study, may not result in decreased total and HDL cholesterol concentrations in cholesterol-fed hamsters. Indeed, Surette *et al.* (45) reported no impact on total cholesterol with doses of n-3 PUFA ranging from 0–1.9% (w/w diet), and no lowering effect on HDL cholesterol levels with doses of 1.5% or less. It is therefore possible that the improvement in plasma total cholesterol concentrations in hamsters fed plant sterols esterified to fish oil FA is related to another mechanism. It could be hypothesized that a higher bioavailability of esterified sterols compared with nonesterified sterols might be implicated. Indeed, sitosterol concentrations in red blood cells were higher in hamsters fed fish oil esters of plant sterols compared with hamsters fed nonesterified sterols, suggesting that sitosterol may be more bioavailable when supplied as fish oil FA esters than in a free form. However, plasma campesterol concentrations were not increased after supplementation in an esterified form compared with a free form. The absorption of campesterol is known to be higher (10–15%) than that of sitosterol (4–7%) (3). The increased concentrations of sitosterol, but

not campesterol, when supplemented in esterified form may suggest that esterification may increase the bioavailability of plant sterols that are usually absorbed in small proportions, such as sitosterol, and that no further increase may be obtained for plant sterols that are already absorbed in high proportions, such as campesterol. Further investigation is required to determine the impact of the esterification of different plant sterols on their bioavailability.

The decrease in plasma total cholesterol concentrations observed with fish oil esters of plant sterols in the present study was reflected in non-HDL cholesterol concentrations, but this effect was significant only in comparison with nonesterified sterols. In guinea pigs, however, fish oil esters of plant sterols resulted in lower non-HDL cholesterol concentrations than the control diet (8). An increase in LDL cholesterol concentrations attributable to fish oil supplementation has been documented in humans (46,47) and hamsters (33,40,41). It is therefore possible that in the present study, the lowering effect of plant sterols may have been counteracted in part by an increasing effect of fish oil on non-HDL cholesterol. Species differences in cholesterol metabolism may therefore be responsible for the discrepancies between the present study in hamsters and results obtained in guinea pigs and hypertensive rats (8,9). Whether fish oil esters of plant sterols may be efficient in decreasing not only total cholesterol but also LDL cholesterol, without affecting HDL cholesterol concentrations in humans, remains to be determined.

The idea behind the esterification of plant sterols with fish oil FA was to maximize their lipid-lowering effects by combining the hypocholesterolemic properties of plant sterols with the hypotriglyceridemic action of fish oil FA. In the present study, plasma TG concentrations were not significantly decreased in hamsters fed fish oil esters of plant sterols compared with hamsters fed nonesterified sterols. These results may appear to be inconsistent with the significant hypotriglyceridemic effect reported in guinea pigs (8) and insulin-resistant rats (9) fed fish oil–phytosterol conjugates. However, a decrease in triglyceridemia following fish oil supplementation has not been consistently observed in hamsters. Although some studies showed decreased plasma TG concentrations following fish oil feeding (33,41,48,49), other reports did not show a beneficial impact on TG levels (40,42–44). Variations in diet composition may be responsible for some of the discrepancies observed between studies in hamsters. It appears that cholesterol feeding may somewhat counteract the beneficial impact of fish oil on plasma TG concentrations in hamsters. In fact, Kubow *et al.* (44) observed higher plasma TG levels in hamsters fed a fish oil rich in cholesterol compared with a low-cholesterol fish oil, as well as in hamsters fed a low-cholesterol fish oil to which cholesterol was added compared with a low-cholesterol fish oil without added cholesterol. In the present study, hamsters were fed 0.25% cholesterol, whereas guinea pigs supplemented with fish oil–plant sterol esters in the study of Ewart *et al.* (8) and insulin-resistant rats in the study of Russel *et al.* (9) were fed regular low-cholesterol rodent diets. The proportion of fish oil esters of plant sterols in the diets and the quantity of EPA and DHA supplemented may also explain in part the discrepancies between the results obtained in the present study in hamsters and the beneficial effects

observed previously in guinea pigs and insulin-resistant rats (8,9). Indeed, increasing the amount of n-3 FA in the diet of hamsters gradually lowered plasma TG concentrations (50). In the study by Ewart *et al.* (8), the diets fed to guinea pigs contained 25 g/kg of phytosterol–fish oil conjugate, whereas the proportion of fish oil esters in the diet fed to hamsters in the present study was only 17.6 g/kg. It is therefore possible that the quantity of EPA and DHA supplied to hamsters in the present study may have been less than the amount of fish oil FA provided to guinea pigs. Interestingly, Russell *et al.* (9) reported a diminution of plasma TG concentrations in obese, insulin-resistant rats fed 2.6 g/kg body weight of phytosterol–fish oil esters, but no effect was observed on blood lipids when the rats were fed 0.5 g/kg of fish oil esters. Since the fish oil ester preparation contained 55% of EPA and DHA, the dose of fish oil FA supplied to the rats by 2.6 and 0.5 g/kg body weight of fish oil–plant sterol conjugate was 0.28 and 1.43 g/kg body weight, respectively (9). In the present study, hamsters were fed approximately 0.23 g EPA and DHA/kg body weight, given an approximate proportion of EPA and DHA in the fish oil–plant sterol conjugate of 23%, an average daily food consumption of 7 g/d, and an average body weight of 125 g. Therefore, the absence of a significant effect of fish oil esters of plant sterols on plasma TG concentrations in the present experiment is in accordance with the absence of a beneficial impact of the lowest dose of phytosterol–fish oil conjugates (0.28 g EPA and DHA/kg body weight) given to obese rats (9). Although the lipid metabolism in hamsters and obese, insulin-resistant rats may differ, results from these studies suggest that more than 0.2 g of fish oil FA/kg body weight is necessary to induce a hypotriglyceridemic effect in rodents when EPA and DHA are supplied in the form of plant sterol esters.

Compared with cholesterol, which is absorbed in the intestine at 35–70%, plant sterols are poorly absorbed (10–15% for campesterol and campestanol, 4–7% for sitosterol, and 1% for sitostanol) (3). Nevertheless, in humans (51) and rodents (37,52,53), an increased consumption of plant sterols leads to higher levels of plant sterols in plasma. When present in the blood circulation, plant sterols are partly incorporated in red blood cell membranes (10,54). In the present study, campesterol and β-sitosterol concentrations were increased in whole red blood cells of hamsters fed nonesterified sterols and fish oil esters of plant sterols compared with hamsters fed diets containing no added plant sterols. The increase in campesterol concentrations was more pronounced than the increase in β-sitosterol levels, reflecting a higher absorption of campesterol (55). Results from a previous study suggested that the replacement of a part of the cholesterol by plant sterols in red cell membranes may decrease red blood cell deformability and life span in stroke-prone spontaneously hypertensive rats (10). In the present experiment, the amount of plant sterols fed to hamsters (1 g/100 g diet) was higher than the quantity supplemented to hypertensive rats (0.2 g/100 g) (10), and no detrimental effect was observed on red blood cell fragility. A possible explanation might be that spontaneously hypertensive rats suffer from a deficiency of cholesterol in the blood and in cell membranes (10). In these rats, plant sterol supplementation leads to lower cholesterol concentrations in erythrocytes, possibly as a conse-

quence of a higher absorption and incorporation of plant sterols in tissues as a substitute for cholesterol (10). Although plant sterol concentrations were increased in hamsters fed the plant sterols in the present study, the cholesterol content in red blood cells was not affected, suggesting that plant sterols replaced only a very small proportion of cholesterol in the cell membranes. In humans, consumption of a diet rich in plant sterols (1 g/1000 kcal) (25,27) and supplementation of plant sterol esters (54) did not affect red cell fragility. These data, along with the findings of the present experiment, suggest that the results obtained in spontaneously hypertensive rats fed plant sterols cannot be extrapolated to other species or to hyperlipidemic, otherwise healthy humans.

Some studies in rats (11,12) and humans (13–15) have suggested that fish oil FA may decrease CVD risk in part by decreasing osmolar fragility and increasing the deformability of red blood cells. In the present study, we tested for the first time the impact on red cell fragility of fish oil FA in the form of plant sterol esters. The fish oil–plant sterol conjugates did not modify the osmolar fragility of erythrocytes in hamsters. This is in accordance with the results obtained from a previous study in guinea pigs showing no effect of fish oil on red blood cell deformability (56). Another study in humans also has shown no effect of supplementation with up to 6 g/d of EPA and DHA ethyl esters (57). Some species differences may explain the discrepancies between the effects observed in different studies, as well as the form and quantity of n-3 PUFA supplemented.

Hence, EPA and DHA esters of plant sterols decreased plasma total cholesterol concentrations in hamsters, whereas nonesterified sterols did not have such a beneficial impact. No significant hypotriglyceridemic effect was observed after fish oil–plant sterol feeding, maybe because of the low dose of EPA and DHA supplemented and the distinctive characteristics of lipid metabolism in the hamster model. The present data show that these new esters of plant sterols have no detrimental effect on red blood cell fragility. Clinical trials are needed to evaluate the impact of these conjugates on the lipoprotein profile and other health risk parameters in humans.

Distribution of 22:6n-3 Newly Synthesized from 18:3n-3 into Glycerolipid Classes from Tissues of Rainbow Trout (*Oncorhynchus mykiss*)

Michael V. Bell* and James R. Dick

Institute of Aquaculture, Faculty of Natural Sciences, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom

ABSTRACT: The distribution of D_5-22:6n-3 following ingestion of a pulse of D_5-18:3n-3 was measured quantitatively by GC–negative chemical ionization MS in lipid classes from liver, cecal mucosa, and brain from rainbow trout to further our understanding of the processes determining accretion and turnover of 22:6n-3 in fish. The accretion of D_5-22:6n-3 was expressed in two ways, as percent enrichment and as ng D_5-22:6n-3/µg 22:6n-3/mg D_5-18:3n-3 eaten. In cecal mucosa at 2 d post-dose, PC was the most enriched lipid class followed by PE and then TAG. Enrichment fell in all lipid classes in cecal mucosa from 2 to 7 d post-dose of D_5-18:3n-3. In liver, PC was also the most enriched lipid class at 2 d, but in this tissue all lipid classes were more enriched in D_5-22:6n-3 by 7 d. When expressed in terms of the 22:6n-3 content of the different lipid classes, TAG became relatively less important in cecal mucosa and more important in liver. Over a time course of 3 to 35 d, the percent enrichment of D_5-22:6n-3 in liver peaked at 7 d in PC, PE, PS, and PI and fell rapidly in TAG from 3 d. PC from liver was the most enriched lipid class at 3 and 7 d, and thereafter PE was the most enriched lipid class. However, TAG had the highest specific activity at all times except 7 d. In brain, the enrichment of D_5-22:6n-3 was very low in all lipid classes at 3 d and increased progressively to 35 d with PC and PE similarly enriched. TAG from brain had the highest specific activity at all times. This study is the first to present quantitative information on rates of accretion and depletion of newly synthesized 22:6n-3 into the main lipid classes of fish tissues.

Paper no. L9486 in *Lipids 40*, 703–708 (July 2005).

There is little information in the literature describing quantitatively the metabolism of PUFA at the whole-animal level, including the partitioning of newly synthesized or ingested PUFA between different tissues and lipid classes. Consequently, it is not possible to model the fate of dietary PUFA, which is a major problem in our understanding of the metabolic interactions between n-3 and n-6 PUFA and the importance of dietary C_{18} vs. C_{20} and C_{22} PUFA. Stable isotope studies are now beginning to address these issues.

We have previously described a method for measuring quantitatively the conversion of 18:3n-3 to 22:6n-3 in fish using a deuterated tracer and GC–negative chemical ionization (CI) MS (1). In rainbow trout fed a diet containing 18:3n-3 as the only n-3 PUFA, conversion of 18:3n-3 to 22:6n-3 was slow, and whole-body accumulation of newly synthesized 22:6n-3 peaked at 4.3 µg/g fish/mg 18:3n-3 eaten after 14 d (1). The amount of newly synthesized 22:6n-3 peaked in liver at 7 d and in brain and eyes at 24 d; in visceral and eye socket adipose tissue it plateaued after 14 d (1). The capacity to synthesize 22:6n-3 from 18:3n-3 changed rapidly during early development in trout (2). First-feeding trout of *ca.* 0.2 g weight gave an initial rate of 5.4 µg 22:6n-3/g fish/mg 18:3n-3 eaten/7 d, which increased rapidly to *ca.* 50 µg 22:6n-3/g fish/mg 18:3n-3 eaten/7 d at around 1 g weight, then declined rapidly to *ca.* 12 µg 22:6n-3/g fish/mg 18:3n-3 eaten/7 d at 2 g weight and continued to fall thereafter (2). Using the same methodology, we showed that, at 2 d post-dose of D_5-18:3n-3, pyloric ceca contained a higher concentration of newly synthesized D_5-22:6n-3 than liver, indicating that pyloric ceca was capable of PUFA synthesis (3). This has since been confirmed directly using fish enterocytes (4).

Few studies have examined the deposition of 22:6n-3 newly synthesized from 18:3n-3 in different phospholipid classes from different tissues. In trout hepatocytes incubated with 1-[14]C-18:3n-3 or 1-[14]C-20:5n-3 for 3 h, 22:6n-3 was the major product PUFA from both substrates and TAG was the major labeled lipid class followed by PC (5). Turbot injected with 1-[14]C 22:6n-3 showed the greatest accumulation of label in PC after 48 h, followed by PE, TAG, and sterol ester (6). Turbot brain cells incubated with 1-[14]C-22:6n-3 for 6 h accumulated 22:6n-3 mainly in PC, followed by PE, with very little in PS or PI (7).

This study was undertaken to obtain quantitative information on the partitioning of newly synthesized 22:6n-3 into lipid classes from three tissues in juvenile rainbow trout after feeding a pulse of D_5-18:3n-3. Liver and cecal mucosa were chosen as tissues synthesizing 22:6n-3 and, over a longer time period, liver was compared with brain, a tissue with a high requirement for 22:6n-3.

MATERIALS AND METHODS

Chemicals. Chloroform, methanol, ethanol, acetic acid, isohexane, and diethyl ether were HPLC grade from Fisher (Loughborough, Leicestershire, United Kingdom). Diisopropylamine, anhydrous acetonitrile, and pentafluorobenzyl (PFB) bromide were obtained from Aldrich (Gillingham, Dorset, United King-

dom). D$_5$(17,17,18,18,18)-linolenic acid was purchased from Cambridge Isotope Laboratories (Andover, MA) as the fatty acid ethyl ester (FAEE). Heneicosatetraenoic acid (Δ6,9,12,15-21:4) ethyl ester was prepared by a one-carbon addition to 20:4n-6 FA (8). All other chemicals were from Sigma (Poole, Dorset, United Kingdom). TLC plates were from Merck (VWR International Ltd., Poole, Dorset, United Kingdom).

Fish and diets. Rainbow trout were obtained from a commercial hatchery and kept in a running freshwater aquarium at ambient temperature (3.5 to 16.5°C) on a 14 h/10 h light/dark cycle. Fish were fed a diet based on casein and a blend of vegetable oil containing predominantly oleic acid with 18:2n-6 and 18:3n-3 at approximately 1% each, this to maximize 22:6n-3 synthesis and satisfy the fishes' EFA requirements. The full composition of the diet was described previously (1). The final diet provided 50% crude protein and 11% oil blended to give, as a percentage of the final diet, 0.99% 18:2n-6, 1.02% 18:3n-3, and 0.12% highly unsaturated FA (20:5n-3 and 22:6n-3) from the fish meal, which was added to make the diet palatable and readily accepted by the fish. The remaining FA were predominantly 16:0 (1.02%) and 18:1n-9 (7.18%). Fish from the longer time course (up to 35 d) weighed 5.6 ± 1.0 g at the start of the experiment and had been reared on the experimental diet for 8 wk before feeding tracer (1). Fish from the shorter time course had been on the experimental diet for 34 wk and weighed 60.1 ± 11.3 g (3).

Preparation of labeled diet. A small portion of diet containing D$_5$-18:3n-3 FAEE and 21:4n-6 FAEE was prepared as follows. An oil sample containing 10 mg D$_5$-18:3n-3 FAEE, 2.5 mg 21:4n-6 FAEE, 153 mg of high oleic acid sunflower oil, and 61 μg antioxidant was dissolved in 0.82 mL of isohexane, and 1.335 g of dry diet mix was added. The isohexane was then removed at 37°C under nitrogen and the diet desiccated *in vacuo* for 18 h. The diet was mixed thoroughly, then 0.95 mL water added and mixed to a stiff paste. This was extruded through a 1-mL disposable syringe, dried at room temperature for 2–3 h and cut into 3–4 mm lengths. The diet was stored under argon at −20°C and was used within 3 d. The 21:4n-6 FAEE was added to diets as a marker since it is much less readily catabolized than 18:3n-3 and therefore gives a higher recovery, enabling more precise determination of the amount of labeled diet eaten by individual fish (1).

Experimental protocol. Groups of fish were acclimated in a 100-L circular tank with running water for at least 4 d before starting an experiment. They were then fed the labeled diet, all of which was observed to be eaten, and fed the normal unlabeled diet daily until sampled. The temperature ranged from 9.0 to 16.0°C during the experiments.

The fish were weighed and individual tissues dissected for analysis as described earlier (1,3). Samples were homogenized in chloroform/methanol 2:1 (vol/vol) using a Potter or Ultra-Turrax homogenizer and an extract was prepared according to Folch *et al.* (9). Tritricosanoyl glycerol (tri23:0) standard was added to each tissue sample before homogenization. Samples were kept on ice under nitrogen during workup and were stored at −20°C under argon.

Preparation of lipid classes. PC, PS, PI, PE, and TAG were prepared from 1 mg of total lipid by TLC (20 × 20 cm, silica gel 60, Merck no. 5721 plates) in methyl acetate/chloroform/propan-2-ol/methanol/0.25% (by wt) KCl (25:25:25:10:9, by vol). The plates were dried *in vacuo* for 30 min and redeveloped in isohexane/diethyl ether/acetic acid (80:20:1, by vol) to separate TAG. The dried plates were then sprayed with 0.1% (wt/vol) 2,7-dichlorofluorescein in 97% (by vol) methanol and the lipid bands visualized under UV light. Bands were scraped from the plates into stoppered test tubes and the lipids saponified *in situ*.

Quantification of FA. Lipid samples were saponified with 2 mL of 0.1 M KOH in 95% (by vol) ethanol under argon for 1 h at 78°C in the presence of 17:0 internal standard to quantify unlabeled FA. Tri23:0 was added to the phospholipid classes to quantify D$_5$-FA. Saponified samples were then diluted with 5 mL of water, acidified, and the FFA extracted with diethyl ether. PFB esters were then prepared using acetonitrile/diisopropylamine/PFB bromide (1000:10:1, by vol) at 60°C for 30 min under nitrogen (12). Excess reagent and solvent were removed under nitrogen and samples dissolved in isohexane and stored at −20°C under argon until analyzed.

Calibration standards of individual FA (18:3n-3, 21:4n-6, and 22:6n-3) with 23:0 were prepared by varying the amount of each FA while keeping the 23:0 constant and plotting the peak area ratio against the mass ratio of the different FA. Sample volumes for analysis were adjusted such that the amount of 23:0 injected onto the gas chromatograph–mass spectrometer (GC–MS) was constant. PFB esters were chromatographed and quantified on a Fisons MD 800 GC–MS fitted with an on-column injector and a ZB wax column (60 m × 0.32 mm i.d., 0.25 μm film thickness; Phenomenex, Macclesfield, Cheshire, United Kingdom), using helium as carrier gas (column head pressure 20 psi) and running in negative CI mode with methane as reagent gas (pressure 7 psi). The temperature program was 80–240°C at 40°C/min, then 240°C for 50 min. FA were identified by selective ion scanning for the required masses using a dwell time of 80 ms and cycle time of 20 ms, and quantified by reference to the appropriate FA calibration curve. Calibration curves were run before and after each batch of samples to check the performance of the electron source.

FA analysis of PFB esters was performed on a Thermo Finnigan Trace GC fitted with an electron capture detector, a split injector (1:10 split ratio) (Thermo Finnigan, Hemel Hempstead, Herts, United Kingdom), and a ZB Wax column (30 m × 0.25 mm i.d., 0.25 μm film thickness) (Phenomenex) using helium as carrier gas at a constant flow rate of 2 mL/min. The temperature was programmed from 110 to 240°C at 20°C/min then held at 240°C for 25 min.

Quantification of lipid classes. Lipid classes were resolved by double-development high-performance TLC (HPTLC; 10 × 10 cm, silica gel 60, Merck no. 5633 plates) using the two solvent systems given earlier (10). After chromatography, plates were dried, sprayed with 3% (wt/vol) cupric acetate in 8% (by vol) phosphoric acid (11), and charred at 160°C for 15 min. Quantification was performed using a Camag TLC scanner 3 (VWR International Ltd.).

Statistical analysis. Sample means were compared using either one-way ANOVA or a paired *t*-test using GraphPad Prism® (San Diego, CA).

RESULTS

PC was the most enriched lipid class in cecal mucosa at all times, with a peak enrichment of 0.1922% at 2 d falling to half this level by 7 d (Fig. 1A). PE was the next most enriched lipid class in cecal mucosa (0.0682% enrichment at 5 d) with low enrichments in TAG, PI, and PS (Fig. 1A). Liver showed the opposite pattern of D_5-22:6n-3 accretion. Enrichments were higher at 7 d than 2 d in all lipid classes from liver (Fig. 1B). In liver, PC was again the most enriched lipid class at all times, but levels increased more than fivefold between 2 and 7 d (0.4053% enrichment at 7 d) (Fig. 1B). Liver PE and TAG showed a large increase between 2 and 7 d (6- and 12-fold, respectively). Amounts of D_5-22:6n-3 in PS and PI, although increasing from 2 to 7 d, were low (Fig. 1B).

When the results are expressed as the amount of D_5-22:6n-3 relative to the content of 22:6n-3 in each lipid class, the pattern of distribution within the different lipid classes changes owing to the contribution of each lipid class to the total lipid class pool and the concentration of 22:6n-3 in that lipid class. The unit ng D_5-22:6n-3/µg 22:6n-3/mg D_5-18:3n-3 eaten is analogous to the term *specific activity* used with radioisotopes, with a correction to account for the different amounts of tracer eaten by individual fish. When expressed in terms of 22:6n-3 content, the differences between phospholipid classes were less marked in cecal mucosa (Fig. 2A). The contribution of TAG also becomes less important because this is the major lipid class in cecal mucosa. PC showed the highest specific activity (5.57 ng D_5-22:6n-3/µg 22:6n-3/mg D_5-18:3n-3 eaten at 2 d), PE and PI were similar, and PS and TAG much lower (Fig.2A). The low content of 22:6n-3 in TAG from liver meant that the specific activity of TAG was higher than that of the four phospholipid classes at all times (Fig. 2B).

Over the longer time course to 35 d, PC was again the main site of deposition of newly synthesized D_5-22:6n-3 in liver with the percent enrichment increasing rapidly from 3 to 7 d to peak

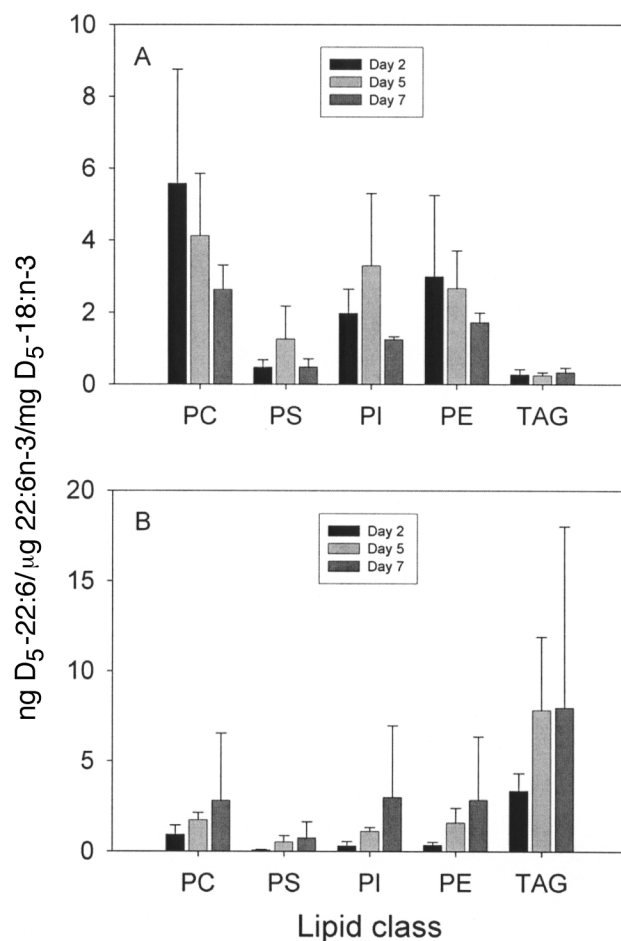
FIG. 1. The percent enrichment of D_5–22:6n-3 in lipid classes from cecal mucosa (A) and liver (B) 2 to 7 d post-feeding D_5-18:3n-3. Bars represent mean ± SD, *n* = 4 for day 2 and *n* = 3 for days 5 and 7. Comparison of day 2 liver vs. day 2 cecal mucosa gave *P* = 0.0253 for PS and *P* = 0.0065 for PI (paired Student *t*-test).


FIG. 2. The distribution of D_5-22:6n-3 in lipid classes from cecal mucosa (A) and liver (B) 2 to 7 d post-feeding D_5-18:3n-3 expressed as ng D_5-22:6n-3/µg 22:6n-3/mg D_5-18:3n-3 eaten. Bars represent mean ± SD, *n* = 4 for day 2 and *n* = 3 for days 5 and 7. Comparison of day 2 cecal mucosa vs. day 2 liver gave *P* = 0.0495 for PC, *P* = 0.0265 for PS, *P* = 0.0232 for PI, and *P* = 0.0082 for TAG (paired Student *t* test).

at 0.2047% then falling steadily to 35 d (Fig. 3A). PE was the next most enriched lipid class in liver, plateauing at 0.061–0.077% enrichment between 7 and 24 d (Fig. 3A). Very little D_5-22:6n-3 was found in PS and PI from liver (<0.0087 and <0.0049%, respectively), but the pattern of accumulation was similar to PE, peaking between 7 and 24 d (Fig. 3A). In TAG, peak enrichment in D_5-22:6n-3 was at 3 d (0.0212%), about one-third the level in PC at that time, and fell steadily to 35 d (Fig. 3A). By 35 d the percent enrichments in PC and PE were very similar and those in PS, PI, and TAG about tenfold lower (Fig. 3A).

In brain, very little D_5-22:6n-3 was present at 3 d in any lipid class (Fig. 3B). D_5-22:6n-3 accumulated in PC and PS up to 35 d (0.0204 and 0.0060% enrichment, respectively) and plateaued in PE and TAG around 14 to 35 d (peaks of 0.0210 and 0.0072% enrichment, respectively) (Fig. 3B). Thus, PC and PE were equally enriched by 35 d, with much lower amounts of D_5-22:6n-3 in PS and TAG. Very little D_5-22:6n-3

was found in PI throughout the time course, peaking at 0.0008% enrichment at 35 d (Fig. 3B).

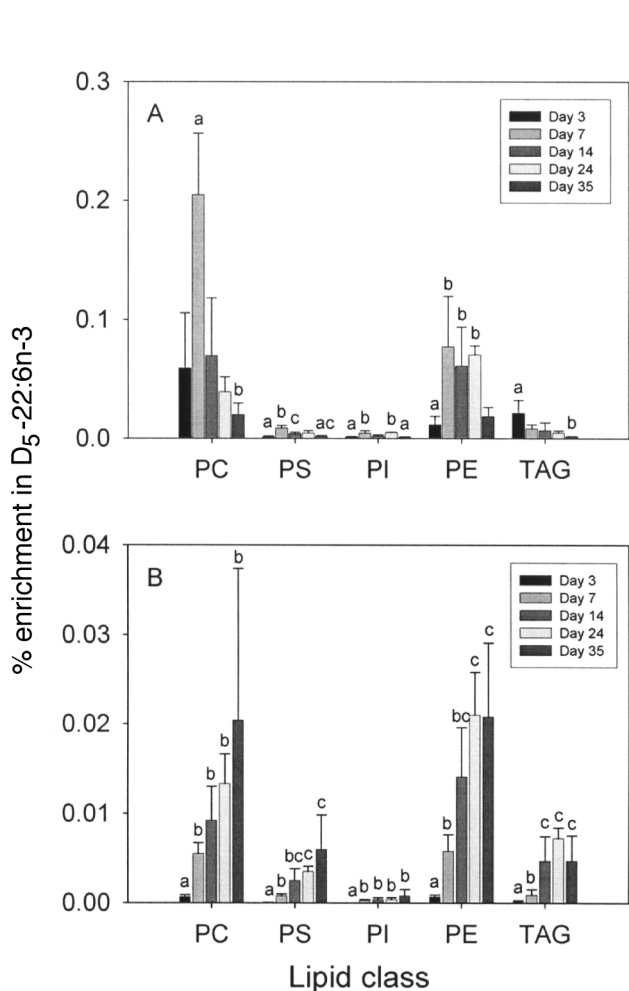
TAG had the highest specific activity of incorporated D_5-22:6n-3 in liver (24.0 ng D_5-22:6n-3/μg 22:6n-3/mg D_5-18:3n-3 eaten at 3 d) owing to the low content of 22:6n-3 (2.9 mol%) (Fig. 4A). PC and PE, with the highest 22:6n-3 contents (23.0 and 27.3 mol%, respectively), become relatively less important with peaks of 21.5 and 12.8 ng D_5-22:6n-3/μg 22:6n-3/mg D_5-18:3n-3 eaten, respectively, at 7 d (Fig. 4A). PS and PI also become more important relative to PC and PE owing to their smaller contributions to the lipid class pool and lower 22:6n-3 content (6.3% in the case of PI). The low amount of 22:6n-3 in TAG from brain (5.5 mol%) compared with PC, PS, and PE (22.7, 34.2, and 32.2 mol%, respectively) gave TAG the highest specific activity at all time points in brain, and markedly so from 14 d onward (Fig. 4B). Within the phospholipid classes


FIG. 3. The percent enrichment of D_5-22:6n-3 in lipid classes from liver (A) and brain (B) 3 to 35 d post-feeding D_5-18:3n-3. Mean ± SD, $n = 5$ for day 3, $n = 4$ for day 7, $n = 5$ for day 14, $n = 3$ for day 24, and $n = 4$ for day 35. One-way ANOVA gave differences for liver of $P = 0.0038$ for PC, $P < 0.0001$ for PS and PI, $P = 0.0002$ for PE, and $P < 0.0007$ for TAG, and for brain of $P < 0.0001$ for PC, PS, PI, PE, and TAG. Different superscripts within classes represent differences significant at $P < 0.01$.
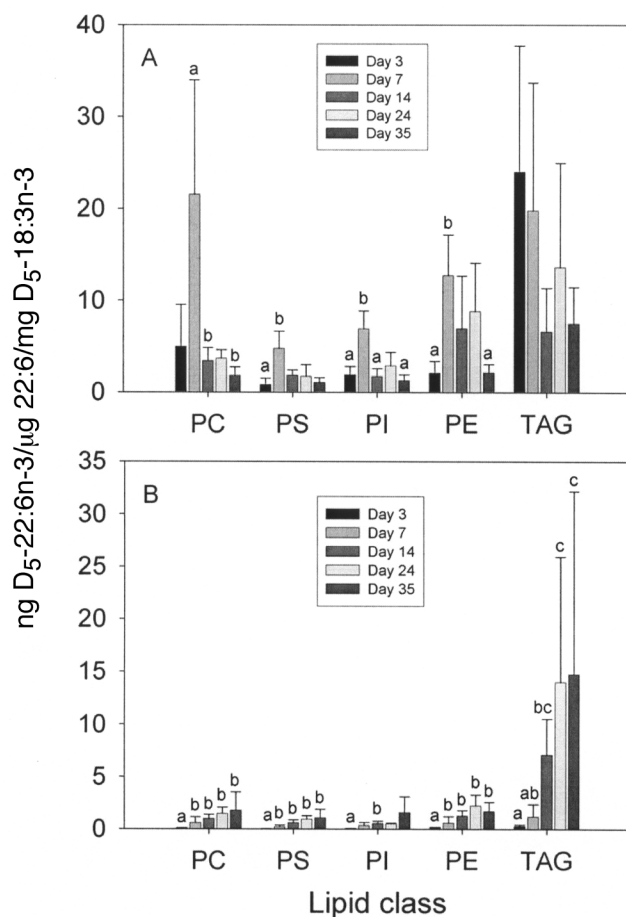

FIG. 4. The distribution of D_5-22:6n-3 in lipid classes from liver (A) and brain (B) 3, 7, 14, 24, and 35 d post-dose of D_5-18:3n-3 presented as ng D_5-22:6n-3/μg 22:6n-3/mg D_5-18:3n-3 eaten. Mean ± SD, $n = 5$ for day 3, $n = 4$ for day 7, $n = 5$ for day 14, $n = 3$ for day 24, and $n = 4$ for day 35. One-way ANOVA gave differences for liver of $P < 0.0007$ for PC, $P = 0.0036$ for PS, $P = 0.0017$ for PI, $P = 0.0010$ for PE, and $P = 0.1757$ for TAG, and for brain of $P < 0.0001$ for PC, PS, PE, and TAG and $P = 0.0098$ for PI. Different superscripts within classes represent differences significant at $P < 0.01$.

from brain, the specific activities of D_5-22:6n-3 were similar throughout the time course (Fig. 4B).

DISCUSSION

In the present study, we examined the distribution of D_5-22:6n-3 in the main lipid classes from three tissues of juvenile trout following ingestion of a pulse of D_5-18:3n-3. The FA compositions of the rearing diet and the diet containing the D_5-18:3n-3 tracer were identical, so the fish were under steady-state conditions with respect to dietary FA intake throughout the pre-experimental and experimental periods. Liver and ceca were examined as tissues involved in 22:6n-3 synthesis, and brain as a tissue with a high requirement for this PUFA (13). A number of factors influence the kinetics of PUFA metabolism and distribution of PUFA within tissues and lipid classes, including the lipid form in which FA tracer is supplied, the route of uptake (ingestion or injection), the nutrient and physiological status of the organism, and developmental stage. The substrate for the desaturases and elongases may be esterified FA, which could influence accretion in different lipid classes. In plants it is well established that FA esterified to PC is the main substrate rather than acyl CoA (14), and a Δ-5 desaturase from rat liver uses *sn*-2 esterified PUFA of lecithin (15). When comparing studies on fish and mammals, other factors are also significant, including slower metabolic processes in poikilotherms, different absolute and relative requirements for n-3 and n-6 PUFA, and gut as well as liver being an important site of 22:6n-3 synthesis in salmonid fish.

Over a short time course of up to 7 d, the distributions of D_5-22:6n-3 in lipid classes from cecal mucosa and liver were very different. Peak accretion of D_5-22:6n-3 was at 2 d in all lipid classes in cecal mucosa whereas, in liver, D_5-22:6n-3 increased in all lipid classes from 2 to 7 d. PC was much more enriched than TAG in cecal mucosa. The amount of D_5-22:6n-3 in PI from cecal mucosa was unexpected since this PUFA is not accumulated in PI to any great extent (e.g., Ref. 16) but it was turned over at a similar rate to PE. In liver, PC was the predominant site of D_5-22:6n-3 accretion, with TAG becoming increasingly important by 7 d, though the large scatter in day 7 data makes interpretation difficult. In trout hepatocytes incubated with ^{14}C-18:3n-3, TAG was the major labeled lipid class at 3 h followed by PC (5).

Liver and cecal mucosa therefore appear to be processing 22:6n-3 in different ways. Gut cells have a high turnover, and therefore substantially more PUFA may be required for local use in this tissue than in liver, which has a major role in the synthesis of PUFA for the whole organism. The increase in D_5-22:6n-3 in liver TAG is suggestive of 22:6n-3 for export, but it is possible that 22:6n-3 is exported from liver, and especially from ceca, as PC or is converted to lysophosphatidylcholine (LPC) (17). Rat liver can secrete large amounts of LPC, which is bound to albumin in the blood, and LPC is often the second most abundant phospholipid in plasma (18). A major proportion of the FA in rat LPC was PUFA (18). It was concluded that LPC may be an important delivery system for PUFA and choline to other tissues (18).

The percent enrichment of D_5-22:6n-3 up to 7 d in the four phospholipid classes from liver was similar over the short and long time courses. The amount of D_5-22:6n-3 fell in all lipid classes from liver from 7 d onward, the decrease being most marked in PC indicating a more rapid turnover of this lipid class. The main differences between the two time courses was that the D_5-22:6n-3 content of TAG fell from 3 d over the long time course whereas it increased from 2 to 7 d over the short time course. This difference may be due to the size of the fish in the two experiments (5.6 g increasing to 10.4 g, long time course, *ca*. 60 g, short time course) with the former group growing rapidly with an increasing lipid pool.

PC and PE from brain were similarly enriched in D_5-22:6n-3 throughout the time course, and by 35 d the specific activity of all four phospholipid classes from brain was similar. TAG from brain showed by far the highest specific activity of D_5-22:6n-3 and therefore turnover of 22:6n-3. The phospholipids in liver were more enriched than their counterparts in brain at 7 d by 10- to 20-fold. A study by Lagarde *et al.* (19) concluded that LPC may be the preferred physiological carrier of 22:6n-3 to the brain. If the blood–brain barrier in fish is similar to that in mammals with respect to FA transport, then 22:6n-3 is probably entering as FFA or LPC and is then incorporated into brain phospholipids, either by deacylation-reacylation reactions or by synthesis of the entire phospholipid *de novo*. The rapid accretion of newly synthesized 22:6n-3 in TAG from brain is therefore rather surprising and underlines our lack of knowledge of these processes in fish brain.

The essentiality of 22:6n-3 in neural tissues is largely imparted by DHA-enriched aminophospholipids, and the brain of rainbow trout contains large amounts of 22:6n-3, much of it as di22:6n-3 molecular species of phospholipids (20). However, despite the crucial importance of 22:6n-3 in neural tissue, the uptake of 22:6n-3 in brain appears to be a slow process. After 7 d, the percent enrichment in PC from liver was 37 times higher than in PC from brain, which was the most enriched lipid class in brain by some margin. In whole trout, the turnover of 22:6n-3 was estimated to be 0.17%/d (1). The data here showed that the accumulation of newly synthesized 22:6n-3 was slow in PE and PS from brain even though this was the most abundant FA in these lipid classes. Several dietary repletion studies in mammals have shown that recovery of 22:6n-3 levels in neural tissues is slow. In rhesus monkeys recovering from an n-3-deficient diet, the half-life of 22:6n-3 in brain PE was estimated to be 21 d (21). n-3-Deficient rats fed a repletion diet replaced 22:6n-3 in serum and liver within 2 wk, but full recovery in brain and retina took 8 wk, suggesting that a slow exchange with 22:5n-6 limited 22:6n-3 repletion in neural tissues (22). Rapoport *et al.* (23) found that after intra-arterial injection of tracer in rats, 2–8% of esterified brain 22:6n-3 was replaced daily by unesterified PUFA in plasma, indicating a half-life of 1–2 wk for plasma–brain exchange of 22:6n-3 in the order PE > PC > TAG > PI > PS. Though the concentration of FFA in plasma was very low, the plasma–brain exchange was very rapid and the rate was thought to be sufficient to supply the brain without the need for exchange of lipoproteins. Slow FA turnover seems to be an inherent property of brain lipids.

In humans, studies on PUFA turnover have concentrated, of necessity, on plasma lipids. Following ingestion of [13]C-22:6n-3 as PC, labeled FA first appeared in plasma as nonesterified FA and TAG, then as LPC and finally as PC and PE (24). This study concluded that the form of ingested 22:6n-3 affected the kinetics and metabolic fate of this FA. In human females, [13]C-22:6n-3 was sevenfold higher in plasma PC than in TAG following ingestion of [13]C-18:3n-3 as FFA (25).

The present study has shown that there are substantial differences in the rates of accretion of newly synthesized 22:6n-3 in lipid classes from different tissues in rainbow trout. Generally, PC, PE, and TAG had higher accretion rates than PS or PI. These differences probably reflect varied functions between tissues and lipid classes. Phospholipid from cecal mucosa contained the great majority of newly synthesized 22:6n-3 in that tissue, whereas in liver TAG was relatively more important. If cecal mucosa exports 22:6n-3, it is likely to be as PC or perhaps LPC and not as TAG. Brain accumulated a surprising amount of D_5-22:6n-3 in TAG, given the abundance and functional significance of 22:6n-3 in phospholipid from this tissue. Much remains to be elucidated regarding the transport of EFA between and within cellular compartments in fish.

ABSTRACT: Atlantic salmon were fed fish meal-based diets supplemented with either 100% fish oil (FO) or 100% rapeseed oil (RO) from an initial weight of 85 g to a final average weight of 280 g. The effects of these diets on the capacity of Atlantic salmon hepatocytes to elongate, desaturate, and esterify [1-^{14}C]18:1n-9 and the immediate substrates for the Δ^5 desaturase, [1-^{14}C]20:3 n-6 and [1-^{14}C]20:4n-3, were investigated. Radiolabeled 18:1n-9 was mainly esterified into cellular TAG, whereas the more polyunsaturated FA, [1-^{14}C]20:3n-6 and [1-^{14}C]20:4n-3, were primarily esterified into cellular PL. More of the elongation product, [1-^{14}C]20:1n-9, was produced from 18:1n-9 and more of the desaturation and elongation products, 22:5n-6 and 22:6n-3, were produced from [1-^{14}C]20:3n-6 and [1-^{14}C]20:4n-3, respectively, in RO hepatocytes than in FO hepatocytes. Further, we studied whether increased addition of [1-^{14}C]18:1n-9 to the hepatocyte culture media would affect the capacity of hepatocytes to oxidize 18:1n-9 to acid-soluble products and CO_2. An increase in exogenous concentration of 18:1n-9 from 7 to 100 µM resulted in a nearly twofold increase in the amount of 18:1n-9 that was oxidized. The conversion of 20:4n-3 and 20:3n-6 to the longer-chain 22:6n-3 and 22:5n-6 was enhanced by RO feeding in Atlantic salmon hepatocytes. The increased capacity of RO hepatocytes to produce 22:6n-3 was, however, not enough to achieve the levels found in FO hepatocytes. Our data further showed that there were no differences in the hepatocyte FA oxidation capacity and the lipid deposition of carcass and liver between the two groups.

Paper no. L9624 in *Lipids 40*, 709–717 (July 2005).

The use of vegetable oils as a substitute for fish oil (FO) in high-energy diets of farmed fish has increased in recent years owing to the limited availability of FO (1–10). A major reason for adding dietary marine oils to salmon feed is to provide adequate amounts of PUFA of the n-3 series in the fish muscle so as to secure the nutritional quality of the fish for human consumption. Many studies in the last decade have shown that salmonids can use vegetable oils in seawater without negative effects on fish growth (1,2,5,7) provided the diets contain enough n-3 PUFA to satisfy EFA requirements (3,4,6,8,11). Rapeseed oil (RO) is a

good supplement for FO in salmon feeds as it has moderate levels of 18:3n-3, is relatively rich in 18:2n-6, and is very rich in 18:1n-9 (7). Culture of salmonids on diets containing high levels of vegetable oils does, however, considerably alter the FA composition of the fish muscle, giving high levels of C_{18} FA and much lower levels of the PUFA 20:5n-3 and 22:6n-3, which are known to have several positive health effects in humans (2,7). The level of these healthful PUFA in fish muscle may be of major importance for the human acceptance of the salmon product. For this reason, there is currently considerable interest in creating diets with FA compositions that can enhance the ability of the fish to produce 20:5n-3 and 22:6n-3 from 18:3n-3, by stimulation of the Δ^5 and Δ^6 desaturases and the elongases involved in the conversion (10). Atlantic salmon can elongate and desaturate C_{18} FA of the n-3 and n-6 series to C_{20} and C_{22} PUFA (8,11–13). The composition of lipids in the diet may, however, modulate the ability of the fish to desaturate and to elongate these FA (11,13–16). Ruyter *et al.* (11) showed that the rates of conversion of 18:3n-3 and 18:2n-6 to 22:6n-3 and 22:5n-6, respectively, are higher in hepatocytes from Atlantic salmon fed an EFA-deficient diet than they are in hepatocytes from fish fed a FO diet. The activity of the Δ^5 desaturase in Atlantic salmon is also found to be higher in hepatocytes from fish fed a diet containing a 1:1 blend of linseed oil and RO than it is in fish fed a diet containing FO (12). This is also the case for fish fed soybean oil diets (17). C_{18} FA were used as radiolabeled substrates for all these studies of desaturation and elongation capacities. It is known, however, that high levels of C_{18} FA may inhibit the conversion of 18:3n-3 to 22:6n-3 in Atlantic salmon, owing to the competition between C_{18} FA and C_{22} FA for the same Δ^6 desaturase (18). In this trial, we incubated with the longer-chain radiolabeled specific Δ^5 desaturase substrates, 20:4n-3 and 20:3n-6, to test whether RO feeding affected the production of 22:6n-3 and 22:5n-6 from C_{20} FA in Atlantic salmon hepatocytes.

To avoid increased lipid deposition, it is important that the FA of the dietary oil is easily oxidized by the fish. *In vitro* studies of mitochondrial β-oxidation in fish suggest that saturated and monounsaturated FA are preferred over PUFA as FA substrates (reviewed by Henderson, 19), but it is not yet known whether RO feeding affects the capacity of salmon liver to oxidize 18:1n-9, which is the dominant FA of RO. Another aim of this study was to investigate whether a dietary supplementation of RO to Atlantic salmon affects the capacity of hepatocytes to oxidize

18:1n-9 and, further, whether it affects lipid deposition in the carcass and the liver.

MATERIALS AND METHODS

Chemicals. The radiolabeled FA [1-^{14}C]18:1n-9, [1-^{14}C]20:3n-6, and [1-^{14}C]20:4n-3 were obtained from American Radiolabeled Chemicals (St. Louis, MO); and nonlabeled FA, BSA that was essentially free of FA, HEPES, 2′,7′-dichlorofluorescein, and collagenase type 1 were obtained from Sigma Chemical Co. (St. Louis, MO). Metacaine (MS-222) was obtained from Norsk Medisinaldepot (Oslo, Norway). Acetic acid, chloroform, petroleum ether, and methanol were all obtained from Merck (Darmstadt, Germany). Benzene was obtained from Rathburn Chemicals Ltd. (Walkerburn, Scotland). Methanolic HCl and 2,2-dimethoxypropane were purchased from Supelco Inc. (Bellefonte, PA). Silica gel K6-coated glass plates were obtained from Whatman International Ltd. (Maidstone, England).

Fish, facilities, and experimental design. The trial was conducted at the AKVAFORSK Research Station, Sunndalsøra, Norway. Atlantic salmon (*Salmo salar*) with a mean initial weight of approximately 85 g were placed into six cylindrical-conical tanks (0.85 m diameter) with 40 fish per tank. The tanks were supplied with seawater at a constant temperature of 12°C. The fish were fed commercial diets before the start of the experiment. The growth trial consisted of one period of 8 wk. Two diets were randomly assigned to triplicate tanks. The feed was distributed by electrically driven disc-feeders (Akvaprodukter AS, Sunndalsøra, Norway). The tanks were designed such that waste feed could be collected from the effluent water in wire mesh boxes. Uneaten feed was collected to monitor daily feed intake in each tank (20).

Diets. The experimental fishmeal-based diets were provided by EWOS Innovation SA (Dirdal, Norway) in the form of 3-mm pellets. The feed contained 0.1% yttrium oxide (Y_2O_3) as an inert marker for determining digestibility (21). The experimental diets, FO and RO, were produced from one common feed mix. The two diets were obtained by coating the common feed pellet with the different oils. The diets contained either 100% FO (capelin oil) or 100% RO. Table 1 shows the formulations and chemical compositions of the diets.

Initial and final sampling. The fish were fasted for 2 d before the initial sampling. The fish from each tank were anesthetized in MS-222, weighed, and measured at the beginning and at the end of the experiment. The fish were not fasted before the final sampling, because of the collection of feces. Five fish from each tank were stripped to collect fecal samples following the procedure described by Austreng (22). Fecal samples from each tank were pooled. The samples were stored at −20°C prior to analyses. A further five fish per tank were anesthetized, killed by a blow to the head, and used for determination of whole body chemical composition.

Chemical analysis. Fish sampled at the beginning and at the end of the experiment were analyzed for dry matter (DM), fat, protein, ash, and energy. DM was determined by drying the fish homogenate to constant weight at 105°C. All diets and fecal samples were analyzed for DM, fat, protein, ash, energy, and yttrium. The amount of protein was determined using a Kjeltec Autoanalyser-N*6.25, whereas the amount of ash was determined by heating to 550°C until constant weight was reached. The amount of fat was determined by ethyl-acetate extraction [NS 9402, 1994 (Atlantic Salmon—Fat Measurement, Norwegian Standards Association, Oslo)], and the amount of yttrium by using inductively coupled plasma-atomic emission spectroscopy at Jordforsk, Ås, Norway, after wet-ashing the samples. Energy in the diets, feces, and whole fish homogenates was analyzed by adiabatic bomb calorimetry using a Parr 1271 bomb calorimeter.

Preparation of salmon hepatocytes. Hepatocytes were isolated from three fish from each tank. The fish were anesthetized in MS-222. The abdominal cavity was exposed and the vena porta cannulated. The liver was perfused, and parenchymal cells were isolated using a two-step collagenase perfusion procedure as described by Seglen *et al.* (23) and modified by Danneving and Berg (24). After collagenase perfusion, the parenchymal cells were easily isolated by gently shaking the liver in Leibowitz-15 medium (L-15). The suspension of parenchymal cells was filtered through a nylon filter with 100-μm mesh. Hepatocytes were isolated from the filtrate by centrifuging it three times, each time for 2 min at $50 \times g$. The hepatocytes were resuspended in L-15 culture medium containing 2% FBS, 2 mM L-glutamine, and 0.1 mg/mL gentamycin. Cell viability was assessed by staining with Trypan blue (0.4%). The protein content of the cell suspension was determined using the method described by Lowry *et al.* (25). Approximately 9×10^6 cells (9–10 mg of protein) were plated onto 75 mL Nunc flasks and left to attach overnight at 12°C.

Incubations with radiolabeled FA. The hepatocytes were thoroughly washed with L-15 medium without additional serum and then incubated at 12°C before the incubation with

radiolabeled FA. We analyzed the desaturation and elongation of FA in hepatocytes incubated for 24 h with 35 nmol [1-^{14}C]18:1n-9, [1-^{14}C]20:3n-6, or [1-^{14}C]20:4n-3 (final concentration 7 µM), and 10 mM lactate in a total volume of 5 mL L-15 medium. The specific radioactivity of the FA was 55 mCi/mmol (1.9 µCi of radioactive FA substrate was added to each cell flask). Hepatocytes were incubated, in a parallel experiment, with 500 nmol of [1-^{14}C]18:1n-9 in a total volume of 5 mL L-15 medium (final concentration 100 µM). The specific radioactivity of the FA was 10 mCi/mmol (5 µCi of radioactive FA substrate was added to each cell flask). The radiolabeled FA were added to the medium in the form of their potassium salts bound to BSA. Control incubations were performed for each radiolabeled FA substrate, and they were treated in the same way as the samples, except that the cell protein was denatured by heating to 80°C prior to the incubations. Samples were incubated for 24 h, and then the culture medium was transferred to vials and centrifuged for 5 min at $50 \times g$. The supernatants were immediately frozen at −40°C and stored until the analysis of radiolabeled lipids. Hepatocytes remaining in the culture flask were washed twice in PBS. The cells were then harvested in PBS, frozen at −40°C, and stored until the analysis of radiolabeled lipids.

Lipid extraction, analysis of lipid classes, and FA composition. Total lipids were extracted from culture media and cells using the method described by Folch *et al.* (26). The chloroform phase produced by the method of Folch *et al.* was then divided in two. One part of the lipid extract was dried under nitrogen gas, and the residual lipid extract was redissolved in hexane. FFA, phospholipids (PL), MAG and DAG (MDG), and TAG were separated by TLC using a mixture of petroleum ether, diethyl ether, and acetic acid (113:20:2 by vol) as the mobile phase. The TLC plates were sprayed with 0.2% (wt/vol) 2′,7′-dichlorofluorescein in methanol and viewed in UV light. Then the lipids classes were identified by comparison with known standards. The spots corresponding to PL, FFA, MDG, and TAG were scraped off into vials containing liquid scintillation fluid (InstaGel II Plus; Packard Instrument, Downers Grove, IL), and radioactivity was measured using a liquid scintillation counter (Tri-Carb 1900TR; Packard Instrument).

The remaining lipid extract was placed into glass tubes and transmethylated overnight with 2,2-dimethoxypropane, methanolic HCl, and benzene at room temperature, as described by Mason and Waller (27). The compositions of the radioactive FA of the total lipid fraction were determined by reversed-phase HPLC as described by Narce *et al.* (28) The mobile phase was acetonitrile/H$_2$O (80:20 vol/vol, isocratic elution) at a flow rate of 1 mL/min at 30°C. A reversed-phase Symmetry 3.5 µm C-18 HPLC column from Waters was used. The levels of radioactivity from FA were measured in a radioactive flow detector A100 (Tri-Carb 1900TR; Packard Instuments). The absorbance of nonradioactive FA was measured in a UV detector (SPD-6AV UV-visible spectrophotometric detector; Shimadzu) at 215 nm. The FA were identified by comparing the sample retention times with the retention times of FA standards.

The total FA compositions of hepatocytes were determined essentially as described by Ruyter *et al.* (17). Lipids were extracted and then transmethylated as described above. The methyl esters of FA thus formed were separated in a gas chromatograph (GC) using a Perkin-Elmer Auto system GC equipped with an injector, programmable split/splitless injector with a CP Wax 52 column (length 25 m, internal diameter 0.25 mm, and film thickness 0.2 µm), FID. The carrier gas was He, and the injector and detector temperatures were 280°C. The oven temperature was raised from 50 to 180°C at the rate of 10°C min^{-1}, and then raised to 240°C at the rate of 0.7°C min^{-1}. The relative quantity of each FA present was determined by measuring the area under the peak corresponding to the particular FA.

Measurement of [1-^{14}C]ASP (acid-soluble products) and [1-^{14}C]CO$_2$. FA oxidation was measured essentially as described by Christiansen *et al.* (29). The amount of gaseous [1-^{14}C]CO$_2$ produced during the incubation was determined by transferring 1.5 mL of medium to a glass vial, which was then sealed. The glass vial had a central well containing Whatman filter paper moistened with 0.3 mL of phenylethylamine/methanol (1:1, vol/vol). The medium was acidified with 0.3 mL 1 M HClO$_4$. The samples were incubated for 1 h, and then the wells, containing the filter papers, were placed into vials for scintillation counting. The quantities of [1-^{14}C]

ASP present were determined by acidifying 1 mL of the medium with 0.5 mL ice-cold 2 M HClO$_4$ and incubating the sample for 60 min at 4°C. The medium was then centrifuged, and an aliquot of the supernatant was collected for scintillation counting.

Calculations. Apparent digestibility coefficients were calculated as described by Austreng *et al.* (21). Hepatosomatic index (HSI), specific growth rate (SGR), and thermal growth coefficient (TGC) were calculated as follows, based on individual recordings of weights and lengths:

$$\text{HSI} = 100 \times \text{liver weight} \times W_f^{-1} \qquad [1]$$

$$\text{SGR} = \{\exp\,[(\ln W_f - \ln W_i)/\text{days}] - 1\} \times 100 \qquad [2]$$

$$\text{TGC} = (W_f^{1/3} - W_i^{1/3}) \times 1000/(\text{d} \times °\text{C}) \qquad [3]$$

where W_i is the initial weight and W_f is the final weight, and

$$\text{recovery} = \text{total nmol of }^{14}\text{C}_{\text{whole incubation}} \qquad [4]$$

where the radioactivity recovered in the whole incubation was the radioactivity recovered in hepatocytes lipid + the radioactivity recovered in the culture media.

Statistical analysis. All data were subjected to two-way ANOVA for the factors "FA" and "diet," and differences were ranked by Duncan's multiple range test. The significance level was set at 5%. Data that were identified as nonhomogeneous by Bartlett's test were subjected to arcsine transformation before analysis.

[a]Values are means ± SEM (*n* = 3). [a,b]Differences between mean values within a given row are significant (*P* ≤ 0.05), as indicated by different superscript letters.
[b]Values are g/100 g wet tissue Atlantic salmon sampled at the beginning (start) and at the end (means ± SEM. *n* = 3) of the experiment were analyzed for dry matter, fat, protein, ash, and energy content. For abbreviations see Table 1.

RESULTS

Growth, feed intake. and nutrient digestibilities. The fish in both dietary groups grew from an initial weight of approximately 85 g to a final weight of approximately 280 g, a three-fold increase. The two groups had the same SGR, 1.8 (Table 2). The feed efficiency ratio (FER) was significantly higher for the fish fed the RO diet (FER = 1.41) than it was for the fish fed the FO diet (FER = 1.23) (Table 2). The total digestibility of FA in both dietary groups was high, approximately 97%. There were no significant differences in nutrient digestibility between the two groups in this trial (Table 2).

Body composition and liver lipid content. Dietary RO did not affect the gross chemical composition of the carcass (Table 2). The total liver lipid content in fish fed the RO and the FO diet was approximately 5%, and there was no statistical difference between the two groups.

FA compositions of diets and hepatocytes. The FA compositions of the diets clearly reflected that of added oils (Table 3). The levels of the n-3 FA, however, were higher in the diets than in the added oils, since the feed contained significant amounts of fish meal. The FO diet was characterized by relatively high levels of the long-chain n-3 FA 20:5n-3 and 22:6n-3, and low

levels of FA with 18-carbon chains. The RO diet, on the other hand, contained approximately 40% 18:1n-9.

Table 3 also shows the endogenous FA composition of the total lipid fraction of hepatocytes. The percentages of 18:1n-9 were 22 and 12 for fish fed the RO and FO diet, respectively. The percentage of 18:2n-6 in the total lipids from hepatocytes was almost five times greater in fish fed the RO diet than in fish fed the FO diet. RO hepatocytes also had significantly higher percentages of the desaturation product of 18:2n-6, 18:3n-6, than FO hepatocytes. The percentage of 20:4n-6 was, however, approximately the same for the FO hepatocytes as it was for the RO hepatocytes. The percentage of the longer-chain n-3 PUFA, 20:5n-3 and 22:6n-3, in the total lipid fraction of hepatocytes was 41% in the FO group, whereas it was 31% in the RO group. The percentage of saturated FA was approximately 22% in the FO hepatocytes and 18% in the RO hepatocytes.

Figure 1 shows the relative distribution of 18:1n-9, 18:2n-6, 20:5n-3, and 22:6n-3 within the lipid classes TAG, PL, and FFA. The percentage of 18:1n-9 found as FFA in RO hepatocytes was significantly higher (about 40% of the total endogenous FFA pool) than in FO hepatocytes (about 12%). RO hepatocytes also had a higher percentage of 18:2n-6 in the PL and FFA fractions than FO hepatocytes. The 22:6n-3 was primarily

[b]Includes 12:0; 15:0; 17:0; 20:0.
[c]Includes 16:1n-9; 18:1n-6; 22:1n-11.
[d]Includes 16:3n-4; 20:4n-3; 20:2n-6; 20:3n-3.

esterified into PL and there were only minor differences in the percentage of this FA in the PL between the two dietary groups. The percentage of 22:6n-3 was, however, about fivefold higher in the FFA fraction of the FO hepatocytes than in RO hepatocytes.

Recovery of [1-^{14}C]FA in lipid classes, extracellular lipids, and oxidation products. Hepatocytes were incubated for 24 h with 7 μM [1-^{14}C]18:1n-9, [1-^{14}C]20:3n-6, or [1-^{14}C]20:4n-3 to study FA uptake, oxidation, and esterification. Table 4 shows the amounts of radioactivity that were incorporated into each fraction during the 24-h incubation as percentages of the total radioactivity recovered from the whole incubation. No significant differences were observed between the FO and RO hepatocytes. In both groups, significantly more radioactivity from the [1-^{14}C]20:3n-6 and [1-^{14}C]20:4n-3 substrates (approximately 70%) was present in hepatocytes than from the [1-^{14}C]18:1n-9 substrate (50–55%). Radiolabeled 18:1n-9 was mainly esterified in the TAG fraction of hepatocytes, where it constituted approximately 30% of the total radioactivity, whereas approximately 15% was esterified in the PL. In contrast, the radiolabeled n-3 and n-6 FA were esterified to a greater extent in the PL fraction, where they constituted 52–56% of the total radioactivity. Esterified n-3 and n-6 FA constituted 6–10% in the TAG and 2–4% in the pooled MAG and DAG (MDG) fraction. Between 4 and 6% of the total radioactivity from the three radioactive substrates was not esterified but recovered as FFA. Table 5 shows also the recovery of

radiolabeled lipids in the culture media. Significantly higher percentages of radiolabeled lipids were recovered from the culture media for cells incubated with [1-^{14}C]18:1n-9 than for cells incubated with [1-^{14}C]20:3n-6 and [1-^{14}C]20:4n-3, which was primarily in the form of FFA (23–25%). More of the substrates [1-^{14}C]18:1n-9 and [1-^{14}C]20:3n-6 was oxidized (approximately 13%) than of the [1-^{14}C]20:4n-3 substrate (10%).

Figure 2 shows the oxidation of [1-^{14}C]18:1n-9 to ASP and CO_2 when the hepatocytes were incubated with either 7 or 100 μM [1-^{14}C]18:1n-9 substrate for 24 h. The higher exogenous

[a]Hepatocytes from fish fed the FO and RO diets were incubated with 7 μM [1-^{14}C] FA. DI = desaturation index; DI$_{20:3n-6}$ was calculated as: (20:4 + 22:4 + 22:5 + 24:5n-6/20:3 +20:4 +22:4 + 22:5 + 24:5) × 100 and DI$_{20:4n-3}$ as: (20:5 + 22:5 + 22:6 + 24:5 + 24:6/20:4 +20:5 + 22:5 + 22:6 + 24:5 + 24:6) × 100. Data are means ± SEM ($n = 3$). [a,b]Differences between mean values within a given row are significant ($P ≤ 0.05$) except for (*) and (**) where $P ≤ 0.01$. Data that were identified as nonhomogeneous by Bartlett's test were subjected to arcsine transformation before analysis. Recovery = nmol of [1-^{14}C]FA recovered in lipid total fractions of hepatocytes after 24 h incubation. The total recoveries of radioactivity of the incubations are shown in Table 4. For other abbreviations see Table 1.
FIG. 2. The effects of different exogenous levels (7 and 100 µM) of [1-^{14}C]18:1n-9 on the capacity of hepatocytes to oxidize [1-^{14}C]18:1n-9. The values are given as means of pmol [1-^{14}C]18:1n-9 oxidized per mg protein per day.

concentration of 18:1n-9 led to a twofold increase in the amount of oxidation products formed compared with the lower concentration. There were no significant differences in the amount of oxidation products formed between the two dietary groups.

Desaturation and elongation of [1-^{14}C]18:1n-9, [1-^{14}C]20:3n-6, and [1-^{14}C]20:4n-3. Table 5 shows the desaturation and chain-elongation of [1-^{14}C]FA in the total lipids of hepatocytes. The main radiolabeled FA recovered from [1-^{14}C]18:1n-9 were the unchanged substrate 18:1n-9 and its elongated product 20:1n-9. The production of 20:1n-9 was significantly higher in RO hepatocytes (13%) than in FO hepatocytes (9%). The main metabolites from [1-^{14}C]20:3n-6 were the unchanged substrate and 20:4n-6. The only significant difference in results between the groups was in the final product, 22:5n-6, which was higher for the RO hepatocytes than it was for the FO hepatocytes. The main metabolites in the lipid fraction from [1-^{14}C]20:4n-3 were the unchanged substrate, 20:5n-3, and 22:6n-3. Further, the percentage of the Δ^5 desaturase product, 20:5n-3, was significantly lower for the RO hepatocytes than it was for the FO hepatocytes. Interestingly, the production of the final elongation product, 22:6n-3, was higher for the RO hepatocytes than it was for the FO hepatocytes.

DISCUSSION

This work shows that RO is an effective substitute for FO in Atlantic salmon diets, giving similar growth rates and having no apparent ill effects on fish health, which is also in agreement with what we have previously shown (2), and which has also been confirmed by more recent studies (7). The endogenous FA composition of hepatocyte lipids was, as expected, influenced by the dietary oils. The RO diet considerably increased the per-

centages of 18:1n-9, 18:2n-6, 18:3n-3, and 20:3n-6 in hepatocyte lipids. These results agree with those of Bell *et al.* (7), who found that the level of 18:1n-9 in the Atlantic salmon liver was well correlated to the dietary level of RO. Further, Ruyter *et al.* (8) found higher levels of total n-6 FA in salmon hepatocytes fed diets supplemented with soybean oil. In our results, these increases were accompanied by decreases in the percentages of 20:5n-3, 22:6n-3, and saturated FA in the total lipids of hepatocytes. The FA 18:3n-6 and 20:3n-6 were detected in RO hepatocytes, although they were not present in the RO diet. Both the appearance of these FA in the hepatocyte lipids and the reduced percentage of hepatocyte 18:2n-6 relative to the diet suggest a substantial desaturation and elongation of 18:2n-6 in the RO hepatocytes. The percentage of 20:4n-6 was, however, not higher in RO hepatocytes than in FO hepatocytes. Similarly, a reduced percentage of 18:3n-3 and increased percentages of 20:5n-3, 22:5n-3, and 22:6n-3 in RO hepatocytes relative to the RO diet may suggest an active desaturation and elongation of 18:3n-3, although not enough to keep the levels of these important FA as high as observed for the FO hepatocytes. This reduction in the very long n-3 FA with vegetable oil feeding has been repeatedly observed, in total salmon lipids as well as in PL and TAG fractions of muscle and organs such as liver and heart (2–4,7–10).

We found that higher percentages of radioactive n-3 and n-6 PUFA (20:3n-6 and 20:4n-3) were incorporated into hepatocyte lipids than the monounsaturated 18:1n-9, indicating that the longer n-3 and n-6 PUFA are more rapidly taken up by the cell than 18:1n-9 during 24 h of incubation. It has recently been reported (30) that salmon muscle cells have a higher capacity for incorporating n-3 FA than they have for n-9 FA. Further, we recovered more than twice as much radioactivity from the [1-^{14}C]18:1n-9 substrate as extracellular FFA and also as secreted radiolabeled TAG in the culture media than we recovered from any of the n-3 and n-6 substrates. The extracellular radiolabeled FFA are probably unmetabolized FA substrates, since FA that are taken up by the cells and then further secreted to the medium are primarily in an esterified form (31).

The distribution of radioactivity among different lipid classes differed for the different [1-^{14}C]FA substrates added to the hepatocytes but was not affected by dietary oil. For both dietary groups, radiolabeled 18:1n-9 was preferentially incorporated into TAG, whereas the longer-chain n-3 and n-6 PUFA were preferentially incorporated into cellular PL. *In vivo* experiments have previously shown that dietary 18:1n-9 is preferentially incorporated into TAG in Atlantic salmon (32), and *in vitro* experiments with [1-^{14}C]18:1n-9 in mammals (33) have shown the same. In contrast, longer-chain n-3 and n-6 PUFA are primarily incorporated into PL (32,34). This is probably due to specificity of the esterification enzymes involved in the formation of PL and TAG (35).

The rate of elongation of 18:1n-9 is reflected in the ratio of 20:1/18:1. This ratio was significantly higher in RO hepatocytes than it was in hepatocytes from fish fed the FO diet. The mechanism behind the increased elongation of 18:1n-9 to 20:1n-9 in the hepatocytes from RO-fed fish is not clear.

Substrate induction due to the high level of 18:1n-9 in the FFA fraction of RO hepatocytes is possible. An elongase of broad substrate specificity is described in the liver of salmon, and its expression may be induced by vegetable oil feeding (36). To what extent this elongase is responsible for the elongation of 18:1n-9 is, however, at present not clarified.

The reason why 18:1n-9 was elongated mainly to 20:1 (dead-end elongated product) rather than desaturated and elongated through the n-9 pathway is explained by competition between 18:1n-9, 18:2n-6, and 18:3n-3 for the Δ^6 desaturase (37). The presence of C_{18} FA of the n-3 and n-6 families prevents formation and accumulation of more unsaturated n-9 FA. Thus, 18:1n-9 is further desaturated and elongated to 20:3n-9 only in the absence of both EFA 18:2n-6 and 18:3n-3 (11,38).

The production of the end-product [1-^{14}C]22:5n-6 from 20:3n-6 was significantly higher in RO than it was in FO hepatocytes. Similarly, in the n-3 series, [1-^{14}C]22:6n-3 also was produced from 20:4n-3 to a greater extent in RO hepatocytes, strongly suggesting that the Δ^5 desaturase activity was higher in these cells. To our knowledge the present study is the first one to use the immediate substrates for the Δ^5 desaturase, and our results agree with studies where C_{18} FA was used (7,10,13,39), showing that the hepatic FA desaturation and elongation activities were increased with dietary inclusion of vegetable oils. The mechanism(s) behind the increased Δ^5 desaturase activity are still being debated. In a recent study (36), dietary linseed oil led to increased mRNA expression of a Δ^5 desaturase in salmon liver. However, in the same study, the apparent Δ^5 desaturase activity, calculated from results after incubation of hepatocytes with radiolabeled 18:3n-3, showed no clear relationship to the level of dietary linseed oil. Feedback inhibition of both Δ^5 and Δ^6 desaturase activities by high levels of 22:6n-3 also has been suggested. This may explain the lower 22:6n-3 production in FO hepatocytes, which contained a relatively higher percentage of 22:6n-3 in the FFA fractions than comparable RO hepatocytes.

Hepatocytes incubated with 100 µM 18:1n-9 had twice as high a capacity to β-oxidize radiolabeled 18:1n-9 than hepatocytes incubated with 7 µM 18:1n-9. However, the higher endogenous percentage of 18:1n-9 in RO hepatocytes (22%) than in FO hepatocytes (12) did not significantly affect the β-oxidation of 18:1n-9. Addition of radiolabeled FA into pools of potentially different FA compositions, as in the present study, may lead to some interpretation problems. The significantly higher percentage of unlabeled 18:1n-9 observed in the FFA fraction of the RO hepatocytes may thus be expected to lead to a higher dilution of the radiolabeled substrate, resulting in an underestimation of the oxidation capacity. If we assume that the endogenous pool of nonlabeled 18:1n-9 FFA would oxidize to the same extent as the exogenously added radiolabeled 18:1n-9, then the actual amount of 18:1n-9 oxidized would be higher in the RO group than in the FO group. Another unlabeled FFA that differs in endogeneous concentration between the two dietary groups and might also influence the oxidation capacity is 22:6n-3. It is known that 22:6n-3 may induce peroxisomal FA oxidation (40).

In conclusion, supplementing the diet of Atlantic salmon with RO changes the endogenous FA composition of hepatocytes and leads to higher endogenous percentages of 18:1n-9, 18:2n-6, 18:3n-3, and 20:3n-6. Our results strongly suggest an increased elongase and Δ^5 desaturase activity, since higher percentages of 20:1n-9, 22:5n-6, and 22:6n-3 were formed from their radiolabeled precursors. The increased capacity of RO hepatocytes to produce 22:6n-3 was, however, not enough to keep the level of this important FA as high as observed in the FO hepatocytes. Further, lipid deposition in the carcass and liver did not differ between the two dietary groups. Increased addition of [1-^{14}C]18:1n-9 to the hepatocyte culture media, however, resulted in an increase in the amount of 18:1n-9 that was oxidized.

Nutrition & Food Safety, Neurobiology of Lipids, INRA (l'Institut National de la Recherche Agronomique), Jouy-en-Josas, France

ABSTRACT: Synthesis of docosahexaenoic acid (DHA) from its metabolic precursors contributes to membrane incorporation of this FA within the central nervous system. Although cultured neural cells are able to produce DHA, the membrane DHA contents resulting from metabolic conversion do not match the high values of those resulting from supplementation with preformed DHA. We have examined whether the DHA precursors downregulate the incorporation of newly formed DHA within human neuroblastoma cells. SH-SY5Y cells were incubated with gradual doses of α-linolenic acid (α-LNA), EPA, or docosapentaenoic acid (DPA), and the incorporation of DHA into ethanolamine glycerophospholipids was analyzed as a reflection of synthesizing activity. The incorporation of EPA, DPA, and preformed DHA followed a dose–response saturating curve, whereas that of DHA synthesized either from α-LNA, EPA, or DPA peaked at concentrations of precursors below 15–30 μM and sharply decreased with higher doses. The mRNA encoding for six FA metabolism genes were quantified using real-time PCR. Two enzymes of the peroxisomal β-oxidation, L-bifunctional protein and peroxisomal acyl-CoA oxidase, were expressed at lower levels than fatty acyl-CoA ligase 3 (FACL3) and Δ6-desaturase (Δ6-D). The Δ6-D mRNA slightly increased between 16 and 48 h of culture, and this effect was abolished in the presence of 70 μM EPA. In contrast, the EPA treatment resulted in a time-dependent increase of FACL3 mRNA. The terminal step of DHA synthesis seems to form a "metabolic bottleneck," resulting in accretion of EPA and DPA when the precursor concentration exceeds a specific threshold value. We conclude that the critical precursor- concentration window of responsiveness may originate from the low basal expression level of peroxisomal enzymes.

Abbreviations: α-LNA, α-linolenic acid; AOX, peroxisomal acyl-CoA oxidase; ChoGpl, choline glycerophospholipids; Ct, threshold cycle number; DBP, D-bifunctional protein; Δ6-D, Δ6-desaturase; DHA, docosahexaenoic acid (22:6n-3); DMA, dimethylacetals; DPA, docosapentaenoic acid (22:5n-3); ELOVL4, brain fatty acid elongase-4; EPA, eicosapentaenoic acid (20:5n-3); ER, endoplasmic reticulum; EtnGpl, ethanolamine-glycerophospholipids; FACL3, fatty acyl-CoA ligase 3; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; LBP, L-bifunctional protein; PlsEtn, 1-*O*-alkyl-1'-enyl-2-acyl-*sn*-glycero-3-phosphoethanolamine; PPAR, peroxisome proliferator-activated receptors; PtdEtn, phosphatidylethanolamine; PtdSer, phosphatidylserine; RT-PCR, reverse-transcription polymerase chain reaction; THA, tetracosahexaenoic acid (24:6n-3).

The incorporation of docosahexaenoic acid (DHA, 22:6n-3) in the nerve membranes during perinatal development is essential to the development of cerebral and retinal functions (reviewed in Refs. 1 and 2). DHA may be taken up through blood vessels by the brain (3) and retina (4), or synthesized by the brain and retinal cells from its dietary precursors, mainly α-linolenic acid (α-LNA, 18:3n-3) and eicosapentaenoic acid (EPA, 20:5n-3). The conversion of α-LNA, the essential precursor, into EPA, docosapentaenoic acid (DPA, 22:5n-3), and tetracosahexaenoic acid (THA, 24:6n-3) occurs in the endoplasmic reticulum (ER) through successive desaturations and elongations. THA is then transferred to the peroxisomes, where it is β-oxidized to give DHA (5,6). The essentiality of this peroxisomal step has been demonstrated in studies on human fibroblasts, in which gene mutations of peroxisomal acyl-CoA oxidase (AOX) or of D-bifunctional protein (DBP) were associated with the loss of DHA synthesis capacity (7,8).

Increasing the α-LNA intakes in humans has been considered as a possible way of increasing DHA synthesis. However, α-LNA dietary intakes do not appear to support DHA levels in the neonate brain as high as those in preformed DHA intake (9–11). Actually, studies in newborn infants fed milk replacers (12–14) and clinical studies in adults (15,16) have shown that the α-LNA nutritional strategy mainly induces the DHA upstream precursors, EPA and DPA, to increase in the blood lipids, not DHA. Clinical studies using stable isotope tracers in adults have demonstrated that the conversion of plasma α-LNA to DHA accounts for much less than 1% (16–20). This could result from the preferential β-oxidation of α-LNA, reducing its entry into the pathway of long-chain synthesis (21–25). It is also proposed that a feedback control mechanism responsive to the plasma concentration of DHA regulates its own synthesis, thereby maintaining DHA homeostasis during dietary changes in n-3 FA (19).

The mechanisms responsible for the low conversion rate at the cellular and molecular levels remain hypothetical. The peroxisomal pathway could be the limiting step, as it requires complex movements of very long chain derivatives between the ER and the peroxisomes (26). On the other hand, α-LNA itself may down-regulate its conversion (23), possibly by competing with 24:5n-3 for Δ6-desaturation. *In vitro* studies have shown that rat astrocytes (27–30), retinal cells in primary cul-

ture (31), and established cell lines from human retinoblastoma (32–34) all have the enzyme activities needed for DHA synthesis. Nevertheless, it has never been shown that the incorporation of precursor-derived DHA into phospholipids can reach levels as high as those resulting from the incubation of cells with equivalent concentrations of preformed DHA. In previous works, we demonstrated that the phospholipid incorporation of preformed DHA in the cells from human neuroblastoma and retinoblastoma lines can reach the high physiological plateau value that is characteristic of the retina and brain (35), whereas the major FA to increase in phospholipids upon incubation with the DHA upstream precursors are EPA and DPA, not DHA (36,37). A possible hypothesis explaining why the incorporation of the newly formed DHA into phospholipids is strongly limited in spite of its actual synthesis may be that the gene expression of some enzymes of the ER and/or peroxisomal pathways is readily down-regulated. We previously found that the mRNA expression of AOX in Y79 retinoblastoma cells was depressed as the α-LNA dose in the medium increased (37), raising the question of whether this effect was induced by α-LNA itself or by one of its downstream products. In the present study, we have considered the hypothesis that transcription of genes involved in DHA synthesis could be modulated in the neuroblastoma cells by EPA, the main long-chain product of α-LNA. We have quantified, in human neuroblastoma cells (SH-SY5Y), the mRNA levels of genes encoding for several key enzymes of both the ER and peroxisomal steps of FA metabolism, i.e., the FA-CoA ligase 3 (FACL3), Δ6-desaturase (Δ6-D), brain FA elongase-4 (ELOVL4), and peroxisomal enzymes of β-oxidation, AOX, DBP, and L-bifunctional protein (LBP). Concurrently, we analyzed, as reflecting n-3 metabolism, the incorporation into cell phospholipids of EPA itself and of the newly formed DPA and DHA. We then examined whether the mRNA profile responded to a dose of EPA found to be inhibiting toward DHA incorporation.

MATERIALS AND METHODS

Cell culture. Human SH-SY5Y neuroblastoma cells, obtained from the European Collection of Animal Cell Culture (Porton Down, Salisbury, United Kingdom), were cultured as a suspension in DMEM supplemented with 10% heat-inactivated FBS, 50 IU/mL penicillin, 50 μg/mL streptomycin, and 2 mM glutamine (Gibco BRL, Cergy-Pontoise, France). The cells were grown in Falcon 75-cm^2 tissue culture flasks in an incubator maintained at 37°C with 5% CO_2 in humidified air as the gas phase. In all experiments, the cells were seeded at a density of 5×10^6 cells/flask and left to adhere to the plastic flask for 24 h before being incubated with FA. The DNA contents were measured using the bisbenzimide fluorescence assay (38) on cells cultured for 16 or 48 h (postadhesion) with 70 μM EPA.

FA analysis. Cells were transferred to media supplemented with gradual concentrations (7 to 70 μM) of α-LNA, EPA, DPA, or DHA that did not exceed their maximum capacity of phospholipid incorporation, for the reason that these concentrations should be considered as bordering on physiological

values (35). FA sodium salts (Nu-Chek-Prep, Elysian, MN) were directly dissolved in the 10% FCS medium to give a concentration of 7, 15, 30, or 70 μM. After 16, 48, or 72 h (postadhesion) of incubation, the cells were trypsinized and harvested by centrifugation, washed with PBS containing 50 μM FA-free albumin (Sigma-Aldrich Chimie, Saint Quentin Fallavier, France) to remove any FA adsorbed onto the cell surface. The total lipids were extracted from 1 vol of cell homogenate with 4 vol of chloroform/methanol (2:1, vol/vol) in the presence of 0.005% (by wt) BHT. The lipid bottom phase was washed, dried, solubilized in chloroform, and stored at −80°C until separation of the ethanolamine-glycerophospholipids including plasmenylethanol-amines (total EtnGpl). The EtnGpl fraction was purified by solid-phase extraction on a 500-mg prepacked aminopropyl cartridge (J.T.Baker, Deventer, The Netherlands) (36). The cartridges were equilibrated beforehand with eluent 1 (isopropanol/chloroform, 1:2, vol/vol). Each sample of total lipids was dried under nitrogen, resolubilized in 250 μL of eluent 1 and deposited onto a single cartridge, which was immediately eluted successively with 3 mL of eluent 1, 3 mL of diethyl ether/acetic acid (98:2, vol/vol), 1 mL of acetonitrile, and 8 mL of acetonitrile/*n*-propanol (3:1, vol/vol) to recover the choline glycerophospholipids (ChoGpl) fraction, and then with 2 mL of acetonitrile/*n*-propanol (1:1, vol/vol) and 3 mL of methanol to recover the EtnGpl fraction consisting of a mixture of phosphatidylethanolamine (PtdEtn) and 1-*O*-alkyl-1′-enyl-2-acyl-*sn*-glycero-3-phosphoethanolamine (PlsEtn). The phosphatidylserine (PtdSer) fraction was recovered by eluting with isopropanol/methanolic HCl (4:1, vol/vol). All fractions were dried under a nitrogen flux and transmethylated by methanol at 90°C in the presence of BF_3. The methyl esters were extracted, washed, and injected through the on-column injector of a 9000 gas chromatograph (Chrompack, Middelburg, The Netherlands) equipped with a retention gap and a CP-WAX 52 CB bonded fused-silica capillary column of 0.25 mm i.d. and 60 m length (Varian, Les Ullis, France). The oven temperature was programmed for 79–212°C at a heating rate of 4°C/min. The instrument responses attributable to FAME and to dimethylacetals (DMA, issuing from transmethylation of the alkenyl-acyl phospholipids) were automatically integrated, and their factor response and ECL were compared with standard compounds. All compositions were expressed as a percentage by weight of total FA.

Quantification of mRNA expression by real-time reverse transcription (RT)-PCR. RNA extraction and cDNA synthesis. Total cellular RNA was prepared from cells cultured for 16 or 48 h with 70 μM of EPA by using an RNeasy Lipid Tissue Midi Kit according to the manufacturer's instructions (Qiagen S.A., Courtaboeuf, France). Total RNA concentrations were determined by absorbance measurements at 260 nm using a Biophotometer (Eppendorf SARL, Le Pecq, France). Subsequently, 6 μg total RNA was reverse-transcribed using the High Capacity cDNA Archive Kit (Applied Biosystems, Foster City, CA) according to the manufacturer's instructions.

Primers. Primers for the target were designed with the assistance of Primer Express 2.0 (Applied Biosystems). Glycer-

[a]Coordinates according to GenBank. AOX, peroxisomal acyl-CoA oxidase; ELOVL4, brain FA elongase-4; FACL3, fatty acyl-CoA ligase 3; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; DBP, D-bifunctional protein; LBP, L-bifunctional protein.

aldehyde-3-phosphate dehydrogenase (GAPDH) was used as a housekeeping gene to normalize the mRNA abundance of each target gene. We conducted BLASTN searches against Gen-Bank to check the total gene specificity of the nucleotide sequences chosen for the primers (Tables 1, 2). The expression of Δ6-D was evalutated using quantitative RT-PCR based on a specific set of primers and probes (Assays-on-Demand, gene expression products; Applied Biosystems). Quantitative values for cDNA amplification were obtained (using Sequence Detector) from the threshold cycle number (Ct) at which the increase in the signal associated with exponential growth of PCR products begins to be detected.

Real-time quantitative PCR amplification. PCR reactions were performed using the ABI Prism 7000 Sequence Detection Systems (Applied Biosystems). Each cDNA was amplified in a 25-μL volume containing 12.5 μL of 2× SYBR Green master mix (Applied Biosystems) and 300-nM concentrations of gene-specific primers (Table 1). Melting curves were used to determine the temperature at which only the amplicon, and not primer dimers, accounted for the SYBR Green-bound fluorescence. For Δ6-D cDNA amplification, the 25-μL reaction volume contained 10 μL of 2× TaqMan Universal Master Mix (Applied Biosys-

tems) and 1 μL of 20× Assays-on-Demand (Hs00188654-m1 and Hs99999905-m1 for Δ6-D and GAPDH, respectively). Thermal cycling conditions comprised an initial denaturation step at 95°C for 10 min and 45 cycles at 95°C for 15 s and 60°C for 1 min. Amplification of cDNA was performed in triplicate for each data point, with each condition (culture duration, incubation with EPA) also being reproduced in triplicate.

Standard curves. To establish the calibration curves, a cDNA fragment of each gene was amplified using conventional PCR (Table 2). These fragments were purified using the Qiaquick Gel Extraction and PCR Purification kits (Qiagen), quantified spectrophotometrically, and sequenced (Genome Express, Meylan, France). PCR amplification was performed with template dilutions ranging from 101 to 106 copies. Overall efficiencies (*E*) of PCR were calculated from the slopes of the standard curves according to the equation

$$E = [10^{-1/\text{slope}}] - 1 \qquad [1]$$

Normalization. All cDNA were amplified with an efficiency above 98%, indicating that GAPDH and target genes were amplified with the same efficiency. Therefore, we used the ΔCt

[a]Coordinates according to GenBank. For abbreviations see Table 1.

method to quantify the PCR products. Triplicate measurements of Ct were performed in each sample (intra-assay variation), and the average of three values was used to determine the ΔCt ($Ct_{GAPDH} - Ct_{gene}$). In theory, when the PCR efficiency is equal to 100%, a gap of 3.3 cycles of amplification between the target gene and the housekeeping gene corresponds to a 10-fold difference in the respective amounts of amplicon. From the ΔCt value, the abundance of each mRNA was thus reported relative to the GAPDH abundance according to the following equation:

$$\text{mRNA relative abundance} = 100/[(\Delta Ct \times 10)/3.3] = 33/\Delta Ct \quad [2]$$
(expressed in percentage of GAPDH)

Statistical analysis. The data were analyzed using StatView+ Graphics software (Abacus Concepts Inc., Berkeley, CA) by one-way ANOVA (time factor or treatment factor) followed by the multiple-comparison Fisher test. The differences due to culture duration in mean values (± SD) for FA within the EtnGpl fraction were compared after 16 and 72 h of culture without n-3 supplementation (time factor) at three levels of significance: $P < 0.02$, $P < 0.01$, or $P < 0.001$. Differences in the relative abundance of mRNA produced by a given target gene after 16 or 48 h of incubation with EPA were compared considering four treatments: 16 h/EPA 0 µM, 48 h/EPA 0 µM, 16 h/EPA 70 µM, and 48 h/EPA 70 µM. The differences in mRNA abundances due to the EPA treatment were considered significant at $P < 0.01$ or $P < 0.001$.

RESULTS

Effect of EPA on cell growth. Supraphysiological concentrations (500 µM) of PUFA in the culture medium have genotoxic effects on hepatocytes, especially in cells cultured without serum or antioxidants (39). Although we used EPA only at physiological concentrations, we checked to ensure that EPA did not reduce the growth rate of SH-SY5Y cells. A 70-µM quantity of EPA had no significant impact on cell growth, even after 48 h in culture (Table 3).

FA composition of cell phospholipids in standard conditions. The FA composition in EtnGpl from cells cultured for 16, 48, and 72 h in 10% FCS medium, and the ChoGpl and PtdSer FA compositions at 72 h are reported in Table 4. The data at 72 h show that the concentration of total n-3 FA was higher in EtnGpl (9.1% of total FA) than in PtdSer (4.4%) and ChoGpl (1.9%). Owing to this specific FA composition, we focused on the impact of the n-3 treatment within the EtnGpl fraction.

The time-dependent changes in the EtnGpl FA composition mainly consisted of a 44% increase in n-3 FA ($P < 0.01$), which compensated for a 55% decrease in n-6 FA ($P < 0.001$). In the absence of supplemental n-3 FA, this change in the FA composition within growing neural cells may reflect the increasing use of n-3 FA from the FCS lipids for membrane biogenesis. Nevertheless, even after 72 h of culture, the n-6 content in the three classes was two times higher than that of n-3 FA, finally reflecting the relative proportions of n-6 and n-3 FA in the

medium (36). It is noteworthy that, at the same time, cells increased their content of trienoic FA, 20:3n-9 and 22:3n-9 ($P < 0.001$), which is indicative of their metabolic ability to compensate for their low content of very long chain PUFA. This "spontaneous" synthesis of trienoic FA suggests that the desaturases are constitutively active in SH-SY5Y cells. Nevertheless, neuroblastoma cells cultured with 10% FCS must be considered as being specifically deficient in DHA, more particularly if their high "avidity" for the preformed DHA is taken into account (35). Actually, the basal DHA content in SH-SY5Y cells (around 5% in EtnGpl) is equivalent to that found in the cortex of rats chronically deprived of dietary n-3 FA (35). However, it has been shown previously in cultured astrocytes that preloading the cells with exogenous DHA reduces their ability to produce new DHA from radiolabeled α-LNA (28). Therefore, the state of spontaneous DHA deficiency within cultured cells seems particularly appropriate for determining their ability to synthesize DHA.

Incorporation of preformed DHA. The dose–response study was performed to determine whether SH-SY5Y cells have the capacity to synthesize DHA from each of its upstream precursors, α-LNA, EPA, or DPA, and especially whether the newly formed DHA was actually incorporated into cell phospholipids. The incorporation of the precursor-derived DHA was compared with that resulting from the incubation of cells with increasing amounts of preformed DHA. The changes of the main n-3 and n-6 FA in EtnGpl, the fraction having the highest content of FA from both series, are presented in Figure 1. The maximum preformed DHA incorporated into the EtnGpl (around 32% of total FA) (Fig. 1A) reached the physiological plateau of brain cells (35), indicating that the uptake, trafficking, and acylation of supplemental DHA are not limiting in SH-SY5Y cells.

Biphasic pattern of neoformed DHA incorporation. Cells incubated with increasing doses of α-LNA (Fig. 1B), EPA (Fig. 1C), or DPA (Fig. 1D) showed an initial increase in DHA incorporation, corresponding to the lower range of concentration of the precursors, and a second phase of decreased incorporation at higher concentrations. The incorporation of newly formed DHA peaked at 9–10% in the EtnGpl of cells incubated with α-LNA (Fig. 1B) and at 8–9% in cells incubated with EPA (Fig. 1C). Cells incubated with DPA showed a maximum of 12% DHA incorporation in EtnGpl (Fig. 1D), equal to only one-third of the maximum incorporation resulting from incubation with DHA itself (see Fig. 1A). In the ChoGpl fraction, the newly formed DHA peaked at only 2.3% of total FA (data not shown).

[a]Cells were cultured in 10% FCS (without n-3 supplementation) for 16, 48, or 72 h. [a]$P < 0.001$; [b]$P < 0.01$; [c]$P < 0.02$; significant changes in EtnGpl (72 vs. 16 h). EtnGpl, ethanolamine-glycerophospholipids; ChoGpl, choline glycerophospholipids; PtdSer, phosphatidylserine; SFA, saturated FA; MUFA, monounsaturated FA; DMA, dimethylacetals.

The value of the precursor concentration that produced the reversion of the neoformed DHA incorporation in EtnGpl, the so-called concentration of reversion, was graphically calculated by using the double reciprocal plot method (35). As shown in Figure 2, the coordinate of the intersection point of the broken line (issuing from the biphasic pattern) is the inverse value of the concentration of reversion. This method led to the values of each concentration of reversion, equal to 15 μM α-LNA, 26 μM EPA, and 30 μM DPA, respectively, thereby indicating that α-LNA, with the lower concentration of reversion, was the least efficient precursor regarding the incorporation of newly formed DHA into cell phospholipids. Moreover, the concentration of reversion of α-LNA (15 μM) is also the concentration at which this FA began to increase in ChoGpl and EtnGpl (Fig. 3). The increase in α-LNA may be the hallmark of a saturating effect on the capacity of cells to metabolize this precursor, which is normally present in very low amounts within the brain phospholipids. However, in cells dosed with 70 μM of α-LNA, the increase of α-LNA in Et-

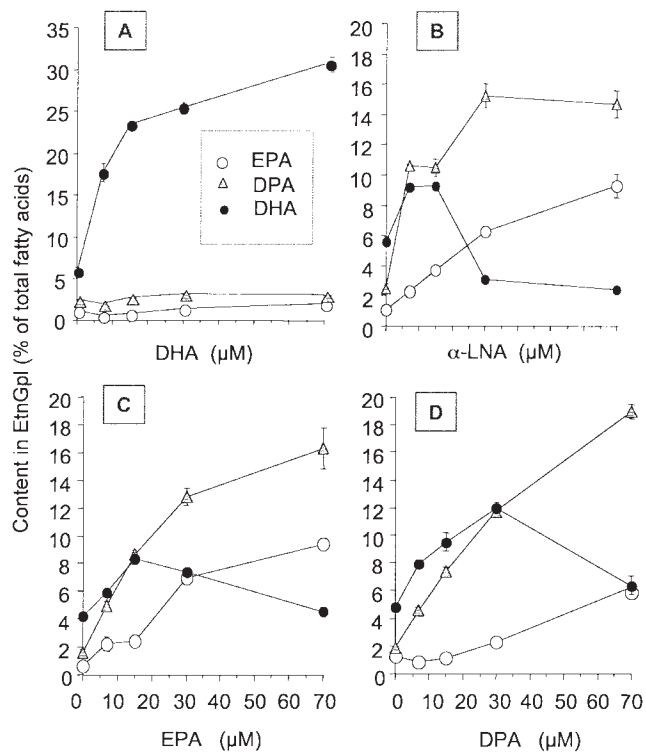
nGpl (plus 1% by weight of total FA) did not compensate for the decreased incorporation of α-LNA-derived DHA (minus 7%). Actually, the supplemental α-LNA was more rapidly and more efficiently incorporated into ChoGpl than into EtnGpl (Fig. 3). Therefore, the increased incorporation of α-LNA into EtnGpl cannot explain the biphasic pattern of DHA incorporation. Thus, SH-SY5Y cells can synthesize DHA from α-LNA, EPA, or DPA and can incorporate the newly formed DHA into phospholipids, but only imperfectly. In contrast, the incorporation of EPA resulting from incubations with α-LNA (Fig. 1B) or DPA (Fig. 1D), and the incorporation of DPA resulting from α-LNA (Fig. 1B) or EPA (Fig. 1C) increased regularly with the concentration of precursor in the medium. The decrease in DHA and the increase in EPA occurred concurrently. However, the increase in EPA was very gradual, in contrast to the biphasic incorporation of newly formed DHA. Moreover, EPA incorporation clearly did not counteract the incorporation of DPA. These data raised the question of whether the increase in EPA was the secondary hallmark of a primary down-regula-


FIG. 1. Distributions of eicosapentaenoic acid (EPA, 20:5n-3), docosapentaenoic acid (DPA, 22:5n-3), and docosahexaenoic acid (DHA, 22:6n-3) in the ethanolamine-glycerophospholipid (EtnGpl) fraction from SH-SY5Y cells cultured with a range of concentrations of (A) DHA, (B) α-linolenic acid (α-LNA, 18:3n-3), (C) EPA, or (D) DPA. Cells were incubated in medium supplemented with 7 to 70 μM unesterified FA. Each value is the mean ± SD of three separate cultures, expressed in percentage by weight of total FA in EtnGpl. Note that the *y*-axis in panel A is different from those in panels B–D.

FIG. 2. Double reciprocal plot drawn from the inverted data (see Ref. 35 for details) of the biphasic incorporation of newly formed DHA (Fig. 1B–D). The intersection point of the V-shaped lines defines the inverse value of the precursor concentration at which the incorporation of newly formed DHA peaked (concentration of reversion). The double reciprocal plot drawn from the incorporation of preformed DHA (not shown) produces a straight line (35). For abbreviations see Figure 1.

tion that led to the decrease in DHA synthesis and/or incorporation. To address this question, we analyzed the effect of 70 μM EPA on the mRNA encoded by genes involved in FA conversion.

Effect of the n-3 FA on endogenous n-6 FA. The incorporation of the main long-chain n-6 FA, 20:4n-6 (arachidonic acid), 22:4n-6 (adrenic acid), and 22:5n-6 (n-6 docosapentaenoic acid), either provided by the serum or synthesized from serum linoleic acid, decreased when the cells were incubated with increasing concentrations of each supplemental n-3 FA, DHA, α-LNA, EPA, or DPA (Fig. 4). The EtnGpl contents of n-6 PUFA decreased to about 50% in cells incubated with 70 μM of each n-3 FA. These patterns indicate that the acylation of the preformed and newly formed n-3 FA counteracts that of the "endogenous" n-6 FA.

Quantification of mRNA encoding for lipid metabolism genes. The mRNA relative abundances show that various lipid metabolism genes produce concentrations of mRNA varying from 3 to 9% that of GAPDH (Fig. 5). This is the first report, to our knowledge, that SH-SY5Y human neuroblastoma cells express the main enzymes of PUFA metabolism. We quantified the mRNA after 16 and 48 h of culture in the presence of 70 μM EPA to determine whether the transcription levels in the EPA-treated cells

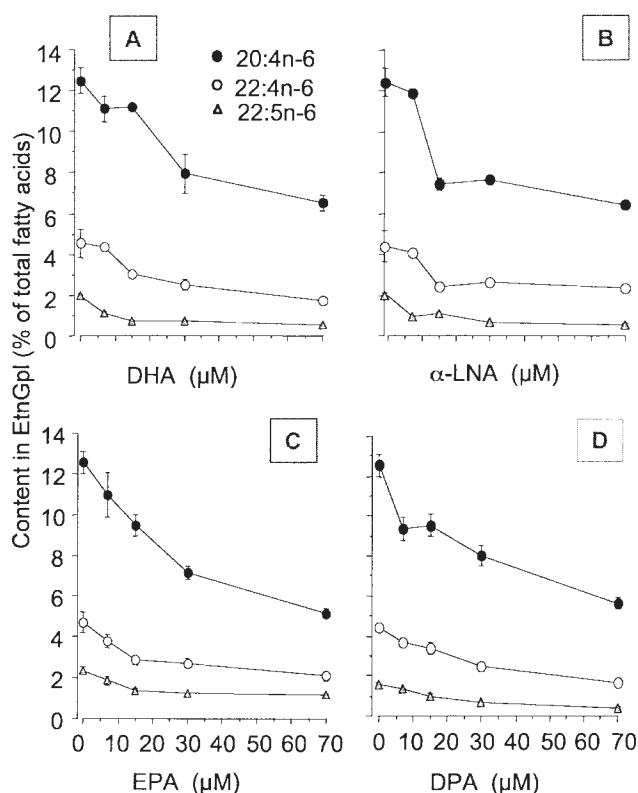
depended on the same duration of treatment as that producing changes in the FA composition. The data clearly show that the mRNA levels depended more on the culture duration than on the presence of EPA. There was a general trend (although not statistically significant regarding each gene) for a transcriptional increase between 16 and 48 h of culture, with the exception of the LBP mRNA abundance, which remained at the same low level throughout experiment. Actually, the relative abundance of Δ6-D mRNA increased by one point between 16 and 48 h in the absence of EPA ($P < 0.001$), but not in the presence of 70 μM EPA, showing that the time-dependent increase in Δ6-D mRNA was lost. On the other hand, incubation with EPA produced a significant time-dependent increase in the relative abundance of FACL3 mRNA ($P < 0.01$). Therefore, EPA had opposing effects on the time-dependent changes in mRNA, attenuating the weak increase in Δ6-D mRNA and slightly amplifying the change in FACL3 mRNA. The EPA treatment had no impact on the mRNA levels of LBP, ELOVL4, AOX, and DBP.

DISCUSSION

The incorporation of newly formed DHA into cell phospholipids results from synthesis, acylation, phospholipid metabolism, and turnover, with the relative content of DHA within membrane phospholipids giving a final reflection of the whole process. Our data show that the FA compositional changes in-
FIG. 3. Incorporation of α-LNA (18:3n-3) in the choline glycerophospholipid (ChoGpl) and EtnGpl fractions from SH-SY5Y cells cultured with a range of concentrations of α-LNA. All conditions are identical to those described in Figure 1B. For other abbreviations see Figure 1.

FIG. 4. Distribution of 20:4n-6 (arachidonic acid), 22:4n-6 (adrenic acid), and 22:5n-6 (n-6 DPA) in the EtnGpl fraction from SH-SY5Y cells cultured with 7 to 70 μM (A) DHA, (B) α-LNA, (C) EPA, or (D) DPA. Cells were incubated in medium containing unesterified FA. Each value is the mean ± SD of three culture flasks, expressed in percentage by weight of total FA in EtnGpl. For abbreviations see Figure 1.

duced by graded doses of the n-3 precursors follow a dose–response effect in EtnGpl, which is representative of the global metabolic capacities of cells. In particular, EtnGpl appeared to be the preferential class for the phospholipid incorporation of DHA in SH-SY5Y cells. This specificity of neuroblastoma cells may have a physiological significance, since it has been shown that DHA is more concentrated in the EtnGpl fraction from rat brain phospholipids than in the other classes (40). (According to that study, rat brain EtnGpl contains around 67 mol% of the total amount of brain DHA, compared with 22 mol% in PtdSer and 10 mol% in ChoGpl.)

The incorporation of n-3 FA into EtnGpl indicates that the synthesis of DPA from α-LNA or from EPA is an active process in SH-SY5Y cells, with the incorporation of DPA responding to the concentration of each precursor in a saturable manner. The increases in DHA and DPA at low precursor concentrations were concurrent, suggesting that newly synthesized DHA (from α-LNA, EPA, or DPA) and DPA did not compete for phospholipid acylation. Therefore, SH-SY5Y cells have the capacity to complete the metabolic chain of n-3 FA conversion through the ER and peroxisomal pathways, leading to DHA synthesis and to its effective incorporation into the membrane phospholipids. However, several features of the FA profile indicate that the peroxisomal step is limited in these cells. First, the DHA level was particularly low in basal conditions of culture despite the influx of n-3 PUFA from the medium. Animal studies of n-3 PUFA deficiency have shown that 22:5n-6 is formed through the action of desaturases and elongases on n-6 precursors, to compensate for the reduced input of n-3 PUFA. Thus, in physiological conditions, 24:5n-6 is formed within the ER and β-oxidized in the peroxisomes to produce 22:5n-6. However, in SH-SY5Y cells, the 22:5n-6 level remained low throughout 72 h of culture, whereas the total n-6 FA accounted for 22% of FA in EtnGpl, suggesting that the formation of the n-6 end product is limited. An impairment of the peroxisomal


synthesis of 22-carbon PUFA from both the n-6 and n-3 series may explain the compensating rise in trienoic FA (20:3n-9 and 22:3n-9), whose synthesis is circumscribed to the ER, contrary to that of 22:5n-6 and DHA, which both require peroxisomal oxidation.

The second observation of our study was that increasing the doses of one n-3 precursor, α-LNA, DPA, or EPA, resulted in a sharp decrease in the incorporation of newly formed DHA, with the concentration of reversion being proportional to the precursor chain length. Hence, the most effective way to increase the DHA incorporation into cell phospholipids (apart from using preformed DHA) is to provide the cells with a 22-carbon precursor (DPA), not 18- or 20-carbon (α-LNA or EPA). Our finding that the concentration of reversion by α-LNA was two times lower than with DPA suggests that α-LNA is, paradoxically, the most potent down-regulator of DHA synthesis and/or incorporation among the DHA precursors. We previously showed that the DHA content of Y79 retinoblastoma cells peaked in the EtnGpl fraction from cells incubated with 7 μM α-LNA, and that it decreased on incubation with higher concentrations (37). The precursor-induced reversion of newly formed DHA incorporation seems to be a common feature of all neural cells in culture. This specific down-regulation
FIG. 5. Relative abundance of mRNA encoding target genes in SH-SY5Y cells incubated for 16 or 48 h with 0 or 70 μM EPA. Each value is the mean ± SD of three culture flasks (one flask value being the mean of three real-time PCR), expressed in percentage of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) abundance. Levels of mRNA with distinct superscripts on histograms [a, b for fatty acyl-CoA ligase 3 (FACL3) or ** for Δ6-desaturase (Δ6-D)] are significantly different at $P < 0.01$ (FACL3) or $P < 0.001$ (Δ6-D). LBP, L-bifunctional protein; ELOVL4, brain FA elongase-4; AOX, peroxisomal acyl-CoA oxidase; DBP, D-bifunctional protein; for other abbreviation see Figure 1.

of DHA incorporation is likely due to competition for phospholipid acylation, as previously shown in CaCo-2 intestinal cells, with the acylation of the newly formed DHA being progressively replaced by that of its major upstream precursor, EPA (41). It was also reported that treatment of CaCo-2 cells with the dose of 100 μM EPA increases the EPA and DPA contents in EtnGpl (without modifying that of DHA) and decreases by 2.5 times the Δ6- and Δ5-D activities, showing that EPA at 100 μM inhibits enzymes of DHA synthesis (42). However, it was not determined in that study whether the desaturase-specific activities decreased through enzyme inhibition by excess substrate or through down-regulation of desaturase gene expression.

Some aspects of DHA incorporation suggest that the biphasic pattern results from mechanisms that are more complex than a simple molecular competition between EPA and DHA. First, the incorporation of α-LNA-derived DHA at low external α-LNA concentrations predominated over the incorporation of newly formed EPA (Fig. 1B), even though the synthesis of EPA necessarily precedes that of DHA. The incorporation of EPA-derived DHA also predominated over that of EPA in cells incubated with low concentrations of preformed EPA (Fig. 1C). Last, the EtnGpl fraction more avidly incorporated preformed DHA than preformed EPA. Therefore, the high specificity and "suddenness" of the reversion process are difficult to explain by the competition of EPA and DHA for acylation alone. In the second part of this study, we examined whether the EPA-induced decrease in DHA incorporation

could also result from transcriptional down-regulation of enzymes involved in DHA synthesis.

The mRNA profile shows that several key genes of the FA metabolism are expressed at relatively low levels, accounting for less than 10% of the housekeeping gene-mRNA abundance. However, Δ6-D mRNA appears to be 1.8 and 2.7 times more abundant than the mRNA of LBP, ELOVL4, and AOX. Moreover, Δ6-D mRNA was the only one whose concentration increased significantly throughout the 48 h in culture, which suggests that the growing neuroblastoma cells increase their capacity to desaturate FA. Therefore, the precursor-induced rise in EPA, DPA, and DHA and the mRNA profile both indicate that Δ6-desaturation is probably not a limiting step in the FA metabolism of SH-SY5Y cells. In comparison, the LBP gene produces the lower amount of mRNA, suggesting that peroxisomal β-oxidation may be rate limiting.

With the notable exception of Δ6-D, the mRNA levels were remarkably stable throughout the 48 h of culture. There was a trend toward increased mRNA abundance between 16 and 48 h, but this was significant only for Δ6-D in the absence of EPA, and only for FACL3 in the presence of EPA. The low amplitude of these transcriptional changes does not seem to support our hypothesis that a depression of mRNA encoding for FA metabolism genes may account for the biphasic pattern of newly formed DHA, at least in the presence of preformed EPA. However, since it has been demonstrated that (i) compounds acting as peroxisome proliferators activate the transcription of β-oxidation enzymes (43), (ii) AOX and LBP genes are direct

targets of peroxisome proliferator-activated receptor-α (PPAR-α) (44–47), and (iii) EPA is able to activate the PPAR-α-mediated transcription of a reporter gene in transfected cells (48,49), the hypothesis is plausible that EPA may be a modulator of mRNA encoding peroxisomal enzymes through the activation of cognate nuclear receptors. It should be noted that EPA exhibited its transcriptional effect (49) within a range of concentrations (250–1000 µM), which should be considered as being supraphysiological, especially regarding the cell capacity for phospholipid incorporation.

It cannot be excluded that transcriptional regulation of other genes (or isotypes), perhaps those involved in the peroxisomal assembly and/or in the functioning of peroxisomal membrane transporters, are key events in the down-regulation of phospholipid incorporation of the newly formed DHA. Alternatively, the biphasic pattern may also directly result from inhibition of enzyme activity(ies) without implicating transcriptional effects. The phospholipid incorporation of newly formed DPA being saturable and not submitted to down-regulation in the SH-SY5Y cells, we can suppose that the enzyme activities taking place in the ER are fully operant, at least until the step of DPA synthesis, whereas the final synthesis of THA and/or the peroxisomal enzyme activities would be inhibited. From this point of view, α-LNA should be the most potent inhibitor among the DHA precursors.

We conclude that, under conditions mimicking an n-3 physiological influx, the incorporation of newly formed DHA into phospholipids is strongly inhibited in SH-SY5Y cells, in spite of their ability to desaturate FA and produce DHA from each of the upstream precursors. The incorporation of newly formed DHA reveals a critical precursor-concentration window of responsiveness that may be related to the low basal transcription level of LBP and AOX without implicating further alterations in the mRNA profile. The biphasic incorporation of DHA probably sets in motion competition with EPA for phospholipid acylation, and possibly impairment of enzyme activities and/or of acyl-CoA carriers that are involved in the peroxisomal step of DHA synthesis. This combination of events results in a much lower incorporation of newly formed DHA into phospholipids than that resulting from an influx of preformed DHA, thereby reproducing in cultured neural cells the bloodstream FA composition of humans receiving the DHA precursors.

ABSTRACT: New iodoacetamide derivatives, containing a dodecyl or a squalenyl moiety, were synthesized. The effect of these new thiol-reacting molecules was studied on two mutants of *Alicyclobacillus acidocaldarius* squalene-hopene cyclase constructed especially for this purpose. In the quintuple mutant, all five cysteine residues of the enzyme are substituted with serine; in the sextuple mutant, this quintuple substitution is accompanied by the substitution of aspartate D376, located at the enzyme's active site, with a cysteine. *N*-Dodecyliodoacetamide had little activity toward either mutant, whereas *N*-squalenyliodoacetamide showed a stronger effect on the sextuple than on the quintuple mutant, as expected.

Paper no. L9759 in *Lipids* 40, 729–735 (July 2005).

Prokaryotic squalene-hopene cyclase (SHC) (EC 5.4.99.17) and eukaryotic 2,3-oxidosqualene-lanosterol cyclase (OSC) (EC 5.4.99.7) are two enzymes that catalyze the conversion of linear isoprenoid precursors to penta- and tetracyclic triterpenes (1–4) (Scheme 1). Bacterial SHC cyclizes squalene to hopene and other pentacyclic triterpenes, whereas OSC cyclizes (3*S*)-2,3-oxidosqualene (OS) to lanosterol in mammals and fungi, and to cycloartenol and other tetra- and pentacyclic triterpenes in plants. The enzymatic cyclization of squalene and OS is a complex and fascinating biochemical reaction, and many studies have been carried out over the last 50 yr in the attempt to elucidate at the atomic level the mechanism that transforms a conformationally flexible substrate, squalene or OS, into a cyclized product, with precise structural and stereochemical control.

OSC and, more recently, SHC have been the targets of inhibition studies. Initially, effective inhibitors that mimicked the carbocationic intermediates formed during the cyclization of OS were obtained by designing squalene-derived structures in which the positively charged carbocation is replaced by a nitrogen (5–7). Different series of cyclized aza derivatives (8) and sulfur-containing OS derivatives (9–11) have been developed. Among the substrate mimics, 2,3;18,19-dioxidosqualene shows strong inhibitory potency (12). Finally, a strategy that has been successfully adopted is to intercept the enzyme's active-site nucleophiles with a stable allylic cation, resulting in an irreversible covalent modification of OSC. Following this strategy, Prestwich and colleagues (13,14), Corey *et al.* (3,15), and our group (16) have synthesized various 2,3-oxidosqualenoid dienes, some of which have proved to be selective and time-dependent inhibitors of yeast or animal OSC. Few specific SHC inhibitors have been developed; the most potent ones include amidrazone and amidoxime derivatives (17), whereas some inhibitors of OSC have been studied for their inhibitory activity on SHC (11,18,19).

Determination of the 3-D crystal structure of SHC from *Alicyclobacillus acidocaldarius* (20,21) and, very recently, of human OSC (22) has been a very important step in determining the aminoacidic residues locating at the active site but has provided little information about the role of the residues directly involved in the cyclization process. The 3-D crystal structure of SHC from *A. acidocaldarius* in the presence of a reversible inhibitor similar to squalene, 2-aza-2,3-dihydrosqualene, has only very recently been described (23).

In a previous paper (24), we reported a new approach to study the arrangement of squalene in the active site cavity of SHC. By exploiting site-directed mutagenesis, this strategy inserts a critically located cysteine residue in the active site, which can act as a "sticking point" for thiol-reacting squalene-like molecules. The goal of this strategy, which may be applicable to many other enzymes different from cyclases, is to covalently bind a structure similar to the natural substrate to the active site so as to facilitate the study of interactions between substrate and residues at the active site by X-ray analysis. Using this approach, we have already studied the interactions of a series of thiol-reacting squalene-like inhibitors with the D376C/C435S mutant of SHC for the purpose of identifying an irreversibly binding molecule that mimics the folding of squalene at the active site of the enzyme (24).

Here we report the results obtained with a pair of new thiol-reacting molecules, *N*-dodecyliodoacetamide **3** and *N*-squalenyliodoacetamide **9** (Scheme 2, Fig. 1) on the C25S/C50S/D376C/C435S/C455S/C537S mutant of SHC (sextuple mutant). In this mutant, all five cysteine residues are substituted with a serine and one of three aspartates at the top of the active

SCHEME 1

site (D376) is substituted with a cysteine. The SHC mutant C25S/C50S/C435S/C455S/C537S (quintuple mutant) was used as control. In this mutant, all the cysteine residues are substituted with a serine to create an enzyme without any suitable points for covalent binding of thiol-reacting molecules.

MATERIALS AND METHODS

Chemicals. ^{1}H NMR spectra were recorded on a Bruker AC 200 instrument (Karlsruhe, Germany) for samples in CDCl$_3$ solution at room temperature, with Me$_4$Si (tetramethylsilane) as internal standard. Coupling constants (*J*) are given in Hz. IR spectra were recorded on a PE 781 (PerkinElmer, Palo Alto, CA) spectrophotometer. Mass spectra were recorded on a Finnigan MAT TSQ 700 spectrometer (San Jose, CA). Microanalyses were determined on an elemental analyzer 1106 (Carlo Erba Strumentazione, Milano, Italy) and were within

±0.3% of the theoretical values. The reactions were monitored by TLC on F$_{254}$ silica gel precoated sheets (Merck, Darmstadt, Germany); after development, the sheets were exposed to iodine vapor. Flash-column chromatography was performed on 230–400 mesh silica gel. Diethyl ether and toluene were dried over sodium benzophenone ketyl. All solvents were distilled prior to flash chromatography.

Squalene, lanosterol, and polyoxyethylene 9 lauryl ether were from Sigma Chemical Co. (St. Louis, MO). 1,1′,2-Tris-nor-squalene aldehyde **4** was obtained as described elsewhere (6). 1,1′,2-Tris-nor-squalene alcohol **5** was obtained as described elsewhere (25), starting from **4** (Fig. 1).

N-Dodecylchloroacetamide (2, Scheme 2). In a two-necked flask containing a solution of chloroacetyl chloride (1 equiv, 244 mg, 2.16 mmol) in ethyl acetate (5 mL), a solution of dodecylamine **1** (2 equiv, 800 mg, 4.32 mmol) in ethyl acetate (2 mL) was added within 10 min. The addition was performed,
SCHEME 2
FIG. 1. Synthesis of *N*-squalenyliodoacetamide **9** starting from 1,1′,2-tris-nor-squalene aldehyde **4**. ZnN$_6$·2Py, zinc azide/bis-pyridine comlex; DIAD, diisopropylazodicarboxylate; **5**, 1,1′,2-tris-nor squalene alcohol; **6**, squalene azide; **7**, squalene amine; **8**, *N*-squalenylchloroacetamide.

under a flux of dry nitrogen, in an ice bath. After the addition was complete, the flask was heated under reflux for 12 h. The reaction mixture was then cooled, diluted with ethyl acetate (20 mL), and washed with water (3 × 20 mL), dried with anhydrous sodium sulfate, and evaporated to dryness. The crude product was purified with silica gel flash chromatography in a gradient elution of petroleum ether/diethyl ether = 95:5, 90:10, 85:15, 80:20, and finally 70:30, vol/vol. *N*-Dodecylchloroacetamide **2** (26,27) (487 mg, 1.86 mmol) was obtained in 43% yield (86% yield referred to chloroacetyl chloride). ^{1}H NMR (CDCl$_3$): δ, 0.84–0.88 (*t*, 3H, CH$_3$), 1.24–1.28 [*m*, 20H, (CH$_2$)$_{10}$CH$_2$N], 3.24–3.34 (*m*, 2H, CH$_2$NH), 4.04 (*s*, 2H, CH$_2$Cl), 6.78 (*m*, 1H, NH). MS (EI): *m/z* 261 (M$^+$, 0.5), 226 (68), 212 (100), 184 (5), 170 (3); MS (CI): *m/z* 262 (100), 228 (16), 226 (0.5), 212 (0.5). Analyzed for C$_{14}$H$_{28}$NOCl (261.84); calcd.: C, 64.22; H, 10.78; N, 5.35; Cl, 13.54; found: C, 64.20; H, 10.77; N, 5.34; Cl, 13.52.

N-Dodecyliodoacetamide (3, Scheme 2). *N*-Dodecylchloroacetamide **2** (1 equiv, 94.3 mg, 0.360 mmol) was dissolved in anhydrous acetone (1 mL) under a flux of dry nitrogen, with stirring. Sodium iodide (1.1 equiv, 59.1 mg, 0.396 mmol) was added, allowed to react for 3 h at room temperature, and then heated under reflux for 2 h. The reaction mixture

was cooled, filtered to remove precipitated sodium chloride, and evaporated to dryness; it was extracted with ethyl acetate (3 × 20 mL) after addition of water (20 mL); the combined extracts were dried over anhydrous sodium sulfate and evaporated to dryness. The crude product was purified with silica gel flash chromatography in a gradient elution of petroleum ether/diethyl ether = 90:10, 85:15, 80:20, 75:25, and finally 70:30, vol/vol. *N*-Dodecyliodoacetamide **3** (80 mg, 0.227 mmol) was obtained in 63% yield. ^{1}H NMR (CDCl$_3$): δ, 0.84–0.90 (*t*, 3H, CH$_3$), 1.24–1.29 [*m*, 20H, (CH$_2$)$_{10}$CH$_2$N], 3.21–3.31 (*m*, 2H, CH$_2$NH), 3.70 (*s*, 2H, CH$_2$I), 6.23 (*m*, 1H, NH). MS (EI): *m/z* 352 (M$^+$, 0.1), 226 (100), 212 (20), 184 (15), 169 (10). MS (CI): *m/z* 354 (100), 352 (34), 339 (0.5), 338 (5), 324 (3), 310 (0.5). Analyzed for C$_{14}$H$_{28}$NOI (352.67); calcd.: C, 47.68; H, 8.00; N, 3.97; I, 35.98; found: C, 47.66; H, 8.01; N, 3.97; I, 35.95.

*Squalene azide: (4E,8E,12E,16E)-4,8,13,17,21-pentamethyl-4,8,12,16,20-docosapentaenyl azide (**6**, Fig. 1)*. Zinc azide/bis-pyridine complex (ZnN$_6$·2Py) was obtained as described elsewhere (28,29). ZnN$_6$·2Py (0.75 equiv, 1.91 g, 6.22 mmol) was added to a solution of 1,1′,2-tris-nor-squalene alcohol **5** (1 equiv, 3.21 g, 8.3 mmol) and triphenylphosphine (2 equiv, 4.35 g, 16.6 mmol) in anhydrous toluene (50 mL) under a flux of dry nitrogen, with stirring. The reaction mixture was cooled in an ice bath, and diisopropylazodicarboxylate (2 equiv, 3.36 g, 2.78 mL, 16.6 mmol) was added dropwise and left to react for 2 h at room temperature. The solvent was evaporated *in vacuo*, and the crude product was purified with silica gel flash chromatography in a gradient elution of petroleum ether/diethyl ether = 99.5:0.5 and 99:1, vol/vol. Squalene azide **6** (3.08 g, 7.47 mmol) was obtained in 90% yield. ^{1}H NMR (CDCl$_3$): δ, 1.61–1.71 (*m*, 18H, allylic CH$_3$), 2.00–2.08 (*m*, 20H, allylic CH$_2$ and NCH$_2$CH$_2$), 3.23 (*t*, 2H, CH$_2$N$_3$), 5.12–5.18 (*m*, 5H, vinylic CH). MS (EI): *m/z* 411 (M$^+$, 3), 384 (4), 368 (9), 314 (18), 300 (5), 246 (18), 192 (10), 178 (20), 137 (30), 110 (61), 95 (30), 81 (74), 69 (100). IR (liquid film): cm^{-1} 3400, 2960, 2920, 2840, 2100, 1650, 1450. Analyzed for C$_{27}$H$_{45}$N$_3$ (411.36); calcd.: C, 78.84; H, 11.03; N, 10.21; found: C, 78.80; H, 11.01; N, 10.22.

*Squalene amine: (4E,8E,12E,16E)-4,8,13,17,21-pentamethyl-4,8,12,16,20-docosapentaenylamine (**7**, Fig. 1)*. Squalene azide **6** (1 equiv, 2.53 g, 6.15 mmol) was dissolved in anhydrous diethyl ether (40 mL) and cooled in an ice bath under a flux of dry argon, with stirring. LiAlH$_4$ (1.13 equiv, 263.5 mg, 6.94 mmol) was added in portions and left at room temperature for 12 h, with stirring. The reaction mixture was then cooled in an ice bath, water was added to destroy unreacted LiAlH$_4$, and the mixture was extracted with diethyl ether (3 × 30 mL). The combined extracts were washed with saturated brine (3 × 30 mL), dried over anhydrous sodium sulfate, and evaporated to dryness. Crude squalene amine **7** (1.71 g, 4.43 mmol, 72% yield) was sufficiently pure for the following step. An analytical sample was obtained by preparative TLC [eluent: CH$_2$Cl$_2$/MeOH/NH$_3$ (32%), 96:1:3]. ^{1}H NMR (CDCl$_3$): δ, 1.61–1.71 (*m*, 18H, allylic CH$_3$), 2.00–2.08 (*m*, 20H, allylic CH$_2$, and NCH$_2$CH$_2$), 3.23 (*t*, 2H, CH$_2$N), 5.12–5.18 (*m*, 5H,

vinylic CH). MS (EI): *m/z* 385 (M$^+$, 3), 356 (10), 288 (18), 248 (13), 220 (32), 180 (10), 152 (100), 138 (11), 112 (58), 95 (74), 69 (93). IR (liquid film): cm^{-1} 3380, 2960, 2920, 2850, 1660, 1570, 1450. Analyzed for C$_{27}$H$_{47}$N (385.68); calcd.: C, 84.08; H, 12.28; N, 3.63; found: C, 84.01; H, 12.27; N, 3.61.

N-Squalenylchloroacetamide: N-[(4E,8E,12E,16E)-4,8,13, 17,21-pentamethyl-4,8,12,16,20-docosapentaenyl]chloro-acetamide (8, Fig. 1). Squalene amine **7** (2 equiv, 733 mg, 1.90 mmol) was added within 10 min to a solution of chloroacetyl chloride (1 equiv, 0.95 mmol, 107 mg, 76 mL) in ethyl acetate (5 mL), in an ice bath, under a flux of dry nitrogen, with stirring. The mixture was heated under reflux in an oil bath for 12 h. After cooling, ethyl acetate (20 mL) was added, and the organic phase was washed with water (3 × 20 mL), dried over anhydrous sodium sulfate, and evaporated to dryness. The crude product was purified with silica gel flash chromatography in a gradient elution of *n*-hexane/dichloromethane = 80:20, 70:30, 60:40, 55:45, 50:50, and finally 45:55, vol/vol. *N*-Squalenylchloroacetamide **8** (351 mg, 0.76 mmol) was obtained in 40% yield (80% yield referred to chloroacetyl chloride), as a pale yellow oil. ^{1}H NMR (CDCl$_3$): δ, 1.67–1.72 (*m*, 18H, allylic CH$_3$), 1.99–2.07 (*m*, 20H, allylic CH$_2$ and N-CH$_2$-*CH$_2$*), 3.22–3.26 (*m*, 2H, CH$_2$-N), 4.03 (*s*, 2H, CH$_2$Cl), 5.12–5.17 (*m*, 5H, vinylic CH), 6.66 (*m*, 1H, NH). MS (EI): *m/z* 461 (M$^+$, 5), 418 (2), 324 (2), 299 (3), 269 (5), 231 (6), 203 (5), 188 (10), 176 (20), 163 (30), 149 (24), 107 (21), 95 (100), 69 (82). MS (CI): *m/z* 462 (100), 428 (2), 413 (2). Analyzed for C$_{29}$H$_{48}$NOCl (461.45); calcd.: C, 75.48; H, 10.48; N, 3.04; Cl, 7.68; found: C, 75.50; H, 10.50; N, 3.03; Cl, 7.66.

N-Squalenyliodoacetamide: N-[(4E,8E,12E,16E)-4,8,13,17, 21-pentamethyl-4,8,12,16,20-docosapentaenyl]iodoacetamide (9, Fig. 1). NaI (1.1 equiv, 35.8 mg, 0.240 mmol) was added to a solution of *N*-squalenylchloroacetamide **8** (1 equiv, 100.6 mg, 0.218 mmol) in anhydrous acetone (2 mL), under a flux of dry argon, with stirring, at room temperature for 4 h. The reaction mixture was filtered to remove NaCl and evaporated to dryness. Ethyl acetate (20 mL) was then added, and the solution was washed with water (2 × 10 mL), dried over anhydrous sodium sulfate, and evaporated to dryness. The crude product was purified with silica gel flash chromatography with petroleum ether/diethyl ether = 80:20, vol/vol. *N*-Squalenyliodoacetamide **9** (73.5 mg, 0.133 mmol) was obtained in 61% yield as a pale yellow oil. ^{1}H NMR (CDCl$_3$): δ 1.60–1.66 (*m*, 18H, allylic CH$_3$), 1.99–2.06 (*m*, 20H, allylic CH$_2$ and NCH$_2$C*H$_2$*), 3.21–3.25 (*m*, 2H, CH$_2$N), 3.69 (*s*, 2H, CH$_2$I), 5.12–5.15 (*m*, 5H, vinylic CH), 6.66 (*m*, 1H, NH). MS (EI): *m/z* 553 (M$^+$, 0.5), 510 (0.5), 484 (1.5), 470 (0.2) 426 (25), 356 (5), 302 (2), 234 (9), 198 (20), 163 (41), 107 (22), 95 (100), 69 (88). MS (EI): *m/z* 554 (100), 514 (0.1), 500 (0.1). IR (liquid film): cm^{-1} 3300, 2940, 2860, 1650, 1555, 1450, 1385, 1305, 1255, 1170, 1120, 985. Analyzed for C$_{29}$H$_{48}$NOI (553.00); calc.: C, 62.99; H, 8.75; N, 2.53; I, 22.95; found: C, 63.00; H, 8.74; N, 2.53; I, 22.91.

Radiochemicals. [2-^{14}C]Mevalonate (50 mCi/mmol) was from NEN (Boston, MA). [^{14}C]-(3*S*)-2,3-Oxidosqualene was prepared as described elsewhere (24). Briefly, 25 mg of pro-

teins of S$_{10}$ supernatant from a pig's liver homogenate was incubated with 1 µCi of [^{14}C]mevalonate in the presence of the OSC inhibitor U14266A 200 µM [U14266A: 3β-(2,2-dimethyl-aminoethoxy)-androst-5-en-17-one] (30), as described by Popjak (31). The nonsaponifiable lipids were separated by two-step TLC on silica gel plates (Merck; 20 × 20 cm, 0.5 mm layer). The plates were first developed for about 10 cm above the origin in light petroleum, then dried and developed to 15 cm above the origin with *n*-hexane/ethyl acetate (90:10; vol/vol). The radioactive area corresponding to OS, was scraped off and eluted with dichloromethane. The solvent was dried under N$_2$, and [^{14}C]-(3*S*)-2,3-oxidosqualene was dissolved in benzene. The radiochemical purity of the product was evaluated by scanning TLC plates with a System 2000 Imaging Scanner (Hewlett-Packard, Palo Alto, CA). Radioactivity was measured by liquid scintillation counting (Beckman LS500 TD; Beckman Instruments, Fullerton, CA). The radiolabeled compound was compared chromatographically with authentic radio-inert samples. Determination of the radioactive substance, as well as isotope counting, was carried out as described elsewhere (25,32).

Generation of mutants. Quintuple and sextuple mutants C25S/C50S/C435S/C455S/C537S and C25S/C50S/D376C/C435S/C455S/C537S were generated using existing plasmids coding for mutants D376C, C435S, and for the quadruple mutant C25S/C50S/C455S/C537S described elsewhere (21,24) and derived from pKK223-3 (Pharmacia, Uppsala, Sweden). The quintuple mutant was obtained by exchanging a *Xho* I–*Xho* I restriction fragment of the quadruple mutant with that of mutant C435S. Both plasmids were digested with *Xho* I, and the restriction fragments were purified by agarose gel electrophoresis and gel extraction. The fragments of interest were ligated using Ready-to-Go ligase (Amersham Bioscience, Buckinghamshire, United Kingdom), and the resulting plasmids were transformed into *Escherichia coli* JM 105 cells following standard protocols (33). The quintuple mutant sequence was validated by DNA sequencing (SeqLab, Göttingen, Germany). In an analogous approach, the sextuple mutant was obtained by exchanging an *Apa* I–*Sac* I restriction fragment of the quintuple mutant plasmid with that of mutant D376C.

Expression and purification. Escherichia coli JM105, transformed with plasmids coding for quintuple and sextuple mutants of SHC, were used for expression and solubilization of the mutant SHC. Cells were grown in LB medium containing 100 µg/mL of ampicillin at 37°C until OD$_{578}$ = 0.6 and then induced for 6 h with 1 mM isopropyl-thio-β-D-galactoside. Cells were sedimented; resuspended in a buffer containing 200 mM Tris, pH 8.00, 0.5 M sucrose, 2.5 mM EDTA, 5 U/mL DNase, 0.1 U/mL RNase, 100 µg/mL PMSF, and 0.1 mg/mL lysozyme; vortexed vigorously, and frozen overnight at −20°C. Cells were then thawed at room temperature, vortexed vigorously, incubated for 15 min at 30°C, and diluted 1:1 with cold deionized water. Cells were disintegrated by indirect sonication (60 W for 2 min, 30-s pulse and 30-s pause) at 4°C. Membranes were sedimented by centrifugation (40,000 × *g*, 60 min at 4°C), resuspended in 0.1 M Na citrate buffer pH 6.00, 1

mg/mL polidocanol, 10% (wt/vol) glycerol, and centrifuged ($40,000 \times g$, 60 min at 4°C). The supernatant contained solubilized enzyme of a good degree of purity (about 90% as estimated by SDS-PAGE).

Enzyme assays. Solubilized SHC (0.3–0.6 mg protein) was incubated at 50°C for 30 min in 1 mL 0.1 M Na citrate buffer pH 6.00, 1 mg/mL polidocanol, 10% (wt/vol), glycerol, and 10 µM [^{14}C]-(3S)-2,3-oxidosqualene (1200 cpm). The reaction was stopped by adding 1 mL 10% KOH in MeOH, and nonsaponifiable lipids were extracted twice with 1 mL petroleum ether and chromatographed on silica gel plates developed in CH_2Cl_2. The radioactivity of chromatographic bands [OS and hop-22(29)-en-3-ol] [34] was evaluated using a System 2000 Imaging Scanner (Packard). IC$_{50}$ values (the concentration of inhibitor that reduced the enzymatic activity by 50%) were determined by adding the inhibitors to the mixture of radiolabeled and nonradiolabeled substrates and by incubating with SHC as described.

Time-dependent inactivation of SHC was determined as described in Reference 35. Briefly, solubilized SHC (0.3–0.6 mg protein) was incubated at 50°C for different times in 1 mL 0.1 M Na citrate buffer, pH 6.00, 1 mg/mL polidocanol, 10% (wt/vol) glycerol, and 10 µM [^{14}C]-(3S)-2,3-oxidosqualene (1200 cpm) in the presence of different concentrations of inhibitor. The reaction was stopped by adding 1 mL 10% KOH in MeOH, and the nonsaponifiable lipids were extracted and analyzed as described.

RESULTS AND DISCUSSION

Chemistry. N-Dodecyliodoacetamide **3** was obtained in two steps (Scheme 2). Condensation between chloroacetyl chloride and a twofold excess of dodecylamine in ethyl acetate under reflux afforded *N*-dodecylchloroacetamide **2** in 86% yield (referred to chloroacetyl chloride). Compound **2** was then reacted with sodium iodide in anhydrous acetone, under reflux, to afford *N*-dodecyliodoacetamide **3** in 63% yield. Initially, we tried a one-pot synthesis, by reacting dodecylamine directly with iodoacetyl chloride, but the yield was very poor.

The synthesis of *N*-squalenyliodoacetamide **9** was then developed (Fig. 1). 1,1′,2-Tris-nor-squalene aldehyde **4**, obtained as described elsewhere (6,11,36), was reduced to 1,1′,2-tris-nor-squalene alcohol **5** with sodium borohydride in methanol and submitted to the Mitsunobu reaction (28,29) to give squalene azide **6** in 90% yield. 1,1′,2-Tris-nor-squalene alcohol **5** and

triphenylphosphine in toluene and then diisopropylazodicarboxylate were added. Squalene azide **6** was reduced to squalene amine **7** with lithium aluminum hydride in 72% yield, and amine **7** was reacted with chloroacetyl chloride in ethyl acetate, to give *N*-squalenylchloroacetamide **8** in 80% yield (referred to as chloroacetyl chloride). Finally, reaction with sodium hydride in acetone gave *N*-squalenyliodoacetamide **9** in 61% yield.

Biological activity. The effect of the new thiol-reacting molecules, *N*-dodecyliodoacetamide **3** and *N*-squalenyliodoacetamide **9**, was studied on two mutants of *A. acidocaldarius* SHC to identify the first irreversible inhibitor able to bind covalently to the active site and mimic the folding of the natural substrate. The squalenic or dodecylic structure of these inhibitors was expected to allow them to reach the lipophilic cavity of the active site, whereas the iodoacetamide moiety should specifically react with critically located cysteine residues (37,38). The mutants used, expressly designed for this study, were a C25S/C50S/C435S/C455S/C537S (quintuple mutant), in which all five cysteine residues are substituted with a serine, and a C25S/C50S/D376C/C435S/C455S/C537S (sextuple mutant), in which all the cysteine residues are substituted, and in addition aspartate D376, located at the top of the active site, is substituted with a cysteine. Because the quintuple mutant lacks all the cysteine residues, we expected thiol-reacting inhibitors to be inactive or poorly active (and reversible, of course) against this mutant, whereas the inhibitors should irreversibly inactivate the sextuple mutant, bearing a cysteine at the active site.

The SHC sextuple mutant lost its ability to cyclize squalene, due to the absence of one of the two critical aspartate residues in the DDTA (a highly conserved aspartate-rich motif) sequence (39), but was still able to cyclize OS, although less efficiently than the wild-type. The inhibitory effect of the two thiol reagents was thus assayed toward OSC activity. Furthermore, SHC quintuple and sextuple mutants are less stable than the wild-type enzyme if incubated at 60°C, which is the optimal temperature for SHC (40); for this reason the SHC activity was determined at 50°C. K_M values for the cyclization of OS are 1.5 µM for the wild-type, 1.0 µM for the quintuple mutant, and 2.3 µM for the sextuple mutant; K_M values for the cyclization of squalene are 13.2 µM for the wild-type and 10.0 µM for the quintuple mutant, whereas the sextuple mutant is totally inactive.

IC$_{50}$ values for the two thiol-reacting molecules (Table 1) show that *N*-dodecyliodoacetamide **3** has little effect against either mutant (IC$_{50}$ > 200 µM), and *N*-squalenyliodoacetamide

TABLE 1
Inhibition Values (IC$_{50}$) of Thiol-Modifying Inhibitor on Oxidosqualene Cyclizing Activity of Squalene-Hopene Cyclase (SHC) Wild-Type, Quintuple Mutant, and Sextuple Mutant

[c]Data are mean values from three independent experiments with a mean deviation of ±10%.
FIG. 2. Inhibition of squalene-hopene cyclase (SHC) quintuple mutant by *N*-dodecyliodoacetamide **3** 200 µM (●) and by *N*-squalenyliodo-acetamide **9** 200 µM (■).

FIG. 3. Inhibition of SHC sextuple mutant by *N*-dodecyliodoacetamide **3** 50 µM (△) and 200 µM (▲), and by *N*-squalenyliodoacetamide **9** 50 µM (□) and 200 µM (■). For abbreviation see Figure 2.

9 has a stronger inhibitory effect on the sextuple than on the quintuple mutant (IC$_{50}$ = 50 µM and >200 µM, respectively). The two molecules are almost inactive on wild-type SHC. A first attempt to clarify the type of inhibition, reversible or irreversible, was made with a classical preincubation and dilution protocol that entails preincubation of SHC mutants for different times in the presence of inhibitors at different concentrations, dilution of the preincubation mixture by almost 1:20 to decrease the concentration of the inhibitor, and finally determination of residual SHC activity. Unfortunately, this protocol could not be applied with the sextuple mutant, as SHC activity of this enzyme is very slight compared with that of the quintuple mutant, and the enzyme was rapidly denatured during incubation; for this reason, it was not possible to determine the residual activity after preincubation and dilution.

To demonstrate the irreversibility of the inactivation of the sextuple mutant by *N*-squalenyliodoacetamide **9**, we used a protocol that does not require the dilution step (35): SHC mutants were incubated for different times in the presence of inhibitors at different concentrations, and the residual activity was compared with the activity of a control incubated without the inhibitor. All the inhibitors proved to have very little effect on the SHC quintuple mutant (Fig. 2), whereas on the sextuple mutant the good activity of *N*-squalenyliodoacetamide **9** was confirmed (Fig. 3). The slopes did not clearly indicate the type of inhibition (reversible or irreversible) of the inhibitors tested. A possible reason could be the complexity of the biphasic system required for the determination of enzymatic activity (i.e., the presence of detergent and hydrophobic compounds) that might influence the availability of substrate and inhibitor.

The novel thiol-reacting molecule, *N*-squalenyliodoacetamide, should in the near future prove itself to be a useful tool to study the exact geometry of the cyclization reaction in eukaryotic OSC. Very recently, human OSC was crystallized and the 3-D structure of this enzyme determined (22). According to the crystallographic data, three critically located cysteine residues are present in human OSC: Cys456, Cys533, and
Cys233 (22). Our approach of labeling a critical cysteine residue with a substrate analog such as *N*-squalenyliodo-acetamide could be profitably applied to human OSC with the goal of preparing a stable covalent enzyme–squalenic molecule complex for structural analysis. The crystallization and 3-D structure determination of this complex will be of great value to elucidate the mechanism whereby a squalenic molecule folds into the OSC active site.

ABSTRACT: The objective of this study was to evaluate the kinetics of both free and esterified forms of cholesterol contained in a emulsion that binds to LDL receptors (LDE) in subjects with heterozygous familial hypercholesterolemia (FH), and the same subjects under the effects of high-dose simvastatin treatment, as compared with a control normolipidemic group (NL). Twenty-one FH patients (44.0 ± 13.0 yr, 12 females, LDL cholesterol levels 6.93 ± 1.60 mmol/L) and 22 normolipidemic patients (44.0 ± 15.0, 10 females, LDL cholesterol levels 3.15 ± 0.62 mmol/L) were injected intravenously with ^{14}C-cholesteryl ester and ^{3}H-cholesterol. FH patients were also evaluated after 2 mon of 40 or 80 mg/d simvastatin treatment, and plasma samples were collected over 24 h to determine the residence time (RT, in h) of both LDE labels, expressed as the median (25%; 75%). The RT of both ^{14}C-cholesteryl ester and ^{3}H-cholesterol were greater in FH than in NL [FH: 36.0 (20.5; 1191.0), NL: 17.0 (12.0–62.5), $P = 0.015$; and FH: 52.0 (30.0; 1515.0); NL 20.5 (14.0–30.0) $P < 0.0001$]. Treatment reduced LDL cholesterol by 36% ($P < 0.0001$), RT of ^{14}C-cholesteryl ester by 49% ($P = 0.0029$ vs. baseline), and ^{3}H-cholesterol RT by 44% ($P = 0.019$ vs. baseline). After treatment, the RT values of ^{14}C-cholesteryl ester in the FH group approached the NL values ($P = 0.58$), but the RT of ^{3}H-cholesterol was still greater than those for the NL group ($P = 0.01$). The removal of LDE cholesteryl esters and free cholesterol was delayed in FH patients. Treatment with a high dose of simvastatin normalized the removal of cholesterol esters but not the removal of free cholesterol.

Paper no. L9724 in *Lipids* 40, 737–743 (July 2005).

Emulsions of defined composition resembling the lipidic structure of plasma lipoproteins have been used as a tool to investigate lipid intravascular metabolism (1–6). Emulsion models of lymph chylomicrons facilitate the study of chylomicron metabolism in several disease states and under the action of antilipidemic drugs (6–10). It is also feasible to use artificial emulsions as probes to explore the metabolism of LDL instead of using the native lipoprotein. In this regard, we have studied the metabolic behavior of a cholesterol-rich emulsion termed LDE that roughly resembles the lipidic structure of LDL. LDE is made without protein, but when injected into the bloodstream it acquires several apolipoproteins, including apo E (2,3). Apo E endows LDE with particles that bind to the LDL receptors, since those receptors recognize not only the apo B present in LDL, but also apo E, which is not found in the LDL fraction (11). Apo E binds to the LDL receptors with a greater affinity than apo B-100 and, as previously shown, is therefore removed more rapidly than the natural lipoprotein (5). The fact that LDE is removed from the plasma faster than native LDL is a methodological advantage because it shortens the period required to perform the plasma kinetics test. Among other advantages of this model is the possibility of using the same preparation to test several subjects. Because of the risk of contamination, this procedure cannot be done with the natural lipoprotein, which requires use of the autologous lipoprotein. Furthermore, LDE is a standard preparation compared with native lipoproteins, which show great variation among individuals; this facilitates labeling by radioactive or other means. All these operational advantages greatly facilitate performing systematic studies on the plasma kinetics of lipids.

The kinetics of LDL in the plasma is traced by labeling apo B, which is virtually the only apolipoprotein present in the LDL particles (12,13). Because apo B is not an exchangeable protein, the kinetics of apo B plasma reflects the kinetics of LDL particles (11). However, lipoproteins are constantly being remodeled, and each lipid component may have a distinct metabolic fate in health and in disease. Tracing the intravascular metabolism of the lipidic components of lipoprotein may be important and is greatly facilitated by the use of artificial probes such as LDE. Indeed, we recently (14) showed that after intravenous injection of LDE doubly labeled with radioactive cholesteryl esters and unesterified cholesterol, the two forms of cholesterol showed different plasma kinetic behaviors in normolipidemic (NL) subjects with coronary artery disease (CAD) and in non-CAD subjects, which can eventually shed new light on the mechanisms of arterial lipid deposition. In fact, comparative investigations of the plasma kinetic behaviors of the two forms of cholesterol have scarcely been explored in the literature (15,16).

Familial hypercholesterolemia (FH) is a dominant autosomic disease wherein the removal from plasma of LDL particles is reduced because of defects in the expression and function of LDL receptors (17). FH is characterized by an

early onset of atherosclerosis caused by an accumulation of LDL and an increase in the cholesterol plasma pool. However, the removal of free cholesterol, which accounts for around 30% of the plasmatic cholesterol pool, was not established in this disease (18).

HMG-CoA reductase inhibitors, such as simvastatin, have been used to reduce LDL cholesterol levels, and consequently the risk of coronary heart disease, in hypercholesterolemia (19). Because of the increased risk of coronary heart disease associated with FH, statins are now a mandatory treatment in adults with this disease (20).

In this study using LDE to model LDL in plasma kinetics, we hypothesized that the LDL receptor defects that cause FH would differently affect the removal of free and esterified forms of cholesterol, i.e., that the decrease in the removal of the esterified cholesterol would be greater than that of the free form in the presence of FH. Furthermore, we were interested in evaluating whether statin treatment, which is universally used, would be more effective in accelerating the removal of one cholesterol form than the other. To address those issues, LDE labeled with free and esterified cholesterol was injected into patients with FH and into control subjects without the disease. Kinetic studies were repeated in FH patients after 8 wk of simvastatin treatment.

MATERIALS AND METHODS

Study subjects. The participants in the study were selected from among outpatients of the Lipid Clinic of the Heart Institute of the São Paulo University Medical School Hospital. Twenty-one recently diagnosed FH patients were studied. All patients were first-degree relatives of subjects that already had the diagnosis of FH and were being followed in our clinic. FH was diagnosed using the U.S. MED PED (Make Early Diagnosis Prevent Early Disease) group criteria (20).They were compared with 22 healthy normolipidemic volunteer subjects (LDL cholesterol < 4.1 mmol/L, plasma TG < 2.2 mmol/L, HDL cholesterol > 1.0 mmol/L). Clinical data for the studied subjects are shown in Table 1. None of the patients were addicted to alcohol consumption or had diabetes, liver, renal, thyroid, or other metabolic diseases. They had not used lipid-lowering drugs for at least the last 2 months prior to the study. There were no differences between the groups regarding age, sex, body mass index, hypertension, and smoking habits. One FH patient had had a myocardial infarction episode 1 yr before enrolling in the study.

Plasma lipids and apolipoproteins. Blood samples for the determination of plasma lipids were collected after a 12-h fast on the same day the kinetic studies were performed. Commercial enzymatic methods were used to determine total cholesterol (Boehringer-Mannheim, Penzberg, Germany) and TG (Abbott Laboratories, Abbott Park, IL). HDL cholesterol was determined by the same method used for total cholesterol after lipoprotein precipitation with magnesium phosphotungstate. VLDL cholesterol and LDL cholesterol were calculated by the formula of Friedewald *et al.* (21).

LDE preparation. LDE was prepared from a lipid mixture

TABLE 1
Clinical Characteristics of Familial Hypercholesterolemia (FH) and Normolipidemic (NL) Subjects

	NL ($n = 22$)	FH ($n = 21$)	P
Age (yr)	44.0 ± 15.0	44.0 ± 14.0	0.9
Female sex, n (%)	10 (47.6)	12 (57)	0.54
Body mass index (kg/m^2)	27.6 ± 5.0	25.3 ± 2.8	0.07
Arterial hypertension, n (%)	2 (9)	4 (19)	0.4
Smokers, n (%)	1 (4.5)	4 (19)	0.18
Coronary heart disease, n (%)	0 (0)	1 (4.7)	0.47

composed of 40 mg cholesteryl oleate, 20 mg egg PC, 1 mg triolein, and 0.5 mg cholesterol, purchased from Nu-Chek-Prep (Elysian, MN). ^{14}C-Cholesteryl ester (cholesteryl oleate) and ^{3}H-cholesterol, purchased from Amersham International (Amersham, United Kingdom), were added to the mixture. The procedures for emulsifying the lipids, i.e., by prolonged ultrasonic irradiation in aqueous media and two-step ultracentrifugation of the crude emulsion with density adjustment by addition of KBr, to obtain the LDE microemulsion were carried out using the method of Ginsburg *et al.* (1), modified by Maranhão *et al.* (2). LDE was dialyzed against saline solution and passed through a 0.22-μm filter for injection into the patients.

LDE plasma kinetics. The participants fasted for 12 h at the beginning of the test, at approximately 9 AM, but they were allowed two standard meals during the study, at approximately 12:30 and 7 PM. LDE containing 37 kBq of ^{14}C-cholesteryl ester and 74 kBq of ^{3}H-cholesterol, for a total of 5–6 mg in a volume of 500 μL, was injected intravenously in a bolus. Plasma samples were collected for 24 h in intervals of 5 min and at 1, 2, 4, 6, and 24 h after the injection. Aliquots (1.5 mL) of blood plasma were extracted with chloroform/methanol/water (2:1:1, by vol) overnight at 4°C (13). The organic phase was transferred to a test tube and dried under nitrogen flux. Lipids were resuspended with 5 mL of the solution described by Folch *et al.* (22) (chloroform/methanol 2:1) and transferred to counting vials containing 7.0 mL of scintillation solution [2,5 diphenyloxazole scintillation grade (PPO)/dimethyl POPOP (1,4-bis[2-(5-phenyl)-oxazolyl]benzene)/Triton X-100/toluene, 5 g/0.5 g/333 mL/667 mL (Merck, Darmstadt, Germany). Radioactivity was counted using a Beckman LS100C spectrometer.

Estimation of plasma residence times (RT) of the radioisotopes. The plasma decay curves for both radioisotopes were determined. The fractional catabolic rates (FCR) of the LDE ^{14}C-cholesteryl ester and ^{3}H-cholesterol were calculated according to the method described by Matthews (23) as FCR, where a_1, a_2, b_1, and b_2 were estimated from biexponential curves obtained from the remaining radioactivity found in plasma after injection, fitted by a least squares procedure, as

$$y = (a_1 \cdot e^{-b_1 t}) + (a_2 \cdot e^{-b_2 t}) \quad [1]$$

where y represents the plasma radioactivity decay as a function of time (t), and a and b indicate the linear coefficient and the angular coefficient, respectively, which represent the FCR in h^{-1}. The FCR were estimated from parameters a_1, b_1, and b_2

by the following equation: RT = $(a_1/b_1 + a_2/b_2)^{-1}$. Calculations were performed using ANACOMP software (24). The RT represent the inverse of the FCR (25).

Simvastatin treatment. After performing the LDE kinetic study, a 30-d treatment with 40 mg simvastatin (Zocor; Merck, Sharpe & Dohme, São Paulo, Brazil) was started in all patients. The dosage was doubled to 80 mg/d for the next 4 wk. Plasma lipids and kinetic studies were repeated in all 21 subjects after the treatment period.

Statistical analysis. Data are expressed as mean ± SD except for the RT of the radioisotopes and plasma TG, which are expressed as medians (25%; 75%). Because of the non-Gaussian distribution of these parameters, they were evaluated by the Kolmogorov–Smirnov procedure. Categorical data were compared between FH and NL by Fisher's exact test. The comparison of parametric and nonparametric data between FH and NL was performed, respectively, by Student's *t*-test and the Mann–Whitney test. The effects of simvastatin treatment on plasma lipids and emulsion kinetics were evaluated by paired *t*-tests or the Wilcoxon signed rank test when necessary. The correlation between the RT of ^{3}H-cholesterol and ^{14}C-cholesterol ester, and of these parameters with plasma lipids in the entire population studied (*n* = 43) were performed by Spearman's rho. In all analyses, a difference in the two-tailed tests of *P* < 0.05 was considered statistically significant.

Informed consent and radiological safety. The experimental protocol was approved by the Ethical Committee of the Heart Institute, and written informed consent was given by all participants. All women of reproductive age were using contraceptive methods, and pregnancy was excluded before beginning the kinetic studies and simvastatin treatment.

The safety of the radioactive dose intravenously injected into the patients was ensured according to the regulations of the International Commission on Radiological Protection (26). The injected dose in each experiment was 0.03 mSv and was well below the annual limit for intake of radionuclides (50 mSv).

RESULTS

Table 2 shows the plasma lipids of FH and NL subjects. Total plasma and LDL cholesterol of the FH subjects were roughly twice the values of the NL. Also, plasma TG were higher in FH than in NL. No significant differences were found in HDL cholesterol between the two groups. Table 2 also shows the effects of simvastatin treatment on the plasma lipids and the RT of the LDE radioisotopic labels. The reduction in LDL cholesterol concentration under simvastatin treatment was 36% (*P* < 0.0001).

Figures 1A and 1B show the plasma decay curves of ^{3}H-cholesterol and ^{14}C-cholesteryl ester in FH patients before and after simvastatin treatment and in controls. Both radioisotopes presented a slower decay in FH than in NL. Accordingly, Table 2 shows that the RT of ^{14}C-cholesteryl ester and ^{3}H-cholesterol in FH subjects were 2.5 and 1.7 times the values of NL subjects (*P* = 0.015 and *P* < 0.0001, respectively). Simvastatin treatment accelerated the plasma decay of both radioisotopes, as shown in Figures 1A and 1B. This trend was seen for both radioisotopes at the 4-, 6-, and 24-h points and was marked at the 24-h point of ^{14}C-cholesteryl ester radioactivity after simvastatin treatment. As shown in Table 2, the reductions in the RT of ^{14}C-cholesteryl ester and ^{3}H-cholesterol were, respectively, 49% (*P* = 0.0029 vs. baseline) and 44% (*P* = 0.019 vs. baseline). Before simvastatin treatment, no differences were found between the RT of both radioisotopes (*P* = 0.17); however, after treatment the RT of ^{14}C-cholesteryl ester became shorter than those of ^{3}H-cholesterol (*P* = 0.011; Table 2). Also, after treatment the RT of ^{14}C-cholesteryl ester in FH subjects were no longer different from those of NL subjects (*P* = 0.84), but the RT of ^{3}H-cholesterol was still increased when compared with NL values (*P* = 0.0084; Table 2).

The RT of ^{3}H-cholesterol, but not that of the ^{14}C-cholesteryl ester, was positively correlated with total and LDL cholesterol levels, respectively (*r* = 0.42, *P* = 0.005 and *r* = 0.39, *P* = 0.009). No correlation was found between the RT of both labels and the other plasma lipids (data not shown). The RT of ^{14}C-cholesteryl ester were not correlated with the plasma lipids. The RT of ^{3}H-cholesterol and ^{14}C-cholesteryl ester presented a positive but weak correlation (*r* = 0.39, *P* = 0.01).

DISCUSSION

Our current results show that the LDE cholesteryl ester was removed slowly in patients with FH, in whom LDL receptors are

defective (17,20). In several studies, we have shown that the radioactively labeled cholesteryl ester moiety of LDE behaves like the labeled apo B of native LDL, although it is removed faster from the plasma than apo B (2,4,5,27). In this respect, as expected from apo B-labeled native LDL (13), the removal of LDE cholesteryl esters was slower in patients with hypercholesterolemia (4) and was accelerated in untreated patients with acute myeloid leukemia (3) because of the LDL receptor up-regulation existing in the neoplastic cells (28). Conversely, after the disease remission achieved by chemotherapy, LDE removal decreased because of destruction of the neoplastic cells with receptor up-regulation (3). The LDE FCR negatively correlates with age (27), which is expected for the native LDL particles, because LDL receptor expression indeed diminishes with aging (29).

In FH, the removal of LDL from the plasma is slow, as had been demonstrated by labeling LDL apo B with radioactive iodine or with stable isotopes (30,31). The slowed removal of LDE cholesteryl ester had not yet been documented in heterozygous hypercholesterolemia, but we expect from our preceding studies with LDE that the impaired clearance of the lipoprotein particles would lead to this effect (3,4,27).

There are substantial and well-known differences between free and esterified cholesterol regarding the stability of the two cholesterol forms in the lipoprotein structure (32,33). Free cholesterol, which originates from both tissue and plasma lipoproteins, can be esterified in the lipoprotein surface monolayer, mainly in HDL but to a lesser extent in β-lipoproteins, by the action of LCAT. Cholesteryl esters are generally incorporated into the lipoprotein core or transferred to other lipoproteins by CETP but also by phospholipid transfer proteins (PLTP). Cholesteryl esters can then be removed by the liver either directly by VLDL and LDL binding to hepatic receptors or indirectly by HDL in the reverse cholesterol transport. The esterification of free cholesterol creates a concentration gradient that permits the efflux of unesterified cholesterol from cells to HDL particles (34,35). Studies have shown that plasma cholesterol esterification is augmented by increased TG levels and increased LDL/HDL ratios (36,37). This concentration gradient seems to be important even when actively mediated transport, such as the one mediated by ATP-binding cassette transporter A1, predominate (38). Despite this evidence, only a few studies have evaluated the plasma cholesterol kinetics in human subjects (15,16). A recent *in vivo* study showed that 70% of cholesteryl esters are generated from free cholesterol in HDL and 30% in LDL, IDL, and VLDL (16).

Similar to native lipoproteins, esterified cholesterol makes up the lipoprotein LDE core and shifts to other lipoprotein

classes by means of the transfer proteins CETP and PLTP (2,33,34). In contrast, unesterified cholesterol, which is slightly polar and is located in the lipoprotein surface monolayer, constitutes a much more unstable plasma cholesterol pool (32). It may freely diffuse from the lipoprotein or the microemulsion to the plasma without the assistance of transfer proteins and may eventually precipitate on the arterial wall. There is evidence that not only cholesteryl esters but also unesterified cholesterol are associated with atherosclerosis. Free cholesterol is found in atherosclerotic plaques in both experimental animals (39,40) and humans (41). Free cholesterol accumulation is a potent inducer of macrophage apoptosis and secondary necrosis, a fact associated with plaque rupture and acute coronary events (41). Also, free cholesterol in modified lipoproteins has been associated with the inflammatory process of atherosclerosis (42). In fact, an increase in the content of unesterified cholesterol of lipoproteins, expressed as an increased free cholesterol/phospholipid ratio, has been found in subjects prone to atherosclerosis (43), such as in persons with diabetes and patients with hyperbetalipoproteinemia, as well as in subjects with CAD in a population study (44). An increase in unesterified cholesterol reduces the extent of cholesteryl ester transfer from VLDL and LDL particles in a concentration-dependent mechanism. Also, it stimulates the transfer of cholesteryl esters out of the HDL particles, thus changing the reverse cholesterol transport unfavorably. In these subjects, it was demonstrated an increase in the influx of unesterified cholesterol from plasma to cells (45,46).

In our recent study (14), we have shown that in CAD non-hypercholesterolemic patients, the free cholesterol of LDE is removed faster than in non-CAD subjects, whereas there is no difference between CAD and non-CAD patients regarding the removal of the LDE cholesteryl esters. This clearly indicates that the two cholesterol forms initially contained in the same lipoprotein or microemulsion particles can have distinct metabolic behaviors in the intravascular compartment and be separately involved in pathophysiological events. Indeed, the weak correlation found in our study subjects between the RT of ^{3}H-cholesterol and ^{14}C-cholesteryl ester supports the assumption that after injection, both labels are metabolized through different metabolic pathways. It is interesting that in hypercholesterolemic patients, the LDE free cholesterol tended to be removed even slower than the cholesteryl esters, although the difference between the two labels was not statistically significant. It is possible that the accumulation of LDL in patients facilitates the transfer of free cholesterol from LDE to the plasma lipoproteins rather than that of the cholesteryl esters, which also depend on transfer proteins (33). Because native circulating lipoproteins are removed slower than LDE, transfer to the lipoprotein fractions is implied in delayed clearance (4,5).

Only very few studies have addressed the issue of *in vivo* kinetics of the free and esterified forms of cholesterol contained in LDL (15,16). Recently, the *in vivo* kinetics of both free and esterified cholesterol contained in the LDL and HDL of bile fistula, and in NL subjects as well as in one homozygous FH subject were evaluated (16). The output of cholesteryl esters from the plasma was similar to that of previous studies that evaluated apo B kinetics, showing that cholesteryl esters are removed from the plasma within the lipoprotein holoparticle. This finding strengthens the validity of labeling LDE with cholesteryl esters to trace the clearance of the microemulsion particles. Specifically, in the sole homozygous FH patient, the output from the plasma of both free and esterified cholesterol in LDL was reduced when compared with the NL and bile fistula subjects. The results from this single patient with the most severe presentation of the disease is in accordance with our present data from heterozygous FH and contribute to other studies in which LDL metabolism was evaluated by LDE kinetics (3,4,27,47).

The introduction of more potent statins, such as atorvastatin, has increased interest in using higher doses of the previous generation of statins—of which simvastatin has been the most widely used—as well as interest in the mechanism of action of these drugs in FH (48). Two mechanisms have been proposed for the effects of statins on plasma lipids: (i) an increase in the removal from the plasma of LDL and its precursors, and (ii) a reduction of the hepatic production of VLDL. The first mechanism has been demonstrated in kinetic studies with the labeling of apo B-containing lipoproteins (12,49) and is reinforced by the results of our study showing a faster removal of LDE after high-dose simvastatin treatment in heterozygous FH patients. The second mechanism was shown in studies with homozygous and compound heterozygous FH patients, in whom receptors are absent or nonfunctional and who presented reductions of about 25% in LDL cholesterol levels with 80–160 mg of simvastatin and 80 mg of atorvastatin (50,51). Treatment with statins increases the removal from plasma of LDL particles, as traced by labeled LDL apo B. Because LDE cholesteryl esters behave like LDL apo B (2–4), the acceleration of removal from plasma of this cholesterol form, as observed in this study, would then be expected. Similar to the effects on LDE kinetics found in this study, statin treatment increased the removal from plasma of chylomicron-like emulsions in subjects with CAD (9). A reduction in the plasma RT of LDL as well as chylomicrons, as shown by the artificial emulsions, implies that these lipoproteins might become less prone to oxidation and therefore would become less atherogenic.

It is noteworthy that the effects of statin treatment on LDE free cholesterol were less marked than in LDE cholesteryl esters. This is probably because of the diminution of CETP that occurs with statin use (52). LDE cholesteryl esters would be less prone to transfer to the plasma native lipoproteins, which are removed slowly in comparison with LDE, whereas the free cholesterol would not be affected by the changes in CETP action, since CETP does not influence free cholesterol shifts among the lipoprotein particles (33). Another issue worth noting in our results is the fact that we found a correlation between the RT of the LDE free cholesterol and total and LDL cholesterol, a correlation that did not exist regarding LDE cholesteryl esters. In fact, this supports the assumption that the two forms of cholesterol composing the structure of the same lipoprotein particles may have different metabolic fates.

One of the limitations of this and previous studies with LDE (3,4,14,27,47) is that our analysis concentrated mainly on the early and fast phase of radioisotope decay. This protocol design aimed to ensure patient comfort in view of the long blood collection period. However, in this study there was an important fall in the radioactivity of ^{14}C-cholesteryl ester remaining in the plasma at the 24-h point after simvastatin treatment. At any rate, in future studies a greater number of blood samples should be taken in the interval between 6 and 24 h to achieve a better description of the late phase of the decay curve.

REVIEW

Furan Fatty Acids: Occurrence, Synthesis, and Reactions. Are Furan Fatty Acids Responsible for the Cardioprotective Effects of a Fish Diet?

Gerhard Spiteller*

Lehrstuhl für Organische Chemie I, University of Bayreuth, D 95440 Bayreuth, Germany

ABSTRACT: Furan FA (F-acids) are tri- or tetrasubstituted furan derivatives characterized by either a propyl or pentyl side chain in one of the α-positions; the other is substituted by a straight long-chain saturated acid with a carboxylic group at its end. F-acids are generated in large amounts in algae, but they are also produced by plants and microorganisms. Fish and other marine organisms as well as mammals consume F-acids in their food and incorporate them into phospholipids and cholesterol esters. F-acids are catabolized to dibasic urofuran acids, which are excreted in the urine. The biogenetic precursor of the most abundant F-acid, F_6, is linoleic acid. Methyl groups in the β-position are derived from adenosylmethionine. Owing to the different alkyl substituents, synthesis of F-acids requires multistep reactions. F-acids react readily with peroxyl radicals to generate dioxoenes. The radical-scavenging ability of F-acids may contribute to the protective properties of fish and fish oil diets against mortality from heart disease.

Atherosclerosis (1,2) is a disease of the Western life style: Cardiovascular diseases account for half of the mortality in countries where people live with a surplus of food, but atherosclerosis is rare where people suffer from starvation. Moreover, a great number of animal and human experiments have revealed that consumption of food rich in cholesterol and fat induces atherosclerosis after a prolonged feeding period (3–8).

Nevertheless, despite their high consumption of fat and cholesterol, atherosclerosis is less common in Greenlanders (9–11), whose traditional diet is rich in fish and marine organisms. Compared with other foods, the content of lipids in fish is generally low, and the composition of the FA in the different lipid classes is somewhat different from other animal-derived food. Lipids of fish (12,13) and fish oils (14) are characterized by a high content of n-3 PUFA, especially of EPA and DHA (12). The connection between consumption of fish or ingestion of fish oils and protection against coronary heart disease mortality has been confirmed in several studies (15,16). Based on the fact that fish and fish oils are rich in n-3 PUFA, it has been deduced that ingestion of n-3 PUFA reduces the risk of death from cardiovascular diseases and their consequences (17–21) although some believe that an adequate explanation of this phenomenon is missing (22).

Fish accumulate dietary-derived n-3 PUFA in large amounts in their tissues as well as furan FA (F-acids) (23); the latter have been shown to be scavengers of hydroxyl (24) and peroxyl radicals (25).

In this paper the occurrence, isolation, biosynthesis, synthesis, and reactions of F-acids are reviewed, and deductions about the possible protective properties of the presence of F-acids in mammalian tissue and blood are presented. How the low amounts of linoleic acid (LA) in fish fat may influence the level of oxidized LDL in humans after fish consumption and how they may contribute to the protective properties of a fish diet against cardiovascular diseases are discussed.

STRUCTURES OF F-ACIDS

F-acids (furanoid FA) (23) are a large group of FA characterized by a furan ring, which carries in one α-position an unbranched FA chain with 9, 11, or 13 carbon atoms and in the other α-position a short straight-chain alkyl group with 3 or 5 carbon atoms. Either both β-positions of the furan ring are substituted by a methyl residue or else there is only a methyl group in the β-position adjacent to the long aliphatic chain (Table 1). The F-acids are numbered by indices according to increasing GC elution times of their dimethyl esters (26) and the letter F. The most common F-acid is F_6, or **6** (see Fig. 4 below), a furan

TABLE 1
Structures of the Most Abundant Furan FA

Number	Compound	m	n	R
1	F_1	2	8	CH_3
2	F_2	4	8	H
3	F_3	4	8	CH_3
4	F_4	2	10	CH_3
5	F_5	4	10	H
6	F_6	4	10	CH_3
7	F_7	4	12	H
8	F_8	4	12	CH_3

Abbreviations: AA, arachidonic acid; CLE, cholesterol ester; F-acid, furan FA; LA, linoleic acid; LOOH, lipid hydroperoxide; LOX, lipoxygenase; LPO, lipid peroxidation; OA, oleic acid; PL, phospholipids; TX, thromboxane.

FA with methyl groups in both β-positions, a pentyl residue in one α-position, and a –(CH$_2$)$_{10}$–COOH residue in the other.

OCCURRENCE

F-acids were detected by Glass *et al*. (26) in the Northern pike (*Esox lucius*). Shortly before, Kluytmans and Zandee (27) had reported on an investigation of the lipids in the same fish, but overlooked the high content of F-acids. In contrast to Glass *et al*. (23), Kluytmans and Zandee (27) had determined only GC retention times. Since F-acids and unsaturated FA with several double bonds of the same chain length have similar retention indices (26) this method is not adequate to distinguish between these two groups of compounds. Thus, Kluytmans and Zandee apparently attributed the peak of the most abundant F-acid, **6,** to 22:3n-3. In contrast, Glass *et al*. (26) used EI mass spectra, which allow unequivocal distinction between F-acids and n-3 PUFA, for compound characterization in addition to determination of retention indices. Measuring retention indices is often used as the only identification method, and this may be the reason why most authors have overlooked the presence of F-acids.

F-acids were found in a great number of freshwater (28,29) and marine fish (29–35) (see Table 2), and some minor compounds with variations in the chain length have been detected (36). Morover, F-acids were found as constituents of cod liver oil (29,36,37). F acids have been detected in invertebrates (38), such as crustaceans (crayfish) (39–41), amphibians (bullfrog) (40), and reptiles (turtle) (40).

F-acids with unusual highly unsaturated chains in α-positions were isolated from marine sponges (42). F-acids were also found in marine bacteria (43–45), algae (46,47), plants (48–50), yeast (49) and fungi (49), food fats such as butter (51) and virgin olive oil (52), mammalian tissue (53), and blood in-

cluding that of humans (54–56). Thus, F-acids seem to be widely distributed in all living matter.

The variations in the content of F-acids in the northern pike during the year and their accumulation in large amounts in testes and the liver of males in spawning times seemed to indicate a correlation between F-acids and the fertilization process (28). Subsequently, these increases in F-acids were correlated with starvation (30). F-acids were detected in all fish tissues examined (28) and in their blood (35). The best source for F-acids was the liver (23,24).

F-acids occur in living cells, like all other FA, as esters, but not in the free form. They are esterified to cholesterol in fish liver, and are found in TG and phospholipids in lower concentration (28). During starvation, the liver cholesterol esters become especially enriched in F-acids (29,30). In contrast, F-acids occur in fish testes nearly exclusively in the TG fraction (28,32). They are also predominantly esterified to glycerol in salmon roe (31). In the flesh of fish they are enriched in the phospholipids fraction (34) where they occur mainly in PC (31). Enrichment of F-acids was also reported in the PC derived from muscle tissue of crustaceae, such as crayfish (41) (see Table 2).

In liver tissue of mammals, F-acids are enriched in the cholesterol ester and in the TG fraction (53), but in mammalian (54) and human blood plasma (54) they are found mainly in the choline and ethanolamine phospholipids (55). Thus, F-acids are not equally distributed in the different organs in either fish or mammals.

F-acids of plant origin occur mainly in phospholipids, where they are predominantly localized in position 2 of the phospholipids. They constitute about 7% of LA, the most abundant FA in sugar cane cell cultures (50).

The reported F-acids that lack methyl substituents (57) are at least in part artifacts originating from lipid peroxidation

[a]PL, phospholipid, CLE, cholesterol ester. The symbols +, ++, +++, and ++++ indicate relative abundances of furan FA (F-acids) in the different species. PL containing F-acids readily undergo oxidative decomposition during chromatographic separation on silica gel columns. Therefore, the absence of F-acids in the PL fraction may be due to complete decomposition (31).

products of PUFA, such as epoxyoxoenes, which are generated by grinding of tissue (see below) (58,59). These products will not be discussed in this review, nor will the disubstituted F-acids obtained by singlet oxygen oxidation of conjugated FA (for a review see Ref. 60).

ISOLATION

As outlined later, F-acids—especially those with two β-methyl substituents—can scavenge peroxyl radicals. These react with F-acids to form dioxoenes (*c.f.*, Fig. 10) (53,61) and further degradation products thereof (62,63). Therefore, F-acids are quantitatively degraded during homogenization of tissue in aqueous solution and escape detection if biological material is processed in buffer solutions. Thus, F-acids were found only occasionally when fish tissue was homogenized in organic solvents (26). After isolation of the lipid fraction according to Folch *et al.* (64) or Bligh and Dyer (65), lipids were separated by TLC into a cholesteryl ester fraction, TG, and phospholipids. The esters were transesterified with methanolic sodium methoxide solution to form FAME (23,26) and investigated by GC–MS. Alternatively, the lipid fraction was saponified with HCl or pancreatic lipase and then methylated (26). To enrich the F-acid methyl esters and to separate them from those of the straight-chain PUFA, the methyl ester fraction was hydrogenated, leaving the F-acids unchanged. The obtained saturated FAME were precipitated by addition of urea (66). The supernatant containing F-acid methyl esters (26,29) was separated from the crystals of the urea complexes of the saturated FAME and subjected to separation by GC in combination with MS (23). Since side reactions are inevitable during hydrogenation with platinum as catalyst (23), hydrogenation is sometimes avoided by subjecting the mixture of methyl esters to urea precipitation followed by silver ion chromatography, which allows separation of methyl esters of unsaturated FA from F-acid methyl esters (23,29). These additional separation steps are especially useful for detection of minor compounds in the F-acid methyl ester fraction (30). F-acid methyl esters show very characteristic mass spectra, which give complete structural information (23). Similar isolation methods are applied to obtain F-acids from mammalian tissue (61). To avoid the time-consuming separation by urea precipitation, enrichment of F-acid methyl esters can be achieved by hydrogenation of the furan rings with a rhodium catalyst on alumina (67) to THF derivatives (54). The latter can easily be separated from saturated and unsaturated FAME owing to their high polarity. Application of multidimensional GC (trapping fractions and analyzing these by using a second gas chromatograph combined with a mass spectrometer registering characteristic ions) is nowadays applied for direct identification of F-acid methyl esters without prior separation from straight-chain fatty acid methyl esters (56).

CATABOLISM OF F-ACIDS

In an investigation of FA excreted in human urine, a previously unknown group of tetra-substituted dicarboxylic acids with a furan ring was detected (68). The structures of the main representatives of this group of compounds were recognized to be 3-carboxy-4-methyl-5-propyl-2-furopropanoic acid, **9**, and 3-carboxy-4-methyl-5-pentyl-2-furopropanoic acid, **10** (Fig. 1) (69). These acids were also found in human blood (70). Later, furan acids lacking the methyl substituent in position 4 of the furan ring were detected in traces in human urine, too (71). Excretion of **10** was enriched three- to sixfold after consumption of a fish diet (72).

Interestingly, the metabolism of F-acids differs considerably in various mammals. The long carboxylic acid α-side chain is degraded stepwise in all mammals to 3 carbon atoms. Additionally, in humans (73) the methyl group adjacent to this side chain is transformed to a carboxylic acid group, whereas in rats (74) and cattle (75) both α-side chains are preferentially oxidized (Fig. 1). An F-acid with a short carboxylic acid side chain, detected in soft corals, probably represents a degradation product of larger molecules (76).

Compounds **9** and **10** are enriched in plasma of patients with chronic renal failure (77). Although F-acids with a pentyl side chain usually are more abundant in the liver, the concentration of the degradation product with a propyl side chain, **9**, greatly exceeds that with a pentyl side chain, **10**, in plasma of subjects
FIG. 1. Catabolism of F-acids.

suffering from chronic renal failure. Since **9** inhibits the hepatic glutathione S-transferase, its enrichment in uremic serum has been connected to the toxic properties of uremic plasma (78). Removal of **9** by conventional hemodialysis is difficult owing to its strong binding to plasma protein (78–80). This property also interferes with the binding of drugs to albumin (81,82). The competitive binding of **9** alters the excretion of various drugs, drug conjugates, and other organic acids (83). Further investigations revealed that only free **9** is ultrafiltered in the glomeruli and then excreted in the urine (84); **9** is an inhibitor of mitochondrial respiration (85) and erythropoiesis and thus may contribute to anemia in renal failure (86). It also decreases the bilirubin-binding capacity (87) and has been hypothesized to be related to neurological abnormalities in uremia (88). Moreover, **9** inhibits proliferation of cultured human T-lymphocytes (89). Efforts to reduce **9** in serum by continuous ambulatory peritoneal analysis were partly successful (86). Several procedures were elaborated to determine **9** by HPLC methods (82,90–92) or by immunoassay (93). By applying these sensitive methods, **9** can be determined even in hair and sweat (94).

BIOSYNTHESIS

Originally, it was believed that F-acids are generated in fish (23). Feeding ^{14}C-labeled acetate to fish revealed that the acetate is incorporated into the carboxylic side chain by chain elongation. Chain shortening of the carboxylic side chain also was observed, but acetate was incorporated neither into the furan ring nor into the alkyl side chain (95), an indication that fish synthesize neither the alkyl side chain nor the furan ring of F-acids.

It is much easier to perform feeding experiments with rats to collect urine samples than with fish. Analysis of the rats' livers indicated the presence of F-acids. In order to prove the hypothesis that F-acids are derived from linoleic acid, a homolog of linoleic acid was fed to rats, but no homologous F-acids could be detected in their livers. As a consequence it was assumed that F-acids may be derived from rat food (96). This assumption was confirmed later by an investigation of plants (49). All investigated plants and algae (the final source of fish food) contained F-acids. In contrast, early hints that 2,5-disubstituted alkylfurans are transformed by incubation with liver homogenates (97) could not be reproduced. The observation that F-acids are generated in plants allowed further studies in cell cultures by feeding labeled compounds. It was thus recognized that plants synthesize the basic skeleton of F-acids from acetate (98). The methyl groups in the β-position of the furan ring originate from methionine (99,100), and the furan oxygen is derived from air (101). Originally, it was assumed that LA (**12**) was the precursor of the carbon skeleton of F-acids having a pentyl side chain by generation of a hydroperoxide in position 13, whereas F-acids with a propyl side chain were hypothesized to be derived from a hydroperoxide in position 12 of linolenic acid (47). Investigation of algal cell cultures proved that F-acids with a pentyl side chain originate from **12** but that F-acids with a propyl side chain are not derived from linolenic acid. Instead, they are generated from 9,12-hexadecadienoic

acid **13** (47). The peroxidation is initiated apparently by an unusual lipoxygenase (LOX) that counts—in contrast to most others—starting from the carboxylic end of the unsaturated FA (47) (Fig. 2).

The F-acids that primarily are generated are elongated by acetate units to higher homologs.

On the basis of the intermediates that were isolated—but without labeling experiments—it was proposed that in marine bacteria living in fish, F-acids are generated in a different way, starting by introduction of a methyl group into *cis*-vaccenic acid, **20**, followed by incorporation of a second double bond. The generated diunsaturated FA is assumed to react with oxygen, followed by ring closure to an F-acid (44) (Fig. 3).

CHEMICAL SYNTHESIS OF F-ACIDS

F-acids represent tri- or tetra-substituted furan derivatives. Their synthesis therefore requires several steps. Originally, **6** was prepared by starting from 3,4-bis(acetoxymethyl)furan, **23**, which was condensed with pentanoic acid anhydride to its
FIG. 2. Biosynthesis of F-acids.
FIG. 3. Proposed biosynthesis of F-acids in marine bacteria.

butylketone **24**, which was then transformed by reduction with hydrazine to the pentylfuran derivative **25**. The hydroxy groups of the latter were exchanged by chlorine. The resultant dichloro derivative **26** was subsequently reduced with $LiAlH_4$ to 3,4-dimethyl-2-pentylfuran, **27**. Introduction of the fourth substituent was achieved after treatment with BuLi by reaction with 1-chloro-10-iododecane. The resulting product **28** was finally converted by exchange of the chlorine to the Li-compound that was reacted with CO_2 to the F-acid **6** (102) (Fig. 4).

The difficult introduction and conversion of the carboxylic acid side chain is facilitated by using the acid chloride of the half ester derived from undecanedioic acid for condensation with 3,4-dimethy-2-pentylfuran, **27,** by catalysis with $SnCl_4$ to

29, followed by removal of the carbonyl function in a Wolff–Kishner reaction leading to **6** (61) (Fig. 5).

The key intermediate, 3,4-dimethyl-2-pentylfuran, **27**, is synthesized (103) by starting from 2,3-dimethyl-2-buten-4-olide **30**, which is reacted with pentylmagnesium bromide in ether to form the condensation product **31**. The latter is readily transformed without isolation by treatment with 2 N sulfuric acid to 3,4-dimethyl-2-pentylfuran, **27** (Fig. 6).

The lactone **30** is obtained by $LiAlH_4$ reduction of 2,3-dimethylmaleic acid anhydride, prepared by methylation of maleic acid anhydride by thermal decomposition of acetic acid (providing methyl radicals) in the presence of 2-aminopyridine (104) or by cyclization of 4-chloro-3-hydroxy-2,3-dimethylbutanoic acid

FIG. 5. Alternative route from 3,4-dimethyl-2-pentylfuran **27** to F$_6$, **6**.
FIG. 6. Generation of the starting material for the synthesis of 3,4-di-methyl-2-pentylfuran **27**.

methyl ester in presence of methoxide (103). The trisubstituted F-acid **5** was prepared by starting from 3-methyl 2-methylfuroate **32**. The pentyl side chain in position 5 of the furan ring was introduced in a manner similar to the route presented in Figure 5 by reaction with valeric acid anhydride and reduction of the resulting ketone, **33**, with hydrazine. The obtained acid, **34**, was decarboxylated to 4-methyl-2-pentylfuran, **35**. The introduction of the second α-side chain to **5** was performed as outlined for F$_6$ (102) (Fig. 7).

F$_6$ labeled in the carboxylic group with ^{14}C, **6a**, was prepared, starting from 3,4-dimethyl-5-pentylfuran, **27**, by introduction of an aldehydic group into the second α-position by a Vilsmeyer reaction to **37**, followed by a Wittig reaction to **38**, hydrogenation of the double bond in the side chain to **6a**, and an Arndt–Eistert reaction with ^{14}CH$_2$N$_2$ (Fig. 8) (105).

The rather moderate yield from these multistep reactions is considerably improved by a synthesis that takes advantage of

the different reactivities of bromine substituents at the furan ring. 4,5-Dibromofurfural, **39**, reacts in a Pd(0)-catalyzed reaction with 10-undecynoic acid benzyl ester by selective coupling in position 2 to **40**. The aldehydic group in **40** is subjected to a Wittig reaction. The bromine atom of the obtained product **41** is then exchanged by a methyl group by treatment with MeZnCl under catalysis of PdCl$_2$(PPh$_3$)$_2$ to the unsaturated benzyl ester **42**, which is transformed in one step by reduction with Pd(OH)$_2$ to **5** (106) (Fig. 9).

The 3,4-unsubstituted F-acids are available by epoxidation of both double bonds in LA, followed by treatment with NaI and propyliodide in dimethylsulfoxide (107).

3,4-Dimethyl-substituted F-acid esters are available starting from 3-methyl F-acids (present in latex rubber plants) by opening of the furan ring with acid to a dioxo ester, followed by methylation with methyl iodide/KOH in dimethylsulfoxide and cyclodehydration with BF$_3$ in methanol (107).

REACTIONS OF F-ACIDS

Like α,α-aryl-substituted furans, α,α-alkyl-substituted F-acids **3** undergo oxidation by ring opening (61,62) to form dioxoenes **43** (Fig. 10), which have been shown to inhibit blood platelet aggregation *in vitro*, albeit at high concentrations (108).

Investigation of the mechanism of this reaction showed that the oxidation is not restricted, as assumed originally, to singlet oxygen (109) but is common to radical-generating agents, such

as the Fenton reagent (Fe^{2+} + LO-OH → Fe^{3+} +OH^- +LO•), hypochlorous acid, or lipid hydroperoxides (110). It was therefore unexpected that this reaction was induced not only by radical-producing oxidizing chemical reagents but also by LOX. This reaction required the presence of LA as co-substrate. Free iron ions react extremely easily with lipid hydroperoxide (LOOH) molecules in the Fenton reaction. Nevertheless, iron ions are used extensively as catalysts for enzymatic redox reactions in nature, for instance in LOX. In order to avoid the Fenton reaction, metal ions are shielded in redox enzymes by complexation. Thus in LOX any contact with released LOOH molecules is prevented. It was therefore suspected (112) from the experiment illustrated in Figure 10 that iron ions were made

available for catalysis by alteration of LOX to induce nonenzymatic lipid peroxidation (LPO) reactions. This was clarified by model reactions using plant LOX (112): When soybean LOX-1 (requiring free PUFA for generation of LOOH molecules) was added to F-acid esters, these remained unchanged. Likewise no oxidation products of F-acids were generated if F-acid esters were incubated with pure LA, but if LA was added to the solution of soybean LOX-1, and F-acid esters, dioxoenes were produced (Fig. 10). This demonstrates involvement of radicals. Radicals are formed in a Fenton reaction requiring bivalent metal ions (113). The only available metal ions in this experiment are those in LOX. Moreover, it has been demonstrated that LOX is inactivated if it is exposed to high amounts of substrate
FIG. 10. Transformation of F-acids to dioxoenes 43.
FIG. 11. F-acids act as scavengers of radicals.

(114,115), which is certainly present if free LA is used as starting material as in the experiment just described. Thus, LOOH molecules were cleaved in the course of the reaction to alkoxyl radicals (116). These added to either position 2 or 5 of the furan ring of an F-acid, forming an intermediate, **44**, that undergoes ring opening to a mesomeric radical **45** of high stability. Consequently, it is much less reactive than a peroxyl or alkoxy radical. This property enhances its lifetime and enables it to trap a second radical, such as an alkoxy radical, generating a ketal, **46**. Thus, a stable molecule is generated and two radicals are removed in the course of the reaction (Fig. 11).

Ultimately, the ketal **46** undergoes hydrolysis to a dioxoene **43**. The catalytic availability of iron ions after alteration of LOX, which has not been taken into account previously, represents an alternative route to the well-known biological sources of iron ions, such as the heme present in blood or ferritin, as discussed by Welch *et al.* (117). The generation of free radicals by LOX iron ions could take place in tissues in which LOX enzymes have been expressed.

The idea that iron ions derived from inactivated oxygenase enzymes might be involved in the induction of radical reactions is further supported by considering that a single iron ion theoretically is able to start a radical chain reaction. In addition, the iron ion now made available to catalyze radical formation should be close to the generated LOOH molecule so as to avoid interruption of the Fenton reaction, for instance by reduction of LOOH to LOH molecules.

Alkoxy radicals attack double allylic activated hydrogens not only of free PUFA, as most LOX do (113), but also of PUFA bound to phospholipids **47** (118) or to cholesterol (118). Alkyl radicals **48** thus generated react with oxygen to form peroxyl radicals **49** (Fig. 12).

The reactivity of peroxyl radicals considerably exceeds that of LOOH or H_2O_2. For instance, LOO• radicals react with secondary alcohol groups by oxidation to carbonyl compounds, as exemplified by oxidation of hydroxy acids to oxo acids (118); with thioethers, such as methionine, to sulfoxides (118); with

amino acids containing a primary amino group, such as lysine, by oxidation to an aldehydic group (118); and with compounds containing double bonds, such as cholesterol (118) and linoleic acid, linolenic acid (119), or oleic acid (OA) (120) to their epoxides. Many of these products are toxic (121,122) or undergo transformation to toxic products (123). Thus, peroxyl radicals, generated in the reaction path outlined in Fig. 12, are a major source of cell-damaging processes.

Preferred substrates for the attack of peroxyl radicals are apparently F-acids, as reflected, for instance, by the observation that F-acids are not detectable after tissue has been homogenized, whereas they are found in plants (40) and tissues of animals (61) if homogenization is carried out after samples have been boiled or worked up with an organic solvent. Since boiling destroys enzymes, and workup in organic solvents usually prevents enzyme activity, as demonstrated long ago in the processing of plant tissues (124), the oxidation reaction is concluded to be induced by an enzymatic reaction (125). Apparently any change in membrane structure, inevitably caused by cell-damaging processes (homogenization), alters also proteins of cell channels combined with influx of Ca^{2+}ions into the cell (126); Ca^{2+} ions activate many phospholipases. These generate free PUFA from phospholipids, which serve as substrates for oxygenases. Inactivation of such enzymes by an accumulation of large amounts of free PUFA may be associated with altered binding activities of iron ions (114,115) and switches the controlled enzymatic LPO to uncontrolled nonenzymatic LPO, resulting in production of peroxyl radicals as already discussed.

Peroxyl radicals attack F-acids by ring opening to dioxoenes **43** (61,62,127) (Fig. 10). F-acids occur in some tissues in form of phospholipids (54). These naturally occurring tetra-alkyl-substituted furan derivatives are prone to oxidation (25,128) by peroxyl radicals, as already mentioned (127). Therefore, F-acids may serve in nature as antioxidants (128) as also suggested by electron spin resonance investigations (24).

Diet-derived F-acids are incorporated into the tissue and blood of mammals, especially into phospholipids (54, 55)
FIG. 12. Generation of peroxyl radicals, exemplified with a phospholipid containing a PUFA.

where they partly substitute for PUFA. As a consequence, they are localized exactly at sites where LPO reactions occur in atherosclerosis and where they are needed to trap radicals. This might increase their value as radical scavengers in comparison with other radical-scavenging compounds, such as tocopherols.

The ring-opening reaction of F-acids to dioxoenes different in α,α,β,β-tetra-alkyl-substituted furans compared with α,α-di-alkyl-substituted furans. The latter are rearranged to rather stable *trans* dioxoenes. This rearrangement is inhibited in tetra-alkyl-substituted furans such as **3**; the products **43** remain in the *cis* form (127). In alkaline solution this isomer undergoes an intramolecular aldol condensation to the cyclopentenolones **50** and **51** (61) (Fig. 13).

Cyclopentenolones **50** and **51** are detectable after homogenation of tissue in aqueous solvents (61,129). Dioxoenes generated as intermediates, such as **52**, add nucleophiles (62) such as water or thiols (62), e.g., glutathione. The addition products are able to react further by ring closure forming a-substituted F-acids (Fig. 14). These can either undergo a second oxidative ring opening, followed by addition of a second nucleophile and a second ring closure reaction (62), or react by loss of the substituent by formation of derivatives with an α,β-double bond (Fig. 14). As a consequence, all of these different artifacts, such as **53–56**, are detectable after processing biological materials.

The preferential oxidation of F-acids by peroxyl radicals, compared with attack on PUFA, becomes evident following investigation of plant (124) or animal tissue samples (130,131). After homogenization in aqueous solution, F-acids are completely missing, whereas the content of PUFA remains largely unchanged (61).

The great tendency of F-acids to undergo oxidation suggests that plants and algae can use these compounds as radical scavengers to defend against the deleterious effect of UV radiation. To remove radiation-induced radicals, plants and algae are assumed to generate F-acids and incorporate them into PC (50). Thus, for instance, antioxidant activity in soybean PC liposomes is recognized (128). The potency of F-acids as scavengers of, for example, hydroxyl radicals (24) is further exemplified by the findings that they suppress hemolysis better than other quenchers of singlet oxygen, such as dimethylfuran, α-tocopherol, ascorbic acid, or uric acid (24).

All these deductions are corroborated by the observation that the content of F-acids in plants increases from nearly zero at the beginning of leaf growth to maximal values in July in the Northern Hemisphere and then remains constant till the end of the vegetation period (Schulz, D., and Spiteller, G. unpublished data).

Phospholipids represent the outermost layer of cells and are therefore exposed first to the attack of microorganisms. This mechanical injury induces a reaction cascade, leading to generation of radicals as already outlined. The defence processes should end once the invader is destroyed. F-acids incorporated in cell membranes seem to contribute to stop the progress of LPO reactions after a successful defense against the invaders.
FIG. 13. Generation of cyclopentenolones **50** and **51** by reaction of dioxoenes with alkali.

Drying of plant material is connected with LPO processes (132) that generate peroxyl radicals that oxidize F-acids. Some of the oxidative degradation products of F-acids generated by plant injury are characterized by a typical smell. For instance, 3-methyl-2,4-nonanedione is responsible for the hay-like scent of dried spinach (133).

In contrast to F-acids, urofuran acids, their biological oxidation products, are rather stable to further oxidation. Nevertheless, they also undergo oxidative ring opening when treated with powerful oxidizing agents, such as hypochlorous acid (134).

ARE F-ACIDS INVOLVED IN PROTECTION AGAINST CARDIOVASCULAR DISEASES?

As pointed out in the introduction, a diet rich in marine food (9,10,15) or fish oil (16, 135–138) was protective against cardiovascular diseases. It lowers the amount of TG in LDL (135,139,140) and—most importantly—decreases the risk of sudden heart death in patients (136,137) apparently closely related with a reduction of Ca^{2+} ion release from cell stores (137,141). Fish oils are thought to increase slightly the HDL level (135,142) and to reduce the level of the VLDL. Since fish are rich in n-3 PUFA, the protective properties of fish consumption have been ascribed to these n-3 PUFA (17,18). These deductions do not consider the possibility that minor natural products might have much greater physiological effects than the major constituents and that n-3 PUFA, like all other PUFA, readily undergo lipid peroxidation, while saturated and mononounsaturated FA remain unaffected.

The increase in susceptibility of LDL to oxidation by an exchange of saturated FA and OA vs. more highly unsaturated PUFA has been experimentally confirmed (143–145). In confirmation, an increase in LPO products was found after n-3 FA were incorporated into plasma and tissue (146). Thus, a fish diet is expected to produce an increase in atherogenic effects, not a decrease, as observed. In fact, some reports claim an increase in the oxidizability of LDL after consumption of fish oil (147).

These controversial observations and deductions require a
FIG. 14. Generation of α-substituted F-acids and their dehydration products.

short discussion about the present knowledge about atherogenesis.

Atherosclerosis (1,2,148) is related to the oxidation of LDL (149–151). Oxidized LDL induces apoptosis of cells (152,153), raising the question of which oxidation products might cause these effects.

LDL is a macromolecule composed of a core of cholesterol esters and a phospholipid membrane in which a protein is embedded (148). The latter is recognized by the LDL receptor of the endothelium (148).

PUFA are incorporated into the phospholipid membrane of LDL and into its cholesterol ester-containing core. Compared with all other constituents of LDL, PUFA show the highest sensitivity to oxidation by molecular oxygen. This sensitivity becomes evident by storage of fat that contains PUFA, resulting in rancidity (154), or by storage of blood plasma that develops atherogenic modifications (155). Likewise, wounding of plant (124) and animal (130,131) tissue is associated with LPO. Therefore, partly oxidized phospholipids are detected after artificial oxidation of LDL (156), after addition of activated human monocytes (157) (corresponding interactions influence the membrane structure), or after storage (155,158). Hydrolysis of such oxidized LDL allows quantification of the different oxidized PUFA products by flow injection electrospray ionization MS (158) or, after saponification, by GC–MS. The latter method revealed that the main oxidation products are derived from LA (159–161), which represents the most abundant PUFA in LDL of people consuming a Western-type diet (148). Compared with LA, arachidonic acid (AA) is present in LDL in much smaller amounts (AA/LA = 1:5). The content of n-3 PUFA is much lower. The most abundant n-6 PUFA in people consuming a Western diet is LA, representing about 20–30% of the total amount of FA in LDL (159).

The content of FA in LDL is strongly dependent on the FA composition of the food consumed, as exemplified by feeding an OA-rich diet to rabbits (162) or humans (144), which changed the LDL fatty composition in favor of OA. Likewise, the content of FA in wild-living fish varies with season and with living conditions. For instance, in starving fish, the content of F-acids increases in the liver cholesterol ester fraction (29).

FA of fish tissue can be distinguished from those of mammalian tissue by the presence of larger amounts of long-chain highly unsaturated n-3 PUFA. EPA amounts in fish are between 7 and 10%, and DHA is between 20 and 40% of the total FA content, depending on the kind of fish and the investigated organ (12–14).

Since the nutritional sources of fats strongly influence the composition of blood fats, it is not surprising that the contents of EPA and DHA in the blood plasma of Greenlanders (9), whose main nutritional source is marine organisms, are much higher than those of people consuming a Western diet, although they are still not a major fraction: EPA is present on the average in the phospholipid and TG fraction to a maximum of 8%, whereas it accumulates in the cholesterol ester fraction to 15% of the total FA content. DHA amounts to values not exceeding

3–4% in all three lipid classes (phospholipids, TG, and cholesterol esters) (10) although DHA is more abundant in most fish than EPA. The presence of relatively large amounts of n-3 FA was assumed to be responsible to the beneficial properties of a fish diet (10).

n-3 PUFA, like n-6 PUFA, possess one or more –CH=CH-CH_2-CH=CH– groups, the prerequisite to undergo a nonenzymatically induced LPO process. Therefore, n-3 PUFA are not distinguished in their capacity to be attacked by radicals, and both classes of PUFA are subjected equally to radical induced LPO reactions. Consequently, the reason for the beneficial properties of a fish diet cannot be a suppresion of LPO reactions.

Owing to the low content of n-3 PUFA in LDL of people living on a Western-style diet (the most abundant n-3 FA, linolenic acid, is present in an amount less than 2%), the contribution of n-3 PUFA to oxidation products of LDL is extremely low. In contrast, the relatively high level of n-3 PUFA in the blood of Greenlanders should contribute to their LPO. Degradation of LPO products of AA and LA produces nearly identical toxic products, such as 2,4-decadienal (123), 4-hydroxynonenal (163,166), or epoxyenoic acids (122). Because LA is much more abundant than AA in LDL, more toxic products are derived by LPO of LA than by AA.

Since n-3 PUFA (164) decompose in nonenzymatic LPO reactions in an analogous manner to n-6 PUFA (165), no change in the production of toxic compounds (166) in bulk-phase reactions is expected by exchange of n-6 PUFA with n-3 PUFA. Nevertheless, consumption of fish or fish oil does decrease the rate of LDL oxidation (147,167). This observation was corroborated by feeding volunteers a fish oil supplement, which caused enrichment of their LDL with EPA and DHA. This LDL proved more stable against *ex vivo* oxidation and less able to induce apoptosis in U 937 cells (168) (a characteristic behavior of atherosclerotic cells) than LDL enriched with LA (169).

This puzzling effect has been explained by arguing that the beneficial effects of food rich in EPA and DHA, which are incorporated in increased amounts into phospholipids with respect to AA, decrease the generation of thromboxane (TX) A_2, which causes platelet aggregation and increases prostacyclin activity (170), thus reducing the risk of atherogenesis. The hypothesis that altering the AA/EPA/DHA relation by consumption of a fish diet reduces the AA amount and therefore TX production does not consider that production of TX is an enzymatic and therefore a physiological process. In contrast, the reactions devastating cells in cardiovascular diseases seem to be induced by radicals. The change in the AA/EPA/DHA relation does not necessarily influence the generation of radicals, since all PUFA are equally able to induce generation of radicals. A decrease in radicals can be achieved only by radical scavengers. Therefore, it seems reasonable to assume that the presence of other components in a diet rich in fish or fish oil, or other factors not taken into account previously, might be responsible for the observed reduction of LDL oxidation, as has been already suggested (171). This assumption is further corroborated by the observation that the amount of propylurofu-

ran acids increased by a factor of 3–6 after consumption of a fish oil diet (72). Since urofuran acids are degradation products of F-acids, this indicates that fish oils are abundant sources of F-acids.

Although F-acids occur in fish only in amounts of around 1% (29,36) they might reduce the oxidation of LDL to a considerable extent because they serve as potential radical scavengers (24) and inhibit progression of nonenzymatic lipid peroxidation reactions (172). And because radicals induce a chain reaction, the amount of F-acids may be sufficient to suppress LDL oxidation.

Although the content of F-acids in fish and fish oils could explain the positive effects of a fish diet, similar effects were reported from fish oils in which n-3 PUFA were enriched. During n-3 PUFA enrichment, at least a reduction in F-acid contents might be expected. But separation of F-acids from other FA is very difficult and requires special workup procedures (66). Such procedures are not used in preparing fish oil supplements. Therefore, F-acids might remain during the enrichment procedure (36).

F-acids are mainly incorporated into phospholipids of blood plasma (54), which is in intimate contact with the surface of endothelial cells where oxidation of LDL occurs (172). Thus, the scavenger molecules (F-acids) are incorporated exactly at the sites where they can prevent lipid oxidation most effectively. Consequently, F-acids may contribute to the protective properties of a fish or fish oil diet. The suggestion that F-acids are effective antioxidants is further corroborated by the observation that phospholipids of eggs from marine salmon withstand lipid peroxidation induced by copper ions much better than do phospholipids of chicken eggs (174). Moreover, it can be assumed that the polar F-acids are more easily in contact with the polar hydroperoxides than with less polar FA esters, as shown by investigations of oil-in-water emulsions (174–176).

DOES THE REDUCTION IN TOTAL PUFA CONTRIBUTE TO THE PROTECTIVE PROPERTIES OF A FISH DIET?

As pointed out earlier, Dyerberg *et al*. (10) compared plasma samples obtained from Greenlanders living nearly exclusively on a marine diet with those of Danes living on a typical Western diet. They noted a substantial increase of EPA and DHA in LDL of Greenlanders compared with LDL of Danes. But the reported FA content also indicates a considerably increased PUFA concentration in all three lipid classes (phospholipids, cholesterol esters, and TG) in Danes compared with Greenlanders. In the phospholipids located at the outer surface of the LDL particle, where lipids are especially exposed to oxidation, the PUFA content exceeds that of saturated and monounsaturated FA by more than twofold; in the cholesterol esters representing the core compounds by one-third; and in the less important class of TG by about 20% (10). Considering that only PUFA are subjected to lipid peroxidation, this means a reduction in the overall likelihood of generating toxic LPO products

in LDL of Greenlanders compared with people living on a Western-style diet.

As shown in many experiments, the plasma FA content reflects with few exceptions (one is the content of DHA) the content of FA consumed in the diet (144,162). Apparently, AA may be substituted by EPA, as recognized from the fact that the amount of AA in the phospholipids of Danes corresponds nearly exactly to the amount of EPA in that of Greenlanders (10).

Although it has been assumed that EPA and DHA are more prone to oxidation compared with n-6 PUFA, which have a lower number of double bonds (161), this deduction may not relate to biological processes because it is based on model reactions with mixtures of pure PUFA carried out by adding an excess of catalytic bivalent metal ions (177). In biological material, such an excess of metal ions is never produced, since decomposition of iron-containing proteins—which allows iron ions to become available for peroxidation catalysis—is a relatively rare event, except if massive mechanical destruction of tissue is performed, for instance by homogenization (131). As a consequence, the total amount of PUFA in LDL combined with the ability to remove generated peroxyl radicals may determine their transformation rate to toxic compounds.

The increase in saturated and monounsaturated FA in plasma of Greenlanders compared with Danes and their decreased incidence of atherogenesis is in contradiction to the statement that ingestion of food rich in saturated FA increases the atherogenic risk (3,7,8). Saturated and monounsaturated FA withstand oxidation; thus these acids are not attacked by LPO, as shown by artificial oxidation of LDL or during storage (159). Although monounsaturated FA are less stable to LPO than saturated ones, they are much less prone to undergo LPO compared with PUFA, as proven experimentally by LDL oxidation (159). Therefore, only PUFA are significantly subjected to LPO in LDL, at least *in vitro*.

The comparison of the nutrition of Greenlanders and Danes on the basis of their blood concentrations of FA indicates that there are more than twice as many PUFA molecules in the phospholipid fraction of Danes compared with that of Greenlanders (10) and perhaps this—besides the content of F-acids—could be responsible for the fact that Greenlanders were less affected in the past to atheroclerosis.

CONCLUSION

F-acids seem to be distributed in all mammals, plants, and algae, where they apparently play an important role in scavenging radicals and contribute to inhibiting the progression of nonenzymatic LPO reactions. F-acids are accumulated in fish, fish products, and other marine organisms. F-acids are also present in plants, although in lower amounts. F-acids are introduced into the body through the diet. This may be one reason why fish consumption reduces the risk of atherogenesis and its eventual complications.

A fish diet has an additional effect: Although it increases the content of n-3 PUFA in tissue and blood, it reduces the total

amount of PUFA in the phospholipid fraction of plasma in favor of saturated and monounsaturated FA in LDL, which withstand oxidation. Since all PUFA are susceptible to LPO, the reduction of the total amount of PUFA in LDL—besides the content of F-acids—might be a second reason for the protective properties of a fish diet.

ABSTRACT: The lipid profiles of cotton fiber cells were determined from total lipid extracts of elongating and maturing cotton fiber cells to see whether the membrane lipid composition changed during the phases of rapid cell elongation or secondary cell wall thickening. Total FA content was highest or increased during elongation and was lower or decreased thereafter, likely reflecting the assembly of the expanding cell membranes during elongation and the shift to membrane maintenance (and increase in secondary cell wall content) in maturing fibers. Analysis of lipid extracts by electrospray ionization and tandem MS (ESI-MS/MS) revealed that in elongating fiber cells (7–10 d post-anthesis), the polar lipids—PC, PE, PI, PA, phosphatidylglycerol, monogalactosyldiacylglycerol, digalactosyldiacylglycerol, and phosphatidylglycerol—were most abundant. These same glycerolipids were found in similar proportions in maturing fiber cells (21 dpa). Detailed molecular species profiles were determined by ESI-MS/MS for all glycerolipid classes, and ESI-MS/MS results were consistent with lipid profiles determined by HPLC and ELSD. The predominant molecular species of PC, PE, PI, and PA was 34:3 (16:0, 18:3), but 36:6 (18:3,18:3) also was prevalent. Total FA analysis of cotton lipids confirmed that indeed linolenic (18:3) and palmitic (16:0) acids were the most abundant FA in these cell types. Bioinformatics data were mined from cotton fiber expressed sequence tag databases in an attempt to reconcile expression of lipid metabolic enzymes with lipid metabolite data. Together, these data form a foundation for future studies of the functional contribution of lipid metabolism to the development of this unusual and economically important cell type.

Paper no. L9784 in *Lipids 40*, 773–785 (August 2005).

Cotton fibers are trichomes that arise from the differentiation of ovular epidermal cells near or on the day of anthesis (1). Development of these cells progresses through stages of elongation and secondary wall deposition forming extremely long single cells, over an inch (2.5 cm) long (2), during a period of about 25 d. This period of rapid cellular elongation requires substantial synthesis of macromolecules, including lipids necessary for the developing vacuoles and plasma membranes. The major research focus on cotton fiber development historically has been on cellulose synthesis, which accounts for the bulk of the mass of mature fiber cells; however lipid metabolism is likely to be an important factor in the development of cotton fibers, and this subject has received little attention.

Electron microscopy studies have shown that fiber initiation occurs near or on the day of anthesis, as fibers emerge as protrusions from the epidermal layer of cotton ovules (3,4). This is followed by elongation, in which the cells undergo rapid expansion with increases in length and diameter, and concurrent primary cell wall formation. On average, this continues for 15–27 d (3). Secondary cell wall synthesis begins around 16–19 d post-anthesis (dpa) and is thought to overlap with elongation (5). This process consists of the deposition of successive layers of cellulose microfibrils in a helical pattern around fiber cells (2,6). Maturation of fibers ends about 45–60 dpa, and it includes seed capsule dehiscion, dehydration, and collapse of fiber cells (2).

Synthesis of cellular constituents, including lipids for incorporation into the vacuole and plasma membranes, must be necessary during the period of rapid cell expansion in cotton fiber cells. In plants, FA biosynthesis occurs *de novo* in plastids. The newly synthesized FA can be either incorporated into plastidial glycerolipids or transported to the endoplasmic reticulum (ER) for incorporation into extraplastidial complex lipids (7) such as those destined for vacuole and plasma membranes. Developing fiber cells, undergoing rapid elongation, have a higher lipid content and were shown to incorporate the majority of ^{14}C-labeled acetate into polar lipids at a rate that declines as cell elongation ceases [from 10 to 20 dpa (2)]. As polar lipids are the major constituents of lipid bilayers, these results suggest that fiber cells are involved in active membrane synthesis during early stages of development.

Recent technical advances now make it possible to perform rapid, detailed glycerolipid profiling (8). Electrospray ionization

(ESI) and tandemmass spectrometry (MS/MS) are currently used to determine the classes, molecular species, and amount of lipids in plant cells (8). Here we have applied this technique to identify and quantify the classes and molecular species of polar lipids in developing cotton fiber cells. These data provide a critical knowledge base of information for how lipid composition changes with fiber development. The results were compared with those from other approaches, including GC-FID, to determine total FA composition, and HPLC analysis combined with ELSD or MS to profile polar lipids as well as sterols, sterol esters, and sterol glycosides (SG) (9,10). SG and their acylated components in cotton fiber cells have been implicated as primers for elongation of β1–4 glucan chains that form cellulose microfibrils during secondary cell wall development (11); hence the sterol composition of cotton fiber cells may be important to understanding more about cell wall formation in these fiber cells.

Several genes that are preferentially expressed in cotton fibers during the rapid elongation process have been identified, including some that are involved in lipid metabolism, such as those encoding a putative acyltransferase and a putative 24-sterol-C methyltransferase (12). Transcripts for a gene encoding a fiber-specific acyl carrier protein (ACP) were highly expressed during the stage of elongation, and this ACP was proposed to play a role in synthesis of membrane lipids (13). Cotton fiber-specific cDNA encoding lipid transfer proteins have been isolated and shown to have a temporal expression pattern, accumulating from 6 to 14 dpa (14,15); transcript levels for one isoform, lipid transfer protein-3, reached a maximum at 15 dpa (16). The results of these studies indicate that transcription of genes involved in lipid metabolism in cotton fiber occurs in a developmentally regulated manner. However, a more global examination of gene expression in cotton fiber cells during the stage of rapid elongation might provide more insights into the mechanisms responsible for the development of these cells.

More than 50,000 expressed sequence tags (EST) from *Gossypium* sp. fiber cells have been sequenced by several laboratories [predominantly Brookhaven National Laboratory (Brookhaven, NY) and Clemson University Genomics Institute (Clemson, SC)] and compiled by The Institute for Genomic Research (TIGR; Rockville, MD) at their web site at http://www.tigr.org. Most all of these EST are derived from cotton fibers at 6 or 7 to 10 dpa, during the stage of rapid cell elongation, and most likely include expressed genes of lipid metabolism important for this development stage. The occurrence of EST for enzymes involved in lipid metabolism can be used to begin to predict which metabolic pathways are operating during this stage of rapid cell elongation, as was done recently for oil biosynthesis in *Arabidopsis* seeds (17). The combination of metabolic profiles and DNA database information provides a unique perspective on membrane biogenesis for fiber cell elongation and will serve as a basis for the development of hypotheses regarding the regulation of membrane biogenesis in this important agricultural plant.

The main objective of this research was to characterize the glyceroplipid metabolites in cotton fiber cells at different stages of development and estimate a gene expression profile for lipid metabolism genes in elongating cotton fibers. Toward this end we compiled a list of EST for enzymes involved in lipid metabolism in developing cotton fibers, using EST data annotated and assembled into tentative consensus (TC) sequences by The Institute for Genomic Research. Unique TC sequences are estimates of individual transcripts in cases such as cotton where the genome has not yet been sequenced. The data on EST profiles were viewed, compared, and correlated with the levels of various lipids (including both lipid classes and their individual molecular species) and were used to predict lipid metabolic pathways in developing cotton fiber cells.

MATERIALS AND METHODS

Plant material. Cotton (*Gossypium hirsutum* L. cv. Coker 312) plants were greenhouse grown in April to October in Denton, Texas, with day/night temperatures of 95/80°F (35/27°C) and an approximate 16 h photoperiod (day length extended with sodium vapor lamps when necessary). Flowering plants were tagged on the day of anthesis, and bolls were harvested at 7–10, 14, 21, and 28 dpa. Material in locules (fiber and ovules) was excised and immediately placed in boiling isopropanol, since experiments in which samples were kept on ice or stored at –20 or –80°C resulted in large amounts of post-harvest-generated PA. Replicate fiber samples were dried overnight at 50°C to determine dry weight of fiber samples. Dry weights ranged from 45 to 100 mg. Total FA profiles also were determined for cv. Stoneville 474 (SG474), grown in Stoneville, Mississippi, over the same period for comparison. In this case, bolls were provided by Dr. Jodi Scheffler, USDA-ARS, Cotton Physiology and Genetics (Stoneville, MS).

Chemicals. Diheptadecanoyl (17:0) L-α-PC, L-α-PC (Type II) from soybean, cabbage phospholipase D (PLD) (Type V), and BSA were obtained from Sigma Chemical Co. (St. Louis, MO). [1-^{14}C]Dipalmitoyl-L-α-PC was purchased from NEN Life Sciences (Boston, MA). All other chemicals were from Fisher Scientific unless otherwise stated. Phospholipid and galactolipid standards for ESI-MS/MS were obtained and quantified as previously described (8).

Lipid extraction and analysis. Total lipid extraction of cotton tissues was by a modified version of the Bligh/Dyer method using isopropanol and chloroform (as described in Ref.18). Approximately, 0.5 g of fiber samples was placed in 2 mL boiling isopropanol (70°C). L-α-Diheptadecanoyl (17:0) PC (1–5 mg) was added to some samples as a quantitative standard, and the tubes were incubated at 70°C for 30 min. The samples were allowed to cool to room temperature, 1 mL of chloroform was added, and the samples were extracted overnight at 4°C. Following overnight extraction, phase separation was achieved by addition of 2 mL of KCl and 1 mL of chloroform, and facilitated by centrifugation at 480 −× *g* for 10 min in a Beckman TJ-6 benchtop centrifuge. The upper, aqueous phase was aspirated, and the remaining organic layer was washed two times with 2 mL 1 M KCl and finally with 1 mL ultrapure water

(Milli-Q). The chloroform was evaporated using a Multivap118 nitrogen evaporator (Organomation Associates, Berlin, MA), and 2 mL of fresh chloroform was added to the remaining lipid extract. The lipid samples were stored under nitrogen at –20°C for subsequent FA analysis, or evaporated to dryness and shipped overnight under nitrogen to the Kansas Lipidomics Research Center (KLRC) Analytical Laboratory for ESI-MS/MS analysis, or to the Eastern Regional Research Laboratory, USDA, for HPLC-ELSD analysis.

For total FA analysis, the lipid extracts were evaporated to dryness with nitrogen gas and transesterified in 1 mL acidic (1% H_2SO_4) methanol for 30 min at 65°C. FAME were extracted into hexanes, washed with 5% (wt/vol) NaCl, and dried over Na_2SO_4 columns. FAME in hexanes were analyzed by GC-FID using a Hewlett-Packard Series II plus 5890 gas chromatograph. Samples were separated over a 30 m SUPELCOW-AX^{TM}-10 fused-silica capillary column (Supelco, Bellefonte, PA) at an oven temperature of 200°C, with nitrogen as the carrier gas, and FID was used to quantify FAME. Injector and detector temperatures were 250°C. Identification of FA in samples was achieved by comparison with lipid standards (FAME Mix GLC–10; Supelco), and the amount of each FA was calculated based on the amount of the internal heptadecanoyl standard (from the transesterification of diheptadecanoyl PC).

The polar lipid classes and molecular species in cotton fiber lipids were determined by direct infusion ESI and MS/MS at the KLRC Analytical Laboratory. The samples were dissolved in chloroform. Two aliquots were taken for MS analysis, one sample of 10 µL for phospholipid analysis and one of 10 µL for galactolipid analysis. For phospholipid analysis, cotton lipid extract in chloroform was combined with solvents and internal standards, such that the ratio of chloroform/methanol/300 mM ammonium acetate in water was 300:665:35, the final volume was 1 mL, and the sample contained 0.66 nmol di14:0-PC, 0.66 nmol di24:1-PC, 0.66 nmol 13:0-lysoPC, 0.66 nmol 19:0-lysoPC, 0.36 nmol di14:0-PE, 0.36 nmol di24:1-PE, 0.36 nmol 14:0-lysoPE, 0.36 nmol 18:0-lysoPE, 0.36 nmol di14:0-phosphatidylglycerol (PG), 0.36 nmol di24:1-PG, 0.36 nmol 14:0-lysoPG, 0.36 nmol 18:0-lysoPG, 0.36 nmol di14:0-PA, 0.36 nmol di20:0(phytanoyl)-PA, 0.24 nmol di14:0-PS, 0.24 nmol di20:0(phytanoyl)-PS, 0.20 nmol 16:0–18:0-PI, and 0.16 nmol di18:0-PI. For galactolipid analysis, plant lipid extract in chloroform was combined with solvent and internal standards, such that the ratio of chloroform/methanol/50 mM sodium acetate in water was 300:665:35, the final volume was 1 mL and the sample contained 2.01 nmol 16:0–18:0-monogalactosyldiacylglycerol (MGDG), 0.39 nmol di18:0-MGDG, 0.49 nmol 16:0–18:0-digalactosyldiacylglycerol (DGDG), and 0.71 nmol di18:0-DGDG.

The samples were analyzed on a triple quadrupole tandem mass spectrometer (API 4000; Applied Biosystems, Foster City, CA) equipped for ESI. The source temperature (heated nebulizer) was 100°C, and -4.5 or +5.5 kV was applied to the electrospray capillary. The two ion source gases were each set at 45 arbitrary units; the curtain gas was set at 20 arbitrary units; the declustering potential was ±100 V for phospholipids,

+150 V for MGDG, and +215V for DGDG; and the entrance potential was ±10 to ±15 V. With the interface heater on, the sample was introduced using an autosampler (LC Mini PAL; CTC Analytics AG, Zwingen, Switzerland) and presented to the ESI needle at 30 µL/min. Precursors of lipid head-group-derived fragments were detected, using the scans previously described (8,19,20). The collision energies, with nitrogen in the collision cell, were 28 V for PE, 40 V for PC, −58 V for PI, −57 V for PA and PG, −34 V for PS, 50 V for monogalactosyldiacylglycerol (MGDG), and 84 V for digalactosyldiacylglyerol (DGDG). The mass analyzers were adjusted to a resolution of 0.7 amu full width at half height. For each spectrum, 9–150 continuum scans were averaged in multiple channel analyzer mode.

Data processing was performed using Analyst software (Applied Biosystems) with a custom script written by Anna Lisyansky of Applied Biosystems. In each spectrum, the background was subtracted, the data were smoothed, and then peak area was determined. Identification of the peaks of interest and calculation of lipid species amounts were performed using Microsoft Excel. Corrections for overlap of isotopic variants (A + 2 peaks) in higher mass lipids were applied. The lipids in each class were quantified in comparison with the two internal standards of that class as described (8).

For the quantitative analysis of the polar and nonpolar lipid classes, the total lipid extract was dissolved in chloroform/methanol (10 mg/mL in 85:15, vol/vol) and injected in an HPLC system equipped with ELSD. The method used an Agilent 1100 HPLC system, a Sedex Model 55 ELSD, and a DIOL column, as previously described (10). Lipid classes were identified by cochromatography with commercial standards and by MS (LC-MS with atmospheric pressure chemical ionization in the positive ion mode).

Bioinformatics and data mining. Cotton EST from different tissues in cotton have been assembled into TC sequences at The Institute for Genomic Research web site at http://www.tigr.org. These include EST from two libraries for cotton fibers at 7–10 dpa and at 6 dpa, which is the stage of rapid cell expansion. We queried these databases to catalog EST to identify the major enzymes involved in lipid metabolism in elongating cotton fiber. At the time of our analysis 38,814 EST were annotated from the 7–10 dpa library, and 8,003 from the 6 dpa library. Hence, the number of EST and TC sequences discussed here are almost exclusively those of the larger (7–10 dpa) library, with certain noted exceptions. Some EST were already annotated, whereas others were identified using the WU-BLAST program with cDNA and protein sequences from other plants as queries. Many of these plant sequences were obtained from a lipid gene database for *Arabidopsis thaliana* housed at http://www.plantbiology.msu.edu/lipids/genesurvey/index.htm (17). In addition, protein motif identification, domain organization analysis, and subcellular location predictions were accomplished with web-based bioinformatics tools (interpro, BLOCKS, NCBI-DART, PSORT, TargetP) where possible. Sequences of lipid metabolism genes in cotton were placed in the context of known lipid metabolism pathways and used to predict

the metabolic capacity for cotton fibers to produce various lipid metabolites. Actual metabolite data were compared with these metabolic schemes to provide an overall view of lipid metabolism in elongating cotton fiber cells.

All experiments were repeated at least three times and the data presented are the means ± SD.

RESULTS

FA composition of cotton fiber cells. Total lipid extracts were obtained from cotton fiber cells (*G. hirsutum*, L., cv. SG474 and Coker 312) harvested at different ages (7, 14, 21, and 28 dpa) representative of different stages of fiber development. Total FA composition was determined by GC-FID using heptadecanoic acid (17:0) as a quantitative internal standard. The percentage by weight of each of the common FA, palmitic (16:0), stearic (18:0), oleic (18:1), linoleic (18:2) and linolenic (18:3), remained relatively constant over the entire period of fiber development (Fig. 1). Linolenic was found to be the most abundant FA, accounting for about 40 to over 50% by weight of total FA. Palmitic was the second-most abundant FA, representing 25–35% by weight of total FA. Linoleic acid constituted

10–15% by weight of FA present, whereas low levels of oleic and even lower levels of stearic acid were observed in all stages of development. A slight increase in the ratio of saturated to unsaturated FA was observed in the later stages of fiber development.

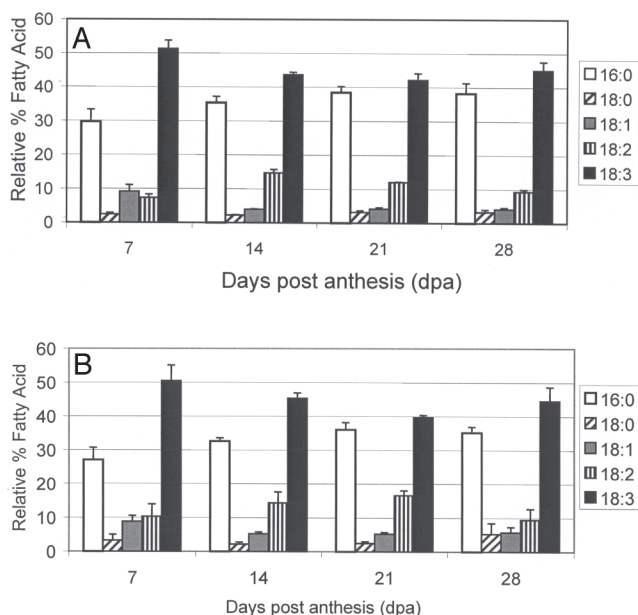
The total amounts of individual FA increased (or were highest) during the elongation stage and decreased thereafter (Fig. 2), despite a relative increase in the size of bolls and fiber content during fruit development. During the early stages of fiber development, cells are undergoing rapid elongation (2) and are engaged in lipid synthesis for membrane development; hence, an increase in fiber mass in bolls is associated with a concomitant increase in lipid content. In maturing fibers, cells are involved in secondary cell wall synthesis, which begins around 16–19 dpa and continues up to 25 dpa (2). During this stage of development, cellulose accumulates and accounts for the bulk of the mass in fiber cells. As a result, the proportion of lipids relative to the overall weight of fiber is lower in maturing fibers. The slight difference in the time course of lipid accumulation between the two cultivars may be genetic or may be environmental; however, the trends are the same, with lipid accumulating early to support cell elongation, and then tapering off as fiber cell wall thickening proceeds. Cotton embryos begin to synthesize seed oil at around 20–25 dpa. Hence, membrane lipid synthesis in fiber cells may decline prior to this period of TAG accumulation during cottonseed development.


FIG. 1. The FA composition of cotton fiber cells at different stages of development [7, 14, 21, and 28 d post-anthesis (dpa)] was determined for two different cultivars–*Gossypium hirsutum* L. cv. Stoneville SG474, upper panel, and cv. Coker 312, lower panel. Total lipids were extracted from fiber cells with addition of diheptadecanoyl (di17:0) PC as an internal standard. Following acid-catalyzed transesterification, total FAME were analyzed by GC-FID and quantified based on the amount of methyl heptadecanoate (17:0) from the internal standard. The relative proportions (wt %) of the common FA present in SG474 fibers and Coker 312 fiber cells were compared. The overall composition was similar for both cultivars throughout the entire period of fiber growth and maturation, and 18:3 and 16:0 were the most abundant FA at each stage of development. Bars represent the means and SD of three (SG474) or four (Coker 312) independent extractions.
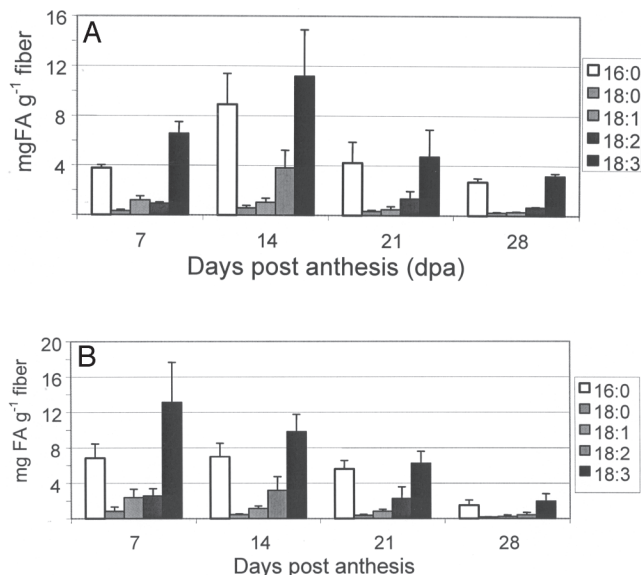

FIG. 2. Individual FA content was quantified (mg per dry weight of fiber) at the different stages of fiber development. In SG474 (A), an increase in 16:0, 18:2, and 18:3 content occurred from 7 to 14 dpa (during cell elongation), with levels declining on a cell dry weight basis thereafter (during maturation). For Coker 312 (B), the levels of individual FA were highest at 7 and 14 dpa (during cell elongation), and similar to SG474. All FA decreased on a cell dry weight basis at 21 and 28 dpa (during maturation). Bars represent the means and SD of three (SG474) or four (Coker 312) independent extractions.
FIG. 3. Comparison of polar lipid classes of elongating (8–10 dpa) and maturing (21 dpa) fiber cells (from cv. Coker 312) determined by HPLC-ELSD and expressed as weight percentage of the total polar lipid (10). Lipids were quantified based on standard curves developed for each lipid class. ASG, acylated sterol glycoside; SG, sterol glycoside; DGDG, digalactosyldiacylglycerol (may include MGDG, monogalactosyldiacylglycerol); PA, phosphatidic acid; LPC, lysophosphatidylcholine. Bars represent the means and SD of three independent extractions.

Polar lipid profiles in cotton fiber cells. The polar lipid classes of elongating and maturing cotton fiber cells were quantitatively analyzed by HPLC-ELSD analysis (Fig. 3). PC was the most abundant lipid class, constituting 47% of elongating and 36% of maturing cell total lipids by weight. PI also was a prevalent polar lipid in cotton fiber cells. Although values were variable when quantified by HPLC-ELSD, PI consistently was more abundant in maturing fibers, averaging 29% of total polar lipids, than in elongating fibers, where PI levels averaged 18% by weight of total polar lipids. PE and DGDG were present in similar proportions in elongating and maturing fibers from 11 to 14% by weight of total polar lipids. Relatively low levels of PA were observed, with only 2 and 4% (by weight) of total polar lipids in elongating and maturing fiber cells, respectively. The levels of acylated sterol glycoside (ASG) were higher in maturing fiber cells (7%) than in elongating fiber cells (2%), whereas similar levels of SG were observed at both developmental stages.

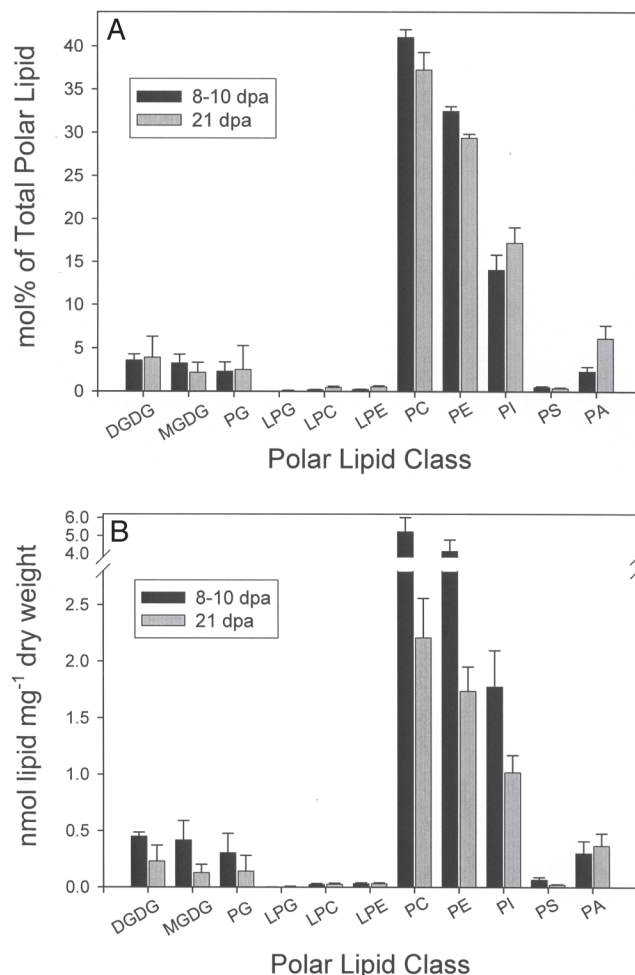
Recent advances MS methods have facilitated detailed class and molecular species analyses of plant glycerolipids (21). The classes and molecular species of polar lipids in elongating and maturing cotton fibers were determined by direct infusion ESI followed by tandem MS. This method does not incorporate HPLC or any other chromatographic separation. Instead, the species in each headgroup class are detected, as they produce a common headgroup fragment following collisionally activated dissociation. Classes are detected by sequential scans during continuous infusion, and quantification is in comparison with two internal standards of each headgroup class (21). The composition and relative proportions of the different glycerolipid classes were similar in elongating and maturing fiber cells (Fig. 4). The only major difference observed was in the relative amounts of lipid per dry weight (Fig. 4B), which was two times higher in elongating than in maturing fiber cells. This was con-


FIG. 4. Comparison of glycerolipid content of elongating (8–10 dpa) and maturing (21 dpa) fiber cells (from cv. Coker 312) determined by ESI-MS/MS. In panel A lipid quantities are presented as mol% of total glycerolipid, and in panel B lipids are quantified on nmol mg^{-1} dry weight basis. Lipid quantities were calculated based on internal standards included for each class (see methods) and the amount for each class represents the sum of individual molecular species for that class. PG; phosphatidylglycerol; LPG, lysophosphatidylglycerol; LPC, lysophosphatidylcholine; LPE, lysophosphatidylethanolamine; PA, phosphatidic acid. Bars represent the means and SD of five independent extractions.

sistent with results from total FA content measured above (Fig. 2) and is likely due to the increase in relative cellulose content at the later stages of fiber maturation. PC, PE, and PI were the predominant phospholipids in cotton fiber cells at both stages, and, consistent with data from HPLC-ELSD, the relative percentage of PI was somewhat higher in maturing than in elongating fiber cells (Fig. 4A).

PE constituted a considerably higher proportion of total polar lipid when measured by ESI-MS/MS (compared with HPLC-ELSD), about 30% of total polar lipid. It is possible that the lower levels of PE measured *via* HPLC-ELSD vs. *via* ESI-MS/MS may occur because PE (a basic lipid) is not accurately separated (chromatographed) by this system (even though the PE standard is used to determine the retention time and the PE

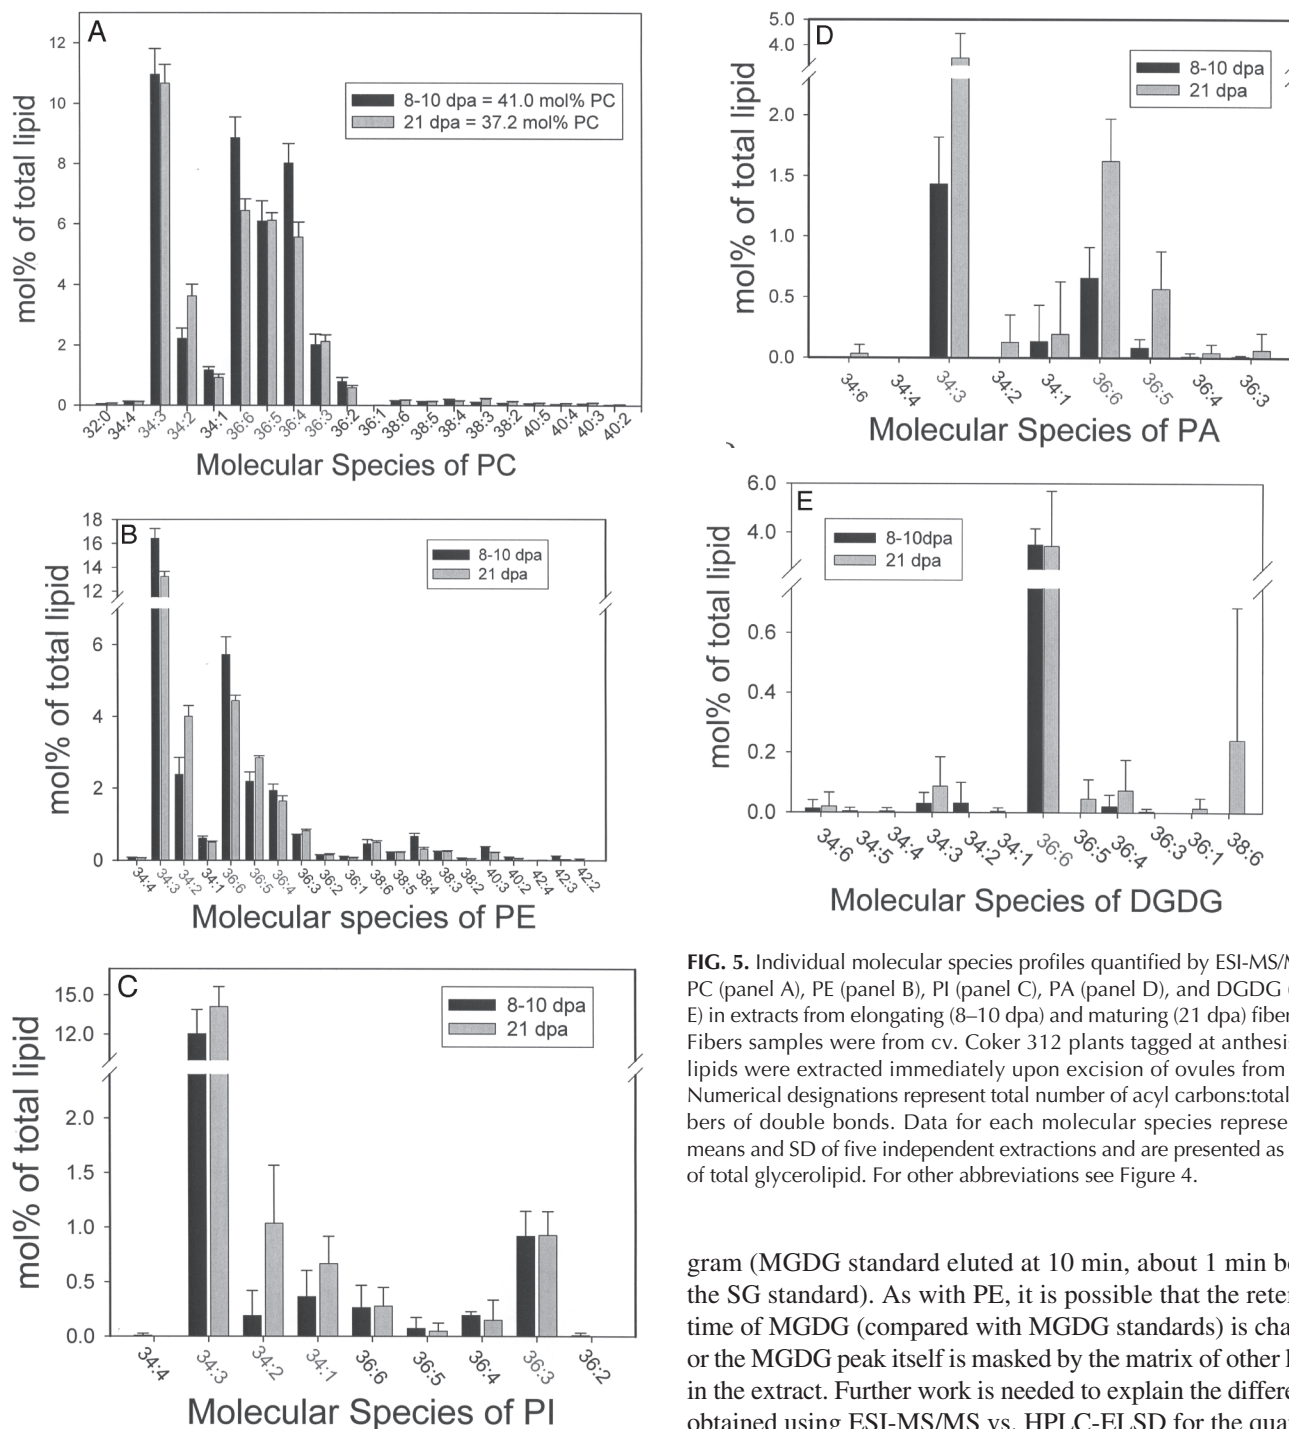
S.W. WANJIE *ET AL.*


FIG. 5. Individual molecular species profiles quantified by ESI-MS/MS for PC (panel A), PE (panel B), PI (panel C), PA (panel D), and DGDG (panel E) in extracts from elongating (8–10 dpa) and maturing (21 dpa) fiber cells. Fibers samples were from cv. Coker 312 plants tagged at anthesis, and lipids were extracted immediately upon excision of ovules from bolls. Numerical designations represent total number of acyl carbons:total numbers of double bonds. Data for each molecular species represent the means and SD of five independent extractions and are presented as mol% of total glycerolipid. For other abbreviations see Figure 4.

standard is used to construct a calibration curve of PE mass vs. PE peak area. A possible explanation is that the retention time of PE (compared with PE standard, which elutes at 23 min) may be changed by the matrix of other lipids (or ions) in the extract, perhaps causing it to bind to another lipid and elute as part of a peak of another lipid class or to bind irreversibly to the column. It should similarly be noted that although MGDG is detected at significant levels *via* ESI-MS/MS (Fig. 4), no peak of MDGD was detected in the HPLC-ELSD chromato-

gram (MGDG standard eluted at 10 min, about 1 min before the SG standard). As with PE, it is possible that the retention time of MGDG (compared with MGDG standards) is changed or the MGDG peak itself is masked by the matrix of other lipids in the extract. Further work is needed to explain the differences obtained using ESI-MS/MS vs. HPLC-ELSD for the quantitative analysis of lipid classes. Although there were differences in the analytical results obtained by these two very different methods, overall trends and amounts of polar lipids quantified were similar.

The detailed molecular species profiles of the major glycerolipid classes were determined (Fig. 5). There were some similarities and differences in the profiles of glycerolipid molecular species, which are presented as the combined acyl composition. Major molecular species of PC and PE were quite similar (Fig. 5A, B), including 34:3 (16:0, 18:3), 34:2 (16:0,

18:2 or 16:1, 18:1), 34:1 (16:0, 18:1), 36:6 (18:3, 18:3), 36:5 (18:2, 18:3), 36:4 (18:1, 18:3 or 18:2, 18:2), and 36:3 (18:0, 18:3 or 18:1, 18:2). Relatively speaking, PE had more minor long-chain species (series of PE38, PE40, and PE42) than PC. PI molecular species profiles were much less complex than profiles of PC or PE (compare Fig. 5A–C), and were almost entirely dominated by PI 34:3 in fiber cells at both stages of development. The most abundant molecular species for PC, PE, PI, and PA was 34:3 (18:3,16:0). In addition, 36:6 (18:3,18:3) also was prevalent in PC, PE and PA, but not in PI (compare Fig. 5A–D). The composition and relative proportions of molecular species found in PA were similar to those found in PC and PE, suggesting that these PA species are indeed metabolites (precursors or products) of the two major phospholipids. The precise identity of the acyl groups is tentative in some of molecular species because multiple combinations of FA at the *sn*-1 and *sn*-2 positions of the glycerolipids can make up the reported total number of acyl carbons and double bonds. However, it should be noted that the prevalence of 18:3- and 16:0-containing molecular species is entirely reasonable, given total FA composition of the lipids in these cells (Fig. 1).

Relatively low levels of PS, PG, MGDG, and DGDG were present in cotton fiber lipid extracts analyzed by ESI and tandem MS (Fig. 4). Longer-chain FA were found to comprise the major molecular species in PS, with PS 40:3 being the most prevalent, and lower levels of PS 38:3 and PS 34:3 were detected (not shown). For PG, the most abundant molecular species were PG 32:0 (16:0, 16:0) and PG 32:1 (16:0,16:1); some PG 34:3 (18:3,16:0) was detected in fiber lipid samples as well (not shown). The major molecular species present in MGDG and DGDG were 36:6 (18:3, 18:3) (Fig. 5E).

Overall, there were subtle but significant differences in molecular species profiles between elongating and maturing fiber cells. The higher relative levels of 34:2 (16:0, 18:2) PC, PE, PI, and PA in the maturing as compared with the elongating cells are consistent with the higher levels of palmitic and linoleic acids in the maturing cells (Fig. 1). Higher levels of PE 36:5 (18:2, 18:3) may also reflect higher 18:2 levels, but higher levels in maturing fiber cells of PA 34:3, 36:5, and 36:6 than in elongating cells probably just reflect the higher total levels of PA in the maturing cells, as determined by ESI-MS/MS. On the other hand, PC 36:6, PC 36:4, PE 34:3, and PE 36:6 were higher on a mol% basis in elongating cells than in maturing fiber cells. It should be emphasized that polar lipid profiles were dramatically different when fiber samples were frozen prior to analysis; considerably higher amounts of PA (up to 40 mol%) were measured by both ESI-MS/MS and HPLC-ELSD in extracts from frozen fiber samples, and several pilot experiments determined that this could be attributed to the post-harvest hydrolytic activity of PLD. This was not observed with other cotton tissues (e.g., leaves) and indicates a considerable capacity for PLD hydrolysis in fiber cells. Caution should be exercised when handling and processing cotton fibers for polar lipid profiles.

Profile of EST in developing cotton fibers. Expressed genes in cotton fibers have been identified through several EST pro-

jects, and these publicly available sequences have been assembled into contigs by the efforts of researchers at The Institute for Genomic Research (http://www.tigr.org). These include EST from two libraries for cotton fibers at 7–10 dpa and 6 dpa, which is the stage of rapid elongation. We used these data to catalog EST for the major enzymes involved in lipid metabolism in elongating cotton fiber cells (Table 1). Approximately 39,000 EST have been derived from the 7–10 dpa library, as compared with only 8,000 from the 6 dpa library. Hence, the number of EST and TC sequences discussed here are mostly representative of the 7–10 dpa library, with certain noted exceptions. In some cases, the EST were already annotated, whereas in other instances homologs were tentatively identified by WU-BLAST with cDNA and/or protein sequences from other plants as queries. Many of these plant sequences were obtained from a lipid gene database for *A. thaliana* housed at http://www.plantbiology.msu.edu/lipids/genesurvey/index.htm (17) which also provides detailed reactions and metabolic pathway(s) for plant lipid metabolism. Hence, we also compared the total number of lipid enzyme EST from all tissues in *A. thaliana* to those in cotton fiber cells. The abundances of EST were used only as an indicator of the potential capacity for fiber cells to produce the different gene products and respective lipid metabolites.

EST for enzymes and proteins of *de novo* FA biosynthesis were prevalent in elongating cotton fiber cDNA libraries, including those encoding subunits of acetyl-CoA carboxylase, ACP, β-ketoacyl-ASP synthase I (KAS I), and stearoyl-ACP desaturase. Several EST were predicted to encode for different isoforms of ACP, including a fiber-specific ACP (13). No EST were annotated as encoding KAS II and KAS III enzymes, but KAS II shares high homology with KAS I, and some of the EST predicted to encode for KAS I could in fact encode for other enzymes. These results support metabolic data that cotton fiber cells at this stage of development have a high capacity for the *de novo* biosynthesis of FA and identify candidate cotton sequences that can be targeted for future functional studies.

The FA synthesized in the plastids can either be transferred from acyl-ACP into plastidial glycerolipids, or cleaved by a thioesterase to form free acyl chains that are exported to the ER for extraplastidial glycerolipid assembly (7). Three EST for FatA, the thioesterase that acts preferentially on unsaturated FA (22), and 11 EST for Fat B, which exhibits a preference for saturated acyl-ACP (23), were identified. Eleven EST were annotated as encoding for acyl-CoA synthetase, which esterifies the free acyl chains to CoA forming acyl-CoA (7), the precursors for ER glycerolipids.

Glycerolipid synthesis initiated by the transfer of acyl chains (from acyl-ACP in plastids or acyl-CoA in the ER) to glycerol-3-phosphate (G3P) forming lysophosphatidic acid (LPA) in a reaction is catalyzed by a G3P acyltransferase (7). Several EST were annotated as acyltransferases. Only a single EST from the 6 dpa library could be annotated as encoding an acyl-ACP acyltransferase. Nine EST, representing one TC, exhibited high identity with sequences of known acyl-CoA acyltransferases. In *A. thaliana*, only two EST for each of these enzymes have been

[a]The number of tentative consensus sequences (TCs) in the 7–10 dpa library is noted and may indicate the potential number of genes for each protein. The EST data were obtained from The Institute for Genomic Research (TIGR) through the web site at http://www.tigr.org. Comparisons were made to EST involved in lipid metabolism in *Arabidopsis thaliana*, using data compiled in the *Arabidopsis* lipid gene database housed at www.plantbiology.msu.edu/lipids/genesurvey/index.htm (17). Lipid metabolic genes for which no EST have been annotated in this database are marked as N/A. ACP, acyl carrier protein; G3P, glycerol-3-phosphate; LPA, lysophosphatidic acid; ER, endoplasmic reticulum; PGP, phosphatidylglycerol phosphate; MGDG, monogalactosyldiacylglycerol; DGDG, digalactosyldiacylglycerol.

identified. Transfer of a second acyl chain to the *sn*-2 position of LPA forms PA, and several EST were identified for the plastidial and ER isoforms of LPA acyltransferase. The occurrence of these EST suggests that the synthesis of PA occurs in both the plastid and ER of fiber cells. Of interest, 66 cotton fiber EST appeared to encode acyltransferases of unidentified function.

PA serves as the precursor to most glycerolipids and is converted to DAG or cytidine diphosphate:diacylglycerol (CDP:DAG) for complex glycerolipid assembly (24). PA may be dephosphorylated by PA phosphatase, forming DAG, and a single EST predicted to encode this enzyme was present, whereas four EST (two TC) for DAG kinase (which catalyzes the reverse reaction) were identified. DAG also is used as a substrate in the synthesis of plastidial galactolipids, MGDG and DGDG. Only EST corresponding to DGDG synthase were identified. DAG may also be acylated by DAG acyltransferase to form TAG, but no EST were identified for this protein, nor were any EST identified as encoding a phospholipid diacylglycerol acytransferase, which catalyzes the transfer of an acyl group from a phospholipid to DAG forming a TAG and a lysophospholipid. These results might be expected since elongating fiber cells are not primary sites for TAG biosynthesis, but rather likely are more involved in the synthesis of membrane glycerolipids.

In the ER, DAG acts as a direct precursor for synthesis of PC

and PE in the ER *via* the action of a phosphotransferase, displacing cytidine monophosphate (CMP) from the nucleotide-activated amino alcohols, CDP-choline or CDP ethanolamine. The amino alcohols are themselves produced in a series of reactions in which they are first phosphorylated, and then reacted with CTP to produce the CDP derivatives (24). Three cotton EST were identified as candidate choline/ethanolamine kinase homologs. Four EST were annotated as encoding the cytidyltransferase enzyme, while 2 EST were predicted to encode an aminoalcohol phosphotransferase. A single aminoalcohol phosphotransferase catalyzes the final step, producing PC or PE (25).

PA may be converted to CDP:DAG by action of CDP:DAG synthase, but surprisingly no EST encoding for this enzyme were identified. CDP:DAG is the precursor for PG, PI, and PS (26). Phosphatidylglycerol phosphate (PGP) synthase uses CDP:DAG and G3P to form PGP, which is the precursor to PG, and 2 EST were predicted to encode for the plastidial isoform of PGP synthase, while a single EST in the 6 dpa library was annotated as encoding for the ER isoform. However, no EST were identified as encoding for PGP phosphatase, which produces PG from PGP. Additionally, no EST were predicted to encode for PI synthase or PS synthase, which both use CDP:DAG as a precursor.

Desaturation of glycerolipid acyl chains occurs in both the plastid and ER and is catalyzed by different proteins in these

organelles. Ten EST predicted to encode for the ER δ-12 desat-urase [fatty acid desaturase 2 (FAD2)] were identified, while only a single EST was annotated as encoding the plastidial iso-form, FAD6. Five EST were identified as an ER Δ-15 desat-urase (FAD3), while eight EST were predicted to encode the plastidial isoforms FAD7/FAD8.

The large number of EST predicted to code for enzymes in-volved in FA elongation and wax biosynthesis suggests that elongating fiber cells are actively engaged in these processes. The FA elongase system, which adds two carbons per cycle to C_{18}-acyl-CoA, consists of four components; β-ketoacyl-CoA synthase, β-ketoacyl -CoA reductase, β-hydroxylacyl-CoA de-hydratase, and enoyl-CoA reductase (23). A large number of EST (150) were identified as encoding for β-ketoacyl-CoA synthase, while15 EST were annotated as encoding for the re-ductase, but no EST were identified for the latter two compo-nents of the pathway. A surprisingly high number of EST were identified for lipid transfer protein precursors, but this is a fea-ture of many cDNA libraries. A total of 218 EST in the 7–10 dpa library and 379 EST in the 6 dpa library were annotated as encoding for this type of protein. Lipid transfer proteins are thought to have a role in cutin/wax deposition (27), and fiber-specific transcripts of this enzyme that were highly expressed during the stage of rapid elongation have been identified in cot-ton (14,16).

Sphingolipids are constituents of membranes (particularly, plasma membranes), and several EST for enzymes involved in their biosynthesis were identified in the cotton fiber databases. Four EST were annotated as encoding a serine palmitoyltrans-ferase, which catalyzes the condensation reaction between ser-ine and palmitoyl-CoA forming 3-ketosphinganine in the first step of the pathway (28). Several EST were identified for 3-ke-tosphinganine reductase, which forms sphinganine. Ceramide synthesis is thought to occur either by acylation of sphinganine with a free FFA or an acyl-Co A donor (28). Ceramide synthase catalyzes the former reaction, and a single EST was identified for this enzyme, while no EST were annotated as encoding for sphinganine acyltransferase, which catalyzes the latter reac-tion. A single EST predicted to encode a sphingolipid desat-urase was identified.

Sterols are minor components of cotton fiber (29), and sev-eral EST encoding enzymes involved in sterol biosynthesis were identified in the cotton fiber databases. These include 21 EST for HMG-CoA reductase, a major precursor in sterol biosynthesis, 14 EST for 24 sterol methytransferase, 2 EST for sterol C_{14} reductase, 2 EST for the Δ 8, Δ 7 isomerase, 5 EST for sterol 4-α methyl oxidase, 6 EST for UDP-glucose: sterol glucosyltransferase, and 8 EST annotated as a *S*-adenosyl-methionine-sterol methyltransferase.

Plant lipids undergo membrane remodeling during growth and development, as well as in response to various environ-mental conditions, and lipases are involved in these processes (30). PLD is known to hydrolyze phospholids producing PA and a headgroup, and multiple isoforms of this enzyme have been identified in plants (31). In the cotton fiber libraries, the most abundant PLD EST were those for PLDβ, for which 25 EST were identified, while only 2 EST were identified as en-coding for PLDβ and a single EST was identified for the PLD δ isoform. Eighty-four EST were grouped as homologs of lysophospholipases. Two EST were specifically annotated as encoding phospholipase A1, which cleaves phospholipids at the *sn*-1 position, while 7 EST were predicted to encode phos-pholipase A2, which cleaves phospholipids at the *sn*-2 posi-tion. Additionally, 12 EST were annotated as encoding PI-spe-cific phospholipase C, suggesting that PI-mediated signaling may be a feature of cotton fiber cell elongation. Orthologs of the recently discovered plant FA amide hydrolase (32) also were expressed in developing cotton fibers.

FA are turned over in plant cells by the peroxisomal β-oxi-dation pathway (33). Several EST for each of the enzymes in-volved in this process were present in the cotton fiber data-bases. These included 8 EST for acyl-CoA synthase, 4 EST for acyl-CoA oxidase, 7 EST for enoyl-CoA hydratase, 3 EST for 3-hydroxybutyryl-CoA dehydrogenase, and 5 EST for 3-keto-cyl-CoA thiolase. The expression of these genes in elongating cotton fiber cells suggests that FA degradation occurs even at the early stages of fiber development.

DISCUSSION

Cotton fibers are single cells that develop relatively synchro-nously, forming extremely long cells in a period of a few days; hence, they represent a good system for studying plant cell ex-pansion (6). The rapid elongation of these cells requires sub-stantial lipid synthesis to support the developing organelle and membranes, and this was supported by estimates of acyl lipid content at several stages of fiber development (Fig. 2). The presence of several EST for enzymes involved in FA biosyn-thesis indicated that this pathway is quite active at the early stage of fiber development (Table 1). A large number of EST were predicted to encode for subunits of acetyl-CoA carboxy-lase, which is considered to be the major regulatory enzyme in the pathway (34). Several EST were identified for ACP, which carry the FA through the assembly process, as well as for KAS I, which participates in fatty acyl chain elongation. Glyc-erolipid synthesis usually begins with incorporation of 16:0 and 18:1 acyl chains onto a glycerol-3-phosphate backbone. KAS II is responsible for the elongation of 16:0 to stearate (18:0), and we hypothesize that some of the EST annotated as encod-ing for KAS I may in fact be KAS II EST, owing to the high sequence homology. Several EST for stearoyl-ACP desaturase, which introduces a double bond in stearate (18:0) to form oleate (18:1), were prevalent as well. These EST profiles indi-cate that cotton fiber cells are capable of producing a substan-tial amount of 16:0 and 18:1, and these FA are then incorpo-rated into complex lipids during plastidial and extraplastidial glycerolipid synthesis and modification. It should be empha-sized that additional quantitative proteomics data (or western blotting) will be required to provide information about actual abundance of proteins in these pathways. Nonetheless, lipid

and EST profiles do confirm the metabolic capacity of cotton fiber cells for these pathways.

The molecular species composition of glycerolipids can be used to gain information as to how these lipids might be synthesized in cells. For example, glycerolipids are usually synthesized in plants from a PA precursor *via* two pathways, the prokaryotic and the eukaryotic pathway (35). In the prokaryotic pathway, 16-carbon FA are found predominantly in the *sn*-2 position. In the eukaryotic pathway, 16-carbon FA, when present, are found at the *sn*-1 position, and 18-carbon FA can be esterified to either position (36). Although acyl positions have only been tentatively assigned to the species identified by ESI-MS/MS, some conclusions can nonetheless be drawn from results such as those presented in Figure 5. DGDG (and MGDG) contained 36:6 (18:3,18:3) as the most abundant molecular species (Fig. 5E); this points to the DAG moieties of these lipids being synthesized *via* the eukaryotic pathway, since this is the only mechanism by which 18-carbon acyl chains are placed at both *sn*-1 and *sn*-2 positions. On the other hand, most of the PG is likely to be synthesized by the prokaryotic pathway, since the major molecular species of PG were 32:0 (16:0, 16:0) and 32:1 (16:0,16:1) (not shown).

In this same context, it is possible to deduce the scheme by which the major phospholipid species are synthesized in cotton fibers, and the EST occurrence supports the metabolic compartmentation scheme for PC (and PE) biosynthesis shown in Figure 6. As in most plant cell types, 16:0 and 18:1 FA are the major FA synthesized in and exported from plastids to the ER for complex lipid formation. These FA are incorporated *via* CoA esters into the *sn*-1 and -2 position of G3P by G3P acyltransferase and LPA acyltransferase, respectively, to form PA. Although not shown, 18:1 (or 18:0) could be incorporated into either acyl position of PA. PA is dephosphorylated to yield DAG, which is used for the synthesis of PC (and PE) *via* the membrane-bound aminoalcohol phosphotransferase enzyme with the appropriate CDP donor. The 18:1 acyl chains are modified by the Δ-12 (FAD2) and the Δ-15 (FAD3) desaturases to yield 18:2 and 18:3 FA.

The principal molecular species of PC (16:0, 18:3) and PE (16:0, 18:3) together were about 25 mol% of the total polar lipid fraction (Figs. 5A and 5B). These two lipids are likely to be the principal phospholipid components of both vacuole and plasma membranes of expanding cotton fiber cells, and they are most likely synthesized by cooperation between the plastidial and ER compartments *via* the scheme shown in Figure 6. Additional molecular species for these two lipid classes wherein 18-carbon FA are at both positions (36:6, 36:5, 36:4, 36:3) together were the majority of the remaining molecular species of both PC and PE, and these metabolites are likely to be synthesized by the same machinery. EST for all of these enzymatic steps were identified, so the molecular informatics and metabolite profiles are consistent for the major phospholipid biosynthetic pathways in elongating cotton fiber cells.

The major molecular species of PI was 34:3, and the acylglycerol backbone could be synthesized using the same machinery for the major PC species described above. Less clear is
FIG. 6. Summary scheme for the cellular compartmentation and proposed pathway leading to the synthesis of PC 34:3 (16:0, 18:3), a major glycerolipid molecular species in both elongating and maturing fiber cells. The diagram is based on both metabolite profiles (Figs. 1–5) and expressed sequence tag (EST) occurrences (numbers in parentheses) for enzymes in these pathways (Table 1), and is consistent with the synthetic pathways described for extraplastidial PC in other types of plant cells (35). The FA are assembled *de novo* in the plastids of fiber cells and exported to the endoplasmic reticulum (ER) for glycerolipid assembly and subsequent modification (e.g., introduction of additional double bonds). The acylglycerol base for other phospholipids, such as PE and PI, can be synthesized using the same machinery. ACCase, acetyl-CoA carboxylase; KAS, ketoacyl ACP synthase; FatA, FA thioesterase A; FatB, FA thioesterase B; G3P, glycerol-3-phosphate; G3PAT, G3P acyltransferase; LPA, lysophosphatidic acid; LPAAT, LPA acyltransferase; PAP, PA phosphatase; AAPT, aminoalcohol phosphotransferase; FAD, FA desaturase. Numerical designations for FA represent total number of acyl carbons:total numbers of double bonds.

how the headgroup of PI is incorporated into this glycerolipid class. No EST were predicted to encode for PI synthase (or PS synthase), which uses CDP:DAG as a precursor. The DAG base could be derived from the PC or PE pathway, but the headgroup metabolism is unclear since no CDP:DAG transferase EST were identified. This is somewhat surprising given the particular abundance of PI in fiber cells, and may indicate that these enzymes have rare or substantially diverged messages not yet identified in these libraries, or that PI, PS, and perhaps even PG are produced *via* alternative pathways in cotton fiber cells.

From the lipid metabolite data, it is possible to make some predictions about how lipid metabolism may be directed in fiber cells as they shift from the rapid elongation phase to the maturation phase. For example, there was a significant reduction in PE 34:3 and PE 34:6, whereas there was an increase in PE 34:2 and a slight increase in PE 34:5. A similar increase was noted in PC 34:2 with a decrease in PC 36:6. These results suggest a reduction in FAD3 activity during the maturation phase and could impart a subtle change in membrane fluidity to fiber cells.

By combining lipid metabolite data with EST profiles it may be possible to identify lipid metabolic pathways important in fiber cells that have not been appreciated previously. For example, saturated FA such as 16:0 and 18:0 are important for

membrane stability, but they also may be elongated to very long-chain FA that serve as precursors for the biosynthesis of surface components such as waxes (27,37). A major amount of 16:0 FA was detected in fibers at all stages of elongation and maturation (Fig. 1). Moreover, an abundance of EST for FA elongation and wax biosynthesis enzymes indicated that elongating fibers may be actively involved in these processes and would certainly require the necessary acyl chain precursors.

Lipid profiling and EST data suggest that sterol metabolism may be important to cotton fiber development, as has been suggested by others (11). ASG levels were higher in maturing fiber cells than in elongating fiber cells (Fig. 3), and ASG is mostly associated with plasma membranes (10,38,39). Others have implicated SG in the biosynthesis of cellulose (11). EST were identified for several sterol/SG enzymes in the elongating fibers, and these represent excellent targets to test the importance of sterol-containing lipids in the shift of fiber cells from the synthesis of primary to secondary cell walls.

Likewise, lipid profiling and EST data may suggest that PLD plays a role in cotton fiber development. PLD EST were quite prevalent in elongating fiber libraries, and the rapid, albeit artifactual, production of PA in frozen fiber cell extracts suggests that there is a substantial capacity for PLD-mediated phospholipid metabolism in fiber cells. It is possible that this signifies that PLD has an important function in the normal development of cotton fiber cells. PLD are thought to interact with cytoskeletal filaments and to influence cell expansion (40–42), and their role in membrane trafficking in mammalian systems is well documented (43). Perhaps the results gleaned from these lipidomics approaches will prompt additional molecular and biochemical experiments to characterize the impact of surface lipids, sterol metabolism, lipid hydrolases, and the like on the development of cotton fibers.

To our knowledge these studies represent the first attempt to reconcile detailed lipid metabolite profiles and EST profiles from DNA databases for this unusual and economically important cell type. It is anticipated that these results will provide the basis for continued efforts to understand the coordinated regulation of cotton fiber development at the molecular, biochemical and physiological levels, and that this approach, originally applied to *Arabidopsis* seeds (17), will encourage additional efforts to integrate metabolic and genomics information to improve our understanding of the importance of lipid metabolism to plant cell growth and development.

ABSTRACT: Fish oil-enriched diets increase n-3 FA in tissue phospholipids; however, a similar effect by plant-derived n-3 FA is poorly defined. To address this question, we determined mass changes in phospholipid FA, individual phospholipid classes, and cholesterol in the liver, heart, and brain of rats fed diets enriched in flax oil (rich in 18:3n-3), fish oil (rich in 22:6n-3 and 20:5n-3), or safflower oil (rich in 18:2n-6) for 8 wk. In the heart and liver phospholipids, 22:6n-3 levels increased only in the fish oil group, although rats fed flax oil accumulated 20:5n-3 and 22:5n-3. However, in the brain, the flax and fish oil diets increased the phospholipid 22:6n-3 mass. In all tissues, these diets decreased the 20:4n-6 mass, although the effect was more marked in the fish oil than in the flax oil group. Although these data do not provide direct evidence for 18:3n-3 elongation and desaturation by the brain, they demonstrate that 18:3n-3-enriched diets reduced tissue 20:4n-6 levels and increased cellular n-3 levels in a tissue-dependent manner. We hypothesize, based on the lack of increased 22:6n-3 but increased 18:3n-3 in the liver and heart, that the flax oil diet increased circulating 18:3n-3, thereby presenting tissue with this EFA for further elongation and desaturation.

Paper no. L9709 in *Lipids 40*, 787–798 (August 2005).

In recent years, many health benefits of n-3 FA have been demonstrated (1,2). These benefits range from improved patient responsiveness to Li$^+$ treatment (3) to improvement in cardiovascular function (4). The premise that the n-3 FA EPA (20:5-n-3) and DHA (22:6n-3) are beneficial stems from two general lines of thought. (i) First, that n-3 FA esterified in membrane phospholipids modulate the biophysical environment of the membrane in such a way as to positively alter physiological function. The membrane order regulates very important processes such as signal transduction (5–7), release of synaptic

vesicles during synaptic transmission (8,9), and heart contraction (10). (ii) Second, that n-3 FA replace n-6 FA, arachidonic acid (20:4n-6) in particular, thereby reducing the potential release of 20:4n-6 under basal conditions and during pathophysiological insult. Mechanistically, this would effectively reduce the basal levels of proinflammatory eicosanoids as well as reduce levels released upon pathophysiological insult or during inflammatory conditions (11). To elevate n-3 cellular levels, it is necessary to increase n-3 dietary intake because mammals are not able to synthesize α-linolenic acid (18:3n-3), the precursor of the n-3 family. The accretion of higher-chain n-3 in tissue phospholipids may be dependent on the particular n-3 FA that is provided in the diet, e.g., 18:3n-3 or 20:5n-3/22:6n-3.

Two metabolic pathways for 18:3n-3 have been demonstrated. The β-oxidation pathway is considered the major catabolic route, as 60–85% of 18:3n-3 goes through this pathway (12,13). However, it is important to note that similar levels of β-oxidation occur with dietary 22:6n-3 (65%) and n-6 FA (50%) (13). Thus, the current idea that dietary 18:3n-3 is β-oxidized to a much greater extent than other dietary FA should be reexamined.

The second fate is the elongation and desaturation of 18:3-n-3 to 20:5n-3, 22:5n-3 (docosapentaenoic acid), and 22:6n-3. A number of studies in mammals demonstrate the effective conversion of 18:3n-3 into 20:5n-3 and 22:5n-3, including studies in rats (14,15), hamsters (16), guinea pigs (17), piglets (18), baboons (19), and humans (20,21). More controversial is the effectiveness of the conversion and accumulation of 22:6n-3 from dietary 18:3n-3 (22). Rats fed diets enriched in 18:3n-3 have a significant accumulation of 22:6n-3 in the brain compared with controls (17,23). Other studies with similar diets did not demonstrate an accumulation of 22:6n-3 in different rat body compartments (14) or in human plasma (21). Because a number of variables can modulate the efficiency of 18:3n-3 conversion to 22:6n-3, including the amount of 18:3n-3 ingested (16), the n-3 to n-6 ratio in the diet (23), and the dietary background of the animals prior to the study (15), it is important to compare, in a single study, the effects flax oil and fish oil diets on tissue n-3 accretion.

Western diets have considerably reduced the consumption of n-3 PUFA in favor of n-6 PUFA (24,25). There have been great efforts to promote fish oil incorporation into the Western diets, since it is considered the best source of 20:5n-3 and

22:6n-3. However, because there is a geographical restriction on the availability of marine sources of n-3 FA, plant-derived n-3 sources (rich in 18:3n-3) have wider availability. Hence, it is critical to have a more complete understanding of 18:3n-3 metabolism and the effectiveness of 18:3n-3 to enhance tissue 20:5n-3 and 22:6n-3 levels as compared with the effects of fish oil on the accretion of these same FA.

To address this question, we determined the effect of flax oil (rich in 18:3n-3) and fish oil (rich in 20:5n-3 and 22:6n-3) on the liver, heart, and brain phospholipid mass and phospholipid acyl chain mass using standard lipid analytical techniques. In both groups, 20:4n-6 mass was decreased in each tissue, although the magnitude of the reduction was less in the flax group than in the fish group. These results clearly indicate that 18:3n-3 was elongated, desaturated, and accumulated and that these processes were highly tissue dependent.

MATERIALS AND METHODS

Animals. Four-month-old male, Sprague-Dawley rats, previously maintained on an n-3 FA-sufficient diet (18:3n-3, 7.0% total FA), were randomly assigned to diets containing either safflower oil (*n* = 5/group), flax oil (*n* = 5/group), or fish oil (*n* = 5/group). Rats were housed under a 12-h light–dark cycle and had free access to diets and water. Following 8 wk of feeding, the rats were euthanized with CO_2, and the brains, hearts, and livers were rapidly removed and frozen in liquid nitrogen. All procedures were approved by the University of Texas Animal Use and Care Committee.

Diets. Diet ingredients were purchased from Dyets, Inc. (Bethlehem, PA), prepared fresh each week and maintained at 4°C. Isocaloric diets were designed to meet the nutritional requirements of rats as determined by the American Institute of Nutrition (26). Diets contained 200 g/kg soy protein, 300 g/kg dextrose, 310 g/kg cornstarch, 35 g/kg cellulose, 100 g/kg lipid, 2 g/kg choline, 1.5 g/kg DL-methionine, 1.5 g/kg L-cysteine, 1.3 g/kg α-tocopherol, 1.2 g/kg γ-tocopherol, 1 g/kg TBHQ, 35 g/kg mineral mix (AIN-93M-MX), and 15 g/kg vitamin mix (AIN-93-VX). The composition of the vitamin and mineral mix has been reported in detail elsewhere (26). Rats were fed one of three semipurified diets differing only in lipid content: (i) 10% w/w safflower oil (safflower) enriched in linoleic acid, (ii) 3% safflower plus 7% flaxseed oil (flax) enriched in 18:3n-3, and (iii) 3% safflower plus 7% fish oil (fish) enriched in 20:5n-3 and 22:6n-3 (Table 1).

Lipid extraction. Tissues were pulverized under liquid nitrogen temperatures to a fine homogeneous powder, and lipids were extracted using *n*-hexane/2-propanol (3:2 vol/vol) (27,28). Tissue extracts were centrifuged at $1,000 \times g$ to pellet debris. The lipid containing the liquid phase was decanted and stored under nitrogen at −80°C until analysis.

TLC. Individual phospholipid classes and neutral lipids were separated by TLC. Whatman silica gel-60 plates (20 × 20 cm, 250 μm) were heat-activated at 110°C for 1 h, and samples were streaked onto the plates. Phospholipids were separated using chloroform/methanol/acetic acid/water (55:37.5:3:2 by

TABLE 1
FA Composition of the Experimental Diets[a]

20:5n-3	—	—	13.63
22:6n-3	—	—	11.85

[a]The three experimental groups were 10% (w/w) safflower oil, 7% flax oil plus 3% safflower oil, and 7% fish oil plus 3% safflower oil. Safflower was added to the flax and fish oil diets as a source of linoleic acid to prevent EFA deficiency. ND, not detected. Additional information regarding the composition of these diets is provided in the Materials and Methods section.

vol) (29). This method separates all the major phospholipids. Neutral lipids were separated in petroleum ether/diethyl ether/acetic acid (75:25:1.3 by vol) (30). This solvent system resolves cholesteryl esters, DAG, nonesterified FA, and TAG. Lipid fractions were identified using authentic standards (Doosan-Serday, Englewood Cliffs, NJ, and Nu-Chek-Prep, Elysian, MN).

Plasmalogen analysis. The plasmalogen mass was determined following separation of individual phospholipid classes in the heart and brain lipid extracts by HPLC (31). One-half of the choline glycerophospholipid (ChoGpl) and ethanolamine glycerophospholipid (EtnGpl) fractions were dried under nitrogen and subjected to mild acidic hydrolysis followed by separation using HPLC (32). The proportion of plasmalogen determined following this separation was used to calculate the plasmalogen mass using the EtnGpl and ChoGpl masses determined following separation by TLC, as reported above.

Phosphorus and cholesterol assay. The phospholipid mass was determined by assaying for the lipid phosphorus content of individual lipid classes separated by TLC as described above (33). The cholesterol and cholesteryl ester masses were assayed using an iron-binding assay after separation by TLC as described previously (34).

FA analysis. The ChoGpl, EtnGpl, phosphatidylinositol (PtdIns), and phosphatidylserine (PtdSer) fractions were subjected to base-catalyzed transesterification, converting the phospholipid acyl chains to FAME. To each fraction, 2 mL of 0.5 M KOH dissolved in anhydrous methanol was added (35). FAME were extracted from the methanol using 2 mL of *n*-hexane, and the *n*-hexane phase containing the FAME was removed. The lower phase was reextracted two more times with 3 mL of *n*-hexane, and these washes were combined with the original aliquot.

Individual FA were separated by GLC using an SP-2330 column (0.32 mm i.d. × 30 m length) and a Trace GLC (ThermoElectron, Austin, TX) equipped with dual autosamplers and dual FID. FA were quantified using a standard curve from commercially purchased standards (Nu-Chek-Prep) and 17:0 was used as the internal standard.

Statistics. Statistical analysis was done using Instat2 from GraphPad (San Diego, CA). Statistical significance was assessed using one-way ANOVA and the Student–Newman–Keuls post-test, with $P < 0.05$ considered to be statistically significant.

RESULTS

Effect of n-3 dietary PUFA on individual phospholipid masses. The total phospholipid mass was not altered as a function of diet in any of the three tissues analyzed; however, some individual phospholipid classes were changed (Table 2). In rats fed fish oil, the liver EtnGpl mass was decreased 23% and the sphingomyelin (CerPCho) mass was increased 1.1-fold as compared with the control (see the Materials and Methods section). In hearts, the EtnGpl mass was decreased 19% in the fish oil group, whereas in this same group the CerPCho and phosphatidic acid (PtdOH) masses were increased 1.3- and 1.6-fold, respectively, as compared with the control (safflower oil). In the flax oil group, the heart PtdSer mass was decreased 23% as compared with the control. In the brain, the Ptd$_2$Gro and PtdIns masses were decreased 33 and 10%, respectively, in the flax oil group, whereas the PtdOH and PtdIns masses were increased

1.5- and 1.1-fold, respectively, in the fish oil group. Hence, there were subtle changes in individual phospholipid masses induced by flax oil or fish oil feeding that differed depending on the tissue analyzed.

Effect of n-3 dietary PUFA on phospholipid subclasses. The brain and heart have considerable amounts of ethanolamine (PlsEtn) and choline plasmalogens (PlsCho) (36–39), and fish oil diets may increase the plasmalogen mass (40). We did not find any significant difference in brain plasmalogens between groups (Table 3); however, the heart PlsEtn mass was decreased by 25% in the fish oil group, but PlsCho was unchanged. These results indicate a moderate effect of dietary n-3 FA on modulating the heart plasmalogen mass.

Effect of n-3 dietary PUFA on cholesterol levels. Cholesterol is an important component of the membranes, and its content may be affected by changes in dietary FA (41). In the liver, the cholesterol mass was not affected in the flax oil group, whereas it was decreased by 21% in the fish oil group (Table 4). This change in cholesterol mass caused a significant 25% decrease in the cholesterol-to-phospholipid ratio. In the fish oil group, the heart cholesterol mass was decreased by 10%, but this change did not alter the cholesterol-to-phospholipid ratio. In

the flax oil group, the brain cholesterol mass was decreased by 17%; consequently, the cholesterol-to-phospholipid ratio was decreased by 17%. In the fish oil group, the brain cholesterol and the cholesterol-to-phospholipid ratio were unchanged.

Effect of n-3 dietary PUFA on the FA mass. The dietary FA content markedly affected the FA mass of EtnGpl, ChoGpl, PtdSer, and PtdIns from the brain, heart, and liver. However, dietary modulation can enhance the formation of other FA not normally found in tissues. For instance, an increase in the 22:5n-6 (docosapentaenoic acid n-6) mass is indicative of n-3 FA-deficient diets (42,43). In the safflower oil group (control), the total brain phospholipids contained a minor amount of 22:5n-6 (0.7% of total FA), similar to that reported for the n-3-sufficient control diets, where 22:5n-6 comprised 0.5 to 0.9% of the total brain phospholipid FA (42,43). Thus, using this parameter, our control group was considered adequate in n-3 FA. Similarly, the absence of 20:3n-9 (Mead acid) indicates that these diets did not produce n-6-deficient rats.

Liver FA changes. The flax oil group accumulated 22:6n-3 only in PtdSer (1.8-fold), but accumulated 20:5n-3 and 22:5n-3 at levels similar to or even higher than those in the fish oil group in the four phospholipid classes (Table 5). In addition, 18:3n-3 was accumulated in EtnGpl and ChoGpl. The arachidonic acid (20:4n-6) mass was decreased by 48% in EtnGpl, 51% in ChoGpl, and 27% in PtdSer but was unaltered in PtdIns. In the fish oil group, 22:6n-3 accumulated in the four individual phospholipid classes (Table 5). The DHA mass was increased 3.0-fold in EtnGpl, 4.4-fold in ChoGpl, 5.0-fold in PtdSer, and 2.2-fold in PtdIns. Consequently, there was a large reduction in 20:4n-6 in each of these phospholipids. In EtnGpl, the reduction was significantly larger than that observed in the flax oil group, 74% vs. 48%. The decrease was lower but still considerable in ChoGpl (56%), PtdSer (49%), and PtdIns (32%). In EtnGpl, the linoleic acid (18:2n-6) mass was decreased by 50%, which is important because it is the precursor for 20:4n-6. In summary, the flax oil diet increased the 18:3n-3,

[a]Values are expressed as mass (nmol/g ww) and represent mean ± SD, $n = 4–5$, for each experimental oil. The asterisk (*) indicates a significant effect of the experimental oils (flax and fish) as compared with the control ($P < 0.05$), and the double asterisk (**) indicates a significant effect of the fish oil vs. flax oil. For abbreviations see Tables 1 and 2.

20:5n-3, and 22:5n-3 masses, whereas the fish oil diet increased the 20:5n-3, 22:5n-3, and 22:6n-3 masses; both lowered 20:4-n-6, although the effect was more marked in the fish oil group than in the flax oil group.

Although large changes were not found in saturated FA in ChoGpl, PtdSer, and PtdIns, the total saturated mass was decreased by 20% in EtnGpl in both experimental diets. In the fish oil group, the total MUFA mass decreased by 54% in Etn-Gpl, whereas in the flax oil group, it was increased 1.9-fold in PtdIns. Although the total PUFA mass (i.e., n-3 plus n-6 FA mass) was not altered by the diet, there were robust changes in the n-3 to n-6 ratio in all the individual phospholipid classes. The increase was higher in the fish oil than in the flax oil group, particularly in EtnGpl (12-fold vs. 4.3-fold), ChoGpl (12-fold vs. 5-fold), and PtdSer (12.6-fold vs. 6.6-fold) and to a lesser degree in PtdIns (4.6-fold vs. 2.2-fold).

Heart FA changes. The pattern of changes in the FA mass of heart tissue was similar to those observed in the liver tissue (Table 6). In the flax oil group, the 22:6n-3 mass was not increased in any of the phospholipid classes analyzed. Nonetheless, the 20:4n-6 mass was decreased by 33% in ChoGpl and 55% in PtdSer in the flax oil group. Interestingly, this group had increased the 22:5n-3 and 20:5n-3 masses above those observed in the fish oil group. Similar to the liver, 18:3n-3 was accumulated in EtnGpl and ChoGpl in the flax oil group. In the fish oil group, the 22:6n-3 mass was increased in all the phospholipid classes, 2.4-fold in EtnGpl, 5.4-fold in ChoGpl, 2.1-fold in PtdSer, and 3.7-fold in PtdIns. Consistent with this increase in the 22:6n-3 mass, the 20:4n-6 mass was dramatically decreased by 73% in EtnGpl, 31% in ChoGpl, and 46% in PtdSer. In addition, the 18:2n-6 mass was decreased by 71% in EtnGpl and 44% in ChoGpl. Therefore, in the heart tissue, the flax oil diet increased the 18:3n-3, 20:5n-3, and 22:5n-3 masses, whereas the fish oil diet increased the 20:5n-3, 22:5n-3, and 22:6n-3 masses. Thus, both experimental diets provoked an increase in the total n-3 FA mass. Conversely, the fish oil diet, and to a lesser extent the flax oil diet, reduced the total n-6 FA mass.

There were no significant changes in the saturated and monounsaturated FA masses in any of the individual phospholipid classes as a function of diet, except in the fish oil group, where the EtnGpl 18:1n-9 (oleic acid) mass was reduced by 45%. The total PUFA mass was not altered by the experimental diets, although very important changes occurred in the n-3 to n-6 ratio. Similar to the liver, these changes were more profound in the fish oil than in the flax oil group. The flax oil diet increased the n-3 to n-6 ratio in the four phospholipid classes between 2- and 3-fold, whereas it was increased 5- to 10-fold in the fish oil group.

Brain FA changes. Both experimental diets increased the mass of n-3 FA (Table 7), with a marked increase in 22:6n-3. In the flax oil group, the 22:6n-3 mass in EtnGpl and ChoGpl was increased 1.2-fold, and 22:5n-3 was accumulated in Etn-Gpl, ChoGpl, and PtdSer. In the same group, the 20:4n-6 mass was reduced by 12% in ChoGpl but was not affected in the rest of the individual phospholipid classes analyzed. In the fish oil group, the 22:6n-3 mass was increased 1.4-fold in EtnGpl and

ChoGpl, 1.3-fold in PtdSer, and 1.5-fold in PtdIns. There was an accumulation of 22:5n-3 similar to that observed in the flax oil group. The 20:4n-6 mass was reduced by 25% in EtnGpl and 17% in ChoGpl. Interestingly, the 20:4n-6 mass in PtdIns was increased 1.2-fold in the fish oil group. Thus, the flax oil and fish oil diets increased the 22:5n-5 and 22:6n-3 masses, increasing the total n-3 FA in brain tissue. The total mass of n-6 FA was reduced in both experimental groups, but to a greater extent in the fish oil group than in the flax oil group.

No major changes occurred in the total saturated and unsaturated FA masses in any of the four phospholipid classes analyzed. The total PUFA mass was not altered, although the n-3-to-n-6 ratio was increased 1.5- to 2.0-fold by either diet in EtnGpl, ChoGpl, and PtdSer.

DISCUSSION

At present, at least four possible mechanisms for the positive effects of n-3 FA on health have been proposed, including: (i) alteration of the membrane order; (ii) substitution of n-3 FA for n-6 FA and, consequently, a decrease in the production of proinflammatory derivatives; (iii) alteration of the gene expression; and (iv) direct generation of second messengers (44–47). None of these provides a mechanism of action for a particular FA that would exclude the rest. Hence, the accumulation of 18:3n-3 or any of its conversion products, 20:5n-3, 22:5n-3, and 22:6n-3, might have potentially beneficial effects on health.

In human trials, plant-derived n-3 FA have demonstrated beneficial effects on health. Diets enriched in 18:3n-3 reduce cardiovascular risk factors (48), decrease the estimated risk of ischemic heart disease (49), and lower plasma TAG concentrations (50). However, these diets do not increase 22:6n-3 content in the plasma (21,51), membrane erythrocytes (21), and neutrophils (20). This lack of 22:6n-3 accumulation and the high estimated percentage lost in β-oxidation (12,52) are the main arguments used to challenge the health benefits of 18:3n-3-enriched diets. However, it is important to note that dietary FA, including 22:6n-3, are oxidized to a similar extent as 18:3n-3 (13).

In this study, we showed that increased dietary 18:3n-3 intake leads to a significant accumulation of the 18:3n-3, 20:5n-3, and 22:5n-3 masses in heart and liver phospholipids, but 22:6n-3 was not increased. Depending on the tissue and phospholipid class, the accumulation of 18:3n-3, 20:5n-3, and 22:5n-3 was higher in the flax group than in rats fed fish oil. These results are in agreement with other studies in different mammals fed 18:3n-3-enriched diets in which 18:3n-3 is efficiently converted to 22:5n-3, but none of them show an accumulation of 22:6n-3 (14–18). In our study, 22:6n-3 was accumulated in the liver and heart only in the fish oil diet group, where the phospholipid 22:6n-3 mass was dramatically increased (Tables 5, 6). Because 18:3n-3 is not converted to 22:6n-3 in the plasma, but rather is found as 18:3n-3, 20:5n-3, and 22:5n-3 (15, 16,21,48,51), our findings suggest that the FA compositions of the liver and heart more closely reflect the FA composition of the plasma compartment.

TABLE 8
Changes in Brain DHA Content in Studies Using ALA- or DHA-Enriched Diets

Study	Species	Sex	Age diet initiated	Duration	Diet	Brain
Arbuckle and Innis, 1992 (72)	Yorkshire piglets	Male	At parturition[a]	15 d	Low ALA diet: 0.7% ALA[b]; high ALA diet: 3.9% ALA; low ALA + DHA diet: 0.6% ALA + 0.3% DHA	The 22:6n-3 in synaptic plasma membrane EtnGpl increased significantly only in the low ALA + DHA diet
Abedin et al., 1999 (17)	Pigmented guinea pigs	Female	3 wk old	12 wk	ALA diet: 7.1%; ALA DHA diet: 1.0% ALA + 1.8% DHA	ALA diet: 22:6n-3 EtnGpl 11.5% total FA (1.3-fold increase vs. control); DHA diet: 22:6n-3 EtnGpl 15.0% total FA (1.7-fold increase vs. control)
Valenzuela et al., 2004 (73)	Wistar rats	Female	Since conception; mothers received experimental diets 40 d before mating	21 d	DHA diet: diet supplemented with 6 mg/kg of DHA-EE; ALA diet: diet supplemented with 60 mg/kg ALA-EE	DHA and ALA diets significantly increased the frontal cortex, cerebellum, and hippocampus DHA mass to similar levels
Lefkowitz et al., 2005 (74)	Long-Evans rats	Both	8 d old[a]	28 d	ALA diet: 1% ALA; DHA diet: 1.1% ALA + 2% DHA	ALA diet: total DHA 5.6 mg/whole brain; DHA diet: total DHA 7.0 mg/whole brain

[a]At this point the pups were raised artificially.
[b]Expressed as percent of total FA. The abbreviations are as follows: ALA, α-linolenic acid (18:3n-3); ALA-EE, AAA ethyl ester; DHA, 22:6n-3; DHA-EE, DHA ethyl ester.

This is important because the elongation and desaturation of 18:2n-6 and 18:3n-3 are thought to occur in the liver, with subsequent distribution of the conversion products to other tissues through the plasma. Our results demonstrated a significant increase in the 22:6n-3 mass in the brains of rats fed flax oil as well as those fed fish oil. Others have shown that rats fed 18:3-n-3 have an increased 22:6n-3 mass in brain EtnGpl (17,23) and in synaptic plasma membrane phospholipids (14). The results obtained from other studies on the effect of 18:3n-3- and 22:6n-3-enriched diets on brain 22:6n-3 accumulation are summarized in Table 8. Our study is important because, unlike these other studies, it was done in adult animals following myelination and because it clearly demonstrates an accretion of 22:6n-3 in the brains of rats fed a diet enriched in 18:3n-3. The intriguing question is the origin of this 22:6n-3 in the rats fed a diet enriched in 18:3n-3—that is, whether it was imported from the blood as preformed 22:6n-3 or synthesized in the brain from plasma-derived 18:3n-3. Although we did not analyze the plasma FA mass, a number of studies demonstrate minimal elongation and desaturation of 18:3n-3 in the plasma, with conversion limited to 20:5n-3 and 22:5n-3 (15,16,21,48,51). Therefore, it is reasonable to conclude that animals fed flax oil would have increased 18:3n-3, 20:5n-3, and 22:5n-3 levels, but not 22:6n-3 levels, in their plasma. Thus, it is unlikely that an increase in the plasma 22:6n-3 mass is responsible for the increased 22:6n-3 in the brain; rather, it suggests that 18:3n-3, 20:5n-3, and 22:5n-3 are taken up by the brain and converted to 22:6n-3.

This is not without precedence, as during postnatal development the rat brain takes up, elongates, and desaturates 18:3n-3 (53,54). The conversion of 18:3n-3 into 20:5n-3, 22:5n-3, and

22:6n-3 is possible because Δ5- and Δ6-desaturase are present in the brain (55,56). In fact, the Δ6-desaturase mRNA content is several times greater in the brain than in other tissues (55,56). Increasing evidence supports the hypothesis that 22:6n-3 can be constitutively synthesized in the brain from its precursors (57). Cultured astrocytes can synthesize 22:6n-3 from 18:3n-3, and this may be a major source of 22:6n-3 in the brain (58). Recently, strong evidence was presented indicating that neurons themselves can elongate 18:3n-3 to 22:6n-3 (Spector, A., personal communication), suggesting a robust ability of the brain to elongate 18:3n-3 to maintain the brain 22:6n-3 mass.

Thus, we hypothesize, based on the lack of increased 22:6n-3 but increased 18:3n-3 in the liver and heart, that the flax oil diet increased plasma 18:3n-3, thereby presenting tissue with this EFA for further elongation and desaturation. The ability to elongate and desaturate 18:3n-3 to 22:6n-3 appears to be highly tissue dependent, suggesting that the brain is uniquely positioned to carry out this process.

In the present study, we showed that the flax oil diet had a lesser effect than the fish oil diet on decreasing EtnGpl 20:4n-6 levels. It is well established that an increase in n-3 dietary PUFA leads to a decrease in n-6 PUFA tissue content, because these two families of EFA compete for the same set of enzymes (59). Decreased n-6 levels are considered beneficial because 20:4n-6 and its cyclooxygenase metabolites are related to the onset of different diseases, such as atherosclerosis (60) and inflammation (61–63), and the promotion of tumor proliferation (64). Nevertheless, all the beneficial effects associated with 22:6n-3- and 20:5n-3-enriched diets have overshadowed the importance of 20:4n-6 in general physiological functioning. A severe decrease in 20:4n-6, such as that observed with a high 22:6n-3 consumption, may compromise the

biosynthesis of prostaglandins, thereby affecting many normal metabolic processes.

Although the total phospholipid mass was not affected by these diets, some of the individual phospholipid class masses were changed. The most remarkable change was the 20% decrease in the EtnGpl mass in heart and liver tissues in rats fed fish oil, including a 25% reduction in the heart PlsEtn (Table 3). Changes in the mass of these phospholipids were not observed in the brain; however, in the liver the EtnGpl mass was significantly reduced, by 23%, in the fish oil group. This result differs from that of a previous study showing an accumulation of EtnGpl in the brain tissue of animals fed fish oil (40). Other studies have demonstrated an effect of saturated vs. unsaturated FA on the phospholipid composition, although there is no consensus regarding these effects on the phospholipid mass (65,66). Rats fed a diet enriched in 20:5n-3 did not have altered EtnGpl and ChoGpl masses in the erythrocytes (67). On the other hand, a soybean oil-enriched diet increased the ChoGpl and decreased the EtnGpl content in macrophages (68). In addition, the liver and heart CerPCho masses were increased in the fish oil group as compared with the other two groups. The increase in the PtdOH mass in the heart and brain suggest a potential reduction in PtdOH utilization for phospholipid biosynthesis, although an alternative hypothesis would be increased formation from a catabolic route. Thus, we demonstrate a profound effect of fish oil-based diets on the liver and heart EtnGpl mass, suggesting that diets enriched in this FA are capable of modulating phospholipid synthesis and degradation to a greater degree than those based on flax oil.

Because the cholesterol-to-phospholipid ratio and the phospholipid acyl chain composition are important factors in determining the biophysical properties of the membrane (41,69–71), it was also important to determine whether changes in n-3 intake would affect the cholesterol content in brain, liver, and heart tissues. In fish oil-fed rats, there was a slight decrease in the cholesterol mass in heart and liver tissues, but the brain was unaffected. In the flax oil-fed rats, the brain cholesterol mass was decreased by 17% as compared with the control, but the liver and heart cholesterol masses were unaffected. These changes resulted in a 17% decrease in the brain cholesterol-to-phospholipid ratio in the flax oil group and a 25% reduction in this ratio in the heart from the fish oil-fed group. These changes, in addition to changes in the phospholipid acyl chain composition, may result in altered brain and heart membrane biophysical parameters that may alter the physiological functioning of these tissues.

In summary, we demonstrated that 18:3n-3-enriched diets significantly increased the n-3 FA mass and decreased the n-6 FA levels, especially 20:4n-6, in the brain, heart, and liver. However, this decrease was of a lesser magnitude in the flax oil group than in the fish oil group. The apparent elongation and desaturation of 18:3n-3 to 22:6n-3 in the brain compared with the limited conversion in the heart and liver may reflect a distinct need by the brain for 22:6n-3. Although these data do not provide direct evidence for 18:3n-3 elongation by the brain, they do demonstrate that the 18:3n-3-enriched diet reduced tissue levels of 20:4n-6 and increased tissue levels of 22:6n-3 in a highly tissue-dependent manner. The accumulation of n-3 PUFA, together with the decrease in n-6 PUFA, might account for the beneficial health effects associated with 18:3n-3-enriched diets.

ABSTRACT: The aging brain undergoes modifications in the lipid composition of cell membranes and especially in plasmalogens. These phospholipids represent between one-half and two-thirds of the ethanolamine phospholipids in the brain. They are known to facilitate membrane fusion and act as endogenous antioxidants. During normal aging and in some pathological conditions, plasmalogen and DHA levels fall. In this context, we aimed to evaluate the influence of n-3 FA intake on plasmalogens in the brain during aging. Littermates from two generations of n-3-deficient rats were fed an n-3-deficient diet or an equilibrated diet containing either α-linolenic acid alone (α-LNA) or with two doses of DHA (0.3 or 0.6% w/w). After weaning, 9 mon of diet, or 21 mon of diet, plasmalogen levels were assessed, and the *sn*-2 substitutions of plasmenylethanolamines were analyzed in the cortex, striatum, and hippocampus. Our results showed that plasmalogen contents were not influenced by the diet. Plasmalogen levels were significantly decreased in aged rats compared with adults, whereas DHA levels increased in the hippocampus and remained stable in the cortex and striatum. DHA levels were significantly and similarly increased in total phospholipids and especially in plasmenylethanolamines after 9 mon of diet containing α-LNA alone or combined with DHA. This study showed that each structure sustained specific age-induced modifications. Dietary n-3 FA may not oppose the physiological decrease in brain plasmalogen levels during aging. Moreover, α-LNA appears to be equally as potent as preformed DHA at replacing DHA in the brain of our rat model.

Paper no. L9756 in *Lipids* **40**, 799–806 (August 2005).

The aging brain is characterized by morphological and neurochemical changes involving numerous biochemical alterations of the neural components, such as modifications in the lipid composition of cell membranes (1). The hippocampus, which is a structure of the limbic system involved in memory storage and retrieval (2), is particularly vulnerable to alterations due to aging. Biomedical research has played an important role in finding ways at least to slow the process of aging. Genetic, environmental, and dietary factors affecting the process of aging have been identified and widely studied. However, few works have considered the fate of plasmalogens, phospholipids distinguished by their vinyl-ether bond at the *sn*-1 position of the glycerol backbone. They are ubiquitous and are found in considerable amounts as a constituent of mammalian cell membranes (3) and represent the major subclass of ethanolamine glycerophospholipids in the brain (between one-half and two-thirds of the ethanolamine phospholipids) (4). Their high content suggests that they play an important role in the structure and function of biological membranes. Plasmenylethanolamines (PlsEtn) are concentrated in several subcellular fractions, which undergo rapid membrane fusion and may thus facilitate synaptic transmission (5). Plasmalogens are also known to be reservoirs of PUFA, as they predominantly contain arachidonic acid or DHA at their *sn*-2 position (6). The involvement of oxidative stress during aging has been postulated by many investigators (7). In this context, plasmalogens are more susceptible to oxidative reactions, as compared with their FA ester analogs, because of the reactivity of their vinyl-ether bond (8). Plasmalogens may act as endogenous antioxidants (9), protecting PUFA at the *sn*-2 position from oxidation. A decline of plasmalogen concentrations has been observed in the brain during normal aging (10) and in some pathological conditions such as Alzheimer's disease (AD) (11). Moreover, patients with AD have extremely low levels of DHA in their brains (12). One of the factors that makes studies in aging difficult is the tight, almost inseparable connection between aging and age-related disease. In this context, n-3-deficient animals constitute an interesting model. Indeed, in a dietary α-linolenic acid(α-LNA)-deficiency model, cognitive processes, learning, and memory were altered in the same way as during aging (13). An n-3-deficiency in the brain is a means to mimic what happens during physiological aging without the impact of age-related diseases. We specifically investigated the effect of DHA because the brain contains high levels of this FA, which is essential in nervous system function (14). Moreover, supplementation with DHA has been shown to correct the modification in PUFA composition with increasing age (15).

In this work, we studied whether dietary α-LNA alone or combined with DHA may prevent biochemical alterations due to aging. We focused on PlsEtn in the brain of rats from two generations of n-3-deficient animals.

MATERIALS AND METHODS

Animals and diets. Animals were housed in animal quarters under controlled temperature (21°C ± 1°C) and light conditions (12-h light/12-h dark cycle). Two generations of Wistar rats (Janvier, Le Genest-St-Isle, France) were fed an α-LNA-deficient diet (diet Def). At weaning, male littermates (average weight, 90 g) were randomly allocated to four experimental

---

groups, which received one of the following diets: diet Def, diet D0 containing 2.5% of α-LNA (w/w) as the only source of n-3 FA, diet D3 containing 1.2% of α-LNA acid and 0.3% of DHA (w/w), or diet D6 containing 1.1% of α-LNA and 0.6% of DHA. The detailed composition of the diets and the dietary lipids is presented in Tables 1 and 2 respectively. Diets were prepared as pellets by UPAE (INRA, Jouy en Josas, France) and were given *ad libitum.* The protocol was carried out according to the current French regulation regarding animal experiments (authorization A 21200 for the animal housing and personal authorization 21 CAE 056 for experimentation on animals).

Tissue collection and lipid analysis. After weaning, 9 mon of diet, or 21 mon of diet, three animals per group were sacrificed by decapitation. Brains were rapidly dissected to remove the frontal cortex, the striatum, and the hippocampus. Each structure was weighed and kept at −80°C in chloroform/methanol (2:1 vol/vol) until the analysis.

Total lipids were extracted according to the procedure of Folch *et al.* (16). Total phospholipids were separated from neutral lipids according to Juanéda and Rocquelin (17) and were transesterified with boron trifluoride (BF_3) in methanol (7 g/L) following the method of Morrison and Smith (18). This reaction yielded mixtures of FAME and plasmalogen-derived dimethylacetals (DMA). They were analyzed on a Hewlett-Packard (Palo Alto, CA) 5890 series II gas chromatograph equipped with a split/splitless injector, an FID, and a BPX 70-silica capillary column (120 m × 0.25 mm i.d.; film thickness 0.25 µm; SGE, Melbourne, Australia). The injector and the detector were maintained at 250 and 280°C, respectively. Hydrogen was used as the carrier gas (inlet pressure 300 kPa). The oven temperature was fixed at 60°C for 1 min, increased to 170°C at a rate of 20°C/min, held at this temperature for 60 min, then increased to 210°C at a rate of 5°C/min and kept at this temperature until the end of the analysis. DMA were identified by comparison of their retention times with those of synthetic standards. They were quantified using nonadecanoic acid methyl ester as internal standard and the Diamir software (JMBS Inc., Portage, MI).

Plasmalogen analysis. Total phospholipids were fractionated by TLC on silica gel plates. Phospholipid standards were

also spotted on a TLC plate to determine migration characteristics of the researched compounds. The plate was developed in a mixture of chloroform/methanol/water (65:25:4, by vol). The band corresponding to phosphoethanolamines ($R_f = 0.45$) was scraped off and extracted two times with a mixture of chloroform and methanol (2:1 vol/vol). Dried phospholipids were exposed to HCl fumes for 5 min to hydrolyze the vinyl-ether bonds of plasmalogens. Hydrolysis products were resuspended in a small volume of chloroform/methanol and spotted on another TLC plate developed with the same solvent system. The standard of lysophosphatidylethanolamine ($R_f = 0.27$) was visualized by placing the plate in iodine vapor. The corresponding band was scraped off, and the phospholipids were transesterified with sodium methanolate. The *sn*-2 position of PlsEtn was analyzed in the same way as total phospholipids.

Separation of phospholipid classes. Phospholipid classes were separated by HPLC (19) and quantified using cholesterol as the external standard. The HPLC instrument was a Varian model 9010 liquid chromatograph using a ternary solvent mixture equipped with a 100-µL Valco compressed-air injector fitted with a loop. The detector was a Cunow light-scattering detector Model 10, connected to filtered compressed air. The column was a Lichrosorb Si60 silica, 5 µm, 250 × 7.5 mm i.d. (Merck, Darmstadt, Germany). The nebulized air pressure was set at 2.1 psi and the additional air at 0.5 psi. The solvents used for the mobile phase gradient were hexane (A), 2-propanol/chloroform (4:1) (B), and 2-propanol/water (1:1) (C). The mobile phase was changed from 42% A/52% B/6% C to 41% A/52% B/7% C in 5 min and then to 32% A/52% B/16% C in 20 min. The heated pipe temperature was 40°C. The flow rate was 2.5 mL/min. Chloroform/methanol (2:1 vol/vol) was used as the injector solvent.

Statistical analysis. Results are presented as mean values with their SE. The data were submitted to a one-way ANOVA with diet or age as factors. Means were compared using Dunnett's test at 9 and 21 mon, independently, to determine the effect of diet (diet Def was chosen as the control group). The effect of age was analyzed by a Kruskal–Wallis test comparing values at 9 and 21 mon independently of the diet. The criterion for statistical significance was $P < 0.05$. All the calculations were performed with NCSS 6.01 software (Alsyd, Meylan, France).

RESULTS AND DISCUSSION

In this report, we present the combined effects of aging and n-3 dietary FA intake on phospholipids and specifically on plasmalogens from the hippocampus, striatum, and cortex of n-3-deficient rats.

The relative content of the major phospholipid classes in the cortex (Fig. 1), the hippocampus, and the striatum (data not shown) was assessed at weaning and after 9 or 21 mon of diet. This parameter was not significantly influenced by the nature and the level of n-3 dietary FA, either after 9 or after 21 mon of diet. However, we can underline the same significant age-induced changes in the three structures studied. After 21 mon, choline glycerophospholipids (ChoGpl) significantly decreased whatever the diet (by 23, 24, 31, and 12% between 9 and 21 mon in the cortex, for diets Def, D0, D3, and D6, respectively). This decrease was balanced by a strong significant increase of phosphatidylinositol (PtdIns) and phosphatidylserine (PtdSer) (a threefold increase in the cortex and hippocampus whatever the diet, a lesser increase in the striatum) and a less important increase of ethanolamine glycerophospholipids (EtnGpl) (by 18% in the striatum and cortex and by 25% in the hippocampus). In previous studies, a decrease in the content in major phospholipid classes, i.e., EtnGpl and ChoGpl, was already observed in the hippocampus of 12-mon-old rats (20) and in the cortex of 24-mon-old rats (21) fed an α-LNA-deficient diet. At the same time, the content of minor phospholipid classes, i.e., PtdIns and PtdSer, was markedly increased. From our results, we can say that n-3 FA intake (α-LNA or DHA) may not prevent the effect of physiologic aging in our experimental model. It has been well established that PtdIns and PtdSer are involved in signal transduction pathways (22). On this basis, one can speculate that the aging brain tries to regulate the programmed cognitive decline by increasing PtdIns and PtdSer levels.

The impact of dietary n-3 FA intake on the FA composition of total phospholipids from the hippocampus (Table 3), cortex (Table 4), and striatum (Table 5) was investigated. At weaning, we observed a classical balance of the n-3 deficiency by high levels of 22:5n-6 and, to a lesser extent, of 22:4n-6 (23). We can notice that the n-3 deficiency affected the acyl composition of phospholipids differently according to the brain regions. The percentage of total PUFA was higher in the frontal cortex than in the hippocampus or striatum (29.0 vs. 19.6 and 26.6%, respectively, see Tables 3–5). Our results are in concordance with previous studies showing a specific composition of each structure of the brain (24). After 9 mon of diet, numerous and similar changes were observed for diets D0, D3, and D6 in the three structures. The 22:5n-6 levels were significantly decreased and the 22:6n-3 levels significantly increased compared with diet Def. The same recovery of DHA in brain phospholipids was observed for diets D0, D3, or D6. This was due to preformed or *in vivo* biosynthesized DHA. It has previously been shown that DHA-deficient animals recovered from losses of 22:6n-3 in the brain when switched to an n-3 FA-adequate diet (25). The recovery of DHA in brain phospholipids was quicker in the cortex and in the striatum than in the hippocampus, whose DHA levels increased again from 9 to 21 mon. Our results clearly demonstrate that α-LNA is equally as potent at replacing DHA and reducing 22:5n-6 levels as is preformed DHA in our n-3-deficient rat model. In addition, such results are consistent with the work of Spector (26). The brain seems to have the capacity to elongate and desaturate α-LNA. Indeed, the cerebral endothelium synthesizes DHA from dietary metabolic precursors, such as α-LNA, *via* Δ6-desaturation and retroconversion
FIG. 1. Percentage of major phospholipid classes of rat cortex at weaning and after having been fed diet Def, D0, D3, or D6 for 9 or 21 mon. Values are mean ± SD, $n = 3$. Values with an asterisk (*) are significantly different from 9 mon at the $P < 0.05$ level as determined by ANOVA followed by a Kruskal–Wallis test. [a]Values are mean ± SD, n = 3. Values with an asterisk (*) are significantly different from diet Def (control group) at the $P < 0.05$ level as determined by ANOVA analysis followed by Dunnett's test.
[b]For composition of the Def, D0, D3, and D6 diets, see Tables 1 and 2. For other abbreviations, see Table 3.

steps, whereas astrocytes are able to synthesize DHA either from 18-, 20-, and 22-carbon n-3 precursors (*via* desaturation and elongation steps) or from 24-carbon precursors (27). In contrast, neurons may be unable to carry out FA desaturation and thus may be dependent on preformed long-chain PUFA released from endothelial cells or astrocytes. In addition, almost all 22:6n-3 is recycled from phospholipid breakdown (28,29), and this recycling ensures a well-regulated level in brain membranes (30).

The impact of aging and dietary n-3 FA intake on plasmalogen levels was assessed by the quantification of DMA (Table 6). The alkenyl chains of plasmalogens are mainly saturated. The most abundant DMA were hexadecanal dimethylacetal and octadecanal dimethylacetal. Minor amounts of monounsaturated species are present. At weaning, plasmalogen levels represented 25% of total phospholipids in the hippocampus, 21% in the striatum, and 17% in the cortex. The diet had no effect on DMA levels in the three structures whatever the age. Our results can be related to previous reports. Indeed, it has been shown that dietary supplementation with DHA-ethyl ester to Zellweger patients whose tissues and cells are strongly deficient in DHA and plasmalogens (31) increased plasmalogen concentrations in erythrocytes after DHA concentrations were normalized (32). In our study, the plasmalogen contents were not different between the four experimental groups, whereas DHA levels were quite different. First, we can suppose that DHA is not the only parameter to influence plasmalogen levels. Second, Zellweger patients received 0.1 g DHA/kg of body mass/d (pharmacological approach), whereas rats in the present study were fed 0.007 or 0.014 g DHA/kg of body mass/d (nutritional approach). Animals were not in a pathological situation, which may explain why the plasmalogen content was not influenced by the DHA level. Between 9 and 21 mon of diet, the plasmalogen levels fell significantly in the hippocampus and cortex. This decrease supports the free radical theory of aging and the potential physiological antioxidant function of plasmalogens. A decline of plasmalogen levels in neuronal tissue has already been observed in normal aging in human beings (10) and in old cattle (33). Moreover, the loss of myelin, a membrane very rich in plasmalogens, is a normal phenomenon in aging brains (34), which may explain the decrease in plasmalogen content in aged rats. Whereas plasmalogen levels decreased after 21 mon of diet, DHA levels increased in the hippocampus and remained stable in the cortex and striatum. Other studies showed a decrease in DHA levels during aging (35). Such a difference may be explained by the experimental model of n-3-deficient animals. We may assume that the intake of α-LNA alone or combined with DHA at nutritional levels may not be sufficient in aged animals to oppose the physiological decrease in plasmalogen levels.

Finally, the impact of dietary FA intake on the *sn*-2 substitution of PlsEtn in the hippocampus (Table 7), cortex (Table 8), and striatum (Table 9) was assessed. PlsEtn were specifically considered because of their high content in the brain. The FA composition of PlsEtn was different in the three brain regions of weaned rats. The *sn*-2 substitutions were mainly saturated FA in the hippocampus and the striatum (45.9% and 43.8%, respectively) whereas monounsaturated FA (40%) and PUFA

TABLE 6
Dimethylacetal Levels[a] (μg/g wet brain) in the Rat Hippocampus, Cortex, and Striatum at Weaning and After Having Been Fed Diet Def, D0, D3, or D6[b] for 9 or 21 mon

		Hippocampus	Cortex	Striatum
Weaning		3.45 (± 0.11)	1.83 (± 0.16)	2.43 (± 0.52)
9 mon	Def	4.58 (± 1.11)	1.62 (± 0.79)	2.64 (± 1.26)
	D0	6.69 (± 2.36)	2.27 (± 0.33)	4.38 (± 2.87)
	D3	8.44 (± 1.08)	2.61 (± 0.03)	5.31 (± 0.68)
	D6	7.88 (± 1.01)	2.57 (± 0.37)	5.14 (± 1.15)
21 mon	Def	2.45 (± 0.83)	1.60 (± 0.14)	2.83 (± 0.63)
	D0	2.89 (± 0.86)	1.86 (± 0.52)	3.26 (± 0.13)
	D3	2.43 (± 0.38)	1.86 (± 0.20)*	3.68 (± 0.45)
	D6	2.62 (± 0.47)	1.94 (± 0.45)*	3.49 (± 0.35)*

[a]Values are mean ± SD, $n = 3$. Values with an asterisk (*) are significantly different from 9 mon at the $P < 0.05$ level as determined by ANOVA analysis followed by a Kruskal–Wallis test.
[b]For composition of the Def, D0, D3, and D6 diets, see Tables 1 and 2. For other abbreviations, see Table 3.

(38%) were more abundant in the cortex. The main changes in the FA composition of PlsEtn were similar for diets D0, D3, and D6. After 9 mon of diet, in our animal model, the n-3 repletion with α-LNA alone or combined with DHA led to the same high and significant increase in DHA levels. Our results are controversial with regard to previous ones showing that DHA is more efficient at restoring DHA levels in the brain than is α-LNA (36–38). These findings indicate that 18:3n–3 supplementation at 0.12 g/100 g of diet may be sufficient to support recovery of the 22:6n-3 concentration in PlsEtn. After 21 mon of diet, PUFA represented more than 40% of the *sn*-2 substitutions in PlsEtn whatever the structure. PUFA levels were the highest in the cortex where they reached 55, 57, and 57% for diets D0, D3, and D6, respectively. DHA was the first major PUFA and arachidonic acid the second. These FA are incorporated selectively in PlsEtn, which represent a reservoir of PUFA. They are released from plasmalogens by the plasmalogen-selective phospholipase A$_2$ (39) to be metabolized into eicosanoids and docosanoids. The rapid turnover of brain plasmalogens (40) may suggest that their antioxidant properties are not their only physiological functions. It is thought that they may function as signaling molecules in the brain, as they do in the heart (41–42).

Docosahexaenoic Acid Supplementation in Vegetarians Effectively Increases Omega-3 Index: A Randomized Trial

Julia Geppert, Veronika Kraft, Hans Demmelmair, and Berthold Koletzko*

Division of Metabolic Diseases and Nutrition, Dr. von Hauner Children's Hospital,
Ludwig Maximilians University of Munich, D-80337 Munich, Germany

ABSTRACT: Low red blood cell (RBC) membrane content of EPA + DHA (hereafter called omega-3 index) has recently been described as an indicator for increased risk of death from coronary heart disease. The relationship between plasma and RBC FA, focusing on omega-3 index, and the response to DHA supplementation were investigated in a double-blind, randomized, placebo-controlled, intervention study. Healthy vegetarians (87 f, 17 m) consumed daily a microalgae oil from *Ulkenia* sp. (0.94 g DHA/d) or olive oil (placebo) for 8 wk. DHA supplementation significantly increased DHA in RBC total lipids (7.9 vs. 4.4 wt%), in RBC PE (12.1 vs. 6.5 wt%), in RBC PC (3.8 vs. 1.4 wt%), and in plasma phospholipids (PL) (7.4 vs. 2.8 wt%), whereas EPA levels rose to a much lesser extent. Microalgae oil supplementation increased the omega-3 index from 4.8 to 8.4 wt%. After intervention, 69% of DHA-supplemented subjects (but no subject of the placebo group) reached an omega-3 index above the desirable value of 8 wt%. Omega-3 index and EPA + DHA levels in RBC PE, RBC PC, and plasma PL were closely correlated (*r* always > 0.9). We conclude that an 8-wk supplementation with 0.94 g DHA/d from microalgae oil achieves a beneficial omega-3 index of ≥8% in most subjects with low basal EPA + DHA status. RBC total FA analyses can be used instead of RBC lipid fraction analyses for assessing essential FA status, e.g., in clinical studies.

Paper no. L9761 in *Lipids 40*, 807-814 (August 2005)

The risk for many chronic diseases, including coronary heart disease (CHD), is influenced by dietary FA intake (1–3). A higher degree of incorporation of n-3 long-chain PUFA (n-3 LCPUFA) into myocardial membranes reduces deaths following myocardial ischemia (4). Harris *et al.* (5) showed that n-3 LCPUFA content in red blood cell (RBC) membranes reflects that of cardiac membranes. A low RBC EPA + DHA percentage content (hereafter called omega-3 index) has recently been identified as a risk indicator for death from CHD (6). The relationship between the omega-3 index and the risk for CHD

death, especially sudden cardiac death, was evaluated using the data from several published primary and secondary prevention studies. An omega-3 index of ≥8% was associated with the greatest cardioprotection, whereas an index of ≤4% was associated with the highest risk. For clinical studies it is of interest to know whether RBC total lipid FA correspond to values found in other lipid classes [plasma phospholipids (PL), RBC PC, RBC PE] in subjects whose FA composition is in a steady state. Harris and von Schacky (6) observed significant increases of the omega-3 index after EPA and DHA supplementation (1 g/d) for 5 mon, ranging after intervention from 5 to 13%. These different levels in people consuming the same amount of EPA + DHA were caused by individual differences in baseline values of the omega-3 index, digestion, absorption, transport, uptake in target tissues, metabolism from storage sites, and *in vivo* conversion of α-linolenic acid (ALA) to LCPUFA derivatives. Consequently, a subject with low baseline omega-3 index may require a larger dose than a person with a high baseline value. Further studies investigating the dose–response relationship between EPA + DHA intake and the omega-3 index in subjects with different background diets are needed.

Ovolacto vegetarians consume minimal amounts of EPA and varying amounts of DHA from eggs, milk, and dairy products (average intakes < 33 mg/d) (7). Vegans consume negligible amounts of n-3 LCPUFA and rely entirely on *in vivo* biosynthesis of n-3 LCPUFA from the precursor ALA, but conversion via desaturation and elongation, especially to DHA, is not efficient (8). Previous studies with stable isotopically labeled ALA have shown conversion of ALA to EPA varying from 6–21% (9–11) to much lower values (0.1–0.2%) (12–14). Reports on the conversion of ALA to DHA range from 4–9% (9,11) to 0.04% (15), or undetectable DHA synthesis (10). Lack of EPA and DHA in vegetarian diets is reflected in reduced amounts of these FA in platelets, RBC, and plasma (16–21). Thus, uptake of preformed DHA from the diet may be critical for maintaining adequate membrane DHA concentrations.

The aim of the present study was to investigate the effects of a supplementation with a single-cell oil derived from microalgae *Ulkenia* sp. (Nutrinova DHA, Nutrinova GmbH, Frankfurt/Main, Germany) on plasma and RBC FA composition in subjects with a low habitual n-3 LCPUFA intake. In addition, the relationship between FA of various lipid fractions, focusing on omega-3 index, was determined.

MATERIALS AND METHODS

Study design and subjects. A randomized, double-blind, placebo-controlled, parallel-intervention study was performed. One hundred fourteen free-living and healthy vegetarians aged from 18–43 yr were recruited in the Munich area *via* posters displayed in health food shops and on the university campus, as well as through personal contacts. For inclusion in the study, volunteers were required to have been on a vegetarian diet for at least 1 yr. A vegetarian was defined as someone who ate no meat and not more than one fish meal a month. Inclusion criteria were age ≥ 18 yr and a body mass index (BMI) between 18 and 25 kg/m^2. Exclusion criteria were intake of medication with known influence on the lipid metabolism during the last 3 mon; intake of supplements with n-3 FA; metabolic, cardiovascular, renal, or neurological diseases; and pregnancy or lactation. The study received ethical approval by the Bavarian Board of Physicians. All subjects provided their written, informed consent before study entry and received financial compensation (200 Euro each) for their participation in the study.

The study was conducted between June and November 2003. The subjects consumed either four capsules per day containing a total of 2.28 g DHA-rich oil from microalgae *Ulkenia* sp., providing 0.94 g DHA/d, or olive oil as placebo for 8 wk. They were randomly assigned to the two intervention groups with stratification for gender. The FA composition of the two study oils is given in Table 1. To ensure that the treatments had the same antioxidant content, each oil contained 1000 ppm mixed natural tocopherols (equals 2.2–2.3 mg mixed natural tocopherols per day).

Before the first visit, subjects had to complete a questionnaire that included a survey on medications, metabolic and cardiovascular diseases, dietary supplements, frequency of fish and egg consumption, and a 3-d dietary record (two weekdays and one weekend day). At the end of the intervention period, they recorded their diet again for 3 d. Subjects were weighed before and after the intervention; height was measured at study entry. Compliance was assessed by counting leftover capsules and by the plausibility of the DHA increase in RBC PE. Subject characteristics ($n = 114$) at entry were age (25.9 ± 5.6 yr;

mean ± SD), BMI (21.3 ± 1.9 kg/m^2), years on a vegetarian diet (9.3 ± 5.2 yr), gender ratio (87 f, 27 m), and proportion of non-smokers (77%) with no significant differences in these parameters between the two groups ($P > 0.05$).

Dietary evaluation. Three-day dietary records were evaluated with the Prodi version 4.5 LE 2003 software (Wissenschaftliche Verlagsgesellschaft mbH, Stuttgart, Germany). Nutrient intake was calculated based on the German Nutrient database BLS, version II.3 (BgVV, Berlin, Germany).

Sample collection procedures. At day 0 (prior to supplementation) and after 56–60 d of capsule intake, blood samples were collected from an antecubital vein of the forearm into EDTA-containing tubes (Sarstedt, Nümbrecht, Germany) after an overnight fast. Blood was centrifuged at $1000 \times g$ for 7 min at room temperature within 2 h. Subsamples of plasma were stored at −80°C and analyzed within 12 mon of storage. Blood cells were washed 3 times with 0.9% NaCl (Baxter, Lessines, Belgium) and the buffy coat was removed. After lysis with distilled water (at least 200 μL/0.5 mL RBC sediment) (B.Braun, Melsungen, Germany), isopropanol (Merck, Darmstadt, Germany) with BHT (50 mg/l) (Fluka, Neu-Ulm, Germany) was added to prevent oxidation, and the tubes were frozen at −80°C. For each lipid fraction, FA analyses of a given subject were performed within the same analytical run.

FA analysis in study oils, plasma, and RBC. Unless otherwise indicated, all reagents used were obtained from Merck. FAME from microalgae and olive oil TG were obtained by reaction with 1.5 M methanolic hydrochloric acid (Supelco, Bellefonte, PA) in *n*-hexane at 90°C for 60 min in closed glass tubes. After adding distilled water and *n*-hexane with BHT (2 g/L), the samples were vortexed and centrifuged. The upper *n*-hexane phase containing the FAME was analyzed by capillary GLC (Hewlett-Packard 5890 Series II gas chromatograph, equipped with a 60 m × 0.32 mm BPX-70 column from SGE, Weiterstadt, Germany). FID signals were evaluated with the software EZ-Chrom Elite version 2.61 (Scientific Software, Pleasanton, CA). FAME peaks were identified by comparison with commercial standards (Nu-Chek-Prep, Elysian, MN). Values were calculated as weight percentages of all FA determined (14–24 C atoms).

Lipids from plasma were extracted three times; initially with *n*-hexane/isopropanol (3:2 vol/vol), then twice with *n*-hexane. PL, free cholesterol, nonesterified FA, TG, and cholesterol ester were separated using TLC (Merck) with *n*-heptane, diisopropylether, and glacial acetic acid (60:40:3, by vol) as mobile phase (22).

Lipids from RBC samples were extracted twice; initially by using 10 mL isopropanol/chloroform (3:2 vol/vol), then by using 4 mL chloroform. TLC with chloroform, methanol, and 25% ammonia solution (73:27:5, by vol) as mobile phase was used for separating RBC PE and PC. For the analysis of RBC total lipids, instead of deposition of the lipids on the TLC plate, they were directly transferred into glass tubes and taken to dryness under nitrogen.

FAME from individual fractions and from total lipids were obtained by reaction with 3 M methanolic hydrochloric acid at 85°C for 45 min in closed glass tubes. Derivatives were extracted into *n*-hexane and stored until GC analysis at −20°C.

TABLE 1
Major FA of Microalgae and Placebo Oils (wt%)[a]

	Microalgae oil ($n = 12$)	Placebo oil ($n = 12$)
SFA	39.99 ± 0.25	14.62 ± 0.98
18:1n-9	0.52 ± 0.03	75.86 ± 0.76
18:1n-7	0.08 ± 0.01	2.37 ± 0.04
18:2n-6	1.21 ± 0.08	5.32 ± 0.14
18:3n-6	0.22 ± 0.01	ND
20:4n-6	0.09 ± 0.01	ND
22:5n-6	9.70 ± 0.14	ND
18:3n-3	0.11 ± 0.01	0.68 ± 0.02
20:5n-3	0.29 ± 0.01	ND
22:5n-3	0.09 ± 0.01	ND
22:6n-3	46.13 ± 0.20	ND

[a]Values are reported as mean ± SD. ND, not detected; SFA, saturated fatty acids.

Analysis of FAME was performed by capillary GLC as described for the microalgae and olive oil. CV (intra- and interassay) were below 10% for all presented FA.

Statistical methods. All statistical analyses were done using the Statistical Package for the Social Sciences, version 12.0 (SPSS Inc., Chicago, IL). After checking for the normal distribution of the data, group differences were tested for significance using Student's unpaired *t*-test for normally distributed variables or the Mann–Whitney U-test for variables not normally distributed. Within-group comparisons were performed by Student's *t*-test for dependent samples or the Wilcoxon nonparametric test, respectively. Correlations between parameters were estimated by computing the Spearman ρ correlation coefficient. For bivariate tabular analysis the χ^2 test was used. In cases of expected values smaller than 5, a Fisher exact test was used instead. Unless otherwise stated, all values are given as mean ± SEM; values of $P < 5\%$ were considered significant.

RESULTS

Two of the 114 subjects recruited in the study dropped out during the intervention period. One subject in the placebo group came down with a renal colic, which was considered unrelated to the dietary supplement, and the contact to one subject of the DHA group was lost. Four subjects were excluded from the analyses. The reasons for exclusions were poor compliance with study protocol ($n = 2$; both from the DHA group) and diarrhea/vomitus for more than 6 d of the intervention period ($n = 2$; one subject from each group). Thus, 108 subjects (94.7%) are included in the analysis.

Body weight, BMI, and dietary intake. Body weight and BMI did not differ between DHA and placebo group at week 0 and week 8. An examination of within-group changes demonstrated a slight but significant increase of body weight (from 61.4 ± 8.6 to 61.9 ± 8.6 kg, mean ± SD, $P = 0.005$) in the placebo group, but no changes in the DHA group.

The proportion of macronutrients and the intakes of energy, alcohol, cholesterol, and n-3 LCPUFA with the background diet (not including supplements for placebo and DHA group) were not different between the two groups before the intervention and did not change (with the exception of energy intake in the DHA group) in both groups during intervention (Table 2). Energy intake in the DHA group was significantly lower during intervention compared with baseline and also tended to be reduced compared with placebo ($P = 0.069$). Dietary fiber intake was comparable between both groups before intervention; during intervention, it was significantly lower in the DHA than in the placebo group. Baseline intakes of EPA + DHA (median, 5th and 95th percentile in parentheses) were 23 mg/d (0, 121 mg/d) in the DHA group and 23 mg/d (3, 118 mg/d) in the placebo group. Before intervention, DHA and placebo group differed in dietary linoleic acid (LA) intake (% of energy) (median: 3.3 vs. 5.0) and LA/ALA ratios (median: 6.6:1 vs. 7.9:1). Dietary LA and LA/ALA ratio decreased in the placebo group during the study, resulting in values comparable to the DHA group at study end. The Spearman ρ correlation coefficients between dietary LA intake (g/d) and LA (wt%) in RBC total lipids, RBC PE, RBC PC, and plasma PL were 0.454, 0.470, 0.391, and 0.318, respectively (P always < 0.01).

FA response to DHA supplementation. FA composition of RBC and plasma lipids was not different between groups at baseline and changed negligibly in the placebo group (Tables 3, 4). After DHA supplementation, no changes or slight increases were observed in saturated FA (16:0 and 18:0). The monounsaturated FA 16:1n-7 and 18:1n-9 decreased significantly in all measured fractions relative to baseline. Microalgae oil supplementation resulted in significant increases of 22:5n-6 [n-6 docosapentaenoic

TABLE 2
Daily Dietary Intakes (not including supplements for DHA and placebo group) Before and During Intervention[a]

	DHA group		Placebo group

[a]Values are reported as mean ± SEM.
[b,c,d]Significant difference between week 0 and week 8 ([b]$P < 0.05$, [c]$P < 0.01$, [d]$P < 0.001$).
[e,f,g]Significant difference between DHA and placebo group at the same time point ([e]$P < 0.05$, [f]$P < 0.01$, [g]$P < 0.001$). PL, phospholipids; RBC, red blood cells.

acid (DPA)], EPA, and DHA levels and significant decreases of 20:3n-9, 18:2n-6, 18:3n-6, 20:3n-6, 20:4n-6 [arachidonic acid (AA)], 22:4n-6, and 22:5n-3 (n-3 DPA) levels in all measured fractions relative to baseline. Relative to placebo, DHA supplementation resulted in significantly higher contents of 16:0, n-6 DPA, EPA (not significant in RBC PE), and DHA, and lower contents of 16:1n-7 (not significant in plasma PL and RBC total lipids), 18:1n-9 (not significant in RBC PE), 20:3n-9, 18:2n-6, 18:3n-6, 20:3n-6, AA, 22:4n-6, 18:3n-3 (not significant in

plasma PL and RBC PC), and n-3 DPA (Tables 3, 4). After DHA supplementation, the highest relative FA changes were observed in DHA, n-6 DPA, and EPA in all measured lipid classes (Fig. 1). The degree of these changes was different in the various lipid classes, with higher percentage changes in RBC PC and plasma PL than in RBC total lipids and RBC PE for DHA, n-6 DPA, and EPA.

Statistically significant increases in EPA + DHA levels vs. baseline values were observed after 8 wk of microalgae oil

FIG. 1. Relative changes of selected FA in RBC total lipids, RBC PE, RBC PC, and plasma PL in the DHA group compared with baseline values (*n* = 52 in RBC total lipids, otherwise *n* = 55). Values were calculated as individual's percent change in each lipid fraction and are reported as mean + SD. PA, 16:0; OA, 18:1n-9; LA, 18:2n-6; ALA, 18:3n-3; AA, 20:4n-6; DPA n-6, 22:5n-6; DPA n-3, 22:5n-3; EPA, 20:5n-3; DHA, 22:6n-3; PL, phospholipids; RBC, red blood cells.

supplementation in all investigated lipid fractions (Tables 3, 4). The omega-3 index rose significantly from 4.8 ± 0.2 wt% to 8.4 ± 0.2 wt% in the DHA-supplemented group, ranging after 8 wk from 4.7 to 11.0 wt%. Relative to placebo application, supplementation with DHA-rich microalgae oil resulted in significantly higher contents of EPA + DHA in all tested lipid fractions. At baseline, 29% of the DHA group and 33% of the placebo group volunteers had an omega-3 index of ≤4%, and no one reached an omega-3 index of ≥8%. After 8 wk of intervention, an omega-3 index of ≤4% did not occur anymore in the DHA group, but remained in 39% of the placebo group subjects ($P < 0.001$). Sixty-nine percent of the DHA-supplemented subjects had an omega-3 index of ≥8%, while no subject of the placebo group showed an omega-3 index above 8% ($P < 0.001$).

Correlations between FA of RBC total lipids and other lipid fractions. Spearman ρ correlation coefficients were computed

between the relative levels of FA in RBC total lipids and FA percentages in RBC PE, RBC PC, and plasma PL for all subjects at both time points (Table 5). Relative FA content in RBC total lipids correlated significantly with the corresponding FA content in the other lipid classes (plasma PL, RBC PC, and RBC PE) (*r* always > 0.49). RBC total lipid DHA and RBC total lipid EPA + DHA consistently showed the strongest correlations with the other lipid fractions at both time points (*r* always > 0.90).

At baseline, correlation coefficients between omega-3 index and EPA + DHA from RBC PE, RBC PC, and plasma PL were almost identical in DHA and placebo groups (Fig. 2). After the intervention, correlation coefficients remained similar to baseline in the placebo group but were lower in the DHA group. The correlations between EPA + DHA at week 0 and EPA + DHA at week 8 were also lower in the DHA group in all tested lipid fractions (in the placebo group *r* = 0.841–0.970; in the DHA group *r* = 0.464–0.856, *P* always < 0.001).

In the DHA group, Spearman ρ correlations were computed between RBC total lipid or plasma PL relative FA changes and percentage changes in the other lipid fractions for LA, AA, n-6 DPA, ALA, EPA, n-3 DPA, DHA, and EPA + DHA. Relative changes in RBC total lipid n-6 and n-3 FA correlated significantly and positively with changes in the other lipid classes (*r* always > 0.48); here, the correlations were highest for n-6 DPA, EPA, DHA, and the omega-3 index (*r* always > 0.75). Relative changes in RBC PE correlated better with RBC total lipid than with plasma PL changes for all tested FA (data not shown). Relative changes in plasma PL correlated best with RBC PC for all tested n-6 and n-3 FA with exception of ALA.

DISCUSSION

A daily intake of 0.94 g DHA from Ulkenia oil markedly increased the DHA content of plasma and RBC phospholipids. Previous studies reported a two- to threefold increase of the DHA content of serum and platelet PL after supplementation

TABLE 5
Spearman ρ Correlations Between RBC Total Lipid FA (wt%) and FA from RBC PE, RBC PC, and Plasma PL at Week 0 and Week 8 in All Subjects (*n* = 103)

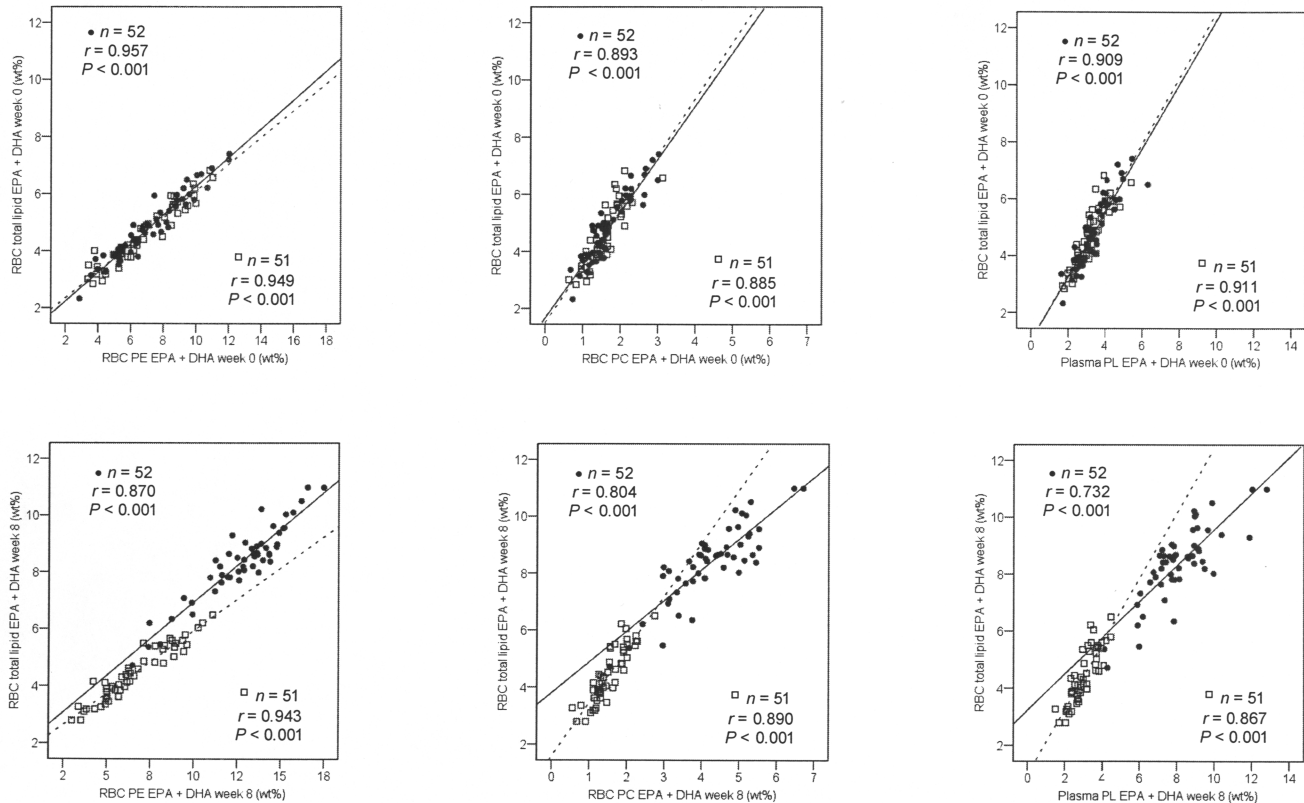
[a]Significant correlations between RBC total lipid FA and FA of the other lipid fractions (*P* < 0.001). For abbreviations see Table 3.


FIG. 2. Correlations between EPA + DHA in RBC total lipids (wt%) vs. EPA + DHA in RBC PE, PC, and plasma PL (Spearman ρ correlation coefficient). □ and dashed line, placebo group; • and solid line, DHA group. For abbreviations see Figure 1.

with 0.75, 1.50, or 1.62 g DHA/d for 6 wk (23–25) and a rise of DHA levels in plasma PL by 76% and in RBC phosphoglycerides by 58%, respectively, after 3 mon of supplementation with 0.7 g DHA/d (26). The observed increase of EPA in RBC and plasma lipids after DHA supplementation in our study appears to reflect retroconversion of DHA, as suggested also by other observations (23,24,27,28). We found a decrease in n-6 LCPUFA (20:3n-6, 20:4n-6, 22:4n-6), accompanied by a decrease in n-3 DPA, consistent with other findings (23–25,27). In contrast, n-3 DPA shows considerable enrichment in serum and platelet phospholipids when fish or seal oils (providing EPA, DHA, and some n-3 DPA) are fed (29,30). Thus, dietary DHA and possibly also n-6 DPA appear to partially replace n-3 DPA in circulating and cellular phospholipids in human subjects. In contrast to other studies using DHA-rich oils from an algal source, which reported significant decreases in n-6 DPA (23,24,27), we observed an increase of n-6 DPA in plasma and RBC PL, which is explained by the significant n-6 DPA content in the tested oil derived from microalgae *Ulkenia* sp. (9.7 wt%).

The omega-3 index rose significantly from 4.8 ± 1.2 (mean ± SD) to 8.4 ± 1.3 wt% in the DHA-supplemented group. A similar increase of the omega-3 index was reported by Harris *et al.* (6) after EPA and DHA supplementation (1 g/d) for 5 mon. We found the relative and absolute changes in omega-3

index to be inversely correlated to baseline levels ($r = -0.760$, $P < 0.001$ and $r = -0.311$, $P = 0.025$, respectively), indicating that the (relative and absolute) increase of the omega-3 index is higher in subjects with lower baseline levels. At baseline, no subject reached a desirable omega-3 index of ≥8 wt%, although more than 50% of the subjects reached or exceeded recommended intakes for LA (2.5% of energy) and ALA (0.5% of energy) and 26% had a dietary LA/ALA ratio below 5:1 as considered desirable (31). These results suggest that the *in vivo* conversion of ALA to n-3 LCPUFA is not adequate to reach a desirable EPA + DHA status even with a low dietary LA/ALA ratio. Thus, a dietary intake of preformed n-3 LCPUFA seems to be necessary to enhance the omega-3 index.

Relative changes of n-6 DPA, EPA, and DHA were greater in plasma PL and RBC PC (Fig. 1) than in RBC total lipids or RBC PE, with strong correlations between RBC PC and plasma PL FA changes. RBC PE and plasma PL FA changes were less closely related. Plasma PL FA change relatively fast and reflect dietary intakes over the past few days (32). RBC PL are asymmetrically distributed between the outer and the inner layer of the membrane (33): the major part of PE is located at the inner layer, whereas PC occurs predominantly on the outer layer and can exchange more easily with plasma lipids. Thus, PC reflects more directly the FA composition of PL of the plasma (34), whereas the FA composition of PE

appears to be more independent from the plasma FA and depends on selective incorporation of PUFA and LCPUFA into PE (35).

Relative changes in RBC total lipid n-6 DPA, EPA, and DHA were lower than their average changes in RBC PE and RBC PC (Fig. 1), indicating that these FA were preferentially incorporated into PE and PC, which constitute about 23 and 22% of total membrane lipids (modified from Ref. 36, calculated without cholesterol), but less in the other lipids of the RBC membrane such as sphingomyelin, PS, glycolipids, and other lipids, constituting about 23, 9, 4, and 18% of total membrane lipids, respectively.

Even though each lipid fraction revealed a distinct and characteristic FA pattern, RBC total lipid FA were significantly correlated with FA from RBC PC, RBC PE, and plasma PL (Table 5) at both time points. In agreement, Vlaardingerbroek and Hornstra (37) and Harris *et al.* (6) also reported strong correlations between RBC and plasma PL LCPUFA. In contrast, a study by Leichsenring *et al.* (38) did not find any relation of RBC DHA (PE, PC, and total lipids) values to DHA levels in plasma PL, which might be due to a greater heterogeneity of their subjects with respect to age and diet.

After supplementation, correlation coefficients between omega-3 index and RBC PE, RBC PC, and plasma PL, EPA + DHA were higher in the placebo than in the DHA group (Fig. 2), and additionally, correlations between omega-3 index from weeks 0 and 8 were stronger for the placebo group. These findings may indicate that EPA + DHA contents in plasma and RBC lipid fractions are not in a steady state after 8 wk of DHA supplementation. Another explanation may be that the supplemented FA show individual differences in digestion, absorption, and preferential incorporation into the different lipid fractions.

Reported energy intake in the DHA group was significantly lower during intervention compared with baseline (−11%), but remained unchanged in the placebo group (Table 2). We observed no changes in body weight over the study period of 8 wk in the DHA group, but a slight weight gain in the placebo group (+0.5 kg). An explanation for the reduced energy intake without weight loss in the DHA group and the weight gain without increased energy intake in the placebo group could be that the energy requirements decreased in both groups during the intervention period, e.g., because of less physical activity related to seasonal influences. The participation in a nutritional study and the intake of oil-containing capsules might have caused larger reductions in dietary intakes and/or a greater "underreporting" of consumed foods than before the intervention in both groups at the days of the dietary record. Since we observed a trend toward lower energy intakes in the DHA group relative to placebo, the tested microalgae oil might have had a different effect on appetite or regulation of food intake than olive oil in the vegetarian subjects studied. As 8-wk supplementation with 0.94 g DHA/d from microalgae oil (*Ulkenia* sp.) achieves a desirable omega-3 index of ≥8% in subjects with low basal n-3 LCPUFA status, microalgae oil might be a valuable alternative to fish/fish oil for vegetarians.

Eicosapentaenoic Acid, but Not Oleic Acid, Stimulates β-Oxidation in Adipocytes

ABSTRACT: The beneficial roles of dietary fish oil in lowering serum TAG levels in animals and humans have been attributed in part to the high content of two n-3 polyunsaturated very long-chain FA, EPA, and DHA. Recent studies show that EPA induces mitochondrial β-oxidation in hepatocytes, which might contribute to the systemic lipid-lowering effect. Whether EPA affects FA storage or oxidation in adipocytes is not clear. To investigate this possibility, 3T3-L1 adipocytes incubated with EPA (100 µM) for 24 h were assayed for β-oxidation, carnitine palmitoyl transferase 1 (CPT-1) activity, protein, and mRNA expression of CPT-1. For comparison, cells treated with oleic acid, octanoic acid, and clofibrate, a synthetic ligand for peroxisome proliferator-activated receptor α were also analyzed. Mitochondria were isolated by differential centrifugation, and the mitochondrial membrane acyl chain composition was measured by GLC. EPA increased the oxidation of endogenous FA but did not inhibit lipogenesis. Oleic acid and clofibrate did not affect FA oxidation or lipogenesis, whereas octanoic acid suppressed the oxidation of endogenous FA and inhibited lipogenesis. Increased β-oxidation by EPA was associated with increased CPT-1 activity but without changes in its mRNA and protein expression. EPA treatment increased the percentage of this FA in the mitochondrial membrane lipids. We suggest that EPA increased the activity of CPT-1 and β-oxidation in adipocytes by altering the structure or dynamics of the mitochondrial membranes.

Paper no. L9788 in *Lipids 40*, 815–821 (August 2005).

The beneficial roles of dietary fish oil in the human diet have been attributed to the high content of two n-3 polyunsaturated very long-chain FA, EPA, and DHA (1–4). Animal studies as well as *in vitro* cell studies have provided some insights into possible mechanisms for these effects (5–10). Both EPA and DHA activate peroxisome proliferator-activated receptor α (PPARα), the nuclear transcription factor that regulates the expression of key enzymes in the control of FA β-oxidation in mitochondria and peroxisomes (6). EPA has been shown to induce mitochondrial FA oxidation and contribute to lipid-lowering effects (7), whereas the effects of DHA are still debatable (7,11). In hepatocytes, EPA increases the expression of carnitine palmitoyl transferase 1 (CPT-1), which increases the flux of FA toward mitochondrial β-oxidation and reduces the sub-

strates for lipid synthesis and lipoprotein secretion. In hepatocytes EPA directly reduces TAG synthesis by direct inhibition of DAG acyltransferase activity (6). EPA also inhibits apolipoprotein secretion in both enterocytes and hepatocytes (12,13). Any one or a combination of these mechanisms could contribute to the systemic lipid-lowering effects of fish oil or EPA dietary supplements.

Several previous reports have shown that fish oil reduces adipocyte cell size and fat pad mass, and that it increases the cellular response to insulin and β-agonist-stimulated lipolysis (1,5,8,14,15). It is not clear whether these effects are caused by n-3 FA acting on adipocytes or are secondary to the changes in hepatic or systemic metabolism. In this work, we studied the effects of EPA on FA oxidation and lipid synthesis in 3T3-L1 adipocytes. We found that EPA significantly increased the β-oxidation of endogenous FA with a concomitant increase in CPT-1 enzyme activity, consistent with the prior studies on hepatocytes. In contrast, treatment with oleic acid or octanoic acid did not affect CPT-1 activity in adipocytes. On the other hand, EPA did not appear to inhibit either *de novo* FA synthesis or TAG synthesis in adipocytes, implying that the mechanisms by which EPA modulated lipid metabolism in hepatocytes (6) might not be directly extrapolated to adipocytes, although both cell types share many of their lipid metabolic pathways.

MATERIALS AND METHODS

Cell culture and FA treatment. 3T3-L1 adipocytes were prepared as described previously (16). For each experiment, cells were incubated with serum-free DMEM for 14 h before the test reagents were added. EPA (100 µM in a complex with 40 µM BSA), oleic acid (100 µM in a complex with 40 µM BSA), octanoic acid (1.0 mM, with 40 µM BSA), and clofibrate (300 µM, with 40 µM BSA) were added to the cells maintained in DMEM. The higher concentration of octanoic acid was required because of the much lower partitioning of this medium-chain FA into the plasma membrane (17). Control cells were maintained in DMEM with 40 µM BSA. All concentrations are given as final concentrations in the incubation medium.

FA oxidation. Adipocytes grown in six-well plates were preincubated with [9,10-^{3}H] oleic acid (0.5 µCi/mL) for 4 d in DMEM with 10% FBS. To enhance the enrichment of isotope in the endogenous pool, fresh isotope tracer was added every day. The absolute amount of oleic acid added by this procedure was very low (<10 nM), and its perturbation of cellular metabolism

Abbreviations: CPT, carnitine palmitoyl transferase; PPARα, peroxisome proliferator-activated receptor α.

was considered to be negligible. Cells were then washed three times with warm PBS and added to 2 mL of phenol red-free DMEM containing the test reagents described above. After 24 h, 1.2 mL of the medium from each incubation was removed into three small plastic vials (0.4 mL/vial), which in turn were placed in one large screw-capped glass vial surrounded with 1.2 mL of unlabeled water and sealed with paraffin. This closed system was placed in an incubator at 58°C for 24 h to allow equilibrium to be reached between the labeled and unlabeled water phases. The small vial containing the original medium was then removed, and the radioactivity absorbed into the bulk water phase through vapor exchange was used for quantification by scintillation counting as described previously (18).

Incorporation of ^3H_2O and [U-^{14}C]glucose into cellular lipids. Adipocytes treated in parallel under the above conditions (except without preincubation of the isotope-labeled FA) were incubated with ^3H_2O (100 μCi/mL) or [U-^{14}C]glucose (0.5 μCi/mL). After 24 h, the cellular lipids were harvested and hydrolyzed as described previously (16). The amount of tritium accumulated in the FA fraction was quantified by β-counting and was used to calculate the amount of FA synthesized *de novo*. The amount of ^{14}C recovered from the glycerol fraction was quantified by β-counting and was used to calculate the amount of TAG synthesized in this period of time.

Mitochondrial isolation and CPT-1 activity. Mitochondria were isolated using a standard protocol (19) with slight modifications. Cultured adipocytes were harvested into 5 mL of homogenization buffer (250 mM sucrose, 10 mM Tris-HCl, 1.0 mM EDTA, 1 mM PMSF, pH 7.0). Cells were homogenized using 10 strokes of a Potter–Elvehjem tissue grinder at the maximum power setting. The homogenate was centrifuged at $600 \times g$ for 10 min. The supernatant was then centrifuged at $16,000 \times g$ for 10 min at 4°C. The pellet was resuspended in 10 mL of sucrose cushion (3 g sucrose dissolved in the same homogenization buffer) and centrifuged at $25,000 \times g$ for 10 min at 4°C. The final mitochondrial pellet was resuspended in CPT assay buffer (150 mM KCl, 5 mM Tris-HCl, 4 mM MgCl$_2$, pH 7.2). CPT activity was measured using a published protocol (20).

The assay mix (100 μL per reaction) was prepared with the assay buffer added with l-[methyl-^{3}H]carnitine (0.5 mM, 10 μCi/mL), 100 μM palmitoyl-CoA, 4 mM ATP, 0.25 mM glutathione, 2 mM KCN, 40 mg/L rotenone, and 0.5% FA-free BSA. The reaction was started by adding 20 μg of mitochondrial protein, and the assay mix was incubated at room temperature for 6 min. The reaction was stopped by adding 100 μL of 1 N HCl, followed by the extraction of palmitoyl-[^{3}H]carnitine using 1-butanol. For each measurement, the CPT activity was measured in the absence (CPT-1 and partial CPT-2) and in the presence of 100 μM malonyl-CoA (CPT-1 inhibited). The CPT-1 activity was calculated as the difference between these two measurements.

Western blot analysis. A cell lysate was prepared using a mammalian cell lysis kit according to the manufacturer's instructions. The proteins were separated by SDS-PAGE with protein loading of 15 μg/lane. The primary antibody for CPT-1

(rabbit-anti-mouse) was from Alpha Diagnostic Inc. (San Antonio, TX). The secondary antibody (goat-anti-rabbit) was from Pierce (Rockford, IL).

Mitochondrial phospholipid FA composition analysis. After measuring the CPT-1 activity, the residual mitochondrial fraction was extracted by the method of Folch *et al.* (21). The lipid mixture was separated by TLC (hexane/ether/acetic acid, 80:20:1). The phospholipid fraction was eluted from the silica gel with CHCl$_3$/CH$_3$OH/NH$_4$OH (1:1:0.07), dried under a stream of N$_2$, and methylated using a BF$_3$/CH$_3$OH kit from Supelco (St. Louis, MO) according to the manufacturer's instructions. The acyl chain composition was analyzed using a GLC method as described previously (16).

RNA analysis. Total RNA was prepared and analyzed as described previously (22). The primer sequence used for CPT-1 was from the literature (23).

Other biochemical assays. Concentrations of cellular TAG, DNA, protein, and glycerol release were measured using commercial kits from Sigma as described previously (16).

Materials. Unless otherwise indicated, all regular cell culture supplies were from Fisher (Agawa, MA); all radioactive isotope-labeled chemicals were from NEN (Boston, MA); and all other reagents and organic solvents were from Sigma.

Statistics. Data are expressed as means ± SE. Comparisons between two groups of data were made using Student's *t*-test. For others, the results were analyzed using one-way ANOVA and Duncan's multiple comparison tests. Differences were considered statistically significant when $P < 0.05$.

RESULTS

EPA increased FA oxidation in adipocytes. To provide a pool of endogenous FA that could be monitored during the experiments with EPA and other additives, cells were prelabeled with [9,10-^{3}H]oleic acid (>95% of the labeled oleic acid was found in TAG after lipid fractionation analysis, data not shown). β-Oxidation was measured by quantifying the release of ^3H_2O from the endogenous esterified [9,10-^{3}H]oleic acid. As shown in Figure 1A, EPA increased β-oxidation of endogenous oleic acid in adipocytes by about 40% ($P < 0.05$, $n = 5$). Incubation with octanoic acid decreased the oxidation of [9,10-^{3}H]oleic acid, probably caused by substrate competition between octanoic acid and oleic acid, which favors octanoic acid because it can be β-oxidized independently of CPT-1 (24). Incubation with oleic acid and clofibrate slightly increased the oxidation of endogenous oleic acid, but the difference was not statistically significant ($P = 0.5$ and 0.7, respectively). The amount of glycerol released from cells treated under these five conditions was similar in all cases (250 ± 10 nmol/24 h/10^{6}cells), implying that the release of endogenous FA did not account for the difference in β-oxidation.

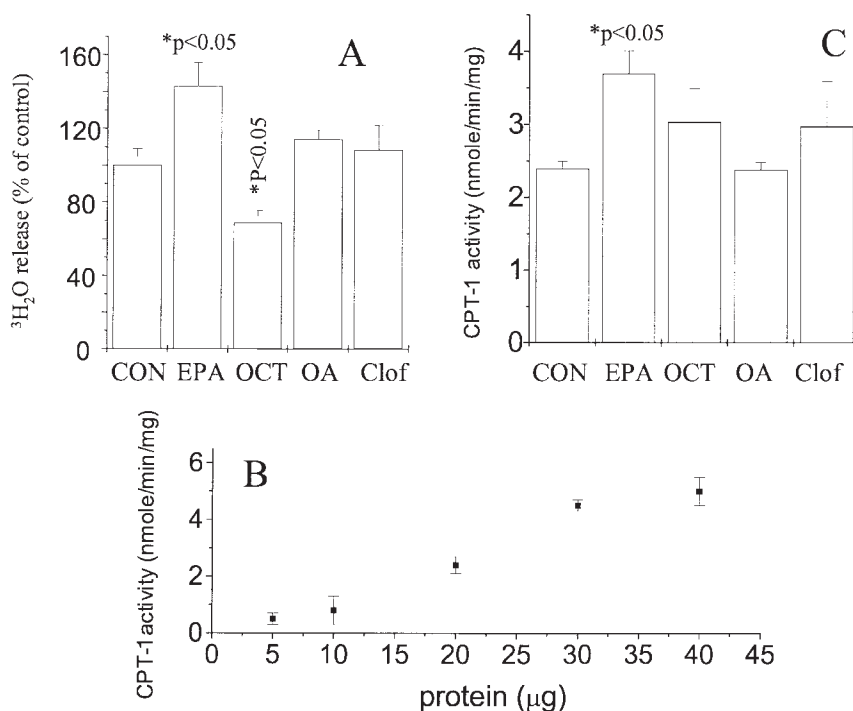
EPA increases in vitro CPT-1 activity of adipocytes. Since CPT-1 is the only known enzyme that transports activated long-chain FA into the mitochondria for β-oxidation (19), we then determined whether the observed changes in β-oxidation were associated with corresponding changes in CPT-1 activity. To


FIG. 1. Effects of EPA on β-oxidation and carnitine palmitoyl transferase 1 (CPT-1) activity. (A) Adipocytes were preincubated with [9,10-^{3}H]oleic acid for 4 d, and then treated with EPA (100 µM), oleic acid (OA, 100 µM), octanoic acid (OCT, 1 mM), or clofibrate (Clof, 300 µM) in serum-free DMEM with 0.5% BSA for 24 h. The amount of ^{3}H$_2$O liberated in this period was measured as the index for β-oxidation of endogenous FA. Data are means ± SE, n = 4; *t-test vs. control (CON). (B) CPT-1 activity was measured with different amounts of mitochondrial crude proteins from the control cells to determine the linear range of measurement. Data are means ± SE, n = 3, for each data point. (C) Cells were treated with EPA and other additives for 24 h, the same as those shown above. The mitochondrial fraction was isolated by sequential centrifugation, and the CPT-1 activity was assayed as described in the Materials and Methods section. Data are means ± SE, n = 5. *P < 0.05, vs. control.

determine the optimal mitochondrial protein concentration for the enzyme activity assay, we first measured the CPT-1 activity using different amounts of proteins prepared from the control cells, which showed a linear range from 5 to 30 µg (Fig. 1B). The final enzyme activity was measured using 20 µg of mitochondrial crude proteins. As shown in Figure 1C, CPT-1 activity in the isolated mitochondria was increased by ~40% after cells were treated with EPA. Under otherwise identical conditions, octanoic acid, oleic acid, and clofibrate did not significantly affect CPT-1 activity (P = 0.2, 0.5, 0.8, respectively). These findings show that the CPT-1 activity assayed from isolated mitochondria was proportional to the rate of β-oxidation in intact cells.

EPA did not change the expression level of CPT-1. To determine whether the changes in CPT-1 activity were associated with increased expression levels of this enzyme, the relative abundance of mRNA and protein of CPT-1 were analyzed by semiquantitative reverse-transcription (RT)-PCR. As shown in Figure 2A, EPA, as well as octanoic acid and oleic acid, did cause detectable effects on CPT-1 mRNA. There was a trend of increased CPT-1 expression in cells treated with clofibrate (Fig. 2A, 2B), but the difference did not reach statistical significance (P = 0.2 and 0.5 for mRNA and protein, respectively, n = 3 for each). The results of these measurements were validated

by PCR measurements using different cycle conditions and by Western blot analysis with different protein loadings to ensure that the results were within the linear range of comparison (data not shown). As an independent verification of our methods, we also measured the mRNA in human hepatoma cells (HepG2) treated in parallel. We found that EPA, oleic acid, and clofibrate increased the expression of CPT-1 by 50, 38, and 72%, respectively (n = 3, P < 0.05 compared with control). whereas octanoic acid had no effect, consistent with previous reports (6).

Alteration in the fatty acyl composition of mitochondrial membrane lipids. Since EPA has been shown to displace proteins from membrane rafts by altering the membrane lipid composition (25), we next investigated whether the changes in CPT-1 enzyme activity were associated with a change in the mitochondrial membrane lipid composition. As shown in Figure 3, EPA typically constitutes a very small fraction of the FA in mitochondrial phospholipids. Incubation with exogenous EPA increased the percentage of EPA in the mitochondrial membrane lipids by about fivefold. This was accompanied by a reduction of 16:1 in the mitochondrial membrane lipids as compared with the control cells. The net change caused an increase in the degree of unsaturation. Incubation with either octanoic acid or clofibrate did not cause detectable changes in the mitochondrial membrane lipid composition (Fig. 3). Adding

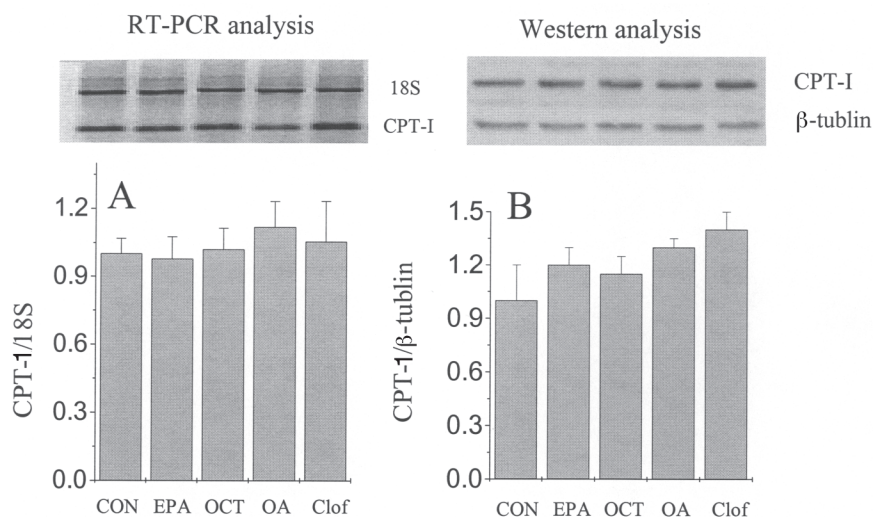
RT-PCR analysis   Western analysis


FIG. 2. Effects of EPA on mRNA (A) and protein (B) expression of CPT-1. Cells were prepared the same as those in Figure 1. RNA and protein were isolated after 24 h of incubation and analyzed as described in the Materials and Methods section (mean ± SE, *n* = 3). RT-PCR, reverse-transcription polymerase chain reaction; for other abbreviations see Figure 1.

oleic acid to the exogenous medium slightly increased the percentage of 18:1 in the membrane lipids, accompanied by a similar decrease of 16:1. Therefore, the overall acyl chain unsaturation remained unchanged.

Lipogenesis in adipocytes treated with EPA and other additives. Since lipid synthesis is one of the major metabolic events that directly affects the storage of fat in adipocytes, we investigated how treatment with EPA would affect this process, in comparison with cells treated with other additives. We found that EPA treatment did not affect *de novo* FA synthesis but increased TAG synthesis, as measured by the incorporation of glucose into the glycerol backbone (Table 1). Treatment with

oleic acid caused a similar result, suggesting this might be a common effect of adding exogenous long-chain FA to cell cultures. Octanoic acid inhibited *de novo* FA synthesis but did not affect TAG synthesis, as reported previously (26). Clofibrate affected neither *de novo* FA synthesis nor TAG synthesis.

Despite the difference in β-oxidation and lipid synthesis, total TAG stores did not differ significantly in adipocytes treated as described in the Materials and Methods section, possibly because most of the stored fat was acquired before the treatments. These results also indicate that it was easier to detect the changes in a smaller pool of FA undergoing β-oxidation than in the much larger pool of FA stored in TAG.
FIG. 3. Effects of EPA on mitochondrial membrane lipid FA composition. Cells were prepared the same as those in Figure 1. Mitochondrial phospholipids were isolated as described in the Materials and Methods section. The fatty acyl methyl esters were analyzed by GLC (*n* = 3). The assignment was done by reference to known fatty acyl methyl ester standards. Small amounts of other acyl chains were also detected (<3%, not shown). For abbreviations see Figures 1 and 2.

TABLE 1
The Effects of EPA on *de novo* FA Synthesis from $^3H_2O^a$, TAG-Glycerol Synthesis[b], and Total Cellular TAG Content[c]

Additives	Control	EPA	Octanoic acid	Oleic acid	Clofibrate
De novo synthesized FA	5.9 ± 0.5	7.0 ± 0.8	1.9 ± 0.2*	5.0 ± 1.0	5.8 ± 0.6
Newly synthesized TAG-[U-^{14}C]glycerol	15.9 ± 0.5	22.8 ± 1.1**	16.1 ± 0.4	25.5 ± 0.7**	16.1 ± 1.1
Cellular TAG	465 ± 31	421 ± 15	441 ± 15	476 ± 21	443 ± 25

[a]Measured as pmol/h/10^6 cells.
[b]Measured as pmol/h/10^6 cells, as TAG-derived [U-^{14}C]glycerol.
[c]Measured as mg/10^6 cells, as total TAG-derived glycerol. Cells were treated as in Figure 1 (mean ± SE, *n* = 4); *$P < 0.05$ significantly reduced; **$P < 0.05$, significantly increased compared with the control.

DISCUSSION

That dietary FA activate FA β-oxidation in hepatocytes has been well established (27–29), but such a direct effect in adipocytes had not been determined in a controlled setting *in vitro*. Our results demonstrate that the β-oxidation of endogenous FA in adipocytes was increased by treatment with EPA but was not affected by oleic acid (Fig. 1A). This is consistent with a previous study showing that feeding rats with n-3 FA, but not monounsaturated FA, stimulated mitochondrial oxidation in adipose tissue (30). Clofibrate, the activating ligand for PPARα, also did not affect FA oxidation. Octanoic acid, on the other hand, inhibited the oxidation of endogenous FA (Fig. 1A). EPA also increased adipocyte mitochondrial CPT-1 activity, whereas oleic acid, octanoic acid, and clofibrate did not (Fig. 1B). EPA, as well as oleic acid and clofibrate, did not affect *de novo* FA synthesis (Table 1). Both EPA and oleic acid increased net TAG synthesis (Table 1). Octanoic acid, on the other hand, inhibited *de novo* FA synthesis but did not affect basal TAG synthesis (Table 1). However, within the 24-h incubation period, none of these changes had a significant effect on total cellular TAG contents.

EPA is known to be an activating ligand for PPARα, the nuclear transcription factor that regulates the expression of FA catabolic genes, including CPT-1 (31–35). An EPA-induced increase in CPT-1 expression is considered to be one of the main mechanisms for increased CPT-1 activity in hepatocytes (6). One would expect that EPA-induced CPT-1 activity in adipocytes might also be a result of ligand activation of PPARα, leading to increased transcription of this enzyme (36). However, we did not detect significant effects of EPA on CPT-1 at either the mRNA or the protein level (Fig. 2). The mRNA levels of PPARα and a few of its downstream targets, including acyl-CoA oxidase and acyl-CoA synthase, were also unchanged by the treatment with EPA or other additives used in this work (data not shown). Therefore, we conclude that under our experiment conditions, EPA-induced CPT-1 activity is not likely mediated through the PPARα pathway. The low abundance of PPARα expressed in adipocytes as compared with its high abundance in hepatocytes might partly explain the discrepancy in the effects of EPA on CPT-1 expression between these two cell types. Even clofibrate, a synthetic PPARα-specific ligand, failed to induce significant changes in CPT-1 expression (Fig. 2), consistent with findings that fenofibrate, another synthetic PPARα-specific ligand, had minimal effects on

the expression of PPARα target genes in either rat adipose tissue or 3T3-L1 adipocytes (37).

On the other hand, although expressed to a limited extent, PPARα has been demonstrated to be functional in adipocytes (23,36,38), and might be regulated by supra-high dosages of synthetic ligands (39). Therefore, the lack of effects of EPA, or oleic acid and clofibrate, on CPT-1 mRNA in adipocytes might not be entirely due to the low expression levels of PPARα in these cells. An alternative possibility is that ligand stimulation of PPARα might already have been saturated in adipocytes because of its constant exposure to high levels of endogenous FA. Most of these FA can also be activating ligands of PPARα (34). In this regard, moderate variations in exogenous FA within a short period of time might not be sufficient to alter the transcriptional activity of PPARα in adipocytes. Hence, an alternative mechanism needs to be considered to interpret the EPA-mediated increase in CPT-1 activity and the associated increase in FA oxidation.

Mitochondrial CPT-1 activity can be modified by the fluidity of the membranes in which it resides, as shown by an earlier study (40). Because mitochondrial lipids contain a low proportion of cholesterol, membrane fluidity is largely controlled by the acyl chain unsaturation of the phospholipids. As shown in Figure 3, exogenous EPA was incorporated into mitochondrial membrane lipids with a simultaneous decrease in palmitoleic acid (16:1). These changes in the mitochondrial membrane lipids are expected to alter membrane structure and cell functions (2,11), as we also confirmed (Fig. 1A, 1B). The direct cause(s) of changes in CPT-1 activity, however, merit further investigation.

In addition to its effects on β-oxidation and CPT-1 activity, EPA has been shown to inhibit lipogenesis and reduce TAG synthesis in hepatocytes (41). In contrast, we found that EPA did not inhibit *de novo* FA synthesis and even increased TAG synthesis in adipocytes, as evidenced by the increased synthesis of the TAG-glycerol moiety (Table 1). Similar results were found when cells were treated with oleic acid but not octanoic acid (26). Such an increase in TAG synthesis is likely caused by an increased availability of exogenous substrates, which implies that EPA can be used for lipid synthesis in adipocyte analogs to oleic acid.

A quantitative comparison of the results in Table 1 shows that the amount of FA or TAG synthesized *de novo* during the 24-h incubation period accounted for only a small fraction of the total storage of TAG, implying that the majority of cellular

TAG was preformed before the incubation was initiated. Hence, although EPA and oleic acid both increased TAG synthesis, they did not substantially change the total TAG storage. In addition, since *de novo* FA synthesis occurred at a slower rate than net TAG synthesis, most of the FA substrate used for TAG synthesis in these cells might come from intracellular FA recycling or from exogenously added FA.

In summary, we showed that EPA increases CPT-1 activity and β-oxidation in adipocytes. Since FA oxidation normally accounts for only a very small part of the fat disposition in adipocytes (18), we did not detect an acute effect of EPA on lipid synthesis and storage in adipocytes, as previously established in hepatocytes. Our results support the hypothesis that the hypolipidemic effect of EPA or fish oil found *in vivo* might be primarily a liver-mediated systemic effect. However, a small but steady increase in β-oxidation might gradually modulate fat storage in adipocytes on a long-term basis.

Effect of Abomasal Infusions of Geometric Isomers of 10,12 Conjugated Linoleic Acid on Milk Fat Synthesis in Dairy Cows

Asgeir Sæbø[a], Per-Christian Sæbø[a], J. Mikko Griinari[b], and Kevin J. Shingfield[c,*]

[a]Natural ASA, N-6160, Hovdebygda, Norway, [b]Department of Animal Science, University of Helsinki, Helsinki, Finland, and [c]Centre for Dairy Research, Department of Animal Science, The University of Reading, Reading, RG6 6AT, United Kingdom

ABSTRACT: The *trans*-10,*cis*-12 isomer of conjugated linoleic acid (CLA) decreases TAG accumulation in 3T3-L1 adipocytes, reduces lipid accretion in growing animals, and inhibits milk fat synthesis in lactating mammals. However, there is evidence to suggest that other FA may also exert antilipogenic effects. In the current experiment, the effects of geometric isomers of 10,12 CLA on milk fat synthesis were examined using four Holstein-British Friesian cows in a 4×4 Latin Square experiment with 14-d periods. Treatments consisted of abomasal infusions of skim milk, or skim milk containing *trans*-10,*cis*-12 CLA (T1), *trans*-10,*trans*-12 CLA (T2), or a mixture of predominantly 10,12 isomers containing (g/100 g) *trans*-10,*cis*-12 (35.0), *cis*-10,*trans*-12 (23.2), *trans*-10,*trans*-12 (14.9), and *cis*-10,*cis*-12 (5.1). CLA supplements were prepared from purified ethyl linoleate and infused as nonesterified FA. Infusions were conducted over a 4-d period with a 10-d interval between treatments and targeted to deliver 4.5 g/d of 10,12 CLA isomers. Compared with the control, *trans*-10, *trans*-12 CLA had no effect ($P > 0.05$) on milk fat yield, whereas treatments T1 and T3 depressed ($P < 0.05$) milk fat content (19.8 and 22.9%, respectively) and decreased milk fat output (20.8 and 21.3%, respectively). Comparable reductions in milk fat synthesis to 4.14 and 1.80 g *trans*-10,*cis*-12/d supplied by treatments T1 and T3 indicate that other 10,12 geometric isomers of CLA have the potential to exert antilipogenic effects. The relative abundance of *cis*-10,*trans*-12 CLA in treatment T3 and the low transfer efficiency of this isomer into milk suggest that *cis*-10,*trans*-12 CLA was the active component..

Paper no. L9762 in *Lipids 40*, 823–832 (August 2005).

It is well established that isomers of CLA are involved in the regulation of lipid metabolism. Supplements of a mixture of CLA isomers containing *trans*-8,*cis*-10; *cis*-9,*trans*-11; *trans*-10,*cis*-12; and *cis*-11,*trans*-13 have been shown to reduce body fat in growing animals and decrease milk fat content in several species including the pig, cow, and human (1). Investigations with pure isomers in the 3T3-L1 adipocyte cell culture model (2), mice (3), and lactating dairy cows (4) have revealed that the antilipogenic effects are attributable to the *trans*-10,*cis*-12 isomer. In addition, studies in dairy cows have also shown that *cis*-9,*trans*-11 (4) or a mixture of CLA isomers containing *trans*-8,*cis*-10 or *cis*-11,*trans*-13 (5) has no effect on milk fat content. Thus far, *trans*-10,*cis*-12 is the only isomer of CLA shown unequivocally to reduce milk fat synthesis in lactating dairy cows.

Formation of *trans*-10,*cis*-12 CLA in the rumen is enhanced when high concentrate–low fiber diets are fed, with an increase in ruminal formation of this isomer being related to decreases in milk fat secretion (6,7). However, during diet-induced milk fat depression, concentrations of *trans*-10,*cis*-12 CLA in milk fat are less than half those when comparable reductions in milk fat secretion are induced with postruminal *trans*-10,*cis*-12 CLA infusions (8). Furthermore, small or negligible increases in *trans*-10,*cis*-12 CLA have been reported during milk fat depression when diets containing marine oils are fed (9,10). Overall, these findings tend to suggest that other biohydrogenation intermediates formed in the rumen also may have a role in the regulation of milk fat synthesis, but the identity of these FA remains unclear.

Park and Pariza (11) reported that a mixture of conjugated nonadecadienoic acid (CNA) isomers, containing *cis*-10,*trans*-12 CNA and *trans*-11,*cis*-13 CNA as major components, decreased fat deposition in mice to a greater extent than *trans*-10,*cis*-12 CLA. Since the CNA supplement contained comparable amounts of *cis*-10,*trans*-12 CNA and *trans*-11,*cis*-13 CNA, isomer-specific effects could not be determined. Owing to the structural analogy with *trans*-10,*cis*-12 CLA, the antilipogenic effects were attributed to the *trans*-11,*cis*-13 isomer of CNA (11). However, it is possible that the antilipogenic effects of *trans*-10,*cis*-12 CLA relate to the position of the 10,12 conjugated double bond structure relative to the carboxyl rather than the methyl group of the FA moiety, with the implication that the reduction in tissue lipid accretion of CNA isomers in mice could be a direct response to *cis*-10,*trans*-12 CNA.

To test this hypothesis, the effects of a mixture of 10,12 CLA isomers containing a structural 18-carbon analog (*cis*-10,*trans*-12 CLA) as a major component on milk fat synthesis in the lactating dairy cow were examined in the current study, relative to *trans*-10,*trans*-12 CLA and the known inhibitor *trans*-10,*cis*-12 CLA.

MATERIALS AND METHODS

Experimental animals and diet. Four multiparous lactating Holstein-British Friesian cows (679 ± 10.3 kg live weight and 303 ± 25.9 d in lactation; mean ± SE) fitted with rumen fistula (100 mm i.d.; Bar Diamond, Parma, ID) were used in the present experiment lasting 56 d. All procedures used were licensed, regulated, and inspected by the United Kingdom Home Office under the Animals (Scientific Procedures) Act of 1986.

*To whom correspondence should be addressed at Animal Production Research, MTT Agrifood Research Finland, FIN 31600, Jokioinen, Finland. E-mail: kevin.shingfield@mtt.fi

Abbreviations: CNA, conjugated nonadecadienoic acid; T1, treatment with *trans*-10,*cis*-12 CLA; T2, treatment with *trans*-10,*trans*-12 CLA; T3, treatment with a mixture of 10,12 geometric isomers of CLA.

The animals were housed in individual stalls within the Metabolism Unit of the Centre for Dairy Research, University of Reading, United Kingdom. Cows were offered a total mixed ration formulated (Table 1) to meet or exceed nutrient requirements according to the Agricultural and Food Research Council (12). Diets were offered *ad libitum* and fed as equal meals at 0800 and 1600. Cows had continuous access to water and trace-mineralized salt blocks (Baby Red Rockies, Winsford, Cheshire, United Kingdom) and were milked at approximately 0600 and 1630.

Experimental design and treatments. Cows were randomly assigned treatments in a 4 × 4 Latin Square design. Treatments consisted of abomasal infusions targeted to provide 0 (control) or 4.5 g/d of *trans*-10,*cis*-12 CLA (T1), *trans*-10,*trans*-12 CLA (T2), or a mixture of 10,12 geometric isomers of CLA (T3). Infusions started at 1630 and lasted for 4 d with a 10-d interval between infusion periods to minimize treatment carry-over effects. Postruminal infusion was used as a convenient means of delivering FA to the small intestine, avoiding ruminal biohydrogenation and possible effects on the microbial population in the rumen and enabling the amount of FA supplied by each treatment to be accurately determined. Infusion lines were established using Nalgene tubing that passed through the rumen fistula and reticulo-omasal orifice and a peristaltic pump

TABLE 1
Diet Formulation and Chemical Composition

Composition	
Ingredient (g/100 g dry matter)	
Grass silage	10.0
Corn silage	30.0
Cracked wheat	16.7
Ground barley	9.2
Rapeseed meal[a]	4.1
Soybean meal	6.1
Molassed sugarbeet pulp[b]	9.2
Wheat feed (middlings)	8.2
Blended cane molasses and urea[c]	4.0
High protein corn gluten meal (Prairie meal)	1.0
Minerals and vitamins[d]	1.5
Chemical composition (g/100 g dry matter)	
Dry matter[e]	50.7
Organic matter	93.0
Crude protein	17.8
Neutral detergent fiber	26.0
Starch	31.5
Water-soluble carbohydrate	2.9
Metabolizable energy (MJ/kg dry matter)	11.8

[a]Solvent-extracted rapeseed meal of low glucosinolate content.
[b]By-product of the manufacture of sugar comprised of dried shredded sugarbeet pulp, to which molasses has been added.
[c]Regumaize 44 (SvG Intermol Limited, Bootle, Merseyside, United Kingdom). Declared composition (g/100 g dry matter) crude protein (44.0), water-soluble carbohydrate (55.0), and metabolizable energy content (11.8 MJ/kg dry matter).
[d]Proprietary mineral and vitamin supplement (Dairy Direct, Bury St. Edmonds, United Kingdom) contained (g/kg) calcium (270), magnesium (60), sodium (40), phosphorus (40), zinc (5.0), manganese (4.0), copper (1.5); (mg/kg), iodine (500), cobalt (50), selenium (15); (IU/g) retinyl acetate (500), cholecalciferol (100), dl-α-tocopheryl acetate (0.5).
[e]Oven dry matter content corrected for volatile losses (16).

(Model 202; Watson-Marlow, High Wycombe, United Kingdom) calibrated to deliver 3 kg of infusate/d. Infusions were conducted over a period of 23 h/d at a rate of 130 g/h to allow time for daily line flushing to prevent deterioration of infusion rates. Four-day infusions were used, since earlier studies showed that reductions in milk fat synthesis due to *trans*-10,*cis*-12 CLA reach a nadir after this period of infusion (4,13).

The CLA treatments in the form of nonesterified FA preparations were infused as an emulsion with skim milk. Three separate skim milk and CLA emulsions (13.5 L/treatment) were prepared in the morning before each infusion period by mixing the appropriate amount of CLA material and skim milk (85°C) with a high-shear mixer (Model L4RT; Silverson Machines, Chesham, United Kingdom) and passing each mixture through a single-stage pressure homogenizer (APV; Rannie, Copenhagen, Denmark). Two passes were performed at pressures of 200 and 50 bar, respectively, to ensure uniform dispersion of the CLA supplements in skim milk. Once prepared, emulsions were stored at 4°C before infusion.

Measurements and sampling. Individual cow intakes were measured daily during each infusion period. Representative samples of fresh diets and feed refusals were composited daily and stored at −20°C. Dry matter contents were determined after drying at 100°C for 24 h. Frozen feed samples were analyzed for volatile components or dried at 60°C, ground, and submitted for the determination of chemical composition using accredited and Parliament-approved procedures for feedstuff analysis (14,15) by a commercial laboratory (Natural Resources Management, Bracknell, United Kingdom). Dry matter content of silage was corrected for volatile losses according to Porter *et al.* (16).

Milk yields were recorded daily. Samples of milk for the determination of fat, protein, and lactose were collected from each cow at each milking 24 h before and during the 96-h infusion period. Milk samples were treated with potassium dichromate preservative (1 mg/mL; Lactabs; Thompson & Capper, Runcorn, United Kingdom) and stored at 4°C prior to analysis. Milk fat, crude protein, and lactose were determined using a Milko-Scan 133B analyzer (Foss Electric Ltd., York, United Kingdom). FA composition was determined in untreated samples of milk collected during the last 24 h of each infusion period and bulked according to yield. Milk samples for FA determinations were stored at −20°C until submitted for analysis.

Synthesis of CLA supplements. The CLA supplements were synthesized by Natural ASA (Hovdebygda, Norway) using a FA ethyl ester distillate prepared from safflower oil (Cognis GmbH, Düsseldorf, Germany) as the starting material. After dissolving in acetone and cooling to −60°C, precipitated oleic acid was removed by filtration, and the ethyl ester contained approximately 95% ethyl linoleate after solvent removal. The purified ethyl linoleate concentrate was heated at 120°C for 3 h with catalytic amounts of potassium ethoxide and ethanol (17) to yield a mixture of *cis*-9,*trans*-11 and *trans*-10,*cis*-12 ethyl esters, which contained less than 3 g/100 g of other CLA isomers. Thereafter, the mixture of conjugated ethyl esters was distilled in a molecular distillation plant, and a concentrate of *trans*-10,*cis*-12 was obtained by low-temperature crystallization at −60°C.

Precipitated material was removed and dried under vacuum. Analysis by GC confirmed the composition of the precipitate as containing (g/100 g total CLA) primarily *trans*-10,*cis*-12 (93.8) and small amounts of *cis*-9,*trans*-11 (4.0).

Part of the *trans*-10,*cis*-12 ethyl ester-enriched fraction was retained, and the remainder was isomerized by heating at 85°C under a nitrogen atmosphere and strong agitation for 9 h with 2% (by weight) concentrated nitric acid (85%) to yield a mixture of 10,12 conjugated ethyl esters. After numerous washes with hot water, oil was dried under vacuum and subjected to repeated low-temperature crystallizations, yielding two fractions containing *trans*-10,*trans*-12 or a mixture of isomers enriched with *cis*-10,*trans*-12. All conjugated ethyl ester fractions synthesized were converted to nonesterified CLA by reaction with aqueous potassium hydroxide and methanol. Reaction mixtures were neutralized with citric acid (18), and the oil obtained was washed with distilled water, dried under vacuum, and stored under nitrogen until infused.

Lipid extraction and preparation of FAME. Before extraction, milk samples were thawed, heated to 40°C, cooled to 20°C, and mixed (IKA-Ultraturrax T50; Janke & Kunkel, Staufen, Germany) for few seconds. Lipid in 1 mL of milk was extracted in duplicate using diethylether/hexane (5:4, vol/vol) according to reference procedures (IDF 1C:1987; IDF 16C:1987; International Dairy Federation, Brussels, Belgium). Extracts were combined and evaporated to dryness at 60°C under nitrogen for 1 h. Samples were dissolved in hexane and methyl acetate and transesterified to FAME using freshly prepared methanolic sodium methoxide (19). The mixture was neutralized with oxalic acid (1 g oxalic acid in 30 mL diethyl ether), centrifuged, and dried using calcium chloride (20). Lipid in samples of infused emulsified CLA treatments was extracted using the same procedures used for milk. FA in CLA supplements and infusion samples were converted to FAME using 1% (vol/vol) sulfuric acid in methanol at 50°C for 30 min (21), and the amount of CLA isomers provided by each infu-

sion treatment was determined using methyl pentacosanoate (Sigma, St. Louis, MO) as an internal standard.

GC analysis of FAME. The FAME prepared from CLA supplements, infused treatments, and milk samples were separated and quantified using a gas chromatograph (Model 6890; Hewlett-Packard, Wilmington, DE) equipped with an FID, quadrupole mass selective detector (Model 5973N; Agilent Technologies Inc.), automatic injector, split injection port, and a 100-m fused-silica capillary column (i.d., 0.25 mm) coated with a 0.2-μm film of cyanopropyl polysiloxane (CP-SIL 88; Chrompack 7489, Middelburg, The Netherlands) using hydrogen as the carrier gas operated at constant pressure (20 psi) and flow rate of 0.5 mL/min. Injector and detector temperatures were maintained at 255°C. The total FAME profile in a 2-μL sample at a split ratio of 1:50 was determined using a temperature gradient program (22). Peaks were identified using authentic FAME standards (GLC #463 and GLC #606; Nu-Chek-Prep, Elysian, MN) and comparison of EI ionization spectra of each peak with that of known standards and an online reference library (http://www.lipids.co.uk/infores/masspec.html; Christie, W.W., personal communication). Individual isomers of 18:1, 18:2, and CLA methyl esters were further resolved in a separate analysis under isothermal conditions at 170°C (22). Under these conditions, it was possible to resolve the *cis*-10,*trans*-12, *cis*-10,*cis*-12, and *trans*-10,*cis*-12 isomers, but *trans*-10,*trans*-12 CLA could not be separated from *trans*-7,*trans*-9 CLA, *trans*-8,*trans*-10 CLA, and *trans*-9,*trans*-11 CLA, which co-elute as a single GC peak (Fig. 1).

Ag⁺-HPLC analysis of FAME. The distribution of isomers in CLA supplements was determined using an HPLC system (Model 1090; Hewlett-Packard), equipped with autosampler, photodiode array detector, 20-μL injection loop, heated column compartment, and four silver-impregnated silica columns (ChromSpher 5 Lipids, 250 × 4.6 mm, 5 μm particle size; Varian Ltd., Walton-on-Thames, United Kingdom) coupled in series. Methyl esters of CLA were separated under isocratic conditions at 22°C using 0.1% (by vol) of acetonitrile (Rathburn
FIG.1. Partial gas chromatogram indicating typical separation of methyl esters of CLA prepared from milk from cows receiving postruminal infusions of a mixture of geometric 10,12 CLA isomers (treatment T3) using a 100-m fused-silica capillary column (CP-SIL 88) under isothermal conditions at 170°C. Peak identification: (1) unresolved *cis*-9,*trans*-11 CLA, *trans*-7,*cis*-9 CLA, and *trans*-8,*cis*-10 CLA, (2) *cis*-10,*trans*-12 CLA, (3) *trans*-9,*cis*-11 CLA, (4) 21:0, (5) *trans*-10,*cis*-12 CLA, (6) unresolved *cis*-9,*cis*-11 CLA and *trans*-11,*cis*-13 CLA, (7) *cis*-10,*cis*-12 CLA, (8) *trans*-11,*trans*-13 CLA, and (9) unresolved *trans*-7,*trans*-9 CLA, *trans*-8,*trans*-10 CLA, *trans*-9,*trans*-11 CLA, and *trans*-10,*trans*-12 CLA
FIG. 2. Partial silver ion-high performance liquid chromatograms indicating the separation of *cis-trans* and *trans-cis* 9,11 and 10,12 isomers of CLA methyl esters prepared from treatment T3 attained using four silver impregnated silica columns coupled in series and a mobile phase containing (A) 0.1% (vol/vol) acetonitrile in heptane (22), or (B) 2.0% (vol/vol) acetic acid (23) under isocratic conditions at 22°C. Peak identification: (1) *trans*-10,*cis*-12 CLA, (2) *cis*-10,*trans*-12 CLA, (3) *cis*-9,*trans*-11 CLA, and (4) *trans*-9,*cis*-11 CLA

Chemicals Limited, Walkerburn, United Kingdom) in heptane at a flow rate of 1 mL/min (total run time 100 min) and monitoring column effluent at 233 and 210 (reference wavelength) nm (22). Even though most isomers were well-resolved, *cis*-10,*trans*-12 and *trans*-10,*cis*-12 CLA co-elute under these conditions (Fig. 2). To achieve baseline separation of these isomers, Ag+-HPLC analysis was repeated under isocratic conditions at 22°C using 2.0% (vol/vol) of acetic acid in heptane as the mobile phase (23) at a flow rate of 1 mL/min (total run time 100 min) and monitoring column effluent at 233 and 210 (reference wavelength) nm. Typical injection volumes were 10–20 μL, representing <250 μg lipid. Identification of CLA isomers was performed using commercially available CLA methyl ester standards (Matreya Incorporated, Pleasant Gap, PA; Sigma), comparison of the elution order reported in the literature (23), and cross-referencing the GC analysis of CLA supplements with reference milk samples for which the distribution of CLA isomers had previously been determined by Ag+-HPLC (22,24). Only the isomer profile in CLA supplements was determined by Ag+-HPLC, since most of the isomers of interest

in milk samples, other than *cis*-9,*cis*-11 CLA and *trans*-10,*trans*-12 CLA, could be determined by GC analysis.

Calculations and statistical analysis. Milk FA composition was expressed as a weight percentage of total FA using response factors determined by analysis of butter oil of known FA composition (CRM 164 milk fat reference standard, Community Bureau of Reference, Brussels, Belgium). Yields of individual FA were determined using tritridecanoin (Nu-Chek-Prep) as an internal standard. Concentrations of specific conjugated isomers in CLA supplements were calculated based on proportionate peak area responses determined by both Ag+-HPLC methods and total CLA weight percentage determined by GC. Apparent transfer efficiencies of infused 10,12 CLA isomers from the abomasum into milk were calculated as: [(amount of isomer secreted in milk during CLA infusion − amount of isomer secreted during the control infusion)/amount of isomer infused]. The apparent transfer of *cis*-9,*trans*-11 CLA and total CLA were not determined, since postruminal infusions of *trans*-10,*cis*-12 CLA inhibit the conversion of *trans*-11 18:1 and reduce endogenous synthesis of *cis*-9,*trans*-11 (4,13).

Nutrient intake, milk production, and milk FA composition data measured on the last day of infusion were evaluated by ANOVA for a 4×4 Latin Square design using the mixed procedure of SAS (25). The statistical model included the random effects of cow and the fixed effects of period and experimental treatment. Treatment effects were considered significant at $P < 0.05$.

RESULTS

Supplements of nonesterified FA preparations used to supply *trans*-10,*cis*-12 CLA or *trans*-10,*trans*-12 CLA were relatively pure, whereas the mixture of geometric 10,12 isomers also contained several other positional isomers of CLA (Table 2). Preparation of CLA supplements as emulsions in skim milk supplied the targeted amounts of total CLA for treatment T2, but the amounts of *trans*-10,*cis*-12 CLA and total 10,12 CLA isomers infused for treatments T1 and T3, respectively, were marginally lower than originally intended (Table 3).

Relative to the control treatment, infusions of *trans*-10,*trans*-12 CLA had no effect on dry matter intake or milk production, whereas treatments T1 and T3 reduced ($P < 0.05$) milk fat content and output (Table 4). Infusion of treatments T1 and T3 resulted in a progressive reduction in milk fat content and secretion (Fig. 3). With the exception of reduced concentrations of lactose ($P < 0.05$) for T3 compared with T2, treatments had no effect.

Treatments caused significant increases in the concentration of specific 10,12 isomers corresponding to those contained in the infused CLA supplement (Table 5). In addition, CLA supplements also resulted in significant ($P < 0.05$) reductions in the *cis*-9 14:1/14:0, *cis*-9 16:1/16:0, *cis*-9 18:1/18:0, and *cis*-9,*trans*-11 CLA/*trans*-11 18:1 desaturase ratios, with relatively minor, but often significant, effects on the concentration of other FA in milk (Table 5). Compared with the control, treatment T2 had no effect on milk FA yield other than increasing ($P < 0.05$) the output of *trans*-10,*trans*-12 CLA in milk, but treatments T1 and T3 decreased the secretion of FA in milk

TABLE 2
FA Composition of CLA Supplements

FA[a] (g/100 g)	Treatment		
	T1	T2	T3
cis-9 18:1	0.89	0.00	2.76
trans-10 18:1	0.17	0.00	0.00
trans-11 18:1	0.19	0.00	0.00
cis-9,cis-11 CLA	0.05	0.02	3.08
cis-9,trans-11 CLA	5.89	0.29	2.80
trans-9,cis-11 CLA	0.00	0.06	2.12
trans-9,trans-11 CLA	1.08	1.30	9.40
cis-10,cis-12 CLA	0.09	0.31	5.13
cis-10,trans-12 CLA	0.00	0.00	23.18

Total CLA	98.46	100.00	96.87

[a]FA composition determined in duplicate based on a combination of GC and Ag+-HPLC analysis of methyl esters. Separation of CLA methyl esters by Ag+-HPLC analysis was conducted under isocratic conditions at 22°C using both 0.1% (vol/vol) acetonitrile in heptane (22) and 2.0% acetic acid (vol/vol) in heptane (23) as the mobile phase.

(Table 6). Reductions in the secretion of C_{4-14}, C_{16}, and C_{18-24} FA accounted for proportionately 0.33, 0.42, and 0.17, and 0.34, 0.40, and 0.22 of the total decrease in milk FA output during abomasal infusions of *trans*-10,*cis*-12 CLA and the mixture of 10,12 geometric CLA isomers, respectively.

Apparent transfer of infused *trans*-10,*cis*-12 and *cis*-10,*trans*-12 at the abomasum was similar, but *trans*-10,*trans*-12 and *cis*-10,*cis*-12 were transferred at a higher efficiency (Table 7).

DISCUSSION

Although *trans*-10,*cis*-12 is the only CLA isomer shown unequivocally to reduce milk fat synthesis in the dairy cow, there is indirect evidence that other FA produced during ruminal biohydrogenation of dietary PUFA also may elicit antilipogenic effects that are similar to or even more potent than those of *trans*-10,*cis*-12 CLA. This comes in part from examination of milk FA composition, which indicates little or no change in *trans*-10,*cis*-12 CLA during diet- induced milk fat depression

TABLE 3
Mean Amounts of CLA Isomers Delivered to the Abomasum During 4-d Infusion Periods

Amount infused[a] (g/d)	Treatment		
	T1	T2	T3
cis-9,cis-11 CLA	0.002 ± <0.001	0.001 ± <0.001	0.159 ± 0.006

[a]Cows received 4-d abomasal infusions (3 kg/d) of skim milk (control), or skim milk containing emulsified supplements of *trans*-10,*cis*-12 CLA (T1), *trans*-10,*trans*-12 CLA (T2), or a mixture of geometric isomers of 10,12 CLA (T3). See Table 2 for the FA composition of CLA supplements.
[b]Error DF, 6.
[c]Values represent the mean for day 4 of infusion for four cows. Means within row not sharing common roman superscripts differ significantly (*P* < 0.05).
FIG.3. Temporal changes in milk fat content and milk fat yield during abomasal infusion of mixtures of CLA supplements. Infusions were continuously infused during a 4-d period. Values represent means from four animals. SEM for milk fat content and milk fat yield was 1.66 g/kg and 53.8 g/d, respectively. The mean amounts of CLA isomers infused for each treatment are listed in Table 3. (+) Control, (○) T1, (▲) T2, (□) T3. For treatment descriptions see Figure 1.

when marine oils are fed and from the observation that supplements of rumen-protected CLA isomers cause larger decreases in milk fat secretion than would be expected based on milk fat *trans*-10,*cis*-12 CLA content (8,26). Reductions in milk fat yield have been reported in response to postruminal infusions of a mixture of CLA isomers devoid of *trans*-10,*cis*-12 CLA (27), and more recent studies have established that *cis*-9,*trans*-11 (4), *trans*-8,*cis*-10, and *cis*-11,*trans*-13 CLA (5) are not involved in the regulation of milk fat synthesis in the dairy cow.

The unique antilipogenic effect of *trans*-10,*cis*-12 CLA also has been demonstrated in growing mice (3) and cultured 3T3-L1 adipocytes (2), indicating a consistency in the response to *trans*-10,*cis*-12 CLA between these experimental models and the inhibitory effects on milk fat synthesis in the lactating bovine (4,13). The lactating dairy cow represents a convenient and robust means for examining potential antilipogenic effects, since changes in milk fat output can be readily quantified over a short period of time (4,13,27), occur in a predictable manner, and are sufficiently sensitive to respond to small amounts of infused FA with antilipogenic activity (28,29). Furthermore, administering CLA treatments by postruminal infusions enables the amount of FA supplied by each treatment to be accurately determined, while avoiding possible effects on the microbial population in the rumen.

It was not possible to produce *cis*-10,*trans*-12 CLA in sufficient quantities for the present experiment, and therefore a mix-

ture of CLA isomers had to be used. The *cis*-10,*trans*-12-enriched CLA supplement was composed of three main positional 10,12 isomers that accounted for proportionately 0.755 of total CLA content, but it also contained positional 9,11 isomers. The occurrence of 9,11 isomers can be attributed to the small amounts of *cis*-9,*trans*-11 ethyl esters in the *trans*-10,*cis*-12 fraction used to synthesize other positional 10,12 CLA isomers, which during isomerization were converted to ethyl esters of *trans*-9,*trans*-11 CLA, *trans*-9,*cis*-11 CLA, and *cis*-9,*cis*-11 CLA.

To account for the contribution of the major 10,12 isomers other than *cis*-10,*trans*-12 to the overall response to the mixture of CLA isomers in treatment T3, the effect of relatively pure preparations of *trans*-10,*cis*-12 CLA and *trans*-10,*trans*-12 CLA on milk fat synthesis also were evaluated. Treatments T1, T2, and T3 supplied 4.19, 4.73, and 4.03 g of geometric 10,12 CLA isomers/d, respectively. Postruminal infusions of 4.62 g *trans*-10,*trans*-12 CLA/d (treatment T2) had no effect on milk fat synthesis but decreased the ratios of *cis*-9 14:1/14:0, *cis*-9 16:1/16:0, *cis*-9 18:1/18:0, and *cis*-9,*trans*-11 CLA/*trans*-11 18:1, which serve as a proxy for Δ-9 stearoyl CoA desaturase in the mammary gland (1). Reductions in desaturase ratios in the absence of changes in milk fat yield are consistent with earlier observations (30) and underline the lack of a direct involvement of Δ-9 stearoyl CoA desaturase in the inhibition of mammary lipid metabolism.

Since postruminal *trans*-10,*trans*-12 CLA infusion had no effect on milk fat yield, the contribution of this isomer to the overall reduction in milk fat yield to treatment T3 can be discounted. Treatments T1 and T3 supplied 4.14 and 3.00 g/d of the other major 10,12 isomers, *trans*-10,*cis*-12 CLA and *cis*-10,*trans*-12 CLA, but resulted in similar decreases in milk fat secretion compared with the control (20.8 and 21.3%, respectively). The reduction in milk fat yield in response to postruminal infusions of *trans*-10,*cis*-12 CLA from treatment T1 is in line with a predicted decrease of 24.8% based on the relationship developed using data from several experiments (28). However, comparable decreases in milk fat output in response to infusions of 4.14 and 1.80 g *trans*-10,*cis*-12 CLA/d supplied by treatments T1 and T3 indicate that other conjugated isomers in the T3 supplement also inhibit milk fat synthesis.

Treatment T3 supplied small amounts of *cis*-10,*cis*-12 CLA (0.26 g/d). The possible involvement of this isomer in the decrease in milk fat synthesis can be examined by comparing the apparent transfer efficiencies of the major CLA isomers from the abomasum into milk fat. Apparent transfer of the known inhibitor *trans*-10,*cis*-12 CLA is typically lower than that of other CLA isomers that are not involved in the regulation of milk fat synthesis (5,27). These observations point toward a relatively low apparent transfer efficiency being a characteristic of conjugated FA that exert antilipogenic effects. It is interesting to note that the transfer of *trans*-10,*cis*-12 CLA and *cis*-10,*trans*-12 CLA from treatment T3 into milk were virtually identical, whereas the transfer efficiency for *cis*-10,*cis*-12 CLA was substantially higher, leading to the overall conclusion that *cis*-10,*cis*-12 CLA is unlikely to have been a causal factor underlying the reduction in milk fat yield to treatment T3 in the

current experiment. However, further studies would be required to confirm the assertion that cis-10,cis-12 CLA is not a potent inhibitor of milk fat synthesis in the dairy cow.

In addition to the 10,12 CLA isomers, the T3 supplement also contained four positional 9,11 isomers that accounted for proportionately 0.180 of total CLA content, and as such treatment T3 supplied 0.48 g trans-9,trans-11 CLA, 0.16 g cis-9,cis-11 CLA, 0.14 g cis-9,trans-11 CLA, and 0.11 g trans-

[a]Cows received 4-d abomasal infusions (3 kg/d) of skim milk (control), or skim milk containing emulsified supplements of *trans*-10,*cis*-12 CLA (T1), *trans*-10,*trans*-12 CLA (T2), or a mixture geometric isomers of 10,12 CLA (T3). See Table 2 for the FA composition of CLA supplements.
[b]Error DF, 6. Means within a row not sharing common roman superscripts differ significantly (*P* < 0.05).
[c]Values represent the mean for day 4 of infusion for four cows. FA composition was determined by GC using both a temperature gradient and isothermal conditions for the separation of 18:1 and 18:2 isomers.
[d]Sum of 18:2 excluding isomers of CLA.
[e]Refers to unresolved *trans*-7,*cis*-9 CLA, *trans*-8,*cis*-10 CLA, and *cis*-9,*trans*-11 CLA.
[f]Refers to unresolved *trans*-7,*trans*-9 CLA, *trans*-8,*trans*-10 CLA, *trans*-9,*trans*-11 CLA, and *trans*-10,*trans*-12 CLA.

9,*cis*-11 CLA/d. Postruminal infusions of *cis*-9,*trans*-11 CLA (4) or *trans*-9,*trans*-11 CLA (31), the predominant 9,11 isomer in treatment T3, are known to have no effects on milk fat synthesis in the dairy cow. Although there is evidence in the literature that *trans*-9,*cis*-11 CLA concentrations are increased in milk from cows fed diets causing milk fat depression (10,24) and may contribute to the reduction in milk fat synthesis when infused postruminally (31), the amount of this isomer supplied by the T3 infusion is very small. Furthermore, a lack of increase in the concentration of *trans*-9,*cis*-11 CLA in milk, which is known to be efficiently transferred in response to postruminal infusions (31), suggests that the amounts of *trans*-9,*cis*-11 CLA available to the mammary gland were extremely small and therefore unlikely to have had a significant role in the regulation of milk fat synthesis in the current experiment. Under the GC conditions used in this study, *cis*-9,*cis*-11 CLA and *trans*-11,*cis*-13 CLA are not resolved and elute as a single peak (22). However, there was no change in the concentration of these co-eluting isomers in milk fat from cows infused with treatment T3, suggesting that the concentration of *cis*-9,*cis*-11 CLA was not substantially increased. In light of the nonsignificant changes in milk fat *cis*-9,*cis*-11 and *trans*-11,*cis*-13 concentrations, it is probable that the amounts of *cis*-9,*cis*-11 CLA available to the mammary gland were not sufficiently large to contribute significantly to the decrease in milk fat yield in response to treatment T3.

It is evident that the decreases in milk fat synthesis in response to treatment T3 are not explained by the amounts of *trans*-10,*cis*-12 CLA supplied by this infusion. *Cis*-10,*trans*-12 was the second-most abundant CLA isomer in treatment T3, and was transferred from the abomasum into milk at a similar efficiency as the known inhibitor *trans*-10,*cis*-12 CLA. In view of the amount of *cis*-10,*trans*-12 CLA supplied by treatment T3 (1.19 g/d), comparable transfer characteristics to the known inhibitor *trans*-10,*cis*-12 CLA, and the relative amounts of other CLA isomers, effects of which can largely be accounted for, leads to the overall conclusion that *cis*-10,*trans*-12 CLA contributed to the reduction in milk fat synthesis in response to treatment T3.

TABLE 7
Apparent Transfer of CLA Isomers from the Abomasum into Milk Fat for Different CLA Supplements

Transfer efficiency[b] (%)	Treatment[a]		
	T1	T2	T3
cis-10,cis-12 CLA	—		39.6 ± 11.52
cis-10,trans-12 CLA	—		16.7 ± 1.69
trans-10,cis-12 CLA	19.2 ± 4.88		14.9 ± 2.03
trans,trans CLA[c]	—	23.0 ± 5.19[d]	

[a]Cows received 4-d abomasal infusions (3 kg/d) of skim milk (control) or skim milk containing emulsified supplements of trans-10,cis-12 CLA (T1), trans-10,trans-12 CLA (T2), or a mixture of 10,12 geometric isomers of CLA (T3). See Table 2 for the FA composition of CLA supplements.
[b]Values represent the apparent transfer efficiency (mean ± SD) from the abomasum into milk for four cows on day 4 of infusion.
[c]Transfer of trans-10,trans-12 CLA was unable to be calculated for treatment T3 owing to the contribution of trans-9,trans-11 in the infused CLA supplement and co-elution of trans-9,trans-11 with trans-10,trans-12 CLA under the GC conditions used to determine milk FA composition.
[d]Infused CLA supplement delivered only small amounts of trans-9,trans-11 CLA (Table 3), and therefore the increase in trans-7,trans-9 CLA, trans-8,trans-10 CLA, trans-9,trans-11 CLA, and trans-10,trans-12 CLA content in milk determined by GC was assumed to be trans-10,trans-12 CLA.

Park and Pariza (11) reported a dramatic reduction in the fat content of growing mice fed supplements containing a mixture of CNA isomers enriched with cis-10,trans-12 19:2 and trans-11,cis-13 19:2. Data from the present experiment suggest that, by structural analogy with cis-10,trans-12 CLA, the cis-10,trans-12 19:2 rather than trans-11,cis-13 19:2 was the isomer of CNA with antilipogenic properties. Furthermore, the effect of CNA on body fat in growing mice was significantly greater than a mixture of CLA isomers containing cis-9,trans-11 CLA and trans-10,cis-12 CLA. Milk fat responses observed in the current study tend to support an increased potency of 10,12 conjugated FA when the trans-10,cis-12 arrangement of double bonds is substituted for the cis-10,trans-12 structure. However, it is important to recognize that the difference in potency between the two 10,12 CLA isomers infused in this experiment was less dramatic in terms of milk fat synthesis compared with the differences in lipid accretion of growing mice fed a mixture of cis-10,trans-12 CNA and trans-11,cis-13 CNA relative to trans-10,cis-12 CLA (11).

Evaluation of several CLA cognates on glycerol release and TAG accumulation in cultured 3T3-L1 adipocytes has pointed toward a trans-10,cis-12 double bond arrangement in conjunction with a free carboxyl group on the first carbon atom as being an integral structural component for antilipogenic effects, with the implication that either a trans-10 or cis-12 double bond is an essential feature (2). Data from the present experiment tend to suggest that the antilipogenic effects of 10,12 geometric isomers of CLA containing both a cis and trans double bond are more pronounced when the double bond closest to the carboxyl group. In support of this, TAG accumulation in fully differentiated 3T3-L1 adipocytes has recently been shown to be reduced during incubation with cis-10 17:1 or cis-10 19:1, albeit to a lesser extent than trans-10,cis-12 CLA, whereas trans-10 17:1 and trans-10 19:1 have no effect (2). Overall these findings are consistent with the position and orientation of the double bond relative to the carboxyl group of the FA moiety being fundamental to the inhibitory effects on lipid accretion in cultured adipocytes or milk fat synthesis in lactating dairy cows.

Further support for the importance of an uninterrupted carbon chain between the trans-10,cis-12 double bond structure and the carboxyl group is provided by studies that have examined the effects of calendic acid (trans-8,trans-10,cis-12 18:3) on body composition of growing mice (32), conjugated 18:3 (cis-6,trans-10,cis-12 18:3) on milk fat synthesis in dairy cows (33), and methyl-branched CLA (α-methyl trans-10,cis-12 18:2) on fat accumulation in adipocytes and hepatocytes (34). In all experimental models the addition of the double bond or a methyl group between the terminal carboxyl group and the trans-10,cis-12 conjugated bond system abolished or markedly reduced the inhibitory effects on lipid synthesis associated with the trans-10,cis-12 carbon–carbon double bond structure.

A complex mixture of CLA isomers was used to examine the role of cis-10,trans-12 CLA in the regulation of milk fat synthesis in the current study. Even though the data suggest that cis-10,trans-12 CLA is a potent inhibitor of milk fat synthesis, these findings need to be confirmed in studies using higher-purity cis-10,trans-12 CLA preparations. Since the unique inhibitory effects of trans-10,cis-12 CLA on lipid synthesis have been demonstrated both in the lactating dairy cow (4,13) and the 3T3-L1 adipocyte cell culture model (2,34), a small amount of cis-10,trans-12 CLA was purified from the isomer mixture infused in this study (treatment T3) and used to examine the effects of this isomer on lipid accumulation of murine 3T3-L1 adipocytes. Adipocyte cells were cultured with cis-10,trans-12 CLA, trans-10,cis-12 CLA, cis-9,trans-11 CLA, or a control medium. Both cis-10,trans-12 CLA and trans-10,cis-12 CLA markedly reduced lipid accumulation (0.27 and 0.24 mg TAG/mg protein, respectively) compared with the control or cis-9,trans-11 CLA treatments (corresponding values 1.00 and 1.20, respectively) (35).

In conclusion, postruminal infusions of a mixture of 10,12 CLA isomers were found to result in similar decreases in milk fat output as relatively pure preparations of trans-10,cis-12 CLA. Comparable reductions in milk fat synthesis in response to 1.80 and 4.14 g trans-10,cis-12/d, supplied by treatments T3 and T1, indicate that other isomers of CLA have the potential to exert antilipogenic effects. Trans-10,trans-12 CLA had no effect on mammary lipid metabolism, and the evidence from this experiment points toward cis-10,trans-12 exerting at least as potent antilipogenic effects as the known inhibitor trans-10,cis-12 CLA.

ABSTRACT: The present work characterizes novel FA in the royal jelly of honeybees (*Apis mellifera*). TLC analysis showed that the chloroform/methanol extract obtained from royal jelly consists mainly of FA. The FABMS spectrum of this extract gave several ion peaks due to compounds with higher M.W. than those of the FA so far reported. The methanol extract was found to contain unknown phospholipids. By means of reversed-phase HPLC with various solvent systems, 13 compounds were obtained in pure state. Their structures including absolute configurations were determined by chemical, NMR, and MS spectral analysis. Six compounds were identified as novel mono- or diesters of 10-hydroxy-2*E*-decenoic acid in which the hydroxyl group was esterified by another FA unit, and one was hydroxy-2*E*-decenoic acid 10-phosphate. In addition, we demonstrated that 9-hydroxy-2*E*-decenoic acid exists as a mixture of optical isomers.

Paper no. L9758 in *Lipids 40*, 833–838 (August 2005).

Royal jelly is a thick, milky substance secreted from the hypopharyngeal and mandibular glands of young worker honeybees. Royal jelly is the sole food of queen bees for all their lives; it is also a popular traditional health food all over the world. Many studies of its biological activities as well as chemical composition have been conducted (1–4).

Up to now, various compounds such as proteins, sugars, lipids, vitamins, minerals, and free amino acids have been identified as its constituents (5,6). In particular, FA are regarded as unique and chemically interesting constituents of royal jelly. Unlike organic acids of most animal and plant materials, the FA of royal jelly have 8–10 carbon atoms, and they are usually either hydroxy FA or dicarboxylic acids (7).

Among them, a major FA was characterized as 10-hydroxy-2*E*-decenoic acid (10-HDA); it constitutes approximately 70% of the diethyl ether-soluble fraction (8–11).

This FA is considered to be one of the active ingredients in royal jelly, and it has been found to have some pharmacological activities (12–14).

Recently we found that the chloroform/methanol extract obtained from royal jelly contains several acids with higher M.W. than those of the FA so far reported. The methanol extract gave, unlike the dark blue spots of the usual glycerophospholipids, a pale blue spot with Dittmer–Lester's reagent (15) on TLC, indicating the presence of new compounds possessing a phosphorus atom.

This study was undertaken to analyze these components in the lipid fraction of royal jelly. By application of a preparative HPLC technique for the isolation of intact compounds in the pure state, 12 FA and one phosphate were obtained from the chloroform/methanol and methanol extracts, respectively. From chemical and NMR and MS spectral data, it was proven that six compounds were novel mono- or diesters of 10-HDA in which the hydroxyl group was esterified by another FA unit, and one was HDA 10-phosphate. Furthermore, we found that 9-HDA exists in royal jelly as an enantio-mixture (*R/S*) in a ratio of *ca* 2:1.

MATERIALS AND METHODS

Materials. Lyophilized royal jelly powder (from China, lot no. 030411B) was supplied by Yamada Apiculture Center Inc. (Okayama, Japan). A voucher specimen was deposited in the Faculty of Pharmaceutical Sciences, Setsunan University.

Instrumentation. Optical rotations were measured at 25°C with a JASCO DIP-140 polarimeter (JASCO, Tokyo, Japan). ^{1}H and ^{13}C NMR spectra were recorded on a JEOL JMN GX400 or ECA 600SN spectrometer (JEOL, Tokyo, Japan), using tetramethylsilane as an internal reference. ^{31}P NMR spectra were recorded on JEOL ECA 600SN using 85% phosphoric acid as an external reference. All samples were measured at a probe temperature of 35°C. The 2-D heteronuclear multiple-bond correlation (HMBC) spectrum was recorded at 600 MHz with 64 scans ($^{2,3}J_{CH}$ = 8 Hz). EI-MS and FABMS, including high-resolution MS, were recorded on a JEOL JMS-700T spectrometer. (EI-MS: ionization voltage, 30 eV; accelerating voltage, 10 kV; FABMS: accelerating voltage, 5 kV; matrix, glycerin or triethanolamine; collision gas, He). TLC was carried out on silica-gel precoated Al sheets (Merck, Darmstadt, Germany). Spots were visualized with 5% sulfuric acid in methanol (by heating) or Dittmer–Lester's reagent. Column

---

chromatography was carried out on Diaion HP-20 (Mitsubishi Chemical Co., Tokyo, Japan), Sephadex LH-20 (Amersham Pharmacia Biotech AB, Uppsala, Sweden), silica gel (Kieselgel 60; Merck), and Cosmosil 75C$_{18}$-OPN (Nacalai Tesque, Inc., Tokyo, Japan). Preparative HPLC was conducted over Mightysil RP-18 GP (5 µm, 20 × 250 mm; Kanto Chemical Co. Inc., Tokyo, Japan), and Mightysil RP-18 GP Aqua (5 µm, 10 × 250 mm; Kanto Chemical Co., Inc.) columns with a JASCO 980-PU (JASCO). The elution profile was monitored by a refractive index detector, RI504R (GL Sciences Inc., Tokyo, Japan).

Isolation of compounds, 1–13. Lyophilized royal jelly powder (1.5 kg) was percolated with 3 L of chloroform, 3 L of chloroform/methanol (2:1, vol/vol), and then 5 L of methanol, successively, each for 7 d at room temperature. Each of the extracts was concentrated *in vacuo* to give chloroform (121.7 g), chloroform/methanol (45.4 g), and methanol (192.3 g) extracts. The chloroform/methanol extract (25.0 g) was chromatographed on a Cosmosil 75C$_{18}$-OPN column using 80% methanol to give two fractions, fr. I (20.7 g) and fr. II (4.0 g). Fr. I (1.5 g) was separated by a Cosmosil 75C$_{18}$-OPN column using 50% methanol to give a mixture of FA. It was further separated on a reversed-phase column (Mightysil RP-18 GP Aqua column) using 70% acetonitrile to give compounds **1** (56.1 mg), **2** (36.7 mg), **3** (3.2 mg), **4** (25.4 mg), **5** (6.7 mg), and **6** (3.7 mg), together with a less polar fraction. The latter fraction (110 mg) was separated by a Mightysil RP-18 GP column using 30% acetonitrile to give compounds **7** (8.7 mg), **8** (14.7 mg), and **9** (15.4 mg). Fr. II (128 mg) was subjected to preparative HPLC with a Mightysil RP-18 GP Aqua column using 80% acetonitrile to give compounds **10** (22.2 mg), **11** (20.3 mg), and **12** (4.2 mg) (Scheme 1). The methanol extract (1.8 g) was placed on a Diaion HP-20 ion exchange resin, washed with excess water, and then eluted with methanol. The methanol layer was concentrated *in vacuo* and chromatographed on silica gel (chloroform/methanol/water, 7:3:0.5 by vol). The eluates were monitored by TLC using chloroform/methanol/water (6:4:1, by vol). Those eluates showing a positive spot on spraying with Dittmer–Lester's reagent (15) were combined and concentrated *in vacuo* to give compound **13** (53.0 mg) (Scheme 1). **1**: FABMS *m/z*: 185 [M − H]⁻. **5**: [α]$_D$ +6.45° at 0.3 g/100 mL in methanol. **7**: High-resolution FABMS *m/z*: 327.2171 (calcd. for C$_{18}$H$_{31}$O$_5$: 327.2172) [M − H]⁻. FABMS *m/z*: 327 [M − H]⁻ (100%), 185 (30%), 159 (38%). **8**: m.p. 35.5–37.0°C. *m/z*: 355 [M − H]⁻ (100%), 187 (26%), 185 (21%), 169 (7%). **9**: m.p. 55.5–58.0°C. *m/z*: 369 [M − H]⁻ (100%), 201 (13%), 185 (20%)). **10**: m.p. 33.0–35.0°C. [α]$_D$ −7.89° at 0.9 g in chloroform. *m/z*: 355 [M − H]⁻ (100%), 187 (38%), 185 (47%). **11**: m.p. 35.0–40.0°C. *m/z*: 497 [M − H]⁻ (100%), 355 (10%), 329 (10%), 185 (19%), 159 (27%). **12**: m.p. 43.0–45.0°C. *m/z*: 525 [M − H]⁻ (100%), 357 (7%), 355 (7%), 187 (28%), 185 (18%), 169 (10%). **13**: Powder, m.p. 260.0–290.0°C (dec.). High-resolution FABMS *m/z*: 265.0843 (calcd. for C$_{10}$H$_{18}$O$_6$P: 265.0841) [M − H]⁻. *m/z*: 265 [M − H]⁻ (100%), 185 (8%). ¹H and ¹³C NMR (600 Mz) spectral data of **1** and **7–13** are shown in Tables 1 and 2.

Methanolysis of 7–12. Compounds **7** through **12** (*ca.* 1.0 mg) were each heated with 3% methanolic hydrogen chloride (0.3 mL) at 90°C for 1 h. The reaction mixture was shaken with 2 mL of chloroform/water (1:1, vol/vol), and the lower layer was analyzed by GC on a Hitachi G-3000 SLF (Hitachi, Tokyo, Japan) using a fused-silica Capillary Column Bonded MPS-50 (OV-17; 0.25 mm × 50 m; column temperature, 230°C; carrier gas, He 33.4 mol; GL Sciences Inc., Tokyo). Retention time (min): 4.6 (methyl 8-hydroxy-octanoate) and 6.0 (methyl 10-hydroxy-2-decenoate) from **7**, 5.4 (methyl 10-hydroxy-decanoate) and 6.0

the mixture was left to stand at room temperature overnight. After removal of the solvent under a nitrogen stream, the reaction mixture was subjected to silica gel column chromatography (*n*-hexane/ethylacetate, 5:1, vol/vol) to give a MTPA derivative. **(–)-MTPA ester of methyl ester of 5**: ^{1}H NMR (400 MHz, CDCl$_3$) δ: 1.28–1.70 (12H, *m*, CH$_2$ × 6), 2.56 (1H, *dd*, *J* = 4.8, 16.0 Hz, Ha-2), 2.64 (1H, *dd*, *J* = 8.0, 16.0 Hz, Hb-2), 3.52 (3H, *s*, OCH$_3$), 3.55 (3H, *s*, OCH$_3$), 3.59 (3H, *s*, CO$_2$CH$_3$), 4.30 (2H, *m*, H$_2$-10), 5.46 (1H, *m*, H-3), 7.40 (6H, *m*, Ph), 7.52 (4H, *m*, Ph). **(+)-MTPA ester of methyl ester of 5**: ^{1}H NMR (400 MHz, CDCl$_3$) δ: 1.20–1.68 (12H, *m*, CH$_2$ × 6), 2.59 (1H, *dd*, *J* = 4.8, 16.0 Hz, Ha-2), 2.69 (1H, *dd*, *J* = 8.4, 16.0 Hz, Hb-2), 3.54 (3H, *s*, OCH$_3$), 3.55 (3H, *s*, OCH$_3$), 3.66 (3H, *s*, CO$_2$CH$_3$), 4.30 (2H, *m*, H$_2$-10), 5.46 (1H, *m*, H-3), 7.40 (6H, *m*, Ph), 7.52 (4H, *m*, Ph). **(–)-MTPA ester of methyl ester of 6**: ^{1}H NMR (400 MHz, CDCl$_3$) δ: 1.16–1.66 (8H, *m*, CH$_2$ × 4), 1.26 (0.96H, *d*, *J* = 6.4 Hz, H$_3$-10 of *S*-form), 1.33 (2.04H, *d*, *J* = 6.4 Hz, H$_3$-10 of *R*-form), 2.15 (2H, *m*, H$_2$-4), 3.53 (0.94H, *m*, OCH$_3$ of *S*-form), 3.56 (2.04H, *m*, OCH$_3$ of *R*-form), 3.73 (3H, *s*, CO$_2$CH$_3$), 5.13 (1H, *m*, H-9), 5.80 (0.68H, *dt*, *J* = 1.6, 15.6 Hz, H-2 of *R*-form), 5.82 (0.32H, *dt*, *J* = 1.6, 15.6 Hz, H-2 of *S*-form), 6.94 (1H, *m*, H-3), 7.38–7.42 (3H, *m*, Ph), 7.52–7.55 (2H, *m*, Ph). **(+)-MTPA ester of methyl ester of 6**: ^{1}H NMR (400 MHz, CDCl$_3$) δ: 1.16–1.66 (8H, *m*, CH$_2$ × 4), 1.26 (2.04H, *d*, *J* = 6.4 Hz, H$_3$-10 of *R*-form), 1.33 (0.96H, *d*, *J* = 6.4 Hz, H$_3$-10 of *S*-form), 2.15 (2H, *m*, H$_2$-4), 3.53 (2.04H, *m*, OCH$_3$ of *R*-form), 3.56 (0.96H, *m*, OCH$_3$ of *S*-form), 3.73 (3H, *s*, CO$_2$CH$_3$), 5.13 (1H, *m*, H-9), 5.80 (0.32H, *dt*, *J* = 1.6, 15.6 Hz, H-2 of *S*-form), 5.81 (0.68H, *dt*, *J* = 1.6, 15.6 Hz, H-2 of *R*-form), 6.94 (1H, *m*, H-3), 7.38–7.42 (3H, *m*, Ph), 7.52–7.55 (2H, *m*, Ph). **(–)-MTPA ester of methyl ester of 10**: ^{1}H NMR (400 MHz, CDCl$_3$) δ: 0.88 (3H, *J* = 7.2 Hz, H$_3$-10′), 1.20–1.68 (22H, *m*, CH$_2$ × 11), 2.20 (1H, *ddt*, *J* = 1.2, 6.5, 6.8 Hz, H$_2$-4), 2.56 (1H, *dd*, *J* = 4.8, 16.0 Hz, Ha-2′), 2.65 (1H, *dd*, *J* = 8.4, 16.0 Hz, Hb-2′), 3.53 (3H, *s*, OCH$_3$), 3.73 (3H, *s*, CO$_2$CH$_3$), 3.98 (2H, *t*, *J* = 6.8 Hz, H$_2$-10), 5.48 (1H, *m*, H-3′), 5.81 (1H, *dt*, *J* = 1.2, 15.6 Hz, H-2), 6.97 (1H, *dt*, *J* = 6.8, 15.6 Hz, H-3), 7.26–7.41 (3H, *m*, Ph), 7.52–7.54 (2H, *m*, Ph). **(+)-MTPA ester of methyl ester of 10**: ^{1}H NMR (400 MHz, CDCl$_3$) δ: 0.87 (3H, *J* = 7.2 Hz, H$_3$-10′), 1.20–1.68 (22H, *m*, CH$_2$ × 11), 2.19 (1H, *ddt*, *J* = 1.2, 6.5, 6.8 Hz, H$_2$-4), 2.60 (1H, *dd*, *J* = 4.8, 16.0 Hz, Ha-2′), 2.70 (1H, *dd*, *J* = 8.4, 16.0 Hz, Hb-2′), 3.54 (3H, *s*, OCH$_3$), 3.73 (3H, *s*, CO$_2$CH$_3$), 4.08 (2H, *t*, *J* = 6.4 Hz, H$_2$-10), 5.48 (1H, *m*, H-3′), 5.82 (1H, *dt*, *J* = 1.2, 15.6 Hz, H-2), 6.97 (1H, *dt*, *J* = 6.8, 15.6 Hz, H-3), 7.26–7.42 (3H, *m*, Ph), 7.52–7.55 (2H, *m*, Ph). The ratio of *R* to *S* of **6** was determined by the intensity of the signals arising from both enantiomers.

RESULTS AND DISCUSSION

Isolation of compounds 1–13. Lyophilized royal jelly powder was extracted successively with chloroform, chloroform/methanol, and methanol. TLC analysis showed that the chloroform and chloroform/methanol extracts consisted mainly of FA.

As described in the Materials and Methods section, we applied a preparative HPLC technique to separate the components of the chloroform/methanol extract and isolated 12 FA (**1–12**) in a pure state (Scheme 1).

On thin-layer plates, the methanol extract gave a pale blue spot with Dittmer–Lester's reagent (15). Its color and R_f value differed from those of common glycerophospholipids, suggesting that the extract contained unknown phospholipids. Separation with a Diaion HP-20 followed by purification by silica gel column chromatography yielded considerable amounts of compound **13**.

Structures of FA, 1–6. Compounds **1–6** were identified, respectively, as 10-HDA (**1**); 8-hydroxy-octanoic (**2**), 10-hydroxy-decanoic (**3**), 9-carboxy-2*E*-nonenoic (**4**), and 3,10-di-hydroxy-decanoic (**5**) acids; and 9-HDA (**6**), based on their NMR and MS spectral data.

The absolute configurations of compounds **5** and **6** were determined by a modified Mosher's method (16,17).

The methyl ester of **5** was converted into its (–)- and (+)-MTPA esters. The ^{1}H NMR spectra of the (±)-MTPA esters showed that the Δδ values [the chemical shift differences, Δδ: δ(–)-MTPA ester − δ(+)-MTPA ester] with regard to the respective Ha-2, Hb-2, and ester methyl proton signals were −0.03, −0.05, and −0.07 ppm. These observations confirmed the configuration of C-3 in **5** to be *R*.

The ^{1}H NMR spectrum of the (–)-MTPA derivative derived from the methyl ester of 9-HDA (**6**) exhibited two sets of signals in the ratio of *ca*. 2:1. Major signals at δ 1.33 and 5.80 were assigned, respectively, as H$_3$-10 and H-2 of a derivative having the *R* configuration, whereas minor signals at δ 1.26 and 5.82 were assigned as those of *S*. The ^{1}H NMR spectrum of the (+)-MTPA derivative also gave two sets of signals similar to those of the (–)-MTPA ester. These findings showed that 9-HDA was a mixture of optical isomers (*R/S*) in a ratio of *ca* 2:1. Scheme 2 shows their structures.

Structures of monoesters of 10-HDA, 7–10. The molecular formula, C$_{18}$H$_{32}$O$_5$, of **7** was established by high-resolution FABMS. The ^{1}H NMR spectrum of **7** showed two *trans* olefinic (δ 5.82, 7.06), hydroxy methyl (δ 3.64), and allylic (δ 2.23) proton signals that were quite similar to those of 10-HDA. In addition, together with approximately 20 aliphatic proton signals, two hydroxy methyl proton signals appeared at δ 4.06 and 2.30. The ^{13}C NMR spectrum exhibited two olefinic (δ 120.7, 152.1) and two carbonyl carbon signals (δ 171.2, 174.0) (Tables 1 and 2). These findings indicated that **7** was a monoester of 10-HDA in which the hydroxyl group was esterified by another FA unit.

Methanolysis of **7** with 3% methanolic hydrogen chloride liberated two FAME. They were identified as methyl esters of 10-HDA and **2** by GC and EI-MS analysis. In the HMBC spectrum of **7**, one carboxyl carbon (δ 171.2, C-1) showed correlation with two olefinic protons (H-2 and H-3), and the other (δ 174.0) showed cross peaks with three protons (H-10, H-2′, and H-3′). The preceding information, combined with the observation of fragment peaks at *m/z* 159 and 185 in its FABMS spectrum, showed that the structure of compound **7** was 10-(8′-hydroxyoctanoyloxy)-2*E*-decenoic acid (Fig. 1).
SCHEME 2

The structures of **8**, **9**, and **10** were elucidated in the same manner as described for **7**. Their chemical and spectral data revealed that they were also monoesters of 10-HDA differing in the FA residue. The configuration of the chiral center in **10** was proven to be *R*.

*Structures of diesters of 10-HDA, **11** and **12**.* The FABMS spectrum of **11** exhibited a [M − H]⁻ ion peak at *m/z* 497, and its mass was approximately three times more than those of known FA in royal jelly. From its ^{1}H and ^{13}C NMR spectral data, **11** was considered to be a diester composed of three FA units involving a 10-HDA residue.

Methanolysis of **11** gave three products, which were identified as methyl esters of compounds **1**, **2**, and **3**. The HMBC spectral data together with diagnostically important fragment ion peaks observed at *m/z* 159 and 329 in its FABMS revealed the sequence of the three FA units; therefore, the structure of **11** was characterized as shown in Figure 2.

Compound **12** was identified in the same manner as described for **11**; it was found to be another diester of 10-HDA that differed from **11** in the FA residue. The terminal 8-hydroxy-octanoyl unit in **11** was replaced by a 10-hydroxy-decanoyl group.

*Structure of 10-HDA phosphate (**13**).* The molecular formula of **13** was determined to be $C_{10}H_{18}O_6P$ by high-resolution FABMS. The presence of one phosphate was further substantiated by a signal at δ 25.6 ppm in the ^{31}P NMR spectrum. Its ^{1}H NMR spectrum showed, on comparison with that of 10-HDA, the signals ascribable to H_2-10 shifted downfield (0.33 ppm). Furthermore, in the ^{13}C NMR spectrum, the signals due to C-9 (*J* = 8.3 Hz) and C-10 (*J* = 4.9 Hz) appeared as doublets owing to coupling with ^{31}P (18). Accordingly, the phosphate group was located at the C-10 position, and the structure of **13** was thus characterized as shown in Scheme 2.
FIG. 1. Heteronuclear multiple-bond correlation of **7**.
FIG. 2. Heteronuclear multiple-bond correlation of **11**.

We isolated seven novel FA esters along with six known FA from the lipid fraction of royal jelly.

In a study of the activity of 10-HDA on tumor cells, Robinson (19) presumed that polyesters were formed from 10-HDA. Later, Pain and coworkers (20) predicted the existence of di- or oligoesters of 10-HDA in the lipid fraction of queen larvae. However, no report on their isolation has so far appeared. We demonstrated that esters of 10-HDA are present in royal jelly.

We also found that royal jelly contains significant amounts of HDA 10-phosphate. In addition, it should be noted that, among the FA having the secondary hydroxyl group isolated in this study, only 9-HDA exists in royal jelly as a mixture of enantiomers.

ABSTRACT: A series of pH-sensitive lipids, **1a–h** [(2,3-bis-alkyl-carbamoyloxy-propyl)-trialkylammonium halide] and **2a–d** (1-dimethylamino-2,3-bis-alkylcarbamoyloxy-propane), with carbamate linkages between the hydrocarbon chains and an ammonium or tertiary amine head, were synthesized for liposome-mediated gene delivery. The variable length of the carbon chains and the quaternary ammonium or neutral tertiary amine heads allowed us to identify the structure–function relationship showing how these factors would affect cationic lipids in gene delivery performance.

Paper no. L9790 in *Lipids 40*, 839–848 (August 2005).

In 1987, Felgner and coworkers (1) first reported the utilization of an unnatural diether-linked cationic lipid as a synthetic carrier to deliver genes to cells. Since then, a number of published reports have described strategies for synthesizing versatile cationic lipids for gene delivery (for reviews of cationic lipid synthesis, see Refs. 2 and 3). These studies cover diverse kinds of cationic lipids, such as glycerol backbone-based, cholesterol-based, cationic peptide-based, poly(ethylenimine)-based, and poly(L-lysine)-based structures (4–18). Cationic lipids, with their prominent nonimmunogenic character and low cellular toxicity in delivering genes, have engendered considerable interest among researchers in the gene therapy community (19,20). It is generally believed that electrostatic interaction brings cationic lipids and polyanionic DNA together to form DNA/liposome complexes. These complexes, once exposed to cells, are then taken up by the cells and the inserted gene is expressed. Most of the spacers in the aforementioned synthesized lipids are ether, ester, or amide bonds, which are either too stable to be biodegraded and thus cause cytotoxicity (e.g., ether linkers) or liable to decompose in the circulation system (e.g., ester linkers). In contrast with these strategies, in a previous paper (21) we developed six carbamate-linked lipids (**1a**, **1d**, **1e**, **1h**, **2a**, and **2d)** having either quaternary ammonium or neutral tertiary amine heads for the purpose of taking advantage of the pH sensitivity of the carbamate bond (Scheme 1).

In our previous work, the dodecyl and octadecyl length of the carbon chain were selected because they represented the two extremes of short and long; however, a series of cationic lipids covering the carbon chain lengths C_{12}, C_{14}, C_{16}, and C_{18} were needed to discuss the gene-delivery properties of these kinds of lipids. In this paper, we introduce the synthesis of the aforementioned lipids **1a–h** and **2a–d**.

Compounds that include a carbamate bond are known to be stable in neutral circumstances and prone to acid-catalyzed hydrolysis. For example, di-*tert*-butyl dicarbonate $[O(boc)_2]$ is usually used as an excellent amino-protective reagent because the carbamate formed can remain stable in the foregoing reaction and can be acid-hydrolyzed in acidic conditions (22). As is well known, the pH value within the cell is 1~2 pH units lower than that in the circulation system; thus, these carbamate-linked lipids are expected to remain stable within the circulation system but decompose to release DNA after entering the cell because of the decrease in pH from outside to inside the cell. Our idea coincides somewhat with those of Boomer and Thompson (23) and Boomer *et al.* (24), who adopted a vinyl ether bond as the linkage in their lipids. Quaternary ammonium heads with or without an ethyl group were used to determine whether different cationic heads would influence their binding with DNA phosphates. Iodide ions rather than chloride ions were adopted here as the counterions to investigate the gene-delivery properties of these kinds of ions; we expected that they would be unlikely to have significantly different gene-delivery properties since the DNA phosphates would exchange with these counterions during the complexation step preceding transfection.

To acquire the aforementioned eight cationic lipids, four intermediates were synthesized, **2a–d**. Compound **2** was then converted to **1** through quaternization with suitable halogenated hydrocarbons. Cationic lipids are known to combine well with the anionic DNA through electrostatic attraction to form DNA/liposome complexes, yet cationic liposomes may also cause cytotoxicity. Here we used the neutral intermediates **2a** and **2b** as a kind of lipid vector and found that liposomes could be formed through the Bangham method (1,25). These lipids are expected to reduce the cytotoxicity caused by their cationic counterparts.

EXPERIMENTAL PROCEDURES

Reagents and apparatus. 3-Chloro-1,2-propanediol, a 33% aqueous dimethylamine solution, laurylamine, tetradecylamine,

hexadecylamine, bis(trichloromethyl)carbonate (BTC), triethyl-amine, and sodium hydroxide (all analytically pure) were from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China). Octadecanamine (analytically pure) was from Acros Organics (Fairlawn, NJ). All solvents (analytically pure) were from Sinopharm Chemical Reagent Co. Ltd.

A model HP6890 gas chromatograph–HP5973 mass spectrometer, a model HP1100 electrospray ionization mass spectrometer, a Micromass LC/Q-TOF high-resolution mass spectrometer, and a Varian INOVA 400-MHz nuclear magnetic resonance spectrometer were used to analyze the products. A model JEM-2000EX transmission electron microscope (JEOL, Tokyo, Japan) was used for transmission electron microscopy (TEM). A KQ218 ultrasonic instrument (Kunshan Ultrasonic Instrument Co. Ltd., Kunshan, China) was used to prepare the liposomes.

Preparation of 1-dimethylamino-2,3-propanediol. Sodium hydroxide (11 g, 0.275 mol) was dissolved in the 33% aqueous dimethylamine solution (74.2 mL, 0.537 mol); 3-chloro-1,2-propanediol (45.4 g, 0.413 mol) was then added dropwise and the mixture was stirred at 30°C for 24 h. The mixture was then gradually heated to 105°C, with the unreacted dimethylamine distilled therefrom being absorbed in water. The water was distilled from the remaining mixture under reduced pressure. The residue from the distillation was cooled to 40°C and mixed with 40 mL of methanol, whereupon sodium chloride precipitated from the mixture. The precipitate was removed by filtration, and the filter cake was washed with another 20 mL of methanol. The methanol in the combined filtrate was recovered by distillation at reduced pressure, and the desired compound was then recovered. Fractional distillation yielded 1-dimethyl-amino-2,3-propanediol [29.5 g, 60% yield, b.p. 102–104°C/2 mmHg; Lit. 111°C/15 mmHg (26)]. ^{1}H NMR (Bruker Avance; 400 MHz, CDCl$_3$): δ 4.56 (*s*, 2H, 2 × OH); 3.78 (*m*, 1H, CH$_2$C*H*CH$_2$N); [3.63 (tetra, *J* = 3.6, 8.0, 3.6, 1H), 3.48 (tetra, *J* = 6.0, 5.6, 5.6, 1H), C*H$_2$*CHCH$_2$N]; [2.49 (tetra, *J* = 9.2, 3.2, 9.2, 1H), 2.23 (tetra, *J* = 4.0, 8.8, 4.0, 1H), CH$_2$CHC*H$_2$*N]; 2.28 [*s*, 6H, N(CH$_3$)$_2$]. MS *m/z*: 42 (10.0%), 58 [100%, (CH$_3$)$_2$N$^+$=CH$_2$], 72 (1.3%), 88 (19.7%), 102 (0.4%), 119 (5.2%); Lit. *m/z*: 42 (5.3%), 58 (100%), 88 (13%), 119 (2.9%) (27).

Preparation of isocyanates. Alkyl amine (30 mmol) in CH$_2$Cl$_2$ solution (150 mL) was added to a three-necked flask, and then a saturated aqueous solution of Na$_2$CO$_3$ (60 mL) was added. After stirring for 5 min, BTC (22 g, 74 mmol) in

CH$_2$Cl$_2$ solution (1 N) was added in batch and the mixture was stirred vigorously at room temperature for 2 h. The organic phase was then separated and the aqueous phase was extracted with CH$_2$Cl$_2$. The combined organic phases were dried (CaCl$_2$) and concentrated with a rotary evaporator to afford the alkyl isocyanates, which were used for the next step without further purification.

Lauryl isocyanate: Yield 63%. ^{1}H NMR (400 M, CDCl$_3$): δ 3.28 (*t*, *J* = 6.8, 6.4, 2H, NCH$_2$), 1.60 (*m*, 2H, NCH$_2$CH$_2$), 1.26 [*s*, 18H, (CH$_2$)$_9$], 0.88 (*t*, *J* = 5.2, 6.8, 3H, CH$_3$). MS *m/z*: 43 (31.6%), 69 (18.9%), 84 (10.5%), 99 (100%, [C$_5$H$_9$NO]$^+$), 126 (23.7%), 154 (5.3%), 182 (3.9%), 210 (5.2%), 238 (6.1%), 253 (4.8%), 281 (2.6%). Lit. *m/z*: 43 (100%), 69 (21.0%), 84 (9.0%), 99 (67%), 126 (6.0%), 154 (0.6%) (28).

Preparation of carbamates. 1-Dimethylamino-2,3-propane-diol (1 g, 8.4 mmol) and alkyl isocyanate (33 mmol) in toluene solution were added to a three-necked flask. Et$_3$N (0.85 g, 8.4 mmol) was then added as the catalyst and the mixture was stirred at 60–70°C for 4 h. The reaction mixture was then concentrated with a rotary evaporator. The white solid formed was dissolved in chloroform, applied to a gel column, and eluted with chloroform/methanol (4:1 vol/vol) to afford the desired compounds.

Compound **2a**: Yield 45%. IR (KBr) ν$_{max}$: 3324 (ν$_{NH}$), 1717 (ν$_{CO}$), 1697 (ν$_{CO}$), 1265–1254 (ν$_{COC}$, ν$_{CN}$). ^{1}H NMR (400 M, CDCl$_3$): δ [5.82, 5.17, 5.07 (OCH, 2 × NH)], [4.29 (*d*, *J* = 11.2, 1H), 4.22 (*d*, *J* = 11.2, 1H), OCH$_2$], [3.24, 3.13, 2.94, (2 × NHCH$_2$, NCH$_2$)], 2.72 [*s*, 6H, N(CH$_3$)$_2$], 1.48 (*m*, 4H, 2 ×

NHCH$_2$CH$_2$), 1.23 [s, 36H, 2 × (CH$_2$)$_9$], 0.86 (t, J = 5.6, 6.8, 6H, 2 × CH$_3$). ^{13}C NMR (400 M, CDCl$_3$): δ 155.98 (C=O), 67.22 (OCH), 63.92 (OCH$_2$), 58.03 (NCH$_2$), 44.23 (NHCH$_2$), 41.44 [N(CH$_3$)$_2$], 32.11–22.88 [(CH$_2$)$_{10}$], 14.32 (CH$_3$). HRMS m/z: found [M + H]$^+$ 710.6770, C$_{43}$H$_{87}$N$_3$O$_4$ calcd. for [M + H]$^+$ 710.6775.

Alkylation of carbamates. A suitable halogenated hydrocarbon (108 mmol) was condensed in a pressure apparatus containing a suitable carbamate **2** (1.8 mmol) with or without a petroleum ether solution. The sealed vessel was stirred behind a safety shield at 70°C for 48 h. After cooling to 0°C, the reaction vessel was opened and the reaction mixture was filtered to eliminate the excess halogenated hydrocarbon/petroleum ether solution. The remaining halogenated hydrocarbons in the filter cake were allowed to evaporate and were then evaporated under reduced pressure. The crude residue was recrystallized from acetonitrile to afford **1**.

Compound **1a**: Yield 97%. IR (KBr) ν$_{max}$: 3461 (ν$_{NH}$), 1728 (ν$_{CO}$), 1711 (ν$_{CO}$), 1267–1248 (ν$_{COC}$, ν$_{CN}$). ^{1}H NMR (400 M, CDCl$_3$): δ [5.98, 5.47, 5.39 (OCH, 2 × NH)], 4.30–4.17 (OCH$_2$, NCH$_2$), 3.50 [s, 9H, N(CH$_3$)$_3$], 3.15 (d, J = 6.8, 4H, 2 × NHCH$_2$), 1.51 (d, J = 6.4, 4H, 2 × NHCH$_2$CH$_2$), 1.26 [s, 36H, 2 × (CH$_2$)$_9$], 0.88 (t, J = 6.4, 6.4, 6H, 2 × CH$_3$). ^{13}C NMR (400 M, CDCl$_3$): δ 155.78 (C=O), 66.76 (OCH), [63.27, 61.28 (OCH$_2$, NCH$_2$)], 55.08 [N(CH$_3$)$_3$], [41.58, 41.38 (2 × NHCH$_2$)], 32.09–22.86 [(CH$_2$)$_{10}$], 14.30 (CH$_3$). Liposome preparation. A solution of lipid (20 mg) in chloroform/methanol (1 mL) was evaporated to dryness under a stream of nitrogen, and the residual solvent was removed under vacuum overnight. Liposomes were prepared by resuspending the lipids in deionized water (2 mL) at 45°C and sonicating them to clarity at this temperature for 2 h in a closed vial.

RESULTS AND DISCUSSION

Preparation of 1-dimethylamino-2,3-propanediol. Alquist and Slagh (29) previously prepared 1-dimethylamino-2,3-propanediol with dimethylamine and glycerol monochlorhydrin under pressure. To prepare 1-dimethylamino-2,3-propanediol in a small quantity, our process used a normal-atmosphere reactor. Glycerol monochlorhydrin was titrated into a mixture of dimethylamine and an aqueous sodium hydroxide solution, and the mixture was heated to 25°C and maintained for 24 h. But after purification, the yield was only 30–40% of the theoretical amount. To obtain a better yield, an $L_{4,3}$ orthogonal test was

used; the four factors were reaction temperature, reaction time, ratio of glycerol monochlorhydrin to dimethylamine, and dimethylamine concentration (30). The results are shown in Table 1. The boldfaced numbers **1**, **2**, and **3** represent three different values for each factor, and **I**, **II**, and **III** represent the sums of yields for **1**, **2**, and **3**, respectively.

As shown in the above data, the reaction time had the greatest range, at 80.18 [max. (**I**, **II**, **III**)–min. (**I**, **II**, **III**) = 153.61–73.43]; the ranges for reaction temperature, monochlorhydrin/dimethylamine ratio, and dimethylamine concentration were 28.04, 25.78, and 4.09, respectively. This meant that reaction time had the greatest influence on the reaction yield. With regard to reaction time, the sum of three yields at 24 h was 153.61, which was the greatest among the yield sums at the three different reaction times of 18, 24, and 36 h. The 24-h reaction time was the best of these three reaction times, so the optimal reaction time was chosen as 24 h. In this way, other optimal factors such as reaction temperature, monochlorhydrin/dimethylamine ratio, and dimethylamine concentration also could be decided. We finally chose the optimal reaction conditions of a 33% dimethylamine concentration, a chloropropanediol/dimethylamine ratio of 1:1.3, 30°C, and 24 h. A 60% yield was finally attained under these conditions (Scheme 2).

1-Dimethylamino-2,3-propanediol was characterized correctly by ^{1}H NMR and MS. The formula weight of 1-dimethylamino-2,3-propanediol was 119, and the highest peak in the fragments, *m/z* 58, was obtained as shown in Scheme 3 (31).

Reagents and conditions: 1.3 equiv dimethylamine in aqueous solution, 1.5 equiv sodium hydroxide, 24 h, 33°C, 60%..

Reagents and conditions: 5 equiv bis(trichloromethyl)carbonate (BTC) in CH_2Cl_2 solution, saturated $NaCO_3$ aqueous solution, 2 h, room temperature, 60%. R = $C_{12}H_{25}$, $C_{14}H_{29}$, $C_{16}H_{33}$, $C_{18}H_{37}$.
SCHEME 6

Preparation of isocyanates. Alkyl isocyanate is commonly prepared by the phosgene route in industrial production (Scheme 4).

As is well known, phosgene is an excellent acylation reagent with high activity, but its strong toxicity limits its application. In our work, BTC was tentatively substituted for phosgene to avoid the strong toxicity of the latter (32). BTC, which is much less toxic than phosgene, can release triple phosgene under nucleophilic catalysis (Scheme 5).

For lauryl isocyanate, for example, for the first time BTC was substituted for triphosgene and reacted with laurylamine under the same conditions as phosgene. BTC was 100% in excess. The amount of pyridine catalyst was 7.1% of the laurylamine mass. A BTC/chlorobenzene solution was titrated into a mixture of laurylamine and a pyridine/chlorobenzene solution, and the mixture was heated to 130°C for 3 h. When the reaction mixture was cooled to room temperature, a large amount of unreacted laurylamine separated out.

A considerable amount of laurylamine in the reaction was unreacted; one reason may be that the organic base pyridine caused BTC to release phosgene so fast that the rapidly created phosgene escaped quickly from the reaction system. To reduce the release rate of phosgene from BTC under these conditions, the catalyst was tentatively substituted with an inorganic base, a saturated aqueous solution of Na_2CO_3 (33). The saturated aqueous solution of Na_2CO_3 was added to an alkyl amine CH_2Cl_2 solution; after stirring for 5 min, a solution of BTC (1 N) in CH_2Cl_2 was added and the mixture was stirred vigorously at room temperature for 2 h (Scheme 6).

Under these conditions, BTC was catalyzed to slowly release phosgene. A little 100% pure lauryl isocyanate was obtained by reduced-pressure distillation and was characterized correctly by GC–MS and ^{1}H NMR. The highest peak in the alkyl isocyanate MS fragments, *m/z* 99, was obtained as shown in Scheme 7 (28,31).

In 1966 Ruth and Philippe (28) researched the mass spectra of short-chain isocyanates (<C_8) and some aromatic isocyanates as well as one long-chain isocyanate (octadecyl isocyanate); they also reached the conclusion that the $[C_5H_9NO]^+$ peak, *m/z* 99, is an important ion when the alkyl chain is long enough. However, the base peak of their octadecyl isocyanate was *m/z* 43, and our conclusion did not agree with theirs, perhaps because the ion source wall of octadecyl isocyanate in their experiment was 74°C.

In the same way, tetradecyl, hexadecyl, and octadecyl isocyanate were also prepared and used for the next step without further purification.

Preparation of carbamates. For **2a**, for example, because isocyanate could react easily with active hydrogen, 1-dimethylamino-2,3-propanediol and lauryl isocyanate were first reacted at room temperature. The catalyst triethylamine also played a role as a solvent because it had no active hydrogen. The product was filtered and recrystallized from chloroform after 15 h. From the IR spectrum of the product, in addition to the vibrations of –C=O at 1583 and 1617 cm^{-1}, an –NH group could be seen in the molecule at 3300 cm^{-1}, which indicated the isocyanate had reacted with the hydroxyl of 1-dimethylamino-2,3-propanediol. However, the detected M.W. of the acquisition was 396, which was not the expected substance. The substance acquired was speculated to be dilauryl urea because in the strongly polar solvent triethylamine there may inevitably be a little water. Under the conditions with triethylamine, isocyanate will be hydrolyzed into alkylamine; thus, the alkylamine generated will react with isocyanate to afford urea. The reaction may take place according to Scheme 8.

SCHEME 5

SCHEME 7

n=6, 8, 10, 12.
SCHEME 8

The speculation was confirmed by ^{1}H NMR data for dilauryl urea as follows: (CDCl$_3$): δ 4.36 (*s*, 2H, 2 × NH), 3.14 (tetra, *J* = 6.0, 6.4, 6.4, 4H, 2 × NHCH$_2$), 1.48 (*s*, 4H, 2 × NHCH$_2$CH$_2$), 1.26 [*s*, 36H, 2 × (CH$_2$)$_9$], 0.88 (*t*, *J* = 5.6, 6.8, 6H, 2 × CH$_3$).

To ensure anhydrous conditions, the solvent was substituted for anhydrous toluene and the amount of triethylamine was reduced to 1 equiv of 1-dimethylamino-2,3-propanediol. The reaction was undertaken at 60–70°C for 4 h (Scheme 9) (34). The reaction mixture was then concentrated and recrystallized from chloroform to afford crude **2a**.

In the atmospheric pressure chemical ionization (APCI)-MS spectrum of crude **2a** under these conditions, in addition to the main [M + H]$^+$ peak at 542.5, we concluded that the M.W. of the product was 541, which was in accordance with **2a**. Another peak at 331.3 referred to a substance with a M.W. of 330, which showed there was a little single-substitution product in the acquisition (Scheme 10).

To acquire pure **2a**, the crude product was applied to a silica gel column and eluted with chloroform/methanol (4:1, vol/vol). Compound **2a** was thus acquired and characterized by IR, atmospheric pressure ionization-electrospray (API-ES) MS, and NMR. The [M + H]$^+$ peak of the single-substitution product in the MS spectrum was eliminated this time. IR, MS, and NMR

data showed that the structure of **2a** was correct and that the purity of **2a** with this method was satisfactory.

Proceeding in a similar manner, **2b**, **2c**, and **2d** were prepared.

Alkylation of carbamates. The four carbamates were reacted with methyl iodide in the petroleum ether solution in a pressure reactor (1). After 48 h at 70°C, the reactions were cooled to room temperature and the pressure reactor was opened. Crude salts were afforded *via* filtration and were purified through recrystallization from an acetonitrile solution (Scheme 11).

Using **1c** as an example, the API-ES MS of **1c** in the positive mode was 668, and it was 127 in the negative mode. The M.W. of **1c**, which was an iodide salt, was 795. Subtracting 127, the atomic weight of iodine, from 795 amounted to 668, which agreed with the data shown in the spectrum.

In ^{1}H NMR, chemical shifts of 5.86 (1H), 5.46 (1H), and 5.27 (1H) referred to protons in OCH and 2 × NH; 4.30 (2H) and 4.22 (2H) were the proton chemical shifts of OCH$_2$ and NCH$_2$. To acquire proof of the assignments of the above signals, 2-D homonuclear correlation spectroscopy, heteronuclear single quantum correlation, and heteronuclear multiple-bond correlation analyses were carried out, which confirmed the

2a R=C$_{12}$H$_{25}$

SCHEME 11

assignments were correct. However, distinguishing the various absolute peaks was difficult because the proton chemical shifts in these two groups were too near to be differentiated or were even mixed together. The chemical shift 3.50 (9H) represented protons in N(CH$_3$)$_3$. The chemical shift 3.15 (4H) referred to protons in CH$_2$ connected to NH, and the chemical shift 1.52 (4H) represented protons in CH$_2$ next to NH. The chemical shift 0.88 (6H) referred to protons of the end CH$_3$ in the lipid chains, and 1.26 (52H) referred to protons in the remaining lipid carbon chains. IR, MS, and NMR data (see the Experimental Procedures section) confirmed that the structure of **1c** was correct.

Proceeding in a similar manner, **1a**, **1b**, and **1d** were prepared.

With regard to reactions between the carbamates and iodoethane, for **1g**, for example, the carbamate was reacted first under the same conditions as methyl iodide. But after reacting

for 48 h followed by purification, we observed almost half of the carbamate in the salts by ^{1}H NMR.

Because the reactivity of iodoethane was lower than that of methyl iodide, some measures had to be taken to increase the reaction velocity. As is well known, the products in these reactions were iodide salts whose polarities were strong, whereas the petroleum ether solvent, with a weak polarity in the reaction system, may have retarded the formation of salts. Hence, in the subsequent reaction, the petroleum ether solvent was abandoned, and the carbamates were submerged directly into the iodoethane liquid. In this manner, after 48 h at 70°C, the reactions were cooled to room temperature and the pressure reactor was opened. Crude salts were afforded *via* filtration and were purified through recrystallization from the acetonitrile solution (Scheme 12).

The API-ES MS of **1g** in the positive mode was 682, and it was 127 in the negative mode. The M.W. of **1g** was 809, which was an iodide salt. Subtracting 127, the atomic weight of

SCHEME 12

iodine, from 809 amounted to 682, which was in accord with the data shown in the spectrum. From the ¹H NMR data, one can see that no remaining carbamate was detected in this way. IR, MS, and NMR data (see the Experimental Procedures section) showed that the structure was correct.

Proceeding in a similar manner, **1e**, **1f**, and **1h** were prepared.

Liposome preparation. Commonly, liposomes are prepared through the Bangham method (25), nonultrasonic stirring (35), the ultrasonic method (36), the injection method (37), or the extrusion method (37). For a particular sample, specific factors must be taken into account.

Dispersant selection. Chloroform is usually used as the solvent in preparing lecithin liposomes, but sometimes if the lipid molecules contain a radical of strong polarity, which decreases its solubility in chloroform and leads to poor dispersibility in the solvent, it is usually necessary to add some methanol. Here, through solution tests, we found that chloroform alone dissolved the lipids well enough, and we finally obtained good dispersibility on the flask wall.

Contrasting lipids selection. Lecithin is a natural lipid that is widely used in controlled-release medicines, and the preparation of lecithin liposomes is classical. Dioctadecyldimethylammonium bromide (DODAB) is also a lipid usually applied in liposome/DNA complex (lipolex) research. Here, the counterpart to DODAB, dioctadecyldimethylammonium chloride (DODAC), as well as lecithin were selected as contrasting lipids for liposome research.

Liposome preparation and negative-stained TEM. Cationic lipids can combined well with anionic DNA through electrostatic attraction to form a DNA/liposome complex, yet cationic liposomes may also cause cytotoxicity. Here we took the neutral intermediates **2a**–**d** also as kinds of lipids to see whether they were able to form liposomes through the Bangham method.

For lecithin, DODAC, **2a,** and **1a,** for example, liposomes were prepared by the Bangham method, and ultrasonication was applied to half of each solution. Both ultrasonicated and nonultrasonicated samples were observed by TEM.

The hydrating temperatures used to make liposomes should usually be above the gel-to-liquid phase-transition temperature of the system (38). Lecithin, DODAC, **2a**, and **1a** are considered to have different transition temperatures; thus, it was convincing that the Bangham method gave no liposome structure if the flask did not warm when the lipid films were mixed with water. Basu *et al.* (39) and Hata *et al.* (40) both concluded that the phase transition temperature of phospholipids, which were similar in structure to the lipids discussed here, was around 40°C. In addition, in studies by Uchegbu *et al.* (41) and Uchegbu and Florence (42), polymers also had a phase transition temperature of around 40°C. For the moment, we used 40°C as the phase transition temperatures of the lipids discussed here, and we hydrated and sonicated them at 45°C to see whether they could form liposomes. Finally, the liposome structure was observed by negative-stained TEM, which in reverse showed that the phase transition temperatures of all the lipids discussed here were under 45°C.
FIG. 1. Lecithin liposomes without sonication.
FIG. 2. Sonicated lecithin liposome.
FIG. 3. Sonicated dioctadecyldimethylammonium chloride liposome.

Commonly, electron microscopy can be divided into freeze-fracture scanning electron microscopy and negative-stained TEM. The latter can clearly indicate the inner structure of the samples (43), which was what we were concerned with. By this means, we could identify the layers and diameters of the liposomes. Negative-stained transmission electron micrographs of the aforementioned liposomes are shown in Figures 1–5.

As one can see from these figures, the unsonicated lecithin liposomes had a multilayered structure, the diameter of which was about 100 nm; this was reduced to 50 nm after sonication. In the unsonicated DODAC, **2a**, and **1a** solutions, no liposome structures were observed. In contrast, single-layered liposomes with a diameter of about 60 nm appeared in the DODAC solution when sonication was applied. Compound **2a** formed multilayered liposomes, the diameters of which were about 40 nm, whereas **1a** formed 50-nm single-layered liposomes after sonication.

One can see that ultrasonication helped smaller liposomes to form. Lecithin could form both multilayered and single-layered liposomes because of the different preparation conditions (Figs. 1, 2). Furthermore, sonication sometimes plays a important role
FIG. 4. Sonicated liposome of **2a**.
FIG. 5. Sonicated liposome of **1a**.

in liposome formation, because the latter three lipids could not form liposomes without sonication. The neutral lipid **2a** easily formed multilayered liposomes (Fig. 4), whereas the cationic lipids **1a** and DODAC preferentially formed single-layered liposomes (Figs. 3, 5). This may be due to the different structures among them. Neutral lipids may be more likely to form multilayered liposomes compared with their cationic counterparts. As gene vectors, multilayered liposomes would probably carry more DNA, whereas single-layered liposomes would probably enter into cells more easily because of their small size. Factors affecting the formation of multilayered or single-layered liposomes and the applications of these liposomes as DNA carriers *in vitro* and *in vivo* need to be discussed further.

A series of carbamate-linked lipids were prepared, and IR, GC–MS, HRMS, and NMR data were used to confirm their structures. Negative-stained TEM showed that these lipids could form single- or multilayered liposomes with a diameter of around 50 nm through an ordinary method. Application of these carbamate-linked cationic lipids as DNA carriers to deliver genes to cells *in vitro* and *in vivo* requires further research.

ABSTRACT: Tea is a widely consumed beverage throughout the world. We assessed the antioxidant activity of six teas, including the aqueous extracts of green tea and oolong tea (*Camellia sinensis*), tochu (*Eucommia ulmoides*), *Gymnema sylvestre*, Japanese mugwort (*Artemisia princeps*), and barley (*Hordeum vulgare*), against 1,1-diphenyl-2-picrylhydrazyl (DPPH) radicals and LDL oxidation, and examined the association of LDL oxidizability with the plasma catechin levels in 10 healthy volunteers with a single dose of 5 g green tea powder. *In vitro*, the inhibitory effects of DPPH radicals and LDL oxidation were found to be strongest in the extract of green tea and weakest in that of barley. After the ingestion of green tea powder, the lag time increased from basal 52.2 ± 4.1 to 60.3 ± 4.2 min at 1 h and 59.5 ± 4.1 min at 2 h, and then returned to the baseline lag time (51.9 ± 1.4 at 4 h and 52.1 ± 4.7 min at 6 h). Regarding the plasma catechin levels, epigallocatechingallate and epicatechingallate significantly increased from basal 3.7 ± 1.3 and 0.8 ± 0.8 ng/mL to 65.7 ± 11.6 and 54.6 ± 12.6 ng/mL at 1 h, and 74.4 ± 18.6 and 49.4 ± 7.1 ng/mL at 2 h, respectively. Green tea therefore showed the strongest antioxidant activity among the six different teas, and the inhibitory effects of green tea on LDL oxidation depended on the plasma catechin levels.

Paper no. L9601 in *Lipids 40,* 849–853 (August 2005).

Oxidized LDL is considered to be an important factor in the atherogenic progression of coronary artery disease (CAD) (1). Oxidized LDL can attract monocytes into the arterial wall where they can be transformed into macrophages—the precursors of foam cells—thus leading to the formation of early atherosclerotic lesions (2,3). As a result, protecting LDL against oxidation is assumed to be a useful therapy for the prevention of atherogenic disease.

Regnstrom *et al.* (4) suggested that LDL oxidizability was associated with the severity of coronary atherosclerosis. *In vitro*, LDL oxidation occurs in three phases: a lag phase, a propagation phase, and a decomposition phase. During the lag phase, endogenous LDL antioxidants are consumed (5). The

consumption of antioxidant foods such as flavonoids and soyfoods has been reported to be associated with either an elevated resistance of LDL to oxidation or a reduced CAD mortality (6,7).

Green tea and oolong tea, which inhibit LDL oxidation *in vitro* (8,9), are manufactured from the same plant species, *Camellia sinensis*. However, the antioxidant effects of the extracts from other plants on LDL oxidation have not yet been investigated. We assessed the antioxidant activity of six teas, consisting of the aqueous extracts of green tea and oolong tea (*C. sinensis*), tochu (*Eucommia ulmoides*), *Gymnema sylvestre*, Japanese mugwort (*Artemisia princeps*), and barley (*Hordeum vulgare* L.), against 1,1-diphenyl-2-picrylhydrazyl (DPPH) radicals; their effects on LDL oxidizability; and the inhibitory effect of green tea on LDL oxidation in 10 healthy volunteers.

MATERIALS AND METHODS

Tea preparations. Six teas, including aqueous extracts of green tea and oolong tea (*C. sinensis*), tochu (*E. ulmoides*), *G. sylvestre*, Japanese mugwort (*A. princeps*) and barley (*H. vulgare*), were prepared by infusing either 6 g (DPPH radicals test) or 1 g (LDL oxidizability test) of each commercially available tea for 1 min at 80°C in 100 mL of water.

Free radical-scavenging activity. The free radical-scavenging activity was determined using DPPH (Wako Pure Chemical Industries, Osaka, Japan). An aliquot of each tea was mixed with 2 mL of 0.1 mM DPPH in ethanol. Following incubation for 20 min at 37°C, the absorbance was measured at 516 nm with a Beckman Model DU 650 spectrophotometer. The volume of each tea required to cause a 50% decrease in the absorbance at 516 nm relative to the control was then calculated.

Isolation and preparation of LDL. Blood samples were collected in sodium EDTA-containing tubes from fasting normolipidemic volunteers after obtaining their informed consent. Plasma samples were immediately prepared by centrifugation at $2,000 \times g$ for 10 min at 4°C. The LDL was separated by single-spin density gradient ultracentrifugation ($417,000 \times g$, 40 min, 4°C) using a TLA-100.4 fixed angle-rotor (Beckman Instruments, Fullerton, CA) (10). The LDL protein concentration was determined using a Micro BCA Protein Assay Kit (Pierce Laboratories, Rockford, IL). Before the start of the oxidation

---

experiments, the LDL samples were diluted with PBS to give a final concentration of 70 µg/mL LDL protein.

Measurement of LDL oxidizability. The LDL oxidizability was measured according to the method described in our previous report (11). The prepared LDL samples were oxidized with or without 5 µL of each tea or 50–400 ng/mL of green tea extract by 400 µM 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile) (AMVN-CH$_3$O; Wako Pure Chemical Industries), which was an oxidative inducer. The kinetics of LDL oxidation were obtained by monitoring the absorbance of conjugated dienes at 234 nm with a Beckman Model DU 650 spectrophotometer at 4 min intervals at 37°C. The lag time of lipid peroxidation is defined as the time interval between the initiation and the intercept of the two tangents drawn to the lag and propagation phase of the absorbance curve at 234 nm, and it was expressed in minutes. All steps in the experiments investigating LDL oxidation were quickly performed on ice by the same laboratory assistant to minimize the loss of antioxidants in LDL.

Clinical study. Our study subjects were 5 male and 5 female healthy volunteers, ranging from 20 to 22 yr of age, whose body mass index was 20 ± 2 (kg/m^2); none of them took any medications, vitamin supplements, or special dietary additives. This study was approved by our ethics committee. All subjects gave their informed consent to participate in the study. We asked all the subjects not to consume any kinds of tea, wine, citrus fruit juices, or supplements for 3 d before the experimental day. After over 12 h of fasting, blood samples were collected between 8:00 and 9:00 A.M. Subjects then ingested 5 g of green tea powder dissolved in 150 mL of hot water over a period of 10 min. The green tea powder contained 3.20 wt% of epigallocatechingallate (EGCg), 0.96 wt% of epicatechingallate (ECg), 0.49 wt% of epicatechin (EC), and 3.81 wt% of caffeine. Plasma samples were taken at baseline, and 1, 2, 4, and 6 h after the green tea powder had been consumed; they were then either analyzed immediately or stored at −20°C until analysis. Of the 10 healthy volunteers, blood samples obtained from the five males were used for an analysis of the plasma catechin levels, because the five females did not agree to give blood samples for the catechin analysis. The analysis of plasma catechin levels was the same as that described in our previous report (12). Briefly, chloroform with ethyl gallate was added to plasma

samples as an internal standard, and sample fractions containing catechins were purified by solid-phase extraction using Bond Elut cartridges (Varian, Harbor City, CA). An analysis of the catechin levels was performed by HPLC with an electrochemical detector.

Statistical analysis. The results are expressed as the mean values ± SEM. The precision of the DPPH radical test and LDL oxidizability was tested before the start of this study. In the DPPH test, the mean ± SD (µL) of 0.9 mg/mL catechin required to cause a 50% decrease in the absorbance at 516 nm relative to the control ($n = 5$) was 7.49 ± 0.66. The CV was 8.8%. In the analysis of LDL oxidizability, the mean ± SD (min) of plasma samples A ($n = 4$) and B ($n = 5$), collected from subjects A and B, respectively, was 41.8 ± 1.6 and 87.8 ± 1.6, respectively. The CV for samples A and B was 3.8 and 1.8%, respectively. The mean ± SD (min) of the lag time for plasma samples C and D (collected from subjects A and B, respectively, and stored at 4°C until analysis), which was measured once a day for 3 d, was 51.4 ± 1.4 and 84.5 ± 1.4, respectively. The CV for samples C and D was 2.8 and 1.6% in an interassay, respectively. Any significant differences in the clinical study were evaluated by a repeated-measures ANOVA and the *post hoc* test (Scheffe test), and a *P* value of <0.05 was considered to be statistically significant.

RESULTS AND DISCUSSION

Antioxidant activity of various teas and green tea extracts. A number of studies on the antioxidant effects of green tea and oolong tea have been reported (8,9,13,14), although the antioxidant effects of teas brewed from other plants have not yet been sufficiently investigated. The present study elucidated the antioxidant activity of various teas regarding DPPH radicals and LDL oxidation. The results of the DPPH radical scavenging activity of various teas are shown in Table 1. Green tea and oolong tea required 1.9 and 5.1 µL, respectively, for scavenging 50% of the DPPH radicals. These teas showed a remarkably higher scavenging activity than the extracts of other plants. Among the teas tested, barley tea was the weakest scavenger and required 119.8 µL, which was several dozen times higher than for green tea and oolong tea.

TABLE 1
Antioxidant Activity of Various Teas

	DPPH test (µL)	LDL oxidizability	
		Lag time (min)[a,b]	Oxidation rate (nmol conjugated diene/ min/mg LDL protein)[a]
Control		21.2 (1.0)	10.3
Green tea	1.9	201.8 (9.9)	3.7
Oolong tea	5.1	62.3 (2.8)	8.4
Tochu tea	21.2	62.4 (2.8)	8.3
Gymnema sylvestre tea	32.1	40.2 (1.8)	11.1
Japanese mugwort tea	35.6	38.7 (1.8)	11.8
Barley tea	119.8	23.5 (1.1)	12.9

[a]Five microliters of each tea was added to the LDL solution (70 µg/mL of LDL protein).
[b]The prolongation rate of the lag time relative to the control is shown in parentheses.

TABLE 2
Dose–Response Effect of Green Tea Components on LDL Oxidizability[a]

Amount added	EC		ECg		EGCg	
(ng/mL)	Lag time (min)	μM	Lag time (min)	μM	Lag time (min)	μM
0	47.2 ± 1.2	0	36.7 ± 0.9	0	32.1 ± 0.8	0
50	78.9 ± 2.0	0.17	39.5 ± 1.0	0.11	37.9 ± 0.9	0.11
100	102.4 ± 2.6	0.34	46.7 ± 1.2	0.23	42.6 ± 1.1	0.22
200	161.8 ± 4.0	0.68	78.7 ± 2.0	0.45	58.2 ± 1.5	0.44
400	186.6 ± 4.7	1.38	118.7 ± 3.0	0.90	88.1 ± 2.2	0.87

[a]The results are expressed as the mean ± SEM ($n = 3$). The M.W. of epicatechin (EC), epicatechingallate (ECg), and epigallocatechin-3-gallate (EGCg) are 290.3, 442.4, and 458.4, respectively.

The inhibitory effects of various teas for LDL oxidation induced by $AMVN\text{-}CH_3O$ are also shown in Table 1. Compared with the control, green tea was the most effective for both the prolongation rate of the lag time (9.9-fold) and the oxidation rate (3.7 nmol conjugated diene/min/mg LDL protein). The inhibitory effects of LDL oxidation were similar for oolong tea and tochu tea as well as for *G. sylvestre* tea and Japanese mugwort tea. Barley tea had the weakest antioxidant activity for LDL oxidation among all the teas used in this experiment. The antioxidant effects of green tea extract components, which are EC, ECg, and EGCg, on LDL oxidation are shown in Table 2. Each catechin prolonged the lag time of LDL oxidation in a dose-dependent manner *in vitro*.

Green tea showed the strongest antioxidant activity among the six teas in both experiments. Herbs such as tochu, *G. sylvestre*, and Japanese mugwort have been widely used as folk medicines for several diseases. Tochu has been considered to have antimutagenicity (15,16), a preventive effect against oxidative gastric injury (17), and an antihypertensive action (18). Tochu tea has an inhibitory effect against LDL oxidation, which was as strong as that for oolong tea in the present study. The scavenging activity of tochu tea on reactive oxygen species correlated with its protocatechuic acid content (19). This substance was not evaluated in our study, but it might also help prevent LDL oxidation. *G. sylvestre* has been used in Indian traditional medicine and as a health food in tea bags and beverages in Japan. Several reports on its pharmacological action showed antihyperglycemic (20) and antidiabetic (21) effects, and these actions might be due to its ability to suppress glucose absorption from the intestinal tract (22). Japanese mugwort is associated with anticoagulation (23), the proliferation of endothelial cells (24), and the inhibition of protein fragmentation damage (25). The antioxidant effects of *G. sylvestre* and Japanese mugwort were moderately strong among the six teas analyzed for this paper. Our study is the first report on the antioxidant ability of *G. sylvestre* and Japanese mugwort. We measured the polyphenol and EGCg content of green and oolong teas, which had the strongest antioxidant activity among all the tested teas. The polyphenol contents of green and oolong tea were 1.4 ± 0.1 and 0.4 ± 0.03 mg/mL, respectively, whereas the EGCg contents of green and oolong tea were 317 ± 29 and 57 ± 6 μg/mL, respectively. Our previous reports showed a positive correlation between the polyphenol content and the antioxidant activities, which are the DPPH radical scavenging activity or the prolongation rate of LDL oxidation-lag time, in vegetables (26).

Clinical trial. Ten subjects consumed green tea, which had the strongest antioxidant activity among the six teas. After ingesting 5 g of green tea powder, the lag time increased from a basal time of 52.2 ± 4.1 to 60.3 ± 4.2 min at 1 h and 59.5 ± 4.1 min at 2 h, and then returned to the baseline lag time (51.9 ± 1.4 min at 4 h and 52.1 ± 4.7 min at 6 h) but these changes did not reach statistical significance (Fig. 1). Of 10 subjects, 5 subjects had the longest lag time at 1 h after the ingestion; the lag time of the other 5 subjects showed a peak at 2 h (Table 3).

Regarding the plasma catechin levels after the consumption of green tea powder, EGCg and ECg significantly increased from a basal value of 3.7 ± 1.3 and 0.8 ± 0.8 ng/mL to 65.7 ± 11.6 and 54.6 ± 12.6 ng/mL at 1 h, and 74.4 ± 18.6 and 49.4 ± 7.1 ng/mL at 2 h, respectively (Fig. 2). Green tea increased the lag time of LDL oxidation after 1 and 2 h, which was related to an increase in the plasma catechin levels. However, we could not find any significant correlation within each individual person between the plasma catechin levels and the lag time of LDL oxidation at different times. No significant increase was seen in the plasma levels of β-carotene, vitamin E, vitamin C, and uric acid. Regarding the effects of small increases in flavonoids on LDL oxidation, Nakagawa *et al.* (27) reported results similar to ours. Plasma EGCg levels slightly increased
FIG. 1. The lag time in 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile)-induced LDL oxidation after the consumption of green tea powder in 10 healthy volunteers.

TABLE 3
The LDL Oxidation-Lag Time (min) After the Consumption of Green Tea Powder in 10 Subjects[a]

Subjects	0 h	1 h	2 h	4 h	6 h
1	44.5	56.1	47.7	50.5	52.8
2	55.9	53.6	56.8	52.6	54.2
3	54.8	58.9	52.3	47.8	52.8
4	50.3	54.8	51.7	50.7	42.1
5	53.7	57.5	58.2	54.6	−
6	82.4	94.8	90.8	−	81.6
7	45.0	48.6	46.4	43.7	38.1
8	43.7	53.4	61.5	57.7	48.4
9	58.0	68.5	69.0	56.3	−
10	33.5	56.7	60.9	53.0	47.1

[a]Subjects 1–5 are male and 6–10 are female.

to 267 pmol/mL, although the plasma PC hydroperoxide levels decreased by half after 60 min with a single oral intake of green tea extract tablet containing 254 mg catechins. In our study, the plasma EGCg levels increased to 74.4 ng/mL (162 pmol/mL) 2 h after the intake of green tea containing 160 mg catechins. In an *in vitro* study, we showed that 50 and 100 ng/mL of EGCg prolonged the lag time by 5.8 and 10.5 min, respectively, and 50 ng/mL of ECg prolonged the lag time by 2.8 min (Table 2). The catechin level found in plasma clearly prolonged the LDL oxidation lag time *in vitro*. It is important to elucidate the fact that catechins are responsible for the increase in the measured lag times. However, we did not measure the catechins in the LDL fraction. An additional experiment is thus called for to clarify the correlation between catechins and LDL fractions. Green tea is well known to be a strong antioxidant beverage (8), due to its catechin content (28). Unno *et al.* (12) showed that the serum catechin level reaches its highest level at approximately 2 h after the ingestion of green tea. Our results for the peak catechin level were thus compatible with theirs. The physiological function of green tea has been studied in animals and in humans (13,14), although few studies determined the plasma catechin level. The plasma or serum catechin level as well as the serum antioxidants such as vitamin E and vitamin C should be analyzed in a future study of green tea intake. Such a study

will allow us to estimate more exactly the physiological and pharmacological action of the green tea component. Regarding the limitations of this study, it was not a placebo-controlled study. To clarify the effects of green tea on LDL oxidation, a further study should be done using a placebo-controlled study in a larger population.

The findings of previous studies confirmed that the French paradox, which is a high intake of dietary fat but low mortality from CAD, may be attributable in part to high wine consumption (29–31). The smoking rate of Japanese males (52.8%) is very high in comparison with that of other industrialized countries such as the United Kingdom (27%) and the United States of America (25.7%) (32), although the mortality rate from CAD is much lower in Japan than in the United States and the United Kingdom (33). We therefore hypothesize that the daily consumption of green tea by Japanese might be an important clue to help elucidate the reason for the "Japanese paradox" regarding CAD.
