ABSTRACT: This systematic review and meta-analysis aimed to evaluate the effect of modifying 18-carbon PUFA [18-C PUFA: α-linolenic acid (ALA, 18:3n-3) and linoleic acid (LA, 18:2n-6)] in the diets of term and preterm infants on DHA (22:6n-3) status, growth, and developmental outcomes. Only randomized controlled trials (RCT) involving formula-fed term and preterm infants, in which the 18-C PUFA composition of the formula was changed and growth or developmental outcomes were measured, were included. Differences were presented as control (standard formula) and treatment (18-C PUFA-supplemented formula). Primary analyses for term infants were 4 and 12 mon and for preterm infants 37–42 and 57 wk postmenstrual age. Five RCT involving term infants and three RCT involving preterm infants were included in the systematic review. Infants fed ALA-supplemented formula had significantly higher plasma and erythrocyte phospholipid DHA levels than control infants. There was no effect of ALA supplementation on the growth of preterm infants. In term infants, ALA supplementation was associated with increased weight and length at 12 mon, which was at least 4 mon after the end of dietary intervention. Developmental indices of term infants did not differ between groups. There was a transient improvement in the retinal function of preterm infants fed ALA-supplemented diets compared with controls. The findings suggest that ALA-supplemented diets improve the DHA status of infants. Further studies are needed to provide convincing evidence regarding the effects of ALA supplementation of formula on infant growth and development.

Paper no. L9673 in *Lipids 40*, 1–11 (January 2005).

DHA (22:6n-3) is a major structural lipid of the brain and can be derived endogenously from α-linolenic acid (ALA, 18:3n-3).

The enhanced development of breast-fed infants relative to formula-fed infants is thought to be due, in part, to the presence of DHA in breast milk (1–3). In the past, infant formulas were not supplemented with DHA, and levels of its precursor, ALA, were low relative to the high levels of the n-6 FA linoleic acid (LA, 18:2n-6). This imbalance in formula fats in favor of LA was largely ignored until animal studies demonstrated that dietary insufficiency of ALA resulted in lower levels of DHA in the brain and retina and loss of visual function (4–6). These studies were the catalyst for clinical intervention trials of both preformed long-chain PUFA (20- and 22-carbon LCPUFA) and variations in the balance of ALA and LA to assess the effect on infant DHA status and visual and neurodevelopment. An early study involving preterm infants that investigated both strategies suggested that a dietary supply of n-3 LCPUFA was more effective than ALA enrichment in enhancing DHA status and visual function to levels comparable with those of breast-fed infants (7,8). Despite the preliminary nature of this pioneering trial, relatively little work has since focused on modifying 18-carbon PUFA (18-C PUFA: ALA and LA) blends in infant formulas as a strategy for increasing infant DHA status and improving developmental outcomes (9–15; Jensen, C.L., Chen, H., Prager, T.C., Fraley, J.K., Anderson, R.E., and Heird, W.C., unpublished report).

A systematic review of trials involving 18-C PUFA is important because levels of 18-C PUFA in formulas have varied over the last 20 yr with little direct evaluation. Meanwhile, formulas containing LCPUFA have become widely available but remain expensive, a possible barrier to their use by some population groups. There is a need to assess the efficacy of simply modifying 18-C PUFA blends on DHA status; function, as measured by cognitive and visual outcomes; and safety, as assessed by growth.

With this in mind, we undertook a systematic review and meta-analysis of randomized controlled trials (RCT) to determine the effect of 18-C PUFA-enriched formula on the growth and development of term and preterm infants. Our review included trials that varied the ALA and/or LA content of the formula. Primary outcomes were weight, length, head circumference, and indices of neurological development. We also examined the

treatment effect on plasma and erythrocyte phospholipid DHA, EPA (20:5n-3), and arachidonic acid (AA, 20:4n-6) levels.

METHODS

Search strategy. A search of the Cochrane Controlled Trials Register and MEDLINE using the key words: *infant AND formula* and one of the following—*linoleic acid, linolenic acid,* or *polyunsaturated fatty acids*—identified relevant trials. In MEDLINE, search limits were *randomized controlled trial* and *human*. Hand-searching of abstracts and conference proceedings was performed. The last literature search was completed in May 2004. Eight trials involving term infants and three trials involving preterm infants were identified as potentially eligible for inclusion and were retrieved for review.

(i) Selection of trials. Trials were eligible for inclusion if they had a randomized design, the ALA and/or LA level of the formula fat was varied but other nutrients in the formula remained the same, and growth or development were reported as an outcome measure. For trials involving term infants, the test formula was to have commenced within 14 d of birth, and the diet duration was at least 8 wk to allow the intervention to have an effect on tissue status. For trials involving preterm infants, the test formula was to have been fed for at least 3 wk based on the usual practice of not feeding preterm formula beyond hospital discharge. Infants consuming test diets that contained LCPUFA were excluded. From the eight RCT involving term infants, two were excluded because the test diet was commenced after the infants were 14 d old (16,17) and another because multiple nutrient components of the formula were modified (19). The five eligible RCT involving term infants were published in seven separate papers (9–13,19,20). The three RCT involving preterm infants were published in eight separate papers (7,8,14,15, 21–23; Jensen, C.L., Chen, H., Prager, T.C., Fraley, J.K., Anderson, R.E., and Heird, W.C., unpublished report).

(ii) Data abstraction and collection. Data abstraction forms were compiled and authors were contacted when published details were unclear. Where growth, development, or FA mean data were assessed but not published at designated time-points, these unpublished data were obtained from the investigators. Unpublished data were received for three trials involving term infants (10,11,13) and two trials involving preterm infants (22; Jensen, C.L., Chen, H., Prager, T.C., Fraley, J.K., Anderson, R.E., and Heird, W.C., unpublished report).

Statistical analysis. Primary analyses for trials involving term infants were made at 4 mon (a time when solid foods were traditionally introduced) and 12 mon of age (when formula feeding often ends). Where data were available, growth, development, and FA status at other time points were included to explore short- and long-term effects. Primary comparisons of trials involving preterm infants were made at 37–42 wk (term) and 57 wk postmenstrual age (PMA). Comparisons were also made at other assessment points where data were available. For trials that included more than two test diets, the control group was specified as the one most closely matching the LA-to-ALA

balance of that found in current commercially available formulas of around 10 to 1.

Meta-analyses were computed using the Metaview program available in Review-Manager 4.2 (Cochrane Collaboration). A fixed-effects model was used where there was no significant heterogeneity, whereas a random-effects model was used if significant heterogeneity existed. Each study was weighted in the meta-analysis according to the SD and the number of infants. Data were reported as weighted mean difference (WMD) with 95% confidence intervals (CI). In a supplementary analysis, mean FA data of term infants at 4 mon of age were plotted as a function of ALA levels in the test formulas (11,19). In the graphs, polynomial regression curves were fitted to the FA data and r^2 values reported.

RESULTS

Trials involving term infants. (i) Summary of included studies. Five trials involving term infants, conducted in North America ($n = 4$) and Australia ($n = 1$), were included in this review (9–13,19,20) (Table 1). Three trials intervened with formula enriched with ALA (between 3.2 and 4.8 wt%), thus also lowering the LA/ALA ratio (11–13,19,20), whereas two trials tested formula enriched with both LA (34 wt%) and ALA (5 wt%) and kept the LA/ALA ratio constant (9,10). None of the included trials tested reducing the LA level of the formula to lower the LA/ALA ratio. Variations in the balance of LA and ALA in the fats of the formulas were obtained through blending vegetable oils including coconut, corn, soy, canola, safflower, sunflower, and palm. The trial by Innis *et al.* (10) included four groups of formula-fed infants that were not included in the analysis because the test formulas contained DHA. The most commonly used developmental outcomes were visual function (9,11,13) and global neurodevelopment (11,13). Visual function was measured by Teller acuity cards (9), visual evoked potential (VEP) acuity (11), and VEP latency (to checkerboard patterns subtending a visual angle of 30-min arc) (11,13). Neurodevelopment was assessed by the Bayley Scales of Infant Development (BSID) First (11) or Second Edition (20). The BSID included both the mental developmental index and psychomotor developmental index. Other developmental assessments included the Clinical Adaptive Test (CAT), Clinical Linguistic and Auditory Milestone Scale (CLAMS), and Gross Motor Scale (GM) of the Revised Gesell Developmental Inventory (20). Developmental quotients (DQ) were determined for language development (CLAMS DQ), visual problem-solving ability (CAT DQ), overall cognition (the mean of CLAMS and CAT DQ), and gross motor development (GM DQ) (20). Growth was measured by standard procedures in all trials.

All trials reported a randomized design with two reporting adequate concealment of allocation (11,13,19,20). Makrides *et al.* (11) and Jensen *et al.* (13,19,20) reported blinding of both parents and trial staff. All trials had relatively small sample sizes. Innis *et al.* (9) reported <20% attrition of infants through to 3 mon of age, and Makrides *et al.* (11) reported <20% attrition through to 4 mon of age.

TABLE 1
Characteristics of Randomized Trials Involving Formula-Fed Term Infants

Trial	PUFA intervention[a]	Number of infants enrolled	Number of infants completing trial (attrition rate)	Growth assessment age (mon)	Neurodevelopment assessment	Visual function assessment[b]	FA assessment age (mon)	Comments[c]
Treatment: Increased ALA level while LA held constant								
Ponder *et al.*, 1992, USA, 2 sites (12)	C - LA/ALA, 31.4/0.8; T - LA/ALA, 34.2/4.8; diet duration = 2 mon	Not stated	Through to 2 mon: C = 14 (unknown) T = 11 (unknown)	0, 1, 2	Not assessed	Not assessed	0, 1, 2	Trial had BM reference group.
Makrides *et al.*, 2000, Australia, 2 sites (11)	C - LA/ALA, 16.9/1.7; T - LA/ALA, 16.6/3.3; diet duration = 8 mon	C = 36 T = 37	Through to 4 mon: C = 30 (17%) T = 30 (19%)	0, 1.5, 4, 8, 12, 24	BSID I (12,24)[d]	VEP_act (4,8) VEP_lat (4)	0, 1.5, 4, 8	Trial had BM reference group.

(ii) Trials involving enrichment with ALA. The trials of Jensen et al. (13,19,20), Makrides et al. (11), and Ponder et al. (12) tested the effect of enhancing the level of ALA while holding the level of LA constant. There were no significant differences in weight, length, and head circumference between groups except at 12 mon of age (Table 2). At this age the infants in the treatment group were longer (WMD: 1.78 cm, 95% CI: 0.58, 2.97; P = 0.004; n = 81) and heavier (WMD: 0.62 kg, 95% CI: 0.09, 1.15; P = 0.02; n = 81) than infants in the control group (Table 2). It is interesting to note that these effects were found at least 4 mon after dietary intervention had ceased, and infants were consuming sources of dietary FA from other milks and solids.

Despite randomization, the treatment group in Makrides et al. (11) was significantly heavier at birth than the control group. This had little effect on the pooled data, and no differences were seen between the birth weight of the control and treatment groups overall (WMD: 0.03 kg, 95% CI: –0.13, 0.18; P = 0.71; n = 122). At birth, there was also no difference in length (WMD: 0.34 cm, 95% CI: –0.21, 0.88; P = 0.23; n = 127) or head circumference (WMD: 0.04 cm, 95% CI: –0.38, 0.46; P = 0.85; n = 127) between groups.

Few infants were assessed for global neurodevelopmental outcomes, and there were no common assessments (Table 3). No difference could be detected between control and treatment groups for any outcome. There were also no differences in visual function between the groups at 4 or 8 mon of age as assessed by VEP latency and acuity (Table 3).

The level of DHA in plasma phospholipids of infants in the ALA-enriched group was consistently higher than in the con-trol group from 2 mon of age and higher in erythrocyte phospholipids from 4 mon of age (Table 4). In the supplementary analysis including all available data at 4 mon of age, increasing ALA dose was associated with increased levels of plasma and erythrocyte phospholipid DHA (Fig. 1). However, dietary ALA enrichment did not result in the DHA levels seen in breast-fed infants (Figs. 1A and 1B). ALA enrichment increased the level of plasma phospholipid EPA from 4 mon of age and erythrocyte phospholipid EPA from 2 mon of age (Table 4), and values reached those seen in breast-fed infants when ALA enrichment was approximately 3% of total FA (Figs. 1C and 1D). ALA supplementation lowered AA in plasma phospholipids at 2 mon of age and erythrocyte phospholipid AA levels at 4 mon of age compared with infants in the control group (Table 4). As dietary ALA increased, infant plasma and erythrocyte AA decreased (Figs. 1E and 1F). Erythrocyte AA levels of formula-fed infants matched those of breast-fed infants.

(iii) Trials involving enrichment with both ALA and LA. The data from the two included studies relating to growth, development, or LCPUFA status could not be combined because one trial did not measure outcomes after 3 mon (9). There were no differences in growth at 4 mon, visual acuity at 3 mon, or LC-PUFA status between the groups (Table 5).

Trials involving preterm infants. Summary of included studies. Three trials involving preterm infants conducted in North America (n = 2) and Europe (n = 1) were included in this systematic review (7,8,14,15,21–23; Jensen, C.L., Chen, H., Prager, T.C., Fraley, J.K., Anderson, R.E., and Heird, W.C., unpublished report) (Table 6). All trials involved enrichment of formula fats with ALA (2.0–3.2 wt%) relative to the control

formula (0.5–1.0 wt%). The most recent trial reported that nutrient-enriched, postdischarge formula was included as part of the feeding regimen available to all randomized groups (Jensen, C.L., Chen, H., Prager, T.C., Fraley, J.K., Anderson, R.E., and Heird, W.C., unpublished report). Two trials assessed growth to 57 wk PMA, whereas the third trial assessed growth up to hospital discharge when infants were 37 wk PMA (Table 6). Uauy et al. (7,8,15,21–23) measured visual function by VEP acuity, electroretinogram (ERG), and forced-choice preferential looking (FPL) acuity, and Jensen et al. (Jensen, C.L., Chen, H., Prager, T.C., Fraley, J.K., Anderson, R.E., and Heird, W.C., unpublished report) measured VEP latency (at a 30-min arc).

All trials reported that infants were randomly allocated to formula groups, but only one reported adequate concealment of allocation (Jensen, C.L., Chen, H., Prager, T.C., Fraley, J.K., Anderson, R.E., and Heird, W.C., unpublished report). Two trials were double-blind (15, Jensen, C.L., Chen, H., Prager, T.C., Fraley, J.K., Anderson, R.E., and Heird, W.C., unpublished report). Billeaud et al. (14) reported <20% attrition of infants at the end of the study (37 wk PMA). Uauy et al. (7,8,15,21–23) and Jensen et al. (Jensen, C.L., Chen, H., Prager, T.C., Fraley,

J.K., Anderson, R.E., and Heird, W.C., unpublished report) reported >20% attrition at 57 wk PMA. There were no significant differences in gestational age at birth (control 31.2 ± 1.2 wk compared with treatment 30.8 ± 1.5 wk) or birth weight (control 1.5 ± 0.2 kg compared with treatment 1.4 ± 0.3 kg). There were no differences in weight, length, or head circumference between the groups through to 57 wk PMA (Table 7).

The included trials measured different aspects of visual function that could not be combined. ERG analysis of one study at 36 wk PMA showed that infants fed increased dietary ALA had more sensitive rod photo receptors (log k WMD: –0.34 scot td-sec, 95% CI: –0.59, –0.09; $P = 0.009$; $n = 43$) and could respond to lower light intensities (rod threshold WMD: –0.37 scot td-sec, 95% CI: –0.66, –0.08; $P = 0.01$; $n = 43$) than infants fed control formula (Table 8). Birch et al. (22) reported that the ALA-enriched group had significantly better FPL acuity than the control group ($P < 0.05$) at 57 wk PMA (mean data unavailable). One trial found no difference in VEP latency between groups (Table 8).

At term and 57 wk PMA, infants in the ALA-enriched group had higher plasma and erythrocyte phospholipid EPA and DHA

than infants in the control group (Table 9). These higher blood levels of n-3 LCPUFA were associated with a reduction in plasma phospholipid AA at term but not at 57 wk PMA.

DISCUSSION

This systematic review and meta-analysis includes trials designed to modify 18-C PUFA in the diets of term and preterm infants in order to improve infant DHA status and assess the effects on growth and development. Our review is unique in that much of the data included were previously unpublished and were made available by the investigators. This maximized the amount of data available for the meta-analysis and decreased the risk of publication bias. However, the review only identified only five trials involving term infants and three trials involving preterm

infants. Although there are three possible dietary strategies to improve the availability of ALA for metabolism to DHA, most trials have simply assessed ALA enrichment without changing LA. Only two studies increased total 18-C PUFA, and no trials attempted to decrease dietary LA. The only studies to address the latter option were successful in improving DHA status but were not considered in this review because they were not randomized (24,25), and no growth or developmental outcome data were reported (25). The small number of trials was surprising given the intense interest in DHA, a major metabolite of ALA. It also highlighted the paucity and lack of commonality of data relating to visual and developmental outcomes.

There was no effect of dietary ALA enrichment on term infant growth except at 12 mon of age where infants consuming ALA-enriched formula were heavier and longer compared with

control infants. This time point was at least 4 mon after dietary intervention had ceased. Furthermore, these findings may have been influenced by the unbalanced randomization in the trial conducted by Makrides et al. (11), which resulted in the ALA-enriched group being consistently heavier and longer at birth and throughout the dietary intervention. Although our meta-analysis showed no differences in weight, length, or head circumference at birth, the majority of 12-mon data were contributed by Makrides et al. (11). The limited data do not support the suggestion that perturbations in blood EPA and AA levels (induced by high-ALA diets) were associated with lower weight or length in term or preterm infants. In fact, the results showed no difference in weight, length, or head circumference even at the specific time-points where levels of erythrocyte AA were lower and EPA erythrocyte levels were higher in the ALA-enriched group compared with controls. Interestingly, the only study to suggest a negative effect of ALA supplementation on weight gain was observed between term infants fed high ALA (3.2 wt%, $n = 13$) and low ALA (0.4 wt%, less than the control group of 1.7 wt% used in this meta-analysis, $n = 17$) at one of four time-points assessed (13). That dietary ALA enrichment did not influence the growth of preterm infants raises questions in our minds as to the validity of the individual finding relating to the growth of term infants and highlights the limitations of single small trials and a meta-analysis performed on few trials with small sample sizes.

It has been suggested that term infants fed formula with at least 2% of total FA as ALA experience normal visual development, whereas such a level may be inadequate for preterm infants (26). The very limited developmental data available from this meta-analysis can throw no light on this issue since much of the data could not be combined and the limited sample sizes did not allow the detection of meaningful differences for most outcomes. Interestingly, the majority of data available were for VEP latency of term infants, and there were no group differences for this outcome. Visual development studies in preterm infants found those fed ALA-supplemented formula (2.7 wt%) had significantly increased retinal function at 36 wk PMA, but this effect was not sustained to 57 wk PMA. No trials of ALA enrichment assessed the neurodevelopment of preterm infants.

Pooled data indicate that infants consuming ALA-enriched diets had significantly increased levels of plasma and erythrocyte DHA compared with controls. However, the strategy of increasing ALA, without decreasing LA, was not effective in increasing formula-fed infant DHA levels to breast-fed infant levels but was effective in increasing EPA and decreasing AA levels. Two nonrandomized studies, not included in this review, aimed to increase infant DHA levels by lowering the LA content of the diet. Clark et al. (25) lowered formula LA to 3.5 wt%, maintained ALA at 1 wt%, and increased erythrocyte DHA levels but not to breast-fed infant levels. Courage et al. (24) assessed term infants fed evaporated milk with an LA/ALA ratio of 2.3:1 and showed increased erythrocyte PE DHA above formula-fed infants but again not to breast-fed infant levels. Trials are needed to address the relative benefits and risks of low-LA formulas.

Recommendations by international expert committees concerning the ALA content of formula have been made in the absence of an extensive database from randomized trials. This review has verified the need for further studies with long-term followup and large numbers of infants to ensure sufficient

statistical power to detect growth and developmental differences between dietary groups, should they exist. Practically, the findings from such trials will ensure that future recommendations regarding the 18-C PUFA levels for term and preterm infant formula will be more rigorous and evidence-based.

Highly Unsaturated Fatty Acid Synthesis in Vertebrates: New Insights with the Cloning and Characterization of a Δ6 Desaturase of Atlantic Salmon

Xiaozhong Zheng, Douglas R. Tocher*, Cathryn A. Dickson, J. Gordon Bell, and Alan J. Teale

Institute of Aquaculture, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom

ABSTRACT: Fish are an important source of the n-3 highly unsaturated fatty acids (HUFA), eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids that are crucial to the health of higher vertebrates. The synthesis of HUFA involves enzyme-mediated desaturation, and a Δ5 fatty acyl desaturase cDNA has been cloned from Atlantic salmon (*Salmo salar*) and functionally characterized previously. Here we report cloning and functional characterization of a Δ6 fatty acyl desaturase of Atlantic salmon and describe its genomic structure, tissue expression, and nutritional regulation. A salmon genomic library was screened with a salmon Δ5 desaturase cDNA and positive recombinant phage isolated and subcloned. The full-length cDNA for the putative fatty acyl desaturase was shown to comprise 2106 bp containing an open reading frame of 1365 bp specifying a protein of 454 amino acids (GenBank accession no. AY458652). The protein sequence included three histidine boxes, two transmembrane regions, and an N-terminal cytochrome b_5 domain containing the heme-binding motif HPGG, all of which are characteristic of microsomal fatty acid desaturases. Functional expression showed that this gene possessed predominantly Δ6 desaturase activity. Screening and sequence analysis of the genomic DNA of a single fish revealed that the Δ6 desaturase gene constituted 13 exons in 7965 bp of genomic DNA. Quantitative real-time PCR assay of gene expression in Atlantic salmon showed that both Δ6 and Δ5 fatty acyl desaturase genes, and a fatty acyl elongase gene, were highly expressed in intestine, liver, and brain, and less so in kidney, heart, gill, adipose tissue, muscle, and spleen. Furthermore, expression of both Δ6 and Δ5 fatty acyl desaturase genes in intestine, liver, red muscle, and adipose tissue was higher in salmon fed a diet containing vegetable oil than in fish fed a diet containing fish oil.

Paper no. L9602 in *Lipids 40*, 13–24 (January 2005).

Highly unsaturated fatty acids (HUFA), including arachidonate (20:4n-6), EPA (20:5n-3), and DHA (22:6n-3), are crucial to the health and normal development of higher vertebrates (1–3). Fish are the most important source of n-3 HUFA for humans, but with fisheries in decline, an increasing proportion of fish are being provided by rapidly expanding aquacul-

ture (4). Paradoxically, aquaculture is itself dependent on fisheries for the provision of fish meals and oils traditionally used in the feed formulations (5). Their use ensures the high nutritional quality of farmed fish through the high levels of n-3 HUFA that fish oil (FO) and fish meal provide. However, feed-grade fisheries have reached sustainable limits. Along with concern over organic contaminants in FO, this has dictated that alternatives to FO must be found if aquaculture is to continue to expand and supply more of the global demand for fish (6).

The only practical, sustainable alternative to FO is vegetable oils (VO), which are rich in C_{18} PUFA but devoid of the n-3 HUFA abundant in FO (7). Consequently, tissue FA compositions in fish fed VO are characterized by increased levels of C_{18} PUFA and decreased levels of n-3 HUFA, which may reduce their nutritional value to the human consumer (8). The extent to which fish can convert C_{18} PUFA to HUFA varies, associated with their complement of FA desaturase enzymes. Although Atlantic salmon (*Salmo salar* L.) are capable of producing DHA from 18:3n-3, and so express the necessary desaturase activities, the production is insufficient to maintain n-3 HUFA in fish fed VO at levels found in fish fed FO (9–11). Our primary hypothesis is that understanding the molecular basis of HUFA biosynthesis and its regulation in fish will enable us to optimize the activity of the pathway to ensure efficient and effective use of VO in aquaculture while maintaining the nutritional quality of farmed fish for the consumer.

Δ5 and Δ6 fatty acyl desaturases and elongases are critical enzymes in the pathways for the biosynthesis of HUFA. In recent years, significant progress has been made in characterizing FA desaturases involved in HUFA synthesis (12). Full-length cDNAs for Δ6 desaturases have been isolated from the filamentous fungus *Mortierella alpina* (13), the nematode *Caenorhabditis elegans* (14), rat (15), mouse and human (16). FA Δ5 desaturase genes have been isolated from *M. alpina* (17), *C. elegans* (18,19), and humans (20,21). Moreover, we have reported isolation of a cDNA of zebrafish (*Danio rerio*, GenBank accession no. AF309556) that has high similarity to mammalian Δ6 desaturase genes. Functional analysis by heterologous expression in the yeast *Saccharomyces cerevisiae* indicated that the zebrafish gene was unique in that the cDNA encoded an enzyme having both Δ6 and Δ5 desaturase activities (22). Putative FA desaturase cDNAs have now also been

isolated and cloned from rainbow trout (*Oncorhynchus mykiss*, GenBank accession no. AF301910) (23) and gilthead seabream (*Sparus aurata*, GenBank accession no. AY055749) (24). Functional analysis showed that these two desaturase genes, along with cDNAs recently cloned from common carp (*Cyprinus carpio*, GenBank accession no. AF309557) and turbot (*Psetta maximus*, GenBank accession no. AF301910) encoded basically unifunctional Δ6 FA desaturase enzymes responsible for the first and possibly rate-limiting step in the biosynthesis of HUFA from 18:3n-3 and 18:2n-6 (25). Recently, a full-length cDNA for a desaturase containing 1365 bp encoding 454 amino acid residues has been cloned from Atlantic salmon (GenBank accession no. AF478472). Functional analysis showed that this gene was primarily a Δ5 desaturase with virtually no Δ6 activity (26). Therefore, it was presumed that other FA desaturase genes should be present in Atlantic salmon.

The objectives of the study described here were, first, to clone and functionally characterize a Δ6 desaturase gene of Atlantic salmon; second, to describe its genomic structure; and third, to place it in evolutionary and physiological contexts. Therefore, we detail the exon/intron organization of a salmon Δ6 desaturase gene, describe the expression profile of both Δ6 and Δ5 fatty acyl desaturase and fatty acyl elongase genes in various tissues, and demonstrate nutritional regulation of the fatty acyl desaturase genes.

MATERIALS AND METHODS

Putative desaturase cloning and its genomic organization. An Atlantic salmon genomic DNA library constructed previously with the lambda FIX II/Xho I partial fill-in vector kit (Stratagene, La Jolla, CA) was probed with a full-length salmon Δ5 fatty acyl desaturase cDNA (GenBank accession no. AF478472). Inserts of positive recombinant phages were isolated and subcloned into the pBluescript KS II vector for sequencing (Stratagene). The full putative desaturase genomic nucleotide sequence was assembled using BioEdit, version 5.0.6 (Tom Hall, Department of Microbiology, North Carolina State University, Raleigh, NC).

Total RNA was extracted from liver tissue of Atlantic salmon fed a standard extruded diet based on fish meal and FO using TRIzol® reagent (GibcoBRL, Grand Island, NY). 3′-RACE (rapid amplification of cDNA ends) cDNA was synthesized using MMLV (Moloney murine leukemia virus) reverse transcriptase (Promega, Madison, WI) primed by the oligonucleotide, T7PolyT, 5′-TACGACTCATATAGGGCGT-GCAGTTTT TTTTTTTT-3′. The specific sense primer, D6P31, 5′-CAGGGGTGGGCCCGGTGGAGGGCTA-3′ was designed for 3′-RACE PCR based on the genomic sequence described above. This was used in conjunction with T7PolyT primer for the RACE PCR isolation of the salmon desaturase cDNA fragment predicted to contain the 3′ UTR (untranslated region). PCR amplification was performed using the Hotstar Taq master kit (Qiagen, Crowley, West Sussex, United Kingdom) and involved an initial denaturation step at 95°C for 15

min, followed by 30 cycles of denaturation at 95°C for 30 s, annealing at 58°C for 30 s, and extension at 72°C for 3 min. The final extension at 72°C was for 10 min. 5′-RACE-cDNA was synthesized using the SMART^TM RACE cDNA amplification kit (Clontech, Palo Alto, CA). The primer, SD6PPR3, 5′-GTCGCATTCCATCCCAATCC-3′ was designed according to the 3′-RACE PCR fragment sequence. This was used in conjunction with universal primer mix: long 5′-CTAATAC-GACTCACTATAGGGCAAGCAGTGGTACAACGGA-GT-3′ and short 5′-CTAATACGACTCACTATAGGGC-3′ to perform 5′-RACE PCR using high-fidelity DNA polymerase (Roche Diagnostics Ltd., Lewes, East Sussex, United Kingdom). Amplification involved an initial step at 95°C for 1 min and 70°C for 3 min, and four cycles of denaturation at 95°C for 15 s, annealing at 62°C for 1 min, and extension at 72°C for 1 min 30 s, followed by 27 cycles of denaturation at 95°C for 15 s, annealing at 56°C for 30 s and extension at 72°C for 1 min 30 s. The final extension at 72°C was for 10 min.

All RACE PCR products were cloned into the pBluescript KS II^+ vector for sequencing. The 3′ and 5′ RACE PCR fragment sequences were aligned to assemble the full nucleotide sequence of the putative desaturase cDNA using BioEdit, version 5.0.6. The assembled putative fatty acyl desaturase cDNA sequence and its genomic DNA sequence were aligned to assign consensus donor and acceptor splice recognition sequences.

Heterologous expression of desaturase open reading frames (ORF) in S. cerevisiae. PCR amplification was carried out to clone the salmon putative desaturase cDNA ORF. Sense primer, D6RF2, 5′-ATGGGGGGCGGAGGCCAGCA-GAATGATTCAG-3′, and antisense primer, D6RR1, 5′-AT-GCGATGGATTAAATCCCG –3′ (located in the 3′ UTR) were designed for first-round PCR after comparing nucleotide sequences of this putative cDNA and the Δ5 desaturase cDNA. Expression primers were designed for a second round of PCR. The sense primer, SalpYESFOR, 5′-CCCAAGCTTAC-TATGGGGGGCGGAGGCC-3′ contains a *HindIII* site (underlined) and antisense primer, SalPYESREV2, 5′- CCG-CTCGAGTCATTTATGGAGATATGCAT-3′ contains an *XhoI* site (underlined). PCR was performed using high-fidelity DNA polymerase (Roche Diagnostics Ltd.) following the manufacturer's instructions. Amplification involved an initial denaturation step at 95°C for 2 min, followed by 30 cycles of denaturation at 95°C for 30 s, annealing at 55°C for 30 s, and extension at 72°C for 2 min and 30 s followed by a final extension at 72°C for 10 min.

Following PCR, the DNA fragments were restricted with the appropriate enzymes, *HindIII* and *XhoI*, and ligated into the similarly digested yeast expression vector pYES2 (Invitrogen Ltd., Paisley, United Kingdom). Ligation products were then used to transform Top10F′ *Escherichia coli* competent cells (Invitrogen Ltd.), which were screened for the presence of recombinants. Transformation of the yeast *S. cerevisiae* (strain InvSc1) with the recombinant plasmids was carried out using the S.c.EasyComp Transformation Kit (Invitrogen Ltd.). Selection of yeast containing the desaturase/pYES2

constructs was on *S. cerevisiae* minimal medium (SCMM) minus uracil. Culture of the recombinant yeast was carried out in SCMM$^{-uracil}$ broth as described previously (22), using galactose induction of gene expression. Each culture was supplemented with one of the following PUFA substrates: α-linolenic acid (18:3n-3), linoleic acid (18:2n-6), eicosatetraenoic acid (20:4n-3), dihomo-γ-linoleic acid (20:3n-6), docosapentaenoic acid (22:5n-3), or docosatetraenoic acid (22:4n-6). PUFA were added to the yeast cultures at concentrations of 0.5 mM (C_{18}), 0.75 mM (C_{20}), and 1 mM (C_{22}), as uptake efficiency decreases with increasing chain length. Yeast cells were harvested, washed, and dried, and lipid was extracted by homogenization in chloroform/methanol (2:1, vol/vol) containing 0.01% BHT as antioxidant as described previously (22). FAME were prepared, extracted, purified by TLC, and analyzed by GC, all as described previously (22). The proportion of substrate FA converted to the longer-chain FA product was calculated from the gas chromatograms as 100 × [product area/(product area + substrate area)]. Unequivocal confirmation of FA products was obtained by GC–MS of the picolinyl derivatives as described in detail previously (22).

Salmon tissue RNA extraction and quantitative real-time PCR (qrtPCR). Tissue expression profiles and effects of diet were investigated in Atlantic salmon that had been fed one of two diets from the first feeding. The diets consisted of a control in which FO was the only added oil and an experimental diet in which 75% of the FO was replaced by a VO blend containing rapeseed, palm, and linseed oils in a 3.7:2:1 ratio. Both diets were fishmeal-based and contained 48% protein, 26% lipid, 7% moisture, and 8% ash as determined by proximate analyses. The FA compositions of the diets (6 mm pellet) are given in Table 1. The diets were prepared by the Nutreco Aquaculture Research Centre (Stavanger, Norway) and formulated to satisfy the nutritional requirements of salmonid fish (27).

Fish were sampled in November 2003, 6 mon after seawater transfer, following 18 mon on the diets, at which point the weights of the fish fed the FO and VO diets were 1250.0 ± 84.9 and 1280.0 ± 79.4 g, respectively. Eight fish per dietary treatment were sampled, and liver, brain, heart, kidney, gill, intestine (pyloric caeca), spleen, white and red muscle, and adipose tissue were collected, frozen immediately in liquid nitrogen, and subsequently stored at –80°C before extraction. Total RNA extraction was performed as described above. Five micrograms of total RNA was reverse-transcribed into cDNA using an MMLV reverse transcriptase first strand cDNA synthesis kit (Promega UK, Southampton, United Kingdom). Gene expression of the fatty acyl Δ6 and Δ5 desaturase, and fatty acyl elongase genes in tissue from individual salmon fed the different diets were studied by quantitative real-time PCR (qrt-PCR). β-Actin was used for normalization of mRNA levels. The PCR primers were designed according to Δ6 desaturase (accession no. AY458652), and the published Δ5 desaturase (accession no. AF478472), elongase (accession no. AY170327), and β-actin (accession no. AF012125) cDNA sequences. For the Δ6 desaturase, the for-

ward primer was 5′-CCCCAGACGTTTGTGTCAG-3′, and the reverse primer was 5′-CCTGGATTGTTGCTTTGGAT-3′. For the Δ5 desaturase, the forward primer was 5′-GTGAATGGGGATCCATAGCA-3′, and the reverse primer was 5′-AAACGAACGGACAACCAGA-3′. For the elongase, the forward and reverse primers were 5′-TGATTTGTGTTCCAAATGGC-3′ and 5′-CTCATGACGGGAACCT CAAT-3′, respectively. For β-actin, 5′-ACATCAAGGAGAAGCTGTGC-3′ and 5′-GACAACGGAACCTCTCGTTA-3′ were the forward and reverse primers, respectively. PCR product sizes were 181, 192, 219, and 141 bp, respectively. The linearized plasmid DNA containing the target sequence for each gene was quantified to generate a standard curve of known copy number. Amplification of cDNA samples and DNA standards was carried out using a SYBR Green PCR kit (Qiagen) under the following conditions: 15 min denaturation at 95°C, 45 cycles of 15 s at 94°C, 15 s at 55°C, and 30 s at 72°C. This was followed by product melt to confirm single PCR products. Thermal cycling and fluorescence detection were conducted in a Rotor-Gene 3000 system (Corbett Research, Cambridge, United Kingdom). The copy numbers of the specific genes in the sample, normalized to total RNA, were used to compare expression levels between different tissues, and the ratios of copy numbers between the target genes

and β-actin were calculated and used to compare the gene expression levels in fish fed the two diets.

Sequence analysis. Nucleotide sequences were determined by standard dye terminator chemistry using a PerkinElmer ABI-377 DNA sequencer following the manufacturer's protocols (PerkinElmer, Applied Biosystems). Deduced amino acid sequences of desaturases from various species were aligned using ClustalX, and sequence phylogenies were predicted using the Neighbour Joining method (28). Confidence in the resulting phylogenetic tree branch topology was measured by bootstrapping through 1000 iterations.

Materials. Eicosatetraenoic (20:4n-3), docosapentaenoic (22:5n-3), and docosatetraenoic (22:4n-6) acids (all >98–99% pure) were purchased from Cayman Chemical Co. (Ann Arbor, MI). Linoleic (18:2n-6), α-linolenic (18:3n-3), and eicosatrienoic (20:3n-6) acids (all >99% pure), BHT, 1,1′-carbonyldiimidazole, 2,2-dimethoxypropane, FA-free BSA, galactose, 3-(hydroxymethyl) pyridine, HBSS, nitrogen base, raffinose, tergitol NP-40, and uracil dropout medium were obtained from Sigma Chemical Co. Ltd. (Dorset, United Kingdom). TLC (20 cm × 20 cm × 0.25 mm) plates precoated with silica gel 60 (without fluorescent indicator) were purchased from Merck (Darmstadt, Germany). All solvents were HPLC grade and were from Fisher Scientific (Loughborough, United Kingdom).

RESULTS

Sequence analyses. The full length of the putative salmon desaturase cDNA (mRNA), as determined by 5′- and 3′-RACE PCR, was shown to be 2106 bp, which included a 5′-UTR of 284 bp and a 3′-UTR of 457 bp. Sequencing revealed that the cDNA included an ORF of 1365 bp, which specified a protein of 454 amino acids (GenBank accession no. AY458652). The protein sequence included all the characteristic features of microsomal FA desaturases, including three histidine boxes and an N-terminal cytochrome b_5 domain containing the heme-binding motif, HPGG (Fig. 1). The protein sequence also contained two transmembrane regions. These features are similar to those of other FA desaturase genes including salmon Δ5 desaturase, the zebrafish Δ6/Δ5 desaturase, and the human Δ5 (GenBank accession no. AF126799) and Δ6 (GenBank accession no. AF199596) desaturases. However, the new salmon desaturase, like the salmon Δ5 desaturase and the rainbow trout Δ6 desaturase sequences, had an insertion of 10 amino acid residues at the N-terminal end.

A pairwise comparison was made between fish and human desaturase sequences. The amino acid sequence predicted by the salmon putative (Δ6) desaturase ORF shows 91% identity to the salmon Δ5 desaturase, and 94% identity to the trout Δ6 desaturase. The salmon cDNA shows 65% identity to that of the zebrafish Δ6/Δ5 desaturase, and 65 and 58% identity to the human Δ6 and Δ5 cDNAs, respectively.

A phylogenetic tree was constructed on the basis of the amino acid sequence alignments between the salmon fatty acyl desaturases and 15 other desaturases of fish and mammals (Fig. 2). The phylogenetic analysis clustered the new Atlantic salmon putative desaturase sequence with the Atlantic salmon Δ5 desaturase, rainbow trout Δ6 desaturase and other, as yet uncharacterized, masou (cherry) salmon (*Oncorhynchus masou*) desaturase genes, but closest to the trout Δ6 desaturase. The salmonid desaturases clustered more closely with turbot, sea bream, and tilapia (*Oreochromis nilotica*) desaturases than with carp Δ6 desaturase and zebrafish Δ5/Δ6 desaturase. All of the fish desaturase genes clustered together, and closer to the mammalian (mouse and human) Δ6 desaturases than to the mammalian Δ5 desaturases.

Functional characterization. The salmon desaturase cDNA was functionally characterized by determining the FA profiles of transformed *S. cerevisiae* containing either the pYES vector alone or the vector with the salmon desaturase cDNA insert, grown in the presence of a variety of potential FA substrates, including Δ6 substrates (18:2n-6 and 18:3n-3), Δ5 substrates (20:3n-6 and 20:4n-3), and Δ4 substrates (22:4n-6 and 22:5n-3). The FA composition of the yeast transformed with the vector alone showed the four main FA normally found in *S. cerevisiae*, namely 16:0, 16:1n-7, 18:0, and 18:1n-9, together with the exogenously derived FA. This is consistent with *S. cerevisiae* not possessing Δ5 or Δ6 FA desaturase activities (Figs. 3 and 4). The most prominent additional peaks were observed in the profiles of transformed yeast grown in the presence of the Δ6 desaturase substrates, 18:3n-3 and 18:2n-6 (Fig. 3). Based on GC retention time and confirmed by GC–MS, the additional peaks associated with the presence of the salmon desaturase cDNA were identified as 18:4n-3 (Fig. 3B) and 18:3n-6 (Fig. 3D), corresponding to the Δ6 desaturation products of 18:3n-3 and 18:2n-6, respectively. Approximately, 60.1% of 18:3n-3 was converted to 18:4n-3 and 14.4% of 18:2n-6 was converted to 18:3n-6 in yeast transformed with the salmon desaturase (Table 2). However, a very small additional peak representing desaturated FA product, as confirmed by GC–MS, was observed in the lipids of *S. cerevisiae* transformed with the desaturase cDNA when the transformed yeast was incubated with 20:4n-3 (Figs. 4A and 4B). About 2.3% of 20:4n-3 (n-3 Δ5 activity) was desaturated by the salmon clone, but no product of desaturation of the 20:3n-6 substrate was detected, indicating no significant n-6 Δ5 desaturase activity. The desaturase cDNA did not express any Δ4 desaturase activity as evidenced by the lack of any observable additional peaks representing desaturated products of 22:5n-3 or 22:4n-6 (data not shown). Overall, therefore, the results showed that the salmon desaturase cDNA-encoded enzyme was essentially a Δ6 fatty acyl desaturase, with only a very low level of Δ5 desaturase activity, and no Δ4 desaturase activity.

Genomic structure. The alignment of the Δ6 fatty acyl desaturase cDNA and the genomic sequences revealed 13 exons spanning 7965 bp of genomic DNA as illustrated in Table 3.

FA desaturase and elongase gene expression in salmon tissues. To identify which tissues were likely to contribute to HUFA synthesis in the Atlantic salmon, reverse transcription qrtPCR was used to examine the tissue distribution of Δ6 and

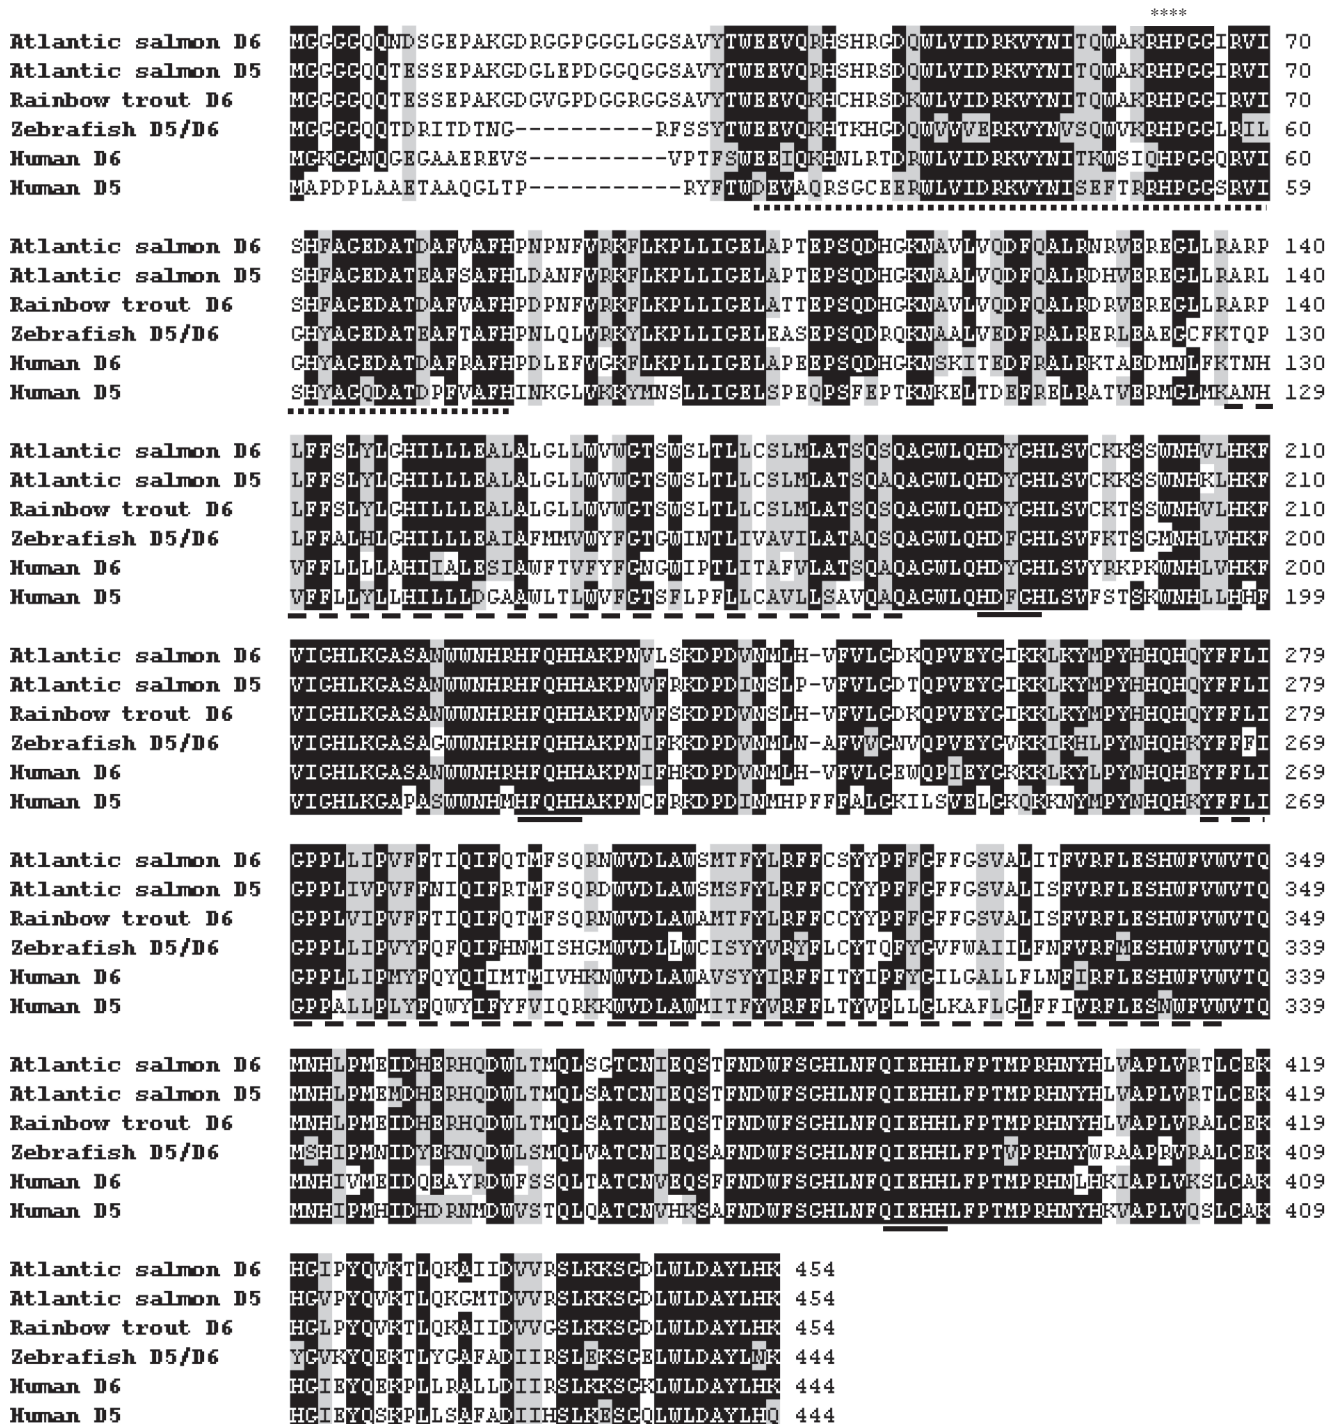

FIG. 1. Comparison of the deduced amino acid sequence of Δ6 and Δ5 polyunsaturated fatty acyl desaturases from Atlantic salmon with that of desaturases from trout, zebrafish, and humans. Identical residues are shaded black, and similar residues are shaded grey. Identity/similarity shading was based on the BLOSUM62 matrix, and the cutoff for shading was 75%. The cytochrome b_5-like domain is dot-underlined, the two transmembrane regions are dash-underlined, the three histidine-rich domains are solid underlined, and asterisks on the top mark the heme-binding motif, HPGG.

Δ5 fatty acyl desaturase and fatty acyl elongase mRNAs. The results showed that the three genes were expressed in all tissues examined, with the highest expression in terms of the absolute copy numbers (mean ± SD, $n = 8$) in intestine, followed by liver and brain (Fig. 5). In comparison with the Δ5 desaturase, the transcript copy abundance for the Δ6 desaturase was higher in these tissues with higher expression, but lower in tissues with lower expression, other than kidney. The transcript copy abundance for fatty acyl elongase was much lower than that for the Δ6 and Δ5 desaturases in all tissues.

The ratios of copy numbers between the target genes and β-actin were determined (means ± SD, $n = 4$), and the fold
FIG. 2. Phylogenetic tree of Δ6 and Δ5 desaturases from salmon, and desaturases from other fish species (zebrafish, cherry salmon, rainbow trout, seabream, common carp, turbot, and tilapia), mammals (mouse and human), fungus (*Mortierella alpina*), and nematode (*Caenorhabditis elegans*). The tree was constructed using the Neighbour Joining method using *ClustalX* and *NJPLOT*. The horizontal branch length is proportional to the amino acid substitution rate per site. The numbers represent the frequencies with which the tree topology presented here was replicated after 1000 bootstrap iterations. Sequences marked with an asterisk are not functionally characterized.

difference between the mean value of target gene expression in the tissue of fish fed VO was calculated relative to the expression in tissues of fish fed FO (Fig. 6). The results revealed that Δ6 and Δ5 fatty acyl desaturase gene expression in liver and red muscle of fish fed VO was significantly increased compared with fish fed the FO diet, whereas the expression of both desaturases in heart and spleen, and Δ5 in gill and kidney was decreased in fish fed VO (Fig. 6). Expression of both desaturases in intestine and adipose tissue was also higher in fish fed VO, although with the high variation these effects were below the level of statistical significance. However, feeding VO decreased the expression of the fatty acyl elongase gene in most tissues, significantly so in heart, gill, brain, adipose, spleen, and kidney (Fig. 6).

DISCUSSION

Several fish desaturases have been cloned and functionally characterized in recent years. These are the bifunctional zebrafish enzyme showing both Δ6 and Δ5 desaturase activity (22), an Atlantic salmon desaturase that was shown to be predominantly an n-3 Δ5 desaturase (26), and common carp, rainbow trout, gilthead seabream, and turbot desaturases that were all shown to be predominantly Δ6 desaturases (25). The bifunctional nature of the Δ6/Δ5 desaturase of zebrafish suggested that it may be a prototypic or ancestral progenitor desaturase (22,29). But the subsequent characterization of several essentially unifunctional Δ6 fish desaturases and the salmon Δ5 desaturase indicates that the zebrafish enzyme might be atypical.
FIG. 3. Functional expression of the Atlantic salmon putative fatty acyl desaturase in transgenic yeast (*Saccharomyces cerevisiae*) grown in the presence of Δ6 substrates, 18:3n-3 and 18:2n-6. FA were extracted from yeast transformed with pYES vector without insert (A and C) or containing the putative FA desaturase cDNA insert (B and D). The first four peaks in panels A–D are the main endogenous FA of *S. cerevisiae*, namely, 16:0 (1), 16:1n-7 (2), 18:0 (3), and 18:1n-9 (with 18:1n-7 as shoulder) (4). Peak 5 in panels A and B, and peak 7 in panels C and D are the exogenously added substrate FA, 18:3n-3 and 18:2n-6, respectively. Peaks 6 and 8 in panels B and D were identified as the resultant desaturated products, namely, 18:4n-3 and 18:3n-6, respectively. Vertical axis, FID response; horizontal axis, retention time.

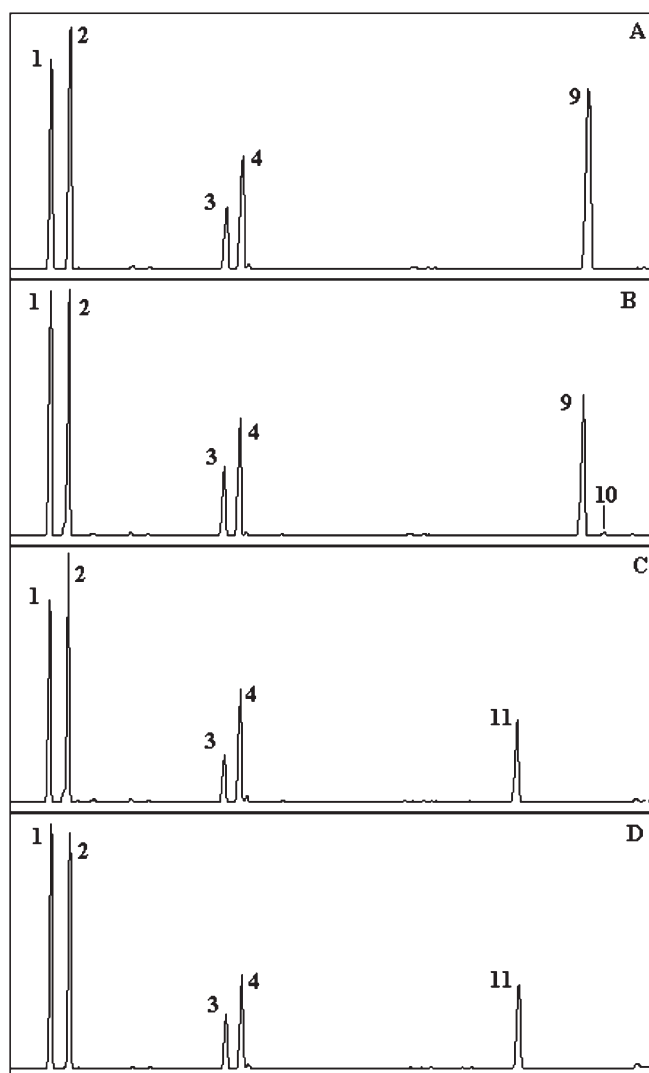
The study described here has further increased our knowledge of PUFA desaturases in fish. The cloning and functional characterization of a predominantly Δ6 desaturase gene makes the Atlantic salmon the first fish species to be shown to have separate and distinct genes for Δ6 and Δ5 desaturases, as reported previously for *C. elegans* (14,18,19) and humans (16,20,21). The salmon Δ6 desaturase clone also showed measurable, but very low, levels of Δ5 activity and thus was similar to other fish Δ6 desaturases of carp, trout, seabream,


FIG. 4. Functional expression of the Atlantic salmon putative fatty acyl desaturase in transgenic yeast (*Saccharomyces cerevisiae*) grown in the presence of Δ5 substrates, 20:4n-3 and 20:3n-6. FA were extracted from yeast transformed with pYES vector without insert (A and C) or containing the putative FA desaturase cDNA insert (B and D). The first four peaks in panels A–D are as described in the caption to Figure 3. Peak 9 in panels A and B, and peak 11 in panels C and D are the exogenously added substrate FA, 20:4n-3 and 20:3n-6, respectively. Peak 10 in panel B was identified as the resultant desaturated product of 20:4n-3, namely, 20:5n-3. Vertical axis, FID response; horizontal axis, retention time.

TABLE 2

Functional Characterization of Salmon FA Desaturase cDNA Clone in the Yeast *Saccharomyces cerevisiae*

PUFA substrates	Products	Desaturase activity	Conversion rate[a] (%)
α-Linolenic acid (18:3n-3)	18:4n-3	Δ6	60.1
Linoleic acid (18:2n-6)	18:3n-6	Δ6	14.4
Eicosatetraenoic acid (20:4n-3)	20:5n-3	Δ5	2.3
Dihomo-γ-linolenic acid (20:3n-6)	20:4n-6	Δ5	0
Docosapentaenoic acid (22:5n-3)	22:6n-3	Δ4	0
Docosatetraenoic acid (22:4n-6)	22:5n-6	Δ4	0

[a]Conversion rates represent the proportion of substrate FA converted to the longer-chain FA product, calculated from the gas chromatograms as 100 × [product area/(product area + substrate area)].

and turbot (25). But, unlike the zebrafish desaturase, which showed very significant Δ5 desaturase activity at around 70% of the Δ6 activity (22), the n-3 Δ5 activity in the salmon cDNA product was only 3.8% of the Δ6 activity. It is likely that the level of Δ5 desaturase activity measured is of limited physiological significance.

The study described here also clearly showed that the salmon Δ6 desaturase has a marked preference for the n-3 substrate 18:3n-3 over the n-6 substrate 18:2n-6. A similar preference for n-3 FA substrates rather than n-6 substrates on heterologous expression in yeast was observed previously with the zebrafish Δ6/Δ5 desaturase, salmon Δ5 desaturase (22,26), and trout, seabream, carp, and turbot Δ6 desaturases (25). These data are consistent with earlier enzymological studies investigating the desaturation of ^{14}C-labeled FA substrates in primary hepatocytes (9), primary brain astrocytes (30), and established cell lines (31). Therefore, it appears that greater activity toward n-3 PUFA may be a characteristic of fish fatty acyl desaturases. In contrast, functional characterization of Δ6 desaturases of other organisms including nematodes, mammals, fungi, mosses, and higher plants failed to show a preference for either 18:3n-3 or 18:2n-6 substrates, although recently Δ6 desaturases have been identified in *Primula* sp. that have a preference for n-3 substrates (32). However, data of these kinds obtained from heterologous expression can be regarded as only semiquantitative, as there are likely to be differences between FA, for example, in their uptake into organisms such as yeasts (33).

The present study shows unequivocally that distinct Δ6 and Δ5 desaturase genes exist in Atlantic salmon, as is the case in humans, and possibly in mammals in general. However, the two salmon cDNAs are very similar in that the predicted amino acid sequence encoded by the Δ6 cDNA is 91%
FIG. 5. Tissue distribution of FA Δ6 and Δ5 desaturase and elongase genes in Atlantic salmon. Transcript (mRNA) copy number was determined by quantitative real-time PCR (qrtPCR) as described in the Materials and Methods section. Results are expressed as the copy numbers in 250 ng of total RNA and are means ± SEM (*n* = 4). L, liver; H, heart; G, gill; WM, white muscle; RM, red muscle; I, intestine; B, brain; A, adipose; S, spleen; K, kidney.

identical with that encoded by the Δ5 desaturase cDNA. In contrast, in humans and *C. elegans*, the two functional Δ6 and Δ5 desaturases share an amino acid identity of only 62 (20) and 45% (19), respectively. Whether or not distinct Δ6 and Δ5 desaturase genes evolved from a common ancestral desaturase progenitor, these data suggest that the process occurred or began more recently in the evolution of Atlantic salmon than in the evolution of humans and *C. elegans*. In this regard, it is pertinent to note that the Atlantic salmon is partially tetraploid, with the tetraploidization event thought to have occurred 25–100 million years ago (34). However, evolution of desaturases in Atlantic salmon and in fish in general remains a subject for speculation. Study of further FA desaturase genes of fish are indicated, and certainly other desaturases are likely to be identified in fish species such as carp and trout, which have the ability to produce DHA from 18:3n-3 (35). But in marine species such as sea bream and turbot, the search for Δ5 desaturases will be particularly intriguing as these species lack the ability to produce EPA and DHA from 18:3n-3. This is attributed to deficiencies in Δ5 desaturation in sea bream, but to C_{18-20} elongation in turbot (36,37).

The salmon Δ6 desaturase showed no Δ4 desaturase activity, perhaps as expected based on the functional characterization of all fish and mammalian Δ6 and Δ5 desaturases reported to date (22,25,26,38). This is consistent with the hypothesis that the synthesis of DHA from EPA in both mammals and fish proceeds *via* elongation to 24:5n-3 followed by a Δ6 desaturation rather than *via* Δ4 desaturation of 22:5n-3 (35,39). Heterologous expression studies of human and rat Δ6 desaturases showed that the same enzymes are active on C_{18} and C_{24} FA (33,40) and that the bifunctional zebrafish desaturase was also capable of desaturating C_{24} FA (41). It will be interesting to determine the activities of all an-

imal Δ6 desaturases toward C_{24} FA substrates. In contrast to higher animals, production of DHA *via* a pathway including Δ4 desaturation appears to operate in some lower organisms such as *Thraustochytrium* sp. (42), and the algae *Euglena gracilis* (43) and *Pavlova lutheri* (44).

Genomic characterization showed that the salmon Δ6 desaturase comprised 13 exons, which is one more than that reported for the human Δ6 desaturase (45). The additional exon in the salmon gene is a small 25 bp exon at the extreme 5′ end. The remaining exons are homologous to the 12 exons in the human Δ6 desaturase, except that exon 2 of the salmon gene is 30 bp longer than exon 1 in the human gene, corresponding to the additional 10 amino acids found in most salmonid desaturases. However, the remaining exons are exactly the same size as their equivalents in the human gene, and splice and acceptor sites are interrupted at similar nucleotide positions, even though the lengths of the introns are quite different. In humans, there is evidence that the desaturase gene cluster has arisen by gene duplication. This is on the basis that the exon organization is nearly identical in the three family members, with each gene consisting of 12 exons and splice and acceptor sites interrupted at identical nucleotide positions within highly conserved codons (45). Further work on the genomic organization of fish desaturases may help to clarify the significance of the additional exon in salmon and the possible evolutionary history of desaturases, as sequence alignments alone are not conclusive (46).

The phylogenetic sequence analyses grouped the fish desaturases largely as expected based on classical phylogeny with the carp and zebrafish (Ostariophysi; cyprinids), trout and salmon (Salmoniformes; salmonidae), and tilapia, sea bream, and turbot (Acanthopterygia; cichlids, perciformes, and pleuronectiformes) appearing in three distinct clusters
FIG. 6. Effect of dietary vegetable oil (VO) on the expression of FA Δ6 and Δ5 desaturase and elongase genes in tissues from Atlantic salmon. Transcript (mRNA) copy number was determined by qrtPCR as described in the Materials and Methods section. The ratios of copy numbers between the target genes and β-actin were calculated as means ± SEM ($n = 4$). Results are expressed as the fold differences by comparison of mean values in fish fed the vegetable oil diet compared with those in fish fed the fish oil (FO) diet (FO = 1). For other abbreviations see Figure 5. *Mean values for fish fed VO are significantly different ($P < 0.05$) from those for fish fed FO as determined by the Student t-test.

(47). However, the cloning of Atlantic salmon Δ6 desaturase revealed that both Δ6 and Δ5 desaturases in salmonids contain additional amino acids by comparison with those of other species, having chain lengths of 454 amino acids (or 452 as

in cherry salmon Des2) compared with 444 for the cyprinid (carp and zebrafish) and human desaturases (16,20,22,23,26). Furthermore, it has been reported that the desaturase cDNAs encode proteins of 445 amino acids in seabream (24) and turbot

(25), one more residue than in cyprinid and human desaturases. These data support our previous observation that differences in polypeptide length are not in these cases related to function (25).

qrtPCR revealed that the expression of fatty acyl desaturase genes was highest in intestine, liver, and brain and lower in heart, gill, white and red muscle, kidney, spleen, and adipose tissue. Previously, by using RT-PCR, it was shown that Δ6 desaturase of rainbow trout and sea bream was expressed in intestinal tissue (23,24). In the present study, salmon intestinal tissue had levels of Δ6 and Δ5 expression 3- and 1.5-fold greater than liver. Similarly, expression of Δ6 and Δ5 in intestine was 7.2- and 1.9-fold greater than in brain. Therefore, these results suggest that intestine, the first organ to encounter dietary FA, has the capacity to play an important role in the primary processing of dietary FA *via* desaturation. Cho *et al.* (20) reported that human liver expressed 4–5 times more Δ5 desaturase and 12 times more Δ6 desaturase than brain. Our results show that salmon liver contained 2.4 times more Δ6 desaturase mRNA than brain, and the Δ5 desaturase mRNA levels in liver and brain were similar. Regardless of which gene has the higher level of mRNA, the observation that all tissues investigated express detectable levels of Δ6 and Δ5 desaturase and elongase mRNAs is consistent with the important roles that desaturase and elongase enzymes play in maintaining cellular membrane HUFA. That intestine expressed such high levels of both Δ6 and Δ5 desaturase is consistent with data from *in vitro* enzyme assays in isolated enterocytes (48,49) and *in vivo* stable isotope studies (50,51), which have shown enterocytes and intestine to be sites of significant HUFA synthesis in salmonids. The level of Δ6 desaturase mRNA in highly expressing tissues was substantially greater than the amount of Δ5 desaturase mRNA, but the level of Δ6 desaturase mRNA in lower-expressing tissues was lower than the amount of Δ5 desaturase mRNA. In comparison, a study of the relative abundance of Δ6 and Δ5 desaturase mRNA in various human tissues revealed that the level of Δ6 desaturase mRNA in eight different tissues was significantly greater than the amount of Δ5 desaturase mRNA (20). This observation is particularly interesting because Δ6 is often considered the enzyme that catalyzes the rate-limiting step in the synthesis of HUFA (52).

The results of this study show that the expression of Δ6 and Δ5 FA desaturases is under nutritional regulation in Atlantic salmon. Thus, the expression of these genes is higher in liver and red muscle (and possibly intestine and adipose tissue) of salmon fed diets containing C_{18} PUFA-rich VO compared with fish fed diets containing HUFA-rich fish oil. Although Δ6 desaturase is regarded as the main rate-limiting step in the HUFA biosynthesis pathway, Δ5 desaturase is reported also to be under nutritional regulation in mammals (53). In a previous study, the expression and activity of fatty acyl elongase appeared to be nutritionally regulated in Atlantic salmon (54). That study showed that dietary linseed oil increased the expression of both Δ5 FA desaturase and elongase genes in salmon liver (54). Similar effects of dietary linseed oil had been reported previously, with the liver transcript level of Δ6 desaturase being higher in trout fed linseed oil than in trout fed FO (23). However, the present study showed that the expression and activity of the elongase decreased in most tissues of salmon fed diets containing the VO blend compared with fish fed diets containing FO. The precise reason for the different responses in elongase gene expression is unclear but may be related to differences in the FA profiles of the linseed oil and VO-blend diets. In the present trial, the total n-3 HUFA level in the diet in which the VO blend replaced 75% of the FO was over 8%, which compares well with 9% HUFA in the diet in the previous trial in which 25% of the FO was replaced by linseed oil, a level of replacement that did not increase elongase activity (54). Elongase activity was increased only by diets in which 50–100% of FO was replaced with linseed oil, resulting in much lower levels of n-3 HUFA (54).

In conclusion, the study reported here has identified and characterized a Δ6 desaturase gene in Atlantic salmon. It had measurable, but very low, levels of Δ5 desaturase activity. The salmon Δ6 desaturase gene comprises 13 exons, one more than the human Δ6 and Δ5 desaturases. Genes for Δ6 and Δ5 desaturases and elongases were expressed in various tissues of salmon, and highly expressed in liver, intestine, and brain. Both Δ6 and Δ5 desaturase gene expression in intestine, liver, red muscle, and adipose tissue were significantly increased in salmon fed VO compared with fish fed FO.

Molecular Evidence That the Rate-Limiting Step for the Biosynthesis of Arachidonic Acid in *Mortierella alpina* Is at the Level of an Elongase

ABSTRACT: The oil-producing fungus *Mortierella alpina* 1S-4 is an industrial strain for arachidonic acid (AA) production. To determine its physiological properties and to clarify the biosynthetic pathways for PUFA, heterologous and homologous gene expression systems were established in this fungus. The first trial was performed with an enhanced green fluorescent protein gene to assess the transformation efficiency for heterologous gene expression. As a result, strong fluorescence was observed in the spores of the obtained transformant, suggesting that the foreign gene was inherited by the spores. The next trial was performed with a homologous PUFA elongase (GLELOp) gene, this enzyme having been reported to catalyze the elongation of GLA (18:3n-6) to dihomo-γ-linolenic acid (20:3n-6), and to be the rate-limiting step of AA production. The FA composition of the transformant was different from that of the host strain: The GLA content was decreased whereas that of AA was increased. These data support the hypothesis that the GLELOp enzyme plays an important role in PUFA synthesis, and may indicate how to control PUFA biosynthesis.

Paper no. L9634 in *Lipids 40*, 25–30 (January 2005).

PUFA can serve as precursors of the eicosanoids of signaling molecules including prostaglandins, thromboxanes, and leukotrienes, and they also play important roles as structural components of membrane phospholipids (1,2). The principal PUFA that act as precursors for eicosanoid synthesis are dihomo-γ-linolenic acid (DGLA, 20:3n-6), arachidonic acid (AA, 20:4n-6), and EPA (20:5n-3). All mammals synthesize eicosanoids, which are involved in regulating inflammatory responses, reproductive function, immune responses, and blood pressure (3). Therefore, studies on PUFA biosynthesis are important in both the medical and pharmaceutical fields.

We found the filamentous fungus, *Mortierella alpina* 1S-4, to be a producer of PUFA-containing lipids (4). This species is unique in its capacity to produce C_{20} PUFA, such as DGLA, AA, and EPA. We have studied FA metabolism in this strain and succeeded in using it for the industrial production of AA

(5). Therefore, this fungus is a good model for analyzing a FA desaturation and/or elongation system from both fundamental and applied standpoints. A number of mutants derived from this fungus that show alterations in the FA synthetic pathways have been determined through analyses of the FA composition or accumulation.

Wynn and Ratledge (6) determined that the rate-limiting step for AA production is at the level of the elongation of GLA (18:3n-6) to DGLA (6). They also predicted that enhancement of the elongase activity would lead to an increase in AA production (6). In plants and mammals, it is believed that microsomal FA elongation is a four-step process comprising one condensation step, two reduction steps, and one dehydration step (7). Biochemical studies have provided indirect evidence that the reaction catalyzed by the condensing enzyme of the elongation system is rate-limiting (7–9). This enzyme regulates the substrate specificity in terms of the chain length and the degree of unsaturation of FA. Recently, the elongase responsible for the conversion of GLA to DGLA, designated as GLELO, was identified through expression studies on a *M. alpina* expression sequence tag library in yeast (10,11).

We have established a transformation system for this fungus (12) and have applied it to the study of PUFA production, especially AA. In this study, we succeeded in increasing AA production by *M. alpina* through metabolic engineering, namely, construction of a *M. alpina* strain over-expressing the GLELO gene: (i) As a first step, the enhanced green fluorescent protein (EGFP) gene was expressed in *M. alpina* 1S-4 to assess expression of two genes (*ura5* and *EGFP*), and (ii) GLELO cDNA was cloned and isolated from the strain, and then over-expressed in the same strain, hereby leading to increased AA production. This is the first report of the significant importance of the FA composition in an AA industrial strain, *M. alpina* 1S-4.

EXPERIMENTAL PROCEDURES

Enzymes and chemicals. Restriction enzymes and other DNA-modifying enzymes were obtained from Takara Bio Inc. (Shiga, Japan) and New England BioLabs (Beverly, MA). All other chemicals were of the highest purity commercially available.

Strains, media, and growth conditions. Mortierella alpina 1S-4 *ura5⁻* (13) was maintained on Potato Dextrose Agar

medium (Difco, Detroit, MI) containing 5-fluoroorotic acid (0.5 mg/mL) and uracil (0.05 mg/mL). GY medium containing glucose and yeast extract was used for FA composition analyses. The composition of the GY medium depended on the kind of assay (see below). The compositions of the Czapek–Dox and SC media were given in a previous paper (13). For sporulation of the *ura5⁻* strain, uracil was added to the Czapek–Dox medium at 0.05 mg/mL. SC medium was used as the uracil-free synthetic medium for cultivation of the *ura5⁻* strains and the transformants. This synthetic medium was also used to maintain the transformants. Fungal strains were cultivated at 28°C with reciprocal shaking (120 strokes/min).

Preparation of genomic DNA and construction of a cDNA library. Preparation of genomic DNA of the *M. alpina* strain was performed according to the method described previously (14). Purification of mRNA and cDNA synthesis were also performed according to the methods described previously (15,16).

Isolation of GLELO cDNA of M. alpina 1S-4 and its expression in Aspergillus oryzae. Two primers were synthesized for amplification of the *M. alpina* 1S-4 GLELO cDNA by PCR with the following primers, designed on the basis of the nucleotide sequence of GLELOp of *M. alpina* ATCC 32221 (10): a sense primer, 5′-ATGGAGTCGATTGCGCAATTCCT-3′, and an anti-sense primer, 5′-TTACTGCAACTTCCTTGCCTTCTCCTT-3′. These primers were used in a Biometra T Gradient thermal cycler (Biometra GmbH, Göttingen, Germany) with a program of 1 min at 94°C, 1 min at 52.5°C, and 2 min at 72°C, for 35 cycles, followed by extension for 10 min at 72°C. The amplified 1.0-kb PCR product was cloned into the pT7Blue T-Vector (Novagen, Madison, WI) to construct pT7-GLELO, and then used to transform *Escherichia coli* DH5α. This clone was determined to encode a protein similar to GLELOp of *M. alpina* ATCC 32221 by DNA sequencing, as described below. Transformation of *A. oryzae* was performed by the method described by Gomi *et al.* (17) and Iimura *et al.* (18). A shuttle vector, pNGA142 (19), with the GLELO cDNA insert was used as the transformation vector for *A. oryzae*. Stable transformants were isolated by repeated sporulation on Czapek–Dox medium plates.

Construction of transformation vectors for the M. alpina 1S-4 ura5⁻ strain. Transformation vector pD4 (20), which was developed for the transformation of *M. alpina*, was kindly supplied by Prof. David B. Archer (University of Nottingham, United Kingdom). pD4 originally contained an expression unit composed of the histone H4.1 promoter, the modified *hpt* gene, and the *N*-(5′-phosphoribosyl)anthranilate isomerase (*trpC*) transcription terminator. The region from the promoter to the terminator was amplified using a forward primer, HisProFX (5′-TAC<u>GAATTC</u>A-AGCGAAAGAGAGATTATGAA-3′), and a reverse primer, TrpCRX (5′-GAA<u>GAATTC</u>CCTCTAAACAAGTGTACCTGT-3′), with pD4 as a template. The two primers contained an *Eco*RI restriction site (underlined). A modified pBluescript® II SK+ (Stratagene, La Jolla, CA) was prepared by deletion of its *Bam*HI site for convenient manipulation in further experiments. The approximately 2.7-kb PCR product was digested with *Eco*RI, followed by ligation into the modified pBluescript® II SK+ digested with *Eco*RI, and designated as pBlues-hpt.

Transformation vectors pDura5GFP and pDura5GLELO were constructed by modification of pDura5 developed as a transformation vector of the *M. alpina* 1S-4 *ura5⁻* strain (12). pDura5GFP is a vector for the expression system of the enhanced green fluorescent protein (EGFP) gene. An EGFP gene was amplified using a forward primer, GFPforward (5′-TCGCCA<u>CCATGG</u>TGAGCAAG-3′), and a reverse primer, GFPreverse (5′-CGC<u>GGATCC</u>TTTACTTGTA-3′), designed on the basis of the sequence of the EGFP gene on the pEGFP vector (Clontech Laboratories Inc., Palo Alto, CA) at an annealing temperature of 58°C with the pEGFP vector as a template. The GFPforward and GFP reverse primers contained *Nco*I and *Bam*HI restriction sites, respectively (underlined). The approximately 700-bp fragment digested with *Nco*I and *Bam*HI was ligated to pBlues-hpt digested with the same enzymes to remove the pre-existing *hpt* gene, resulting in the construction of a vector designated as pBlues-GFP. The EGFP gene expression unit obtained from pBlues-GFP on digestion with *Eco*RI was ligated to the *Eco*RI site of pDura5, resulting in the construction of pDura5GFP (Fig. 1).
FIG. 1. Two transformation vectors for *Mortierella alpina* 1S-4 *ura5⁻* mutant. The details of each gene and the method for constructing these vectors are given in the Experimental Procedures section. Restriction sites: *E, Eco*RI; *N, Nco*I; *B, Bam*HI; *X, Xba*I; *H, Hin*dIII; *S, Ssp*I.

pDura5GLELO is a vector for expression of the GLELO gene. *Mortierella alpina* 1S-4 GLELO cDNA was amplified using a forward primer, GLELOF (5′-CA<u>CCATGG</u>AGTC-GATTGCGC-3′), and a reverse primer, GLELOR (5′-GT-<u>GGATCC</u>TTACTGCAACTTCCTTGCCTT-3′), at an annealing temperature of 54°C with the 1S-4 cDNA library as a template. The GLELOF and GLELOR primers contained *Nco*I and *Bam*HI sites, respectively (underlined). The approximately 1.0-kb PCR product was ligated to the pT7Blue T-Vector to construct pT7-GLELO. By following the same strategy as for the construction of pDura5GFP, pDura5GLELO was constructed (Fig. 1).

Transformation of the M. alpina 1S-4 ura5⁻ strain. Transformation of the *M. alpina* 1S-4 *ura5⁻* strain with pDura5GFP or pDura5GLELO was performed with a PDS-1000/He Particle Delivery System (Bio-Rad Laboratories Inc., Hercules, CA) as described previously (12).

Isolation of stable transformants and checking of transformation by PCR were performed by the methods described previously (12).

FA analyses. The *A. oryzae* recombinant transformed with the *M. alpina* 1S-4 GLELOp cDNA was inoculated into a test tube containing 5 mL GY medium containing 2% glucose and 1% yeast extract, and then cultivated at 28°C with reciprocal shaking (120 strokes/min) for 3–4 d. The spores or mycelia of *M. alpina* 1S-4 recombinants transformed with pDura5GLELO and the host cells were inoculated into 20-mL Erlenmeyer flasks containing 4 mL of GY medium containing 2 or 5% glucose, 1% yeast extract, and 0.05 mg/mL of uracil. The culture was performed at 28°C with reciprocal shaking (120 strokes/min) for the desired period. FA analysis was performed basically as described in the previous paper (21).

Nucleotide sequence accession numbers. The nucleotide sequences of the GLELO genomic gene cloned from *M. alpina* 1S-4 have been assigned DDBJ accession no. AB193123.

RESULTS AND DISCUSSION

Transformation of the M. alpina 1S-4 ura5⁻ strain with pDura5GFP. The first trial involved expression of the EGFP gene in the *M. alpina* 1S-4 *ura5⁻* strain using a homologous *ura5* gene-containing vector. This would directly demonstrate that a two-gene expression system is feasible, and that heterologous gene expression in *M. alpina*, which will lead to further applications, has been achieved. The EGFP gene was placed under the control of the same promoter and terminator as previously used for expression of the homologous *ura5* gene (12). On the basis of this idea, an EGFP-expression vector, pDura5GFP, was constructed and used for transformation of the *ura5⁻* strain. Transformation was successfully performed, and six stable transformants were selected from the 45 isolated. All the stable ones were determined to be transformed through vector insertion into the rDNA locus (data not shown). When both host cells (*ura5⁻* strain) and ones of the transformants were cultivated in various media and observed under a fluorescence microscope, strong fluorescence was detected, mainly in

the outer part of the cells. To remove this fluorescence, protoplasts were prepared, but the resulting cells still had a strong fluorescence. Although these transformants seemed to show strong fluorescence in their cytoplasm, the observation could not be thought to be sufficient evidence that the EGFP gene was truly expressed.

How the self-fluorescence of this fungus is produced remains unclear, as it was impossible to detect the fluorescence from the EGFP protein precisely in the mycelial cells. On the other hand, when spores were observed under the fluorescence microscope, a strong fluorescence was detected only in those of the transformants (data not shown). This finding implies that the foreign gene could be inherited by both the daughter cells and spores and indicates that the EGFP and *ura5* genes were both successfully expressed in this fungus. Hence, we expected that the same strategies could be used for expression of genes involved in PUFA syntheses, leading to elucidation of FA metabolism and improvement of PUFA production.

Isolation and heterologous expression of the GLELO gene of M. alpina 1S-4. The gene encoding GLELOp, which catalyzes elongation of GLA to DGLA, has previously been cloned from *M. alpina* ATCC 32221 and characterized (10). To perform homologous expression of the GLELO gene, the GLELO cDNA of *M. alpina* 1S-4 was isolated. As a result, a fragment containing an open reading frame with a length of 957 bp, starting with an ATG codon and ending with a TAA codon, was isolated. The gene was suggested to encode a protein consisting of 318 amino acids with a M.W. of 37,000 (data not shown). A computer-aided homology search of the amino acid sequences of other proteins in a database revealed that the deduced amino acid sequence of the resultant gene exhibits 95.9% identity with that of the GLELOp of *M. alpina* ATCC 32221, and 33.5 and 32.5% identity with those of elongation of very long chain FA protein 2 (ELO2) of mouse and human, respectively (22,23). The amino acid sequence of GLELOp showed several regions of identity, including a common histidine box motif, with ELO2. A

[a]Two *M. alpina* 1S-4 recombinants transformed with pDura5GLELO, #3 and #8, and host cells were grown at 28°C for 4 or 10 d in 4 mL of GY medium containing uracil under reciprocal shaking (120 strokes/min).
[b]These values are the means of triplicate experiments. AA, arachidonic acid; for other abbreviations see Table 1.

hydropathy plot (Kyte and Doolittle) of GLELOp indicated that this protein is hydrophobic in nature and contains several presumptive transmembrane domains (data not shown). Furthermore, functional analyses were also performed on gene expression in *A. oryzae* (Table 1). The *Mortierella alpina* 1S-4 GLELO cDNA was ligated to fungal expression vector pNGA142. In the resultant plasmid, designated as pGEGA10, expression of the cloned GLELOp gene was controlled by a glucoamylase promoter of *A. oryzae*. The FA composition of the selected *A. oryzae* transformant, MG-5, was different from that of the control strain without the GLELO gene: The new peak in the chromatogram of FAME from the transformant cultured in GY medium for 4 d exhibited a retention time identical to the FAME standard of 20:2n-6, which is produced through an elongase reaction on endogenous 18:2n-6. In the presence of exogenous GLA, a new peak of DGLA was observed only for the transformant, indicating conversion of GLA to DGLA at the rate of 39%, whereas the rate of conversion of endogenous 18:2n-6 to 20:2n-6 was 5.9%, and 18:1n-9 and 18:3n-3 were not converted to the corresponding 20-carbon PUFA at all. Another experiment indicated that exogenous 18:1n-12 was converted to 20:1n-12 with a conversion rate of 2.1% (data not shown). The GLELOp of *M. alpina* ATCC 32221 showed the same characteristics as that of *M. alpina* 1S-4 (10,11). Thus, the cDNA was determined to be the gene encoding GLELOp throughout this analysis.

It is generally believed that the elongation activity involves four distinct subunit enzymes: a condensing enzyme, two reductases, and a dehydrase. It is unlikely that one protein exhibits all four activities (11). Therefore, the elongase activity of GLELOp in the *Aspergillus* transformants is likely to arise from interaction with other endogenous components of *Aspergillus* elongase.

Transformation of M. alpina 1S-4 with pDura5GLELO. A transformation vector, pDura5GLELO (Fig. 1), was constructed

and used for transformation of the *ura5⁻* strain to over-express the GLELO gene. Out of the 36 transformants obtained, 9 were determined to be stable transformants with pDura5GLELO (data not shown). To investigate their properties, two transformants (#3 and #8) were cultivated in GY medium, containing 5% glucose, 1% yeast extract, and 0.05 mg/mL of uracil, for 4 or 10 d to investigate their FA compositions (Table 2). It was verified that complementation of *ura5* genes does not influence the FA composition of the host cells (data not shown). Transformant #8 showed the same FA composition as that of the host cells, regardless of the cultivation period. On the other hand, transformant #3 exhibited a different FA composition from that of the host cells: GLA, which serves as a substrate for GLELOp, was decreased and AA was increased. For further investigation, time course experiments were performed with transformant #3 and the host cells (Fig. 2). The accumulation of AA continued after 4 d in both strains, regardless of the culture conditions. With 5% glucose in the medium, AA content remained low in comparison with that with 2% glucose. Although this observation was in accordance with results previously reported, the AA productivity (mg/mL of culture broth) was proportional to the glucose concentration (data not shown) (4). In the case of 2% glucose (Figs. 2A and B), the AA content increased linearly after 4 d in the transformant but not in the host cells. Our previous report also stated that significant AA accumulation was observed in the stationary phase (5,24), and this phase is thought to correspond to the period after 4 d in the present experiment.

The final content of AA in the transformant was higher than that in the host cells. Hence, over-expression of the GLELO gene clearly occurred in this lipogenic phase rather than in the growth phases. With 5% glucose (Figs. 2C and 2D), differences in the FA profile appeared clearly: The AA content of transformant #3 increased more than that of the host cells after 5 d. The GLA content of the transformant cells remained lower than that of the host cells, especially after 4 d. The DGLA content increased at the beginning of cultivation and then decreased concomitantly with the increase in the AA content. The AA content of transformant #3 was 1.4-fold higher than that of the host cells at the end point. The significance of this increase can be appreciated from our previous efforts to enhance the productivity, which did not achieve such significant change. This major increase must therefore have resulted from the enzyme playing an important role in AA biosynthesis. In addition, the analysis of real-time quantitative PCR showed that the quantity of GLELO RNA in transformant #3 was 7.4-fold higher than that of the host strain on 4 d (data not shown). Therefore, the results obtained for stable transformant #3 must be directly due to GLELO gene expression.

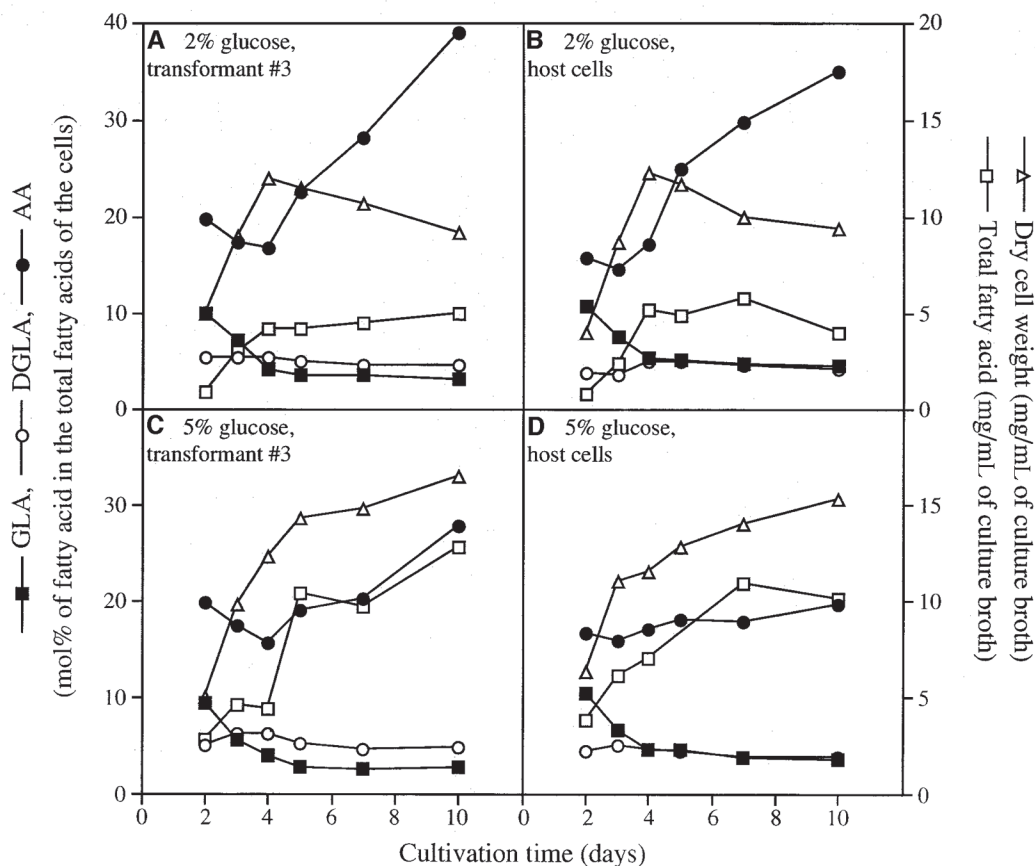
In conclusion, GLELOp catalyzes the conversion of GLA to DGLA and serves as the rate-limiting step in AA production. As predicted by Wynn and Ratledge (6), AA productivity can be increased through enhancement of the enzyme activity. This is the first report that genetic manipulation led to an increase in AA production by an industrial oleaginous strain, *M. alpina* 1S-4.


FIG. 2. Time courses of changes in the mycelial FA content in the GLELO-over-expressing *M. alpina* 1S-4 transformant and the host cells. All cultivations were started by inoculation of the respective spores and performed with reciprocal shaking (120 strokes/min) at 28°C. The culture conditions were as follows: (A, B) GY medium containing 2% glucose. (C, D) GY medium containing 5% glucose. All media also contained 1% yeast extract and 0.05 mg/mL uracil. The strains used were as follows: (A, C) transformant; (B, D) host cells. FA analysis was performed with total biomass obtained from each cultivation. The values are the means of triplicate experiments. DGLA, dihomo-γ-linolenic acid; AA, arachidonic acid.

Over-expression of Hepatic Neutral Cytosolic Cholesteryl Ester Hydrolase in Mice Increases Free Cholesterol and Reduces Expression of HMG-CoAR, CYP27, and CYP7A1

ABSTRACT: Hepatic neutral cytosolic cholesteryl ester hydrolase (hncCEH) is a key enzyme in the regulation of hepatic free cholesterol (FC). In examining the effects of over-expression of this enzyme on cholesterol homeostasis, mice were infected with a recombinant adenovirus construct (AdCEH) of the rat hncCEH cDNA driven by the human cytomegalovirus promoter. Cholesteryl esterase and p-nitrophenylcaprylate (PNPC) esterase activities were measured in liver postmitochondrial supernatants at 1, 3, 7, and 11 d after infection with AdCEH or a control virus expressing β-galactosidase (AdβGAL). The PNPC esterase activity of AdCEH mice peaked threefold higher than controls on day 2, declining on subsequent days. In contrast, cholesteryl esterase peaked eightfold higher than controls on day 3, indicating a shift in substrate selectivity of hncCEH. Hepatic FC peaked at 144% of controls, 7 d postinfection. The mRNAs for cholesterol 7α-hydroxylase, sterol 27-hydroxylase, and HMG-CoA reductase decreased to 47, 46, and 58% of controls, respectively, on day 7, coinciding with peak FC concentrations. Coinciding with increased cholesteryl esterase activity, hepatic esterified cholesterol dropped precipitously from day 3 onward, to 11% of controls by day 11. Hepatic TAG levels also declined, consistent with the reported TAG lipase activity of hncCEH. These results demonstrate elevation of FC and depletion of cholesteryl esters by over-expression of hncCEH, which were resistant to compensatory responses by other enzymes of cholesterol homeostasis.

Paper no. L9627 in *Lipids 40*, 31–38 (January 2005).

Free cholesterol (FC) is an essential component of membranes and an important determinant of their physicochemical properties. FC is also the precursor to bile acids, steroid hormones, and oxysterols that regulate pathways of lipid metabolism, including cholesterol biosynthesis (1–3). Indicative of the metabolic and regulatory significance of these roles, intracellular FC levels are maintained within relatively narrow ranges over a broad range of dietary intakes and metabolic states (4–7). Among the homeostatic processes contributing to this stability is the cycle of esterification with long-chain FA and hydrolysis of the resulting cholesteryl esters (CE) to regenerate metabolically active FC. The hydrolytic component of this CE cycle is catalyzed by the hepatic neutral cytosolic CE hydrolase (hncCEH), which has been cloned and characterized in this laboratory (8–11). The hncCEH is a broad-specificity carboxylesterase that hydrolyzes TAG (12) and water-soluble esters of p-nitrophenol, as well as CE (8,9,12). Similar to other enzymes in cholesterol metabolism, the hncCEH promoter has active sterol responsive elements that regulate hncCEH expression (10,13,14). Moreover, hncCEH mRNA, protein, and enzymatic activity are altered in response to perturbations of sterol flux, consistent with the hypothesis that hncCEH plays a significant role in cholesterol homeostasis (8,10,15).

Cholesterol homeostasis is maintained in the liver by regulation of the various input and output pathways for metabolism and transport. In addition to hncCEH, these include (i) ACAT, which catalyzes the esterification component of the CE cycle; (ii) HMG-CoA reductase (HMGCoAR), the rate-determining enzyme in the *de novo* synthesis of cholesterol; (iii) cholesterol 7α-hydroxylase (CYP7A1), and sterol 27-hydroxylase (CYP27), which catalyze the initial steps in the classic and alternative pathways, respectively, for bile acid synthesis; and (iv) lipoprotein synthesis, uptake, and degradation (16,17). The response of each of these to perturbations in the metabolically active cholesterol pools is the means by which the liver maintains cholesterol homeostasis.

Although a number of studies have examined the effects of perturbations of cholesterol homeostasis on hncCEH, the current studies were designed to determine the effects of over-expression of hncCEH on hepatic sterol metabolism and other key enzymes of cholesterol homeostasis. To this end, an adenoviral vector was constructed with a cytomegalovirus promoter to constitutively express hncCEH. We describe the validation of this construct in cell culture and mice and the effects of over-expression of hncCEH on hepatic lipid levels and mRNAs of several enzymes known to exhibit compensatory responses to altered sterol flux through the liver.

MATERIALS AND METHODS

Chemicals and supplies. Radionuclides were purchased from New England Nuclear (Boston, MA); p-nitrophenylcaprylate

Abbreviations: AdβGAL, adenovirus over-expressing β-galactosidase; AdCEH, adenovirus over-expressing cholesteryl ester hydrolase; CE, cholesteryl ester; CYP7A1, cholesterol 7α-hydroxylase; CYP27, sterol 27-hydroxylase; FC, free cholesterol; GAPDH, glyceraldehyde-3-phosphate-dehydrogenase; HMG-CoAR, HMG-CoA reductase; hncCEH, hepatic neutral cytosolic cholesteryl ester hydrolase; HSL, hormone-sensitive lipase; pfu, plaque-forming units; PNPC, p-nitrophenylcaprylate.

(PNPC) from Sigma Laboratories (St. Louis, MO); CsCl, tissue culture ware, and solvents from Fisher Scientific (Columbia, MD); and C57BL/6 mice from the National Cancer Institute (National Institutes of Health, Bethesda, MD). Mice were fed Teklad (Harlan, Indianapolis, IN) rodent diet *ad libitum* and then fasted for 12 h prior to sacrifice. Mice were maintained on an alternating 12-h light/12-h dark schedule. A single 100-µL injection of virus was administered *via* tail vein. Serum levels of liver enzymes, aspartate aminotransferase and alanine aminotransferase, were measured in animals infected with virus. Since these enzymes were elevated in some mice from each group, regardless of dose, construct, or level of expression (data not shown), weight was used as a discriminator. Mice losing >2% in body weight postinjection were excluded from these studies.

Construction of the transfer vector, viral purification, and plaque assay. The cDNA for hncCEH (9) was cut from pCR3-CEH using *XhoI*. The transfer vector, pSCT1, was digested with *SalI*, and hncCEH cDNA was ligated into the transfer vector through the complementary *XhoI/SalI* sites. Insertion of hncCEH cDNA was verified by restriction digestion and sequencing. Homologous recombination was performed by the Massey Cancer Center Adenoviral Core Facility to produce infectious particles. Several viral lines were selected for DNA isolation and sequencing. Because the poly-A signal of hncCEH was provided by the vector, the hncCEH mRNA was extended by approximately 200 bases during transcription from the viral genome. The elongated message allowed the hncCEH transcript to be distinguished from endogenous mRNAs for homologous mouse esterase in Northern blots using the full-length cDNA as a probe.

Virus was purified essentially as described by Gerard and Meidell (18). Fifty 180 cm^2 dishes were seeded with 293 cells at a density of 10%. Medium was changed every 48 h until cells were confluent. Confluent 293 cells were infected at MOI (multiplicity of infection) 200 for 24 h. The medium was then aspirated and replenished. Sixty hours after infection, floating cells were collected, pelleted, and immediately lysed by six freeze/thaw cycles (–80°C ethanol bath followed by 18°C water bath). Cellular debris was removed by centrifugation and the cleared viral lysate was layered over a discontinuous CsCl gradient (1.24–1.40 g/mL) in six Beckman Ultra-Clear tubes (14 × 89 mm). The tubes were centrifuged in an SW40 rotor at 155,000 × *g* for 2 h. The viral band was collected and layered onto a 1.33 g/mL continuous CsCl cushion in two Ultra-Clear tubes. The tubes were centrifuged in an SW40 rotor at 155,000 × *g* for 18 h. Occasionally, the virus would aggregate and, although the viral band was thick, these preparations were found to have very low titers. Preparations that aggregated were discarded. The viral band was collected and dialyzed in a Pierce dialyzer cassette with a 10,000-MW cutoff against 4 L of dialysis buffer [10 mM Tris, 1 mM MgCl$_2$, pH 7.4, and 10% (vol/vol) glycerol] at 4°C for 24 h. The solution was aliquotted into cryogenic vials, snap-frozen in liquid N$_2$ vapor, and stored at –80°C.

Plaque assays were performed on a small aliquot from the pure virus that was frozen separately. Confluent 293 cells in 25 cm^2 flasks were infected with aliquots of virus in serial dilutions and incubated overnight. Medium was removed and 4 mL of complete media with 1.25% agarose was added. After 4 d, 4 mL of agarose medium with 0.02% neutral red dye (AdCEH) or X-Gal (AdβGAL) was added and flasks were monitored for plaques for 10 more days.

Cell culture of human embryonic 293 cells. The 293 cells were cultured in DMEM with high glucose (4.5 g/mL), L-glutamine (0.292 g/mL), penicillin (100 U/mL), streptomycin (100 µg/mL), and 10% heat-inactivated FBS, in a humidified environment at 37°C with 5% CO$_2$.

Preparation of total RNA and Northern blot analysis. Total RNA from livers was prepared by CsCl pelleting (10). Aliquots with 2.5, 5, and 8 µg RNA from each mouse were electrophoresed on 1% agarose gels with formaldehyde. Northern blots were prepared using GeneScreen™ (NEN Life Science Products, Boston, MA) membranes as described previously (19). Blots were simultaneously hybridized to ^{32}P-labeled cDNAs of rat hncCEH and the internal loading standard, mouse glyceraldehyde-3-phosphate-dehydrogenase (GAPDH). Hybridizing bands were visualized by exposure on a phosphor K-screen (Bio-Rad, Hercules, CA) and the Molecular Imager FX system. Densitometry was performed using Quantity One software (Bio-Rad). Density values from bands hybridizing to hncCEH were normalized to GAPDH.

Lipid extraction and determination. Total lipids were extracted by the method of Bligh and Dyer (20). Extracts were dried under N$_2$ and resuspended in 1 mL isopropanol for lipid determination. Hepatic TAG were measured with the Sigma Diagnostics Triglyceride GPO-Trender kit; hepatic total cholesterol, with Sigma Diagnostics Infinity Cholesterol Reagent; and hepatic FC, with the Boehringer Mannheim (Indianapolis, IN) cholesterol kit using standards certified by suppliers. Esterified cholesterol was calculated by the difference between total cholesterol and FC.

Ribonuclease protection assay. Ribonuclease protection assays were performed as described previously using an Ambion RPA II system (Austin, TX) (21). The gel was dried and placed on film overnight at –80°C. Bands were quantified with a Molecular Dynamics densitometer and Bio-Rad Quantity One software. Values were normalized to cyclophilin.

Enzyme assays. Cholesteryl esterase activity was measured by hydrolysis of cholesteryl [1-^{14}C]oleate using the radiometric method of Ghosh and Grogan (22). hncCEH is a broad-specificity esterase that exhibits higher activity with water-soluble *p*-nitrophenyl esters than with lipophilic substrates. These esters provide a rapid and sensitive screen for catalytic activity. PNPC esterase activity was determined spectrophotometrically with PNPC as described earlier (12). PNPC hydrolysis was determined in 1 mL assay buffer with 1–200 µg protein. Two hundred nanomoles of PNPC was added to start the reaction, which was incubated for 1–15 min at 37°C. Absorbance was measured at 400 nm.

The β-galactosidase assay was started by addition of 150 µL of β-galactosidase substrate buffer (200 mM Na$_2$HPO$_4$, 2 mM MgCl$_2$, 100 mM β-mercaptoethanol, and 1.33 mg/mL *o*-nitro-

phenyl β-D-galactopyranoside) to 150 μL of sample (12). The reaction mixture was incubated at 37°C until the reaction was stopped with 500 μL of 1 M $NaHCO_3$. Absorbance was measured at 420 nm.

Statistical analysis. Data presented in Figures 4–6 and Table 1 are correlated; i.e., they are collected from the same set of mice. Data were analyzed for statistically significant differences using the unpaired *t*-test, testing for equal SD. A Welch correction was used for comparison of means with significant differences in SD.

RESULTS

Validation of adenoviral constructs in cell culture. hncCEH is a broad-specificity esterase that hydrolyzes the synthetic water-soluble substrate PNPC more efficiently than natural lipophilic substrates (12). Moreover, since earlier studies showed that cholesteryl esterase activity of hncCEH varied with its level of phosphorylation, PNPC-esterase activity provides a more reliable index for over-expression of this enzyme (12). Thus, PNPC-esterase was used in the initial screening for catalytic activity. To determine the effectiveness of the adenoviral constructs as expression vectors, PNPC-esterase and β-galactosidase activities were measured in COS-7 cells infected with AdCEH and control construct AdβGAL. As shown in Figure 1, β-galactosidase activity was 40-fold higher in AdβGAL controls than in AdCEH-infected cells, whereas PNPC-esterase activity of AdβGAL controls was not different from that of uninfected cells (0.779 μmol/h/mg protein). Thus, virus infection itself did not elevate PNPC-esterase activity in cell culture. In contrast, PNPC-esterase was 460-fold higher in AdCEH infected cells (358 μmol/h/mg protein) than in AdβGAL controls, whereas β-galactosidase was not elevated. Thus, elevated PNPC-esterase levels were attributed specifically to expression of the hncCEH cDNA.

Optimization of conditions for adenovirus expression in mice. Mice were injected with various doses of AdβGAL to optimize expression and determine maximum tolerated doses of virus. A dose of 10^{13} pfu (plaque-forming units) produced no β-galactosidase activity above saline-injected controls. Mice injected with 10^{14}, $10^{14.5}$, and 10^{15} pfu AdβGAL exhibited 2-, 8- and 83-fold higher β-galactosidase activities, respectively, than controls on day 3 postinjection (data not shown). All dosages were tolerated, except 10^{15} pfu, which was lethal to 40% of the mice. Whereas $10^{14.5}$ pfu produced an eightfold increase in activity without acute toxicity or weight loss (data not shown), this dosage was selected for subsequent studies. β-Galactosidase was then measured in the livers of mice at various times after injection with $10^{14.5}$ pfu AdβGAL. β-Galactosidase activity was 117-, 76- and 8-fold higher than saline-injected controls 1, 2, and 3 d postinfection, declining to control values by day 7 (data not shown).

Optimization of expression of hncCEH in mice. To determine a minimum dosage necessary for expression of hncCEH, the hncCEH mRNA was measured in total RNA extracts from livers of mice infected with various doses of AdCEH. As de-

FIG. 1. *p*-Nitrophenylcaprylate (PNPC) esterase and β-galactosidase activities in postmitochondrial supernatants of COS-7 cells infected with AdCEH (adenovirus over-expressing cholesteryl ester hydrolase) or Adβ-GAL (adenovirus over-expressing β-galactosidase). Cells were infected at MOI (multiplicity of infection) 100, harvested 72 h postinfection, and assayed for both substrates. The controls were infected cells assayed for the activity that was not associated with the infecting virus. Activity is expressed as mean ± SEM for two different cultures at three protein concentrations, each in triplicate.

picted in Figure 2, the larger exogenous rat mRNA transcript of AdCEH was distinguishable from homologous endogenous mouse mRNA (23) that also hybridized with the hncCEH probe. The hncCEH mRNA was visible on Northern blots 3 d after infection with 10^{13} pfu (lanes 10–12), whereas only bands corresponding with endogenous carboxylesterases were visible at lower doses (lanes 1–9). Mice injected with AdβGAL expressed only the endogenous mRNA (data not shown). Thus, the well-tolerated dose $10^{14.5}$ pfu was well above the minimum necessary for expression of hncCEH mRNA.
FIG. 2. Northern blot showing expression of hepatic neutral cytosolic cholesteryl ester hydrolase (hncCEH) mRNA in livers of mice injected with various doses of AdCEH. Mice were injected by tail vein with 1 × 10^{10} to 1 × 10^{13} plaque-forming units (pfu) AdCEH or AdβGAL (not shown). Livers were harvested and total RNA extracted 72 h after infection. Northern blots were probed with full-length hncCEH cDNA and glyceraldehyde-3-phosphate-dehydrogenase (GAPDH) (constitutive loading standard) probe as described in the Materials and Methods section. Rat trans gene (exogenous hncCEH) is 200 bp larger than homologous mouse transcript (endogenous hncCEH) due to inclusion of the viral poly A tail. Lanes 1–3: 1 × 10^{10}, Lanes 4–6: 1 × 10^{11}, Lanes 7–9: 1 × 10^{12}, Lanes 10–12: 1 × 10^{13}; three individual mice were used for each dosage. For abbreviations see Figure 1.
FIG. 3. Rat hncCEH (exog) and homologous mouse esterase (endog) mRNA in mice over-expressing hncCEH or control β-galactosidase. Mice were injected with $1 \times 10^{14.5}$ pfu AdCEH or AdβGAL. Livers were harvested at the indicated times and hncCEH mRNA or endogenous mouse esterase mRNA was measured and normalized to the loading standard GAPDH by quantitative Northern blot as described in the Materials and Methods section (see Fig. 2 for representative autoradiogram). Correlated cholesteryl esterase activities corresponding with the mRNA levels are graphed on the right axis as % AdβGAL control (- - -). Normalized activities are expressed as average ± SEM for three mice, except day 1, for which the AdCEH group contained two mice; (*) indicates $P < 0.05$. CEH, cholesteryl ester hydrolase; β-Gal, β-galactosidase; for other abbreviations see Figures 1 and 2.

Time course for expression of hncCEH in mice. Mice were injected with $10^{14.5}$ pfu AdCEH or AdβGAL, and livers were harvested at 1, 3, 7, and 11 d postinfection. The rat hncCEH (exogenous) and mouse endogenous mRNAs were measured by quantitative Northern blotting. As shown in Figure 3, hncCEH (exogenous) mRNA was present in AdCEH-infected mice on all days, whereas this transcript was absent from the AdβGAL controls. Three days after infection, hncCEH mRNA peaked fourfold higher than endogenous message but declined on subsequent days. Consistent with the function of hncCEH, cholesteryl esterase activity measured in the same liver samples (dotted line) correlated well with the hncCEH mRNA levels. Endogenous mRNA hybridizing with the cDNA for hncCEH was increased 24 h postinfection by AdCEH, possibly reflecting a transient increase in expression of the homologous mouse esterase-22 (23) not seen in AdβGAL controls. However, this increase in endogenous mRNA was not seen on day 3. By days 7 and 11, endogenous mRNA was significantly lower in the AdCEH-infected mice, suggesting a compensatory lowering of the homologous mouse esterase in response to elevated levels of hncCEH activity.

Both PNPC-esterase and cholesteryl esterase activities were measured in liver homogenates at 1, 2, 3, 7, and 11 d postinjection. As shown in Figure 4, PNPC-esterase activity was elevated by AdCEH within 24 h, peaked at 300% of controls on day 2, remained elevated through day 7, but declined to 62% of controls by day 11. In contrast, cholesteryl esterase activity
FIG. 4. Time course for expression of hepatic PNPC and cholesteryl esterase activities in mice infected with AdCEH or AdβGAL. Mice were injected by tail vein with $10^{14.5}$ pfu AdβGAL or AdCEH. Postmitochondrial supernatants were assayed for esterase activity using PNPC or cholesteryl $[1\text{-}^{14}C]$oleate. Assays were performed at two different protein concentrations, each in triplicate. Activity is expressed as % AdβGAL control ± SEM for three mice/group, except day 1, for which the AdCEH group contained two mice; (*) indicates different from controls, $P < 0.05$. For abbreviations see Figures 1 and 3.

was not significantly elevated until day 3, when it rose to 829% of controls. Cholesteryl esterase activity then declined gradually but remained 76% higher than controls on day 11. Thus, the two esterase activities followed somewhat different time courses of expression. It is possible that the lag in expression of cholesteryl esterase reflects protein kinase activation, which is not required for the expression of PNPC esterase activity by this enzyme (22).

Effects of hncCEH over-expression on liver cholesterol and TAG. As presented in Table 1, FC, the product of hncCEH, trended higher in AdCEH mice on all days postinjection. FC was 44% higher ($P < 0.03$) than AdβGAL controls on day 7, following a peak in hepatic cholesteryl esterase activity. Moreover, the mean FC was significantly higher than controls ($P < 0.02$, $n = 9$) when values were pooled for days 3, 7, and 11, the period of elevated cholesteryl esterase. Also consistent with the time course for cholesteryl esterase activity, hepatic esterified cholesterol was not significantly different from controls on days 1 and 3 but trended lower on day 7 and fell to 11% of control values by day 11 ($P < 0.02$). Thus, over-expression of hncCEH elevated hepatic FC and depleted esterified cholesterol, the physiological substrate for this enzyme. The associated depletion of esterified cholesterol most likely limited the elevation of FC on days 7 and 11 while cholesteryl esterase remained elevated. The two groups exhibited no significant differences in serum total cholesterol on any single day, although the pooled values for days 7 and 11 were slightly lower than controls (Table 1).

As reported earlier, hncCEH also hydrolyzes TAG *in vitro* and is activated by cAMP-dependent protein kinase, suggesting that this enzyme also functions as the hepatic hormone-sensitive TAG lipase (12,24,25). Consistent with such a functional role, hepatic TAG also dropped well below control levels in

[a]Mice were injected with $10^{14.5}$ pfu adenovirus over-expressing cholesteryl ester (CE) hydrolase (AdCEH) or control β-galactosidase (AdβGal). At the specified time postinjection, liver or serum lipid extracts from three mice/group were analyzed in triplicate for TAG and free and total cholesterol; esterified cholesterol was calculated as the difference, total cholesterol – free cholesterol. Values are means ± SEM. *Significantly different from AdβGAL controls, *$P < 0.005$; **$P < 0.03$; ***$P < 0.02$; ****$P < 0.01$; *****$P < 0.003$. Infection + 3-11 = mean of all values for days 3,7, and 11 ($n = 9$). Infection + 7-11 = mean of all values for days 7 and 11 ($n = 6$).

AdCEH-injected mice after day 3, following a pattern similar to that of CE (see Table 1). TAG were higher than controls in AdCEH-injected mice on days 1 and 3, prior to induction of cholesteryl esterase activity. However, the subsequent mobilization reduced TAG to 17% of control levels ($P < 0.01$) by day 7 and 35% of controls ($P < 0.003$) for the pools of all mice from days 7 and 11.

Effects of hncCEH over-expression on other hepatic enzymes of cholesterol homeostasis. The hepatic mRNAs for HMGCoAR, CYP7A1, and CYP27 were measured by ribonuclease protection assays in the same mice injected with AdCEH at time points corresponding with increased cholesteryl esterase activities and FC levels. As seen in Figure 5, mRNAs for all three enzymes were initially slightly higher than controls in AdCEH-injected mice, although this trend was significant only for CYP7A1 on day 1. Like the early elevations in endogenous carboxylesterase mRNA and TAG, this apparent elevation was modest in comparison with changes occurring at later time points and probably reflects transient perturbations of the system, since cholesteryl esterase activity was not expressed on day 1. Following the appearance of cholesteryl esterase activity and the resulting increase in hepatic free cholesterol, mRNAs for all three enzymes declined markedly and were significantly lower than controls in AdCEH mice on day 7. The resulting decline in mRNA levels from day 3 to day 7 was 46% for CYP27 and 47% for CYP7A1. Moreover, 44% higher FC

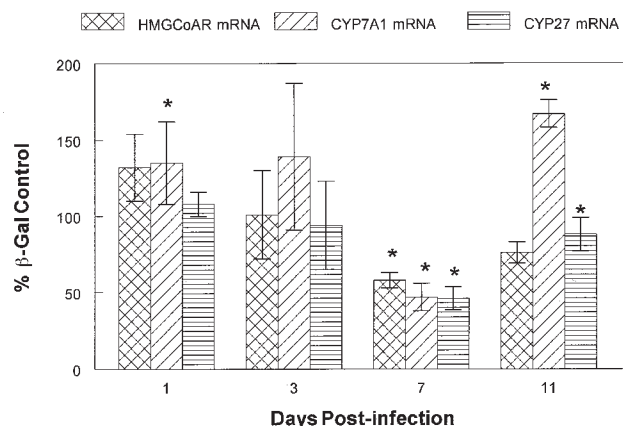
levels in AdCEH mice were accompanied by 42% lower HMGCoAR mRNA on day 7, consistent with the well-known feedback regulation of this enzyme (1,3).


FIG. 5. Effects of hncCEH over expression on hepatic mRNAs for HMG-CoA reductase (HMGCoAR), cholesterol 7α-hydroxylase (CYP7A1), and sterol 27-hydroxylase (CYP27). Mice were injected by tail vein with $10^{14.5}$ pfu AdβGAL or AdCEH. Livers were harvested at the indicated times and total RNAs extracted for measurement of mRNAs by quantitative ribonuclease protection assays as detailed in the Materials and Methods section. Values represent mean % control ± SEM for three mice, except day 1 for which the AdCEH group contained two mice; (*) indicates $P < 0.05$. For other abbreviations see Figures 1 and 2.

DISCUSSION

As noted earlier, a number of studies have shown that hncCEH mRNA, enzyme protein, and catalytic activity are regulated in response to perturbations of cholesterol homeostasis that are known to result in altered sterol flux through the liver (8,10,11,13). However, the current study is the first to show that over-expression of hncCEH both perturbs hepatic lipid levels and produces predictable compensatory responses in other enzymes involved in regulation of cholesterol homeostasis. Both hncCEH mRNA (Fig. 3) and cholesteryl esterase activity (Fig. 4) were elevated in AdCEH mice after day 2, remaining three- and sixfold higher than AdβGal controls on day 7, by which time FC was elevated 44% over controls (Table 1). Although FC dropped thereafter, it is likely that this increase would have been greater and more sustained if these changes had not been accompanied by substantial depletion of the hepatic CE substrate pool (Table 1). Although mRNA for HMGCoAR, the rate-limiting step in cholesterol biosynthesis, decreased 42% from day 3 to day 7, which would tend to oppose the effects of hncCEH over-expression, this compensatory change did not prevent an increase in FC. Moreover, the initial enzymes in the acidic and neutral bile acid biosynthetic pathways were also suppressed on day 7. Although this is counterintuitive in terms of the expected effects on intracellular FC, it is nevertheless apparent that homeostatic responses did not fully compensate for the effects of hncCEH over-expression, even when CE were in limited supply. This underscores the importance of hncCEH in maintaining cholesterol homeostasis.

Whereas hncCEH hydrolyzes CE and TAG stores in the liver, hormone-sensitive lipase (HSL) is responsible for this activity in adipose, steroidogenic, and mammary tissues. Since hncCEH and HSL perform essentially the same function in different tissues, over-expression of hncCEH and HSL should produce similar effects. Escary *et al*. (26) used a plasmid vector to over-express HSL in lipid-laden adipocytes treated with an ACAT inhibitor and observed a two- to threefold increase in hydrolysis of CE (26). In that study, HSL over-expression resulted in almost complete hydrolysis of intracellular CE stores within 6 h. Whereas an ACAT inhibitor was required for depletion of CE stores in that study, in the current study, liver CE stores were almost completely depleted by over-expression of hncCEH (Table 1), without inhibition of ACAT. More recently, Okazaki *et al*. (27) used an adenovirus construct to over-express HSL in lipid-laden macrophage foam cells, which also resulted in depletion of CE stores. In those studies, increased CE hydrolysis was apparently compensated by increased cholesterol efflux, analogous to reverse cholesterol transport from the cells, preventing significant increases in cellular FC levels over a broad range of viral titers and CE levels. Although the liver also exports FC, it is apparent from the current study that neither of these processes in the bile and in serum lipoproteins compensated for the elevation in FC produced by over-expression of hncCEH (Table 1). To the contrary, the 18% reduction in serum cholesterol levels on days 7 and 11 could reflect decreased lipoprotein secretion resulting from depleted CE and TAG stores. Increased biliary cholesterol secretion remains a possible compensatory mechanism, although this was not measured in the current study.

Like HSL, hncCEH hydrolyzes TAG as well as CE (12). Sztalryd *et al*. (28) showed that over-expression of HSL in cultured adipocytes prevented accumulation of TAG. In the current study, over-expression of hncCEH was similarly associated with a substantial depletion of liver TAG *in vivo* (Table 1). Inasmuch as both enzymes are also activated by cyclic AMP-dependent protein kinase, these data suggest that hncCEH and HSL may play similar multifunctional roles in liver and extrahepatic tissues, respectively (22,29). However, unlike hncCEH, there is as yet no evidence that HSL plays a central regulatory role in cholesterol homeostasis (8,10,11,13).

As the hydrolytic component of the CE cycle in the liver, hncCEH promotes production of both FC and oxysterols, potent regulators of sterol and bile acid synthesis. To date, most studies have been focused on ACAT, the biosynthetic component of the CE cycle in the liver and most other tissues. Several investigators have used ACAT inhibitors to shift the balance toward net hydrolysis, relying on an unspecified endogenous CE hydrolase to mobilize endogenous CE (30–32). The resulting increases in FC were associated with decreased activity and mRNA for enzymes of cholesterol biosynthesis and increased activity and mRNA for CYP7A1, the rate-limiting enzyme in the acidic bile acid biosynthetic pathway. These investigators concluded that expansion of the FC pool provides both substrate and inducer for CYP7A1. This induction is mediated by increased oxysterol concentrations through the nuclear hormone receptor LXRα (liver X receptor α), which up-regulates transcription of the CYP7A1 gene (33,34). The role of oxysterols in suppressing enzymes of cholesterol biosynthesis is well documented (35,36).

Similar to the effects of ACAT inhibition, over-expression of hncCEH in the current study was accompanied by lower HMGCoAR levels on days 7 and 11, following peak cholesteryl esterase activity and coinciding with the highest levels of FC observed. Moreover, CYP7A1 mRNA was elevated on day 11, following several days of elevated cholesteryl esterase activity and a peak in FC levels. Paradoxically, both CYP7A1 and CYP27 mRNA levels were suppressed on day 7. This may reflect feedback inhibition of these pathways by transient overproduction of bile acids in response to increased FC levels (37). Both CYP7A1 and CYP27 are negatively regulated by cholate. Cholate not only decreases the stability of CYP27 mRNA but is also a ligand for the FXR (farnesoid X receptor), which stimulates expression of the negative regulatory factor SHP (small heterodimer partner), which in turn represses transcription of CYP7A1 (38–41). Although attempts were made to test this possibility by measuring biliary bile acids, variation between animals was too high to detect any trends (data not shown). Nevertheless, these data indicate that the capacity of bile acid biosynthetic pathways to compensate for mobilization of CE stores is limited by mechanisms that override the effects of intracellular FC. This is not unexpected, given the potential toxicity of bile acids (42).

β-Oxidation Capacity of Red and White Muscle and Liver in Atlantic Salmon (*Salmo salar* L.)—Effects of Increasing Dietary Rapeseed Oil and Olive Oil to Replace Capelin Oil

Ingunn Stubhaug*, Livar Frøyland, and Bente E. Torstensen

National Institute of Nutrition and Seafood Research (NIFES), Nordnes, 5817 Bergen, Norway

ABSTRACT: Post-smolt Atlantic salmon (*Salmo salar*) were fed six diets in which capelin oil was replaced with 0, 25, 50, 75, or 100% rapeseed oil (RO; low-erucic acid) or 50% olive oil (OO). The experimental diets were fed to single groups of Atlantic salmon for 42 wk, whereas the 100% capelin oil (0% RO) diet was fed in duplicate. The β-oxidation capacity of palmitoyl-CoA was determined, using a method optimized for salmon tissues, at the start of the experiment, after 21 wk (October), and after 42 wk (March) in red and white muscle and in liver. Red muscle showed the highest specific β-oxidation capacity, but when expressed as total β-oxidation capacity for the whole tissue, white muscle was the most important tissue for the β-oxidation of FA. From the initial to the final sampling, the β-oxidation capacity of white muscle increased significantly, whereas the β-oxidation capacity in liver decreased significantly. After 22 wk, white muscle exhibited an increased β-oxidation capacity when the dietary RO content was raised from 25 to 75%, with similar effects in red muscle and liver after 42 wk of feeding. The present results also show that the β-oxidation capacity increased with an increase in fish size.

Paper no. L9581 in *Lipids 40*, 39–47 (January 2005).

Lipids of marine origin have beneficial effects on human health, including the possible prevention of cardiac diseases (1,2). Farmed Atlantic salmon (*Salmo salar* L.) are normally fed a diet with a high lipid content, in which the lipids traditionally originate from other marine sources. Since the availability of marine lipid resources is declining, it is desirable to investigate the possibility of incorporating vegetable oil into fish feeds while maintaining fish welfare and the beneficial effects of fish consumption on human health. However, to monitor the possible effects of vegetable oils on fish welfare, increased knowledge regarding the basic mechanisms of lipid metabolism is needed.

Vegetable oils do not contain FA whose chain lengths exceed 18 carbons. Rapeseed oil (low-erucic acid) and olive oil have low levels of 18:3n-3, moderate levels of 18:2n-6, and high levels of 18:1n-9 compared with other vegetable oils. Marine oils typically have high levels of n-3 FA, containing 22:6n-3 (DHA) and 20:5n-3 (EPA) and monounsaturated FA (MUFA) with backbones exceeding 18 carbons in length such as 20:1n-9 and 22:1n-11.

β-Oxidation occurs in mitochondria and peroxisomes in both fish and mammals (3–7). In studies in which mitochondrial and peroxisomal β-oxidation have been measured separately, peroxisomal β-oxidation has been shown to constitute as much as 30% of total hepatic β-oxidation in *Notothenia gibberifrons*, an Antarctic cod (8), and 50% in Longhorn sculpins (*Myoxocephalus octodecimspinosus*) (9). A study measuring mitochondrial and peroxisomal β-oxidation in Atlantic salmon showed that 20 and 40% of the total β-oxidation capacity originated from peroxisomes in red and white muscle, respectively (10).

Previous studies have found that red muscle has the highest capacity for β-oxidation (10,11) and white muscle the lowest. In a study by Torstensen *et al.* (12), Atlantic salmon were fed diets in which capelin oil was replaced with either palm oil or oleic acid-enriched sunflower oil. Compared with the capelin oil diet, the diet containing palm oil exhibited lower digestibility, but no significant differences in β-oxidation in red muscle were found. Metabolic processes in fish, including lipid metabolism, are affected by season (13–15), temperature [reviewed by Guderley (16)], and fish size (10,17,18).

The aim of the present study was to investigate the effects on β-oxidation capacity due to an altered dietary lipid composition. In particular, the effect of increasing dietary levels of rapeseed oil (RO) and olive oil (OO) at the expense of capelin oil was studied. OO is a major component in the Mediterranean diet, which is known to have benefits for human health. RO and OO both have high levels of 18:1n-9; thus, a comparison between these two alternative oil sources was of interest. In addition, the method for measuring β-oxidation capacity was optimized for Atlantic salmon tissues.

MATERIALS AND METHODS

Raising conditions. The fish experiment was carried out at the Gildeskaal research station in Norway (67° North) from May 2001 to March 2002. Atlantic salmon with a mean initial weight of 142 ± 1 g were divided into 7 net pens of 125 m³,

with approximately 600 fish in each net pen. Biomass and mean fish weight in each of the net pens were determined by bulk weighing and were determined for all fish at each sampling. The diets were fed to satiation by hand, and any dead fish were removed daily and recorded. The fish were exposed to continuous light from December 22 to May 1. Before and after this period, the fish were exposed to natural light. The temperature was measured monthly and ranged from 4 to 15°C (see Ref. 19 for further details).

The diets were produced by Nutreco ARC (Stavanger, Norway) and were formulated to contain 450 g·kg^{-1} protein, 300 g·kg^{-1} lipid, 60 g·kg^{-1} moisture, 70 g·kg^{-1} ash, and 120 g·kg^{-1} nitrogen-free extract. The experimental diets had increasing levels of RO, 0, 25, 50, 75, and 100%, at the expense of capelin oil, and one diet in which 50% OO was added instead of capelin oil. The diets had complete vitamin and mineral contents. The 0% RO diet was fed to duplicate groups, whereas the other diets were fed to single groups in a regression design.

Sampling procedure and preparation of tissue homogenates. The fish were fasted 24 h prior to sampling. Fish were randomly selected and anesthetized with metomidate (7 g·L^{-1}; Norwegian Medicinal Depot, Oslo, Norway) before being killed by a blow to the head. Samples were taken at three stages during the experimental period: a first sampling in May (initial sampling), an intermediate sampling in October (22 wk), and a final sampling in March (42 wk).

For measurements of β-oxidation capacity (performed on-site), 15 fish were sampled and 5 fish were then pooled, yielding three subsamples from each net pen. Red and white muscle and liver were dissected out immediately. Red muscle was taken from a region starting at the dorsal fin and extending to the tail, and was dissected free from skin and white muscle. The portion of white muscle was taken from the "Norwegian quality cut" region, between the dorsal and ventral fins. Approximately 1 g of red and white muscle and liver were sampled from each fish (a total of 5 g for each subsample).

Samples from the red and white muscle and liver were then transferred to 50-mL plastic tubes containing 20 mL of buffer and were homogenized using an UltraTurrax homogenizer. The homogenization buffer contained 10 mM HEPES (all chemicals were obtained from Sigma Chemical Co., St. Louis, MO, unless otherwise stated), 1 mM EDTA, and 0.25 M sucrose (Merck KGaA, Darmstadt, Germany), and was adjusted to pH 7.4. The resulting homogenate was centrifuged at $1500 \times g$ for 10 min at 4°C. The postnuclear fractions (E-fractions), which contained mitochondria, peroxisomes, and other organelles, were collected. The E-fraction from each tissue sample was divided into three analytical parallels and one blank. An aliquot of the fraction was retained for protein determination and stored at –20°C until analyzed.

FA composition. The FA composition of total lipids in the experimental diets (stored at –20°C) was analyzed using methods described previously (20,21). The methyl esters were separated using a Trace 2000 gas chromatograph (Fison CE Instru-

ments, Milan, Italy; "cold on-column" injection, 60°C for 1 min at 25°C min^{-1}, 160°C for 28 min at 25°C min^{-1}, 190°C for 17 min at 25°C min^{-1}, and 220°C for 10 min), equipped with a 50-m CP-Sil 88 (Chrompack, Middelburg, The Netherlands) fused-silica capillary column (i.d., 0.32 mm) The FA were identified by retention times using standard mixtures of methyl esters (Nu-Chek-Prep, Elysian, MN), and the FA composition (wt%) was calculated using an integrator (TotalChrom software, Version 6.2, PerkinElmer Life and Analytical Sciences, Inc., Boston, MA), connected to the gas chromatograph. The content of FA per gram of diet was calculated using 19:0 methyl as the internal standard.

Enzyme activity. The rate of β-oxidation was measured for each of the three tissues using [1-^{14}C]palmitoyl-CoA as substrate. A buffer mix was made in two steps: A HEPES buffer adjusted to pH 8.1 (20 mM of HEPES with 125 mM of KCl (Merck KGaA) was first made and stored. On the day of the assay, the following components were added to 10 mL of the HEPES buffer: 1 mL of 10 mM EDTA, 1 mL of 250 mM MgCl$_2$ (Merck KgaA), 2 mL of 100 mM DL-DTT (DL-dithiothreitol), 150 μL of 20 mM NAD, 1 mL of 100 mM ADP, and 12.5 μL of 25 mM L-carnitine. The following volumes of E-fraction were then mixed with 250 μL of buffer mix in 10-mL plastic tubes: 30 μL for red muscle, 300 μL for white muscle, and 30 μL for liver (diluted 1:5 with homogenization buffer).

The tubes containing homogenized tissue and buffer mix (called the assay mix) were pre-incubated in a water bath at 20°C for 2 min before adding 5 μL of 1.5 mM [1-^{14}C]palmitoyl-CoA (0.4 kBq; American Radiolabeled Chemicals Inc., St. Louis, MO). The reaction was stopped after 10 min by adding 150 μL of 1.5 mM KOH (Merck KGaA). To bind nonoxidized FA, 25 μL of FA-free BSA (FAF-BSA; 100 mg·mL^{-1}) was added and the tubes were shaken. The BSA–FA complex was then precipitated by adding 500 μL of ice-cold 4 M HClO$_4$ (Merck KGaA). The tubes were centrifuged for 10 min at $2400 \times g$. A 500-μL aliquot of the supernatant, which then contained products from mitochondrial and peroxisomal β-oxidation, was added to 8 mL of scintillation cocktail (LumaSafe Plus^{TM}; Lumac·LSC, Groningen, The Netherlands). Disintegrations per minute (dpm) were measured in a scintillation counter (Packard 1900 TR liquid scintillation analyzer). One blank was made for each sample in the same way as for the analytical samples except that [1-^{14}C]palmitoyl-CoA was added after KOH had been added to the tubes. β-Oxidation capacity was expressed as the specific activity (Eq. 1) in the acid-soluble supernatant:

$$\text{specific activity} = \frac{\text{parallels} - \text{blank}}{\text{mg protein} \cdot \text{incubation time} \cdot \text{standard}} \cdot 100 \quad [1]$$

where parallels and blanks are expressed in dpm, incubation time in minutes, and standard is the specific activity of the radiolabeled FA added to the reaction (dpm·nmol^{-1}). The β-oxidation activity, expressed per minute per gram of wet tissue and per minute per tissue, is calculated as given in Equations 2 and 3:

$$\text{per g wet tissue} = \frac{[\text{Eq. 1}] \cdot \text{mg protein} \cdot \text{mL E-fraction}}{\text{g tissue used}} \quad [2]$$

$$\text{per tissue} = [\text{Eq. 2}] \cdot \text{mean fish weight} \cdot \text{tissue factor} \quad [3]$$

where a tissue factor of 0.6 was used for white muscle, 0.05 was used for red muscle, and 0.01 was used for liver (22).

Method optimization. Prior to conducting the fish experiment, the method of measuring β-oxidation capacity in tissue homogenates was improved from previously described methods (10,23). The improved method was tested for different protein concentrations (E-fractions) added to the buffer mix for all three tissues and with different pH in the buffer mix (adjustment of pH in the HEPES buffer). This was done to find a linear relationship between the velocity of the reaction and the protein concentration for all three tissues. For optimization of the method, Atlantic salmon raised at the Institute of Marine Research in Bergen, Norway, were used. The fish weighed 725 ± 205 g and were 41 ± 4 cm long. These fish were fed a commercial fish feed (Orion MP 400-60A; Skretting, Stavanger, Norway), which contained 430 g·kg^{-1} (crude) protein, 330 g·kg^{-1} lipids, 72 g·kg^{-1} ash, and 9 g·kg^{-1} fiber.

Tissue preparation and enzyme activity measurements were performed as described previously except that the pH of the initial buffer mix (chemicals added to the HEPES buffer) and the amount of E-fractions added to the buffer mix varied. The pH was measured using a pH meter (inoLab pH level 1; WTW, Weilheim, Germany).

Statistical analysis. Data from the method optimization were calculated using GraphPad Prism, version 4.0 (GraphPad Software, Inc., San Diego, CA). To create a curve-fitting plot for the data, a one-site binding equation for hyperbolic curves was used:

$$Y = \frac{B_{\max} \cdot X}{(K_d + X)} \quad [4]$$

where Y is the velocity measured in dpm, $B_{\max}$ is the maximal binding, K_d is the protein concentration (amount of enzyme) required to reach half binding, and X is the protein concentration. Data for the fish experiment were analyzed for statistical differences using the nonparametric Kruskal–Wallis method (Statistica, version 6.0; StatSoft Inc., Tulsa, OK), owing to the fact that subsamples were used in this experiment (24).

RESULTS

Method improvement. A linear relationship was found between milligrams of protein and amount of product produced (dpm) for all tissues (Fig. 1). Less protein had to be added to the assay for red muscle and for liver than in the original protocol to obtain linearity. The left panels of Figure 1 show the relationship between dpm and protein up to the point of saturation. The right panels of Figure 1 exhibit the linear portion of the curve. When the pH of the buffer increased, the velocity of the reaction increased, and the points followed a hyperbolic curve better than when a lower pH was used (Fig. 1, left panels). The

linear range for white muscle was from 0.6 to 4.5 mg protein, for red muscle the linear range was between 0.02 and 0.13 mg protein, and for liver the range was between 0.04 and 0.18 mg protein (Fig. 1, right panels).

The liver homogenate had the highest pH, 7.4 ± 0.3 (diluted E-fraction, 1 + 4), whereas the white muscle homogenate had the lowest pH, 6.29 ± 0.04. Red muscle homogenate had a pH of 6.8 ± 0.1. In the assay mix, the pH of white muscle increased from 6.5 to 6.7, for red muscle the pH increased from 6.0 to 7.0, and in the liver the pH increased from 5.5 to 6.7 with an increase in pH of the buffer.

Fish experiment. The mean weight of fish from the initial sampling to the final sampling increased from 146 ± 28 to 1572 ± 301 g, with a mean weight of 993 ± 213 g in the intermediate sampling. Mortalities were negligible throughout the experiment. The sampled fish were randomly selected and did not differ in mass from the bulk weighing of the fish (19). The FA composition of the different diets is given in Table 1. With increasing RO in the diet, the amount of dietary saturated FA and n-3 FA decreased. Within the n-3 FA, the amount of α-linolenic acid (18:3n-3) increased, whereas the levels of DHA and EPA decreased. Furthermore, total MUFA and total n-6 FA increased with increasing RO levels in the diet. The MUFA 18:1n-9 was the FA responsible for the increase of MUFA. The FA composition of the 50% OO diet group was most similar to that of the 50% RO diet group.

The total β-oxidation capacity (both mitochondrial and peroxisomal β-oxidation activity) of oxidized [1-^{14}C]palmitoyl-CoA (β-oxidation capacity) of red and white muscle and liver is presented in Figure 2. There was a significant increase in β-oxidation capacity in white muscle from May to March and a significant decrease in liver β-oxidation from May to October.

Within the sampling performed in October, the β-oxidation capacity in white muscle increased 1.7-fold when Atlantic salmon were fed 75% RO compared with 0% RO; however, this change was not statistically significant. Atlantic salmon fed 75% RO had a significantly higher β-oxidation capacity compared with Atlantic salmon fed 100% RO (Fig. 2, top panel). In the final sampling period, the differences between the dietary groups in white muscle β-oxidation were smaller than in October, although all the dietary groups increased their β-oxidation capacity compared with October, with the exception of the group fed the 75% RO diet.

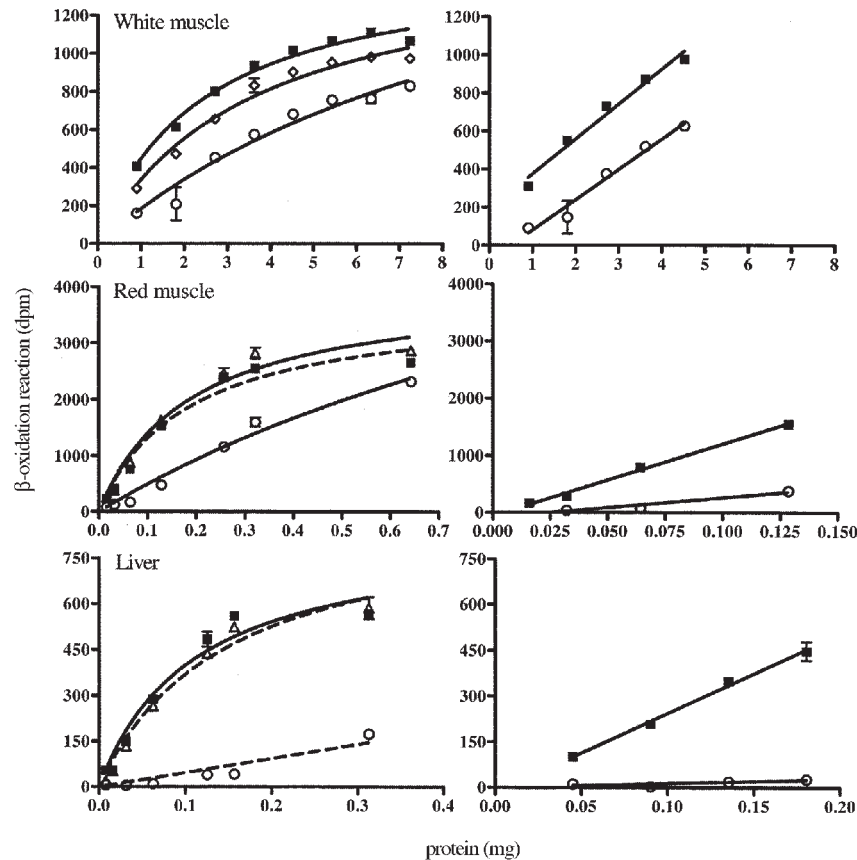
Irrespective of diet, red muscle had the highest β-oxidation capacity of the tissues measured. There were no statistically significant differences between sample times or between dietary groups (Fig. 2, middle panel). However, the β-oxidation capacity between the dietary groups was more or less the same within each sample period, and the red muscle sampled in March showed a β-oxidation capacity similar to that of the white muscle sampled in October and to the liver sampled in March (Fig. 2, bottom panel). Fish fed 50% OO had the highest β-oxidation capacity in red muscle in October compared with the other dietary groups, showing a 1.6-fold increase compared with fish fed 0% RO. The β-oxidation capacity of red muscle was lower in March than in October.


FIG. 1. The β-oxidation activity in white (top panels) and red (middle panels) muscle and in liver (bottom panels) homogenates using $[1-^{14}C]$palmitoyl-CoA as substrate. Increasing concentrations and different pH in the buffer were tested. The figures on the left side show the β-oxidation activity with increasing tissue concentrations up to the point of saturation between the substrate and protein. The figures on the right side show the β-oxidation activity within the linear range of the reaction. The activity is expressed as net disintegrations per minute (dpm). The different symbols relate to the pH of the HEPES buffer used in the buffer mix: pH 7.3 (○), 7.8 (◇), 8.1 (■), and 8.3 (△). Closed symbols indicate the preferred pH (see discussion for details). Each data point is the average of three parallel measurements, and the error bars show SD. The values on the *x*-axis for red muscle in the original protocol (middle left panel) are estimated, using a factor of 0.0083 between the protein values (mg) and volumes of E-fraction (postnuclear supernatant; μL) added on the basis of other experiments performed and the mean relationship between measured milligrams of protein and volume of the E-fraction.

In October the liver exhibited a significantly increased β-oxidation capacity in Atlantic salmon fed the 50% OO diet, compared with fish fed the 0% RO diet (Fig. 2, bottom panel). Data on livers of the other dietary groups in the October samples were lost due to a mistake in preparation of the assay buffer. There were no statistical differences in hepatic β-oxidation capacity between the dietary groups within the final sampling.

Figures 3 and 4 show the β-oxidation capacity for white and red muscle and for liver expressed per gram of tissue and per tissue (i.e., accounting for total tissue mass), respectively. When accounting for total tissue mass, white muscle had the highest β-oxidation capacity of the three tissues measured (Fig. 4). Liver, on the other hand, had the lowest β-oxidation capacity per tissue. The β-oxidation capacity in white muscle and in liver increased during the experimental period (Fig. 4). Irrespective of how the β-oxidation capacity was expressed, the pattern within a sample period or the relative changes between sample times did not change in the muscle. When expressing the data on a per-tissue basis (Fig. 4), there was an increased β-oxidation capacity in Atlantic salmon fed 0% RO in the initial sampling period compared with the other sampling times for all three tissues.

DISCUSSION

Method improvement. To enable measurement of the maximum β-oxidation activity (capacity) and to observe changes in the capacity of the β-oxidation reaction, it is necessary to find the range of tissue concentrations over which a linear relationship

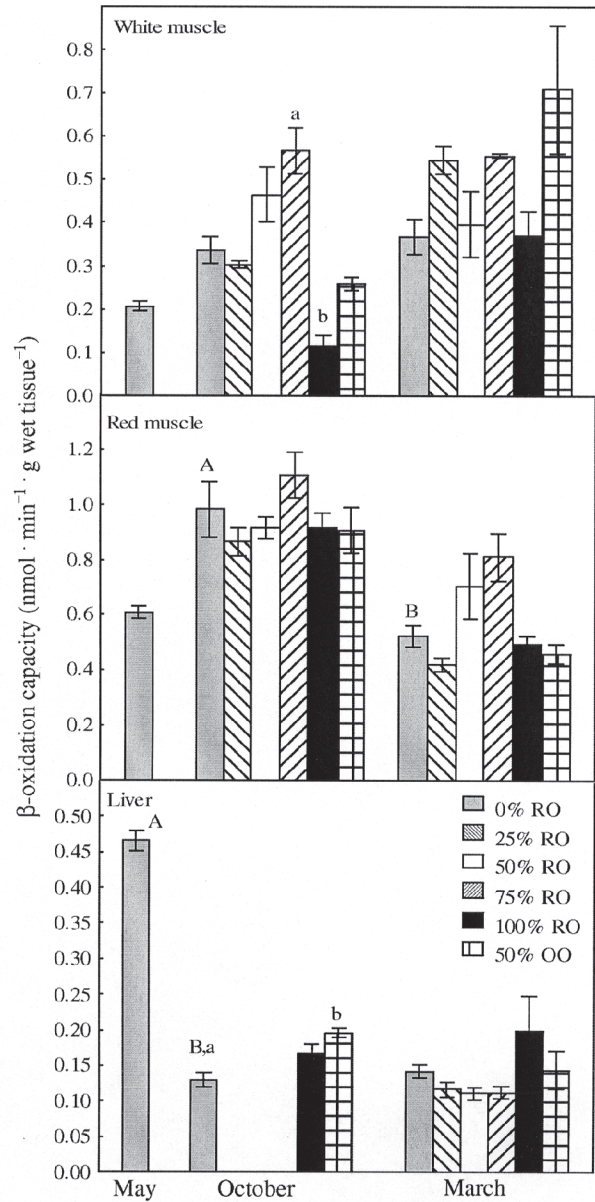
exists between tissue content and β-oxidation rate in Atlantic salmon tissues. Thus, the purpose of the current study was to determine experimentally the conditions under which the substrate and other co-factors were in excess and only the enzymes of β-oxidation were rate-limiting for red and white muscle and liver. A linear range was found for the three tissues tested.

Assay pH played a major role in obtaining reliable, reproducible results. If the pH of the assay mix was not near the enzymes' pH optimum, the functionality of the enzyme was reduced, and saturation of activity was not achieved (Fig. 1, pH 7.3). The rate of β-oxidation activity increased the most in liver when the pH was increased from pH 7.3 to 8.1, whereas the smallest increase was found in white muscle. Increasing the pH further for white muscle did not result in a better curve (data not shown). Based on this and the minor differences associated with raising the pH from 8.1 to 8.3, the optimal pH level in the HEPES buffer was set at 8.1. Salmonids use white muscle for fast swimming and red muscle for prolonged and sustainable swimming (25). During fast swimming (anaerobic work), the muscle produces lactic acid that acts to lower the pH in the muscle (26). This may indicate that enzymes in white muscle are adapted to function in a more acidic environment and therefore have a broader pH optimum. Alternatively, the observations reported here may be explained by white muscle having a higher buffering capacity compared with liver and red muscle.

Another methodological aspect that requires consideration is the production and possible escape of radiolabeled CO_2 from oxidized [1-^{14}C]palmitoyl-CoA. The last step in energy production results in ATP, H_2O, and CO_2. Intuitively, therefore, a measure of CO_2 production during the assay could be used to compensate for this potentially lost label and thus be used to calculate exact β-oxidation rates. However, it has previously been found that measuring only the [^{14}C]CO_2 production did not give satisfying results when estimating the [^{14}C]FA oxidation rate (27). Another study found that insignificant amounts of [^{14}C]CO_2 were produced during the β-oxidation reaction, even after 1 h of incubation (9). The reaction in the present study was run for 10 min; it may therefore be assumed that the amount of [^{14}C]CO_2 produced in the β-oxidation reaction was negligible.


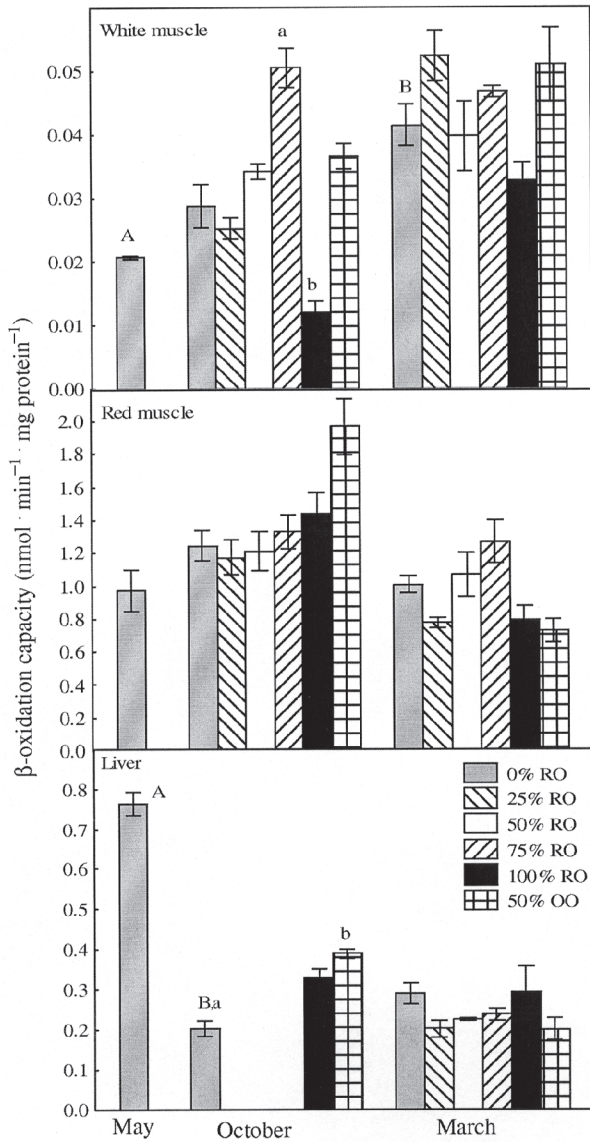
Fish experiment. Fish growth did not vary significantly among the dietary groups [details on growth parameters are given in Torstensen *et al.* (19)]. This result is in line with previous studies regarding the replacement of fish oil with vegetable


FIG. 2. β-Oxidation capacity, measured using [1-^{14}C]palmitoyl-CoA as substrate in white muscle, red muscle, and liver from post-smolt Atlantic salmon fed diets containing 0, 25, 50, 75, or 100% of the lipid content as rapeseed oil (RO) or 50% as olive oil (OO) to replace capelin oil for 42 wk (March). An intermediate sampling was performed after 22 wk (October). β-Oxidation capacity is expressed as nmol·min^{-1}·mg protein^{-1}. Data are presented as means ± SEM ($n = 3$). Capital letters indicate statistically significant differences between 0% RO for every sampling; small letters indicate differences within each sampling. No letters indicate no statistically significant differences. Data were analyzed using the nonparametric Kruskal–Wallis test. Note that the scaling on the *y*-axis differs between tissues.

FIG. 3. β-Oxidation capacity, measured using [1-^{14}C]palmitoyl-CoA as substrate in white muscle, red muscle, and liver from post-smolt Atlantic salmon fed diets containing 0, 25, 50, 75, or 100% of the lipid content as RO or 50% as OO to replace capelin oil for 42 wk (March). An intermediate sampling was performed after 22 wk (October). β-Oxidation capacity is expressed as nmol·min^{-1}· g wet tissue^{-1}. Data are presented as mean ± SEM ($n = 3$). Capital letters indicate statistically significant differences between 0% RO for every sampling; small letters indicate differences within each sampling. Data were analyzed using the nonparametric Kruskal–Wallis test. Note that the scaling on the *y*-axis differs between tissues. For abbreviations see Figure 2.

oils (12,28–30). FA composition was analyzed in red and white muscle and in liver in the present experiment and has been reported by Torstensen *et al.* (21). FA compositions of both types of muscle were highly reflective of the dietary FA compositions, which is in agreement with earlier findings (31–34).

In the present experiment, red muscle had the highest specific β-oxidation capacity, whereas white muscle had the lowest (Fig. 1). This is in agreement with earlier results (12,35). However,

when considering the total amount of energy produced by β-oxidation in the different tissues, white muscle is the most important tissue (Fig. 4), since white muscle makes up approximately 60% of the total body mass in Atlantic salmon (22). These results are also supported by previous studies (10,11).

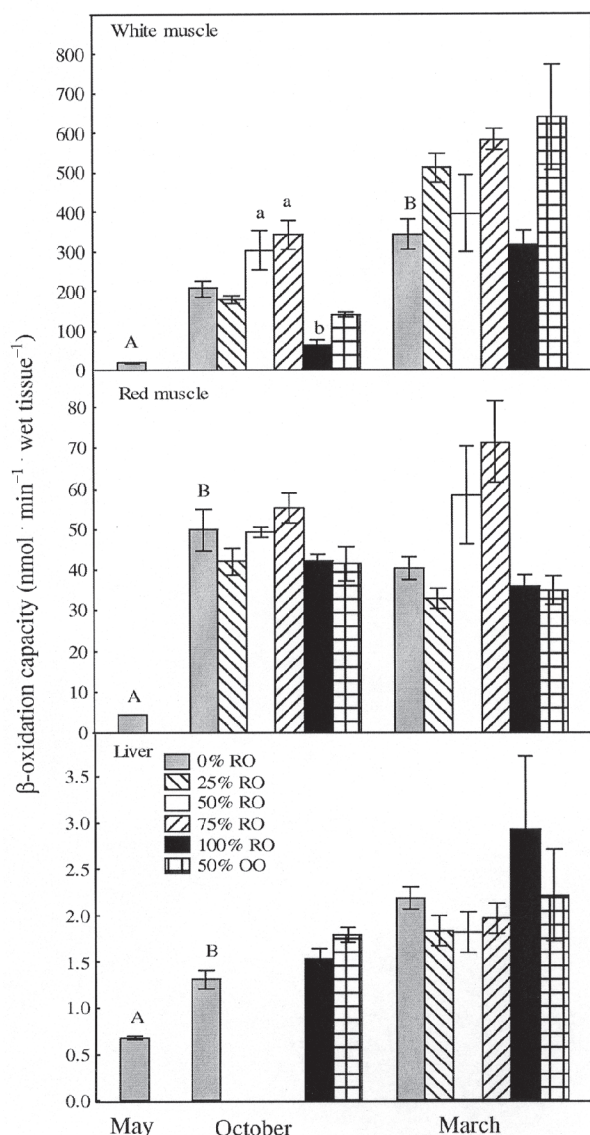
All fish in the present experiment were fed a commercial feed


FIG. 4. β-Oxidation capacity, measured using [1-^{14}C]palmitoyl-CoA as substrate in white muscle, red muscle, and liver from post-smolt Atlantic salmon fed diets containing 0, 25, 50, 75, or 100% of the lipid content as RO or 50% as OO to replace capelin oil for 42 wk (March). An intermediate sampling was performed after 22 wk (October). β-Oxidation capacity is expressed as nmol·min^{-1}· wet tissue^{-1}. Data are presented as mean ± SEM ($n = 3$). Capital letters indicate statistically significant differences between 0% RO for every sampling; small letters indicate differences within each sampling. Data were analyzed using the nonparametric Kruskal–Wallis test. Note that the scaling on the *y*-axis differs between tissues. For abbreviations see Figure 2.

the initial and the intermediate sampling (Fig. 2, bottom panel). Red muscle showed no significant differences over the course of the experiment. It was reported earlier that β-oxidation capacity decreases with an increase in fish size (10,12). The results from the present study showed that the β-oxidation capacity in all three tissues increased with size, especially in the first growth phase after seawater transfer (Fig. 4; 0% RO). Kiessling *et al.* (17) did not find any differences in muscle 3-hydroxyacyl-CoA dehydrogenase activity, a key enzyme in β-oxidation, in the seawater phase. However, both the size of the fish (36) and the method for measuring β-oxidation capacity differed between these studies, and this may explain the variation between the two results. Since white and red muscle together constitute approximately 65% of the total body weight (22), it can therefore be concluded that the β-oxidation capacity in Atlantic salmon increased during growth.

The β-oxidation capacity in white muscle in Atlantic salmon was highest during winter (March), coinciding with the lowest temperature, whereas liver had the highest β-oxidation capacity in the spring (May; medium temperature). Earlier studies showed that the β-oxidation enzyme activity in muscle is affected by temperature [reviewed by Guderley (16)] and by season (13) and might increase during acclimatization to the cold. In the present experiment, the temperature varied from 7.7°C in May to 3.7°C in March to 9.7°C in October. The statistically significant increase in β-oxidation capacity seen in white muscle in March (Fig. 2) could therefore be due to acclimatization to lower temperatures. This increase was not observed for the other two tissues.

Three possible mechanisms may account for the increase in β-oxidation capacity: enhanced mitochondria or peroxisome content in the cells, increased enzyme content (e.g., increase in the volume of organelles), or a stimulation in the relative activity of the enzymes [reviewed by Reddy and Mannaerts (7)]. The increased β-oxidation capacity of white and red muscle from the 25% RO to the 75% RO dietary group in October, and of red muscle and liver in the final sampling period, indicated that there was a positive correlation between increasing RO content in the feed and β-oxidation capacity (Fig. 2). Thus, a single FA or a combination of FA that induced β-oxidation capacity might be present in the feed. Substrate preferences for the β-oxidation reaction have been found in both rainbow trout (37–39) and Atlantic salmon (38). It was previously shown that in rainbow trout red muscle mitochondria, MUFA, especially 16:1n-7, 18:1n-9, 22:1n-9, and 22:6n-3, were β-oxidized at the same rate, whereas 18:2n-6 and 18:3n-3 had lower β-oxidation rates (37). In a recent study (40), 50% of the 18:1n-9 or 20:5n-3 added to skeletal muscle cells was β-oxidized. In addition, 22:1n-11 is scarce in the phospholipids of fish biomembranes in spite of high dietary levels and is therefore thought to be a good substrate for β-oxidation (41). The increased β-oxidation capacity in white muscle with increasing dietary RO content could be due to the increased level of dietary MUFA that accompanied this diet. Although similar trends were observed in red muscle and in liver, there were no statistically significant effects. Similarly, in a study in which dietary capelin oil was

prior to the experiment. The main differences between the initial sampling period and the 0% RO diet group in the final sampling would reflect the combined effects of growth, ontogeny, temperature, light regime, and season. White muscle had a significantly increased β-oxidation capacity between the initial and final sampling, whereas liver had a decreased β-oxidation capacity over the same time period, with statistical differences noted between

replaced with 50 and 100% oleic acid-enriched sunflower oil and 100% palm oil, no significant differences in the β-oxidation capacity in Atlantic salmon red muscle were observed after 21 wk (12). Analysis of the FA composition of fish in the present study indicated a relatively low retention of 18:2n-6, 18:3n-3, and MUFA in white muscle (21). Additionally, EPA and DHA exhibited increased tissue retention with increasing dietary RO content, whereas 18:1n-9 and 18:2n-6 displayed decreased retention. It has been suggested in several studies that in fish, the FA present in excess are preferentially β-oxidized over those present in lower amounts (21,42). In the present study, the amount of both 18:2n-6 and 18:3n-3 increased with increasing dietary RO, coinciding with an increased β-oxidation capacity in white muscle in October, and in red muscle and liver in March. This result indicates that when 18:2n-6 and 18:3n-3 are fed in high concentrations, they become good substrates for the β-oxidation reaction and might even be inducers of the reaction in white muscle.

From the same sampled fish as those used in the present study, Torstensen *et al.* (19) showed that the lipid content decreased in October with increasing dietary RO and in the 50% OO diet. In addition, there was a tendency for lower fish growth with increasing diet RO and in the OO group in October (with no significant differences in growth of the sampled fish, data not shown). However, in March, differences in fish growth were masked by a decreased specific growth rate, and observed differences in lipid content in white muscle were smoothed out (19). The observed decline in lipid content in October (19) was not reflected by changes in β-oxidation capacity in the muscle (Fig. 2). Since the content of lipids depends on a number of factors in addition to their use for energy metabolism, it is likely that processes such as growth, absorption, and deposition of fat may better reflect the changes in lipid content. Another possibility for the decreased lipid content in white muscle was that a change in lipid deposition occurred that did not favor the storage of lipids in white muscle. Several studies have shown that lipid deposition in muscle is affected when Atlantic salmon are fed vegetable oil (29,30).

Increasing the dietary RO content from 75 to 100% resulted in an 8% increase in the specific β-oxidation capacity in red muscle, compared with a 75% decrease in white muscle in the October sampling period (Fig. 2). In the same dietary groups, the β-oxidation capacity decreased in both red and white muscle by 37 and 30%, respectively, in the March sampling. Thus, the FA composition of the 100% RO diet may not have favored β-oxidation in the muscles. When 50% of the capelin oil was replaced with OO, the effects of β-oxidation capacity were more or less the same as when the capelin oil was replaced with 50% RO (Fig. 2). However, there was an increased β-oxidation capacity in red muscle and in liver in October when Atlantic salmon were fed 50% OO, but this difference was not seen in March. If the growth of the fish had been greater over the last sampling period, then an improved β-oxidation capacity may have been seen.

Similar dietary effects on β-oxidation capacity in red and white muscle and in liver were observed when the data were expressed per gram of wet tissue or per gram of protein (Figs. 2, 3). This indicates that there were no differences in protein concentration between the samples. However, when the data were expressed as β-oxidation capacity per tissue, red muscle and liver exhibited different responses (Figs. 2, 4), indicating that tissue size is an important factor to consider when determining β-oxidation capacity, especially for the liver. In examining the three tissues measured in the present study, one can conclude that the tissues responded differently to diets, seasons, and growth. In addition, it is difficult to know which factor was most influential on the β-oxidation capacity. Further studies are therefore needed to understand more regarding the contribution of whole tissue to the overall lipid metabolism of fish, and what factors can be manipulated to maximize both the metabolism of aquacultural species and economic factors. White muscle is clearly an important tissue in this perspective.

ABSTRACT: FA with varying chain lengths and an α-methyl group and/or a sulfur in the β-position were tested as peroxisome proliferator-activated receptor (PPAR)α, -δ(β), and -γ ligands by transient transfection in COS-1 cells using chimeric receptor expression plasmids, containing cDNAs encoding the ligand-binding domain of PPARα, -δ, and -γ. For PPARα, an increasing activation was found with increasing chain length of the sulfur-substituted FA up to C_{14}-S acetic acid (tetradecylthioacetic acid = TTA). The derivatives were poor, and nonsignificant, activators of PPARδ. For PPARγ, activation increased with increasing chain length up to C_{16}-S acetic acid. A methyl group was introduced in the α-position of palmitic acid, TTA, EPA, DHA, *cis*9,*trans*11 CLA, and *trans*10,*cis*12 CLA. An increased activation of PPARα was obtained for the α-methyl derivatives compared with the unmethylated FA. This increase also resulted in increased expression of the two PPARα target genes acyl-CoA oxidase and liver FA-binding protein for α-methyl TTA, α-methyl EPA, and α-methyl DHA. Decreased or altered metabolism of these derivatives in the cells cannot be excluded. In conclusion, saturated FA with sulfur in the β-position and increasing carbon chain length from C_9-S acetic acid to C_{14}-S acetic acid have increasing effects as activators of PPARα and -γ in transfection assays. Furthermore, α-methyl FA derivatives of a saturated natural FA (palmitic acid), a sulfur-substituted FA (TTA), and PUFA (EPA, DHA, *c*9,*t*11 CLA, and *t*10,*c*12 CLA) are stronger PPARα activators than the unmethylated compounds.

Paper no. L9588 in *Lipids 40*, 49–57 (January 2005).

FA are key substrates in several metabolic pathways, and organisms have evolved complex mechanisms to maintain a proper balance between absorption, metabolism, and storage of FA. In mammals, several of these mechanisms involve nuclear transcription factors. The peroxisome proliferator-activated receptors (PPARs) belong to the nuclear receptor superfamily, which are activated by, e.g., FA and peroxisome proliferators. These receptors control the expression of genes regulating lipid and glucose metabolism as well as adipogenesis (1–4). The PPAR family consists of three subtypes encoded by separate genes: PPARα, PPARδ (also called hNUC1, PPARβ, or FAAR), and PPARγ1 and –γ2 (5–7). PPARα is expressed mainly in liver and kidney and to a lesser extent in skeletal muscle, heart, and intestine; PPARδ , in contrast, is expressed ubiquitously (8). PPARγ1 is expressed in various organs such as liver, heart, and muscle, whereas PPARγ2 is expressed almost exclusively in adipose tissue. All three PPARs form heterodimers with retinoid X receptor (RXR), and these heterodimers regulate expression of their target genes by binding to specific consensus DNA sequences, termed peroxisome proliferator-responsive elements (9,10).

Synthetic compounds that induce peroxisomal proliferation in rodents and hypolipidemic agents such as clofibrate and WY-14,643 have been shown to specifically bind to and activate PPARα (11,12). Saturated (11,13,14) and unsaturated FA [EPA (20:5n-3) and DHA (22:6n-3)] (11), branched-chain FA (15), and some eicosanoids (11,16) are among the natural ligands for PPARα. Unsaturated FA, 8(*S*)HETE, bezafibrate, eicosatetraynoic acid, and the synthetic compound GW501516 [2-methyl-4-((4-methyl-2-(4-trifluoromethylphenyl)-1,3-thiazol-5-yl)-methylsulfanyl)phenoxy-acetic acid] (12,17) bind to and activate PPARδ. Antidiabetic compounds of the thiazolidinedione class, a prostaglandin J_2 metabolite, and some unsaturated FA are PPARγ ligands (12,18–20).

Our group has been studying the effects and metabolism of 3-thia FA for many years. The 3-thia FA are metabolized by ω-oxidation followed by β-oxidation from the ω-end (21), and by sulfur oxidation to sulfoxide by flavine-containing monooxygenase (22). It has previously been shown that 3-thia FA derivatives and some unsaturated α-methyl FA induce peroxisomal β-oxidation in liver (23–25) and hepatoma cells (26). Furthermore, Madsen *et al*. (27) have published that tetradecylthioacetic acid (TTA) is a stronger ligand for PPARα than for PPARδ and -γ.

Phytanic acid (3,7,11,15- tetramethylhexadecanoic acid) is a branched-chain FA with one of its methyl groups in the β-position and is present in ruminant fats and meat. It is primarily degraded in peroxisomes by α-oxidation to pristanic acid (2,6,10,14-tetramethylpentadecanoic acid), which is a branched-chain FA with one of its methyl groups in the α-position. Zomer *et al*. (15) have shown that pristanic acid is a better ligand for PPARα than phytanic acid. Since branched-chain FA accumulate in a variety of inherited peroxisomal disorders (28,29), it is

of interest to study the effects of these FA on activation of nuclear receptors.

CLA are a group of positional and geometric isomers of linoleic acid (18:2n-6) found in ruminant fat and dairy products (30). The predominant isomers in food and commercial CLA preparations are *cis*9,*trans*11 CLA (*c*9,*t*11 CLA) and *trans*10,*cis*12 CLA (*t*10,*c*12 CLA) (30). In animal studies, *t*10,*c*12 CLA has been shown to alter body composition by reducing body fat mass and increasing lean body mass (31). We showed that *t*10,*c*12 CLA prevents lipid accumulation in 3T3-L1 adipocytes, in part by acting as a PPARγ modulator (32). Furthermore, we recently showed that small structural changes in the *t*10,*c*12 CLA molecule (changing from *t*10,*c*12 to *t*10,*t*12 or introducing a methyl group in the α-position of *t*10,*c*12 CLA) totally abolish the lipid preventive effect observed for *t*10,*c*12 CLA (33).

In light of the aforementioned studies, it is clear that small changes in the molecular structure of FA have a great influence on their ability to activate the different PPAR subtypes.

The aim of this study was to investigate whether increasing the chain length and introducing an α-methyl group (Fig. 1) in different FA and derivatives affect their activation of the three PPAR subtypes.

MATERIALS AND METHODS

Materials. Lipofectamine™, FBS, fungizone, and penicillin/streptomycin were obtained from Invitrogen (Carlsbad, CA). Reporter Lysis buffer (Promega) was bought from AH Diagnostics (Aarhus, Denmark). Hybond-N+-membranes and the Megaprime DNA labeling system kit were purchased from Amersham Biosciences (Oslo, Norway). DMEM, Hams F10 medium, Williams E-medium, and EPA were from Sigma. The two CLA isomers (purity >90%) were gifts from Natural ASA (Hovdebygda, Norway); DHA (purity >90%) was a gift from Norsk Hydro (Oslo, Norway). α-Methyl- and α-ethyl EPA were synthesized as previously described (26). TTA was synthesized according to Spydevold and Bremer (25). α-Methyl TTA was prepared by the same procedure using thiolactic acid instead of thioacetic acid.

Synthesis of α-methyl FA. The NMR spectra were recorded in CDCl$_3$, with a Bruker Avance DPX 200 instrument or a Bruker Avance DPX 300 instrument. The IR spectra were obtained with a PerkinElmer 1310 IR spectrophotometer or a Nicolet Magna-IR 550 spectrometer. Mass spectra were recorded at 70 eV with a Fisons VG Pro spectrometer. All reactions were performed under a nitrogen or argon atmosphere.

(i) Esterification of CLA. To a solution of CLA (2.0 g, 7.1 mmol) in methanol (50 mL) was added one drop of concentrated H$_2$SO$_4$. The mixture was stirred overnight at room temperature. Hexane and water were added. The aqueous phase was collected and extracted with ether. The combined organic phase was washed with brine and water and then dried (MgSO$_4$). Filtration and evaporation under reduced pressure gave the methyl ester (2.1 g, 100%).
FIG. 1. Structural formulas of α-methyl tetradecylthioacetic acid (TTA), α-methyl EPA, α-methyl DHA, α-methyl *cis*9,*trans*11 CLA, and α-methyl *trans*10,*cis*12 CLA.

(ii) Methyl (9Z,11E)-octadecadienoate[1]. δ$_H$ (300 MHz): 0.85 (3H, *br t*, *J* = 6.5 Hz), 1.20–1.50 (16H, *m*), 1.59 (2H, *m*), 2.00–2.20 (4H, *m*), 2.26 (2H, *t*, *J* = 7.5 Hz), 3.62 (3H, *s*), 5.20–5.35 (1H, *m*), 5.61 (1H, *dt*, *J* = 15.0 Hz, *J* = 7.0 Hz), 5.89 (1H, *t*, *J* = 10.9 Hz), 6.24 (1H, *ddd*, *J* = 15.0 Hz, *J* = 10.9 Hz, *J* = 1.1 Hz); δ$_C$ (75 MHz): 13.99, 22.54, 24.84, 27.55, 28.84, 28.95, 29.02, 29.04, 29.31, 29.57, 31.67, 32.81, 33.97, 51.26, 125.51, 128.64, 129.73, 134.59, 174.09.

(iii) Methyl (10E,12Z)-octadecadienoate δ$_H$ (300 MHz): 0.86 (3H, *br t*, *J* = 6.6 Hz), 1.20–1.50 (16H, *m*), 1.59 (2H, *m*), 2.00–2.20 (4H, *m*), 2.27 (2H, *t*, *J* = 7.6 Hz), 3.64 (3H, *s*), 5.27 (1H, *dt*, *J* = 10.9 Hz, *J* = 7.6 Hz), 5.62 (1H, *dt*, *J* = 15.0 Hz, *J* = 7.0 Hz), 5.91 (1H, *t*, *J* = 10.9 Hz), 6.26 (1H, *ddd*, *J* =15.0 Hz, *J* = 10.9 Hz, *J* = 1.1 Hz); δ$_C$ (75 MHz): 14.02, 22.53, 24.91, 27.63, 29.11 (2 × CH$_2$), 29.16, 29.26, 29.34, 29.39, 31.46, 32.83, 34.07, 51.38, 125.63, 128.55, 130.09, 134.53, 174.27.

Preparation of α-methyl acids. General procedure. The procedure is based on a literature procedure (26). Butyllithium (1.2 equiv, 1.6 M in hexane) was added dropwise to a stirred solution of diisopropylamine (1.4 equiv) in dry THF (0.47 mmol/mL) under argon at –20°C. The mixture was stirred at –78°C for 45 min before dropwise addition of the methyl ester (1.0 equiv) in dry THF (0.17 mmol/mL). The mixture was stirred at –78°C for 30 min before addition of methyl iodide (1.6 equiv). The mixture was allowed to warm to –20°C over 1.5 h. The mixture was then poured into water, and the water phase was collected and extracted with hexane. The combined organic phase was washed

---

[1]The NMR spectrum of methyl (9Z,11*E*)-octadecadienoate has been published by Lie Ken Jie *et al.* (34–36). The spectral data for the olefinic protons and in particular the coupling constants differ in all their publications. Other published NMR spectra of the corresponding acid support our data (37,38).

with 1 M HCl, then water, and dried (MgSO$_4$). Filtration and evaporation under reduced pressure gave the ester. The α-methyl ester (1.0 equiv) was dissolved in ethanol (0.23 mmol/mL) at room temperature and added to a stirred solution of LiOH (7.4 equiv) in water (1.7 mmol/mL). The mixture was left stirring overnight. Water and hexane were added, and the organic phase was collected. The organic phase was washed with an aqueous LiOH solution (1.5 M). The water phase was acidified with 5% HCl to pH 2 and extracted with ether. The organic phase was washed with brine, then water, and dried (MgSO$_4$). Filtration and evaporation gave the acids.

(i) 2-Methyl (9Z,11E)-octadecadienoic acid (α-methyl c9,t11 CLA. The 2-methyl (9Z,11*E*)-octadecadienoic acid was obtained from methyl (9Z,11*E*)-octadecadienoate in 74% yield according to the general procedure. ν_{max} (film)/cm^{-1} 2926, 2855, 1706; δ_H (300 MHz): 0.86 (3H, *br t, J* = 6.7Hz), 1.15 (3H, *d, J* = 7.0 Hz), 1.20–1.50 (17H, *m*), 1.60–1.70 (1H, *m*), 2.00–2.20 (4H, *m*), 2.35–2.50 (1H, *m*), 5.20–5.35 (1H, *m*), 5.63 (1H, *dt, J* = 15.0 Hz, *J* = 7.0 Hz), 5.92 (1H, *t, J* = 10.9 Hz), 6.27 (1H, *ddd, J* = 15.0 Hz, *J* = 10.9, Hz, *J* = 1.0 Hz), 10.4–10.6 (1H, *br s*); δ_C (75 MHz): 14.07, 16.78, 22.60, 27.07, 27.62, 28.90, 29.04, 29.36 (2 × CH$_2$), 29.64, 31.72, 32.87, 33.48, 39.35, 125.55, 128.68, 129.86, 134.73, 183.40; *m/z* (EI) 294 (M$^+$, 63%), 95, 81, 67 (100) [high-resolution MS (HRMS): found 294.255499. C$_{19}$H$_{34}$O$_2$ requires 294.255881].

(ii) 2-Methyl (10E,12Z)-octadecadienoic acid (α-methyl t10,c12 CLA). The 2-methyl (10*E*,12*Z*)-octadecadienoic acid was obtained from the methyl (10*E*,12*Z*)-octadecadienoate in 80% yield according to the general procedure. ν_{max} (film)/cm^{-1} 2925, 2854, 1705; δ_H (300 MHz): 0.87 (3H, *br t, J* = 6.8 Hz), 1.16 (3H, *d, J* = 7.0 Hz), 1.20–1.50 (17H, *m*), 1.60–1.70 (1H, *m*), 2.00–2.20 (4H, *m*), 2.35–2.50 (1H, *m*), 5.28 (1H, *dt, J* = 10.9 Hz, *J* = 7.6 Hz), 5.63 (1H, *dt, J* = 15.0 Hz, *J* = 7.0 Hz), 5.92 (1H, *t, J* = 10.9 Hz), 6.27 (1H, *ddd, J* = 15.0 Hz, *J* = 10.9 Hz, *J* = 1.0 Hz), 10.4–10.6 (1H, *br s*); δ_C (75 MHz): 14.03, 16.78, 22.54, 27.11, 27.65, 29.14, 29.29, 29.36, 29.41, 29.42, 31.47, 32.84, 33.48, 39.38, 125.65, 128.58, 130.08, 134.53, 183.60; *m/z* (EI) 294 (M$^+$, 61%), 95, 81, 67 (100) (HRMS: found 294.254987. C$_{19}$H$_{34}$O$_2$ requires 294.255881).

(iii) 2-Methyldocosa-(all-Z)-4,7,10,13,16,19-hexaenoic acid (α-methyl DHA). The α-methyl DHA was obtained from DHA ethyl ester in 81% yield according to the general procedure, except that THF (2 mL/mmol ester) was added in the hydrolysis to increase the reaction rate. ν_{max} (film)/cm^{-1} 3013, 2966, 1708; δ_H (300 MHz): 0.96 (3H, *t, J* = 7.5 Hz), 1.18 (3H, *d, J* = 6.8 Hz), 2.06 (2H, *m*), 2.20–2.30 (1H, *m*), 2.35–2.55 (2H, *m*), 2.75–2.95 (10H, *m*), 5.25–5.55 (12H, *m*); δ_C (75 MHz) 14.25, 16.34, 20.55, 25.53, 26.63, 30.90, 39.41, 126.32, 127.01, 127.87, 127.98, 128.08, 128.11, 128.23, 128.56, 130.26, 132.03 (10 × CH), 128.27 (2 × CH), 182.37; *m/z* (CI) 343 (M + 1, 1.65%), 215, 93 (100) (HRMS: found M + 1 343.262563. C$_{23}$H$_{35}$O$_2$ requires 343.263706).

Cell cultures. COS-1 cells (ATCC no. CRL 1650) were cultured in DMEM supplemented with L-glutamine (2 mM), penicillin (50 U/mL), streptomycin (50 µg/mL), fungizone (2.5 µg/mL), and 10% inactivated FBS. The cells were incubated at 37°C in a humidified atmosphere of 5% CO$_2$ and 95% air and
FIG. 2. Description of the transfection procedure. The ligand-binding domain (LBD) of peroxisome proliferator-activated receptors (PPAR)α/δ/γ was cloned together with GAL4 DNA-binding domain (DBD) into the pSG5 vector (Stratagene, LaJolla, CA). GAL4 is a yeast activator that controls the transcription of genes, and the regulation is exercised at the upstream activating sequence (UAS). The SV40 promoter ascertains transcription of the GAL4 DBD and PPAR LBD. Ligand binding to the PPAR LBD activates GAL4 DBD in a way that promotes binding to a UAS region on the reporter construct. Binding to the UAS region stimulates the tk promoter to drive luciferase (LUC) expression and thus increases the amounts of LUC enzyme. Up to five GAL4 DBD–PPAR LBD dimers can bind to the reporter construct at the same time, as regulated by the amount and affinity of the PPAR ligand.

used for transient transfections. Every third day, the cells in each flask were split into new flasks containing fresh media.

The establishment, cloning, and cell propagation of the 7800C1 Morris rat hepatoma cell line have been described by Richardson *et al.* (39). Growth conditions were described earlier (24).

Transfection. pSG5-GAL4-PPARα, pSG5-GAL4-PPARδ, and pSG5-GAL4-PPARγ chimera expression constructs containing the ligand-binding domain (LBD) of mouse PPARα, PPARδ, and PPARγ and the (UAS)$_5$-tk-LUC (where UAS = upstream activating sequence and LUC = luciferase) reporter construct (Fig. 2) were generous gifts from Dr. Krister Bamberg (Astra Zeneca, Mølndalen, Sweden).

Cells (1.5×10^5 COS-1) were plated in 30-mm tissue dishes (six-well plates), 1 d before transfection. Transient transfection by lipofection was performed as described by Invitrogen (Carlsbad, CA). Each well received 0.4 µg of the reporter construct (UAS)$_5$-tk-LUC, 0.8 µg pGL3-basic (Promega, Madison, WI), and 0.04 µg pSG5-GAL4-PPARα, pSG5-GAL4-PPARδ, or pSG5-GAL4-PPARγ. pGL3-basic, an empty vector, was added to obtain the recommended amount of total DNA per well and per µL Lipofectamine. Ligands or FA-free BSA (control) was added to the media 5 h after transfection. FA stock solutions (6 mM) were made on FA-free BSA (2.4 mM), and stored frozen. Unsaturated FA stock solutions were kept under argon to avoid oxidation. Transfected cells were maintained for 24 h before lysis by Reporter Lysis buffer. Binding of the FA to the LBD of PPAR activates GAL4 binding to UAS, which in turn stimulates the tk promoter to drive luciferase expression (Fig. 2). Luciferase activity was measured using a luminometer (TD-20/20 luminometer; Turner Designs, Sunnyvale, CA) and normalized against protein content. The PPARα and -γ constructs were used by our group in an earlier study (32).

*Protein content.* Protein content was measured by the Bio-Rad protein assay (Bio-Rad Laboratories, Hercules, CA).

RNA extraction and Northern blot analysis. Total RNA from 7800C1 Morris hepatoma cells was extracted with Ultraspec (Ultraspec RNA, Biotecx Laboratories, Inc., Houston, TX). For Northern analysis, the RNA samples (20 µg) were fractionated in 1.5% formaldehyde agarose gel by electrophoresis, and then transferred to nylon filters. The abundance of the transcript was determined by Northern hybridization using a specific cDNA probe for rat acyl CoA oxidase (ACO), rat liver-specific FA-binding protein (L-FABP), and the ribosomal protein L27 (ATCC #107385). Probes were obtained by PCR using the following primers: ACO Fwd, 5′-cacgcaatagttctggctca-3′; ACO Rev, 5′-gccattcgacattcttcgat-3′; L-FABP Fwd, 5′-tgggaaaggaaac-ctcattg-3′; L-FABP Rev, 5′-gccttgtctaaattctcttgctg-3′. The cDNA was labeled with (α-^{32}P)dCTP using the Megaprime DNA labeling system kit. L27 was used as control for equal loading.

Statistics. Results are presented as means ± SD. Significant differences were evaluated by Student's *t*-test, and the significance level was set at *P* < 0.05.

RESULTS

Saturated FA with a sulfur atom in the β-position as activators of PPARα and -γ. Transient transfections were done in COS-1 cells, according to the description in the Materials and Methods section and Figure 2. For the purpose of determining the most suitable concentration of FA/derivatives, concentration curves were made in the range of 1–100 µM. Based on these concentration curves, 10 and 50 µM were chosen as the most optimal concentrations for activation of PPARα and -γ, respectively. We found that saturated FA with sulfur in the β-position and increasing carbon chain length from C_9-S acetic acid (AcA) to C_{14}-S AcA (= TTA), had increasing effects as activators of the GAL4-PPARα and -γ chimera in the transfection assay (Fig. 3). Seventeenfold activation of PPARα was observed with C_{14}-S AcA, whereas derivatives with chain lengths above C_{14}-S AcA were poorer PPARα activators (Fig. 3A). Furthermore, the C_{15}-S – C_{18}-S AcA were stronger PPARγ-activators than C_{14}-S AcA (sixfold activation) with C_{16}-S AcA having the strongest effect (increasing the activation 10-fold) (Fig. 3B). The sulfur-substituted FA were poor activators of PPARδ, and we found no significant effect compared with the control. The results are therefore not shown.

Palmitic acid derivatives with sulfur in the β-position and/or α-methyl group, as activators of PPARα. Figure 4A shows that adding a methyl group in the α-position of palmitic acid increased its ligand-binding activity sevenfold, compared with palmitic acid, at 50 µM concentration (*P* < 0.05). Palmitic acid itself induced a twofold activation and seemed to be a poor activator of PPARα. Furthermore, C_{14}-S AcA (= TTA), which corresponds to palmitic acid with an additional sulfur in the β-position, was an even stronger PPARα activator than α-methyl palmitic acid (*P* < 0.05 at 0.5, 1, and 10 µM). Finally, palmitic acid with both an additional sulfur in the β-position and a methyl group in the α-position (α-methyl TTA) was a significantly stronger activator than TTA at concentrations of 0.5–50 µM

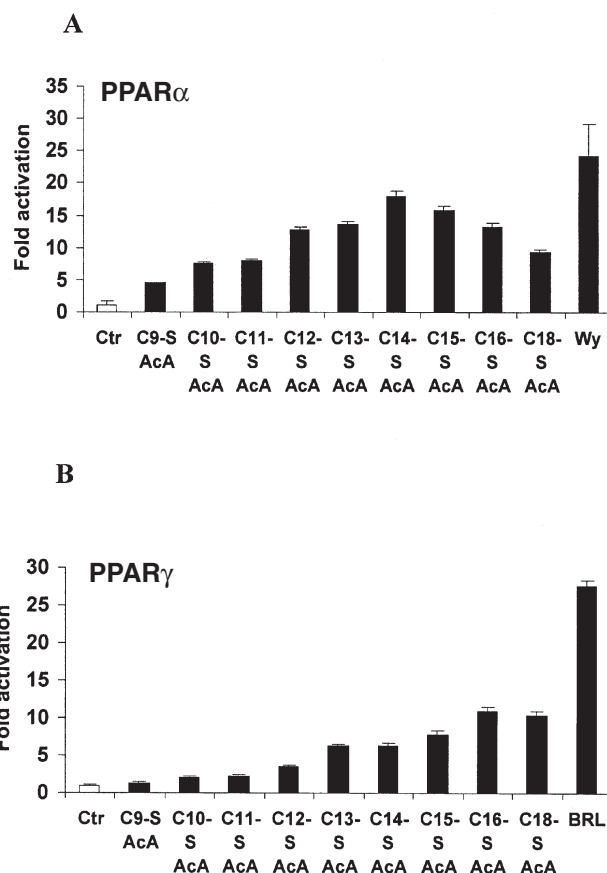
B


**FIG. 3.** FA derivatives with a sulfur atom in the β-position and varying chain length as activators of PPARα and PPARγ. COS-1 cells were transiently transfected by lipofection with a chimeric receptor expression plasmid, pSG5-GAL4-mPPARα (A) or -mPPARγ (B) and the reporter plasmid (UAS)$_5$-tk-LUC as described in the Materials and Methods section and Figure 2. The cells were treated with FA derivatives: (A) 10 µM or (B) 50 µM (10 µM BRL) for 24 h before cell harvesting. WY-14,643 and BRL 49653 were included since they are known activators of PPARα and PPARγ, respectively. Luciferase/protein ratios are expressed relative to luciferase/protein ratios in cotransfected cells stimulated with vehicle (BSA) as control (Ctr). The results represent the means ± SD of three experiments, each performed in triplicate. All derivatives activated PPARα and PPARγ significantly more than the control (*P* < 0.05). BRL 49653, rosiglitazone; WY-14,643, pirinixic acid, also known as 4-chloro-6-(2,3-xylidino)-2-pyrimidinylthioacetic acidd; AcA, acetic acid; for other abbreviations see Figure 2.

(*P* < 0.05). WY-14,643 was included in the test since it is a well-known PPARα ligand.

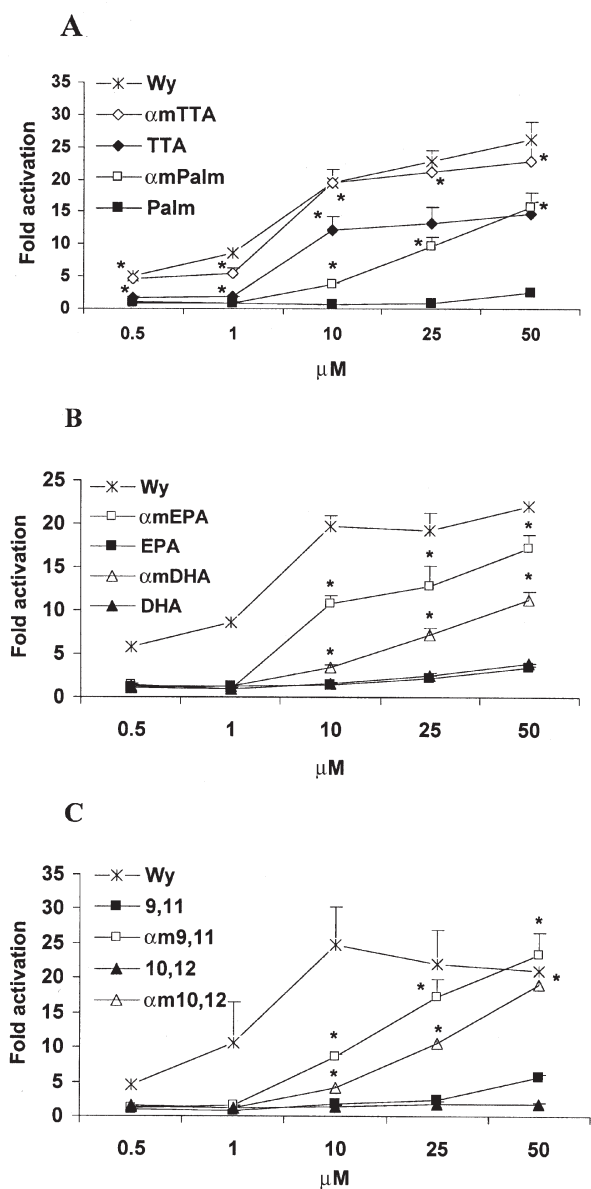
PUFA, with or without a methyl group in the α-position, as activators of PPARα. Since saturated FA with a methyl group on the α-carbon seemed to be stronger PPARα activators than the parent FA, we wanted to see if the same effect could be obtained by adding a methyl-group to the α-carbon of PUFA. α-Methyl derivatives of EPA (20:5n-3) and DHA (22:6n-3) were made and tested for their ability to activate the PPARα LBD in the transfection assay in COS-1 cells. As with saturated FA, PUFA with an α-methyl group activated PPARα more than the parent FA (*P* < 0.05) (Fig. 4B). The concentration of FA and derivatives in


FIG. 4. Effects of increasing concentrations of FA and FA derivatives on activation of PPARα, compared with the known PPARα ligand, WY-14,643. COS-1 cells were transiently transfected by lipofection with a chimeric receptor expression plasmid, pSG5-GAL4-mPPARα, and the reporter plasmid (UAS)₅-tk-LUC as described in the Materials and Methods section and Figure 2. The cells were treated with WY-14,643 (Wy) and (A) α-methyl palmitic acid (αmPalm), palmitic acid (Palm), tetradecylthioacetic acid (TTA), and α-methyl tetradecylthioacetic acid (αmTTA); (B) EPA, α-methyl EPA (αmEPA), DHA, and α-methyl DHA (αmDHA); (C) *cis*9,*trans*11 CLA (9,11), α-methyl *cis*9,*trans*11CLA (αm9,11), *trans*10,*cis*12 CLA (10,12), α-methyl *trans*10,*cis*12CLA (αm10,12). Transfected cells were maintained for 24 h before harvesting. Luciferase activity was correlated to protein concentration. Results are presented as fold activation relative to luciferase/protein ratios in cotransfected cells stimulated with vehicle (BSA) as control and given as mean ± SD of three experiments, each performed in triplicate. One representative experiment is presented in A, B and C. Student's *t*-test was performed on the data, and an asterisk (*) indicates *P* < 0.05 for (A): values that were judged statistically different from the corresponding values in the immediately below curve (i.e., αmTTA vs. TTA, TTA vs. αmPalm, and αmPalm vs. Palm); (B) and (C): PPARα activation by α methyl derivatives significantly higher than PPARα activation by the unmethylated FA.
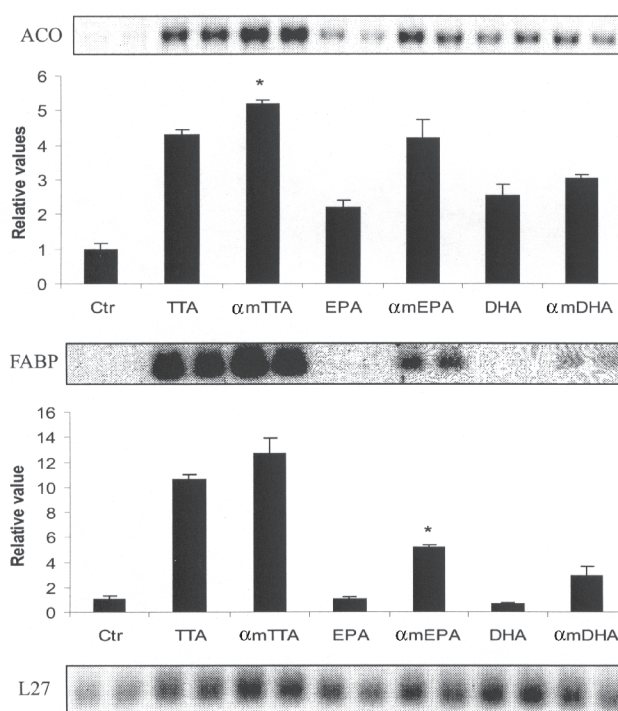

FIG. 5. Induction of PPARα-responsive genes. 7800C1 Morris hepatoma cells were treated with 50 μM FA/FA derivative, whereas control cells received BSA, for 24 h. RNA was extracted and applied (20 μg per lane) to nylon filters by gel electrophoresis and blotting. Filters were hybridized with ³²P-labeled cDNA for acyl-CoA oxidase (ACO), liver-specific FA-binding protein (L-FABP), and the ribosomal protein L27. The scans of the ACO and FABP mRNAs were calculated against scans of the L27 bands, which were examined in the same samples and used as a loading control. The values are presented relative to values obtained from cells stimulated with vehicle (BSA) as control, and given as the means ± SD of two experiments. Each experiment included two parallels per treatment. *Significantly (*P* ≤ 0.05) different from the corresponding unmethylated compound. For abbreviations see Figure 1.

the cell medium was increased from 0.5 to a saturating level at 50 μM. At 50 μM the PPARα activation was increased from 3- to 22-fold for α-methyl EPA compared with EPA and from 4- to 11-fold for α-methyl DHA compared with DHA. EPA and DHA and their α-methyl derivatives were tested as activators of PPARδ and -γ in the same way as for PPARα. Both derivatives were stronger activators of PPARδ and -γ than EPA and DHA, but the effects were not as strong as for PPARα (data not shown). EPA with an ethyl group in the α-position was made (26) and tested as a PPARα activator. It activated PPARα with equal strength as α-methyl EPA (data not shown).

In agreement with earlier studies, we found that *c*9,*t*11 CLA, and *t*10,*c*12 CLA were relatively weak PPARα activators (32), but *c*9,*t*11 CLA was a more efficacious PPARα activator than *t*10,*c*12 CLA (fivefold compared with twofold activation at 50 μM concentration). α-Methyl derivatives of the two CLA isomers were found to be stronger activators of PPARα than the parent CLA (*P* < 0.05) (Fig. 4C), with α-methyl *c*9,*t*11 CLA (23-fold activation) being a stronger activator than α-methyl *t*10,*c*12 CLA (19-fold activation). However, both derivatives were much weaker

activators than WY-14,643 at low concentrations. Also for PPARγ, the α-methyl CLA were found to be stronger PPARγ activators than the natural CLA but much weaker activators than the known PPARγ ligand, BRL 49653 (rosiglitazone) (data not shown). Because of the much lower effects of the derivatives as PPARγ activators compared with PPARα, we chose to focus on PPARα target genes in our next step in the present study.

Effects on PPARα target genes. To verify our results from the transfection studies in a more physiologic system, we tested the effects of FA derivatives on PPARα target genes. For this experiment 7800C1 Morris rat hepatoma cells were used. This cell line was used extensively in our earlier studies on lipid metabolism (24,25,40–43) and is well suited for this purpose. Rat and mouse PPARα LBD have a high degree of homology (44). Since no sign of toxic effects was observed at a ligand concentration of 50 μM in the medium, the cells were treated with 50 μM FA for 24 h, and gene expression of ACO and L-FABP were studied by Northern hybridization. Figure 5 shows that all of the ligands induced the transcription of the ACO-gene more than was obtained with vehicle (BSA) only (control). α-Methyl TTA, α-methyl EPA, and α-methyl DHA induced ACO gene expression more than TTA, EPA, and DHA, respectively, although only α-methyl TTA acted at a significant level ($P \leq 0.05$). As for ACO, the expression of FABP was increased after treatment with TTA, α-methyl TTA, α-methyl EPA, and α-methyl DHA, and the methylated FA had stronger effects than the corresponding unmethylated FA. However, no effect on transcription of the two PPARα-target genes was found for the two α-methyl CLA derivatives, compared with the parent FA and control (data not shown).

DISCUSSION

TTA is known to increase peroxisomal β-oxidation activity in rat hepatocytes and hepatoma cells (25). It has been shown to be a potent PPARα-ligand (11,14), inducing increased transcription of several PPARα-target genes (42), and to induce peroxisomal proliferation in rat liver cells (23,45). In this study we asked the question: Will the effects of FA with sulfur in the β-position vary with varying chain length?

We found that increasing the carbon chain length increased the luciferase activity in the transfection assays, indicating stronger PPARα and -γ activators. The FA derivatives C_{13}-S AcA – C_{15}-S AcA were the strongest PPARα activators, whereas C_{16}-S AcA was the strongest PPARγ activator. As a comparison, feeding studies have shown that the activity and mRNA level of the PPARα-responsive gene ACO increases as a function of chain length of 3-thia FA, with the effect of the C_{12}-, C_{13}-, C_{14}-, and C_{15}-S AcA being strongest (46,47). Xu and coworkers (14) have shown in competition assays that saturated FA containing 12 carbon atoms or fewer were unable to interact with the three PPARs. They also found that saturated FA with chain lengths from 14 to 16 carbon units bind to PPARα, bind more weakly to PPARδ, and fail to interact efficiently with PPARγ. Furthermore, saturated FA with chain lengths of 20 or more carbon units failed to bind well with any of the PPARs. These results correspond

well with our present results. Comparison of the values for palmitic acid as a PPARα activator at 10 μM (Fig. 4A) (unchanged luciferase activity) with C_{14}-S AcA (TTA) in the same figure (a 12× increase) shows that the sulfur-substituted FA are stronger activators than the comparable unmodified saturated FA. In studying the geometry and chemical composition of the PPAR ligand-binding cavity, the reason why some FA are better activators than others might be clearer: According to Cronet and coworkers (48), the structure of PPARα LBD is very similar to both PPARγ LBD and PPARδ LBD, about 60–65% identical. EPA, which is a PPARδ ligand, has a hydrophilic head group that forms hydrogen bonds to amino acids in the vicinity in the LBD cavity. Its long hydrophobic tail forms interactions with hydrophobic amino acids in other parts of the ligand-binding cavity (14). This could explain why shorter saturated FA do not activate PPARs, e.g., they cannot make sufficient hydrophobic interactions required for stable ligand binding. Another feature common to several of the peroxisome proliferators and PPARα activators is an oxygen atom in the β-position (49) that enters into hydrogen bond formation with a serine residue in the ligand- binding cavity (44). Both sulfur and oxygen atoms are capable of making hydrogen bonds with serine; hence WY-14,643, with a sulfur in the β-position, is a strong PPARα ligand (5). In comparison, all of the thia FA in this study have a sulfur in the β-position, which might explain the relatively strong activation compared with unmodified saturated FA.

Our next question was whether a methyl group in the α-position of saturated or unsaturated FA would have any influence on their properties as PPARα activators.

We found that adding one methyl group to the α-carbon of palmitic acid (= α-methyl palmitic acid) increased its PPARα activation significantly. Adding a sulfur in the β-position of palmitic acid (= TTA) increased the activation even more, and TTA had a significantly stronger effect than α-methyl palmitic acid. Introducing both an α-methyl group and a β-sulfur (= α-methyl TTA) increased the activation even further and significantly more than TTA. We also found that α-methylation of PUFA made them into stronger PPARα activators. The same effect is observed by moving a methyl group from a β- to an α-position of naturally occurring branched-chain FA such as phytanic and pristanic acid (15). As a comparison, clofibric acid and several other compounds known as strong peroxisome proliferators and PPARα activators also can be seen as carboxylic acids with one or two α-methyl group(s) (49). Altogether, our studies and studies by others might suggest the presence of a pocket for methyl groups as well as flexibility in the PPARα ligand-binding cavity, close to the binding site for the carboxylic group.

According to these hypotheses, α-methyl TTA fulfills the three criteria of having the required chain length, a sulfur that can make a hydrogen bond with the serine residue, and a methyl group that fits into the suggested pocket in the LBD of PPARα. α-Methyl TTA was found to be the strongest PPARα activator in this study next to WY-14,643.

In agreement with our results showing increased PPARα activation, α-methyl TTA, α-methyl EPA, and α-methyl DHA also showed increased mRNA levels of the PPARα target genes

ACO and L-FABP in 7800C1 Morris hepatoma cells. This corresponds well with our earlier *in vitro* studies, which showed that α-methyl EPA is incorporated into cell phospholipids and increases ACO activity in hepatoma cells more than EPA (26). To our knowledge, the effects of α-methyl DHA have not been studied before. The increased transcription of ACO by TTA, α-methyl TTA, EPA, α-methyl EPA, DHA, and α-methyl DHA compared with the control may indicate increased β-oxidation of FA. Also, in feeding experiments, α-methyl TTA is a stronger inducer of ACO than TTA (50). Earlier studies showed that TTA decreases serum TG and cholesterol concentrations in animals fed this derivative (51–53). Others have shown that α-methyl EPA decreases plasma TG values more than EPA when given to rats (54). α-Methyl EPA is also a stronger inhibitor of platelet aggregation than EPA, both *in vitro* (26) and *in vivo* (54).

In addition, we found that α-methyl EPA, α-methyl DHA, and α-methyl TTA increased the expression of L-FABP more than EPA, DHA, and TTA, respectively. L-FABP is a cytosolic protein that binds endogenous FA, including branched-chain FA (55) and long-chain PUFA (56). This protein is involved in the uptake and intracellular transport of FA to either peroxisomal membranes or to the nucleus (57) for activation of PPARs (58). Furthermore, phytanic acid is a transcriptional activator of L-FABP expression, and this effect is mediated by PPARα (55).

The α-methyl CLA did not increase the mRNA for the same two PPARα target genes. This indicates that PPAR activators do not always induce the transcription of PPAR-responsive genes. Coactivators and corepressors play important roles in the regulation of transcription and may be differently recruited by various PPAR activators (59,60). Also, the regulation of PPAR target genes in lipid homeostasis is likely to be the consequence of a complex interplay among multiple PPAR and RXR isoforms and the ligands to these receptors (4,9,10). Prohibition of the dimerization by different ligands will prevent transcription of the PPARα target genes. Further, the α-methyl CLA might be antagonists, occupying the LBD and preventing transcription of ACO and L-FABP. Finally, we also speculate on the probability that the metabolism of these derivatives in 7800C1 Morris hepatoma cells may be different from the metabolism of the other derivatives used in this study.

The delayed catabolism of 3-thia FA and α-methyl FA may contribute to the increased effects of these FA derivatives compared with their unmodified counterparts, as shown in this paper. The degradation of FA differs according to their chemistry. Saturated and unsaturated straight-chain FA with a chain length of 4–20 carbon atoms are β-oxidized in mitochondria, whereas longer FA (C_{20}–C_{24}) have to be chain-shortened by β-oxidation in peroxisomes. Introduction of a methyl group in the α-position of FA is sufficient to decrease its β-oxidation in mitochondria (61), leading to peroxisomal oxidation by a specific noninducible branched-chain fatty acyl-CoA oxidase (62). Substituting a sulfur atom at the β-position in the carbon chain of a saturated FA prevents normal β-oxidation of the FA derivative. In addition to decreased or altered metabolism, it also remains possible that these compounds have altered affinity for serum- or intracellular binding proteins, which in turn might influence their PPARα activation.

In conclusion, saturated FA with sulfur in the β-position and increasing carbon chain length until C_{14}-S acetic acid have increasing effects as activators of PPARα and -γ in transfection assays. Furthermore, α-methyl FA derivatives of the saturated natural FA palmitic acid, the sulfur-substituted FA TTA, and PUFA (EPA, DHA, *c*9,*t*11 CLA, and *t*10,*c*12 CLA) are stronger PPARα activators than the unmethylated compounds.

High-Fat Diets Impede the Lowering Effect of Cyclosporine A on Rat Brain Lipids and Interact with the Expression of Apolipoproteins E and J

ABSTRACT: Cyclosporine A (CsA), a common immunosuppressive agent, produces hyperlipidemia and apolipoprotein profile alterations in plasma as well as neurological and psychiatric complications. In rats, 10 mg CsA/kg/d treatments for 3 wk induce alterations of the electroencephalogram, and of the blood and brain lipids. Using this model, we evaluated whether triacylglycerol (TG)- and lecithin (PC)-enriched diets, reported to decrease epileptic episodes (TG) and to improve memory, could modify the effects of CsA treatment on brain lipids and possibly change apolipoprotein (apo) E and apoJ gene expression. To evaluate this hypothesis, three groups of rats were treated for 3 wk with CsA and received a low-fat, PC, or TG diet. Three other groups were fed the above-mentioned diets and were treated with the CsA solvent. As a control, one group was fed only the low-fat diet. The CsA-mediated decreases in brain cholesterol and PC contents, under a low-fat diet, were eliminated by the TG and PC diets. These high-fat diets induced a global increase in hippocampal transcriptional activity, as revealed by elevated polyadenylated RNA levels. The apoE and apoJ mRNA levels in the cortex and hippocampus of rats receiving the solvent were not statistically different between the TG- and PC-enriched diets but showed important variations compared with the low-fat diet solvent-treated group. A differential effect between the two high-fat diets was observed in the hippocampus, resulting in a significant increase of the apoE to apoJ ratio with the PC diet. The balance between apoE and apoJ is presumed to be important in encephalopathic mechanisms, by its involvement through low levels of brain cholesterol and PC, that might be associated with mental disorders. Our results therefore suggest that diet enrichment with polyunsaturated fat might be beneficial during CsA therapy. However, if the high levels in PC used here are more beneficial on CsA peripheral side effects than similar enrichment in TG, this does not seem to be the case in the brain. Thus, lower levels in PC should be tested.

Cyclosporine A (CsA), a potent immunosuppressive drug, is used in the treatment of autoimmune disorders (1) and after transplantation. However, a number of side effects occur quite often (2,3). Hepatic and renal dysfunction are the most frequent, but neurological and psychiatric complications are described as well (4–8). Seizures, memory and mood impairments, or psychotic episodes (4,7) are reported and are probably related to a drug accumulation in the brain. Such accumulation results from a combination of several types of CsA-mediated tissue, cellular, and molecular alterations (9–12). At the blood–brain barrier level, vascular injuries associated with anatomic disruption (9) and a decrease in the expression of the P-glycoprotein have been described in patients (10) and in CsA-treated rodents (12). Some neuropathological symptoms seen in patients were reproduced in rats, such as preepileptic alterations of the electroencephalograms (EEG) previously reported after 2 wk of treatment (13). The rat model therefore provided the opportunity to characterize the cellular and molecular events associated with CsA-mediated neurological dysfunction. Accumulation of phosphorylated neurofilaments was observed in rats exposed to CsA (14). The preepileptic alterations of the EEG and the accumulation of insoluble material as neurofilaments are typical features in latent epilepsy and Alzheimer's disease, respectively, and are presumed to be related to the neuropathology observed (15,16). Nevertheless, even if the expected similarities with the animal model of Alzheimer's disease and epilepsy at the level of apolipoprotein expression have not yet been described (15,17–19), the observed alterations in brain lipid content suggest that some neuropathological mechanisms might be analogous between CsA-induced mental disorders and several human neurological or mental disorders (i.e., Alzheimer's, memory loss, depression, and suicide). Such changes have been suggested to be associated with decreases in brain cholesterol and abnormalities of lipid metabolism (20–22). Vegetable n-6 polyunsaturated soybean lecithin (phosphatidylcholine: PC), rich in n-6 PUFA, seems to be a suitable dietary supplement during immunosuppressive treatment with CsA since it has been shown to reduce hypercholesterolemia (23), as well as to improve memory and possibly Alzheimer's deficits (24–27). Dietary triacyglycerol (TG) supplements have no positive effect

on blood cholesterol in rats, but have also been shown to improve learning (28). In addition, the major known effect of dietary TG consists of positive effects on brain excitability used as "ketogenic diets" since the 1920s to decrease seizure frequency in refractory childhood epilepsy (29,30). Thus, we hypothesized in the present work that the content in the brain of unesterified cholesterol and PC, seen to be altered following CsA treatment, could be restored by an appropriate lipid enrichment of the diet, which might be helpful in preventing CsA-mediated neurological side effects.

MATERIALS AND METHODS

Animals. Male Wistar rats (255 ± 10 g) were fed low- or high-fat diets for 3 wk (Table 1). The daily dietary intakes were isoenergetic (390 kJ/d for high-fat diets and 380 kJ/d for the standard low-fat diet). Animals were divided into seven groups, each group comprising six rats. They received care in compliance with the guidelines of the Animal Research Committee (INSERM guidelines, approved by the Minister of Agriculture no. 107 150). One group did not receive any treatment and was fed the standard low-fat diet (control group C). Daily intraperitoneal injections (200 µL/kg/d) were performed for 3 wk in the six other groups fed either the low-fat diet, or high-fat diets consisting of either a 20% enriched soybean TG diet (TG group) or a 20% enriched soybean PC diet (PC group). The fatty acid (FA) composition was similar in the TG and PC groups: In both high-fat diets, the levels of the main FA were as follows (molar percentage): palmitic acid, 11.3%; oleic acid, 18.0%; linoleic acid, 59.0%; α-linolenic acid, 7.7%. In addition, the high-fat diets had a lower content of carbohydrates compared with the C group (starch, 140 and 240 g/kg; sucrose, 123 and 183 g/kg in the high-fat and C groups, respectively). Half of the treated animals received only a volume of the CsA solvent (S group), a sixfold dilution of Cremophor in 0.9% NaCl (Novartis, Rueil Malmaison, France). The other half re-ceived the same volume with 10 mg/kg/d of CsA (Novartis). After the 3-wk period, rats were anesthetized after an overnight fast by an intramuscular injection containing 20 mg/kg xylazine (Rompun; Bayer, Puteaux, France) and 15 mg/kg ketamine (Imalgène; Rhône Merieux, Lyon, France). Plasma and brain were recovered and stored at −80°C.

RNA analysis. Brains were thawed in ice-cold 0.12 M PBS, (pH 7.4) and dissected on ice. Cortices and hippocampi of each animal were weighed and homogenized separately in the amount of tri-instapur solution indicated by the supplier in order to have identical conditions of RNA extraction (Eurogentec, Seraing Belgium). A reliable polyadenylated RNA (poly A+) quantitative assay was used to assess the transcriptional activity in the cortex and the hippocampus of each animal in relation to possible effects of the treatments. The preparations of total RNA were used for dot blot analysis as described previously (31). Briefly, they were denatured in 150 µL of 20× SSC (standard sodium citrate 1× = 0.15 M NaCl/0.015 M sodium citrate, pH 7.2) for 5 min at 70°C and dot blotted under vacuum in a dot blot apparatus (Schleicher and Schuell, Keene, NH); the 150 ng (for polyA+ dosage) or 1200 ng [for apolipoprotein (ApoE) and apoJ mRNA quantifications) of total RNA loaded on the membrane was fixed at 80°C for 1 h. RNA dots prehybridized (TechneHybridiser HB-ID) at 45°C for 2 h in a phosphate hybridization buffer containing 250 mM Na_2HPO_4, 7% SDS, and 1% BSA fraction V, at pH 6.5, were then hybridized following removal of the used prehybridization solution in a solution containing the same ingredients plus 5×10^6 cpm/mL of the radioactive probe [or 10×10^6 cpm/mL in the case of the oligodeoxythymidyl (oligodT) probe, to have the appropriate molecular concentration]. Following overnight hybridization, membranes were washed twice at room temperature for 30 min in 250 mM Na_2HPO_4 and 1% SDS, and once at 45°C in 250 mM Na_2HPO_4 and 0.1% SDS. Autoradiograms of the membranes were obtained at different times of exposure to control for linearity with a standard liver mRNA loaded at

various concentrations. Optical density (O.D.) of each dot on the autoradiogram signals corresponding to total RNA from rat cerebral cortex or hippocampus and to a control dot allowed us to quantify the levels of expression of the mRNA species specifically hybridized with the labeled oligomeric sequence. For quantification of the poly A+, negative hybridization controls were made using various amounts of a mix containing rRNA and tRNA. No signal was detected up to 20 µg, an amount about 100 times above the amounts loaded on the experimental dots containing only a natural abundance of these RNA species. Densitometric measurements were obtained using Image 1.36 MacintoshII software (Wayne Rasband, National Institute of Mental Health, Bethesda, MD) following calibration with Kodak calibration step tablet 809ST601 as a standard. Unsaturated autoradiograms were measured from three independent hybridization experiments.

Synthesis and labeling of the probes. The oligodT template (19–24 mer) was purchased from Pharmacia (Piscataway, NJ). Oligomers used to probe apoE and apoJ mRNA species were customized by Eurogentec. Rat sequences for these messengers were obtained through Genbank (accession numbers J00705 and X13231, respectively, for apoE and apoJ). Oligonucleotide sequences were controlled for specificity and secondary structure using Oligo r 4.03 (primer analysis software; National Biosciences Inc., Plymouth, MN). ApoE and apoJ probes were complementary to the coding sequences from nucleotide 518 to 552 and from nucleotide 449 to 476, respectively.

The labeling of the probes was performed at 37°C using 50 units of terminal deoxytransferase (Eurogentec) (or 100 units for the oligodT probe) and 50 µCi (or 120 mCi for the oligodT probe) of ^{32}P dTTP (800 Ci/mmol; Amersham, Les Ulis, France). The 50-µL reaction mixture containing 10 pmol of oligomer (or 15 pmol of oligodT template, and 4 pmol of cold dTTP) was incubated for 20 min (or overnight in the case of the oligodT probe). The probes obtained were either tailed with an average of 4 to 8 nucleotides for the specific messenger probes or with an average of 20 to 30 nucleotides for the oligodT probe as seen on a 15% acrylamide gel.

Protein assay. The dosage of the plasmatic and brain protein contents was determined with a Pierce kit (Rockford, IL).

Lipid assays. TG concentrations were evaluated by the enzymatic method of Fossati and Prencipe (32); total and unesterified cholesterol, respectively, were measured by the enzymatic methods of Siedel *et al.* (33) and Stähler *et al.* (34); and PC was measured by an enzymatic method based on the presence of the choline moiety (35). Serum was used directly, and brain lipids were extracted by the method of Folch *et al* (36).

Analysis of plasmatic biological markers. Blood samples were taken at sacrifice after an overnight fast. Using the enzymatic assay described by Ziegenhorn *et al.* (37), the glucose level in each rat plasma was measured, as were the plasma activities of glutamic oxaloacetate transaminase and glutamic pyruvate transaminase (38). Plasma urea and uric acid concentrations were also measured with Boehringer kits (Boehringer, Paris, France).

The Anionic Peptide Factor (APF) was purified from rat HDL$_3$ isolated by sequential ultracentrifugation at density 1.21 and tangential ultracentrifugation (Filtron, Coignières, France). The supernatant was processed successively through 100–10-kDa hydrophobic membranes. Using the purified 7-kDa APF, ELISA assays were performed with a polyclonal antibody (MD 94) from immunized rabbits and a monoclonal antibody (MAB 32) from Balb/c mice. These two antibodies had been characterized previously and did not cross-react with apoA-I. The determinations of APF concentrations in the samples were of two types: (i) an ELISA with direct antigen binding, and (ii) an ELISA with competitive antigen displacement as described previously (39). The standard curve allowed us to detect APF concentrations ranging from 0.2 to 5 µg/mL.

Statistical analysis. All the results are expressed as the arithmetical means of each group with their SE. Significance was analyzed by a one-way ANOVA, and the differences between groups were evaluated according to Fisher's test at $P < 0.05$. All calculations were performed using StatView^{TM} SE and Graphics (Abacus Concepts, Inc., Berkeley, CA; version 19 for Macintosh computer).

RESULTS

Plasma analysis. (i) Biological markers for peripheral dysfunctions. Blood urea was significantly increased by CsA. A comparison between the S groups and the corresponding CsA-treated groups showed increases of 65, 40, and 91% ($P < 0.01$), respectively, in the low-fat, TG-enriched, and PC-enriched diet groups (Table 2). Uremic response was more limited with the TG-enriched diet, and the levels were not significantly higher than those measured in naïve C group rats. None of the CsA-treated groups had uremia levels indicating serious renal failure or damage, and there was no pathological risk to the brain or other organs.

None of the rats treated with CsA showed increases in transaminase blood activities (Table 2). Thus, there was no CsA-mediated liver cytotoxicity in any experimental groups. Hypoglycemia, which might have increased the encephalopathic mechanism (40,41), was not observed. Following one night of fasting, glycemia was higher in animals fed the TG-enriched diet (groups TG-S and TG-CsA) than in the other groups; however, this diet effect was moderate and the values remained in the physiological range.

(ii) Lipidemia. On the low-fat diets (groups C, S, and CsA), plasma TG, total cholesterol, and unesterified cholesterol were significantly increased in the group treated with CsA (Table 2). However, as previously reported (17), the plasma unesterified cholesterol was already increased by the solvent, whereas the other blood lipids were selectively increased by CsA. A significant ($P < 0.05$) 1.6-fold increase in the ratio of unesterified to total cholesterol blood content (Table 2) was found in both the solvent and the CsA groups fed the low-fat diet. Feeding the rats a TG- or PC-enriched diet (groups TG-S and PC-S) eliminated the solvent-mediated increase of the unesterified to total cholesterol ratio. Concomitantly, the TG- and PC-enriched diets

[a]Comparisons were made between the seven animal groups comprising the control group (C) of unlabeled animals, and the experimental groups receiving either 10 mg/kg/d of CsA or the CsA solvents with a low-fat or a TG- or PC-enriched diet. Results are expressed as means ± SE (n = 10 in groups C, S, and CSA; n = 8 in groups TG-S, TG-CsA, PC-S, and PC-CsA). Glu, glucose; GPT, glutamic pyruvate transaminase; GOT, glutamic oxaloacetate transaminase; TC, total cholesterol; EC, esterified cholesterol; UC, unesterified cholesterol; APF, Anionic Peptide Factor; for other abbreviations see Table 1. Significance of the data was evaluated by Fisher's test. The presence of a superscript lowercase letter after the values given for an experimental group indicates statistical significance of at least $P < 0.05$. The letters correspond to the following comparisons: [a]C vs. S; [b]C vs. CsA; [c]S vs. CsA; [d]S vs. TG-S; [e]S vs. PC-S; [f]TG-S vs. PC-S; [g]CsA vs. TG-CsA; [h]CsA vs. PC-CsA; [i]TG-CsA vs. PC-CsA; [j]TG-S vs. TG-CsA; [k]PC-S vs. PC-CsA.
[b]To convert mmol/L to mg/L, multiply Glu by 18, TC by 38.6, and TG by 88.5.

induced increases in total cholesterolemia of 18 ($P < 0.05$) and 34% ($P < 0.05$), respectively, without a parallel increase in the unesterified cholesterol plasma level in the TG-enriched diet, whereas in the PC-fed group, a 20% ($P < 0.05$) increase in the unesterified cholesterol level was also measured (Table 2). Concerning selective CsA-mediated increases in the concentrations of plasma total cholesterol and TG seen in the low-fat-fed rats, we observed that only the TG-enriched diet countered this drug effect. With the PC-enriched diet, the CsA-mediated increase in TG plasma levels was still observed, reaching 74% ($P < 0.05$) (Table 2). To further analyze the beneficial or detrimental aspects of lipidemia alterations observed in the various experimental groups, we measured the 7-kDa APF. This peptide was described previously as a minor apolipoprotein in HDL (HDL$_3$). With a low-fat diet, we observed an important solvent-mediated decrease in APF (Table 2). The two high-fat diets, and particularly the PC diet, drastically increased the plasma APF level. No change in the APF level was observed when the CsA treatment was added to the TG-enriched diet (group TG-CsA), whereas the APF level was significantly lowered by CsA in the PC-fed group. However, in this last group (group PC-CsA), the APF level remained significantly higher than in the two other CsA-treated groups (groups CsA and TG-CsA), and it was still significantly above the levels measured in the C group.

Brain lipid concentrations. Brain unesterified cholesterol levels were significantly higher in the groups fed high-fat diets (groups TG-S and PC-S) compared with the low-fat diet (group S) (Table 3); the TG- and PC-enriched diets produced increases of 25% ($P < 0.01$) and 16% ($P < 0.05$), respectively (Table 3). With the CsA-treatment, brain unesterified cholesterol remained above normal in rats fed the high-fat diets. There was a maximal effect of CsA with the low-fat diet, on the concentration of brain unesterified cholesterol inducing significantly

lower levels than normal. The effect was limited with the TG-enriched diet, inducing a 12% decrease compared with the S group fed the TG diet, and there was no effect with the PC-enriched diet (Table 3). The levels in the TG- and PC-fed groups were not significantly different.

TG were present at low concentrations in the brain. Their levels were unchanged in the CsA group fed the low-fat diet compared with the S group. When rats were fed the TG- and the PC-enriched diets, significant increases in brain TG levels were measured, reaching 54 and 31%, respectively, compared with the S group fed the low-fat diet. CsA administration significantly reduced the effect of the TG diet on the brain TG levels, whereas it had no effect when applied with the PC-enriched diet. A comparison of brain TG levels in the three groups treated with CsA showed that the two high-fat-fed groups had significantly higher brain TG levels.

As previously reported with a low-fat diet, the brain levels of PC in both the CsA and S groups showed a significant drug-related decrease. In the TG and PC groups receiving the solvent, the brain PC levels showed significant increases (by 54 and 17%, respectively) compared with the S group fed a low-fat diet. When the CsA treatment was applied to high-fat-fed animals, a lowering effect on brain PC was observed only in the TG-enriched diet group. In spite of this 23% decrease ($P < 0.01$), the PC levels remained 18% above the levels measured in the C group and 48% above the levels measured in the low-fat CsA-treated group. In the PC-enriched diet-fed group treated with CsA, the PC levels were 31% ($P < 0.05$) above the control, 54% above the levels measured in the CsA-treated group fed a low-fat diet, and 10% above the levels measured in the CsA-treated group fed a TG-enriched diet (Table 2).

Cortical and hippocampal global transcription. There were no significant differences in the cortical transcriptional steady

TABLE 3
Effect of CsA and Its Solvent on Brain Lipids in Rats Fed a Low- or High-Fat Diet[a]

	Control	Solvent			CsA

PL nmol/mg protein	710.5 ± 58.9	733.5 ± 35.7	1128.3 ± 37.0[c]	861.9 ± 20.6[g]	616.0 ± 33.8[b]	864.6 ± 31.5[d,e]	933.1 ± 38.1[f]

[a]Comparisons were made between the seven animal groups comprising the control group (C) of unlabeled animals, and the experimental groups receiving either 10 mg/kg/d of CsA or the CsA solvent (S) under a low-fat or a TG- or PC-enriched diet. Results are expressed as means ± SE (n = 10 in groups C, S, and CsA; n = 8 in groups TG-S, TG-CsA, PC-S, and PC-CsA). PL, phospholipids; for other abbreviations see Tables 1 and 2. Significance of the data were evaluated by Fisher's test. Presence of a lowercase superscript letter after the values given for an experimental group indicates statistical significance of at least $P <$ 0.05. The letters correspond to the following comparisons: [a]C vs. CsA; [b]S vs. CsA; [c]S vs. TG-S; [d]CsA vs. TG-CsA; [e]TG-S vs. TG-CsA; [f]CsA vs. PC-CsA; [g]TG-S vs. PC-S.

state between the different groups. In contrast, in the hippocampus, the transcriptional activities in the two TG groups receiving either solvent or CsA were, respectively, 48% and 56.5% ($P <$ 0.05) above the activity measured in the C group. In all CsA-treated groups, increases in the transcriptional level were measured, and this effect in the PC-fed group brought the hippocampus polyA+ level up to 30% ($P <$ 0.05) above basal levels (data described only in the text).

ApoE gene expression. Significant treatment-dependent alterations of transcriptional activity were observed; therefore, it was more appropriate to evaluate the concentration of apoE mRNA species in the cortex and hippocampus using known values of the polyA+ RNA loaded for each preparation.

In the cortex, and even more so in the hippocampus, the effect of CsA on apoE gene expression was clearly dependent on the lipid contents of the diets. In rats fed the low-fat diet, there was no CsA-mediated alteration in apoE mRNA levels, whereas for the high-fat-fed rats, CsA influenced the regulation of apoE mRNA levels (Table 4). The latter were already modified by the TG-enriched diet, which had minor and opposite effects on the cortical and hippocampal apoE mRNA levels. In the S groups, the TG diet induced a nonsignificant increase of 17.5% and a decrease of 15%, respectively, in these brain areas, compared with the low-fat-fed rats. The CsA treatment applied with the TG-enriched diet nullified these effects,

mediating a significant (33%) cortical decrease and a 32% hippocampal increase in apoE mRNA expression. Compared with the TG-enriched diet, the PC-enriched diet produced a minor increase in cortical apoE gene expression (15%; nonsignificant) but had a much greater effect on hippocampal apoE mRNA levels, producing a decrease of 55%. When CsA treatment was applied with the PC-enriched diet, a cortical decrease was observed, but it did not reach significance (22%). In the hippocampus, a major CsA-mediated increase (51%) was measured, restoring the apoE mRNA to basal levels (Table 4).

Cortical and hippocampal apoJ gene expression. Compared with the low-fat diet, the TG-enriched diet group showed a significant (29%) increase in cortical apoJ mRNA expression and a significant (51%) decrease in hippocampal apoJ expression. Enrichment of the diet with PC produced a significant (34%) increase in cortical apoJ mRNA levels and a nonsignificant (29%) decrease in hippocampal levels (Table 4).

Compared with the rats fed the TG-enriched diet (group TG-S) or an PC-enriched diet (group PC-S), the rats receiving CsA with these two diets showed a drop in cortical apoJ mRNA expression: −45% ($P <$ 0.01) and −42% ($P <$ 0.01) for the TG- and PC-fed groups, respectively. In the hippocampus, the effects of the TG-enriched diets were eliminated by the drug treatment (*cf.* groups TG-S vs. TG-CsA), and a CsA-mediated increase in apoJ mRNA hippocampal expression was observed:

TABLE 4
Effect of CsA and Its Solvent on Brain Apolipoprotein (apo) E and apoJ mRNA in Rats Fed a Low- or High-Fat Diet[a]

[a]Comparisons were made between the seven animal groups comprising the control group (C) of unlabeled animals, and the experimental groups receiving either 10 mg/kg/d of CsA or the CsA solvent with a low-fat or a TG- or PC-enriched diet. Results are expressed as means ± SE (n = 10 in groups C, S, and CsA; n = 8 in groups TG-S, TG-CsA, PC-S, and PC-CsA). For abbreviations see Table 1. Significance of the data were evaluated by Fisher's test. Presence of a lowercase superscript letter after the values given for an experimental group indicates statistical significance of at least $P <$ 0.05. The letters correspond to the following comparisons: [a]S vs. TG-S; [b]S vs. PC-S; [c]TG-S vs. TG-CsA; [d]CsA vs. PC-CsA; [e]TG-CsA vs. PC-CsA; [f]PC-S vs. PC-CsA.

+58% ($P < 0.01$). In contrast, the CsA treatment further decreased apoJ mRNA expression when animals were fed the PC-enriched diet (groups PC-CsA vs. S), and the decrease reached –43% ($P < 0.01$) (Table 4).

DISCUSSION

TG- or PC-enriched diets have been used for their beneficial effects on central nervous system (CNS) functional disorders (24–30). The aim of this study was to determine whether these diets modified some aspects of the previously observed alterations of brain lipid metabolism in response to CsA treatment (17), and whether these diets might be useful in a preventive approach toward CsA-induced neurological and psychiatric disorders. Thus, we now report that these high-fat diets can compensate for the CsA-mediated decreases in brain unesterified cholesterol and PC concentrations observed in rats fed a low-fat diet. In addition, we observed the regulation of brain apolipoprotein gene expression by both the TG- and PC-enriched diets, and differential interactions of CsA treatment with these regulatory mechanisms, depending on the high-fat diet, the region of the brain and the apolipoprotein being considered.

Concerning nutritional aspects, there have been several studies showing that the metabolic effects of dietary PC are not only those of adding the effects of dietary TG to those of choline, but also are specific to the PC supplementation (23,42–45). When free choline was administered alone, the observed effects were not as profound as those of PC: First, there was no drastic and acute hypocholesterolemic effect, as with PC (42); second, unlike dietary PC, choline did not significantly increase the biliary phospholipid and cholesterol output (42). The anti-atherogenic effects of PC, characterized by a hypocholesterolemic effect and the reduction of the aortic fatty streak area in hypercholesterolemic animals, are in fact reduced following dietary ingestion of TG plus choline (43). Thus, the two types of diets, enriched in either PC or TG plus choline, are not equivalent in their metabolic effects. Finally, PC is more efficient in terms of its overall benefits to the health; in addition, it seems better able to manipulate brain choline homeostasis indirectly using the choline precursor rather than directly using choline administration (44–46). Thus, we have chosen to compare lipoprotein and lipid metabolism at the brain level after consumption of either a PC- or a TG-enriched diet.

CsA treatment administered at a dose of 10 mg/kg/d for 2 or 3 wk is known to produce hepatic alterations (47,48), increased lipidemia (49,50), and brain EEG abnormalities without convulsions (13), but major toxicity is not commonly observed. Indeed, in the experimental groups receiving the CsA treatment, none of the rats had behavioral abnormalities or health-threatening alterations of the peripheral toxicity markers whatever the diet considered. Consistent with previous reports on solvent cholestatic effects (47,48), we observed an increase in phospholipidemia and an alteration of the balance between total and unesterified cholesterol. When CsA was added, the known effect of CsA itself was observed, with additional hyperlipidemic responses in rats fed the low-fat diet. In contrast, we now report that the high-fat diets led to different alterations of lipidemia during CsA treatment. Feeding the rats with TG-enriched diet did not significantly modify lipidemia and prevented a CsA-induced increase in cholesterolemia. The PC-enriched diet by itself modified lipidemia, resulting in an increase in plasma TG, and mainly in total cholesterol. CsA treatment with this diet further increased total cholesterol and TG. It is interesting to note that both high-fat diets conferred a solvent effect on lipidemia. We also found a large and significant increase in plasma APF concentration. APF, a minor HDL_3 apolipoprotein component, was previously shown to be a carrier of unesterified cholesterol, stimulating reverse cholesterol transport from the plasma toward the liver and bile (51). With the PC-enriched diet, we observed that the hyperlipidemic responses to CsA were maintained. Cholesterolemia was further increased by CsA but was nevertheless associated with quite a high level of APF (10- and 2.75-fold higher than in the solvent- and CsA-treated low-fat-fed groups). Furthermore, the comparison of blood markers for cholesterol metabolism following CsA treatment showed a 1.2-fold increase in cholesterolemia without an increase in APF in the low-fat conditions and a 1.1-fold increase in cholesterolemia associated with a 12-fold increase in APF in the PC-enriched diet-fed group. Therefore, supplying high levels of dietary phospholipids might be a unique stimulus to better tissue and cellular disposal of cholesterol and to improve reverse cholesterol transport during the immunosuppressive treatment. These first results on peripheral lipid metabolism support the possibility of using high-fat diets to improve CsA-mediated CNS disorders. We have previously reported that the solvent had no effect on lipid metabolism in the brain, whereas CsA produced a lowering of unesterified cholesterol and phospholipid. This latter response contrasts with the brain cholesterol overloading and lipid release occurring in hypercholesterolemic and epileptic models, and might explain why there was no CsA-induced alteration in apoE and apoJ gene expression (17). These unchanged levels in apoE and apoJ mRNA species initially led us to suppose that CsA-induced neurological effects, compared with those described in other encephalopathies such as Alzheimer's disease and epilepsy, are not related to alterations in brain apolipoprotein expression. We thus hypothesized, first, that the low concentration of unesterified cholesterol and phospholipids in the brain could be involved in some of the memory impairment, depressive symptoms, or manic episodes described in CsA-treated patients (4,20,21,52,53). This is supported by the literature reporting correlations between increased risks for mental disorders and disturbances of cholesterol metabolism.

However, we are now reporting that with high-fat diets modifying the normal levels of apolipoprotein gene expression in untreated rats, CsA treatment led to modifications of the levels of apoE and apoJ brain mRNA, and the CsA-mediated decreases in brain phospholipids and unesterified cholesterol were nullified by the high-fat diets. In view of these results, it is possible to hypothesize that in the reported cases of psychiatric or neurological dysfunction seen with CsA treatment, either a reduction of brain lipids or an unbalanced expression

of apoE and apoJ, as seen in chronic epilepsy and in Alzheimer's disease, could be involved. Finally, it is important to focus on the differential effect of CsA on brain lipid concentrations and on cortical or hippocampal apolipoprotein expression under the two high-fat diets. On one hand, the TG-enriched diet did not suppress the CsA-mediated changes; rather it decreased the brain unesterified cholesterol and phospholipid contents but by itself produced an increase in these lipids that compensated for the drug effect. On the other hand, the PC-enriched diet suppressed CsA-mediated decreases in the two types of brain lipids but did not by itself change the levels of either the unesterified cholesterol or phospholipids.

In contrast with PC, dietary TG have not been used to improve neurological symptoms such as those observed in Alzheimer's disease, but rather to decrease the frequency of seizures in children suffering from refractory epilepsy (29,30); such high-fat diets act through the elevation of plasma ketones that produce beneficial effects on energy metabolism and neuronal excitability, and probably on detrimental glial activation in the brain (54). These findings are relevant, given that in our experimental high-fat diets, the level of carbohydrates was also decreased, as recommended in antiepileptic diets. Phospholipid diet supplements have been suggested to improve memory deficits and Alzheimer's dementia in humans as well as in animal models, and are believed to act by increasing phospholipid, and in particular PC, availability in the brain (24–27). In animals, however, memory improvement was reported with soy TG supplementation, and the increased brain phospholipid concentrations observed in our experiment in response to the TG-enriched diet might be related to these previous observations (28).

TG are much less abundant in the brain than are cholesterol and phospholipids, but their variation could be meaningful and was also evaluated. There was an increase in brain TG in response to the TG- or PC-enriched diets, whereas plasma TG remained stable, as already discussed. When the CsA treatment was applied to high-fat-fed animals, the brain TG content remained unaltered in the group fed the PC-enriched diet (for the low-fat diet group) and were decreased by the drug treatment in the TG-enriched diet-fed rats.

The effect of CsA on the lipid steady state in the brain appeared to be different in rats fed the low-fat, TG-enriched, or PC-enriched diet. It is possible to hypothesize that different pathological mechanisms involving various aspects of brain lipid metabolism might occur in different CsA-treated patients depending on their genetic or nutritional background. In patients having initially low lipid levels, it is possible that lipid enrichment of the diet might reverse neurological risk. PC-enrichment, already shown to be beneficial on CsA-induced hepatic alterations (47,48), appears superior since it blocks CsA-induced brain alterations rather than only compensating for these alterations, as did the TG-enriched diet. Alternatively, in patients already having a high level of brain apolipoprotein expression due to genetic or environmental causes, CsA treatment might produce modifications of apoE and apoJ expression, as also observed in treated rats fed high-fat diets. If prolonged, such a situation might increase encephalopathic risk. ApoE and

apoJ are supposed to be pro-amyloidogenic and anti-amyloidogenic, respectively (19,55). ApoE has a propensity to form fibrils, increasing the various forms of deposits described in brains of Alzheimer's patients. ApoJ is involved in the transport of the β-amyloid peptide responsible in part for the progression of Alzheimer's disease. It is believed that the balance between the two brain apolipoproteins is important in avoiding Alzheimer's disease and epilepsy (19,55). Feeding a diet highly enriched in lecithin might nevertheless produce a long-term unfavorable balance of apolipoproteins in the hippocampus. Amyloidogenic accumulation might occur in this structure known to be involved in some seizure initiation and memory, and high levels of cyclophillin might be expressed, with massive overexpression following seizures. In contrast, in the cortex, PC seemed to improve the ratio in favor of a better elimination of the amyloid component and to lessen the trend toward deposition of apoE. It is important to point out that a previous study showed better improvement of memory in a mouse model when using a 2% phospholipid-enrichment compared with an 8% enrichment (56). This suggests that a lower content of PC in the diet should be tolerated better than a 20% PC diet, and might restore a normal ratio between apoE and apoJ in the hippocampus.

In conclusion, dietary management might help to reduce some long-term side effects of CsA. An enrichment of the diet with soybean lipids might benefit several aspects of the neurological side effects of the drug. Both soybean TG and PC prevent CsA-induced decreases in unesterified cholesterol and phospholipid content of the brain. All these effects should be clarified in further studies to improve our ability to mediate pharmacological immunosuppression without risk to the CNS. However, testing a lower PC content in the diet would probably be better. This study provides a broad perspective on the use of nutritional lipids to alleviate the consequences of brain injury induced by a toxic substance and demonstrates that this approach could potentially prevent adverse side effects.

Restoration of Depressed Prostanoid-Induced Ileal Contraction in Spontaneously Hypertensive Rats by Dietary Fish Oil

Glen S. Patten*, Michael J. Adams, Julie A. Dallimore, Paul F. Rogers, David L. Topping, and Mahinda Y. Abeywardena

CSIRO Health Sciences & Nutrition, Adelaide, South Australia 5000, Australia

ABSTRACT: We have reported that dietary fish oil (FO) rich in n-3 PUFA modulates gut contractility. It was further demonstrated that the gut of spontaneously hypertensive rats (SHR) has a depressed contractility response to prostaglandins (PG) compared with normotensive Wistar-Kyoto (WKY) rats. We investigated whether feeding diets supplemented with n-3 PUFA increased gut contractility and restored the depressed prostanoid response in SHR gut. Thirteen-week-old SHR were fed diets containing fat at 5 g/100 g as coconut oil (CO), lard, canola oil containing 10% (w/w) n-3 FA as α-linolenic acid (18:3n-3), or FO (as HiDHA®, 22:6n-3) for 12 wk. A control WKY group was fed 5 g/100 g CO in the diet. As confirmed, the SHR CO group had a significantly lower gut response to PGE_2 and $PGF_{2\alpha}$ compared with the WKY CO group. Feeding FO increased the maximal contraction response to acetylcholine in the ileum compared with all diets and in the colon compared with lard, and restored the depressed response to PGE_2 and $PGF_{2\alpha}$ in the ileum but not the colon of SHR. FO feeding also led to a significant increase in gut total phospholipid n-3 PUFA as DHA (22:6n-3) with lower n-6 PUFA as arachidonic acid (20:4n-6). Canola feeding led to a small increase in ileal EPA (20:5n-3) and DHA and in colonic DHA without affecting contractility. However, there was no change in ileal membrane muscarinic binding properties due to FO feeding. This report confirms that dietary FO increases muscarinic- and eicosanoid receptor-induced contractility in ileum and that the depressed prostanoid response in SHR ileum, but not colon, is restored by tissue incorporation of DHA as the active nutrient.

Paper no. L9578 in *Lipids 40,* 69–79 (January 2005).

Increasing evidence is emerging from animal experiments and human epidemiological and clinical studies that dietary n-3 long-chain (LC) PUFA from marine sources are beneficial for bowel function, aid gut repair (1–3), and ameliorate inflammatory conditions, but this is yet to be translated into clinical practice (4). Results from our previous animal studies showed that dietary fish oil (FO) supplementation led to modified contractility properties of isolated gut tissue (5,6). For the guinea pig, a diet containing 3% tuna FO, and high in

DHA (22:6n-3), led to a lower voltage threshold to initiate contraction and a lower sensitivity to the isoprostane 8-*iso*-prostaglandin (PG) E_2 in the ileum with increased n-3 PUFA content in the tissue total phospholipid fraction (5). In a subsequent study, Sprague-Dawley rats were fed 10% FO rich in EPA (20:5n-3) (EPA/DHA, 17:11) (6). In this strain of rat, dietary FO supplementation led to an increased maximal contraction in the ileum, elicited by muscarinic and eicosanoid agonists, that was not observed for the colon. However, both ileum and colon had similar increases in tissue n-3 PUFA EPA, docosapentaenoic acid (DPA, 22:5n-3), and DHA (6). This tissue-specific difference was explained by possible differences of n-3 PUFA modulation of receptor subtype populations that have been described for many systems (7,8) or the different functionality of the small intestine compared with large bowel (9).

Our most recent study demonstrated that there were no marked effects of a large range of dietary saturated fat (SF) on rat ileal contractility, unlike that demonstrated for n-3 PUFA (6). However, there was a trend for depressed PGE_2 and $PGF_{2\alpha}$ contractility responses in the ileum and colon of spontaneously hypertensive rats (SHR) that was not evident for isoprostane, muscarinic, or angiotensin receptor systems (10). This trend of depressed prostanoid activity became significant when the groups fed the three levels of dietary fat were combined (10). The aims of the present study were to confirm a depressed prostanoid response in SHR gut compared with Wistar-Kyoto (WKY) rats and, if confirmation was made, to determine whether feeding FO containing high DHA or canola oil rich in n-3 PUFA as α-linolenic acid (ALA) increased the muscarinic receptor-induced response and restored the depressed prostanoid response in gut from SHR. We also investigated the effects of two autocoid peptides, angiotensin II and bradykinin, which have potent activity in smooth muscle cells and which are involved in pathophysiological conditions such as inflammation and hypertension (11,12).

MATERIALS AND METHODS

Animals and diets. Male SHR and WKY rats were purchased from Animal Resource Centre (Canning Vale, Western Australia, Australia) at 12 wk of age and housed in the small animal colony of CSIRO Health Sciences and Nutrition (HSN). The rats were fed standard commercial laboratory rat chow

containing approximately 5% fat (Glen Forrest Stockfeeders, Glen Forrest, Western Australia, Australia) and water *ad libitum* for 1 wk to acclimatize. They were subjected to a 12-h light/dark cycle at 23°C. The rats were housed and the experiment conducted with the approval of the CSIRO HSN animal ethics committee.

At 13 wk of age, the rats were separated into one dietary group of 12 WKY rats and four groups of 16 SHR, housed 3–5 per cage and fed synthetic diets *ad libitum* for 12 wk. To avoid oxidation, diets were stored at −20°C and changed daily. The isoenergetic semipurified diets were based on the AIN-93M diet (13) and contained (g/kg): casein, 180; mineral mix, 35; vitamin mix, 10; α-cellulose, 50; cornstarch, 580.7; L-cysteine, 1.8; choline chloride, 2.5; and sucrose, 90. In addition, the control diet contained 5% (50 g/kg) coconut oil (CO) (Meadow Lea Coconut Oil; Goodman Fielder Pty. Ltd., North Ryde, Sydney, New South Wales, Australia) for a WKY group and SHR group or 5% fat as lard (SF) (Chapman's; George Weston Foods Ltd., Thebarton, South Australia, Australia), 5% canola oil (Can) (Meadow Lea GOLD'N Canola Oil; Goodman Fielder Pty. Ltd.), or 5% FO (HiDHA®; Clover Corporation Ltd., Altona North, Victoria, Australia) for the three other SHR groups. The FA compositions of the diets are shown in Table 1.

Diet FA content. The FA content of the 5% fat-supplemented diets had a wide range of SF levels, with the CO and lard (SF) diets containing 89.4 and 47% compared with the FO and Can diets, which contained 37.7 and 8%, respectively. CO diet SF are predominantly from 10:0 to 16:0, whereas the lard fat is 16:0 to 18:0. The Can diet contained predominantly the plant-derived monosaturated FA oleic acid (18:1n-9) at 62% and the shorter n-3 PUFA, ALA (18:3n-3) at 10.5%. This contrasts with the FO (HiDHA®) diet, which contains

the LC PUFA EPA and DHA at 6.5 and 22.5% of FA, respectively. The n-6/n-3 ratios of the CO, SF, Can, and FO diets were 16.7, 13.3, 1.9, and 0.2, respectively (Table 1).

Blood pressure (BP) measurements. The BP of a subset of WKY and SHR was measured every 4 wk using the tail cuff method (14) in a 29°C cabinet with restraining tubes (models 805 and 815; IITC Inc., Life Science Instruments, Woodland Hills, CA) using a model 229 blood pressure amplifier/pump and recorded using model 31 blood pressure software version 2.34 (IITC Inc.).

Tissue collection. At the completion of the 12-wk feeding experiment, the rats were fasted overnight, weighed, anesthetized with Nembutal (sodium pentobarbitone, 60 mg/kg intraperitoneal), and then killed by exsanguination. The small intestine and colon were removed and prepared for physiologic recordings as described (5,6,10). Tissue samples were snap-frozen in liquid nitrogen at −80°C for later tissue total phospholipid FA analysis.

Total phospholipid FA analysis of ileal and colonic tissue. Small frozen sections (150 mg) of ileum or colon were ground in a glass homogenizer, total lipids were extracted in methanol/chloroform/water (2:4:1) and separated by TLC, and the FA were methylated and analyzed by GLC as described previously (5,6).

Physiologic recording of ileal and colonic contractility. Sections of the ileum, proximal colon, or distal colon (0.03–0.04 m) were secured in an organ chamber with buffer conditions, organ chamber mechanics, and contraction properties determined as described (5,6,10). Ileal and colonic tissue were run in parallel. Results are given as volts per gram of (gut) tissue (V/g).

Electrically induced contraction of colon. The colon was induced to contract by electrical stimulation at 60 V for 5 ms at 0.02 Hz using a Grass S48 stimulator (Astro-Med Inc., West Norwich, RI) *via* 10-mm circular stainless steel electrodes placed above and below the tissue. Maximal colonic contractions were reached at approximately 20 min, after which time the stimulator was turned off.

Contraction of quiescent ileum and colon. The gastrointestinal agonists were added sequentially to the bath containing ileal or colonic tissue. Dose–response curves were generated by cumulative addition of agonists added as a small bolus to the incubating tissue. Each agent was washed out from the bath after maximal contraction had been achieved and the tissue stabilized at baseline for 15 min before the addition of the next agonist (5,6,10).

Preparation of gut membrane fraction. Frozen gut tissue was coarsely ground by pestle and mortar under liquid nitrogen and taken up into ice-cold isolating medium (1:10, wt/vol) containing (in mM) 250 sucrose, 50 Tris, 1 EDTA, 1 $MgCl_2$, pH 7.4. The tissue was homogenized in 10 mL of the above medium by UltraTurrax® (Janke&Kunkel GmbH, Staufen, Germany) at setting 4 for 3 bursts for 10 s (15). The brei was filtered through several layers of wide-weave cheesecloth and centrifuged at $6000 \times g$ for 15 min in a J2-21 centrifuge (Beckman Instruments Co., Palo Alto, CA) at 4°C.

TABLE 1

[a]Values are means of two samples performed in duplicate. Percentages were derived from the full FA set.
[b]Abbreviations: CO, coconut oil diet; SF, saturated fat (lard) diet; Can, canola oil diet; FO, fish oil diet; ND, not detected.

The supernatant was decanted and retained and the pellet resuspended in isolating medium and recentrifuged as before. The supernatants were combined and spun at $50,000 \times g$ for 30 min. The final pellet was resuspended in (mmol/L) 50 Tris, 1 EGTA, 10 MgCl$_2$, pH 7.4 assay buffer that contained protease inhibitors diluted into this buffer at 1:1000 (vol/vol). The stock protease inhibitor concentrations were (mg/mL, solvent): phenylmethylsulfonyl fluoride 17.4, DMSO; aprotinin 1, H$_2$O; iodoacetate 184, H$_2$O; and pepstatin A 1.37, DMSO (16). The final tissue concentration was approximately 5 mg/mL, and the stock solution was stored in aliquots at −80°C for muscarinic binding assays.

Muscarinic receptor binding assay. Receptor radio-ligand binding activity was determined in the gut membrane fraction $(6,000–50,000 \times g)$ with the nonselective tritiated muscarinic antagonist, quinuclidinyl benzylate ([^{3}H]QNB) (16). For saturation binding assays, membranes (approximately 100 µg protein/tube) were incubated with shaking in assay buffer with increasing concentrations of [^{3}H]QNB (specific activity 1.6 TBq/mmol; NEN, Sydney Australia) (0.05–2 nmol/L) at 30°C for 1 h. Preliminary experiments performed in triplicate (not shown) established that [^{3}H]QNB binding to the gut membrane preparation was linear between 20 and 200 µg protein and that at 100 µg protein per assay, maximal binding occurred by 40 min. The reaction was stopped *via* rapid filtration through Whatman GF/C glass fiber filters. After washing with 3×4 mL ice-cold assay buffer, filters were placed into vials and counted in 3 mL water-soluble scintillation cocktail (Aquasol-2; NEN Research Products) at about 50% efficiency. Nonspecific binding was measured in the presence of 10^{-6} mol/L atropine and did not exceed 15% of total binding.

Protein determination. Values for the gut membrane protein content were determined after solubilization in 0.1 M NaOH and 1% (wt/vol) SDS using BSA as standard (17).

Pharmacologic agents and suppliers. The pharmacological agents (concentration range in nmol/L used in organ bath or assay) and suppliers were as follows: acetylcholine (10–22,000), atropine sulfate (0.1–1,000), bradykinin (0.1–1,000), carbamylcholine chloride (carbachol) (10–22,000), and fine chemicals were from Sigma Chemical (Sydney, NSW, Australia); and PGF$_{2\alpha}$ (1–7,000), PGE$_2$ (1–7,000), and 8-*iso*-PGE$_2$ (10–7,000) were from Sapphire Bioscience (Crows Nest, NSW, Australia). For the ileum, the order of agonists was acetylcholine, angiotensin II, 8-*iso*-PGE$_2$, PGF$_{2\alpha}$, and PGE$_2$. Because the colon does not tolerate multiple additions well, the order of agonists after electrical stimulation was as follows: proximal colon: acetylcholine, angiotensin II, 8-*iso*-PGE$_2$; distal colon: carbachol, PGF$_{2\alpha}$, and PGE$_2$.

Data analysis. Data are shown as means ± SEM. Statistical evaluation was performed by ANOVA, with a Bonferroni multiple comparison post-test performed when the *F*-test was significant at $P < 0.05$ or by Student's *t*-test. The EC$_{50}$ (nmol/L) and maximal contraction (V/g of tissue) values, and maximal binding (B_{max}) and 50% of maximal binding (K_d) were determined from concentration-dose curves and satura-

tion binding isotherms using graph fits in GraphPad Prism 4.0 (GraphPad Software, San Diego, CA) with $R^2 > 0.99$.

RESULTS

Animal weights. The initial (13 wk) and final (25 wk) weights (g) of the experimental animal groups as mean ± SEM (*n*) were as follows: WKY CO, 276 ± 6, 414 ± 8 (12); SHR CO, 290 ± 5, 427 ± 8 (16); SHR SF, 294 ± 4, 419 ± 4 (16); SHR Can, 307 ± 5, 417 ± 4 (16); and SHR FO, 308 ± 4, 428 ± 6 (16). There was no significant difference between weights for WKY or SHR CO groups or between final or Δ (final minus initial) weights between SHR dietary groups.

Blood pressure. The initial (13 wk) and final (25 wk) systolic BP measurements (mm Hg) as mean ± SEM for $n = 6$–8 rats were as follows: WKY CO, 147 ± 3, 146 ± 5; SHR CO, 175 ± 4, 184 ± 4; SHR SF, 180 ±5, 187 ± 4; SHR Can, 174 ± 5, 195 ± 3; and SHR FO, 168 ± 5, 191 ± 4. The initial ($P < 0.05$) and final BP ($P < 0.001$) of the WKY group was significantly different from all SHR groups. There was no significant difference in BP between SHR dietary groups.

FA content of total phospholipids of ileum and colon. There were no major differences in the FA composition of ileum or colon in WKY and SHR groups fed CO diets with n-6/n-3 ratios of ileum 11.5 and 11.4 and colon 11.5 and 10.6, respectively. The shorter-chain saturated fats in the CO diet (10:0–14:0) were not incorporated into ileal or colonic tissue. The FA profiles of ileal and colonic tissue in the SHR fed CO or SF were similar. The major differences observed for the Can diet from the two saturated fat diets (CO and SF) were an increase in the n-3 content as DHA ($P < 0.05$), with a modest drop in the n-6/n-3 ratio in ileum to 7.9 and colon to 8.2. However, the FO diet dramatically increased the DHA content in both tissue types ($P < 0.001$) with resultant n-6/n-3 ratios of 2.3 and 1.7 ($P < 0.001$) at the expense of arachidonic acid (20:4n-6) and the total n-6 content ($P < 0.01$). With the FO diet (high in DHA), there was no detectable tissue phospholipid ALA or EPA (Tables 2, 3).

Electrically induced contraction of colon. There was no difference in electrically induced maximal contraction (V/g tissue) between WKY and SHR CO groups for the proximal or distal colon. For the SHR groups across the diets, there was an increase in the maximal contraction of the proximal colon in the FO group compared with the SF group ($P < 0.01$) that was not evident for the distal colon (Table 4).

Gastrointestinal agonist-induced contraction of ileum and colon from WKY and SHR fed the CO diet. The comparison of dose–response curves of WKY and SHR fed CO diets for agonist-induced contraction by PGF$_{2\alpha}$ and PGE$_2$ for ileum and colon is shown in Figure 1 with the calculated EC$_{50}$ (nmol/L) and maximal contraction (V/g tissue) values for all agonists shown in Table 5 for ileum and Table 6 for colon. For ileum, PGF$_{2\alpha}$ (Fig. 1A) produced a lower maximal contraction ($P < 0.003$) for SHR compared with WKY, and for PGE$_2$ (Fig. 1C) there was a lower maximal contraction ($P < 0.01$) and

TABLE 4
Effect of Electrically Driven Contraction on Colon from WKY and SHR Fed 5% Fat-Supplemented Diets for 12 wk[a]

| Tissue/Diet | WKY | SHR | | | |
	CO	CO	SF	Can	FO
			V/g		
Proximal colon	2.2 ± 0.2	2.3 ± 0.2	1.7 ± 0.2[a]	2.1 ± 0.2	2.9 ± 0.3[b]
Distal colon	2.1 ± 0.2	2.1 ± 0.2	2.1 ± 0.2	1.7 ± 0.2	2.1 ± 0.2

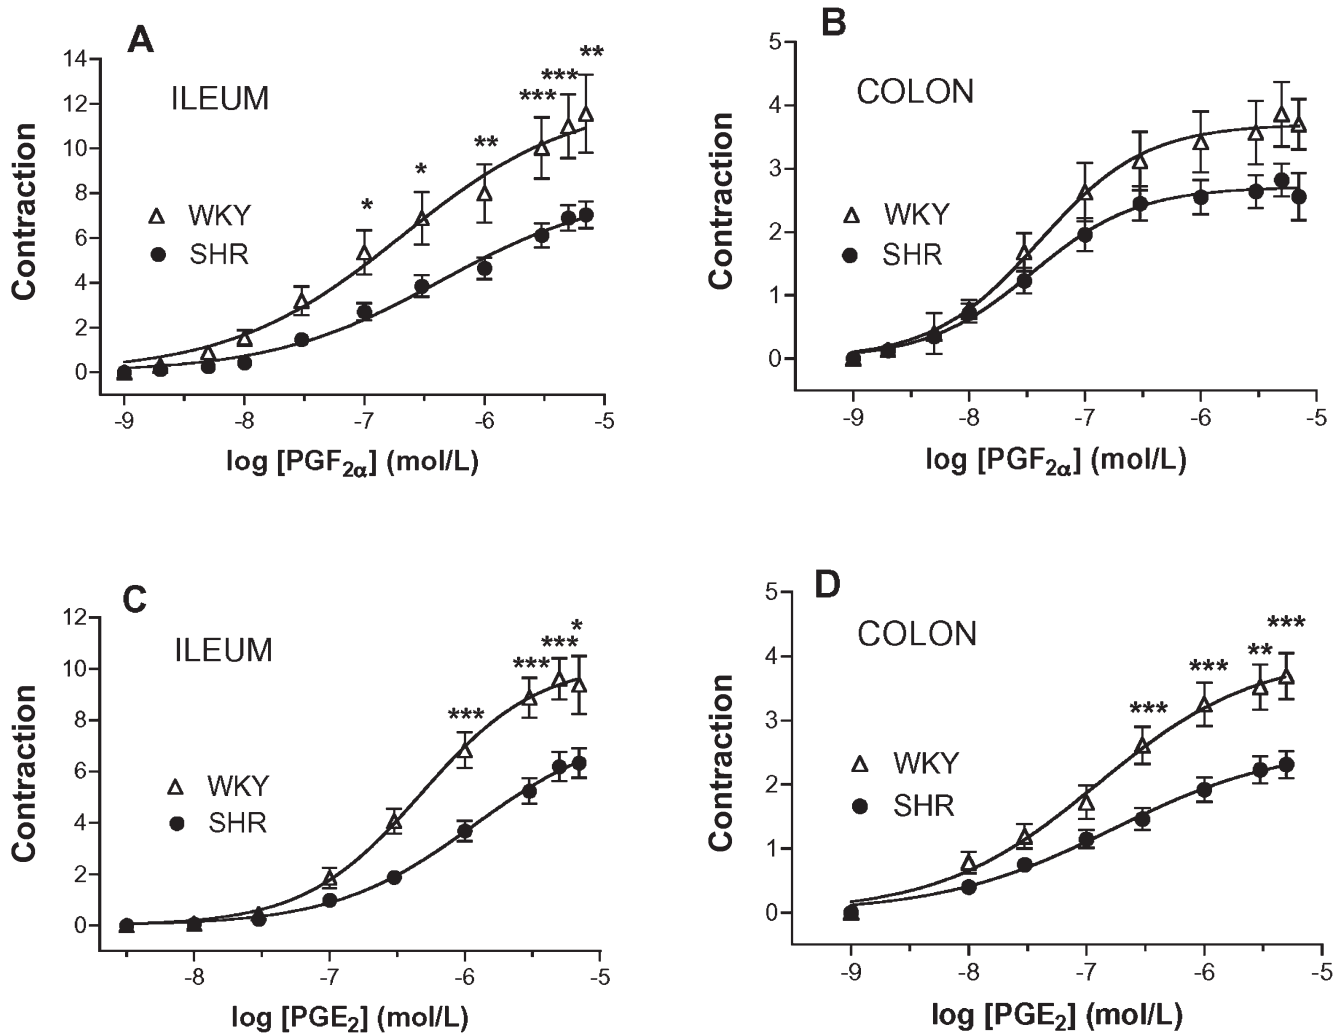
[a]Values are mean ± SEM for *n* = 12 for WKY and *n* = 16 for SHR. Means for an SHR tissue in a row with superscripts without a common letter differ; *P* < 0.01. For abbreviations see Tables 1 and 2.


FIG. 1. Effects of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) on the contraction of ileum (A) and colon (B) and PGE_2 on contraction of ileum (C) and colon (D) from Wistar Kyoto rats (WKY) ($\triangle$) and spontaneously hypertensive rats (SHR) ($\bullet$) fed a 5 g/100 g coconut oil (CO)-supplemented diet. The results are plotted as means ± SEM generated from pooled data for contractions from $n = 12$ WKY and $n = 16$ SHR individual pieces of ileum determined as voltage per gram of tissue (V/g). Significant differences for individual concentrations determined by Student's t-test with significance indicated as follows: $*P < 0.05$, $**P < 0.01$, $***P < 0.001$. The calculated EC_{50} (nmol/L) and maximal contraction (V/g tissue) values for $PGF_{2\alpha}$ and PGE_2 are shown in Table 5 for ileum and Table 6 for colon.

lower sensitivity ($P < 0.002$) for SHR compared with WKY. For the colon, the agonists $PGF_{2\alpha}$ (Fig. 1B) and PGE_2 (Fig. 1D) produced a lower maximal contraction of SHR compared with WKY ($P < 0.02$ and $P < 0.05$, respectively).

Gastrointestinal agonist-induced contraction of ileum and colon from SHR fed the CO, SF, Can, and FO diets. Comparison of the effects of experimental diets on SHR ileal and colonic tissue agonist-induced contraction is shown in Figures 2 and 3. The EC_{50} (nmol/L) and maximal contraction (V/g) values for ileal and colonic tissue are given in Tables 5 and 6, respectively. For ileum, acetylcholine (Fig. 2A), $PGF_{2\alpha}$ (Fig. 2E), and PGE_2 (Fig. 2F) produced higher maximal contraction in the FO group than in the other three dietary groups ($P < 0.01$). The FO group also had higher maximal contraction responses to angiotensin II compared with the SF group

($P < 0.05$) (Fig. 2B) and a higher maximal contraction response to bradykinin compared with the Can group ($P < 0.05$) (Fig. 2C) in ileum. Although there was a trend for increased contraction for 8-*iso*-PGE_2 by FO compared with the other dietary groups, it did not reach significance. For colon, in response to acetylcholine the FO group had higher maximal contraction compared with the SF group ($P < 0.001$) (Fig. 3A) and a higher sensitivity compared with the Can group ($P < 0.01$). The FO group also had a higher maximal contraction response to 8-*iso*-PGE_2 compared with SF ($P < 0.05$) (Fig. 3C) and Can ($P < 0.05$) groups and a higher sensitivity in response to carbachol compared with the SF group ($P < 0.05$) (Fig. 3D). There were no significant differences across the dietary groups for colon in response to angiotensin II, $PGF_{2\alpha}$, or PGE_2.

TABLE 5

EC$_{50}$ (nmol/L) and Maximal Contraction (V/g) Values Derived from Concentration–Response Curves for Agonists Applied to Ileum from WKY and SHR Fed 5 g/100 g Fat-Supplemented Diets for 12 wk[a]

[a]Values are mean ± SEM for $n = 16$ for acetylcholine, 8-*iso*-PGE$_2$, carbachol, PGF$_{2\alpha}$, and PGE$_2$, and $n = 8$ for angiotensin II. Means for a SHR tissue in a row with superscripts without a common letter differ; $P < 0.05$. Carbachol, carbamylcholine chloride; for other abbreviations see Tables 1, 2, and 5.

Muscarinic binding in ileal membrane preparations. The K_d (nmol/L) calculated for individual saturation binding isotherms for SF was $0.21 ± 0.01$ and for FO was $0.20 ± 0.003$ with maximal binding (B_{max}) (fmol/mg membrane protein) for SF of $540 ± 42$ and for FO of $457 ± 24$, which were not significantly different (Fig. 4). By comparison, the maximal contraction (V/g) for ileal tissue from the same SHR subset fed SF in response to acetylcholine was $6.4 ± 1.8$ compared with FO of $14.3 ± 2.1$ ($n = 5$) ($P < 0.02$) [see Fig. 2A and Table 5 for comparison of calculated EC$_{50}$ and maximal contraction (V/g) values compared across diets].

DISCUSSION

We have previously shown that dietary FO rich in EPA and DHA can increase the muscarinic- and eicosanoid-induced ileal responses in the normotensive Sprague-Dawley rat (6). This study investigated whether the recently observed depres-

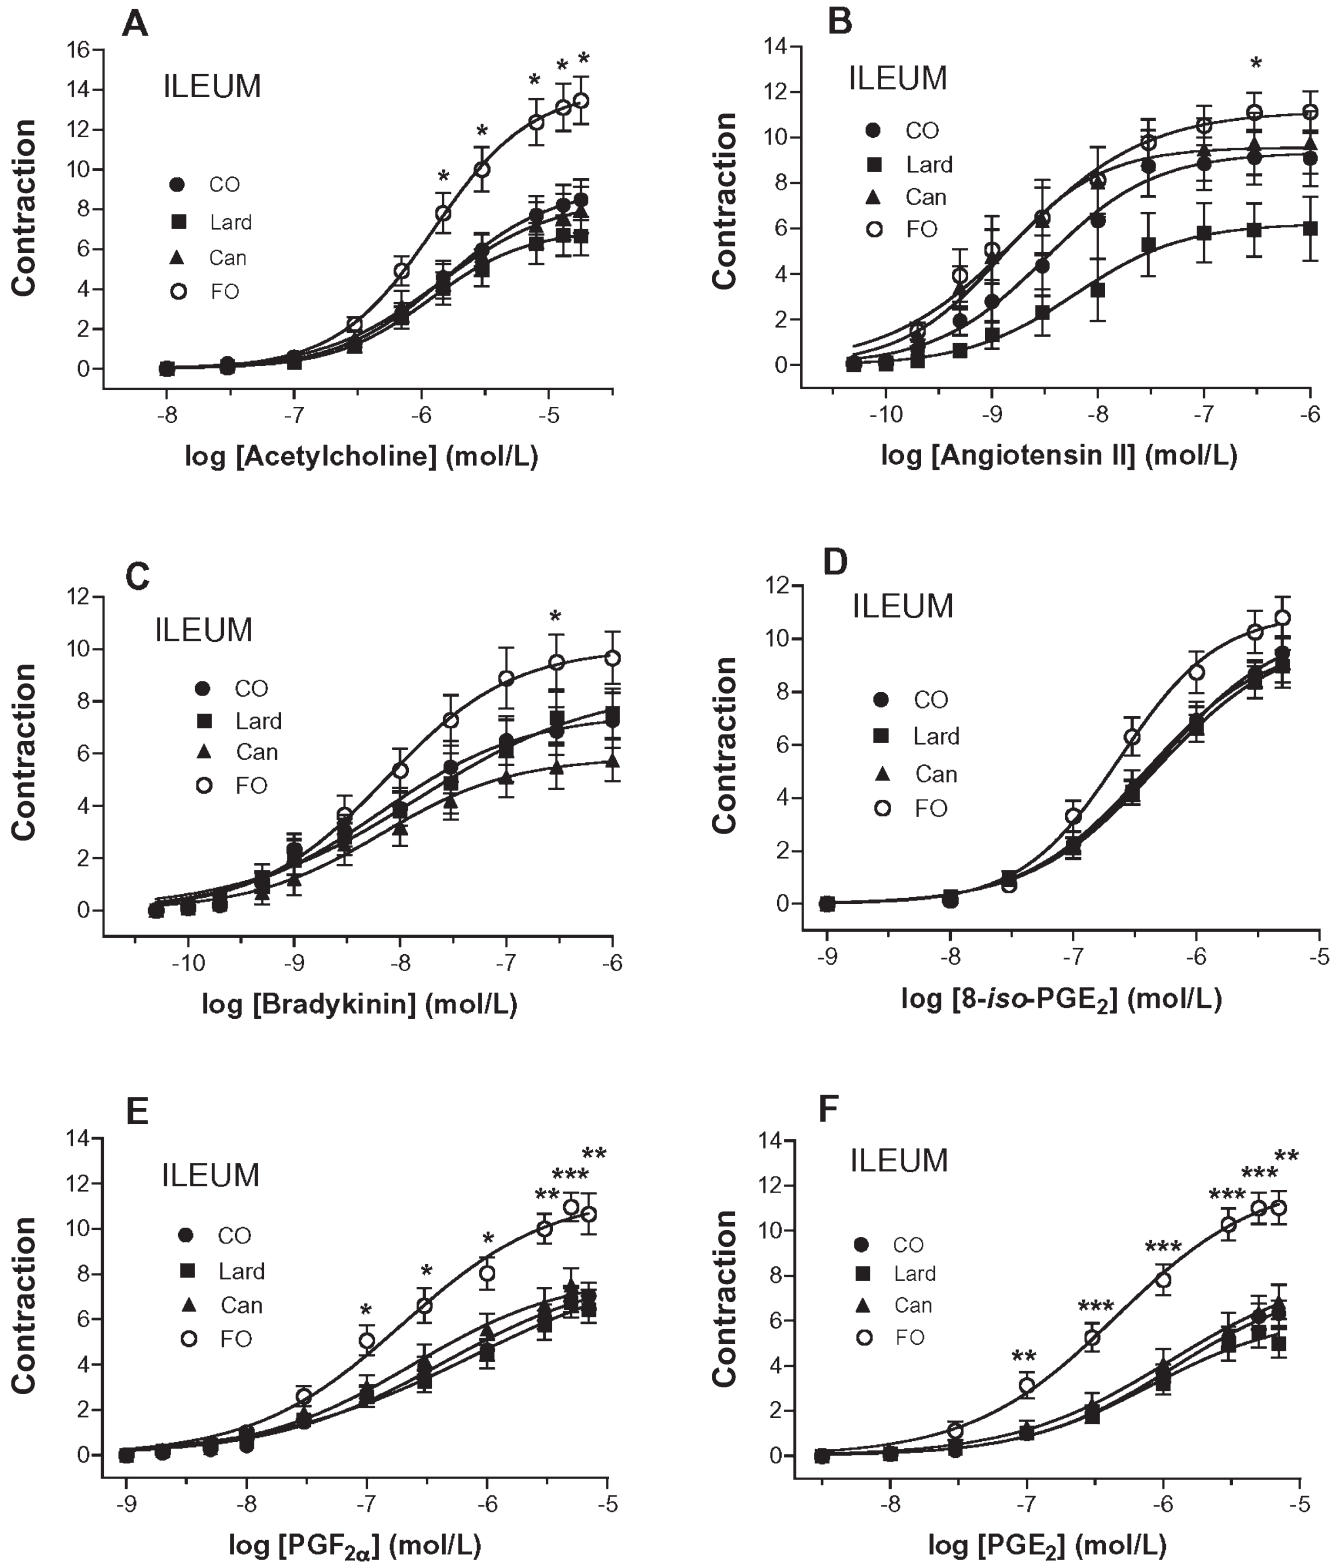
sion in prostanoid-induced contraction in gut tissue of SHR (10) could be restored by n-3 PUFA from plant or fish sources. To test this, we fed 13-wk-old SHR diets supplemented with 5% as canola oil rich in ALA (18:3n-3) or as a fish oil fraction high in DHA (22:6n-3) with SF and CO as controls. In this study, there were no significant lowering effects on BP by n-3 PUFA feeding. Using animal models, a blood pressure lowering has previously been noted using both EPA and DHA mixtures, DHA alone, and Can (18–20). In those studies and other reports, the n-3 PUFA was delivered at the development stage of hypertension (3–7 wk) compared with 13 wk, the established stage of hypertension in this study (21). Dietary supplementation with LC n-3 PUFA diets delivered at 3 mon or later also have been found to lower SHR blood pressure when fed for a long term of 12–18 mon (22). In this study, the modulation of gut smooth muscle contractility by n-3 PUFA is discussed in relation to hypertension and other potentially related pathological conditions.


FIG. 2. Effects of acetylcholine (A), angiotensin II (B), bradykinin (C), 8-*iso*-PGE$_2$ (D), PGF$_{2\alpha}$ (E), and PGE$_2$ (F) on the contraction of ileum from SHR fed diets supplemented with 5 g/100 g coconut oil (CO) (●), lard (■), canola oil (Can) (▲), or fish oil (FO) (○). The results are plotted as means ± SEM generated from pooled data for contractions from *n* = 16 individual pieces of ileum determined as voltage per gram of tissue (V/g). Significant differences for individual concentrations determined by ANOVA with the Bonferroni post test indicated as follows: *$P < 0.05$, **$P < 0.01$, ***$P < 0.001$. Table 5 shows comparisons of the calculated EC$_{50}$ and maximal contraction (V/g) values for ileum for all agonists. For other abbreviations see Figure 1.
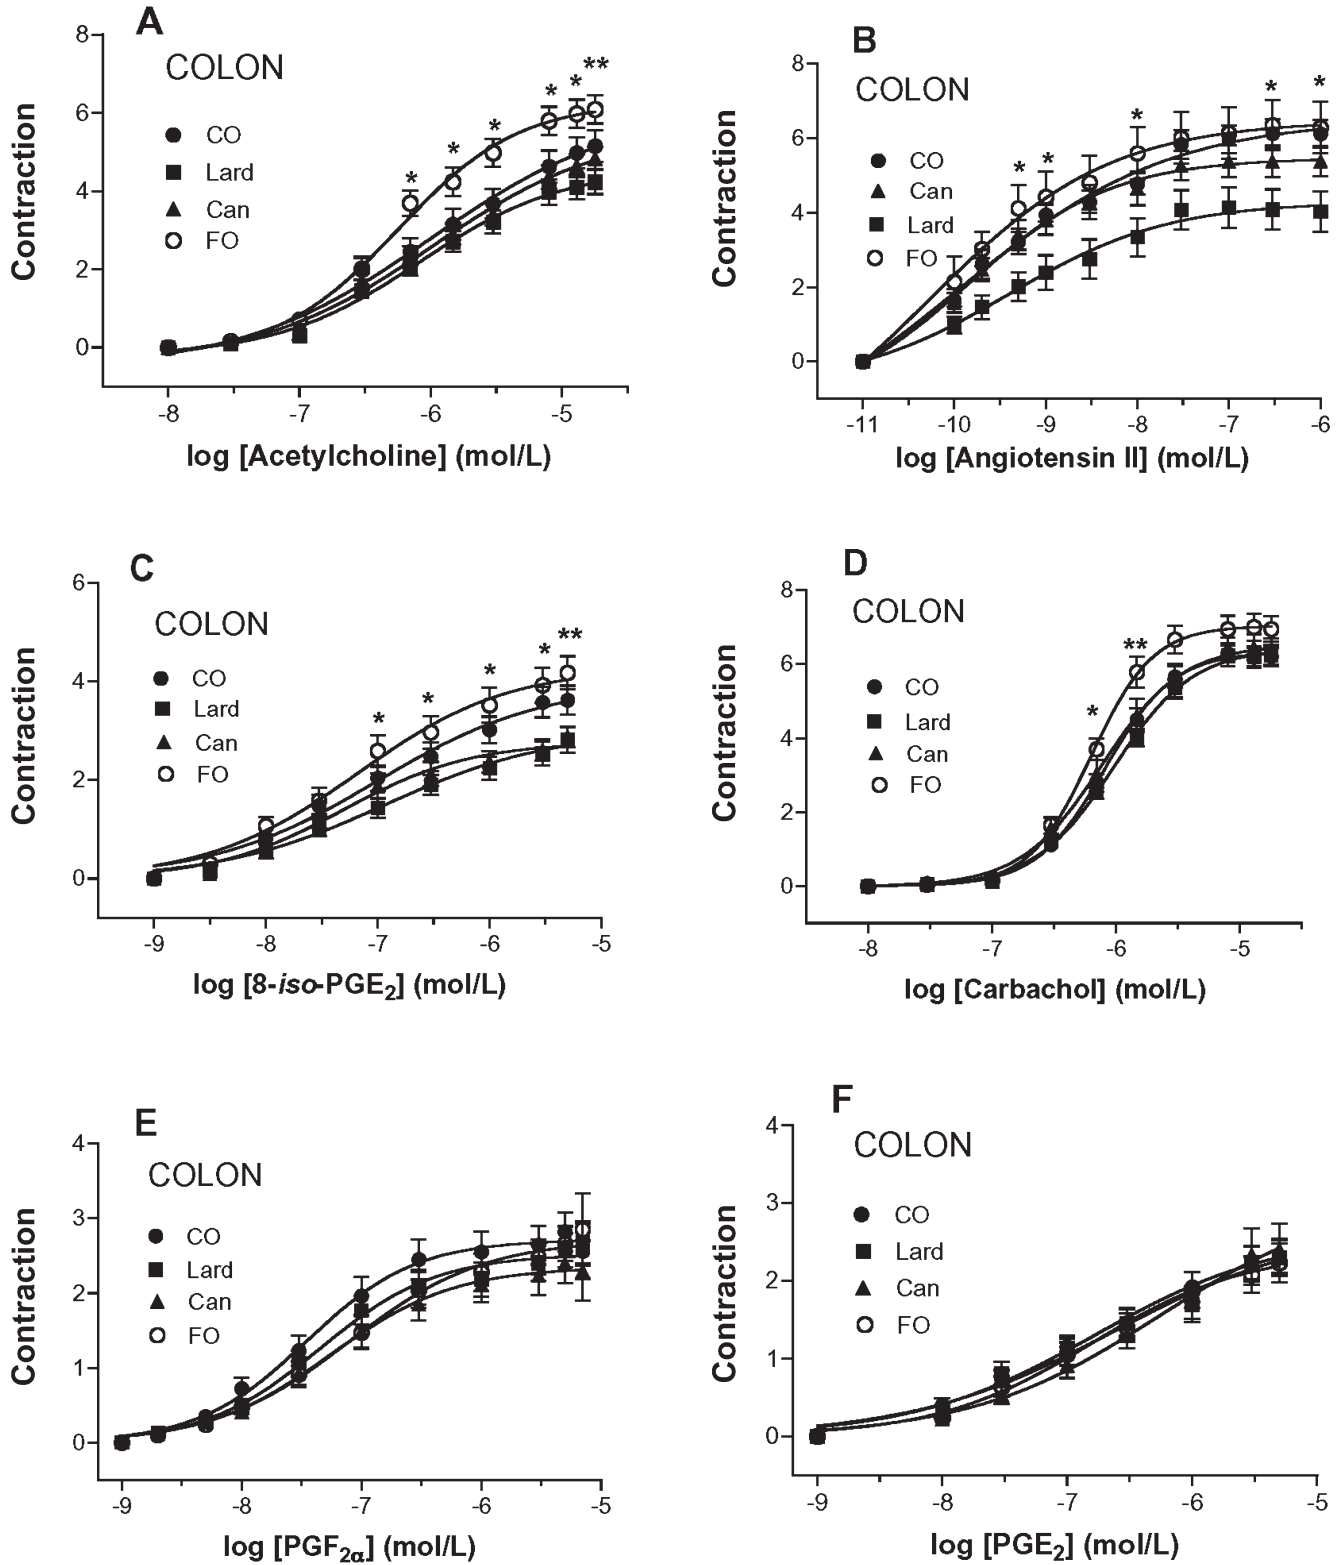

FIG. 3. Effects of acetylcholine (A), angiotensin II (B), 8-*iso*-PGE$_2$ (C) on proximal colon, and carbachol (D), PGF$_{2\alpha}$ (E), and PGE$_2$ (F) on distal colon contraction from SHR fed diets supplemented with 5 g/100 g coconut oil (CO) (●), lard (■), canola oil (Can) (▲), or fish oil (FO) (○). The results are plotted as means ± SEM generated from pooled data for contractions from n =16 SHR individual pieces of colon determined as voltage per gram of tissue (V/g). Significant differences for individual concentrations determined by Student's *t*-test with significance indicated as follows: *$P < 0.05$, **$P < 0.01$. Table 6 shows comparisons of the calculated EC$_{50}$ (nmol/L) and maximal contraction (V/g tissue) values for colon for all agonists.
FIG. 4. Saturation binding isotherms for the tritiated muscarinic antagonist quinuclidynyl benzylate ([^{3}H]QNB) from the pooled data from ileal tissues from $n = 5$ SHR fed diets supplemented with 5 g/100 g fat as lard (SF) (■) or fish oil (FO) (○). Results are plotted at each concentration as mean ± SEM. Figure 2A shows acetylcholine dose curves for ileum from groups fed diets supplemented with 5 g/100 kg fat as coconut oil, lard, canola oil, or fish oil, and Table 5 shows comparisons of calculated EC_{50} and maximal contraction (V/g) values for ileum for acetylcholine and other agonists. There were no significant differences for K_d (concentration at half-maximal binding) or B_{max} (maximal binding) values for SHR ileum across SF or FO dietary groups. For other abbreviations see Figure 1.

First, it was established that SHR fed a diet of SF as CO exhibited a significantly depressed PGE_2 and $PGF_{2\alpha}$ response in ileum and colon compared with the WKY control group. This depressed response was not observed for muscarinic, isoprostane, or autocoid peptide agonists angiotensin II or bradykinin. We report here that the FO diet, with high DHA as the most likely active nutrient, restored the depressed prostanoid effect in ileal but not colonic tissue. This effect was not observed for the Can-supplemented diet rich in ALA that produced only a marginal increase in EPA and DHA in ileum and only DHA in colon. It is to be determined whether FO feeding alters the PG receptor properties of ileal and colonic tissue in a manner that may explain the differences in tissue reactivity. Functionally, the large intestine is primarily for drying and storage of digestive waste material, whereas the contractile properties influenced by n-3 PUFA in the ileum may not be translated to the distal bowel (6).

Using SHR, we have also confirmed that FO feeding resulted in higher maximal contraction responses to muscarinic and prostanoid agonists in the ileum that we previously demonstrated in normotensive Sprague-Dawley rats (6). We also investigated the effects of potent gastrointestinal peptide agonists. The first, angiotensin II, plays a key role in the renin–angiotensin system (23), especially as it relates to hypertension and the development of disease (24,25). The second, bradykinin, is a potent autocoid that can act on endogenous smooth muscle cells (11,12) and is also involved with gut pathophysiological conditions (18,24) and co-involved with the renin–angiotensin system (23). Both peptides lead to increased maximal contraction of ileum after FO dietary supplementation compared with SF or Can.

Electrically driven contraction of colon is predominantly induced by acetylcholine release (25), and we found a significant increase in maximal contraction in the proximal colon by FO feeding compared with the SF diet. This observation was supported by a significantly higher acetylcholine-induced contraction of proximal colon by the FO diet compared with the SF diet, but not by the muscarinic mimetic, carbachol, in the distal colon, although there was an increase in sensitivity. This observation was not seen for normotensive Sprague-Dawley rats in our previous study (6). However, we note that FO supplementation did not increase contractility due to angiotensin II or again to prostanoids in colon.

Dietary FO can affect membrane receptor properties of various systems in different tissues, such as the α- and β-adrenergic (7,26), angiotensin II (27), various eicosanoids (thromboxane A_2/PGH_2) (28), as well as insulin (29) and other G-protein-coupled systems (8). In an attempt to determine the mechanism of n-3 PUFA effects on gut contractility, we measured muscarinic binding properties of ileal membrane preparations to determine whether FO supplementation modified ileal receptor characteristics. Although FO feeding markedly increased ileal maximal contraction compared with an SF diet in response to acetylcholine, there was no change in the muscarinic receptor population. There may have been a change in muscarinic subtype (30), which we are now investigating. However, it may be that the n-3 PUFA modification is post receptor and the involvement of calcium handling is to be determined (21,31).

In previous FO feeding studies, guinea pigs received diets with 4.2% ALA, 1.5% EPA, and 5% DHA as fat that resulted in 2.1% ALA, 0.8% EPA, and 3.6% DHA as FA in the ileal phospholipid fraction from very low levels. This led to alterations in voltage- and isoprostane-induced sensitivity changes in ileal contractility measurements (5). The recent rat study involved feeding FO containing 1% ALA, 11% EPA, and 7% DHA as fat that resulted in 0% ALA, 9% EPA, and 7% DHA as rat ileal membrane FA (6). That n-3 PUFA ratio correlated with increased ileal muscarinic- and eicosanoid-induced contractility properties. The study described herein used a high-DHA FO source in the diet containing 1% ALA, 6.5% EPA, and 22% DHA as fat that resulted in 0% ALA, 0% EPA, and 10% DHA in ileal membrane FA. It is therefore postulated that DHA is the active nutrient involved in the physiological alterations to agonist-induced gut contractility. Can rich in ALA resulted in only a modest increase in tissue DHA levels with no effect on contractility. Incorporation of Can is animal- and tissue-type dependent and relies on the ability of the tissue to elongate and desaturate ALA to longer n-3 PUFA. However, it is also to be determined whether diets with very high ALA levels or diets rich in only EPA that markedly increased tissue n-3 PUFA levels manifest increased gut contractility.

There are advantages and disadvantages of various experimental models of bowel disease (32). Although patients with inflammatory bowel disease (IBD) rarely have hypertension (33), and Crohn's disease may be negatively correlated with BP (34), it may be suggested that the SHR model with depressed

prostanoid-induced contractility responses may mimic a moderate case of IBD. Models of chemically induced ileitis have revealed a hyporesponsiveness in receptor-mediated strength of contraction of circular muscle due to carbachol and histamine (35) and modulation of purinergic nerve activity (36). Additionally, intestinal inflammation induced by *Trichinella spiralis* infection led to functional and structural changes, characterized by a decreased response to electrical field stimulation (37). Finally, and in relation to this study, tissue concentration of prostanoids was markedly elevated and their receptor population altered in the tissue of animals and humans with intestinal inflammation (38).

Models of IBD including ileitis and ulcerative colitis (UC) have both tissue damage and altered contractility properties. Administration of human recombinant interleukin-11 in a trinitrobenzenesulfonic acid colitis rabbit model partially normalized changes in contractile properties toward receptor-specific (motilin, acetylcholine, substance P) and receptor-independent (KCl) stimuli (39) and also suppressed intestinal inflammation and reversed intestinal smooth muscle dysfunction (carbachol, KCl) in HLA-B27 transgenic rats (40). Chemical-induced colitis in rats (dextran sulfate sodium) and mice (dinitrobenzene sulfonic acid) has been improved by butyrate enema and dietary curcumin (component of the spice turmeric) proposed to be in part *via* the transcription factor, nuclear factor kappa B that is involved in the production of inflammatory chemokines (41).

Recent studies report that dietary FO results in suppressed production of proinflammatory cytokines (42). Trinitrobenzenesulfonic acid-treated rats with UC fed FO for 1 wk showed significantly less macroscopic and microscopic damage and lower biochemical and histochemical markers of tissue damage (alkaline phosphatase, myeloperoxidase, and PGE_2) (43). Results of human trials suggest that dietary FO supplementation may improve Crohn's disease (4). It is now reasonable to assume that n-3 PUFA may have a major role to play in IBD not only by reducing symptoms of tissue pathology but also by improving contractility and functionality. Small-animal IBD models may soon demonstrate this important duality of n-3 PUFA function. Transgenic technology has recently produced a mouse that can convert n-6 to n-3 FA and that has the potential to be genetically backcrossed with mouse disease models such as IBD to test the effects of n-3 PUFA on the pathogenesis and treatment of disease (44) and complement dietary studies without the use of pharmaceuticals (45).

ABSTRACT: Dietary flaxseed oil, which is enriched in α-linolenic acid, and fish oil, which is enriched in EPA and DHA, possess anti-inflammatory properties when compared with safflower oil, which is enriched in linoleic acid. The influence of flaxseed oil and fish oil feeding on lipid metabolism in T-lymphocytes is currently unknown. This study directly compared the effects of feeding safflower oil, flaxseed oil, and fish oil for 8 wk on splenic T-lymphocyte proliferation, phospholipid mass, and acyl-CoA binding protein expression in the rat. The data show that both flaxseed oil and fish oil increased acyl-CoA binding protein expression and phosphatidic acid mass in unstimulated T-lymphocytes when compared with safflower oil feeding. Fish oil feeding increased cardiolipin mass, whereas flaxseed oil had no effect. After stimulation, flaxseed oil and fish oil blunted T-lymphocyte interleukin-2 production and subsequent proliferation, which was associated with the lack of increased acyl-CoA binding protein expression. The results reported show evidence for a novel mechanism by which dietary flaxseed oil and fish oil suppress T-lymphocyte proliferation *via* changes in acyl-CoA binding protein expression and phospholipid mass.

Paper no. L9590 in *Lipids 40*, 81–87 (January 2005).

In general, the n-3 PUFA are considered to be anti-inflammatory, whereas the n-6 PUFA are considered to be pro-inflammatory (1,2). Some reports show that, within the n-3 series, dietary lipids such as fish oil, which is enriched in EPA and DHA, possess more potent anti-inflammatory properties than flaxseed oil, which is enriched in α-linolenic acid (α-LNA) (3,4). It is well known that one of the major targets of dietary n-3 PUFA is the T-lymphocyte, a cell that is important in determining the type and extent of an immune response (5). Several reports show that flaxseed oil (linseed oil) and fish oil may have a similar potency in inhibiting lymphocyte proliferation *ex vivo* (6,7). *In vivo*, feeding flaxseed oil can dramatically blunt the development of autoimmune disease in mice, a result that is similar to that seen in fish oil feeding (8).

Acyl-CoA binding protein (ACBP) is a 10 kDa intracellular protein that binds acyl-CoA with high affinity and is found in every tissue tested including the spleen (9,10). Several recent reports have shown that ACBP may be an important regulator of cell function. For example, depletion of ACBP in human cell lines inhibits proliferation (11) and blocks adipocyte differentiation (12). Furthermore, transformed colon cells have increased ACBP expression (13).In rat liver microsomes, one potential mechanism by which ACBP may regulate cell function is by increasing phosphatidic acid (PtdOH) biosynthesis (14). This is important because PtdOH is the precursor for all glycerophospholipids and TG. Recent evidence using liver mitochondria suggests that ACBP may be an important determinant in the positional distribution of FA within phospholipids (15). Although most studies indicate that ACBP may play a positive role in cell function, one report has shown that ACBP may be involved in increasing apoptosis (16).

To date, only one report has examined the impact of diet on ACBP expression; it was shown that a high-fat diet increased ACBP expression in the liver (17). The role of ACBP in T-lymphocyte function and the mechanism by which different dietary lipid types affect the expression of ACBP are currently unknown. Whereas the impact of dietary n-3 PUFA on T-lymphocyte FA composition is well known, the influence on phospholipid mass of flaxseed oil is relatively unexplored. Therefore, this study aimed to determine the impact of diets enriched in α-LNA (flaxseed) or EPA and DHA (fish oil) on ACBP protein expression and phospholipid mass in splenic T-lymphocytes.

MATERIALS AND METHODS

Animals. Male Sprague-Dawley rats (five per group) were randomly assigned to a safflower oil diet (Saff), flaxseed oil diet (Flax), or fish oil diet (Fish). Six-month-old rats, weighing roughly 500 g each, were housed two per cage in a 12-h light/12-h dark room and had free access to diets and water. Following 8 wks of feeding, rats were euthanized by CO_2 asphyxiation, and livers and spleens were aseptically harvested. All procedures were approved by the University of Texas Animal Use and Care Committee.

Diets. Diet ingredients were purchased from Dyets, Inc. (Bethelehem, PA), prepared fresh each week, and maintained at 4°C. Isocaloric diets were designed to meet the nutritional

Abbreviations: ACBP, acyl CoA binding protein AP-1, activating protein-1; LA, linoleic acid; α-LNA, α-linolenic acid; IL-2, interleukin-2; mtGPAT, mitochondrial glycerol-3-phosphate acyltransferase; MTT, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide; PL, phospholipids; PPARγ, peroxisomal proliferator-activated receptor γ; PtdOH, phosphatidic acid.

requirements of rats as determined by the American Institute of Nutrition (18). Diets contained (g/kg) 200 soy protein, 300 dextrose, 310 cornstarch, 35 cellulose, 100 lipid, 2 choline, 1.5 DL-methionine, 1.5 L-cysteine, 1.3 α-tocopherol, 1.2 γ-tocopherol, 1 TBHQ, 35 mineral mix (AIN-93M-MX), and 15 vitamin mix (AIN-93-VX). Detailed composition of the vitamin and mineral mix has been reported elsewhere (18). Rats were fed, 30 g/d, one of three semipurified diets differing only in lipid content: (i) 10% w/w safflower oil (Saff) enriched in α-linoleic acid (α-LA), (ii) 3% Saff plus 7% flaxseed oil (Flax) enriched in α-LNA, and (iii) 3% Saff plus 7% fish oil (Fish) enriched in EPA and DHA. Safflower, flaxseed, and fish (menhaden) oils were all purchased from Dyets, Inc. Saff was added to the Flax and Fish diets as a source of LA to prevent EFA deficiency. Two separate feeding trials were performed because all the experiments could not be obtained from one rat. Feeding trial 1 consisted of performing proliferation, interleukin-2 (IL-2) secretion, and phospholipid (PL) mass determinations. Feeding trial 2 consisted of performing proliferation (to ensure consistency between diet studies) and Western immunoblotting.

T-lymphocyte isolation and culture conditions. Sprague-Dawley rat splenic T-lymphocytes were isolated using negative selection Immulan columns (Biotecx, Inc., Houston, TX) per the manufacturer's instructions as previously described (19), yielding a 90% pure splenic T-lymphocyte population. Isolation by negative selection prevents the stimulation of the T-lymphocyte's receptor during the isolation procedure, as occurs with positive selection methods. T-lymphocytes were counted using a Cell-Dyn 900 Hematology Analyzer (Sequoia-Turner Corp., Mountainview, CA). T-lymphocytes, 25×10^6 cells per petri dish, were stimulated at 37°C for 30 min in pre-warmed complete culture media (10% heat-inactivated FBS plus 100 U/mL penicillin, 100 μg/mL streptomycin, 10 μM 2-mercaptoethanol, and 100 mM L-glutamine) with 10 μg/mL plate-bound anti-CD3 to mimic *in vivo* antigenic stimulation.

FA analysis. FA analysis was performed on the diet and liver samples. Liver samples were homogenized and washed with cold PBS prior to lipid extraction. Lipids were extracted from both diet and liver samples with *n*-hexane/2-propanol (3:2, vol/vol) (20). The lipid extracts were centrifuged at $800 \times g$ to pellet cellular debris. The lipid-containing supernatants were filtered through a 0.2-μm nylon filter, dried under nitrogen, and redissolved in methanol. The samples were converted to FAME using the method of Brockerhoff (21). Briefly, methanolic KOH was added, followed by 0.2 M aqueous H_2SO_4. The FAME were extracted by *n*-hexane, dried under nitrogen, and redissolved in *n*-hexane for cleanup by TLC. Cleanup was performed to remove glycerol or other nonmethylated lipids prior to analysis by GC. The samples were run in parallel with authentic FAME standards (Sigma, St. Louis, MO) on Silica 60G plates, prerun with acetone, with a toluene solvent system. FAME were visualized with a 0.1% 8-anilino-1-naphthalene-sulfonic acid salt solution under UV light, and the corresponding FAME bands were scraped and redissolved in methanol. The FAME were again extracted by *n*-hexane prior to separa-

tion by GLC. FAME were separated using a Varian 3900GC equipped with an FID and a Varian CP-Wax 52CB WCOT fused-silica 50 m × 0.32 mm column. The injector and detector temperatures were set to 200 and 270°C, respectively. The split ratio was 1:10, and helium was used as the carrier gas at a flow of 1.5 mL/min. The column temperature was initially set to 50°C, increased to 140°C at a rate of 20°C/min, held for 5 min, increased to 200°C at 4°C/min, increased to 240°C at 2°C/min, and held for 30 min. FAME standards, as well as a 17:0 internal standard, were used to establish relative retention times. Peak area data were collected and analyzed using Varian Star Chromatography Workstation Version 5.52 software.

Proliferation. T-lymphocyte proliferation was measured using the MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] Cell Proliferation Assay as described by the manufacturer (American Type Cell Culture, Manassas, VA). A plastic 96-well plate was precoated with either anti-CD3 at a concentration of 0.01 μg/μL in $NaHCO_3$ or $NaHCO_3$ alone before addition of cells. The plate was incubated in a humidified incubator containing 5% CO_2 at 37°C for 4 h to facilitate binding of the antibody to the wells. Plates were washed with sterile PBS, and 1.5 million cells in 100 μL of cell culture media were added to their corresponding wells. Cells were incubated for 18 h at 37°C to induce proliferation. Then 20 μL MTT reagent was added to each well, mixed gently, and incubated for approximately 4 h. The cells were permeabilized with 100 μL of detergent and incubated at room temperature for 2 h. The plate was read at an absorbance of 570 nm, and absorbance values were background-corrected.

IL-2 secretion. IL-2 secretion into the culture media was measured using a commercially available IL-2 ELISA kit from R&D Systems (Minneapolis, MN). Stimulated and unstimulated cells, prepared as described above for proliferation studies, were pelleted and their supernatants collected. The ELISA was performed according to the manufacturer's instructions. IL-2 was quantified using IL-2 standards supplied by the manufacturer of the kit and then reading the absorbance at 415 nm using an UltraMarc plate reader (BioRad, Hercules, CA). All samples were run in duplicate and the average absorbances used for quantification.

PL mass analysis. Frozen T-lymphocytes were thawed and the lipids extracted by the addition of 2-propanol (1 mL) to the tube containing the cells. This was added to a test tube containing hexane (3 mL) and the original tube containing the cells rinsed with another aliquot of 2-propanol (22). This results in a quantitative single-phase extraction of cellular PL and neutral lipids (23,24). The single-phase extract was thoroughly mixed, and the residue pelleted by centrifugation. The lipid-containing organic fraction was removed and concentrated to dryness under nitrogen, and a known amount of solvent was added. The samples were quantitatively spotted on a heat-activated Whatman LK6 TLC plate and developed in a solvent system containing chloroform/methanol/acetic acid/water (60:30:3:1 by vol). Individual bands corresponding to commercially prepared standards were scraped into acid-washed tubes and analyzed for phosphorus content. Phosphorus content was calculated by

linear regression of a standard curve. A 1:1 ratio was used to convert phosphorus to PL values except for cardiolipin (2:1) because each PL contains only one phosphorus atom, except cardiolipin, which contains two phosphorus atoms (25).

The protein pellet was air-dried overnight and then incubated with 0.2 M KOH at 65°C overnight to resolubilize the proteins. Protein concentration was determined using a modified dye-binding assay with BSA for the standard curve (26).

Western immunoblotting. Stimulated or unstimulated T-lymphocytes were pelleted and lysed in 50 μL of lysis buffer containing 5 mM Tris·HCl, 10 mM EDTA, 0.15 M NaCl, 0.1% Tween 20, 1 μL/mL β-mercaptoethanol, and 7 μL/mL protease inhibitors, pH 7.4. Lysates were centrifuged, and the protein-containing supernatants were quantified using the BioRad Protein Assay. Protein was separated by SDS-PAGE using Bio-Rad's Kaleidoscope Prestained Standards for running standards. The protein was transferred onto PolyScreen polyvinylidene difluoride membranes (NEN Life Sciences, Boston, MA), and the membranes were blocked with 15 mL blocking solution containing 25 mM Tris·HCl, 0.125 M NaCl, 4% nonfat milk, 0.1% Tween 20, pH 8.0. Membranes were probed with antiACBP antibody (provided by Dr. Jens Knudsen). Bands were detected using an alkaline phosphatase-conjugated goat-anti-rabbit secondary antibody and CDP-Star chemiluminescence reagent (NEN Life Sciences). The membrane was visualized using autoradiography, and densitometry was performed using a BioRad Gel Documentation System. The data are presented as arbitrary units, which refer to the densitometric (density) values obtained by the gel documentation system. The membrane was also probed with an anti-cbl-b antibody to control for lane loading variation.

Statistical analysis. Data were analyzed using one-way ANOVA and significant differences determined using Tukey's multiple comparison test with GraphPad Prism software (San Diego, CA). A *P* value that was <0.05 was considered significantly different. An asterisk or different numbers of asterisks

represent a significant difference from any other group within that experiment. Pearson's correlation was used to determine the correlation between ACBP, cardiolipin mass, and T-lymphocyte proliferation and IL-2 production.

RESULTS

Diet and liver FA analysis. Table 1 shows that the Saff diet contained 78% of its total FA as LA, with undetectable levels of α-LNA, EPA, and DHA. There was no significant difference in the total weight of the liver lipid between the diet groups. The Flax diet contained 46% of its total FA as α-LNA and 28% as LA, whereas EPA and DHA were undetectable. The Fish diet contained 12% of its total FA as EPA, 12% as DHA, 22% as LA, and trace amounts of α-LNA. Table 2 shows the impact of feeding the different diets for 8 wk on the FA composition of the liver. Livers from animals fed the Flax diet contained significantly (*P* < 0.05) higher levels of LA (25%) when compared with the Saff (20%) or Fish (16%) diet groups. The Flax diet was the only diet that resulted in a significant accumulation of α-LNA in the liver. Both the Flax and Fish diets were equally effective

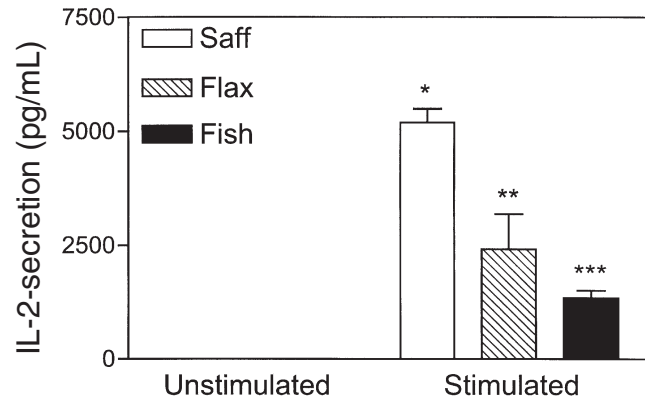
[a]For diet abbreviations see Table 1; *n* = 4 or 5; an asterisk or different numbers of asterisks represent a significant difference from any other group within that experiment.
FIG. 1. Dietary flaxseed and fish oil differentially inhibit T-lymphocyte proliferation. Rats were fed a diet enriched in safflower oil (Saff), flaxseed oil (Flax), or fish oil (Fish) for 8 wk. Splenic T-lymphocytes were isolated and cultured with (Stimulated) or without (Unstimulated) anti-CD3 monoclonal antibody for 18 h. Proliferation was determined using the MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] dye uptake test as described in the Materials and Methods section. Bars represent the mean ± SEM of five individual rats. Different numbers of asterisks represent a significant difference from any other group within that experiment.


FIG. 2. Dietary flaxseed and fish oil inhibit T-lymphocyte interleukin-2 (IL-2) secretion. Rats were fed a diet enriched in safflower oil (Saff), flaxseed oil (Flax), or fish oil (Fish) for 8 wk. Splenic T-lymphocytes were isolated and cultured with (Stimulated) or without (Unstimulated) anti-CD3 monoclonal antibody as described in the caption for Figure 1. After 24 h, culture supernatants were collected and IL-2 was quantified using an ELISA kit as described in the Materials and Methods section. Bars represent the mean ± SEM of five individual rats. Different numbers of asterisks represent a significant difference from any other group within that experiment.

at reducing the arachidonic acid levels to 11 and 10%, respectively, when compared with the 24% found in the Saff group. The Flax and Fish diet groups contained similar levels of EPA, which was undetectable in the Saff diet group. The Fish diet group contained significantly ($P < 0.05$) more DHA (16%) than the Saff and Flax diet groups, which contained approximately 4% DHA.

T-lymphocyte function. Figure 1 shows that diet did not affect spontaneous splenic T-lymphocyte proliferation in the absence of the anti-CD3 stimuli. Addition of anti-CD3 antibody significantly ($P < 0.05$) increased T-lymphocyte proliferation, which was blunted by approximately 20 and 35% in the Flax and Fish diet groups, respectively. Figure 2 shows that, as would be expected, IL-2 is not secreted by the T-lymphocytes into the culture media in the absence of stimulation with anti-CD3. Addition of anti-CD3 antibody significantly ($P < 0.05$) increased T-lymphocyte IL-2 secretion, which was blunted by approximately 50 and 70% in the Flax and Fish diet groups, respectively.

Phospholipid mass in T-lymphocytes. Table 3 shows that diet did not have a significant effect on PE, PC, PI, PS, or sphingomyelin mass in splenic T-lymphocytes. The Fish diet group had significantly ($P < 0.05$) greater PtdOH mass (21 nmol/mg protein) when compared with the Saff and Flax diets, which had 13 and 7 nmol/mg protein, respectively. Fish and Flax feeding significantly ($P < 0.05$) increased cardiolipin mass to 15 and 7 nmol/mg protein, respectively, when compared with the 3 nmol/mg protein found in the Saff group.

ACBP expression in T-lymphocytes. Figure 3A shows the influence of stimulation and diet on ACBP expression in T-lymphocytes. Feeding fish oil almost doubled ACBP expression, whereas flaxseed oil feeding increased ACBP protein expression by 50% when compared with the Saff diet group in unstimulated T-lymphocytes. Stimulation increased ACBP expression by 25% but there was no significant effect of stimulation in the Flax diet group. In contrast, stimulation significantly ($P < 0.05$) decreased ACBP expression in the Fish diet group.

TABLE 3
Influence of Dietary n-3 PUFA on T-Lymphocyte Phospholipid Mass[a]

Phospholipid	Phospholipid composition (nmol/mg protein)		
	Saff	Flax	Fish
Cardiolipin (CL)	2.7 ± 2.3	7.1 ± 2.8**	14.6 ± 2.6*
Phosphatidic acid	13.2 ± 5.9	7.2 ± 3.9	21.1 ± 4.1*
Phosphatidylethanolamine	75.3 ± 8.4	72.5 ± 7.4	76.1 ± 3.8
Phosphatidylinositol	24.0 ± 2.5	18.9 ± 3.4	27.4 ± 3.9
Phosphatidylserine	29.7 ± 6.7	27.5 ± 3.4	34.1 ± 7.5
Phosphatidylcholine	175.4 ± 23.4	155.5 ± 16.8	172.2 ± 21.9
Sphingomyelin	148.5 ± 34.6	171.3 ± 26.5	149.2 ± 23.2
Total	468.8 ± 83.8	459.8 ± 64.1	494.8 ± 67.0

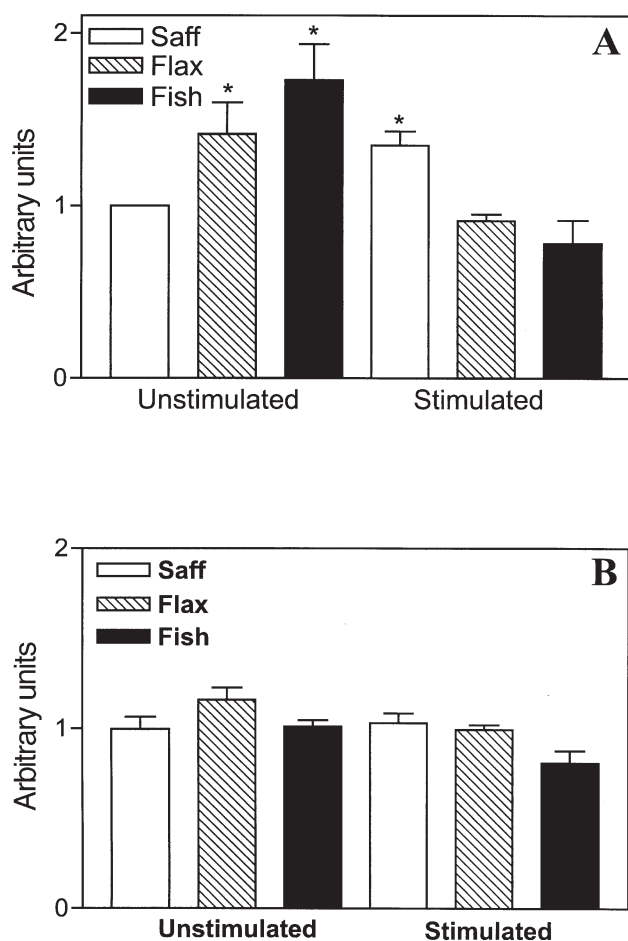
[a]For diet abbreviations see Table 1. An asterisk or different numbers of asterisks represent a significant difference from any other group within that experiment.


FIG. 3. Acyl-CoA binding protein (ACBP) expression is differentially regulated in resting and activated T-lymphocytes. Rats were fed a diet enriched in safflower oil (Saff), flaxseed oil (Flax), or fish oil (Fish) for 8 wk. Splenic T-lymphocytes were isolated and cultured with (Stimulated) or without (Unstimulated) anti-CD3 monoclonal antibody as described in the caption for Figure 1. After 30 min, T-lymphocytes were harvested and total cellular protein was extracted and subjected to Western immunoblotting for ACBP (A) or cbl-b (B) as described in the Materials and Methods section. Bars represent the mean ± SEM of 4 or 5 individual rats. An asterisk represents a significant difference from any other group within that experiment.

Figure 3B serves as lane-loading controls for Figure 3A since cbl-b expression is known to not change with CD3 stimulation (19). Overall, there was a significant positive correlation (0.864, $P < 0.001$) between diet, proliferation, and ACBP levels. There also was a significant negative correlation (−0.689, $P < 0.004$) between diet, ACBP levels, and cardiolipin mass.

DISCUSSION

Our results showing that both the Flax and Fish oil diets decreased liver arachidonic acid levels to the same extent are similar to those reported in the spleens of chickens (27), rats (28), and mice (29). These results are different from a previous report in which the feeding of canola oil, also enriched in α-LNA, did

not significantly affect arachidonic acid levels in the liver (30). The reason for this difference is most likely due to the fact that the authors fed the rats for only 6 d, whereas our study fed the rats for 8 wk. This is important because it explains how both Flax and Fish feeding reduces prostaglandin production to a similar extent in spleen lymphocytes (28). Decreasing arachidonic acid-derived prostaglandin production is a well-known mechanism by which n-3 PUFA are thought to regulate immune function. However, decreased prostaglandin production cannot be the primary mechanism by which the Flax and Fish diets inhibit T-lymphocyte function in our system because the Fish diet was more potent than the Flax diet at suppressing T-lymphocyte IL-2 secretion and subsequent proliferation. This explanation is supported by our findings that feeding arachidonic acid to mice did not affect splenic lymphocyte function (5).

The dietary Flax group had a higher LA content in their livers when compared with the Saff diet-fed group. This may be due to the conversion of LA to arachidonic acid in the Saff diet group, as suggested by the higher arachidonic acid content in the livers of the Saff diet group, which was not found in the Flax or Fish diet groups. The Flax diet group also had a slightly higher LA content than the Fish diet group, which may be due to the higher LA content in the Flax vs. the Fish diet. Interestingly, the livers of all three diet groups contained significant quantities of the *trans* FA elaidic acid. Elaidic acid was most likely already present in the livers prior to the start of the study and could have come from the commercial chow the rats were initially fed, since *trans* FA were not detected in the semipurified diets used in this study and rats cannot endogenously make *trans* FA.

The Flax and Fish diets selectively increased cardiolipin mass, whereas only the Fish diet increased PtdOH mass. Increasing cardiolipin mass suggests that the n-3 PUFA may be acting directly on the mitochondria since cardiolipin is found primarily in mitochondria. The ability of dietary n-3 PUFA to regulate mitochondrial cardiolipin FA unsaturation selectively has been shown in colonocytes and is correlated with increased caspase-3 activity, suggesting that the n-3 PUFA have antiproliferative effects (31). This is in agreement with our findings that the results of both Flax and Fish feeding are antiproliferative with respect to T-lymphocytes. Furthermore, the Fish diet, when compared with the Flax diet, was more potent at reducing T-lymphocyte proliferation and was also able to increase PtdOH mass, which is the immediate precursor PL to cardiolipin. This is the first study to report the impact of dietary n-3 PUFA feeding on T-lymphocyte phospholipid mass. The mechanism by which Fish and Flax diet feeding increases cardiolipin mass is unknown but may involve up-regulation of mitochondrial glycerol-3-phosphate acyltransferase (mtGPAT). The mtGPAT enzyme catalyzes the rate-limiting step in PtdOH biosynthesis (32) and is thus a likely target of dietary n-3 PUFA feeding. Indeed, mtGPAT gene expression was shown to be regulated by hormones, dietary starvation, and high carbohydrate feeding in liver and adipocytes (33). Specifically, n-3 PUFA feeding was shown to increase liver phospholipid mass, although an increase in mtGPAT activity was not observed (34). In another report, both n-3 and n-6 PUFA feeding increased mtGPAT activity in

rat liver (35). The reason for this discrepancy is most likely due to differences in dietary lipid levels fed and timing of tissue collection; however, these reports do set the precedent for n-3 PUFA feeding to alter mtGPAT activity and phospholipid mass. The influence of n-3 PUFA feeding on T-lymphocyte mtGPAT activity is currently unknown.

The increase in cardiolipin and PtdOH mass was correlated with increased ACBP expression, with the Fish diet being the most potent in unstimulated T-lymphocytes. This is consistent with evidence showing that ACBP can increase the activities of both the microsomal (36) and mitochondrial isoforms (15) of GPAT. The Flax and Fish diet feeding increased ACBP expression in unstimulated T-lymphocytes; however, Flax and Fish diet feeding prevented the increase in ACBP expression in stimulated T-lymphocytes. It is not unusual that the changes in ACBP in unstimulated T-lymphocytes did not have an impact on proliferation or IL-2 secretion in unstimulated cultures. T-lymphocytes do not proliferate or secrete IL-2 without appropriate antigenic stimulation (i.e., anti-CD3); therefore, it is not surprising that the increased ACBP expression in unstimulated cultures does not alter proliferation or IL-2 secretion. The differential influence of n-3 PUFA feeding may be related to how the ACBP gene is regulated. The ACBP promoter contains a binding site for activating protein-1 (AP-1), which is a fos/jun heterodimer, and peroxisomal proliferator-activated receptor γ (PPARγ) (37). Activation of the rat ACBP gene has been shown to occur in response to PPARγ in adipocytes (38). Recent evidence suggests that PPARγ may be a potent anti-inflammatory agent inhibiting T-lymphocyte proliferation (39,40). Since n-3 PUFA are PPARγ ligands, the increase in ACBP expression would be expected in T-lymphocytes. The lack of induction of ACBP expression in response to stimulation in Flax- and Fish-diet-fed rat T-lymphocytes may be due to reduced activation of the AP-1 transcription factor. It is well known that dietary n-3 PUFA feeding suppresses T-lymphocyte signal transduction (5). This study is the first report to show the rapid (i.e., 30-min) induction of ACBP expression, indicating that it may play an important role in cell function, as has been suggested by others (11–13).

In summary, we have shown that dietary n-3 PUFA increase cardiolipin and PtdOH mass in resting T-lymphocytes, which is correlated with increased ACBP expression. Furthermore, we have shown that ACBP expression can be increased following T-lymphocyte activation and that this response is blunted by dietary n-3 PUFA. Regulation of ACBP expression and phospholipid mass may be a novel mechanism by which dietary n-3 PUFA exert their anti-inflammatory effects on T-lymphocytes.

ABSTRACT: It has been previously established that *trans*-10,*cis*-12 CLA is a potent inhibitor of milk fat synthesis. Although the mechanism of this action is not completely understood, it has been speculated that eicosanoid-like metabolites of this isomer formed by the activity of tissue desaturases may be responsible for its activity. The objective of this study was to investigate the effects of an enrichment containing an 18:3 conjugated diene, produced in the metabolism of *trans*-10,*cis*-12 CLA, on milk fat synthesis. Three rumen-fistulated Holstein cows (210 ± 8 d in milk) were randomly assigned in a 3 × 3 Latin square experiment. Treatments were (i) control, (ii) *trans*-10,*cis*-12 CLA supplement (2.1 g/d; positive control), (iii) enrichment providing two conjugated diene 18:3 isomers (2.6 g/d of *cis*-6,*trans*-10,*cis*-12 and 4.0 g/d of *cis*-6,*trans*-8,*cis*-12) and *trans*-10,*cis*-12 CLA (2.1 g/d). Treatments were abomasally infused for 5 d at 4-h intervals, and there was a 7-d interval between periods. Milk yield, dry matter intake, and milk protein yield were unaffected by treatments. In contrast, the *trans*-10,*cis*-12 CLA supplement reduced milk fat yield by 27%, whereas the supplement enriched with conjugated diene 18:3 isomers (treatment iii) had no effect on milk fat yield beyond that attributable to its *trans*-10,*cis*-12 CLA content. The transfer efficiency of *trans*-10,*cis*-12 CLA into milk fat was 25 and 24% for treatments ii and iii, respectively. At the same time, the abomasally infused conjugated diene 18:3 isomers were transferred to milk fat with an efficiency of 33 and 41% for *cis*-6,*trans*-10,*cis*-12 and *cis*-6,*trans*-8,*cis*-12 18:3, respectively. Overall, short-term abomasal infusion of the conjugated diene 18:3 isomers had no effect on milk fat synthesis, thereby offering no support for an involvement of metabolites of *trans*-10,*cis*-12 CLA in the regulation of milk fat synthesis.

Paper no. L9525 in *Lipids 40*, 89–95 (January 2005).

CLA have a number of biological effects, one of which involves the regulation of lipid metabolism. Supplementation of CLA has been shown to reduce milk fat content in lactating species including cows, pigs, and nursing women (1). Dietary CLA also reduces fat deposition in a number of animal growth models such as mice, rats, and pigs (2). Specifically, the *trans*-10,*cis*-12 CLA isomer is involved in the inhibition of milk fat synthesis (3) as well as the reduction of body fat accretion (4). However, the mechanism by which *trans*-10,*cis*-12 CLA effects lipid metabolism is not fully understood.

Many of the biological effects of PUFA can be attributed to FA intermediates formed during metabolism; a specific example is the formation of eicosanoids from n-3 and n-6 FA (5). Therefore, it is possible that the *trans*-10,*cis*-12 CLA isomer *per se* does not regulate lipid metabolism, but rather a specific FA formed during its metabolism may be responsible for the biological activity. Several of the proposed theories for the mechanisms of action of CLA involve their metabolism. These theories include: interfering with the synthesis and function of eicosanoids, the activation of peroxisome proliferator-activated receptor γ by metabolites of CLA isomers, and the ability of CLA metabolites to act as eicosanoids (6,7).

Metabolites of CLA isomers have been identified in CLA-supplemented animals (7,8), and the *trans*-10,*cis*-12 CLA isomer has been shown to be elongated and desaturated in a manner similar to linoleic acid (7–10). Although it has been postulated that *trans*-10,*cis*-12 CLA acts directly to alter lipid metabolism (1,11), the involvement of metabolites of *trans*-10,*cis*-12 CLA in the regulation of lipid metabolism has not been directly evaluated. In an attempt to better understand the role of CLA metabolites in situations where *trans*-10,*cis*-12 CLA causes a reduction in milk fat synthesis, an enrichment containing *cis*-6, *trans*-10,*cis*-12 18:3 was provided to dairy cows and effects on milk fat synthesis were examined. This partially conjugated triene is formed by Δ^6-desaturation in the initial step in the metabolism of *trans*-10,*cis*-12 CLA; following the example of Banni (7), we will refer to it as a conjugated diene 18:3 (CD 18:3).

EXPERIMENTAL PROCEDURES

The Cornell University Institutional Animal Care and Use Committee approved all procedures involving animals. Three rumen-fistulated lactating Holstein cows [210 ± 8 d in milk (DIM); mean ± SE] were randomly assigned in a 3 × 3 Latin square experiment. Cows were housed in tie stalls at the Cornell University Large Animal Teaching and Research Unit and

Other	<0.1	18.9

[a]Total compositions of supplements were determined using GC analysis, whereas HPLC and GC/MS/MS analysis were used to separate and identify the conjugated diene (CD) 18:3 isomers. ND = not detected.

fed a total mixed ration formulated to meet or exceed nutrient requirements for energy, protein, minerals, and vitamins (12) using the Cornell Net Carbohydrate and Protein System (13). Chopped alfalfa was the major forage component, with cracked corn as the major concentrate (Table 1). Cows were fed *ad libitum* with equal portions of feed offered at 0700 and 1900 h daily. Dry matter intake (DMI) was measured daily, and water was provided at all times.

Cows were milked at 0700 and 1900 h daily. Yield was determined and samples were taken from each milking. One aliquot was stored with preservative (bronopol tablet; D&F Control System, San Ramon, CA) at 4°C until it was analyzed for fat and protein content by IR spectroscopy (Dairy One, Ithaca, NY) using methods detailed by Bernal-Santos *et al.* (14). A second aliquot was stored without preservative at –20°C until analyzed for FA composition.

Ethanol was used as a carrier for the FA supplements, and infusates provided <100 mL/d of ethanol. Treatments were abomasal infusion of (i) ethanol (control), (ii) *trans*-10,*cis*-12 CLA (2.1 g/d; positive control), and (iii) enrichment providing two CD 18:3 isomers (2.6 g/d of *cis*-6,*trans*-10,*cis*-12 18:3 and 4.0 g/d of *cis*-6,*trans*-8,*cis*-12 18:3) plus *trans*-10,*cis*-12 CLA (2.1 g/d). The composition of the supplements (Natural ASA, Hovdebygda, Norway) is provided in Table 2. The CD 18:3 enrichment was made by a mild alkaline isomerization procedure of a concentrate of γ-linolenic acid. On isomerization of linoleic acid, this procedure yields approximately 50% each of *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA, and less than 1% each of *cis-cis* and *trans-trans* isomers. The CD 18:3 supplement was therefore expected to contain predominantly *cis*-6, *trans*-8,*cis*-12 and *cis*-6,*trans*-10,*cis*-12 18:3 FA.

Identification of the specific CD 18:3 isomers present in the enrichment was accomplished by first isolating the FA by

HPLC and then determining their structure by GC/tandem MS (GC/MS/MS) analysis. HPLC fractionation and quantitative analysis of CD 18:3 were carried out using a Waters 2995 chromatographic system (Waters Associates, Milford, MA) equipped with a Waters 2695 PDA detector (acquiring 200–300 nm), and three ChromSpher 5 Lipids columns (each 4.6 mm i.d.; length 250 mm stainless steel; 5 µm particle size; Varian Inc., Walnut Creek, CA) in series maintained at 20°C. CD 18:3 were eluted with 50:50 (% by vol) hexane/0.4% acetonitrile in an isooctane mobile phase at 1.0 mL/min. Single chromatograms were extracted at 233 nm. After identifying the CLA isomers present in the CD 18:3 enrichment by comparison with reference material, the other two major peaks showing characteristic UV conjugated diene spectra were fractionated (Fig. 1). Once separated, fractions were subjected to acetontrile CI MS/MS as described in detail previously (15). Single-stage MS data revealed that the two FAME were indeed partially conjugated 18:3 FA based on the [M + 54 – 32]/[M + 54] ratios. MS/MS fragments for both CD 18:3 isomers were observed at *m/z* 276 and 232, establishing that double bonds were in the 6- and 12-positions, with an additional double bond internal to these positions. A fragment at *m/z* 222 showed that the internal double bond in one CD 18:3 isomer was in the 8-position, whereas a fragment at *m/z* 178 for the other isomer demonstrated the internal double bond was in the 10-position. The intensity of peaks was consistent with assignment for both FAME as *cis-trans-cis*. The two CD 18:3 isomers were thus assigned as *cis*-6,*trans*-10,*cis*-12 and *cis*-6,*trans*-8,*cis*-12.

Infusates were prepared from the same source each experimental period and stored under nitrogen gas at 4°C until they were infused during the experimental period. The *trans*-10,*cis*-12 CLA supplement and the CD 18:3 supplement treatments were targeted to provide an equal amount of *trans*-10,*cis*-12 CLA. Average amounts of CLA isomers provided by the treatments over the three infusion periods are presented in Table 3. Treatment periods were 5 d in duration, and treatments were abomasally infused six times a day at 4-h intervals. At each time point, equal volumes were infused into the abomasum *via* 0.5 cm (i.d.) polyvinyl chloride tubing that was passed through
FIG. 1. Partial chromatogram demonstrating the HPLC separation of the two conjugated diene (CD) 18:3 isomers present in the CD 18:3 supplement.

the rumen fistula and sulcus omasi as described by Spires *et al.* (16). Abomasal infusion of supplements was used as a convenient experimental means to prevent rumen biohydrogenation of the PUFA contained in the supplements and to accurately account for the quantity of FA supplied by the different treatments. Treatment periods were followed by a 7-d washout to minimize carryover effects in the next treatment period.

FA analysis. Milk fat was extracted using the method of Hara and Radin (17), and FAME were prepared by base-catalyzed transmethylation according to Christie (18) with modifications by Chouinard *et al.* (19). FAME were quantified using a gas chromatograph (GC system HP 6890+; Hewlett Packard, Wilmington, DE) equipped with a CP-SIL 88 fused-silica capillary column [100 m × 0.25 mm (i.d.) with 0.2-µm film thickness; Varian, Inc.]. GC conditions were as described previously (20). FA peaks were identified using pure methyl ester standards (Nu-Chek-Prep, Elysian, MN). Additional standards for CLA isomers were obtained from Natural ASA, and a butter oil reference standard (CRM 164; Commission of the European Community Bureau of References, Brussels, Belgium) was

TABLE 3
Quantities of FA Provided by Abomasal Infusion of Supplements[a]

[a]For abbreviation see Table 2.

used to determine recoveries and correction factors for individual FA. In addition, a milk fat sample from each cow receiving the CD 18:3 supplement was analyzed by HPLC using the conditions stated previously to determine the percentages of the two CD 18:3 isomers present in the single peak identified by GC.

Statistical analysis. Data were statistically analyzed as a 3×3 Latin square design using the PROC MIXED procedure of SAS (21) with the model: $Y_{ijk} = \mu + T_i + R_j + C_k + E_{ijk}$ where Y_{ijk} is observation, μ is overall mean, T_i is treatment ($i = 1, 2,$ and 3), R_j is period ($j = 1, 2,$ and 3), C_k is cow ($k = 1, 2,$ and 3), and E_{ijk} is residual error. Values presented are least square means and significance was set at $P < 0.05$.

RESULTS AND DISCUSSION

The metabolism of CLA to conjugated intermediates has been shown in mice (22), rats (10,23–25), and lambs (26). *Trans*-10,*cis*-12 CLA is a potent inhibitor of milk fat synthesis. and its metabolism involves an initial desaturation by Δ^6-desaturase to give a CD 18:3, followed by an elongation and desaturation producing CD 20:3 and CD 20:4, respectively (Fig. 2). These can be further metabolized in the same manner as linoleic acid to eicosanoid-like compounds. In the present study, we examined the effect of a CD 18:3 enrichment containing *cis*-6,*trans*-10,*cis*-12 to determine whether this metabolite of *trans*-10,*cis*-12 CLA was involved in the mechanism of the regulation of milk fat synthesis. Owing to the lack of pure *cis*-6,*trans*-10,*cis*-12 18:3, a FA enrichment was used that also contained a second CD 18:3 isomer (*cis*-6,*trans*-8,*cis*-12) as well as *trans*-10,*cis*-12 CLA. The *trans*-10,*cis*-12 CLA supplement (positive control treatment) and the CD 18:3 supplement were supplied in quantities so that each provided 2.1 g/d of *trans*-10,*cis*-12 CLA. This dose of *trans*-10,*cis*-12 CLA is far less than the

amount (~10 g/d) required to achieve nadir for the reduction in milk fat yield based on the dose–response relationships described previously (27). Therefore, if the mechanism of action for *trans*-10,*cis*-12 CLA is due to this initial metabolite (*cis*-6,*trans*-10,*cis*-12 18:3) or the formation of subsequent metabolites, additional milk fat depression should have occurred in the treatment group receiving the CD 18:3 supplement. This was not observed, and overall the treatment groups receiving the *trans*-10,*cis*-12 CLA supplement and the CD 18:3 supplement had similar reductions in milk fat content and milk fat yield (Table 4). Further, the magnitude of the reductions in milk fat yield observed for the *trans*-10,*cis*-12 CLA supplement and CD 18:3 supplement is consistent with results previously reported for abomasal infusion of pure *trans*-10,*cis*-12 CLA (27,28).

The temporal pattern for milk fat yield illustrated a progressive reduction for cows receiving the FA supplements, while no change in milk fat yield was observed for the control (Fig. 3). On termination of the supplements, milk fat yield returned to normal for both the *trans*-10,*cis*-12 CLA and CD 18:3 treatment groups. In contrast to effects on milk fat, FA supplements had no effect on DMI, milk yield, or milk protein (Table 4). The lack of change in these variables is consistent with other studies that have abomasally infused CLA isomers and observed a reduction in milk fat synthesis (3,19,27–32).

The FA composition of the milk fat from the three treatment groups is presented in Table 5. The observed decrease in milk fat yield for the positive control and the CD 18:3 treatments was the result of reductions in most FA. Milk FA composition was shifted owing to a greater reduction of *de novo* synthesized FA, resulting in a relative increase in the proportion of preformed long-chain FA. Shifts in milk fat composition are comparable to results previously observed in studies in which CLA caused a reduction in milk fat synthesis (3,19,28–33). Consistent within these studies was a reduced secretion of all milk FA, with a greater reduction of the FA containing ≤16 carbons resulting in a proportional increase of the FA of >16 carbons.

Partial chromatograms of representative milk fat samples from the three treatment groups depicting the elution of the CLA and partially conjugated 18:3 isomers are shown in Fig-

ure 4. The partially conjugated 18:3 isomers present in the CD 18:3 supplement eluted as a single peak under our GC conditions, and this peak was not present in the milk fat of either the control or *trans*-10,*cis*-12 CLA treatment groups (Fig. 4). Clearly, the CD 18:3 isomers were taken up by the mammary gland and incorporated into milk fat. Milk fat from each cow receiving the CD 18:3 supplement was further analyzed by HPLC and GC/MS/MS to determine the isomer mixture in the single CD 18:3 peak identified by GC analysis. Based on these analyses, 35% of the peak was *cis*-6,*trans*-10,*cis*-12 18:3, and the other 65% was *cis*-6,*trans*-8,*cis*-12 18:3. By using these values, it was determined that the abomasally infused dose was transferred to milk fat with an efficiency of 33% for *cis*-6,*trans*-10,*cis*-12 18:3 and 41% for *cis*-6,*trans*-8,*cis*-12 18:3. Milk fat content of the *trans*-10,*cis*-12 CLA isomer was at the limit of detection in the control group. However, as expected, a similar increase in the milk fat content of this isomer was observed when cows received the *trans*-10,*cis*-12 CLA supplement
FIG. 3. Temporal pattern of milk fat yield during abomasal infusion of FA supplements. Infusions were for 5 d and are indicated by the dotted lines. Values represent means from three cows; SEM = 0.06 kg/d.

[a]Values represent an average of day 5 of abomasal infusion of FA supplements.
[b]Statistical probability of treatment effects. Means within a row with different superscripts differ.
[c]FA <C_{16} originate from *de novo* synthesis, FA >C_{16} are preformed FA taken up by the mammary gland, and C_{16} + $C_{16:1}$ FA come from both *de novo* and preformed sources.

(0.11% of total FA) and the CD 18:3 supplement (0.10% of total FA) (Table 5). These increases reflect similar transfer efficiencies for the *trans*-10,*cis*-12 CLA isomer into milk fat from the *trans*-10,*cis*-12 CLA supplement (mean = 25%, range = 20–29%) and the CD 18:3 supplement (mean = 24%, range = 19–27%). In a summary of six studies, de Veth *et al*. (27) reported an average transfer efficiency of 22% for abomasally infused *trans*-10,*cis*-12 CLA. Thus, the transfer of *trans*-10,*cis*-12 CLA into milk fat is less than that observed for the two CD 18:3 isomers. This difference cannot be accounted for by the metabolism of *trans*-10,*cis*-12 CLA to *cis*-6,*trans*-10,*cis*-12 18:3, because this partially conjugated 18:3 isomer was not present in the milk fat of the control or the treatment group receiving the *trans*-10,*cis*-12 CLA supplement (Fig. 4).

The desaturase index comprises four ratios of FA that represent a proxy for the Δ^9-desaturase enzyme in the mammary gland (1). These ratios were not different among treatment groups, with the exception of an increase in the ratio of *cis*-9,*trans*-11 CLA to *trans*-11 18:1 observed when cows received the CD 18:3 supplement (Table 5). This increase was expected due to the presence of *cis*-9,*trans*-11 CLA isomer in the CD 18:3 supplement (Table 2), which resulted in an increase of this CLA isomer in milk fat (Table 5). Previous studies involving growing rodents have demonstrated that the *trans*-10,*cis*-12 CLA isomer affects both enzyme activity and gene expression for Δ^9-desaturase (34). High doses of *trans*-10,*cis*-12 CLA have also been noted to alter the milk fat desaturase index in dairy cows (1,35). However, the present study is similar to others
FIG. 4. Partial gas chromatogram of milk fat from cows that had received treatments involving control (A), *trans*-10,*cis*-12 CLA supplement (B), and CD 18:3 supplement (mixture of *cis*-6,*trans*-10,*cis*-12 18:3 and cis-6,*trans*-8,*cis*-12 18:3, plus *trans*-10,*cis*-12 CLA) (C). For abbreviation see Figure 1.

in that low doses of *trans*-10,*cis*-12 CLA do not alter the desaturase index in the milk fat (14,28).

Overall, abomasal infusion of *trans*-10,*cis*-12 CLA caused a reduction in milk fat synthesis that was consistent with previous studies. A greater reduction in milk fat synthesis was not observed for the treatment group receiving the CD 18:3 supplement. This indicates that despite being taken up and incorporated into milk fat, neither the Δ^6 desaturation product of *trans*-10,*cis*-12 CLA (*cis*-6,*trans*-10,*cis*-12 18:3) nor the other CD 18:3 isomer present in the supplement (*cis*-6,*trans*-8,*cis*-12 18:3) had any effect on milk fat synthesis. Therefore, these data support a mechanism of action for *trans*-10,*cis*-12 CLA involving this specific isomer, *per se*, in the reduction of milk fat synthesis, and they provide no support that the mechanism involves a metabolite of *trans*-10,*cis*-12 CLA.

ABSTRACT: The FA composition of 12 strains of marine aerobic anoxygenic phototrophic bacteria belonging to the genera *Erythrobacter, Roseobacter*, and *Citromicrobium* was investigated. GC–MS analyses of different types of derivatives were performed to determine the structures of the main FA present in these organisms. All the analyzed strains contained the relatively rare 11-methyloctadec-12-enoic acid, and three contained 12-methyloctadec-11-enoic acid, which has apparently never been reported before. High amounts of the very unusual octadeca-5,11-dienoic acid were present in 9 of the 12 strains analyzed. A FA containing a furan ring was detected in three strains. Analytical data indicated that this FA was 10,13-epoxy-11-methyloctadeca-10,12-dienoic acid. A very interesting enzymatic peroxidation of the allylic carbon 10 of *cis*-vaccenic acid was observed in three strains. Deuterium labeling and GC–MS analyses enabled us to demonstrate that this enzymatic process involves the initial dioxygenase-mediated formation of 10-hydroperoxyoctadec-11(*cis*)-enoic acid, which is then isomerized to 10-hydroperoxyoctadec-11(*trans*)-enoic acid and converted to the corresponding hydroxyacids and oxoacids. Different biosynthetic pathways were proposed for these different compounds.

Paper no. L9671 in *Lipids 40*, 97–108 (January 2005).

It has long been known that various forms of bacteriochlorophyll (BChl) are present in prokaryotes, which perform anoxygenic photosynthesis under anaerobic conditions. In 1978, however, BChl *a* was detected in three strains of obligate aerobic bacteria (1,2). Since then, several strains of aerobic bacteria containing BChl *a* have been reported [for reviews see Shimada (3) and Yurkov and Beatty (4)]. The novel aspect of this increasingly large group of bacteria is that they are strict aerobes unable to grow under anaerobiosis. Apparently, these organisms, which are widely known as aerobic anoxygenic phototrophs (AAP) (4), might represent an evolutionary transient phase from anaerobic phototrophs to aerobic heterotrophs (3).

Until recently, AAP were thought to be confined only to specialized niches such as the surface of seaweed, coastal sands, cyanobacterial mats, and water in high tidal zones (5,6). However, in 1999, a significant activity of anoxygenic photosynthesis was discovered in the open ocean by BChl *a* fluorescence emission measurement and was attributed to the presence of AAP (7). Later, the presence of AAP was reported from the euphotic zone of various marine environments (8–11).

Little is known about AAP diversity. All the marine AAP isolates reported to date have been classified as members of four genera: *Erythrobacter*, *Roseobacter*, *Citromicrobium*, and *Roseibium* (6,12–15). Phylogenetically, the *Erythrobacter* and *Citromicrobium* genera belong to the Sphingomonadaceae family (α-4 subclass of the *Proteobacteria*), and the *Roseobacter* and *Roseibium* genera belong to the Rhodobacteriaceae family (α-3 subclass of the *Proteobacteria*).

In the present work, we analyzed the lipid composition of several isolates of marine AAP belonging to the *Erythrobacter*, *Roseobacter*, and *Citromicrobium* genera. The structures of FA were determined by GC–MS analysis of different derivatives.

MATERIALS AND METHODS

Organisms. Twelve strains containing functional bacterial photosynthetic reaction centers were isolated from diverse marine environments (Table 1). Isolation and characterization of these strains were described previously (10,15). The isolates were grown under fully aerobic conditions exposed to a light–dark cycle (12/12 h) at 23°C. The cultures were inoculated into Erlenmeyer flasks containing an organic enriched seawater medium supplemented with 0.5 g peptone and 0.1 g yeast extract per liter (15). The cells were harvested in a stationary phase by centrifugation at $10,000 \times g$.

Alkaline hydrolysis. Saponification was carried out on approximately 15 mg (dry weight) of wet cells of AAP; 25 mL of water, 25 mL of methanol, and 2.8 g of potassium hydroxide were added and the mixture was saponified by refluxing for 2 h. The content of the flask was acidified with hydrochloric acid (pH 1) after cooling and was subsequently extracted three times with dichloromethane. The combined dichloromethane extracts were dried over anhydrous Na_2SO_4, filtered, and concentrated by rotary evaporation at 40°C to give the total solvent-extractable lipid compounds.

Acidic hydrolysis. The residues obtained after alkaline hydrolysis were treated with 2 M HCl by refluxing for 4 h. After cooling, the reaction mixture was extracted three times with dichloromethane. The combined extracts were then dried over

anhydrous Na_2SO_4, filtered, and concentrated by rotary evaporation at 40°C.

Lipid extraction. Approximately 15 mg (dry weight) of wet cells of AAP were extracted ultrasonically with chloroform/methanol/water (1:2:0.8, by vol) (16). Chloroform and deionized water were added to the combined extracts to obtain the final chloroform/methanol/water ratio of 1:1:0.9 (by vol) to initiate phase separation. The lipids were recovered in the lower chloroform phase, which was dried over anhydrous Na_2SO_4, filtered, and concentrated by rotary evaporation at 40°C.

Reduction. Reduction of allylic hydroperoxyacids and oxoacids to alcohols was performed in methanol (25 mL) by excess $NaBH_4$ or $NaBD_4$ (10 mg per 1 mg of extract). The mixture was agitated for 30 min at 20°C using magnetic stirring (17). After reduction, water and KOH were added and saponification was carried out as described in the *Alkaline hydrolysis* section.

Acetylation. Extracts were taken up in a mixture of 300 µL pyridine and acetic anhydride (2:1, vol/vol). The mixture was incubated overnight at 50°C and then evaporated to dryness under nitrogen. Under these conditions, hydroperoxides are quantitatively transformed to the corresponding ketones (18). After acetylation, saponification was carried out as described in the *Alkaline hydrolysis* section.

Osmium tetroxide oxidation. Lipid extracts and OsO_4 (1:2, w/w) were added to a pyridine/dioxane mixture (1:8, vol/vol; 5 mL) and incubated for 1 h at room temperature. Then 6 mL of Na_2SO_3 suspension (8.5 mL of 16% Na_2SO_3 in water/methanol, 8.5:2.5, vol/vol) was added and the mixture was again incubated for 1.5 h. The resulting mixture was gently acidified (pH 3) with HCl and extracted three times with dichloromethane (5 mL). The combined dichloromethane extracts were subsequently dried over anhydrous Na_2SO_4, filtered, and concentrated.

Formation of pyrrolidide derivatives. Lipid extracts were taken up in 2 mL of BF_3/methanol (14%) and heated at 80°C for 1 h. After cooling, an excess of water was added, and methyl esters were extracted three times with hexane, dried over anhydrous Na_2SO_4, filtered, and concentrated using rotary evaporation. The methyl esters obtained were dissolved in

1 mL of pyrrolidine. Then 0.1 mL of acetic acid was added and the mixture was heated at 100°C for 1 h. The excess pyrrolidine was removed under a stream of nitrogen at 50°C, and the residue was taken up in hexane/diethyl ether (1:1, vol/vol; 8 mL) and washed three times with water (4-mL portions). The organic phase was dried over anhydrous Na_2SO_4, filtered, and evaporated to obtain the required pyrrolidide derivatives.

Catalytic hydrogenation. Lipid extracts were hydrogenated overnight under magnetic stirring in methanol with $Pd/CaCO_3$ (10–20 mg/mg of extract) (Aldrich, St. Quentin Fallavier, France) as a catalyst. After hydrogenation, the catalyst was removed by filtration and the filtrate was concentrated by rotary evaporation.

Silylation. After evaporation of the solvent, each residue was taken up in 300 µL of a mixture of anhydrous pyridine and bis(trimethylsilyl)trifluoroacetamide (BSTFA) (Supelco, St. Quentin Fallavier, France) (2:1, vol/vol) and silylated for 1 h at 50°C. After evaporation to dryness under nitrogen, the residue was redissolved in ethyl acetate (2 mL/mg) and BSTFA (0.1 mL) and then analyzed by GC–MS.

GC–MS analysis. GC–EIMS analyses (under EI) were carried out with a HP 5890 Series II Plus gas chromatograph connected to an HP 5972 mass spectrometer. The following operating conditions were used: 30 m × 0.25 mm (i.d.) column coated with SolGel-1 (SGE, Ringwood, Australia; film thickness, 0.25 µm); oven temperature programmed from 60 to 130°C at a rate of 30°C min^{-1} and then from 250 to 300°C at 4°C min^{-1}; carrier gas (He) maintained at 1.04 bar until the end of the temperature program and then programmed from 1.04 to 1.5 bar at a rate of 0.04 bar min^{-1}; injector (on-column with retention gap) temperature, 50°C; electron energy, 70 eV; source temperature, 170°C; cycle time, 1.5 s.

Structural assignments were based on interpretation of the MS fragmentations and confirmed by comparison of retention times and mass spectra with those of authentic compounds when these were available.

Analyses of a blank treatment without cells and of AAP grown on glutamate (instead of yeast extract) were done in parallel to check for possible contamination.

RESULTS AND DISCUSSION

Saturated FA. The FA compositions of the different strains analyzed are summarized in Table 2. AAP contained a standard pattern of saturated FA ranging from C_{12} to C_{18}, which were rather uninformative. We failed to detect significant amounts of C_{15} and C_{17} branched saturated FA, which is in a good agreement with the well-known lack of such FA in most of the Gram-negative bacteria (19,20).

Monounsaturated FA. In EI mass spectra of monounsaturated FA methyl or trimethylsilyl esters, no feature permits the double bond to be located, because the double bond can migrate when the alkyl chain is ionized in the mass spectrometer. This phenomenon appeared to be particularly prominent in the case of branched FA (21). To avoid the migration problem, it was necessary to prepare specific derivatives of unsaturated FA that "fixed" the double bond. Two methods were used: OsO_4 oxidation (22) and pyrrolidide formation (23). The OsO_4 method involves the formation of diols by stereospecific oxidation of double bonds and subsequent analyses of the silylated diols by GC–MS. The position of the double bond can be deduced from the mass fragmentation patterns of these derivatized compounds. Pyrrolidide derivatives were chosen for this study since: (i) they are prepared under relatively mild conditions, (ii) they are stable chemically, and (iii) they are well suited to the structural characterization of branched unsaturated FA.

The AAP strains investigated contained monounsaturated FA ranging from C_{12} to C_{19} and were dominated by octadec-11(*cis*)-enoic acid (*cis*-vaccenic acid) (Table 2). Two interesting branched 19:1 FA were detected: the 11-methyloctadec-12-enoic and the 12-methyloctadec-11-enoic acids. The mass spectra of the bis-trimethylsilyloxy and pyrrolidide derivatives of the 11-methyloctadec-12-enoic acid are shown in Figure 1. The mass spectrum of the bis-trimethylsilyloxy derivative (obtained after OsO_4 oxidation of the double bond and subsequent silylation), exhibited two strong fragment ions at *m/z* 173 and

A

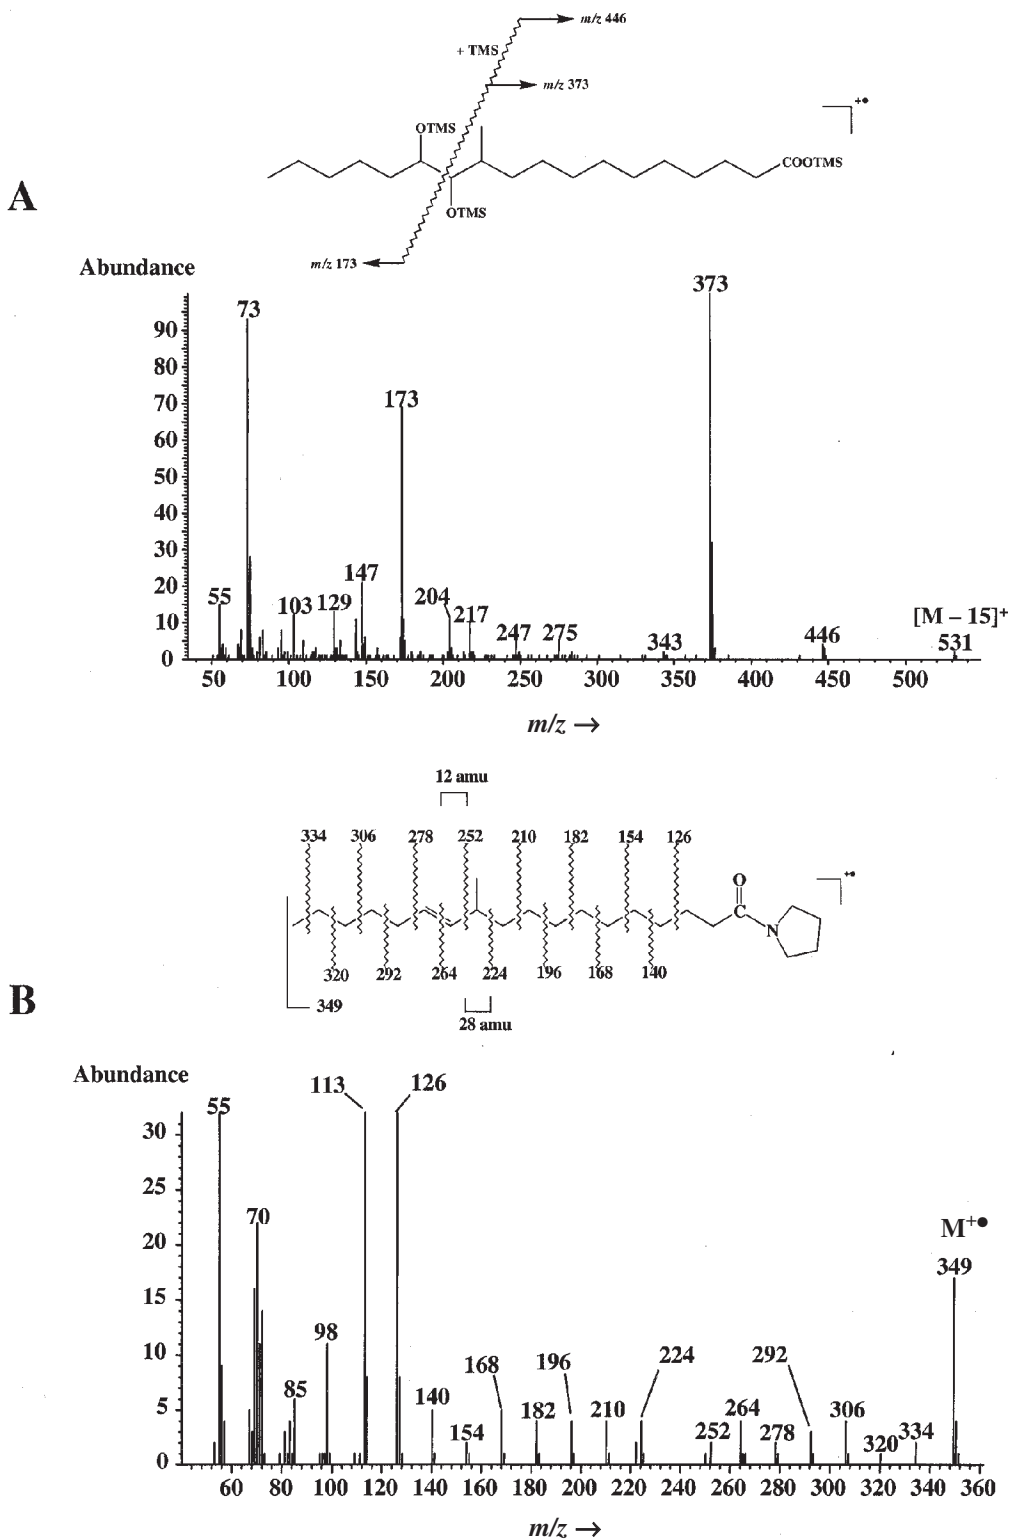
B


FIG. 1. EI mass spectra of the silylated OsO$_4$ (A) and pyrrolidide (B) derivatives of 11-methyloctadec-12-enoic acid. TMS, trimethylsilyl.

373 resulting from the cleavage of the bond between the two carbon atoms bearing the trimethylsilyloxy groups (Fig. 1A). This proved the presence of a double bond in position 12 in the parent FA. The useful ion at *m/z* 446 resulting from trimethyl-silyl transfer toward the carboxylic group (24,25) confirmed that the fragment ion at *m/z* 373 contained the carboxylic group. In the mass spectrum of the pyrrolidide derivative (Fig. 1B), the gap of 28 amu between *m/z* 224 and 252 localized the methyl

branch on the carbon C11 (26), whereas the gap of 12 amu between m/z 252 and 264 confirmed the presence of the double bond in position 12. Indeed, if an interval of 12 amu, instead of the regular 14, was observed between the most intense peaks of clusters of fragments containing n and n – 1 carbon atoms of the acid moiety, the double bond was located between carbon n and n + 1 in the molecule (23). 12-Methyloctadec-11-enoic acid was also identified from the mass spectra of its bis-trimethylsilyloxy and pyrrolidide derivatives (Fig. 2). In the mass spectrum of the pyrrolidide derivative (Fig. 2B), the gap

of 12 amu between m/z 224 and 236 showed a double bond in position 11, whereas the gap of 28 amu between m/z 236 and 264 localized the methyl branch on the carbon C12. This assignment was also supported by the presence of fragment ions at m/z 201 (base peak), 345, and 418 in the mass spectrum of the bis-trimethylsilyloxy derivative (Fig. 2A).

11-Methyloctadec-12-enoic acid was present in all the AAP strains analyzed (Table 2). This acid was previously detected in other bacteria such as mycobacteria (27), *Shewanella putrefaciens* (28), *Thiobacillus* (29), *Thiohalocapsa halophila*, and

A

B

FIG. 3. EI mass spectra of the silylated OsO$_4$ (A) and pyrrolidide (B) derivatives of octadeca-5,11-dienoic acid. For abbreviation see Figure 1.

Halochromatium salexigens (Rontani, J.-F., unpublished data). It seems to be a FA typical of bacteria. In contrast, 12-methyloctadec-11-enoic acid was found in only three strains of AAP (Table 2). To our knowledge, this compound has never been reported before.

PUFA. Small amounts of octadeca-9,12-dienoic acid (linoleic acid) were detected in all the strains of AAP analyzed. This result is very surprising, since it is generally believed that bacteria are unable to synthesize methylene-interrupted PUFA (19). After careful examination, it appeared that this acid resulted from contamination during the analytical treatment.

Nine of the 12 strains of AAP analyzed contained a significant proportion of the unusual octadeca-5,11-dienoic acid (Table 2). The mass spectra of the tetra-trimethylsilyloxy and

pyrrolidide derivatives of this acid are shown in Figure 3. The presence of double bonds in positions 5 and 11 is well supported by the intense fragment ions at *m/z* 187, 261, and 334 observed in the mass spectrum of the tetra-trimethylsilyloxy derivative (Fig. 3A) and by the gaps of 12 amu between *m/z* 140 and 152 and between *m/z* 222 and 234 in the mass spectrum of the pyrrolidide derivative (Fig. 3B).

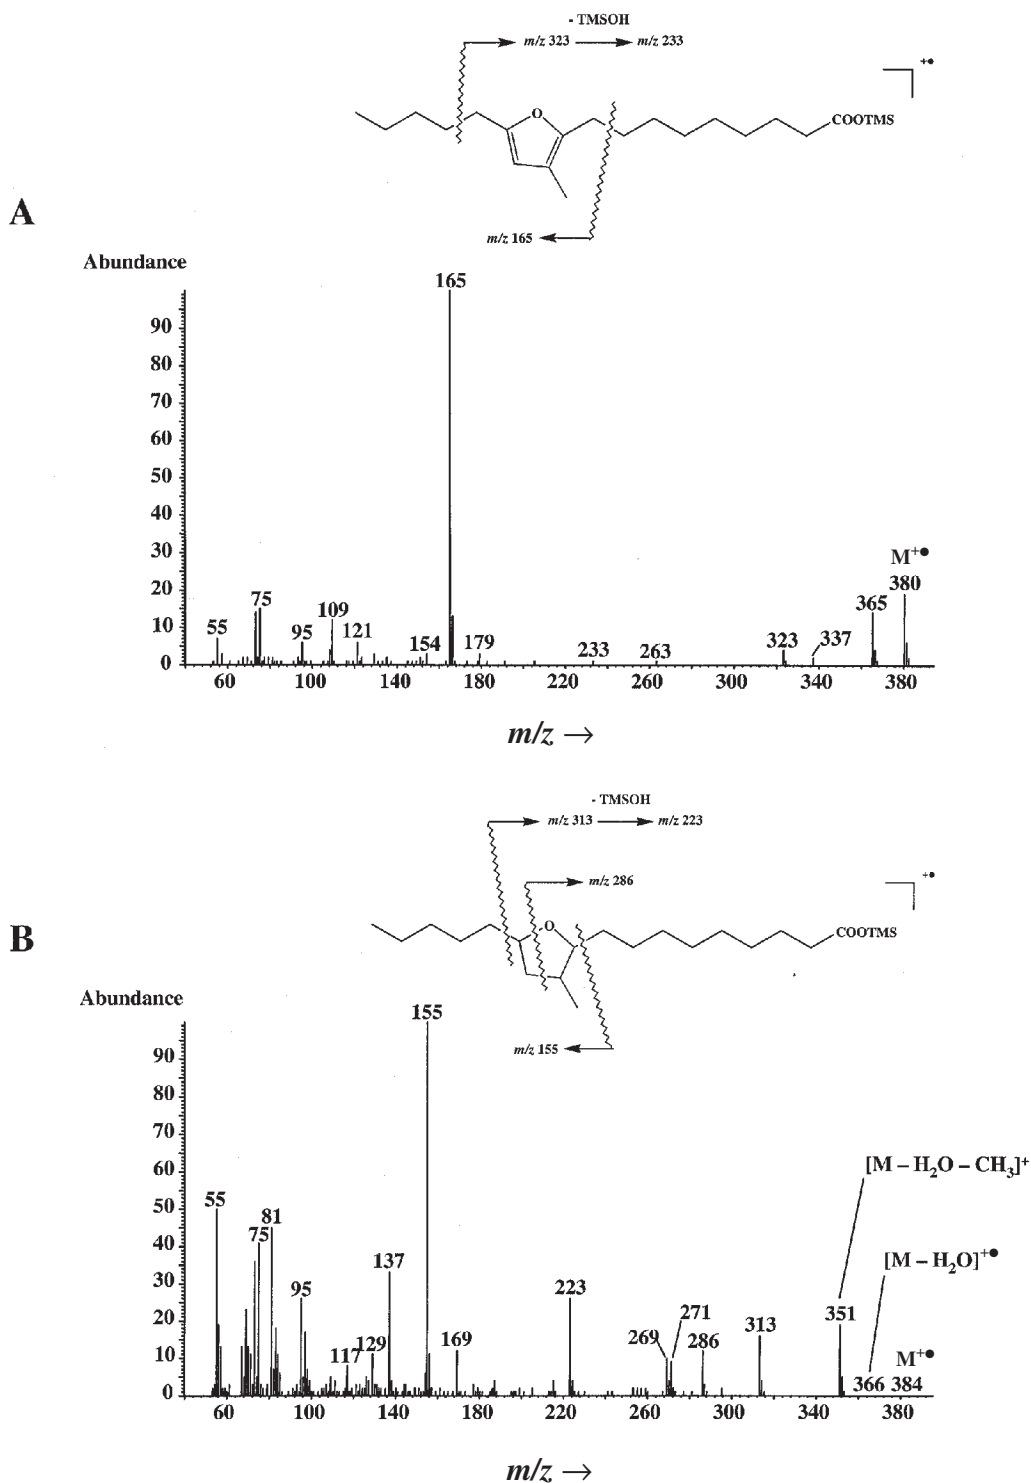
Octadeca-5,11-dienoic acid was previously found in the seed oil of some gymnosperms, e.g., *Ginkgo biloba* (30), and occasionally in sponge lipids (Christie, W.W., unpublished results), always as a minor component. To our knowledge, the presence of this unusual FA has never been reported in phytoplankton (31–34) or in anaerobic photosynthetic bacteria (35). Even though this acid was not detected in all the strains analyzed


FIG. 4. EI mass spectra of silylated 10,13-epoxy-11-methyloctadeca-10,12-dienoic (A) and 10,13-epoxy-11-methyl-octadecanoic (B) acids. For abbreviation see Figure 1.

(Table 2), it could constitute a useful indicator of the presence of AAP because of its relative abundance in these organisms.

Cyclic FA. 11,12-Methyleneoctadecanoic acid (lactobacillic acid) was detected in six strains of AAP (Table 2). A particularly high proportion was present in the strain BS110. This cyclopropane FA has been differentiated from its corresponding olefinic isomers after catalytic hydrogenation (36). The first step in the biosynthesis of the cyclopropane ring in a FA is similar to that for certain methyl-branched FA, and involves initial addition of a methyl group from *S*-adenosylmethionine to a double bond and subsequent loss of a proton. Thus, lactobacillic acid must be formed by the addition of a methylene group

across the double bond of *cis*-vaccenic acid. This acid has been found in a wide range of bacterial species of many different types, both Gram-negative and Gram-positive, from strict anaerobes to obligate aerobes.

A furan FA, 10,13-epoxy-11-methyloctadeca-10,12-dienoic acid, was detected in the strains BS110, BS36, and COL2P (Table 2). The mass spectrum of this silylated FA is shown in Figure 4A. Allylic cleavage of the alkylcarboxylic chain at the furan ring produced the base peak at *m/z* 165, whereas allylic cleavage of the alkyl chain yielded a fragment ion at *m/z* 323. The furan ring itself gave rise to a fragment ion at *m/z* 109 characteristic of trisubstituted furan acids (37). The position of the methyl group was determined after hydrogenation (in the presence of Pd as catalyst) (Fig. 4B), thanks to the THF-specific ring cleavage at *m/z* 286 enabling the unambiguous localization of the methyl substituent (38).

10,13-Epoxy-11-methyloctadeca-10,12-dienoic acid was previously detected in several strains of marine bacteria (*S. putrefasciens, Listonella anguillarum, Marinomonas communis, Pseudomonas fluorescens, Enterobacter agglomerans*) (28,37). A very interesting biosynthetic pathway of this acid starting from *cis*-vaccenic acid was proposed by Shirasaka *et al.* (28). The first step of this pathway is thought to be the formation of 11-methyloctadec-12-enoic acid through methylation of *cis*-vaccenic acid; 11-methyloctadeca-10,12-dienoic acid is then produced through desaturation. The next step involves a lipoxygenase-type oxidation, followed by ring closure. The involvement of such a process in BS110, BS36, and COL2P is well supported by the presence of relatively high proportions of 11-methyloctadec-12-enoic acid in these three strains (Table 2). However, the intermediate 11-methyloctadeca-10,12-dienoic acid, which was previously detected by Shirasaka *et al.* (28), has not been observed in these strains.
FIG. 6. Characterization of allylic hydroperoxy, hydroxy-, and oxoacids after parallel acetylation and NaBD$_4$ reduction. For abbreviation see Figure 1.

Hydroxyacids. Sphingomonadaceae are generally characterized by the presence of sphingolipids and 2-hydroxyacids and by the lack of 3-hydroxyacids (39). Indeed, all the tested *Erythrobacter-* and *Citromicrobium*-related strains belonging to the Sphingomonadaceae family contain 2-hydroxytetradecanoic, 2-hydroxypentadecanoic, and 2-hydroxyhexadecanoic acids (Table 2). The content of 2-hydroxyacids increases significantly when the acidic hydrolysis is carried out after saponification. This suggests that these compounds are components of sphingolipidic structures linked to sphingosine by amide bonds, which are only partially hydrolyzed during saponification. It is interesting to note that the hydrolysis of these amide bonds is induced during the natural senescence of AAP, when a significant increase in the 2-hydroxyacid content occurs (40).

3-Hydroxyacids were present only in *Roseobacter*-related AAP (Table 2). These compounds, which are typically produced as intermediates in the β-oxidation of monocarboxylic acids,

constitute a classical component of the cell wall lipopolysaccharides of several Gram-negative bacteria (35,41). Interestingly, the *Roseobacter*-related strains COL2P and BS110, in addition to 3-hydroxyacids, also contained 2-hydroxyacids (Table 2).

Cis and *trans* 10-hydroxyoctadec-11-enoic acids were detected in the strains MG3, BS36, and BS110 (Fig. 5, Table 2). The mass spectra of their silylated derivatives were described previously (42). They exhibited a strong fragment ion at *m/z* 213 corresponding to the cleavage at the carbon-bearing –OSiMe$_3$ group. Determination of *cis-* and *trans-*isomers was based on comparison of the retention times with standards. A similar regiospecific oxygenation of the allylic carbon 10 of *cis*-vaccenic acid has been observed previously in senescent cells of the halophilic purple sulfur bacterium *Thiohalocapsa halophila* incubated under aerobic conditions in the dark (42). This enzymatic process was attributed to the involvement of a lipoxygenase. Lipoxygenases are nonheme iron-containing dioxygenases that catalyze the addition of molecular oxygen to
FIG. 7. Proposed pathways for the enzymatic oxygenation of *cis*-vaccenic acid in the strains BS110, BS36, and MG3.

PUFA with a (*cis,cis*)-1,4-pentadiene system to give an unsaturated FA hydroperoxide (43). Lipoxygenases may also catalyze the oxygenation of monounsaturated FA such as oleic (44–47), octadec-*cis*-12-enoic (47), or *cis*-vaccenic (42) acid. These processes afford mainly hydroxy-, hydroperoxy-, or oxoacids. Lipoxygenases are widely distributed in plants, fungi, and animals (48). Recently, these enzymes were also detected in bacteria (45,49). The presence of lipoxygenase in the strains BS110 and BS36 is consistent with their relatively high content of furan FA (Table 2). The amounts of *cis* and *trans* 10-hydroxyoctadec-11-enoic acids increased considerably when the samples were reduced with NaBH$_4$ before the alkaline hydrolysis (Fig. 5). Some tests involving deuterium labeling, acetylation, and GC–MS analyses (Fig. 6) were carried out to determine whether this additional production of hydroxyacids resulted from the reduction of the corresponding hydroperoxy- or oxoacids during the treatment. The organic extracts were divided into two fractions. One part was reduced by NaBD$_4$ and saponified, whereas the other was first acetylated (to dehydrate the hydroperoxides to ketones) and then saponified. Comparison of the amounts of unlabeled hydroxyacids present after acetylation (naturally occurring hydroxyacids) and after reduction (naturally occurring + hydroperoxide reduction-derived hydroxyacids) allowed us to estimate the proportion of hydroperoxyacids and hydroxyacids present in the samples, whereas quantification of the deuterated hydroxyacids after reduction (thanks to the fragment ion at *m/z* 214) (Fig. 6) corresponded to the amount of oxoacids. The allylic oxoacids could not be characterized directly since these compounds do not survive alkaline hydrolysis and are cleaved after hydration and retro-aldol reactions (50). These tests cannot be carried out on the strain BS36 since 10-hydroxyoctadec-11-enoic acids were present in only trace amounts in this strain (Table 2). The results obtained proved that strains BS110 and MG3 contained hydroperoxyacids, oxoacids, and hydroxyacids (Table 3). The presence of significant proportions of hydroperoxides is very surprising since they are extremely cytotoxic and cause dam-

age to membranes and proteins in particular (51). Several enzymatic processes causing further reactions of the hydroperoxides and avoiding their accumulation have been described previously. These processes involve: (i) reduction to the corresponding hydroxyacids (51), (ii) homolytic cleavage of the O–O bond resulting in the formation of oxoacids (48), (iii) dehydration to allene oxides and subsequent hydrolysis of these unstable intermediates (52), and (iv) direct cleavage of the hydroperoxides to aldehydes and oxoacids (53). Only the first two degradation processes seem to act significantly in the strains BS110 and MG3. The reduction of hydroperoxyacids to the corresponding hydroxyacids is generally attributed to the lipoxygenases themselves (51), whereas the breakdown of hydroperoxyacids to oxoacids is induced by lipohydroperoxidases (48). Similar to enzymatic conversion, the hydroperoxides formed may also undergo chemical decomposition under mild conditions. The majority of these decomposition reactions involve free radicals and are promoted by heat, photolysis, metal ions, and metalloproteins. The products of these reactions are similar to those of enzymatic transformations or are either homologs or isomers of the enzymatically produced compounds (48). The quite distinct proportions of hydroperoxyacids, hydroxyacids, and oxoacids observed in the case of the

TABLE 3

cis and *trans* isomers (Table 3) allowed us to exclude the involvement of such abiotic processes during the degradation of *cis* and *trans* 10-hydroperoxyoctadec-11-enoic acid. Allylic hydroperoxides may also undergo highly stereoselective free radical allylic rearrangement (54). These processes, which can act on both *cis* and *trans* allylic hydroperoxides, afford only *trans* configurations (54). The detection of trace amounts of 12-hydroperoxyoctadec-10(*trans*)-enoic acid and its corresponding hydroxyacid and oxoacid in BS110 and MG3 strongly suggests that isomerization of 10-hydroperoxyoctadec-11(*cis*)-enoic acid results from such a rearrangement (Fig. 7).

In conclusion, the FA composition of AAP is characterized by saturated and monounsaturated FA ranging from C_{12} to C_{18} and from C_{12} to C_{19}, respectively, with *cis*-vaccenic acid as the major component. All the AAP analyzed contained the relatively rare 11-methyloctadec-12-enoic acid. This acid was previously detected in some marine bacteria (27–29). It seems to be a typical bacterial FA. The strains NAP1, AT8, and BA13 contained small amounts of the 12-methyloctadec-11-enoic acid, which apparently has never been reported before.

The presence of relatively high proportions of the octadec-5,11-dienoic acid in 9 of the 12 strains of AAP analyzed is very surprising since bacteria usually do not contain PUFA. This unusual acid could constitute a useful indicator of the presence of AAP in the marine environment.

An interesting regiospecific enzymatic peroxidation of the allylic carbon 10 of *cis*-vaccenic acid was observed in the strains BS110, BS36, and MG3. A similar oxidation process was previously described in the case of the purple sulfur bacterium *Thiohalocapsa halophila* (42) and attributed to the involvement of a lipoxygenase. This enzymatic attack of *cis*-vaccenic acid seems to be a characteristic of some (aerobic and anaerobic) phototrophic bacteria. The presence of a lipoxygenase in AAP is well supported by the detection of significant amounts of a furan FA, the 10,13-epoxy-11-methyloctadeca-10,12-dienoic acid in the strains BS110, BS36, and COL2P.

All the strains analyzed belonging to the *Erythrobacter* and *Citromicrobium* genera contained 2-hydroxyacids linked by amide bonds in sphingolipidic structures. These compounds are released during the natural senescence of these organisms. In contrast, all the *Roseobacter*-like strains contained 3-hydroxyacids.

COMMUNICATION

Preparation and Fractionation of Conjugated Trienes from α-Linolenic Acid and Their Growth-Inhibitory Effects on Human Tumor Cells and Fibroblasts

Miki Igarashi and Teruo Miyazawa*

Laboratory of Food & Biodynamic Chemistry, Graduate School of Agricultural
Science, Tohoku University, Sendai 981-8555, Japan

ABSTRACT: Conjugated α-linolenic acid (CLnA) was prepared from α-linolenic acid (9,12,15-18:3n-3, LnA) by alkaline treatment; we fractionated CLnA into three peaks by reversed-phase column-HPLC as evidenced by monitoring absorbance at 205, 235, and 268 nm. Peak I was a conjugated dienoic FA derived from LnA, whereas Peaks II and III were conjugated trienoic LnA. Proton NMR analysis showed that Peak III consisted of the all-*trans* isomer. The methylated Peak III was further divided into five peaks (Peaks IV–VIII) by silver ion column-HPLC. Peak V, a major constituent in the Peak III fraction, was identified as conjugated 10*t*,12*t*,14*t*-LnA by GC-EIMS and ^{1}H NMR analysis. Peaks III and V, which consisted of conjugated all-*trans* trienoic LnA, had stronger growth-inhibitory effects on human tumor cell lines than the other collected peaks and strongly induced lipid peroxidation as compared with Peaks I, II, and LnA. We propose that conjugated all-*trans* trienoic FA have the strongest growth-inhibitory effect among the conjugated trienoic acids and conjugated dienoic acids produced by alkaline treatment of α-LnA, and that this effect is mediated by lipid peroxidation.

Paper no. L9522 in *Lipids 40*, 109–113 (January 2005).

Conjugated FA can be prepared from nonconjugated FA by alkaline treatment (1). A conjugated FA frequently used for research is conjugated linoleic acid (CLA), which is prepared from linoleic acid (18:2n-6) or linoleic acid-rich oils such as safflower oil by alkaline treatment (2–4). We have also reported that conjugated FA can be prepared from α-linolenic acid (18:3n-3, LnA), EPA (20:5n-3), and DHA (22:6n-3) by alkaline treatment (5,6). However, alkaline treatment yields a mixture of geometrical and positional isomers (1,6). For example, alkaline treatment of linoleic acid produces mainly 9*c*,11*t*- and 10*t*,12*c*-CLA (1,2), whereas alkaline treatment of LnA produces a mixture of conjugated dienes and trienes termed conjugated α-linolenic acid (CLnA) (6,7).

CLnA, conjugated EPA, and conjugated DHA prepared by alkaline treatment are more cytotoxic against human tumor cells than their nonconjugated counterparts and CLA (6). Moreover, the conjugated FA that have an absorbance maximum at 268 nm (conjugated trienes) are more strongly cytotoxic than the conjugated FA with an absorbance maximum at 235 nm (conjugated dienes) (6) or 315 nm (conjugated tetraenes) (5). Therefore, a conjugated trienoic acid may be more cytotoxic than conjugated dienoic and tetraenoic acids prepared from the same FA.

Some reports have indicated that 10*t*,12*c*-CLA, but not 9*c*,11*t*-CLA, is the active cytotoxic compound in CLA prepared by alkaline treatment (8–10). Al-Madaney *et al.* (11) suggested that 9*c*,11*c*-CLA increases the formation of thromboxane B$_2$ compared with other CLA isomers. Thus, we proposed that the cytotoxic efficacy of CLnA, conjugated EPA, and conjugated DHA depends on their geometrical and positional chemical structures.

In this study, we investigated the geometrical and positional chemical structures of CLnA isomers after their formation by alkaline treatment and their abilities to inhibit the growth of tumor cells.

MATERIALS AND METHODS

Preparation of CLnA by alkaline treatment. LnA (10 mg; a gift from Bizen Chemical, Okayama, Japan) was added to 1 mL of 21% potassium hydroxide/ethylene glycol (KOH/EG, wt/vol) solution in a test tube (10-mL volume) (1,5,6). Nitrogen gas was bubbled into the mixture, after which the tube was sealed with a screw cap and allowed to stand for 10 min at 180°C. The reaction mixture was then cooled, and 1 mL of methanol and 2 mL of 6 N HCl were added. After dilution with 2 mL of distilled water, the conjugated FA was extracted with 5 mL of hexane. The hexane extract was washed with 3 mL of 30% methanol and 3 mL of distilled water before being dried under a nitrogen gas stream. The CLnA preparation was stored at –20°C after being purged with nitrogen gas. UV/vis spectrophotometric analysis of the conjugated FA was performed with a spectrophotometer (Shimadzu UV-2400P; Shimadzu Corporation, Kyoto, Japan). Spectrophotometric readings confirmed the formation of the conjugated FA of dienes (235 nm) and trienes (268 nm) (1,12).

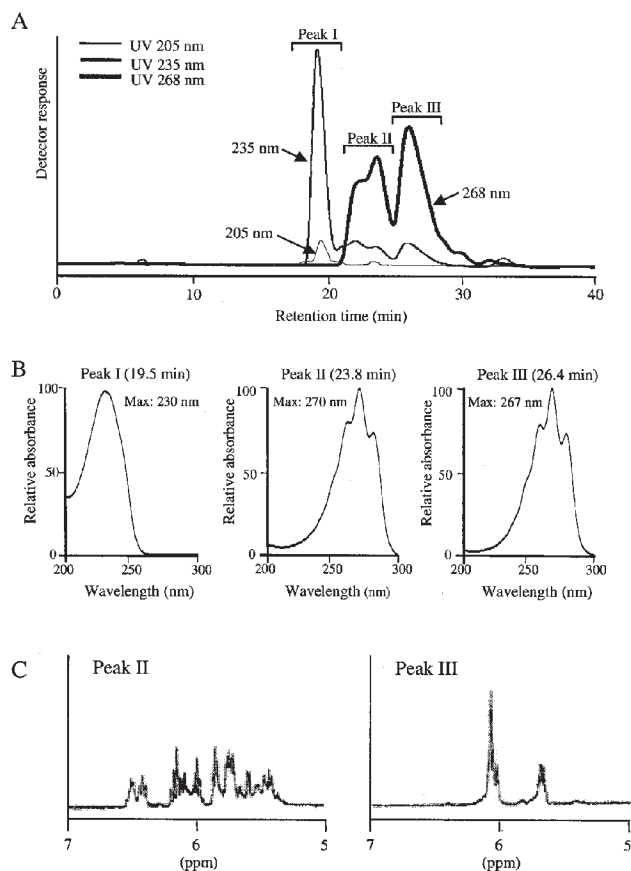
Reversed-phase column-HPLC fractionation. CLnA was dissolved in acetonitrile, and this solution was fractionated by


FIG. 1. Reversed-phase HPLC chromatogram of conjugated α-linolenic acid prepared using a 21% KOH solution for 10 min (A), UV spectra of the HPLC-separated peaks (B), and ^{1}H NMR spectra at 500 MHz of Peaks II and III (C).

reversed-phase column-HPLC using a pump (880-PU; Jasco, Inc., Tokyo, Japan) with a diode array detector (SPD-M10AVP; Shimadzu Corporation). The reversed-phase column was Inertsil ODS 10 (10 μm particle size, 4.6 × 250 mm; GL Sciences, Inc., Tokyo, Japan) fitted with a guard column containing similar ODS packing material (9.5 × 50 mm). The mobile phase was acetonitrile/water (70:30, vol/vol), and the flow rate was 1.5 mL/min. Detection was at 205 nm, 235 nm (conjugated diene), and 268 nm (conjugated triene). Typical chromatograms of CLnA and the spectra of peaks are shown in Figure 1A. Peaks I–III were collected individually and dried completely under nitrogen gas.

Silver ion column-HPLC fractionation. Peak III was methylated with 14% BF$_3$/methanol (Wako Pure Chemicals Industries, Ltd., Osaka, Japan) at room temperature for 30 min (13,14). The methylated FA was then dissolved in hexane, and this solution was fractionated using silver-ion HPLC and a diode array detector. The silver ion column-HPLC (Ag$^+$-HPLC) column was ChromSpher Lipids (5 μm particle size, 4.6 × 250 mm; Chrompack, Bridgewater, NJ). The mobile phase was hexane/acetonitrile (100:0.15, vol/vol), and the flow rate was 1.0 mL/min. Detection was at 268 nm (conjugated triene). A typical

chromatogram is shown in Figure 2A. Peaks IV–VIII were collected and dried completely under nitrogen gas.

GC-EIMS. The FAME fractions IV to VIII were hydrolyzed to their FFA with a 0.2 N KOH solution at 40°C for 90 min. The FA were then converted to 4,4-dimethyloxazoline (DMOX) derivatives (15). The GC-EIMS analysis was performed as described previously (4).

NMR spectroscopy. The FFA were dissolved in acetonitrile-d_3 (ICN Pharmaceuticals, Inc., Costa Mesa, CA) at a concentration of 1.0 mg/mL. Proton NMR (^{1}H NMR) spectroscopy was performed on a Varian Unity INOVA 500 (500 MHz) (Varian, Inc., Palo Alto, CA).

Cell cultures. Human tumor cells (DLD-1, HepG2, A549, MCF-7, and MKN-7) were obtained from the Cell Resource Center for Biochemical Research at Tohoku University (Sendai, Japan). Human fibroblasts (MRC-5, TIG-103, and KMS-6) were purchased from the Human Science Research Resources Bank (Osaka, Japan). The cells were cultured as described previously (5,6).

MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] dye reduction assay. To examine the growth-inhibitory effect of conjugated FA on human tumor cells and fibroblasts, we performed the MTT dye reduction assay (5,6). Briefly, stock solutions of FA were prepared in ethanol at a concentration of 25 mM. The FA were diluted to the final concentrations of 25 μM in RPMI 1640 (for tumor cells; Sigma, St. Louis, MO) or MEM (for fibroblasts; Sigma) supplemented with 0.5% BSA (these served as the test media). Control cells were exposed to test medium supplemented with 0.1% ethanol. The α- and β-eleostearic acids used were purified from tung oil by reversed-phase column-HPLC (4).

Determination of TBARS. The semiconfluent cells seeded in a 60-mm diameter dish were cultured in test media containing FA. After incubation for 24 h, DLD-1 cells were assayed for the amount of TBARS as a conventional index for lipid peroxidation according to the method of Gavino *et al.* (16).

Statistical analysis. Statistical comparisons among several groups were made using one-way ANOVA, followed by the Newman–Keuls test for multiple comparisons among the groups. The Student's *t*-test was used for comparisons between two groups. Differences were considered significant at $P < 0.05$.

RESULTS AND DISCUSSION

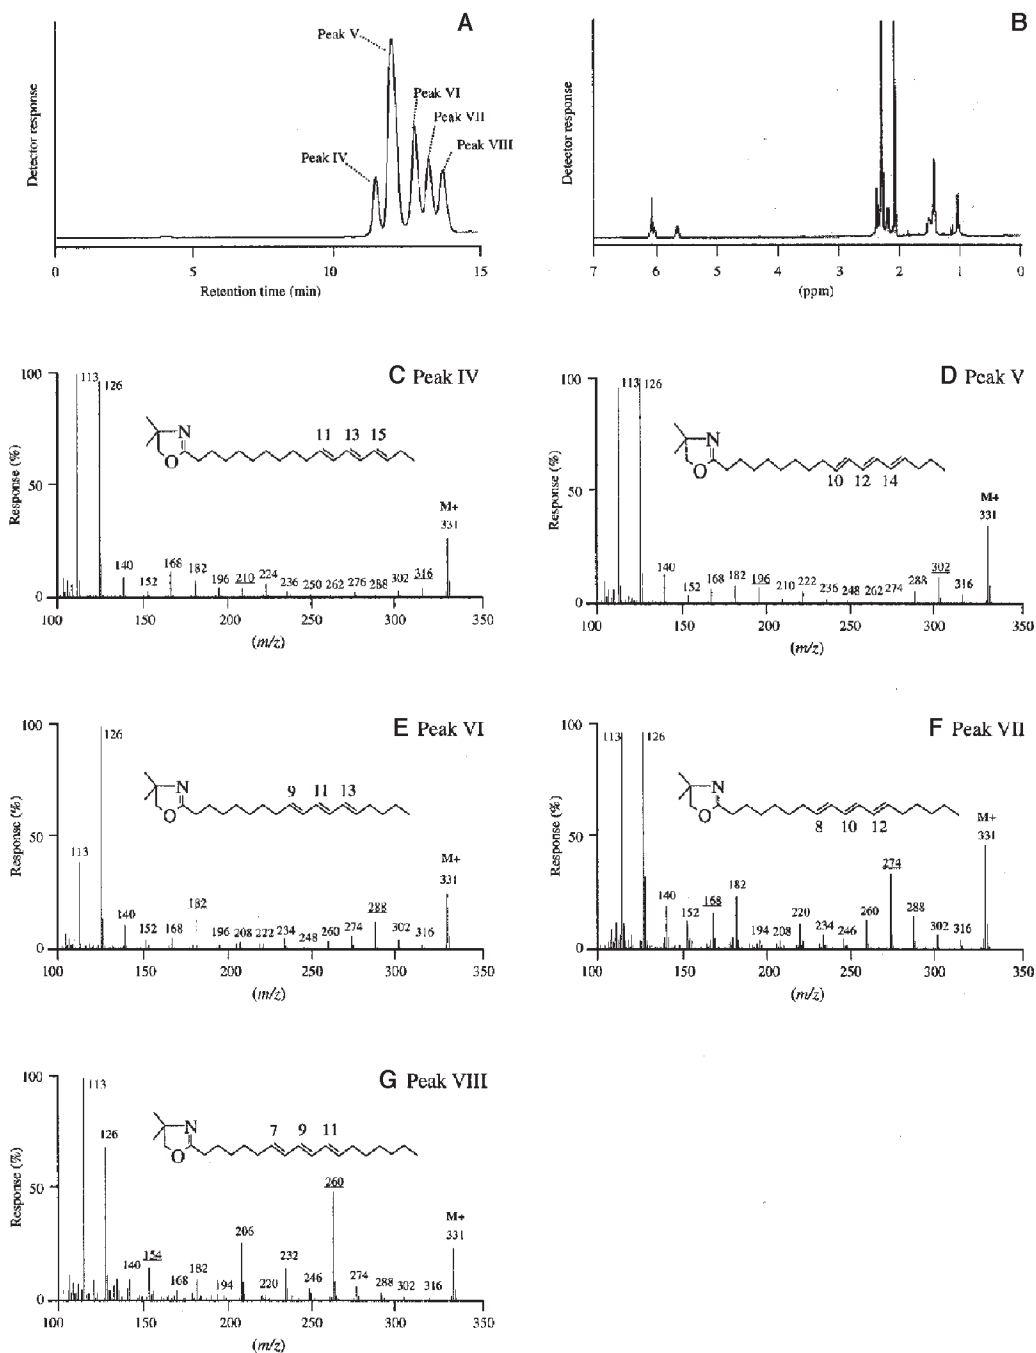
CLnA prepared by alkaline treatment was separated into three peaks by reversed-phase column-HPLC with monitoring at 205, 235, and 268 nm. The chromatogram is shown in Figure 1A; the retention times for Peaks I, II, and III were at 19.5, 23.8, and 26.4 min, respectively. These peaks showed maximal absorption at 230, 270, and 267 nm, respectively (Fig. 1B). These results suggest that Peak I contains conjugated dienoic LnA (LnA, which is monoconjugated plus one isolated double bond), whereas Peaks II and III consist of conjugated trienoic LnA. From the 10 mg LnA initially used for alkaline isomerization, 70% was converted to conjugated FA (6). The yield for Peaks I, II, and III was 2.1, 2.3, and 2.0 mg, respectively. The ^{1}H NMR signals arising from


FIG. 2. Ag⁺-HPLC chromatogram of methylated Peak III (A), ¹H NMR spectrum at 500 MHz of Peak V (B), and GC-EIMS spectra of the 4,4-dimethyloxazoline derivatives of Peaks IV (C), V (D), VI (E), VII (F), and VIII (G). Allylic cleavage fragments are underlined.

Peaks II and III were also examined. The olefinic proton signal (5.5–6.5 ppm) reveals the geometrical configuration of the conjugated double bond. On the basis of comparison with the spectra of commercial α- and β-eleostearic acids (data not shown; Larodan Fine Chemicals AB, Malmo, Sweden), and of previous reports (17,18), it appears Peak III was composed of all-*trans*

isomers (Fig. 1C) whereas Peak II consisted of several *trans* and *cis* isomers (mono-*cis*, di-*trans* CLnA; di-*cis*, mono-*trans* CLnA; and all-*cis* CLnA) (Fig. 1C).

Methylated Peak III (which consists of all-*trans* isomers, as determined by ¹H NMR) was separated into five peaks by Ag⁺-HPLC by monitoring the eluate at 265 nm. The fractions were:

[c]MRC-5, male lung (JCRB0521; TIG-103, female skin (JCRB0528); KMS-6 female embryonal (JCRB0432).
[d]CLnA, conjugated α-linolenic acid prepared with 21% KOH solution for 10 min.
[e]ESA, eleostearic acid.

Peak IV 9.1%, Peak V 45.1%, Peak VI 17.9%, Peak VII 16.3%, Peak VIII 11.6% (Fig. 2A). After the fractionation, each peak was hydrolyzed to their FFA. Peak V consisted of 0.8 mg obtained from the original starting material of 10 mg LnA. The DMOX derivatives of each of the five peaks were similarly prepared and analyzed by GC-EIMS (4,15). Figure 2D shows the GC-EIMS spectra of the DMOX derivative of Peak V. The spectrum exhibited a molecular ion at m/z 331, and allylic cleavages of the fatty acyl chain at m/z 196 and 302. The mass spectrum exhibited mass differences of 12 mass units between m/z 210 and 222, between m/z 236 and 248, and between m/z 262 and 274, indicating that this was a conjugated triene (Fig. 2D). Peak V was consistent with the structure 10t,12t,14t-CLnA (Fig. 2D). The structural confirmation of all the other peaks was determined in the same way. Peaks IV, VI, VII, and VIII were therefore assigned the structures 11t,13t,15t-CLnA (Fig. 2C), 9t,11t,13t-CLnA (Fig. 2E), 8t,10t,12t-CLnA (Fig. 2F), and 7t,9t,11t-CLnA (Fig. 2G), respectively. Spitzer *et al.* (7) previously reported that 10,12,14-CLnA and 9,11,13-CLnA were detected when CLnA was prepared with a 6.5% KOH/EG solution.

We examined the growth-inhibitory effects of each peak that had been collected by reversed-phase column-HPLC and Ag⁺-HPLC on five human tumor cell lines (DLD-1, HepG2, A549, MCF-7, and MKN-7) and three human fibroblast lines (TIG-103, MRC-5 and KMS-6) (Table 1). At a concentration of 25 μM, Peak III (all-*trans* conjugated triene) had the strongest growth-inhibitory effect on tumor cell lines compared with Peaks I and II. The growth-inhibitory effect of Peak III on DLD-1 was shown to be dose- (data not shown; 0–100 μM) and time-dependent (data not shown; from 0 to 24 h). Thus, the all-*trans* conjugated trienoic FA appears to have a strong growth-inhibitory effect on human tumor cell lines. The growth-inhibitory effect of Peak V (10t,12t,14t-CLnA) on DLD-1 was at the same level as that of Peak III, and was stronger than that of β-eleostearic acid (9t,11t,13t-octadecatrienoic acid purified from tung oil). Moreover, β-eleostearic

acid had a higher growth-inhibitory effect compared with α-eleostearic acid (9c,11t,13t-octadecatrienoic acid purified from tung oil). It was shown previously that 10t,12c-CLA is the active CLA isomer rather than 9c,11t-CLA (8–10). Thus, the differences in the growth-inhibitory effects of conjugated trienoic acids appear to be related to specific geometric and positional isomers. The all-*trans* conjugated trienoic acids we tested (Peak III and β-eleostearic acid) also showed growth-inhibitory effects in human fibroblasts.

We previously reported that conjugated EPA and DHA induce apoptosis *via* lipid peroxidation (5). We thus tested the ability of the different isolated conjugated FA to induce lipid peroxidation by assaying for TBARS levels. The level of TBARS for Peak V (10t,12t,14t-CLnA) in the culture was greater compared with Peaks I–III after 24 h incubation (Fig. 3). Moreover, β-eleostearic acid induced more lipid peroxidation than α-eleostearic acid (Fig. 3). These results suggest that
FIG. 3. TBARS formation in DLD-1 cells supplemented with conjugated α-linolenic acids. DLD-1 cells were incubated for 24 h with 25 μM of each FA. Values not sharing a common superscript letter (a–e) are significantly different by the Newman–Keuls test. *, $P < 0.05$ by Student's t-test. Values shown are the mean ± SE ($n = 4$ or 5). (1) Control; (2) α-linolenic acid; (3) conjugated α-linolenic acid prepared with alkaline solution; (4) Peak I; (5) Peak II; (6) Peak III; (7) Peak V; (8), α-eleostearic acid; (9) β-eleostearic acid.

all-*trans* trienoic CLnA induces lipid peroxidation compared with the other geometrical isomers, and that CLnA generated by alkaline treatment induces lipid peroxidation, which ultimately inhibits cell growth.

Recently, we reported that tung oil, which is rich in α-eleostearic acid, lacked toxicity and was better at decreasing tumor tissue weight in DLD-1-transplanted mice than CLA (17). This suggests that conjugated trienoic acid, especially conjugated all-*trans* isomers, may be developed into anticancer drugs of broad utility.

n-3 Fatty Acid Enrichment of Edible Tissue of Poultry: A Review

C. Rymer* and D.I. Givens

Nutritional Sciences Research Unit, Department of Agriculture, University of Reading, Reading, RG6 6AR, United Kingdom

ABSTRACT: There is clear evidence of the nutritional benefits of consuming long-chain n-3 PUFA, which are found predominantly in oily fish. However, oily fish consumption, particularly in the United Kingdom, is declining, as is the consumption of all meats with the exception of poultry, which has increased in consumption by 73% in the last 30 yr. This pattern, if less marked, is reflected throughout Europe, and therefore one means of increasing long-chain n-3 PUFA consumption would be to increase the long-chain n-3 PUFA content in the edible tissues of poultry. This review considers the feasibility of doing this, concentrating particularly on chickens and turkeys. It begins by summarizing the benefits to human health of consuming greater quantities of n-3 FA and the sources of n-3 PUFA in the human diet. The literature on altering the FA composition of poultry meat is then reviewed, and the factors affecting the incorporation of n-3 PUFA into edible tissues of poultry are investigated. The concentration of α-linolenic acid (ALA) in the edible tissues of poultry is readily increased by increasing the concentration of ALA in the birds' diet (particularly meat with skin, and dark meat to a greater extent than white meat). The concentration of EPA in both white and dark meat is also increased when the birds' diet is supplemented with EPA, although supplementing the diet with the precursor (ALA) does not result in a noticeable increase in EPA content in the edible tissues. Although supplementing the birds' diets with relatively high concentrations of DHA does result in an increased concentration of DHA in the tissues, the relationship between dietary and tissue concentrations of DHA is much weaker than that observed with ALA and EPA. The impact that altering the FA composition of edible poultry tissue may have on the organoleptic and storage qualities of poultry products is also considered.

Paper no. L9582 in *Lipids 40*, 121–130 (February 2005).

The role of n-3 FA in the prevention of coronary heart disease and, in the case of 22:6n-3 (DHA), as a vital component in the retina and the membrane phospholipids of the brain is well established. Emken and his colleagues (1) demonstrated that 20:5n-3 (EPA) and DHA can be produced in humans by the sequential elongation and desaturation of 18:3n-3 (α-linolenic acid, ALA), but the rates of these conversions are low (1–3) and appear to be more limited in young men than young women (4–7), suggesting that DHA synthesis may be up-regulated in situations where there may be a greater demand for DHA, such as to meet the possible needs of a fetus or neonate. It has been suggested that this poor conversion of ALA to DHA is the result of an ancient diet that was rich in DHA, which reduced an evolutionary need to maintain an active conversion apparatus (8). Infants are able to convert ALA to DHA (9–11), but the requirements for DHA in the neonate are extremely high. A review by Salem *et al.* in 2001 (12) concluded (on the evidence of brain and retinal function in preterm and term infants fed either breast milk or formula that was supplemented or otherwise with long-chain PUFA) that it would be prudent to ensure preformed DHA was included in the infant diet.

In the adult, the conversion of ALA to DHA may not meet the long-term demand for DHA in diabetics, as the activity of Δ-5 and Δ-6 desaturases is reduced in the diabetic state (13). Alcohol also inhibits the activity of Δ-5 and Δ-6 desaturase and reduces the concentration of long-chain n-3 PUFA in the tissues (14). The competition for Δ6 desaturase in the conversion of ALA to 18:4n-3 and 18:2n-6 (linoleic acid, LA) to 18:3n-6 (γ-linolenic acid) means that diets with high n-6 FA contents can reduce n-3 FA conversion by as much as 40% (1). Since Western diets typically have a high ratio of n-6/n-3 FA, the conversion of ALA to DHA is likely to be compromised. The need for an adequate intake of ALA, with an appropriate balance of n-6/n-3 FA, is therefore well recognized, and the inclusion of preformed DHA in circumstances where the conversion of ALA to DHA may be insufficient is acknowledged.

SOURCES OF N-3 PUFA

ALA is found in certain seed oils (such as linseed and canola) and green vegetables. Dietary sources of both EPA and DHA are confined almost entirely to fish products. Adequate intakes of EPA and DHA may be achieved by consuming two portions of fish each week, and of these portions one should be of oily fish (15). However, fish consumption in the United Kingdom is very low, as is the proportion of the population that eat fish (16), and this pattern is reflected throughout northern Europe. Clearly, other sources of n-3 PUFA need to be developed if the northern European population is to achieve the recommended intakes of these EFA. One approach is to incorporate microencapsulated n-3 PUFA into "standard" foods. The other is to alter the FA composition of foods that make a significant contribution to fat intake. A survey of European diets revealed that 26% of total fat intake came from dairy products, and meat and meat products accounted for 21% (17). A review of experiments that investigated the potential of enhancing the EPA and DHA content of bovine milk by altering the cow's diet con-

Abbreviations: ALA, α-linolenic acid; LA, linoleic acid; PI, peroxidizability index.

cluded that this approach had only limited success (18), but there may be possible advantages to increasing the n-3 PUFA content of meat. Poultry meat accounts for 41% of the consumption of meat and meat products in the United Kingdom (19) and so is potentially a valuable route for increasing the intake of long-chain n-3 PUFA. The objective of this review is to consider the factors that affect the efficiency with which dietary n-3 PUFA is incorporated into the edible tissues of poultry.

POULTRY AS A SOURCE OF N-3 PUFA

Compared with mammals, the n-3 PUFA content of skeletal muscle in birds is lower and that of n-6 higher (20), and when birds are fed typical diets, the concentrations of n-3 PUFA in their edible tissues are relatively low (21). Of the n-3 PUFA that are present, ALA is concentrated in the TAG fraction, whereas EPA and DHA are more prevalent in the phospholipid fraction (21). White (breast) meat is the most popular poultry meat, but although its lipids are rich in phospholipids, and so relatively rich in EPA and DHA, dark (leg) meat and skin are the richest sources of all n-3 FA because of the higher lipid content of these tissues (Table 1).

In a study of nine species of birds (fed different diets and managed independently), the concentration of DHA in skeletal muscle phospholipids was negatively related to body size (20). It was suggested that smaller species of birds, with their higher metabolic rates, required higher concentrations of DHA to help maintain sodium and calcium pumps. This might suggest that, when fed similar diets, turkeys would have a lower DHA content in their edible tissues than would broilers.

No direct comparisons between chickens and turkeys of the n-3 PUFA content of their edible tissues could be found in the literature. However, two studies (22,23) in which similar diets were fed estimated the n-3 PUFA content of edible tissues in chickens and turkeys, respectively. In these studies, n-3 PUFA-rich oils were added to the birds' diets, but the results summarized in Table 2 relate to the control diets. However, even in

these diets, fishmeal was added as a protein source (as is widely done in the industry), and this feedstuff would also supply some n-3 PUFA to the birds' diets. It is clear from these data that dark meat is a richer source of ALA than is white meat, although there is little difference between the white and dark meats in terms of their longer-chain n-3 PUFA contents. Turkeys appear to be a richer source of ALA than chickens, and females had a higher ALA content in their meat than did males. The long-chain n-3 PUFA content of chicken meat (white or dark) and turkey white meat was similar, despite the higher fishmeal content of the turkeys' diet (49.5 g/kg fishmeal vs. 40 g/kg redfish meal for the broilers). This observation may support the notion that smaller birds have inherently higher DHA contents in their muscles than do larger birds (20). However, the turkey dark meat had a much higher long-chain n-3 PUFA and ALA content than did the other tissues. This partly reflects the higher lipid content of dark meat compared with white meat, and the high long-chain n-3 PUFA content of turkey dark meat may also be a result of the higher fishmeal content of the turkeys' diet compared with the broilers' diet. Clearly this area requires further research.

ENHANCEMENT OF N-3 PUFA CONTENT OF POULTRY MEAT

The FA composition of both pigs and poultry can in theory be relatively easily modified by dietary means. As early as 1963, it was noted that the FA compositions of broilers' breast, thigh, and skin tissues were similar to those of the broilers' diet (24), and in the 1960s Neudoerffer and Lea demonstrated that feeding fish oil to turkeys increased the concentrations of EPA and DHA in the depot fat (25) and muscle lipids (26) of the turkeys. Consequently, it is possible to increase the proportion of n-3 PUFA substantially in both eggs and the edible tissues of pigs and poultry (21,27–30). Much work has been done to enhance the n-3 PUFA content of poultry meat by dietary means, and this can result in nutritionally meaningful intakes of n-3 PUFA

TABLE 1
Lipid Content and Composition, and FA Composition of Different Edible Tissues in Poultry Fed a Standard Diet[a]

by people who consume these products (31). There are some drawbacks to this practice, most notably the reduced shelf life of the products (29,32), and the negative effect that n-3 PUFA enrichment appears to have on the organoleptic qualities of poultry meat (21,26,27,33).

It is relatively easy to measurably increase the ALA content of poultry meat by supplementing the diet with feeds rich in ALA. Such feeds typically include oilseeds such as linseed or canola. As ALA is associated more with the TAG rather than the phospholipids, most of the ALA that is found in edible tissues accumulates in the dark meat and skin. A number of authors have reported the proportionate response of increased ALA content in edible tissues to increasing dietary concentrations of ALA (22,23,31–44). These data are presented in Figure 1 to illustrate the responses observed across a range of different experiments, and also analyzed by linear regression; the relationships that were observed are summarized in Table 3 and illustrated in Figure 1.

The response of the ALA content of skinless white meat (in turkeys or broilers) to increasing dietary ALA concentration is poor. However, strong relationships were observed between dietary ALA content and the ALA content of meat with skin, be it white or dark. The response of the ALA content of skinless dark meat (both in turkeys and broilers) to increasing dietary ALA content was intermediate. This is understandable, as it is the skin and to a lesser extent the dark meat that has the highest lipid content and the greater proportion of TAG (in which ALA accumulates). These therefore are the tissues that respond most to increased dietary ALA with an increased tissue concentration of ALA. Most of the data in Figure 1 were collected from experiments on broilers, and so although the regression coefficients between dietary ALA content and turkey tissue ALA content are high (0.986–0.993), these are primarily a reflection of the very few, but well spaced, data points that were included in the regressions. A much more rigorous comparison is needed to determine whether real differences exist between broilers and turkeys in terms of their response to increasing dietary ALA concentrations.

One of the few direct comparisons between turkeys and chickens found that young (between 1 and 3 wk of age) turkeys were more efficient at digesting saturated fats than were young chickens (45). This difference between the two species disappeared at 3 wk of age, and there was much less of a difference when unsaturated lipids were fed. The digestibility of dietary lipids that are designed to enhance the n-3 PUFA content of the meat is therefore not likely to be significantly different between finishing turkeys and chickens.

No difference between different breeds or sexes of chicken in their response to dietary PUFA was identified (21,31). Very few data in Figure 1 were collected from male broilers, as birds were either analyzed as a mixed sex group, or females were used instead. However, the data in Figure 2 have been segregated into male and female broilers to illustrate the response in dark meat ALA concentration to increasing dietary ALA concentration. Although the regression slope with the male birds appears slightly steeper than that of the females, the confidence intervals of the two coefficients overlap and there is no evidence of any difference between the sexes in
FIG. 1. Effect of increasing dietary concentrations of α-linolenic acid (ALA) on the concentration of ALA in the edible tissues of poultry meat. Line 5, (○) skinless, white broiler meat ($R^2 = 0.309$); Line 4, (●) skinless dark broiler meat ($R^2 = 0.772$); Line 2, (□) white broiler meat with skin ($R^2 = 0.995$); Line 1, (■) dark broiler meat with skin ($R^2 = 0.963$); Line 6, (△) white (skinless) turkey meat ($R^2 = 0.986$); Line 3, (▲) dark (skinless) turkey meat ($R^2 = 0.993$).

terms of their response. This may be a reflection of the physiological immaturity of broilers when they are slaughtered, and it is possible that the adult birds might show a sex difference in their response to dietary ALA. However, since the vast majority of table chickens are slaughtered before they reach puberty, any such differences are unlikely to be of practical importance.

The source of ALA may affect the efficiency with which it is incorporated into body tissues, perhaps because of the presence of other antinutritional factors in the oil's source, or the interaction with other nutrients in the diet. A number of confounding factors in the responses to increasing dietary ALA content with different ALA sources are illustrated in Figure 3 and summarized in Table 4. However, one can see that there is no real relationship between dietary and tissue ALA concentration when fish oil is fed, mainly because of the very low ALA content of fish oil. The data do show that the richest source of dietary ALA, and therefore the most effective means of increasing the ALA content of edible poultry tissues, is linseed oil. From these data, there is no clear evidence of oil source affecting the efficiency with which ALA is incorporated into body tissue. Data presented by Ajuyah *et al.* (34), however, do show that the physical form in which the oil is presented may affect the tissue ALA content of birds that consume the oil. These authors observed that feeding a reconstituted mixture of the extracted oilseed meal and free oil resulted in significantly higher ALA contents in both white and dark meat for linseed, but there was no significant difference with canola. These results illustrate that the efficiency with which dietary ALA is transferred from the diet to the edible tissues of poultry is affected by the digestibility of the feed. Certain oilseeds (for example, linseed, but not apparently canola) require some processing to ensure that broilers consuming the seed are able to digest and absorb the oil supplied.

EPA

There is a generally linear relationship between the concentration of EPA in the diet and the EPA content of edible tissues (Fig. 4), although there is considerable variation in the response
FIG. 2. The effect of broiler sex on the ALA content of dark meat in response to increasing dietary concentrations of ALA. (—) (●) Male (R^2 = 0.971, slope = 0.133 ± 0.0094); (----); (○) female (R^2 = 0.819, slope = 0.112 ± 0.0108). For abbreviation see Figure 1.
FIG. 3. The effect of different oil sources on the relationship between increasing dietary ALA concentration and the concentration of ALA in the dark meat of broilers. (●) Fish oil, R^2 = 0.102; (■) linseed oil, R^2 = 0.674; (○) canola oil, R^2 = 0.315.

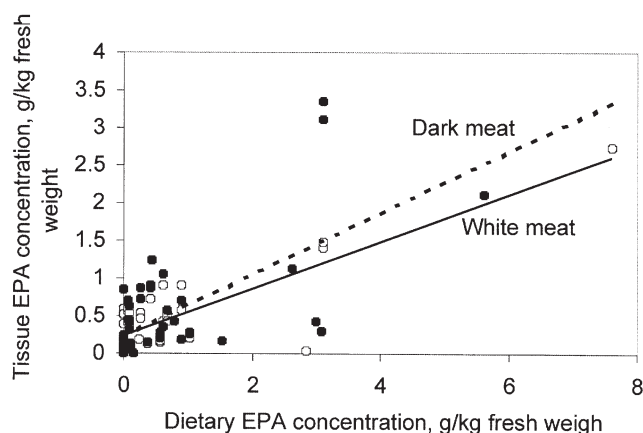
[a]For abbreviation see Table 1.

with low dietary EPA contents. The two data points that indicate a very high response to dietary EPA content are from Komprda *et al*. (23) where EPA and DHA were not distinguished from each other, and these points therefore illustrate the tissue response in terms of total EPA + DHA concentration. Much of the tissue EPA content in these instances could therefore in fact be DHA. No clear distinctions could be made between meat with and without skin, but this was mostly because of insufficient data ($n = 4$ for white meat with skin). However, since EPA is concentrated in the phospholipids and the skin lipids are predominantly TAG, the contribution that skin would make to the EPA content of edible tissues would be small. This is in contrast to what was observed with ALA, because of the accumulation of ALA that occurs in TAG. There was also no marked difference between white and dark meats in their EPA content, suggesting that white meat (the more popular of the two) is as good a source of EPA as is dark meat.


The relationship between dietary and tissue EPA content is described by Equations 1 and 2:

$$[EPA]_{white\ meat} = 0.219 + 0.311[EPA]_{diet} \qquad [1]$$

$R^2 = 0.671$, $s = 0.284$, $P = 0.000$; and

$$[EPA]_{dark\ meat} = 0.231 + 0.408[EPA]_{diet} \qquad [2]$$

$R^2 = 0.448$, $s = 0.497$, $P = 0.000$, where $[EPA]_{white\ meat}$, $[EPA]_{dark\ meat}$, $[EPA]_{diet}$ are the concentrations (g/kg fresh

weight) of EPA in the white meat, dark meat, and diet, respectively.

EPA in the tissues may come from either the direct incorporation of dietary EPA or the conversion of dietary ALA to EPA by the bird. When the diet is supplemented with terrestrial sources of n-3 PUFA, this is the only means by which EPA may accumulate in the tissues, since the EPA content of terrestrial plant oils is negligible. In Figure 5, the concentration of dietary ALA has been plotted against tissue EPA concentration. There is at best a very weak relationship between dietary ALA content and tissue EPA content, illustrating that supplementing the poultry diet with ALA (the potential precursor of EPA) does not enhance the EPA content of edible poultry tissues to any nutritionally meaningful extent (23,27,28,42,44). There is evidence that dietary ALA supplementation does result in conversion of ALA to EPA by the bird, but the EPA that is synthesized accumulates in the liver rather than the edible tissues (46). There were relatively high concentrations of EPA with some diets that had very low ALA contents (Fig. 5), because of the inclusion of fishmeal as a protein source in these diets, which would also supply a dietary source of EPA.

DHA

The increase in the DHA content of poultry lipids, particularly in breast muscle, following the addition of fish oils or marine algae to poultry diets is well established (21,22,25–27,29,41,43,47). However, the clear linear relationship between the n-3 FA concentration in the diet and the corresponding n-3 FA content of edible tissues that was observed with ALA and EPA is not evident for DHA (Fig. 6). Relatively high
FIG. 4. Relationship between the concentration of EPA in the diet and the concentration of EPA in the edible tissues of poultry meat. (○—) White meat, $R^2 = 0.671$; (●----) dark meat, $R^2 = 0.448$.

FIG. 5. Relationship between ALA concentration in the diet and EPA content in the edible tissues of poultry. (○) White meat, $R^2 = 0.0002$; (●) dark meat, $R^2 = 0.010$.
FIG. 6. Relationship between DHA concentration in the diet and DHA content in the edible tissues of poultry. (○—) White meat, $R^2 = 0.093$; (●----) dark meat, $R^2 = 0.143$.

intakes of DHA (achieved by high inclusion rates of fish oil or fishmeal) show a more obvious relationship (Fig. 7), but the regression statistics for these relationships are much weaker than the corresponding relationships observed for EPA. The equations describing the relationships between DHA content in the diet and in white and dark meat are as follows:

$$[DHA]_{white\ meat} = 0.420 + 0.173[DHA]_{diet} \qquad [3]$$

$R^2 = 0.158$, $s = 0.6558$, $P = 0.179$, and

$$[DHA]_{dark\ meat} = 0.442 + 0.109[DHA]_{diet} \qquad [4]$$

$R^2 = 0.344$, $s = 0.288$, $P = 0.017$, where $[DHA]_{white\ meat}$, $[DHA]_{dark\ meat}$, and $[DHA]_{diet}$ are the concentrations (g/kg fresh weight) of DHA in the white meat, dark meat, and diet respectively.

It is evident from Figure 6 that, even when the diet contains little or no DHA, some DHA is to be found in the edible tissues of poultry (albeit at very low concentrations), and more would

FIG. 7. Relationship between DHA concentration in the diet and DHA content in the edible tissues of poultry when the diets are supplemented with marine oils or meals. (○—) White meat, $R^2 = 0.158$; (●----) dark meat, $R^2 = 0.344$.

be found in their brain and nervous system. Birds are able to synthesize DHA, but increasing the supply of substrate (ALA) by increasing the ALA content of the diet clearly does not result in an increase in the DHA content of the edible tissues (Fig. 8). Indeed, it would almost appear that high ALA concentrations in the diet reduce the accumulation of DHA in the tissues. This lack of relationship between ALA intake and edible tissue DHA content may be because the DHA that is synthesized is not then partitioned to skeletal muscle (42), being accumulated in the liver instead (46); or it could be that, as in the human, an increase in ALA supply does not result in an increase in DHA synthesis but rather an increase in β-oxidation of ALA (48) or an accumulation of ALA in the tissues (49). In conclusion, it is evident that dietary modifications can increase the DHA content of the edible tissues of poultry, but the magnitude of the response and the factors that affect that response are unclear.

OXIDATIVE STABILITY AND ORGANOLEPTIC QUALITY OF N-3 PUFA-ENRICHED POULTRY MEAT

Unsaturated lipids readily undergo oxidation to produce peroxides and aldehydes that are responsible for the reduction in storage quality that is often associated with poultry meat with an enhanced PUFA content (21,29). The oxidative stability of unsaturated lipids decreases as their degree of unsaturation increases, and so poultry meat with an enhanced ALA content will be more susceptible to oxidation than poultry meat with a similar concentration of LA. The peroxidizability index (PI) of a lipid reflects the relative rate of peroxidation of each FA (50), and is calculated from Equation 5 (51):

$$PI = (\%monoenoic \times 0.025) + (\%dienoic \times 1) + (\%trienoic \times 2) + (\%tetraenoic \times 4) + (\%pentaenoic \times 6) + (\%hexaenoic \times 8) \quad [5]$$

From this equation, it is clear that poultry meat with a higher concentration of ALA compared with LA will be more susceptible to oxidation, and also that poultry meat with an enhanced concentration of EPA and DHA will be particularly susceptible to oxidative damage. The balance of volatile compounds pro-

duced from the oxidative breakdown of n-3 FA produces the fishy aroma and off-taste that is characteristic of meat from poultry that have been fed n-3 FA (26,50,52), although if the oxidation process can be limited or halted then the meat should remain acceptable for human consumption. Indeed, Moran (53) concluded from his review of the literature that the FA composition of fat in lean tissue had minimal effect on the organoleptic qualities of meat once peroxidation products had been eliminated.

Synthetic antioxidants such as BHA or BHT that may be added to the diet can help prevent oxidation of unsaturated dietary lipids, at least prior to consumption. Small amounts of these antioxidants may then be found in the birds' tissues (54), which may then reduce the rate of oxidation of the lipid in the meat (54,55). At lower inclusion rates of BHT, however (0.05 g/kg compared with 0.8 g/kg), the protective action of dietary BHT did not extend to the meat (37). The use of α-tocopherol as an antioxidant is effective at reducing the oxidation of unsaturated lipids in meat, thereby preventing or delaying the onset of off-flavors (32,52), and it appears that there is a concerted action in the tissues to protect n-3 PUFA, with α-tocopherol being an excellent protector of these FA (56). Supplementing birds' diets with α-tocopherol (beyond their nutritional requirements) does appear to be an effective means of increasing the oxidative stability and organoleptic acceptability of poultry meat with enhanced concentrations of n-3 PUFA (32,52,56).

Meat from poultry fed oxidized oils (as a result of heat treatment or other spoilage) appears to be particularly susceptible to oxidation (37,54), but it is not clear from the literature whether this is because of an increased consumption of peroxides and other oxidation markers, which then increase the rate of peroxidation of PUFA in meat tissue (and deplete the stores of α-tocopherol and other antioxidants), or whether heated oils that are incorporated into muscle tissue are more prone to oxidation than fresh oils. Supplementing diets containing oxidized oils with α-tocopherol reduced the rate of oxidation of the meat (37,52). However it is clearly preferable to ensure when feeding lipids with a high PI (as is the case when trying to increase the concentration of ALA, EPA, or DHA in poultry meat) that the dietary lipids used have not been subjected to heating or other pro-oxidative processes, while also ensuring that the birds' diet is supplemented with α-tocopherol to maintain the oxidative stability of the meat (56).

The method of cooking may also affect the flavor of meat from chickens fed fish oil. No unusual tastes were observed in chickens fed 20 g/kg cod liver oil when their meat was fried and served warm, but a fishy flavor became apparent when the meat cooled, and a definite unpleasant flavor was observed when the chicken was stewed or roasted (57). The susceptibility of different tissues to the development of off-flavors is also variable. The higher degree of unsaturation in white meat lipids compared with dark meat means that the lipids in white meat are more susceptible to oxidation (52,58), particularly as it is the phospholipid fraction (more concentrated in the white meat than the dark meat) that is the main contributor to the development of oxidation products (58). However, the higher fat content of dark meat compared with white meat means that oxidation and the development of off-flavors occur more quickly in dark meat compared with white meat (32,50,58). A treatment that resulted in breast meat with an acceptable flavor and high long-chain n-3 PUFA content also produced wings that were unacceptable (33). Although thighs and wings are less commercially valuable than breast meat, such a treatment would clearly have a negative impact on the whole-carcass market (33). Poultry meat with enhanced long-chain n-3 FA contents may also be more liable to the development of a warmed-over flavor, which results from the rapid onset of rancidity in cooked meat during short-term refrigerated storage (59). Although the concentration of oxidation markers in freshly cooked chicken meat from broilers fed up to 120 g/kg fishmeal was not significantly different from that of meat from birds fed no fishmeal, noticeable differences were observed after 4 d of refrigerated storage (52). In a separate (unpublished) study of the experiment reported by Ratnayake *et al.* (22), this was associated after just 2 d with the development of off-flavors in the warmed-over meat from birds supplemented with 120 g/kg fishmeal (60).

In attempting to reduce the development of off-flavors in n-3 FA-enhanced poultry meat, many studies have focused on reducing or removing fish oils from the poultry diet for varying periods of time before slaughter (41). Although this has often been effective in making the product more acceptable to consumers, it also has the effect of reducing the n-3 PUFA content of the poultry meat. This approach therefore needs to find a balance between maximizing n-3 PUFA content of edible tissues and maintaining an acceptable taste in the product. When using fish oils to increase the long-chain n-3 PUFA content of poultry meat, Leskanich and Noble (21) recommended that only high-quality (i.e., unoxidized) materials should be used, the amount of fish oil or fishmeal in the diet should be limited (to 10 and 120 g/kg, respectively), and supplementary antioxidants should be included in the diet.

The feeding of marine algae rather than fish oil can result in enhanced tissue EPA and DHA content, but without some of the problems associated with off-flavors. This is probably because the oil droplets in algae are encapsulated within the algal cell and this protects them, at least in part, from oxidative deterioration (38). It is also possible that the algae contain more natural antioxidants than fish oil. However, when broiler diets were supplemented with fish oil or with natural golden marine algae, a reduction in the flavor score was still observed although this was less marked with the algae supplement (38). In human nutrition, an alternative means of consuming n-3 FA is to microencapsulate them and then include them in other foods. This greatly increases their shelf life and palatability while also maintaining their bio-availability (61). It is possible that processed products containing poultry meat could incorporate microencapsulated n-3 FA, although the whole chicken and whole turkey market could not benefit in this way. An alternative approach may be to include microencapsulated fish oils in poultry diets. This would ensure that the lipids absorbed by the birds were not oxidized, which would in itself reduce the development of off-flavors, but the meat itself would still need protection from oxidation occurring during storage.

CONCLUSIONS

In adult humans, the conversion of ALA to EPA is limited, and the further conversion to DHA appears to be marginal at best. Increasing ALA intake does not increase the concentration of EPA and DHA in the circulation, and there is no clear evidence that it reduces any of the risk factors associated with coronary heat disease. There is clearly a need for preformed EPA and DHA in the human diet, but the intake of fish (the principal source of EPA and DHA) is extremely low in northern European diets.

When poultry are fed typical diets, their n-3 PUFA content is low, with no evidence of any differences between sexes and genotypes of different species of poultry. There may be some differences between different poultry species, although no clear comparisons could be found in the literature. However, in two separate experiments in which broilers and turkeys had been fed broadly similar diets, the ALA content of turkey meat was greater than that of broiler meat. There was little difference in the total EPA and DHA content of the broiler meat (both white and dark) compared with turkey white meat, but the concentration of these FA in turkey dark meat appeared to be greater. Dark meat is a relatively rich source of ALA, whereas EPA and DHA accumulate in the white meat. However, the low lipid content of white meat compared with dark meat results in the concentration of EPA and DHA in white and dark meats being broadly similar.

Increasing the concentration of n-3 PUFA in poultry diets results in an increase in the n-3 PUFA content of poultry meat. Including feeds such as linseed in the diet increases the diet's ALA content, whereas marine sources (fish oil, fishmeal, or marine algae) increase the diet's EPA and DHA content. Linear relationships between diet ALA concentration and the ALA content of edible poultry tissues were observed, particularly for dark meat with skin. Skinless white meat had only a poor relationship between diet and tissue ALA content. There was no evidence of bird sex or genotype affecting these relationships, and data were insufficient to make a comparison between species. However, one study suggested that the response to increased ALA content may be lower in turkey white meat, but greater in turkey dark meat compared with the corresponding tissues in broilers.

The EPA content of poultry meat was increased by feeding marine products (fishmeal, fish oil, and marine algae), and a linear relationship between the concentration of EPA in the diet and in both white and dark meat was observed. However, feeding ALA did not cause a noticeable increase in EPA content, suggesting that, as with humans, an increased supply of substrate (ALA) did not induce an increased synthesis of product (EPA). Some DHA was found in the edible tissues of poultry even when no DHA was fed, but the concentrations were low. The DHA content of edible poultry tissues was increased when DHA was included in the diet (from marine products), but there was no clear relationship between diet and tissue in terms of their respective DHA contents.

Feeding marine products to poultry will increase their long-chain n-3 PUFA content, but the oxidative stability of the meat will decrease as a result. This has negative effects on both the shelf life and the flavor of the meat. These shortcomings may be overcome by ensuring that only good-quality materials are used, by limiting the inclusion rate of fish oil or fishmeal in the diet, and by including antioxidants such as α-tocopherol in the diet at supranutritional concentrations (100 IU/kg). This can then result in nutritionally meaningful amounts of long-chain n-3 PUFA being delivered from the edible tissues of poultry and could have beneficial effects on the health of consumers.

Maternal Dietary Conjugated Linoleic Acid Alters Hepatic Triacylglycerol and Tissue Fatty Acids in Hatched Chicks

Gita Cherian*, Wu Ai, and Mary P. Goeger

Department of Animal Sciences, Oregon State University, Corvallis, Oregon, 97331-6702

ABSTRACT: The effects of feeding CLA to hens on newly hatched chick hepatic and carcass lipid content, liver TAG accumulation, and FA incorporation in chick tissues such as liver, heart, brain, and adipose were studied. These tissues were selected owing to their respective roles in lipid assimilation (liver), as a major oxidation site (heart), as a site enriched with long-chain polyunsaturates for function (brain), and as a storage depot (adipose). Eggs with no, low, or high levels of CLA were produced by feeding hens a corn–soybean meal–basal diet containing 3% (w/w) corn oil (Control), 2.5% corn oil + 0.5% CLA oil (CLA1), or 2% corn oil + 1.0% CLA oil (CLA2). The egg yolk content of total CLA was 0.0, 1.0, and 2.6% for Control, CLA1, and CLA2, respectively ($P < 0.05$). Maternal dietary CLA resulted in a decrease in chick carcass total fat ($P < 0.05$). Liver tissue of CLA2 chicks had the lowest fat content ($P < 0.05$). The liver TAG content was 8.2, 5.8, and 5.1 mg/g for Control, CLA1, and CLA2 chicks, respectively ($P < 0.05$). The chicks hatched from CLA1 and CLA2 incorporated higher levels of *cis*-9,*trans*-11 CLA in the liver, plasma, adipose, and brain than Control ($P < 0.05$). The content of 18:0 was higher in the liver, plasma, adipose, and brain of CLA1 and CLA2 than Control ($P < 0.05$), but no difference was observed in the 18:0 content of heart tissue. A significant reduction in 18:1 was observed in the liver, plasma, adipose, heart, and brain of CLA1 and CLA2 chicks ($P < 0.05$). DHA (22:6n-3) was reduced in the heart and brain of CLA1 and CLA2 chicks ($P < 0.05$). No difference was observed in carcass weight, dry matter, or ash content of chicks ($P > 0.05$). The hatchabilities of fertile eggs were 78, 34, and 38% for Control, CLA1, and CLA2, respectively ($P < 0.05$). The early dead chicks were higher in CLA1 and CLA2 than Control (18 and 32% compared with 9% for Control), and alive but not hatched chicks were 15 and 19% for CLA1 and CLA2, compared with 8% for Control ($P < 0.05$). Maternal supplementation with CLA leads to a reduction in hatchability, liver TAG, and carcass total fat in newly hatched chicks.

Paper no. L9648 in *Lipids 40*, 131–136 (February 2005).

CLA have received considerable attention for their potential to repartition body mass in growing animals (1–3) and for their suggested health-promoting effects (4–6). CLA is a collective term used for a group of positional and geometric dienoic isomers of essential linoleic acid (18:2n-6). Among the CLA isomers, *cis*-9,*trans*-11 (*c*9,*t*11) and *trans*-10,*cis*-12 (*t*10,*c*12) are the predominant ones found in foods of ruminant origins where they are synthesized by rumen microbes. Because a major proportion of fat in the U.S. diet is of animal origin, feeding strategies have been adopted to increase the content of CLA in foods of ruminant as well as nonruminant origin, such as pork, chicken eggs, and meat (7–9), because of the possible health-promoting properties of CLA (4–6).

Enriching eggs with up to 14.8% CLA has been reported through manipulation of the diets of laying hen (10). CLA incorporation in eggs resulted in a significant increase in saturated FA (SFA) (16:0, 18:0) with a concomitant reduction in monounsaturated FA (MUFA) (16:1, 18:1n-9) (10,11). However, feeding CLA had little effect on the total fat content of egg. Yolk fat is primarily TAG (68%) and phospholipids (28%). During the 21-d incubation period, the chicken embryo utilizes over 80% of the yolk fat for energy production, for formation of fat stores, and for synthesis of membrane phospholipids (12,13). The yolk-derived lipids are reassembled into TAG-rich lipoproteins by the endodermal cells of the yolk sac membrane (12). Tissue maturation in the embryo is also dependent on the incorporation of highly characteristic FA profiles into cell membrane phospholipids. Recent studies suggest that phospholipids containing long-chain n-6 and n-3 PUFA are involved in many cellular signaling mechanisms such as cardiac rhythm, neurotransmission, and photoreception (14). Therefore, FA delivery, partitioning, and tissue uptake during incubation affects embryonic health and hatchability. Adverse effects of yolk CLA on hatchability (15), yolk absorption and reduction in chick VLDL TAG were reported (16). Because the CLA composition of egg yolk can be manipulated by diet, the CLA-modified egg is a useful research tool for studying the role of maternal dietary CLA on lipid metabolism in the progeny. Given that CLA are known to have significant effects on lipid partitioning in mammals, it is important to evaluate the extent to which supplementation of CLA during development through maternal supply (yolk) influences FA composition and TAG allocation in hatched chicks. The objectives of the present study were to investigate the effects of feeding CLA to hens on chick hepatic and carcass lipid content, liver TAG accumulation, and FA incorporation into chick tissues such as liver, heart, brain, and adipose. These tissues were selected because of

---

their respective roles in lipid assimilation (liver), oxidation (heart), functional long-chain PUFA incorporation (brain), and storage (adipose).

MATERIALS AND METHODS

These experiments were reviewed by the Oregon State University Animal Care and Use Committee to ensure adherence to Animal Care Guidelines.

Maternal diet and egg enrichment of CLA. Eggs with different levels of CLA were obtained by feeding New Hampshire breeder hens a corn–soybean meal-based diet containing 3% corn oil (Control), 2.5% corn oil + 0.5% CLA oil (CLA1), and 2% corn oil + 1% CLA oil (CLA2). All the diets were isoenergetic (2900 kcal/kg feed) and isonitrogenous (16% crude protein). The FA composition of the diets is shown in Table 1. Corn oil was purchased from a local market. The CLA oil containing 75% FFA oil was donated from a commercial source (CLA One®; Pharmanutrients, Lake Bluff, IL) and was made of approximately equal amounts of *c*9,*t*11 and *t*10,*c*12. The other FA in the CLA oil were 16:0 (4.4%), 18:0 (2.8%), 18:1 (15.4%), and 18:2 n-6 (1.8%). The diets were mixed weekly and were stored in a cold room (4°C) in airtight containers. The experimental diets were fed to hens (*n* = 30; 10 per treatment) for a period of 6 wk. The birds were kept individually in cages and were maintained on a 16:8 light/dark photoperiod and standard conditions of temperature and ventilation as per Oregon State University Poultry Farm standard operating procedures. Water and feed were provided *ad libitum.*

Sample collection. After 5 wk on experimental diet, hens were artificially inseminated with 0.05 mL of pooled semen collected immediately before insemination. Eggs were gathered for 10 d after insemination and were held in a cold room at 65°F (18.3°C). All eggs were warmed to room temperature before setting in the incubator. All the eggs were distributed randomly in the incubator. A total of 180 eggs (60 eggs per treatment) were incubated at 37°C and 85% RH. Hatching

times were observed from day 21 onward in the morning and evening. The hatched chicks from all treatments were counted in the early morning of Day 22. The eggs that did not hatch were removed from the incubator and were also counted. The eggs were broken open and the number of embryos that were dead or pips (i.e., alive and pipped through the shell, but not free of the shell) were also counted. The hatched chicks (five per treatment) were sacrificed, and heart, adipose, liver, and blood (1 mL) were collected. From the remaining hatched chicks five were taken for proximate analysis. All samples were stored at −80°C and were analyzed within 2 mon of collection.

Carcass pressure cooking. The carcasses were autoclaved individually in pyrex beakers at 121°C (15 psi) for 2.5 h. When cool, the contents of each beaker were homogenized in a 4-L Waring heavy-duty laboratory blender on high speed (20,000 rpm) for 5 min. The resulting slurry was taken for lipid and proximate analysis according to methods of the Association of Official Analytical Chemists (17).

Lipid analyses. Total lipids were extracted from feed, egg yolk, liver, heart, adipose, plasma, and carcass slurry by the method of Folch *et al.* (18). About 1 g of yolk, feed, carcass slurry, adipose, or whole tissues (heart, brain, liver) was weighed into a screw-capped test tube with 18 mL of chloroform/methanol (2:1, vol/vol), and homogenized with a polytron (Type PT10/35; Brinkman Instruments, Westbury, NY) for 15 to 20 s at high speed. After an overnight incubation at 4°C, 4 mL of 0.88% sodium chloride solution was added and mixed. The phases were separated by centrifugation, and the lower chloroform layer was collected for lipid and FA analysis. Total lipids were determined gravimetrically for liver, egg yolk, and carcass. The lipid extract (2 mL) was taken into a 16-mL screw-capped glass tube and dried in a block heater at 39°C under a gentle stream of nitrogen. The dried lipids were resolubilized in 2 mL of boron trifluoride/methanol (10% w/w) and were heated in a 95–100°C water bath for 60 min and FAME were prepared. The FAME were separated and quantified by GC.

Analysis of FA composition was performed with an HP 6890 gas chromatograph (Hewlett-Packard Co., Wilmington, DE) equipped with an autosampler, FID, and fused-silica capillary column, 100 m × 0.25 mm × 0.2 µm film thickness (SP-2560; Supelco, Bellefonte, PA). Sample (2 µL) was injected with helium as a carrier gas onto the column programmed for ramped oven temperatures (initial temperature was 110°C, held for 0.5 min, then ramped at 20°C/min to 200°C and held for 50 min, then ramped at 10°C/min to 230°C and held for 5.0 min). Inlet and detector temperatures were both 250°C (12). Peak areas and percentages were calculated using Hewlett-Packard ChemStation software. FAME were identified by comparison with retention times of authentic standards (Matreya, Pleasant Gap, PA). FA values and total lipids are expressed as weight percentages.

Liver TAG were estimated by adapting an enzyme-based procedure with a colorimetric end point, originally developed for serum as reported earlier (19). The liver tissue total lipid extract served as substrate. A glycerol standard (G1394-5ML;

[a]Control diet contained 3% corn oil. CLA1 and CLA2 represent corn oil + 0.5% CLA or corn oil + 1% CLA, respectively. SFA, saturated FA; MUFA, monounsaturated FA.

Sigma Chemical, St. Louis, MO) was used for calibration of the assay, and Accutrol normal control serum (A2034-1VL; Sigma Chemical) for quality control.

Statistical analysis. The effects of maternal diet on carcass lipids, hepatic and plasma lipids, TAG, and FA were analyzed by ANOVA using SAS (version 8.2) (SAS Institute, Cary, NC) (20). Student–Newman–Keuls multiple range test (21) was used to compare differences among treatment means ($P < 0.05$). Mean values and SEM are reported.

RESULTS AND DISCUSSION

All the diets were isoenergetic, isonitrogenous, and had added 3% oil, which was within the limits of energy and protein supplied to breeder hens. Addition of CLA oil altered the $c9,t11$ and $t10,c12$ content of the diets (Table 1). CLA were present only in the CLA-supplemented diets (CLA1 and CLA2) and consisted of both $c9,t11$ and $t10,c12$. Incorporating CLA oil in the diet resulted in a significant increase in $c9,t11$ and $t10,c12$ content of eggs (Fig. 1A). The content of total CLA was 1.0 and 2.6%, respectively, in CLA1 and CLA2 eggs. Inclusion of CLA also resulted in an increase in SFA (16:0, 18:0) with a concomitant reduction in MUFA (18:1) resulting in an increase in SFA/MUFA ratio in CLA1 and CLA2 eggs (Fig. 1B). These results also corroborate our previous reported results and those of others (10,11). This decrease in MUFA may be due to inhibition of the expression of the stearoyl-CoA desaturase-1 (SCD-1) enzyme that converts 16:0 and 18:0 to 16:1 and 18:1 by CLA, respectively (22). Inclusion of CLA did not alter the total lipid content of egg, which was 30.6, 31.2, and 29.9 for Control, CLA1, and CLA2, eggs, respectively ($P > 0.05$).

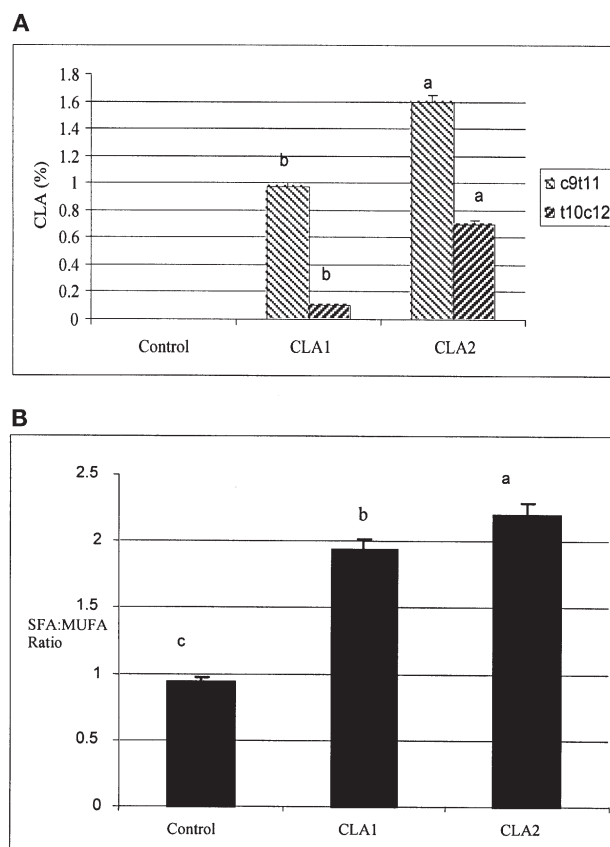
Liver lipids, TAG, and FA. A significant effect of dietary CLA on hepatic total lipid was noted. Livers of chicks hatched from hens fed CLA2 were lower in total lipids than Control chicks ($P < 0.05$) (Fig. 2A). The decrease in liver lipids by yolk CLA could be the consequence of a higher oxidation rate of these FA as reported in mice fed $t10,c12$ CLA (23). The decrease in liver lipids was associated with a decrease in hepatic TAG concentration in both CLA1 and CLA2 chicks ($P < 0.05$) (Table 2). To our knowledge, effects of maternal dietary CLA on liver TAG concentrations in hatched chicks have not been previously reported. Transfer of lipids and fat-soluble nutrients from the egg yolk to the embryonic liver is accomplished by TAG-rich lipoproteins through the yolk sac membrane (24). The percentage of TAG in VLDL particles has been reported to be lower in chicks hatched from hens fed CLA (16). These researchers also observed a reduction in remnant yolk in the chicks hatched from hens fed CLA, suggesting that CLA enrichment in the yolk leads to either an impairment in yolk lipid removal or hepatic tissue TAG accretion during the incubation period. Since yolk TAG is the main source of energy for avian embryos, a lack of mobilization or an impairment in absorption may affect chick health. In our study, the percentages of early dead chicks were higher in CLA1 and CLA2 than Control (18 and 32% compared with 9% for Control), and alive but not hatched (pipped) chicks were 15 and 19% for CLA1 and


FIG. 1. CLA isomers (%) (A) and total saturated to monounsaturated ratio (B) in the egg yolk from breeder hens fed diets containing 0.0, 0.5%, or 1.0% CLA. [a–c]Means with different superscripts differ significantly for each bar ($P < 0.05$) ($n = 5$). Control diet contained 3% corn oil. CLA1 and CLA2 represent 2.5% corn oil + 0.5% CLA or 2% corn oil +1% CLA.

CLA2 compared with 8% for Control. The hatchabilities of fertile eggs were 78, 34, and 38% for Control, CLA1, and CLA2, respectively ($P < 0.05$). CLA have been reported to accumulate in the liver mitochondrial matrix affecting the oxidation of other FA (23). Because the avian embryo derives 90% of its energy from oxidation of FA, a reduced energy source may lead to embryonic death or an increase in live but not hatched chicks, as noted in our study.

An increase in egg yolk CLA resulted in a dramatic change in the chick liver SFA and MUFA content (Table 2). A significant increase in 18:0 with a concomitant decrease in 18:1 was observed in CLA1 and CLA2 chicks. The inhibitory action of CLA on SCD-1, the enzyme capable of converting 18:0 to 18:1, has been reported (22). In the present study, yolk and liver 18:0 was significantly higher in the CLA1 and CLA2 groups, indicating the inhibitory action of maternal CLA on SCD-1. An alteration of Δ-6 desaturase in chick liver due to an altered n-6/n-3 FA ratio in the maternal diet has been reported (25). These results suggest that maternal FA may have a profound effect on liver enzyme activities affecting unsaturated FA metabolism during avian embryonic development. Total CLA
FIG. 2. Hepatic total lipid (A) and TAG (B) content of newly hatched chicks from breeder hens fed diets with or without CLA. [a–b]Means with different superscripts differ significantly ($P < 0.05$) ($n = 5$). Control diet contained 3% corn oil. CLA1 and CLA2 represent 2.5% corn oil + 0.5% CLA or 2% corn oil +1% CLA.

were higher in the liver of CLA2 chicks. The *c9,t*11 isomer was the predominant isomer and was higher ($P < 0.05$) in livers from CLA1 and CLA2 chicks (Table 2). In addition to the changes in SFA and MUFA, the content of 18:2n-6 and total n-6 FA was higher in CLA1 and CLA2 chicks ($P < 0.05$). The level of DHA (22:6n-3) was lower in CLA2 chicks ($P < 0.05$).

The FA composition of chick plasma, adipose, heart, and brain tissue is shown in Tables 3 and 4. Stearic acid (18:0) was increased significantly in the plasma and brain of CLA1 and CLA2 chicks compared with the Control (Table 3). However, no difference was observed in the heart tissue content of 18:0 in CLA1 and CLA2, suggesting that the activities of SCD-1 in chickens may be tissue-specific. Consistent with findings in the liver, 18:1 was significantly reduced in the plasma, heart, and brain tissue of CLA1 and CLA2 chicks (Tables 3 and 4). Inclu-

Total n-3 PUFA	0.4 ± 0[b]	0.9 ± 0[a]	0.9 ± 0[a]

[a]Control diet contained 3% corn oil. CLA1 and CLA2 represent 2.5% corn oil + 0.5% CLA or 2% corn oil + 1% CLA. [a–c]Means ± SD with different superscripts within a row differ significantly ($P < 0.05$) (n = 5). For abbreviations see Table 1.

sion of CLA also resulted in a significant increase in linoleic acid (18:2 n-6) in CLA1 and CLA2 chicks in the plasma, heart, and brain. The enrichment of total CLA due to maternal diet in the order of magnitude was adipose > liver > plasma > brain. No CLA was detected in the heart tissue. The contents of long-chain n-6 PUFA such as arachidonic acid (20:4n-6), 22:4n-6, and 22:5n-6 were higher in the brain tissue of CLA1 and CLA2 chicks than in Control chicks ($P < 0.05$). However, DHA (22:6n-3) was lower in the heart and brain tissue of CLA1 and CLA2 chicks by maternal supplementation of CLA than in control chicks ($P < 0.05$). Although an adverse effect of yolk CLA on hatchability has been reported (15), very few studies have investigated the role of egg CLA during avian embryonic development. The alteration of n-6 and n-3 FA observed in the chick tissues in the current study may also affect eicosanoid metabolism in these tissues. Feeding CLA has been reported to reduce the levels of brain prostaglandin E_2 in mice (26). The decrease in the concentration of 18:1 and the altered SFA/MUFA ratio, along with impaired eicosanoid metabolism

through alteration in n-6 and n-3 FA ratio, may all contribute to embryonic health and survival in CLA-enriched eggs.

Enrichment of yolk with CLA did not affect the carcass weight, carcass dry matter, or ash content (Table 5). However, chick carcasses from CLA1 and CLA2 were lower in total fat than in Control ($P < 0.05$). The carcass fat for CLA2 chicks was 26% less than Control chicks. Latour *et al*. (16) reported an increase in the retention of remnant yolk in chicks hatched from eggs containing CLA. Inhibition of yolk fat absorption or transfer through the yolk sac or an increase in oxidation may contribute to the reduced fat accumulation in CLA1 and CLA2 chicks. The beneficial effect of CLA in reducing body fat mass has attracted great attention and has been reported in various species (2,3). Feeding CLA at 2 or 3% has been associated with reduced carcass fat in broilers (27). The moisture and ash contents of chick carcasses in our study were not affected by ma-

[a]Control diet contained 3% corn oil. CLA1 and CLA2 represent 2.5% corn oil + 0.5% CLA or 2% corn oil + 1% CLA. [a–b]Means ± SD with different superscripts within a row differ significantly ($P < 0.05$) ($n = 5$).

ternal dietary CLA, in agreement with studies reported in broiler chickens fed diets containing 2 or 3% CLA (27).

Poor hatchability and an increase in culls are major economic losses to hatching egg producers. Owing to the current interest in increasing the CLA content of ruminant and non-ruminant foods, fats and FA from rendered sources may enter the livestock and avian feed chain. Inclusion of such rendered fat in the diets of breeder birds and egg-laying species may affect the health of the progeny. The results from the present study demonstrating that increasing yolk CLA alters lipid metabolism in chicks suggest that further investigations are needed on the use of CLA in breeder animal feeding and also on the long-term clinical use of CLA supplementation in lactating women.

Effects of Specific CLA Isomers on Plasma Fatty Acid Profile and Expression of Desaturases in Humans

Myriam A.M.A. Thijssen[a,]*, Corinne Malpuech-Brugère[b], Stéphane Gregoire[c], Jean Michel Chardigny[c], Jean Louis Sébédio[c], and Ronald P. Mensink[a]

[a]Department of Human Biology, Maastricht University, Maastricht, The Netherlands, [b]Unité du Métabolisme Protéino-Energétique, Institut National de la Recherche Agronomique (INRA), Clermont Ferrand, France, and [c]Unité de Nutrition Lipidique, INRA, Dijon, France

ABSTRACT: Human studies suggest that CLA changes metabolism, possibly through effects on mRNA expression of desaturase and elongase enzymes. In this respect, differential effects of the two most common dietary CLA isomers, *cis*-9,*trans*-11 (*c*9,*t*11) and *trans*-10,*cis*-12 (*t*10,*c*12) CLA, have hardly been studied. We therefore gave 25 healthy, overweight men and women daily for 6 wk a drinkable dairy product containing 3 g of oil that was rich in oleic acid. For the next 18 wk, the control group ($n = 7$) continued to use this product, whereas the second ($n = 9$) and third groups ($n = 9$) received products with 3 g of purified *c*9,*t*11 CLA or *t*10,*c*12 CLA. For each gram of *c*9,*t*11 CLA consumed, the proportion in plasma phospholipids increased by 0.26%. For *t*10,*c*12 CLA, this value was 0.20%. The *t*10,*c*12 CLA isomer increased plasma TAG levels of conjugated 18:3, whereas *c*9,*t*11 CLA increased those of both conjugated 18:3 and 20:3. In plasma phospholipids, the $\Delta 9$ desaturation index of 18:0 (18:1n-9/18:0) was decreased by *t*10,*c*12 CLA ($P = 0.03$ for diet effects), and the $\Delta 6$ desaturation index [(18:3n-6 + 20:3n-6)/18:2n-6] was decreased by both CLA isomers ($P < 0.01$ for diet effects). The $\Delta 5$ desaturation index (20:4n-6/20:3n-6) and the $\Delta 9$ desaturation index of 16:0 (16:1n-7/16:0) were not affected. No effects were seen on mRNA expression of desaturases and elongase in peripheral blood mononuclear cells (PBMC). We therefore conclude that incorporation of *c*9,*t*11 and *t*10,*c*12 CLA into plasma lipids reflects dietary intakes. Compared with oleic acid, $\Delta 9$ and $\Delta 6$ desaturation indices in plasma phospholipids are decreased after consumption of *c*9,*t*11 or *t*10,*c*12 CLA. Effects on desaturation indices were, however, not reflected by changes at the transcriptional level for the various desaturases and elongase enzymes in PBMC.

Paper no. L9653 in *Lipids 40*, 137–145 (February 2005).

CLA refers to a group of positional and geometrical isomers of linoleic acid containing conjugated double bonds. *Cis*-9,*trans*-11 (*c*9,*t*11) CLA is the most common CLA isomer in nature and is present in ruminant products, whereas commercially available capsules enriched with CLA also contain other isomers such as *trans*-10,*cis*-12 (*t*10,*c*12) CLA (1). Because of their postulated health benefits (2,3), dietary supplements with CLA are now widely available. To explain these health effects, several mechanisms have been proposed, including regulation of genes coding for enzymes known to modulate lipid and FA metabolism, such as desaturases (2,4).

Desaturases are involved in the formation of long-chain metabolites from precursor FA such as stearic, linoleic, and α-linolenic acids. Studies in mice and rats have indeed reported that CLA, mainly the *t*10,*c*12 isomer, suppressed $\Delta 9$ desaturase mRNA expression or enzyme activity (5–7). Moreover, the *c*9,*t*11 isomer decreased $\Delta 6$ desaturase activity in liver microsomes (5). In cell culture studies, effects of *t*10,*c*12 CLA on $\Delta 9$ desaturase activity were confirmed in a human hepatoma-derived cell line (HepG2) (8,9). However, effects of *c*9,*t*11 CLA on desaturase activities are inconsistent (8,9). Furthermore, effects of both CLA isomers at the mRNA expression level of desaturases have hardly been studied. Because desaturation products play an important role in many processes including eicosanoid production, lipid metabolism, and immune function (2,3), inhibition of desaturation may influence health. Most human studies, however, have been carried out using a mixture of CLA isomers and have not focused on specific effects of the major CLA isomers (10–12). Isomer-specific effects of CLA, as observed in animal studies, may explain conflicting results in humans (4,13). Therefore, to examine whether *c*9,*t*11 CLA and *t*10,*c*12 CLA affect desaturation differently in humans, we investigated the effects of these two CLA isomers on the FA compositions of plasma phospholipids (PL), cholesteryl esters (CE), and TAG. In addition, effects on mRNA expression of $\Delta 9$, $\Delta 6$, and $\Delta 5$ desaturases and of elongase by peripheral blood mononuclear cells (PBMC) were studied. Recently, the human $\Delta 5$ (14), $\Delta 6$ (15), and $\Delta 9$ (16) desaturase and elongase (17) genes have been characterized, and reverse transcription quantitative PCR (RT-qPCR) were developed based upon the desaturase and elongase gene sequences.

EXPERIMENTAL PROCEDURES

Subjects. Healthy male and female volunteers were recruited *via* advertisements in local newspapers. Interested people were informed about the purposes and requirements of the study and

---

---

had to give their written informed consent before they entered the screening procedure. This procedure consisted of two fasting blood samples for analysis of serum lipids and lipoproteins, hematological parameters, C-reactive protein, and liver and kidney functions, measurement of blood pressure, and collection of a morning urine specimen for analysis of glucose. Participants had to meet all of the eligibility criteria: aged 35–65 yr, body mass index between 25 and 30 kg/m^2, diastolic blood pressure below 95 mmHg and systolic blood pressure below 160 mmHg, fasting serum total cholesterol concentrations less than 7.0 mmol/L, serum TAG concentrations below 3.0 mmol/L, and plasma glucose below 6.0 mmol/L. Furthermore, subjects were apparently healthy as indicated by a medical questionnaire, not pregnant, and weight stable during the past 3 mon; had no history of atherosclerotic disease or malignancy within the past 5 yr, normal liver and kidney function, no glycosuria or anemia, no abuse of drugs or alcohol, and no use of any medication known to affect lipid or glucose metabolism. Blood donation or participation in another biomedical trial was not allowed within 4 wk before the start of the study or during the study.

The Medical Ethics Committee of Maastricht University approved the study protocol. This study was part of a multicenter study as reported elsewhere (18). For 25 subjects of the placebo group and the high-dose CLA groups of the Maastricht cohort, desaturase expression in PBMC and FA compositions of plasma lipids were analyzed. During the screening period, their body mass indexes ranged from 24.4 to 30.5 kg/m^2 (mean 27.4 kg/m^2). The subjects' fasting serum lipid levels ranged from 3.2 to 6.8 mmol/L for total cholesterol (mean 5.0 mmol/L), from 0.8 to 2.8 mmol/L for HDL cholesterol (mean 1.2 mmol/L), and from 0.4 to 2.4 mmol/L for TAG (mean 1.2 mmol/L).

Study design. The study had a randomized, double-blind, placebo-controlled, parallel design. During the first 6 wk of the trial (run-in period), all volunteers consumed daily a dietary supplement providing 3 g of high-oleic sunflower oil (placebo). After the run-in period, subjects were randomly allocated to one of the three treatment groups. For the next 18 wk of the study (intervention period), one group ($n = 7$) continued to consume the placebo dairy product daily. The second ($n = 9$) and third ($n = 9$) groups consumed the dairy product with 3 g of purified *c*9,*t*11 CLA or 3 g of *t*10,*c*12 CLA, respectively.

Dietary supplements containing CLA were provided as an acidified drinkable dairy product produced by Danone (Palaiseau, France) as described earlier (18). The two different isomers of CLA, *c*9,*t*11 CLA and *t*10,*c*12 CLA, were incorporated as a TAG in the dairy drinks and were produced by Natural Lipids Ltd. (Hovdebygda, Norway). Different flavors were added to the products. The placebo product used during the run-in period had a different flavor from the one used during the intervention period. Bottles were packaged in boxes of 14.

Participants consumed one bottle daily (100 mL) of this dietary supplement between lunch and dinner. In a diary, participants had to record the daily time of consumption of the supplements and to note any signs of illness, medication used, alcohol consumption, and any deviations from the study protocol. Subjects were urged not to change their habitual diet, level of physical exercise, smoking habits, or use of alcohol during the study. Volunteers visited the university at least once every 2 wk to receive a new supply of supplements. Supplements that were left over had to be returned and were counted as a measure of compliance. Compliance was also checked by analysis of the FA composition of plasma PL. Furthermore, at each visit a dietitian checked the diary.

Blood sampling. Blood samples were obtained at the end of the run-in period (week 6) and at the end of the intervention period (week 24) after an overnight fast. Moreover, participants were instructed not to use alcohol during the previous day and not to smoke on the morning before blood sampling. Venous blood was sampled using a vacutainer system with the volunteer in a recumbent position. For RNA isolation from PBMC, blood was collected into two EDTA tubes and kept on ice until leukocyte isolation. In addition, one EDTA tube was collected to obtain plasma for analysis of the FA composition of plasma lipids. This tube was centrifuged within 1 h after venipuncture at $3500 \times g$ for 30 min at 4°C. Plasma samples were snap-frozen in liquid nitrogen and stored at –80°C.

Leukocyte isolation. PBMC were isolated from blood by gradient centrifugation using Lymphoprep (Nycomed Ltd., Birmingham, United Kingdom). Before isolation of PBMC, blood was diluted by addition of an equal volume of Hanks' balanced salt solution (HBSS; Gibco BRL, Life Technologies, Breda, The Netherlands). Then 2 vol of diluted blood was layered over 1 vol of Lymphoprep in a 50-mL centrifuge tube (Greiner Bio-One, Alphen a/d Rijn, The Netherlands). After centrifugation at $800 \times g$ for 30 min at 4°C, the interphase containing PBMC was transferred into a new 50-mL centrifuge tube. PBMC were washed with an equal volume of HBSS and centrifuged for 10 min at $250 \times g$ at 4°C. The cell pellet was resuspended in 1.5 mL Trizol reagent (Gibco BRL, Gaithersburg, MD) and transferred into an RNase-free 2 mL tube (Eppendorf, Hamburg, Germany).

RNA preparation. Total RNA from PBMC was prepared according to the manufacturer's instructions of the Trizol reagent (Gibco BRL). Briefly, 300 μL chloroform was added to separate phases. After incubation for 2–3 min at room temperature and centrifugation for 15 min at $12,000 \times g$ (4°C), the water phase, containing the RNA, was pipetted into a clean RNase-free tube. Then, the RNA was precipitated by addition of 750 μL isopropanol. After incubation for 20 min at –80°C and centrifugation for 10 min at $12,000 \times g$ (4°C), the RNA pellet was washed twice with 75% ethanol. In each washing step, the samples were centrifuged for 5 min at $7,500 \times g$ (4°C). Finally, RNA was dried and dissolved in 50 μL RNase-free water by incubation at 55–60°C for 10 min. Subsequently, both RNA samples were pooled and further purified using the RNeasy Mini Kit (Qiagen, Leusden, The Netherlands). During this purification procedure, RNA was treated on-column with DNase (RNase-free DNase set; Qiagen) as described in the manufacturer's protocol. Before storage at –80°C, the RNA concentrations were measured spectrophotometrically at 260 nm. All RNA preparations must have an A260/A280 ratio of >1.8 to ensure RNA purity.

cDNA synthesis. Aliquots of 350 ng of total cellular RNA were reverse-transcribed. All samples were denatured for 5 min at 85°C. Reverse transcription of RNA was performed in 40 µL RT mixture containing first strand buffer, 10 mM DTT, 400 U Moloney mouse murine leukemia reverse transcriptase, 20 U ribonuclease inhibitor (all provided by Gibco BRL), 5 µM random hexamers (Applied Biosystems, Nieuwerkerk a/d Ijssel, The Netherlands), and 375 µM deoxynucleotides (Amersham Pharmacia Biotech, Woerden, The Netherlands). After hexanucleotides had been annealed for 10 min at 22°C, cDNA synthesis was performed for 90 min at 37°C, followed by an enzyme inactivation step for 3 min at 95°C. Finally, cDNA was rapidly chilled to 4°C and stored at –20°C until use.

RT-qPCR. A RT-qPCR protocol was developed for the quantification of the human housekeeping gene β-actin and desaturase and elongase enzymes. Primers and probe for the desaturase and elongase assays were derived from Genbank sequence NM_013402 for Δ5 desaturase (FA desaturase 1), NM_004265 for Δ6 desaturase (FA desaturase 2), NM_005063 for Δ9 desaturase (stearoyl-CoA desaturase), and NM_021814 for elongase (ELOVL5) using Primer Express 1.5 software (Applied Biosystems). To prevent pseudogene amplification of Δ9 desaturase, a minor groove binder (MGB) probe was developed to anneal specifically to the cDNA strand of the functional gene. Primer and probe sequences for β-actin were identical to those described by Kreuzer *et al.* (19) and those for Δ6 desaturase similar as described by Leonard *et al.* (20). All probes were dual-labeled with a fluorescent FAM (6-carboxyfluorescein) reporter dye at the 5′ end and a TAMRA (6-carboxytetramethylrhodamine) quencher dye (or a nonfluorescent quencher and MGB for Δ9 desaturase) at the 3′ end. Primer and probe sequences are listed in Table 1.

Thirty-five nanograms of cDNA was amplified in a total reaction volume of 25 µL containing 12.5 µL universal master mix (Applied Biosystems), 7.5 pmol of each primer, and 5 pmol probe. PCR reactions were performed in an optical 96-well reaction plate (Applied Biosystems) on an ABI PRISM 7000 Sequence Detection System (Applied Biosystems). PCR cycling conditions were: 2 min at 50°C for optimal AmpErase UNG enzyme activity and 10 min at 95°C to activate the polymerase enzyme, followed by 45 two-step cycles of 95°C for 15 s and 60°C for 60 s. Fluorescence intensity of all wells was monitored every cycle. The number of PCR cycles to reach the fluorescence (Rn) threshold value is the cycle threshold (Ct) and is presented by the system. The Ct value for each sample is proportional to the log of the initial amount of target cDNA copies. Relative mRNA quantification was performed using the comparative ΔΔCt method (21). Moreover, to check PCR efficiencies, on every plate calibration curves for all different assays were constructed using five different dilutions of a cDNA standard (8.75 ng/µL) made from a human RNA pool.

FA composition of lipids. Analyses of FA compositions of plasma PL at the end of the run-in and experimental periods and of CE and TAG at the end of the experimental period was performed as previously described by Sébédio *et al.* (22). Briefly, plasma lipids were extracted using a mixture of chloroform and methanol (2:1, vol/vol) (23). Lipid classes were then fractionated into PL, CE, and TAG using NH_2 cartridges (Phase Separation Products, Saint Quentin en Yvelines, France) (24). After esterification and transmethylation of FA, the resultant FAME were analyzed by GLC using an HP 5890 series II gas chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a CP-Sil 88 capillary column (100 m × 0.25 µm i.d., 0.2 µm film thickness; Chrompack, Middelburg, The Netherlands) and an FID (25). The detection limit was 0.01% (w/w).

Statistics. Effects of the experimental products were examined by ANOVA using the general linear model (GLM) procedure of the SPSS 11 package for Mac OS X. When the analyses indicated a significant effect of diet ($P < 0.05$), the diets were compared pair-wise. *P*-Values were corrected for three-group comparisons by the Bonferroni correction. Confidence intervals (CI, 95%) were calculated for the differences between the diets. Values are presented as means ± SD. Pearson correlations were determined by pairwise comparisons between parameters. A probability level (*P*-value) of less than 0.05 was considered statistically significant.

[b]Values in a row without a common roman superscript differ from each other ($P < 0.017$).

RESULTS

Twenty-two of the 25 subjects completed the study protocol. Two men withdrew during the run-in period and one woman from the t10,c12 group during the experimental period. Moreover, results of two women (one woman from the c9,t11 and one woman from the t10,c12 group) were excluded from statistical analyses, because no chromatograms were available. In addition, for one man from the c9,t11 group the isolated RNA concentration was too low to measure mRNA levels reliably.

Incorporation of CLA isomers and their metabolites into plasma lipid classes. Dietary adherence to the CLA supplements was confirmed by the presence of the individual CLA isomers in plasma PL, CE, and TAG (Tables 2 and 3). As shown in Table 2, the c9,t11 CLA isomer was already present in plasma PL during the run-in period, owing to its presence in the habitual diets of the subjects. When consuming 3 g of the individual CLA isomers, the proportion of c9,t11 CLA in PL increased by 0.77%—from 0.11 to 0.88%—in the c9,t11 group, whereas the proportion of t10,c12 CLA increased from 0.00 to 0.61% in the t10,c12 group. Metabolites of the CLA isomers, the 18:3 and 20:3 conjugated isomers, were only detected in TAG (Table 3). The proportion of the conjugated 18:3 isomer

($P < 0.001$ for diet effects) was increased in the t10,c12-supplemented group ($P < 0.001$) relative to both other groups, whereas that of the conjugated 20:3 isomer ($P = 0.011$ for diet effects) was higher in the c9,t11 group ($P < 0.01$), relative to the placebo group and t10,c12 group. Moreover, proportions of vaccenic acid (t11 18:1), a precursor for the synthesis of c9,t11 CLA, in TAG ($P = 0.044$ for diet effects) was significantly decreased in the c9,t11 group ($P = 0.017$) and tended to decrease in the t10,c12 group ($P = 0.061$) relative to the placebo group.

Positive associations were observed between the proportions of c9,t11 CLA in PL with those in CE and TAG ($r = 0.944$, $P < 0.001$ and $r = 0.901$, $P < 0.001$, respectively). Similar associations were found between the proportions of t10,c12 CLA in PL with those in CE and TAG ($r = 0.987$, $P < 0.001$ and $r = 0.968$, $P < 0.001$, respectively).

FA compositions of plasma lipid classes. At baseline, only the proportion of Mead acid (20:3n-9) in PL was significantly different between the three diet groups ($P = 0.048$ for differences between the three groups). Supplementation of CLA isomers resulted in decreases in the proportions of oleic acid (18:1n-9), 16:1n-9, 20:3n-9, and dihomo-γ-linolenic acid (20:3n-6) in one or more plasma lipid classes (Tables 4 and 5). Although these decreases were more pronounced in the t10,c12

22:6n-3	2.40 ± 0.48	2.85 ± 0.59	3.42 ± 0.90	2.79 ± 0.93	3.34 ± 0.95	3.10 ± 0.90

[a]Values are means ± SD.
[b]Values in a row without a common roman superscript differ from each other ($P < 0.017$).

group, differences between the two CLA groups never reached statistical significance. The decreases were compensated for by increases in linoleic acid (18:2n-6) and CLA. In CE ($P = 0.029$ for diet effects), the proportions of 18:2n-6 were higher in the $t10,c12$ CLA group than in the $c9,t11$ CLA ($P = 0.044$) and the placebo group ($P = 0.011$). Moreover, in TAG ($P = 0.017$ for diet effects), proportions of 18:2n-6 were higher in both CLA

intervention groups ($P = 0.038$ for $c9,t11$ and $P < 0.01$ for $t10,c12$) than in the placebo group.

Effects of individual CLA isomers on desaturation indices and mRNA expressions. From the FA compositions of PL, CE, and TAG, the ratio of 20:4n-6/20:3n-6 was calculated as an index for $\Delta5$ desaturation, the ratio of (18:3n-6 + 20:3n-6)/18:2n-6 for $\Delta6$ desaturation, and the ratios of 16:1n-7/16:0

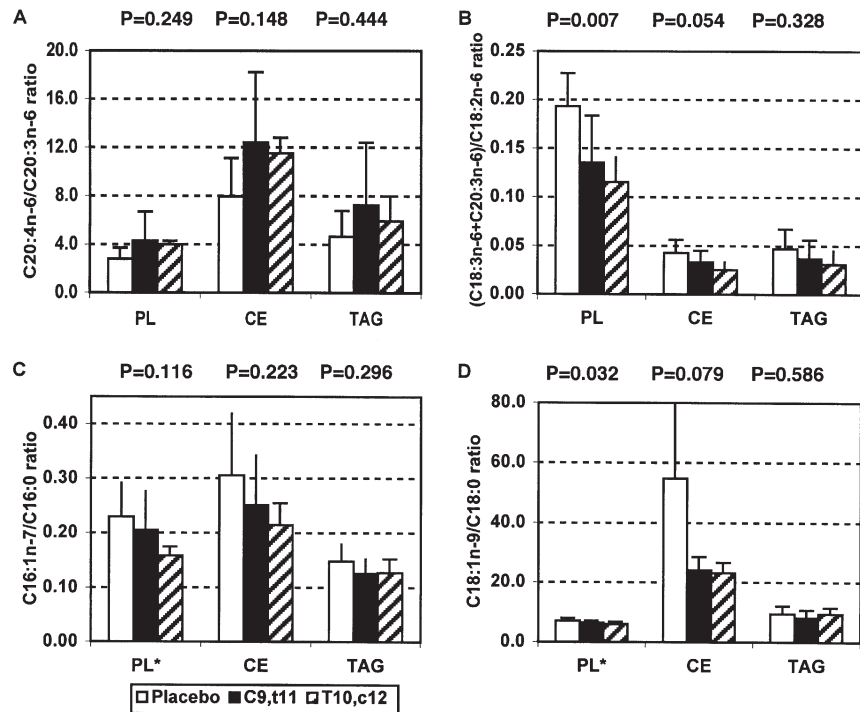
[a]Values are means ± SD. ND, not detectable (<0.01%).
[b]For each lipid class, values in a row without a common roman superscript differ from each other ($P < 0.017$).


FIG. 1. Effects of placebo, *c*9,*t*11, and *t*10,*c*12 CLA on (A) Δ5 (20:4n-6/20:3n-6), (B) Δ6 [(18:3n-6 + 20:3n-6)/18:2n-6] and (C,D) Δ9 (16:1n-7/16:0 and 18:1n-9/18:0) desaturation indices. Values are means ± SD. *n* = 6 in the placebo group, *n* = 7 in the *c*9,*t*11 group for cholesteryl ester (CE) and TAG, *n* = 8 for phospholipids (PL), and *n* = 6 in the *t*10,*c*12. *Δ9 Desaturation indices in PL are multiplied by 10, because indices are very low owing to the high abundance of saturated FA in PL.

and of 18:1n-9/18:0 for Δ9 desaturation (Fig. 1). With respect to the Δ5 and Δ6 desaturation indices, comparable patterns were seen in all three lipid classes. The Δ5 desaturation index was slightly higher in both CLA groups than in the placebo group, but differences between groups did not reach statistical significance ($P = 0.249$ in PL, $P = 0.148$ in CE, $P = 0.444$ in TAG for diet effects). The Δ6 desaturation index in PL was significantly decreased in both CLA groups ($P < 0.01$ for diet effects). Compared with the placebo group, the decrease in the *c*9,*t*11 group was 0.06 ($P = 0.013$, 95% confidence interval (CI) for the difference: –0.102 to –0.014) and in the *t*10,*c*12 group 0.08 ($P < 0.01$, 95% CI for the difference: –0.125 to –0.031). This change nearly reached statistical significance in CE ($P = 0.054$ for diet effects), but not in TAG ($P = 0.328$ for diet effects). Also for the Δ9 desaturation index, dietary effects were observed. Compared with the placebo group, the 18:1n-9/18:0 ratio in PL ($P = 0.032$ for diet effects) was significantly decreased in the *t*10,*c*12 CLA-supplemented group ($P = 0.010$, 95% CI for the difference: –0.232 to –0.010) and tended to decrease in the *c*9,*t*11 group ($P = 0.102$, 95% CI for the difference: –0.172 to 0.036). In CE, effects on the same index nearly reached statistical significance ($P = 0.079$ for diet effects), and both CLA isomers tended to decrease the Δ9 desaturation index relative to the placebo ($P = 0.048$ for *c*9,*t*11 CLA, 95% CI for the difference: –68.85 to 7.65 and $P = 0.050$ for *t*10,*c*12 CLA, 95% CI for the difference: –71.17 to 8.22). In contrast, intervention groups did not differ significantly in their effects on the Δ9 desaturation index when calculated as 16:1n-7/16:0 ($P = 0.116$ in PL, $P = 0.223$ in CE, $P = 0.296$ in TAG).

mRNA expression of Δ5, Δ6, and Δ9 desaturases and elongase did not differ between the three intervention groups (Fig. 2). *P*-Values for diet effects were, respectively, 0.914 for Δ5 desaturase, 0.563 for Δ6 desaturase, 0.234 for Δ9 desaturase, and 0.807 for elongase. The various desaturation indices in PL, CE, and TAG were not correlated with their respective mRNA levels.
FIG. 2. Effects of placebo, *c*9,*t*11, and *t*10,*c*12 CLA on Δ5, Δ6, and Δ9 desaturase and elongase expression ratios. Values (means ± SD) are obtained using TaqMan procedures (comparative cycle threshold method) and are normalized to the housekeeping gene β-actin and relative to the run-in period. No statistically significant differences were observed between treatments. All samples were analyzed in duplicate. *n* = 6 in the placebo group, *n* = 7 in the *c*9,*t*11 group, and *n* = 6 in the *t*10,*c*12 group.

DISCUSSION

In this study we evaluated the effects of *c*9,*t*11 CLA and *t*10,*c*12 CLA, the two most common CLA isomers in the diet, on the FA compositions of plasma PL, CE, and TAG. As these effects may be mediated through effects of CLA on desaturase activity, we also studied effects on mRNA expression of Δ5, Δ6, and Δ9 desaturases and elongase by PBMC. Our results suggest that *c*9,*t*11 CLA and *t*10,*c*12 CLA affect the FA composition of plasma lipid classes differently but do not change mRNA expression of desaturases or elongase in PBMC.

Both *c*9,*t*11 CLA and *t*10,*c*12 CLA were incorporated into plasma PL, CE, and TAG. Based on the proportional increases in PL, it can be estimated that each gram of *c*9,*t*11 CLA in the diet increases its proportion in PL by 0.26%. For *t*10,*c*12 CLA, this estimate is 0.20%. These values are in good agreement with those of a recent study in which healthy men received each CLA isomer in increasing doses from 0.00 to 0.6 to 1.2 to 2.4 g per day (26). In that study, both isomers were incorporated in a dose-dependent manner into plasma PC and CE, and into total lipids of PBMC. In plasma PC, the proportions of *c*9,*t*11 CLA increased from 0.21 to 0.32 to 0.52 to 0.79% in PC, or on average 0.25% per g of *c*9,*t*11 CLA. Similarly, for *t*10,*c*12 CLA it can be calculated that for each gram increase in the diet, the increase in PC was 0.17%. These estimates agree very well with our values. Moreover, these findings are in accordance with studies in rats and mice, in which incorporation of *c*9,*t*11 CLA into lipid fractions was also slightly higher than that of *t*10,*c*12 CLA (27,28).

Because *c*9,*t*11 CLA—not the *t*10,*c*12 CLA isomer—was already present in plasma PL after the run-in period, this CLA isomer should have been provided by the habitual diet. By assuming a linear relationship between the intake of *c*9,*t*11 CLA and its incorporation into plasma PL (26), it can be calculated that the habitual diet of our subjects should have provided daily about 430 mg of *c*9,*t*11 CLA. This is much higher than the mean estimated intake of 200 mg in the Netherlands Cohort Study (29). In other Western countries, comparable dietary CLA intakes were observed (30). Foods that provide the *c*9,*t*11 CLA isomer are ruminant products such as meat, cheese, milk, and yogurt, in which *c*9,*t*11 CLA accounts for 75–90% of total CLA (1). Part of the discrepancy between our estimates and these studies can be explained by the fact that methods to assess dietary intakes underestimate real intakes (30). However, the largest part may be explained by the conversion of vaccenic acid (*t*11 18:1) into *c*9,*t*11 CLA *in vivo*, as observed in several human studies (31,32). If one assumes a conversion rate of 19% of *t*11 18:1 into *c*9,*t*11 CLA (32), a habitual daily intake of approximately 1200 mg of *t*11 18:1 is necessary to explain a difference of 230 mg in *c*9,*t*11 CLA intake. In the Netherlands Cohort Study, daily intake of *t*11 18:1 was 700–800 mg (29). Thus, our data on *c*9,*t*11 CLA levels in plasma PL after the run-in period can be explained by habitual intakes of this isomer and by the conversion of *t*11 18:1 into *c*9,*t*11 CLA.

The FA composition of plasma TAG suggested that the *t*10,*c*12 CLA isomer was mainly converted into the conjugated 18:3 metabolite, whereas supplementation with the *c*9,*t*11 CLA isomer increased both 18:3 and 20:3 CLA metabolites, though to a lesser extent. Similar results have been observed in rats (28). This might suggest a blockade of the elongation step by *t*10,*c*12 CLA, which we could not, however, demonstrate at the mRNA expression level in PBMC. It is also possible that the conjugated 18:3 metabolite of *t*10,*c*12 CLA has a lower affinity for elongase than the conjugated 18:3 metabolite of *c*9,*t*11 CLA.

In contrast to several other studies (10,11), CLA supplementation significantly changed the FA compositions of plasma PL, TAG, and CE. In general, proportions of 18:1n-9, 16:1n-9, 20:3n-9, and 20:3n-6 acids decreased at the expense of CLA and 18:2n-6. These effects were more pronounced in the *t*10,*c*12 CLA group than in the *c*9,*t*11 CLA-supplemented group, although differences between the two CLA groups did not reach statistical significance. Smedman and Vessby (12) found comparable effects on the FA composition of serum PL in humans consuming 4.2 g of CLA isomers (*c*9,*t*11/*t*10,*c*12 as 50:50) per day for 12 wk. In addition, in that study proportions of stearic (18:0), γ-linoleic (18:3n-6), docosatetraenoic (22:4n-6), and docosapentaenoic (22:5n-3) acids increased and that of palmitic acid (16:0) decreased. It is possible that the intervention periods of 4 wk (11) or 45 d (10) were too short to change the composition of plasma lipids. Surprisingly, in our study proportions of linoleic acid increased. Thus, linoleic acid was not displaced by CLA in plasma lipids as suggested earlier (12). Because linoleic acid is an EFA and is not produced endogenously, this effect might suggest a decrease in Δ6 desaturation. However, unlike some other studies (5,9,11), we did not find decreased proportions of longer-chain metabolites of linoleic acid including arachidonic acid, which is an important precursor for eicosanoids.

With respect to the Δ9 desaturation index, our data confirmed those of Smedman and Vessby (12). In their study, a daily supplement of 4.2 g of a mixture of CLA isomers resulted in a decreased Δ9 desaturation index (12). Although the Δ9 desaturation index in that study was only calculated from the conversion of 18:0 into 18:1n-9, we calculated it also from the conversion of 16:0 into 16:1n-7. However, only the 18:1n-9/18:0 ratio was significantly reduced in PL by the *t*10,*c*12 CLA isomer. This may indicate that the preferred substrate of Δ9 desaturase is 18:0 rather than 16:0, as also is suggested by stable-isotope studies in humans (33,34). In addition, 16:0 is preferentially elongated instead of Δ9- desaturated (34). Also in cell culture (8,9) and animal studies (5–7), the *t*10,*c*12 CLA isomer inhibited Δ9 desaturase activity. In contrast, the *c*9,*t*11 CLA isomer did not affect Δ9 desaturase activity in all these studies, except for one. In a human hepatoma-derived cell line (HepG2 cells), the *c*9,*t*11 CLA isomer slightly decreased Δ9 desaturase activity when added at nonphysiological concentrations (9).

As for a mixture of CLA isomers (12), the Δ6 desaturation index was decreased by *c*9,*t*11 as well as by *t*10,*c*12 CLA. In contrast, in HepG2 cells *t*10,*c*12 CLA, but not *c*9,*t*11 CLA, suppressed Δ6 desaturation (9). Furthermore, in hepatic rat microsomes *c*9,*t*11 CLA decreased the Δ6 desaturation of linoleic

acid, but not that of α-linolenic acid. In that study, $t10,c12$ CLA decreased the Δ6 desaturation of linoleic acid only at the highest concentration (5). Taken together, whereas *in vitro* effects of the individual CLA isomers on Δ6 desaturation are rather inconsistent, *in vivo* both CLA isomers seem to decrease Δ6 desaturation activity in humans. Unlike Smedman and Vessby (12), who reported an increase in the Δ5 desaturation index, we found no effect on this index. In contrast, in HepG2 cells, $t10,c12$ CLA even suppressed Δ5 desaturation (9). Therefore, effects of the individual CLA isomers on Δ5 desaturase activities are until now rather inconsistent and clearly deserve further exploration.

No effects of the $t10,c12$ and $c9,t11$ CLA isomers on mRNA expression in PBMC were evident. Only a few studies have evaluated the effects of CLA on mRNA expression of desaturases before (7,8). In mice that were fed a mixture of CLA isomers, other isomers than $c9,t11$ CLA were held responsible for the inhibitory effect on stearoyl-CoA desaturase gene 1 mRNA expression (7). However, in cell culture studies, Choi *et al.* (8) found that the $t10,c12$ and $c9,t11$ CLA isomers did not influence mRNA expression in human-derived HepG2 cells. In that study, $t10,c12$ CLA decreased Δ9 desaturase activity but did not change desaturase protein levels. Hence, $t10,c12$ CLA might regulate the activity of Δ9 desaturase without any effect at the transcriptional level.

To quantify mRNA expression ratios of the Δ5, Δ6, and Δ9 desaturases and elongase we developed RT-qPCR assays. With this method, the PCR product is already accurately detected during the PCR amplification, which is less time-consuming and laborious than conventional PCR techniques because no post-PCR handling is required. Although assays for Δ5, Δ6 desaturase, and elongase were easily developed, for Δ9 desaturase or stearoyl-CoA desaturase a pseudogene has been reported (16), which called for additional precautions. Instead of the more regular dual-labeled probes, we therefore used an MGB probe, which is more specific to the target sequence and does not anneal to the pseudogene sequence. These assays can easily be used in large-scale human studies. Tissue accessibility, however, remains a problem. We chose to analyze desaturase expression in PBMC, as liver tissue is for obvious reasons difficult to obtain. Although for some genes a correlation between liver and PBMC mRNA levels has been demonstrated (35), it is still unknown whether mRNA expression ratios of Δ5, Δ6, and Δ9 desaturases and elongase in PBMC are representative for those in the liver. This may also explain the lack of effects of the two CLA isomers on mRNA expression. Future studies should therefore concentrate to validate molecular signatures (e.g., mRNA, protein, and metabolic profiles) in PBMC as a marker for other, less accessible tissues and organs.

In conclusion, incorporation of the individual CLA isomers, $c9,t11$ and $t10,c12$, into plasma lipids (PL, CE, and TAG) reflects dietary intakes. Compared with oleic acid, Δ9 and Δ6 desaturation indices in plasma PL are decreased after consumption of $c9,t11$ or $t10,c12$ CLA. Effects on desaturation indices, however, were not reflected by changes at the transcriptional level for the various desaturases and elongase enzymes in PBMC.

ABSTRACT: During the course of our recent study on the anti-tumor effect of conjugated eicosapentaenoic acids (CEPA), we found that acid mixtures prepared by treating EPA with KOH in ethylene glycol induced potent apoptotic cell death in human tumor cells via membrane phospholipid peroxidation. Interestingly, the KOH-treated CEPA mixtures were more cytotoxic than EPA and CLA and had no effect on normal human fibroblast cells. To identify the specific cytotoxic FA in the CEPA mixture, we synthesized possible candidates for the active species. Here, we report the synthesis of (5*E*,7*E*,9*E*,14*Z*,17*Z*)-5,7,9,14,17-eicosapentaenoic acid (E-CEPA) and its 5-(*Z*) isomer (Z-CEPA), both of which are conjugated trienes that exist naturally in red algae (*Ptilota filicina* J. Agardh). E-CEPA and Z-CEPA were synthesized from methyl 5-oxopentanoate in six steps, using three types of Wittig reactions as the key steps. Next, we examined the cytotoxicity of E-CEPA and Z-CEPA in human tumor cells and confirmed their bioactivity. Both E-CEPA and Z-CEPA had a strong cytotoxic reaction in tumor cells, and this effect occurred through induction of apoptosis.

Paper no. L9599 in *Lipids* 40, 147–154 (February 2005).

Conjugated FA is a generic term for FA with conjugated double bond systems, as exemplified by CLA (1). Several CLA isomers exist as a result of positional and geometrical isomerism of the conjugated double bonds, and the major naturally occurring CLA isomer is referred to as 9*Z*,11*E*-18:2 (Scheme 1). CLA was first reported to have an anticarcinogenic effect, and subsequently various other physiological effects have been shown, including an antiarteriosclerotic effect and a role in regulation of lipid metabolism (1–5). These activities of CLA are associated with its conjugated double bond system. CLA is found naturally, especially ruminant fats such as beef tallow and milk fat (1). However, the CLA level in these foodstuffs is around 1% (w/w), and hence natural fats can-

not be used as health-promoting CLA-containing supplements. Therefore, at present, oils that include CLA are prepared from alkali isomerization of vegetable oils such as safflower oil, and these products are marketed as health supplements.

Conjugated FA other than CLA exist in nature. Seed oils of certain plants include conjugated triene FA, such as α-eleostearic acid (9*Z*,11*E*,13*E*-18:3) and calendic acid (8*E*,10*E*,12*Z*-18:3), at levels of 30 to 80% (w/w) (6,7), and seaweeds such as red and green algae contain conjugated EPA (CEPA; 5*E*,7*E*,9*E*,14*Z*,17*Z*-20:5 and 5*Z*,7*E*,9*E*,14*Z*,17*Z*-20:5) (Scheme 1) (8). We are particularly interested in seeds and algae that contain conjugated FA, and we have studied the properties of these materials extensively (9–16). During the course of our recent study on the antitumor effect of CEPA *in vivo* and *in vitro*, we found that acid mixtures prepared by treating all-(*Z*)-5,8,11,14,17-eicosapentaenoic acid (EPA, Scheme 1) with KOH in ethylene glycol under a number of different reaction conditions induced potent apoptotic cell death in several kinds of tumor cells, through membrane phospholipid peroxi-

dation (9,12). Interestingly, the KOH-treated mixtures were more cytotoxic than the EPA mixture itself but had no effect on normal human fibroblast cell lines. UV spectroscopic analysis of the KOH-treated mixtures showed that they contained various conjugated diene, triene, tetraene, and pentaene FA, which were present at various ratios, depending on the reaction conditions used. Among these mixtures, the one containing a higher amount of conjugated triene FA (UV λ_{max}: 268 nm) exhibited the highest cytotoxicity, suggesting that the most important component for cytotoxicity may be an EPA containing a conjugated triene structure.

To identify the specific cytotoxic FA, we have synthesized possible candidates for the active species. Here, we report the synthesis of (5E,7E,9E,14Z,17Z)-5,7,9,14,17-eicosapentaenoic acid (E-CEPA, Scheme 1) and its 5-(Z)- isomer (Z-CEPA, Scheme. 1), which both exist naturally in the red alga (*Ptilota filicina* J. Agardh). We then examined the cytotoxicity of these molecules in human tumor cells and confirmed that both isomers have strong bioactivity.

EXPERIMENTAL PROCEDURES

Synthesis of E-CEPA and Z-CEPA (Fig. 1). Methyl 5-oxopentanoate (**3**) was prepared in two steps from δ-valerolactone, according to the literature method (17). Methyl (5Z,8Z)-5,8-undecadienoate (**4a**) was prepared by a one-pot double-Wittig protocol developed by Pohnert and Boland (18). $KN[Si(CH_3)_2]_2$, abbrevi-

ated as KHMDS (0.5 M in toluene, 50 mL, 25 mmol), was added dropwise to a stirred suspension of 1,3-propanediylbis(triphenylphosphonium) dibromide (9.00 g, 12.3 mmol) in THF (120 mL) at –78°C under a nitrogen atmosphere. The mixture was allowed to warm to room temperature gradually over 2 h and stirred for an additional 30 min. Hexamethyl phosphoramide (6 mL) was added to the mixture, and the resulting homogeneous orange solution was recooled to –78°C. Propanal (1.00 mL, 14.0 mmol) was added dropwise to the solution, and the mixture was allowed to warm to 0°C over 2 h, stirred for an additional 30 min, and then recooled to –78°C. A solution of **3** (1.00 g, 7.70 mmol) in THF (15 mL) was added dropwise to the reaction mixture, and the mixture was allowed to warm gradually to room temperature. After being quenched with a saturated aqueous NH_4Cl solution, the mixture was extracted with ether. The extract was washed with brine, dried (using $MgSO_4$), and concentrated *in vacuo*. The residue was chromatographed over SiO_2 (150 g, elution with a 90:1 hexane/ethyl acetate mixture) to give **4a**.

Reduction of **4a** with diisobutylaluminum hydride (DIBAL) gave (5Z,8Z)-5,8-undecadienal (**4b**), which was then subjected to a four-carbon elongation reaction using methyl (E)-4-(diethoxyphosphoryl)but-2-enoate (19). DIBAL (0.95 M in hexane, 13.6 mL, 12.9 mmol) was added dropwise to a stirred solution of **4a** (2.40 g, 12.3 mmol) in CH_2Cl_2 (70 mL) at –78°C. After 30 min, the reaction mixture was quenched with a saturated aqueous NH_4Cl solution, and allowed to warm gradually to room temperature. Celite® was added to the mixture, and the resulting slurry was filtered through a Celite pad. The filtrate was dried (using $MgSO_4$) and concentrated *in vacuo*. The residue was chromatographed over SiO_2 (45 g, elution with a 100:1 hexane/ethyl acetate mixture) to give **4b**.

A mixture of **4b** (1.00 g, 6.00 mmol), methyl (E)-4-(diethoxyphosphoryl)but-2-enoate (6.70 mmol, 1.60 g). and $LiOH \cdot H_2O$ (275 mg, 6.70 mmol) in THF (50 mL) containing pulverized 4 Å molecular sieves (6.5 g) was stirred at reflux temperature for 14 h. The reaction mixture was filtered through a Celite pad, and the filtrate was concentrated *in vacuo*. The residue was chromatographed over SiO_2 (75 g, elution with a 40:1 hexane/ethyl acetate mixture) to give methyl (2E,4E,9Z,12Z)-2,4,9,12-pentadecatetraenoate (**5a**). DIBAL (0.95 M in hexane, 1.1 mL, 1.05 mmol) was added dropwise to a stirred solution of **5a** (120 mg, 0.5 mmol) in CH_2Cl_2 (8 mL) at –78°C. After 30 min, the mixture was worked up in a similar manner to that described for the preparation of **4b** to give (2E,4E,9Z,12Z)-2,4,9,12-pentadecatetraenol (**5b**) after SiO_2 chromatographic purification (5 g, elution with a 5:1 hexane/ethyl acetate mixture).

A mixture of **5b** (584 mg, 2.65 mmol) and MnO_2 (chemically treated, 8 g; Wako Pure Chemical Industries, Ltd., Tokyo, Japan) in CH_2Cl_2 (250 mL) was sonicated with a sonic cleaner (Honda Ultrasonic Cleaner W221) for 4 h at room temperature. The mixture was filtered through a pad of Celite, and the filtrate was concentrated *in vacuo* to give (2E,4E,9Z,12Z)-2,4,9,12-pentadecatetraenal (**5c**). Butyllithium (1.58 M in hexane, 0.30 mL, 0.47 mmol) was added dropwise to a stirred solution of 1,1,1,3,3,3-hexamethyldisilazane (80 mg, 0.50 mmol) in THF (2 mL) at 0°C, and the mixture was stirred for 20 min. The resulting solution was added

dropwise to a suspension of (4-carboxybutyl)triphenylphosphonium bromide (100 mg, 0.225 mmol) in THF (1 mL) at room temperature, and the mixture was stirred for 30 min, giving an orange solution. A solution of **5c** (50 mg, 0.2 mmol) in THF (0.5 mL) was added to the orange solution at room temperature. After being stirred for 30 min, the mixture was quenched with a saturated aqueous oxalic acid solution (1 mL) and extracted with ether. The extract, which contained (5*E*,7*E*,9*E*,14*Z*,17*Z*)-5,7,9,14,17-eicosapentaenoic acid (**1a**) and (5*Z*,7*E*,9*E*,14*Z*,17*Z*)-5,7,9,14,17-eicosapentaenoic acid (**2a**), was treated with an ethereal diazomethane (prepared from *N*-nitroso-*N*-methylurea) to give a mixture of methyl (5*E*,7*E*,9*E*,14*Z*,17*Z*)-5,7,9,14,17-eicosapentaenoate (**1b**) and methyl (5*Z*,7*E*,9*E*,14*Z*,17*Z*)-5,7,9,14,17-eicosapentaenoate (**2b**) after concentration *in vacuo*.

The mixture was repeatedly chromatographed over SiO_2 (25 g silica gel 60, 230–400 mesh; Merck, Darmstadt, Germany; elution with a 50:1 hexane/ether mixture) to give **1b** and **2b**. Two conjugated EPA methyl esters (**1b** and **2b**) were isolated using HPLC, based on the method we used before (16). Two CEPA methyl esters were dissolved in hexane, and this solution was fractionated by normal-phase HPLC using an 880-PU pump (Jasco, Inc., Tokyo, Japan) with an SPD-M10AVP detector (Shimadzu, Kyoto, Japan). A ChromSpher Lipids column impregnated with silver (5 μm particle size, 4.6 × 250 mm; Chrompack, Bridgewater, NJ) was used. A hexane/acetonitrile (100:0.15, vol/vol) mobile phase was used, and the flow rate was 1.0 mL/min. Detection was at 270 nm (FAME with a conjugated triene). A substance showing a large peak at 270 nm was repeatedly fractionated, and the two fractions collected (**1b** and **2b**) were purified. The collected fractions were dried completely under nitrogen gas.

IR spectra were measured as films, using a JASCO IR Report-100 spectrometer. ^{1}H NMR spectra were recorded in $CDCl_3$ (Wako Pure Chemicals Industries, Ltd., Osaka, Japan) with tetramethylsilane as an internal standard, using a Varian Gemini 2000 spectrometer (300 MHz) or a Varian UNITYplus-500 spectrometer (500 MHz). Mass spectra were obtained with a JEOL JMS-700 spectrometer operating in EI mode. Merck silica gel 60 (70–230 mesh) was used for silica gel column chromatography, unless otherwise stated. UV/vis spectrophotometric analysis of the conjugated EPA methyl esters was performed with a Shimadzu UV-2400P instrument. Geometric isomerism of the conjugated double bonds was distinguished easily using ^{13}C NMR under ^{13}C NMR conditions similar to those we have previously reported (16). Conjugated EPA methyl esters were dissolved in $CDCl_3$ at a concentration of 1 mg/mL. The ^{13}C NMR spectra were recorded on a Varian Unity 600 spectrometer (Varian, Inc., Palo Alto, CA) operating at 150 MHz.

Materials for cell culture. RPMI 1640 medium (containing 0.3 mg/mL L-glutamine and 2.0 mg/mL sodium bicarbonate) and all-(*Z*)-5,8,11,14,17- EPA were obtained from Sigma (St. Louis, MO). FBS was purchased from Dainippon Pharmaceutical (Osaka, Japan). Penicillin and streptomycin were products of Gibco BRL (Rockville, MD). 9*Z*,11*E*-CLA (99% purity) and 10*E*,12*Z*-CLA (99% purity) were obtained from Cayman Chemical Co. (Ann Arbor, MI).

Preparation of conjugated EPA (Mix-CEPA). In our previous study, CEPA (a FA with a conjugated trienoic structure) had the strongest cytotoxic effect compared with CLA, conjugated linolenic acid, and conjugated DHA (9,12). In the current study, CEPA was prepared from EPA by alkaline isomerization, using the previously reported method (9,12,20), and the initial product is henceforth referred to as mix-CEPA. The CEPA concentrate was stored at –20°C after being purged with nitrogen gas. UV/vis spectrophotometric analysis of the conjugated FA was performed with a Shimadzu UV-2400PC, and confirmed the presence of conjugated FA containing dienes (absorption maximum at 235 nm), trienes (268 nm), tetraenes (315 nm), pentaenes (345 nm), and hexaenes (375 nm) (21). The CEPA oil (Mix-CEPA) used in the subsequent experiments consisted of 57.6% conjugated dienes, 34.5% conjugated trienes, 6.7% conjugated tetraenes, and 1.2% conjugated pentaenes.

Cells and cell cultures. DLD-1 (colorectal adenocarcinoma), HepG2 (hepatoma), A549 (lung adenocarcinoma), and HL-60 (acute promyelocytic leukemia) human tumor cells were obtained from the Cell Resource Center for Biochemical Research at Tohoku University (Sendai, Japan). All tumor cells were cultured in RPMI 1640 medium (containing 0.3 mg/mL L-glutamine and 2.0 mg/mL sodium bicarbonate) supplemented with 10% FBS, 100 units/mL penicillin, and 100 mg/mL streptomycin. Cells were maintained at 37°C in a humidified atmosphere of 95% air and 5% CO_2.

Cell viability test using CLA and CEPA. Cell viability was assessed by the WST-1 method (13,22). The cells (DLD-1, HepG2, A549, and HL-60) were seeded onto 96-well culture plates at a density of 1×10^5 cells/well in 100 μL RPMI-1640 containing 10% FBS. Stock solutions of 9*Z*,11*E*-CLA, 10*E*,12*Z*-CLA, Mix-CEPA, E-CEPA (**1a**) and Z-EPA (**2a**) were prepared in ethanol at concentrations of 100 mM. For these experiments, the FA were prepared from the stock solution and diluted to final concentrations of 0–20 μM in FBS-free RPMI-1640. The final concentration of ethanol never exceeded 0.1% (vol/vol). After incubation for 24 h at 37°C, the cells were placed in 100 μL of fresh FBS-free RPMI-1640 medium with various concentrations of the FA. After 24, 10 μL of WST-1 solution was added to each well to evaluate cell viability. After incubation for 3 h at 37°C, cell viability was measured using a microplate reader (Model 550; Bio-Rad, Tokyo, Japan) at a wavelength of 450 nm and a reference wavelength of 655 nm.

Fluorescence dye staining analysis in DLD-1 cells (apoptosis assay) (9). DLD-1 cells were seeded on coverslips treated with ethanol (control), 2.5 mM E-CEPA, or 2.5 mM Z-CEPA for 24 h. After incubation, cells were washed in PBS and fixed in 4% formaldehyde. The fixed cells were stained for nuclei with Hoechst 33342 (1 μg/mL in PBS) for 10 min, washed in PBS, and mounted using 50% glycerol. The stained cells were observed by IX-FLA fluorescence microscopy (Olympus, Tokyo, Japan). Apoptotic cells were identified based on brightness due to condensed chromatin.

DNA fragmentation ladder assay in DLD-1 cells (apoptosis assay) (12,13). DLD-1 cells (1×10^5/mL) were seeded onto 10-cm dishes treated with ethanol (control), 2.5 μM E-CEPA, or 2.5 μM Z-CEPA for 24 h, and then transferred into a glass tube. Cells were suspended in lysis buffer (5 mM Tris, 20 mM EDTA, 0.5% Triton X-100, pH 8.0) and incubated for 30 min at 4°C. After

incubation, the tube was spun at $17,400 \times g$ for 20 min to separate the intact chromatin from the DNA fragments. Following centrifugation, 2 µL of RNase A (1 mg/mL; Sigma) was added to the supernatant, and the mixture was incubated at 37°C for 1 h. Proteinase K (2 µL; 1 mg/mL; Sigma) was then added, and incubation was continued for an additional 1 h. DNA was precipitated with a mixture of 20 µL of 5 M NaCl and 120 µL of 2-propanol overnight at –20°C. Following centrifugation, pellets were air-dried and dissolved in 20 µL of TE buffer (10 mM Tris and 1 mM EDTA, pH 7.4). Extracted DNA was separated by electrophoresis in a 2.0% agarose gel at 100 V in a pH 8.4 buffer containing 90 mM Tris, 90 mM boric acid, and 2 mM EDTA. Each gel was stained with ethidium bromide and photographed under UV light.

Statistics. Statistical analysis was performed using a one-way ANOVA, followed by a Newman–Keuls test for multiple comparisons among several groups. A difference was considered to be significant at $P < 0.05$.

RESULTS

Synthesis of Z-CEPA and E-CEPA (Fig. 1). The synthesis began with preparation of homoconjugated diene **4a** by the one-pot double-Wittig protocol developed by Pohnert and Boland (18). According to the reported procedure, the bis-ylide obtained by treating 1,3-propanediylbis(triphenylphosphonium) dibromide with 2 equiv of KHMDS was allowed to react sequentially with propanal and methyl 5-oxopentanoate (**3**) to give 487 mg (32 %) of **4a**. IR ν_{max} cm^{-1}: 3000 (*m*), 1740 (*s*); ^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.97 (3H, *t*, *J* = 7.6 Hz, 11-H$_3$), 1.71 (2H, *qui*, *J* = 7.3 Hz, 3-H$_2$), 2.01–2.15 (4H, *m*, 4-H$_2$, 10-H$_2$), 2.33 (2H, *t*, *J* = 7.3 Hz, 2-H$_2$), 2.77 (2H, *t*, *J* = 6.5 Hz, 7-H$_2$), 3.67 (3H, *s*, OCH$_3$), 5.22–5.46 (4H, *m*, 5-H, 6-H, 8-H, 9-H); HR-EIMS *m/z* (M$^+$): calcd. for C$_{12}$H$_{20}$O, 196.1464; found, 196.1463.

Reduction of **4a** with DIBAL gave 1.30 g (64%) of **4b**, IR ν_{max} cm^{-1}: 3000 (*m*), 2710 (*s*), 1720 (*s*); ^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.97 (3H, *t*, *J* = 7.4 Hz, 11-H$_3$), 1.71 (2H, *qui*, *J* = 7.3 Hz, 3-H$_2$), 2.01–2.16 (4H, *m*, 4-H$_2$, 10-H$_2$), 2.45 (2H, *td*, *J* = 7.3, 1.7 Hz, 2-H$_2$), 2.77 (2H, *t*, *J* = 6.7 Hz, 7-H$_2$), 5.23–5.47 (4H, *m*, 5-H, 6-H, 8-H, 9-H), 9.78 (1H, *t*, *J* = 1.7 Hz, 1-H). HR-EIMS *m/z* (M$^+$): calcd. for C$_{11}$H$_{18}$O, 166.1357; found, 166.1359. Compound **4b** was then subjected to a four-carbon elongation reaction using methyl (*E*)-4-(diethoxyphosphoryl)but-2-enoate. Reduction of **4b** gave 684 mg (46%) of **5a**, IR ν_{max} cm^{-1}: 3000 (*m*), 1720 (*vs*), 1640 (*s*); ^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.97 (3H, *t*, *J* = 7.6 Hz, 15-H$_3$), 1.51 (2H, *qui*, *J* = 7.4 Hz, 7-H$_2$), 2.01–2.13 (4H, *m*, 8-H$_2$, 14-H$_2$), 2.19 (2H, *q*, *J* = 7.4 Hz, 6-H$_2$), 2.77 (2H, *t*, *J* = 6.5 Hz, 11-H$_2$), 3.74 (3H, *s*, OCH$_3$), 5.24–5.44 (4H, *m*, 9-H, 10-H, 12-H, 13-H), 5.79 (1H, *d*, *J* = 15.7 Hz, 2-H), 6.07–6.24 (2H, *m*, 4-H, 5-H), 7.27 (1H, *dd*, *J* = 15.4, 10.2 Hz, 3-H). HR-EIMS *m/z* (M$^+$): calcd. for C$_{16}$H$_{24}$O$_2$, 248.1776; found, 248.1778.

The resulting tetraene-ester (**5a**) was converted in a conventional manner into aldehyde **5c** *via* alcohol **5b**. Reduction of **5a** gave 85 mg (80%) of **5b**, IR ν_{max} cm^{-1}: 3350 (*m*), 3000 (*m*), 980 (*s*); ^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.97 (3H, *t*, *J* = 7.6 Hz, 15-H$_3$), 1.28 (1H, *br*, OH), 1.46 (2H, *qui*, *J* = 7.4 Hz, 7-H$_2$), 2.02–2.14 (6H, *m*, 6-H$_2$, 8-H$_2$, 14-H$_2$), 2.77 (2H, *t*, *J* = 5.9 Hz, 11-H$_2$), 4.17
FIG. 2. HPLC chromatograms and UV absorption spectra of two synthetic conjugated EPA (CEPA) methyl esters. Two synthetic CEPA were separated with HPLC. The flow-rate was 1 mL/min with a hexane/acetonitrile (100:0.15) mobile phase, and detection at 270 nm (FAME with a conjugated triene). (A) HPLC chromatogram of E-CEPA methyl ester (retention time 36–37 min); (B) HPLC chromatograms of Z-CEPA methyl ester (retention time 39–41 min); (C) UV absorption spectrum of E-CEPA methyl ester (λ_{max} = 258, 268, 279); (D) UV absorption spectrum of Z-CEPA methyl ester (λ_{max} = 256, 266, 275). For abbreviations see Figure 1.

(2H, *d*, *J* = 5.5 Hz, 1-H$_2$), 5.26–5.44 (4H, *m*, 9-H, 10-H, 12-H, 13-H), 5.66–5.78 (2H, *m*, 2-H, 5-H), 6.06 (1H, *dd*, *J* = 15.1, 10.4 Hz, 4-H), 6.23 (1H, *dd*, *J* = 15.1, 10.4 Hz, 3-H). HR-EIMS *m/z* (M$^+$): calcd. for C$_{15}$H$_{24}$O, 220.1827; found, 220.1827.

Oxidation of **5b** gave 456 mg (79%) of **5c**, IR ν_{max} cm^{-1}: 2720 (*w*), 1680 (*s*), 1635 (*s*), 980 (*m*); ^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.97 (3H, *t*, *J* = 7.6 Hz, 15-H$_3$), 1.54 (2H, *qui*, *J* = 7.0 Hz, 7-H$_2$), 2.04–2.14 (4H, *m*, 8-H$_2$, 14-H$_2$), 2.24 (2H, *q*, *J* = 7.0 Hz, 6-H$_2$), 2.77 (2H, *t*, *J* = 6.6 Hz, 11-H$_2$), 5.29 (1H, *dt*, *J* = 10.3, 7.0 Hz, 9-H), 5.34–5.43 (3H, *m*, 10-H, 12-H, 13-H), 6.08 (1H, *dd*, *J* = 15.3, 8.0 Hz, 2-H), 6.28 (1H, *dt*, *J* = 15.3, 7.0 Hz, 5-H), 6.33 (1H, *dd*, *J* = 15.3, 10.4 Hz, 4-H), 7.09 (1H, *dd*, *J* = 15.3, 10.4 Hz, 3-H), 9.54 (1H, *d*, *J* = 8.0 Hz, 1-H). HR-EIMS *m/z* (M$^+$): calcd. for C$_{15}$H$_{22}$O, 218.1671; found, 218.1676.

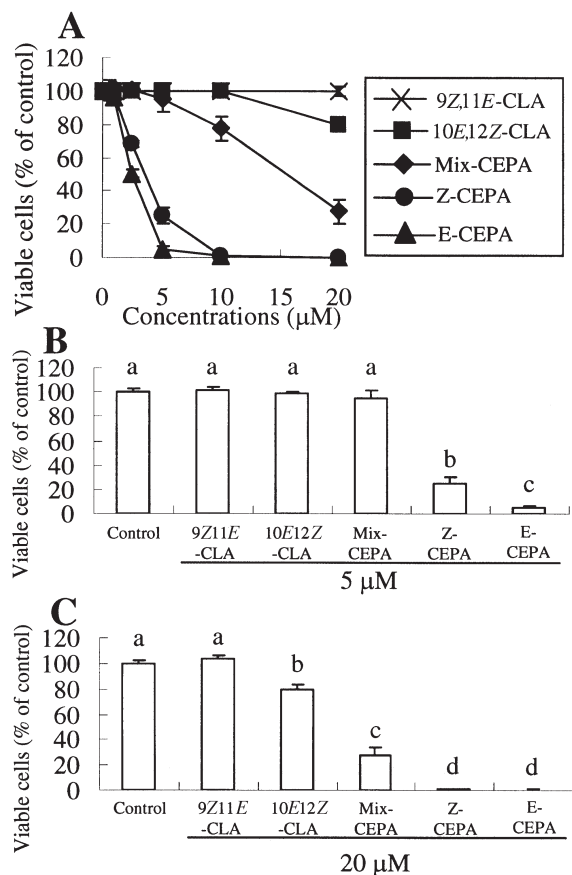
Finally, an (*E*)-selective Wittig olefination of **5c** with (4-carboxybutyl)triphenylphosphonium bromide gave a mixture of **1a** and **2a** (23). Since the spectroscopic characterization of the acids had been conducted in their methyl ester forms, the acid mixture was immediately treated with diazomethane to furnish 28 mg (44%) of **1b** and 14 mg (22%) of **2b** after chromatographic purification (Figs. 2A, 2B). **1b**: IR ν_{max} cm^{-1}: 3000 (*s*), 1740 (*s*), 1650 (*w*), 1640 (*w*), 1240 (*m*), 1200 (*m*), 1165 (*m*), 995 (*s*); ^{1}H NMR (CDCl$_3$) δ: 0.97 (3H, *t*, *J* = 7.6 Hz, 20-H$_3$), 1.46 (2H, *qui*, *J* = 7.6 Hz, 12-H$_2$), 1.73 (2H, *qui*, *J* = 7.3 Hz, 3-H$_2$), 2.02–2.15 (8H, *m*, 4-H$_2$, 11-H$_2$, 13-H$_2$, 19-H$_2$), 2.31 (2H, *t*, *J* = 7.3 Hz, 2-H$_2$), 2.77 (2H, *br t*, *J* = 5.9, 16-H$_2$), 3.66 (3H, *s*, OCH$_3$), 5.24–5.42 (4H, *m*, 14-H, 15-H, 17-H, 18-H), 5.61(1H, *dt*, *J* = 14.2, 7.2 Hz, 5-H), 5.67 (1H, *dt*, *J* = 14.5, 7.3 Hz, 10-H), 6.01–6.11 (4H, *m*, 6-H, 7-H, 8-H, 9-


FIG. 3. Cell viability test using 9*Z*,11*E*-CLA, 10*E*,12*Z*-CLA, Mix-CEPA, Z-CEPA, and E-CEPA in DLD-1 cells (A–C). DLD-1 cells were incubated for 24 h after treatment with each FA. (A) DLD-1 cells were incubated after treatment with 0–20 μM FA. (B) DLD-1 cells were incubated after treatment with ethanol (control) and 5 μM FA. (C) DLD-1 cells were incubated after treatment with ethanol (control) and 20 μM FA. Values are shown as the mean ± SD (*n* = 6). a,b,c,d: values with different superscripts are significantly different at *P* < 0.05. For abbreviations see Figure 1.

FIG. 4. Apoptosis assay (fluorescence dye staining analysis and DNA fragmentation ladder analysis) using Z-CEPA and E-CEPA in DLD-1 cells (A-E). Fluorescence dye staining analysis of DLD-1 cells treated with ethanol (control, A), 2.5 μM Z-CEPA (B), and 2.5 μM E-CEPA (C). Cells were incubated for 24 h after treatment with CEPA. Magnification: 100×. (D) Fluorescence dye staining analysis of DLD-1 cells treated with 2.5 μM Z-CEPA. Cells were incubated for 24 h after supplementation of Z-CEPA. Magnification: 200×. The arrows indicate apoptotic cells. (E) DNA fragmentation ladder analysis of DLD-1 cells treated with CEPA. Agarose gel electrophoresis of low-M.W. DNA extracted from DLD-1 cells. DLD-1 cells were exposed to ethanol (control), 2.5 μM Z-CEPA, or 2.5 μM E-CEPA. M: M.W. markers. For abbreviations see Figure 1.

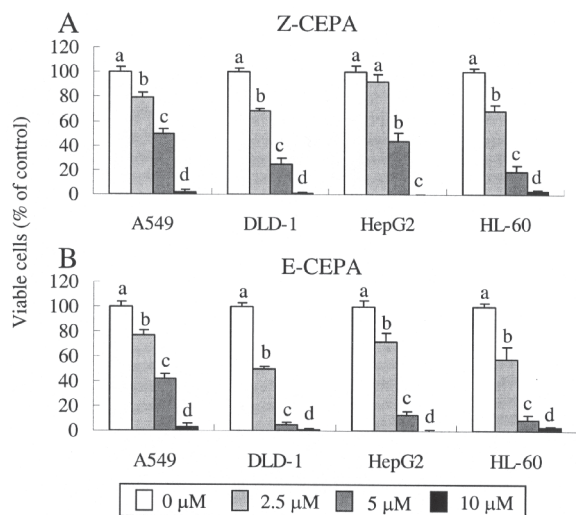
Cell viability test using E-CEPA and Z-CEPA in DLD-1 cells. The cytotoxicity of the synthetic CEPA isomers (E-CEPA and Z-CEPA) was examined in comparison with that of Mix-CEPA and CLA. DLD-1 cells were treated with 0 to 20 μM of five FA (9*Z*,11*E*-CLA, 10*E*,12*Z*-CLA, Mix-CEPA, E-CEPA, or Z-CEPA) at a purity of 99%, and cell viability 24 h after administration was measured using the WST-1 method. E-CEPA and Z-CEPA showed dose-dependent cytotoxicity reactions in DLD-1 cells, and these effects were stronger than those of CLA and Mix-CEPA (Fig. 3A). After administration of Z-CEPA and E-CEPA at a dose of 5 μM, the cell survival rates were 25 and 5%, respectively, compared with the control (Figs. 3A, 3B). Compared with Z-CEPA, E-CEPA showed a stronger cytotoxicity reaction in DLD-1 cells. After administration of 10*E*,12*Z*-CLA and Mix-CEPA at a dose of 20 μM, the cell survival rates were 80 and 27%, respectively, compared with the control (Figs. 3A, 3C). Hence, Mix-CEPA showed a stronger cytotoxicity reaction in DLD-1 cells, compared with 10*E*,12*Z*-CLA. Compound 9*Z*,11*E*-CLA at a dose of 20 μM did not show a cyto-


FIG. 5. Cell viability test using Z-CEPA (A) and E-CEPA (B) in various human tumor cells. Human tumor cells (A549, DLD-1, HepG2, HL-60 cells) were incubated for 24 h after treatment with FA. Values are shown as the mean ± SD (*n* = 6). a,b,c,d: values with different superscripts are significantly different at *P* < 0.05. For abbreviations see Figure 1.

toxicity reaction in DLD-1 cells (Fig. 3). The Mix-CEPA, Z-CEPA, and E-CEPA concentrations for 50% suppression of cell viability were approximately 15, 3, and 2.5 µM, respectively. Hence, the order of cytotoxicity reaction in DLD-1 cells was E-CEPA > Z-CEPA > Mix-CEPA > 10*E*,12*Z*-CLA > 9*Z*.11*E*-CLA.

Apoptosis assays (fluorescence dye staining analysis and DNA fragmentation ladder analysis) in DLD-1 cells. To characterize the mechanism of cell death, cytological alterations and cellular DNA degradation were analyzed. DLD-1 cell death caused by E-CEPA and Z-CEPA was accompanied by marked changes in cellular morphology. Nuclear condensation and brightness were observed by fluorescent microscopy in Hoechst 33342-stained cells treated with E-CEPA and Z-CEPA, compared with cells treated with ethanol only (Fig. 4A–D), and treatment of DLD-1 cells with 2.5 µM E-CEPA or Z-CEPA resulted in a DNA fragmentation ladder (Fig. 4E). Hence, it was shown that E-CEPA and Z-CEPA induced apoptosis in DLD-1 cells.

Cell viability test using E-CEPA and Z-CEPA in various human tumor cells. The cytotoxicity of the CEPA isomers was examined in three other human tumor cell lines (HepG2, A549, and HL-60), in addition to DLD-1 cells. Both E-CEPA and Z-CEPA showed strong dose-dependent cytotoxicity reactions in all the cultured human tumor cells examined (Fig. 5), with these effects being particularly strong in DLD-1 and HL-60 cells, compared with A549 and HepG2 cells.

DISCUSSION

In this study, we have synthesized two naturally occurring CEPA isomers and examined their cytotoxicity reaction in human tumor cells, compared with that of CLA. Consequently, we confirmed that E-CEPA and Z-CEPA, both of which contain a conjugated triene system, have a strong cytotoxicity reaction in tumor cells and that this occurs through induction of apoptosis. As far as we are aware, this is the first study to verify the cytotoxicity reaction of a naturally occurring CEPA.

We previously reported that CEPA has some potentially interesting physiological effects (9,12). However, in those studies, we used CEPA prepared by alkaline isomerization, and the CEPA was therefore a mixture of several isomers. At present, it is difficult to identify all of these isomers, and it is possible that some isomers produced by alkaline isomerization have little antitumor effect and may even have harmful side reactions . Therefore, the bioactivity of each isomer needs to be investigated. CEPA isomers such as 5*Z*,7*E*,9*E*,14*Z*,17*Z*–20:5 and 5*E*,7*E*,9*E*,14*Z*,17*Z*–20:5 (Scheme 1) are found in red algae (8), but the amounts of these molecules are extremely small and it is very difficult to extract and purify CEPA from red algae. Hence, synthesis of these molecules provides an alternative approach, and in this study we succeeded in the synthesis of two CEPA isomers, beginning from δ-valerolactone (Figs. 1, 2). The UV, ^{1}H NMR, and ^{13}C NMR spectral data of the synthetic CEPA isomers (E-CEPA and Z-CEPA) were identical to the respective authentic data (8).

Most CLA in nature is in the form of 9*Z*,11*E*-CLA (1). However, natural sources contain only a small amount of CLA, and therefore CLA used experimentally is generally prepared from linoleic acid by alkali isomerization, which gives a mixture of two isomers: 9*Z*,11*E*-CLA and 10*E*,12*Z*-CLA (Scheme 1). Several studies have shown an antitumor effect of the CLA mixture prepared by alkali isomerization (1,4,5), but it was only recently verified in a comparative study of the isomers that 9*Z*,11*E*-CLA had little effect and 10*E*,12*Z*-CLA, the minor component in nature, had a strong effect (24). This result was confirmed in the current study, which showed that 10*E*,12*Z*-CLA had a stronger cytotoxic effect than 9*Z*,11*E*-CLA (Fig. 3). In evaluating the cytotoxic effect of synthesized CEPA (E-CEPA and Z-CEPA) in tumor cells, 9*Z*,11*E*-CLA, 10*E*,12*Z*-CLA and Mix-CEPA (a CEPA mixture prepared from EPA by alkali isomerization) were used as positive controls. The results showed that E-CEPA and Z-CEPA had an extremely strong cytotoxic effect in tumor cells, compared with the CLA (Fig. 3). Therefore, both E-CEPA and Z-CEPA, which have a stronger physiological effect than CLA, are expected to be effective as physiologically active lipids.

The results also showed that E-CEPA and Z-CEPA had an extremely strong cytotoxic effect in tumor cells, compared with Mix-CEPA (Fig. 3). Mix-CEPA contains many structural isomers, and it is likely that some isomers that are only weakly bioactive are present in Mix-CEPA. We have previously clarified that conjugated FA with a conjugated triene system have a far stronger cytotoxicity reaction than conjugated FA with a conjugated diene system (13). The content of Mix-CEPA includes 58% conjugated diene FA and 35% conjugated triene FA, whereas the synthetic CEPA isomers contain only a conjugated triene system, perhaps accounting for the stronger activity of E-CEPA and Z-CEPA.

The synthetic CEPA isomers were observed to promote nuclear condensation and DNA fragmentation in DLD-1 cells, indicating induction of apoptosis (Fig. 4). This suggests that synthetic CEPA is safe, because apoptosis, and not necrosis, was induced in

the cancer cells. Furthermore, the synthetic CEPA isomers showed strong cytotoxicity reaction not only in the DLD-1 colorectal cancer cells but also in pulmonary carcinoma, hepatoma, and leukemia cells (Fig. 5). Therefore, it is anticipated that the synthetic CEPA will act on various carcinomas. E-CEPA, which contains an all-(E) conjugated triene structure, showed stronger cytotoxicity reaction than Z-CEPA, in which the conjugated triene structure contains both E and Z unsaturation configurations (Scheme 1; Figs. 3, 5). Hence, geometrical isomerism can influence the bioactivity of conjugated triene FA, and it appears that an all-(E) configuration leads to a stronger cytotoxicity reaction.

The mechanisms reportedly underlying the antitumor effects of FA include lipid peroxidation, modulation of eicosanoid production by changes in FA composition, and changes in membrane fluidity (25). Some studies have suggested that lipid peroxidation itself induces apoptosis and suppression of cell viability (26–33), and we have previously reported that some conjugated FA with a conjugated triene system can induce apoptosis in tumor cells *via* lipid peroxidation. It is likely that synthetic CEPA also induces apoptosis through lipid peroxidation. Hence the use of CEPA in food and medicine has considerable potential, once its safety is confirmed in animal studies and clinical trials.

Production and Protein Kinase C Activation of Diacylglycerols Containing Polymethylene-Interrupted PUFA

Jun-ichi Morishige, Yoshimichi Takai, Kaoru Hirano, Tamotsu Tanaka*, and Kiyoshi Satouchi

Department of Applied Biological Science, Fukuyama University, Fukuyama 729-0292, Japan

ABSTRACT: Sciadonic acid (20:3, Δ-5c,11c,14c) is a polymethylene-interrupted PUFA (PMI-PUFA) that is present in conifer seeds and known to be incorporated into animal cells and to accumulate in membrane PI as a substitute for arachidonate. In this study, we investigated whether PI having sciadonate could serve as source of DAG that could activate protein kinase C (PKC). When Swiss 3T3 cells cultured with sciadonic acid were stimulated with 100 nM of bombesin, 1-stearoyl-2-sciadonoyl-glycerol (G) and 1-stearoyl-2-arachidonoyl-G were produced. The net increments of these two molecular species of DAG reflected the levels of the two molecular species in the PI in the cells. When cells cultured with juniperonic acid (20:4, Δ-5c,11c,14c,17c) were stimulated, 1-stearoyl-2-juniperonoyl-G was produced in proportion to the level of this molecular species in PI in the cells. We also examined PKC activation by synthetic DAG using a partially purified PKC fraction from rat brain and found that both 1-stearoyl-2-sciadonoyl-G and 1-stearoyl-2-juniperonoyl-G could activate PKC comparably to 1-stearoyl-2-arachidonoyl-G. These results indicate that 1-stearoyl-PI having these C_{20} PMI-PUFA residues can serve as sources of potential signaling molecules.

Paper no. L9613 in *Lipids* **40**, 155–162 (February 2005).

The alignment of the double bonds of typical PUFA, such as arachidonic acid (AA) and EPA, are interrupted by one methylene group. However, the alignment of the double bonds in some PUFA are interrupted by two or more methylenes. The PUFA with this characteristic alignment of double bonds are categorized as nonmethylene-interrupted PUFA or as polymethylene-interrupted-PUFA (PMI-PUFA). PMI-PUFA, such as pinolenic acid (18:3, Δ-5,9,12), sciadonic acid (20:3, Δ-5,11,14; SciA), and juniperonic acid (20:4, Δ-5,11,14,17; JA), have been shown to exist widely in coniferous plants (1-4). Currently, conifer seed oils are not directly used as dietary oils, but some kinds of conifer seeds are consumed in some countries, such as Italy, Korea, and Japan. Pasquier *et al.* (5) proposed that conifer seeds be considered as a potential source of dietary oil because dietary conifer seed oils have shown substantial lipid-lowering potential in experimental animals (6,7).

PMI-PUFA are known to serve as substrates for enzymes of glycerolipid biosynthesis and FA oxidation (8). The incorpora-tion of PMI-PUFA into membrane phospholipids of animal cells in both *in vivo* and *in vitro* experiments has been reported (5,6,9–13). Our recent investigation demonstrated that SciA (lacking the Δ8 double bond of AA) and JA (lacking the Δ8 double bond of EPA) (Scheme 1) were metabolized in a manner similar to AA and EPA, respectively, in the process of acylation to phospholipids in HepG2 cells (13). We also demonstrated that SciA is an effective substitute for arachidonate of PI in HepG2 cells (12). The *in vivo* accumulation of sciadonate in hepatic PI of mice has been demonstrated using *Platycladus orientalis* (*Biota orientalis*) seed oil, which contains only 2.9% SciA (9,10).

A well-known characteristic of PI in mammalian cells is an abundance of arachidonate. At the molecular level, PI has been reported to be composed mainly of 1-stearoyl-2-arachidonoyl species in various organs and cells of mammals (14–19). Since inositolphospholipid is a main source of DAG in cell signaling, the predominant molecular species of DAG produced during the early response to agonistic stimulation is 1-stearoyl-2-arachidonoyl-glycerol (-G) (20). Therefore, the replacement of arachidonate in membrane PI with a PMI-PUFA residue implies structural modification of the source of signaling molecules. In this study, we investigated whether molecular species of PI having a PMI-PUFA residue could serve as source of DAG. Such information is helpful for better understanding the

metabolic fate of dietary PMI-PUFA and the mechanisms of the beneficial effects of PMI-PUFA-containing conifer seeds used as a traditional Chinese medicine (21). For this purpose, we conducted experiments using Swiss 3T3 cells, a well-documented cell line in the research on inositolphospholipid signaling. We also examined the efficacies of activation of protein kinase C (PKC) by synthetic DAG homologs including PMI-PUFA-containing molecular species.

MATERIALS AND METHODS

Materials. Dulbecco's modified Eagle's medium (DMEM), penicillin, streptomycin, and FBS were obtained from Gibco BRL and Life Technologies, Inc. (Rockville, MD). Essentially FA-free BSA, 1-stearoyl-2-lyso-*sn*-glycero-3-phosphocholine, bombesin, phospholipase C (PLC) (from *Bacillus cereus*), myelin basic protein from bovine brain, and histone from calf thymus were obtained from Sigma Chemical Co. (St. Louis, MO). AA, EPA, and linoleic acid were purchased from Serdary Research Laboratories (London, Ontario, Canada). [γ-^{32}P]ATP (3,000 Ci/mmol) was obtained from PerkinElmer Life Sciences, Inc. (Boston, MA). Biota and umbrella pine seeds were purchased from a nursery. The seeds were milled in methanol, and lipids were extracted by the method of Folch *et al.* (22). The lipid extract of the seeds was dissolved in 5% methanolic HCl, and FAME were prepared (23). SciA and JA were purified using argentation-TLC from FAME prepared from umbrella pine and biota seeds, respectively (23), and used after saponification. The purities of these PMI-PUFA were checked by GC and were over 98%. The double-bond positions of purified PMI-PUFA were confirmed by GC–MS, as described in Reference 23. All other reagents were of reagent grade.

Cell culture and analysis of cellular lipids. Swiss 3T3 cells obtained from the American Type Culture Collection (Manassas, VA) were plated in 100-mm plastic dishes at 4×10^5 cells/dish, and maintained in 10 mL of DMEM containing 10% FBS in a humidified atmosphere of 10% CO$_2$, 90% air at 37°C. After they had grown to confluence, 50 µM of FA was added to the cell cultures three times (12, 24, and 48 h before harvest) as a BSA complex (24). The cells were washed with PBS and harvested by trypsinization. The lipids of the cells were extracted by the method of Bligh and Dyer (25). The PI of the Swiss 3T3 cells was isolated from the lipid extract by 2-D TLC using chloroform/methanol/28% ammonia (65:35:5, by vol) for the first solvent system and chloroform/acetone/methanol/acetic acid/water (50:20:10:13:5, by vol) for second solvent system. The FA composition of the PI was analyzed by GC (Shimadzu GC-14A; Shimadzu, Kyoto, Japan) equipped with a capillary column coated with CBP 20 (0.25 µm film, 30 m length; Shimadzu) as FAME obtained by transmethylesterification (23). The carrier gas was nitrogen. The temperature of the injection/FID was set at 250°C. The initial column temperature was set at 170°C and then raised to 225°C at 5°C/min. The molecular species of the PI was determined by HPLC as a 1,2-DAG-dinitrobenzoyl derivative (DAG-DNB). A portion of the PI was hydrolyzed with PLC from *B. cereus*, and the result-

ing DAG was reacted with 3,5-DNB-chloride (26). The DAG-DNB formed was purified by TLC using hexane/diethyl ether (70:30, vol/vol) as the solvent system and analyzed by HPLC (Tosoh CCPD, Tokyo, Japan) equipped with a 0.45×25 cm Inertsil ODS-2 column (GL Science Inc., Tokyo, Japan) using acetonitrile/isopropanol (80:20, vol/vol) as the eluent (13). The molecular species of PC of Swiss 3T3 cells was analyzed as a DNB derivative by a similar method. To assign each peak, the eluate corresponding to each molecular species peak was collected, and direct FA analysis of each fraction was conducted by GC after transmethylesterification of DAG-DNB as described above. The trypan blue exclusion test showed that there was no significant difference in cell viability among the cells cultured with various PUFA.

DAG-production assay. Swiss 3T3 cells cultured with various FA (linoleic acid, SciA, JA, or EPA) were washed, harvested and suspended in a buffer consisting of 20 mM HEPES (pH 7.4), 115 mM NaCl, 5.4 mM KCl, 0.8 mM MgCl$_2$, 1.8 mM CaCl$_2$, and 13.8 mM glucose (buffer A) at density of 1×10^6 cells/mL. After 3 min of preincubation, the suspension (4 mL) of cells was incubated with 100 nM bombesin for 10 s under continuous stirring at 37°C. Then, the cell suspension was mixed with 15 mL of a mixture of chloroform/methanol (1:2, vol/vol) and 540 pmol of 1,2-distearoyl-G as an internal standard, and sonicated for 30 s. Lipids were extracted by the method of Bligh and Dyer (25). The 1,2-DAG was isolated from the lipid extract by TLC using hexane/diethyl ether/acetic acid (20:80:1, by vol) as the solvent system. The purified 1,2-DAG was converted to DAG-DNB and analyzed by HPLC as described above. Peaks in the chromatograms were assigned from the data obtained in the molecular species analyses of PC and PI of Swiss 3T3 cells. Amounts of each molecular species of DAG were determined based on the peak area relative to that of the DNB-derivative of 1,2-distearoyl-G as the internal standard.

Synthesis of DAG. DAG for PKC assay were prepared by hydrolysis of synthetic PC with PLC (27). Briefly, AA, SciA, JA, or EPA was converted to its respective fatty acyl chloride by treatment with oxalyl chloride at 4°C for 3 h in the dark. 1-Stearoyl-2-lyso-*sn*-glycero-3-phosphocholine suspended in dry hexamethylphosphoric triamide was allowed to react with the fatty acyl chloride at 4°C for 24 h in the dark. The resultant PC was purified by TLC using chloroform/methanol/water (65:35:6, by vol) as the solvent system. The purities of the PC having SciA or JA, novel PC synthesized in this study, were confirmed by matrix-assisted laser desorption/ionization time-of-flight MS in a Voyager DE STR (Applied Biosystems, Framingham, MA,) using 2,5-dihydroxybenzoic acid as a matrix (28). 1-Stearoyl-2-sciadonoyl-PC and 1-stearoyl-2-juniperonoyl-PC gave a set of three intense signals of [M + H]$^+$, [M + Na]$^+$, and [M + K]$^+$ at *m/z* 812.6, 834.6, and 850.6 (sciadonoyl-PC) and *m/z* 810.6, 832.6, and 848.6 (juniperonoyl-PC), respectively. DAG was obtained by digestion of the PC with PLC from *B. cereus*. The resultant DAG was used for PKC assay after purification by TLC using hexane/diethyl ether/acetic acid (20:80:1, by vol) as the solvent system. The amount of DAG was determined by GC using heptadecanoic acid as the internal standard.

Preparation of PKC fraction. The PKC fraction was prepared from rat brain soluble fractions (29). Male Wistar rats (250 g body weight) were anesthetized with diethyl ether and sacrificed by decapitation. The whole brains (1.5–1.6 g each) from eight rats were homogenized in a Potter-Elvehjem glass-Teflon homogenizer with 160 mL of buffer consisting of 25 mM Tris-HCl (pH 7.5), 50 mM 2-mercaptoethanol, 2 mM EGTA, 1 mM PMSF, and 0.25 M sucrose. The homogenate was centrifuged for 90 min at $75,000 \times g$. The supernatant was applied to a DEAE-cellulofine column (2.5×11 cm; Seikagaku Kogyo, Tokyo, Japan), which was equilibrated beforehand with a buffer consisting of 25 mM Tris-HCl (pH 7.5), 50 mM 2-mercaptoethanol, and 2 mM EGTA (buffer B). After washing the column with 200 mL of buffer B at a flow rate of 0.7 mL/min, proteins retained in the column were eluted by the application of 400 mL of a linear NaCl gradient (0–400 mM) in buffer B at a flow rate of 0.5 mL/min. The eluate was fractionated (7 mL each), and the absorbance at 280 nm and PKC activities of each fraction were measured as described below.

PKC assay. 1-Stearoyl-2-oleoyl-*sn*-glycero-3-phosphoserine (PS) (62.5 nmol) and DAG (15.5 nmol) in a mixture of chloroform/methanol (1:1,vol/vol) were placed in a round-bottomed tube, and the solvents were removed under reduced pressure in a rotary evaporator. The resulting thin films of mixed lipids were suspended in 1 mL of 125 mM Tris-HCl buffer (pH 7.4) by vortexing. The suspension was then sonicated for 1 min in a bath-type sonicator (200 W, 42 kHz) at 25°C. A PKC assay was conducted with the resulting lipid vesicles. The reaction mixture (50 μL) contained 25 mM Tris-HCl (pH 7.4), 5 mM $MgCl_2$, 1 μM $CaCl_2$, 25 μg of calf thymus histone, 10 μM $[\gamma$-$^{32}P]ATP$ (0.5 μCi), lipid vesicles (12.5 μM PS and 3.1 μM DAG), and 3 μg protein of the PKC fraction. In the experiment using myelin basic protein from bovine brain (25 μg) as the PKC substrate, 1.5 μg protein of the PKC fraction was used. The reaction was started by addition of the PKC fraction. After incubation for 5 min at 30°C, the reaction was terminated by addition of 20 mM ATP (50 μL), and 50 μL of the mixture was spotted on P-81 ion-exchange paper (Whatman). The paper was washed three times with 75 mM phosphoric acid solution and dried for 1 h at 80°C. The radioactivity of the phosphorylated proteins that were adsorbed on the paper was measured by liquid scintillation counting.

RESULTS

Bombesin-induced DAG-production in Swiss 3T3 cells cultured with various PUFA. Bombesin has been reported to be a potent stimulator that induces biphasic DAG generation (30). In a time-course experiment using Swiss 3T3 cells labeled with $[^3H]AA$, the highest DAG production was observed at 10 s of incubation with 100 nM of bombesin (data not shown). Therefore, the DAG-production assay of Swiss 3T3 cells cultured with or without (control) various PUFA was conducted in this condition. The amounts of each DAG molecular species were determined by HPLC using 1,2-distearoyl-G as the internal standard (Figs. 1,2). Although the FA profile of PI in animal

tissues shows an abundance of arachidonate, the PI of the control cells had molecular species containing not only AA but also oleic acid (18:1, Δ-9) and Mead acid (20:3, Δ-5,8,11; MA) (Table 1). The abundance of n-9 series unsaturated FA in membrane lipids indicated that the cells without FA supplementation were in a condition of FA deficiency and that MA compensated for the AA deficiency in PI. The DAG-production assay revealed that both 1-stearoyl-2-arachidonoyl-G and 1-stearoyl-G containing MA increased markedly in control cells stimulated with bombesin (Fig. 1). The net increments of 1-stearoyl-2-arachidonoyl-G and 1-stearoyl-G containing MA were calculated to be 115 and 78 pmol/4×10^6 cells, respectively (Fig. 2). The ratio of the amounts of these DAG (approximately 1:1) reflected the abundance of corresponding molecular species in the PI (22 and 20%, respectively) of control cells (Table 1). We confirmed here that DAG produced under our assay conditions were PI-derived, because both AA and MA were scarcely detected in the PC of the control cells (data not shown). Similar experimental results using Swiss 3T3 cells have been reported by Pettitt and Wakelam (31).

When the cells were cultured with linoleic acid, the level of 1-stearoyl-2-arachidonoyl-PI increased markedly (64%) (Table 1). Consistent with changes in the molecular species composition of PI, only the molecular species 1-stearoyl-2-arachidonoyl-G increased, from 76 to 209 pmol/4×10^6 cells, upon the stimulation with bombesin (Figs. 1,2).

As seen in HepG2 cells (13), SciA was available as an acyl group of PI in Swiss 3T3 cells. As a result, 1-stearoyl-2-sciadonoyl-PI emerged in place of 1,2-dioleoyl-PI and 1-stearoyl-PI containing MA (Table 1). The HPLC analysis of DAG-DNB prepared from cells cultured with SciA showed that the levels of 1-stearoyl-2-arachidonoyl-G and the mixture of 1-stearoyl-2-sciadonoyl-G + 1,2-dipalmitoyl-G increased on bombesin stimulation (Figs. 1,2). Almost all the increments in the level of the latter mixed DAG were considered attributable to the increase in the amount of 1-stearoyl-2-sciadonoyl-G, because 1,2-dipalmitoyl species did not exist in the PI of SciA-supplemented cells, and the level of 1,2-dipalmitoyl-G in other cells was not changed much by agonistic stimulation. Accordingly, the net increment of 1-stearoyl-2-sciadonoyl-G could be estimated as 98 pmol/4×10^6 cells, which was approximately twice the increment of 1-stearoyl-2-arachidonoyl-G (54 pmol/4×10^6 cells). The relative amounts of these DAG reflected the abundance of corresponding molecular species in PI (22 and 38%, respectively) in the cells cultured with SciA. This result indicated that PI having sciadonate is used as a source of DAG equally to PI having arachidonate.

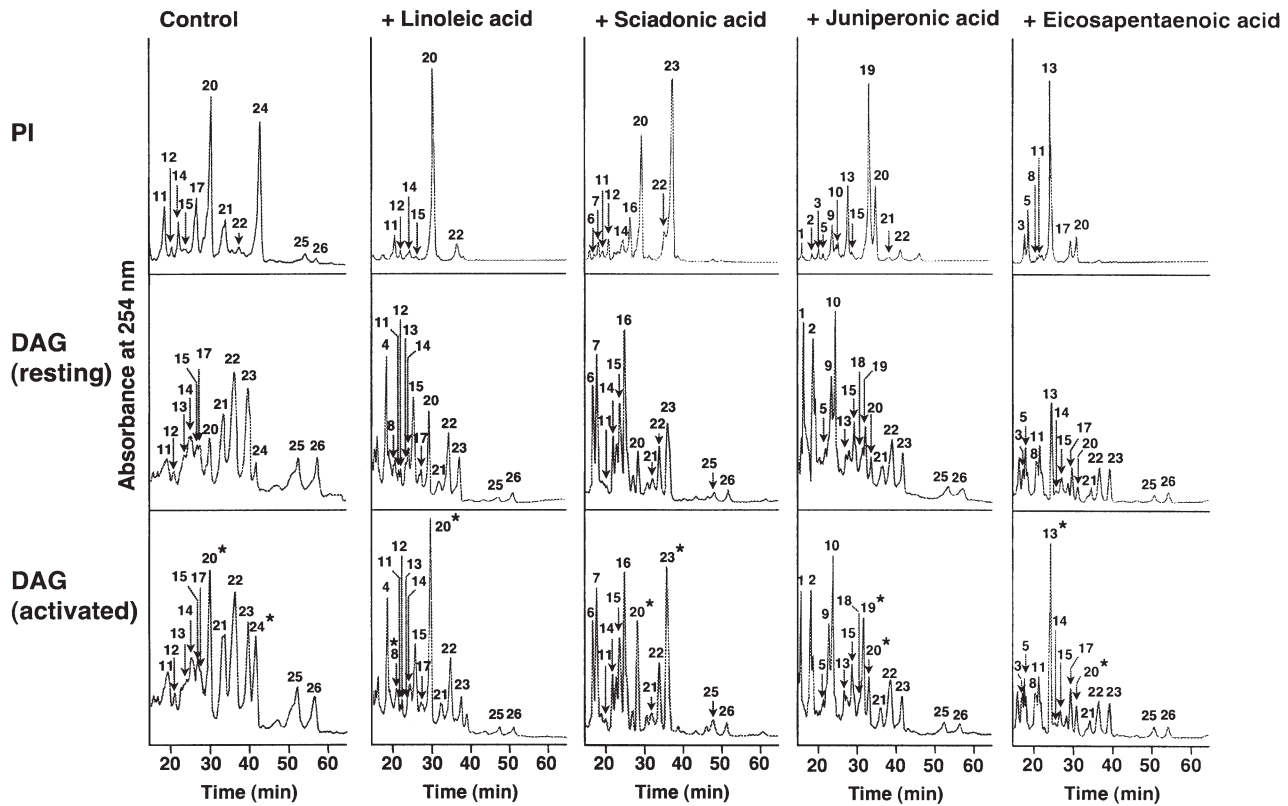
Like SciA, JA was extensively acylated to PI in Swiss 3T3 cells. As a result, 1-stearoyl-2-juniperonoyl-PI constituted 42% of the total molecular species of PI (Table 1). When the cells were stimulated with bombesin, two molecular species of DAG, namely 1-stearoyl-2-arachidonoyl-G and 1-stearoyl-2-juniperonoyl-G, were produced (Figs. 1,2). The net increments of these DAG were calculated to be 46 and 87 pmol/4×10^6 cells, respectively. The ratio of the amounts of these DAG (approximately 1:2) reflected the abundance of corresponding mo-


FIG. 1. HPLC of dinitrobenzoyl (DNB) derivatives of PI and DAG obtained from Swiss 3T3 cells cultured with or without PUFA. Swiss 3T3 cells cultured without fa (control) or with 50 μM PUFA were incubated with (activated) or without (resting) 100 nM of bombesin for 10 s. The lipids were extracted after addition of 1,2-distearoyl-glycerol (-G) as an internal standard. The isolated DAG was converted to a DNB derivative and analyzed by HPLC. The DNB derivative of 1,2-distearoyl-G was eluted at 80 min. HPLC of the DNB derivative of PI isolated from the resting cells is also shown. Peaks observed in the molecular species analysis of PI and PC were assigned by direct analysis with GC after transmethylesterification. From these data, peaks in the chromatograms of DAG were assigned. The numbers above peaks correspond to the peak numbers of molecular species shown in Table 1 and Figure 2. An asterisk (*) indicates significantly increased from resting cells.

lecular species in the PI (15 and 42%, respectively) in the cells cultured with JA (Table 1).

Similar experiments were conducted with EPA. 1-Stearoyl-2-eicosapentaenoyl-PI was the predominant molecular species (53%) of PI in cells cultured with EPA (Table 1). In these cells, 1-stearoyl-2-arachidonoyl-PI constituted only 9% of the total molecular species of PI. Consistent with this profile of the molecular species of PI, the predominant molecular species of DAG produced due to the stimulation was 1-stearoyl-2-eicosapentaenoyl-G. The increments of 1-stearoyl-2-arachidonoyl-G and 1-stearoyl-2-eicosapentaenoyl-G were estimated to be 16 and 99 pmol/4×10^6 cells, respectively (Figs. 1,2). The relative productions of these DAG (approximately 1:6) were in good agreement with the abundance of each molecular species in PI in the cells.

Activation of PKC by synthetic DAG homologs. We examined the efficacies of PKC activation by DAG having PMI-PUFA residues (Table 2). Because of the low activity of the enzyme, efficacies of PKC activation by different DAG could not be determined using commercially obtained PKC. Therefore, the enzyme fraction used here was prepared from rat brain cytosol using DEAE ion-exchange coumn chromatography by the method reported by Inagaki *et al.* (29). The fraction with the

highest PKC activity was eluted from the column at 150 mM NaCl and used for the PKC assay after appropriate dilution. This PKC fraction has been shown to contain cPKC as major isoenzymes (32). In fact, the PKC activity was found to be highly dependent on cofactors (Figs. 3A,B): It required >10 μM PS, >6 μM 1-stearoyl-2-arachidonoyl-G, and >1 μM Ca^{2+}. On the basis of these results, the assay was conducted in the presence of 12.5 μM of PS, 3.1 μM of synthetic DAG, and 1 μM of Ca^{2+}. The potencies of DAG for PKC activation were examined using histone or myelin basic protein as the substrate (Table 2). Although actual PKC activities were higher in the experiments with myelin basic protein than those with histone in all DAG species, the relative potencies of DAG were essentially similar with both substrates. The DAG with the highest potency for activation of the PKC fraction was 1-stearoyl-2-arachidonoyl-G. In contrast, DAG having a palmitoyl (*sn*-1) or linoleoyl group (*sn*-2) were poor activators, indicating that the structural requirement of DAG for PKC activation could be determined under our assay condition. The levels of PKC activation by both 1-stearoyl-2-sciadonoyl-G and 1-stearoyl-2-juniperonoyl-G were comparable to that by 1-stearoyl-2-arachidonoyl-G. We also prepared mixed DAG vesicles containing 1-stearoyl-2-arachidonoyl-G and 1-stearoyl-G having C_{20}
FIG. 2. Bombesin-induced DAG-production in Swiss 3T3 cells cultured with various PUFA. Swiss 3T3 cells cultured without or with 50 μM PUFA were incubated with (hatched bar) or without (open bar) 100 nM bombesin for 10 s. DAG isolated from the cells were analyzed by HPLC as shown in Figure 1, and the amounts of each DAG were determined on the basis of the peak area relative to that of DNB of 1,2-distearoyl-G as internal standard. Values are expressed as pmol/4 × 10^6 cells ± SD from three independent experiments. JA, juniperonic acid; SciA, sciadonic acid; AA, arachidonic acid; MA, Mead acid; DGLA, dihomo-γ-linolenic acid; +C2, chain-elongated metabolite. For other abbreviation see Figure 1. *, **, ***Significantly different from resting cells using Student's *t*-test (*$P < 0.05$, **$P < 0.01$, ***$P < 0.001$).

[a]The peak number corresponds to the number of molecular species shown in Figures 1 and 2. Values are percentages of the total molecular species, means ± SD (three or four harvests of cells). AA, arachidonic acid; SciA, sciadonic acid; JA, juniperonic acid; MA, Mead acid; DGLA, dihomo-γ-linolenic acid; +C2, chain-elongated metabolite. N.D., not detected.
[b]Judging from the GC analysis, peak 23 did not contain 16:0/16:0 at significant concentration.

PMI-PUFA residue at a molar ratio 1:1 and used them for PKC assay. The results showed that the relative potencies of the mixture of 1-stearoyl-2-arachidonoyl-G and 1-stearoyl-2-sciadonoyl-G, and the mixture of 1-stearoyl-2-arachidonoyl-G and 1-stearoyl-2-juniperonoyl-G were 100 and 91%, respectively, compared with that of 1-stearoyl-2-arachidonoyl-G alone. These results indicated that the potencies of 1-stearoyl-G having C_{20} PMI-PUFA residues are comparable to that of 1-stearoyl-2-arachidonoyl-G.

DISCUSSION

Previously, we demonstrated that SciA, an n-6 series C_{20} PMI-PUFA, is an effective substitute for AA residue of PI in HepG2 cells (12,13). The accumulation of SciA in PI has been observed in mice fed biota seed oil, which contains 2.9% SciA (9,10). In this study using Swiss 3T3 cells, supplementation of SciA to cells caused enrichment of newly formed 1-stearoyl-2-sciadonoyl-PI, which was the most abundant molecular species in PI (38%) (Table 1). Although our previous study with HepG2

cells showed that neither JA nor EPA accumulated in PI at levels similar to SciA (13), these n-3 PUFA were effectively acylated to PI in Swiss 3T3 cells (Table 1). The reason for the difference in the metabolic behaviors of these n-3 PUFA in HepG2 cells and Swiss 3T3 cells is unknown, but it might be ascribed to differences in the substrate specificity of enzymes, such as acyl CoA:1-acyl-2-lyso-PI acyltransferase, CoA-dependent transacylase, and enzymes involved in the phosphoinositide cycle, responsible for biosynthesis of PI in the respective cell lines. In any event, supplementation of SciA and JA to Swiss 3T3 cells modified the molecular species composition of PI extensively.

A portion of PI in the membrane is metabolized by PI 4-kinase and PI 5-kinase. The resulting PIP_2 is hydrolyzed by activated PLC in response to the agonistic stimulation. Our results indicated that 1-stearoyl-2-sciadonoyl-PI is sequentially metabolized by these PI-kinases and PLC in a similar manner to 1-stearoyl-2-arachidonoyl-PI, because 1-stearoyl-2-sciadonoyl-G and 1-stearoyl-2-arachidonoyl-G were produced in response to stimulation with bombesin in proportion to the level of each molecular species in PI of the cells cultured with SciA. This was

TABLE 2
Efficacy of PKC Activation of Various DAG[a]

[a]Protein kinase C (PKC) assay was conducted in the presence of $CaCl_2$ (1 µM), PS (12.5 µM), DAG (3.1 µM), and calf thymus histone (25 µg/0.05 mL) or bovine brain myelin basic protein (25 µg/0.05 mL) as described in the Materials and Methods section. The partially purified PKC fraction from rat brain (3 and 1.5 µg protein/0.05 mL) was used for the experiments with histone and myelin basic protein, respectively. Data are expressed as nmol per 5 min per mg protein, means ± SD, from three to ten independent assays. Values in parentheses are the percentage of PKC activity with 1-stearoyl-2-arachidonoyl-glycerol. For abbreviations see Table 1.
[b]Significantly different from 1-stearoyl-2-arachidonoyl-glycerol using Student's t-test, $P < 0.001$.

also the case for the 1-stearoyl-2-juniperonoyl-PI. From these observations, it is possible to conclude that 1-stearoyl-PI containing these C_{20} PMI-PUFA localize at the cell membrane in a manner similar to 1-stearoyl-2-arachidonoyl-PI, and that PI-kinases and PLC in Swiss 3T3 cells do not discriminate the structural differences between AA residue and SciA or JA residue in inositolphospholipids.

In this study, we showed that the most potent activator of the PKC fraction was 1-stearoyl-2-arachidonoyl-G, the predominant molecular species in PI in various organs and mammalian cells (14–19). Although the level of activation of the PKC fraction by 1-stearoyl-2-eicosapentaenoyl-G was somewhat lower than that by 1-stearoyl-2-arachidonoyl-G, as re-

ported by Marignani *et al*. (33) and Madani *et al*. (34), both 1-stearoyl-2-sciadonoyl-G and 1-stearoyl-2-juniperonoyl-G activated the PKC fraction comparably to 1-stearoyl-2-arachidonoyl-G. The activation of PKC in living cell is a complicated process. The specific anchoring protein (35) and free PUFA (36) are reported to mediate PKC translocation, and its phosphorylation modulates the activity of PKC (37). Because our data on PKC activation are limited to the *in vitro* condition, the possibilities that processes of translocation of PKC or interaction with the PKC substrate are affected in the cells treated with PMI-PUFA cannot be ruled out, but the results presented above indicate that the PKC used in our assay do not discriminate the structural difference between the arachidonate and C_{20} PMI-PUFA residues in DAG molecules.

In conclusion, we found that PI having sciadonate or juniperonate are converted to DAG with similar efficacy as PI having arachidonate. The resulting DAG having these C_{20} PMI-PUFA residues were shown to be potent activators for the PKC fraction. It is thus possible to consider that PI having these C_{20} PMI-PUFA residues can serve as sources of potential signaling molecules.

FIG. 3. Characterization of protein kinase C (PKC) fraction obtained from rat brain cytosol. The PKC fraction was prepared from rat brain cytosol by DEAE ion-exchange column chromatography. PKC activity was measured using the fraction (3 µg protein/0.05 mL) with the highest PKC activity in the presence of 12.5 µM PS, 1 µM $CaCl_2$ and various concentrations of 1-stearoyl-2-arachidonoyl-G (A), or in the presence of 1.55 µM 1-stearoyl-2-arachidonoyl-G, 1 µM $CaCl_2$, and various concentrations of PS (B). In both experiments, calf thymus histone (25 µg/0.05 mL) was used as the PKC substrate. Data are expressed as nmol per 5 min per mg protein, means ± SD, from experiments performed in duplicate. For other abbreviation see Figure 1.

Divisions of [a]Cardiology and [b]Endocrinology & Metabolism, Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan, and [c]Institute of Industrial Hygiene and Occupational Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan

ABSTRACT: Decreased serum adiponectin is associated with dyslipidemia. However, serum adiponectin status has never before been studied in patients with familial-related severe primary hypercholesterolemia (FRSPH). The aim of this study is to measure serum adiponectin level in a group of young patients with FRSPH and determine its correlation with insulin-resistant status. Twenty-three patients with FRSPH [average LDL-cholesterol (LDL-C) = 250.8 (190–610) mg/dL] without clinical manifestations of metabolic syndrome as well as 46 healthy (control) adolescents and young adults (<30 yr old) were included. The serum adiponectin, fasting sugar, insulin, lipids, systolic and diastolic blood pressure (SBP and DBP), and anthropometrical indices such as body mass index and waist circumference were obtained. The homeostasis model assessment (HOMA) was calculated to estimate the insulin resistant status. Compared with healthy controls, patients with FRSPH had a significantly lower mean serum adiponectin level (7.7 ± 1.8 µg/mL vs. 10.1 ± 4.3 µg/mL, $P = 0.013$). After adjustment for HOMA and associated covariates, multiple linear regression analysis showed that patients with FRSPH are significantly associated with hypoadiponectinemia. Compared with healthy controls, patients with FRSPH had a significantly lower mean serum adiponectin level (7.7 ± 1.8 µg/mL vs. 10.1 ± 4.3 µg/mL, $P = 0.013$). After adjustment for HOMA and associated covariates, multiple linear regression analysis showed that patients with FRSPH are significantly associated with hypoadiponectinemia. The serum adiponectin levels are lower in young patients with FRSPH without clinical manifestations of metabolic syndrome. The mechanism of hypoadiponectinemia in patients with FRSPH is probably independent of insulin resistance.

Paper no. L9652 in *Lipids 40*, 163–167 (February 2005).

Adipose tissue is now known not to be simply an inert storage depot for lipids but rather an important endocrine organ that plays a key role for the control of energy homeostasis through secretion of a variety of hormones and cytokines called adipocytokines (1). Adiponectin, an adipocytokine that is abundantly expressed in adipose tissue, has been associated with systemic insulin sensitivity both *in vivo* and *in vitro* (2–4). Clinical observations also have shown that serum adiponectin is reduced in patients with obesity, type 2 diabetes, coronary artery diseases (CHD), and hypertension (5–7), and all of them are closely related to insulin resistance.

In addition to hypertension and diabetes mellitus (DM), dyslipidemia was closely related to decreased serum adiponectin (6,8). Hotta *et al.* (6) observed a significant negative correlation between serum adiponectin and TG levels and a positive correlation between adiponectin and HDL-cholesterol (HDL-C) levels in type 2 DM (6). Matsubara *et al.* (8) extended this finding by demonstrating similar correlations in nondiabetic female subjects. The mechanism underlying the observed close association may be attributable to insulin resistance and/or hyperinsulinemia (2–4,8), a main component of metabolic syndrome. One proposed mechanism is that adiponectin decreases circulating FFA by increasing FA oxidation muscle (2,9). This results in decreased TG content in muscle, which has been associated with improved insulin sensitivity (10). In addition, liver FFA influx also is decreased in the presence of adiponectin, which might lead to decreased hepatic TG content and improve hepatic insulin sensitivity and reduce glucose output (2).

Familial-related severe primary hypercholesterolemia (FRSPH) is associated with excessive cardiovascular mortality and morbidity (11). Recently, it has been demonstrated that decreased plasma adiponectin levels are associated with CHD and with CHD risk (6,12). It is of great interest to measure the adiponectin levels in this population. Because older patients often have unhealthy physical conditions that are closely related to insulin resistance, such as hypertension, obesity, and diabetes, we tested the hypothesis of decreased adiponectin levels in a group of young patients with FRSPH and without comorbidities of metabolic syndrome. The aim of this study is to compare serum adiponectin level in young patients with FRSPH and matched healthy controls and to determine its correlation with insulin-resistant status and lipid profile.

SUBJECTS AND METHODS

Subjects. We studied a total of 23 FRSPH adolescents and young adults (<30 yr old) who were recruited for familial

Abbreviations: BMI, body mass index; BP, blood pressure; CHD, coronary artery diseases; DBP, diastolic blood pressure; DM, diabetes mellitus; FH, familial hypercholesterolemia; FRSPH, familial-related severe primary hypercholesterolemia; HDL-C, HDL cholesterol; HOMA, homeostasis model assessment; hs-CRP, high-sensitive C-reactive protein; LDL-C, LDL cholesterol; SBP, systolic blood pressure; WC, waist circumference.

hypercholesterolemia screening (FH) during 2002 at the lipid clinic of National Taiwan University Hospital. These patients were diagnosed to have FRSPH on the basis of having LDL-cholesterol (LDL-C) levels in themselves and in two or more first-degree relatives that were above 190 mg/dL and/or the presence of tendinous xanthomas within the kindred. Subjects having serum levels of HDL-C and TG in the normal range, and subjects with any etiologies of secondary hyperlipidemia, such as nephritic syndrome, obstructive liver disease, hypothyroidism, DM, or use of drugs affecting lipid levels were excluded. The genetic basis of FRSPH is heterogeneous and is associated not only with a high number of different LDL receptor gene mutations and other genetic abnormalities but also with differences in frequencies of specific mutations between populations. Thus, in the absence of genetic confirmation, we defined our study subjects as having FRSPH but as not having FH. However, about half of them had strong evidence of pathognomonic stigmata, namely, tuberous xanthoma or tendinous xanthoma of FH, and their LDL-C levels all were above 95th percentile for sex and age. Another age- and gender-matched 57 healthy controls, whose LDL-C levels were <130 mg/dL, were recruited from the healthy examination. Subjects with a history of hypertension, DM, and cardiovascular diseases or with serum creatinine over 1.5 mg/dl, serum TG over 150 mg/dL, resting blood pressure (BP) at or above 130/85 mmHg, or fasting plasma sugar over 110 mg/dL were excluded in this study. All subjects received a detailed medical history review and physical examination. Subjects' weight and height as well as their waist circumference (WC) were also obtained. The body mass index (BMI) was calculated by dividing the weight in kilograms by the square of the height in meters. The systolic BP (SBP) and diastolic BP (DBP) readings were recorded to the nearest 2 mmHg as the mean of two measurements by mercury sphygmomanometer with the subjects seated.

Serum markers. A venous blood sample was taken from subjects after an overnight fast of 12 h for measuring plasma glucose, insulin, TG, total cholesterol, LDL-C, and HDL-C by an autoanalyzer (Hitachi 7250 Special; Hitachi, Tokyo, Japan). Serum insulin level was measured by using a Microparticle Enzyme immunoassay (AxSYM Insulin; Abbott Diagnostic Division, Tokyo, Japan), and the insulin resistance index derived by homeostasis model assessment (HOMA) was as previously described (13). Serum high sensitive C-reactive protein (hs-CRP) and adiponectin were measured by using a chemiluminescent enzyme-labeled immunometric assay (Immulite C-Reactive Protein; Diagnostic Products Co., Los Angeles, CA) and a quantitative sandwich enzyme-linked immunoassay (Quantikine Human Adiponectin/Acrp30 Immunoassay; R&D, Minneapolis, MN), respectively. The protocol was reviewed and approved by the Ethical Committee of the National Taiwan University Hospital and institutional review board.

Statistics. Data were presented as means and SD, unless indicated otherwise. Log transformation was performed for variables with significant deviation from normal distribution before further analyses. All statistical analyses were performed using the SPSS/PC statistical program (version 10.0 for Windows; SPSS, Inc., Chicago, IL). The continuous variables between patients and healthy controls were compared by Student's *t*-test whereas the category parameters were by Mann–Whitney U test. The correlations between the adiponectin level and other variables were tested by Pearson's correlation. Multiple linear regression models were performed using serum adiponectin levels as the dependent variable and using age, gender, BMI, WC residuals (after adjustment for BMI), HOMA, mean BP, TG, and HDL-C as independent variables. Adjusted R^2 values were used to estimate the variance explained in each model.

RESULTS

As shown in Table 1, the mean serum LDL-C level was 250.8 (190–610) mg/dL in FRSPH and 99.4 (30.0–130.0) mg/dL in healthy controls. Patients with FRSPH had a significantly lower mean serum adiponectin level compared with healthy controls (7.7 ± 1.8 vs. 10.1 ± 4.13 µg/mL, *P*-value = 0.013). Except for the serum TG levels (*P* = 0.048), we also found that other demographic and clinical characteristics were not significantly different between the two groups. For small study populations, we used several linear regression models to adjust potential confounding factors. After the adjustment of other covariates (see Table 2), patients with FRSPH still had a significantly lower mean serum adiponectin level.

Correlation analysis between the serum adiponectin levels and other covariates were performed in patients with FRSPH, healthy controls, and total study populations. As demonstrated in Table 3, the serum adiponectin levels generally were negatively correlated with DBP, BMI, and the levels TG, hs-CRP, and HOMA, and were positively associated with the serum HDL-C levels, suggesting that within each group, factors considered to be part of metabolic syndrome were closely associated with serum adiponectin levels.

DISCUSSION

The present study demonstrated that serum adiponectin is decreased in young patients with FRSPH and without clinical manifestations of metabolic syndrome. Although the mechanism responsible for hypoadiponectinemia in FRSPH is still unclear, it indeed deserved further studies.

FH is a common autosomal dominant disorder in which LDL clearance from the circulation is impaired. In the absence of other causes of insulin resistance, patients with FH have been shown to have normal fasting insulin levels and not to be insulin resistant (14). Adiponectin has been negatively correlated with serum TG and positively correlated with serum HDL-C both in patients with dyslipidemia and in healthy adolescents (6,8,15). Interestingly, our present study found that in young FRSPH subjects with extreme serum LDL-C levels, the serum adiponectin levels were lower regardless of the adjustment of other insulin sensitivity markers. These observations indicate that the correlation between hypercholesterolemia and

TABLE 1
Demographic and Clinical Characteristics of the Study Subjects[a]

Variables	FRSPH $n = 23$	Healthy controls $n = 46$	
LDL-C, mg/dL	250.8 (190–610)	99.4 (30.0–130)	P
Age (yr)	19.7 ± 5.8	19.9 ± 4.7	0.868
Gender (male/female)	12/11	24/22	0.998
Body mass index (kg/m^2)	20.3 ± 3.3	21.4 ± 3.9	0.246
Waist circumference (cm)	71.9 ± 9.9	73.7 ± 11.2	0.520
Systolic BP (mmHg)	105.4 ± 13.7	102.2 ± 13.8	0.368
Diastolic BP (mmHg)	67.1 ± 10.4	68.4 ± 9.8	0.624
Fasting glucose (mg/dL)	84.2 ± 7.1	86.0 ± 5.7	0.358
Fasting insulin (mU/L)	6.9 ± 3.8	7.9 ± 4.9	0.393

Cholesterol (mg/dL)	339.5 ± 101.1	179.6 ± 26.5	<0.001
HDL-C (mg/dL)	53.2 ± 7.2	54.9 ± 8.7	0.418
TG (mg/dL)	88.3 ± 26.5	74.8 ± 26.3	0.048
hs-CRP (mg/dL)	0.14 ± 0.32	0.16 ± 0.6	0.905
Adiponectin (mg/mL)	7.7 ± 1.8	10.1 ± 4.3	0.013

[a]Abbreviations: FRSPH, familial-related severe primary hypercholesterolemia; BP, blood pressure; HOMA-IR, insulin resistance index derived by homeostasis model assessment; HDL-C, HDL-cholesterol; LDL-C, LDL-cholesterol; hs-CRP, high-sensitive C-reactive protein.

hypoadiponectinemia may be mediated through a pathway that is independent of insulin resistance. It is well known that cytokines such as TNF-α and interleukin-6 can inhibit the secretion of adiponectin from adipocytes (17–20). It is possible that the cytokines elicited by extreme hypercholesterolemia (21–23) may result in decreased adiponectin secretion in patients with FRSPH.

Table 2 revealed a consistent negative association of FRSPH with serum adiponectin levels after multiple linear regression analysis in different models, which corroborated the current hypothesis in this study. However, although both HDL-C and TG were found to be associated with serum adiponectin levels as in previous studies, we are the first to demonstrate the significant negative association between FRSPH and serum adiponectin levels. Thus, all the evidence and inferences should be under careful scrutiny.

In FH, early CHD is a complex trait that results from a large monogenic component of susceptibility that is due to extremely high levels of LDL-C (24). However, the mecha-

nism beyond LDL-C and the possible association with metabolic trait of adiponectin have never been reported. The finding of low adiponectin in these patients may have additive effects in increasing cardiovascular disease risk. In addition to its metabolic effects, adiponectin was found to protect vessels from damage through various mechanisms. It was demonstrated that adiponectin could inhibit monocyte adhesion to endothelial cells (25,26) and transformation of macrophages to foam cells (27). In one *in vivo* study, adiponectin-deficient mice exhibited excessive vascular remodeling following acute injury (28). In another mouse atherosclerosis model, enhanced adiponectin expression reduced atherosclerotic changes (29). It was also demonstrated that adiponectin directly stimulated the production of nitric oxide, an important mediator that regulates vascular tone and function (30). In one recent report, high plasma adiponectin concentrations were associated with lower risk of myocardial infarction in men, and this relationship could be only partly explained by differences in blood lipids and was independent of inflammation

and glycemic status (12). In addition to the standard lipid-lowering medication, it is possible that agents or methods that can increase serum adiponectin might help in inhibiting the development of cardiovascular diseases.

ABSTRACT: Plant sterols, soy proteins, viscous fibers, and nuts are advised for cholesterol reduction, but their combined effect on plant sterol absorption has never been tested. We assessed their combined action on serum sterols in hyperlipidemic subjects who were following low-saturated fat diets before starting the study and who returned to these diets post-test. The 1-month test (combination) diet was high in plant sterols (1 g/1,000 kcal), soy protein (23 g/1,000 kcal), viscous fiber (9 g/1,000 kcal), and almonds (14 g/1000 kcal). Fasting blood was obtained for serum lipids and sterols, and erythrocytes were obtained for fragility prior to and at 2-wk intervals during the study. The combination diet raised serum campesterol concentrations by 50% and β-sitosterol by 27%, although these changes were not significant after Bonferroni correction; near-maximal rises were found by the end of the first week, but no change was found in red cell fragility despite a 29% reduction in the LDL cholesterol level. No significant associations were observed between changes in red cell fragility and blood lipids or sterols. We conclude that plant sterols had a minimal impact on serum sterol concentrations or red cell fragility in hyperlipidemic subjects on diets that greatly reduced their serum lipids.

Paper no. L9398 in *Lipids 40*, 169–174 (February 2005).

Plant sterols have been shown to lower serum LDL cholesterol (1–3) by 8–12% in the absence of other dietary modifications (e.g., vs. low-fat diets) in a meta-analysis by Law (4). Despite broad acceptance of the safety of plant sterols by most Western countries, concerns have been raised that absorption of plant sterols may have adverse consequences, possibly by modifying cell membrane fragility resulting from the displacement of cholesterol (5). Few data are available from human studies concerning the influence of dietary sterols on membrane fragility and serum sterols, especially using diets that result in marked reductions in serum cholesterol levels (6,7). We therefore assessed the effect on serum plant sterols of diets high in other cholesterol-lowering dietary components. These components, which included viscous fiber (8–11), soy protein (12,13), and almonds in

combination (dietary portfolio), have been shown to produce a marked reduction in serum cholesterol (6,7). The specific objective was to assess whether a plant sterol-enriched diet, combined with other agents known to reduce circulating cholesterol levels, would result in a change in cell membrane fragility and circulating plant sterol and lipid concentrations in hyperlipidemic individuals.

EXPERIMENTAL PROCEDURES

Subjects. Thirteen subjects (7 men and 6 postmenopausal women), aged (mean ± SE) 65 ± 3 yr (median 64 yr; range 43–84 yr); body mass index 25.6 ± 0.9 kg/m^2 (median 26.1 kg/m^2; range 20.6–30.7 kg/m^2); baseline LDL cholesterol 4.22 ± 0.11 mmol/L (median 4.27 mmol/L; range 3.51–4.99 mmol/L) were recruited from patients attending the Risk Factor Modification Center, St. Michael's Hospital. All subjects had taken part in previous dietary studies, were experienced in following dietary protocols and previously had had raised LDL cholesterol levels (>4.1 mmol/L) (14). At the time of the study, 5 subjects had raised LDL cholesterol levels, one subject had raised TG levels (>2.30 mmol/L, range 0.7–5.1 mmol/L), 3 subjects had both raised LDL cholesterol and TG levels, one subject had a low HDL cholesterol concentration (<0.9 mmol/L), and 3 subjects had blood lipids in the normal range (14). None of the subjects had a history of diabetes, renal disease, or liver disease, and none were taking medications known to influence serum lipids. One subject completed only 3 wk and withdrew because of dyspepsia associated with a *Helicobacter pylori* infection requiring antibiotic therapy.

Dietary advice on low-saturated fat (<7% dietary calories) and low-cholesterol diets (<200 mg/d) had been reinforced on at least two occasions over the previous year, and at entry to the study, 6 subjects had recorded diets with <7% (total energy) saturated fat and 9 subjects had followed diets with <200 mg/d cholesterol.

Study protocol. Subjects were followed on their own low-saturated fat therapeutic diets for 1 wk prior to the start of the study, and for an additional 2 wk after the study on return to their low-saturated fat therapeutic diets. During the middle 4

Dietary cholesterol (mg/1,000 kcal)	99 ± 13	10 ± 3	79 ± 9
Alcohol (% of energy)	1.5 ± 0.5	0.2 ± 0.1	1.0 ± 0.4
Satiety (–3 to +3)[b]	1.3 ± 0.2	2.9 ± 0.2	1.3 ± 0.3

[a]SFA, saturated FA; MUFA, monounsaturated FA; PUFA, polyunsaturated FA.
[b]Satiety: –3, extreme hunger; +3, extremely full.

wk, subjects followed a combination diet in which all foods were provided with the exception of fresh fruit and most vegetables. Blood samples and body weights were obtained after 12-h overnight fasts at weekly intervals and at week 2 of the washout. Seven-day weighed diet histories were obtained for the week prior to and for 2 wk following the combination diet. Completed menu checklists were returned at weekly intervals during the 4-wk combination diet period.

The study was approved by the Ethics Committee of the University of Toronto and St. Michael's Hospital, and informed consent was obtained from the subjects.

Diets. Diets eaten before and after the 4-wk combination diet were the subjects' routine therapeutic low-fat diets, which approximated National Cholesterol Education Program Step 2 guidelines (<7% energy from saturated fat and <200 mg/d dietary cholesterol) (Table 1) (14). Subjects were provided with self-taring electronic scales and asked to weigh all food items consumed during the study period. During the combination diet period, all foods consumed by the subjects were provided at weekly clinic visits with the exception of fruit and low-calorie vegetables (i.e., non-starch-containing vegetables), which subjects were instructed to obtain from their local stores. Subjects were provided with a 7-d rotating menu plan, including specified fruits and vegetables, on which they checked off each item as it was eaten and confirmed the weight of the foods. The same menu plan was used for all subjects but was modified to suit individual preferences, providing the goals for viscous fiber, soy protein, plant sterols, and almond consumption were met. For ease of consumption, where possible, items were prescribed in whole units.

The aim of the combination diet (dietary portfolio) was to provide 1 g of plant sterols per 1,000 kcal as an enriched margarine. The Unilever margarine contained approximately 46% sitosterol, 26% campesterol, 19% stigmasterol, 2.7% brassicasterol, 1.3% sitostanol, 0.8% campestanol, and 0.8% avenasterol, with the remainder made up of various other plant sterols. The Unilever margarine provided 12% plant sterol (w/w). Two

grams of plant sterol was contained in 25 g of margarine, for 82 kcal. In addition, the diet supplied 8.2 g of viscous fiber per 1,000 kcal from oats, barley, and psyllium and 22.7 g of soy protein per 1,000 kcal as soy milk or meat analogs. Raw, unblanched almonds also provided vegetable protein (2.9 g/1,000 kcal). Emphasis was placed on eggplant and okra as additional sources of viscous fiber (0.55 g/1,000 kcal and 0.67 g/1,000 kcal, respectively). Thus, 200 g of eggplant and 100 g of okra were prescribed to be eaten on a 2,000-kcal diet each day. Diets were provided at a targeted intake to maintain body weight based on estimated caloric requirements (15).

Compliance was assessed from the completed weekly checklists and from the return of uneaten food items.

Analyses. Serum lipid data were reported previously (6). All samples were stored at –70°C prior to analysis. Sera for plant sterol analysis were unavailable for one subject, and an additional 3 subjects were missing one or both week 1 and week 3 samples. As also mentioned earlier, one subject dropped out at week 3. Plant sterols and cholesterol in serum and membrane were measured by GLC (HP 5890 Series II; Hewlett-Packard, Palo Alto, CA). Briefly, 5α-cholestane was added to each sample as an internal standard. Samples were saponified with 0.5 M methanol-KOH for 1 h at 100°C, and sterols were extracted using petroleum ether and injected into the gas–liquid chromatograph. The column temperature was 285°C. Isothermal running conditions (oven temperature 285°C) were maintained for 42 min. The injector and detector were set at 300 and 310°C, respectively. The carrier gas (helium) flow rate was 1.2 mL/min with the inlet splitter set at 100:1. Individual plant sterols and cholesterol were identified using authentic standards (Sigma-Aldrich Canada Ltd., Oakville, Ontario). The CV in the plant sterol measurement was 4% (16). Serum was analyzed according to the Lipid Research Clinics' protocol (17) for total cholesterol, TG, and HDL cholesterol, after dextran sulfate–magnesium chloride precipitation (18). Levels of LDL cholesterol were calculated (19). Serum apolipoprotein A-l and B were measured

by nephelometry (20). All samples from a given individual wer-analyzed in the same batch.

Red cell fragility was assessed on fresh red cells collected in vacutainer tubes containing EDTA (Becton Dickinson, Mississauga, Ontario). Packed red cells (0.02 mL) were added to 2 mL unbuffered saline covering the range of sodium chloride concentrations from 0.20 to 0.70 g/L in 0.05 g/L increments. After 1 h, the cells were centrifuged at $1,000 \times g$ at room temperature for 5 min and the supernatant was read at 540 nm (21). Data are presented as unadjusted O.D. readings and as adjusted percentages of the maximum O.D. obtained for both tests combined. The adjusted values were used to calculate the saline concentration that corresponded to the 50% hemolysis value. The p50 value for red cell hemolysis (50% hemolysis value) was calculated, assuming a linear response between the two consecutive O.D. readings spanning the half-point of the maximum hemolysis recorded for the subject. For each subject, the maximum O.D. (maximum hemolysis) obtained from both tests combined represented the 100% hemolysis value for that subject. Preliminary data on red cell fragility expressed as 50% hemolysis were reported previously (6).

Diets were analyzed using a program based on USDA data (22) with additional data on foods analyzed in the laboratory for protein, total fat, and dietary fiber using AOAC methods (23). FA were analyzed by GLC (24). Additional dietary fiber values were obtained from the tables of Anderson and Bridges (25).

Statistical analysis. The results were expressed as means ± SE. The significance of the differences between the pretreatment diet, combination diet, and post-treatment diet was assessed by the least squares means test with the Tukey–Kramer adjustment for multiplicity of simultaneous comparisons (PROC MIXED/SAS 8.2) (26). The model used had the treatment value as the response variable and the week and interaction term diet by sex as main effects and a random term corresponding to subject nested within sex. Student's paired *t*-test (two-tailed) was used to assess the significance of the percentage change from pretreatment.

With the present subject numbers for red cell fragility, assuming a SD of effect of 3.4%, a 3% difference could be detected as significant ($P < 0.05$). Likewise, assuming a SD of effect of 0.015 g/100 mL, a difference of 0.013 g/100 mL should be detected as significant.

The concentration required to obtain 50% hemolysis was determined assuming a linear response between consecutive observations. For each subject, the maximal O.D. obtained from both tests combined represented the 100% hemolysis value for that subject. A Pearson correlation analysis was used to assess relations between plant sterol measurements and other measurements. A Bonferroni adjustment was also made to the significance levels to allow for the multiple comparisons (26). Six largely independent primary measures were recognized: change in red cell fragility, serum campesterol and β-sitosterol, and LDL cholesterol, HDL cholesterol, and TG.

RESULTS

Demographics and compliance. Throughout the period of observation, subjects tended to lose weight: [–0.10 ± 0.05 kg/wk ($P = 0.127$) over the combination diet, and –0.2 ± 0.05 kg/wk ($P = 0.001$) during the run-out phase]. In the majority of subjects, compliance in terms of caloric intake was good, with 92.5 ± 2.9% of the calories prescribed being consumed.

Serum plant sterols. Serum plant sterol concentrations tended to increase over the 1-mon combination diet (Fig. 1). Serum campesterol concentrations increased by 50 ± 15% from baseline for weeks 2–4; the respective increase for serum sitosterol was 27 ± 14% (Table 2). For campesterol, the unadjusted rise was significant ($P = 0.007$) but disappeared after Bonferroni correction ($P = 0.139$).

Serum lipids. Full details of the blood lipid responses were reported previously (6). Significant reductions in blood lipids were seen at the end of the combination diet compared with the run-in and run-out periods (Table 2). From baseline, reductions were seen in LDL cholesterol (29.0 ± 2.7%, $P < 0.001$), apolipoprotein B (24.3 ± 2.0%, $P < 0.001$), and the total/HDL cholesterol ratio (19.8 ± 2.9%, $P = 0.004$).

Red cell fragility. No significant difference was seen in red cell fragility between the pretreatment and week 4 of the com-
FIG. 1. Mean plasma values for campesterol and sitosterol over 6 wk in 7 subjects. (hatched bar) Administration period of sterols. Plant sterol data were unavailable for one subject, an additional subject dropped out prior to the week 4 sample, and 3 subjects were lacking one or both week 1 and week 3 samples.

TABLE 2
Blood Lipids[a] and Apolipoproteins at Baseline and on the Combination Diet

	Baseline (week 0)	Mean treatment[b] (weeks 2–4)	P[c]
Cholesterol[d] (mmol/L)			
Total-C	6.46 ± 0.21	5.01 ± 0.20	<0.001

bination diet (saline concentration for 50% hemolysis, 0.436 ± 0.007 g/100 mL vs. 0.441 ± 0.006 g/100 mL, $P = 0.223$, unadjusted, $P = 0.734$ adjusted). No significant differences between mean pre- and postcombination diet values were seen at any time point when expressed as unadjusted O.D. readings at 540 nm (Fig. 2A) or as percent hemolysis, where the highest O.D. value for each individual was taken as 100% for that individual (Fig. 2B).

Relation of plant sterols to other measurements. No significant associations were seen between change in serum sterols and red cell fragility (serum campesterol, $r = -0.09$, $P = 0.803$; sitosterol $r = 0.12$, $P = 0.717$). The negative values indicate the tendency of a reduced fragility (reduced saline concentration for hemolysis) with increasing plant sterols, although no associations were significant.

For serum sterols, an association was seen at baseline between plasma sitosterol and total cholesterol ($r = 0.72$, $P = 0.008$), LDL cholesterol ($r = 0.83$, $P = 0.001$), and apolipoprotein B ($r = 0.91$, $P < 0.001$). No relation was seen between changes in serum sterols and blood lipids.

DISCUSSION

Supplementation with plant sterols in a diet that also contained high levels of viscous fibers, soy protein, and almonds produced large reductions in serum lipids but was associated with only relatively small increases in plasma sterol concentrations. There has been concern that significant increases in plasma sterols may result in modification of membrane lipids with the exclusion of cholesterol and that this change would increase membrane fragility (5). The present data indicate that the small changes in serum lipids do not relate significantly to red cell osmotic fragility.

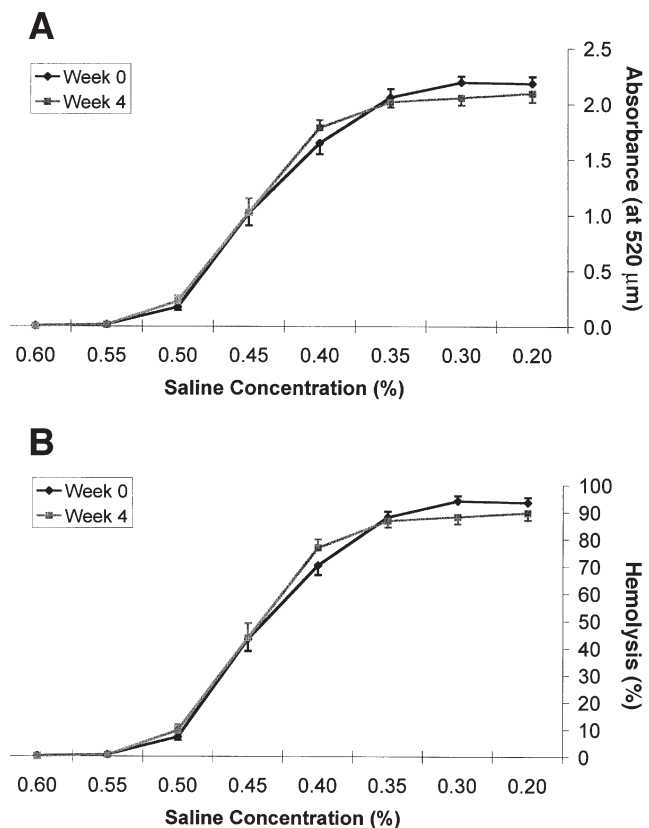
The absence of effect on red cell fragility indices examined opposes recent findings in rats suggesting that diets high in


FIG. 2. (A) Osmotic fragility of red blood cells from subjects at baseline (week 0) and week 4 of the combination diet after 6 h of exposure to varying saline concentrations. Data are presented as unadjusted O.D. readings. (B) Osmotic fragility of red blood cells from subjects at baseline (week 0) and week 4 of the combination diet after 6 h of exposure to varying saline concentrations. Data are presented as the percentage of hemolysis, with the maximal O.D. reading obtained for each subject representing 100% hemolysis.

plant sterols may increase the predisposition to hemorrhagic events (5). Clearly, more effort is required to define the real risk of hemorrhagic sequelae in the use of plant sterols as cholesterol-lowering agents at the levels provided in functional foods.

Components used in this combination diet were based on the hypothesis that during the course of human evolution, the diet was likely to have been high in vegetable proteins, dietary fiber, and plant sterols. All these components have now been recognized to lower serum cholesterol (1–3,8–13, 27, 28). Vegetable protein as soy (13), viscous dietary fiber, oats (27), psyllium (10), and, most recently, plant sterols (4) have received FDA approval for health claims for coronary heart disease risk reduction. These components, together with almonds (29,30), which may combine several cholesterol-lowering components, were the focus of the present diet.

In a previous study an attempt was made to reconstruct diets that may have been eaten at an earlier stage in human evolution by using plant foods readily available in the supermarket (31). The plant sterol intake on this "Myocene," or 4–7 million-year-old, diet was 1 g/d for men, indicating that historically high plant sterol intakes may have been associated with diets high in fiber and vegetable protein (31). The cholesterol lowering achieved with this evolutionary model diet was of a magnitude similar to that seen in the present study, in which the diet was high in the same active ingredients.

It is possible that almonds and viscous fiber in the present diet may have protective effects on red cell fragility and that adverse effects of plant sterols may have been masked. However, there are no data on the effects of nuts or viscous fiber on red cell fragility. Equally, it could be argued that nuts, which are good sources of plant sterols, might be expected to add to any adverse effect of the sterol margarine if such existed and that this might be compounded by viscous fiber, which further reduces serum cholesterol levels, possibly increasing the stiffness of the membrane and increasing the risk of hemolysis. Nevertheless, these points are purely speculative since no significant change in hemolysis was observed.

It is also possible that 4 wk was not long enough to demonstrate more subtle changes in red cell hemolysis since the red cell half-life in humans is 25–35 d for a mean life span of 120 d (32). In the rat the red cell half-life is of the order of 19 d with a life span of 60 d (33). In this situation, 1-mon studies might be more appropriate; however, this was the time frame used in rat studies that showed increased hemolysis with plant sterols by 4–5% (5). Based on studies of spontaneously hypertensive rats (5), it has been suggested that increased plant sterol intakes, especially from canola oil, may increase the risk of hemorrhagic stroke (5). This effect is thought to be due to increased cell membrane fragility (5,21) secondary to displacement of cholesterol by plant sterols in the membrane. However, the similar survival of olive oil-fed and corn-oil fed spontaneously hypertensive rats leaves questions remaining as to the role of phytosterol intakes in this process. Also, we found no relation between serum plant sterol levels and red cell osmotic fragility. A good relation, however, has been observed between plasma and membrane plant sterols in a study involving hypercholes-

terolemic children (34). Furthermore, there was no significant association between the change in concentration of plasma sterols and red cell fragility, although our subject numbers are small. These data add support to the general acceptance of plant sterol-enriched margarine for use by the public. An additional reason why the present study demonstrated no difference in red cell fragility may relate to the lack of sensitivity of the test itself. Pre-incubated erythrocytes are more sensitive indicators of red cell fragility than fresh erythrocytes, especially in situations of pathologically increased fragility (35). However, the rat studies demonstrating the ill effects of plant sterols did not use pre-incubated cells. Our study therefore endeavored to use the same type of analysis to allow direct comparison.

Were plant sterol consumption to be restricted, then the guidelines promoting increased intakes of fruit, vegetables, whole-grain cereals, legumes, and unhydrogenated vegetable oils would need to be revised. Such diets deliver appreciable amounts of plant sterols, and it could be argued that, from the evolutionary perspective, these are the diets to which we have adapted in the context of high-fiber, vegetable protein, and plant sterol intakes. The lack of these plant food components results in unacceptable levels of serum cholesterol that will qualify a significant proportion of the adult population for cholesterol-lowering medications (14).

In conclusion, high plant sterol intakes in the context of high-fiber vegetable protein diets have only a small effect on serum plant sterol concentrations despite large reductions in serum lipids. Moreover, high plant sterol-containing diets do not alter red cell fragility, a finding that should be examined further, given the recently reported promotion of hemorrhagic events by plant sterols in rats.

University, Ste. Anne de Bellevue, Québec, Canada H9X 3V9

ABSTRACT: The aim of this study was to assess the efficacy of a novel water-soluble phytostanol analog, disodium ascorbyl phytostanyl phosphates (DAPP), on plasma lipid levels and red blood cell fragility in hamsters fed atherogenic diets. For 5 wk, 50 male Golden Syrian hamsters were fed a semipurified diet without added cholesterol (noncholesterol, group 1), or a semipurified diet with 0.25% cholesterol (cholesterol-control, group 2). Groups 3–5 were fed the cholesterol-control diet with an addition of 1% phytostanols (diet 3), 0.71% DAPP (DAPP 0.7%, diet 4), or 1.43% DAPP (DAPP 1.4%, diet 5). Diets 4 and 5 provided 0.5 and 1% phytostanols, respectively. Supplementation of 0.71 and 1.43% DAPP decreased plasma total cholesterol concentrations by 34 ($P < 0.001$) and 46% ($P < 0.001$), respectively, in comparison with the cholesterol-control group, whereas free stanols reduced ($P = 0.007$) plasma cholesterol concentrations by 14%. Similarly, non-HDL-cholesterol concentrations were reduced by 39 ($P < 0.001$) and 54% ($P < 0.001$) in hamsters supplemented with DAPP 0.7% and DAPP 1.4%, respectively, relative to the cholesterol-control group. The hypocholesterolemic effect of DAPP 1.4% was threefold stronger than that of free stanols. In hamsters supplemented with DAPP 1.4%, plasma TG concentrations were 45% lower ($P = 0.018$) than in cholesterol-control-fed hamsters, whereas no such beneficial effect was observed in the free stanol group. Erythrocyte fragility was unaffected by DAPP or free phytostanols. Results of the current study demonstrate that DAPP lowers cholesterol more efficiently than free stanols, without an adverse effect on erythrocyte fragility in hamsters.

Paper no. L9517 in *Lipids 40*, 175–180 (February 2005).

The cholesterol-lowering effects of plant sterols have been well established (1–4). Meta-analyses have shown that dietary supplementation of plant sterols can reduce plasma LDL cholesterol levels by 8–12% in humans (4,5). The cholesterol-lowering effects of plant sterols reportedly result from the inhibition of dietary cholesterol absorption and biliary cholesterol reabsorption by inhibiting cholesterol incorporation into micelles in the intestine (2,6–8).

Through the process of hydrogenation, plant sterols are converted to plant stanols (also called phytostanols), which are ab-

sorbed at a negligible level (9,10). Based on previous data in animal and human studies, free plant stanols are believed to be more effective than free sterols in lowering plasma cholesterol (9–17). Esterification of free plant sterols and stanols with fat-soluble compounds, such as FA, increases their fat solubility. Several studies have demonstrated that the esterification of plant sterols with long-chain FA increases fat solubility, resulting in an increased suspension of plant sterols in the dietary fats or oils (5,8,18). In addition, some human trials comparing plant sterol esters with plant stanol esters have demonstrated that sterol esters and stanol esters appear to be roughly equivalent in their cholesterol-lowering efficacy (6,7,19–21). Progressively, the solubility and physical state of plant sterols and stanols appear to be determining factors in their cholesterol-lowering efficiency (22).

More recently, a water-soluble analog of phytostanols, disodium ascorbyl phytostanyl phosphates (DAPP), was developed through chemical modifications (23,24). DAPP were produced by covalently linking ascorbate to the *sn*-3 position of the phytostanol *via* a phosphodiester bond. The two major components of DAPP are disodium ascorbyl campestanyl phosphate and disodium ascorbyl sitostanyl phosphate. Results from a study in apolipoprotein E knockout mice showed that DAPP was more efficient in lowering cholesterol than the unesterified stanols (24). However, there have been no comparative studies on the effects of DAPP and unesterified stanols in wild-type animal models in which circulating cholesterol levels are increased by feeding atherogenic diets.

The ingestion of plant sterols is associated with increased plant sterol levels in red blood cell (RBC) membranes (25). Studies in hyperlipidemic, otherwise healthy individuals have shown no detrimental effect of plant sterols on RBC fragility in humans (25–27). However, a recent animal study suggested that plant sterols may decrease RBC deformability and life span in spontaneously hypertensive rats (28), raising the question of whether dietary supplementation with plant sterols or stanols is safe. Therefore, the present study was undertaken to compare the cholesterol-lowering efficacy of a water-soluble stanol analog (DAPP) and its parent compound, free stanols, and to determine their impacts on RBC fragility in hamsters fed atherogenic diets.

MATERIALS AND METHODS

Animals and diets. Fifty male Golden Syrian hamsters weighing 90–110 g (Charles River Laboratories, Montréal, Québec,

Abbreviations: ABC, ATP-binding cassette; DAPP, disodium ascorbyl phytostanyl phosphates; RBC, red blood cell; SHRSP, stroke-prone spontaneously hypertensive rat.

Canada) were randomly divided into 5 groups. Animals were housed individually in stainless-steel colony cages with a 12 h (light)/12 h (dark) light cycle. The room temperature was set at 20 ± 1°C. After a 2-wk acclimatization period on the regular rodent chow (Charles River Laboratories), animals were randomly assigned into 5 groups and fed experimental diets for 5 wk. Groups 1 and 2 were fed a semipurified diet without cholesterol (noncholesterol) and with 0.25% cholesterol (cholesterol-control), respectively. Groups 3–5 were fed the cholesterol-control diet, with an addition of 1% (w/w) of unesterified phytostanol (stanol), 0.71% of DAPP (DAPP 0.7%), or 1.43% of DAPP (DAPP 1.4%), respectively. Diets DAPP 0.7% and DAPP 1.4% were designed to provide 0.5% and 1% of free phytostanols (parent phytostanols), respectively, based on the M.W. of the phytostanols and DAPP. DAPP contained 65% (w/w) sitostanol and 35% campestanol. Unesterified phytostanols and DAPP were provided by Forbes Medi-Tech Inc. (Vancouver, British Columbia, Canada). All diets contained 5% fat provided in the form of a mix of beef tallow and safflower oil to yield a polyunsaturated to saturated FA ratio of 0.4.

The compositions of the diets are presented in Table 1. The experiment was reviewed and approved by the Animal Care and Research Ethics Committee of McGill University and was conducted in accordance with the guidelines of the Canadian Council on Animal Care.

Blood sample collection and plasma cholesterol analyses. After 5 wk of feeding on the experimental diets, hamsters were fasted overnight prior to anesthetization with halothane. Blood samples were collected by decapitation into tubes containing EDTA and placed on ice. Plasma and RBC were separated by centrifugation at $350 \times g$ rpm for 15 min. Plasma samples were stored at −80°C until analyses. Plasma total, HDL, and non-HDL cholesterol, as well as TG concentrations, were measured in duplicate by enzymatic methods (Roche Diagnostics, Laval, Québec, Canada) (29,30). HDL cholesterol was measured after precipitation of apolipoprotein B containing lipoproteins with dextran sulfate and magnesium chloride (31). Since the Friede-

wald equation (32) may not be applicable to hamsters, non-HDL cholesterol was used instead of LDL cholesterol; this was calculated by subtracting HDL cholesterol from total cholesterol.

Measurement of RBC fragility. RBC fragility was measured using fresh RBC collected in vacutainer tubes containing EDTA. An aliquot of 0.2 mL RBC was added to 2 mL unbuffered saline solution with a sodium chloride concentration ranging from 0.20 to 0.60%. After 1 h, the cells were centrifuged at $210 \times g$ for 5 min at room temperature. The supernatants were collected and measured for absorbance at 520 nm (33). The saline concentration for 50% hemolysis was calculated and considered as the median osmotic fragility. The concentration required to obtain 50% hemolysis was determined by assuming that a linear response existed between consecutive observations.

Data analysis and statistics. Results are expressed as means ± SEM, and a *P* value of <0.05 was considered significant. Data were subjected to an ANOVA using the general linear model procedure of the Statistical Analysis System (SAS Institute, Cary, NC) to determine the main treatment effects. When a significant effect was detected, Duncan's New Multiple Range test was performed to identify differences among treatment groups. The relationships between plasma cholesterol concentrations and the median osmotic RBC fragility were tested using Pearson's correlation coefficients.

RESULTS

Body weight and food consumption. No significant difference was observed in final body weight among the treatment groups after 5 wk of feeding. However, hamsters fed DAPP 1.4% had relatively lower final body weights compared with other groups, although the difference was not statistically significant. Similarly, there were no significant differences among the groups in average or total food consumption during the 5-wk period.

Plasma lipid concentrations. Effects of the experimental diets on plasma total, HDL, and non-HDL cholesterol levels are

TABLE 1
Composition of Experimental Diets[a]

Diet (% w/w)	Nonchol	Chol-control	Stanol	DAPP 0.7%	DAPP 1.4%

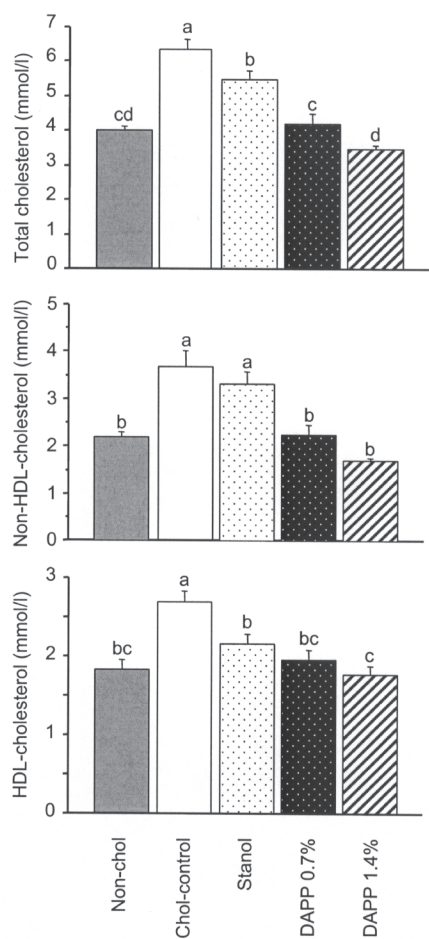
[a]Nonchol, control diet without added cholesterol; Chol-control, control diet with 0.25% added cholesterol; Stanol, chol-control with 1% added phytostanols; DAPP (disodium ascorbyl phytostanyl phosphates), chol-cholesterol with added DAPP.
[b]DAPP 0.7% and DAPP 1.4% contained 0.5 and 1.0% unesterified phytostanols, respectively.


FIG. 1. Effects of phytostanols and their water-soluble analogs on plasma total cholesterol, non-HDL cholesterol, and HDL cholesterol levels in hamsters. Data are expressed as means and SEM (n = 10). Bars carrying different superscripts are significantly different (P < 0.05). Non-chol, control diet without added cholesterol; Chol-control, control diet with 0.25% added cholesterol; Stanol, chol-control with 1% added phytostanols; DAPP 0.7%, chol-cholesterol with 0.71% added disodium ascorbyl phytostanyl phosphates; DAPP 1.4%, chol-cholesterol with 1.43% added disodium ascorbyl phytostanyl phosphates.

shown in Figure 1. In hamsters fed DAPP 0.7% and DAPP 1.4%, total cholesterol was reduced by 34 (P < 0.001) and 47% (P < 0.001), respectively, in comparison with the cholesterol-control group, and these values were similar to the noncholesterol group. Similarly, non-HDL cholesterol levels in hamsters supplemented with DAPP 0.7% and DAPP 1.4% were 39 (P < 0.001) and 54% (P < 0.001) lower, respectively, than in those fed the cholesterol-control diet. The stanol diet lowered (P = 0.007)

total cholesterol by 14% relative to the cholesterol-control diet. HDL cholesterol levels were lower in the two DAPP (P < 0.001) and stanol (P = 0.005) groups in comparison with the cholesterol-control group, and the values were similar with the noncholesterol group. However, changes in HDL cholesterol levels after feeding the DAPP and stanol diets were not reflected by changes in total cholesterol/HDL cholesterol and non-HDL cholesterol/HDL cholesterol ratios, which were decreased in the DAPP 1.4% group compared with the cholesterol-control (P = 0.028) and stanol groups (P = 0.006) (data not shown).

Effects of diet treatments on plasma TG concentrations are shown in Table 2. Although the free stanol diet did not affect plasma TG concentrations in comparison with the cholesterol-control diet, DAPP 1.4% reduced TG concentrations by 45% (P = 0.018) compared with the cholesterol-control group. Additionally, plasma TG concentrations were decreased by 42 (P = 0.022) and 49% (P = 0.004), respectively, in hamsters fed DAPP 0.7% and DAPP 1.4% compared with hamsters fed the free stanol diet.

RBC fragility. The saline concentration associated with the median osmotic fragility was (in %) 0.481 ± 0.004, 0.467 ± 0.007, 0.489 ± 0.007, 0.486 ± 0.005, and 0.478 ± 0.009 in DAPP 0.7%, DAPP 1.4%, stanols, cholesterol-control, and noncholesterol, respectively. There were no differences among the treatment groups. Likewise, there was no significant difference in RBC fragility across the treatment groups at any saline concentration (Fig. 2). Positive correlations were observed between the median osmotic fragility (%) and plasma total cholesterol (mmol/L) (r = 0.44, P = 0.003) and non-HDL cholesterol concentrations (r = 0.43, P = 0.004).

DISCUSSION

This is the first study to show a more potent hypocholesterolemic effect from DAPP compared with unesterified phytostanols in non-gene-treated animals with diet-induced higher circulating cholesterol levels. In hamsters fed DAPP, a strong cholesterol-lowering effect was observed, which resulted in total and non-HDL cholesterol levels similar to those observed in hamsters fed the noncholesterol diet. The DAPP diet showed a stronger hypocholesterolemic effect than the stanol diet, with a dose-dependent response being observed. Similar to the current finding, the cholesterol-lowering effect of DAPP on circulating cholesterol levels has been reported in other animal studies. For example, gerbils given 1 and 2% (w/w) DAPP in the diet, or 2 and 4% DAPP in drinking water had decreased total and LDL cholesterol levels (23,34). Recently, Lukic *et al.* (24) reported that in comparison with the control diet, a 4-wk administration of DAPP

TABLE 2
Effects of Phytostanols and Their Water-Soluble Analogs on Plasma TG Concentrations in Hamsters[a]

Diet	TG (mmol/L)	Diet[b]	TG (mmol/L)
Nonchol	4.50 ± 0.34[a,b,c]	DAPP 0.7%	3.64 ± 0.46[b,c]
Chol-control	5.88 ± 0.66[a,b]	DAPP 1.4%	3.23 ± 0.30[c]
Stanol	6.30 ± 0.96[a]		

[a]Values are mean ± SEM (n = 10 per group). Values carrying different superscripts (a–c) are significantly different (P < 0.05). For diet descriptions, see Table 1.
FIG. 2. Effects of phytostanols and their water-soluble analogs on red blood cell fragility in hamsters. Data are expressed as means and SEM (*n* = 9, except the chol-control group, where *n* = 7). For diet descriptions, see Figure 1.

at a dose as low as 0.5% reduced total cholesterol concentrations by approximately 75% in cholesterol-fed apolipoprotein E knockout mice.

Inhibition of cholesterol absorption from the intestine is a well-established mechanism through which plant sterols/stanols lower plasma cholesterol concentrations (2,35–39). DAPP has been shown to reduce cholesterol absorption in rats in a dose-dependent manner (40). The current study showed a stronger hypocholesterolemic effect from DAPP than from the corresponding unesterified stanols, despite the same amount of stanols being provided in the DAPP 1.4% and stanols groups. The effects of the individual components of DAPP on circulating cholesterol levels were examined previously only in apolipoprotein E-deficient mice (24). Those results indicated that DAPP resulted in an extreme lowering of total cholesterol concentrations in that model, whereas less favorable effects were observed with a mixture of ascorbic acid and unesterified stanols. Results of the present study, together with previous ones, suggest that the esterification of stanols with ascorbic acid is responsible for the increased hypocholesterolemic effect of DAPP relative to unesterified stanols. The present results also suggest that increasing the water solubility of plant stanols could be an approach to reducing the effective dose of plant sterols or stanols in lowering blood lipids.

Currently, the mechanism of action of DAPP on cholesterol absorption is not fully understood. A widely accepted explanation is that sterols and stanols compete with cholesterol in the intestine during their incorporation into micelles and thus decrease cholesterol uptake by enterocytes (40). In an *in vitro* study, DAPP decreased cholesterol accumulation in Caco-2 cells, suggesting that DAPP may modify some extracellular mechanisms of cholesterol influx and efflux (41). Most recently, Wasan *et al.* (42) observed that DAPP reduced the accumulation of cholesterol in cultured rat small intestinal crypt cells and speculated that DAPP might inhibit the interaction of cholesterol or cholesterol micelles with the receptors of enterocytes or act as an antagonist of cholesterol influx channels. Transporters of the ATP-binding cassette (ABC) family appear to play important roles in regulating cholesterol absorption and excretion (43,44). Support-

ive data were obtained by Berge *et al.* (45) that the increased accumulation of dietary cholesterol in subjects with autosomal recessive disorder was caused by mutations in the adjacent region of ABCG5 and ABCG8 genes. More studies are required to define the roles of ABCG5 and ABCG8 in the inhibition of cholesterol absorption by plant sterols and stanols.

A few studies have examined the potential TG-lowering effect of DAPP. When gerbils were given DAPP at concentration of 4% dissolved in the drinking water for 8 wk, TG concentrations were reduced compared with controls that did not receive DAPP (34). However, this effect was not observed in another study in which gerbils were fed 2% of DAPP for 4 wk (23). In a study conducted in apolipoprotein E knockout mice, plasma TG were reduced after feeding a 2% DAPP diet for 4 and 8 wk, respectively, in comparison with the control group, whereas no difference was observed after 12 wk (24). In the current study, we observed that DAPP was effective at lower concentrations in decreasing plasma TG levels compared with the cholesterol-control diets, as well as the unesterified phytostanol diet, whereas unesterified stanols showed no effect. In addition to the DAPP 1.4% group, although not statistically significant, the DAPP 0.7% group showed lower average TG levels in comparison with the noncholesterol-control group, implying the existence of a hypolipidemic effect of DAPP. The mechanisms through which DAPP lowers plasma TG are currently unknown. Further studies are required to verify the TG-lowering actions of DAPP and to elucidate the underlying mechanisms.

It has been suggested that plant sterols/stanols may increase the risk of hemorrhagic stroke, based on studies in stroke-prone spontaneously hypertensive rats (SHRSP) (28,46). In these hypertensive animals, when 0.2% (w/w) plant sterols were administered in their diets, decreased erythrocyte deformability was detected by using an ektacytometer, which can measure relatively minor alterations in RBC membrane rigidity, internal viscosity, and the ratio of surface area to volume (28). However, the osmotic fragility test detected no detrimental effects in the present animal model even though a higher dose of plant stanols (1%) was applied. Using the same method applied in the present study, Jenkins *et al.* (26) reported no significant changes in RBC fragility in humans after 4 wk of a low saturated fat diet enriched with plant sterols, soy protein, and viscous fibers. In addition, this research group illustrated constant results on fragility in another recent study (27). Hendriks *et al.* (25) reported that increased plant sterol concentrations in RBC membrane after long-term (1-yr) consumption of a plant sterol ester-enriched spread did not affect RBC deformability, which was measured by a method similar to that described in the study of SHRSP. Therefore, it is possible that the results obtained in SHRSP cannot be readily extrapolated to healthy animals or to other species. A significant decrease in the intestinal mRNA expressions of ABCG5 and ABCG8, which are involved in the selective transport of dietary sterols in the intestine, has been reported in SHRSP compared with Wistar rats (47). Results of this study suggest that the unfavorable effects on enterocytes observed in the SHRSP following supplementation of plant sterols are due to the increased absorption of plant sterols in this species. The present data, obtained in hypercholes-

terolemic, otherwise healthy animals, and the observations previously done in humans suggest that the use of plant stanols as food-based cholesterol-lowering agents may not be associated with an increased risk of hemorrhagic stroke for the general population. However, more effort is warranted to evaluate the risk of hemorrhagic sequelae with plant sterols or stanols used at the levels provided in functional foods. The incubated fragility test is one of the most sensitive measurements for detecting subtle changes in fragility (48,49). Since the adverse effects of plant sterols and stanols on RBC fragility are small, the incubated fragility test might be beneficial for detecting minor changes induced by dietary manipulation.

In the present study, positive correlations have been observed between the median osmotic fragility and plasma total cholesterol and non-HDL cholesterol concentrations, indicating that lowered plasma cholesterols have the potential to fortify RBC membranes against osmotic stimulation. Replacement of a part of the cholesterol with plant sterols in erythrocyte membranes has been shown to cause adverse events on RBC deformability and results in a decreased life span in spontaneously hypertensive rats (28). In contrast, a recent study that provided 0.5% cholesterol diets to Wistar rats suggested that erythrocytes become more fragile in animals with high plasma cholesterol concentrations; when cholesterol-lowering agents were added to the diet, the fragility of the RBC was partially reversed (50). Correlations observed in the present study between osmotic fragility and plasma cholesterol levels appear to support the latter observation. Plant sterols have been reported to alter plasma cholesterols as well as RBC cholesterol simultaneously in spontaneously hypertensive rats (28,46). High plasma cholesterol has been demonstrated to increase RBC fragility; therefore, plant sterols may have positive effects on RBC fragility, since sterols lower plasma cholesterol. However, plant sterols may also have unfavorable effects on RBC deformability, since sterols lower RBC cholesterol, which is essential for membrane integrity. In view of the fact that plant sterols may have either beneficial or detrimental effects on RBC fragility, this may account for the differing results seen in previous studies (25–28).

In conclusion, the results of the present study demonstrate that the esterification of plant stanols with a water-soluble compound, such as ascorbic acid, increases their cholesterol-lowering efficacy in hamsters fed atherogenic diets. DAPP could therefore offer a more efficient treatment alternative to hypercholesterolemic subjects than the other existing forms such as stanol esters with FA and free stanols. The findings of the current study also suggest that ascorbyl phytostanyl phosphate has potential for treating hypertriglyceridemia. The absence of a detrimental effect of DAPP on RBC fragility indicates that dietary supplementation with DAPP at the dose used in the current study may not be a trigger of plant sterol-induced adverse events on erythrocyte homeostasis.

A Comparison of the Effect of Medium- vs. Long-Chain Triglycerides on the *in vitro* Solubilization of Cholesterol and/or Phytosterol into Mixed Micelles

ABSTRACT: Despite clinical evidence of the cholesterol-lowering effects of phytosterols, the exact mechanisms involved are still unclear. Displacement of cholesterol by phytosterols from mixed micelles, which is due to their greater hydrophobicity, is one of the hypotheses for the lumenal effects contributing to the reduction of intestinal cholesterol absorption. In this study a dynamic *in vitro* lipolysis method was used to examine the solubilization behavior of cholesterol and/or phytosterols during lipolysis to probe the efficacy of cholesterol displacement from mixed micelles by phytosterols. The effects of lipid chain length on sterol solubilization were studied by using microcrystalline suspensions containing 17% phytosterol or cholesterol, formulated in long-chain TG (LCT) and medium-chain TG (MCT). When digesting cholesterol suspended in LCT, the entire cholesterol dose was incorporated into the micellar phase. For the cholesterol formulation suspended in MCT, 50.3% of the initial dose was recovered in the micelles. Under the respective conditions, we observed lower solubilization of phytosterols than of cholesterol (roughly fourfold). Only 25% of the initial phytosterol dose was solubilized from suspensions formulated with LCT, and 13% was solubilized from MCT formulations. Co-administration of phytosterol and cholesterol suspensions showed a significant reduction of cholesterol solubilization, particularly when dosed in MCT, with ~25% of the cholesterol dose solubilized. Insignificant amounts of cholesterol were displaced by phytosterols when cholesterol was presolubilized in the mixed micelles. The results show that, compared with LCT, mixed micelles containing MCT lipolysis products have a reduced solubilizing capacity for cholesterol, which adds to the effectiveness of the phytosterols in displacing cholesterol. This suggests potential benefits of using medium chain length lipids in cholesterol-lowering phytosterol products.

Paper no. L9616 in *Lipids* 40, 181–190 (February 2005).

Since the early 1950s, the cholesterol-lowering properties of phytosterols in humans have been known (1). In plants, sterols are always present as a mixture, and they have the same func-tion as cholesterol in animals: They are essential components of cell membranes (2,3). When consumed at a level of 1–3 g/d, an LDL cholesterol-lowering effect of up to 10% can be achieved (4,5). Thus, today phytosterols are incorporated into a wide variety of food products, referred to as functional foods. The intake of phytosterols from natural sources in the Western diet is at levels of approximately 100–500 mg/d (6–8).

Cholesterol enters the intestinal tract from two major sources, typically two-thirds from biliary secretion and one-third from dietary sources (9,10). Phytosterols are structurally related to cholesterol but differ from cholesterol only in their unsaturation level and/or side-chain configuration. However, less than 2% of the ingested phytosterols are absorbed in humans and other mammals, considerably less than the absorption of cholesterol, which can be up to 60% (11). Furthermore, the amount of absorption varies among the individual phytosterols depending on both the sterol nucleus and the length of the side chain (7,12). The most prevalent phytosterol, sitosterol, has an absorption value of 0.5%, whereas sitostanol, without the double bond in the sterol nucleus, has the lowest value, at 0.04% (11).

Although phytosterols are absorbed less efficiently than cholesterol, their lumenal processing is similar to that of cholesterol and is intimately connected to the overall process of lipid digestion (e.g., 134). Because of the hydrophobicity of phytosterols, solubilization into intestinal mixed micelles is a prerequisite for reaching the site of absorption, the extent of which is greatly enhanced in the presence of products of TG digestion (MG and FA) (13,15). As a result of micellar solubilization, the diffusion of sterols is improved through the unstirred water layer at the intestinal brush border.

Presently, the cholesterol-lowering effects of phytosterols are attributed to both luminal- and enterocyte-based processes, but their exact mechanisms, relative extent, and importance still need further investigation. Recent findings link cholesterol absorption to active influx and efflux sterol transporters in the enterocytes, whereas the lumenal effects of phytosterols have mainly been based on their greater hydrophobicity, which imparts a greater affinity for mixed micelles during fat digestion (7,16,17). Thus, they may displace dietary and intestinal cholesterol from the micelles, thereby reducing the solubilization

of intestinal cholesterol. Some evidence of the exclusion of cholesterol from mixed micelles has been presented in a static (nondigesting) solubilization study utilizing mixed micelles composed of bile salts (BS), phospholipids (PL), and long-chain MG and FA (18). However, no studies incorporating the lipolysis process or the effect of lipid chain length have previously been published.

For lipophilic or hydrophobic drugs, improved oral absorption after postprandial administration or when formulated with lipids is mainly attributed to the increased solubilizing capacity of the intestinal BS/PL mixed micelles afforded by the incorporation of lipolysis products (MG and FA) and/or lipidic excipients (19–21). Similar to the sterols, solubilization of poorly water-soluble drugs into intestinal mixed micelles will greatly facilitate their transfer to the site of absorption. The mechanistic aspects of drug solubilization during lipolysis have been examined in several recent studies using an *in vitro* digestion method, which incorporates the dynamics of the lipolysis process. Although a simplification of the *in vivo* situation, the *in vitro* method has shown its usefulness in predicting the relative effectiveness of different lipid formulations *in vivo* (22–25). One of the major findings of these studies, as well as accompanying studies on the solubilizing capacity of colloidal species produced (26), was the understanding that medium chain length (C_8–C_{10}) lipids may be less suitable for co-administration with highly lipophilic drugs since the MG and FA produced thereof form smaller mixed micelles compared with lipids of longer chain lengths (C_{14}–C_{18}), thereby having lower solubilizing capacity and providing reduced benefits for oral absorption.

In the current study, the dynamic *in vitro* digestion method was used to examine the solubilization behavior of cholesterol and/or phytosterols during lipolysis to probe the efficacy of cholesterol displacement from mixed micelles by phytosterols. The effects of lipid chain length on the solubilization capacity and displacement of cholesterol were studied by using sterol suspensions formulated in long-chain TG (LCT) or medium-chain TG (MCT). To use formulations with relevance *in vivo*, the suspensions were prepared according to the method previously developed to produce a cholesterol-lowering microcrystalline phytosterol suspension in oil (27,28). This suspension,

formulated in rapeseed oil, has been shown to reduce plasma total and LDL cholesterol concentrations in a clinical study (5).

EXPERIMENTAL PROCEDURES

Materials. Phytosterol was purchased as β-sitosterol (≥78.5% β-sitosterol, 8.7% campesterol, 10% β-sitostanol, and 1% campestanol) from Merck (Darmstadt, Germany), and cholesterol (>99%) was from Sigma Chemical Co. (St. Louis, MO). Soybean oil (SBO, LCT; ≥85% linoleic, oleic, and linolenic acid) was a Sigma product and Captex 355 (MCT; ≥95% caprylic and capric acid) was a product from Abitech Corporation (Janesville, WI). More detailed FA compositions of SBO and Captex 355 can be found in Kaukonen *et al.* (23). Sodium taurodeoxycholate (NaTDC) (Sigma Chemical Co.), egg lecithin, Lipoid E 80 (approximately 81.8% PC; Lipoid GmbH, Ludwigshafen, Germany), and chloroform (Rathburn Chemicals Ltd., Walkerburn, Scotland) were used in the preparation of mixed micelles. The lipolysis buffer contained Trizma® maleate, sodium chloride, sodium hydroxide, and sodium azide, all obtained from Sigma, and calcium chloride dihydrate from Riedel-de-Haën (Seelze, Germany). Water was obtained from a Milli-Q (Millipore, Milford, MA) water purification system. Pancreatin from porcine pancreas (8× USP specifications activity) was a Sigma product, and 4-bromophenylboronic acid (BPBA) was purchased from Aldrich Chemical Co. (St. Louis, MO). Sodium hydroxide (1 M, Fixanal®; Riedel-de-Haën) was used to prepare a 0.2 M NaOH titration solution.

Preparation of phytosterol and cholesterol suspensions. The suspensions were prepared by heating phytosterol (see Table 1 for the individual phytosterol concentrations determined) or cholesterol and either SBO or Captex 355 in a vessel while stirring. The phytosterol or cholesterol was dissolved at about 100°C, and a clear solution was formed (27,28). After cooling to about 90°C, purified water at the same temperature was added to the suspension containing phytosterol. The vessel was immediately immersed in ice, and the suspension was stirred until it had reached at least room temperature (+25°C). The phytosterol suspension contained 17% (w/w) phytosterol, 70% MCT or LCT oil and 13% water, whereas the cholesterol sus-

pension contained 17% cholesterol and 83% MCT or LCT oil. The suspension preparation was validated by analysis of the sterol content in triplicate. The variation in the presumed sterol content of the suspensions was 102.2% (SD ± 3.0, $n = 3$) for cholesterol and 98.3% (SD ± 4.7, $n = 3$) for phytosterols.

In vitro lipid digestion. The *in vitro* lipolysis experiments were conducted in the same manner as those described earlier (22,23,29,30). Cholesterol and/or phytosterol suspensions were dispersed in 9 mL of BS/PL mixed micelles prepared in a pH 7.5 buffer (50 mM Trizma maleate, 150 mM NaCl, 5 mM CaCl$_2$). All digests contained a total of 50 mg of LCT (6 mM) or MCT (10 mM), i.e., 25 mg of pure TG was added when only cholesterol or phytosterol suspensions were studied. Two levels of BS/PL concentrations were used to represent fed-state (20 mM NaTDC/5 mM PC) or fasted-state (5 mM NaTDC/1.25 mM PC) small intestinal conditions (31–33). Phytosterol was dosed at either 14 or 28 µmol, whereas cholesterol was dosed at 15 µmol. The fed micelles contained 0.08 mM cholesterol, because of residual cholesterol in the egg lecithin, but are referred to as cholesterol-free in the text. Cholesterol-loaded micelles with 1.5 mM cholesterol were also used to simulate the presence of endogenous or presolubilized cholesterol (a total of 15 µmol in 10 mL) under fed-state conditions (32,33). Lipolysis experiments were performed at 37°C in a stirred and thermostated glass vessel and were initiated by the addition of 1 mL of a 20% pancreatin suspension (1 g of pancreatin to 5 mL of digestion buffer). The lipolysis was performed over 60 min using a pH-Stat titration unit (Radiometer, Copenhagen, Denmark) that maintained the pH at 7.5. The FA produced by TG lipolysis were titrated with 0.2 M NaOH. At the end of each experiment, a lipolysis inhibitor (50 µL of 0.5 M BPBA in methanol) was added to the digestion mixture to stop further digestion. Two 4-mL aliquots of the postdigestion mixtures were then ultracentrifuged in polyallomer centrifuge tubes (34 min at 37°C and 300,000 × g) to separate the digests into an oil phase, an aqueous phase, and a precipitated pellet. The aqueous phase was aspirated into a syringe by penetrating the side of the tube and was transferred into glass vials. Finally, the samples were dried overnight in a lyophilizer (LyoPro 3000 freeze dryer; Heto, Allerød, Denmark) before analyzing by GC. *t*-Tests (SigmaStat 2.0; SYSTAT Software Inc., Point Richmond, CA) were performed on assayed sterol concentrations in the micellar phases to statistically compare the results between the MCT and LCT systems. These results are presented in Table 2.

Phytosterol solubility determination. Solubility was determined by adding anhydrous phytosterol crystals (dried over night at 80°C, 0% RH) to the aqueous phase obtained after *in vitro* lipolysis of 50 mg of LCT or MCT in fed-state micelles preloaded with 1.5 mM cholesterol. A total of four digests were performed (for both MCT and LCT) to obtain the aqueous phase after separation by ultracentrifugation. Solid phytosterol was added (1 mg phytosterol/1 mL aqueous phase; total volume ~7 mL), after which the samples were incubated at +37°C for the entire period of the solubility studies and vortexed periodically. Sterol concentrations were analyzed by GC from samples taken at the start of the experiment and after 6, 24, 48, and 120 h incubation. The samples (0.5 mL) were filtered (13-mm syringe filter with a 0.2-µm polyvinylidene difluoride membrane) prior to determination, and the filtrate was collected for analysis. To assess the potential loss of solubilized sterol by filtration, aqueous-phase samples from digests containing both cholesterol and phytosterols were analyzed prior to and post filtration. The loss of sterols was ≤1.7 %. No apparent physical or visual changes were observed during the solubility study.

Sample preparation and GC analysis of sterols. Sterols were analyzed after alkaline hydrolysis of the samples by a GC method using an internal standard for quantification as pre-

sented earlier (34,35). The dried samples were suspended in 1 mL water and the internal standard was added (0.2 mg dihydrocholesterol, ≈95%; Sigma-Aldrich). The samples were subjected to alkaline hydrolysis (35), the unsaponifiable lipid fractions were purified using a SiOH cartridge (Bond Elut, 500 mg; Varian, Harbor City, CA), and sterols in aliquots of one-tenth of the sterol fraction were converted to trimethylsilyl ethers (TMS) (34). The TMS sterols were dissolved in 200 µL of heptane before analysis by GC.

An Agilent Technologies 6890N Network GC system gas chromatograph equipped with an autosampler, on-column 7683 Series injector, and FID (300°C) was used. The column was a RTX®-5w/INTEGRA fused-silica column [diphenyl and dimethyl polysiloxane (5:95), 60 m × 0.32 mm i.d., 0.1-µm film with 10-m Integra-Guard column; Restek Corp., Bellefonte, PA). GC analysis of the TMS sterols was performed as described earlier (34). An in-house reference sample (rapeseed oil) was used to monitor the analytical level each day. The CV was 1.86% for total sterol concentration and 2.12% for β-sitosterol (*n* = 19). GC separation and quantification were monitored daily by injecting a sterol standard mixture containing dihydrocholesterol, cholesterol, and stigmasterol. The determination limit of sterols in a sample after the sample preparation procedure was 5 µg.

RESULTS

Across all systems studied, the digestion of MCT and LCT was essentially complete after 60 min with no oily layer remaining after centrifugation. The only exception was when digesting LCT in the presence of fasted mixed micelles. In this case, it was possible to distinguish a few minute oil droplets in addition to the aqueous- and pellet-phase postultracentrifugation. A 50-mg dose of lipids was used to produce similar endpoints of digestion with the two lipids where practically all of the digestion products were likely to be incorporated into mixed micelles (24,26). This enabled comparison of the two systems on more equal terms with regard to the solubilizing capacity of the colloidal phases formed. Although fed-state conditions might be considered more relevant, fasted-state conditions were also studied to probe the effects of the BS/PL level on solubilization. This was warranted, not only by the wide range of BS/PL levels determined in aspirates from different subjects (31–33), but also because reduced gall bladder emptying has been observed after ingestion of MCT lipids (31).

Solubilization of cholesterol or phytosterols into mixed micelles during lipolysis. Digestion experiments with LCT or MCT lipids containing either cholesterol or phytosterol were conducted to establish their individual solubilization behavior. Under fed-state conditions, the solubilization of cholesterol from the LCT suspension formulation into the micelles was markedly different compared with the formulation containing MCT (Fig. 1A and Table 2). When digesting cholesterol suspended in LCT, the entire cholesterol dose (*n* = 3) was incorporated into the micellar phase. For the MCT suspension formulation of cholesterol, only 50.3% (±1.5%, *n* = 3) of the initial cholesterol dose was recovered in the micellar phase. A

reduction in the BS/PL concentration (fasted state) did not diminish cholesterol solubilization in the LCT system, and the entire cholesterol dose was again solubilized into the mixed micellar phase. On the other hand, cholesterol solubilization into fasted mixed micelles containing MCT digestion products decreased significantly (39.7 ± 1.8%, *n* = 3) compared with the corresponding event in the fed state.

Phytosterol solubilization was determined using fed-state mixed micelles (Fig. 1B, Table 2). As with cholesterol, phytosterols were incorporated into the mixed micellar phase but to a substantially lower degree than the cholesterol. Only 25% of the initial phytosterol dose was solubilized from suspensions containing LCT, and only 13% was solubilized from MCT formulations. However, the relative solubilizing capacity of the LCT and MCT systems was comparable to that observed with cholesterol. For MCT suspensions, increasing the phytosterol dose from 14 to 28 µmol led to a slight increase in the concentration of solubilized phytosterol (163 vs. 183 µM), as only 7% of the higher phytosterol dose was incorporated into the micelles. A more distinct increase in the concentration of solubilized phytosterol (329 vs. 452 µM) could be observed from the suspension prepared in LCT; however, not more than 15.9% of the phytosterol dose was solubilized at the higher dose.

Solubilization of co-administered cholesterol and phytosterols into mixed micelles during lipolysis. Digestion of co-administered phytosterol and cholesterol suspensions in either LCT or MCT was performed to simulate dietary intake of both sterols and to study the capacity of phytosterol to reduce cholesterol solubilization. The amounts of lipid and individual sterols were identical to those of the digests presented in the previous section.

When LCT suspensions were used under fed-state conditions, the extent of cholesterol solubilization in the micelles decreased to 85.8% (± 11.8%, *n* = 3) (Fig. 2, Table 2). The solubilization was not affected by a decline in the BS concentration (87.9 ± 11.0%, *n* = 3). A more significant decrease of cholesterol solubilization in mixed micelles was observed when co-administering phytosterol and cholesterol suspended in MCT. In the fed state, the content of cholesterol in micelles decreased to 24.4% (± 3.1, *n* = 3) of the initial cholesterol dose and was even lower in the fasted state (18.4, ± 4.7%, *n* = 3). The results indicate that when cholesterol and phytosterols are simultaneously present during lipid digestion, less cholesterol will be solubilized by the mixed micelles. However, it would seem that phytosterols together with MCT act as a more efficient limiting factor in the micelles' capacity to solubilize cholesterol.

Solubilization of phytosterols into cholesterol-loaded mixed micelles. Micelles preloaded with cholesterol represent a truer system than micelles without, since some cholesterol, as an integral component of bile, will be presolubilized in the intestinal mixed micelles under *in vivo* conditions (18,32). The preloaded fed-state micelles contained 1.5 mM cholesterol (15 µmol in 10 mL), which is within the range of concentrations observed in small intestinal aspirates after ingestion of a test meal (32,33). Phytosterols were administered as described previously at a dose of 14 µmol.

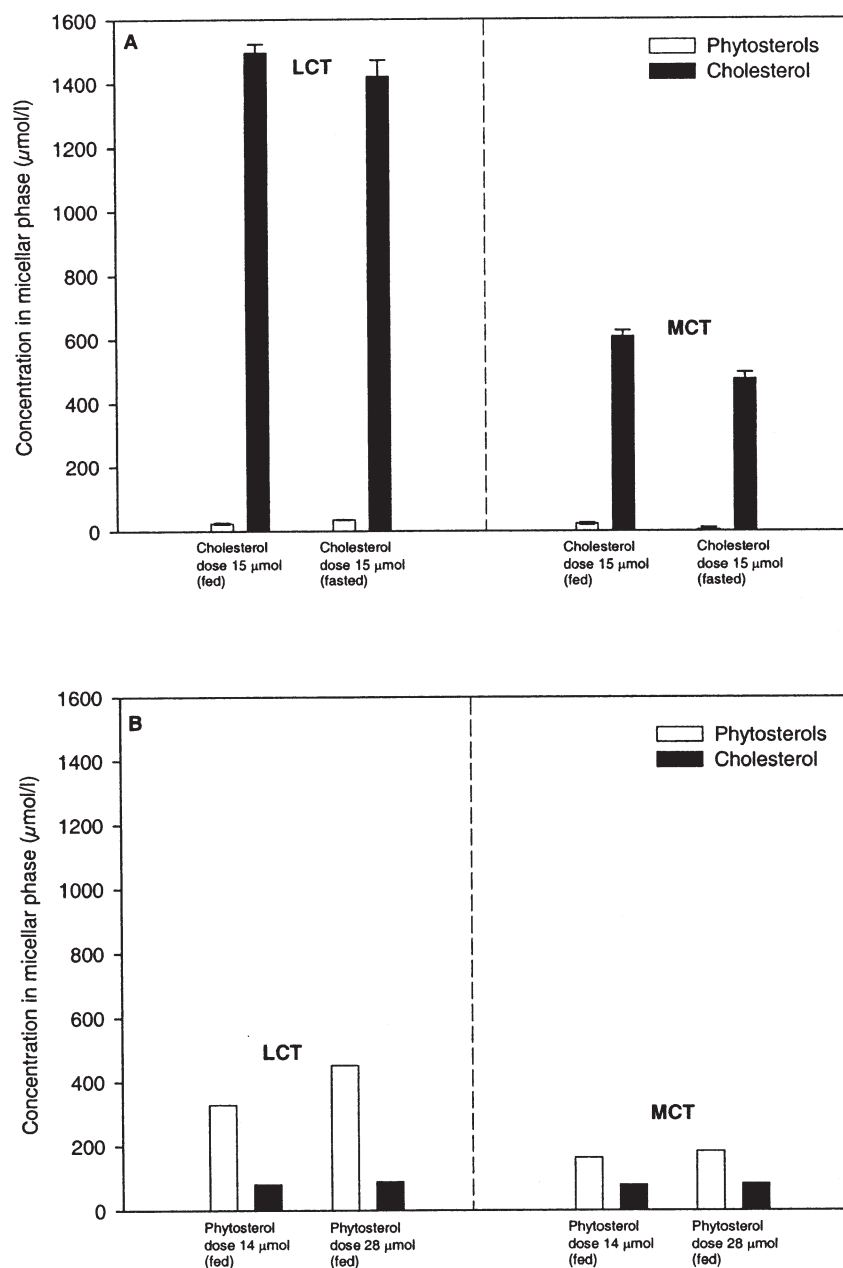
The phytosterols, administered as either MCT or LCT suspen-


FIG. 1. The impact of lipid chain length on the micellar solubilization of sterols during lipid digestion. The sterols were administered with a total of 50 mg of either long-chain TG (LCT) or medium-chain TG (MCT). (A) Solubilization of cholesterol (dose 15 μmol) into mixed micelles under a fed state [20 mM sodium taurodeoxycholate (NaTDC)/5 mM PC] or a fasted state (5 mM NaTDC/1.25 mM PC) ($n = 3$). (B) Solubilization of phytosterols (dose either 14 μmol or 28 μmol) into mixed micelles under a fed state ($n = 1$). Error bars represent SD.

sions, were solubilized into the cholesterol-loaded micelles to an extent similar to that during digestion with the cholesterol-free micelles (Figs. 3 and 1B, Table 2). Again, the solubilization of phytosterols suspended in LCT was more effective ($24.2 \pm 1.9\%$, $n = 3$) compared with the MCT-based suspension ($15.6 \pm 0.5\%$, $n = 3$). However, the incorporation of phytosterols into the cholesterol-preloaded mixed micelles did not significantly decrease the cho-

lesterol content. The cholesterol content in the micellar phase was 95.6% ($\pm 3.8\%$, $n = 3$) of the administered dose when phytosterols suspended in MCT were digested, and a similar cholesterol content was achieved with the LCT formulation ($96.1 \pm 3.7\%$, $n = 3$). A twofold increase in the phytosterol dose (28 μmol) did not further reduce the cholesterol content in the micelles (see Table 2).

Phytosterol solubility in MCT and LCT postdigestion
FIG. 2. Solubilization of co-administered phytosterol and cholesterol into mixed micelles. The sterol suspensions contained a total of 50 mg of either LCT or MCT. The bile salt (BS)/phospholipids (PL) concentration levels were 20 mM NaTDC/5 mM PC (fed state) or 5 mM NaTDC/1.25 mM PC (fasted state) ($n = 3$). For other abbreviations see Figure 1. Error bars represent SD.

phases. The solubility of phytosterols was determined in MCT and LCT postdigestion aqueous phases obtained with cholesterol-loaded micelles. This was done to further probe the validity of the results showing little displacement of presolubilized cholesterol by phytosterol suspensions during lipolysis.

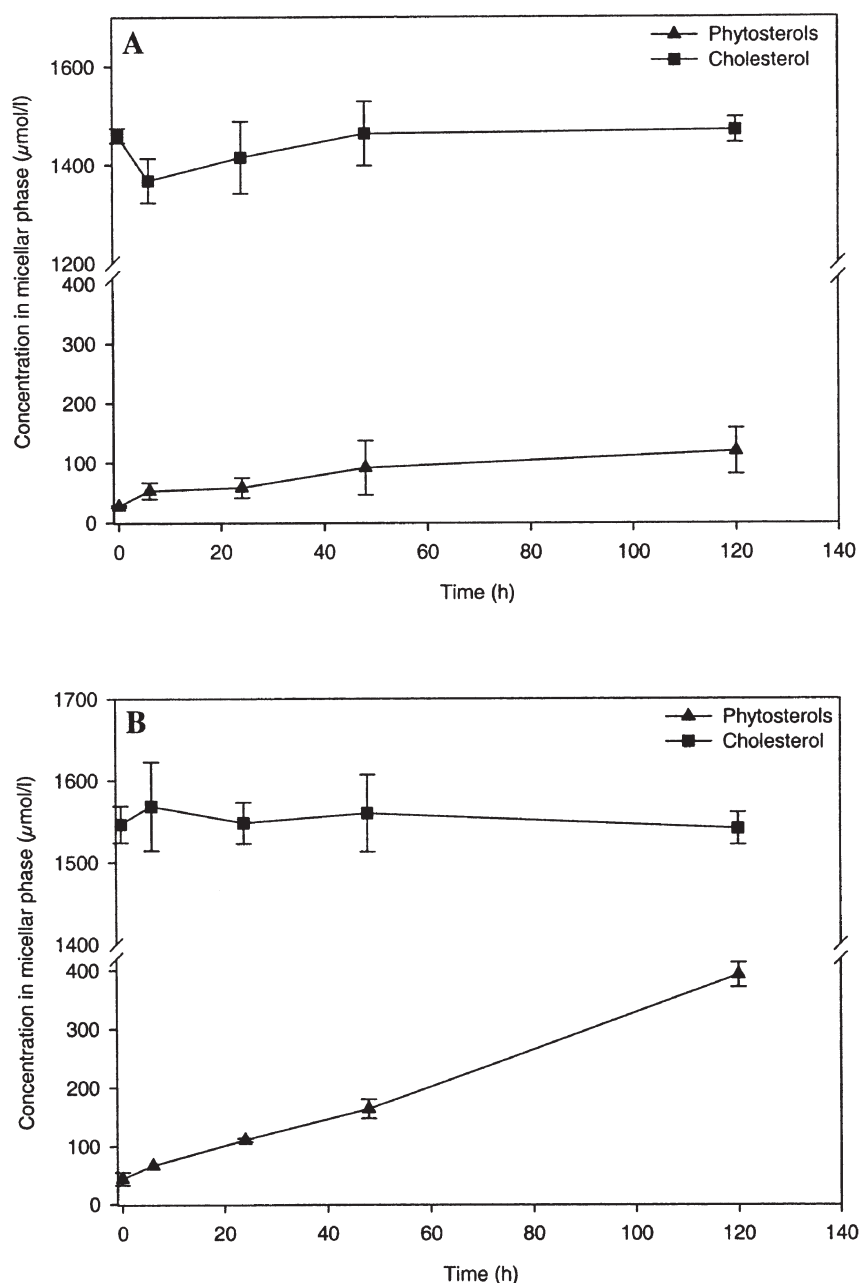
An increase in the phytosterol concentration was observed as a function of time for both MCT and LCT mixed micellar phases (Fig. 4). At 120 h, the solubilization of phytosterol into the micelles was 119 μM (± 38, $n = 3$) for the MCT phase (Fig. 4A), compared with 392 μM (± 21, $n = 3$) for the LCT phase (Fig. 4B). These results emphasize the efficacy of the lipolysis process, since approximately the same amount of phytosterol was incor-
FIG. 3. Solubilization of phytosterol (dose either 14 μmol or 28 μmol) into micelles preloaded with 1.5 mM cholesterol. Phytosterols were administered with 50 mg of either LCT or MCT. The BS/PL concentration level was 20 mM NaTDC/5 mM PC (fed state) ($n = 3$). For abbreviations see Figures 1 and 2. Error bars represent SD.


FIG. 4. Phytosterol solubility (+37°C, up to 120 h) in the mixed micellar phase obtained after *in vitro* lipolysis of 50 mg of (A) MCT or (B) LCT in fed-state micelles (20mM NaTDC/5mM PC) preloaded with 1.5 mM cholesterol (*n* = 4). For abbreviations see Figure 1. Error bars represent SD.

porated into the micelles during 120 h as during 1 h of lipolysis (see Fig. 1B).

Congruent with the lipolysis results, the solubilization of phytosterols into the micelles did not affect the content of cholesterol significantly. The cholesterol content in the micelles containing MCT digestion products varied (during 120 h) from 1367 (± 45, *n* = 3) to 1470 µM (± 26, *n* = 3), whereas the content in the LCT digestion phase varied from 1541 (± 20, *n* = 3) to 1568 µM (± 54,

n = 3) during the same time interval. These results suggest that presolubilized cholesterol may be difficult to displace.

Worth mentioning is that equilibrium sterol solubilities were not achieved with certainty during this study. Phytosterol concentrations sampled at 120 h were significantly higher than those at 48 h, which was more pronounced in samples from LCT micellar solutions (an increase of 139%) compared with MCT samples (30%, respectively).

DISCUSSION

For cholesterol, the crucial step in its lumenal processing is solubilization into mixed micelles, a prerequisite for the transport toward the brush border membrane. Previous *in vitro* studies have shown that very lipophilic drugs, with high log *P* (e.g., halofantrine, log *P* 8.86) are solubilized better into mixed micelles containing digestion products of LCT, whereas lower log *P* drugs (e.g., griseofulvin, log *P* 2.18) favor the systems containing medium-chain FA (23,26). Subsequent *in vivo* studies support these findings and give credence to the use of the dynamic *in vitro* lipolysis method as a predictive model of intestinal solubilization processes (24,25). Table 1 demonstrates log *P* values for all the sterols present in this study. If our results are consistent with the preceding findings, the high log *P* values suggest that incorporating sterols into mixed micelles containing long-chain FA is more efficient. This *in vitro* lipolysis study was performed to probe the above hypothesis on sterol solubilization and to further examine whether phytosterols are able to displace cholesterol from mixed micelles during lipid digestion. The experimental conditions were designed according to the previous studies producing *in vitro–in vivo* correlations (24).

We found, indeed, that the mixed-micellar phase containing digestion products of LCT was able to incorporate significantly higher amounts of cholesterol than that obtained after digestion of MCT (Fig. 1A). Replacing the long chain length (C_{14}–C_{18}) TG with one containing medium chain length (C_8–C_{10}) FA decreased the amount of solubilized cholesterol by 50% in the aqueous phase. Interestingly, comparable trends have been observed *in vivo*. Kritchevsky and Tepper (36) reported a similar reduction in serum total cholesterol concentration following ingestion of MCT compared with LCT in rats. Similarly, they stated that the cholesterol level was reduced by 50% of the initial amount in liver and serum when rats were fed MCT instead of coconut or corn oil. Notably, rats are not the ideal model when evaluating lipid digestion, since bile secretion in the rat is continuous and not food dependent as in humans (24). However, similar results were also obtained when Borel *et al.* (37) compared the effect of MCT and LCT on the bioavailability of fat-soluble β-carotene (log *P* 15.5) in humans. They found β-carotene plasma levels to be markedly diminished when administered together with MCT instead of LCT. These results, together with the results on lipophilic drugs (24,25), indicate that the less efficient *in vitro* solubilization of sterols provided by MCT digestion products may have relevance for *in vivo* absorption.

Regardless of lipid chain length, the amount of cholesterol solubilized into the micelles was roughly fourfold compared with that of phytosterols in the respective system (Table 2), with the individual phytosterols solubilized in proportion to their respective quantity in the solid (see Table 1). In contrast, results from a static dissolution study using simulated mixed micelles reported similar solubilization for cholesterol and β-sitosterol but showed reduced solubilization for sitostanol (18). With increasing hydrophobicity (see Table 1 for log *P* values

and aqueous solubility), the micellar solubilizing capacity for phytosterols is reduced compared with cholesterol (38). However, the relative benefits derived from solubilization also increase with increasing hydrophobicity, thereby affording the more hydrophobic phytosterols a higher affinity to the micelles (39). The selectivity for sterol hydrophobicity will depend on the hydrophilicity of the BS, i.e., on the number of hydroxyl groups and conjugating moiety (38,39). This may explain our dissimilar results as the dihydroxy BS in the present study (NaTDC) are likely to be more selective than the BS mixture used by Mel'nikov *et al.* (18).

Co-administration of phytosterol and cholesterol, particularly when suspended in MCT, showed a significant reduction of solubilized cholesterol in digests using cholesterol-free micelles (Fig. 2, Table 2). As was previously mentioned, the entire cholesterol dose administered was solubilized into mixed micelles containing LCT digestion products (see *Solubilization of cholesterol or phytosterols into mixed micelles during lipolysis* section). The amount of cholesterol solubilized into the micellar phase was reduced to 50.3% (±1.5%, *n* = 3) when digested with MCT. When MCT suspensions of phytosterols and cholesterol were co-administered, the solubilization of cholesterol into the mixed micelles containing MCT digestion products was further reduced to 24.4% (±3.1%, *n* = 3) of the administered dose.

The effects observed during MCT digestion of co-administered sterols are in excess of that observed with LCT, where reduction of cholesterol solubilization was 14.2%. These results are in agreement with the results and hypothesis presented by previous authors stating that the presence of phytosterols will reduce the micellar solubilization of cholesterol because of the limited solubilizing capacity of the mixed micelles or thermodynamic preferences (18). The lower solubilizing capacity for highly lipophilic compounds of the mixed micelles from MCT digests, compared with those of LCT lipids, would therefore further exacerbate the situation (24–26).

Despite the promising results with co-administered sterols, we were practically unable to displace presolubilized cholesterol during digestion in either the MCT or LCT system (Fig. 3); these results were supported by the solubility studies (Fig. 4). Potential reasons for this are the extent of micellar saturation, the lack of solid cholesterol to promote precipitation, and the time span of the experiment. Mel'nikov *et al.* (18) showed that phytosterols and β-stanols were able to compete with and displace preloaded cholesterol from mixed micelles containing long-chain FA, provided the micelles were loaded with sufficient amounts of cholesterol. Even in the presence of solid cholesterol, phytosterols were able to displace cholesterol from the mixed micelles only when the preloaded micelles were saturated (1.0 mM), whereas both cholesterol and phytosterols were incorporated into micelles at lower preloading (0.2 mM). Maximal displacement was obtained progressively over several hours of incubation. The cholesterol dose (1.5 mM) in the present study, although higher than that producing cholesterol precipitation in the study by Mel'nikov *et al.*, may not have been high enough to form saturated micelles because of higher

concentrations of the lipolysis products. An additional factor includes the dynamic processing during lipid digestion, which may promote supersaturation of colloidal (especially vesicular) structures (22–25). This would contribute to the lack of difference observed between the MCT and LCT lipids, as the presence of presolubilized cholesterol is likely to promote and stabilize vesicular structures, which for MCT systems would impart a relatively higher impact on the solubilizing capacity (26).

In a previous study Plat *et al*. (40), stated that consumption of 2.5 g of phytosterols in either one or three meals during the day was equally effective in lowering plasma LDL cholesterol levels. This suggests that phytosterols might also affect cholesterol absorption through other than lumenal mechanisms, e.g., through effects on the enterocyte level. A specific protein in jejunal enterocytes, called Niemann–Pick C1 L1 (NPC1L1), was recently found to facilitate cholesterol absorption through the brush border membrane (41). Similarly, NPC1L1 seems to play an important role in the intestinal influx of phytosterol. The ATP-binding cassette (ABC) transporters ABCG5, ABCG8, and ABCA1 are involved in the transport of excess sterol from the enterocytes back into the intestine (42,43). These transport systems appear to be unable to differentiate between cholesterol and phytosterols, whereby an increased amount of phytosterols in the intestine or in the enterocytes would increase the amount of cholesterol excreted (44,45). However, effects of phytosterol on the lumenal processing of cholesterol may also contribute to the findings of Plat *et al*. (40). In view of the high amount of phytosterol ingested in one dose, it is likely that much of the phytosterol would remain unsolubilized and precipitate in the intestine, later to be resolubilized when food is again ingested. In this way, phytosterols would be reintroduced into the solubilization process of cholesterol during lipolysis of the ingested lipids contained in the food. This kind of resolubilization process has been suggested to account for the observed double peaking in plasma concentration–time profiles with halofantrine, which is a highly lipophilic, poorly water-soluble drug (46).

The present study showed that cholesterol solubilization into mixed micelles is reduced in the presence of MCT digestion products and that phytosterols formulated in MCT could reduce cholesterol amounts even further and in excess of that observed with LCT systems. These interesting *in vitro* results raise questions about the potential benefits of medium chain length lipids in cholesterol-lowering phytosterol products. Today, approximately 95% of the ingested fat is LCT, although MCT should pose little or no risk from toxicity when consumed as a dietary supplement at levels up to 15% of the daily dietary calories or about 50% of the total daily dietary fats (47,48). However, potential risks for increased serum TG concentrations should be recognized at high levels of MCT (48,49). The *in vitro* lipolysis model is a fairly new method used to simulate the intestinal dissolution conditions in humans (22–25,30,50). Although the method has shown promising predictive capacity, the complex dynamic composition of fluids *in vivo*, especially during the fed state, is difficult to simulate and warrants additional experiments (both *in vitro* and *in vivo*) to probe this hypothesis further.

A Study on the Causes for the Elevated n-3 Fatty Acids in Cows' Milk of Alpine Origin

Florian Leiber, Michael Kreuzer*, Daniel Nigg,
Hans-Rudolf Wettstein, and Martin Richard Leo Scheeder

Institute of Animal Science, Swiss Federal Institute of Technology (ETH), Zurich, Switzerland

ABSTRACT: The influence of grass-only diets either from ryegrass-dominated lowland pastures (400 m above sea level) or botanically diverse alpine pastures (2000 m) on the FA profile of milk was investigated using three groups of six Brown Swiss cows each. Two groups were fed grass-only on pasture (P) or freshly harvested in barn (B), both for two experimental periods in the lowlands and, consecutively, two periods on the alp. Group C served as the control, receiving a silage-concentrate diet and permanently staying in the lowlands. Effects of vegetation stage or pasture vs. barn feeding on milk fat composition were negligible. Compared with the control, α-linolenic acid (18:3n-3) consumption was elevated in groups P and B (79%; $P < 0.001$) during the lowland periods but decreased on the alp to the level of C owing to feed intake depression and lower 18:3n-3 concentration in the alpine forage. Average 18:3n-3 contents of milk fat were higher in groups P and B than in C by 33% ($P < 0.01$) at low and by 96% ($P < 0.001$) at high altitude, indicating that 18:3n-3 levels in milk were to some extent independent of 18:3n-3 consumption. The *cis*-9,*trans*-11 CLA content in milk of grass-fed cows was higher compared with C but lower for the alpine vs. lowland periods whereas the *trans*-11,*cis*-13 isomer further increased with altitude. Long-chain n-3 FA and phytanic acid increased while arachidonic acid decreased with grass-only feeding, but none of them responded to altitude. Grass-only feeding increased milk α-tocopherol concentration by 86 and 134% at low and high altitude ($P < 0.001$), respectively. Changes in the ruminal ecosystem due to energy shortage or specific secondary plant metabolites are discussed as possible causes for the high 18:3n-3 concentrations in alpine milk.

Paper no. L9566 in *Lipids 40*, 191–202 (February 2005).

Recently, elevated contents of beneficial functional FA in cows' milk and cheese derived from alpine grazing systems were reported (1–4). Increased contents of n-3 PUFA and an improved ratio of n-3 to n-6 PUFA in milk of cows grazing on alpine pastures were shown (3,5). It was even hypothesized that a relation between high levels of α-linolenic acid (18:3n-3) in alpine cheese and a favorable cardiovascular health status of the alpine population may exist (4). Generally, n-3 PUFA are known to be essential for human health, and problems may arise if they are consumed in too low a proportion relative to n-6 FA (6). Furthermore, the content of CLA (18:2 *cis*-9,*trans*-11 isomer), a FA that also has shown potential to benefit human health (7), was found to be clearly enriched in milk (3) or cheese (1,2) from alpine production systems compared with those from intensive lowland production. Additionally, the proportion of short- and medium-chain saturated FA (SFA), which are supposed to increase the risk of cardiovascular diseases (8), was found to be markedly lower in milk and milk products originating from cows grazing high alpine pastures (2,4,5).

Milk fat derived from cows grazing high alpine pastures therefore seems to have a considerably higher dietetic value than conventional milk, but the reasons for these differences are still unclear. To our knowledge, in previous studies the individual factors of the alpine sojourn of cows potentially affecting milk fat composition were never differentiated, and diets fed in the lowlands for control were either not specified or not restricted to herbage-only, as is usual practice in Swiss alpine dairy systems. Known mechanisms influencing the FA profile in lowland milk are (i) the basic effect of grazing and the related body fat mobilization (9,10) as well as influences of the herbage's botanical composition (10,11), (ii) the degree of usage of concentrates, in particular wheat, barley, and maize in the diets, which mainly contribute SFA, 18:1, and 18:2n-6 but very little 18:3n-3 (10,12,13), and (iii) the effect of herbage conservation (13–15). These factors could also contribute to the differences in composition between common lowland milk and milk from alpine pastures. It is, however, still unclear whether, in addition, specific plants (16), the 18:3n-3 content of the alpine flora (3,17) and even the hypoxic environment *per se* (4) are responsible for the typically high contents of CLA and n-3 PUFA of alpine milk products. Otherwise, the "alpine paradox" (4) would actually be a general phenomenon of feeding grass at any altitude and mainly reflect the difference from mixed, often maize-based, diet types. The objective of the present study was to determine experimentally the factors responsible for the composition of milk fat of cows consuming grass at high altitude. Comparisons included grass-only vs. mixed diets in the lowland, high altitude vs. lowland grazing of the cows, pasture vs. indoor feeding, and young vs. mature swards.

EXPERIMENTAL PROCEDURES

Animals. Eighteen Brown Swiss cows, having been 94 (65 to 127) d into their second lactation at the beginning of the experiment, were blocked by calving date and allocated to three groups (P, pasture group; B, barn-fed group; C, control group) with minimal between-group variance for energy-corrected milk yield, milk protein, and milk fat percentage. Average milk yield, at the start of the experiment, was 21.7, 22.2, and 22.3 kg/d for groups P, B, and C, respectively. The corresponding average contents per kilogram of milk were 43.6, 42.0, and 41.4 g fat; 30.3, 31.1, and 31.8 g protein; and 50.6, 50.4, and 49.1 g lactose, respectively.

Experimental schedule. Six subperiods (S0 to S5) were defined. Each subperiod lasted for 21 d, and intensive sampling was always done during the respective third week. All data and data points in the figures refer to the average values of these intensive sampling weeks within each subperiod. The first part of the experiment took place at the ETH research station Chamau in central Switzerland at 400 m above sea level. During the baseline subperiod (S0) all cows were tethered in a barn and fed a mixed control diet. During the "lowland period," comprising the two subperiods S1 and S2, group P was turned out to pasture for 24 h/d, while groups B and C remained in the barn. Group B was fed only freshly harvested grass *ad libitum*, and group C remained on the control diet. After S2, all cows were kept in the barn again until the alpine vegetation was ready for grazing and harvest. During this time, groups P and B stayed on the grass-only diet at *ad libitum* access. At the end of this transition period, which lasted for 28 d, just before and after the transport to the alpine location, additional milk samples were taken. These samples provided the additional data points in Figures 3 to 6. For the "alpine period," Groups P and B were transported to the alpine ETH research station Alp Weissenstein located at 2000 m above sea level in the Eastern Swiss alps. Half of the group P and B cows were switched to the respective other group in order to counterbalance possible residual effects of the previous treatment. This balanced rearrangement of groups P and B is indicated in the figures by the dotted line. Group C remained in the lowlands and continued to serve as control group. Like the lowland period, the alpine period consisted of two subperiods (S3 and S4). S5 as a final baseline evaluation was carried out with all cows kept in the lowland barn again and fed the control diet.

During the intensive sampling weeks, milk yield was recorded and proportionate milk samples of each cow and each milking were obtained. The samples were frozen at −20°C immediately after sampling. Cows were weighed and blood samples were taken at days 2 and 6 within each sampling week. Two feed samples were drawn every day in each group during the sampling weeks of the subperiods. An aliquot of each feed sample was dried at 60°C for 48 h, and a second was frozen at −20°. Feces were sampled once a day from each animal and frozen. Later, all samples were defrosted, pooled per sampling week (feed) or per animal and sampling week (feces), and then dried and ground through a 0.75-mm sieve for analy-sis. Feed intake was measured daily for cows kept in barn. On pasture, feed samples were obtained mimicking the selection behavior of the cows for at least 3 h distributed over the whole daytime, and feed intake was calculated using the double-alkane technique (18). As the source for the synthetic marker alkanes (C_{32} and C_{36}), controlled release alkane capsules (CRC; Captec, Auckland, New Zealand) were introduced into the rumen of the cows 8 d prior to each sampling week. Odd-chain alkanes (C_{31} and C_{33}) in feed were used as internal markers. The actual alkane recovery rates in feces were determined with the known feed intake of the group B cows that had also received CRC.

Diets. S1 started at the earliest possible vegetation stage of the first growth; S2 followed 3 wk later on a now more mature sward. The same principle was followed for S3 and S4 at the alpine location. The lowland areas were intensively managed leys with regular manure fertilization. The alpine pasture was native and not fertilized. The botanical composition was visually estimated in the standing sward within each sampling week in eight systematically distributed 9-m^2 plots (four per pasture and harvest paddock, respectively) according to the method of Braun-Blanquet (19). The main species characteristics of the experimental sites are shown in Table 1. The analyzed nutrient and FA composition of the experimental feeds is listed in Table 2. Data for individual vegetation stages are not displayed since vegetation stage effects on milk fat composition were found to be not significant.

Herbage for group B was harvested daily in the early morning from paddocks adjoining those grazed by group P cows; the two were similar in botanical composition. It was then kept tightly packed to avoid any possible losses of FA by wilting of the forage (15). The control diet contained hay, ryegrass silage, and maize silage in proportions of 0.1:0.6:0.3 on a dry-matter (DM) basis, was provided *ad libitum*, and was supplemented by concentrates according to milk yield. The two commercial concentrates used contained rumen-protected fat (Table 2), which made up 410 g/kg of total dietary FA in the control diet. The cows of all groups had *ad libitum* access to NaCl and a nonvitaminized mineral mix (Ca:P = 2:1; Nährkosan, Büron, Switzerland) during the whole experiment.

Analysis. Frozen milk samples were defrosted and pooled per cow and sampling week. After direct transesterification, according to Suter *et al.* (20), the FAME were extracted with *n*-heptane and then separated and quantified with GC using a Sil 88 column (100 m × 0.25 mm, 0.2 μm; Varian Inc, Darmstadt, Germany) on an HP 6890 (Hewlett-Packard, Wilmington, DE). Hydrogen flow was 1.5 mL/min; 0.5 mL of *n*-heptane containing the FAME was injected on column. The temperature program was: 60°C for 5 min; increase by 14°C/min up to 165°C; 2°C/min up to 225°C; isothermal for another 15 min. Temperature program and peak identification were adapted from Collomb and Bühler (21) with some modifications. The peaks for 16:1*trans* and 20:1*trans* may contain some branched-chain FA (22). They were therefore only included in the calculation of total FAME and not separately shown in the tables. The applied chromatographic method also is not able to separate *trans-*

TABLE 1
Frequent Plant Species in the Lowland and the Alpine Pastures Used in the Experiment

[a]Visually estimated according to the method of Braun-Blanquet (19).

8,*cis*-10 and *trans*-7,*cis*-9 from the major *cis*-9,*trans*-11 CLA-isomer as well as *trans*-11,*cis*-13 from *cis*-9,*cis*-11 (3,23). However, the concentration of the *trans*-7,*cis*-9 isomer has been described to be about 100-fold lower than the *cis*-9,*trans*-11 isomer in milk, and changes due to (alpine) feeding occurred on a rather low level (3,24). Proportions of and effects on *trans*-8,*cis*-10 are even lower than for *trans*-7,*cis*-9 (24). Thus, we conclude that any distortion of the effect on the *cis*-9,*trans*-11 isomer is small, although it might be slightly biased because both of these minor isomers are likely to increase with altitude of the site where the dairy cows are kept (24). Similarly, the *cis*-9,*cis*-11 isomer, coeluting with the *trans*-11,*cis*-13 isomer, seems to be present only in traces if at all (24; Collomb, M., personal communication); we therefore refer to this peak as *trans*-11,*cis*-13. Response factors were determined using BCR 164 standard milk fat (Certified Reference Material; EC Reference Materials, Brussels, Belgium) as a reference. The milk fat content measured with a standard NIR procedure (Milkoscan 4000; Foss, Höganäs, Sweden) closely correlated with the amount of total FAME obtained with GC (r^2 = 0.93). Phytanic acid (3,7,11,15-tetramethylhexadecanoic acid) was separated and quantified in the milk samples of S2 and S3 and in the samples drawn directly before and after transfer to the alp, using an

RTX225 column (30 m × 0.32 mm, 0.5 µm; Restek Corporation, Bellefonte, PA). Injection volume was 1 µL in a 30:1 split modus at 240°C. Hydrogen flow was 4.0 mL/min. The temperature program was 140°C for 2 min, ramp 5°C/min up to 215°C, isothermal for 5 min.

Lipids from feeds were extracted by accelerated solvent extraction (ASE 200; Dionex Corp., Sunnyvale CA) using hexane/isopropanol (2:1 vol/vol) and transformed into FAME according to Wettstein *et al.* (25). FAME were dissolved in hexane and analyzed with GC on a Supelcowax™-10 column (30 m × 0.32 mm, 0.25 µm; Supelco Inc., Bellefonte, PA) after split injection (1:30) at 270°C. The injection volume was 2 µL; hydrogen flow was 2.2 mL/min. The temperature program was 160°C for 1 min, ramp 20°C/min up to 190°C, ramp 7°C/min up to 230°C; isotherm at 230°C for 4 min, ramp 20°C/min up to 250°C, isotherm for 4 min.

Tocopherols in milk were analyzed after saponification with KOH with normal-phase HPLC on a Merck-Hitachi system with UV detection (La Chrom; Darmstadt, Germany) according to Rettenmaier and Schüepp (26). The β-, γ-, and δ-tocopherols were always below the detection limit.

Feed contents of DM and nitrogen (N × 6.25 = crude protein) were analyzed with standard methods as described previ-

TABLE 2

[b]NE$_L$: net energy for lactation, calculated based on formula of RAP (28).
[c]SFA: saturated FA (sum of 10:0 through 24:0).
[d]Average of two subperiods with two samples per subperiod; each sample pooled from 7 d.
[e]g/kg DM: wheat, 300; barley, 190; wheat bran, 150; oats, 120; straw meal, 50; maize, 50; crystalline fat (rumen-protected; Alikon, Bützberg, Switzerland), 40; maize gluten, 30; molasses, 30; canola cake, 20; sugar beet pulp, 20.
[f]g/kg DM: soybean meal, 480; maize gluten, 220; straw meal, 60; wheat, 40; crystalline fat, 40; sugar beet pulp, 40; molasses, 30; wheat bran, 10.

ously (27). Contents of net energy for lactation were calculated based on the equations used in the official Swiss feed evaluation (28). Plasma metabolites and insulin were analyzed with standard assays. Plasma insulin was measured with a radioimmunoassay kit (No. 1064 1401; Pharmacia, Uppsala, Sweden). Plasma concentrations of nonesterified FA (NEFA), β-hydroxybutyrate (BHB), glucose, and urea were analyzed on a COBAS-MIRA chemistry analyzer (Roche, Basel, Switzerland), with the following assays: NEFA with NEFA-C WA 994-75409 (Wako, Neuss, Germany), BHB with product 310-A (Sigma, Buchs, Switzerland), glucose with assay No. 1447513 and urea with assay No. 1489364 (both Roche).

Statistics. Data were evaluated with three mixed models by SAS V8.2e (PROC MIXED; SAS Institute, Cary, NC;). Model 1 included group (P, B, or C) and calving date (classified in three blocks of similar calving date) as fixed factors. Animal was included as random effect, and the individual baseline (S0) values were used as a covariate. The least squares (LS) means and all significances of the group × period interaction, shown in Tables 3 and 4, are based on model 1. The same model, but without the covariate S0, was used to obtain LS means of all subperiods (including S0) for the illustration in the figures. A third model was applied for the calculation of the altitude and the vegetation stage effects, considering vegetation stage (two classes: young or mature) and main period (lowland or alps) as additional fixed effects. Group C, for which feed and altitude remained unchanged, was excluded from the calculations with model 3.

RESULTS

Feed intake and metabolic energy supply. During the lowland period, the DM intake of the grass-only fed cows was lower than in cows of group C [significantly for group P ($P < 0.05$) and as a tendency for group B ($P < 0.1$); Table 3]. Nevertheless, the calculated net energy intake of B and P cows did not differ significantly from C cows during the lowland period (Fig. 1A), and milk yield decreased only slightly (Fig. 2B). However, unlike C cows, P and B cows lost weight from S0 to S1 ($P < 0.05$; Fig. 2A), and all blood plasma metabolites indicated a certain catabolic state (Table 3). In the alpine period (S3 and S4), DM intake in groups P and B decreased ($P < 0.001$) compared with the lowland period and with C cows, and net energy intake was reduced by approximately one-third ($P < 0.01$). Accordingly, milk yield markedly decreased when cows were transferred to the alpine location ($P < 0.001$; Fig. 2). Although body weight did not further decline, plasma levels of BHB ($P < 0.001$) and NEFA ($P < 0.001$) still increased and plasma glucose ($P < 0.05$) and insulin ($P < 0.001$) further decreased during the alpine sojourn of the cows (Table 3).

FA intake. In S1 and S2, individual FA consumption of the grass-only fed cows differed from that of the C cows (Table 3) since lowland grass had clearly higher levels of 18:3n-3 but much lower levels of SFA, monounsaturated FA, and 18:2n-6 than the control diet (*cf.* Table 2). Thus, 18:3n-3 was the main dietary FA for groups P and B, whereas for group C, 16:0 and

[e]Superscript roman letters a–d indicate significant differences ($P < 0.05$) between group × period interaction means according to model 1.
[f]Values marked with asterisks are significantly different ($P < 0.05$) from the respective control group value according to model 1.
[g]BHB, β-hydroxybutyrate; NEFA, nonesterified FA.
[h]NS, not significant; for other abbreviation see Table 2.

18:0, originating from the concentrates, and 18:1 and 18:2n-6, coming from both the concentrates and the maize silage, were the major dietary FA. In the alpine period, the total FA content of the herbage tended to be lower ($P < 0.1$; t-test) than during the lowland period (Table 2). Additionally, the 18:3n-3 proportion of total FA in the herbage declined ($P < 0.01$; t-test). This resulted in a reduced intake of total FA and 18:3n-3 by 23 and 43%, respectively, in the alpine compared with the lowland period for both P and B ($P < 0.001$; Table 3 and Fig. 1B).

Fat content and saturated FA in milk. The fat content in milk was not affected by the grass-only diets in the lowlands but (with concomitantly decreased milk yields) it increased in group P ($P < 0.001$) and in group B ($P < 0.1$) after transport to the alps. With the start of grass feeding in S1, the proportion of the even-chain SFA 6:0 through 14:0 in total milk FAME of groups P and B initially increased ($P < 0.001$). From subperiod S2 on, there was an almost linear decrease in the proportions of these FA in total FAME and in the milk of the P and B cows, with the values finally decreasing below the levels of control group (representatively shown for 10:0 and 12:0 in Fig. 3). Figure 3 illustrates that this was a continuous decline that, to a considerable extent, had already taken place before the transfer to the alpine site. In S5, the concentration of 6:0 through 14:0 returned to the baseline values represented by the C cows. During the lowland period, a decrease in the proportion of 16:0 as part of the total FAME occurred with the herbage-only diets (P cows: $P < 0.01$; B cows: $P < 0.05$) compared with the control diet (C), whereas 17:0 moderately increased ($P < 0.05$ for both groups) and the proportion of 18:0 remained unaffected. With

the alpine sojourn of P and B groups, the 18:0 proportion of total FAME significantly increased whereas those of 16:0 and 17:0 were not affected by the location.

18:1 FA in milk. Among the identified 18:1 *trans* isomers, the 18:1*trans*-10/*trans*-11 proportions of total FAME increased ($P < 0.001$) with lowland grass-only diets by more than 3.3-fold, whereas the 18:1*trans*-4-*trans*-9 isomers were moderately reduced, particularly in group B ($P < 0.01$), compared with C cows (Table 4). During the alpine period, compared with the lowland values in groups P and B, the double-peak comprising 18:1*trans*-11 (*trans*-vaccenic acid) clearly decreased, whereas the concentration of the 18:1*trans*-4 to *trans*-9 in total FAME significantly increased. The proportion of 18:1*cis*-9, as the dominating 18:1, remained unaffected by the grass-only diets in the lowlands but was elevated at high altitude by 32% ($P < 0.001$) compared with the lowland values in P and B cows.

CLA in milk. All identified CLA isomers increased markedly as a proportion of the total FAME when grass-only diets were fed in groups P and B ($P < 0.001$; Table 4). Accordingly, during the lowland periods, the proportion of the main isomer, 18:2 *cis*-9,*trans*-11, was on average 1.9-fold higher in milk fat of P and B cows than in the milk of C cows. From S0 to S1, CLA increased in both P and B cows ($P < 0.001$); from S1 to S2 a further increase occurred only in P cows ($P < 0.05$). This was the reason for the significant difference between P and B cows in the lowland period ($P < 0.01$; Table 4, Fig. 4). During the alpine sojourn, the concentration of the main CLA isomer, 18:2 *cis*-9,*trans*-11, in total FAME decreased ($P < 0.01$), whereas the 18:2 *trans*-11,*cis*-13 isomer significantly increased in the P and B groups

($P < 0.001$). In S5, the CLA concentration and secretion returned to the baseline value (Fig. 4).

Linolenic acid in milk. Whereas the γ-linolenic acid (18:3n-6) proportion of total FAME decreased with grass-only diets ($P < 0.01$) in the lowland period, the concentration of α-linolenic acid (18:3n-3) increased by 34% ($P < 0.001$; Table 4). Slightly lower 18:3n-3 proportions were observed for B cows compared with P cows ($P < 0.01$) and for S2 compared with S1 ($P < 0.05$; Fig. 5). After transfer to the alpine site, 18:3n-3 proportions of total FAME of pastured cows (group P) were 0.63-fold higher compared with the respective lowland levels

($P < 0.001$) and 1.14-fold higher than the value found in the C group ($P < 0.001$). The increase in B cows was less pronounced. The analysis of the milk samples obtained directly before and after the transfer to the alps showed that the increase of 18:3n-3 proportion was a direct response to the alpine sojourn rather than a continuous time effect of grass feeding (Fig. 5). In contrast to the proportionate values, the absolute daily 18:3n-3 secretion with milk remained unaffected by feeding grass to cows kept in barn. The pastured cows still showed a significantly higher daily 18:3n-3 secretion in the lowlands ($P < 0.01$) and at the alpine site ($P < 0.001$) compared with the

control cows. In S5, 18:3n-3 concentration returned to the baseline value (Fig. 5).

Long-chain PUFA in milk. Concentrations of the long-chain n-3 PUFA (EPA, 20:5n-3; docosapentaenoic acid, 22:5n-3; DHA, 22:6n-3) were higher in milk samples of the grass-only groups than in C cows (*P* < 0.01), whereas 20:4n-6 (arachidonic acid) was somewhat lower in P and B cows (Table 4). The ratio of all n-6/n-3 PUFA was diminished by half in P and B compared with C. The long-chain PUFA responded neither to the alpine sojourn (Table 4) nor to the stage of vegetation (data not shown).

Phytanic acid. Phytanic acid concentration in milk fat, which was analyzed in a smaller subset of samples (S2, transition period, and S3), was markedly higher with grass-only feeding compared with the control diet (*P* < 0.001; Fig. 6). There was a slight, but not significant, additional increase with alpine sojourn.

α-Tocopherol. The α-tocopherol concentration was 0.86- and 1.31-fold higher in milk of P and B cows than that of C

cows during the lowland and the alpine period, respectively (*P* < 0.001; Table 4). In S5, the values of the previously grass-fed groups dropped nearly to the baseline level (from 1.57 mg/L in S4 to 0.95 mg/L in S5; the baseline value in S0 had been 0.79 mg/L for P and B on average).

DISCUSSION

Impact of feeding grass only on milk FA profile. In the lowland period, turnout to pasture and the concurrent start of feeding only grass in the barn did not markedly change the net energy intake relative to controls but clearly altered the amount and composition of the ingested lipids and the FA composition of the milk lipids. The intake of SFA, 18:1, and 18:2n-6 declined for groups P and B in the lowlands, since the concentrates and the included rumen-protected fat, maize, and cereals were no longer available. In turn, 18:3n-3-intake was nearly doubled (Fig. 1).

Among the unsaturated FA, 18:3n-3 is one of those most
FIG. 6. Phytanic acid concentration in milk fat. S2, lowland period; S3, alpine period. ● Pasture group; ▲ indoor grass group; ■ control group; n = 6 per group. susceptible to ruminal biohydrogenation (29). Up to 99% of the dietary 18:3n-3 can be partially or completely hydrogenated (30). Main derivatives of 18:3n-3 biohydrogenation are 18:1*trans*-11 and 18:0 (31), which are partly desaturated at the Δ9 position to *cis*-9,*trans*-11 CLA and 18:1*cis*-9, respectively, in the mammary gland (32). As a consequence, under normal ruminal conditions, the high proportion of 18:3n-3 in grass-only diets explains the elevated contents of CLA and 18:1*trans*-11 in milk fat as also found in the current study (Fig. 4, Table 4). However, the increase of *cis*-9,*trans*-11 CLA during lowland grazing in our case was even more pronounced than in other studies (3,10,11,33). We did not find a substantial reduction of CLA in milk fat when harvested grass was fed instead of grazing, as has been previously described by Elgersma *et al.* (34), but this is probably a problem related to the wilting during storage (15), which we had carefully avoided.

The small proportion of 18:3n-3 passing by the rumen may appear in milk in its native form or in the form of endogenous derivatives (20:5n-3, 22:5n-3, and 22:6n-3; 35). Accordingly, all 20- and 22n-3 PUFA were higher in the milk fat of grass-only fed cows compared with the control. However, the moderate increase of these n-3 PUFA proportion found in milk fat in the lowland period of the present study (Table 4) did not reflect the massive increase in 18:3n-3 intake of cows fed only grass (Fig. 1; Table 3). This underlines the high extent and relevance of the biohydrogenation of 18:3n-3 during the lowland period. We assume that the supply of fermentable energy during this period was sufficiently high to support extensive biohydrogenation. Furthermore, mobilized body fat, as indicated by the decrease in body weight (Fig. 2) and the significantly higher NEFA concentration in plasma of the pasture group (Table 3), may have contributed to the 18:3n-3 in milk fat (36). Thus, the actual recovery of ingested 18:3n-3 in the milk can be assumed to be even lower than the apparent recovery.

The relatively sharp increase in the proportion of 6:0 to 14:0

in milk of P and B cows at the beginning of the lowland period (Fig. 3) may be explained by a shift in ruminal production from propionate to acetate, when all concentrates were withdrawn since acetate is the substrate for the FA *de novo* synthesis in the mammary gland. The subsequent continuously decreasing amount of medium-chain SFA might have been a result of a decreased energy intake and mobilization of body fat stores at the expense of *de novo* synthesis. However, as a moderate decrease of these medium-chain SFA also occurred in the control group, which was not exposed to dietary changes, a general effect linked to the progression of lactation may be assumed.

Impact of feeding alpine grass on the milk FA profile. Unlike Kraft *et al.* (3), we found that *cis*-9,*trans*-11 CLA and 18:1*trans*-11 concentrations in milk fat were not further elevated when P and B cows received alpine instead of lowland grass (Fig. 4). These are not necessarily conflicting results, because other influencing factors apart from alpine effects cannot be excluded, since Kraft *et al.* (3) compared milk from different herds. Ferlay *et al.* (12) found a considerable reduction of CLA after 3 wk of alpine grazing and related this to the stage of plant development (17). In the present experiment, no corresponding effect of stage of vegetation occurred at any experimental site (Fig. 4). In contrast to what was indicated by the results of Fievez *et al.* (11), there was also no noticeable effect of forage biodiversity on the CLA concentration. Thus, feeding only grass, irrespective of site and vegetative stage, may *per se* be a main contributor to high *cis*-9,*trans*-11 CLA proportions in milk fat. Whereas the main isomer, *cis*-9,*trans*-11, slightly declined owing to alpine feeding, the *trans*-11,*cis*-13 isomer was further increased, making it an interesting marker and potential target of experiments elucidating its possible physiological effects.

The 18:3n-3 contents of forages were described to decrease with maturation of the grass (37). In the present study, this was also found in the alpine grass (6.81 vs. 4.13 g 18:3n-3/kg DM for young vs. mature grass) but not in the lowlands (6.76 vs. 9.01 g 18:3n-3/kg DM). Furthermore, *Lolium perenne* and *Trifolium repens*, two of the dominant species in the lowland pasture (Table 1), contain far higher contents of 18:3n-3 than many other grasses and legumes (37). The absence of these species and the on-average higher maturity of the alpine forages (27) may at least partly explain the lower 18:3n-3 proportion in total FAME of the alpine grass. Together with alpine-specific anorexia of the cows (27), this drastically decreased 18:3n-3 intake (Fig. 1). In contrast to this, the most surprising and, with respect to human nutrition, most important effect of the alpine sojourn was the sharp increase of 18:3n-3 concentrations in milk fat, which in our case was definitely not related to the 18:3n-3 supply from food as suggested elsewhere (3,17).

Three hypotheses will be discussed here that could explain, alone or in combination, this discrepancy between intake of 18:3n-3 and its concentration in milk fat. One hypothesis (i) is that body fat mobilization with a preference for 18:3n-3 took place as a result of the energy deficiency associated with high altitude. The other hypotheses are that ruminal biohydrogenation activity was reduced by either energy deficiency (ii) or specific

secondary plant ingredients that inhibit ruminal microbes (iii). The fact that less than 10% of 18:3n-3 escapes biohydrogenation in the rumen (30) makes it likely that even small changes in the ruminal ecosystem, influencing hydrogenating microbes, may have large effects on the amount of 18:3n-3 available at the duodenum.

(i) Metabolic energy deficiency related to altitude. One key issue might be the decrease in energy intake of the cows transferred to the alpine site. Although cows partially reduced the energy deficit by a sharp decline in milk yield, as found in previous studies (27,38), there were several indications of a persisting metabolic energy deficit such as decreased plasma glucose and insulin levels and increased body fat mobilization (as indicated by elevated plasma NEFA and BHB levels). Mobilization of body fat depots is typical for cows kept in high alpine regions (27,39), and a preferential release of 18-PUFA from body fat was observed in undernourished ruminants (36). This would suggest that the elevated 18:3n-3 concentrations in the milk fat obtained in the alpine period (Fig. 5) could originate at least partially from body fat. This hypothesis is underlined by the fact that 18:3n-3 was even more highly concentrated in the P cows because grazing activity is assumed to cause additional energy expenditure in this hypoxic and uneven environment (38). The differences in plasma BHB and NEFA concentrations between the P and the B group during the alpine period further support this explanation. The higher proportion of 18:1*cis*-9 in the alpine milk vs. control and of the milk from P vs. B cows also fits this hypothesis, because 18:1*cis*-9, the major FA in depot fat, is likely to be released from body stores.

(ii) Ruminal energy deficiency. Kelly *et al.* (33) considered ruminal ecosystem changes to be responsible for alterations in PUFA proportions of milk fat. In our study, in response to the nutritional energy deficiency during the alpine period in groups P and B (here: lack of fermentable organic matter), the rumen microbial capacity for biohydrogenation may have been reduced and more 18:3n-3 could have remained available for absorption. This would explain the negative response of *cis*-9,*trans*-11 CLA and 18:1*trans*-11 to alpine sojourn on the one hand and the positive response of 18:3n-3 on the other hand, which was found when comparing lowland and alpine milk samples derived from the grass-fed cows in our experiment (Table 4; Figs. 4 and 5). Milk of cows having restricted access to pasture was reported to have lower 18:3n-3 and increased 18:1*trans*-11 and *cis*-9,*trans*-11 CLA proportions when the animals were supplemented with grain (10). Also, Sasaki *et al.* (30) reported an increase of ruminal biohydrogenation of 18:3n-3 in sheep from 93 to 99% when a roughage-only diet was supplemented with concentrate at 400 g/kg. This supports the assumption of fermentable organic matter being one key factor for milk FA profile.

Both the mobilization hypothesis and the hypothesis of a reduced ruminal biohydrogenation are based on the presence of a serious energy deficiency during high-altitude grazing, which is underlined by many variables concerning performance and metabolic profile. Data are consistent with those of Agenäs *et al.* (9) where, at turnout to pasture, an impaired energy balance

of the cows was associated with elevated 18:3n-3 concentrations in milk.

(iii) Inhibition of ruminal biohydrogenation by dietary components. Another explanation, which would rely on a specific high-alpine phenomenon, is the assumption that typically high concentrations of secondary plant ingredients, such as polyphenols and terpenoids (40,41) as well as others, may inhibit hydrogenating microorganisms in the rumen. Tannins were shown to inhibit several strains of *Butyrivibrio fibrisolvens* (42), one of the most important biohydrogenating ruminal bacteria species (31). On the other hand, the findings of Dewhurst *et al.* (43) that 18:3n-3 biohydrogenation was reduced when feeding *Trifolium pratense* instead of *T. repens* suggest that plant constituents other than tannins also may influence biohydrogenation. In the present study, *T. pratense* was the most abundant legume in the alpine pasture but made up only 1.6% of the lowland forage. We assume that a complex interaction of different factors determines CLA and 18:3n-3 concentrations in milk rather than a monofactorial alpine mechanism. This implies that CLA and 18:3n-3 may be variable across milks from different alpine origins, which also may explain part of the differences between studies.

All hypotheses discussed to explain the higher 18:3n-3 concentrations in alpine pasture-derived milk fat would include the expectation of enhanced 20:5n-3 (EPA) and 22:6n-3 (DHA) content too, as 18:3n-3 can be converted to some extent into these FA in mammals (35). Although all 20- and 22n-3 PUFA were significantly higher in milk of groups P and B compared with group C and thus showed a diet effect, no additional effect of the alpine sojourn was found. It can be speculated that the maximal transfer rate was already reached at the 18:3n-3 concentration met in the lowlands by groups P and B. Furthermore, the transfer of PUFA from blood into milk also has to be considered: In particular, 20 and 22n-3 PUFA are reported to be preferentially bound to phospholipids in lipoproteins and therefore are hardly cleaved by lipoprotein lipases in the mammary gland. This could explain the low transfer rate into milk (44). The answer to the question—Which are the limiting factors of EPA and DHA synthesis and secretion?—is not yet clear (44), but it seems relevant to examine this question, since these n-3 PUFA are of an even higher specificity and importance for human health than 18:3n-3 (35).

Phytanic acid. This branched-chain 20:0 FA, being present in the plasma lipids of cows in proportions as high as 130 g/kg total FA (45), was strongly discriminated for by the mammary gland and was found in milk fat in concentrations between 10 and 500 mg/kg (46). The markedly increased values that were reached on pasture in the present study are at the upper limit of the literature values for butter as reviewed by Brown *et al.* (46). Similar to CLA, phytanic acid is supposed to act as a gene transcription factor and is assumed to exert antidiabetic effects (47). However, in this context a general risk of consuming higher amounts of phytanic acid for Refsum's disease patients, who suffer from inherited disorders of peroxisomal α-oxidation (48), must be considered.

α-Tocopherol. A reduced oxidative stability may be a prob-

lem in PUFA-rich milk lipids (49), including technological, flavor-related, and human health aspects. Our results indicate that pasture in any form obviously provides high amounts of α-tocopherol for milk synthesis and that its concentration is even higher in milk derived from alpine pasture. The α-tocopherol concentrations in pasture-derived milk were much higher than the minima suggested by Al-Mabruk *et al.* (49) to ensure a favorable oxidative stability of milk. According to Jensen *et al.* (50), α-tocopherol is actively secreted into the milk, and its daily amounts excreted with milk remain constant at levels between 20 and 30 mg/d. Indeed, in the grass-only fed cows, the absolute excretion of α-tocopherol per day with milk was on average higher during the lowland than during the alpine period. Thus, the significantly higher concentrations in milk produced during the alpine period were mainly a consequence of the reduced milk yield. On the other hand, the control cows on average did not reach a level of 20 mg α-tocopherol excretion per day, suggesting that the supply with this diet was too low to reach the naturally determined range.

General implications. Concerning high CLA and n-3 PUFA contents, a low n-6/n-3 ratio, and low concentrations of SFA, the alpine milk in this study, as in previous studies, constituted a more favorable FA pattern than conventionally produced lowland milk (2,3,8). However, levels of *cis*-9,*trans*-11-CLA were not different from milk obtained with lowland grazing, even though this pasture was intensively managed and poor in species diversity. We therefore conclude that the effects on this CLA isomer and on 18:1*trans*-FA are linked to grazing in general rather than being the result of a specific alpine pasture effect. In agreement with Kraft *et al.* (3), the same seems to hold true for the long-chain PUFA (20:5, 22:5, and 22:6 n-3). The situation is obviously different for 18:3n-3, which was markedly elevated by the alpine conditions, thus confirming previous findings (3,4). However, the real nature of the alpine grazing effect on 18:3n-3 concentration in milk still has to be elucidated. Where specific plant constituents are one of the major reasons affecting CLA and n-3 PUFA contents, strategies to increase 18:3n-3 further would be applicable also for lowland milk production systems. Where energy deficiency is the major driving factor, there would be only a very limited potential since a conflict would arise between product quality and animal welfare.

METHODS

Quantitative Determination of Total Lipid Hydroperoxides by a Flow Injection Analysis System

Jeong-Ho Sohn, Yusuke Taki, Hideki Ushio, and Toshiaki Ohshima*

Department of Food Science and Technology, Tokyo University of Marine Science
and Technology, Konan 4, Minato-ku, Tokyo 108-8477, Japan

ABSTRACT: A flow injection analysis (FIA) system coupled with a fluorescence detection system using diphenyl-1-pyrenylphosphine (DPPP) was developed as a highly sensitive and reproducible quantitative method of total lipid hydroperoxide analysis. Fluorescence analysis of DPPP oxide generated by the reaction of lipid hydroperoxides with DPPP enabled a quantitative determination of the total amount of lipid hydroperoxides. Use of 1-myristoyl-2-(12-((7-nitro-2-1,3-benzoxadiazol-4-yl)amino) dodecanoyl)-sn-glycero-3-phosphocholine as the internal standard improved the sensitivity and reproducibility of the analysis. Several commercially available edible oils, including soybean oil, rapeseed oil, olive oil, corn oil, canola oil, safflower oil, mixed vegetable oils, cod liver oil, and sardine oil were analyzed by the FIA system for the quantitative determination of total lipid hydroperoxides. The minimal amounts of sample oils required were 50 µg of soybean oil (PV = 2.71 meq/kg) and 3 mg of sardine oil (PV = 0.38 meq/kg) for a single injection. Thus, sensitivity was sufficient for the detection of a small amount and/or low concentration of hydroperoxides in common edible oils. The recovery of sample oils for the FIA system ranged between 87.2 ± 2.6% and 102 ± 5.1% when PV ranged between 0.38 and 58.8 meq/kg. The CV in the analyses of soybean oil (PV = 3.25 meq/kg), cod liver oil (PV = 6.71 meq/kg), rapeseed oil (PV = 12.3 meq/kg), and sardine oil (PV = 63.8 meq/kg) were 4.31, 5.66, 8.27, and 11.2%, respectively, demonstrating sufficient reproducibility of the FIA system for the determination of lipid hydroperoxides. The squared correlation (r^2) between the FIA system and the official AOCS iodometric titration method in a linear regression analysis was estimated at 0.9976 within the range of 0.35–77.8 meq/kg of PV (n = 42). Thus, the FIA system provided satisfactory detection limits, recovery, and reproducibility. The FIA system was further applied to evaluate changes in the total amounts of lipid hydroperoxides in fish muscle stored on ice.

Paper no. L9651 in *Lipids 40*, 203–209 (February 2005).

Lipid oxidation occurring in food is a major cause of quality deterioration in flavor, texture, consistency, and appearance. It is also a decisive factor in the causes of aging and some diseases (1). Since lipid oxidation is one of the most important problems in food chemistry, a great deal of research has been devoted to its mechanisms and the development of effective antioxidants. Although various methods have been proposed to measure hydroperoxides, the instability and diversity of hydroperoxides in a complex food system becomes a hindrance to an accurate and simple analysis. The widely accepted iodometric titration (2,3) and the enzymatic assay (4) have inherent problems such as sensitivity, selectivity, and interference with contaminants. It is therefore very important and necessary to develop more efficient analytical methods to evaluate lipid peroxidation in complex food systems.

In the analysis of hydroperoxides by HPLC, quantitative determination by UV light absorption at around 235 nm is based on the oxidation reaction of the conjugated double bond of the lipid (5). However, with respect to applications evaluating the early stage of lipid oxidation, there are problems involving specificity and detection sensitivity. In response to these problems, Yamada *et al.* (6) used an electrochemical detection method that utilized the redox potential of hydroperoxides to detect the primary lipid peroxidation product. However, the detection sensitivity was inadequate to analyze trace amounts of lipid hydroperoxides. One solution to this problem involves a postcolumn chemiluminescence detection based on luminol or isoluminol oxidation during the reaction of hydroperoxide and cytochrome C (7,8). Some applications to biological systems also have been reported (9–11). Generally, nonpolar solvent systems based on *n*-hexane are used in HPLC for the separation of hydroperoxide positional isomers (12). However, a postcolumn reaction of luminol to luminol oxide progresses only under aqueous alkaline conditions (9). Therefore, the number and types of organic solvents used for the mobile phase are relatively limited, since hydrophobic nonpolar solvent mixtures do not mix well with hydrophilic luminol reagents in a postcolumn reaction coil.

Diphenyl-1-pyrenylphosphine (DPPP) is a fluorescence reagent that reacts specifically with various lipid hydroperoxides to form DPPP oxide, even in the presence of lipid alcohols. The DPPP oxide is excited at 352 nm of UV light and gives the emission wavelength (λ_{em}) of 380 nm. The DPPP solution has been confirmed as having sufficient stability by holding it at –25°C in the dark. The stability of DPPP itself has been maintained for more than 20 mon at 5°C in the dark (13). This reaction progresses in different types of solvents (14). A few applications of this system have already been reported for the analyses of hydroperoxides of TAG, cholesterol, cholesterol esters, and phospholipids in biological systems (15–20). This method has also been applied to analyze the distributions of

hydroperoxide isomers of FAME (21–24). However, since various lipid classes coexist in food, separating and analyzing each hydroperoxide with a different chemical structure is complicated. Therefore, a simultaneous method that can determine total lipid hydroperoxides in food and other complex systems is required.

The aim of this study was to establish an accurate and simple analytical methodology that could enable the quantitative determination of total amounts of lipid hydroperoxides in complex food systems. For the analytical method proposed in this study, an HPLC separation column was replaced by a stainless-steel reaction coil, and an appropriate internal standard was introduced to facilitate study of the total lipid hydroperoxide contents.

MATERIALS AND METHODS

Chemicals and materials. DPPP was purchased from Dojindo Laboratories Co., Ltd. (Kumamoto, Japan). BHT was purchased from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). 1-Myristoyl-2-(12-((7-nitro-2-1,3-benzoxadiazol-4-yl)amino)dodecanoyl)-*sn*-glycero-3-phosphocholine (NBD-labeled PC) was purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). Methanol of HPLC grade from Kokusan Chemical Co., Ltd. (Tokyo, Japan) and 1-butanol from Kishida Chemical Co., Ltd. (Osaka, Japan) were used after degassing. All other chemicals were of analytical grade.

Commercially available soybean oil (Miyazawa Yakuhin Co., Ltd., Tokyo, Japan), rapeseed oil (Yamahiko Hayasi Co., Tokyo, Japan), olive oil, corn oil, canola oil, safflower oil (Ajinomoto Co., Inc., Tokyo, Japan), mixed vegetable oils (Nisshin Oillio Ltd., Tokyo, Japan), cod liver oil (Toho Co., Tokyo,

Japan), and sardine oil (extracted and purified in the laboratory) were used as sample oils. Briefly, sardine oil was extracted by the Bligh and Dyer procedure (25) and purified by open column chromatography (72 cm length × 6 cm i.d.) on Spherical silica gel 60 40–50 μm, Kanto Chemical Co. Inc., Tokyo, Japan) using *n*-hexane followed by 5% (vol/vol) diethyl ether in *n*-hexane as the eluates.

The flow injection analysis (FIA) system. A diagram of the FIA system with a fluorescence detection system using DPPP is illustrated in Figure 1. The mobile phase (a mixture of 200 mL of 1-butanol and 100 mL of methanol) was passed through a Shimadzu model LC-9A HPLC pump (Kyoto, Japan) at a flow rate of 0.5 mL/min and subsequently transferred to a stainless-steel reaction coil (0.25 mm i.d. × 40 m) immersed in a water bath (NTT-1400; Eyela, Tokyo, Japan) controlled at 89°C. The nonfluorescent DPPP reagent reacted with lipid hydroperoxides to produce fluorescent DPPP oxide quantitatively in the coil. After the reaction, the eluent from the coil was cooled by passing it through a short stainless-steel coil (0.25 mm i.d. × 1 m) immersed in an ice-water bath. At the inlet of the reaction coil, a DPPP solution (5 mg of DPPP and 100 mg of BHT dissolved in a mixture of 200 mL of 1-butanol and 100 mL of methanol) was pumped with a Shimadzu model LC-10AS (Kyoto, Japan) and mixed with the eluent from the column in a T-connector. The DPPP solution, which was kept in a brown bottle on ice in the dark, was pumped at a flow rate of 0.3 mL/min. The fluorescence intensity of the DPPP oxides was monitored at 352 nm of excitation wavelength (λ_{ex}) and at 380 nm of λ_{em} with a Shimadzu model RF 535 fluorescence detector. The NBD-labeled PC used as an internal standard was monitored at 460 nm of λ_{ex} and at 534 nm of λ_{em} with a Shimadzu model RF-10A fluorescence detector, which was set in

the flow line behind the first fluorescence detector. The fluorescence intensity signals were integrated with two Shimadzu Chromatopac C-R6A chromatographic integrators. The injection volume was 20 μL, and all samples were analyzed in triplicate.

To find the most appropriate flow rates for the mobile phase as well as the DPPP solution, a mixture of 0.03 mg of sardine oil (PV = 82 meq/kg) and the internal standard (4.82 nmol) was dissolved in 10 mL of chloroform and introduced into the FIA system. Flow rates of the mobile phase and DPPP solution were increased stepwise from 0.2 to 0.8 mL/min and from 0.03 to 0.5 mL/min, respectively.

To evaluate the effects of the reaction coil temperature, each of the 20-μL portions containing 0.2, 0.4, or 0.6 mg of rapeseed oil (PV = 4.0 meq/kg) as well as 9.64 pmol of NBD-labeled PC was injected separately into the FIA system at the range of 60 to 90°C.

Calibration curve. A calibration curve was used to determine total lipid hydroperoxides with the FIA system in cod liver oils with different degrees of peroxidation. Five solutions with different mixing ratios (0.2:1.0, 0.5:1.0, 1.0:1.0, 2.0:1.0, and 3.0:1.0, mL/mL) of cod liver oil (PV = 22.3 meq/kg, 1.0330 g oil/10 mL chloroform) and the internal standard (4.82 nmol/mL methanol) were prepared quantitatively. Each solution was made up to 10 mL by chloroform, and each 20-μL portion was injected separately into the FIA system in triplicate.

Determination of PV. PV of the oils were determined by iodometric titration according to AOCS Official Method Cd 8-53 (2).

Fish sample preparation. Cultured live yellowtail (*Seriola quinqueradiata*) was obtained from a Misaki fishing port in Kanagawa, Japan. The yellowtail were sacrificed and immediately stored on ice during 1 h of transportation to the laboratory. The fish muscle specimen was separated into dorsal, ventral, and dark muscle. The separated muscle was thoroughly minced with a model MK-K50 cooking cutter (National, Tokyo, Japan) and stored on ice in polyethylene bags.

A 5-g portion of the fish muscle was extracted and purified according to the method of Bligh and Dyer (25). A 1-mL solution of NBD-labeled PC (4.82 nmol/mL in methanol) was added as an internal standard prior to homogenization. The homogenate was centrifuged at $1700 \times g$ for 8 min at 4°C. The lower layer was dehydrated by anhydrous sodium sulfate and filtered through a membrane filter (PTFE 0.20 μm; Advantec Toyo Roshi Kaisha, Ltd., Tokyo, Japan), and the filtrate thus obtained was made up to 10 mL by chloroform. A 20-μL portion of the sample solution containing 9.64 pmol of the internal standard was injected into the FIA system to determine the total lipid hydroperoxides.

Statistics. Measurements of hydroperoxide contents were carried out in triplicate and are represented as the mean ± SD. Student's *t*-test (26) was used to distinguish significant differences among the mean values. A statistically significant difference was selected at $P < 0.01$. A simple linear regression was calculated from the calibration curve, and the correlation between hydroperoxide contents obtained by the FIA system and the iodometric titration method was evaluated.

RESULTS AND DISCUSSION

Flow rates. Effects of the flow rates of the mobile phase and DPPP solution on peak areas are shown in Figure 2. The peak area ratios of the oil decreased gradually with the increase in flow rate of the mobile phase. Higher sensitivities in the detection of lipid hydroperoxides were obtained by reducing the flow rates; however, flow rates below 0.3 mL/min caused the constant flow by the pump to decline (Fig. 2B). On the other hand, the peak area ratios increased gradually with an increase in the flow rate of the DPPP solution up to 0.3 mL/min and plateaued at flow rates over 0.4 mL/min (Fig. 2B). Thus, the flow rates of the mobile phase and DPPP solution were set at 0.5 mL/min and 0.3 mL/min, respectively, to obtain sharp peaks and stable baselines on the chromatograms.

Reaction temperature. Changes in the peak area ratios were plotted in terms of the temperature of the reaction coil and are illustrated in Figure 3. For all the lines with different amounts of hydroperoxides injected, the peak area ratios increased gradually with an increase in reaction temperature. Indeed, the peak area ratios obtained at reaction temperatures of 70, 80, and 90°C were 138–141, 183–191, and 250–253%, respectively, of those obtained at 60°C. When the reaction temperature was increased to 90°C, the peak area ratios did not plateau and still tended to increase. The baselines of DPPP oxide and NBD-labeled PC on the chromatograms, however, became remarkably unstable at temperatures over 91°C due to solvent boiling. From the results of these preliminary examinations, the reaction
FIG. 2. Effects of flow rates of the mobile phase (A) and the DPPP solution (B) on the peak area ratios of sardine oil with a PV of 82 meq/kg. A 20-μL portion of a sardine oil/chloroform solution (1.5 mg/mL) containing 9.64 pmol of 1-myristoyl-2(12-((7-nitro-2-1,3-benzoxadiazol-4-yl)amino)dodecanoyl)-*sn*-glycero-3-phosphocholine (NBD-labeled PC) was injected into the FIA system at a reaction coil temperature of 89°C. For other abbreviation see Figure 1.

**FIG. 3.** Effects of reaction coil temperature on the peak area ratios of DPPP oxide and NBD-labeled PC used as an internal standard. Twenty-microliter portions containing 0.2 (-○-), 0.4 (-△-), or 0.6 mg (-□-) of rapeseed oils (PV = 4.0 meq/kg) were injected separately.

temperature was set at 89°C to obtain the highest reaction efficiency under the present experimental conditions.

The FIA system. Several organic solvents, including chloroform, ethanol, methanol, acetone, benzene, diethyl ether, and *n*-hexane, were investigated to find suitable injection solvents for the FIA system. All injected solvents other than *n*-hexane had no effects on the fluctuation in intensity and provided no peaks on the baseline of the chromatogram. However, certain solvent characteristics, such as the toxicity of methanol and benzene, the insolubility of phospholipids in acetone and ethanol, and the flammability of diethyl ether, made certain injection solvents unsuitable for the FIA system. *n*-Hexane represented a small peak on the chromatogram when monitored at 352 nm of λ_{ex} and at 380 nm of λ_{em}. The effects of *n*-hexane on the peak signals of the sample were not negligible, especially for the analyses of small amounts and/or low concentrations of hydroperoxides in the lipid samples. From these results, we concluded that chloroform was the most suitable solvent for the FIA system (Fig. 4A). Additionally, the effects of radical trapping agents such as BHT and α-tocopherol on the fluorescence detection system were investigated. A chloroform solution of 200 ppm BHT or 200 ppm α-tocopherol showed no influence on the chromatogram (data not shown) as reported previously (22,27).

The primary fluorescence spectra of the DPPP oxide and the internal standard ranged between 360 and 410 nm and between 500 and 560 nm, respectively (data not shown), suggesting that no interference occurred in excited fluorescence intensities between the DPPP oxide and the internal standard.

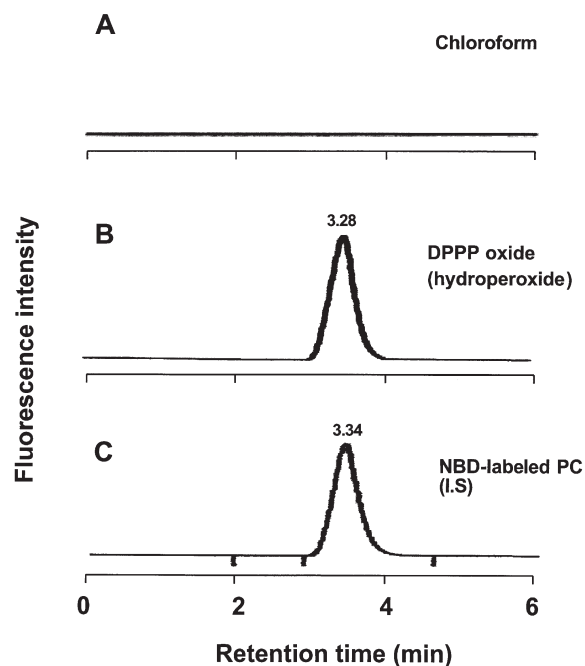
The chromatograms of fish oil and the internal standard were monitored at the most suitable flow rates of the mobile phase (0.5 mL/min) and the DPPP solution (0.3 mL/min) as shown in Figures 4B and 4C, respectively. The retention times of DPPP oxide and the internal standard were approximately 3.2 and 3.3 min, respectively. Thus, the total lipid hydroperoxides of the sample were determined as a single peak in a short


FIG. 4. Typical chromatograms obtained by the FIA system. (A) Chloroform as an injection solvent; (B) DPPP oxide reacted with total lipid hydroperoxide in the total lipid extracted from ordinary muscle of yellowtail (ca. 0.8 mg oil/injection); (C) NBD-labeled PC used as an internal standard (9.64 pmol/injection).

time. These results indicate that the FIA system is a rapid and simple method for the determination of hydroperoxides in lipids compared with the traditional iodometric determination.

Calibration curve. A calibration curve for the determination of total lipid hydroperoxides is shown in Figure 5. A linear relationship was obtained, with a squared correlation (r^2) of 0.9977 between the peak area ratios and the molar ratios of DPPP oxide peak areas and NBD-labeled PC. The minimal detectable amount of total hydroperoxides on the calibration curve was 24.0 pmol per injection.

Reproducibility and recovery. To obtain reproducibility in the quantitative determination of hydroperoxides with the FIA system, the hydroperoxide contents of several commercially available edible oils were analyzed in replicate, as summarized in Table 1. The CV for soybean oil, rapeseed oil, cod liver oil, and sardine oil were 4.31, 8.27, 5.66, and 11.2%, respectively, suggesting that the FIA system provided satisfactory reproducibility for the quantitative determination of lipid hydroperoxides.

Recoveries of authentic cumene hydroperoxides previously added to several edible oils were measured, as shown in Table 2. Recoveries ranged between 87.2 and 102%, suggesting that the FIA system provided sufficient recovery and reproducibility for the determination of total lipid hydroperoxides in edible oils.

Application to commercially available edible oils. The FIA system was applied to the quantitative determination of total lipid hydroperoxides in commercially available edible oils, including
FIG. 5. A simple linear regression curve between the area ratios (DPPP oxide/NBD-labeled PC) and the molar ratios (cod liver oil hydroperoxide/NBD-labeled PC). The minimal detectable amount of total hydroperoxide on the calibration curve was 24.0 pmol of hydroperoxide per an injection.

soybean, rapeseed, olive, corn, canola, safflower, mixed vegetable, cod liver, and sardine oils. The hydroperoxide contents determined by the FIA system were compared with those determined by the official AOCS iodometric titration method, as shown in Figure 6. The simple linear regression curve, with $r^2 = 0.9976$ ($n = 42$) between the hydroperoxide contents determined by the FIA system and the iodometric titration method, suggested that the FIA system could be used not only as a practical alternative to the iodometric titration method but also as more sensitive and specific methodology for the quantitative determination of trace amounts of lipid hydroperoxides.

Application to muscle lipids. Changes in total lipid hydroperoxides in the muscle of cultured yellowtail during iced storage were measured with the FIA system and are illustrated in Figure 7. Although the total lipid hydroperoxide contents in the ventral and dorsal muscle were low and remained unchanged, those in the dark muscle contained significantly higher amounts of total hydroperoxides ($P < 0.01$) compared with those of the ventral and dorsal muscle throughout the storage time up to 4 d. These results coincided well with those obtained by Nakamura *et al.* (28), who reported that the PV of dark muscle were higher than ordinary muscle in wild yellowtail. The total lipid hydroperoxide content became sixfold that of the ventral and dorsal muscle after 4 d of storage, suggesting that the rate of lipid oxidation in the edible part of whole muscle is mainly due to the high lipid oxidation rate in the dark muscle. The off-flavor caused by rancidity in the dark muscle was confirmed after 3 d (data not shown) in this particular case, suggesting that lipid hydroperoxide contents determined by the FIA system offer an alternative oxidative index that is more sensitive than sensory evaluation.

In the case of muscle foods with lipid contents of less than 1%, such as flatfish muscle, 500–1000 g of muscle would be required to extract 5–10 g of total lipids, which would be a minimal amount for one iodometric titration for hydroperoxide determination. For the analyses in triplicate, at least 1500–3000 g of muscle would be required. The FIA system required less than 1 g of muscle for an accurate and reproducible determination of lipid hydroperoxide contents. Indeed, the present study showed that the lipid hydroperoxide content in the ordinary muscle of yellowtail with a total lipid content of 8% was approximately 200 neq/5 g muscle just after the fish were sacrificed; the hydroperoxide content of lipids was 0.5 meq/kg. To obtain the hydroperoxide content of ordinary yellowtail muscle by the iodometric titration method, approximately 120 g of ordinary muscle would be required for one titration trial, which is a disadvantage of the iodometric method. In comparison, the FIA system required only 5 g of muscle for a single determination. In particular, the present FIA system showed sufficient sensitivity and reproducibility to evaluate the early stage of oxidization of lean fish muscle.

FIG. 6. Relationship between the total lipid hydroperoxide contents determined by the proposed FIA system and those obtained by the iodometric titration method. (A) in a wide range of PV between 0 and 80 meq/kg; (B) in a narrow range of PV between 0 and 3.2 meq/kg.

Although the iodometric titration method has been widely used to determine hydroperoxide contents, it may be unreliable at very low oxidation levels, i.e., <1 meq/kg, because of interference by molecular oxygen, the reaction of liberated iodine with other components, and uncertainty in the titration endpoint. Moreover, to determine the hydroperoxide content in edible oils with PV between 1 and 10 meq/kg, 5–10 g of oils would be required for a traditional iodometric titration. In contrast, in the FIA system the actual amount of soybean oil required was only 0.05 mg when the hydroperoxide content of the oil was 2.7 ± 0.24 meq/kg ($n = 15$). In a practical analysis with the FIA system, however, approximately 10 mg of oil would be enough for accurate weighing of the oil.

In summary, in the proposed FIA system quantitative determination of total lipid hydroperoxides was accomplished with high reproducibility, even at extremely low hydroperoxide concentrations, not only in refined fats and oils but also in oils in foods and foodstuffs.

sn-Position Determination of Phospholipid-Linked Fatty Acids Derived from Erythrocytes by Liquid Chromatography Electrospray Ionization Ion-Trap Mass Spectrometry

Christopher Beermann*, Michael Möbius, Nadine Winterling, Joachim J. Schmitt, and Günther Boehm

Numico Research Germany, D-61381 Friedrichsdorf, Germany

ABSTRACT: The *sn*-position of FA in membrane lipids has an influence on the physiological function of cells, is predictive for diseases, and therefore is useful for diagnostics. The current study compares the compositions of acyl chain substituents in the *sn*-1 and *sn*-2 positions of the glycerol backbones of phospholipids derived from human erythrocytes by using RP-HPLC coupled with on-line electrospray ionization ion trap MS. Preferential loss of the acyl group in the *sn*-1 position was used to determine the degree of regiospecific preference exhibited by the phospholipid molecules. The identities of the molecular species and the positions of the acyl substituents were identified using product-ion spectra of major precursor ions selected from the mass spectra averaged across peaks in the total ion chromatogram. Saturated FA were found to be located mainly in the *sn*-1 position of the glycerol backbones of erythrocyte phospholipids, whereas PUFA were found primarily in the *sn*-2 position. All measured phospholipids revealed palmitic acid (16:0) at the *sn*-1 position. Linoleic acid (18:2n-6) and arachidonic acid (20:4n-6) were found to be attached exclusively to the *sn*-2 position of the backbone, whereas eicosadienoic (20:2n-6) and eicosatrienoic acid (20:3n-9) occurred in both positions of the backbone of PC. Oleic (18:1n-9), linoleic (18:2n-6), and octadecatrienoic (18:3) acids of PE and PS were linked to both positions. Lignoceric acid (24:1n-9) was found to be strictly localized at the *sn*-2 position, whereas nervonic (24:1n-9) acid of PS was associated with both positions of the backbone. A detailed analysis of the blood cell membrane lipids by MS might be helpful to characterize postprandial kinetics of pharmacological or dietary lipid applications, as well as environmental influences on cell membranes.

Paper no. L9604 in *Lipids 40*, 211–218 (February 2005).

The membrane lipids of human red blood cells consist mainly of cholesterol (Chol), glycerophospholipids, sphingomyelin (SM), and glycosphingolipids. Each glycerophospholipid possesses a distinctive FA composition distributed between the *sn*-1 or *sn*-2 position and determined by acyltransferases during biosynthesis. The ester linkage in a phospholipid may be re-placed by a vinyl ether linkage to form a plasmalogen, or one FA may be lost altogether, which results in a lysophospholipid (1). However, the alkylacyl and alkenylacyl species of choline and ethanolamime phosphatides are not part of the present study. The *sn*-position of FA is important to characterize the physiological function of lipids integrated into cellular membranes. Besides, it indicates condition, state, and dysfunction of cells. In this study, the regiospecificity of FA of membrane lipids derived from human erythrocytes is determined by LC coupled with MS for routine measurements. The *sn*-position of FA of phospholipids has a significant impact on membrane function, cell signaling, and substrate specificity of enzymes. Unfavorable distribution of the *sn*-positions of FA is associated with several diseases including sickle cell anemia. In this case, the erythrocyte membrane contains more saturated and mononounsaturated FA, but less PUFA at the *sn*-2 position, which affects cation balance, membrane phospholipid asymmetry, and hypercoagulability (2). SM and Chol have been found to segregate into self-assembled domains referred to as membrane rafts, which act as the physiological surroundings for intrinsic membrane proteins. These lipid rafts are obviously important for the activity of growth factors, membrane-associated enzymes (3), receptor–ligand interactions, and cell signaling (4). A higher degree of unsaturation in FA of PE in the *sn*-2 position is thought to influence physical characteristics of lipid rafts (5). Therefore, signal transduction through the membrane might be influenced by the alkyl-chain properties of membrane lipids. In addition, it has been demonstrated by Brooks *et al.* (6) that thermal stress in carp liver microsomes induces specific alterations in the distribution of the *sn*-position in mononounsaturated and polyunsaturated FA of phospholipids (6).

The heterogeneous enzyme class of phospholipase A2 (PLA-2) hydrolyzes FA from the *sn*-2 position of membrane phospholipids. PUFA, which are located in this position, have been described to be precursors of hormone-like multifunctional eicosanoids. Thus, the PLA-2 substrate specificity is involved in platelet aggregation (7), cell cycle progression (8), and inflammatory immune response (9), which reveal the importance of the *sn*-position of FA. A prolonged stimulation of PLA-2 has been hypothesized to decrease membrane integrity found in the neurodegenerative Alzheimer's disease (10).

Several studies have shown that the FA composition of

Abbreviations: CGC, capillary gas chromatography; Chol, cholesterol; ESI, electrospray ionization; FAB, fast atom bombardment; ITMS, ion trap MS; MS[n], sequenced MS; PLA-2 phospholipase A2; RP, reversed-phase; RT, retention time; SIC, selected ion chromatogram; SM, sphingomyelin; TIC, total ion chromatogram.

blood and organs, such as heart or liver, can be influenced by nutritional or pharmacological lipid applications (9). The postprandial kinetics of the applied FA are reflected by alterations of the FA composition of plasma and red blood cells. Plasma-derived FFA are actively incorporated into lysophosphatides of erythrocytes and usually appear in the *sn*-2 position of the glycerol (1). The specific *sn*-positions of FA present in pharmacological or dietary lipid applications have been found to determine the digestibility in the gastrointestinal tract, the absorption by intestinal enterocytes, lipoprotein transport pathways of the portal or lymph system, and the incorporation and distribution into body organs and cellular membranes (11). Therefore, the *sn*-position of FA of the target organ represents an important parameter in characterizing the physiological efficiency of the applied active FA.

Apart from the common method used to determine the *sn*-position of FA linked to phospholipids, which involves specific enzymatic digestion and subsequent LC or GC analysis (12), various MS methods are currently available. For structural analysis of phosphatidyldiacylglycerols of erythrocytes, fast atom bombardment (FAB) (13), matrix-assisted laser desorption/ionization time of flight (14), and electrospray ionization (ESI) techniques with triple-quadrupole tandem (15) as well as ion trap MS (ITMS) detections (16) have been applied. These procedures differ considerably with regard to sample application (range of M.W. and polarity), ion fragmentation, and detection sensitivity. ESI is described as a soft ionization technology compared with chemical or electronic ionization and is therefore feasible to characterize amphiphilic molecules. Kerwin *et al.* (17) identified glycerophospholipid and SM species by generating H^+-ions of the polar phosphoryl group and $RCOO^-$-ions of the acyl constituents with ESI-MS (17). This technique provides the fragmentation of defined parent ions and a detailed molecular structural analysis *via* sequenced MS (MS^n) experiments (18,19). Marzilli *et al.* (20) described a structural characterization of TAG using ESI sources and MS^n experiments with ITMS detection. This determination is based on the formation of *sn*-position-specific acyl product ions and on acylketene moieties, which are subject to collision voltage within MS^3 experiments. The ratio of the signal intensities of the distinct fragment ions has been used to distinguish between the first and second position. Likewise, this preferential acyl group cleavage from the *sn*-1 position of phospholipids might be applicable to determine the regiospecificity of phospholipids with distinct ion fragmentation by MS^n experiments and ITMS. The current study successfully characterized the *sn*-position of FA linked to phospholipids derived from erythrocytes. The lipid class separation was carried out by normal-phase HPLC combined with ESI–ITMS on-line coupled with a low-flow-rate reversed-phase (RP)-HPLC within one step (LC/ESI-ITMS).

MATERIALS AND METHODS

Erythrocytes. Fresh venous blood samples from healthy volunteers were collected in heparin-coated tubes. The samples were pooled and centrifuged at $1500 \times g$ for 10 min to separate erythrocytes and plasma.

Total lipid extraction of polar lipids. The erythrocytes were disintegrated according to the method of Rose and Oaklander (21). One volume equivalent of distilled water was added to an aliquot of erythrocytes. After 15 min incubation time, 5.5 vol equiv of isopropanol (–20°C) were added dropwise while stirring. This was followed by the addition of 3.5 vol equiv chloroform, to achieve a water/isopropanol/ $CHCl_3$ ratio of 2:11:7. The solution was centrifuged for 20 min at $2000 \times g$. The supernatant was evaporated with nitrogen to dryness. The lipids were extracted with chloroform/methanol/distilled water (10:10:9, by vol) according to Bligh and Dyer (22).

Separation of phospholipids and fractionation by HPLC. The phospholipid classes were separated by HPLC and fractionated *via* automatic fractionation sampling (23). An aliquot of the lipid extract was dissolved in chloroform/methanol (1:1, vol/vol) at a concentration of 0.5–2.5 mg/mL. The lipid class separation was completed with an HPLC Alliance 2695 Separation module from Waters (Waters GmbH, Eschborn, Germany) coupled with a PL-ELS 1000 evaporative light scattering detection system (Polymer Laboratories, Darmstadt, Germany). The detection was established at 100°C for the nebulizer and 100°C for the evaporator. For the lipid class separation, a polyvinyl alcohol chemically bound stationary phase PVA Sil column (5 µm, 250×4 mm) (YMC Europe, Schermbeck, Germany) was used.

The eluent system corresponded to that of Christie (24): A, *n*-hexane/*tert*-methylbutylether (98:2; vol/vol); B, isopropanol/acetonitrile/chloroform/acetic acid (84:8:8:0.025; by vol); C, isopropanol/water (twice-distilled)/triethylamine (50:50:0.2, by vol). All applied solvents were of HPLC-grade or supra-solvent quality (Merck Eurolab, Darmstadt, Germany). The solvent-gradient system was as follows: 0–1 min A/B/C (%) 98:2:0, 1–5 min A/B/C (%) 80:20:0, 5–20 min A/B/C (%) 42:52:6, 20–27 min A/B/C (%) 32:52:16, 27–30 min A/B/C 30:54:16, 30–33 min A/B/C (%) 30:70:0, 33–40 min A/B/C (%) 98:2:0. The flow rate was 1 mL/min. The distinct lipid classes were characterized by retention time (RT).

The distinct lipid species were collected with an automatic fraction-sampler from Waters by peak signal recognition. The fractions were collected in 5 mL screw-cap-closure glass tubes.

Determination of the sn-position of FA linked to phospholipids by LC/ESI-ITMS. The analysis of the *sn*-position was acquired on the LC MS system LCQ Deca (ThermoFinnigan, San Jose, CA). The distinct phospholipid fractions (10–80 µg/fraction) were separated into the molecular species by RP chromatography using a C18 RP column, Thermo Hypersil C18 200×1 mm (ThermoFinnigan). The eluent system corresponded to the one described by Patton (25): isocratic: 20 mM formic acid in methanol/water/acetonitrile (90.5:7:2.5, by vol) at a flow rate of 80 µL/min. All solvents used were of HPLC grade or supra-solvent quality (Merck Eurolab). The liquid chromatograph was coupled to the mass spectrum spectrometer with an on-line ESI source. The tip voltage was set at 4.5 kV in the positive mode. The capillary voltage was 40 V, the capillary temperature

was held at 200°C. The ion collision energy in the MS^n experiments was adjusted to between 30 and 35%. The mass range was set between 200 and 1200 Da. The total measurement time was 60 min. The following standards were used: 2-oleyl-1-palmitoyl-*sn*-glycero-3-phosphocholine, 1-oleyl-2-palmitoyl-*sn*-glycero-3-phosphocholine, 2-oleyl-1-palmitoyl-*sn*-glycero-3-phosphoethanol-amine (all Sigma-Aldrich Chemie GmbH, Taufkirchen, Germany), and 2-oleyl-1-palmitoyl-*sn*-glycero-3-phosphoserine (Avanti Polar Lipids Inc., Alabaster, AL).

FAME analysis by capillary gas chromatography (CGC). The separated fractions of the HPLC fractionation were evaporated with nitrogen to dryness. For the derivatization, the samples were dissolved in 2 mL methanol/hexane (4:1, vol/vol) plus 0.5% pyrogallol and were methylated according to Lepage and Roy (26) with 200 µL acetylchloride at 100°C, 1 h; 5 mL 6% K_2CO_3 was added, and the resultant mixture was centrifuged for 10 min at $2200 \times g$. The upper hexane phase containing the FAME was removed and dried with Na_2SO_4.

The FAME were analyzed by CGC performed on the Varian Chrompack LS 32 system (Varian Chrompack, Middelburg, The Netherlands) fitted with a cold split/splitless injector to prevent FA discrimination. A chemically bound 50% cyanopropyl-methylpolysiloxane capillary column DB23, 40 m Fisons (Varian Chrompack) was used for the separation of FA species. The chromatographic conditions were as follows: injector (PTV): 65 to 270°C, split ratio 15:1, carrier gas: helium at a 40 cm/s flow rate. The signals were identified by an FID at 280°C. FA were identified according to their RT. The column oven temperatures were as follows: initial temperature: 60°C for 0.1 min; from 60 to 180°C at 40°C/min; 180°C for 2

min; from 180 to 210°C at 2°C/min; 210°C for 3 min; from 210 to 240°C at 3°C/min; 240°C for 10 min.

RESULTS AND DISCUSSION

The membrane lipid composition of blood cells, such as thrombocytes, leucocytes and erythrocytes, is correlated to cell structure, maturation state, function, and activity. Kew *et al.* (27) have suggested that the FA composition of immune cells mainly determines immune response variations. The activation of monocytes and macrophages has been found to correlate with alterations in the composition of membrane phospholipids (28). Besides, volume and reactivity of platelets are influenced by the FA composition of the membrane (29). Within the physiological homeostasis of blood cell membranes, the composition of polar lipids and associated FA reflects the plasma FA composition, which has been shown to be directly influenced by the diet, several diseases, and other environmental FA (9).

In this study, the pooled membrane lipids of erythrocytes derived from healthy volunteers were characterized by HPLC analysis. The erythrocyte membranes predominantly contained Chol, PA, PE, PC, PI, PS, as well as SM. This result essentially corresponds to the current literature. However, no phospholipid lysoforms could be detected, as previously found by Cooper (1) (Fig. 1). The alkylacyl and alkenylacyl species of choline and ethanolamine phosphatides, which have been described to make up a major part of the erythrocyte membrane, were not part of the present study (1). To characterize the FA composition of distinct phospholipid classes, the glycerylphospholipids of the erythrocytes were fractionated. Louis *et al.* (30) have
FIG. 1. HPLC separation and fractionation of membrane lipids from human erythrocytes. For separation, a polyvinylalcohol chemically bonded stationary phase was used. Eluent gradient A, *n*-hexane/*tert*-methylbutylether (vol/vol) 98:2; B, isopropanol/acetonitrile/chloroform/acetic acid (by vol) 84:8:8:0.025; C, isopropanol/distilled water/triethylamine (by vol) 50:50:0.2 at a flow rate of 1 mL/min. The samples were measured by evaporated light scattering detection. Chol, cholesterol; SM, sphingomyelin; TG, triacylglycerol.

[a]The FA composition was measured by FAME capillary gas chromatographic analysis. Data are presented in weight percentage (wt%). The regiospecificity was analyzed by LC–electrospray ionization–MS. SAFA, saturated FA; MUFA, monounsaturated FA.

shown that saturated and monounsaturated FA are predominant (30). In our study, the total FA composition of erythrocyte lipids was dominated by palmitic acid, (16:0) stearic acid (18:0), lignoceric acid (24:0), and oleic acid (18:1n-9). PUFA of the n-6 family, such as linoleic acid (18:2n-6), arachidonic acid (20:4n-6), and adrenic acid (22:4n-6), predominate compared with the content of α-linolenic (18:3n-3), stearidonic (20:4n-3), eicosapentaenoic (20:5n-3), docosapentaenoic (22:5n-3) and docosahexaenoic (22:6n-3) acids of the n-3 family (Table 1). Likewise, a heterogeneous distribution of FA within the distinct lipid classes of erythrocytes could be detected. This study focused on three different membrane phospholipids: (i) PC as the major membrane phospholipid of erythrocytes, which roughly reflects the total FA pattern of erythrocyte lipids; and (ii) PE and (iii) PS, which are considerably different from PC. The analysis revealed that palmitic and oleic acids are mainly linked to PC and PE, which is in accordance with the current literature (1). Whereas PS is rich in lignoceric and nervonic (24:1n-9) acids, erucic acid (22:1n-9) is highly associated with PE. In comparison, PUFA were predominantly associated with PC, whereas saturated FA were mainly associated with PS.

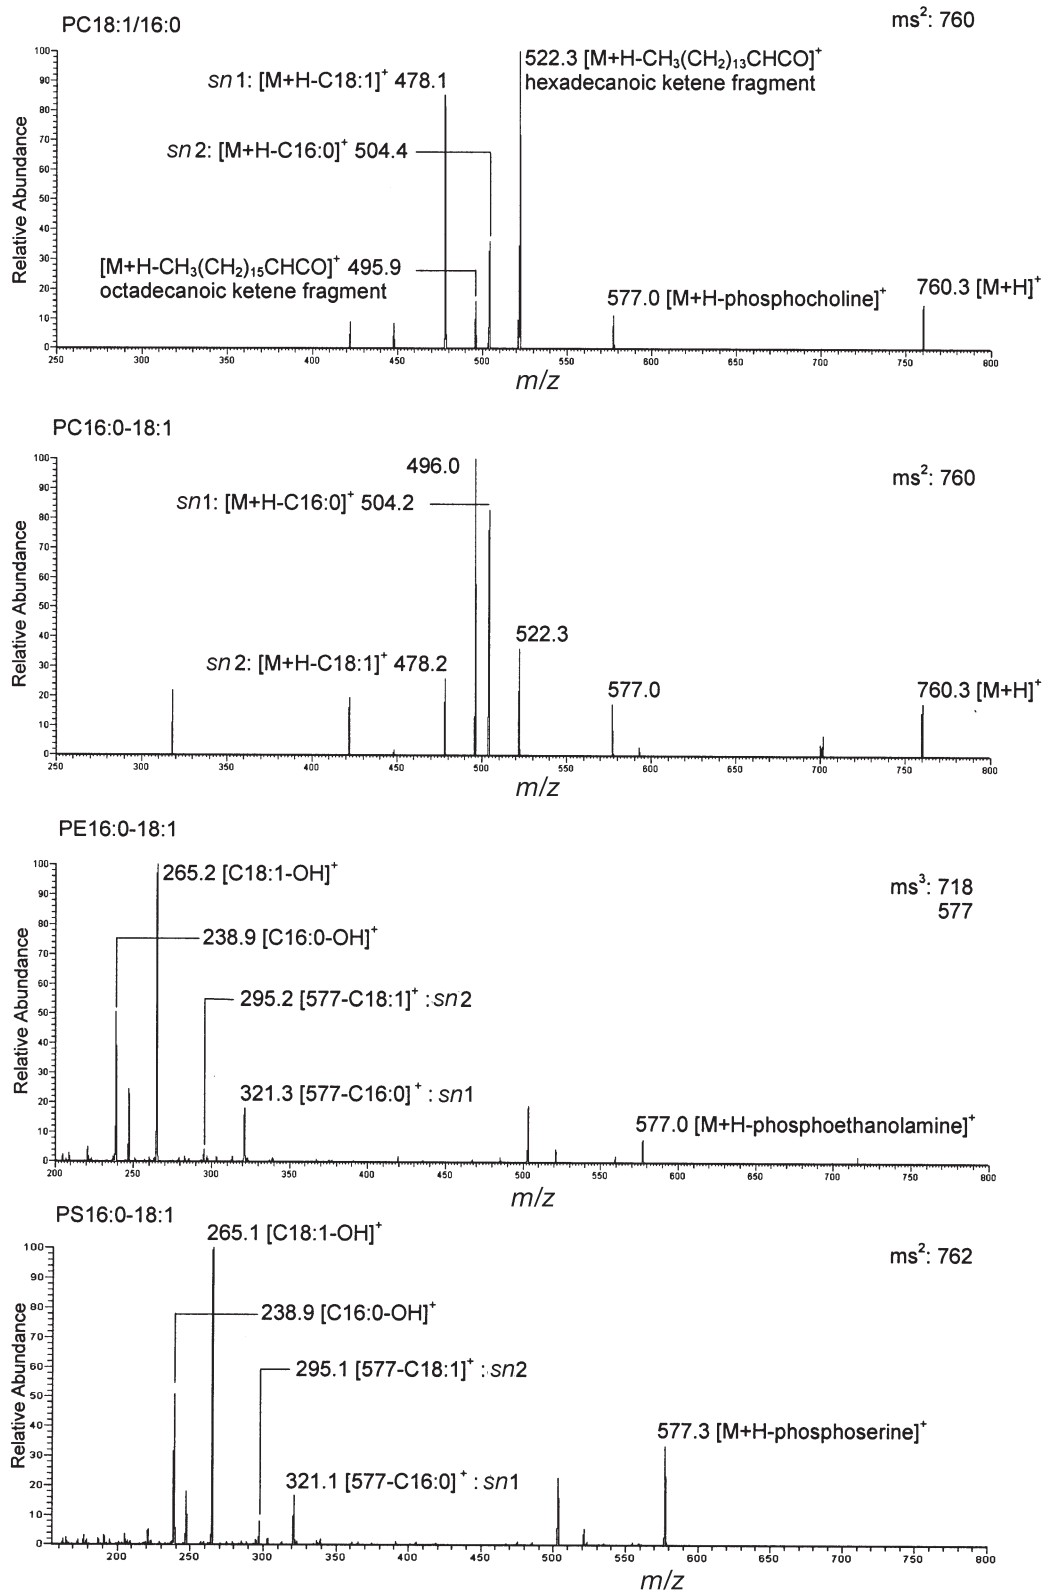
In the next step, the sn-positions of FA linked to glycerol were determined by MS[n] experiments. The location of double bonds of associated FA is not detectable via LC/ITMS. Therefore, the n-3, n-6, and n-9 families were concluded from the CGC analysis of the respective FA. To prove whether it is possible to differentiate the identity and sn-position of acyl substituents of asymmetrical phospholipids with ESI-ITMS, two PC standards with an identical but asymmetrical FA composition were measured (Fig. 2). The asymmetrical oleyl-palmitoyl-phosphocholine standards revealed the same mass per charge (m/z) value of 760. The MS–MS experiments of 760 Da indicated that both standards were fragmented into the same pattern: (m/z) values 577, 522, 504, 478, and 495. The ratio between the 504 Da (M – palmitic acid) and 478 Da (M – oleic acid) fragments could be used to distinguish between the first and second position. As the sn-1 position is preferentially cleaved from the glycerol backbone, the minor ion signal indicated the sn-2 position, whereas the dominating ion signal indicated the sn-1 position in a ratio of 2:1. As already described by Hsu and Turk (31), the cleavage of the ester linkage between FA and glycerol leads to the formation of the acid ion (RCOOH[+]) and the ketene ion (RCHCO[+]), which could be identified additionally (Fig. 2).


FIG. 2. Determination of the sn-position of asymmetrical PC, PE, and PS standards by electrospray ionization sequenced MS (ESI-MS^n). Mass spectra were acquired on an MS system with an on-line ESI source. The tip voltage was set at 4.5 kV in the positive mode. The ion collision energy in the MS^n experiments was adjusted between 30 and 35%. The data are presented as mass per charge (*m/z*).

In contrast to PC, the polar group of PE did influence the MS–MS fragmentation pattern, possibly owing to electron shifts induced by the amino group *via* communicating covalent bindings. Thus, no valid ratio between the ion signals indicating the *sn*-positions could be established. However, the functional head group disappeared from the 2-oleyl-1-palmitoyl-PE within the MS^3 experiment, based on the 718 Da ion signal. As a result, the 577 Da (M – phosphoethanolamine) fragment ion enabled the determination of the *sn*-positions. Again, the ratio of 2:1 between 321.3 Da (M – palmitic acid) for the *sn*-1 position and 295.2 Da (M – oleic acid) for the *sn*-2 position was demonstrated. The 238 (palmitic acid + OH) and 265 Da (olecic acid – OH) ions indicated the cleaved FA. The polar head group of the PS-standard 2-oleyl-1-palmitoyl-PS did not affect the fragmentation pattern within the MS–MS experiment. The parent ion of 762 Da disintegrated into 577 Da (M – phosphoserine), 321 Da (M – palmitic acid), and 295 Da (M – oleic acid) ions. With the ratio of 2:1 between the 321 Da fragment for the *sn*-1 position and the 295 Da fragment for the *sn*-2 position, it was possible to distinguish between the *sn*-positions. Likewise, the 238 Da fragment (palmitic acid – OH) and the 265 Da fragment (oleic acid – OH) indicated the cleaved FA.

Although various studies such as that by Han (32) described triple quadrupole applications with direct infusion into the ESI source, the distinct phospholipid classes of the native erythrocyte matrix used in this study resulted in inadequate ionization patterns. These patterns are insufficient for MS^n measurement with ITMS if the sample is directly applied with a syringe pump. This might be due to an ion overload of the ion trap that competes with the analyte ion signal and therefore impairs adequate signal recognition with this technique. Thus, the *sn*-position of FA associated with PC, PE, and PS was analyzed by coupling the MS measurement with RP LC to separate the different molecular phospholipid species. The total ion chromatogram (TIC) was scanned manually or automatically (triple play modus) within a mass range of 700–1500 Da, to select specific ion signals. After that, sequenced MS^n experiments based on the selected ions were established to identify molecular species and the position of the acyl substituents (Fig. 3).

The TIC of the PC fraction revealed five different and two asymmetrical molecular species with RT of 31.1–32.8, 32.9–39.0, 39.1–43.1, 49.1–55.1, and 55.2–60 min, which is illustrated by the selected ion chromatogram (SIC) of 758, 760, 782, 784, and 786 Da (Fig. 3). For instance, the MS–MS experiment with the 784 Da parent ion indicated a ratio of 1:1 between the 478.3 Da (M – eicosatrienoic acid) and 528 Da (M – palmitic acid) fragments. Asymmetrical FA distribution between the *sn*-1 and *sn*-2 position explains this ratio. Again, (+18 Da) fragments accompanied the signals that declared the respective *sn*-position. In contrast to the fragmentation pattern of the PC-standard (Fig. 2), a fragment ion of 725 Da (M – 59 Da) arose from native PC, which indicates the loss of the choline-fragment $[M + H – N(CH_3)_3]^+$. This different fragmentation pattern might be due to the associated FA, which differ in length and degree of saturation. The MS–MS experiments of the PC fractions derived from erythrocytes confirm that the

linkage energy of acyl substituents and the glycerol backbone is associated with the molecular structure of FA. The higher the degree of unsaturation of FA, the more energy is needed for MS^n fragmentation. Analyses of neutral lipids with FAB/MS and ESI/MS of the triple quadrupole type have demonstrated that the specific loss of FA is reduced when the chain length and number of double bonds increase (15,33). However, in this study the *sn*-position of FA was measurable in a range of length and degree of saturation between 16:0 and 20:4, which might be due to the polarity of phospholipids and the ion trap detection. In general, the FA distribution of PC showed mainly palmitic acid in the *sn*-2 position, and oleic, linoleic, and arachidonic acids exclusively in the *sn*-2 position. Eicosadienoic and eicosatrienoic acids were an exception, because they were associated with both positions (Table 1). This distribution seems to correspond to the physiological demands. For instance, palmitic acid as a structural membrane element is located in the *sn*-1 position, whereas arachidonic acid, which as a substrate for PLA-2 is necessary for the eicosanoid metabolic pathway (9), is located in the *sn*-2 position.

Likewise, palmitic acid of PE and PS was predominantly linked to the *sn*-1 position, whereas oleic, linoleic, and octadecatrienoic (18:3) acids were linked to both positions. Lignoceric acid of PS was strictly located in the *sn*-2 position, but nervonic acid was associated with both positions.

Although ESI-coupled RP-HPLC is always a compromise with regard to chromatographic and ionization requirements, the separation of the fractionated lipid classes is sufficient to produce distinct molecular species for subsequent MS^n experiments. The distribution of the *sn*-position of FA associated with PC and PS was directly measurable in the positive mode as well as in the negative mode (data not shown) *via* MS–MS. However, the determination of the *sn*-position of FA associated with PE required MS^3. Although 10–80 μg of the phospholipid fraction was applied onto the RP-HPLC column, minor molecular species of the membrane lipid spectrum with FA of up to 8 wt% were not detectable, owing to limited signal intensities of TIC and SIC. With regard to necessary amounts of sample and the corresponding measurement intensity, the LC/ESI-ITMS analysis of the *sn*-position is not comparable to the enzyme/CGC analysis, but is a reproducible method for routine determination of the *sn*-position of physiologically relevant, nonmodified phospholipid species. Apart from the aperture of the spraying needle and the applied voltage, the ionization by ESI depends on the spray and droplet size (34). Micro- or nano ESI techniques using low liquid flow rates to produce an accurate spray with a small droplet shape have been described and offer feasible possibilities to ionize polar lipids effectively (35,36). Therefore, the next steps to improve analytical sensitivity of this chromatography–MS application should be a down-scale to micro- or nano ESI with flow rates between 2 and 20 μL/min.

These results demonstrate that ESI-ITMS is a strategy that can be used for the direct structural determination of phospholipids derived from native matrices. A detailed analysis of the blood cell membrane lipids using LC coupled with ITMS
FIG. 3. Determination of the sn-position of PC from human erythrocytes by RP-HPLC coupled with ESI-MS[n]. For the LC, a stationary C18 reversed-phase column was used. Isocratic eluent: 20 mM formic acid in methanol/water/acetonitrile 90.5:7:2.5 (by vol) at a flow rate of 80 µL/min. The separation of phospholipid species is presented as a total ion chromatogram (TIC) and a selected ion chromatogram (SIC). The mass spectra were acquired on an MS system with an on-line ESI source. The tip voltage was set at 4.5 kV in the positive mode. The capillary voltage was 40 V, the capillary temperature was held at 200°C. The ion collision energy in the MS[n] experiments was adjusted to between 30 and 35%. The data are presented as m/z. For other abbreviations, see Figure 2.

Astonishing Diversity of Natural Surfactants: 2. Polyether Glycosidic Ionophores and Macrocyclic Glycosides

Valery M. Dembitsky*

Department of Organic Chemistry and School of Pharmacy, Hebrew University, Jerusalem, Israel

ABSTRACT: Polyether glycosidic ionophores and macrocyclic glycosides are of great interest, especially for the medicinal and pharmaceutical industries. These biologically active natural surfactants are good prospects for the future chemical preparation of compounds useful as antibiotics, anticancer agents, or in industry. More than 300 interesting and unusual natural surfactants are described in this review article, including their chemical structures and biological activities.

Paper no. L9676 in *Lipids 40,* 219–248 (March 2005).

The diversity of natural surfactants and their biomedical activity has recently been partly reviewed in some articles (1–6) and books (7–10). Polyether glycosidic ionophores and macrocyclic glycosides are a large group of structurally related polyketide natural surfactants (2,11–13). The polyether glycosidic ionophores are characterized by multiple tetrahydrofuran and tetrahydropyrane (or more) rings connected by aliphatic bridges, direct C–C linkage, or spiro-linkages, and they also contain one or more sugar moieties. Other features include a free carboxyl function, many lower alkyl groups, and a variety of functional oxygen groups. These structural features enable the molecule to form a cyclic conformation with the oxygen functions at the center and the alkyl groups on the outer surface. Accordingly, this conformation results in lipid solubility, even for the salt forms, enabling transport of cations across lipid membranes (14–16). The term ionophore was first used by Pressman *et al.* to describe compounds that can transport ions across artificial or natural membranes (17). The polyethers

Abbreviations: EC_{50}, the median effect concentration, being a statistically-derived concentration of a substance that can be expected to cause (i) an adverse reaction in 50% of organisms or (ii) a 50% reduction in growth or in the growth rate of organisms; ED_{50} (effective dose$_{50}$), the amount of material required to produce a specified effect in 50% of an animal population; GI, growth inhibition; GI_{50}, the concentration needed to reduce the growth of treated cells to half that of untreated (i.e., control) cells; HSV-1, herpes simplex virus type 1; IC, inhibitory concentration; IC_{50}, concentration at which growth or activity is inhibited by 50% (applies to ligand and growth inhibition); %ILS, percent increase in life span; LC_{50} for drugs with a cytotoxic effect, the concentration of drug at which 50% of cells die (a 50% reduction in the measured protein at the end of the drug treatment as compared with that at the beginning); LD_{50}, (lethal dose$_{50}$), the dose of a chemical that kills 50% of a sample population; log IC (log EC), IC (or EC) in a log 10 scale (a log 10 scale is frequently used when *x* values are a serial dilution, as a better estimate of the SE is obtained); log GI_{50}, log concentrations that reduced cell growth to 50% of the level at the start of the experiment; $log_{10} RC_{50}$, root elongation half inhibition concentration (mol/L) in logarithmic form; LD, lethal dose; LD_{50}, the dose at which 50% of test subjects die; LPS, lipopolysaccharide; MIC, minimal inhibitory concentration; RC_{50}, concentration at which there is a 50% reduction in the number of offspring as compared with controls; TRAP, tartrate-resistant acid phosphatase; VZV, varicella-zoster virus.

are sometimes referred to as carboxylic acid ionophores to distinguish some antibiotics from other compounds showing ionophoretic activity (18,19). Individual polyether ionophores exhibit varying specificities for cations (20,21).

Many macrolide glycosides are well-established antimicrobial agents in both clinical and veterinary medicine (22–25). These agents can be administered orally and are generally used to treat infections in the respiratory tract, skin and soft tissues, and genital tract caused by Gram-positive organisms, such as *Mycoplasma* species, and by certain susceptible Gram-negative and anaerobic bacteria (26–28).

The macrolide class is large and structurally diverse (2,12,29–31). Macrolides are produced by the fermentation of microorganisms and/or are found in marine invertebrates, such as sponges, bryozoa, or marine cyanobacteria, and in dinoflagellate species belonging to the genera *Amphidinium*, *Gambierdiscus*, *Prymnesium,* and *Protoceratium* (32–34). Additionally, structural modifications using both chemical and microbiological means have yielded biologically active semisynthetic derivatives. The term macrolide was introduced in 1957 by Woodward (35) to denote the class of substances produced by *Streptomyces* species containing a macrocyclic lactone ring. The generalized structure is a highly substituted monocyclic lactone (aglycone) to which is attached one or more saccharides glycosidically linked to hydroxyl groups on either the aglycone or another saccharide (12,30). The aglycones are derived *via* similar polyketide biosynthetic pathways and thus share many structural features in terms of pattern and stereochemistry of substituents (36, and references cited). Traditional macrolide antibiotics are divided into three families according to the size of the aglycone, which can be 12-, 14-, or 16-membered, but more recently macrolides with 30–72-membered macrolactone glycosides have been isolated (2,12,29–31). Because one or more amino sugars are usually present, these compounds are basic and can form acid addition salts. In addition, one or more neutral sugars are often present. The saccharides share some common features: They tend to be highly deoxygenated and N- and/or O-methylated, and the amino groups are located at either position 3 or 4. The most common macrocyclic glycosides are given below.

POLYETHER GLYCOSIDIC IONOPHORES

Ionophores are used as food antibiotics throughout the world in the beef and poultry industries. The efficiency of cattle production is increased by altering rumen fermentation and controlling the protozoa that cause coccidiosis. Ionophores act by

interrupting the transmembrane movement and intracellular equilibrium of ions in certain classes of bacteria and protozoa that inhabit the gastrointestinal tract. The actions of ionophores provide a competitive advantage for certain microbes at the expense of others (37).

More than 100 polyether ionophores have been discovered from microorganisms, marine invertebrates, and algal species, and only some compounds contain sugar(s) (38–42).

SIMPLE GLYCOSIDIC POLYETHERS

Some simple glycosidic ionophores were isolated nearly 30 years ago from fungi belonging to the order Hyphomycetes. In 1977, Traxler and coworkers (43–45) reported the isolation and characterization of a family of novel antifungal antibiotics, named papulacandins A, B, C, D **1–3**, and **6a**, from *Papularia sphaerosperma*, with *in vitro* activity against *Candida albicans* and other yeasts. In general these compounds showed acceptable inhibition of β-1,3-glucan synthase and whole-cell activity, although little or no efficacy in animal models was found (46–48). Papulacandins A, B, and C contain a spirocyclic diglycoside and two unsaturated FA, linked as esters to two hydroxyl groups of the diglycosides. Papulacandin D, a monosaccharide relative, is the simplest member of the family (44,45,48). The common opportunistic infection in AIDS patients, *Pneumocystis carinii* pneumonia, has been effectively overcome by newer members of the papulacandin family, Mer-WF3010 **4** and L-687-781 **5** (49–51). Papulacandin D, which lacks the short FA and the galactose residue, exhibits antifungal activity; hence, less complex molecules may result in enhanced biological activity or provide a better understanding of the elements required for activity. Saricandin **6** has been isolated from the pathogenic fungus *Fusarium* sp. (52).

dinoflagellates belonging to the genus *Amphidinium* (53–55). Colopsinol A **7**, a novel polyhydroxyl compound, has been isolated from the cultured marine dinoflagellate *Amphidinium* sp. (strain number Y-5). Colopsinol A **7** is the first member of a new class of polyketide natural products possessing a gentiobioside moiety and a sulfate ester. The polyketide aglycone consisted of a C_{56}-linear aliphatic chain with one exo-methylene and two methyl branches as well as two ketones, five hydroxyl groups, and a tetrahydropyran and two epoxide rings (53). Colopsinol A **7** inhibited DNA polymerases α and β, and colopsinol C **10** exhibited cytotoxicity (53,54). Colopsinol E **8** exhibited cytotoxicity against L1210 murine leukemia cells [IC_{50} value (concentration at which growth or activity is inhibited by 50%) = 7 μg/mL], whereas colopsinol D **11** showed less cytotoxicity (IC_{50}, 20 μg/mL) (55,56).

Simple glycosidic ionophores, colopsinols A–E **7–11**, have also recently been discovered from different strains of marine
LIPOPHILIC POLYETHER GLYCOSIDES

Streptomycetes produce a wide variety of commercially important polyketide compounds, including the well-known macrolide, polyene, and polyether antibiotics that exhibit antibacterial, antifungal, anthelminthic, antitumor, and immuno-

suppressive activities. Biosynthesis of these antibiotics is catalyzed by a large family of polyketide synthases using malonyl-CoA, methylmalonyl-CoA, and ethylmalonyl-CoA as extender units for building the polyketide backbone (57–60).

Maduramicin **12**, known as antibiotic X-14868A, a novel ionophore that contains an unusual dimethoxy sugar, has been isolated from *Actinomadura yumaensis*, and its biosynthesis was reported (11,41,61,62). The biosynthesis of α- and β-maduramicin in a culture has been studied using ^{13}C-, ^{14}C-, and ^{18}O-labeled precursors. The results are consistent with the initial formation of a triene, which is converted to maduramicin by cyclization of the triepoxide.

Lenoremycin **13** and the closely related metabolites dianemycin, leuseramycin, and moyukamycin are pentacyclic ethers containing a second tetrahydropyran–tetrahydrofuran spiroketal in place of the more commonly occurring pair of tetrahydrofuran rings typical of monensin, and are produced by *Streptomyces hygroscopicus* X-14540 (63). Biosynthesis of lenoremycin was reported by Cane and Hubbard (64).

Carriomycin **14**, a polyether antibiotic, was isolated from culture broth of *S. hygroscopicus* strain T-42082. It is active against Gram-positive bacteria, several fungi, yeasts, and mycoplasma, and it is also coccidiostatic (65). Carriomycin, lonomycin, and etheromycin efficiently transported K$^+$, Rb$^+$, and Na$^+$ through a CCl$_4$ barrier. These antibiotics caused a massive release of K$^+$, Rb$^+$, or Na$^+$, but not of Li$^+$ and Cs$^+$, from mitochondria previously loaded with these cations by valinomycin or monazomycin. Carriomycin is a monovalent cation-selective ionophore (66), as are lonomycin and etheromycin.

K-41 **15**, known as A32887 and antibiotic RP37454, is produced by *S. hygroscopicus* (67). This antibiotic was characterized as a polycyclic polyether compound and was active against Gram-positive bacteria. K-41A **16** and two other new pentacyclic polyethers are produced by a marine bacterium belonging to the order Actinomycetales (68).
Two antibiotics, SF2324 **17** and SF2370, produced by *Actinomadura roseorura* (69,70), and an unusual ionophore, LL-C23201γ **18**, were isolated after fermentation from *Streptomyces olivaceo-griseus* sp. nov. (71). Both antibiotics showed antibacterial and anticoccidial activities. The natural antibiotic A80789 **19**, which is used in cattle feeds and is related to lonomycin A, was isolated from *S. hygroscopicus* (72). A new polyether antibiotic, CP-82009 **20**, closely related to septamycin **21**, was isolated by solvent extraction from the fermentation broth of *Actinomadura* sp. (ATCC 53676). CP-82009 is among the most potent anticoccidial agents known, effectively controlling the *Eimeria* species that are the major causative agents of chicken coccidiosis at doses of 5 mg/kg or less in feed. It is also active *in vitro* against certain Gram-positive bacteria, as well as the spirochete *Serpulina (Treponema) hyodysenteriae* (73).
Unusual and rare polyethers with spiroketal moieties, everninomicins B, C, and D **22–24**, are a new class of oligosaccharide antibiotics (74–78) produced by *Micromonospora carbonacea* that possess highly potent activity against Gram-positive bacteria. More important, everninomicins demonstrate antibacterial activity both *in vitro* and *in vivo* against multiply resistant strains of methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant enterococci (79,80). The major component, Ziracin (SCH 27899) **25**, demonstrated potent activity against Gram-positive bacteria both *in vitro* and *in vivo* including multiply resistant strains of methicillin-resistant *S. aureus* and vancomycin-resistant *Enterococcus faecalis*. A new member of the everninomicin family of compounds, Sch 58761 **26**, was isolated from the fermentation broth of *M. carbonaceae* (81).
A novel everninomicin, Sch 49088 **27**, containing an unusual hydroxylamino-ether sugar with activity against methicillin-resistant *Staphylococci*, also has been isolated from *M. carbonacea* (82). A new oligosaccharide antibiotic, everninomicin-6 (EV-6) **28**, resembled everninomicin D quite closely except for the absence of the nitrosugar and the replacement on ring G of the CH_2OMe group with a CH_2OH group; it was isolated from *M. carbonacea* (83).
Four polyether antibiotics, **29**–**32**, isolated from a hitherto undescribed *Nocardia* culture (strain X-14868), were reported by Hoffman-La Roche in 1983 (84,85). Biological profiling revealed that all four compounds are moderately active against Gram-positive bacteria. Polyether **29** is active against *Serpulina hyodysenteriae*, and both **29** and **30** are potent anticoccidial agents *in vivo* vs. *Eimeria tenella*. CP-60993 **33**, having a

moderate activity against Gram-positive bacteria, was isolated in 1990 from the fermentation broth of a culture of *S. hygroscopicus* ATCC 39305 (86,87). Endusamycin **34** (known as CP-63517) was first identified from a new strain of *Streptomyces endus* subsp. *aureus* ATCC 39574 (88). Endusamycin **34** demonstrates an excellent spectrum of Gram-positive antibacterial and anticoccidial activities, both *in vitro* and *in vivo*. CP-80219 **35** demonstrated good activity against Gram-positive bacteria, as well as antiserpulina activity vs. *S. hyodysenteriae* (89).
Screening the extract from *S. hygroscopicus* TM-581 has led to the discovery of the dianemycin **36** analog moyukamycin (90). Originally isolated from a culture of *Streptomyces* sp. X-14931, this ionophore demonstrated *in vitro* activity against Gram-positive microorganisms such as cocci, bacilli, mycobacteria, molds, and yeasts. It also showed activity against a mixed *Eimeria* infection (91). Isodianemycin **37** has demonstrated antibacterial properties comparable to the original antibiotic dianemycin (92).

Maduramycin **38** and the 12-methylportmicin ionophore CP-84657 **39** both have been isolated from a fermentation broth of *Actinomadura* sp. ATCC 53708. One similar to ionophore **39** was isolated from *A. fibrosa* and named A82810 (93). Polyether **39** is among the most potent anticoccidial agents known, effectively controlling the major *Eimeria* species (*E. tenella, E. acervulina, E. maxima*, and *E. necatrix*) responsible for avian coccidiosis at doses of 5 mg/kg or less in feed. This compound is also active against certain Gram-positive bacteria *in vitro* as well as the spirochete *S. hyodysenteriae*, the causative agent in swine dysentery (94,95). The ionophores W341C **40** and CP-120509 **41** (96) were produced by *Streptomyces* W341 (57).
Antibiotic 6016 **42**, produced by the fermentation of *Streptomyces albus* 6016, was isolated as its sodium salt (97). Fermentation of *Actinomadura roseorufa* Huang sp. nov. ATCC 39697 produces UK-58852 **43** together with minor amounts of CP-70228 **44** and CP-70828 **45** (98,99). Treatment of **43** with *para*-toluenesulfonic acid in acetonitrile/water yielded a mixture of two compounds, including semduramicin **46**. This compound, also known as UK-61689, was obtained by fermentation of a mutant of the *A. roseorufa* and shows activity against both *E. tenella* and *E. maxima* (100). CP-91243 **47** and CP-91244 **48**, along with **45**, were isolated from a mutant of *A. roseorufa* ATCC 53666 (101).

HIGHLY OXYGENATED LIPOPHILIC TOXINS

New antitumor compounds named protoceratins I (without sugar), II **53**, III **52**, and IV **54** have recently been isolated from culture broths of the dinoflagellate *Protoceratium* cf. *reticulatum* (107). Isolated compounds showed extremely potent cytotoxicity against human tumor cell lines. The major principle, protoceratin I, proved to be identical with 2-homoyessotoxin, a well-known shellfish toxin. Protoceratins II **53**, III **52**, and IV **54** were determined to be di-, mono-, and triarabinosides of protoceratin I (without sugar), respectively.

Etheromycin **49**, produced by *Streptomyces* C20-12 FERM P-2736 and *S. hygroscopicus* ATCC 31050 (57,102), and the new 3-*O*-methylseptamycin **50** (analog of **21**) have recently been discovered by Mülhaupt (103). Polyether ionophore **51**, named nanchangmycin, was discovered by Chinese scientists (104–106); it was produced by *Streptomyces nanchangensis* (NS3226), and showed insecticidal activities.

Prymnesium parvum (Division Haptophyta, Class Prymnesiophyceae, Family Haptophyceae) is a unicellular red tide microalga that blooms in marine and brackish water and causes massive fish kills worldwide (108,109). Ichthyotoxins with very surprising structures, prymnesin-1 **55** and prymnesin-2 **56**, have been isolated from *P. parvum* (110,111). The prymnesins are highly oxygenated lipophilic toxins reminiscent of dinoflagellate toxins such as ciguatoxin, brevetoxin, maitotoxin, and palytoxin. The C_{90} carbon (!) skeleton has no carbon

branching except for one methyl group. Five contiguous ether rings resemble those of the dinoflagellate toxins. Prymnesins **55** and **56** contain multiple functional groups such as conjugated double and triple bonds, chlorine atoms, an amino group, and glycosidic residues, including the uncommon L-xylose. They are the major hemolytic and ichthyotoxic agents in the red tide microalga *P. parvum* (112), with **56** causing 50% hemolysis of a 1% suspension of canine red blood cells at 0.5 nM. The lethality of **56** on the freshwater fish *Tanichthys albonubes* was comparable to that of brevetoxin; the ichthyotoxicity was markedly enhanced by Ca^{2+} and by a slight elevation of pH. The LC_{50} (concentration of drug at which 50% of cells die) in a Ca^{2+}-free medium (pH 7.0) was 300 nM, and in the presence of 2 mM Ca^{2+} (pH 8.0) it was 3 nM (112).
MACROCYCLIC GLYCOSIDES

Many FA glucosides in lactone form, named macrolides (or macrocyclic glycosides), have been isolated from bacteria, lower invertebrates, and/or fungi (2,3,5,9,12,13,18,26,29, 30,32,34,113,114). Some macrocyclic glycosides were found in plants (115). At present, more than 100 microbial products continue to be used clinically as antibiotics, antitumor agents, and agrichemicals (3,30,32). The importance of these compounds in medicine has served to underscore their importance in pharmacology, chemistry, and industry. Throughout the years, extensive chemical programs have been developed worldwide to synthesize these compounds and to understand the structural foundations for their bioactivity. Still today, massive efforts are underway in the pharmaceutical industry to explore soil bacterial fermentation products. These studies continue to show exciting results. Examples of such polyketides include erythromycin (antibacterial), nystatin (antifungal), avermectin (antiparasitic), rapamycin (immunosuppressant), daunorubicin (antitumor), and many others (12,13,29,113,114).

SIMPLE DIARYLHEPTANOID GLYCOSIDES

Diarylheptanoids are a family of natural plant metabolites whose characteristic structural feature is the presence of two hydroxylated aromatic rings tethered by a linear seven-carbon chain. They can be further divided into three subgroups, namely, linear and biaryl macrocycles (**57–61**) and *m,p*-cyclophane (**62–68**) (115). Evidence has accumulated suggesting that the linear diarylheptanoids are the biogenetic precursors of the macrocyclic congeners **57–61** and **62–68** (116–118).

Many new simple diarylheptanoids and their glycosides, named acerogenin and aceroside, were isolated from the stem bark of *Acer nikoense, A. griseum*, and *A. triflorum* (119). Three new cyclic diarylheptanoids, acerosides B1 **57** and B2 **58** and aceroketoside **59**, were isolated together with 20 known compounds from a Japanese folk medicine, the stem bark of *A. nikoense*. The principal diarylheptanoid constituents were found to exhibit inhibitory activity on nitric oxide (NO) production in lipopolysaccharide-activated macrophages (120). The stem bark of the Aceraceae plant *A. nikoense*, which is indigenous to Japan, has been used as a folk medicine for hepatic disorders and eye diseases. It has been reported that the biphenyl-type diarylheptanoids from *Myrica rubra* showed inhibitory activities on the release of β-hexosaminidase from RBL-2H3 cells (121) and on NO production in lipopolysaccharide (LPS)-activated macrophages (122). Macrocyclic diaryl ether heptanoids as ovalifoliolatins A and B from the Indian tree *Boswellia ovalifoliolata* also showed antibacterial activity against the Gram-negative bacteria *Chromobacterium violaceum* (ATCC #12472), *Klebsiella aerogenes* (ATCC #15380), *Pseudomonas aeroginosa* (ATCC #25619), and *Pseudomonas fluorescens* (ATCC #13525) and against the Gram-positive bacteria *S. aureus* (ATCC #9144), *Bacillus subtilis* (ATCC #6051), and *Bacillus sphaericus* (ATCC #14577) (123). Aceroside I **60** and IV **61** were isolated from *A. nikoense* (119).
Myricanols **62**, **65**, and **66**; myricanone **63**; neomyricanone **64**; myricanene A **67** and B **68**; and their five new glycosides were isolated from the stem bark of Chinese *M. rubra*, and myricanone and galeon from the stem of *Myrica gale* var. *tomentosa* (121). The Myricaceae plant *M. rubra* is widely distributed in China, Taiwan, Japan, and Korea. The bark of *M. rubra* (Myricae cortex) has been used locally as an astringent, antidote, and antidiarrheic in Japanese folk medicine and also has been used externally for burns and skin diseases in Chinese traditional medicine. Biphenyl-type diarylheptanoids showed inhibitory activities on the release of β-hexosaminidase from RBL-2H3 cells and on NO production in LPS-activated macrophages (121).

67 Myricanene A

68 Myricanene B
DIMERIC MACROCYCLIC GLYCOSIDES

Dimeric macrolide glycosides are a rare group of biologically active compounds produced by some microorganisms and marine sponges (2). The elaiophylin **69** and two new methyl derivatives **70** and **71** were isolated from the mycelium cake of *Streptomyces* strains HKI-0113 and HKI-0114. Elaiophylin **69**, with C-2 symmetry was originally isolated from *Streptomyces melanosporus* (124), later as azalomycin B from *S. hygroscopicus* var. *azalomyceticus* (125) and also from *Streptomyces violaceoniger* (Tu 905) (126). It is now available in large quantities by fermentation of other naturally high-producing *Streptomyces* spp., for example, strains DSM-4137 and DSM-3816. Elaiophylin **69** is known to be active as an antibacterial and antihelminthic; to have antitumor and immunosuppressant properties; and to inhibit NO synthesis (127, and references cited).

Halichoblelide **72**, a novel macrolide with potent cytotoxicity against tumor cells in culture, has been isolated from a strain of *S. hygroscopicus* originally separated from the marine fish *Halichoeres bleekeri* (128). Halichoblelide exhibited potent cytotoxic activity against the murine P388 cell line [ED$_{50}$ (effective dose$_{50}$, the amount of material required to produce a specified effect in 50% of an animal population) 0.63 µg] and 39 human cancer cell lines (BSY-1, NCI-H522, MKN74, and others). The tested mean value of log GI$_{50}$ (log concentrations that reduced cell growth to 50% of the level at the start of the experiment) over all cell lines appeared to be −5.25.
Clavosolides A–D **73**–**76**, dimeric macrolides incorporating cyclopropyl, tetrahydropyranyl, and glycosidic ring systems, were isolated from the cytotoxic extract of a Philippines collection of the marine sponge *Myriastra clavosa* (129). Clavosolides A **73** and B **74** also were recently reported metabolites from *M. clavosa* (130). The dimeric monoterpenoid glycoside **77** was isolated from the aqueous ethanol extract of the whole plants of *Dicliptera riparia* (131). The dimeric secoiridoid glycoside lisianthoside **78** was isolated from plant *Lisianthius jefensis* (Gentianaceae) (132).

73 Clavosolide A, R = R₁ = R₂ = Me
74 Clavosolide B, R = R₁ = Me, R₂ = H
75 Clavosolide C, R = R₂ = Me, R₁ = H
76 Clavosolide D, R = H, R₁ = R₂ = Me

77 Dicliripariside A

78 Lisianthoside
Pakistolides A **79** and B **80**, novel dimeric β-(glucosyloxy)benzoates were isolated from the Pakistani tree *Berchemia pakistanica* belonging to the genus *Berchemia* (Rhamnaceae), which comprises *ca.* 10 species scattered throughout the tropics of Asia, Africa, and America (133). The roots and stems of *Berchemia* species are traditionally used for the treatment of gallstones, liver diseases, neuralgia, and stomach cramps in Japan, and also are used in traditional Chinese medicine as an antipyretic, a diuretic, and for the treatment of rheumatism and lumbago (134). Both **79** and **80** showed high lipoxygenase inhibition activity and promising potential to inhibit lipoxygenase *in vivo*. They also were found to have inhibitory activity against β-glucosidase (133).

70 R = H, R₁ = Me
71 R = R₁ = Me

72 Halichoblelide

79 Pakistolide A

80 Pakistolide B
More than 160 macrocyclic hydrolyzable tannins were hitherto known (135,136), along with oenotheins, cuphiins, eugeniflorins, camellins, and woodfordins, which have been isolated from the genera *Oenothera* (137), *Cuphea* (138), *Eugenia* (139), *Gordonia* (140), and *Woodfordia* (141). Structures of these dimeric compounds are similar to **81**–**84**, and they constitute an important class of oligomers with unique macrocyclic

structures. Many of these compounds showed antitumor activity, inhibition of DNA topoisomerase II, and induced apoptosis in K562 cells (136). The antitumor activities of four macrocyclic hydrolyzable tannin dimers, cuphiin D1 **81**, cuphiin D2 **82**, woodfordin C **83**, and oenothein B **84**, isolated from *Cuphea hyssopifolia* (Lythraceae), were studied (142). All compounds significantly inhibited the growth of the human carcinoma cell lines KB, HeLa, DU-145, and Hep 3B and the leukemia cell line HL-60, and they showed less cytotoxicity than adriamycin against a normal cell line (WISH). All four compounds inhibited the viability of S-180 tumor cells in an *in vitro* assay and an *in vivo* S-180 tumor-bearing ICR mouse model. Oenothein B **83** demonstrated the greatest cytotoxicity (IC_{50} = 11.4 µg/mL) against S-180 tumor cells in culture, whereas cuphiin D1 **81** resulted in the greatest increase in survival of S-180 tumor-bearing mice [ILS (increase in life span) = 84.1%]. These findings suggest not only that the antitumor effects of these compounds are related to their cytotoxicity on carcinoma cell lines but also that they depended on a host-mediated mechanism; they may therefore have potential for antitumor applications (142). Cuphiin D1 **81** induced cytotoxicity in HL-60 cells, and the IC_{50} was 16 µM after 36 h of treatment; it also inhibited Bcl-2 expression in the HL-60 cells and induced apoptosis (143).
81 Cuphiin D1, R = α-galloyl, R_1 = β-galloyl
82 Cuphiin D2, R = H, R_1 = β-galloyl
83 Woodfordin C, R = α-galloyl, R_1 = H
84 Oenothein B, R = R_1 = H

Two new cyclic compounds with long-chain fatty acyl esters, glucolipsin A **85** and B **86**, were isolated from the butanol extracts of *Streptomyces purpurogeniscleroticus* WC71634 and *Nocardia vaccinii* WC65712, respectively (144). Glucolipsins A **85** and B **86** relieved the inhibition of glucokinase by FAC (fatty acyl CoA) with RC_{50} values (i.e., concentration at which there is a 50% reduction in the number of offspring as compared with controls; log10 RC_{50}, root elongation half inhibition concentration [mol/L] in logarithmic form) of 5.4 and 4.6 µM.

Streptomyces microflavus strain 2445 produced the major

product fattiviracin FV-8 **87**, which consists of four glucose and two trihydroxy FA residues (145). Fattiviracin FV-8, purified from the culture broth of *S. microflavus*, showed potent antiviral activities against HIV type 1 (HIV-1), herpes simplex virus type 1 (HSV-1), varicella-zoster virus (VZV), and influenza viruses A and B (146).
The actinomycete strain *Kibdelosporangium albatum* R761-7 (ATCC 55061) produced new antiviral antibiotics, cycloviracins B1 **88** and B2. They showed weak activity against Gram-positive bacteria and potent antiviral activity against HSV-1 (147,148). A novel antiherpetic agent, fattiviracin A1, was isolated from the culture broth of strain no. 2445, identified as *S. microflavus* (149). The structure of fattiviracin A1 is a new macrocyclic diester consisting of four D-glucose units and two (C_{24} and C_{33}) hydroxy FA. It is closely related to the cycloviracins B1 **88** and B2 but differs from these known compounds in both the length of its side chain and the sugar moiety. Fattiviracin A1 showed potent antiviral activities against HSV-1, VZV, influenza virus A, and HIV-1. It showed no cytotoxicity against Vero cells. Fattiviracin A1 exhibited no significant antibacterial or antifungal activities. Treatment of HSV-1 with fattiviracin A1 decreased its infectivity to Vero cells. The mechanism of its antiviral activity may be due to inactivation of the viral particles and inhibition of viral entry into the host cells (150).
Macroviracins **89–96** are a new class of macrocyclic compounds that were isolated from the mycelium extracts of *Streptomyces* sp. BA-2836,1 and were classified into eight types of congeners (A–D) by the length (C_{22} or C_{24}) of the constitutive

FA. These natural products exhibit a powerful antiviral activity against HSV-1 and VZV, and their potency is reported to be 10 times that of acyclovir. Structurally, macroviracins are related to sugar-FA lactones such as cycloviracins and fattiviracins, and differ remarkably in the size of the macrocyclic ring systems (151,152).

89 Macroviracin A, n = n₂ = 1

93 Macroviracin C1, n = 1, n₁ = n₂ = 2
94 Macroviracin C2, n = n₂ = 2, n₁ = 1
95 Macroviracin C3, n = n₁ = 2, n₂ = 1
96 Macroviracin D, n = n₁ = n₂ = 2
HYBRID MACROCYCLIC GLYCOSIDES

Hybrid macrocyclic glycosides are usually FA macrolactones or their derivatives bearing one or more (rare) sugar(s) and produced by microorganisms, lower invertebrates, microalgae, fungi, and/or plant species (2). Hybrid macrocyclic glycosides also can be formed with many other substituents.

10–13-MEMBERED RING GLYCOSIDIC MACROLIDES

A few 10-membered ring macrolide glycosides are found in nature. Thus, the leaves of a small tree *Gonocaryum calleryanum* (family Icaciaceae), named Balotangginto, has afforded new secoiridoid glycosides acylated with 2,3-dihydroxy-2-methylbutanoic acid, three of which (**97a–c**) have a novel 10-membered dilactone ring (153). *Gonocaryum calleryanum* is mainly distributed from Indonesia to Taiwan. Its leaves are used in Philippine folk medicine for the treatment of stomach diseases (154). More recently, Chan *et al.* (155) of the Taiwan Medicinal College isolated **97a** and **97b** from leaves, branches, stems, and root bark from the same species (*G. calleryanum*) grown in the southern part of Taiwan.

The novel highly cytotoxic metabolites apicularen A and apicularen B **98** were isolated in a screening of the myxobacterial genus *Chondromyces* (156). The structure of the apicularens A and B was characterized by a salicylic acid residue as part of a 10-membered lactone, which bears an acylenamine side chain. Apicularens are present in nearly every strain of *C. apiculatus*, *C. pediculatus*, *C. lanuginosus,* and *C. robustus*. Apicularen B **98** was identified as 11-*O*-(2-*N*-acetamido-2-

deoxy-β-D-gluco-pyranosyl)apicularen. According to feeding experiments with ¹³C-labeled acetates, glycine, and methionine, apicularens A and B are acetate-derived polyketides containing a glycine residue as precursor of the enamine. The glycoside apicularen B showed weak antimicrobial activity against Gram-positive bacteria, e.g., *Micrococcus luteus* [minimal inhibitory concentration (MIC) 12.5 µg/mL] and *Corynebacterium fascians* (MIC 25 µg/mL), and moderate cytotoxic activity, with IC_{50} values between 0.2 and 1.2 µg/mL with nine different human cancer cell lines, including the multidrug-resistant line KB-V1 (157).

97a Gonocaryoside A, R = Me
97b Gonocaryoside B, R = H

98 Apicularen B

97c Gonocaryoside C
Two novel 10-membered ring chlorinated glycosidic macrolides, latrunculinosides A **99a** and B **99b**, containing substituted 2-oxecanones (decalactones) were isolated from the marine sponge *Latrunculia corticata* (158). Both glycosides contain unusual saccharides such as β-D-olivose, β-L-digitoxose, β-L-amicetose, and β-D-oliose. These compounds gave positive results in antifeeding assays (for goldfish), **99a** 1.7 µg/mL and **99b** 3.3 µg/mL, respectively (158).

99a Latrunculinoside A

99b Latrunculinoside B
The 10–12-membered ring macrocyclic compounds, tannin derivatives **100a–f**, and **102a,b** have been isolated from

the aerial parts of *Cunonia macrophylla* (an endemic Cunoni-aceae, New Caledonia) (159), *Pelargonium reniforme* (Berlin, Germany) (160), *Tellima grandiflora* (fringe cups, Saxifragaceae, Germany) (161), and from fruits of *Punica granatum* (California) (162).

Furosin **100f** was isolated from the whole plant of *Euphorbia helioscopia* (Euphorbiaceae), collected at Cheongju City (Korea); this hydrolyzable tannin markedly decreased the differentiation of both murine bone marrow mononuclear cells and Raw264.7 cells into osteoclasts, as revealed by the reduced number of tartrate-resistant acid phosphatase (TRAP)-positive multinucleated cells and decreased TRAP activity (163). A gallotannin-containing fraction of *Phyllanthus amarus* and the isolated ellagitannins corilagin **100c** and geraniin (isomer of furosin **100f**) were the most potent mediators of antiviral activities. The *P. amarus*-derived preparations blocked the interaction of HIV-1 gp120 with its primary cellular receptor CD4 at an IC$_{50}$ of 2.65 (water/alcohol extract) to 0.48 µg/mL (geraniin). Inhibition was also evident for the HIV-1 enzymes integrase (0.48–0.16 µg/mL), reverse transcriptase (8.17–2.53 µg/mL), and protease (21.80–6.28 µg/mL) (164,165). Corilagin **100c** also has shown antimicrobial activity against human bacterial pathogens (*S. aureus*, *Corynebacterium accolans*), a plant pathogen (*Erwinia carotovora*), and a human pathogenic yeast (*C. albicans*) (159).

Cornusiin E **101** isolated from *Tellima grandiflora* was catalyzed by an oxygen-dependent laccase-type phenol oxidase (161). Punicalagins **102a,b** are major polyphenols of *Punica granatum* (162), and their hydrolyzed derivatives punicalin and

2-*O*-galloylpunicalin, from *Terminalia triflora* leaves, showed inhibitory activity against an HIV-1 reverse transcriptase; punicalin showed an IC$_{50}$ of 0.11 µg/mL and 2-*O*-galloylpunicalin an IC$_{50}$ of 0.10 µg/mL (165).

101 Cornusiin E, R = galloyl

102a Punicalagin, R = α-OH
102b Punicalagin, R = β-OH
A few glycosidic macrolides having a 12-membered ring system also are found in nature. Thus, methymycin **103**, neomethymycin **104**, and YC-17 **105** were found in culture broths of a *Streptomyces* species (166–168). A new macrolide, **106**, named novamethymycin, was similar to compounds **103**–**105** and was isolated from *S. venezuelae* (169).

The spinosyns **107**–**112** are novel macrolides produced by *Saccharopolyspora spinosa* (170). Spinosyns are comprised of a tetracyclic macrolide containing forosamine and tri-*O*-methyl rhamnose, with different degrees of methylation on the polyketide or deoxysugars (171–173). The two major factors in the *S. spinosa* fermentation, spinosyn A **107** and spinosyn D **108**, differ from each other by a single methyl substituent at position 6 of the polyketide. Spinosad, a combination of spinosyn A and spinosyn D, is marketed by Dow AgroSciences for the control of agricultural insect pests. Spinosads are highly effective against target insects and have an excellent environmental and mammalian toxicological profile (174–176). Cloning and analysis of the spinosad biosynthetic gene cluster of *S. spinosa* have recently been reported (177). Novel spinosyns, **113**–**118**, have been prepared by biotransformation using a genetically engineered strain of *Saccharopolyspora erythraea*, in which the β-D-forosamine moiety in glycosidic linkage to the hydroxy group at C-17 was replaced by α-L-mycarose (178). Lepicidin A **119** was isolated in 1990 from the fermentation broth of the soil microbe *S. spinosa* by Eli Lilly Co. (179). Lepicidin A exhibits insecticidal activity, particularly against *Lepidoptera* larvae.

This group of antibiotics is characterized by excellent antibacterial activity, particularly against Gram-positive bacteria. Macrolides can be defined and distinguished from the other groups of antibiotics by the unique feature of their chemical structure. They are polyfunctional macrocyclic lactones, and the majority of them contain at least one amino sugar moiety, which is the cause of the basicity of the molecules.

118 R = Me, R₁ = D-Glc

119 (+)-Lepicidin A
Two new cytotoxic macrolide glycosides, auriside A **120** and auriside B **121**, have recently been isolated from the Japanese sea hare *Dolabella auricularia* (180). Both aurisides showed cytotoxicity against HeLa S$_3$ cells, with IC$_{50}$ values of 0.17 and 1.2 µg/mL, respectively.

A glycosidic macrolide having a structure similar to aurisides, lyngbouilloside **122**, was characterized from the marine cyanobacterium *Lyngbya bouillonii*, collected in Papua New Guinea. Lyngbouilloside was modestly cytotoxic to neuroblastoma cells (IC$_{50}$ value of 17 µM) (181). Also, a new glycoside macrolide termed lyngbyaloside B **123** was isolated from a Palauan collection of the marine cyanobacterium *Lyngbya* sp. and exhibited slight cytotoxicity (182).

Callipeltoside A **124**, B **125**, and C **126**, bioactive marine glycoside macrolides, were isolated from the marine sponge *Callipelta* sp. (183). Callipeltose A **124** was found to protect against HIV virus infection *in vitro* (184) and also showed activity in cytotoxic assays against KB and P388 cells.

The macrolide polycavernoside A **127a** is a toxic metabolite produced by the marine red alga *Polycavernosa tsudi* (formerly *Gracilaria edulis*) (185). More recently, another four polycavernosides, A2 **127b**, A3 **127c**, B **128a**, and B2 **128b**, were also found in the same alga *P. tsudi* (186).

New antibiotics named decatromicins A **129** and B **130** were isolated from the culture broth of *Actinomadura* sp. MK73-NF4 (187,188). Decatromicins A and B inhibited the growth of Gram-positive bacteria, including methicillin-resistant *S. aureus* (187). These antibiotics are closely related to pyrrolosporin A **131**. Pyrrolosporin A **131**, new macrolide antitumor antibiotic possessing an unusual spiro-α-acyltetronic acid moiety, was isolated from the fermentation broth of *Micromonospora* sp. strain C39217-R109-7 (189). Pyrrolosporin A **131** showed antimicrobial activity against Gram-positive bacteria, was weakly active against Gram-negative bacteria, and prolonged the life span of mice inoculated with P388 leukemia cells (190).

131 Pyrrolosporin A
14-MEMBERED RING GLYCOSIDIC MACROLIDES

The 14-membered ring glycosidic macrolides represent a large group of natural compounds. Biologically active antibiotics, lactone glycosides named erythromycins A **132**, B **133**, C **134**, D **135**, F **136**, and E **137** have been isolated from *Streptomyces erythreus* (191–193) and *Nocardia* species (194,195). Oleandomycin **138** and oleandomycin Y **139** were produced by *Streptomyces antibioticus* (196–198). Pikromycin **140**, narbomycin **141**, and 5-*O*-mycaminosyl-narbonolide **142** were isolated from *Streptomyces felleus* (199,200) and *Streptomyces narbonensis* (201). 10,11-Dihydropikromycin **143** and kayamicin **144** were produced by *S. narbonensis* (202). Tri-*O*-

acetyloleandomycin **145** and erythromycin esters **146–149** also have been isolated from *Streptomyces* sp. (203–206).
Megalomicin A **150**, B **151**, C₁ **152**, C₂ **153**, and XK-41-B₂ **154** were obtained for the first time from *Micromonospora megalomicea* (207) and were later isolated from culture broths of *Micromonospora inositola* (208,209). 3″-*O*-Demethyl-2″,3″-anhydrolankamycin **155**, lankamycin **156**, kujimycin A **157**, 15-dehydrolankamycin **158**, 15-*O*-(4-*O*-acetyllar-canosyl)-lankamycin **159**, and 23672-RP **160** belonging to the lankamycin/kujimycin group have been isolated from *Streptomyces violaceoniger* and *Streptomyces spinichromogenes* (210–217). The brominated glycosidic macrolide lyngbyalo-side **160a** is produced by the marine cyanobacterium *Lyngbya bouillonii* (218).
A new class of potent antifungal agents that comprise a 14-membered macrocyclic lactam ring attached to a sugar flu-virucin B1 **163** (also known as Sch 38516) and B2 **164** (Sch 38518) have been isolated from *Actinomadura vulgaris* subsp. *lanata* (219,220). Fluvirucin B1 was active against *Candida* sp. (MIC 0.91 µg/mL), and it also exhibited activity against the influenza A virus. More recently, the 14-membered lactams flu-virucins A1 **161**, A2 **162**, B1 **163**, B2 **164**, B3, B4, and B5 (with common aglycon like B1) have been isolated from dif-

ferent strains of actinomycetes, have been shown to be active against the influenza A virus, and belong to the same family of compounds (221–223). The morphology, chemotaxonomy, and cultural and physiological characteristics of the five strains of actinomycetes that produce antiviral antibiotics, fluvirucin con-geners, have been studied. All strains have meso-2,6-di-aminopimelic acid in the cell wall. Four strains, Q464-31, L407-5, R359-5, and R516-16, belong to the maduromycetes since they have madurose in the whole cell. The remaining one strain, R869-90, has rhamnose but no madurose and was a no-cardioform actinomycete. These five strains were classified and designated as follows: Strain Q464-31 (fluvirucin A1 producer) was *Microtetraspora tyrrhenii* sp. nov. (group of *Actinomadura pusilla*), and strain L407-5 (fluvirucin B2 producer) was a maduromycete. Strain R359-5 (fluvirucin B1 producer) was *Microtetraspora pusilla* (group of *A. pusilla*). Strain R869-90 (fluvirucin A2 producer) was *Saccharothrix mutabilis*, and strain R516-16 (fluvirucins B2, B3, B4, and B5 producer) was a maduromycete (224). Also, fluvirucin B2 from *Streptomyces* sp. MJ677-72F5 was found to inhibit PI-specific phospholipase C (225).
15-MEMBERED RING MACROLIDES

Two antibiotics containing the sugar leucanicidin **165** and 19-*O*-methylleucanicidin **166** are potent inhibitors of larval devel-opment in the parasitic nematode *Haemonchus contortus* (226), and they have been isolated from *Streptomyces* isolates A233, A239, and A240.

A new 15-membered macrocyclic glycolipid lactone, cus-cutic resinoside A **167**, was isolated from the seeds of *Cuscuta chinensis* (Convolvulaceae), which showed potency for stimu-lating MCF-7 cell proliferation. The compound significantly stimulated not only MCF-7 cell proliferation but also T47D human breast cancer cells at a concentration of 10 µM (227).
16-MEMBERED RING GLYCOSIDIC MACROLIDES

The 16-membered ring as well as the 14-membered ring macrolides are also a large group of natural macrocyclic com-pounds produced by microorganisms and lower invertebrates.

The avermectins **168–179** are a family of naturally occurring macrocyclic lactones with exceedingly high activity against helminths and arthropods (228,229). A primary fermentation product of S*treptomyces avermitilis*, avermectin B1 **170**, is an important and widely used agricultural pesticide (230). Although compound **168** is extremely effective against mites, it is much less effective against nematodes, especially the cabbage looper, the corn earworm, and the southern armyworm (230). The level of activity against these species is insufficient to justify commercial development for these uses. A mixture of naturally occurring avermectins significantly suppressed the growth of the ascites Ehrlich carcinoma and P388 lympholeukemia and the solid Ehrlich and 755 carcinomata (231).
Two novel unusual flavonol epimeric macrocyclic derivatives, **180** and **181**, have been isolated from the wild water lily *Nymphaea lotus* (232). This is the first report of such a macrocycle from any source. *Nymphaea lotus* is widespread on the Nile River and its tributaries in central and southern Sudan. Throughout this region, the roots of the plant are usually cooked as a starchy vegetable, whereas the roots and particularly the leaves have been used in traditional Sudanese medicine as a remedy for dysentery, to treat tumors (233), and as an antibacterial (234).

180 Nympholide A

181 Nympholide B
The spiramicins antibiotics **182–188** were isolated from culture broths of *Streptomyces ambofaciens* (235–238). High-speed countercurrent chromatography was successfully applied to the separation of spiramycin types I, II, and III (239). The tylosin group antibiotics **189–195** and related compounds **196–199** were produced by microorganisms *Streptomyces fradie* (240–242), and *S. hygroscopicus* (243).
A series of leucomycins, A$_1$ **200**, A$_5$ **201**, A$_7$ **202**, A$_9$ **203**, V **204**, A$_3$ (= josamycin) **205**, A$_4$ **206**, A$_6$ **207**, A$_8$ **208**, U **209**, platenomicin A$_1$ **210**, medicamycin A$_2$ **211**, medicamycin A$_1$ (= espinomycin A$_1$; platenomycin B$_1$) **212**, platenomycin C$_2$ (= espinomycin A$_3$) **213**, DHP **214**, espinomycin A$_2$ **215**, and platenomycin A$_0$ **216** have been isolated from *Streptoverticillium (Streptomyces) kitasatoensis* (232). A$_3$ (= josamycin) **205** also was obtained from culture broths of *Streptoverticillium (Streptomyces)* var. *josamyceticus* (233). Antibiotics containing epoxy groups (positions 12,13), named maridomycin I (= platenomycin C$_3$) **217**, VII **218**, III (= platenomycin C$_1$) **219**, V **220**, II (= platenomycin C$_4$) **221**, IV **222**, and VI **223**, were obtained from culture broths of *S. hygroscopicus* (244–252). Compounds **224–229** also have been isolated from culture broths of *S. hygroscopicus* (253).
Some related 16-membered ring macrolides containing an amino sugar, such as carbomycin B **230**, platenomycin W$_1$ **231**, platenomycin W$_2$ **232**, niddamycin **233**, midecamycin A$_4$ **234**, midecamycin A$_3$ **235**, DOA **236**, and DOP **237**, have been obtained from *Streptomyces platensis* subsp. *malvinus* (253–258). A

series designated by abbreviations (SF-837 and its derivatives A_1–A_4) were obtained from another strain of *Streptomyces mycarofaciens* (259–263), whereas niddamycin **233** was produced by culture broths of *Streptomyces djakatensis* (264). Other macrolides have a 12,13-epoxide. Acumycin **238** was isolated from culture broths of *Streptomyces griseoflavus* (265). The same compound was isolated from culture broths of *Streptomyces fradiae* var. *acinicolor* and designated cirramycin B **238**. A6888C (cirramycin F-1) **239** and cirramycin F-2 **240** were produced by *Streptomyces flocculus* (266), whereas the closely related macrolide M119-A **241** was produced by an alkalophilic actinomycete (267). Similar derivatives with additional methoxyglycosides include angolamycin **242**, isolated from *Streptomyces eurythermus* (268), and staphcoccomycin **243**, produced by culture broths of *Streptomyces* sp. AS-NG-16 (269).

Cirramycin A_1 **244** was obtained from culture broths of *Streptomyces cirratus* (270–272). Rosaramicin **245**, formerly rosamicin, was produced by *Micromonospora rosaria* and shown to be 4'-deoxycirramycin A_1 (273,274). Structures of four related compounds produced by *Micromonospora capillata* (275,276), including izenamicin A_3 **246**, juvenimicin A_4 **247**, M-4365 A_1 **248**, and juvenimicin A_2 **249**, are shown below. Hydrolysis of both neutral sugars from tylosin yielded 5-*O*-mecaminosyl-tylonolide (OMT, **250**) (277). Analogous hydrolysis of mycarose from DMOT, GS-77-3, and GS-77-1 yielded compounds **251**–**258** (278–280). A series named mycinamicines I–VII, **259**–**265**, respectively, have been isolated from culture broths of *Micromonospora griseorubida* (281–284).
Three antibiotics having a similar structure, chalcomycin **266** (285–287), neutramycin **267** (288–290), and CP-70-662 **268** (291), are produced by *Streptomyces bikiniensis, S. rimosus*, and *S. hirsutus,* respectively. Aldgamycin F **269**, G **270** (also known as 8-deoxyaldgamycin F), and E **271** have been isolated from culture broths of *S. lavendulae* (292) and *S. avidinii* (293), and swalpamycin **272** was isolated from *S. anandii* subsp. *swalpus* (294,295).

272
17–28-MEMBERED RING MACROCYCLIC GLYCOSIDES

A novel 17-membered ring macrolide named versipelostatin **273**, a metabolite of *Streptomyces versipellis* 4083-SVS6, was isolated as a GRP78 molecular chaperone down-regulator (296). GRP78 acts as a molecular chaperone in the endoplasmic reticulum by associating transiently with incipient proteins to facilitate protein folding (297). Overexpression of GRP78 enables solid tumor cells to grow in hypoxic and glucose-starved conditions, which is the characteristic circumstance of the core of a solid tumor (298). Biosynthesis of versipelostatin also was reported (299).

A new 18-membered ring resin glycoside, mammoside A **274**, and three resin-glycosides, named mammosides B, H1, and H2, were isolated from the tuber of *Merremia mammosa* (Convolvulaceae) (300). The antifungal macrocyclic lactone antibiotic, irumamycin **275**, was found in the culture broth of *Streptomyces subflavus* subsp. *irumaensis* nov. subsp. (301). More recently, irumamycin **275** and two analogs, **275a,b**, were produced by newly isolated *Streptomyces* sp. strain US80 (302). Irumamycin and the two analogs showed antimicrobial activities against Gram-positive and Gram-negative bacteria (*Escherichia coli* ATCC 8739, *Micrococcus luteus* LB 14110, *Bacillus subtilis* ATCC 6633, and *S. aureus* ATCC 6538). All three pure compounds, **275** and **275a,b**, inhibited growth of the two filamentous fungi (*Verticillium dahliae*, *Fusarium* sp.) and *Candida tropicalis* R2 CIP203; the highest antifungal activity was shown by irumamycin **275** (302).

Concanamycin A **276** and related compounds B and C were isolated from the mycelium of *Streptomyces diastatochromogenes* S-45 as effective inhibitors of concanavalin A-stimulated proliferation of mouse splenic lymphocytes (303). They repre-

sent a new class of 18-membered macrolide antibiotics and are biologically active *in vitro* against several fungi and yeasts, but not bacteria. Concanamycin A, the main component, has been identified with the antifungal antibiotics folimycin and A-661-I; it is a potent and specific ATPase inhibitor (304).

276 Concanamycin A
The tiacumicins are a group of 18-membered macrolide antibiotics originally isolated from the fermentation broth of *Dactylosporangium aurantiacum* subsp. *hamdenensis* (305–310). Tiacumicin B **277a**, the major antibiotic component produced by this culture, contains an unsaturated 18-membered macrolide ring with a seven-carbon sugar at carbon 11 and a 6-deoxysugar at carbon 20. This compound is apparently identical to one of the lipiarmycins, a previously described group of lipiarmycin antibiotics, **277c,d**, produced by *Actinoplanes deccanensis*, and to clostomicin B1, an antibiotic from *Micromonospora echinospora* (309). Tiacumicin C **277b** differs

in the position of butyrate esterification on the seven-carbon sugar. Tiacumicin C appears to be identical to clostomicin B2, a member of the clostomicin complex isolated from *M. echinospora* (309). Tiacumicins B **277a** and C **277b** showed *in vitro* activity against 15 strains of *Clostridium difficile* (MIC 0.12 μg/mL for B, and 0.25 μg/mL for C) (309,310).

The first macrocyclic anthocyanin pigment was discovered in 1998 by Bloor (311). He examined flowers of the red/mauve carnation (*Dianthus caryophyllus*) cultivars 'Kortina Chanel' and 'Purple Torres' grown in New Zealand and found them to contain the unique macrocyclic anthocyanin pigment **278a**, a malylated cyanidin 3,5-diglucoside in which the malyl group is linked to both sugars (311). More recently, **278a** and **278b** were isolated from the same plant grown in Japan (312). Macrocyclic compound **278b** also was found in the 'Cyclamen Red' (or pink) flowers from Italy, France, and The Netherlands ('Red Rox') (313). The modified violet carnation cultivars 'Moondust' and 'Moonshadow' (*Dianthus caryophyllus*) produce a cyclic delphinidin type anthocyanin elphinidin, **279** (314). A new antitumor antibiotic (against human colon carcinoma Co-3), vicenistatin **280**, was isolated from the culture broth of *Streptomyces* sp. HC34 and is a unique 20-membered macrocylic lactam with a novel amino sugar vicenisamine (315).

A new antifungal 24-membered polyene macrolide, tetrin **281**, and the related compounds tetrins A **282** and B **283**, and tetramycins A **284** and B **285** have been isolated from *Streptomyces* sp. GK9244 (316). Maduralide **286**, a novel macrolide possessing a 24-membered ring, was isolated from a marine actinomycete grown in liquid culture (317).

Pimaricin **287** and the analog de-epoxy-pimaricin **288** are 24-member ring lactone antifungal antibiotics (318) produced by *Streptomyces natalensis* ATCC 27448, which is widely used in the food industry to prevent mold contamination on cheese and other nonsterile foods (319,320). The anti-inflammatory pentaene 28-membered ring lactones eurocidins C, D **289**, and E have been isolated from the culture broth of *Streptoverticillium eurocidicum* IFO 13491 as the inhibitors (321–323). Eurocidins C and E do not contain sugar moieties in their structure.

287 Pimaricin

288 De-epoxy-pimaricin

289 Eurocidin D
30–72-MEMBERED RING MACROCYCLIC GLYCOSIDES

A new macrolide lactone antifungal antibiotic, brasilinolide A **290**, was isolated from the fermentation broth of *Nocardia* sp. IFM 0406. The producer was identified as *Nocardia brasiliensis* (324,325). This macrolide was active only against *Aspergillus niger* but not against other fungi including yeasts or other filamentous fungi and bacteria. Brasilinolide A also showed an immunosuppressant activity in the mixed lymphocyte reaction with an IC_{50} of 0.625 µg mL^{-1}. More recently, brasilinolides B **290a** and C **290b** were isolated from *N. brasiliensis* and from *N. brasiliensis* strain IFM0406 (326). The **290b** showed cytotoxicity against murine lymphoma P388 cells (IC_{50} 8.3 µg/mL), whereas **290** was not cytotoxic at IC_{50} 100 µg/mL.

290 Brasilinolide A, R = COCH₂COOH, R₁ = COC₄H₉
290a Brasilinolide B, R = COC(C₄H₉)COOMe, R₁ = Me
290b Brasilinolide C, R = R₁ = H
The new, highly complex chlorinated pyrrole-containing macrolide colubricidin A **291** was isolated from the fermentation broth of a new *Streptomyces* sp. LL-C13122 (327). It showed nematocidal activity against *Caenorhabditis elegans* and also demonstrated potent activity against Gram-positive bacteria.

291 Colubricidin A
The polyene macrolide antibiotic nystatin **292** produced by *Streptomyces noursei* ATCC 11455 is an important antifungal agent. The nystatin molecule contains a polyketide moiety represented by a macrolactone ring to which the deoxy sugar mycosamine is attached (328). The biosynthetic pathway of nystatin has been elucidated (328).

Amphotericin B **293**, the first commercially significant antifungal drug, has been available for more than 30 years and was described by Oura *et al*. (329). According to the National Library of Medicine (Bethesda, MD), more than 13,000 experimental and review articles have been published on amphotericin B **293** during the last 30 years. This polyene macrolide antifungal agent continues to play a major role in the treatment of systemic fungal infections, despite the introduction of newer agents such as the azoles. Because of the proven efficacy of amphotericin B and the increasing number of indications for antifungal agents, an extensive review of this drug has been published (330). This paper discusses the clinical uses of amphotericin B, including its application in AIDS-related fungal infections, in neutropenic cancer patients who are persistently febrile, and in infections of the central nervous system, lungs, peritoneum, genitourinary system, eyes, and skin. The paper also reviews the drug's adverse reactions, with a discussion of administration techniques that may reduce these reactions, and its spectrum of activity, pharmacokinetics, and dosage and administration (330).

Candicidin **294**, an aromatic heptaene antibiotic produced by *Streptomyces griseus* IMRU 3570, was discovered by Lechevalier (331) and named antibiotic C135, although it was renamed candicidin because of its strong activity against species of *Candida*. Candicidin was used to treat vaginal candidiasis (332–334) and prostatic hyperplasia (335).

292 Nystatin

293 Amphotericin B

294 Candicidin D
A few 42-membered macrolactone glycosides have been isolated from the microorganisms. Oasomycin B **295** contains α-D-mannose at the 22 carbon atom produced by *Streptoverticillium baldacci* subsp. *netropse* (strain FH-S 1625) (336), as

do desertomycin A **296** and B **297**. Oasomycin B **295** and desertomycins **296** and **297** vary in the side chains located at carbon atom 41 and in the α-1-*O*-linked D-mannose moiety attached to carbon atom 22. Desertomycin A **296** exhibits selective antifungal and broad antibacterial activity *in vitro* as well as considerable cytotoxic effects. The acute toxicity in mice was reported to be in the range of 1–12 mg/kg [LD_{50} (dose at which 50% of test subjects die) = 1.5 mg/kg s.c. (337) and 12 mg/kg p.o. (338)]. Mathemycins A **298** and B **299**, new antifungal macrolactone glycosides, have been isolated from *Actinomycete* species (339–341). The compounds of **298** and **299** show moderate *in vitro* activity against the following phytopathogens, with minimum active concentration values of 62.5 mg/L: *Fusarium culmorum, Alternaria mali, Botrytis cirea, Pellicularia sasaki, Leptosphaeria nodorum, Pyricularia oryzae, Pseudocercosporella herpotrichoides*, and *Phytophthora infestans*.

298 Mathemycin A, R = H
299 Mathemycin B, R =

Archaebacteria thrive in environments characterized by anaerobiosis, saturated salt, and both high and low extremes of temperature and pH. The bulk of their membrane lipids are polar, characterized by the archaeal structural features typified by ether linkage of the glycerol backbone to isoprenoid chains of constant length, often fully saturated, and with *sn*-2,3 stereochemistry opposite that of glycerolipids of bacteria and eukarya (343). Molecular species of C_{40} isoprenoid chains, having different numbers of cyclopentane rings, were detected in the ether core lipid of *Thermoplasma acidophilum* (344,345). The average cyclization number of the hydrocarbon chains in the lipids increased with increasing growth temperatures. Two neutral glycolipids, **301** and **302**, isolated from *T. acidophilum* provide examples of the unusual 72-membered ring macrocyclic structures of archaebacteria lipids. The same glycolipids are produced by some other archaebacteria (343).
300 α-Cyclosophorohexadecaose
UNUSUAL BOLAFORM AMPHIPHILES

Bolaform amphiphilic compounds exhibit diverse surface activities, biodegradability, reactivity, and antimicrobial properties (346). Bola-amphiphiles are molecules with two polar head groups separated by one or more hydrophobic spacer groups; three general types can be identified (see Fig. 1). The polar groups include glycerol and related polyols and are connected to the hydrophobic chain through ether, acetal, ester, and amide links (347). Compounds of type A can form micelles or monolayer lipid vesicles for a range of variants in the structure, but more complex behavior has been observed for bis(azacrown ether) bola-amphiphiles (micelle or multilamellar vesicle formation depending on the length of the spacer group) (348). Compounds with polyhydroxy head groups act as gelling agents in water by forming fiber-like aggregates (349); similar rods and tubules are formed by self-assembly of bola-amphiphiles with amino acid and ammonium functionalities as the head groups (350). One interesting property of many bola-amphiphiles is their capacity to become incorporated into lipid membranes. Depending on its structure, the bola-amphiphile can act either as a membrane-disrupting agent (351,352) or as a membrane stabilizer (353). Most studies of bola-amphiphiles that interact with membranes involve either pseudomacrocyclic type B or macrocyclic type C structures. These are analogs of the lipid constituents of the highly stable membranes from archaebacteria (see structures **301** and **302**). These bacterial membranes are made up of macrocyclic lipids (type C) with two polyisoprenoid spacer groups attached to the glycerol head groups by ether linkages (354). The nondenaturing properties of bolaform amphiphilic compounds, sugar-based nonionic surfactants, may provide interesting advantages for these compounds in cosmetic, pharmaceutical, and food applications.

The novel pseudomacrocyclic bola-amphiphilic (type B) compounds **303** and **304** have been synthesized (355,356), as
FIG. 1. Basic structures of bolaform surfactants: Type A, single-chain bolaform; Type B, pseudomacrocyclic bolaform; Type C, macrocyclic bolaform.

have galactose-based (type C) macrocyclic surfactant **305** analogs of archaeobacterial membrane components (356). Compound **305** and the pseudomacrocyclic bolaforms **303** and **304** display interesting new surface tension properties; they are insoluble in water and undergo monolayer compression.
Macrocyclic compounds such as porphyrins, their analogs and derivatives have been widely used as photosensitizers in photodynamic therapy for cancer diseases (357–360). The photosensitizer **306**, 3,12,13,22-tetraethyl-8,17-bis[(2-amino-2-deoxy-α,β-D-glucopyranose)-carbonylethyl]-2,7,18,23-tetra-methyl-sapphyrin, has been synthesized (361), and the biolocalization and photochemical properties of this sapphyrin **306** have been investigated (361). This photosensitizer absorbs in the far visible region, shows good tumor localization, and demonstrates a significantly larger absolute and relative tumor to normal tissue ratio (ratio T/N; amount in tumor, 330 μg g^{-1} wet tissue, T/N = 19.0). Raman spectroscopic studies indicate that the monomerized photosensitizer **306** effectively damaged BSA and calf thymus DNA after light excitation under the con-

ditions of a large excess of this macromolecule. Porphyrin derivatives with eight sugars, **307** and **308**, with activity against some cancer cells, also were synthesized (362).
Fujimoto *et al.* (362) also synthesized the new biologically active saccharide-coated macrocycles **309** and **310**, and found that rat hepatoma cells bind a calixarene having two galactoses on each of its four aromatic rings. Spleen cells lacking specific galactoside receptors did not bind this calixerene, nor did rat hepatoma cells bind the calixarene substituted with glucose instead of galactose. The more effective analogs **311–315**, with two galacto-calixarene macrocycles covalently joined by a long spacer and belonging to type B bolaform surfactants, were synthesized by Menger and co-workers (363); the authors proposed that the new bolaforms **311–315** might "glycotarget" a group of cancer cells and thereby interconnect them for therapeutic purposes.
Over the last 50 years, a great number of new therapeutic agents have been discovered. However, in spite of the unquestionable advances in pharmacotherapy, it is calculated that a satisfactory treatment has yet to be developed for two out of every three diseases. This is the case for numerous forms of cancer and viral or heart diseases. The need for new, more specific. and better adapted medicines is greater each day. We have reviewed more than 300 natural glycoside-containing compounds, and some of them and/or their synthetic derivatives could eventually be used as potent therapeutic agents. The marine environment constitutes a vast potential source of new bioactive molecules. One of the most interesting groups of substances of marine origin, from the pharmacological point of view, is that of the acyclic or cyclic polyethers, which generally present a great diversity in size and potent biological activities.

With the examples of recent product innovations from bolaform chemistry and the successful development of synthetic capabilities and biologically potent products, the potential for drug development in this area also has been demonstrated. Combining novel marine and terrestial raw materials, as well as deriving new synthetic methods to form new products, will also be a challenge for research and development in the future, as will be the development of products for polymer or composite applications. Extensive basic investigations, especially regarding the use of new natural surfactant derivatives, can be expected in the near future.

Novel Oxylipins Formed from Docosahexaenoic Acid by Potato Lipoxygenase—10(*S*)-Hydroxydocosahexaenoic Acid and 10,20-Dihydroxydocosahexaenoic Acid

Igor A. Butovich*, Mats Hamberg, and Olof Rådmark

Division of Physiological Chemistry II, Department of Medical Biochemistry
and Biophysics, Karolinska Institute, S-171 77, Stockholm, Sweden

ABSTRACT: Potato tuber lipoxygenase (ptLOX) has been shown to catalyze the aerobic formation of at least four major oxygenated derivatives of DHA. Two of the products—7,17(*S*)- and 10,17(*S*)-dihydro(pero)xy-DHA [7,17- and 10,17-diH(P)DHA]—were formed from soybean 15-LOX-derived 17(*S*)-hydro(pero)xy-DHA [17(*S*)-H(P)DHA], whereas two novel oxylipin compounds—10(*S*)-hydro(pero)xy-DHA and 10,20-dihydro(pero)xy-DHA [10(*S*)-H(P)DHA and 10,20-diH(P)DHA, respectively]—were the major direct products of DHA oxidation by ptLOX. The reactions proceeded relatively slowly but could be stimulated by catalytic amounts of SDS. Micromolar concentrations of 10(*S*)-HPDHA effectively abolished the kinetic lag period of ptLOX activation. Enzymatic activity with DHA or 17(*S*)-HPDHA as substrate was about 8% of that with linoleic acid—a standard natural ptLOX substrate—whereas 17(*S*)-HDHA was converted at a rate of ~1%. The enzyme was relatively unstable and quickly inactivated during the reaction with DHA on with 17(*S*)-HPDHA (first-order kinetic constant of inactivation $k_{in} = 1.5 \pm 0.3$ min^{-1}), but not with 17(*S*)-HDHA. Both 7,17- and 10,20-diH(P)DHA were clearly products of double oxygenation catalyzed by soybean 15-LOX and/or ptLOX. Our observation that ptLOX could convert 17-HDHA to 10,17-diH(P)DHA indicates that this dihydroxylated derivative of DHA also can be formed *via* a double lipoxygenation mechanism.

Paper no. L9683 in *Lipids 40*, 249–257 (March 2005).

Potato tuber lipoxygenase (ptLOX, EC 1.14.18.1) has been shown to catalyze oxygenation of a range of PUFA (1–4) as well as some of their derivatives, e.g., linoleic acid methyl ester (5), glyceryl ester (6), and linoleyl alcohol (7,8). The reactions proceed in micellar solutions with maximal reaction rates at pH values slightly below neutrality, typically 6.3 to 6.5. Under these conditions, ptLOX substrates—PUFA and their derivatives—are poorly soluble and tend to aggregate quickly. To make the reaction mixtures more thermodynamically stable and homogeneous, it was proposed to include in the reaction mixtures small amounts of the nonionic detergent Lubrol PX (5,9–11) or a similar compound, the monododecyl ether of decaethylene glycol ($C_{12}E_{10}$) (6–8). The rates of the dioxygenation reactions were greatly enhanced in the presence of certain acidic amphiphilic compounds (activators) (6–8,10,11; and references therein). The product profile was not noticeably affected by inclusion of the activators (5,6,8). Under these conditions, ptLOX formed several positional and geometrical isomers of the oxygenated products, which occurred partly owing to the dual (normal and inverse) orientation of the substrate molecule in the enzyme's catalytic center, and partly because of enzyme-triggered nonenzymatic reactions (6,8). It was found that inclusion of free-radical scavengers [e.g., TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxy)] in the reaction mixtures substantially increased the optical purity of the oxygenation products by suppressing nonenzymatic free-radical chain reactions (6,8).

Recently, several DHA oxygenation products have been identified, including mono-, di- and trihydro(pero)xy-DHA (4,12–14)], a common feature of which is oxygenation at C17 of DHA. This group of compounds was termed "resolvins" because they were formed during the resolution phase of an acute inflammatory response, after treatment of experimental animals and cells with acetylsalicylic acid (ASA) and DHA. The mechanism of formation of some of them, *e.g.*, 7,17(*R*)-dihydroperoxydocosahexaenoic acid [7,17(*R*)-diHPDHA], was postulated to start with oxygenation of DHA by cyclooxygenase-2 acetylated with ASA (4,12), although in a recent paper it was proposed that a LOX-catalyzed formation of 17(*S*)-HPDHA could also be a starting point in making 10,17(*S*)-dihydroxy DHA (diHDHA) (14). The same group found that many of these singly, doubly, and triply oxygenated compounds could also be formed in "one-pot reactions" of DHA oxidation catalyzed by ptLOX and soybean 15-LOX (4,12). However, no detailed information on the reactions was provided.

In this report, we describe two novel oxylipins formed from DHA by ptLOX, as well as further studies on the conversion by ptLOX of soybean 15-LOX-derived 17(*S*)-HPDHA and 17(*S*)-HDHA.

EXPERIMENTAL PROCEDURES

DHA was purchased from Nu-Chek-Prep (Elysian, MN). Soybean 15-LOX type 1-B (100 KU/mg solid; activity measured as described by the manufacturer) was a product of Sigma-Aldrich (Stockholm, Sweden). Potato LOX was purchased from Cayman Chemical (Ann Arbor, MI) and according to the manufacturer's data was 98% pure. The purity of the protein was retested by SDS-PAGE. The enzyme produced a single band on a 10–15% gradient gel on a PhastSystem (Pharmacia-LKB) with Coomassie® brilliant blue G-250 staining. For preparative synthesis of lipid metabolites, semipurified ptLOX from locally grown potato tubers was used. (In preliminary experiments, the purity of the enzyme preparations was shown to have no effect on the product profile of DHA oxidation.) Other compounds were purchased from Sigma-Aldrich. A Waters Spherisorb Si 5 µm 3.2 × 250 mm straight-phase HPLC (SP-HPLC) column was a product of Supelco (Bellefonte, PA). A Chiralcel OB-H 4.6 × 250 mm chiral column was manufactured by Daicel Chemical Industries, Ltd. (Tokyo, Japan). HPLC-grade solvents were obtained from Rathburn Chemical Ltd. (Walkerburn, Scotland). A Hewlett-Packard HPLC system equipped with a 1040A diode-array detector and Chem-Station software was used in chromatographic experiments.

Enzymatic oxidation of DHA by soybean 15-LOX. Soybean 15-LOX-catalyzed oxidation of DHA resulting in formation of 17(*S*)-HPDHA was described earlier (15). In our modified procedure, virtually 100% conversion of DHA into 17(*S*)-HPDHA was obtained. Briefly, a 10-mL aliquot of 100 µM DHA dissolved in aerated 0.05 M sodium borate buffer (pH 9.0) was mixed with ~100 µg soybean 15-LOX and left at 4°C for 10 min under constant stirring. To convert the newly formed hydroperoxide(s) of DHA into the corresponding hydroxides, a solution of $NaBH_4$ in 1 M NaOH was added to the reaction mixture at the end of the incubation period (final concentration of the reducing agent, 0.5 mg/mL), and the mixture was left for another 15 min at 4°C under gentle stirring (foaming!). The reaction was then stopped, and the excess of $NaBH_4$ was decomposed by adding 0.1 mL of glacial acetic acid after which the mixture was allowed to stand on ice for another 15 min. When the target product was 17(*S*)-HPDHA, the reduction step was omitted from the procedure. Finally, the product was passed through a 500-mg Supelco Discovery C18 solid-phase extraction cartridge in accordance with the manufacturer's recommendations, the cartridge was washed with distilled water, and the products were eluted with absolute ethanol. After evaporation of the solvent, 17(*S*)-HDHA was redissolved in absolute ethanol and stored at –20°C under argon for a week without noticeable degradation of the sample. The extent of reduction was monitored by SP-HPLC analysis of the products in a hexane/2-propanol/acetic acid (989:10:1, by vol) solvent mixture as described below. Under these conditions, 17-HDHA had a shorter retention time (RT) than 17-HPDHA.

Enzymatic oxidation of DHA by ptLOX. The reactions were performed essentially as described before for linoleyl alcohol (7,8) and 1-monolinoleoyl glycerol (6). For preparative-scale

synthesis of DHA metabolites, the reaction mixture was composed of 100 µM DHA, 0.02% $C_{12}E_{10}$, 100 µM SDS, and 1 mM TEMPO dissolved in 10 mL of aerated 0.05 M MES-NaOH buffer with pH 6.3. The reaction was started by adding ~2 U of ptLOX [1 U was defined as the amount of enzyme that catalyzed formation of 1 µmol of 9(*S*)-hydroperoxyoctadecadienoic acid (HPODE)/min with linoleic acid (LA) as substrate], and the mixture was incubated for 15 min at 4°C under constant stirring. At the end of the incubation period, the reaction was stopped with acetic acid; the products were extracted as described above for soybean 15-LOX products, redissolved in absolute ethanol, and stored at –20°C under argon. For kinetic experiments performed spectrophotometrically as described earlier for other LOX substrates (5,6,8,9), TEMPO was excluded from the mixture because its high absorptivity interfered with UV analysis, and the total volume of the reaction mixture typically was 0.5 mL. The reactions were carried out in quartz spectrophotometric cells at room temperature (23 ± 1°C). The reactions were started by adding enzyme aliquots followed by vigorous mixing of the solution with a pipette and were monitored at 238 (for conjugated dienes) or 272 nm (for conjugated trienes, see below). Molar absorption coefficients (ε_m) of the conjugated dienes and trienes formed during the reaction were assumed to be 25,000 $M^{-1} cm^{-1}$ (16) and 40,000 $M^{-1} cm^{-1}$ (estimate), respectively.

Enzymatic synthesis of 7,17- and 10,17-diH(P)DHA. The doubly oxygenated metabolites of DHA were prepared using the procedure described above for DHA by incubating either 17(*S*)-HDHA or 17(*S*)-HPDHA (100 µM final concentration) with ~2 U of ptLOX.

SP-HPLC on silica gel. Crude product mixtures were analyzed chromatographically on a Waters Spherisorb Si 5 µm 3.2 × 250 mm SP-HPLC column. Detection of the eluted peaks was performed simultaneously at 236 (conjugated dienes) and 270 nm (conjugated trienes). Monohydroxylated FA were eluted by a hexane/2-propanol/acetic acid (989:10:1, by vol) solvent mixture at a flow rate of 1 mL/min, whereas dihydroxylated acids were separated in a hexane/2-propanol/acetic acid (979:20:1, by vol) mixture at the same flow rate, unless indicated otherwise. The individual fractions of oxygenated DHA metabolites were collected manually, and their purities were rechecked under the same conditions.

GC–MS. The isolated fractions of individual lipids were subjected to catalytic hydrogenation with H_2 over PtO_2 (15). Then the samples were trimethylsilylated with a trimethylchlorosilane/pyridine mixture and evaporated under vacuum; the residue was redissolved in a small volume of dry hexane and then analyzed by GC–MS. A Hewlett-Packard model 5970 mass selective detector connected to a Hewlett-Packard model 5890 gas chromatograph was used for GC–MS. A capillary column of 5% phenylmethylsiloxane (length, 12 m; film thickness, 0.33 µm; carrier gas, helium) was used. The temperature was raised from 120 to 260°C at a rate of 10°C/min.

GLC. GLC was carried out with a Hewlett-Packard model 5890 gas chromatograph equipped with an FID and a methylsilicone capillary column (length, 25 m; film thickness, 0.33

μm; carrier gas, helium). The column temperature was raised 2°C/min starting at 190°C.

Steric analysis of the products. Determination of the absolute configuration of allylic alcohol groups in LOX-generated metabolites was carried out by GLC analysis of (−)-menthoxycarbonyl (MC) derivatives of short-chain esters formed upon oxidative ozonolysis (17). The analyte (10 μg or less) was derivatized by treatment with (−)-menthoxycarbonyl chloride (20 μmol; Aldrich) in a mixture of toluene (30 μL) and dry pyridine (5 μL) at 23°C for 1 h. The reaction mixture was subjected to TLC using a solvent system of ethyl acetate/hexane (5:95, vol/vol). A broad zone of silica gel corresponding to R_f 0.6–0.8 was scraped off and eluted with distilled diethyl ether. The MC derivative thus eluted was dissolved in 0.5 mL of chloroform, cooled to −20°C, and exposed to a stream of ozone/oxygen (1:9, vol/vol) for 30 s. Solvent was removed under argon and the residue treated with 0.1 mL of peracetic acid at 40°C for 15 h. The residue obtained following evaporation of the reagent was treated with diazomethane and analyzed by GLC and GC–MS using a reference sample of the MC derivative of dimethyl (±)-malate. Under the conditions used, MC derivatives of 2(*S*)-hydroxyesters or diesters elute at shorter RT compared with those of the corresponding 2(*R*)-hydroxy derivatives.

The mono- and dihydroxylated DHA (methyl esters) were also analyzed on a Chiralcel OB-H chiral column. The monohydroxylated derivatives were eluted with hexane/2-propanol (99:1, vol/vol) solvent mixture, whereas dihydroxylated compounds were analyzed in a hexane/2-propanol (80:20, vol/vol) solvent mixture, both at a flow rate of 1 mL/min. Peaks were detected at 236 and/or 270 nm.

RESULTS

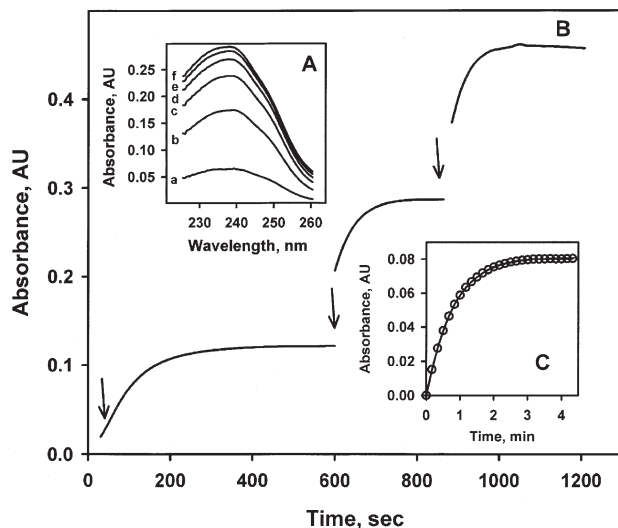
Oxidation of DHA. Under aerobic conditions, ptLOX transformed DHA into a compound with a λ_{max} at 238 nm, indicative of a 1,4-pentadiene to 1,3-conjugated diene transformation usually associated with LOX-catalyzed monooxygenation of unsaturated FA (Fig. 1A). Then the catalytic activity of the enzyme was determined spectrophotometrically by monitoring the progress curves of the reaction at 238 nm. Under similar conditions, ptLOX activity with DHA as substrate was found to be ~7.5% of that with LA. Unlike the reaction with LA, ptLOX-catalyzed oxygenation of DHA stopped long before the FA and molecular oxygen had been depleted, thus giving a relatively low product yield (Fig. 1B, curve **a**). When equal aliquots of active enzyme were added to the same reaction mixture, the reaction proceeded with reaction rates and product yields approaching those of the first incubation (Fig. 1B, curves **b** and **c**). The yield of the lipid oxidation product was proportional to the amount of the enzyme added: a 3-fold increase in the initial enzyme concentration in the reaction mixture led to a ~2.8-fold increase in the product formation. Also, the same patterns of enzyme inactivation/inhibition during reaction, and of reaction restoration with fresh enzyme, were observed at higher enzyme concentrations (data not shown). The kinetics


FIG. 1. Oxidation of DHA by potato tuber lipoxygenase (ptLOX). (A) Formation of the conjugated dienes during oxidation of 100 μM DHA by ptLOX. Experimental conditions: as described in the Experimental Procedures section. The reaction was initiated by adding 5 μL of ptLOX stock solution. Spectra **a** to **f** were recorded at 30-s intervals. (B) Kinetic curves of DHA oxidation by ptLOX. Experimental conditions: as described in the Experimental Procedures section. Substrate: 100 μM DHA. The reaction was initiated by adding 2.5 μL of ptLOX stock solution. Absorbance was measured at 238 nm. Arrows indicate the time points when equal ptLOX aliquots were added. (C) Reaction inactivation of ptLOX on oxidation of 100 μM DHA. Open circles: experimental points. Solid line: kinetic curve computed using Equation 1 and the following parameters: $V_0 = 0.10398$ AU/min; $k_{in} = 1.28$ min^{-1}.

of ptLOX inactivation during oxidation of DHA was investigated in more detail. A previously described mathematical approach (18; and references therein) was applied to determine an apparent first-order kinetic constant of ptLOX inactivation during the reaction (k_{in}). We thus found that the progress curve of 100 μM DHA oxidation by ptLOX in the presence of 5 μM 10-HPDHA [added to eliminate the well-known lag period of the enzyme activation (5,6,8,9,19) was adequately described by a simple reaction inactivation equation:

$$P_t = \frac{V_0}{k_{in}} \times (1 - e^{-k_{in} \times t}) \qquad [1]$$

where P_t is the product concentration (in absorbance units, AU) at time t, and V_0 is the initial reaction rate (Fig. 1C). The values of V_0 and k_{in} were found to be 0.104 AU/min and 1.28 min^{-1}, respectively (as $\varepsilon_{238} = 25,000$ M$^{-1} \times$ cm^{-1}, the rate of 0.104 AU/min translates into ~4.2 μM of product/min). A 3-fold increase in the initial concentration of ptLOX led to a 3.5 ± 0.5 fold increase in the V_0 and a concurrent increase in k_{in} to ~1.8 min^{-1}. According to Equation 1, when $t \to \infty$, then $P_t \to V_0/k_{in} = P_{lim}$, i.e., the product yield at the end of the catalytic reaction in which an enzyme undergoes fast inactivation. Simple calculations of the reaction yield using the values determined for V_0 and k_{in} showed that a 3-fold increase in the initial enzyme concentration should give a 2.6-fold increase in the product formation, which is close to the value obtained experimentally (2.8).

Oxidative conversion of 17(S)-H(P)DHA. During incubation of 17(S)-HPDHA with ptLOX, the hydroperoxide was effectively transformed into another product, which had a UV-spectrum of a 1,3,5-conjugated triene with clear maxima at 272 and 280 nm (Fig. 2). The increase in the optical density in the region from 260 to 280 nm was accompanied by a simultaneous decrease in the absorbance at λ 238 nm. A single isosbestic point (λ 251 nm) has been found in the electronic spectra of the reaction mixture taken while the reaction progressed (Fig. 2), which is indicative of a direct transformation of 1,3-conjugated diene into 1,3,5-conjugated triene (Scheme 1):

SCHEME 1

In a manner similar to the oxidation of DHA, a rapid loss of the enzymatic activity with k_{in} = 1 min^{-1} was observed during the reaction with 17(S)-HPDHA (data not shown). The observed reaction rate was ~8.3% of that with LA as substrate (Table 1).

17(S)-HDHA was converted by ptLOX into a new product possessing a similar electronic spectrum with a triplet 260, 270, and 280 nm and an isosbestic point at 250 nm (Fig. 3). The reaction rate of 17(S)-HDHA conversion was noticeably slower than that of 17(S)-HPDHA, but the former reaction eventually gave a comparable, or even higher, yield of the triene(s) owing to a much slower enzyme inactivation/inhibition (Fig. 4). The

TABLE 1
Comparison of the Activity of ptLOX with Various Substrates[a]

Substrate 100 μM	Product formed	Analytical wave-length, nm	Activity[b], %	k_{in}, min^{-1}
Linoleic acid	9(S)-HPODE	234	100	0.2[c]
DHA	Hydroperoxy-DHA	238	7.6	1.5 ± 0.3
17(S)-HPDHA	Triene(s)	272	8.3	~1
17(S)-HDHA	Triene(s)	272	1	NA

[a]ptLox, potato tuber lipoxygenase; 9(S)-HPODE, 9(S)-hydroperoxyoctadecadienoic acid; 17(S)-H(P)DHA, 17(S)-hydro(pero)xy-DHA; NA, not available. [b]When calculating the activity of ptLOX with different substrates, ε_{238} = 25,000 M^{-1} × cm^{-1} and ε_{272} = 40,000 M^{-1} × cm^{-1} were used. Composition of the reaction mixture was as follows: 0.5 mL of 0.1 mM substrate, 0.1 mM SDS, 0.02% (wt/vol) monododecyl ether of decaethylene glycol (C$_{12}$E$_{10}$), 0.05 M MES/NaOH buffer pH 6.3, ambient temperature (23 ± 1°C). [c]From Reference 9.

value of k_{in} could not be computed because of the complex form of the kinetic curve. Interestingly, a noticeable lag period of ptLOX activation was observed with 17(S)-HDHA as substrate because the reaction achieved its maximal rate only after 12 min into the reaction (Fig. 4, inset). The lag was visible on both the progress curves—17(S)-HDHA decomposition and the conjugated triene formation—and was virtually nonexistent in the case of 17(S)-HPDHA (Fig. 2, inset).

Characterization of the oxygenated products. For elucidation of the molecular structures of the main products of DHA oxidation, the lipids were extracted and analyzed by SP-HPLC and GC–MS. A typical chromatogram of the products of DHA oxidation (Fig. 5) showed two major products (compounds **I** and **II**), with considerably different retention times on a silica gel column. The UV spectrum of the less polar compound **I** with λ_{max} 236 nm is typical for monohydroxylated PUFA, whereas the much more polar compound **II**, dissolved in the mobile phase, showed a less common electronic spectrum (Fig. 5, inset) with two maxima at 224 and 242 nm (A$_{224}$/A$_{242}$ = 1.37). To ensure that the UV spectrum of compound **II** was not a superposition of spectra of two different co-eluting substances, compound **II** was rechromatographed in several hexane/2-propanol/acetic acid mixtures either in the form of a free acid or methyl ester (data not shown). It was concluded that compound **II** indeed possessed the electronic absorption spectrum depicted in Figure 5. Interestingly, the same sample of purified compound **II** dissolved in ethanol showed a somewhat different UV spectrum with a primary maximum at about 243 nm and a secondary maximum (or a shoulder) at 224 nm with A$_{224}$/A$_{243}$ = 0.7.

Compounds **I** and **II** were isolated by SP-HPLC and, after catalytic hydrogenation and trimethylsilylation, subjected to EI GC–MS analysis. A total ion chromatogram of compound I (Fig. 6A) revealed the presence of one major peak with an RT of ~16.1 min. The fragmentation pattern of the di-trimethylsilyl (di-TMS) derivative of the totally hydrogenated compound **I** showed three prominent fragments with *m/z* 73, 271, and 331, and less intense fragments 469 and 485 (Fig. 6B). All the major fragments were shown to coelute as a single peak if plotted as a single ion monitoring chromatogram

FIG. 2. ptLOX-catalyzed conversion of 100 μM 17-hydroperoxy DHA (17-HPDHA) into a conjugated triene. Experimental conditions: as described in the Experimental Procedures section for DHA. The reaction was initiated by adding 10 μL of ptLOX stock solution. Spectra **a** to **e** were recorded at 1-min intervals. Inset: Kinetic curves of ptLOX-catalyzed conversion of 100 μM 17-HPDHA recorded at 238 and 272 nm. For other abbreviation see Figure 1.

FIG. 3. ptLOX-catalyzed conversion of 100 μM 17-hydroxy DHA (17-HDHA) into a conjugated triene. Experimental conditions: as described in the Experimental Procedures section for DHA. The reaction was initiated by adding 20 μL of ptLOX stock solution. Spectra **a** to **d** were recorded at 2-min intervals. For other abbreviation see Figure 1.
FIG. 4. Kinetic curves of ptLOX-catalyzed conversion of 17-HDHA recorded at 238 and 272 nm. Experimental conditions: See the Experimental Procedures section and Figure 2. The reaction was initiated by adding 10 μL of ptLOX stock solution. Inset: The dependency of the reaction rate of 17(*S*)-HDHA transformation by ptLOX on the reaction time. The data were taken from the main portion of this figure, numerically differentiated, and plotted as reaction rate vs. time. For abbreviations see Figures 1 and 3.
FIG. 5. Straight-phase HPLC (SP-HPLC) analysis of the DHA lipoxygenation products. Inset: a UV spectrum of compound **II** taken during the HPLC analysis.

(Fig. 6C). These data provide strong evidence that the compound in hand is fully hydrogenated diTMS-10-HDHA (M.W. 500.9), whereas the starting compound **I** is 10-HDHA.

Fully trimethylsilylated and hydrogenated compound **II** produced characteristic fragments with *m/z* 73, 117 (minor), 131, 331, 359, and 469 (Fig. 7). The following assignments of the common fragments were made: *m/z* 73 − Si(CH$_3$)$_3$, 117 − COOSi(CH$_3$)$_3$, 131 − CH$_3$CH$_2$CHOSi(CH$_3$)$_3$, 469 − (588 − TMSiOH − CH$_2$CH$_3$), M.W. 589.1, exact mass 588.4. The rest of the fragments are depicted in Figure 7. These data, in combination with the fragmentation pattern of the same compound **II** treated with diazomethane prior to trimethylsilylation (*m/z* 73, 131, 273, 359, and 515, data not shown) proved that it is a C$_{22}$ FA with two hydroxyls at carbons 10 and 20, i.e., 10,20-diHDHA.

To determine whether 10-HDHA had been formed as a single optical isomer, it was converted into the methyl ester and analyzed by HPLC on a chiral column as described in the Experimental Procedures section. The compound eluted as a single major peak (>90%) with an RT of 26 min in hexane/2-propanol (99:1, vol/vol, flow rate 1 mL/min) and a minor (<10%) component with a longer RT of 30.2 min. The determination of the absolute stereochemistry of 10-HDHA was performed by its oxidative ozonolysis of its MC-derivative as described earlier for 9- and 13-hydroxyoctadecadienoic acids (17). The enzymatically formed 10-HDHA gave a single product peak, which coeluted with the MC derivative of dimethyl (*S*)-malate. Therefore, the configuration of the hydroxyl at the carbon atom number 10 is *(S)*, and the major monooxygenated product of ptLOX oxidation of DHA is 10(*S*)-HPDHA.

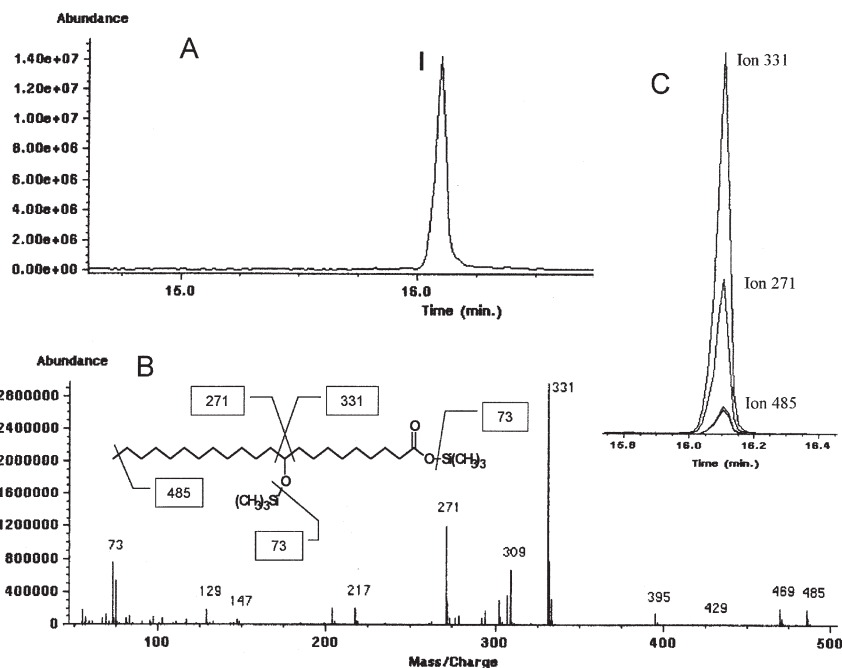
10,20-DiHDHA was eluted as a single peak on a Chiralcel OB-H column in solvent mixtures of hexane/2-propanol (90:10, vol/vol; flow rate 1 mL/min; RT 31.5 min: and 80:20, vol/vol; flow rate 1 mL/min; RT 13.5 min). No traces of other compounds were detected, suggesting that 10,20-diHDHA


FIG. 6. GC–MS analysis of compound **I** after hydrogenation with H_2/PtO_2 and trimethylsilylation. (A) Total ion chromatograph (TIC); (B) electron impact MS (EI MS) fragmentation pattern; (C) single ion monitoring chromatogram: ions with *m/z* ratios of 271, 331, and 485 were monitored.
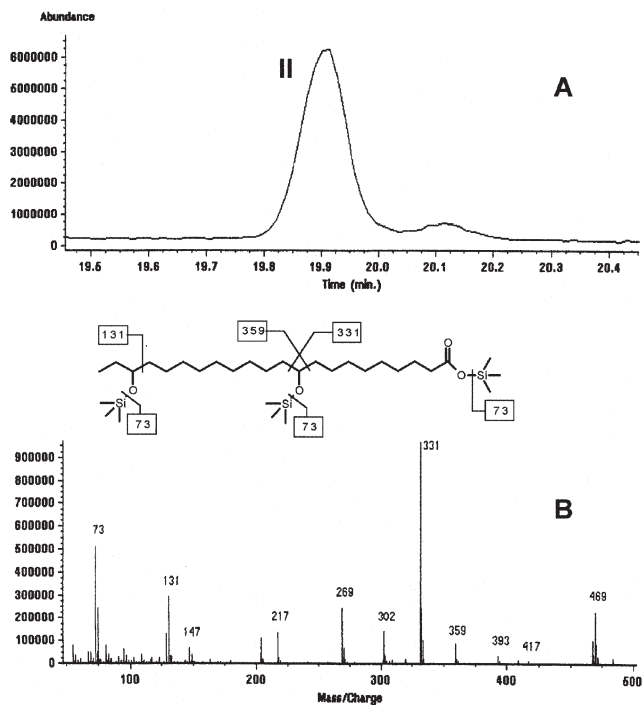

FIG. 7. GC–MS analysis of compound **II** after hydrogenation with H_2/PtO_2 and trimethylsilylation. (A) TIC of compound **II** and (B) its EI MS fragmentation pattern. For abbreviations see Figure 6.

was present as a single stereoisomer. The absolute stereochemistry of the hydroxyl group at C20 remains to be determined.

In the reaction of ptLOX with 17(*S*)-HPDHA, there were three major product peaks detected after reduction of the product mixture with $NaBH_4$ (compounds **III**, **IV**, and **V**; Figs. 8A and 8B). Compound **III** was positively identified as 17(*S*)-HDHA. The UV spectrum of the less polar compound **IV** (Fig. 8C) was virtually identical to that of 10,20-diHDHA (Fig. 5), whereas compound **V** (Figs. 8B and 8D) was identified as a conjugated triene with λ_{max} 260, 270, and 280 nm. GC–MS analysis of the hydrogenated TMS derivative of compound **IV** revealed characteristic fragments with *m/z* ratios of 73, 173, 289, 402, 427, 517, and 573, which were indicative of a triTMS derivative of fully hydrogenated 7,17-diHDHA. The corresponding derivative of compound **V** produced fragments 73, 173, 331, 359, 427, 517, and 573 (M.W. 589.1, exact mass 588.4), suggesting that it was 10,17-diHDHA.

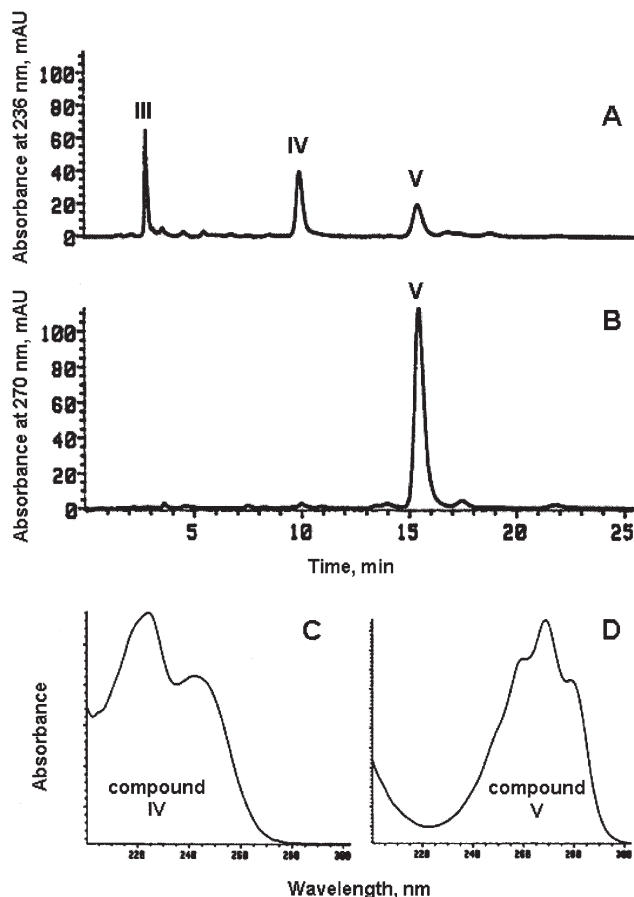
10,17-DiHDHA was also found as a major metabolite in the lipid product mixture obtained by incubating 17-HDHA and ptLOX followed by reduction of the reaction products with $NaBH_4$ (compound **V**, Fig. 9). Interestingly, with 17-HDHA as substrate, production of 7,17-diHDHA (compound **IV**) was considerably reduced (but still present) compared with the experiments with 17-HPDHA (compare Figs. 9A and 8A). The molecular structures of the DHA metabolites are presented in Scheme 2.


FIG. 8. SP-HPLC analysis of 17(*S*)-HPDHA lipoxygenation products. Analytical wavelengths: (A) 236 nm; (B) 270 nm. Panels C and D: UV spectra of compounds **IV** and **V**. For abbreviations see Figures 2 and 5.

DISCUSSION

Under aerobic conditions in a mixed micellar solution composed of a nonionic detergent $C_{12}E_{10}$, SDS, and DHA, ptLOX oxidized DHA at a rate of ~8% of that with LA as substrate, which makes DHA a relatively poor substrate for ptLOX. Nevertheless, the enzymatic activity was high enough to generate sufficient amounts of the reaction products. Noticeable was the fast enzyme inactivation/inhibition during the reaction with the rate constant of inactivation of 1 to 2 min^{-1}, the reasons for which are yet not known. Interestingly, transformation of 17(*S*)-HPDHA into 10,17-diH(P)DHA proceeded quickly but also caused rapid loss of the enzymatic activity, whereas in the reaction with 17(*S*)-HDHA, ptLOX was much more stable, although the reaction was slower and was accompanied by a noticeable lag period. There is no doubt that the differences in kinetics were caused by the presence of the hydroperoxy group in 17(*S*)-HPDHA that may serve as a ptLOX activator that readily converts the "resting" ferrous form of ptLOX into a catalytically active ferric form (19), thus minimizing the catalytic lag and, in certain cases, enhancing the apparent activity of LOX (20). On the contrary, 17(*S*)-HDHA, being unable to convert Fe^{2+} to Fe^{3+}, was expectedly a poorer substrate in terms of the reaction rate.
FIG. 9. SP-HPLC analysis of 17(*S*)-HDHA lipoxygenation products. Analytical wavelengths: (A) 236 nm; (B) 270 nm. Inset: UV spectrum of compound **V**. For abbreviations see Figures 3 and 5.

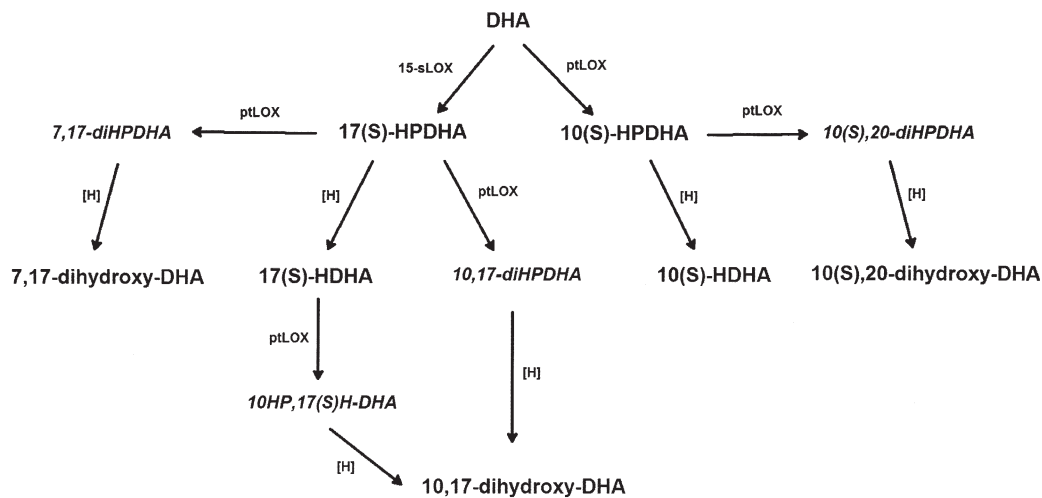
Oxygenation of DHA catalyzed by ptLOX generated two novel oxylipins—10(*S*)-H(P)DHA and a doubly oxygenated product 10,20-diH(P)DHA. Oxygenation of DHA at C10 was shown to proceed stereospecifically to yield the 10(*S*)-hydroperoxide of DHA. The absolute stereochemistry of 10,20-diH(P)DHA remains to be determined, but based on the stereospecificity of DHA oxygenation, it is reasonable to assume that in 10,20-diH(P)DHA the hydro(pero)xy group at C10 position has the (*S*)-configuration too. Since no 20-H(P)DHA was identified among the products [although ptLOX produced several minor metabolites with elution times close to the one for 10-H(P)DHA], oxygenation of DHA at C10 seems to be the first step in making 10,20-diH(P)DHA, followed by the secondary
SCHEME 2

reaction at C20. The latter would necessitate abstraction of a hydrogen atom from the methylene C18.

In the ptLOX-catalyzed reaction, which involves formation of a carbon-centered free radical, hydrogen abstraction at C12 is followed by isomerization of the radical to C10 and its reaction with molecular oxygen at this position (Scheme 3):

SCHEME 3
When conversion of 17(*S*)-H(P)DHA into 10,17(*S*)-diHDHA was described previously, it was proposed that 17-HPDHA is converted into 10,17-diHDHA with *trans,trans,cis*-geometry of the conjugated double bonds by an LOX-like activity *via* an epoxidation/isomerization reaction (13). Our observation that 10,17-HDHA can also be formed from 17-HDHA by ptLOX points toward a different reaction mechanism (i.e., double lipoxygenation), with likely *trans,cis,trans*-geometry of the conjugated double bonds. An interesting result was the UV spectra of 7,17- and 10,20-diHDHA recorded during HPLC experiments (Figs. 5 and 8C). The splitting of the λ_{max} was most likely caused by the presence of the following fragment present in both compounds (Scheme 4):

SCHEME 4
In nonpolar solvents such as the HPLC mixtures used in this study, interaction of the two polar hydroxy groups by an *intramolecular* hydrogen bond could be facilitated by solvophobic effects of hexane. Indicatively, the very same sample of 10,20-diHDHA, after being dissolved in a much more polar solvent (ethanol), showed a reversed UV spectrum with a primary absorption maximum at 243 nm and a suppressed maximum (or shoulder) at 224 nm. This solvatochromic effect is probably due to the ability of the alcohol to form hydrogen bonds with the hydroxyl groups of 10,20-diHDHA thus partly disrupting the intramolecular hydrogen bond postulated in Scheme 4. Though theoretically possible, an interaction of two or more molecules of 7,17- or 10,20-diHDA through formation of *intermolecular* hydrogen bonds seems unlikely because the effect would be concentration-dependent, which was not the case. A direct involvement of the carboxyl group of the dihydroxylated compounds is also implausible because (i) the methyl ester derivatives showed the same spectral properties as the free acids, and (ii) the distances between the carboxyl group and the hydroxyls of 7,17- and 10,20-diHDHA differ from compound to compound without affecting their spectra. Thus, the UV maximum with λ_{max} of 224 nm is, probably, characteristic of the structure presented in Scheme 4, whereas the second maximum of 243 nm is related to the same compound with disrupted intramolecular hydrogen bond. Both forms seem to coexist in equilibrium, which depends on the ability of the solvent to form hydrogen bonds with the hydroxyl groups of 7,17- and 10,20-diHDHA. It is noteworthy that a similarly split spectrum (with a secondary maximum at 226 nm and a primary maximum at 243 nm) was previously described for an arachidonic acid metabolite formed by double lipoxygenation (5,15-dihydroxyeicosatetraenoic acid) (21–26), although no explanation for it was provided.

In summary, ptLOX has been shown to catalyze formation of at least four major oxygenated derivatives of DHA. Two of these—7,17- and 10,17-diH(P)DHA—were formed from the


SCHEME 5

soybean 15-LOX product 17(*S*)-H(P)DHA, whereas two novel compounds—10(S)-HPDHA and 10,20-diH(P)DHA—were direct ptLOX products of DHA oxidation (see Schemes 2 and 5). PUFA of the n-3 class have effects in normal physiology and disease (27,28). Some of these effects may be due to metabolites formed by LOX-catalyzed reactions, such as the docosanoids formed from DHA (29). As described here, DHA metabolites can be generated in substantial amounts using plant LOX for use in further studies of (patho)physiological effects of these oxygenated FA in human cells and tissues.

Effect of Homocysteine, Folates, and Cobalamin on Endothelial Cell- and Copper-Induced LDL Oxidation

Instituto de Nutrición y Tecnología de los Alimentos (INTA), Universidad de Chile, Casilla 138-11, Santiago, Chile

ABSTRACT: Oxidation of LDL contributes to endothelial dysfunction and atherosclerosis. This process could be associated with hyperhomocysteinemia, a condition that can be reduced after folic acid treatment. Because a reduction in LDL oxidation may improve endothelial function, we studied the effect of some vitamins (folic acid, 5-methyltetrahydrofolic acid, and vitamin B-12) on LDL oxidation, either in the presence or absence of homocysteine. For this purpose, two *in vitro* systems were used: an endothelial cell-catalyzed LDL oxidation system and a cell-free copper-initiated LDL oxidation system. The kinetics of copper-catalyzed LDL oxidation was determined by continuous monitoring of the production of conjugated dienes in the reaction medium. TBARS production, a parameter of lipid peroxidation, was also evaluated. In both *in vitro* systems, only 5-methyltetrahydrofolic acid was able to decrease TBARS production in a concentration-dependent manner, independently of the presence or absence of homocysteine. In the copper-induced LDL oxidation system, vitamin B-12 and 5-methyltetrahydrofolic acid increased the lag time of conjugated diene production by 25 and 47%, respectively, suggesting that both vitamins in this system had antioxidant properties. Folic acid was unable to show antioxidant properties when included in either *in vitro* system. The results demonstrate that 5-methyltetrahydrofolic acid and vitamin B-12 are important protective agents against LDL oxidative modifications.

Paper no. L9644 in *Lipids 40*, 259–264 (March 2005).

LDL are susceptible to oxidation by the vascular wall cells, which contributes to the initiation of endothelial dysfunction (1,2). This condition is a key process in atherosclerosis and has been reported in chronic mild fasting hyperhomocysteinemia (3). The mechanism associated with homocysteine (Hcy)-induced endothelial dysfunction is probably mediated by oxidative stress, leading to increased levels of oxidized LDL (3,4). Hcy, a thiol-containing amino acid derived from the demethylation of dietary methionine, may generate partially reduced reactive oxygen species that are able to stimulate the lipid peroxidation involved in the atherosclerotic process (5). In this process, oxidatively modified LDL may play an important role in endocytosis *via* the macrophage scavenger receptor (2).

The plasma Hcy level in humans is determined by genetic and nutritional factors and is inversely related to the levels of some vitamins such as B-6, B-12, and folic acid (6). These vitamins are necessary for the metabolic remethylation and transsulfuration pathways during Hcy synthesis (3).

Bellamy *et al.* (7) demonstrated that folic acid supplementation reduces plasma levels of Hcy and improves endothelium-dependent vasodilation. On the other hand, recent findings reported by our group showed that hyperhomocysteinemia was not associated with vascular reactivity and oxidative stress in subjects with normal serum folate concentrations (8). The administration of 5-methyltetrahydrofolate (5-MTHF), the active form of folic acid, improved endothelial function in hypercholesterolemic subjects not presenting vascular disease (9). Furthermore, oral folic acid prolonged the lag time of LDL oxidation in children with chronic renal failure (10). In cultured human endothelial cells, 5-MTHF has intrinsic antioxidant actions caused by reducing intracellular production of superoxides (11). In addition, folate has been shown to reduce the susceptibility of LDL to oxidation *in vitro* (12).

Considering that conditions decreasing LDL oxidation could be related to an improvement of endothelial function, the main aim of the present work was to evaluate whether vitamins (folates or vitamin B-12), either in the absence or presence of Hcy, are able to modify LDL oxidation. For this purpose, two *in vitro* systems were used: a cell-free copper-catalyzed system and a human umbilical vein endothelial cell (HUVEC)-mediated oxidative modification of LDL.

MATERIALS AND METHODS

Chemicals. DL-Hcy (95% purity; 2 amino-4-mercaptobutyric acid), folic acid (pteroyl-L-glutamic acid), 5-methyltetrahydrofolic acid (5-methyl-5,6,7,8-tetrahydropteroyl-L-glutamic acid disodium salt), and vitamin B-12 (cyanocobalamin) were from Sigma (St. Louis, MO).

Isolation of LDL. LDL from healthy volunteers were isolated from freshly prepared EDTA-plasma by sequential ultracentrifugation in the density range of 1.019–1.063 g/mL (13) and subsequent dialysis against PBS, pH 7.4, for 24 h; the LDL was used immediately after the dialysis procedure. To determine LDL protein concentration, the BioRad Protein Assay (Bio-Rad Laboratories, Hercules, CA) was used.

HUVEC cultures. HUVEC were isolated from recently

TABLE 1
Effect of Vitamin B-12, Folic Acid, and 5-Methyltetrahydrofolate (5-MTHF) on the Lag Time and Oxidation Rate of Conjugated Diene Production During Copper-Induced LDL Oxidation[a]

Treatment	Lag time (% of control)	Oxidation rate (% of control)
Control (Cu^{2+})	100	100
Vitamin B-12 (10 µmol/L)	125.5 ± 15.3*	66.2 ± 14.2*
Folic acid (10 µmol/L)	108.2 ± 10.2	95.0 ± 9.3
5-MTHF (10 µmol/L)	147.0 ± 19.6*	105.3 ± 7.6

[a]An asterisk (*) indicates $P < 0.01$.

delivered umbilical cords after treatment with collagenase. Cells were grown in M-199 supplemented with 20% FBS (Gibco, Invitrogen Corp., Carlsbad, CA) and 15 µg/mL of endothelial cell growth supplement until confluence. Dishes were trypsinized and cultured until passage 6 to 8 (14).

Kinetics of copper-catalyzed LDL oxidation. Recently dialyzed LDL (50 µg) was incubated at 37°C in PBS, pH 7.4, containing 5 µmol/L CuSO$_4$ in the absence (control) or presence of folic acid (10 µmol/L), vitamin B-12 (10 µmol/L), or 5-MTHF (10 µmol/L). The kinetics of Cu^{2+}-catalyzed LDL oxidation was followed by determining the changes in absorbance at 234 nm every 10 min for 230 min in a Shimadzu UV-160A spectrophotometer. Appropriate reagent blanks were used. Lag times (min) of conjugated diene formation (nmol/mL) were determined (15). The slopes from the curves obtained in the kinetic studies represent the oxidation rates of conjugated diene production.

Kinetics of TBARS production. LDL (100 µg/mL) were incubated at 37°C for 30, 60, and 120 min with 5 µmol/L CuSO$_4$ in PBS (1 mL final volume) in the presence of Hcy (15 or 100 µmol/L) and different 5-MTHF concentrations. At the indicated times, cold TCA was added to the tubes (5% final concentration). After centrifugation, the solution was assayed for lipid peroxides by measuring TBARS in the presence of 0.67% thiobarbituric acid and 40 µmol/L BHT. After boiling for 20 min, absorbance was measured at 530 nm. Results were expressed as TBARS production (nmol/mg LDL) using the appropriate standard solution of 1,1,1,1,-tetraethoxypropane (a malondialdehyde analog) and a molar extinction coefficient of $1.56 \times 10^5 \text{ M}^{-1}\text{cm}^{-1}$ (16).

HUVEC-mediated LDL oxidation. Human endothelial cells (3×10^5) were treated with Hcy (15 or 100 µmol/L) and 100 µg/mL LDL in the absence or presence of folic acid (100 µmol/L), vitamin B-12 (100 µmol/L), or 5-MTHF (100 µmol/L) in M-199 medium without phenol red. After 24 h, the medium was collected and assayed for lipid peroxidation by measuring TBARS as described in the preceding section.

Statistical methods. Data were analyzed using the Sigma Stat program (version 2002; Systat Software Inc., Richmond, CA). Results were expressed as the mean ± SD. Statistical differences involving multiple treatments were determined by Friedman ANOVA and the Kruskal–Wallis nonparametric tests. When treatment differences were revealed by those tests, the differences between individual treatments were determined with Dunn's *post hoc* test. The observed slopes and lag time
FIG. 1. Formation of conjugated dienes during copper-initiated oxidation of LDL: effect of folic acid, vitamin B-12, and 5-methyltetrahydrofolate (5-MTHF). LDL (50 µg/mL) was incubated at 37°C in PBS containing 5 µmol/L CuSO$_4$ and folic acid (10 µmol/L), vitamin B-12 (10 µmol/L), or 5-MTHF (10 µmol/L). Changes in absorbance at 234 nm were measured every 10 min for 230 min as described in the Materials and Methods section. Values are means of duplicates from one of three representative experiments.

TABLE 2
Effect of Different Doses of Homocysteine (Hcy) and 5-MTHF on TBARS (nmol/mg LDL) Formed During Copper-Initiated LDL Oxidation[a]

Treatment	Incubation time (min)		
	30	60	120
Control	8.5 ± 1.2	22.8 ± 2.5	73.2 ± 5.8
Hcy (15 µmol/L)	8.8 ± 1.3	9.4 ± 1.4*	10.0 ± 0.5*
Hcy (100 µmol/L)	7.2 ± 0.3	8.8 ± 0.8*	9.1 ± 0.7*
5-MTHF (10 µmol/L)	9.8 ± 1.2	12.7 ± 1.0*	75.4 ± 5.6
5-MTHF (50 µmol/L)	6.0 ± 1.3	13.5 ± 1.4*	15.3 ± 0.5*
5-MTHF (100 µmol/L)	8.9 ± 1.1	11.2 ± 1.5*	17.3 ± 1.2*

[a]An asterisk (*) indicates $P < 0.01$. For other abbreviation see Table 1.

values, expressed as percentages of control, were compared with results of the nonparametric chi-square test (Table 1). Significances are reported at $P \leq 0.05$.

RESULTS

Copper-catalyzed LDL oxidation. The kinetics of Cu^{2+}-catalyzed oxidation of LDL was followed spectrophotometrically at 234 nm to determine the lag time for conjugated diene formation. Furthermore, LDL oxidation rates were calculated, as assessed by the slope of diene formation (Fig. 1). As expected, when copper was used to initiate oxidation, increasing incubation times produced sequential elevations of the O.D. of the reaction mixtures. Figure 1 shows that only vitamin B-12 and 5-MTHF delayed conjugated diene formation, by 25 and 47%, respectively, indicating that both compounds had antioxidant properties. Folic acid did not show antioxidant properties (Fig. 1, Table 1). Interestingly, vitamin B-12, in addition to significantly increasing the lag time, also greatly reduced the oxidation rate (Table 1). In the cell-free system, the kinetics of TBARS production was followed for 2 h at 30 min intervals; as usual, Cu^{2+} was used to catalyze LDL oxidation (Table 2). Production of TBARS was highly reduced when Hcy (15 or 100 µmol/L) was added to the incubation media, an effect significant after 60 min of incubation and maintained for at least 120 min. A reduced production of TBARS also was obtained when 50 or 100 µmol/L of 5-MTHF was added to the LDL oxidation system (Table 2). This effect was observed after 60 min of incubation and was maintained for 120 min. The reduced TBARS production obtained with the lower concentration of 5-MTHF tested (10 µmol/L) was evident until 60 min of incubation, after which TBARS production reached levels similar to those observed in the control group at 2 h of incubation (Table 2).

Cell-catalyzed LDL oxidation. When HUVEC were incubated in the absence of Hcy with control buffer, folic acid, or vitamin B-12 for 24 h, there were no differences in cell-initiated LDL oxidation, as assessed by TBARS production measurements. TBARS values were in the range of 35–40 nmol/mg LDL in all the aforementioned experimental conditions (Fig. 2). Conversely, TBARS production was dramatically decreased

to approximately 6 nmol/mg LDL when cells were incubated with 100 µmol/L 5-MTHF either in the presence or absence of Hcy.
FIG. 2. TBARS production during human endothelial cell-catalyzed oxidation of LDL. Effect of folic acid, vitamin B-12, and 5-MTHF in the presence or absence of homocysteine (Hcy). Human endothelial cells (3 × 10[5]) were incubated with LDL (100 µg/mL) at 37°C for 24 h in the presence or absence of 15 or 100 µmol/L of Hcy and folic acid (100 µmol/L), vitamin B-12 (100 µmol/L), or 5-MTHF (100 µmol/L). TBARS production in the incubation media was determined as described in the Materials and Methods section. Data are expressed in nmol/mg LDL and are given as means ± SD of three separate experiments with different cell cultures (passage 3 to 6). *$P < 0.05$. For other abbreviation see Figure 1.

DISCUSSION

This study demonstrates for the first time a protective effect of 5-MTHF against *in vitro* HUVEC-catalyzed oxidation of LDL. We also demonstrate here a vitamin B-12-mediated protection against LDL oxidation; however, this effect was evident only in the copper-induced LDL oxidation system and not in the HUVEC-mediated oxidation of LDL. Furthermore, the vitamin B-12 antioxidant effect was manifested not only by increased lag times of conjugated diene production but also by reduced LDL oxidation rates. These unexpected results are difficult to explain, but it is quite possible that they are related mainly to the structural forms of vitamin B-12, which may present different oxidation states of the cobalt atom bonded to the molecule (17,18). We suggest here that the cyanocobalamin—a cob(III)alamin—used in this study, may generate "base-off" cobalamin species in water solutions (where the dimethylbenzimidazol ligand axially coordinated to cobalt is detached by protonation to the nitrogen imidazol). Base-off configuration has a tendency to change the cobalt coordination number from six to five and even to four [Co(III), Co(II), and Co(I), respectively] (19–21). Thus, the cobalt present in cyanocobalamin solutions may have +1 (I), +2 (II), and +3 (III) oxidation states. All these chemical species may participate in redox reactions involving Co(III/II) and Co(II/I) couples with different redox potentials (22). According to these antecedents, cyanocobalamin in solution may show a dynamic equilibrium among different chemical species: cob(I)alamin, cob(II)alamin, and cob(III)alamin. The presence of Cu^{2+} in the incubations as the initiator of LDL oxidation could, in our case, affect cob(I)-/cob(II)-/cob(III)alamin equilibrium to preferentially increase the cob(III)alamin oxidized form. These sequential redox reactions should also transform Cu^{2+} to Cu^{1+} to some extent. Since the low-oxidation-state copper ion is not an inducer of lipoperoxidation, the presence of this ion should not result in LDL oxidation. Thus, in our *in vitro* system vitamin B-12 might participate in sequential redox reactions that, as a result, reduce Cu^{2+} to Cu^{1+}, a condition that obviously avoids LDL oxidation. Therefore, vitamin B-12 is able to protect LDL indirectly against Cu^{2+}-initiated oxidation as a consequence of its ability to reduce Cu^{2+} to Cu^{1+}. This hypothesis could explain the lack of antioxidant effect of cyanocobalamin in the HUVEC-initiated LDL oxidation system and also the reduced copper-induced oxidation rate of LDL, an effect not elicited by 5-MTHF. This effect of cyanocobalamin could be of physiological relevance, having a therapeutic potential in several pathologies involving alterations in transition metal homeostasis and redox activity conducive to the development of neurodegenerative disorders (18,23). In addition, of main interest could be the clinical use of the most reduced forms of vitamin B-12 [cob(I)alamin], such as methylcobalamin and adenosylcobalamin (17).

In both *in vitro* oxidation systems, 5-MTHF was capable of protecting against LDL oxidation, an effect evidenced by decreased TBARS production in the incubation media. These results agree with previously published data demonstrating that 5-MTHF was able to produce a potent protective effect on the copper-mediated oxidation of LDL (12). Nevertheless, folic acid was unable to protect LDL, indicating no antioxidant properties of this folate form and suggesting that this last compound was not converted to 5-MTHF in HUVEC. Nevertheless, it is worth mentioning that most dietary folates are converted to 5-MTHF (the main circulating form of folates) in the intestinal cells (24).

Rezk *et al*. (25) recently reported that folic acid has a poor antioxidant activity in peroxynitrite scavenging and lipid peroxidation inhibition. Conversely, fully reduced folate forms such as tetrahydrofolate (THF) and 5-MTHF showed the higher antioxidant activities (25). The antioxidant activity of folates could mainly reside in the pterin moiety, being optimal when it is fully reduced. The reduced pterin moiety may have electron-donating effects that are likely involved in the antioxidant activity of THF and 5-MTHF (25,26). The antioxidant potency of 5-MTHF also may be enhanced by the methyl group present at the 5-amino group, which is able to increase the electron-donating effect of the group. This may explain the high antioxidant activity of 5-MTHF against LDL oxidation found in the present study. Although we observed an inhibition of TBARS production with 10 μmol/L 5-MTHF, this concentration was not high enough to support antioxidant activity during the whole incubation time (Table 2). In addition, the absence of a significant difference in the protective effect when 50 or 100 μmol/L of 5-MTHF was added indicates that, under our experimental conditions, a maximum protective effect could be reached in a range of concentrations greater than 10 and equal to or less than 50 μmol/L.

The relevance of these *in vitro* observations could be unclear, because the usual plasma concentration for folates is in the low nanomolar range (9), and we used relatively high concentrations of 5-MTHF in our experiments. However, is important to note that red-cell folates rise to the micromolar range after 5 mg of oral supplementation of folic acid (27).

The 5-MTHF antioxidant effect was independent of Hcy concentration, thus discarding the involvement of indirect actions of Hcy on free radical-induced oxidation of LDL. Although in this study intracellular oxidative stress was not evaluated, the lowering effects of 5-MTHF on TBARS production, together with previous results showing reduced levels of superoxide ions in 5-MTHF-treated endothelial cells (11), suggest that the 5-MTHF antioxidant effect could be related to decreased levels of intracellular reactive oxygen species (28).

This study also demonstrates that pathophysiological noncytotoxic Hcy concentrations have no effect on TBARS production in the endothelial cell system. The lack of oxidative effect of Hcy is in accordance with our previous clinical findings in mild hyperhomocysteinemic subjects (8). When copper ions were used to initiate oxidation, 15 and 100 μmol/L of Hcy reduced the generation of lipid peroxides after 60–120 min of incubation. The protective antioxidant effect of Hcy may be explained by its free radical-scavenging properties due to the presence of thiol groups, which are more evident at higher Hcy concentrations and lower incubation periods (29). The similar

inhibitory effect on TBARS production with 15 or 100 μmol/L Hcy revealed that a plateau could have been reached even with the lowest Hcy concentration used, indicating that at those incubation times, lower concentrations of Hcy should have been sufficient to reduce the copper-induced oxidative effects on LDL lipids. A previous study reported a mild increase and a decrease in lipid peroxide and TBARS production when low (6 and 25 μmol/L) or high (>100 μmol/L) Hcy concentrations, respectively, were added to a copper-induced LDL oxidation system (29). Nevertheless, in our cell-free system, 15 μmol/L of Hcy protected against LDL oxidation; this apparent discrepancy may be explained by the different incubation times used in both studies.

A protective effect of Hcy (>25 μmol/L) in a mononuclear cell system for at least 6 h of incubation was described previously (1); however, in our HUVEC-initiated LDL oxidation system, Hcy was unable to protect against LDL oxidation. Discrepancies between those results and ours could be attributable to the different cells used and to the possible oxidation of Hcy to homocystine due to the longer incubation time of our experiments (24 h). Although pro-oxidant properties of Hcy were shown previously, the experimental conditions were completely different from the ones in this study (30).

Several *in vitro* studies have demonstrated that Hcy can alter the vasoactive properties of cultured endothelial cells by impairing the production or bioavailability of some cellular mediators (31–33). However, those results were obtained with >200 μmol/L Hcy in the culture medium, a concentration that, although not deleterious for endothelial cell survival, may affect cell function (31). Since the Hcy concentrations added to the culture media were similar to those commonly found in hyperhomocysteinemic subjects (≥15 μmol/L) (8), it is suggested here that, under mild hyperhomocysteinemia, Hcy may be unable to alter LDL oxidation and perhaps other cell mediators within the endothelium.

In summary, the main results presented in this study permit us to postulate that 5-MTHF protects against oxidative modifications of LDL in endothelial cells, an effect independent of Hcy concentration. This 5-MTHF-mediated antioxidant effect may be related to a decreased oxidative stress status in endothelial cells. The finding showing the antioxidant activity of cyanocobalamin could have relevant therapeutic potential in alterations in transition metal homeostasis and redox activity conducive to several degenerative disorders and may suggest priority for the clinical use of the most reduced vitamin B-12 forms.

ABSTRACT: Ingestion of CLA activates β-oxidation and causes loss of body fat in rodents. We investigated the effects of dietary CLA on endurance capacity and energy metabolism during exercise in mice. Five-week-old male BALB/c mice were fed a control diet containing 1.0% linoleic acid or a diet containing 0.5% CLA that replaced an equivalent amount of linoleic acid for 1 wk. The maximum swimming time until fatigue was significantly higher in the CLA-fed group than in the control group. During treadmill running, the respiratory exchange ratio was significantly lower in the CLA-fed group, but oxygen consumption did not differ significantly between groups, suggesting that FA contributed more as an energy substrate in the CLA-fed mice. The muscle lipoprotein lipase activity was significantly higher in the CLA-fed group than in the control group. These results suggest that CLA ingestion increases endurance exercise capacity by promoting fat oxidation during exercise.

Paper no. L9626 in *Lipids 40*, 265–271 (March 2005).

CLA refers to a group of positional and geometric isomers derived from linoleic acid (LA). CLA is found in foods such as ruminant meats, pasteurized dairy products, and processed cheeses (1–3). Dietary CLA has many potential health benefits, such as reducing fat mass and the risk of carcinogenesis (4–8) and atherosclerosis (9,10).

Ingesting CLA for several weeks can reduce body fat content. For example, a CLA-supplemented diet (0.5–1.5% CLA) decreases adipose tissue mass in mice (11–13). The metabolic rate is higher in mice fed a CLA-supplemented diet than in mice fed a control diet for six (13) to eight weeks (14); similar results have been reported in rats (15). We previously demonstrated that a single oral administration of CLA increases serum concentrations of catecholamines and FFA, fat oxidation, and energy expenditure in mice (16). Others have reported that CLA enhances the β-oxidation of FA acids in various tissues, assessed by measuring the activity of carnitine palmitoyltransferase (CPT), the rate-limiting enzyme of the mitochondrial β-oxidation system (12,17). These results suggest that CLA reduces body fat levels by enhancing fat oxidation.

One important effect of endurance exercise training is the sparing of muscle glycogen stores during exercise through an increased ability of skeletal muscle to oxidize fat (18,19). This suggests that enhancing fat oxidation decreases carbohydrate consumption by the muscle (especially muscle glycogen) and increases endurance capacity. For example, oral administration of capsaicin increases the endurance capacity of mice by enhancing the secretion of catecholamines and the use of FA as a substrate (20). We speculated that CLA, which enhances fat oxidation, might increase endurance exercise performance. To our knowledge, no research has reported the effects of CLA on endurance exercise performance. The purpose of this study was to investigate the possible benefits of CLA as a dietary supplement to increase endurance exercise performance.

MATERIALS AND METHODS

Animals and diets. Five-week-old male BALB/c mice (Japan Shizuoka Laboratory Center, Hamamatsu, Japan) were used. The mice were housed in standard cages (33 × 23 × 12 cm) under controlled conditions of temperature (22 ± 0.5°C), RH (50%), and lighting (lights on 1800–0600 h). They were given free access to water and a control diet (1.0% LA) or a diet containing 0.5% CLA incorporated into the diet by replacing an equivalent amount (w/w) of LA. Table 1 shows the composition of the experimental diets based on the AIN-76 formulation containing CLA. This composition was described fully in our previous report (14). Food intake was recorded every 2 d. The care and treatment of the experimental animals conformed to

TABLE 1
Composition of Experimental Diets[a]

Ingredient (g/kg)	Group	
	Control	CLA
Casein	195.8	195.8
L-Methionine	3.0	3.0
Cornstarch	665.3	665.3
Soybean oil	30.0	30.0
CLA	0.0	5.0

[a]LA, linoleic acid.

the Kyoto University guidelines for ethical treatment of laboratory animals.

Materials. We used unesterified safflower LA in the control diet and synthesized CLA from unesterified safflower LA, both of which were synthesized from safflower oil and analyzed by Rinoru Oil Mills Co., Ltd. (Tokyo, Japan). The composition of samples was 17.4% palmitic acid, 2.3% stearic acid, 6.5% oleic acid, and 73.5% LA or CLA. The composition of CLA was analyzed by GC and determined to consist of 34.0% *cis*-9,*trans*-11 and *trans*-9,*cis*-11 CLA; 35.1% *trans*-10,*cis*-12 CLA; 2.5% *cis*-9,*trans*-11 and *cis*-10,*cis*-12 CLA; and 1.9% *trans*-9,*trans*-11 and *trans*-10,*trans*-12 CLA.

Maximum swimming time. In the first week, 5-wk-old BALB/c mice (*n* = 32) were made to swim for 30 min in a current with a flow rate of 5 L/min twice on two consecutive days to accustom them to swimming. The baseline swimming time to exhaustion was measured at a flow rate of 7 L/min on three occasions every 2 d. We calculated the means and SD of the three maximum swimming times and selected SD values of 10 min or less. We then eliminated the mice with the longest or the shortest mean maximum swimming times, until the final SD values approached 20% of the means. Finally, we selected 16 mice from the original 32 according to these criteria and divided them into two groups, a CLA-fed group and a control group, with equivalent average swimming times. Details of these methods have been described in a previous report (21). Mice were fasted for 2 h before the measurement of maximum swimming time. All mice were provided the control diet during the first week. In the second week, all mice, including nonexercised (sedentary) mice, were provided with the CLA diet or control diet for 1 wk and swam to exhaustion at a flow rate of 7 L/min to measure the maximum swimming time.

Organ weights and energy substrates. Mice were killed by decapitation immediately after swimming to exhaustion, with nonexercised control mice killed at the same time. Blood was rapidly collected from the neck. The gastrocnemius and quadriceps muscles; epididymal, perirenal, and inguinal fat; brown adipose tissue; and liver, heart, spleen, and kidneys were removed and weighed. The gastrocnemius and quadriceps muscles and liver were rapidly frozen in liquid nitrogen and stored at −80°C for subsequent analysis of tissue glycogen concentration and muscle lipoprotein lipase (LPL) activity. The muscle and liver glycogen contents were measured spectrophotometrically using enzymatic techniques as described elsewhere (22). Serum was obtained by centrifugation ($740 \times g$ for 10 min) and stored at −70°C until analyzed. Serum concentrations of glucose (Glucose-ARII; Wako Pure Chemical Industries, Osaka, Japan), FFA (NEFA C Test Wako; Wako Pure Chemical Industries), TG (Triglyceride G Test Wako; Wako Pure Chemical Industries), and ketone bodies (Ketone Test; Sanwa Chemical Institute, Nagoya, Japan) were measured using commercial kits.

Respiratory gas analysis. The mice not used for measuring the maximal swimming time were made to run for 30 min at 21 m/min twice during the week before the experiment to accustom them to the treadmill. This speed elicited about 60% of maximal oxygen consumption in our pilot experiment and was assumed to represent a moderate level of exercise that slightly exceeded the animals' lactic acid threshold. We selected 12 mice from the 16 nonswimmers by eliminating those mice with the highest and lowest body weights. Six days after assigning all mice to their respective groups, these mice were placed in a treadmill chamber and made to run for 42 min. The initial running speed was 6 m/min for 2 min, and the speed was increased 3 m/min every 2 min until reaching 21 m/min, after which it remained constant for 30 min. Respiratory gas was monitored throughout the run.

Apparatus. The system used to measure the swimming time to exhaustion was an adjustable-current swimming apparatus for mice. The details have been described previously (23). Briefly, an acrylic plastic pool ($90 \times 45 \times 45$ cm) was filled with water to a depth of 38 cm, the current was generated with a pump (type C-P60H; Hitachi, Tokyo, Japan), and the water temperature was maintained precisely at 34°C with an electric heater. This swimming apparatus has been used previously to evaluate the effects of food and nutrients such as capsaicin (20), an overdose of caffeine (23), hydroxycitrate (24), Nanpao® (25), and medium-chain TG (26).

The gas analyzer used to assess metabolic rate consisted of CO_2 and O_2 analyzers (model RL-600; Alco System, Tokyo, Japan), and a switching system (model ANI6-A-S; Alco System) to sample gas from each metabolic chamber. Mice were separated into two groups, and each mouse was placed in a metabolic chamber designed to measure respiratory gas. The details of the methods have been described in a previous report (24). Briefly, room air was pumped through the chambers, and expired air was dried in a thin cotton column and then directed to an O_2/CO_2 analyzer. The amounts of oxidized fat and carbohydrate were estimated from the oxygen consumption and respiratory exchange ratio (RER) values using the RL-600 software. Details of the equations have been described elsewhere (24). Data for each chamber were collected every 2 min.

The running system was a treadmill (model Simplex II; Columbus Instruments, Columbus, OH) apparatus for mice. The system consisted of three running lanes of equal dimensions ($28.8 \times 4.7 \times 4$ cm); each lane was encased in a metabolic chamber with an inside volume of ~1000 cm^3. An electric fan was used to mix the air. The system independently monitored respiratory gases for one to three mice.

Measurement of muscle LPL activity. The muscle LPL activity was measured using a fluorescent method described elsewhere (27). Samples (40–60 mg) of skeletal muscle (quadriceps) were ground in liquid nitrogen and incubated in 400 µL of Krebs–Ringer solution, 10 mM Tris-HCl buffer (pH 8.4) containing 150 mM NaCl, 2 mM EDTA, 1 g/100 mL of BSA, and 5 U (100 mg/L) heparin (28), with gentle shaking at 25°C. After 30 min, the tissue was removed from the medium by centrifugation for 5 min ($8,300 \times g$), and the supernatant was used to measure LPL activity using a commercial kit that includes a nonfluorescent substrate emulsion that becomes intensely fluorescent upon interaction with LPL (Roar Biomedical, New York, NY). The total protein content of each sample was measured by the Bradford method with Coomassie brilliant blue
FIG. 1. The maximum swimming time to fatigue in BALB/c mice measured at baseline and after 1 wk. Mice were fed either a diet containing 0.5% CLA or a control diet for 1 wk. Values are means ± SE for eight mice. Swimming capacity was measured at a flow rate of 7 L/min. *Significant difference between groups (*P* < 0.05, unpaired Student's *t*-test).

solution. LPL activity was assessed relative to the protein content of the tissue.

Statistical analysis. Data are expressed as means ± SEM. Student's *t*-test was used to compare the two dietary groups after dietary intervention. Analyses were performed with the StatView software package (Macintosh Version J 5.0; Abacus Concepts, Berkeley, CA); *P* < 0.05 was accepted as significant.

RESULTS

Food intake did not differ significantly between the two dietary groups. The accumulated 7-d food intake was 24.8 ± 1.5 g/mouse (3.5 g/mouse per day) in the CLA-fed group and 25.4 ± 1.4 g (3.6 g/mouse per day) in the control group. Swimming endurance did not differ significantly between the control and CLA-fed groups before the start of dietary intervention (Fig.

1). After 1 wk of the control diet or the diet containing 0.5% CLA, swimming endurance capacity was significantly higher, by 25%, in CLA-fed mice than in control mice (Fig. 1). The maximal swimming time of the control group was similar before and after dietary intervention.

Oxygen consumption during running did not differ between the two dietary groups (Fig. 2A). The RER increased throughout the first 20 min and then decreased in both groups and was significantly lower in CLA-fed mice than in control mice (Fig. 2B). Fat oxidation, calculated from the RER and oxygen consumption, was consistently higher in the CLA group than in the control group (Fig. 3A). Carbohydrate oxidation during the 42-min run was lower in the CLA group than in the control group (Fig. 3B).

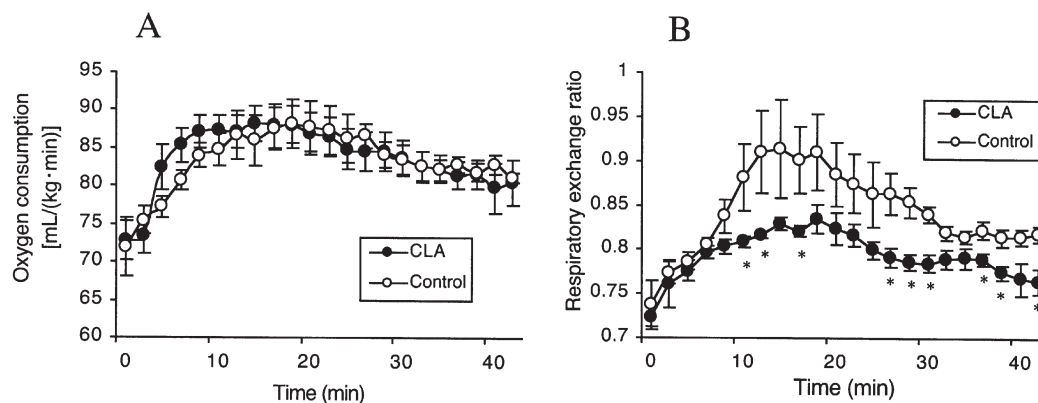
Sedentary mice were included as an indicator of the nonexercised, resting state. The body weight of sedentary mice did not change significantly after the week of dietary intervention. The weights of adipose tissue from various sites, including epididymal fat, perirenal fat, inguinal fat, and brown adipose tissue, were significantly lower in the sedentary CLA-fed mice than in the sedentary control mice (Table 2). Similar trends (i.e., lower adipose tissue weights in CLA-fed mice) were observed in mice sacrificed after swimming to fatigue (data not shown). In sedentary mice, serum glucose concentrations did not differ significantly between the two dietary groups. The serum concentrations of FFA and ketone bodies were significantly lower, and serum TG concentration tended to be lower in the sedentary CLA group than in the sedentary control group (Table 3). Similar trends (i.e., lower concentrations of FFA, ketone bodies, and TG) were observed in CLA-fed mice sacrificed after swimming to fatigue, but these values did not differ significantly. After swimming to fatigue, the serum glucose concentrations of the control and CLA-fed groups were higher than in their respective sedentary groups, and the serum concentrations of FFA, ketone bodies, and TG were significantly higher in the CLA-fed mice than in the CLA-fed sedentary


FIG. 2. Oxygen consumption (A) and respiratory exchange ratio (B) during treadmill running in BALB/c mice fed the 0.5% CLA-containing diet for 6 d. Values are means ± SE for 5–7 mice that ran in the treadmill chamber for 42 min. The initial running speed was 6 m/min, and speed was increased 3 m/min every 2 min until it reached 21 m/min, after which it remained constant. *Significant difference between groups (*P* < 0.05, unpaired Student's *t*-test).
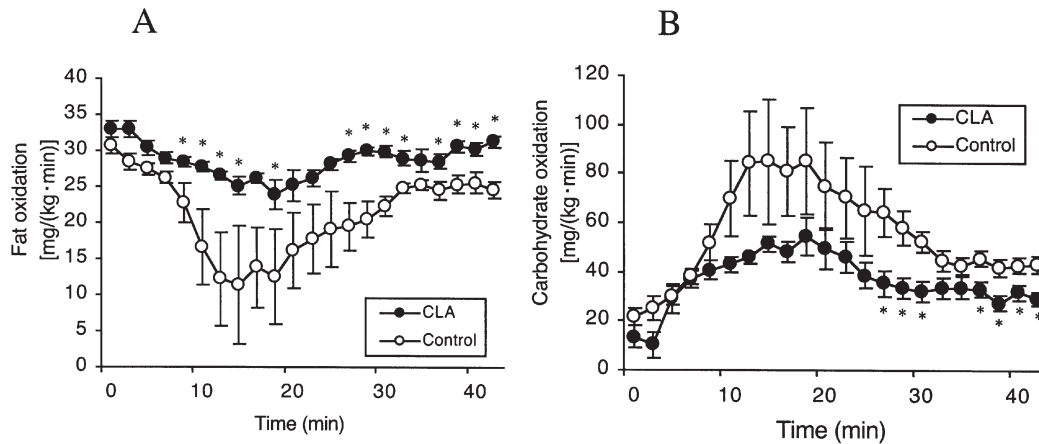

FIG. 3. Fat oxidation (A) and carbohydrate oxidation (B) during treadmill running in BALB/c mice fed the 0.5% CLA-containing diet for 6 d. Values are means ± SE for 5–7 mice that ran in the treadmill chamber for 42 min. The initial running speed was 6 m/min, and speed was increased 3 m/min every 2 min until it reached 21 m/min, after which it remained constant. Fat and carbohydrate oxidation were calculated from the respiratory exchange ratio and oxygen consumption (24). *Significant difference between groups ($P < 0.05$, unpaired Student's *t*-test).

group. The concentrations of liver and gastrocnemius muscle glycogen did not differ between dietary groups in the sedentary mice or in the exercised mice (Table 4).

LPL activity was measured to determine whether CLA feeding increased fat oxidation in skeletal muscle. LPL activity in skeletal muscle was significantly higher after swimming to fatigue in the CLA group than in the control group (Fig. 4); LPL activity also tended to be higher in the sedentary CLA-fed mice than in the sedentary control mice (data not shown).

DISCUSSION

Previous studies (11–13) demonstrated that CLA supplementation causes weight loss in rodents; we reported previously that CLA supplementation decreases body weight and adipose tissue weight in a dose-dependent manner (14). These changes appear to be independent of diet and have been found with high-fat and high-carbohydrate diets (13). This reduction in body fat is not related to energy intake (29,30). It has been speculated that the reduction in fat mass reflects an increase in energy expenditure and fat oxidation (12). Our previous study showed that oxygen consumption increased in mice fed a diet containing 1.0% CLA for 8 wk (14). Several investigators have reported that CLA enhances CPT activity in some tissues, indicating a greater efficiency of FA oxidation. Greater CPT activity in skeletal muscle (12,17), brown adipose tissue, and liver (17) may inhibit TG storage in adipose tissue and decrease fat accumulation. A previous study showed that a single oral administration of CLA increased both fat oxidation and oxygen consumption in mice (16).

During moderate-intensity exercise, muscle uses circulating FFA, extramuscular glucose, muscle TG, and muscle glycogen as substrates (31–33). The amount of glycogen stored in working muscles is an important determinant of endurance exercise capacity (34). Increased fat utilization during endurance exer-

cise improves endurance capacity by sparing muscle glycogen stores (35,36). For example, caffeine elevates the plasma concentration of FFA and decreases the rate of glycogen depletion during exercise, enhancing fat oxidation and decreasing muscle glycogen utilization (37). We found that 1 wk of the CLA diet significantly increased endurance capacity in mice. To determine whether enhanced fat use caused the increase in endurance capacity, we analyzed the respiratory gas of mice running in the treadmill chamber. Analysis of respiratory gas enables one to evaluate energy metabolism continuously during exercise. As expected, during running, estimated fat oxidation was higher and estimated carbohydrate oxidation lower in the CLA group than in the control group (Fig. 3). These data suggest that the increase in endurance capacity was caused by enhanced fat utilization during exercise. We did not examine the muscle glycogen concentration continuously during exercise because it was difficult to include enough swimming mice in this protocol. However, two studies have reported increased en-

TABLE 2
Body Weight and Organ Weights in Mice Fed 0.5% CLA-Containing Diet or the Control Diet for 1 wk[a]

Variable (g)	Control	CLA
Body weight	22.9 ± 0.5	22.7 ± 0.6
Gastrocnemius	0.244 ± 0.007	0.252 ± 0.006
Quadriceps	0.354 ± 0.006	0.367 ± 0.012
Liver	1.217 ± 0.048	1.318 ± 0.038
Heart	0.119 ± 0.004	0.123 ± 0.004
Spleen	0.098 ± 0.005	0.099 ± 0.005
Kidney	0.383 ± 0.016	0.393 ± 0.009
Perirenal fat	0.170 ± 0.014	0.064 ± 0.003*
Epididymal fat	0.351 ± 0.022	0.175 ± 0.009*
Brown adipose tissue	0.085 ± 0.003	0.061 ± 0.005*
Inguinal fat	0.237 ± 0.018	0.099 ± 0.012*

[a]Values are means ± SE for 7–9 mice. *Significantly different from control group ($P < 0.05$).

TABLE 3
Serum Concentrations of Substrates in Mice Fed 0.5% CLA-Containing Diet or the Control Diet for 1 wk[a]

	Sedentary		Swimming to Fatigue	
	Control	CLA	Control	CLA
Glucose (mg/dL)	153.4 ± 4.2	172.3 ± 2.8	$199.5 \pm 2.8^{\dagger}$	$222.4 \pm 2.8^{\dagger}$
FFA (mEq/L)	1.23 ± 0.05	$0.78 \pm 0.03^*$	1.22 ± 0.02	$1.08 \pm 0.02^{\dagger}$
Ketone body (mg/dL)	369.3 ± 30.4	$135.5 \pm 19.89^*$	381.4 ± 12.4	$288.5 \pm 10.2^{\dagger}$

[a]Values are means ± SE for 7–9 mice.

durance swimming capacity after feeding capsaicin (20) and hydroxycitric acid (24), and both proposed that the increased endurance capacity might be caused by increased fat utilization during exercise, which spared muscle glycogen. We believe that CLA produced a similar effect in our study.

The blood lactic acid threshold correlates with the exercise intensity that produces excess lactic acid and reflects increasing reliance on carbohydrate utilization, because lactic acid is produced only by anaerobic glycolysis. The blood pH is constantly adjusted within a relatively narrow range, and carbon dioxide is liberated from carbonate in the blood, which helps maintain pH when lactic acid accumulates in the blood during intense exercise. The liberated carbon dioxide is expired from the lungs, increasing the RER. RER was lower during exercise in the CLA group than in the control group, indicating greater use of FFA and less of carbohydrate as a substrate; we speculate that blood lactic acid concentration was also lower during exercise in the CLA group.

The mechanism responsible for the enhanced fat oxidation induced by CLA remains unclear. LPL activity was significantly higher in the CLA group than in the control group. Blood TG is hydrolyzed by LPL in the muscle capillaries, releasing FA that are taken up by skeletal muscle. LPL activity in skeletal muscle increases after exercise training (38). Several investigators have reported that CLA enhances CPT activity (12,17). In addition, increased muscle LPL activity may play a role in enhanced FA oxidation in skeletal muscle. Previous studies have shown that CLA inhibits LPL activity in a dose-dependent manner in 3T3-L1 adipocytes (12) and that LPL activity in adipose tissue decreases in mice fed CLA for 4 d (39). It has been suggested that LPL is regulated independently in various tissues; for example, Ong *et al*. (40) reported that exercise training increased LPL activity in skeletal muscle but not

in adipose tissue and heart. Our results, showing an increase in LPL activity in skeletal muscle in the CLA group, are consistent with those obtained in adipose tissue. It is possible that CLA inhibits lipogenesis in adipose tissue and promotes fat oxidation in skeletal muscle.

In this study, the serum concentration of ketone bodies was lower in the sedentary CLA group than in the sedentary control group (Table 3). Ketone bodies are produced in the liver from FA and oxidized in extrahepatic tissue; enhanced oxidation of ketone bodies in the extrahepatic tissue in the CLA group might be responsible for the CLA-mediated reduction of the serum concentration of ketone bodies. Similarly, the serum
FIG. 4. Muscle lipoprotein lipase (LPL) activity after swimming to fatigue in BALB/c mice fed the 0.5% CLA-containing diet for 1 wk. Values are means ± SE for 6–7 mice. *Significant difference between groups ($P < 0.05$, unpaired Student's *t*-test).

concentration of FFA was lower in the sedentary CLA group than in the sedentary control group. Our data are consistent with those from a previous report, which speculated that the lower serum concentration of FFA might have been caused by decreased adipose tissue mass in the CLA group (15).

Several isomers of CLA act as high-affinity ligands and activators of peroxisome proliferator-activated receptor (PPAR)α (41). CLA may stimulate fat oxidation by inducing PPARα, which plays an important role in fat metabolism. PPARα regulates acyl-CoA oxidase, cytochrome P4504A1, and liver FA-binding protein (42), which may activate the oxidation of body fat. However, dietary CLA reduces adipose tissue weight and induces some PPAR-responsive genes in liver to a similar extent in PPARα-null mice fed a diet containing CLA and in wild-type mice (43). It is possible that CLA modulates fat metabolism *via* mechanisms involving other isoforms of PPAR. For example, it has been reported that CLA increases PPARγ mRNA in adipose tissue (44).

There appears to be an isomer-specific effect of CLA. The *trans*-10,*cis*-12 CLA isomer is much more effective at lowering adipose tissue mass than the *cis*-9,*trans*-11 CLA isomer in mice (45) and rats (15), and *trans*-10,*cis*-12 CLA appears to be the effective isomer for modulating gene expression in cultured 3T3-L1 preadipocytes (46). To ensure consistency between studies, we used the same mixture of CLA in this study as in our previous experiments (14,16). It is possible that our results are due to the *trans*-10,*cis*-12 CLA contained in the mixture.

In humans, the effects of CLA on weight loss are inconclusive at present (47–50), most likely because the dosages of CLA relative to body weight were lower in human than in animal studies. Our dosage was 0.9 g/kg, and the dosage used in other studies on mice was about 1.0 g/kg, whereas the highest reported dosage in humans was 6.8 g/d (0.075 g/kg body weight) (47). Thus, CLA might not reach the effective dosage in humans. However, two studies have shown that these doses were adequate to increase insulin resistance, lipid peroxidation, and inflammation in humans (51,52). In human studies, supplementation with high doses should be conducted carefully until further information becomes available on the effects and adverse side effects of CLA. It is also possible that the effectiveness differs between isomers according to species because the mechanism underlying the action of CLA is not clearly known. Furthermore, Ohnuki *et al.* (16) suggested that CLA enhances sympathetic nervous activity and energy metabolism. The marked effects of CLA in rodent models could arise *via* activation of brown adipose tissue by enhanced sympathetic nervous activity, an effect that would not occur in older humans. At present, we cannot rule out brown adipose tissue as a cause of weight loss in CLA-fed rodents.

In summary, feeding mice a diet containing 0.5% CLA for 6 to 7 d increased endurance exercise capacity and fat oxidation and reduced RER and carbohydrate utilization during exercise. Muscle LPL activity increased in CLA-fed mice, suggesting that LPL plays a role in enhancing FA oxidation. These results suggest that the increase in endurance capacity induced by CLA feeding in mice might be explained by the promotion of fat oxidation during exercise.

Size and Number of Lymph Particles Measured by a Particle Sizer During Absorption of Structured Oils in Rats

Trine Porsgaard*, Jirí Kánský, Sarah Mason, and Huiling Mu

BioCentrum-DTU and Center for Advanced Food Studies (LMC),
Technical University of Denmark, 2800 Lyngby, Denmark

ABSTRACT: Chylomicrons transport absorbed fat from the intestine to the circulation. During dietary fat absorption, the chylomicrons become larger in diameter, and in some studies an increase in chylomicron number has been observed as well. In the present study, we compared particle size and number in rat lymph following administration of four different oils. We administered fish oil, medium-chain TAG (MCT), and two structured oils differing in intramolecular structure, with either medium-chain FA in the outer positions of the TAG and long-chain n-3 PUFA in the *sn*-2 position (MLM oil) or with the reverse structure (LML oil), to lymph-cannulated rats and collected lymph in fractions for the following 8 h. Chylomicron size was measured by a particle size analyzer immediately after collection, and from these data the number of chylomicrons present was estimated. The number of particles in lymph increased during the absorption of oils containing long-chain PUFA (MLM, LML, and fish oil), whereas it was not affected by administration of MCT. The FA from MCT were probably absorbed *via* the portal vein; therefore, only a small number of particles were measured in lymph. When comparing the two structured oils, we observed a tendency toward a higher number of particles after LML administration, although the difference was not statistically significant. The highest number of particles after administration of all oils was observed in the size intervals 53–80 and 80–121 nm and probably represented small chylomicrons. Thus, the FA composition influenced the number of particles in lymph during absorption, whereas TAG structure had only a minor influence.

Paper no. L9665 in *Lipids 40*, 273–279 (March 2005).

Chylomicrons are the transport vehicles for intestinally absorbed fat, and the FA composition of the chylomicrons reflects the FA composition of dietary fat. During absorption, chylomicrons are formed in the enterocytes, are released to the lymphatics, and then enter the circulation. Chylomicron formation can be regulated through changes in the size and number of particles secreted to the lymph. Some studies suggest that chylomicron size depends mainly on the amount of fat absorbed and transported to the lymphatics, and that during fat absorption the particles increase in diameter (1–3). Hayashi *et al.* (2) observed that infusion of triolein in rats increased the size but not the number of chylomicrons produced by the small intestine. The size of the chylomicrons formed during absorption may be influenced by the degree of saturation of the dietary fats, since studies have shown that absorption of unsaturated fats produces larger chylomicrons compared with absorption of saturated fats (1,4,5). Some studies have suggested an influence on chylomicron number during absorption of dietary fat as well. Kalogeris and Story (4) suggested that feeding different fat sources influences the number of chylomicrons produced, since they observed a greater phospholipid output in rat lymph during infusion of butter oil compared with infusion of corn oil. Degrace *et al.* (6) observed that chylomicrons were large after administration of a bolus of corn oil to lymph-cannulated rats and were small and more numerous after cod liver oil administration. This means that diverse results have been obtained regarding the size and number of chylomicrons produced during absorption.

Differences in the FA composition and structure as well as differences in the size of chylomicrons in response to dietary lipids affect the clearance of these TAG-rich lipoproteins in plasma (1,7–9), and this may further influence the extent of the postprandial lipemia. Zilversmith (10) suggested that raised levels of chylomicrons and chylomicron remnants, which circulate following a meal, play a role in the development of atherosclerosis. Furthermore, Levy *et al.* (1) suggested that large chylomicrons are removed faster than smaller ones. This fast removal could be the reason for the low plasma TAG level observed after feeding diets rich in unsaturated fats, since unsaturated FA give rise to large chylomicrons. Contrary to this result, Martins *et al.* (8) found that when a similar number of particles were injected into rats, the small particles were removed faster than the large particles. These differences may be the result of differences in experimental design.

The effect on chylomicron composition, size, and number of differences in intramolecular structure of dietary TAG has been investigated in several studies. Aoe *et al.* (11) showed that the positional distribution of FA influenced the size and composition of chylomicrons in rats but not the number of chylomicrons during absorption. In contrast to this study, Carvajal *et al.* (12) observed no effect of different dietary TAG structures on chylomicron size. Previously performed studies on lymphatic absorption of structured lipids showed that the TAG structure influenced the absorption of dietary lipids (13–15) and thereby may influence the clearance of chylomicrons from circulation.

Abbreviations: LML, specific structured TAG (M = medium-chain FA, L = long-chain FA); MCT, medium-chain TAG; MLM, specific structured TAG (M = medium-chain FA, L = long-chain FA).

The aim of the present study was to compare the size and number of lymph particles produced during absorption of a bolus of structured TAG containing decanoic acid (10:0) and n-3 PUFA of marine origin. Animal and human feeding studies have revealed that the intake of diets rich in n-3 PUFA has important effects on postprandial lipemia and lipoprotein metabolism, as reviewed by Harris (16). Two structured TAG were produced by enzymatic interesterification, giving rise to TAG with different intramolecular structures, and the impact of these structures on lymph particle size and number was compared with the impact of fish oil and a medium-chain TAG (MCT). The absorption of oils was followed for 8 h with frequent collection of lymph fractions. In most studies involving chylomicron size determinations, the usual approach has been to examine the lymph particles by electron microscopy followed by measurements of particle diameter (1,5,6,11,12). In the present study, we analyzed the lymph fractions immediately after collection using a particle sizer (Mastersizer 2000; Malvern Instruments, Malvern, Worcestershire, United Kingdom). The laser diffraction technique is rapid and can measure many particles, thereby reducing the time for analysis by severalfold in comparison with electron microscopy. The particle sizer determined the drop size distribution based on the scattering pattern produced by particles moving through the path of a laser beam. From the particle size and lymph volume, the number of particles in each fraction was calculated. We are not aware of this technique being used to determine the size of lymph particles, and this could be an area to pursue further. However, Leuschner *et al.* (17) reported good agreement between a laser light-scattering method using a Malvern Mastersizer and a scanning transmission electron microscopy method used to measure particle size distributions of *Bacillus* spore suspensions with a median size of 900 nm.

MATERIALS AND METHODS

Experimental oils. Fish oil was purchased from Aarhus United A/S (Aarhus, Denmark), and MCT was from Grünau GmbH Illertissen (Illertissen, Germany). Two specific structured oils were produced by enzymatic interesterification. MLM (where M = medium-chain FA and L = long-chain FA) was made by a specific reaction between enriched fish oil (Epax 4510 TG; Pronova Biocare a.s., Lysaker, Norway) and 10:0 (Henkel Kimianika Sdn. Bhd., Selangor, Malaysia) catalyzed by Lipozyme RM IM (Novozymes, Bagsværd, Denmark), resulting in regiospecific TAG with n-3 PUFA mainly in the *sn*-2 position. LML was produced by a specific reaction between tri-10:0 (Grünau GmbH Illertissen) and ethyl esters produced from marine oils (Epax 6000 EE containing ~60% n-3 FA; Pronova Biocare) catalyzed by Lipozyme RM IM, resulting in regiospecific TAG with n-3 PUFA mainly in the *sn*-1,3 positions. The interesterifications were performed in a packed-bed reactor, and the products were purified by short-path distillation (18,19). The FA composition of TAG and the structure of TAG represented by the FA composition in *sn*-2 MAG (Table 1) were measured as described previously (20).

Housing of animals. Male Specific Pathogen-Free Wistar rats (Taconic M&B, Ll. Skensved, Denmark) were housed two per plastic cage in a temperature- (21°C) and humidity- (50%) controlled environment on a 12 h/12 h light/dark cycle with a standard nonpurified diet (Altromin No. 1324; Chr. Petersen A/S, Ringsted, Denmark) and with water freely available. They were acclimatized to the housing conditions for 10 d before surgery and weighed 250–310 g at the time of surgery. The experiment was approved by the Danish Committee for Animal Experiments.

[a]Values are the mean of two determinations for FA composition and three determinations for *sn*-2 MAG. A dash (—) means not detected. 20:1 includes the isomers of n-9 and n-7, whereas 22:1 includes the isomers of n-11 and n-9.

Surgery of rats. Rats were anesthetized i.m. with a Zoletil mixture (0.06 mL/100 g; The Royal Veterinary and Agricultural University, Copenhagen, Denmark) and were subjected to cannulation of the main mesenteric lymph duct (21) with a clear vinyl tube (o.d. 0.8 mm, i.d. 0.5 mm; Critchley Electrical Products, New South Wales, Australia). A silicone feeding tube (o.d. 3.0 mm, i.d. 1.0 mm; Polystan, Værløse, Denmark) was inserted into the fundus region of the stomach and fixed with a purse-string suture. After surgery, the rats were placed in individual restraining cages at 25°C (22) with tap water freely available but without food and with a steady infusion of saline–glucose (0.15 M NaCl, 0.004 M KCl, and 0.28 M glucose) at 2 mL/h through the feeding tube. After surgery, the rats were given 0.05 mL of antidote (atipamezol hydrochloride, 5 mg/mL; Antisedan, Orion, Espoo, Finland). To reduce pain and stress, the rats received 0.3 mL of Rimadyl (carprofen, 50 mg/mL, diluted 1:10 with sterile water; Pfizer, Ballerup, Denmark) and 0.2 mL of Stesolid (diazepam, 5 mg/mL; Dumex-Alpharma A/S, Copenhagen, Denmark) after the operation and then regularly during the experiment.

Collection of lymph and administration of oil. Lymph collection was initiated in the afternoon after the operation, and an overnight fraction of lymph [with 0.7 mL of a 10% (wt/vol) Na$_2$ EDTA solution (E. Merck, Darmstadt, Germany) added to prevent coagulation] was collected to obtain a baseline fraction. In the morning on the first postoperative day, a sonicated emulsion of 0.5 mL of oil and 0.5 mL of a solution containing 20 mM taurocholate (Sigma, St. Louis, MO) and 10 mg/mL choline (Sigma) in distilled water was given as a bolus injection through the feeding tube followed by 0.5 mL of saline, and the infusion of saline–glucose was continued at 2 mL/h. Lymph was collected in tubes containing 100 or 200 μL of the EDTA solution in the following fractions: 0–2, 2–3, 3–4, 4–6, and 6–8 h after oil administration. Immediately after collection, the samples were analyzed by a particle sizer.

Particle-sizing procedure. Lymph samples were analyzed using a Mastersizer 2000 (Malvern Instruments Ltd.) with both the red light source (a helium–neon laser) and the blue solid-state light source. Dispersed droplets and particles in the size range of 20 nm to 2,000 μm can be measured, which is suitable for chylomicrons that have an expected size range of between 40 and 300 nm. The measured light-scattering pattern is assumed to come from spherical droplets, which is not a limitation in this case since the chylomicrons were expected to be spherical. The general purpose analysis model for unimodal drop size distributions was selected. A refractive index of 1.33 was used for the dispersant (distilled water); the particle refractive index was 1.470 and the absorption value was 0.01, which are the values for milk fat. The measurement procedure was as follows: First, 100 mL of distilled water was added to the Hydro SM dispersing unit, the stirrer was set at 2,500 rpm, and background calibration with water was initiated. Lymph fractions were weighed, and the entire fraction (4 or 10 mL for baseline fractions) was added and stirred for 1 min before beginning measurements. Three measurements were made on a sample as it circulated in the Hydro SM unit to confirm that the

size distribution of the sample did not change with time during measurement.

Calculation of particle number. Chylomicron samples of between 1 and 4 mL were dispersed in 100 mL of water for measurement in the Mastersizer 2000. The sizer measured a volume concentration, c, which was equal to the volume of particles in the measurement system divided by the total volume of liquid in the system. The volume of particles present can be calculated using Equation 1:

$$V_P = c(V_1 + V_2) \qquad [1]$$

where V_P is the volume occupied by the particles in the system, V_1 is the volume of the sample aliquot containing the chylomicrons that was added to the sizer, and V_2 is the volume of water used to disperse the sample. Volume $V_1 = V_P + V_m$, where V_m is the volume of the saline and EDTA solution mixture in which the particles are suspended.

The sizer also measures the volume fraction, R_i, of particles with an average diameter D_i present in size interval i. The volume of particles in size interval i is

$$V_i = R_i V_P \qquad [2]$$

whereas for spherical particles it is

$$V_i = N_i \pi D_i^3/6 \qquad [3]$$

where N_i is the number of particles present in that size interval. Combining Equations 1, 2, and 3 gives

$$N_i = (6R_i/\pi D_i^3)c(V_1 + V_2) \qquad [4]$$

For these experiments, V_2 was 100 mL (±2 mL), and V_1 was between 1.00 and 4.00 mL. The weight of the sample aliquot containing the chylomicrons in grams was set equal to its volume in milliliters when using Equation 4, since the fraction of chylomicrons in the sample aliquot was less than 2% by volume. The total number of particles in the sample is the sum of the number of particles present within each individual size interval.

Since samples were collected over time periods of either 1 or 2 h, the number of particles measured was standardized to a time interval of 1 h for all comparisons.

Statistics. Data represent the mean ± SEM of 5 rats in each group. Differences in lymph flow between the baseline and maximum flow rate in the different groups were tested using a *t*-test. To test differences between groups in the total number of lymph particles and in the number of particles in different size intervals, one-way ANOVA with Tukey's multiple comparison post test was performed using GraphPad Prism, version 3.02 (GraphPad software, San Diego, CA).

RESULTS

Particle size distribution curve. An example of a particle size distribution curve obtained from the Mastersizer instrument
FIG. 1. Particle size distribution curve in lymph after administration of MLM (specific structured TAG, where M = medium-chain FA and L = long-chain FA) as obtained from the Mastersizer instrument (Malvern Instruments Ltd., Malvern, Worcestershire, United Kingdom). Volume percentage is plotted as a function of particle size in nanometers. The vertical lines indicate the focus region for further analysis. The coding refers to animal 5, fraction number 2 or 5, along with a measurement reference code.

FIG. 2. Total particle number in lymph in relation to the fraction after administration of MLM, LML (specific structured TAG, where M = medium-chain FA and L = long-chain FA), medium-chain TAG (MCT), or fish oil. Data represent mean ± SEM.

after administration of MLM oil is shown in Figure 1. The major peak was in the interval 40–1,000 nm, representing lipoproteins in the lymph. In some measurements we also observed a much smaller but broader peak in the size interval 10,000–100,000 nm representing cells. Since this peak did not interfere with the size measurements of the lipoproteins, we decided not to use a centrifugation step to remove the cells and thereby kept the method as simple as possible.

FA composition of TAG and in the sn-2 position of oils. The MLM and LML oils had almost the same content of major FA in the TAG, with 40 mol% of 10:0 and 34–36 mol% of long-chain n-3 PUFA (EPA, 20:5n-3, and DHA, 22:6n-3), but the structure represented by the FA in the *sn*-2 position of TAG differed, with high contents of 20:5n-3 and 22:6n-3 in the MLM oil and a high content of 10:0 in the LML oil (Table 1). MCT contained octanoic acid (8:0) and 10:0, and the fish oil had high contents of palmitic acid (16:0), oleic acid (18:1n-9), 20:5n-3, and 22:6n-3 with enrichment of the n-3 PUFA in the *sn*-2 position.

Lymph flow. Lymph flow at the baseline represented by lymph collected during the night following surgery, where rats were in the fasting state, was 1.5 ± 0.1 mL/h for all rats with no differences between groups. As a result of fat administration, the lymph flow increased significantly ($P < 0.05$) compared with the baseline flow. Maximum flow rates were observed in the fraction at 0–2 h for MLM, MCT, and fish oil, with values reaching 2.4 ± 0.2, 2.0 ± 0.3, and 2.5 ± 0.3 mL/h, respectively, whereas the maximum flow rate after LML administration was in the fraction at 2–3 h, reaching a value of 2.7 ± 0.2 mL/h.

Particle size and numbers in lymph. Although slight differences in particle size distribution were observed among the four oils, the difference in *c* differed greatly, indicating that the number of particles collected in the different fractions differed. Therefore, the volume distribution was converted to a number distribution, and the number of particles in the different frac-

tions collected was calculated as described in the Materials and Methods section. In the baseline fractions, the total number of particles was between 1.0^{14} and 1.2^{14} (Fig. 2). Compared with the number at baseline, the number of particles following fat administration increased severalfold for the MLM, LML, and fish oil groups, whereas MCT administration resulted only in a small, nonsignificant increase in particle number. The highest number of lymph particles after fish oil administration was observed in the 2–3 h fraction, after MLM and LML administration in the 3–4 h fraction, and after MCT administration in the 4–6 h fraction. In most fractions, except baseline and 0–2 h, the total number of particles after MCT administration was significantly lower compared with the other fats ($P < 0.05$). The highest number of particles was observed after LML administration, although this number was not significantly different from those after MLM and fish oil administration.
The number of particles in each size interval was very low for all four oils in the baseline fraction (Fig. 3). Following lipid administration, the number in each size interval increased dramatically within the first 2 h after MLM administration, more slowly after LML and fish oil administration, and even more slowly after MCT administration; the highest number was reached in the last two fractions from 4 to 8 h. Lipid absorption resulted primarily in increases in particle numbers in the size intervals 53–80 and 80–121 nm and in minor increases in the other size intervals. No particles were observed with sizes larger than 270 nm. Administration of MCT resulted in very few particles of sizes of 158–182 and 182–270 nm, whereas the other oils led to increases in the number of particles in the intervals of larger particle size as well.

DISCUSSION

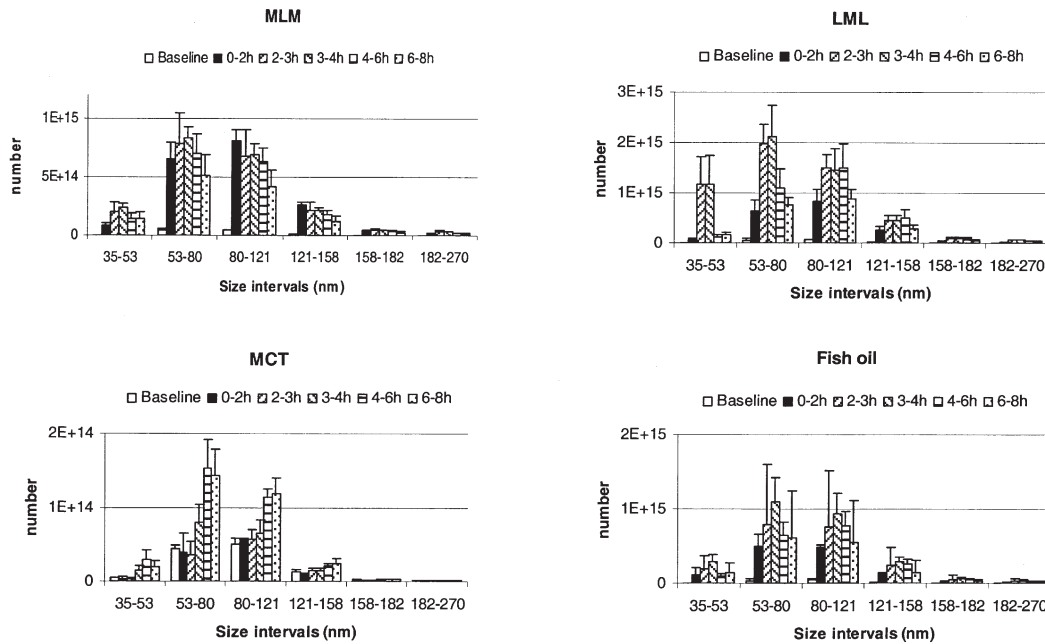
Our results suggest that the number of particles in lymph increased during the absorption of lipids containing long-chain PUFA, but not during administration of MCT. Lipids containing long- and medium-chain FA positioned differently on the TAG molecule gave similar numbers of lymph particles,


FIG. 3. Number of particles in different size intervals and in the different fractions after administration of MLM, LML, MCT, or fish oil, respectively. Data represent mean ± SEM. Notice the different scales in the four figures. For abbreviations see Figures 1 and 2.

although there was a tendency toward a higher number with the LML oil compared with the MLM oil. The highest number of particles was observed in the size intervals of 53–80 and 80–121 nm. The size of lymph particles was easily measured by a particle sizer immediately after collection. This method was fast and without time-consuming sample preparation.

Dietary TAG are hydrolyzed in the intestinal tract by the preduodenal lipases and the pancreatic lipase into *sn*-2 MAG and FFA (23,24). The hydrolysis products are absorbed into the enterocytes, with high conservation of the FA located in the *sn*-2 position of the dietary fat (25). In the enterocytes, the *sn*-2 MAG are reesterified with FA of exogenous and endogenous origin to form a new population of TAG; these are packed into chylomicrons and secreted to the lymph. Because of the high polarity of short- and medium-chain FA, the low affinity for the cytosolic FA-binding proteins, and the low activation to CoA esters, these are primarily absorbed *via* the portal vein for oxidation in the liver (26), with less absorption through the lymphatic system as the chain length of the FA becomes shorter (27). The MCT used in this study contained 62 mol% 8:0 and 36 mol% 10:0. With this FA composition, it was expected that the oil would primarily be absorbed *via* the portal vein (26,27), and this was probably the reason we did not observe an increase in number of lymph particles following administration of MCT. Although no obvious maximum number of lymph particles was observed after MCT administration, the highest number occurred in the last two fractions that were collected in the experiment. The *sn*-2 MAG from the hydrolysis of MCT were absorbed into the enterocytes for TAG resynthesis, whereas the FFA primarily were led to the portal vein; this may have caused a shortage of FA for TAG resynthesis in the enterocytes. There-

fore, endogenous FA stores had to be mobilized before TAG resynthesis could take place, and this may be the cause for the delay in the maximum number of lymph particles after MCT administration.

Structured TAG may combine the advantages of the easily digested and absorbed MCT with the delivery of different PUFA with specific effects in the body. In the present study, we combined medium-chain FA with n-3 PUFA of marine origin. A high intake of n-3 PUFA has been correlated with beneficial effects on the plasma lipid profile, leading to a low incidence of coronary heart disease (16,28). Furthermore, n-3 PUFA were shown to influence brain and visual development during infancy (29) and to have immunomodulatory effects (30). The interest in these effects has led to studies on the potential benefits of structured TAG containing n-3 PUFA. In the present study, we compared the effects of MLM and LML structured lipids with n-3 PUFA on lymph particle size and number. Both oils resulted in increases in the number of particles during absorption, and there was a tendency toward a higher number of particles following LML administration. Because of the structure of MLM, we expected that parts of the medium-chain FA hydrolyzed from the outer positions of the TAG would be absorbed *via* the portal vein and therefore result in less FFA for resynthesis in the enterocytes, and thus in a lower number of lymph particles compared with LML. Furthermore, a shortage of FFA for the resynthesis of TAG after MLM administration could explain why the maximum number of lymph particles was not observed before the 3–4 h fraction. The maximum number of particles was observed in the same fraction after LML administration. The tendency for acyl migration is higher when medium-chain FA are located in the *sn*-2 position of TAG

(13) compared with long-chain FA in the *sn*-2 position (25). This could lead to a shortage of *sn*-2 MAG, which would delay TAG resynthesis in the enterocytes. Fish oil was enriched with n-3 PUFA in the *sn*-2 position, which caused the structure to resemble MLM more than it resembled LML, whereas the overall FA composition differed due to the high content of medium-chain FA in the MLM oil. The maximum number of particles appeared in an earlier fraction after fish oil administration compared with administration of MLM and LML. We have investigated the *in vitro* rate of pancreatic lipase hydrolysis and the lymphatic absorption of these three oils, and have observed a faster hydrolysis and a faster absorption of fish oil compared with the two structured oils (Porsgaard, T., Xu, X., Göttsche, J., and Mu, H., unpublished report), which correlates well with the earlier time for the maximum number of particles observed after fish oil administration in the present study. The number of particles observed after fish oil administration was between the numbers observed after MLM and LML administration although it was not significantly different from either.

VLDL (diameter 30–90 nm) are the predominant lipoproteins secreted by the intestine during the fasting state. After fat ingestion, the secretion of chylomicrons is induced and the diameter of chylomicrons in the postprandial state is between 40 and 300 nm (2,5,11,12) depending on the nature of the administered fats. Tso *et al*. (31) suggested that chylomicron synthesis is induced during fat absorption because at high FA concentrations, the VLDL secreted is saturated. In the present study, the highest number of particles in the fasting state was found in the size intervals of 53–80 and 80–121 nm. They probably represented mostly VLDL particles. During fat absorption, increases in particle numbers were observed in all size intervals after administering all four oils but especially in the intervals of 53–80 and 80–121 nm. Since we did not separate the lymph particles into chylomicrons and VLDL, we may conclude either that we observed an increase in the number of VLDL particles in the absorptive state or that the absorption of the administered fats resulted in increases in the number of small chylomicrons. Kalogeris and Story (5) measured the mean diameters of lymph chylomicrons isolated by ultracentrifugation between 87 and 112 nm after infusion in rats of corn, butter, and olive oil, which were sizes close to those measured in our experiment. Levy *et al*. (1) found that the diameter of chylomicrons isolated after MCT administration (60 nm) was smaller compared with the diameter of chylomicrons isolated after safflower (185 nm) and coconut oil (140 nm) administration. Therefore, we conclude that administration of structured oils as well as fish oil and MCT under the experimental conditions applied in this study primarily resulted in increases in the numbers of small chylomicrons. Although we also observed increases in the larger size intervals, we measured increases in the numbers rather than increases in the sizes during absorption of the administered oils. This is in contrast to what was observed by Hayashi *et al*. (2), in which triolein absorption led to the expansion of chylomicron size instead of increases in the number of secreted chylomicrons. Differences in experimental conditions could be a reason for this discrepancy, since Hayashi

et al. used an 8-h intraduodenal infusion of lipid and followed the absorption during and after establishing steady-state TAG transport, whereas we followed the absorption of a single bolus of oil. On the contrary, this cannot be the entire story, since Kalogeris and Story (4) observed differences in chylomicron size as well as in number after using experimental conditions similar to those of Hayashi *et al*. Degrace *et al*. (6) suggested that the size and number of chylomicrons secreted during absorption depends on the time involved in absorption of the individual fats, and thereby also the length of the small intestine that is involved in the absorption process.

Few other studies have investigated the effect of structured lipids on chylomicron size and number. Carvajal *et al*. (12) performed experiments with MLM and LML structured oils containing medium-chain FA and linoleic acid (18:2n-6). Rats were fed experimental diets containing the structured oils for 3 wk followed by lymph collection. No effect from differences in intramolecular structures was found in lymph lipid output, lipid composition of the chylomicrons, or particle size. The particle size was slightly higher (120–140 nm) than we measured. Aoe *et al*. (11) compared the effect of positional distribution of dioleoyl-palmitoyl glycerol on chylomicron transport, composition, and size in rats and observed that the mean diameter of chylomicrons was larger after an infusion of 1,3-dioleoyl-2-palmitoyl glycerol compared with 1,2-dioleoyl-3-palmitoyl glycerol. On the basis of the experiments performed with structured oils, no overall conclusion can be drawn on whether the intramolecular structure of dietary TAG influences the size and number of chylomicrons produced during absorption and therefore also whether the structured oils influence postprandial lipemia differently.

[a]Biological Science Laboratories, Kao Corporation, Tochigi 321-3497, Japan, [b]Health Care Products Research Laboratories No. 1, Kao Corporation, Tokyo 131-8501, Japan, and [c]Department of Biochemistry, Teikyo University School of Medicine, Tokyo 173-8605, Japan

ABSTRACT: The present study investigated the metabolic fate of dietary TAG and DAG and also their digestion products in the stomach and small intestine. A diet containing 10% TAG or DAG oil, enriched in 1,3-DAG, was fed to Wistar rats *ad libitum* for 9 d. After 18 h of fasting, each diet was re-fed *ad libitum* for 1 h. The weights of the contents of the stomach and small intestine were measured, and the acylglycerol and FFA levels were analyzed by GC at 0, 1, and 4 h after the 1-h re-feeding. The amounts of re-fed diet ingested and the gastric and small intestinal content were not different between the two diet groups. In the TAG diet group, the main products were TAG and DAG, especially 1(3),2-DAG. In addition, 1,3-DAG and 1(3)-MAG were present in the stomach, and the 1,3-DAG levels increased over time after the re-feeding period. In the DAG diet group, the main products in the stomach were DAG, MAG, FFA, and TAG. There were significantly greater amounts of 1,3-DAG, 1(3)-MAG, and FFA in the DAG diet group in the stomach compared with the TAG diet group. The amount of FFA in the stomach relative to the amount of ingested TAG plus DAG in the DAG diet group was higher than that in the TAG diet group. Acylglycerol and FFA levels were considerably lower in the small intestine than in the stomach. These results indicate that, in the stomach, where acyl migration might occur, the digestion products were already different between TAG and DAG oil ingestion, and that DAG might be more readily digested by lingual lipase compared with TAG. Furthermore, almost all of the dietary lipid was absorbed, irrespective of the structure of the acylglycerol present in the small intestine.

Paper no. L9593 in *Lipids 40*, 281–286 (March 2005).

Although the majority of the digestion of dietary lipids is completed in the small intestine, the digestion starts in the stomach. From 10 to 30% of ingested lipid is digested in the stomach by gastric lipase, and, as a result, gastric lipid digestion has an important role in humans (1,2), especially in neonates and in patients with cystic fibrosis or pancreatitis (3–6). In rats, the digestion of lipids in the stomach is catalyzed by lingual lipase (7–11), which has considerable homology with the amino acid sequence of human gastric lipase (12,13). This enzyme preferentially cleaves the ester bonds at the *sn*-3 position relative to the *sn*-1 position under acidic conditions (pH 3.0 to 6.5) (7,8).

Hamosh *et al*. (11) measured gastric TAG levels after feeding a diet containing corn oil to rats *ad libitum* for 10 or 20 min. They reported that approximately 20 and 29% of the ingested TAG was digested after 10- and 20-min feeding periods, respectively. Lai and Ney (14) reported that the gastric TAG levels were approximately 38 to 50%, 12 to 17%, and 2 to 4% of the ingested TAG at 2, 5, and 9 h, respectively, after a diet containing corn oil or palm oil was fed to rats. In these studies, only changes in the ingested TAG levels were determined, and changes in makeup of digestion products (DAG, MAG, and FFA) were not investigated. Differences in the rate and extent of digestion of lipids by gastric and pancreatic lipases depend on the nature of the FA present. Medium-chain TAG that contain FA such as octanoic and decanoic acids were reported to be digested more rapidly than long-chain TAG (15). However, differences in the digestion of lipids with respect to the number and position of FA attached to the glycerol backbone have not been examined extensively.

TAG constitutes the greater portion of dietary lipids of animal and vegetable origin as a high energy source, whereas DAG, a type of natural structured lipid contained in many edible oils and fats, makes up a few to approximately 10% of the dietary lipids from animals and vegetables (16,17). A dietary DAG oil rich in 1,3-DAG decreases serum TAG levels (18,19), prevents postprandial hyperlipidemia (20–22), and suppresses visceral fat accumulation (23–26) in animals and humans in comparison with TAG oil with a similar FA composition. Taguchi *et al*. (27) also reported that the absorption coefficient of DAG oil was 96%, similar to that of TAG oil. However, a detailed understanding of the digestion products of DAG oil compared with TAG oil is limited.

In this study, we administered a diet containing TAG or DAG oil with a similar FA composition to rats and investigated the metabolic features of the dietary lipids, which differed in structure, by analyzing the digestion products in the stomach and small intestine, the main locations where digestion occurs.

EXPERIMENTAL PROCEDURES

Test oil. TAG oil was prepared by mixing rapeseed oil, safflower oil, and perilla oil to conform to the FA composition of DAG oil. DAG oil was prepared by esterifying glycerol with FFA from rapeseed oil and soybean oil by the method of

1(3),2-DAG	1.1	27.9
1,3-DAG	1.2	57.9
MAG	0	0.4

Huge-Jensen *et al.* (28). The FA and acylglycerol composition of each oil, as analyzed by GC, is shown in Table 1. The FA composition of the TAG oil was very similar to that of the DAG oil. The DAG concentration of the DAG oil was 85.8 g/100 g and the ratio of 1(3),2- to 1,3-DAG was 32.5:67.5.

Diet. The test diet contained 10 g/100 g of either TAG or DAG oil. Ingredients other than the test oil were casein (20 g/100 g), cellulose (4 g/100 g), AIN-76 mineral mixture (29) (4 g/100 g), AIN-76 vitamin mixture (29) (1 g/100 g), and potato starch (61 g/100 g). Each diet was prepared in one batch for the entire experimental period and was stored at 5°C.

Animals and experimental design. Male Wistar rats (7 wk old, 189 ± 7.8 g), obtained from CLEA Japan (Tokyo, Japan), were housed in metal cages and had free access to commercial rodent diet CE-2 (CLEA Japan) and drinking water. They were maintained in a temperature-controlled environment (23 ± 2°C) under a 12-h light/dark cycle. After a 7-d acclimatization period, they were divided into two groups so that the body weight of each group was approximately equal and transferred to individual metabolic cages. The rats in one group were fed the TAG oil diet, and the others were fed the DAG oil diet (TAG diet group and DAG diet group, respectively) for 9 d to accustom the animals to eating each test diet. Food intake was recorded every 3 or 4 d. The body weights of all rats were recorded at day 1 and 9. After ingestion of the test diets for 9 d, the rats were fasted for 18 h and then re-fed each diet *ad libitum* for 1 h. At the defined time points, 0, 1, and 4 h after re-feeding the test diets, the rats were anesthetized with diethyl ether and killed by withdrawing blood from the abdominal aorta. The stomach and small intestine (60 cm from the pylorus) were removed and washed three times with 5 mL of ice-cold 150 mM NaCl, respectively. Each content was mixed with 15 mL of ethanol and stored at −70°C until measurement. The groups that were killed at 0, 1, and 4 h after re-feeding of the

test diets are referred to hereafter as the 0 h, 1 h, and 4 h groups, respectively. The group that was not re-fed is referred to as the fasting group. The animal experiments were performed with the approval of the Ethics Committee for Experimental Animals of the Kao Corporation.

Lipid extraction. The lipids were extracted from aliquots of the freeze-dried gastric and small intestinal contents homogenized using a mortar, and a chloroform solution of pentadecanoic acid methyl ester (Sigma Chemical Co., St. Louis, MO), as an internal standard, was added using a modification of the method of Folch *et al.* (30).

Lipids analysis by GC. The lipid contents of the extracted total lipids were analyzed by GC. The lipids were purified using Sep-Pak silica (Waters, Milford, MA). The lipids were silylated with trimethylchlorosilane TMSI-H (GL Science, Tokyo, Japan) by a modification of the American Oil Chemists' Society official method (31) and the method of Taguchi *et al.* (27). The trimethylsilyl esters dissolved in hexane were separated on a GC-18A gas chromatograph (Shimadzu, Kyoto, Japan) connected to a FID and fitted with a DB-1 capillary column (15 m × 0.25 mm × 0.1 µm; J&W Scientific, Folsom, CA). Operating conditions were: initial temperature, 80°C; rate of temperature increase, 10°C/min; final temperature, 335°C (held for 44.5 min); injection and detector temperature, 350°C; carrier gas, helium at 1.78 mL/min. Peak detection was performed using a GC work station CLASS-GC 10 (Shimadzu) programmed for peak identification.

Materials for GC. Palmitic, stearic, oleic, linoleic, and linolenic acids as the FFA standards, 1-monooleoyl-glycerol as the 1(3)-MAG standard, and 2-monooleoyl-glycerol as the 2-MAG standard were purchased from Sigma Chemical Co. 1-Oleoyl-2-palmitoyl-glycerol and 1-oleoyl-3-palmitoyl-glycerol were purchased from Funakoshi (Tokyo, Japan). 1,2-Dioleoyl-glycerol and 1,3-dioleoyl-glycerol were purchased from Sigma Chemical Co. 1-Oleoyl-2-palmitoyl-glycerol and 1,2-dioleoyl-glycerol were used as the 1(3),2-DAG standards, 1-oleoyl-3-palmitoyl-glycerol and 1,3-dioleoyl-glycerol were used as the 1,3-DAG standards. 1,3-Dioleoyl-2-palmitoyl-glycerol, from Sigma Chemical Co, and trioleoyl-glycerol, from Wako (Osaka, Japan) were used as the TAG standards.

Statistical analyses. Data are expressed as the means ± SD. Statistical significance of the differences ($P < 0.05$) between the two diet groups were determined by Student's *t*-test and a two-way ANOVA using StatView for Windows version 5.0 (SAS Institute, Inc., Cary, NC).

RESULTS AND DISCUSSION

Food intake and body weight. The amounts of food intake in the TAG and DAG diet groups for 9 d were 152.1 ± 9.2 and 147.7 ± 10 g/rat, respectively. Body weights of the fasting, 0, 1, and 4 h groups in the TAG diet group after ingestion for 9 d were 234.2 ± 10.2, 247.6 ± 7.5, 236.7 ± 9.7, and 248.5 ± 6.5 g, respectively. The values for the fasting, 0, 1, and 4 h groups in the DAG diet group after ingestion for 9 d were 234.2 ± 8.9, 240.8 ± 6.4, 235.9 ± 12.8, and 244.5 ± 11.5 g, respectively. The

amounts of food intake during the re-feeding period (for 1 h) of the 0, 1, and 4 h groups in the TAG diet group after 18 h of fasting were 4.3 ± 1.2, 4.1 ± 1.9, and 4.7 ± 1.2 g, respectively. The values for 0, 1, and 4 h groups in the DAG diet group after 18 h of fasting were 5.0 ± 1.4, 4.1 ± 1.1, and 5.0 ± 1.3 g, respectively. There were no differences at any point between the two diet groups in the amounts of food consumed for 9 d, body weights, and amounts of food intake during the re-feeding period . All rats remained healthy during the study period.

Gastric/intestinal contents. The dried gastric and small intestinal (60 cm from the pylorus) contents at 0, 1, and 4 h after the re-feeding period in the TAG and DAG diet groups and the fasting group are shown in Table 2. The gastric contents decreased over time after the re-feeding period in both the TAG and DAG diet groups. At 4 h after the re-feeding period, the gastric contents in the TAG and DAG diet groups were 34.1 ± 9.3 and 34.1 ± 4.8% of the weight of the re-fed diet, respectively. In the two diet groups, the small intestinal contents were

highest at 1 h after the re-feeding period. At 1 h after the re-feeding period, the small intestinal contents in the TAG and DAG diet groups were 7.1 ± 3.2 and 7.1 ± 1.6% of the weight of the re-fed diet, respectively. There were no differences in the gastric and small intestinal contents between the two diet groups.

Acylglycerols and FFA in the gastric content. Acylglycerol and FFA levels in the gastric contents of the TAG and DAG diet groups are shown in Table 3. The gastric contents in the fasting group were small, and there were no differences in the acylglycerol and FFA levels between the two diet groups.

In the TAG diet group, the main products were TAG and DAG, especially 1(3),2-DAG. The TAG and 1(3),2-DAG levels decreased over time after the re-feeding period, whereas the 1,3-DAG level increased over time after the re-feeding period. The 1(3)-MAG, 2-MAG, and FFA levels were highest at 1 h after the re-feeding period. The TAG intakes, which were calculated from the food intake and the TAG content in the TAG

[a]For footnotes see Table 3.

diet, were 452 ± 126, 430 ± 199, and 540 ± 110 mg/rat in the 0, 1, and 4 h groups, respectively. The TAG levels in the gastric contents in the TAG diet group were 219 ± 97, 155 ± 73, and 155 ± 51 mg/rat in the 0, 1, and 4 h groups, amounting to 47 ± 9, 36 ± 5, and 28 ± 6% of the TAG intakes, respectively. Lai and Ney (14) reported that the gastric TAG levels were approximately 38 to 50% and 12 to 17% of the TAG intakes at 2 and 5 h, respectively, after a diet containing 16% corn oil was fed to rats. Therefore, the results of the present study were consistent with those of Lai and Ney. TAG is digested into DAG, MAG, or FFA by lingual lipase or gastric lipase under acidic conditions (pH 3.0–6.5) (1,2,11). The main products of digestion of TAG in the stomach include 1,2-DAG and 2-MAG, since these lipases preferentially cleave the ester bond at the *sn*-3 position relative to the *sn*-1 position (7,8). In the present study, DAG and MAG, detected in the stomach of the TAG diet group were mainly 1(3),2-DAG and 2-MAG, as has been previously reported (8); in addition, 1,3-DAG and 1(3)-MAG digestion products were present. It is noteworthy that the 1,3-DAG levels increased over time after the re-feeding period. This finding raises the possibility that 1(3),2-DAG, a digestion product of TAG, might have been converted to 1,3-DAG in the stomach under acidic conditions as the result of acyl migration, as heat and acid treatment promotes the migration of acyl groups in the DAG molecule (32). Meanwhile, 1(3)-MAG might be produced as a digestion product of 1,3-DAG.

In the DAG diet group, the main products were DAG, MAG, FFA, and TAG. The TAG, 1(3),2-DAG, 1,3-DAG, 1(3)-MAG, 2-MAG, and FFA levels decreased over time after the re-feeding period. There were no differences in the 1(3),2-DAG level in the gastric contents between the TAG diet group and the DAG diet group. The 1,3-DAG and 1(3)-MAG levels in the DAG diet group were higher than those in the TAG diet group. The levels of 2-MAG and FFA, and the gastric FFA contents relative to the amount of ingested fat (TAG plus DAG) in the DAG diet group were higher than those in the TAG diet group. Murase *et al*. (25) and Kondo *et al*. (33) reported that the levels of 1(3)-MAG and FFA, as digestion products in the small intestinal lumen after the administration of a 1,3-[carboxyl-^{14}C]DAG emulsion into the small intestine, were higher than those after the administration of a [carboxyl-^{14}C]TAG

emulsion. The data presented herein confirm 1(3)-MAG and FFA as metabolic features of DAG oil, also in the stomach, in the case of rats fed a DAG diet. We hypothesize that the 1(3)-MAG levels in the DAG diet group were higher than those in the TAG diet group because an ester bond in 1,3-DAG, a major constituent of the DAG diet, was cleaved at the *sn*-3 position by lingual lipase, as was demonstrated for TAG (7,8). The FFA levels and the gastric FFA contents relative to the amount of ingested fat [FFA/ingested TAG plus DAG (%)] in the DAG diet group were higher than those in the TAG diet group. These findings indicate that DAG might be more readily digested by lipase compared with TAG in the stomach. The rate constant (k_1) in the first step, in which TAG is digested into 1(3),2-DAG and FFA by pancreatic lipase, was lower than that (k_2) in the second step, in which 1(3),2-DAG is digested into 2-MAG and FFA, suggesting that pancreatic lipase more markedly promotes digestion of DAG (34). In adipose tissue, hormone-sensitive lipase (HSL) has a high affinity for DAG compared with TAG (35). To our knowledge, there are no analogous reports of differences between lingual and gastric lipase; however, the results reported herein suggest that lingual and gastric lipase promote the preferential digestion of DAG rather than the digestion of TAG, as demonstrated for pancreatic lipase and HSL.

Acylglycerols and FFA in the small intestinal content. The acylglycerol and FFA levels in the small intestinal contents of the TAG and DAG diet groups are shown in Table 4. In the fasting group, there were no differences between the two diet groups in the acylglycerol and FFA levels in the small intestinal contents. Nor were there differences in the 1(3),2-DAG, 1,3-DAG, 1(3)-MAG, 2-MAG, and FFA levels between the two diet groups. The TAG level in the DAG diet group was significantly higher than that in the TAG diet group at 0 h after the re-feeding period; however, there were no differences at 1 and 4 h after the re-feeding period. As just above, DAG might be more readily digested by lipase compared with TAG in the stomach. Thus, in the DAG diet group, the digestion of TAG in the presence of DAG might be delayed compared with DAG digestion, and the TAG content in the small intestine might be transiently higher than that in the TAG diet group. In both the TAG and DAG diet groups, the acylglycerol and FFA levels in the small intestine were markedly lower than those in the stomach. The amounts of

acylglycerols plus FFA in the small intestinal contents were 0.4% or less of the amounts of ingested TAG or DAG oil. Lai and Ney (14) reported that the amount of TAG in the small intestinal contents was less than 0.7% of the total amount of ingested TAG oil. Therefore, the results of the present study are consistent with those reported by Lai and Ney. Our results also demonstrated that both TAG and DAG oils are nearly completely digested and absorbed in the small intestine.

Our results suggest that, in the stomach of the rat, acyl migration from 1,2-DAG to 1,3-DAG may occur and the digestion products of TAG and DAG oil ingestion are different. Moreover, DAG oil is more readily digested than TAG oil. Therefore, DAG oil might be useful for neonates with underdeveloped digestion and absorption, and patients with cystic fibrosis or pancreatitis.

Tissue-Dependent Alterations in Lipid Mass in Mice Lacking Glycerol Kinase

Mikhail Y. Golovko[a], Johnathan T. Hovda[a], Zong-Jin Cai[c], William J. Craigen[c], and Eric J. Murphy[a,b,*]

Departments of [a]Pharmacology, Physiology, and Therapeutics and [b]Chemistry, University of North Dakota, Grand Forks, North Dakota 58202-9037, and [c]Departments of Molecular and Human Genetics and Pediatrics, Baylor College of Medicine, Houston, Texas 77030

ABSTRACT: Glycerol kinase (ATP:glycerol-3-phosphotransferase, EC 2.7.1.30, glycerokinase) (Gyk) has a central role in plasma glycerol extraction and utilization by tissues for lipid biosynthesis. Gyk deficiency causes various phenotypic changes ranging from asymptomatic hyperglycerolemia to a severe metabolic disorder with growth and psychomotor retardation. To better understand the potential role of Gyk in tissue lipid metabolism, we determined phospholipid (PL), cholesterol (Chol), and triacylglycerol (TG) mass in a number of tissues from mice lacking Gyk. We report a tissue-dependent response to Gyk gene deletion. Tissues with elevated total PL mass (brain, kidney, muscle) were characterized by the increased mass of ethanolamine glycerophospholipids (EtnGpl), choline glycerophospholipids, and phosphatidylserine (PtdSer). In heart, lipid changes were characterized by a reduction in total PL, including decreased EtnGpl, phosphatidylinositol, and PtdSer mass and decreased TG and FFA mass. In parallel with tissue PL alterations, tissue Chol was also changed, maintaining a normal Chol/PL ratio. Under conditions of Gyk deficiency, we speculate that glycerol-3-phosphate and lipid production is maintained *via* alternative biosynthesis, including glycolysis, glyceroneogenesis, or by direct acylation of glycerol in brain, muscle, kidney, and liver, but not in heart.

Paper no. L9641 in *Lipids 40*, 287–293 (March 2005).

In mammals, the main sources of glycerol are either triacylglycerol (TG) hydrolysis in tissues or direct synthesis *via* glyceroneogenesis (1). Once inside the cell, glycerol is immediately phosphorylated by glycerol kinase (Gyk), thereby targeting glycerol to different metabolic pathways and maintaining an inward gradient for glycerol flux (2). The importance of glycerol in mammals is demonstrated by a high turnover rate of whole-body glycerol, which is equivalent to that for glucose (3–5). The bulk of total glycerol is used by liver and kidney (6), whereas the remainder of the glycerol is used by nonhepatic, nonrenal tissues, including muscle (7), brain (8,9), heart, and adipose tissue (10). The predominant use of glycerol in tissue is for TG and phospholipid (PL) biosynthesis (1,7,9,11,12). For example, in liver the half-life of glycerol is 0.5 h for TG and several hours for PL (13). The half-life of glycerol in brain PC is 3 d (14), and 5 d in the total lipid fraction (15). Glycerol can also be used for glucose and amino acid synthesis (8), accounting for up to 20–25% of total glucose production (4,16). Further, it can also be directly oxidized to CO_2, representing 3–10% of total body CO_2 output (3), and it can be used for formation of a hydrogen shuttle system in mitochondria (17).

Because Gyk has a central role in plasma glycerol extraction and utilization by tissues, its activity could be critical for the formation of membrane PL and deposited lipids, such as TG, as well as for carbohydrate homeostasis and energy production by tissues. X-Linked Gyk deficiency in humans causes various phenotypic changes ranging from asymptomatic hyperglycerolemia to a severe metabolic disorder with growth and psychomotor retardation (18). Gyk deficiency may be associated with Duchenne muscular dystrophy and congenital adrenal hypoplasia as part of a contiguous gene deletion syndrome (18). In contrast, a number of intragenic mutations at the Gyk locus have been reported in humans with isolated Gyk deficiency (19–22); however, the biochemical effects of Gyk deficiency on multiple metabolic pathways remain unknown.

To study the physiological role of Gyk and the pathophysiology of Gyk deficiency, we previously generated Gyk-deficient mice by gene-targeted deletion (23). In contrast to Gyk-deficient humans, the affected males die 3–4 d after birth and are characterized by normal plasma glucose, 80-fold elevation in plasma glycerol level, and a 3-fold elevation of plasma FFA. Further, these mice demonstrate induction of gluconeogenic genes, probably *via* elevated glucocorticoids. Others have observed that Gyk deficiency inhibits glycerol utilization in PL and TG biosynthesis (24), confirming the importance of Gyk in lipid metabolism.

To better understand the potential role of Gyk on tissue lipid metabolism, we determined PL mass and composition. In addition, cholesterol (Chol), FFA, and TG mass were measured in these tissues. We report tissue-dependent differences in response to loss of Gyk activity. In parallel with alteration in PL mass, Chol mass was also changed, maintaining a normal Chol/PL ratio. In the absence of Gyk-produced glycerol-3-phosphate (Gro-3-P), we speculate that lipid production is maintained *via* alternative biosynthesis, including glycolysis

and glyceroneogenesis, or by direct acylation of glycerol in brain, muscle, kidney, and liver, but not in heart.

MATERIALS AND METHODS

Animals. X-Linked Gyk-deficient mice were generated by gene targeting in embryonic stem cells (23). Male pups were killed on postnatal day 2 and tissues were collected by dissection followed by snap-freezing in liquid nitrogen. The genotypes of the mice were then determined by a PCR-based assay, and male littermates with an intact Gyk gene served as controls. All studies were performed following approval by the Baylor College of Medicine institutional animal use review committee.

Tissue lipid extraction. Frozen tissue was pulverized under liquid nitrogen temperatures. Lipids from the tissue powder were extracted using a Tenbroeck tissue homogenizer and *n*-hexane/2-propanol (3:2, vol/vol) (25,26). Briefly, tissue was homogenized in 1.8 mL *n*-hexane/2-propanol (3:2, vol/vol) per 0.1 g tissue and quantitatively transferred to a test tube, using an additional 3 mL of *n*-hexane/2-propanol (3:2, vol/vol) per 0.1 g tissue to rinse the homogenizer. The protein-containing residue was pelleted by centrifugation.

Sample preparation for analysis. Lipid extracts were prepared for separation by HPLC by reducing the sample volume under a stream of nitrogen and filtering the samples through a 0.2 µm Nylon filter (Rainin, Emeryville, CA). The filtered sample was then dried to completeness and redissolved in a known volume of HPLC-grade *n*-hexane/2-propanol (3:2, vol/vol) for PL separation and in *n*-hexane/2-propanol/acetic acid (98.7:1.2:0.1, by vol) for neutral lipid separation.

PL mass determination. The PL were separated by HPLC using a gradient of *n*-hexane/2-propanol (3:2 vol/vol) and *n*-hexane/2-propanol/water (56.7:37.8:5.5, by vol) as previously described (27,28). This method gives baseline resolution of all the major classes of PL. The eluant absorbance was monitored at 205 nm. Individual PL mass was determined by assay of lipid phosphorus (29).

Chol mass determination. The neutral lipid-containing fraction was collected during the PL separation described above. The neutral lipids were separated using a binary solvent system consisting of *n*-hexane/2-propanol/acetic acid (98.7:1.2:0.1, by vol) and *n*-hexane (30,31). The eluant absorbance was monitored at 205 nm. Chol concentration was determined based on a Chol (Nu-Chek-Prep, Elysian, MN) standard curve.

FFA analysis. FFA fraction from the neutral lipid separation described above was subjected to acid-catalyzed esterification (32), and FFA were analyzed by GLC.

TG mass determination. PL and neutral lipids were separated by liquid column chromatography, using activated silicic acid (Clarkson Chemical Company, Inc., Williamsport, PA) as the stationary phase (33). Neutral lipids were eluted with 10 vol of chloroform/methanol (58:1 vol/vol), and PL were eluted with 10 vol of methanol. The collected neutral lipid fraction was separated by HPLC as described above. The eluent was monitored by a light-scattering detector, and TG mass was determined by using a standard curve from commercially pur-

chased standards (Nu-Chek-Prep). TG mass was converted from grams to moles using the M.W. for tristearoylglycerol.

Total PL FA composition. The PL fraction was collected after liquid column chromatography as described above. PL were subjected to base-catalyzed transesterification (34) and analyzed by GLC.

HPLC. The HPLC system consisted of a Selectosil column (5 µm, 4.6 × 250 mm; Phenomenex, Torrance, CA), a Beckman 126 pump (Fullerton, CA), and a Beckman 166 UV/Vis detector or ELSD (model 301; ESA Inc., Chelmsford, MA).

GLC. The gas–liquid chromatograph (model 14A; Shimadzu, Kyoto, Japan) was equipped with a capillary column (SP 2330; 30 m × 0.32 mm i.d.; Supelco, Bellefonte, PA) and an FID. FA were quantified using a standard curve from commercially purchased standards (Nu-Chek-Prep), and 17:0 was the internal standard.

Protein assay. Proteins were measured using a modified dye-binding assay (35). The dried protein residue from the lipid extract was digested overnight in 0.2 M KOH at 65°C. After digestion, aliquots were used to measure the protein concentration by converting absorbance to concentration using BSA as a standard.

Statistics. Statistical analysis was done using a one-way ANOVA combined with a Tukey–Kramer *post hoc* test using Instat II (Graphpad, San Diego, CA). Statistical significance was defined as <0.05.

RESULTS

The total PL mass of brain, heart, liver, kidney, and muscle of wild-type males, and Gyk-deficient hemizygous males are presented in Table 1. In brain, kidney, and muscle of affected males, the total PL mass was elevated 1.3-fold in each tissue. In contrast, the PL mass was decreased 24% in heart tissue of Gyk-deficient males, whereas liver tissue PL mass was not statistically different between groups.

The changes in Chol mass in brain, heart, liver, kidney, and muscle tissues of Gyk-deficient animals are presented in Table 1. Similar to total PL mass, the Chol mass was increased 1.5-fold in brain and 1.6-fold in muscle of affected males. Chol mass was not significantly changed in heart, liver, and kidney between groups. Despite dramatic changes in total PL in brain, heart, muscle, and kidney and in Chol in brain and muscle, the Chol/PL ratio was not affected in Gyk-deficient mice (Table 1).

We have previously shown that Gyk-deficient mice exhibit an 80-fold increase in plasma glycerol (23). High plasma glycerol is excreted in the urine, which leads to osmotic diuresis, salt loss, and dehydration (36). To test the hypothesis that the changes in PL concentration in some tissues are the result of tissue dehydration, we measured protein mass in the tissues. There were no statistically significant differences between groups in protein mass per gram of wet tissue (data not shown).

The individual PL class mass was determined for each tissue (Table 2). All Gyk-deficient tissues with elevated total PL mass, i.e., brain, kidney, muscle, are characterized by an

TABLE 1

[a]Values are expressed as means ± SD. The numbers in parentheses indicate the number of samples tested. *$P < 0.05$. Gyk, glycerol kinase; ww, wet weight; +/o, tissues from wild-type male mice; –/o, tissues from knockout male mice.

elevation in individual PL masses; and in the heart, the decrease of total PL mass paralleled the decrease in individual PL masses (Table 2).

In brains of affected males, EtnGpl, PtdSer, and ChoGpl masses were elevated 1.3-, 1.4-, and 1.2-fold, respectively (Table 2), but PL composition was not different between groups (data not shown).

In muscles of affected males, EtnGpl and ChoGpl masses also were elevated 1.3- and 1.4-fold, respectively (Table 2), but PL composition was not different between groups (data not shown).

In kidney samples of Gyk-deficient males, PtdSer mass was elevated 1.5-fold (Table 2), and PL composition was not different between groups (data not shown).

In contrast to other tissues examined, heart EtnGpl, PtdSer, and phosphatidylinositol (PtdIns) masses were decreased 23, 43, and 26%, respectively, in affected males (Table 2). The mole composition of PL also was altered, with PtdIns decreased by 23%, as compared with wild-type animals (data not shown).

In liver, there were no differences in individual PL mass or distribution (Table 2 and data not shown).

In culture systems, Gyk deficiency decreases glycerol incorporation into TG (24). Also, the plasma FFA mass is increased threefold in Gyk-deficient mice (23). To determine the effect of Gyk deficiency on the tissue neutral lipid mass, TG and FFA masses were determined for brain (tissue with elevated PL mass), liver (tissue with unaffected PL), and heart (tissue with decreased PL mass) (Table 3). The changes in TG mass were consistent with those observed for PL. In brain, TG mass was increased 1.4-fold, in liver TG mass was unaffected, and in heart TG mass was decreased 84%. FFA mass in heart was also decreased 56% (Table 3), consistent with PL mass decreases in hearts of affected males.

The potential that Gyk deficiency could alter the FA composition of total brain and liver PL was also determined. No changes in brain and liver PL FA composition were found between groups (Table 4), indicating that there were no preferences in the FA entering PL.

DISCUSSION

Glycerol has a significant role in lipid biosynthesis, but this role is not limited to tissues with the highest Gyk activity (kidney and liver); it is also important in muscle (7), in brain (9,37), and to a lesser extent in heart (37,38). Gyk catalyzes the initial reaction of glycerol utilization by tissues, making it an important participant in lipid synthesis. For instance, in fibroblasts from humans with Gyk deficiency, the targeting of glycerol for use in PL and TG biosynthesis is decreased 98%, but the utilization of glucose for PL and TG biosynthesis is not affected (24). In Gyk-deficient mice, the esterification of glycerol is also disrupted, as demonstrated by an observed 80-fold hyperglycerolemia and a 3-fold elevation of plasma FFA (23). Collectively, these results suggest that Gyk deficiency could lead to decreased tissue PL mass. To address this question, we determined tissue lipid mass from Gyk-deficient mice to provide greater insight into the role of Gyk in lipid biosynthesis.

In contrast to the putative role for Gyk in PL biosynthesis, the mass of total PL and the mass of some individual PL were increased in brain, kidney, and muscle from affected males (Tables 1 and 2) or else were unaffected, as in liver (Tables 1 and

2). The changes in TG mass in brain, liver, and heart were consistent with those observed for PL. Several explanations may account for the observed increase in PL mass in kidney and muscle, and in PL and TG in brain of Gyk-deficient mice.

In Gyk-deficient mice, it would be reasonable that the lack of Gro-3-P production from free glycerol is compensated for by alternative mechanisms of Gro-3-P formation and lipid synthesis in kidney, muscle, brain, liver, and, to a lesser extent, in heart. Several compensatory mechanisms are possible. Gro-3-P production may be maintained from glucose *via* glycolysis, or from pyruvate (lactate) and from glycogenic amino acids *via* glyconeogenesis, also referred to as glyceroneogenesis (1). These routes lead to increased dihydroxyacetone phosphate production. Dihydroxyacetone phosphate can be directly acylated, reduced, and then used for glycerolipid or TG formation or reduced to Gro-3-P and then used for lipid synthesis (39).

The glyceroneogenesis pathway has an important role in the liver and muscle and possibly in other organs. It contributes up to 65% of the glycerolipids secreted by liver (1) and from 52 (fed animals) to 70% (fasted animals) of Gro-3-P used for lipid synthesis in muscle (40). It is noteworthy that in soleus muscle, which has a low rate of glucose utilization, the contribution of

glucose to Gro-3-$\underline{P}$ formation is significantly lower than in quadriceps, which has a higher rate of glucose utilization (40). This suggests that tissues with a low rate of glucose utilization may have a lower capability of maintaining Gro-3-$\underline{P}$ production through the use of glucose. This observation could explain, at least in part, the decrease of PL and TG in the heart of Gyk-deficient mice. As the glycolytic flux, measured as pyruvate production, in heart (20 $\mu mol \times min^{-1} \times g^{-1}$ tissue) is 4- to 14-fold lower than in muscle (41), brain (42,43), and kidney (44), the requirements for heart Gro-3-$\underline{P}$ may not be well compensated for by the use of glucose in Gyk-deficient mice, whereas in brain, kidney, and muscle such a compensation is a reasonable expectation.

If it is true that the lack of Gro-3-$\underline{P}$ production from glycerol is compensated for by glucose utilization under Gyk-deficient conditions, then the rate of glucose utilization, and possibly production, should be increased in Gyk-deficient tissues. In humans, the Gyk deficiency may be accompanied by hypoglycemia (18), perhaps reflecting the increased use of plasma glucose. Hypoglycemia is also observed in mice deficient in dihydroxyacetone-phosphate dehydrogenases (36). In Gyk-deficient mice, the glucose concentration did not differ significantly from the control values (23); however, the amount of corticosterone was increased threefold and the activity of the gluconeogenic enzyme phosphoenolpyruvate carboxykinase was increased 2.7-fold (23). This simultaneous increase in glucose production by tissues stimulated by corticosterone provides a potential source of glucose or its precursors for Gro-3-$\underline{P}$ synthesis.

Alternatively, lipid synthesis in Gyk-deficient conditions could use glycerol that is directly acylated (45). The direct acylation of glycerol occurs when Gyk is inhibited or at high glycerol concentrations (2 mM) (45). We speculate that this non-physiological pathway is less regulated and, under conditions of excess substrate availability, leads to increased PL and TG synthesis in brain, kidney, and muscle.

However, in liver the PL and TG masses were unaffected and in heart they were decreased (Tables 1–3). These results support the contention that osmotic diuresis does not account for the increase in PL mass. This observation may reflect limited glycerol availability for heart tissue. Because the acylation of glycerol is regulated by its tissue availability (45), the direct acylation pathway for PL synthesis may not be compensated for in tissues with limited capability to transport glycerol through the plasma membrane. The movement of alcohols across cell membranes is regulated by aquaporin/aquaglyceroporin channels (2,8). Some aquaglyceroporin channels, such as the glycerol intrinsic protein, are widely expressed in different mammalian tissues, including muscle, kidney, and brain, but not in heart and liver (46). Heart and liver express abundant aquaporin channels (AQP8), which are not permeable to glycerol (46); however, liver expresses the specific aquaglyceroporin channel AQP9 (37). The lack of glycerol-permeable channels in heart may limit glycerol flux, thereby decreasing the capability of heart to use glycerol for lipid synthesis *via* direct acylation. As heart TG are an important reserve of the tissue FFA used for energy supply (47–49), the dramatic 84% decrease in heart TG could significantly alter heart energy metabolism. This assumption is consistent with 56% decrease in FFA mass observed in heart of affected males (Table 3).

The activation of direct acylation could explain, in part, the observed increase of the main glycerophospholipid species, i.e., ChoGpl, EtnGpl, and PtdSer, in brain and muscle, and PtdSer in kidney, whereas PtdIns was not affected in Gyk-deficient mice (Table 2). The Kennedy pathway for ChoGpl, EtnGpl, and PtdSer synthesis requires DAG (50–52), which can be easily synthesized *via* a direct acylation pathway. In contrast, PtdIns synthesis requires PA as a direct precursor (53), the formation of which from glycerol would be limited in Gyk-deficient tissues.

In Gyk-deficient mouse tissues, the Chol mass was altered in parallel with PL mass (Table 1). As a result, the Chol/PL ratio was not disturbed. This is of great importance, as alterations in the Chol/PL ratio could lead to significant changes in membrane biophysical properties and lead to various cellular dysfunctions (54–56). Thus, changes in the Chol level in Gyk-deficient tissues could act as a protective mechanism against PL alterations, similar to what is observed in other pathophysiological conditions (57).

In summary, three groups of tissues could be selected according to their response to Gyk deficiency conditions: tissues with increased total PL mass (brain, muscle, and kidney); decreased total PL mass (heart); or unaffected total PL mass (liver). In parallel with PL alterations, Chol was also changed, maintaining a normal Chol/PL ratio. Tissues with elevated total PL mass (brain, kidney, muscle) were characterized by an increased mass of some individual glycerophospholipids (EtnGpl, ChoGpl, PtdSer). Other glycerophospholipid species, including PtdIns, were not affected in these tissues. Under conditions of Gyk deficiency, we speculate that production of Gro-3-$\underline{P}$ and lipid is maintained *via* alternative biosynthesis, including glycolysis and glyceroneogenesis, or by direct acylation of glycerol in brain, muscle, kidney, and liver, but not in heart.

ABSTRACT: Hepatic metabolism of vaccenic acid (VA), especially its conversion into CLA, was studied in the bovine (ruminant species that synthesizes CLA) and in the rat (model for nonruminant) by using the *in vitro* technique of liver explants. Liver tissue samples were collected from fed animals (5 male Wistar rats and 5 Charolais steers) and incubated at 37°C for 17 h under an atmosphere of 95% O_2/5% CO_2 in medium supplemented with 0.75 mM of FA mixture and with 55 µM [1-^{14}C]VA. VA uptake was about sixfold lower in bovine than in rat liver slices ($P <$ 0.01). For both species, VA that was oxidized to partial oxidation products represented about 20% of VA incorporated by cells. The chemical structure of VA was not modified in bovine liver cells, whereas in rat liver cells, 3.2% of VA was converted into 16:0 and only 0.33% into CLA. The extent of esterification of VA was similar for both animal species (70–80% of incorporated VA). Secretion of VA as part of VLDL particles was very low and similar in rat and bovine liver (around 0.07% of incorporated VA). In conclusion, characteristics of the hepatic metabolism of VA were similar for rat and bovine animals, the liver not being involved in tissue VA conversion into CLA in spite of its high capacity for FA desaturation especially in the rat. This indicates that endogenous synthesis of CLA should take place exclusively in peripheral tissues.

Paper no. L9672 in *Lipids* 40, 295–301 (March 2005).

Trans FA (TFA) are mainly found in ruminant fats (dairy products, bovine and lamb meat) as a result of the hydrogenation and trans isomerization chain reaction of dietary PUFA by rumen bacteria. They are also found in shortenings and table spreads, produced by industrial catalytic hydrogenation of vegetable oils. *Trans* positional isomers in fats originating from industrial hydrogenation, where a mixture of isomers is found, differ somewhat from those in fats derived from ruminant fermentation, which result in a predominance of vaccenic acid (VA, 18:1 *trans*11) (1). Evidence suggests potentially adverse effects of TFA on the risk of coronary heart disease (2,3). However, VA is also a precursor of CLA, which is believed to possess important beneficial properties for human health, as suggested from experiments using different animal models (4). Conversion by desaturation of VA to CLA takes place in tissues of ruminants where the Δ9-desaturase enzyme (EC

1.14.99.5) is expressed, i.e., mammary gland in the lactating ruminant and adipose tissue in the growing ruminant (5,6). Moreover, endogenous synthesis of CLA from VA, based on the increase of CLA concentration in either serum, adipose tissue, or milk observed with diets supplemented with VA, also has been shown in mice (7,8), rats (9,10), pigs (11), and humans (12–14).

In considering suggested properties of VA, which may be either deleterious (risks of coronary heart disease) or beneficial (precursor of CLA), it is important to determine with precision the metabolic fate of VA in the ruminant (as a species that produces CLA) and the rat (as an animal model of nonruminant species). Among the different tissues and organs that are involved in FA metabolism, the liver appears to play a central role in lipid metabolism (15). Indeed, once in the liver, FA can be either extensively or partially oxidized in mitochondria to produce energy and generate CO_2 and ketone bodies, or esterified into triacylglycerols (TG), phospholipids (PL), and cholesterol esters in the cytoplasm. The alternative fate of TG in the liver is their exportation in the blood circulation as part of particles of VLDL (15,16). Previous studies using the *in vitro* method of incubated liver slices have demonstrated that hepatic FA metabolism varies with either the nature of FA (17,18) or the animal species (19). No data are available on hepatic metabolism of TFA except for a study by Guzman *et al.* (20), who have shown that elaidic acid is preferentially oxidized in rat hepatocytes, whereas oleic acid is preferentially esterified, indicating that double bond configuration of FA may also affect the metabolic fate of FA.

In this context, the aim of our study was to compare, by using the *in vitro* method of incubated liver slices, characteristics of hepatic metabolism of VA in the bovine with that of the rat. For this purpose, we determined the relative intensity of the different successive pathways of the hepatic VA metabolism, i.e., uptake, oxidation, bioconversion, and esterification, and finally its secretion as part of VLDL particles.

EXPERIMENTAL PROCEDURES

Chemicals and materials. The medium for incubation of liver slices (RPMI-1640), BSA free of FA, glutamine (300 mg/L), FA, and an antibiotic-antimycotic cocktail (penicillin, 100 U/mL; streptomycin, 0.1 mg/mL; amphoterine B 0.25 µg/mL) were purchased from Sigma Chemical (St. Louis, MO). Tri [9,10 ^{3}H]olein (185 MBq/mL) and 1,2 dipalmitoyl L-3-phos-

phatidyl[*N*-methyl-^{3}H]choline (37 MBq/mL) were purchased from Amersham International (Bucks, United Kingdom). [1-^{14}C]VA (1.97 GBq/mmol) was graciously provided by the Atomic Energy Centre (Saclay, Gif/Yvette, France). Hyamine hydroxide was purchased from ICN Biochemicals (Irvine, CA). Perchloric acid and organic solvents (chloroform, methanol, propanol, diethyl ether, acetic acid) were purchased from Polylabo (Paris, France). Ready Safe® scintillation cocktail was purchased from Beckman Instruments (Fullerton, CA). Plastic Petri dishes for organ culture were purchased from Beckton Dickinson (Cockeysville, MD). Plastic center wells were purchased from Kontes (Vineland, NJ) and aminopropyl-activated silica Sep-Pak® cartridges were purchased from Waters (Milford, MA).

Tissue preparation and liver slice incubation. All experiments were conducted in a manner compatible with national legislation on animal care (Certificate of Authorisation to Experiment on Living Animal no. 7740, Ministry of Agriculture and Fish Products, Paris, France). Five male Wistar rats (age 16 ± 1 wk) were fed *ad libitum* a standard chow diet and allowed free access to water. In the same way, five Charolais steers (age 25 ± 1 mon; live weight 713 ± 39 kg) were fed a conventional diet (hay and cereal concentrate, 45 and 55% dry matter, respectively). Liver tissue samples were taken from rats under general anesthesia (diethyl ether) and from steers just after slaughtering. Then liver samples were quickly rinsed of blood in an ice-cold saline solution (NaCl, 9 g/L), connective tissue was trimmed, and liver samples were cut into 0.5-mm slices. Approximately 200-mg portions of fresh liver were placed on stainless grids positioned either on a plastic organ culture Petri dish (for quantification of FA bioconversion, esterification, and secretion) or in a 25-mL flask equipped with suspended plastic wells (for measurement of specific CO_2 production) in the presence of RPMI-1640 medium (0.9 mL per dish and 1.4 mL per flask) supplemented with the antibiotic-antimycotic cocktail. Liver samples were placed under a water-saturated atmosphere (95% O_2 and 5% CO_2) for 3 h at 37°C to deplete hepatic cells with intracellular FA. The medium was then replaced with similar fresh medium containing a mixture of FA (21) representative in composition and concentration of bovine plasma nonesterified FA [0.75 mM final concentration, which consisted of caprylic acid (16 µM), capric acid (16 µM), myristic acid (58 µM), palmitic acid (200 µM), stearic acid (220 µM), oleic acid (213 µM), and linoleic acid (26 µM)] in addition to [1-^{14}C]VA (55 µM) complexed with BSA (FA/albumin molar ratio 4:1). Kinetic experiments have been performed to verify the correct viability of liver slices until 24 h (17). Consequently, liver slice incubations were stopped after 17 h of labeling: Briefly, media (2.5 mL) were collected and liver slices were washed with 2 mL of buffered solution (KCl, 0.4 g/L; Na_2HPO_4, 0.60 g/L; NaH_2PO_4, 0.2 g/L; pH 7.4; and D-glucose 2 g/L) before their homogenization with a Dounce homogenizer in 2 mL of 0.25 mM Tris-HCl (pH 8.0) and 50 mM NaCl (pH 8.0).

Determination of FA oxidation. CO_2 excreted in the atmosphere by liver cells was complexed with hyamine hydroxide

(500 µL) placed into suspended plastic center wells inside flasks at the beginning of the incubation as described earlier (19). After 17 h of incubation, wells were introduced into scintillation vials containing 4 mL of Ready Safe scintillation cocktail for radioactivity quantification. The production of ketone bodies was estimated according to the method of Graulet *et al.* (19). Briefly, cell homogenates (250 µL) and media (500 µL) were treated for 20 min at 4°C with ice-cold perchloric acid (0.2 mM final). After centrifugation for 20 min at 4°C at 1,850 $\times g$, an aliquot of supernatant containing the acid-soluble products (ASP) (mainly ketone bodies) was introduced into a scintillation vial and the radioactivity was counted.

Determination of FA bioconversion. Total liver lipids were extracted according to the method of Folch *et al.* (22), and their corresponding FA were liberated and methylated by transmethylation at room temperature according to the method of Christie *et al.* (23). FAME containing [^{14}C]FAME were analyzed by GLC using an HP 5890 series II gas chromatograph (Hewlett-Packard, Palo Alto, CA), equipped with a splitless injector and a fused Stabilwax wide-bore silica column (60 m × 0.53 mm i.d.; 0.50 µm film thickness; Restek, Evry, France). The outflow from the column was split between an FID (10%) and a copper oxide oven heated at 700°C to transform the [^{14}C]FA into $^{14}CO_2$ (90%). Radioactivity was quantified with a radiodetector (GC-RAM) (Lablogic, Sheffield, United Kingdom) by counting $^{14}CO_2$ after its mixing with a 9:1 ratio of argon/methane, as previously described (24). Data were computed using Laura software (Lablogic).

Determination of FA esterification into neutral and polar lipids. Total liver lipids were extracted according to the method of Folch *et al.* (22) after addition of a standard (nonradioactive) liver homogenate (850 µL containing approximately 10 mg of lipids) as a lipid carrier and of [^{3}H]trioleylglycerol (67 Bq) and [^{3}H]PC (100 Bq) as internal TG and PL standards (19). Neutral and polar lipids were separated by affinity-LC with aminopropyl-activated silica Sep-Pak® cartridge according to Kaluzny *et al.* (25). They were directly collected into scintillation vials, evaporated to dryness under an air stream, and counted for radioactivity.

Hepatic secretion of VLDL. Newly secreted [^{14}C]VLDL were purified by ultracentrifugation according to Graulet *et al.* (19). Hence, the medium (3 mL) previously supplemented with purified plasma bovine VLDL (0.3 mg of VLDL-TG per 12-mL tube) as a carrier for VLDL during ultracentrifugation was adjusted to the density of 1.063 g/L with potassium bromide and overlaid with 9 mL of saline solution. VLDL particles were isolated by ultracentrifugal flotation at $100,000 \times g$ for 16 h at 15°C in a Kontron Centrikon T-2060 ultracentrifuge equipped with a TST 41-14 rotor (Kontron, Zürich, Switzerland). Two milliliters was collected at the top of each tube and recentrifuged under the same conditions, except that pure albumin (50 mg/tube) was added to remove traces of free [^{14}C]FA adsorbed onto VLDL particles. Finally, purified VLDL (2.5 mL) were counted for radioactivity in scintillation vials.

Statistical analysis. Values are expressed as means ± SEM for the five independent experiments per each animal species.

Comparison of means between animal species was tested by using the Student's *t*-test for unpaired data.

RESULTS

VA uptake. The amount of VA taken up by the hepatocytes of rat and bovine animals (expressed in nmol per g fresh tissue) corresponded to the sum of FA incorporated into the hepatic lipids (neutral and polar lipids) plus FA oxidized into ASP in the homogenate plus FA oxidized to CO_2 and subsequently excreted to the atmosphere. After 17 h of incubation, hepatic uptake of VA by bovine hepatocytes was 17.8% of that by rat hepatocytes (15.2 vs. 85.5 nmol/g of fresh liver, $P < 0.001$) (Fig. 1A). A similar result was observed when the intensity of VA uptake was expressed as the percentage of radioactivity introduced in the incubation medium (Fig. 1B).

VA oxidation. The extent of β-oxidation, calculated as the ratio of total oxidation products (sum of ASP and CO_2) to total incorporated VA in hepatocytes, was similar in bovine and in rat liver slices (Table 1). It corresponded to about 28 and 19% of VA incorporated by cells for bovine and rat hepatocytes, respectively. Oxidation of VA led for the most part to the production of ASP (>90% total oxidized VA) in both species. This partial oxidation, expressed as the percentage of oxidized VA, constituted a greater portion of that oxidized in the bovine than in the rat hepatocytes (+8.5%, $P < 0.01$). In the same way, in spite of the slow rate of VA total oxidation (determined as the amount of [^{14}C]CO_2 excreted) in both species (<10% total oxidized VA), total oxidation of VA into CO_2 in the bovine liver, expressed as a percentage of oxidized VA, was one-fifth that of rat liver ($P < 0.01$) (Table 1).

*Bioconversion of VA.* Total lipids were extracted from liver homogenates after 17 h of incubation. Their FA composition was determined by GLC analysis and their relative radioactivity quantified by a radiodetector. In our experimental conditions, VA was not converted by desaturation into higher unsaturated FA or CLA isomers by bovine hepatocytes (Fig. 2A). In contrast, in rat hepatocytes (Fig. 2B), a low quantity of VA was converted into CLA 9*cis*,11*trans* (0.33 ± 0.19% of total VA). Moreover, radioactivity was also recovered in 16:0 but at a higher extent (3.2 ± 2% of total incorporated radioactivity). These new labeled FA were identified according to the similarity of their respective retention times with those of corresponding standards.

VA esterification. The extent of VA esterification (expressed as a percentage of FA converted into neutral and polar lipids out of total VA incorporated into cells), which was similar for the two species, corresponded to about 72 and 81% of VA incorporated by bovine and rat hepatocytes, respectively (Table 2). VA was preferentially esterified into polar lipids by the bovine liver (56.5% of esterified VA, $P < 0.05$) and, conversely, into neutral lipids by the rat liver (61.1% of esterified VA, $P < 0.05$).

VA secretion as part of VLDL particles. The extent of VA secretion as part of VLDL particles by the liver slices for 17 h (Fig. 3A) was very low for both species. This secretion by bovine liver was less than 20% ($P < 0.02$) that of rat liver (0.012 vs. 0.066 nmol of secreted VA/g fresh tissue, respectively). However, when expressed as the percentage of VA taken up by the hepatic cells, VA secreted as part of VLDL particles was not significantly different between the two animal species (Fig. 3B) (0.067 and 0.085% for bovine and rat liver, respectively).

DISCUSSION

The specific metabolism of VA, especially how it is channeled toward the esterification, oxidation, or bioconversion pathways in tissues or organs (more precisely, in the liver), is not documented in spite of the importance of VA availability to peripheral tissues, especially as a precursor of CLA. Moreover, the liver might be directly implicated in the synthesis of CLA from VA due to its high desaturase activity. In this context, our study
FIG. 1. Uptake of vaccenic acid (VA) by bovine and rat liver slices. Liver slices from bovine and rat were incubated in medium containing a mixture of FA (0.75 mM) and 55 µM [1-^{14}C]VA for 17 h. Uptake of VA by liver slices was calculated as the sum of VA converted into CO_2 and into acid-soluble products, and incorporated into total cellular lipids after 17 h of incubation. Values are expressed per g of fresh liver (A) or as the percentage of VA introduced in culture medium (B). TVA, *trans*-vaccenic acid. Data are means ± SE of 5 animals per group. ^{a,b}Mean values with unlike superscript letters were significantly different using Student's *t*-test ($P < 0.01$).

TABLE 1
Oxidation of Vaccenic Acid (VA) into Acid-Soluble Products (ASP) and CO_2 in Rat and Bovine Liver Slices^a

	Bovine^b	Rat^b
Extent of VA oxidation (% of VA incorporated by cells)	28.03 ± 3.09	19.06 ± 4.18
Production of acid-soluble products (% of oxidized VA equivalents)	98.12 ± 0.53	90.38 ± 1.89*
Production of CO_2 (% of oxidized VA equivalents)	1.88 ± 0.53	9.62 ± 1.89*

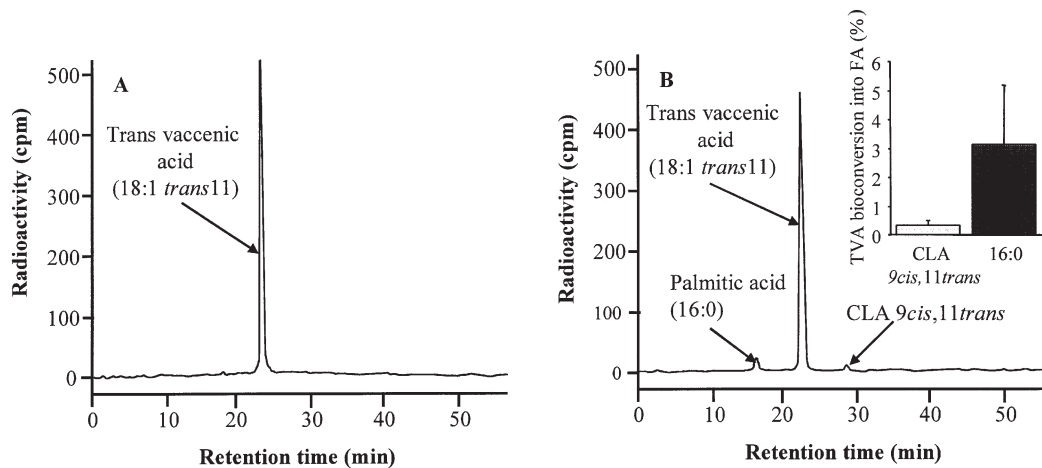
^{a}Liver slices from bovine and rat were incubated for 17 h in a medium containing [1-^{14}C]VA. The extent of oxidation was calculated as the ratio of total oxidation products (sum of ASP and CO_2) to total VA incorporated into liver explants. ASP produced by liver slices were purified from cell homogenate and medium by perchloric acid treatment, and secreted CO_2 was complexed into hyamine hydroxide.
^{b}Data are means ± SEM of 5 animals per group. The significance of differences between species was tested by Student's *t*-test. *$P < 0.01$.


FIG. 2. Representative radiochromatograms of [^{14}C]VA bioconversion into other FA in bovine and rat liver slices. Liver slices from bovine (A) and rat (B) were incubated in medium containing a mixture of FA (0.75 mM) and 55 μM [1-^{14}C]VA for 17 h. Cellular lipids were extracted, transformed into methyl esters, and analyzed by GLC. The outflow from the column was split between an FID (10%) and a copper oxide oven to transform the labeled FA into ^{14}CO$_2$ (90%). The radioactivity was determined with a radiodetector by counting ^{14}CO$_2$. The proportions of radioactivity recovered in other FA were calculated as the ratio between the radioactivity corresponding to the metabolite and the sum of the radioactivity present in peaks of VA plus their corresponding metabolite. For abbreviation see Figure 1.

is the first that investigates, by using the *in vitro* method of incubated liver slices, the specificity of VA metabolism in the liver of the bovine (a species that produces CLA) and the rat (an animal model for monogastrics).

In our experimental conditions, the lower VA uptake by liver of the bovine compared with that of the rat confirmed previous data with oleate in calf and rat liver slices (19). Uptake of long-chain FA across the plasma membrane is known to involve two mechanisms: a passive diffusion through the membrane bilayer (26) and a protein-facilitated transfer (27). However, Bojesen and Bojesen (28) have proposed a third mechanism of FA diffusion in protein-defined annular lipid domains that is not carrier-mediated. These authors showed that binding and membrane transfer rates of PUFA in sheep red cells were less than half of those measured for human red cells, probably because of the difference between species in composition of membranes. Nevertheless, higher VA uptake by rat liver slices compared with that of bovine might be attributable to a higher rate of intracellular FA utilization (oxidation, esterification) increasing cellular needs (26), to more efficient or more numerous FA transporters (27), or to differences in membrane composition between rat and bovine hepatocytes.

Once in hepatocytes, VA catabolism was determined by the production of ^{14}CO$_2$ and ^{14}C-ASP from [1-^{14}C]VA. The use of [1-^{14}C]VA might be limiting to describe VA catabolism since it only reflected the initial rate of oxidation contrary to the use of [U-^{14}C]VA. However, the aim of the present work was not to describe VA catabolism exhaustively but rather to describe VA behavior in the liver and its channel toward the different metabolic pathways. Moreover, Chatzidakis and Otto (29) previously demonstrated that the use of [1-^{14}C]FA gave data quite similar to [U-^{14}C]FA, being therefore a good choice for studies

of FA oxidation in cells. The catabolism of FA in the liver is mostly directed toward the synthesis of ketone bodies for energy utilization by tissues (30) as shown in the present study in which products of VA oxidation were dominated by ASP (more than 90% of total oxidation products). The proportion of VA oxidized to CO$_2$, although minor, differed between the rat and the bovine liver, as previously reported by Reid and Husbands (31), who showed that the rate of oleate oxidation to CO$_2$ was twofold higher in hepatic mitochondria of rat than in that of sheep, and by Kleppe *et al.* (32), who reported that oxidation of oleate to CO$_2$ was three- to fourfold lower in goat compared with rat hepatocytes. This difference can be attributed to a lower capacity of the Krebs cycle relative to that of the β-oxidation pathway in large mammals (such as bovine) than in rats

TABLE 2
Esterification of VA into Phospholipids and Neutral Lipids in Rat and Bovine Liver Slices[a]

	Bovine[b]	Rat[b]
Extent of VA esterification (% of VA incorporated by cells)	72.0 ± 3.09	80.9 ± 4.18
Production of phospholipids (% of esterified VA equivalents)	56.5 ± 6.77	39.0 ± 2.78*
Production of neutral lipids (% of esterified VA equivalents)	43.5 ± 6.77	61.0 ± 2.78*

[a]Bovine and rat liver slices were incubated for 17 h in a medium containing [1-^{14}C]VA. Esterification rate was calculated as the ratio of total esterification (sum of neutral and polar lipids) to total VA incorporated into liver explants. Total lipids from homogenate were extracted with chloroform/methanol (2:1), and the different lipid classes were separated on aminopropyl-activated silica cartridges.
[b]Data are means ± SEM of 5 animals per group. The significance of differences between species was tested by Student's *t*-test. *$P < 0.05$. For abbreviation see Table 1.
FIG. 3. Secretion of VA as part of lipids in VLDL particles by bovine and rat liver slices. Liver slices from bovine and rat were incubated in medium containing a mixture of FA (0.75 mM) and 55 μM [1-^{14}C]VA for 17 h. VLDL were purified by ultracentrifugal flotation. Values were expressed per g fresh liver (A) or as percentage of VA incorporated into liver slices (B). Data are means ± SE of 5 animals per group. For abbreviation see Figure 1. ^{c,d}Mean values with unlike superscript letters were significantly different using the Student's *t*-test ($P < 0.02$).

in relation to a lower energy requirement of the liver in large-sized than in small-sized animals (33). However, the proportion of VA readily oxidized by bovine and rat liver slices was similar in both species (around 20%) and was similar to that of oleate as determined by the same methodology in the preruminant calf and the rat (18,19). It can be concluded that differences noted in intensity of VA oxidation between species were directly linked with differences in VA uptake. However, the only study in rat describing characteristics of *trans* FA metabolism in hepatocytes showed that elaidic acid (18:1 Δ9*trans*) was oxidized to a greater extent than oleic acid (18:1 Δ9*cis*) (80 vs. 60% of metabolized FA) (20). Discrepancies between the two studies could be explained either by differences in the chemical structure of *trans* FA (18:1 Δ11*trans* vs. 18:1 Δ9*trans*) or, more probably, by differences in the incubation conditions of *trans* FA (elaidic acid was added alone into the medium whereas VA was added with a mixture of FA similar to bovine plasma nonesterified FA to simulate *in vivo* physiological conditions). In the study of Guzman *et al.* (20), the addition of elaidic acid alone to the medium might explain its high rate of oxidation since it represented the only energy source provided to hepatocytes.

The lack of VA bioconversion into more desaturated or elongated derivatives such as CLA in both species was not expected since several studies had reported an endogenous production of *cis*9,*trans*11 CLA from VA (5,6,9,10). Synthesis of CLA from VA is clearly catalyzed by the Δ9-desaturase, as demonstrated by using different specific stimulators or inhibitors of the activity of this enzyme (5,6). In rodents, the Δ9-desaturase is predominantly located in the liver (34), and Pollard *et al.* (35) demonstrated that VA was efficiently desaturated in the rat liver microsomes by Δ9-desaturation. In contrast, in growing and lactating ruminants, Δ9-desaturase is mainly present in the adipose tissues and the mammary gland, respectively (36,37) although Ward *et al.* (37) recently demonstrated the presence of a significant amount of Δ9-desaturase

transcripts in the liver of ovine. Moreover, Chang *et al.* (38) showed that a high-fat diet induced Δ9-desaturase activity in ruminant liver. The lack of VA bioconversion in the present study might be explained by the difference between our experimental conditions and those of Pollard *et al.* (35). Indeed, the mixed FA added to the medium, and therefore potentially available for hepatocytes, contained preferred substrates (16:0, 18:0) for the Δ9-desaturase leading to production of oleic and palmitoleic acids, respectively (39). Moreover, the *ex vivo* system was chosen to preserve the normal architecture of the liver tissue, to avoid dedifferentiation of hepatocytes, and finally, to preserve the regulatory effect as under *in vivo* conditions (40). It was not the case for the study of Pollard *et al.* (35) using isolated rat liver microsomal systems of which activities of other cellular constituents were excluded. Consequently, the rat liver would have a low capacity to convert VA into CLA, and adipose tissue would be the major site of endogenous synthesis of CLA, as previously proposed by Santora *et al.* (8) in mice and by Bauchart *et al.* (41) in bovine.

Surprisingly, a small but nonnegligible part of the ^{14}C VA was recovered as ^{14}C 16:0 in the rat liver slices (3.2% of incorporated VA). It has been demonstrated that *trans* FA may undergo partial β-oxidation in peroxisomes (20), a process in which FA are shortened by two carbon atoms per cycle. The shortened FA may escape from the peroxisomes and be further metabolized in the mitochondria or incorporated into different lipid classes. Thus, 16:0 may be produced by peroxisomal β-oxidation. Further, the ^{14}C-acetate released from peroxisomes could be reincorporated into 16:0 by *de novo* synthesis (42). Similar catabolic processes have already been demonstrated in the liver of rat in the case of mono-*trans* isomers of linoleic and α-linolenic acids (43) and of CLA (44,45), and in the liver of preruminant calf fed a coconut oil-based milk diet rich in 12:0 and 14:0 (42).

Differences in the way of esterification of VA and metabolites between rat (into neutral lipids) and bovine (into polar lipids) have not previously been reported. However, the slight differences observed between animal species were in agreement with previous data showing a preferential esterification of oleate into polar lipids in the bovine liver (De La Torre, A., Gruffat, D., Chardigny, J.M., Durand, D., and Bauchart, D., unpublished data) and into the neutral lipids in the rat liver (18).

The extent of secretion of VA incorporated into TG as part of VLDL particles by both bovine and rat liver slices was, in intensity, rather low in our experimental conditions (less than 0.1% of VA incorporated into cells), which is in agreement with the fact that newly synthesized TG represented only a small part (4 to 13%) of lipids secreted by the liver as parts of VLDL (46). Neosynthesized TG are stored primary in cytosolic droplets from which they enter into a hydrolysis/esterification cycle to return to the endoplasmic reticulum for VLDL assembly (47). Therefore, it is not excluded that, in our experimental conditions, the time of incubation for liver slices would be too short to allow the return of a significant amount of TG to the secretion pool. Differences between species of VA secretion intensity probably resulted from differences in VA uptake rather

than in capacity to secrete VA in VLDL since no difference was noted when results were expressed as the percentage of VA incorporated by cells.

In conclusion, the *in vitro* model of liver slices allows us to compare the main metabolic pathways of VA in bovine and rat animals. We clearly demonstrated that the hepatic metabolism of VA was not significantly different between the two animal species since differences in intensity of the different metabolic pathways of VA were directly linked to differences in uptake efficiency of VA between these two animal species. It is important to note that VA was not converted into CLA by the liver of either species. The extrahepatic sites for endogenous synthesis of CLA included adipose tissue, as suggested by an *in vivo* experiment with mice given a VA supplement, which showed a large incorporation of CLA from VA into lipids in adipose tissue (8). Indeed metabolic experiments using adipose tissue slices would be necessary to verify this hypothesis.

ABSTRACT: 4-*O*-Podophyllotoxinyl 12-hydroxyl-octadec-*Z*-9-enoate (PHEFE) is a structurally novel FA analog of podophyllotoxin. In the present study, *in vitro* effects of PHEFE on a panel of 60 human tumor cell lines and its potential modes of anticancer action were investigated. PHEFE exhibited strong growth-inhibitory action in a number of solid tumor cells *in vitro*. It did not inhibit tubulin polymerization as podophyllotoxin does; rather, it inhibited the catalytic activity of topoisomerase II. Flow cytometry and staining assay with 4,6-diamidine-2-phenylindole dihydrochloride showed that PHEFE blocked the cell cycle at the G_2/M phase and induced apoptosis in HL-60 cells. These analyses suggest that PHEFE has promising anticancer characteristics that differ from podophyllotoxin and etoposide.

Paper no. L9621 in *Lipids 40*, 303–308 (March 2005).

The present generation of antineoplastic agents offers limited therapeutic benefits for most human malignancies, and the problem of resistance compromises the effectiveness of these drugs. Thus, there is a continuing need for identification and development of new agents with novel mechanisms of action and improved therapeutic potential. Although empirical evaluation of clinical efficacy remains the cornerstone for the clinical development of novel agents, an understanding of the mechanism of action of putative new antineoplastic agents is an area of profound importance.

Podophyllotoxin (Fig. 1), the bioactive principle of genus *Podophyllum*, is known for its potent antitumor activity (1,2). It functions as a mitotic inhibitor by binding reversibly to tubulin and inhibiting microtubule assembly (2,3). The main deficiency of podophyllotoxin is its lack of selectivity against tumor cells, which greatly restricts its clinical utility. Numerous synthetic approaches have been undertaken to develop analogs of podophyllotoxin, resulting in a growing number of compounds with improved therapeutic indices. Extensive studies have permitted the clinical development of two widely used glycosylated semisynthetic derivatives, etoposide and teniposide. They inhibit the essential enzyme DNA topoisomerase II (Topo II) by stabilizing the cleavage complex that results in DNA damage (3–5). Although etoposide and teniposide are known to be useful against various types of tumors, the problems of drug resistance, myelosuppression, and low bioavailability have limited their therapeutic application. New podophyllotoxin derivatives that possess altered pharmacological profiles and different antitumor mechanisms of action could expand the utility of this class. Recently, we reported an efficient and high-yielding method for synthesis of C_4-FA analogs of podophyllotoxin, as well as preliminary investigations of *in vitro* anticancer activity (6). Out of these 10 analogs, eight compounds demonstrated significant growth inhibition in four human solid tumor (SK-MEL, KB, BT-549, SK-OV-3) and leukemia (HL-60) cells with IC_{50} values ranging from 0.07 to 4.0 µM but did not inhibit growth of noncancerous VERO cells, unlike podophyllotoxin, which showed an IC_{50} of 0.55 µM for VERO cells. This suggested their mechanism of action may be different from that of podophyllotoxin. The IC_{50} for the most active derivative, 4-*O*-podophyllotoxinyl 12-hydroxyl-octadec-*Z*-9-enoate (PHEFE) ranged from 0.07 to 0.3 µM (6). With this view, efforts were directed to exploring the anticancer activity of one of these structurally novel compounds, the most active derivative, PHEFE (Fig. 1), against the National Cancer Institute's (NCI's) 60 human tumor cell lines screening panel. To understand the mode of action for anticancer activity, we also studied the effect of PHEFE on microtubule assembly, topoisomerases, cell cycle, and apoptosis in HL-60 cells. Here, we report the findings of these investigations.

MATERIALS AND METHODS

Chemicals and reagents. PHEFE was synthesized as described previously (6). Cell culture reagents were purchased from Quality Biological, Inc. (Gaithersburg, MD), except for FBS, which was purchased from Atlanta Biochemical, Inc. (Atlanta, GA). 4,6-Diamidine-2-phenylindole dihydrochloride (DAPI) and all other reagents were obtained from Sigma (St. Louis, MO). Lyophilized tubulin was purchased from Cytoskeleton Inc. (Denver, CO). Purified human topoisomerase enzymes and kinetoplast DNA (kDNA) were purchased from TopoGen Inc. (Columbus, OH).

Cell lines and cultures. HL-60 promyelocytic leukemia cells from the American Type Culture Collection (ATCC; Rockville, MD) were grown in RPMI 1640 medium supplemented with 10% FBS, 2 mM L-glutamine, and 10, 000 U/mL penicillin G
FIG. 1. Chemical structure of podophyllotoxin (**1**) and 4-*O*-podophyllotoxinyl 12-hydroxyl-octadec-Z-9-enoate (PHEFE) (**2**).

sodium in an atmosphere of 95% humidity and 5% CO_2 at 37°C. The details of cell lines used in the NCI anticancer drug discovery program are available at http://dtp.nci.nih.gov.

Evaluation of in vitro antitumor activity. Antitumor activity of PHEFE was determined at NCI through the antitumor screening program that consists of a panel of 60 human tumor cell lines (7). The activity was tested at a minimum of five concentrations at 10-fold dilutions (0.01 to 100 μM). Cells were exposed to the drug for 48 h, and the cell viability was determined by sulforhodamine B protein assay (http://dtp.nci.nih.gov). The activity is reported in terms of GI_{50} (concentration that causes a growth inhibition of 50%).

Microtubule polymerization assay. The assay for microtubule polymerization was performed in Corning Costar 96-well plates using CytoDYNAMIX Screen from Cytoskeleton Inc. Bovine brain tubulin used in the assay contained 90% tubulin and 10% microtubule-associated proteins. The lyophilized tubulin was reconstituted to 2 mg/mL in G-PEM buffer consisting of 80 mM Pipes [piperazine-*N*,*N*′-bis(2-ethanesulfonic acid)] sesquisodium salt, 2 mM $MgCl_2$, 0.5 mM EGTA, and 1 mM GTP, pH 6.9. When 100 μL of reconstituted tubulin is pipetted to a well of a prewarmed plate, it polymerizes efficiently at 37°C. Tubulin polymerization is measured by recording the increase in absorbance at 340 nm for 30 min on a Bio-Tek PowerWaveXS (Bio-Tek Instruments, Inc., Winooski, VT) plate reader. Taxol (10 μM) and podophyllotoxin (10 μM) were included as known ligands (stabilizer and inhibitor, respectively) for tubulin polymerization. PHEFE was tested up to a concentration of 25 μM using a stock of 5 mM in DMSO. The final DMSO concentration was 0.5% in the assay and did not affect the rate of tubulin assembly.

Assay for inhibition of topoisomerase II. (i) Catalytic activity. Measurement of the catalytic activity of Topo II was based on the conversion of kDNA to decatenated kDNA. The assay was performed in a total volume of 20 μL containing 200 ng kDNA, test compound, and 2 units of Topo II in assay buffer (50 mM Tris-HCl, pH 8.0, 120 mM KCl, 10 mM $MgCl_2$, 0.5 mM ATP, 0.5 mM DTT, and 30 μg/mL BSA). The mixture was incubated at 37°C for 30 min, and the reaction was terminated by the addition of 4 μL of stop buffer [5% sarkosyl (*n*-lauroyl-

sarcosine, sodium salt), 0.125% bromophenol blue, 25% glycerol]. DNA was analyzed by electrophoresis on 1% agarose gel in TAE buffer (40 mM Tris-acetate, 2 mM EDTA, pH 8.5). Ethidium bromide (0.5 μg/mL) was added to the agarose gel and running buffer. After destaining with water, the gel was photographed on a Gel Doc system, and DNA was quantified by densitometric analysis using NIH Image 1.52. One unit of enzyme is defined as the amount of enzyme that can decatenate 200 ng of kDNA in 30 min at 37°C. Enzyme activity was measured in terms of the percentage of substrate kDNA converted to product (decatenated kDNA). The concentration of the test compound (PHEFE) that prevented 50% of the substrate from being converted to the product (IC_{50}) was calculated.

(ii) Cleavage assay. The assay was performed as just given with 4 units of Topo II in the cleavage buffer (30 mM Tris-HCl, pH 7.6, 120 mM NaCl, 8.0 mM $MgCl_2$, 3.0 mM ATP, and 15 mM β-mercaptoethanol). The reaction was terminated by addition of 2 μL SDS (10%) followed by addition of Proteinase K (50 μg/mL; Sigma Chemical) and further incubation at 37°C for 30 min. The loading buffer (10×) was added, and DNA was extracted with an equal volume of CIA (chloroform/isoamyl alcohol, 24:1). DNA was analyzed by electrophoresis and photodocumented as already described. Cleavage buffer is optimized to detect formation of cleavage complexes, and the decatenation activity is less robust in this buffer. Including ethidium bromide in the gel and buffer allows clear resolution of cleavage products and detection of linear DNA.

Cell cycle analysis. Cell cycle analysis of HL-60 cells was performed using flow cytometry. HL-60 cells were treated with vehicle, PHEFE (0.5 μM), or podophyllotoxin (0.02 μM) for 0–48 h. The cells ($2–4 \times 10^5$) were harvested and then washed with ice-cold PBS, followed by the immediate addition of 1 mL of ice-cold 70% ethanol. After fixation overnight at 4°C, cells were washed twice with PBS again, treated with RNase A (40 μg/mL) for 10 min, and stained with propidium iodide (50 μg/mL) for 15 min. Flow cytometry analysis was performed on a Becton Dickinson FACScan equipped with Becton Dickinson CELL Quest software.

Morphological assessment of cell death. Exponentially growing HL-60 cells were treated with vehicle, PHEFE (0.5

μM), or podophyllotoxin (0.02 μM) for 48 h. The cells were harvested by centrifugation and washed three times with PBS and fixed in a solution of 3.7% formaldehyde and then in methanol for 10 min each. Fixed cells were stained with 4 μg/mL of DAPI for 10 min. The nuclear morphology of cells was observed using a Nikon Universal Condenser C-CU fluorescence microscope equipped with a 100× oil immersion objective and UV-2A filter cubes. Images were acquired with Kodak camera tools-DC 290 and digitized using IPLab Spectrum (Scanalytics, Fairfax, VA) software.

All assays described were performed at least in duplicate, and the representative data are shown in the figures and table.

RESULTS

Anticancer activity against a panel of 60 human cancer cell lines in vitro. The growth-inhibitory activities of PHEFE against a panel of human cancer cell lines were evaluated in the NCI disease-oriented anticancer drug screen program. PHEFE inhibited the growth of a number of cancer cell lines tested in a concentration-dependent manner. However, there were significant differences in the sensitivity of these cells to PHEFE. Table1 lists the GI_{50} values of PHEFE in comparison with the GI_{50} values of etoposide. It can be seen that non-small-cell lung cancer NCI-H522, melanoma UACC-257, and breast cancer MDA-MB-435 cells were the most sensitive ($GI_{50} < 0.01$ μM), followed by non-small-cell lung cancer NCI-H23, colon cancer HCT-116, HT29 and KM12, CNS cancer SF-295, melanoma M14 and SK-MEL-2, renal cancer ACHN and SN12C, and breast cancer MDA-MB-231/ATCC cells (GI_{50} values ranging from 0.04 to 0.96 μM). Several other cells listed in Table 1 were moderately sensitive to PHEFE (GI_{50} values 1.17 to 8.95 μM) whereas some were least sensitive ($GI_{50} > 100$ μM). The pattern of sensitivity of cell lines was different for etoposide (VP-16), and compared with etoposide, a higher sensitivity of various cell lines to PHEFE was observed. However, prostate cancer and leukemia cells (except K562) were more sensitive to etoposide than PHEFE. Among solid tumors, cells most sensitive to PHEFE were not sensitive to etopside, e.g., NCI-H522, UACC-257, and MDA-MB-435.

Effect of PHEFE on tubulin polymerization. To explore the mechanism of anticancer action of PHEFE, we assessed the effect of PHEFE on tubulin polymerization *in vitro* and compared that result with the known ligands podophyllotoxin and taxol. As shown in Figure 2, PHEFE did not inhibit or stimulate the rate and extent of tubulin polymerization. However, as expected, podophyllotoxin inhibited and taxol stimulated tubulin polymerization. Thus, the anticancer action of PHEFE does not involve interaction with tubulin and does not resemble that of its parent compound podophyllotoxin.

Inhibition of topoisomerases. To study whether the cytotoxic action of PHEFE is also associated with inhibition of topoisomerases, the effects of PHEFE on human DNA Topo I and II were investigated. The activity of Topo I was not affected by PHEFE (data not shown). It inhibited Topo II-mediated decatenation of kDNA (catalytic activity of Topo II), as

TABLE 1
Anticancer Activity of PHEFE in Comparison with Etoposide[a]

[a]PHEFE, 4-*O*-podophyllotoxinyl 12-hydroxy-octadec-*Z*-9-enoate; CNS, central nervous system. GI_{50}, concentration required to achieve 50% growth inhibition.

shown in Figure 3A (lanes 6–8), in a dose-dependent manner (90, 70, and 5% inhibition at 70, 14, and 2.8 μM). An IC_{50} of 10 μM was computed from the dose curve (Fig. 3B). Podophyllotoxin did not affect the decatenation activity of Topo II (Fig. 3A, lanes 3–5). In the cleavage assay, PHEFE did not show any cleavage complex stabilization activity (lanes 4–6 in Fig. 4)
FIG. 2. Effect of PHEFE on tubulin polymerization. Tubulin polymerization of purified bovine brain was determined in presence of PHEFE (25 µM), podophyllotoxin (10 µM), and taxol (10 µM) as described in the Materials and Methods section. The extent of tubulin polymerization ($A_{340 \text{ nm}}$) is plotted as a function of time.

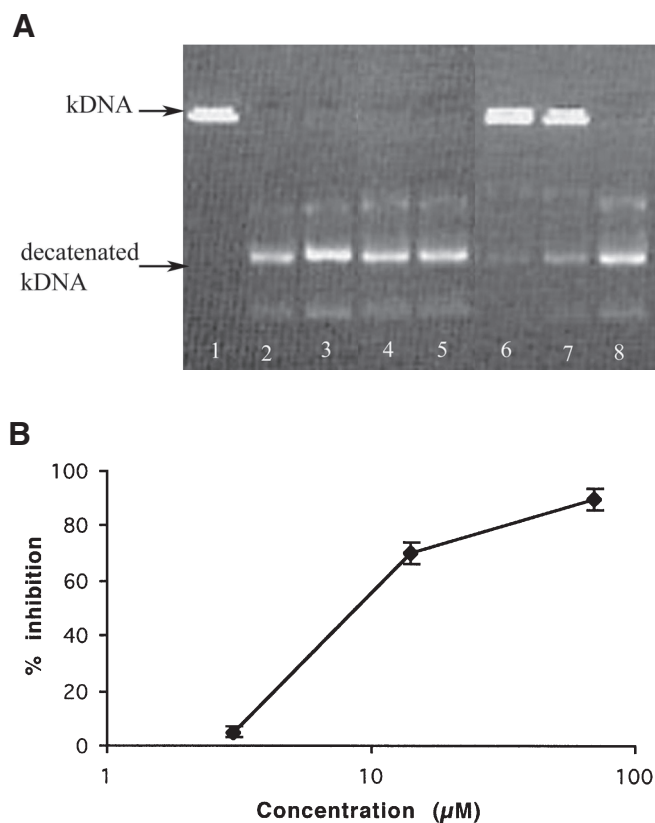

FIG. 3. Topoisomerase (Topo) II assay. (A) Determination of catalytic activity. Kinetoplast DNA (kDNA: 200 ng) was incubated with 2 units of Topo II in assay buffer with and without test drugs. Reaction was stopped and DNA was analyzed on agarose gel as described in the Material and Methods section. Lane 1: Substrate control (no enzyme); lane 2: Topo II activity without drug (DMSO control); lanes 3–5 and 6–8: Topo II activity in presence of podophyllotoxin and PHEFE (70, 14, and 2.8 µM, respectively). (B) Inhibition of catalytic activity of Topo II by PHEFE. Percent inhibition was calculated after quantifying the DNA bands. Error bar reflects the mean ± SEM of two determinations. For other abbreviation see Figure 1.
FIG. 4. Topo II assay: Determination of cleavage complex stabilization activity. Kinetoplast DNA (kDNA: 200 ng) was incubated with 4 units of Topo II in cleavage buffer with and without test drugs. The reaction was stopped with SDS and Proteinase K; after extraction with chloroform/isoamyl alcohol (24:1), DNA was analyzed on agarose gel as described in the Materials and Methods section. Lane 1: Substrate control (no enzyme); lane 2: kDNA and Topo II without drug (DMSO control); lane 3: kDNA, Topo II, and podophyllotoxin (70 µM), lanes 4–6: kDNA, Topo II, and PHEFE (70, 14, 2.8 µM); lanes 7–9: kDNA, Topo II, and etoposide (50, 25, and 12.5 µM). For other abbreviations see Figures 1 and 3.

and did not result in the formation of linear DNA as seen with etoposide (lanes 7 and 8 in Fig. 4). On the basis of these results, it is clear that PHEFE does not resemble podophyllotoxin (Fig. 3A) or etoposide (Fig. 4) with regard to its action on Topo II.

Induction of cell cycle arrest. To investigate the effects on cell cycle arrest, we examined the effects in HL-60 leukemia cells. As shown in Figure 5, at 6 h after the treatment with 0.5 µM of PHEFE, the cells began to arrest in the G_2/M phase of the cell accompanied by reduction of G_0/G_1 cycle. After 12 h, the majority of the surviving cells were in $G_2/M$ phase. At 24 h after treatment, the cells showed fragmented DNA (hypodiploids, HD) smaller than that of G_1 phase cells associated with apoptotic cell death. By 48 h, most cells had reached G_2/M and died. Likewise, podophyllotoxin treatment (0.02 mM) also arrested HL-60 cells at the G_2/M phase.

Induction of apoptosis. It is well established that prolonged cell cycle arrest leads to programmed cell death (apoptosis) (8,9). Therefore, we also tested the apoptosis-inducing ability of PHEFE in HL-60 cells by DAPI staining assay. As shown in Figure 6, after 48 h exposure, PHEFE (0.5 µM) induced extensive nuclear condensation and fragmentation in HL-60 cells, indicating that apoptosis was induced as a result of PHEFE treatment. Podophyllotoxin (0.02 µM) also induced apoptosis in HL-60 cells.

DISCUSSION

PHEFE is a C_4 α-bifunctional (12-hydroxyl-Z-9-ene) FA analog of podophyllotoxin. Our preliminary study showed that PHEFE suppressed the growth of a panel of five human cancer cells (SK-MEL, KB, BT-549, SK-OV-3, and HL-60) without affecting the growth of normal cells (6), suggesting that PHEFE might have a different molecular mechanism by which antitumor activity is achieved. In a continuation of this work, we further examined the anticancer activity of PHEFE on a broader panel of 60 tumor cells available at NCI (Table 1). The result demonstrated that PHEFE significantly inhibited the growth of a number of human tumor cells in a concentration-
FIG. 5. Effects of PHEFE (a) and podophyllotoxin (b) on cell cycle arrest in HL-60 cells. HL-60 cells in log phase growth were incubated with 0.5 μM PHEFE or 0. 02 μM podophyllotoxin for 0–48 h. Samples were taken at the times indicated in each panel for flow cytometric cell cycle analysis as described in the Materials and Methods section. Data shown represent relative numbers of cells (*y* axis) as a function of fluorescence intensity (*x* axis). For abbreviation see Figure 1.

FIG. 6. Induction of apoptosis by PHEFE in HL-60 cells. HL-60 cells were exposed to vehicle (a), 0.5 μM PHEFE (b), or 0.02 μM podophyllotoxin (c) for 48 h. Cells were harvested and washed with ice-cold PBS, followed by fixation in 3.7% formaldehyde and methanol. Fixed cells were incubated with 4 μg/mL of 4,6-diamidine-2-phenylindole dihydrochloride, and nuclear morphology was examined by using a fluorescent microscope. Arrows indicate apoptotic cells with condensed and fragmented nuclei.

dependent manner. Non-small-cell lung cancer NCI-H522, melanoma UACC-257, and breast cancer MDA-MB-435 cells were highly sensitive to this compound ($GI_{50} < 0.01$ μM), suggesting that PHEFE may turn out to be active against non-small-cell lung cancer, melanoma, and breast cancers. After comparison with etoposide, it was interesting to note that the pattern of sensitivity of the cells to PHEFE was not similar to etoposide. This is indicative of a different mode of action. Action of PHEFE on tubulin and Topo II also indicated that this compound does not resemble podophyllotoxin or etoposide in affecting these targets. It is well recognized that solid tumors are hard to treat, as they metastasize and develop resistance toward chemotherapy and radiation (10). PHEFE showed more potent anticancer activity against solid tumors than leukemia, which may be beneficial in the treatment of solid tumors. It is worth further exploring the potential of PHEFE to develop it as a possible new chemotherapeutic agent.

Since FA-derived podophyllotoxin molecules are a relatively new class of compounds (6,11,12), the molecular targets by which they exert antitumor activity have not yet been studied. In this report, we investigated the effects of the C_4-mono FA analog, PHEFE, on tubulin polymerization, topoisomerase activity, cell cycle progression, and apoptosis for the first time.

Microtubules are cytoskeletal structures formed by highly dynamic assemblies of tubulin heterodimers, and they play a crucial role in many biological processes, including mitosis, intracellular transport, exocytosis, and cell growth. An essential function of microtubules is to partition duplicated chromosomes into daughter cells during cell division. Microtubule dynamics are dramatically increased during mitosis and are very sensitive to interferences, thereby constituting an important target in cancer chemotherapy (2). The mechanism by which podophyllotoxin blocks cell division is known to be related to its inhibition of microtubule assembly in the mitotic apparatus (2,13). Unlike podophyllotoxin and a variety of its C_4 analogs (2), PHEFE did not inhibit tubulin polymerization. This observation suggests a unique profile of anticancer activity for PHEFE, involving mechanisms unrelated to inhibition of tubulin polymerization.

Topoisomerases are cellular enzymes that are intricately involved in maintaining the topographic structure of circular DNA during translation, transcription, and mitosis (14,15). These enzymes are well known as targets for a number of anticancer drugs (16–18). Catalytic Topo II inhibitors such as aclarubicin, merbarone, novobiocin, MST-16, ICRF-187, and ICRF-193 are emerging as an interesting new class of compounds in cancer

therapy for a variety of reasons (17,18). PHEFE inhibited the catalytic activity of Topo II without showing any cleavage complex stabilization effects. This effect is different from that observed for the epipodophyllotoxin analogs (βC-4, epimers) etoposide and teniposide, which are known to act *via* Topo II cleavage complex stabilization (16). Therefore, PHEFE may be a candidate of pharmaceutical significance, because of its α-stereochemistry at C-4 and its interaction with Topo II, similar to the class of catalytic inhibitors (17,18). In cell cycle analysis, both PHEFE and podophyllotoxin block the cell cycle at the G_2/M phase. However, the mechanism of action by which they induce cell cycle arrest is different. Podophyllotoxin blocks cell cycle progression in association with inhibition of tubulin polymerization, whereas PHEFE lacks the tubulin inhibition but elicits G_2/M blockage in association with inhibition of Topo II. The IC_{50} for Topo II inhibition (10 μM) is much higher than the concentration required to induce cell cycle arrest and apoptosis (0.5 μM). This suggests that, in addition to Topo II inhibition, another cellular mechanism or mechanisms may also be involved in the cytotoxic action of PHEFE.

The mode of cell death induced by PHEFE and podophyllotoxin was further investigated by DAPI staining assay. There are two known mechanisms of cell death: necrosis and apoptosis. Necrosis is usually considered to result from physical injury. Apoptosis is a deliberate and genetically controlled cellular response to developmental and environmental stimuli; it is characterized by cell shrinkage and chromatin condensation, followed by fragmentation of nuclear components (19). Selective induction of apoptosis in cancer cells or malignant tissues represents an efficient strategy for cancer chemotherapy. In this study, apoptosis was detected within 48 h of drug treatment by DAPI staining assay at cytotoxic concentrations. PHEFE and podophyllotoxin induced extensive nuclear condensation and DNA fragmentation. The results of studies by flow cytometry show that there was extensive HD debris, perhaps from apoptotic cells. These investigations indicate that PHEFE and podophyllotoxin, although displaying distinct pharmacological properties, both induce cellular responses that lead to induction of apoptosis.

Unlike podophyllotoxin, etoposide, and teniposide, PHEFE neither inhibited microtubulin polymerization nor stabilized the cleavage complex of DNA Topo II. Rather, it inhibited the catalytic activity of Topo II. The overall effect of PHEFE also resulted in cell cycle arrest and apoptosis.

ABSTRACT: Differences in the FA composition of subcellular fractions from healthy and cancerous kidney tissues from the same patients were examined. Only minor differences in CLA content were found between the healthy and the cancerous tissue portions. Regarding the distribution pattern, CLA incorporation into nuclei and cytosol was significantly higher than incorporation into plasma membranes and mitochondria, which could be correlated to the neutral lipid content of these fractions. The subcellular distribution pattern of CLA was similar to that observed with monounsaturated FA but unlike that found with 18:2n-6, which underlines the different physiological properties of CLA and 18:2n-6. Because PUFA have been suggested to have an effect on cancer risk, the contents of n-3 and n-6 PUFA were determined in kidney and renal cell carcinoma (RCC). The 18:2n-6 content and Δ^5 desaturase activity were significantly lower, and the 18:3n-6, 20:3n-6, and 20:5n-3 contents and Δ^6 desaturase activity were significantly higher in RCC than in healthy renal tissue, indicating a changed PUFA metabolism in RCC. Previous research has suggested that CLA inhibits the elongation and desaturation of 18:2n-6 into 20:4n-6. In that case, one might speculate that a diet enriched in CLA would be a useful tool in preventing RCC. However, the involvement of CLA in preventing renal cancer could not be demonstrated definitively from the design of this experiment. Further understanding of the cause and/or consequence of the difference in FA metabolism may lead to a better understanding of RCC.

Paper no. L9605 in *Lipids 40*, 309–315 (March 2005).

CLA describes a group of positional and stereochemical isomers of 18:2n-6 that contain two conjugated double bonds. CLA can be found in natural food sources, such as dairy products or the meat of ruminant animals (1). At the end of the 1980s, CLA was found to possess anticarcinogenic properties, and nowadays the anticarcinogenic effect of CLA is well known from several *in vivo* and *in vitro* studies (2,3). However, the mechanism(s) of the anticarcinogenic effect of CLA have not yet been clarified, although several studies have shown that diets containing CLA are associated with altered phospholipid-associated FA metabolism and eicosanoid formation (4,5).

The existing data suggest that dietary CLA might also be used in humans for the prevention of cancer, and the feasibility of increasing the CLA content of food is already being considered to increase the CLA intake in humans (6). In spite of such potential, few studies are available that deal with the association between CLA and cancer in humans. In 2000 Aro *et al.* (7) examined the relationship between dietary or serum CLA in women and the risk of breast cancer. They found dietary or serum CLA to be significantly lower in cancer cases than in controls, suggesting a protective effect of CLA on breast cancer risk, but only in postmenopausal patients. In contrast, a cohort study, carried out in 2002, estimated dietary intake of CLA to be associated with increased risk of breast cancer in postmenopausal patients (8). The correlation between CLA and cancers other than breast cancer in humans has not been examined so far.

Renal cell cancer (RCC) is responsible for about 2% of all cancer deaths in developed countries and represents 80–85% of all tumors of the kidney. The risk of RCC is known to be influenced by many environmental factors, such as tobacco smoking, elevated body mass index (BMI), a few medical conditions, and a family history of the disease. Furthermore, many dietary factors have been considered in relation to RCC. Vegetables, fruit, vitamin C, and carotenoids have shown protective effects, whereas meat and milk products have been risk factors; however, the findings have not been uniform (9).

In the present study, differences in the FA composition of subcellular fractions from healthy and affected kidney tissues from the same patients were examined. In detail, the contents of CLA isomers and the long-chain n-6 and n-3 FA, which are involved in eicosanoid biosynthesis, were determined and the appropriate ratios for the calculation of Δ^9, Δ^6, and Δ^5 desaturase and elongase activities were formed. Several studies have already focused on the incorporation of CLA into individual tissue lipid classes (10,11). Only a few studies, however, have dealt with the distribution of CLA in cell organelles (12,13), and no study has reported on the distribution of CLA in cell organelles in human tissues. The intracellular distribution of CLA is of interest because it could provide valuable clues to potential biochemical target sites.

MATERIALS AND METHODS

Tissue procurement. Patients with a clinical diagnosis of renal cancer underwent surgical resection of their tumors at the Department of Urology, General Hospital Barmbek, Hamburg. All patients had a radical nephrectomy of the involved kidney and gave written consent to a protocol approved by the ethics commission of the Hamburg Medical Association. A piece of cancerous tissue and a piece of healthy renal tissue were removed from the nephrectomy specimen for study immediately following resection. Tissue sectioning was performed by a pathologist in the Department of Pathology, General Hospital Barmbek, Hamburg, so as not to compromise the histological diagnosis. Samples were snap-frozen in liquid nitrogen and stored at −80°C until analyzed.

Cell fractionation. Tissue specimens were fractionated into nuclear, mitochondrial, plasma membrane, and cytosolic fractions as described previously (14). Briefly, tissue specimens were suspended in a 10-fold volume of homogenization medium (0.25 M sucrose, 0.01 M Tris-HCl, 1 mM EDTA, pH 7.5) and homogenized, first in an UltraTurrax homogenizer for 5 s and then in a Potter–Elvehjem homogenizer with six up-and-down strokes of a Teflon pestle. The homogenate was filtered through a coarse metal sieve and was centrifuged at 1,000 × *g* for 10 min. The crude pellet, representing the nuclear fraction, was resuspended in 1.38 M sucrose and purified by centrifugation at 40,000 × *g* for 80 min. After separation of the crude nuclear fraction, the supernatant fluid was centrifuged at 39,000 × *g* for 45 min to sediment mitochondria and plasma membranes. The 39,000 × *g* supernatant was regarded as the cytosolic fraction. To separate the plasma membranes from the mitochondria, the pellet was resuspended in 1.38 M sucrose and homogenized in a Potter–Elvehjem homogenizer with three up-and-down strokes. Sucrose (0.25 M) was loaded on top of the suspension and the resulting discontinuous gradient was centrifuged at 57,000 × *g* for 90 min. The plasma membranes appeared as a band at the sucrose interface, and the mitochondria were in the bottom pellet.

To determine the purity of the subcellular fractions, the activities of marker enzymes were measured. Succinate dehydrogenase was used as a marker for mitochondria, alkaline phosphatase for plasma membranes, acid phosphatase for lysosomes, NADPH-cytochrome c reductase for microsomes, lactate dehydrogenase for cytosol, and catalase for peroxisomes. All these assays were carried out as described previously (15–18). For calculation of enzyme activities, the protein contents of tissue homogenates and subcellular fractions were measured by the method of Bradford (19). All fractions were highly enriched in their corresponding marker enzymes. The fraction designated the cytosolic fraction contained not only cytosol but also microsomes and lysosomes.

Lipid analysis. Lipids were isolated from whole tissue homogenates as well as from cell fractions by extracting them twice with dichloromethane/methanol (2:1, vol/vol) and once with hexane. Subsequently, FAME were generated by derivatization of the lipid extract with 5% potassium methoxide in methanol (Merck-Schuchardt, Hohenbrunn, Germany) at 60°C for 15 min according to the method of Pfalzgraf *et al.* (20). The pattern of total FAME was analyzed by GC (Hewlett-Packard GC system 6890 with FID, Waldbronn, Germany) using a CP-Sil 88 capillary column (100 m × 0.25 mm i.d. with a 0.2-µm film thickness; Chrompack, Middelburg, The Netherlands). The following three-step temperature run was used to separate FAME: initial 70°C, held 3 min; 8°C/min to 180°C, held 10 min; 3°C/min to 235°C, held 10 min. The inlet temperature was 200°C and the detector temperature was 260°C. A 2-µL volume was injected at a split ratio of 10:1. Hydrogen was used as the carrier gas at 1.5 mL/min.

CLA isomer distribution was determined by silver ion HPLC analysis (21). Separation was carried out with a Waters 515 HPLC system (Waters, Milford, MA) equipped with a photodiode array detector 996. Two silver-loaded Chromspher 5 Lipids columns (Chrompack), 5-mm particle size, 250 × 4.6 mm, were used series-wound with a mobile phase of hexane/acetonitrile (100:0.5, vol/vol) at a flow rate of 1 mL/min. Because of their conjugated double bonds, CLA isomers could be detected at 234 nm, whereas unconjugated unsaturated FA absorbed at 200 nm.

FAME standards, including a mixture of CLA isomers, were used to identify and quantify sample FAME (Sigma Chemical Co., Deisenhofen, Germany).

Statistical analysis. All data are expressed as mean ± SD. Statistical comparisons between healthy renal tissue and RCC were made using Student's two-tailed *t*-test for paired values ($P < 0.05$). One-way ANOVA with Scheffé, Student–Newman–Keuls, and Tukey-B as *post hoc* tests were used to determine significant differences in FA distribution between the subcellular fractions ($P < 0.05$). All statistics were performed using SPSS Statistical Software, version 11.5.2.1 (SPSS Inc., Chicago, IL).

RESULTS

All 23 patients studied had RCC. Table 1 shows clinical characteristics of the tumors. Three patients suffered additional diseases, namely, alimentary adiposity, family hyperlipidemia, or type 2 diabetes. Two patients were smokers. All patients, male and female, were born between 1921 and 1957 and had a mean BMI of 25.95 ± 2.85. All clinical and anthropomorphic data were collected at the Departments of Urology and Pathology, General Hospital Barmbek (Hamburg, Germany).

CLA content was readily detected in the total lipid extracts of healthy human renal tissue and RCC as well as in nuclear, mitochondrial, plasma membrane, and cytosolic fractions of these tissues (Fig. 1). For kidney, CLA incorporation was significantly higher in nuclei and cytosol compared with total lipid extract, plasma membranes, and mitochondria. For RCC, similar CLA contents were measured, with the exception of plasma membranes. The CLA content in plasma membranes of RCC was significantly higher than in plasma membranes of healthy renal tissue (0.33 ± 0.18 and 0.21 ± 0.06%, respectively). No further differences in total CLA content between the two types of tissue were detected.

The distribution pattern of the monounsaturated FA (MUFA) 14:1*cis*9, 16:1*cis*9, 18:1*cis*9, 20:1*cis*11, 22:1*cis*13, and 24:1*cis*15 in sum in the subcellular fractions was similar to the distribution pattern observed with total CLA and unlike that found with 18:2n-6 (Figs. 2, 3). The 18:2n-6 content was highest in mitochondria and lowest in total lipid extracts of both types of tissue. The MUFA content was significantly lower in the nuclear, cytosolic, and plasma membrane subcellular fractions of healthy compared with RCC tissues, whereas 18:2n-6 was significantly lower in total lipid extracts and significantly higher in the nuclear fraction of RCC.

The individual CLA isomers present in these tissues are shown in Figure 4. The *cis*9,*trans*11-CLA was shown to be the prominent CLA isomer in healthy renal tissue as well as in RCC with more than 80% of total CLA. A significant difference between the two types of tissues was detected only for *cis*11,*trans*13-CLA; the content was higher in RCC than in healthy renal tissue (2.67 ± 1.39 and $1.49 \pm 0.70\%$, respectively).

In addition to the CLA contents, the total FA profiles were determined; 16:0, 18:0, 18:1*cis*9, 18:2n-6, and 20:4n-6 were found to be the major FA in all subcellular fractions from both types of kidney tissue studied (data not shown). In detail, we examined the contents of the long-chain n-6 (18:2n-6, 18:3n-6, 20:3n-6, and 20:4n-6) and n-3 PUFA (18:3n-3, 20:5n-3, and 22:6n-3) (Fig. 5A– C).

The appropriate product/precursor ratios were calculated for Δ^9, Δ^6, and Δ^5 desaturase and elongase activities (Figs. 6A, 6B). For Δ^9 desaturase activity, the ratio Δ^9-MUFA (14:1*cis*9, 16:1*cis*9, and 18:1*cis*9)/saturated FA (SFA) (14:0, 16:0, and 18:0), for Δ^6 desaturase activity the ratio 18:3n-6/18:2n-6, for elongase activity the ratio 20:3n-6/18:3n-6, and for Δ^5 desaturase activity the ratio 20:4n-6/20:3n-6 were calculated.

Significant differences were observed for 18:2n-6, 18:3n-6, 20:3n-6, 20:5n-3, Δ^6 desaturase, and Δ^5 desaturase activities, with 18:2n-6 content (13.73 ± 1.78 and $14.7 \pm 2.04\%$, respectively) and Δ^5 desaturase activity being lower, and with 18:3n-6 (0.12 ± 0.08 and $0.04 \pm 0.02\%$, respectively), 20:3n-6 ($1.71 \pm$
FIG. 1. CLA content in tissue samples of human kidney and renal cell carcinoma as well as in their subcellular fractions. Values are means ± SD ($n = 23$). Columns marked with different letters within one kind of tissue are significantly different ($P < 0.05$). (*), Corresponding healthy and cancerous tissues were significantly different at $P < 0.05$.
FIG. 2. Content of the monounsaturated FA (MUFA) 14:1*cis*9, 16:1*cis*9, 18:1*cis*9, 20:1*cis*11, 22:1*cis*13, and 24:1*cis*15 in sum in tissue samples of human kidney and renal cell carcinoma as well as in their subcellular fractions. Values are means ± SD ($n = 23$). Columns marked with different letters within one kind of tissue are significantly different ($P < 0.05$). (*), Corresponding healthy and cancerous tissues were significantly different at $P < 0.05$.
FIG. 3. 18:2n-6 content in tissue samples of human kidney and renal cell carcinoma as well as in their subcellular fractions. Values are means ± SD (*n* = 23). Columns marked with different letters within one kind of tissue are significantly different (*P* < 0.05). (*), Corresponding healthy and cancerous tissues were significantly different at *P* < 0.05.

0.50 and 1.10 ± 0.38%, respectively), and 20:5n-3 contents (0.36 ± 0.20 and 0.24 ± 0.16%, respectively) and Δ^6 desaturase activity being higher in RCC than in healthy renal tissue. The 20:4n-6 content (12.82 ± 4.18 and 15.12 ± 5.84%, respectively) and the elongase activity tended to be lower, whereas the 22:6n-3 content (1.79 ± 1.27 and 1.23 ± 0.70%, respectively) tended to be higher in RCC than in healthy renal tissue, but the differences were not significant. No differences at all between cancerous and healthy tissue were found for the 18:3n-3 content (0.50 ± 0.21 and 0.45 ± 0.17%, respectively) and Δ^9 desaturase activity.

DISCUSSION

Several studies dealing with the incorporation and distribution of CLA into different types of animal tissue are described in the literature (10,11,22–24). Unfortunately, the results of animal studies cannot easily be assigned to humans because of species and age differences. For this reason, studies on humans are indispensable. The present study is a first step to providing valuable clues to potential biochemical target sites of CLA in human renal
FIG. 4. Contents of CLA isomers in tissue samples of human kidney (white column) and renal cell carcinoma (black column). Values are means ± SD (*n* = 23). (*), Corresponding healthy and cancerous tissues were significantly different at *P* < 0.05.
FIG. 5. Contents of (A) 18:2n-6 and 20:4n-6, (B) 18:3n-6 and 20:3n-6, and (C) 18:3n-3, 20:5n-3, and 22:6n-3 in tissue samples of human kidney (white column) and renal cell carcinoma (black column). Values are means ± SD (*n* = 23). (*), Corresponding healthy and cancerous tissues were significantly different at *P* < 0.05.

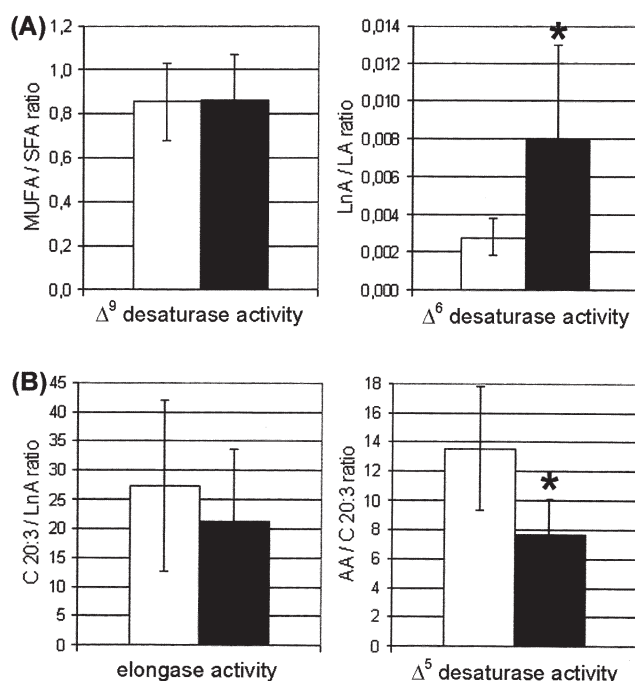
cancer by comparing the subcellular distribution of CLA in healthy and cancerous tissue samples from the same patients. The study design is limited by missing information on dietary intake values, and there is no comparison of true healthy vs. cancerous kidney tissues. However, as human tissues can be acquired only as waste products accruing at operations, systematic nutritional studies on human cancer are impossible. The examination of healthy and cancerous tissue samples from the same patients offered the possibility of comparing paired tissue samples with the same nutritional status. And even within this limited experimental design, significant differences in FA distribution were found between healthy and cancerous renal tissue, which emphasizes the importance of these results.


FIG. 6. Activity of (A) Δ^9 and Δ^6 desaturase and (B) elongase and Δ^5 desaturase in tissue samples of human kidney (white column) and renal cell carcinoma (black column). Values are means ± SD (n = 23). (*), Corresponding healthy and cancerous tissues were significantly different at $P < 0.05$. SFA, saturated FA; LA, linoleic acid; LnA, linolenic acid; AA, arachidonic acid; for other abbreviation see Figure 2.

The variation in CLA content between healthy and cancerous kidney tissue was generally very small. No significant difference in total CLA content between renal tissue and RCC could be observed. This result is in accordance with the results of Chajès *et al.* (25), who found no significant difference in mean CLA levels between patients with invasive breast carcinoma and patients with benign breast pathologies. However, Lavillonnière and Bougnoux (26) showed that the CLA content of breast tissue was higher in women with benign disease than in women with carcinoma of the breast.

Because of these contradictory results, the aim of this study was to examine the content of CLA in cancerous tissues more thoroughly. Therefore, total CLA content was measured not only in human RCC and the corresponding unaffected renal tissue of human tumor-bearing kidneys, but also in subcellular fractions of these tissues.

The distribution of CLA over cell organelles is only rarely described in the literature. Demarée *et al.* (12) found that more than 50% less CLA is incorporated into microsomes than into membrane fractions (containing plasma membranes, nuclei, and mitochondria) and nonmembrane fractions (containing nonpolar lipids) of adipose tissue and longissimus muscle of postweanling pigs. Because the microsomes are mainly part of the cytosolic fraction (14) and it was shown that CLA is incorporated best into nuclei and cytosol and significantly less into plasma membranes and mitochondria of renal tissue, the results of Demarée *et al.* (12) are in disagreement with this study.

Banni *et al.* (11) found that CLA is preferentially incorpo-

rated into neutral lipids. Therefore, it is of interest to discuss whether the CLA levels were higher in subcellular fractions containing higher levels of neutral lipids compared with phospholipids. For mitochondria, all values reported for total lipids as the percentage of dry weight and the proportion as phospholipids are in relatively good agreement. It is clear that pig and beef heart and mouse and rat liver mitochondria all have very similar total lipid contents (about 27%) and that about 90% of the total lipids are phospholipids (27). Nuclei have not been studied adequately for total lipid content. A value of 11% was reported for rat liver nuclei, and phospholipids were found to represent only about 3% of the dry weight of a pure preparation of nuclei (27). For plasma membranes, total lipid values of 30.5 and 32.8% were reported for rat and mouse liver, respectively, of which 60.0 and 55.0%, respectively, comprised phospholipids (28). Therefore, the neutral lipid content is much higher in nuclei than in mitochondria and plasma membranes, which explains the preferential incorporation of CLA into nuclei compared with mitochondria and plasma membranes. No data on the neutral lipid content of cytosolic fractions are reported in the literature.

Van Hoeven and Emmelot (28) found increased contents of neutral lipids in hepatoma plasma membranes from mice and rats compared with normal liver plasma membranes. That might explain the significant enhancement of CLA content in the plasma membranes from RCC in comparison with healthy renal tissue. However, no data have been reported in the literature on the lipid class composition of RCC plasma membranes.

The subcellular distribution of CLA was compared with the distribution patterns of 18:2n-6 and the MUFA 14:1*cis*9, 16:1*cis*9, 18:1*cis*9, 20:1*cis*11, 22:1*cis*13, and 24:1*cis*15 in sum. We found that CLA and MUFA were similarly distributed, which is easily explained by the stereochemical structure of CLA. The most prominent CLA isomers in renal tissue and RCC are the *cis*,*trans* and *trans*,*cis* isomers, respectively. *Trans* unsaturated FA show a stereochemical structure similar to that of SFA; consequently, *cis*,*trans* and *trans*,*cis* unsaturated FA show a stereochemical structure similar to that of *cis*-MUFA. The subcellular distribution of 18:2n-6 is different from that of CLA, supporting the results of Banni *et al.* (11), who found that 18:2n-6 is distributed mainly in phospholipids, whereas CLA is incorporated primarily in the neutral lipids of rat liver. Therefore, the different cellular distributions of CLA and 18:2n-6 underline the different physiological properties of these two FA.

In addition, the incorporation of single CLA isomers was examined. No marked differences were found between healthy and cancerous renal tissues. Only the content of the *cis*11,*trans*13-CLA isomer was slightly, but significantly, increased in RCC. *Cis*11,*trans*13-CLA is one of the CLA isomers that is found mainly in commercial CLA preparations (29,30). It differs from the opposite 11,13-CLA geometric isomer *trans*11,*cis*13-CLA, which is generally present in natural dairy fats (31). However, Fritsche *et al.* (32) also reported on the occurrence of *cis*11,*trans*13-CLA in beef samples. Kramer *et al.* (33) examined the distribution of CLA isomers in tissue lipid classes of pigs fed a commercial CLA mixture. They found a

preferential accumulation of *cis*11,*trans*13-CLA in cardiac lipids compared with liver lipids, inner back fat, and omental fat. No data on kidney lipids have been reported, but the occurrence of *cis*11,*trans*13-CLA in kidney and RCC lipids might be due to a comparable accumulation of this isomer from trace amounts in foods, as observed for cardiac lipids.

In addition to CLA, total lipid profiles were determined. As discussed previously, marked variations in FA contents between the subcellular fractions of the two types of kidney tissue studied were detectable (14). However, because of variations between different kinds of tissues and species, no general statement on the characteristic FA profiles of single subcellular fractions was possible. The goal of the present study was a detailed, statistical examination of the n-3 PUFA 18:3n-3, 20:5n-3, and 22:6n-3 and the n-6 PUFA 18:2n-6, 18:3n-6, 20:3n-6, and 20:4n-6 in kidney and RCC, as PUFA have been suggested to have an effect on cancer risk by increasing the formation of eicosanoids in the tumor tissue (34). The contents of the n-6 PUFA measured were in good agreement with the results of Geers *et al*. (35), who analyzed the phospholipid composition of nephromas and the unaffected cortex of 15 tumor-bearing human kidneys. They found 18:2n-6 (11.1 ± 2.7 and 15.3 ± 1.5%, respectively) to be significantly decreased; 20:4n-6 + 22:1 (11.1 ± 3.7 and 14.9 ± 4%, respectively) tended to be decreased; and 20:3n-6 + 22:0 (3.9 ± 2.0 and 3.1 ± 0.5%, respectively) tended to be increased in the nephromas. No data on the contents of n-3 PUFA in renal tissue samples are reported in the literature.

The differences determined in n-3 and n-6 FA distribution and the resulting differences in desaturase and elongase activities between healthy renal tissue and RCC indicate a changed PUFA metabolism in RCC. No literature so far has linked n-3 and n-6 metabolism and RCC *via* its role as an eicosanoid precursor, but an abnormal cholesterol metabolism is described, which leads to the speculation that not only cholesterol metabolism but also other FA metabolic pathways may be abnormal (36). Furthermore, there is already evidence linking PUFA metabolism and breast cancer (7) or prostate cancer, another urological cancer (37). The greater 18:3n-6/18:2n-6 ratio but lower 20:3n-6/18:3n-6 and 20:4n-6/20:3n-6 ratios calculated in this study lead to the assumption that the low 20:4n-6 levels may be a result of decreased elongase and Δ^5 desaturase activities. Another explanation for the lower RCC contents of 20:4n-6 as well as 20:5n-3, substrates for the synthesis of eicosanoids by cyclooxygenase or lipoxygenase, might be an increased production of eicosanoids, which has previously been postulated for prostate cancer (37) and which has already been shown for breast cancer (38).

Further understanding of the cause and/or consequence of the differences in FA metabolism between healthy renal tissue and RCC may lead to a better understanding of RCC. Banni *et al*. (4) suggested that CLA inhibits the elongation and desaturation of 18:2n-6 into 20:4n-6. In that case, one might speculate that a diet enriched in CLA is a useful tool in preventing RCC. However, differences in CLA content and isomer distribution between healthy and cancerous kidney tissues from the same patients appeared to be minimal in the present study. Therefore, the involvement of CLA in preventing cancer of the kidneys cannot be definitively demonstrated from the design of this experiment.

Tavani and La Vecchia have shown that meat and milk products are risk factors in RCC (9). Results from studies on the association between consumption of dairy products and risk of breast cancer have been controversial. Some studies have found a significant inverse association, some a significant positive association, and some no association (39). Possible reasons for the discrepancy include different effects by different components of diary products. CLA, alone or together with other ingredients of dairy products, may be a factor that is responsible for a positive effect. This view is supported by the anticarcinogenic effects of CLA observed in experimental animal studies. On the other hand, a high consumption of processed meat and poultry, as reflected in an increased proportion of 20:4n-6 in serum FA, may increase the risk of breast cancer or RCC. Another possible explanation for the lack of an association between the intake of foods rich in CLA, such as ruminant products, and the occurrence of RCC is that the amount of CLA stored in human tissues may be too low to induce any protective effect on tumor development. CLA remains at a level at which inhibition of tumor growth has never been documented in animals.

Identification of Δ^7 Phytosterols and Phytosteryl Glucosides in the Wood and Bark of Several *Acacia* Species

Carmen S.R. Freire, Dora S.C. Coelho, Nuno M. Santos, Armando J.D. Silvestre*, and Carlos Pascoal Neto

Center for Research in Ceramics and Composite Materials (CICECO)
and Department of Chemistry, University of Aveiro, 3810-193 Aveiro, Portugal

ABSTRACT: The wood and bark of four *Acacia* species growing in Portugal, namely, *A. longifolia, A. dealbata, A. melanoxylon,* and *A. retinodes*, were investigated for their sterol content. The lipids fractions of the different wood and bark samples were isolated, and the sterols were identified and quantified by GC–MS. Two Δ^7 sterols, specifically, spinasterol and dihydrospinasterol, were the main sterols found in considerable amounts, particularly in wood tissues (more than 0.5 g/kg of dry wood in the case of *A. melanoxylon* and *A. retinodes*). The corresponding unusual steryl glucosides were also identified in significant amounts in the wood and bark extracts.

Paper no. L9682 in *Lipids 40,* 317–322 (March 2005).

Sterols are a very important group of lipidic compounds because of their broad range of biological functions and activities. In the Plant Kingdom, a large number of sterols (phytosterols) have been identified, of which the Δ^5 sterols, such as β-sitosterol (stigmasta-5-en-3-β-ol) and stigmasterol, are the most abundant (1,2). The homologous Δ^7 sterols, spinasterol and dihydrospinasterol (stigmastadien-7,22*E*-3-β-ol and stigmasta-7-en-3-β-ol, respectively), are the major components of only a few plant families, e.g., Caryophylaceae and Cactaceae (2). Furthermore, phytosterols can occur in free form, esterified with FA and aromatic acids, or as glucosides (2).

Phytosterols play a key role in stabilizing the cell membranes in plants (as cholesterol does in animals). Moreover, their beneficial effects on human health (3), of which the reduction of blood cholesterol level is the most well known, have been recognized for many years. However, the most significant advances in this field, and particularly in the use of phytosterols as ingredients in functional foods, have been made in the last decade (3). Currently, a wide range of functional foods supplemented with phytosterols are available on the market (4), leading to an increasing demand for abundant sources of these natural products.

Acacia trees are not cultivated in Portugal; however, they represent the main invasive plant species of the Portuguese pine and eucalyptus forests, as well as of the coastal dune systems (5). Every year a large number of *Acacia* trees are harvested to avoid the propagation of these exotic species, leading to the production of considerable amounts of biomass that are mainly used for domestic energy production. The wood and bark of these exotic species could represent a renewable source of fine chemicals. In fact, a large number of publications have been published describing the composition of *Acacia* species, and the most relevant results have recently been reviewed (6). However, only a few publications discuss the sterol composition of specific *Acacia* species (7–10). Since information on the chemical composition of *Acacia* species growing in Portugal is still lacking, we set out to characterize the most relevant species, namely, *A. longifolia*, *A. dealbata*, *A. melanoxylon*, and *A. retinodes*.

In the present work, the different *Acacia* wood and bark lipids were isolated by Soxhlet extraction and characterized by GC–MS. We report, for the first time, the identification of considerably high amounts of the less common Δ^7 sterols, namely, spinasterol and dihydrospinasterol, and the corresponding glucosides in the lipidic extracts of the wood and bark of the main *Acacia* species growing in Portugal.

MATERIALS AND METHODS

Samples. *Acacia* wood and bark samples were randomly sampled from 6 to 8 trees growing in the forests of the region of Aveiro, Portugal, at the end of May 2004. Samples were collected from the stem 1 m above the ground. Wood and bark samples were air-dried for 2 wk and then ground and sieved, and the granulometric fractions of 40–60 mesh were used for analysis.

Extraction of lipids from wood and bark samples. Three powdered aliquots (20 g) of each sample were Soxhlet extracted with dichloromethane for 8 h. The solvent was evaporated to dryness and the lipophilic extracts were weighed. The results were expressed as a percentage of dry wood or bark.

GC–MS analysis and quantification of the lipophilic extracts. (i) Extract derivatization. Prior to GC–MS analysis, approximately 20 mg of each dried extract was trimethylsilylated according to a known procedure (11): The residue was dissolved in 250 µL of dry pyridine, and compounds containing carboxyl and hydroxyl groups were converted into trimethylsilyl (TMS) esters and ethers, respectively, by adding 250 µL of bis(trimethylsilyl)trifluoroacetamide (BSTFA) and 50 µL of trimethylchlorosilane (TMSCl). After the mixture had stood at 70°C for 30 min, the derivatized extracts were analyzed by GC–MS.

*To whom correspondence should be addressed. E-mail: armsil@dq.ua.pt

Abbreviations: BSTFA, bis(trimethylsilyl)trifluoroacetamide; IS, internal standard; TMS, trimethylsilyl; TMSCl, trimethylchlorosilane.

(ii) GC–MS analysis procedure. Free sterols were analyzed and quantified in a Trace 2000 Series gas chromatograph equipped with a Finnigan Trace MS mass spectrometer, using helium as carrier gas (35 cm/s), and a J&W DB-1 capillary column (30 m × 0.32 mm i.d., 0.25 µm film thickness; J&W Scientific, Folsom, CA). The chromatographic conditions were as follows: initial temperature, 80°C; temperature rate, 4°C/min; final temperature, 285°C; injector temperature, 290°C; transfer-line temperature, 290°C; split ratio, 1:100.

Steryl glucosides were analyzed and quantified by GC–MS using a shorter length J&W DB-1 capillary column (15 m × 0.32 mm i.d., 0.25 µm film thickness). The chromatographic conditions were as follows (11): initial temperature, 100°C for 3 min; temperature rate, 5°C/min; final temperature, 340°C for 12 min; injector temperature, 320°C; transfer-line temperature, 290°C; split ratio, 1:100.

(iii) Identification and quantification of free sterols and steryl glucosides. Compounds were identified as TMS derivatives by comparing their mass spectra with the GC–MS spectral library, with data from the literature, and in some cases by injection of standards. For quantitative analysis, GC–MS was calibrated with the pure reference compounds stigmasterol and β-sitosteryl glucoside relative to tetracosane, the internal standard used. The respective multiplication factors needed to obtain correct quantification of the peak areas were calculated as an average of six GC–MS runs. All bark and wood extracts were injected in triplicate.

Mass spectra of Δ^7 steryl glucosides (TMS derivatives). Spinasteryl glucoside: 73 (14.8), 147 (7.1), 204 (100), 217 (13.8), 255 (3.1) 305 (1.4), 361 (2.7), 395 (7.4), 513 (4.0), 667 (0.5), 757 (0.5). Dihydrospinasteryl glucoside: 73 (10.1), 147 (7.2), 204 (100), 217 (13.2), 255 (1.2), 305 (1.3), 361 (1.8), 397 (12.9), 515 (3.5), 669 (0.5), 759 (0.5).

Chemicals. Stigmasterol (95% purity) and tetracosane (99% purity), BSTFA (99% purity), TMSCl (99% purity), dichloromethane (analytical grade), and pyridine (analytical grade) were supplied by Sigma Chemicals Co. (Madrid, Spain). Pyridine was dried by distillation over sodium hydroxide. Pure sitosteryl glucoside was isolated from a plant extract enriched in this steryl glucoside (12).

RESULTS AND DISCUSSION

The different *Acacia* species studied here, *A. longifolia*, *A. dealbata*, *A. melanoxylon*, and *A. retinodes*, presented similar wood lipid contents (Table 1), 0.3–0.5% of dry wood weight, which are values of the same order as those previously reported for *A. mangium* (10). The lipids contents of the bark samples (0.9–2.7%) were also very similar between the different *Acacia* species (Table 1); however, they were generally considerably higher that those found in the corresponding woods.

The GC–MS analysis of the lipophilic extracts of the four *Acacia* woods showed that they had very similar compositions, with FA and sterols as the main components (Fig. 1). Steryl glucosides were also found in all wood extracts, although in lower amounts. In addition, we found steryl esters, MG, and

TABLE 1
Lipidic Fraction (dichloromethane extractives) Yields (%, dry basis) of the Four *Acacia* Wood and Bark Samples

	Wood	Bark
A. longifolia	0.31 ± 0.01	0.92 ± 0.01
A. dealbata	0.36 ± 0.03	2.00 ± 0.06
A. melanoxylon	0.50 ± 0.03	2.04 ± 0.06
A. retinodes	0.31 ± 0.01	2.71 ± 0.09

long-chain alcohols among the minor components of the *Acacia* wood extracts.

Compositions of the *Acacia* bark extracts were similar; however, in these extracts long-chain fatty alcohols and MG were major components, along with FA and alcohols (Fig. 1). Therefore, the GC–MS chromatograms of the bark lipophilic extractives were much more complex than those observed for the corresponding wood extracts (Fig. 1). From a practical point of view, this could represent a disadvantage when considering the isolation of particular components.

Free sterols. As shown in Table 2, free sterols were more abundant in *Acacia* woods than in the corresponding bark tissues. *Acacia melanoxylon* and *A. retinodes* woods, in particular, contained notable amounts of these compounds (more than 500 mg of free sterols/kg of dry wood). These results were in good agreement with those published for *A. mangium* and *A. crassicarpa* (10). However, in these species, such high amounts of free sterols were found only in heartwood tissues (10). Bark samples contained around 200–300 mg of sterols/kg of dry bark.

Two Δ^7 sterols, namely, spinasterol and dihydrospinasterol (Fig. 2), were the main sterols identified in the wood and bark extracts of *A. dealbata*, *A. melanoxylon*, and *A. retinodes* (Table 2); on the other hand, *A. longifolia* contained similar amounts of the homologous Δ^5 (stigmasterol and β-sitosterol) and Δ^7 (spinasterol and dihydrospinasterol) sterols (Figs. 1 and 2, Table 2). As mentioned, these sterols have been reported previously in other *Acacia* species (7,8,10). However, the simultaneous occurrence of Δ^5 and Δ^7 sterols is quite unusual in woody plants. Campesterol, stigmastanol, and β-sitostanol also were found in some wood and bark samples but as minor components.

The sterols referred to here were identified based on their characteristic retention times (11) and on well-documented fragmentation patterns of their TMS derivatives (13,14). The homologous Δ^5 and Δ^7 sterols were easily distinguished by MS: (i) The ion $[M -129]^+$ was the characteristic base peak of the TMS derivatives of Δ^5 sterols, whereas it was absent from the mass spectra of the Δ^7 sterols; (ii) Δ^7 sterols, in particular the monounsaturated ones, in general presented a strong molecular ion and lost their lateral chain much more easily, leading to a characteristic intense peak at *m/z* 255.

Steryl glucosides. The steryl glucosides present in the lipidic fraction of *Acacia* woods and barks accounted for 31.5–159.0 mg/kg of dry wood and 146.0–352.6 mg/kg of dry bark (Table 3). Although it is commonly accepted that complete extraction of steryl glucosides requires more polar solvents (15), a recent
FIG. 1. GC–MS chromatograms, obtained with a 15-m DB-1 capillary column (J&W Scientific, Folsom, CA), of the lipidic fraction extracts of the *Acacia longifolia* wood and bark. 16:0, palmitic acid; 18:2, linoleic acid; 18:1, oleic acid; 18:0, stearic acid; IS, internal standard; 1, stigmasterol; 2, spinasterol; 3, β-sitosterol; 4, β-sitostanol; 5, dihydrospinasterol; 6, campesteryl glucoside; 7, stigmasteryl glucoside; 8, spinasteryl glucoside; 9, β-sitosteryl glucoside; 10, dihydrospinasteryl glucoside.

publication showed that similar yields could be obtained with dichloromethane (16); and in the case of woody plants, we observed that after extraction with dichloromethane, only small amounts of steryl glucosides (less than 3%) remained in the sample (12,17). Therefore, these values are expected to be representative of the total content of steryl glucosides of the different *Acacia* wood and bark tissues.

As observed with free sterols, the Δ⁷ steryl glucosides, that is, spinasteryl glucoside and dihydrospinasteryl glucoside, were identified in *A. dealbata*, *A. melanoxylon*, and *A. retin-*

odes wood and bark lipids (Figs. 1, 2), whereas a mixture of the homologous Δ^5 and Δ^7 steryl glucosides was found in the wood and bark lipophilic extracts of *A. longifolia* (Figs. 1, 2). To our knowledge, steryl glucosides have not been reported previously as *Acacia* wood and bark components, although spinasteryl glucoside and dihydrospinasteryl glucoside have been reported as components of *A. concinna* seed pods (18). In addition, steryl glucosides are not common components of woody plants, although spinasteryl glucoside has been reported as a component of *Albizia julibrissin* bark (19).

Steryl glucosides were also identified by GC–MS as TMS derivatives based on their characteristic fragmentation patterns (12,15,20). However, the mass spectra of the TMS derivatives of Δ^5 and Δ^7 steryl glucosides were very similar: The molecular ions were not observed, but their M.W. could be determined based on the mass of the $[M - 15]^+$, $[M - 15 - 90]^+$, and $[M - 15 - 90 - 90]^+$ ions. Cleavage of the sterol 3-C–O bond with charge retention on the sterol portion produced intense ions corresponding to the sterol moiety, that is, 383 for campesteryl glucoside, 395 for stigmasteryl and spinasteryl glucosides, and 397 for β-sitosteryl glucoside and dihydrospinasteryl glucosides, respectively. Finally, charge retention on the monosaccharide portion and cleavage of the C–O-glucosidic bond gave characteristic ions of the hexoses at *m/z* 451, 361, 217, 204, and 147. Furthermore, the ion at *m/z* 204 was very prominent, which is an indication of the hexose pyranoside configuration (19).

The distinction between the homologous Δ^5 and Δ^7 steryl glucosides was then established based on previous knowledge

[a]Obtained with a 15-m DB-1 column (J&W Scientific, Folsom, CA). (Note that these are the same column and chromatographic conditions as shown in Fig. 1.) *Sum of the abundances of partially overlying campesteryl glucoside and stigmasteryl glucoside; **sum of the abundances of co-eluting sitosteryl glucoside and spinasteryl glucoside. t_R, retention time (min). A dash indicates "not detected."

of the retention times of Δ^5 steryl glucosides (12) and on the co-injection of a sample enriched in these compounds (12), assuming that they presented the same profile as that observed with the corresponding free sterols. Therefore, the Δ^7 steryl glucosides, spinasteryl glucoside, and dihydrospinasteryl glucoside eluted after the corresponding Δ^5 steryl glucosides, stigmasteryl glucoside, and β-sitosteryl glucoside.

Steryl esters were detected only in the wood and bark of *A. longifolia*. The peaks assigned to steryl esters (Fig. 1) showed characteristic retention times and fragmentations of this group of compounds (21). However, the presence of some other unexpected fragments suggests that such peaks co-eluted with other components and therefore unambiguous identification was not possible.

Finally, acylsteryl glucosides, normally detected together with steryl glucoside, were not found in the present study, although they could have been detected easily under the experimental conditions used (17,20).

In conclusion, the wood and bark of the *Acacia* species investigated were rich natural sources of bioactive sterols, particularly of the Δ^7 sterols spinasterol and dihydrospinasterol (which can be easily isolated by simple solvent extraction), as well as of the corresponding steryl glucosides. A wide variety of biological activities have been attributed to these sterols. The effect of spinasterol on reducing plasma and liver cholesterol levels has been recognized for many years (22). The antitumorigenic potential of spinasterol also was demonstrated previously (23), and more recently, spinasterol was found to have considerable therapeutic potential in modulating the development and/or progression of diabetic nephropathy (24). On the other hand, dihydrospinasterol showed a potent inhibitory effect on the Epstein–Barr virus early antigen (25), whereas its glucoside exhibited anticarcinogenic and cytotoxic potential (26).

METHOD

Foam Fractionation of Exo-lipases from a Growing Fungus (*Pleurotus sapidus*)

Diana Linke[a], Holger Zorn[a], Birte Gerken[b], Harun Parlar[b], and Ralf G. Berger[a,*]

[a]Universität Hannover, Institut für Lebensmittelchemie, D-30453 Hannover, Germany, and [b]TU München, Lehrstuhl für Chemisch-Technische Analyse und Chemische Lebensmitteltechnologie, D-85354 Freising, Germany

ABSTRACT: Active lipases were isolated from the culture supernatant of the basidiomycetous fungus *Pleurotus sapidus* by foam fractionation. The pH value, the gas flow, and the foaming period were systematically varied to optimize the transport of the enzymes into the foam phase. On a 70-mL scale, a maximum recovery of hydrolytic activity of 95% was obtained at pH 7.0 and 60 mL N_2 min^{-1} after 50 min. The procedure, with minor modifications, was also applicable to native pellet cultures of *P. sapidus*. The same recovery of 95% was achieved, with purification and enrichment factors of 11.6 and 28.0, respectively.

Paper no. L9684 in *Lipids 40*, 323–327 (March 2005).

Foam fractionation belongs to the group of adsorptive bubble separation techniques. As bubbles rise through a liquid phase that contains the target solute, the most surface-active molecules preferentially adsorb onto the interfacial area. Bubbles leaving the surface of the feed solution carry both adsorbed compound and bulk liquid into the emerging column of foam. The interstitial liquid drains back along the lamella of the bubbles and returns nonadsorbed solutes to the retentate. The emerging foam does not reach a thermodynamic equilibrium; it becomes drier, shows coalescence, and finally collapses into a liquid foamate. Because of the high surface-to-volume ratio of a foam, the foamate is enriched in the surface-active target compound. Ostwald (1) investigated foam fractionation for the isolation of natural compounds and attained patent protection of this technology as early as 1920. In recent years, foam fractionation has been increasingly researched for the separation of surface-active, low-molecular-mass compounds from diluted aqueous solutions (2,3). As amphiphilic species, proteins are foaming agents, and several researchers have used foam fractionation successfully for the isolation of β-casein and plant storage proteins (4,5). However, by adsorption of a protein onto the anisotropic gas–liquid interface, partial unfolding of the tertiary structure may occur, resulting in a decrease or loss of bioactivity (6,7). Generally, the ability to develop a stable foam depends on the surface properties of the protein molecules (8). With increasing hydrophobicity, the surface tension of the solution decreases and the concentration of the target protein in the foam is increased (9,10). The dynamics of foam formation, foam structure, and foam properties are affected by a number of operational parameters, e.g., gas flow rate (11). Mathematical models of foam fractionation processes have been compiled by Du *et al.* (3) and Suzuki and Maruyama (12).

Typically, lipases are bipolar molecules distinguished by an interfacial mode of catalytic action (13), which may render them particularly suitable for isolation by foam fractionation. In submerged cultures of fungi, some of the lipases are secreted into the growth medium (14,15). This suggests their immediate separation by a batch-type foaming of the nutrient medium. In this study, lipases were produced by the basidiomycete *Pleurotus sapidus*, using Tween 80 as an inducer, and were isolated from either the clear supernatant or the pellet suspension culture.

METHODS

Chemicals. Tris hydrochloride and agarose were obtained from Roth (Karlsruhe, Germany); manganese sulfate monohydrate, ammonium nitrate, BSA, and dipotassium hydrogen phosphate were from Fluka (Seelze, Germany); D-(+)-glucose monohydrate, L-asparagine monohydrate, yeast extract, potassium dihydrogen phosphate, sodium hydroxide, hydrochloric acid, Coomassie Brilliant Blue G-250, and EDTA were from Merck (Darmstadt, Germany); Tween 80, magnesium sulfate, ferrous(III) chloride × $6H_2O$, calcium chloride × $2H_2O$, sodium chloride, and copper sulfate × $7H_2O$ were from Riedel-de Haën (Seelze, Germany); and zinc sulfate × $7H_2O$ and phenolphthalein were from J.T.Baker B.V. (Deventer, The Netherlands). Ethanol (96%) was from Kraul & Wilkening und Stelling (Hannover, Germany). High-purity water was prepared with an E-pure water purification system (Barnstead, Dubuque, IA).

Cultivation and lipase production. Mycelia of *P. sapidus* [8266 DSM (Deutsche Sammlung von Mikroorganismen und Zellkulturen)] were maintained on 1.5% agar plates with standard nutrient liquid (SNL) medium according to Zorn *et al.* (15). Precultures of *P. sapidus* were prepared from a mycelial block (1 cm^2) as inoculum, which was excised from the agar plate and placed in a 300-mL Erlenmeyer flask containing 100 mL of SNL medium. After treatment with an UltraTurrax homogenizer (Janke & Kunkel, Staufen, Germany), the fungal culture was incubated for 7 d at 150 rpm and 24°C. For the production of lipase, three different main cultures were prepared in 500-mL Erlenmeyer flasks containing 250 mL SNL, 250 mL

SNL without glucose, and 250 mL mineral salt medium by transferring 20 mL of the preculture into each flask (15). The secretion of lipase into the medium was induced by addition of 0.4% (vol/vol) Tween 80 to the main cultures, which were then incubated at 150 rpm and 24°C. At the time of maximal lipase activity, the supernatant was separated from the mycelium by filtration under reduced pressure (filter paper #595; Schleicher & Schuell, Dassel, Germany). Media and equipment were autoclaved prior to use, and sterile techniques were applied throughout the procedures.

Protein determination. Protein concentration was determined according to Lowry *et al.* (16) using BSA as a standard.

Lipase assay. Hydrolytic activity was quantified by monitoring the FFA resulting from the hydrolysis of Tween 80 by a titrimetric assay. Samples were adjusted to pH 7.0 with 0.1 M NaOH or 0.1 M HCl. The reaction mixture containing 2.16 g of Tween 80, 5 mL of 50 mM Tris/HCl buffer, pH 7.0, and 2 mL of test solution were incubated in a water bath at 37°C and 160 rpm for 15 to 60 min depending on enzyme activity. The reaction was terminated by adding 5 mL of ethanol. Blanks were prepared with an inactivated enzyme solution. The FFA were titrated with 50 mM NaOH using 2% ethanolic phenolphthalein as an indicator. The lipase activity was calculated from the difference between the blank and the sample. One unit of enzyme was defined as 1 μmol of FFA released per minute under the specified conditions.

Isoelectric focusing (IEF) and lipase activity staining. IEF PAGE was performed on a Multiphor II system (Pharmacia LKB) using Servalyt^{TM} Precotes^{TM} precast gels with an immobilized pH gradient of pH 3 to 6 (Serva, Heidelberg, Germany). The isoelectric point (pI) of the lipase was estimated using a low-pI (2.8 to 6.5) calibration kit (Amersham Biosciences, Freiburg, Germany). Gels were silver stained. For activity staining, a Tween 80–agarose-overlay gel was developed. Agarose (2%) was dissolved in a solution of 0.004 mg mL^{-1} Tris and 0.0125 mg mL^{-1} NaCl under boiling. Equivalent volumes of 0.5 mg mL^{-1} Tween 80 and 0.01 mg mL^{-1} CaCl$_2$ were added, and the pH was adjusted to 7.0 using 0.01 N NaOH. After focusing, the IEF gel was incubated on the Tween 80–agarose overlay at 37°C for 3.5 h, and the overlay gel was covered with 0.1 N NaOH to visualize the hydrolytic activity.

Configuration of equipment and experimental procedure for foam fractionation. The foaming device consisted of a cylindrical glass chamber (length, 18 cm; diameter, 3 cm) with a porous frit (P3, porosity 16 to 40 μm), a column (length, 27 cm; diameter, 1.6 cm), a glass bowl (250 mL, 7.7 cm equatorial diameter, or 500 mL, 9.5 cm equatorial diameter), a horseshoe bend, and a receiving flask (Fig. 1). Experiments were carried out with 70 mL of enzyme solution. Nitrogen was passed through the frit, and the rising foam collapsed in the receiver. Samples for protein and activity analyses were taken from the initial solution, from the foamed sample solution (retentate), and from the liquefied foam.

Calculations. The following calculations were made for each foam fractionation:
FIG. 1. Scheme of the foam fractionation device.

recovery of protein (RP) =

$$\frac{\text{mass of protein (mg) in the liquefied foam}}{\text{mass of protein (mg) in the initial solution}} \times 100\% \qquad [1]$$

recovery of activity (Ra) =

$$\frac{\text{activity (U) in the liquefied foam}}{\text{activity (U) in the initial solution}} \times 100\% \qquad [2]$$

purification factor (P) =

$$\frac{\text{specific activity (U mg}^{-1}\text{) in the liquefied foam}}{\text{specific activity (U mg}^{-1}\text{) in the initial solution}} \qquad [3]$$

enrichment factor (E) =

RESULTS

Influence of medium composition on extracellular lipase activity. The extracellular lipase activity of *P. sapidus* cultures containing different carbon sources was determined over a period of 7 d. The highest hydrolytic activity (312 U L^{-1}) was observed after 5 d in SNL medium without glucose (Fig. 2). This supernatant was used for foam fractionation as described in the following section.

Foam fractionation of lipases from the culture supernatant. The Rp and Ra were examined at varying pH values of the enzyme-containing solutions. The following parameters were held constant: 40 mL N$_2$ min^{-1}, 50-min foaming period, 24°C. The pH was adjusted from 5.0 to 8.0 with 0.1 N NaOH or 0.1 N HCl, respectively. The optimal pH value was 7.0, where 54% of activity was received in the foam, and the loss of activity during the fractionation process was about 5%. The minimal recovery in the foam and a loss of activity of 28% were observed at pH 8.0
FIG. 2. Lipase production as affected by the carbon source. Standard nutrient liquid (SNL) medium containing 3% (wt/vol) glucose and 0.4% (vol/vol) Tween 80 (●) (solution became highly viscous after 5 d); SNL without glucose but 0.4% (vol/vol) Tween 80 (▲); mineral salt medium with 0.4% (vol/vol) Tween 80 (■).

(Fig. 3). The kinetics of enzyme transport into the foam phase was investigated over a period of 90 min. A foaming period of 50 min gave the highest Ra. By increasing the gas flow to 60 mL min^{-1}, the recovery of hydrolytic activity rose to 95% (Fig. 4). A marginal loss of total activity (2.8%) was observed, i.e., 2.2% of activity remained in the retentate. P was calculated as 2.9, and E was 3.3.

Foam fractionation of the native pellet culture. When a native suspension culture of *P. sapidus* was submitted to the foaming procedure, most of the mycelium pellets remained in the retentate. Some smaller pellets rose up with the foam and were easily separated using a suction filter funnel. The recovery of hydrolytic activity in the liquefied, cell-free foam was 93%, with a loss of total activity of 6%. P was estimated as 3.0 and E was 3.8. To observe the kinetics of transport of lipases during the foaming period, samples were drawn every 5 min, and the liquefied samples were tested for activity on a Tween 80–agarose gel. Hydrolytic activity was detectable in each of the foam fractions, but no quantitative analyses were performed.

To increase the E and P of foam fractionation of the suspension culture, the volume of the glass bowl was doubled to 500

FIG. 4. Recovery of lipase activity in the foam phase after foam fractionation from culture supernatant as a function of flow rate (pH 7.0, 50 min, 24°C, 250-mL glass bowl).

mL. The aging foam became drier due to the increased drainage effect. As a result, the E and P were significantly enhanced (Fig. 5).

DISCUSSION

Separation of active lipases. Foam systems consist of a thin liquid film including a gas phase (10,17). The two phases are separated by a thin interfacial region to which amphiphilic solutes may adsorb. It has been common academic opinion that adsorption of an enzyme onto an interface comes along with denaturation (18). Betancor *et al.* (19) successfully prevented enzyme inactivation by coating the enzyme surface using a hydrophilic shell of dextran-aldehyde. In the present study, no modifications of the protein structure were necessary to separate active lipases from growing cultures of *P. sapidus* (Fig. 2) by foam fractionation.

pH dependence. Surface activity, stability, and packaging at the gas–liquid interface of a protein are maximal at its pI (20–22). Accordingly, transport of the target protein into the foam phase should be most efficient at its pI. However, the maximal transport of the lipase of *P. sapidus* was observed at pH 7.0 (Fig. 3), far from the pI of the native isoenzymes (4.5 to 5.4), and only about 3 to 6% of the catalytic activity of the enzymes was lost during the process (Fig. 4).

FIG. 3. Recovery of lipase activity in the foam after foam fractionation from culture supernatant as a function of pH (50 min, 40 mL N$_2$ min^{-1}, 24°C, 250-mL glass bowl).

FIG. 5. Recovery of activity (Ra) and total protein (Rp), purification factor (P), and enrichment factor (E) of foam fractionation from native suspension cultures of *Pleurotus sapidus* (pH 7.0, 50 min, 24°C, 500-mL glass bowl).

Liu *et al.* (23) accumulated about 40% of trypsin and about 50% of catalase activity from aqueous solutions into the foam. In the absence of a detergent, recoveries depended on the type of sparging gas used rather than on the actual pH value. In the present experiments, however, the loss of total hydrolytic activity increased with an increasing distance from the pH optimum (Fig. 3).

Effect of Tween 80. As mentioned, the optimal pH value for the separation process was 7.0 and not the pI. This is explained by residual amounts of the lipase inducer, Tween 80, in the feed solution. The detergent may have formed associations with the enzyme molecules possessing deviating apparent pI values. Proteins are generally less surface active than low-molecular-mass detergents, such as polyoxyethylene sorbitan monostearate, because of the high free energy levels of protein coverage of the interface (8). The addition of Tween 80 to processed foods, such as bakery products and ice cream, is common in Europe (EU Declaration Numbers E491 to E495) and in other countries worldwide. Looking at the low absolute concentration of technical enzymes, a carryover into processed foods may be tolerable.

Gas flow. Gas flow was identified as another quantifiable parameter of the foaming process. Flow rates of 6 mL min^{-1} resulted in a distinct degradation of β-glucosidase (24). Lipases in the present study were more shear tolerant, as indicated by the quantitative transport of the hydrolytic activity at a gas flow rate of 60 mL min^{-1} (Fig. 4).

Design of the foam fractionation device. Foam drainage and competition for the interface determine the E of a protein and hence the overall efficiency of the separation. Whereas the population of molecules at the interface depends on chemical parameters, such as concentration, hydrophobicity, diffusivity, and conformational flexibility (10), the drainage (or kinetic stability) of a foam can be affected by processing parameters, such as flow rate, and by the design of the foaming device. As in previous work on low-molecular-mass compounds (5), lengthening the height of the foaming column was inefficient. Doubling the volume of the glass bowl improved the E and P (Fig. 5). Under the conditions chosen, the process time was long enough to allow for adequate drainage of the interstitial liquid and short enough to minimize protein residence and unfolding at the interface. Because the liquid film of the lamella drained continuously, the final volume of the liquefied foam was much smaller than the volume of the feed phase.

Comparison with alternative processes. Conventional purification processes of two lipase isoforms of *Candida rugosa* (Lip1 and Lip2) by precipitation, hydrophobic interaction chromatography, dialysis, and anionic exchange chromatography recovered 45% of Lip1, with P of 5.3, and 4.7% of Lip2, with P of 4.1 (25). Yadav *et al.* (26) purified a lipase from *Aspergillus terreus* in five steps with a yield of 18% and a P of 11.9. The present experiments yielded lipase recoveries of 95% of total activity, with P of 11.6. Because an increase in hydrophobicity leads to a corresponding increase in protein adsorption onto the gas–liquid interface, the results indicate that fungal lipases appear to possess sufficient hydrophobic moi-

eties to be suitable for a separation by foam fractionation. In line with this consideration, Fernandes *et al.* (9) attached a hydrophobic fusion tag (Trp-Pro)$_4$ to a recombinant cutinase from *Fusarium solani pisi* and achieved higher recoveries in the foam (98%) as compared with the wild-type cutinase (52%). Thus, foam fractionation of fungal lipases offers potential as a valuable component of novel purification schemes.

ABSTRACT: Apolipoprotein E (apoE), an important determinant of plasma lipoprotein metabolism, has three common alleles (ε2, ε3, and ε4). Population studies have shown that the risk of diseases characterized by oxidative damage, such as coronary heart disease and Alzheimer's disease, is significantly higher in ε4 carriers. We evaluated the association between apoE genotypes and plasma F$_2$-isoprostane levels, an index of lipid peroxidation, in humans. Two hundred seventy-four healthy subjects (104 males, 170 females; 46.9 ± 13.0 yr; 200 whites, 74 blacks; 81 nonsmokers, 64 passive smokers, and 129 active smokers) recruited for a randomized clinical antioxidant intervention trial were included in this analysis. ApoE genotype was determined by PCR and restriction enzyme digestion. Free plasma F$_2$-isoprostane was measured by GC–MS. Genotype groups were compared using multiple regression analysis with adjustment for sex, age, race, smoking status, body mass index, plasma ascorbic acid, and β-carotene. Subjects with ε3/ε4 and ε4/ε4 genotype (ε4-carriers) and with ε2/ε3 and ε3/ε3 (non-ε4-carriers) were pooled for analysis. In subjects with high cholesterol levels (total cholesterol above 200 mg/dl), plasma F$_2$-isoprostane levels were 29% higher in ε4 carriers than in non-ε4-carriers ($P = 0.0056$). High-cholesterol subjects that are ε4 carriers have significantly higher levels of lipid peroxidation as assessed by circulating F$_2$-isoprostane levels.

Paper no. L9670 in *Lipids 40,* 329–334 (April 2005).

Apolipoprotein E (apoE) genotype is recognized as a determinant of cardiovascular disease and Alzheimer's disease (AD) risk (1–5). The majority of the apoE protein is produced by the liver and is traditionally known as a mediator of lipoprotein metabolism in both hepatic and extrahepatic tissue (6,7). In the circulation, it is found as an integral component of chylomicrons (CM), VLDL, and HDL. In addition to being centrally involved in lipoprotein metabolism, new localized roles for apoE in cardiovascular biology have recently been identified (8,9).

Point mutations in the gene locus for apoE, located on the long arm of chromosome 19, result in changes in the primary structure of the 299-amino acid protein end product with Arg/Cys substitutions at positions 112 and 158 (apoε2 Cys 112 Cys 158, apoε3 Cys 112 Arg 158, apoε4 Arg 112 Arg 158). In all populations, the ε3 allele is the most frequent. Apoε3 homozygotes (ε3/ε3), apoε2 heterozygotes and homozygotes (ε2/ε3, ε2/ε2), and ε4 heterozygotes and homozygotes (ε3/ε4, ε4/ε4) constitute approximately 55–70, 5–15, and 20–35%, respectively, of North American and European populations (10,11). Numerous observation studies have confirmed that chronic diseases such as coronary heart disease (CHD), stroke, and AD are significantly higher in ε4 carriers (1–5). In a meta-analysis of 10 published studies, Wilson and co-workers (1) reported odds ratios (OR) of CHD of 0.76–2.44 for clinical CHD associated with carrying the ε4 allele relative to the common ε3/ε3 genotype. Furthermore, apoE genotype is highly predictive of maturity-onset AD. In a community-based study involving 6,000 AD patients, the OR for AD was 3.2 and 14.9 in ε3/ε4 and ε4/ε4 (1–3% of Westernized populations), respectively, when individuals were compared with matched controls (ε3/ε3) (4). These differences in disease risk have traditionally been attributed to higher circulating LDL cholesterol (LDLC) levels in the apoε4 subgroups, which are thought to be due to the combined effects of reduced hepatic LDL-receptor expression, increased VLDL to LDL conversion, and an increased utilization of dietary cholesterol (12–14) in this subgroup. However, it is unlikely that the 3–8% higher LDLC observed in apoε4 carriers (14,15) is solely responsible for the increased CHD and AD incidence.

It is well recognized that free radical-mediated oxidative stress is involved in both the initiation and progression of many chronic diseases (16–19). Sources of oxidative stress include exogenous factors such as cigarette smoke or UV light exposure as well as endogenous sources such as reactive oxygen/nitrogen species (ROS/RNS) produced during normal physiological processes including phagocytosis and oxidative phosphorylation (18).

We hypothesize that the pathogenesis of these oxidative stress-associated diseases may be attributable in part to a differential antioxidant capacity of the endogenous apoE isoforms. Reduced antioxidant function of apoε4 has previously been described in *in vitro*, cell culture, animal, and *ex vivo*

models of AD (20–22). Studies in mice have shown that F_2-isoprostanes, a lipid peroxidation biomarker of oxidative stress, are increased in the brains of apoE-deficient mice (22), indicating that apoE may be associated with oxidant/antioxidant balance *in vivo*. Studies in Alzheimer patients showed that lipid peroxidation was significantly elevated in tissues of subjects who are homozygous for the ε4 allele compared with ε3/ε3 cases and controls (23). However, the impact of apoE genotype on oxidative stress status in nondiseased, apparently healthy individuals is largely unknown and is the subject of the current investigation.

SUBJECTS AND METHODS

Subjects (81 nonsmokers, 64 passive smokers, and 129 active smokers) were enrolled in an intervention study on the effect of antioxidant supplements on oxidative damage in active and passive smokers (24). The study was conducted in Berkeley and Oakland, California, between 1998 and 1999, and was approved by the institutional review boards of the University of California, Berkeley, and of Kaiser Permanente. Exclusion criteria for participation in the study were reported consumption of ≥4 servings of fruit and vegetables per day; intake of more than 2 alcoholic drinks per day; a history of alcohol problems less than 1 year ago; pregnancy; use of blood-thinning drugs; a history of hemochromatosis, kidney stones, or any other kidney problems, hepatitis, diabetes, or HIV infection; and cancer, stroke, or heart attack within the past 5 years. The detailed design of the antioxidant intervention study on active smokers and passive smokers is described elsewhere (24,25). Baseline plasma samples from the intervention study were used for this analysis.

Clinical protocols. Blood samples were obtained from all participants after an overnight 12-h fast. Venous blood was drawn into EDTA vacutainers and centrifuged at 5°C for 10 min at $1200 \times g$. Plasma isolation and freezing of samples (−70°C) was conducted within 1 h of taking the sample. Plasma measures included carotenoids, ascorbic acid, α- and γ-tocopherol, cholesterol, LDLC, HDL cholesterol, triglycerides (TG), transferrin saturation, C-reactive protein, malondialdehyde, F_2-isoprostanes, and cotinine. All participants completed the 1998 version of the Block food-frequency questionnaire. Other data obtained included body mass index (BMI), blood pressure, and alcohol intake.

Laboratory measurements. (i) Measurement of F_2-isoprostanes in plasma. Free F_2-isoprostane levels in plasma were quantified, after purification and derivatization, by selected ion monitoring GC/negative ion chemical ionization-MS employing $[^2H_4]8$-iso-$PGF_{2\alpha}$ as an internal standard. Compounds were analyzed as pentafluorobenzyl ester and trimethylsilyl ether derivatives by monitoring the M − 181 ions (*m/z* 569 Da for endogenous F_2-isoprostane and *m/z* 573 Da for $[^2H_4]8$-iso-$PGF_{2\alpha}$). This assay has an intra-individual variability precision of ±6% and an accuracy of 96% as measured by using an internal standard. Interday variability is <6% (26).

(ii) Measurement of apoE genotype. Genomic DNA was isolated from buffy coat using the QIAamp DNA Blood Mini Kit protocol (Qiagen Ltd., Crawley, United Kingdom), followed by PCR to amplify specific sequences of DNA as described earlier (14). ApoE genotype was identified by restriction enzyme digestion with PAGE used to separate the PCR fragments. Individual genotypes were characterized from the fragment patterns.

(iii) Plasma analysis. Carotenoids were measured by RP-HPLC (27). Ascorbic acid was determined spectrophotometrically using 2,4-dinitrophenylhydrazine as a chromogen (28). Concentrations of cotinine were determined by GC with nitrogen-phosphorus detection (29,30). Total cholesterol and TG levels were measured by end point spectroscopy (Sigma-Aldrich, St. Louis, MO).

Statistical analysis. Statistical analyses were conducted using SAS Version 8.2 (Cary, NC). Subjects with ε3/ε4 and ε4/ε4 genotypes were pooled due to small sample size in the ε4/ε4 genotype group. Non-ε4 subjects (ε2/ε3, ε3/ε3) were pooled to serve as the reference group. Subjects with ε2/ε4 genotype were excluded due to small sample size (*n* = 5). Subjects of race other than white and black were also excluded owing to the small sample size. Multiple regression analysis was conducted with the dependent variable plasma F_2-isoprostanes log-transformed. Variables examined as potential covariates included sex, race, age, BMI, smoking status, plasma vitamin C, α-tocopherol, γ-tocopherol, β-carotene, HDL cholesterol, LDLC, total cholesterol, TG, and cotinine levels. Potential effect modification was examined, including interactions of genotype with baseline plasma antioxidant levels, sex, race, total cholesterol, and LDLC. In Tables 2 and 3 the data are dichotomized by total cholesterol above and below 200 mg/dL.

RESULTS

One hundred four male and 170 female subjects were included in the analysis, with a mean (±SD) age of 46.9 ± 13.0 yr. In Table 1, apoε4 carriers (*n* = 73) and noncarriers (*n* = 201) were compared. No significant differences at *P* < 0.05 between these two groups were evident for any of the outcomes measured. However, the expected trends toward higher LDLC and total cholesterol in ε4 carriers were observed, although the 5–7% intergroup differences did not reach statistical significance.

While examining effect modification, a significant interaction between apoE genotype and plasma total cholesterol levels was found (*P* = 0.014). Therefore, subsequent stratification analysis was performed on the subgroups with circulating cholesterol levels above or below the clinical standard of total cholesterol (200 mg/dL). The subject characteristics were similar for the high and low cholesterol group (data not shown).

As shown in Table 2 and Figure 1, the apoε4 genotype was significantly associated with higher plasma F_2-isoprostane levels among high-cholesterol subjects (*P* = 0.0056), with 29% higher levels evident in this subgroup. Cholesterol, TG, and the lipid-soluble antioxidant vitamins α- and γ-tocopherol were investigated as possible covariates. They were not significantly

TABLE 1
Baseline Characteristics for All Subjects, and by Apolipoprotein (apoE) Genotype

| | | ApoE genotype | | |

Plasma ascorbic acid		10.33	0.0018
Plasma β-carotene		17.49	<0.0001

[a]Adjusted for the other variables shown.
[b]The F statistic measures the contribution of each variable to the prediction of plasma F$_2$-isoprostane levels.
[c]The P value represents the result after adjustment for all the other variables shown, performed by multiple regression analysis.
FIG. 1. Plasma F$_2$-isoprostane levels by genotype in subjects with plasma total cholesterol above 200 mg/dL. These are adjusted means (±SE); *significantly different: P = 0.0056.

TABLE 3
Adjusted Mean F$_2$-Isoprostane Levels by Genotype in Subjects with Plasma Total Cholesterol Below 200 mg/dL (n = 162)

Factor	Adjusted[a] mean F$_2$-isoprostane level (pmol/L)	F statistic[b]	P value[c]
ApoE genotype		0.72	0.3987
ε3/ε4 and ε4/ε4	99.5 (86.5, 114.5)		
ε2/ε3 and ε3/ε3	106.6 (97.1, 117.0)		
Sex		19.05	<0.0001
Age		0.00	0.9649
Race		14.69	0.0002
Current smoking status		3.72	0.0265
Body mass index		4.37	0.0143
Plasma ascorbic acid		9.39	0.0026
Plasma β-carotene		5.31	0.0225

[a]Adjusted for the other variables shown.
[b]The *F* statistic measures the contribution of each variable to the prediction of plasma F$_2$-isoprostane levels.
[c]The *P* value represents the result after adjustment for all the other variables shown, performed by multiple regression analysis.

associated with the dependent variable F$_2$-isoprostanes and therefore not included in the model, with inclusion/exclusion having little effect on the overall apoE/isoprostane relationship (data not shown).

No statistically significant association was observed between apoE genotype and F$_2$-isoprostane levels in individuals with a cholesterol level <200 mg/dL (P = 0.3987, Table 3). In addition, strong significant independent associations between sex, race, smoking status, BMI, plasma ascorbic acid, β-carotene, and circulating F$_2$-isoprostane were observed in both cholesterol subgroups. This has been previously reported by our group (31).

DISCUSSION

The effect of apoE genotype on LDL cholesterol cannot alone explain the differences in AD and CHD risk between ε4 carriers and the ε2 and ε3 subgroups. In advanced atherogenesis, a significant proportion of total apoE is produced by macrophages within the arterial lining (32). It is speculated that any differences in the antioxidant capacity of the apoE isoforms within the antioxidant-depleted, transition metal-rich environment of the vascular intima, which is rich in free radical-producing inflammatory cells, could make a significant contribution to atherogenesis.

In the current investigation, circulating levels of F$_2$-isoprostanes were used as an index of oxidative stress and lipid peroxidation. F$_2$-Isoprostanes have been widely used as a sensitive and specific marker of lipid peroxidation with significantly higher levels evident in CHD patients compared with matched controls (33). Specifically, levels have been shown to increase with advancing age, smoking, hypercholesterolemia, and diabetes (34–39). Furthermore, in addition to serving as an oxidative marker, F$_2$-isoprostanes exert direct proatherogenic proinflammatory properties and have been shown to act as vasoconstrictors and to stimulate platelet activation (33).

Our finding of higher plasma F$_2$-isoprostane levels in hy-

percholesterolemic individuals was consistent with earlier findings (38,39). For example, in the study of Davi and coworkers (39), a greater than twofold higher F$_2$-isoprostane level was evident in hypercholesterolemic subjects compared with age- and sex-matched controls. In the current study, a significant negative association between plasma β-carotene and F$_2$-isoprostane levels (P < 0.0001) as well as between plasma vitamin C and F$_2$-isoprostane levels was observed in the high-cholesterol group (P = 0.0018). This finding is consistent with previously published studies (31,40–42).

In individuals with a circulating cholesterol level below 200 mg/dL, apoE genotype did not emerge as an independent determinant of lipid peroxidation. However, in those subjects with total cholesterol above 200 mg/dL, a 29% higher F$_2$-isoprostane level was evident in apoε4 carriers relative to noncarriers. Differences in levels of lipid peroxidation between the apoE subgroups may be attributable to differences in the antioxidant activities of the apoE isoforms.

The antioxidant capacity of the apoE protein was first investigated with respect to neuronal damage in AD. In 1996, Miyata and Smith (21) investigated the antioxidant potential of the apoE isoforms with respect to their ability to protect against rat neuronal B12 cell death on exposure to hydrogen peroxide (H$_2$O$_2$). At physiological concentrations, all three apoE proteins significantly reduced H$_2$O$_2$-induced cell death, in the following order, ε2 > ε3 > ε4, with the ε2 protein being approximately twofold more effective compared with ε4 (21). Subsequent *in vitro* assays were consistent with the initial cellular work, with the authors indicating that differences in antioxidant capacity were attributable to the differential ability of the protein to bind transition metal ions. Consistent with these findings are data that demonstrate a differential *in vitro* oxidation of recombinant apoE using the myeloperoxidase system, with apoε4 being more susceptible than apoε3, which is in turn more susceptible than apoε2 (20). Furthermore, basal and activated oxidative damage and lipid peroxide levels in the following order, ε4 > ε3 > ε2, were evident in the postmortem brains of AD patients (23).

Evidence regarding the contribution of the apoE isoform to oxidative stress and of its implications for localized events in the artery wall that contribute to atherogenesis is limited. In the Northwick Park Heart Study II (NHPSII), following correction of the data for blood lipids and other known risk factors, Humphries and coworkers (43) speculated that the 2.79-fold increased risk of CHD events in ε4 smokers relative to the non-smoking combined group, with OR of 0.85 and 1.47 observed in ε2 carriers and ε3 homozygotes, respectively, may be due to the differential antioxidant capacity of the apoE protein isoforms. Although no direct evidence was provided by the authors, the data were suggestive of an exacerbation of oxidative stress in smokers by the apoε4 phenotype relative to the ε3 and ε2 smoking groups.

It is speculated that apoE isoform differences in antioxidant capacity could be attributable to a change in the tertiary configuration of the metal binding site of the protein. The mature 299-amino acid protein consists of an amino acid (residues 20–165)

and a carboxyl (225–299) terminal (NT and CT) separated by a hinge region, which in relation to lipoprotein metabolism are responsible for the ligand and lipid binding, respectively (44,45). The 3-D structure of the NT domain consists of four helix bundles, within which is thought to lie the tetrahedral metal-binding peptide sequence (46). It is speculated that variations in the Arg and Cys content of the isoforms lead to conformational changes in the protein structure owing to disruption in salt bridge formation (47), which could alter the metal-binding capacity. Likewise, although all three isoforms contain eight methionine residues, an apoE-specific protein conformational change may result in differences in exposure of methionine residues in the ε2, ε3, and ε4 isoforms. Methionine has been shown to act as an internal antioxidant within proteins (48). For example, the methionine residues of apoA1 and A2 have been shown to make a significant contribution to a reduction in hydroperoxides associated with human HDL (49). Furthermore, variations in the number of cysteine residues, with ε2, ε3, and ε4 having 2, 1, and 0, respectively, may contribute to variations in levels of lipid peroxidation products.

The current study provides data demonstrating greater lipid peroxidation in individuals with an apoε4 genotype (20–35% of U.S. and European populations). It contributes to the limited available evidence that the increased risk of chronic disease associated with an apoε4 genotype is in part attributable to an imbalance in oxidant/antioxidant homeostasis. It is likely that in hypercholesterolemic groups with an apoε4 genotype, and in particular smokers, antioxidant therapy, such as for example increased vitamin C intakes, may negate in part the increased CHD risk in these individuals.

ABSTRACT: Antioxidant micronutrients have been reported to be associated with an improvement in the blood profile, but the results are not consistent. The aim of the present study was to assess the effects of antioxidant supplementation on changes in the serum lipid profile of adult participants in the SU.VI.MAX study. French adults (n = 12,741: 7,713 females aged 35–60 yr, and 5,028 males aged 45–60 yr) received daily antioxidant supplementation (120 mg vitamin C, 30 mg vitamin E, 6 mg β-carotene, 100 μg selenium, and 20 mg zinc) or a matching placebo. Median follow-up time was 7.5 yr. After 7.5 yr, no effect of supplementation on total cholesterol was observed in men or women after adjusting for baseline total cholesterol levels and lipid-lowering medications. The prevalence of hypercholesterolemia (≥6.5 mmol/L) showed a trend toward being higher in women who received supplements compared with those who received the placebo (P = 0.06). In both sexes, the group receiving supplements exhibited higher mean serum TG concentrations than did the placebo group (P = 0.06 in men; P = 0.05 in women). The prevalence of hypertriglyceridemia (≥2.3 mmol/L) was also significantly higher in men who received supplements (P = 0.03), but not in women. Our results suggest than long-term daily supplementation with low doses of β-carotene, vitamins C and E, selenium, and zinc does not result in an improved lipid profile and could even adversely affect some blood lipids, possibly with a higher risk of hyperlipidemia in women.

Paper no. L9659 in *Lipids 40*, 335–342 (April 2005).

The SU.VI.MAX study is a randomized, double-blind, placebo-controlled primary prevention trial that showed—in a middle-aged French population presumably free of cardiovascular disease (CVD) and of cancer at baseline—that daily low-dose antioxidant vitamin and trace element supplementation for 7.5 years lowered the total incidence of cancer in men, but not in women (1). No effect on the incidence of CVD was found in either gender. However, preclinical studies suggested that a diet rich in various compounds with antioxidant properties inhibited the atherogenic process (2). Moreover, numerous large prospective studies have shown significant inverse associations between overall mortality (3) and cardiovascular events (4), and antioxidant status and intake. Several mechanistic hypotheses suggest that antioxidants play a role in the inhibition of atherogenic processes (5). However, the primary prevention trials and most of the secondary prevention trials that have evaluated the effect of different antioxidant supplements on CVD (6–10) have been unable to detect any beneficial effects, as in the SU.VI.MAX study, and two of these (8,9) have even suggested harmful effects on cardiovascular events.

In fact, the beneficial effects of antioxidants in preventing CVD are still open to debate, since different mechanisms have been proposed whereby antioxidant nutrients could decrease or increase the risk of CVD (11).

The hypothesis of the protective effect of antioxidants is supported by the fact they can inhibit the oxidation of LDL cholesterol, a particularly atherogenic molecule (11). Antioxidant micronutrients (vitamins and trace elements) also are reportedly associated with an improved blood profile, but these results are not consistent (12) since β-carotene and zinc are suspected of affecting the serum lipid profile adversely (13,14). Moreover, most of the antioxidant supplementation trials testing the impact on circulating lipid concentrations have been short term, have involved a small number of participants, and have presented some methodological limitations.

Therefore, the aim of the present work was to investigate the relationship between antioxidant status and lipid profile, and to assess the effects of supplementation with nutritional doses of antioxidant vitamins and trace elements on total, LDL, and HDL cholesterol and TG levels after 7.5 yr of follow-up in the SU.VI.MAX trial.

EXPERIMENTAL PROCEDURES

Subjects and methods. Details concerning the study rationale, design, methods, and participant characteristics have been reported previously (1,15). In brief, 12,741 French adults (7,713 females aged 35–60 yr and 5,028 males aged 45–60 yr) were randomly allocated to receive either a combination of antioxidants [120 mg vitamin C, 30 mg vitamin E (all-*rac*-α-tocopherol), 6 mg β-carotene, 100 μg selenium (as selenium-enriched yeast), and 20 mg zinc (as gluconate)] or a matching placebo in a single daily capsule. Eligibility criteria were lack of diseases likely to hinder active participation or threaten 5-yr survival, acceptance of the possibility of receiving a placebo and of the implications of participation, lack of regular supplementation with any of the vitamins or trace elements in the supplement, and absence of extreme beliefs or behaviors regarding diet. The median follow-up time was 7.54 yr.

The protocol was approved by a medical ethics committee and the national committee for the protection of privacy and civil liberties.

Educational level, smoking status, menopausal status, and contraceptive use were obtained from a questionnaire at baseline. Level of education was coded in three categories according to the highest certification obtained (primary school, high school, university, or equivalent).

Blood samples were obtained in Vacutainer tubes (Becton Dickinson, Le Pont de Claix, France) after a 12-h fast at inclusion and at the last check-up after 7.5 yr of follow-up (antioxidant markers were measured, at 7.5 yr, on only a randomized subsample of 1,400 subjects).

All biochemical measurements were performed in a central laboratory. Vitamin C status was evaluated by serum ascorbic acid determination using an automated method based on the continuous flow principle. Serum β-carotene and tocopherol levels were measured by HPLC. Serum zinc was determined by flame atomic absorption spectrometry, and serum selenium was measured by electrothermal atomic absorption spectrometry with a Zeeman effect.

Total cholesterol and TG were assayed using an enzymatic method [at baseline, Technicon Dax 24, Bayer Diagnostics (Tarreytown, NY), and 7.5 yr later, Advia 1650, Bayer Diagnostics]. CV for cholesterol and TG assays were 0.7 and 1.4%, respectively. HDL cholesterol was measured only at the end of the study (CV = 1.3%). The LDL cholesterol concentration was computed with the Friedewald formula only for subjects who had a TG value ≤4 mmol/L (350 mg/dL). Among the 12,741 subjects, 739 (5.8%) withdrew consent during the study (6.7% of women, and 4.4% of men); 343 (5.4%) were in the intervention group (mean follow-up time ± SD: 2.0 ± 1.5 yr), and 396 (6.2%) were in the placebo group (mean follow-up time ± SD: 1.9 ± 1.5 yr). Seven hundred thirty-six subjects (5.8%) were lost to follow-up (6.0% for women, and 5.5% of men) for various reasons: 367 in the intervention group (follow-up time: 5.1 ± 2.2 yr) and 369 in the placebo group (follow-up time: 5.0 ± 2.3 yr). No differences in the percentage of subjects lost to follow-up or who withdrew consent were observed between groups within each gender. There were no differences in capsule consumption between the groups (mean percentage of capsules taken: 79% in each). Data are presented from the intention-to-treat analysis; the results were unchanged with a per-protocol analysis on subjects who took either >75 or >90% of the supplements assigned.

Statistical methods. All analyses comparing the placebo and the intervention groups were performed by intention-to-treat, separately in men and women. Baseline and end-trial characteristics of the two groups were compared by Student's *t*-test and the chi-square test where appropriate. Results are expressed as percentages or means ± SD. Because of the skewed distributions for TG, β-carotene, and vitamin C values, these variables were logarithmically transformed, and geometric means as well as 95% confidence intervals are presented. Relationships between lipid and antioxidant concentrations at baseline, after adjustment for use of lipid-lowering medications, were assessed by computing partial Spearman rank correlation coefficients. We calculated sex-specific tertiles of baseline antioxidant levels in the placebo group and performed analyses of covariance (ANCOVA) with tests for linear trend, in both the placebo and intervention groups, according to these tertiles. Means ± SD are presented, after adjustment for lipid medication use at the end of the study. Data were processed on an Alpha-VMS system, and a specific database was developed using Statistical Analysis System software, version 8.2 (SAS Institute Inc., Cary, NC).

RESULTS

Characteristics of participants and the relationship between serum antioxidant concentrations and lipid profile at baseline. Baseline characteristics are presented in Table 1. In both men and women, the placebo and the intervention group did not differ in terms of age; smoking habits; contraception use and menopausal status; body mass index; and serum values of antioxidants, vitamins, and trace elements, except that in women the intervention group had a slightly lower level of serum zinc ($P = 0.05$) and a higher level of education ($P = 0.02$) compared with those in the placebo group ($P = 0.02$). A significantly higher level of serum cholesterol ($P < 0.04$) was found in women taking supplements, and a lower percentage of subjects taking lipid-lowering medications was observed at baseline ($P < 0.02$). Conversely, a higher mean level of apolipoprotein (apo) A-1 ($P = 0.02$) and a higher percentage of lipid-lowering medications ($P < 0.002$) were found in men taking supplements compared with those in the placebo group.

Correlation coefficients between baseline lipid markers and baseline serum values of antioxidant status, after taking into account the use of lipid-lowering medications, are presented in Table 2. In both sexes, serum β-carotene was positively correlated with total cholesterol and apoA-1 (and with apoB in women) and negatively correlated with TG. Serum vitamin C was not significantly related to total cholesterol, but was inversely correlated with TG and was positively correlated with apoA-1 (and in men, inversely correlated with apoB). Serum

[a]Values in italics represent statistical significance.
[b]Geometric means (95% confidence intervals) because of skewed distributions. apo, apolipoprotein.

α-tocopherol, serum zinc, and serum selenium levels were positively correlated with all lipid markers in both sexes (except for TG and selenium).

Changes in lipid profile according to baseline antioxidant status in the placebo group. Table 3 presents changes in the serum total cholesterol and TG levels in the placebo group after 7.5 yr of follow-up, adjusted for use of lipid-lowering drugs and after exclusion of subjects taking lipid-lowering medications at baseline.

In both men and women, an overall significant decrease in total cholesterol levels and a significant increase in serum TG was observed. The decrease in total cholesterol was significantly more pronounced in women in the highest tertile for baseline serum concentrations of β-carotene, α-tocopherol, selenium, and zinc, and no linear trend was observed with baseline serum vitamin C levels. In men, similar trends were observed, although these were significant only for serum α-tocopherol and zinc.

Conversely, for TG, the highest increase was observed in women in the highest tertile for serum β-carotene and serum selenium and in the lowest tertile for serum vitamin E. For vitamin E, the trend was the same in men.

Effect of antioxidant supplementation on antioxidant markers and lipid profile. Serum β-carotene; vitamins C and E; zinc;

selenium; total, HDL, and LDL cholesterol; and TG concentrations, at 7.5 yr, in the supplemented and placebo groups are presented in Table 4. Statistically significant differences were observed between the intervention and placebo groups for all antioxidants markers at 7.5 yr. In women, we observed a slightly significant difference in mean total serum cholesterol in the group of women receiving supplements (P = 0.05); however, this difference disappeared after adjusting for lipid-lowering medications and baseline total cholesterol level (P = 0.37). HDL cholesterol was significantly lower in women receiving supplements, but not in men. No significant difference was observed for LDL cholesterol. The prevalence of hypercholesterolemia (≥6.5 mmol/L) was higher in women receiving supplements than in the placebo group (P = 0.06). No difference between the two groups was observed in men.

Concerning serum TG, the group receiving supplements exhibited a higher mean serum concentration, even after adjustment (P = 0.06 in men, and P = 0.05 in women). The percentage of hypertriglyceridemia (≥2.3 mmol/L) was significantly higher only in men receiving supplements (P = 0.03). The percentage of subjects taking lipid-lowering medications at the end of the intervention was significantly higher in men receiving supplements (P = 0.02).

DISCUSSION

Dietary antioxidants are suggested to protect against lipid peroxidation (5). Many observational studies have shown that a high dietary intake or high blood concentration of antioxidant vitamins is associated with a reduced risk of CVD (3,4). However, randomized controlled studies investigating the clinical use of antioxidant supplementation to prevent CVD have provided conflicting, even disappointing, results (16). In the SU.VI.MAX study, after 7.5 yr of supplementation with a combination of nutritional doses of antioxidants, no major effect was seen on the incidence of ischemic CVD. The purpose of the present analysis was to determine the effect of this supplementation on modifiable risk factors for atherosclerotic CVD, such as blood lipids.

After 7.5 yr of follow-up, we observed an overall significant decrease in total cholesterol levels and a significant increase in serum TG in the placebo group (adjusted for the use of lipid-lowering drugs at the end of the study). This may be related to the fact that at baseline, we screened all subjects and detected

hypercholesterolemia in 36% of men and 26% of women. Because they were under the care of the heath services, they may have decreased their cholesterol concentrations by modifying their lifestyles or adapting their drug use. The screening detected hypertriglyceridemia at baseline to a lesser extent than hypercholesterolemia (11.7% in men, and 2.2% in women), and the potential effect of hypotriglyceridemic treatment in decreasing the mean TG concentration in serum might consequently have been less obvious at the end of the study.

The main findings presented here show that long-term supplementation with a combination of β-carotene, vitamins C and E, zinc, and selenium is associated with an increase in serum TG in men and women, and with a higher percentage of hypertriglyceridemia in men. The increase in serum TG was slight but significant and still led to mean values in the physiological range; its biological or pathological significance is unknown.

The changes in total cholesterol concentration were less obvious. In women receiving supplements, we observed an increase in total cholesterol, but this alteration disappeared after adjusting for lipid-lowering medications and baseline total cholesterol

[b]Geometric means (95% confidence intervals) because of skewed distributions.

level. HDL cholesterol was significantly lower in women receiving supplements, but not in men, and the prevalence of hypercholesterolemia also was higher. At the end of intervention, the percentage of subjects taking lipid-lowering medications was significantly higher in the group of men receiving supplements.

The relationship between lipid metabolism and antioxidant status is supported by a substantial body of data. The majority of published data on this topic are concerned with lipid metabolism and vitamin C status. Animal experiments have shown that marginal vitamin C deficiency in guinea pigs increases plasma and tissue cholesterol levels, and that vitamin C supplementation decreases cholesterol levels in guinea pigs, rabbits, and vitamin C-dependent rats fed an atherogenic diet (17). But results of human studies, both observational and experimental, are less consistent than those of their animal counterparts. In several observational studies, plasma ascorbic acid and vitamin C intakes were positively associated with HDL cholesterol concentrations (18,19) and apoA-1, and were inversely associated with total cholesterol (20), but other studies did not demonstrate such associations (21). Few intervention trials using antioxidant nutrients alone or in pairs have been performed, but until now, most of them have consistently shown no significant effect on serum total cholesterol, HDL cholesterol, or TG levels with either β-carotene (22,23), vitamin C (12,24), a combination of vitamins C and E (25), or vitamins C and E associated with β-carotene supplementation (26). However, most of these trials have presented flaws, such as a low statistical power, failure to blind treatment, or nonrandom allocation of supplements. Furthermore, they have included a small number of participants (10 to 440 subjects) or short-term supplementation (most from 3 wk to 12 mon; only a few had a long follow-up), and some have been concerned with specific patients. None of these studies have pointed out an adverse effect of vitamin C consumption at nutritional doses on lipid profiles at the level given in the SU.VI.MAX study. Hence, nutritional doses of vitamin C cannot be suspected to increase TG in serum, and an optimal nutritional intake of these nutrients, by consuming an adequate amount of fruits and vegetables, must always be encouraged.

Our subjects also received 30 mg/d of α-tocopherol in the supplement. This is more than twofold the usual dietary recommendations, and given the dietary mean intakes of vitamin

[c]Geometric means (95% confidence intervals) because of skewed distributions.
[d]Calculated using the Friedewald formula.

E in our population, it can be postulated that the supplemented group exhibited a total daily intake of around 40 mg/d of vitamin E. This important supply, over a long period of time, could be partly responsible for an adaptive mechanism involving a stimulation of VLDL synthesis and TG metabolism, with an increase in the transport and incorporation of vitamin E in membranes and lipoproteins. A synergistic effect with β-carotene cannot be totally ruled out, and β-carotene might be implicated in deleterious effects on TG. The hypothesis of a specific role of β-carotene (alone or stimulated by vitamin E) is consistent with data from a subsample of 52 participants in the CARET study (14). In this randomized cancer chemoprevention trial, long-term supplementation with 30 mg of β-carotene and 25,000 IU retinyl palmitate showed a nonsignificant increase in serum TG levels during the supplementation period, and a decrease in serum TG levels 10 months after the intervention was discontinued.

In our supplement, there were also antioxidant trace elements, and lipid metabolism may be further modulated by trace element status. Suboptimal intakes of zinc and selenium are associated with modified lipid and lipoprotein profiles and increased risk factors for CVD and diabetes (27,28). In addition

to several antioxidants present in LDL particles, selenium acts against oxidative processes, and there is no evidence of an adverse effect of selenium on the lipid profile. It has been demonstrated that selenium deficiencies negatively influence cholesterol metabolism and contribute to LDL oxidation (29). Moreover, the membrane-bound form of the enzyme GPx can efficiently reduce hydroperoxides in the phospholipids and cholesterol esters associated with LDL and HDL cholesterol (30). Other animal studies showed that endothelial function is impaired in selenium-deficient hypercholesterolemic rats (31). Results from interventional studies involving selenium and lipids are scarce. A slight improvement in the serum lipoprotein profile was reported in subjects with a low initial selenium status who received selenium yeast tablets (96 μg/d) for 2 wk (32), and in the elderly, supplementation with 100 μg/d of selenium resulted in a decreased malondialdehyde plasma level and decreased TG levels (33). In the present study, in addition to daily dietary intakes, the supplemental amount of zinc led to daily zinc intakes that could be estimated around 30 mg/d. At this dose, no deleterious effects have been reported on immunity, antioxidant function, and enzymatic activities. Zinc supplementation, at pharmacological doses (160 to 300 mg/d or

even 30 to 60 mg/d), resulted in lower HDL cholesterol in healthy adults, which may be related to the negative effects on copper status (34). The antagonistic association between copper and zinc is also thought to be partly responsible for numerous metabolic abnormalities, including hypercholesterolemia (35).

Data on the impact of pharmacological doses of zinc on lipid metabolism are scarce and controversial. Two randomized studies with zinc showed a decrease in HDL cholesterol or total cholesterol (36,37), and four showed no change in the lipid profile (38–41). Among the three nonrandomized studies, one showed undesirable changes in HDL and LDL cholesterol (42), another (43) showed no effect on the lipid profile, and the third (44) showed an increase in HDL cholesterol and a decrease in LDL cholesterol 8 wk after supplementation with zinc was stopped. Cross-sectional studies also have produced inconsistent results. In a study of 152 men, aged 57 to 76 yr, the correlation coefficients for serum zinc with total cholesterol or HDL cholesterol were near zero (45). Similarly, a study of 186 volunteers, with ages ranging from 15 to 67 yr, reported no association between serum zinc and serum lipid levels (46). More recently, in a large population sample of adults aged 20 to 80 yr in Belgium, a significant positive relationship was shown between serum zinc levels and both total cholesterol and the "antiatherogenic" HDL cholesterol (47).

The slight increase in TG serum levels we observed in our study could also possibly be due to zinc-induced leptin production. Whereas zinc deficiency results in decreased leptinemia (48), zinc supplementation induces an increase in leptin activity, which is known to increase the efflux of FA from adipocytes (49).

Our results suggest than long-term combined antioxidant supplementation with β-carotene, vitamins C and E, selenium, and zinc is not associated with an improvement in the lipid profile. This observation is consistent with the lack of effect of such supplementation on the incidence of CVD in our population. The observed increase in the TG levels of subjects receiving supplements is slight, but it can be considered an adverse and unexpected effect. It may be hypothetized that supranutritional amounts of zinc and vitamin E could activate adaptive mechanisms and lipogenesis. Interactions with other dietary factors, especially β-carotene, cannot be totally ruled out. Consideration of these data are important, since they underline that long-term supplementation, even at low doses, results in adaptive mechanisms and modified metabolism, especially with supranutritional doses of zinc and vitamin E.

The Impact of Age, Body Mass Index, and Fish Intake on the EPA and DHA Content of Human Erythrocytes

Scott A. Sands, Kimberly J. Reid, Sheryl L. Windsor, and William S. Harris*

Mid America Heart Institute, Saint Luke's Hospital, Kansas City, Missouri 64111,
and the Department of Medicine, University of Missouri–Kansas City, Kansas City, Missouri 64108

ABSTRACT: n-3 FA are beneficial for cardiovascular health, reducing platelet aggregation, TG levels, and the risk of sudden death from myocardial infarction. The percentage of EPA + DHA in red blood cells (RBC), also known as the Omega-3 Index, has recently been proposed as a risk marker for death from coronary heart disease (CHD). The purpose of this study was to begin to explore the factors that can influence RBC EPA + DHA. We collected information on the number of servings of tuna or nonfried fish consumed per month, as well as on age, gender, ethnicity, smoking status, the presence of diabetes, and body mass index (BMI) in 163 adults in Kansas City who were not taking fish oil supplements. The average RBC EPA + DHA in this population was 4.9 ± 2.1%. On a multivariate analysis, four factors significantly and independently influenced the Omega-3 Index: fish servings, age, BMI, and diabetes. The Index increased by 0.24 units with each additional monthly serving of tuna or nonfried fish ($P < 0.0001$), and by 0.5 units for each additional decade in age ($P < 0.0001$). The Index was 1.13% units lower in subjects with diabetes ($P = 0.015$) and decreased by 0.3% units with each 3-unit increase in BMI ($P = 0.001$). Gender or smoking status had no effect, and the univariate relationship with ethnicity vanished after controlling for fish intake. Given the importance of n-3 FA in influencing risk for death from CHD, further studies are warranted to delineate the nondietary factors that influence RBC EPA + DHA content.

Paper no. L9662 in *Lipids 40*, 343–347 (April 2005).

The n-3 FA EPA and DHA are known to have cardioprotective effects (1). Some of these effects include a reduction of platelet aggregation (2,3) and serum TG levels (4), and an increased heart rate variability (5), the latter being predictive of a lower risk of mortality due to cardiac arrhythmia (6). In the GISSI-Prevenzione study (7), n-3 FA supplementation produced a 20% reduction in total mortality and a 45% reduction in relative risk for sudden cardiac death, consistent with a reduced risk for arrhythmias. Because of these and other findings, the American Heart Association (AHA) now recommends that patients with known coronary heart disease (CHD) consume about 1 g/d of EPA + DHA. For individuals without known CHD, the AHA recommends at least two servings/wk of (preferably oily) fish to reduce the risk of cardio-

vascular disease (1). This would equate to approximately 500 mg/d of EPA + DHA.

The percentage of EPA + DHA in the red blood cell (RBC) membranes is a well-known biomarker of long-chain n-3 FA intake. Recently termed the "Omega-3 Index," it has been proposed as a new risk marker for CHD death (8). The RBC EPA + DHA has been shown to be responsive to increased intakes of n-3 FA (8), a valid surrogate for human myocardial n-3 content (9), and to be strongly associated with reduced risk of sudden cardiac death (10,11). Based on these previous studies, an RBC EPA + DHA of 8% or above has been proposed as a target cardioprotective level (8). The EPA + DHA content of RBC membranes varies across populations, presumably as a function of fish intake. Levels are generally low in Europeans (12,13), Americans (14,15), and Canadians (16), and high in Japanese (17) and Norwegians (18). Factors other than diet that may influence the incorporation of EPA + DHA in RBC have not been systematically investigated. The purpose of this study was to estimate average values for RBC EPA + DHA in a sample of adults from a Midwestern U.S. city, and to begin exploring the effects of gender, age, body mass index (BMI), ethnicity, smoking status, and the presence of diabetes on RBC EPA + DHA independent of fish intake.

MATERIALS AND METHODS

Volunteer selection. Healthy men and women between the ages of 20 and 80 from the Kansas City Metropolitan area were invited to participate in this study. Although generally healthy individuals were sought, those with self-reported, well-controlled type 1 or type 2 diabetes mellitus qualified as well. Individuals reporting consumption of fish oil supplements were excluded. The demographic information collected included age, gender, height, weight, ethnicity, smoking, diabetes, and the number of servings of tuna or nonfried fish consumed per month (hereafter referred to as "fish intake"). Weekly fish intake was calculated based on the reported monthly intake. The intake of tuna or nonfried fish was specifically queried because the answer to this question proved to be a powerful predictor of risk for death from ischemic heart disease in the Cardiovascular Health Study (19). Hence, we sought to determine whether it would correlate with RBC EPA + DHA. The protocol was approved by the Saint Luke's Hospital Institutional Review Board, and informed, written consent was obtained.

Laboratory methods. The sum of the EPA and the DHA, expressed as a percentage of total RBC FA, was measured as described previously (8). Briefly, blood was collected in EDTA, and the RBC pellet was isolated by centrifugation. After discarding the plasma and buffy coat, RBC were frozen at –70°C. The RBC pellet was warmed to room temperature, and an aliquot was extracted with isopropanol and hexane (each containing 50 mg/L of the antioxidant BHT). The lipid extract was dried under nitrogen and methylated for 10 min at 100°C with BF_3–methanol (Sigma, St. Louis, MO). After cooling, the FAME were extracted with hexane after the addition of water. The sample was again dried under nitrogen, reconstituted with hexane, and analyzed by flame ionization GC (Shimadzu GC-14A; Shimadzu Corporation, Kyoto, Japan) using a capillary column (SUPELCOWAX 10, 30 m length, 0.32 mm i.d., 0.25 µm film thickness; Supelco, Bellefonte, PA). FA were identified by comparison with known standards, and FA composition was reported as the weight percentage of total FA.

Statistical analysis. Univariate regression and one-way ANOVA models were used to determine the effects of each patient characteristic on RBC EPA + DHA. Analysis of covariance (ANCOVA) was used to determine the effect of fish consumption on RBC EPA + DHA after considering other possible influences (age, BMI, diabetes, gender, race, smoking). Nonlinear relationships were explored by testing quadratic terms in the ANCOVA models. Model assumptions were checked and verified. A critical alpha level of 0.05 was used to determine significance, and all significance tests were two-tailed. All data were analyzed using SAS, version 8.02 (SAS Institute, Cary, NC).

RESULTS

The study population included 163 individuals, 74 males and 89 females [Caucasian, 134 (82%); African American, 13 (8%); Hispanic, 10 (6%); Native American, Asian, East Indian, Arabic, 6 (3.6%)], with an average (±SD) age of 48 ± 15 yr (ages 20–29, 24; ages 30–39, 27; ages 40–49, 36; ages 50–59, 35; 60 and above, 41). Other study population characteristics were as follows: BMI, 26.2 ± 4.8 (range 18–47); servings per

month of tuna and nonfried fish, 4.2 ± 4.2 (range 0–30); smokers, 13 (8%); persons with diabetes, 13 (8%). The mean (±SD) RBC EPA + DHA was 4.9 ± 2.1%, with a range of 1.7 to 12.4% (Fig. 1). RBC EPA + DHA was below 8% in 91% of the sample and below 4% in 44% of the sample (Fig. 1).

Of the seven patient characteristics examined, five (all but gender and smoking status) proved to be significant predictors of RBC EPA + DHA on a univariate analysis (Table 1). On a multivariate analysis, ethnicity ceased to be a predictor, leaving BMI, age, diabetes, and fish intake as independent predictors. From Table 1, one can see that every additional 10 yr of age increased RBC EPA + DHA by 0.5 units, that each 3-unit rise in BMI decreased the Omega-3 Index by 0.3 units, and that the presence of diabetes was associated with a 1.13-unit decrease in RBC EPA + DHA. For every reported monthly serving of tuna or other nonfried fish, RBC EPA + DHA increased by 0.24 units. The relationships between reported fish intake (by frequency category and continuously) and the Omega-3 Index are presented in Figures 2 and 3. In both cases, there was a highly significant positive relationship between intake and this biomarker.

Although overall, men and women did not have significantly different unadjusted values for RBC EPA + DHA (5.0 ± 1.9 vs. 4.7 ± 2.2, *P* = 0.25), an examination of the male–female difference by decade suggested that women tended to have slightly higher levels than men (except for the 30s; Fig.
FIG. 1. Distribution of the percentage of red blood cell (RBC) EPA + DHA values (Omega-3 Index) in the study population. Lines at 8% and 4% indicate proposed low- and high-risk horizons, respectively, and the dotted line at 4.9% is the population average.

TABLE 1
Red Blood Cell EPA + DHA Model Results

Independent variable	Univariate[a]				Multivariate[b]			
	Estimate	Lower 95% CI	Upper 95% CI	*P*-value	Estimate	Lower 95% CI	Upper 95% CI	*P*-value
Fish servings	0.30	0.24	0.36	<0.0001	0.24	0.18	0.29	<0.0001
Age (10 yr)	0.53	0.33	0.73	<0.0001	0.49	0.33	0.66	<0.0001

FIG. 2. Percentage of RBC EPA + DHA (Omega-3 Index) by category of reported consumption of tuna or nonfried fish per month. Groups differed by ANOVA ($P < 0.0001$), with the highest RBC EPA + DHA group differing significantly from all others ($P < 0.05$) and the second highest differing from the first ($P < 0.05$) by Tukey's *post hoc* test. The percentage of the population falling into each intake group is given in parentheses. For abbreviation see Figure 1.
FIG. 3. The continuous relationship between the percentage of RBC EPA + DHA (Omega-3 Index) and reported monthly intake of tuna and nonfried fish. $R = 0.61$, $P < 0.0001$. For abbreviation see Figure 1.

4). On the multivariate analysis (which included a variety of relevant covariates), women did not have higher levels of RBC EPA + DHA (Table 1).

DISCUSSION

The average RBC EPA + DHA in this sample of 163 individuals not taking n-3 FA supplements was 4.9%. This value is well below the proposed 8% target value associated with a significantly reduced risk of CHD death; consistent with past reports (8), it is close to the high-risk value of 4% that has recently been proposed. RBC EPA + DHA varied by over sevenfold in this sample. Although we assumed that much of this variance was due to differences in fish intake, other factors influencing the Omega-3 Index had not been examined previously.

The number of servings of oily fish consumed per month did indeed have a major effect on long-chain n-3 FA blood
FIG. 4. Percentage of RBC EPA + DHA (Omega-3 Index) as a function of sex within age categories by univariate analysis. Male–female differences within categories were not significantly different. For abbreviation see Figure 1.

levels (Figs. 2 and 3). This was, of course, expected and suggests that simply inquiring about the number of tuna or nonfried fish meals a patient is consuming on a monthly basis will provide a reasonable estimate of his or her RBC EPA + DHA. This finding confirms what has already been shown with n-3 FA capsules, i.e., that the EPA + DHA content of RBC membranes is a valid reflection of n-3 FA intake (8).

Age was an independent predictor of RBC EPA + DHA, even after adjusting for fish intake. Interestingly, older rats have been reported to have higher cardiac DHA levels than younger rats fed the same diet (20). A similar association between age and plasma phospholipid n-3 FA content was observed in three separate populations in Quebec—the James Bay Cree, the Inuit of Nunavik, and individuals living in and around Quebec City (21–23). These authors attributed this relationship to the fact that older people traditionally consume more fish than younger individuals, but they did not report fish intake or adjust for it (23). One could speculate that older individuals may consume more α-linolenic acid or may convert it to longer-chain n-3 FA more readily than younger people. In addition, the rise in RBC EPA + DHA with age could reflect an increasingly slower turnover of n-3 FA in tissues. More studies in humans are needed to explore these possibilities.

An increase in BMI was associated with decreasing proportions of EPA + DHA in human erythrocyte membranes, again independent of reported frequency of fish intake. A simplistic interpretation of this observation may be that since fish is not typically served on a body-weight basis, obese individuals would consume a smaller "dose" of fish per unit of body weight than leaner individuals. This could lead to a lower concentration of long-chain n-3 FA in the larger total lipid pool. Alternatively, Cazzola *et al.* (24) recently showed that RBC from obese individuals are more susceptible to oxidative stress. They also found, as we did, a lower n-3 FA content in RBC membranes. Hence, the lower n-3 FA content could be secondary to increased oxidative processes characteristic of the obese state.

It has recently been reported that women may have a greater capacity to synthesize long-chain n-3 FA from short-

chain n-3 FA (25), and they tend to have higher plasma n-3 FA levels than men (26–28). This may reflect their physiological need to provide preformed DHA to the developing fetus. In light of these observations, we expected the women in our survey to have higher proportions of EPA + DHA in RBC membranes than the men. A trend toward this was seen in the univariate analysis, but the trend was reversed when other covariates were considered. Hence, sex alone does not appear to be a determinant of RBC EPA + DHA. Larger studies with greater power will be needed to examine this relationship.

The number of subjects who smoked, were diabetic, or were members of minority groups was small; thus, conclusions from these subgroups are only suggestive. In this study, smoking was not associated with reduced levels of EPA + DHA in RBC. This is in agreement with some studies (22,26) but not others (27,29). The presence of diabetes was associated with reduced RBC EPA + DHA values, in agreement with some studies (30) but not others (30–32). The inhibition of Δ6- and Δ5-desaturases (the enzymes responsible for converting α-linolenic acid to long-chain n-3 FA) in the diabetic state has been reported (33), but whether it applies in type 2 as well as type 1 diabetes is not clear. Ethnicity (i.e., not Caucasian) ceased to be a significant predictor of RBC EPA + DHA in the multivariate analysis. In other words, the lower RBC EPA + DHA seen in the non-Caucasian groups was likely the result of their generally being younger, heavier, and less likely to consume fish than the Caucasian group.

The RBC EPA + DHA, as measured here, may not be comparable to that reported by other workers for several reasons. First, in an effort to focus on the FA composition of the glycerophospholipids (and to exclude those from RBC sphingolipids), we methylated the lipid extract for 10, not 45, min. This also made the assay quicker to perform, which has obvious advantages in a clinical setting. Second, our method included one freeze–thaw cycle. This was shown in preliminary experiments to reduce the EPA + DHA content by about 10% compared with fresh RBC, but no further loss was noted with two or three freeze–thaw cycles. Since we anticipate that samples from most future research projects (i.e., large, prospective randomized trials with hard cardiovascular disease events as end points) will have been frozen at baseline, we chose to include this step in the routine assay so that cut-points identified with these frozen samples will be applicable in the clinical setting as well. Finally, myriad GC variables, pre- and postprocessing, known and unknown, conspire to almost guarantee significant laboratory-to-laboratory (and instrument-to-instrument) variability in an assay that is based on percent composition.

In conclusion, the content of EPA + DHA in human RBC membranes is a valid marker of the intake of long-chain n-3 FA from tuna and other nonfried fish. In addition, at least two factors besides n-3 FA intake appear to influence their incorporation into RBC membranes: age and BMI, with a suggestion that diabetes may also have an effect. Further studies are warranted to define the other factors that influence this emerging CHD risk factor more carefully.

Triacylglycerol Hydroperoxides Not Detected in Pig Small Intestinal Epithelial Cells After a Diet Rich in Oxidized Triacylglycerols

Jukka-Pekka Suomela[a,*], **Markku Ahotupa**[b], **and Heikki Kallio**[a]

Departments of [a]Biochemistry and Food Chemistry and [b]Biomedicine, University of Turku, FI-20014 Turku, Finland

ABSTRACT: The presence of TAG hydroperoxides in the epithelial cells of the small intestines in growing pigs was studied after they had consumed a diet rich in either nonoxidized or oxidized sunflower seed oil (PV in oils, 1 and 190 mequiv O_2/kg, respectively). To obtain molecular-level information on the oxidized TAG structures, a new approach based on TLC and HPLC-electrospray ionization-MS was used in the analysis of the samples. TAG hydroperoxides were not detected in the small intestinal mucosa or adipose tissue of either group, whereas TAG hydroxides, ketones, and epoxides were detected in all samples. The results suggest that dietary TAG hydroperoxides do not lead to the appearance of these molecules in the tissues.

Paper no. L9660 in *Lipids 40*, 349–353 (April 2005).

Various studies suggest that oxidized FA within dietary lipids increase the oxidation level of human lipoproteins (1–3). Thus, it seems that the oxidized lipids are absorbed in the small intestine and/or they initiate a cascade of subsequent reactions that result in the increased oxidation of lipoproteins. It is unclear, however, in what degree different types of lipid oxidation products survive from mouth to small intestine and beyond, and whether all forms of oxidized lipids are absorbed.

The studies of Kanner and Lapidot (4) suggest that human stomach fluid, having a low pH, may be a good medium for food lipid peroxidation. On the other hand, in studies performed in rats by Kanazawa and Ashida (5,6), linoleic acid hydroperoxides did not reach the small intestine when dosed intragastrically at moderate levels as such or as trilinoleoylglycerol hydroperoxides. Only when very high doses (200 μmol or more) of linoleic acid hydroperoxides were used was partial transport to the small intestine observed. In the stomach, trilinoleoylglycerol hydroperoxides were broken down to linoleic acid hydroperoxides and hydroxides. Pure linoleic acid hydroperoxides given intragastrically were decomposed to hydroxides, epoxyketones, and aldehydes. Only aldehydes entered the small intestine when moderate levels of hydroperoxides were used. Aldehydes also seemed to be partly absorbed into the body.

If lipid hydroperoxides, either originating from diet or formed in the gastrointestinal tract (4,7), are present in the

small intestine, then they seem to be effectively removed by glutathione peroxidase under normal conditions. However, the hydroperoxides may be transported into lymph in conditions where the supply of glutathione is limited (8,9).

To study the effect of diet on the presence of FA hydroperoxides in tissue TAG, we investigated the small intestine mucosa and the adipose tissue of growing pigs after a 2-wk period of consuming a diet rich in either nonoxidized or oxidized sunflower seed oil. An approach based on TLC and HPLC-electrospray ionization (ESI)-MS was used in the analysis of the oxidized tissue lipids (10).

MATERIALS AND METHODS

Chemicals and reagents. 3-Chloroperoxybenzoic acid, triphenyl phosphine, and activated manganese dioxide (MnO_2) were obtained from Aldrich Chemical Co. (Milwaukee, WI). Reagents were of reagent grade or better quality. All solvents were of chromatography or reagent grade and were purchased from local suppliers. HPLC standard (G-1) containing synthetic monoacid TAG was obtained from Nu-Chek-Prep, Inc. (Elysian, MN). Synthetic 1,3-distearoyl-2-oleoyl-*sn*-glycerol was obtained from Sigma Chemical Co. (St. Louis, MO). 1,3-Didocosanoyl-2-oleoyl-*sn*-glycerol and 1-linoleoyl-2-oleoyl-3-palmitoyl-*sn*-glycerol were obtained from Larodan Fine Chemicals AB (Malmö, Sweden).

Preparation of reference compounds. The oxidized derivatives of synthetic TAG were prepared as described earlier (10). TAG hydroperoxides were prepared by photosensitized oxidation. TAG (10–20 mg) was added to 3 mL of methylene blue solution (0.1 mM methylene blue in dichloromethane) in a test tube that was placed in an ice bath under a 250 W photographer's lamp for 28 h. The distance between the sample solution and the lamp was approximately 20 cm. Hydroperoxides were purified by TLC as described below.

Animals and diets. The study plan was approved by the Test Animal Committee of MTT Agrifood Research Finland. Growing pigs (castrated boars) were used in the study. For 2 wk, two groups of three pigs (groups 1 and 2) were fed a diet (Table 1) containing 16% nonoxidized or oxidized sunflower seed oil. The average weight of the animals (average age 11 wk) was 28.1 ± 3.5 kg at the beginning of the feeding period and 39.5 ± 4.3 kg at the end of the period. The oil of group 1 was not oxidized (PV, 1 mequiv O_2/kg), whereas the oil of

[c]PV, 190 mequiv O_2/kg oil.

group 2 was oxidized in a convection oven at 60°C until a PV of 190 mequiv O_2/kg was reached. The PV determinations were made according to the AOCS Official Method Cd 8-53 (11). The vitamin E contents of the oils were as follows: group 1, 550 mg/kg; group 2, 103 mg/kg. The vitamin E determinations were made according to IUPAC 2.432 method (12). FA compositions of the oils (Table 2) were determined as described below.

The pigs were fed twice a day. During the first week, the pigs were fed 200 g oil/d and during the second week 230 g oil/d. Because of the high fat load, the pigs were fed in total 161 mg vitamin E/kg feed, not including vitamin E from the oils (Table 1).

Sample preparation. Pigs were killed 2–3 h after the last meal (half of the daily dose). An approximately 40-cm length of small intestine was detached at a distance of 80–200 cm from the beginning of the small intestine, the distance depending on the progress of intestinal contents. After the ends were tied, the detached intestinal portion was placed into a box containing physiological salt solution at 0°C. Later, the portion was split in the longitudinal direction. The contents were removed and the piece was rinsed with tepid water. The epithelial cells were scraped off the intestinal wall, and the lipids were extracted using chloroform/methanol (2:1, vol/vol).

Also, a small portion of adipose tissue was detached from the neck after slaughter. The lipids of the tissue were extracted using chloroform/methanol (2:1, vol/vol).

Purification of TAG and their oxidation products. For FA analysis, the TAG of small intestinal mucosa and adipose tissue were purified using Sep-Pak® (Milford, MA) prepacked silica columns (13). Normal-phase TLC was used to purify the oxidation products of the reference compounds and of the tissue TAG (14). Heptane/di-isopropyl ether/acetic acid (60:40:4, by vol) solution was used as the mobile eluent. Samples were applied to silica G-plates. The TAG band (R_f typically 0.59) and/or the fractions containing the oxidized TAG molecules (below the TAG band) were scraped off the plates. The lipids were recovered from the silica gel by extraction with chloroform/methanol (2:1, vol/vol). The extracts were washed with distilled water. TAG and their oxidation products were detected in UV light after spraying with 2,7-dichlorofluorescein.

FA analysis. The FAME of TAG were prepared by sodium methoxide-catalyzed transesterification (15). Methyl esters were dissolved in hexane and analyzed by GC (PerkinElmer AutoSystem, Norwalk, CT) using a DB-23 column (30 m × 0.32 mm i.d., 0.25 µm film thickness; Agilent Technologies, Palo Alto, CA). The instrument was equipped with an FID.

Analysis of samples by HPLC-ESI-MS. The oxidation products of TAG were separated by RP-HPLC (10). The HPLC system consisted of a Hitachi (Tokyo, Japan) L-6200 Intelligent Pump with a Discovery® HS C18 column (250 × 4.6 mm i.d.; Supelco Inc., Bellefonte, PA). The column was eluted at 0.85 mL/min and a linear gradient was used: 20% 2-propanol in methanol was changed to 80% 2-propanol in 20 min. The final composition was held for 10 min. Eighty-five percent of the effluent (0.72 mL/min) was led to a Sedex 75 (S.E.D.E.R.E., Alfortville, France) ELSD. An evaporation temperature of 70°C and nebulizer gas (air) pressure of 2.7 bar were used in the ELSD. Fifteen percent of the effluent (0.13 mL/min) was led to a Finnigan MAT TSQ 700 triple quadrupole mass spectrometer (Finnigan, San Jose, CA) equipped with a nebulizer-assisted electrospray interface. Full-scan MS spectra were collected in positive ionization mode (*m/z* 450–1100). The electrospray voltage used was +4.5 kV.

Statistical analysis. SPSS 12.0 for Windows (Chicago, IL) was used for data analysis. The comparison of FA compositions was carried out with independent samples *t*-test and Mann–Whitney U-test.

RESULTS AND DISCUSSION

The FA compositions of the TAG extracted from the small intestinal mucosa of the pigs are presented in Table 3. The TAG represent mainly the reassembled molecules formed inside the epithelial cells. Minor amounts of the TAG may also originate from the luminal side of the cells, representing molecules not broken down by gastric and pancreatic lipases and not detached by rinsing. As expected, the FA compositions reflected to a large degree those of the dietary sunflower seed oils. However, the relative amounts of 16:0 were higher and those of 18:1n-9 were lower in the mucosa of both groups compared with the test oils. In group 2, but not in group 1, the relative amount of mucosal 18:2n-6 seemed to be lower compared with the corresponding test oil.

TABLE 3
FA Compositions of the Small Intestine Mucosal TAG[a]

FA	Group 1[b]	Group 2[c]
16:0	8.2 ± 0.1	9.4 ± 0.5
16:1n-7	0.0 ± 0.0	0.3 ± 0.1
18:0	3.6 ± 0.1	5.0 ± 0.6
18:1n-9	22.5 ± 0.2	23.6 ± 0.1
18:1n-7	0.7 ± 0.0	0.8 ± 0.1
18:2n-6	63.4 ± 0.2	58.2 ± 0.0
18:3n-3	0.8 ± 0.1	0.7 ± 0.1
20:0	0.0 ± 0.1	0.2 ± 0.2
20:1n-9	0.1 ± 0.1	0.1 ± 0.1
20:4n-6	0.7 ± 0.3	1.0 ± 0.0

[a]Results expressed as percentage of total FA (mean ± SD).
[b]$n = 3$.
[c]$n = 2$.

The relative amounts of 16:0, 18:0, and 18:1n-9 seemed to be higher and the relative amounts of 18:2n-6 lower in group 2 and test oil 2 compared with group 1 and test oil 1, respectively (Table 3). However, the differences were larger in the mucosal FA compared with the test oil FA. None of the differences between groups 1 and 2 reached statistical significance, evidently because of small group sizes. We were able to analyze all three mucosal samples of group 1, but only two samples of group 2. In spite of this, it seems likely that the differences in mucosal TAG FA composition between the groups were caused by different dietary oils.

The relative amount of 16:0 appeared to be slightly higher and that of 18:2n-6 slightly lower in the adipose tissue of group 2 compared with group 1 (Table 4). This indicates an effect of test oil autoxidation on adipose tissue FA composition.

The oxidized TAG molecules were detected by extracting peaks of a specific m/z value from the MS chromatograms of HPLC runs (Fig. 1). Only sodium adduct ions were formed from the molecules in the positive ionization mode, which simplified identification. If the retention time for a peak of an m/z value suggested a certain type of oxidation product and a particular FA composition, and a homologous series of ions was found in the chromatogram, this was regarded as evidence of a certain molecular structure (10).

TABLE 4
FA Compositions of the Adipose Tissue TAG[a]

FA	Group 1[b]	Group 2[b]
14:0	1.0 ± 0.2	1.1 ± 0.1
16:0	19.1 ± 0.9	20.6 ± 1.4
16:1n-7	3.0 ± 0.8	3.0 ± 1.1
18:0	8.6 ± 1.3	8.6 ± 1.5

FIG. 1. Ion chromatograms showing the major TAG hydroperoxide species of the oxidized sunflower seed oil (PV, 190 mequiv O_2/kg). Molecular ions ($[M + Na]^+$) with an acyl carbon number of 54 are shown.

The molecular ions of the reference compounds containing a hydroperoxide group could be detected in mass chromatograms as simultaneously appearing peaks with a difference of 18 mass units, which helped in the identification of such molecules. The phenomenon was due to a cleavage of H_2O in the ion source.

In the oxidized test oil, TAG monohydroperoxides were the major class of oxidized TAG. The monohydroperoxides that were detected were formed from TAG with ACN:DB (acyl carbon number:number of double bonds) 52:2, 52:3, 52:4, 54:3, 54:4, 54:5, and 54:6. Dihydroperoxides were formed from TAG with ACN:DB 52:4, 54:6, and 54:5. However, these TAG hydroperoxides were not detected in the mucosa or the adipose tissue samples, neither as such nor as a combination of hydroperoxy and oxo/epoxy groups. This indicates an absence of these molecules in the tissue TAG, or a considerable decrease in their level compared with the oxidized sunflower seed oil. In taking the sensitivity of the instrumentation into consideration, the decrease was estimated to be at least 80% in the case of monohydroperoxides.

TAG hydroxides, ketones, and epoxides were detected in the tissue samples of both groups (Tables 5 and 6). No core aldehydes were detected. The same oxidized TAG molecular species were detected in both groups. Differences in the relative amounts of oxidized molecules could not be analyzed because of the small number of samples and, in case of mucosal samples, the overlapping of different acylglycerols and their derivatives in ELSD chromatograms. In our lipoprotein study (16) in which the same oils were employed, the amount of oxidized TAG (no hydroperoxides detected) was significantly higher in the lipoproteins of pigs fed the oxidized oil compared with the nonoxidized oil. Nonetheless, the same oxidized TAG molecular species were present in the lipoproteins of both groups.

It is interesting that TAG hydroxides, ketones, and epoxides were also detected in both the nonoxidized and oxidized test oils, although only traces of hydroperoxides were seen in the nonoxidized oil. These findings indicate that our method sensitively detects the secondary oxidation products of TAG present in different matrices.

[b]Acyl carbon number of the molecule.
[c]Uncertain/very weak peak in the chromatogram.

It is noteworthy that our HPLC system was not optimized for the analysis of TAG trihydroperoxides and other equally polar TAG oxidation products. Also, the possibility that some decomposition of hydroperoxy structures had occurred during sample preparation cannot be excluded. However, in our studies, TAG hydroperoxides have been observed to be relatively stable during extraction procedures, TLC, and HPLC runs.

Our results suggest an effective degradation of hydroperoxides before and/or during the reassembly of TAG molecules in the epithelial cells of small intestinal mucosa. The findings are in line with the results of Kanazawa and Ashida (5,6), which showed a very limited transport of hydroperoxides into the small intestine. The results obtained from a limited number of samples encourage further research on the physiological consequences of dietary fat oxidation, which is an area currently not too well understood.

ABSTRACT: Supercritical fluid extracts of New Zealand green-lipped mussels (NZGLM) have been suggested to have therapeutic properties related to their oil components. The large number of minor FA in NZGLM extract was characterized by a GC–CIMS/MS method that excels at identification of double-bond positions in FAME. The extract contained five major lipid classes: sterol esters, TAG, FFA, sterols, and polar lipids. The total FA content of the lipid extract was 0.664 g/mL. Fifty-three unsaturated FA (UFA) were fully identified, of which 37 were PUFA, and a further 21 UFA were detected for which concentrations were too low for assignment of double-bond positions. There were 17 saturated FA, with 14:0, 16:0, and 18:0 present in the greatest concentration. The 10 n-3 PUFA detected included 20:5n-3 and 22:6n-3, the two main n-3 FA; n-3 PUFA at low concentrations were 18:3, 18:4, 20:3, 20:4, 21:5, 22:5, 24:6, and 28:8. There were 43 UFA from the n-4, n-5, n-6, n-7, n-8, n-9, n-10, n-11 families, with 16:2n-4, 16:1n-5, 18:1n-5, 18:2n-6, 20:4n-6, 16:1n-7, 20:1n-7, 16:1n-9, 18:1n-9, and 20:1n-9 being the most abundant. In general, we estimated that FAME concentrations greater than 0.05% (w/w) were sufficient to assign double-bond positions. In total, 91 FA were detected in an extract of the NZGLM, whereas previous studies of fresh flesh from the NZGLM had reported identification of 42 FA. These data demonstrate a remarkable diversity of NZGLM FA.

Paper no. L9596 in *Lipids 40*, 355–360 (April 2005).

The New Zealand green-lipped mussel (NZGLM), *Perna canaliculus*, is a bivalve native marine mussel from the mollusc family Mytilidae that is found in the deep-sea beds in the Hauraki Gulf in New Zealand's North Island waters (1). It is distinguishable from other bivalve species by the presence of a bright green stripe around the posterior ventral margin of the shell and its distinctive green lip, which is visible on the inside of the shell.

For a number of years, it has been claimed that preparations from the NZGLM have therapeutic value in the treatment of inflammatory conditions including arthritis (2) and asthma (3). Animal studies suggest a reduction in adjuvant-induced polyarthritis, collagen-induced arthritis, or carageenan-induced footpad edema when treated with extracts from the NZGLM (4,5). Two commercial products from the NZGLM have been produced. One is a stabilized freeze-dried powder extract known as Seatone® (MacLab, Abbotsford, Victoria, Australia); the other is a supercritical carbon dioxide oil extract from the freeze-dried stabilized powder, sold in capsules after the addition of olive oil and vitamin E, that is known as Lyprinol® (Pharmalink International, Queensland, Australia).

A recently developed CI–tandem MS (CI–MS/MS) method using acetonitrile reagent gas enables identification of the number and position of double bonds in FAME (6,7). In this method, acetonitrile self-reacts to produce the reagent (1-methyleneimino)-1-ethenylium of mass 54 *via* a previously described mechanism (8). The CI reaction yields diagnostic ions of $[M + 54]^+$, MH^+, $[MH - 32]^+$, and $[MH - 32 - 18]^+$, which are used to identify carbon chain length and number of double bonds. The $[M + 54]^+$ ion is isolated for MS^2 analysis, where fragmentation patterns vary depending on the number of double bonds. In monoenes, cleavage takes place at bonds allylic to the double bond; dienes exhibit fragmentation vinylic to the double bonds. For higher-order polyenes, cleavage is at sites vinylic to the second double bond from each end of the carbon chain. The two diagnostic ions, previously designated α (ester-containing) and ω (terminal methyl-containing), were used to identify the location of the double bonds within the FAME (7). Since full identification is possible using the highly predictable fragments, FA standards are not needed, and less common FA are readily identified. The advantages of this method have been discussed previously (7). This identification method has been used in several studies identifying FA within a sample, including those present at less than 1% (w/w), in bovine milk fat (9), mouse liver, primate brain (7), and other marine oils (10). The aim of the present study was to examine the FA in the main lipids found in the lipid extract from the NZGLM.

MATERIALS AND METHODS

The extract from NZGLM was obtained from McFarlane Marketing (Melbourne, Australia). Briefly, to obtain the lipid extract, mussels were harvested, crushed and stabilized, and centrifuged; the supernatant extract from the mussels was frozen and then freeze-dried. The lipids from the freeze-dried powder were extracted in commercial quantities by supercritical CO_2.

TLC. TLC was used to separate individual neutral lipid classes [polar lipids (PL), TAG, FFA, sterols (ST), and sterol esters (SE)] using a solvent system of hexane/diethyl ether/glacial acetic acid (60:17:0.1). Individual fractions from TLC separation were transmethylated with BF_3 (14%) for 10 min at 100°C. A complete oil sample plus an internal standard of tricosanoic acid (23:0) was treated similarly to the TLC fractions. Following methylation, heptane and a saturated NaCl solution were then added to the mixture. The organic layer containing FAME was then removed for analysis. *Instrumentation.* In all analyses, a Varian Saturn 2000 ion trap mass spectrometer coupled to a Varian 3400 gas chromatograph (GC) equipped with a Varian 8200 autoinjector (Varian, Walnut Creek, CA) was used. The column was an SGE Chromatography Supplies (Austin, TX) BPX-70 (0.32 mm × 0.25 μm × 60 m). The GC oven temperature was ramped from 60 to 170°C at 50°C/min, held for 5 min, ramped to 200°C at 4°C/min, held for 5 min, ramped to 255°C at 49°C/min, and held for 9.18 min.

Analysis to determine FA identities was conducted using CI–MS with acetonitrile as the CI reagent. The "CI Auto" option in the software with the following CI parameters was used: CI storage level = 22.0 *m/z*, ejection amplitude = 8.0 V, background mass = 65 *m/z*, maximum ionization time = 2500 μs, maximum reaction time = 100 ms, target total ion chromatogram = 5000 counts, and prescan ionization time = 100 μs. Additional mass spectrometer parameters were: emission current = 20 μA; mass defect = 116 mmu/100 u; trap temperature = 175°C; manifold temperature = 45°C; transfer line temperature = 200°C; axial modulation = 3.6 V. Through CI–MS, the chain length and number of double bonds were determined. In CI–MS/MS with acetonitrile, the $[M + 54]^+$ ion is trapped and then forms two diagnostic ions used to determine the location of the double bond (7).

Percent composition and concentrations of FA were determined through EI–MS. Samples were run in triplicate and peaks were integrated using Varian Saturn GC–MS Workstation software, version 5.2.1. In these runs, each FA had a different ionization efficiency, resulting in peak areas not proportional to their concentration. To compensate for this, an equal-weight FAME mixture, 68A (Nu-Chek-Prep, Elysian, MN), was run along with samples to generate instrumental response factors. Response factors for all FA in the sample were based on comparable FA in the 68A mixture. For FA not included in 68A, the response factor was interpolated from those directly calculated. Factors used in interpolation include: number of carbons, number of double bonds, and location of the double bond relative to the end of the chain. All factors were normalized relative to 16:0. The raw peak area was multiplied by the appropriate response factor to generate peak areas proportional to the amount of FA in the sample. The adjusted peak areas were used to determine the percent composition of the FA in the sample. Concentrations were determined based on the known concentration of the internal standard added to the original sample.

RESULTS

The lipid extract contained five major fractions as separated by TLC, which corresponded to SE, TAG, FFA, ST, and PL. The total FA content of the lipid extract, derived from the analysis of the total FA, amounted to 664 mg/mL of the sample; SE was present at 41.4% (230 mg/mL); TAG, 7.7% (43 mg/mL); FFA, 46.8% (260 mg/mL); and PL, 4.1% (23 mg/mL). The identity of the bands between ST and PL has not been established; however, they may be partial glycerides. In contrast to this commercial extract, the lipid extract of fresh NZGLM contains 57–62% phospholipids (11).

Table 1 shows all FA revealed from analysis, including 70 fully identified FA and 21 for which it was not possible to assign the identification of the position of the double bonds. Eighteen unresolved FA pairs were present. Seventeen saturated FA were identified, the main ones being 14:0, 16:0, and 18:0. There were 10 n-3 PUFA identified, including EPA and DHA as the two main n-3 PUFA. Other n-3 PUFA included 18:3, 18:4, 20:3, 20:4, 21:5, 22:5, 24:6, and 28:8.

Forty-three UFA from the n-4, n-5, n-6, n-7, n-8, n-9, n-10, families were also identified, with 16:2n-4, 16:1n-5, 18:1n-5, 18:2n-6, 20:4n-6, 16:1n-7, 20:1n-7, 16:1n-9, 18:1n-9, and 20:1n-9 being the most abundant FA in these six families.

Eighteen FA pairs could not be separated by this technique. The two most abundant were 20:5/20:4n-3 and 22:2/22:4. It was not possible to assign the position of double bonds in 21 FA. The reason for this was their low proportion, in general less than 0.05% (w/w), in the total mixture. The 20:5 present in the unresolved peak was an unidentified isomer, separate from the major, fully resolved component, 20:5n-3.

Of the 91 FA reported, only 16 represented more than 1% of the total FA. In decreasing order of abundance, these were EPA, 16:0, DHA, 14:0, 16:1n-7, 18:0, 18:1n-5, 18:4n-3, 18:2n-6, 20:4n-6, 18:3n-3, 16:1n-5, 20:1n-9, 18:1n-9, 15:0, and 16:1n-9.

The FA of the four main FA-containing fractions were also analyzed, as shown in Table 2. The proportion of the main FA in these fractions was not the same, with the most obvious differences being for 14:0, which varied from 5.29% of PL FA to 8.72% of FFA; 16:0, which varied from 12.27% of PL FA to 23.04% of FFA; 20:5n-3, which varied from 16.89% for TAG to 26.91% for PL FA; and 22:6n-3, which varied from 11.40% for TAG to 18.44% for PL FA. In terms of FA composition, the FFA and TAG FA were the most similar of the four fractions.

[a]Results shown as mean ± SD of triplicate determinations.

DISCUSSION

The gas phase derivatization reaction developed in our laboratory (7) allowed for the more detailed FA profile. Previous analysis of fresh NZGLM flesh by nonpolar GC identified 42 FA, of which 16 accounted for greater than 1% of total FA (11). In the current analysis, no FA unique to the NZGLM were found. However, several less common FA were observed in the sample, including 14:1n-5, 14:1n-7, 15:1n-9, 16:2n-4, 16:3n-4, 17:1n-4, 17:1n-5, 17:1n-7, 17:1n-9, 17:1n-11, 18:2n-4, 18:3n-4, 18:4n-4, 19:1n-7, 19:4n-5, and 21:5n-3. The presence of these particular FA is consistent with previous analyses of FA in marine life, including the mussel species *Mytilus galloprovincialis* (12,13). There is no record of these FA appearing in mammals or other terrestrial species. As with previous occurrences of these FA, they appeared as a minor fraction of the total FA found and were present at less than 1% of the total lipid composition. Other samples have

also been analyzed using this method to find minor FA components. Samples from golden algae (*Schizochytrium* sp.), primate brain white matter, and mouse liver were examined, and all showed a number of minor components (7).

In the analysis of saturated FA, four were found to appear in multiple peaks: 14:0 (3 peaks), 15:0 (3 peaks), 16:0 (3 peaks), 17:0 (3 peaks). This occurrence is most likely the result of branched-chain FA including isoprenoid FA, with different isomers being resolved in the chromatographic analysis. Our method applies only to UFA since reaction with a double bond is required; thus, chain branching in saturated FA cannot be established. Murphy *et al.* (11) reported three branched-chain FA in fresh samples of the NZGLM (4,8,12-trimethyl tetradecanoic acid, *i*17:0, *i*18:0).

Omega-3 (n-3) FA made up a significant amount of the FA in the sample, with 40% of all FA being in this category. DHA and EPA accounted for 84% of the n-3 PUFA. EPA and DHA are also present in high amounts in other species, including

the bivalves *Ostrea lutaria* and *Crassostrea gigas*; in another New Zealand mollusc, *M. canaliculus,* DHA and EPA account for 85% of n-3 FA (14).

The very long chain FA 28:8n-3 was also found in this sample. This FA was discovered in dinoflagellate oils (10,15), as well as the in the Tasmanian blue mussel (*M. edulis)* (11). It has been

[a]Results shown as mean ± SD of triplicate determinations.

suggested that the presence of 28:8n-3 in the mussel species is dietary in origin, with algae being a source (15). Since its recent discovery, it has been detected in marine oils but not in tissues of terrestrial mammals. Because it is 4-5 desaturated, 28:8n-3 is a structural analog of 22:6n-3; however, no physiological properties have yet been reported for this FA in mammals.

The technique used for this analysis allowed for a more detailed FA profile of the analyte. Previously, FA were quantified using GC–FID, and the GC–MS method used here was used only for qualitative determination of FA. Through the use of EI–MS, the amount of the various FA was determined. Response factors for the various FA were more difficult to determine. However, this method is advantageous also in that a smaller sample amount is required for analysis. In decreasing the sample concentration, GC resolution increased, permitting the observation of those FA present in small amounts, especially those present at less than 1% of the whole sample. Full identification was still not possible for some FA present in low concentrations owing to inefficient ionization or reaction with the CI reagent. In these cases, the amount of [M + 54]$^+$ ion formed was not enough to allow for proper MS–MS analysis.

ABSTRACT: FA components of 11 musts made from grape cultivars grown for making red wine in various regions of Japan and of wines made from the musts were compared to elucidate variety-dependent characteristics and to clarify their effect on FA ethyl ester (FAEE) formation in wine. Sixteen FA with carbon chain lengths from 12 to 26 were detected in all musts, with palmitic, linoleic, and linolenic acids generally predominating. Higher levels of linoleic acid were found in musts from a cold region (Hokkaido), and higher levels of oleic acid occurred in musts from a warm region (Honshu). Moreover, the unsaturation indexes (1.31–1.56) of five grape musts from the cold region showed significant differences among varieties, corresponding to the grapevines' degree of cryotolerance. The FA levels (610–6,610 nmol/100 mL) of all wines were extremely low (1.2–12.8%) compared with those of must, but the FA compositions were similar to those of must. Additionally, significant amounts of FAEE, possibly derived from yeast activity, were found in wines by using a solid-phase extraction method. The amounts of FAEE in wine significantly differed among samples (245–904 nmol/100 mL) and were inversely correlated with the percentage of linoleic acid in musts ($R = -0.883$). Thus, higher linoleic acid levels in must may be related to lower FAEE formation by yeast.

Paper no. L9646 in *Lipids 40,* 361–367 (April 2005).

Although lipid moieties derived from grapes and microbes exist in wine (1,2), there has been little research on the lipid components of wine compared with studies of other alcoholic beverages such as sake, beer, and whisky made from grains. The lipid components of rice used for making sake were found to correlate strongly with sake quality (3,4). Therefore, the relationship between the lipids in raw materials and yeast-mediated aroma formation, including esters, during alcoholic fermentation would be of particular interest in wine making.

As for the lipid-related components of wine, some research has detected only carotenoids and aroma components such as higher alcohols and esters (5–7). However, we recently reported that the FA composition of 12 commercial red wines differed with production method, grape harvest area, and aging

duration (8). Moreover, when changes in FA levels during wine production were investigated, high FA levels that were noted in must (29.5 mg/100 mL) declined to less than 4% by the bottled wine stage, accompanied by a decreased unsaturated FA proportion (8). In this study, the FA characteristics of 11 musts harvested in Japan, differing in both cultivation areas and grape varieties, were investigated, particularly with respect to whether the FA values may be useful as a way to identify the grape growing region and to variety-dependent characteristics such as cryotolerance. Moreover, we examined the wine after alcoholic fermentation to clarify the relationship between the FA levels of must and the formation of fatty acid ethyl ester (FAEE), an important flavor compound in wine.

MATERIALS AND METHODS

Must and wine samples. Eleven grape samples (approximately 10 kg each), listed in Table 1, were used in 2002 for wine production at Tokachi-Ikeda Research Institute for Viticulture and Enology (Ikeda, Hokkaido, Japan). The musts (nos. 1–5) from five grape varieties grown in Hokkaido in 2001 and 2003 also were analyzed. Three samples (nos. 6, 7, and 10), two samples (nos. 8 and 11) and sample no. 9 were kindly donated by the National Research Institute of Brewing (Higashihiroshima, Japan), University of Yamanashi (Kofu, Japan), and Asahi-machi-wine (Yamagata, Japan), respectively. Must was obtained from a free run of destemmed and crushed grapes prior to alcoholic fermentation. Alcoholic fermentation was carried out using a commercial yeast (Lalvin EC1118; Lallemand Inc., Montréal, Canada), at 25°C. Wine was at the stage after the first racking, subsequent to alcoholic fermentation (at 1 mon from must and before malo-lactic fermentation). The samples were immediately frozen at −30°C after sampling, and were stored at this temperature until analysis. Samples obtained were immediately subjected to general analysis and lipid extraction.

Grape varieties used in this study were collected from the northern part of Japan, in Hokkaido, to the southwestern part of Japan, in Hiroshima (Fig. 1). Since Hokkaido is located close to the northern limit of grape cultivation in Japan (around latitude 43°), where minimum temperatures can reach −30°C in winter, common grape varieties do not survive (9). Therefore, grape varieties for vinification were bred

[a]Air temperature means the summation of average air temperature of four months from June to September.
[b]Total acidity (mL) was estimated as the tartaric acid equivalent.

with high cryotolerance (samples 2 and 3) by using the cross-breeding method with *Vitis vinifera* and wild grape (*V. amurensis* Rupr.; sample 4).

The cryotolerance of the five grapevines grown in Hokkaido was greatest in wild grape, followed by Kiyomai ≅ Yamasachi, Kiyomi, and lowest in Zweigeltrebe (9). Total acidity in musts ranged from 4.8 to 33.5; musts from grapes grown in the cold region (Hokkaido) showed particularly higher values, from 8.8 to 33.5, compared with those of the other six samples (Table 1). Wild grape, with a notably high cryotolerance, exhibited the highest total acidity value (33.5), estimated as tartaric acid equivalent. However, the differences in cultivation areas led to significant differences in total acidities (4.8–7.9), even in the same variety such as Muscat Bailey A (samples nos. 6–9).

General analysis of must and wine. The specific gravity, sugar contents, pH, and total acidity were analyzed according to the Official Method of the Japan National Tax Administration (10).

FA analysis. Lipophilic components were extracted from must and wine with a mixture of chloroform and methanol, and were then reacted with methanolic 5% HCl for 2 h at 95°C to prepare FAME, as described previously (8). The FAME were analyzed using a Shimadzu GC-2010 gas–liquid chromatograph equipped with a hydrogen FID and a capillary column of CP-SIL 88 (50 m × 0.25 mm i.d., film thickness 0.2 mm; GL Science, Tokyo, Japan). The column was programmed from 80 to 180°C at 15°C/min, then increased to 220°C at 2°C/min, and finally held for 10 min. Nitrogen was used as the carrier gas, and the injector and detector temperatures were maintained at 210 and 210°C, respectively. Tridecanoic acid was used as an internal standard for quantitative analyses. To identify FAME, GC–MS was conducted using a Shimadzu QP-2010 gas chromatograph–mass spectrometer equipped with the same capillary column that was used for GC. Helium was used as the carrier gas, the injector temperature was maintained at 240°C, and the ionizing energy was 70 eV.

Analysis of the FAEE by solid-phase extraction and GC–MS. The FAEE component of wine was separated using a

solid-phase extraction method (11). Briefly, a cartridge (LiChrolut EN 200 mg/3 mL; Merck, Darmstadt, Germany) was rinsed with 4 mL dichloromethane, 4 mL methanol, and finally 4 mL 12% ethanol. Wine (50 mL) was centrifuged at $1,500 \times g$ for 15 min. After transferring the supernatant, the pellet was washed with 25 mL of 12% ethanol (vol/vol) and separated by centrifugation. The combined supernatant was loaded into the preconditioned cartridge, approximately 2 mL/min. Then the sorbent was dried by letting air pass through it using an aspirator for 10 min and eluted with 1.3 mL hexane/diethyl ether (9:1, vol/vol). Five microliters of ethyl tridecylate solution (1 mg/mL hexane) as an internal standard and an appropriate amount of anhydrous Na_2SO_4 were added to the eluted sample. FAEE was analyzed using GC–MS for the FA analysis. The column temperature was initially 40°C for 5 min, then programmed from 40 to 70°C at 4°C/min, and finally at 8°C/min to 230°C, and held for 5 min. The reproducibility

[a]For harvest area see Table 1.
[b]($\times 10^2$ nmol/100 mL)
[c]ΣSFA = Σ saturated FA; ΣUFA = Σ unsaturated FA.
[d]Unsaturation index = (Σmi · ni)/100, where mi is the percentage of each FA and ni is the number of C–C double bonds in each FA i.

of the method was determined by using standard ethyl butyrate, ethyl caprate, ethyl palmitate, ethyl oleate, and ethyl linoleate in a model wine solution, which contained 0.75 g/100 mL tartaric acid and 12% ethanol at pH 3.5 in distilled water. The recoveries of the five compounds ranged from 92 to 97%.

Statistical analysis. All data for lipid analyses are presented as averages from at least three independent experiments, along with the SD. Statistical significance was evaluated by ANOVA and tested by Scheffé analysis. For all statistical analyses, significance was established at $P < 0.05$, $P < 0.01$, and $P < 0.001$.

RESULTS

FA in must. Total FA concentrations ranged from 30,500 to 82,400 nmol/100 mL in the musts (Table 2). Considerable amounts of FA were detected in four samples (Kiyomi, Kiyomai, Yamasachi, and wild grape) from cryotolerant grapes grown in Hokkaido; concentrations were 56,600 to 82,400 nmol/100 mL. Sixteen FA with carbon chain lengths from 12 to 26 were detected in all samples (Table 2). Palmitic, linoleic, and linolenic acids were generally present as major components at 21.6 to 30.1%, 26.6 to 47.4%, and 9.2 to 20.5%, respectively. However, linoleic acid proportions showed significant differences among the samples, being particularly higher in five must samples from Hokkaido compared with those from other regions. Oleic acid was also one of the major FA, with levels at 13.7 to 21.3% in four Muscat Bailey A samples (nos. 6–9) and one Merlot sample (no. 10).

Unsaturation indexes, indicating the degree of FA unsatura-

tion (Table 2), ranged from 1.30 to 1.58 for five must samples (nos. 1–5) grown in Hokkaido; these values were higher than those in musts prepared from grapes grown in lower latitudes (1.18–1.29). Moreover, among the five grapes grown in Hokkaido, the order of the unsaturation indexes in must was identical to the level of cryotolerance (Table 2). Wild grape (sample no. 4), with the highest cryotolerance, showed the highest unsaturation index (1.58), whereas Zweigeltrebe (sample no. 5), with the lowest cryotolerance, showed the lowest value (1.30). It thus follows that the FA compositions of musts, derived from grapes from the same cultivation area, have individual specific profiles related to their variety-dependent characteristics. To confirm this, the FA compositions of five grape musts grown in Hokkaido from 2001 to 2003 were compared (Fig. 2). The unsaturation indexes over 3 yr showed significant differences among the five varieties tested.

Comparison of FA components between musts and wines. Total FA concentrations in wines (after the first racking subsequent to alcoholic fermentation) ranged from 610 to 6,610 nmol/100 mL (Table 3), markedly lower than the must stage (Table 2) for all samples tested. This decrease compared with must was least at 87.2% for sample no. 9 and was highest, at 98.1%, for sample no. 5. There was also a positive correlation ($R = 0.775$, $P < 0.01$) between the total acyl concentrations of each must sample and wine sample (Fig. 3).

As for the FA components of wine, 10:0 (capric acid) was detected as a new component (0.9–4.9%), in addition to 16 other FA with carbon chain lengths from 12 to 26 (all being already present in must). Of those, palmitic and linoleic acids
FIG. 2. Annual comparison of unsaturation indexes of FA in musts of five black grape varieties grown in Hokkaido for 3 yr. Unsaturation index means $(\Sigma m i \cdot n i)/100$, where m*i* is the percentage of each FA and n*i* is the number of C–C double bonds in each FA *i*. Data are represented as means ± SD. Different superscript letters indicate significant differences. The order of the cryotolerance strength of the grapevines is as follows: wild grape > Kiyomai ≅ Yamasachi > Kiyomi > Zweigeltrebe.

were generally predominant at 26.7–37.5% and 12.1–35.6%, respectively, in all samples (Table 3). High proportions of oleic acid, as well as both palmitic and linoleic acids, at 11.0 to 18.6%, were detected in wines made from grapes harvested in regions outside Hokkaido (nos. 6–11). Moreover, there were differences in the *cis*-9-palmitoleic acid compositions between wines from Hokkaido (nos. 1–5) and other wines, with the lat-

ter being notably higher at 4.8 to 11.0%. From must to wine, the relative proportions of PUFA, including linoleic and linolenic acids, decreased (the former at 4.9 to 28.3%, the latter at 4.8 to 10.6%), whereas those of saturated FA, including palmitic and stearic acids, increased (the former at 0.7 to 12.1%, the latter at 4.1 to 10.9%). In accordance with these changes, the wine unsaturation indexes ranged from 0.59 to 1.05, indicating that the degree of FA unsaturation decreased after alcoholic fermentation. The proportions of medium-chain FA, such as lauric and myristic acids, in each wine sample were higher than those in musts, although this difference was not significant.

The relationships between musts and wines were evaluated with respect to their proportions of palmitic, oleic, linoleic, and linolenic acids. Strong positive correlations ($R = 0.922$ for oleic acid, $R = 0.738$ for linoleic acid, and $R = 0.770$ for linolenic acid) were found for the latter three components, but not for palmitic acid (Fig. 4). The FA characteristics of wine were therefore similar to those of must, although FA concentrations and compositions were changed from the must stage by the alcoholic fermentation of the grapes.

Analysis of FAEE in wine. A hexane/diethyl ether (9:1, vol/vol)-eluted fraction was prepared from wine made from the Kiyomi grape using the solid-phase extraction method, then analyzed by capillary GC–MS (Fig. 5). When fragment ions of m/z 88, characteristic of FAEE, were monitored, 13 FAEE, from ethyl butyrate (peak 1) to ethyl linolenate (peak 13), as well as ethyl tridecylate (peak 6, used as an internal standard) were detected. In addition, a large peak with a retention time of ~13 min was judged to be isoamyl alcohol by comparison of

FIG. 3. Correlation of total acyl concentration between must and wine. Data are represented as means of triplicate analyses.

FIG. 5. (A) Total ion chromatograms (TIC) and (B) mass chromatograms of FA ethyl esters from wine (Kiyomi) determined by a combination of solid-phase extraction and GC–MS. Peaks 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, and 13 correspond to ethyl esters of 4:0, 6:0, 8:0, 10:0, 12:0, 13:0, 14:0, 16:0, 16:1, 18:0, 18:1, 18:2, and 18:3, respectively.
its mass spectrum and retention time with the standard compound.

Values for FAEE in each wine are shown in Table 4. Total amounts of FAEE ranged from 245 to 904 nmol/100 mL, with all Muscat Bailey A samples (nos. 6–9) showing high amounts (565–904 nmol/100 mL). Low amounts of FAEE were detected in wines produced from grapes grown in the cold region (nos. 1–5), compared with those from the other regions. When the effects of FA components in must on FAEE concentrations were examined, a strong negative correlation ($R = -0.882$, $P < 0.001$) was identified between the percentage of linoleic acid in must and the FAEE concentration in wine. This may suggest that the high linoleic acid proportion of the lipid constituents of must inhibit FAEE formation by yeast during alcoholic fermentation.

Ethyl butyrate, ethyl caproate, ethyl caprylate, and ethyl caprate were present as major FAEE, at 7.7 to 13.1%, 27.1 to 45.8%, 14.4 to 36.8%, and 6.5 to 9.7%, respectively (Table 4). Characteristically high levels of ethyl 9-palmitoleate and oleate were present in sample 10 (Merlot) at 11.8 and 4.4%, respec-

tively, whereas ethyl palmitate and ethyl linoleate were present in sample 1 (Kiyomi) at 10.0 and 13.6%, respectively. In addition, ethyl decenoate was detected in six samples including Kiyomai, although it was not detected in wine prepared from the Kiyomi grape (Fig. 5).

DISCUSSION

It was recently reported that palmitic, myristic, and lauric acids were the major FA in 12 commercial red wines, and that differences in wine production methods and grape cultivation regions (different countries, including Japan) could possibly influence the FA compositions of red wine (8). In the present study, the FA composition of grape musts from various cultivation areas in Japan and their wines were compared for the first time. The FA composition of Muscat Bailey A musts differed according to the area where the grapes were grown (Table 2), even though they were from the same variety. Alberto *et al.* (12) previously reported on the FA composition in must from Cabernet Sauvignon. Linoleic (20.6%), stearic (15.7%), and oleic acids (10.9%) were present as major FA. But for the most part, this differed considerably from the Cabernet Sauvignon (sample no. 11) used in this study. This discrepancy also may be due to differences in the cultivation areas. On the other hand, the unsaturation indexes of musts made from grapes grown in Hokkaido were higher than those in samples from the other regions, which means that the FA composition of grapes could change with different temperatures during maturation. Since the characteristics of the FA compositions of musts were also partially reflected in red wines after alcoholic fermentation (Fig. 4), FA analysis of wine may possibly be used as one of the parameters to determine grape harvest areas. The unsaturation indexes of must were found to differ significantly among the five varieties, possibly in relation to the different cryotolerance levels of the grape vines. Thus, the higher levels observed in musts from Hokkaido appear to be related to the greater cryotolerance of grapevines grown in Hokkaido (also observed in grape inner bark) (13).

[b](nmol/100 mL).

However, FA concentrations in all wines were lower than those in their must stages, which agrees with our previous study comparing the FA compositions of must and wine from the Kiyomi variety (8). We assumed that most of the lipophilic components of the wines tested would no longer be present through lees removal after alcoholic fermentation. We determined from the results that the FA levels in must decreased to 1/10 following filtration through a 0.45-μm filter compared with prefiltration levels (data not shown). A high proportion of *cis*-9-palmitoleic acid was present in wine samples nos. 6 to 11 compared with that in wines from Hokkaido (nos. 1–5). This may possibly indicate that *cis*-9-palmitoleic acid formation by yeast is inhibited by the high linoleic acid levels in musts from grapes grown in the cold region (14,15). Thus, it was clear that the differences in the FA compositions of musts influenced the FA components of the resulting wines.

Since the levels of medium-chain FA, such as capric acid, and *cis*-9-palmitoleic acid (probably produced by yeast) had increased in the wines, we tried to examine the FAEE that were produced during alcoholic fermentation. Although the FAEE is one of the lipid components of wine, the ethyl esters of lower FA cannot be recovered by the processes of washing and concentrating in the general lipid extraction method. These components therefore generally have been analyzed together with many other flavor components (16,17). However, it became clear that FA esters could be determined more easily by directly analyzing 50-mL wine samples using a combination of solid-phase extraction and capillary GC–MS rather than using the headspace method. The decrease in FA concentrations from the must stage to the wine stage as well as the FAEE compositions of wine (Tables 3, 4) differed among wines (samples nos. 1–5) prepared by the same wine production methods. It was assumed that differences in the FA compositions of the starting materials would influence yeast (*Saccharomyces cerevisiae*) growth, FA *de novo* synthesis, and enzymatic activity concerned with ethyl

ester formation (3,14,15,18,19). Therefore, low levels of FAEE (Table 4) were present in wines produced from grapes grown in Hokkaido, which contained much more linoleic acid (Table 2), corresponding to the negative correlation observed between the proportion of linoleic acid added to the yeast culture medium and the amount of isoamyl acetate formation (3). The linoleic acid included in the medium was directly incorporated into yeast cellular lipids such as PC, one of the major components of biomembrane lipids (3,15). Consequently, it was assumed that FA *de novo* synthesis in yeast was inhibited, which caused decreased levels of FAEE formation (3).

Linoleic acid and its ethyl ester, undesirable in "shochu" and beer manufacture because they cause an off-flavor (20,21), would not have an adverse influence on wine quality because PUFA derived from grapes are removed from wine mainly as lees during the wine-making process. Conversely, the PUFA released from grape cells appear to enhance the yeast's tolerance to alcohol and to low temperatures during and after fermentation, which is expected to increase aroma compounds by low-temperature fermentation (22).

Lipid Characterization of Seed Oils from High-Palmitic, Low-Palmitoleic, and Very High-Stearic Acid Sunflower Lines

María J. Serrano-Vega, Enrique Martínez-Force, and Rafael Garcés*

Instituto de la Grasa, Consejo Superior de Investigaciónes Científicas (CSIC), 41012 Sevilla, Spain

ABSTRACT: Information obtained in recent years regarding the enzymes involved in FA synthesis can now be applied to develop novel sunflower lines by incorporating enzymes with specific characteristics into lines with a defined background. We have generated three highly saturated mutant lines in this way and characterized their FA content. The new high-palmitic, low-palmitoleic lines CAS-18 and CAS-25, the latter on a high-oleic background, have been selected from the high-stearic mutant CAS-3 by introducing a deficient stearic acid desaturase in a high-palmitic background from the previously developed mutant lines CAS-5 and CAS-12, respectively. As such, the desaturation of palmitic acid and the synthesis of palmitoleic acid and its derivatives (asclepic and palmitolinoleic acids) were reduced in these high-palmitic lines, increasing the stearic acid content. Likewise, introducing a FA thioesterase from a high-palmitic line (e.g., CAS-5) into the high-stearic CAS-3 increased the stearic acid content from 27 to 32% in the new high-stearic line CAS-31. As previously described in high-palmitic lines, high growth temperatures did not reduce the linoleic acid content of the oil. Furthermore, the FA composition of TAG, DAG, and phospholipids was modified in these lines. Besides a high degree of saturation, the TAG from these new vegetable oils have a low content of saturated FA in the sn-2 position. The α asymmetric coefficient obtained also indicates that the saturated FA are asymmetrically distributed within the TAG molecules. Indeed, the disaturated TAG content rose from 31.8 to 48.2%. These values of disaturated TAG are the highest to date in a temperate oilseed.

Paper no. L9698 in *Lipids 40*, 369–374 (April 2005).

The synthesis of FA in oilseeds up to the length of oleic acid occurs within the plastid. The enzymatic complex FA synthase I (FAS I) synthesizes up to the palmitoyl-acyl carrier protein (ACP), whereas FA synthase II (FAS II) elongates the palmitoyl-ACP to stearoyl-ACP. Finally, the stearoyl-ACP desaturase (SAD) introduces the first double bond into the molecule to produce oleoyl-ACP. The acyl-ACP are hydrolyzed by the action of the acyl-ACP thioesterases (TE), FatA or FatB, which have distinct preferences for unsaturated or saturated acyl-ACP, respectively. Nascent free FA are then exported to the cytoplasm and used as acyl-CoA for the syn-

thesis of glycerolipids in oilseeds, mainly TAG. In general, palmitic, stearic, and oleic acids are the main FA synthesized within the plastid in oilseeds, although later on oleic acid can then be desaturated, elongated, and so on.

Recently, some highly saturated sunflower mutant lines were generated by mutagenesis in an attempt to increase genetic variability (1,2). When the seed lipids from these mutant lines were analyzed, an increase in saturated FA content was observed, particularly in the TAG (3). From these mutants, two independent high palmitic acid lines were selected, both containing around 30% palmitic acid. Whereas one of these is on a standard high linoleic acid background (CAS-5), the other one is on a high oleic acid background (CAS-12). As a consequence, the seeds of these lines accumulated some palmitoleic (16:1n-7) and asclepic (18:1n-7) acids. Furthermore, the CAS-5 mutant also accumulated palmitolinoleic acid (16:2n-4). At least three partially recessive genes are responsible for the production of high quantities of palmitic FA in these mutants (4). Biochemical characterization of these mutants showed that the keto-acyl synthase II (KASII), an enzyme of the FAS II complex, was less active than the standard sunflower KASII. At the same time, an increase in TE activity on saturated FA was observed (5). The reduction in KASII activity led to an increase of palmitoyl-ACP production within the plastid, whereas the increase in TE activity on saturated FA promoted hydrolysis of the palmitoyl-ACP and subsequent export into the cytoplasm. On the other hand, some palmitoyl-ACP is desaturated within the plastid to palmitoleoyl-ACP owing to the activity of SAD, and this palmitoleoyl-ACP can be elongated to ascleployl-ACP by the action of the FAS II. Both these FA can then be exported into the cytoplasm where palmitoleic acid is converted to palmitolinoleic acid in the case of CAS-5 (5). Another highly saturated sunflower mutant with a high stearic acid content in the seed oil (CAS-3) was also obtained by mutagenesis (1). In this case, two partial dominant genes control the characteristic accumulation of FA (6). Biochemical characterization of this line identified a deficiency in the SAD activity and an increase in TE activity toward stearoyl-ACP that was responsible for this new trait (7). This mutant did not show any side effects due to the increase in its intraplastidial stearoyl-ACP content.

By considering all the available biochemical information and the channeling model proposed for the intraplastidial FA biosynthesis in the sunflower (8), we have generated a

Abbreviations: ACP, acyl carrier protein; FAS I and II, FA synthase I and II; KASII, keto-acyl synthase II; SAD, stearoyl-ACP desaturase; TE, thioesterase.

hypothesis to further increase the saturated FA content of recombinant lines obtained from these initial mutants. For example, the introduction of the mutated SAD gene from the CAS-3 line into high-palmitic lines should reduce the amount of palmitoleic, asclepic, and palmitolinoleic acids that accumulate in the storage oil. Similarly, if the different TE activities described in both mutants depend on independent genes and are complementary, then an increase in saturated FA content would be expected when both activities are brought together. In this paper we characterize new lines obtained by crossing high-palmitic and high-stearic lines in accordance with this hypothesis.

EXPERIMENTAL PROCEDURES

Plant material. Sunflower seeds (*Helianthus annuus* L.) from the mutant lines CAS-5 and CAS-12 with high palmitic acid content, and the CAS-3 line with high stearic acid content were used in this work (1,2). The control seeds with a normal FA composition were from the public line RHA-274, from the USDA. The new sunflower lines described here were obtained by crossing high-palmitic and high-stearic acid mutants and selecting the lines of interest. Plants were cultivated in growth chambers at 25/15°C (day/night) cycles or at the temperatures indicated. A 16-h photoperiod was used with a photon flux density of 300 µmol $E \cdot m^{-2} \cdot s^{-1}$.

Lipid extraction and separation. About 500 mg of peeled seeds were ground in a screw-capped glass tube (10×13 mm) with a pestle and sand. The total lipids were extracted and separated by TLC on 0.25-mm-thick silica gel plates that were developed with hexane/ethyl ether/formic acid (75:25:1, by vol). The TLC plates were partially covered with a glass plate and exposed to iodine vapor. Unexposed TAG, DAG, and phospholipid fractions were scraped off the plates and eluted from the silica with chloroform/methanol (1:2, vol/vol). To determine their FA composition, phospholipids were further separated either on TLC silica gel plates developed with chloroform/methanol/acetic acid/H_2O (85:15:10:3.5, by vol) or on $(NH_4)_2SO_4$-impregnated silica gel plates developed with acetone/benzene/H_2O (90:30:10, by vol; 9). Individual polar lipids were identified by comparison with commercial standards, developed at the same time on the same TLC plate, and scraped off the plates.

Lipase hydrolysis. For positional analysis of FA in TAG, 10 mg of purified TAG was hydrolyzed with 2 mg pancreatic lipase in 1 mL of buffer containing 1 M Tris pH 8, 0.1 mL $CaCl_2$ (22%), and 0.25 mL deoxycholate (0.1%) (10). When approximately 60% of the TAG had been hydrolyzed (1–2 min), the reaction was stopped by adding 0.5 mL of 6 N HCl and the lipids were extracted three times with 1.5 mL ethyl ether. The reaction products were separated by TLC as indicated above. The FFA and *sn*-2-MAG bands, representing positions *sn*-(1+3) and *sn*-2 of TAG, respectively, were scraped off the plate and transmethylated. The FA composition of the original TAG was compared with that which remained after partial hydrolysis.

Lipid analysis. Isolated acyl lipids were converted to FAME from the isolated lipids by heating the samples at 80°C for 1 h in a 3-mL solution of methanol/toluene/H_2SO_4 (88:10:2, by vol; 11). After cooling, 1 mL of heptane was added and mixed. The FAME were recovered from the upper phase, then separated and quantified using a Hewlett-Packard 5890A gas chromatograph with a Supelco SP-2380 capillary column of fused silica (30 m length; 0.32 mm i.d.; 0.20 µm film thickness; Bellefonte, PA). Hydrogen was used as the carrier gas. The FA were identified by comparison with known standards and quantified with a hydrogen FID.

TAG species were separated and quantified by GLC using a Hewlett-Packard 6890 gas chromatograph with a Quadrex aluminum-clad bonded methyl 65% phenyl silicone 15M, 400-65HT-15-0.1F column (New Haven, CT). The TAG were identified and quantified by correcting the data for the relative FID response (12). After holding for 5 min, the oven temperature was ramped from 340 to 355°C at 1°C/min, the detector and injector temperatures were 400°C, and the split ratio was 1:100. Hydrogen was used as carrier gas, the linear rate being 31 cm/s.

The distribution of saturated FA in the external positions of TAG, *sn*-1 and *sn*-3, was calculated as the coefficient of asymmetry as previously developed (13). This coefficient was determined as the α of the TAG of the type SatUnsSat/SatUnsUns ($\alpha_{SUU/SUS}$) as we recommended for vegetable oils with a low content of saturated FA in the *sn*-2 position (13). An α value of 0.5 indicates that saturated FA are distributed equally between the *sn*-1 and *sn*-3 TAG stereochemical positions.

RESULTS AND DISCUSSION

FA composition of the oils. The FA composition of three recombinant lines, CAS-18, CAS-25, and CAS-31, was determined and is shown in Table 1.The CAS-18 and CAS-25 lines were selected from crosses of the high-stearic mutant CAS-3 with the high-palmitic mutants CAS-5 and CAS-12, respectively, keeping the high-palmitic background. These plants had inherited the low SAD activity from CAS-3 and consequently, had lower palmitoleic, asclepic, and palmitolinoleic acid contents. The CAS-31 line was obtained from the cross between CAS-3 and CAS-5, keeping the high-stearic background, and the efficient TE activity on saturated FA in this line increased the stearic and palmitic acid contents with respect to CAS-3. The FA composition of the RHA-274 control line and the parental lines, CAS-3, CAS-5, and CAS-12, are also shown (Table 1).

Thus, as proposed in our hypothesis, it appears that recombinant lines with reduced palmitoleic, asclepic, and palmitolinoleic acid contents could be selected by crossing the CAS-5 and CAS-12 with the CAS-3 line. In these plants, the palmitoleic acid content was reduced from 5.1 and 7.4% to 1.4 and 2.1%, respectively, whereas the asclepic acid content was reduced from 3.4 and 3.9% to 1.4 and 2.3%. It was no longer possible to detect palmitolinoleic acid in either CAS-18 or CAS-25. On the other hand, and as expected from the reduced

SAD activity, the stearic acid content increased in both lines to as much as 11.4 and 6.8%, respectively.

The CAS-31 recombinant line had more stearic acid than the parental CAS-3 line. Moreover, a slight increase in the palmitic acid content was observed after improving the TE activity on saturated FA with respect to that from CAS-5. These FA represented 31.9 and 8.8% of the total FA respectively, compared with 27.1 and 7.4% in CAS-3. As the result of competition for substrate between the TE from CAS-5 and the FAS II from CAS-3, and according to the channeling proposal for FA biosynthesis within the sunflower plastid (8), a small increase in palmitic acid would be expected. Similar results were also found in other lipids, as will be shown shortly.

DAG and TAG components. The FA composition of the TAG of these sunflower oils was similar to the FA composition in the corresponding oils (see Table 2). Given that 95% of the oil's content is made up of TAG, this is not an unexpected result. DAG are precursors in the synthesis of TAG, but they are found in only minor amounts in the oil with respect to the TAG. The saturated FA content in the DAG was lower than in TAG, but we assumed that if they have a similar behavior to the neutral lipids in most vegetable oils, then saturated FA would be found in only the *sn*-1 position. To confirm that these TAG behaved as normal vegetable oil TAG, we analyzed the FA composition at positions *sn*-2 and *sn*-(1+3) of the purified TAG by partial hydrolysis using lipase (Table 3). In spite of the very high content of saturated FA in the TAG, the content of saturated FA in position *sn*-2 was very low, between 1.4 and 2.0% of the total saturated FA content. This figure was even lower than expected because in

CAS-31 TAG, stearic acid was elevated to 6.3-fold of that found in the control line RHA-274, from 31.9 to 5.1%, but in the *sn*-2 position only a 3.8-fold change was observed, from 1.5 to 0.4% (3). No very long chain FA, behenic and arachidic acids, were detected at the *sn*-2 position in these oils. The *sn*-(1+3) positions were mainly occupied by saturated FA, between 42.2 and 49.3%, around 20-fold that in the *sn*-2 position. As expected, the main unsaturated FA in the *sn*-2 position of the high-oleic line CAS-25 was oleic acid (76.4%), and in CAS-18 and CAS-31 linoleic acid represented 90.9 and 71.7%, respectively. Palmitoleic and asclepic acids are atypically distributed since, despite being unsaturated, they are mainly found at positions *sn*-(1+3). This suggests that the *sn*-2 lysophosphatidylcholine acyltransferase shows a higher specificity for oleic and linoleic acids than for saturated FA. All these data together suggest that these specialty oils are more similar to cacao butter (also called cocoa butter) than to saturated animal fats, indicating that they probably have good nutritional properties and are more healthful than animal or chemically modified vegetable fats (14,15).

TAG species. TAG are made up of three FA bound to a glycerol backbone. Two different oils with a similar FA composition could have different TAG compositions. As a consequence, the TAG composition of an oil provides more information than the FA composition. Indeed, the concept that oils are made up of TAG and not just FFA is very important. The TAG composition of these new oils can be seen in Table 4. The most important characteristic of these oils is the very high levels of disaturated TAG, whereas these are minor components or present in only trace amounts in normal sunflower

[a]Mean and SD of threee independent experiments. —, <0.2%.
[b]These peaks did not separate and are included in the upper identification number. A, arachidic acid; As, asclepic acid; B, behenic acid; L, linoleic acid; O, oleic acid; P, palmitic acid; Po, palmitoleic acid; S, stearic acid.

25.1 and 14.5% of the total TAG content in this line as opposed to the 14.5 and 4.2% contributed in the corresponding parental line CAS-5 (12). In the high-oleic-, high-palmitic-, low-palmitoleic-derived line CAS-25, the main disaturated TAG species were POP and POS (where O = oleic acid), which corresponded to 20.2 and 8.3%. In the parental CAS-12 line, these TAG species represented 19.4 and 2.4% of the total TAG. In both the CAS-18 and CAS-25 lines, there was a considerable reduction in the TAG species containing palmitoleic and asclepic acids. This was expected given their lower representation in the oils of these lines with respect to the parental lines. Another common characteristic was the increase in PLS and POS, respectively, as a consequence of the increase of stearic acid.

In the high-linoleic, high-stearic CAS-31 there was a very important increase in PLS and SLS, from 6.8 to 8.1% and from 12.0 to 15.3%, respectively, when compared with the parental CAS-3 line (12). This was due to the increase in the stearic acid content and to a lesser extent, to the small increase in palmitic acid.

These new lines demonstrate an important increase with respect to their parental and standard sunflower lines in both saturated FA and in TAG with two saturated FA. The total disaturated TAG content was 31.8% in CAS-25, 39.3% in CAS-31, and 48.2% in CAS-18, this latter line probably constituting the temperate seed oil with the highest disaturated TAG content established to date. It has previously been shown that saturated FA are not symmetrically distributed between the *sn*-1 and *sn*-3 stereochemical positions in TAG molecules, and an asymmetrical α coefficient has been proposed to calculate this asymmetry (13). The calculated α SatUnsSat/SatUnsUns is that which is recommended for vegetable oils with a low content of saturated FA in the *sn*-2 position (13). Thus, to estimate this asymmetry in the new oils, we determined their α coefficient. The α for saturated TAG of the high-palmitic line CAS-18 was 0.42, higher than the 0.38 found in high-stearic line CAS-31, since their saturated FA are more symmetrically distributed. These results suggest that the acyltransferases involved in TAG biosynthesis have a different selectivity for palmitic or stearic acid. A similar effect was found when comparing the high-linoleic and high-oleic lines, for which the α coefficient for CAS-25 was 0.35. The smaller α value in the high-oleic lines is most likely related to the specificity of the acyltransferases.

Influence of the growth temperature. In previous studies, the content of linoleic acid in the high-palmitic line CAS-5 did not show big variations at different growth temperatures, even at a 30/20°C day/night growth temperature (16). This effect was not found in the high-stearic lines, such as CAS-3, or in the standard control lines. To determine whether these new very-high-palmitic lines behave in a similar fashion, the high-palmitic CAS-18 line and the high-palmitic, high-oleic CAS-25 line were grown at three different temperatures (Table 5). At high temperatures, the amount of linoleic acid produced by the CAS-18 line increased from 47.1 to 50.0%, reminiscent of the behavior of the high-palmitic CAS-5 sunflower mutants. A similar effect was found in the CAS-25 line with respect to oleic acid, which was coupled with a slight reduction in their linoleic acid content at a high growth temperature. This probably reflects the origin of this line from a high oleic acid background, which induces a behavior distinct from that of CAS-18. Nevertheless, the palmitic acid contents of all lines were similar and independent of the growth temperature. Furthermore, no differences were found among any other FA analyzed in these oils. This phenomenon may reflect the fact that membranes with a high palmitic acid content are always rigid and need to maximize their unsaturated linoleic acid content to maintain their membrane fluidity, a behavior that it is not found in the high-stearic lines (16).

Phospholipids. The FA composition of the main phospholipids in the seeds of these sunflower lines is shown in Table 6: PC, PI, and PE. As the sunflower seed is not a photosynthetic tissue, only small amounts of galactolipids accumulate. All phospholipids in these lines contain high levels of saturated FA, more than in standard control lines and even more than the highly saturated parental lines (3). The saturated FA content in PI was close to 50% in all the recombinant lines: 47.1% in CAS-18, 43.1% in CAS-25, and 45.3% in CAS-31. These values are similar to those that have been found for PI isolated from other sunflower lines (3). The contents of the other main phospholipids, PE and PC, were more variable, but always with a high level of saturated FA that reflected the principal saturated FA found in each line.

This study substantiates that biochemical data obtained from the analysis of sunflower mutant lines are important tools to guide the selection of new mutants with modified FA composition. In CAS-18 and CAS-25 lines, thanks to the introduction of a mutated SAD from the high-stearic line CAS-3, it has been possible to reduce the amount of palmitoleic, asclepic, and palmitolinoleic acids. In a similar way, the introduction of a TE activity that acts well on saturated FA in the new CAS-31 line elevated the stearic acid content in the oil up to 32%, improving the already high-stearic line CAS-3. These results confirm all previous biochemical findings regarding the association between SAD and TE in the generation of the mutant phenotypes of CAS-3, CAS-5, and CAS-12. Finally, by characterizing the lipids from these lines, we highlight the importance of the TAG composition and the asymmetric α coefficient for the saturated FA in these TAG.

ABSTRACT: This paper represents the first synthesis, spectroscopic characterization, and antitumor evaluation of F-, N-, and S-containing $C_4\alpha$-FA derivatives of podophyllotoxin. In a synthetic strategy, a FA unit of 4-*O*-podophyllotoxinyl 12-hydroxy-octadec-*Z*-9-enoate **2**, a derivative of podophyllotoxin, was functionalized at the C-12 position by incorporating the F atom and N-containing moieties. The FA olefin (*Z*, C-9/C-10) of **2** was hydrogenated to produce a derivative possessing a hydroxy function (C-12) on a saturated C_{18} FA chain. In another synthetic strategy, two *S*-ethers of podophyllotoxin ($C_4\alpha$) were synthesized from a terminal unsaturated FA analog, 4-*O*-podophyllotoxinyl undec-10-enoate. Syntheses were achieved through effective synthetic procedures; ^{1}H NMR, ^{13}C NMR, IR, and high-resolution mass data proved excellent tools to characterize these derivatives. *In vitro* antitumor activity was investigated against a panel of five human neoplastic cell lines, SK-MEL (malignant, melanoma), KB (epidermal carcinoma, oral), BT-549 (ductal carcinoma, breast), SK-OV-3 (ovary carcinoma), and HL-60 (human leukemia). Keeping in view the severe lack of tumor selectivity of podophyllotoxin over normal cells, we assayed new analogs against noncancerous mammalian VERO (African green monkey kidney fibroblast) cell lines to gauge their extent of toxicity. Several of these compounds showed excellent moderation of antitumor activity. In general, we found excellent growth inhibition against the human leukemia cell line (HL-60), particularly for the analogs containing *S*-ethers and carbamates. None of the compounds were toxic to normal cell lines.

Paper no. L9656 in *Lipids 40*, 375–382 (April 2005).

Chemotherapy involves the administration of specific anticancer therapeutic chemicals to cancer patients (1,2). Because of physiological similarities between cancerous and noncancerous cells, the clinical efficacy of most anticancer drugs is limited by varying degrees of toxicity toward normal cells (3). The undesired side effects result from the lack of selectivity and the appearance of acquired resistance (2). Like most antineoplastic agents, the natural product podophyllotoxin **1** (4,5) also lacks tumor selectivity, which limits its clinical utility for cancer chemotherapy and that of many of its related products (6,7). Alterations of its
structure have yielded two semisynthetic derivatives, etoposide and teniposide, which are in clinical use (5,7,8). Drug resistance, metabolic inactivation, myelosuppression, and bioavailability have greatly undermined the clinical applications of these two drugs (5,9,10). Approaches to facilitate tumor-selective chemotherapy have been the topic of recent investigations (3,11).

Current trends in the treatment of human cancers favor drug combinations that result in improved responses, where the contributions of a variety of FA have been proved highly significant (12,13). A number of FA are part of our diet; therefore, nutritional dietary supplements highly enriched in certain FA have been suggested to prevent the side effects of cancer therapy (13,14). That certain TG and FA have the potential to prevent or inhibit carcinogenesis has been proposed (15–18). FA substituents on podophyllotoxin **1** may lead to analogs with enhanced cytotoxicity, but this strategy has not yet been explored except in a few studies (19,20). We recently demonstrated the efficient synthesis of a series of FA-based $C_4\alpha$-derivatives of **1** and their significant *in vitro* selectivity for inhibiting the growth of cancer cells over normal ones (21–23). One of these compounds, 4-*O*-podophyllotoxinyl 12-hydroxy-octadec-*Z*-9-enoate **2**, has been assayed *in vitro* against a panel of 60 human cancer cell lines at the National Cancer Institute (NCI) under a drug discovery program. Data produced by NCI for **2** have shown strong tumor inhibition activity against a wide spectrum of cancer cell lines (23). Our preliminary studies have indicated a mode of antitumor action for **2** that differs from podophyllotoxin, etoposide, and teniposide (23). These results encouraged the present work, which is directed toward the synthesis of $C_4\alpha$-FA analogs of **1** possessing F, N, and S and evaluation of their *in vitro* anticancer activity.

Here, we report the first synthesis of $C_4\alpha$-FA analogs of podophyllotoxin **1** containing the F and N atoms, obtained by chemical transformations of the hydroxy group present at the C-12 position on the FA chain of compound **2**. Further, this communication also presents the first synthesis of $C_4\alpha$-*S*-ether (thioether) FA analogs of **1**. A total of eight unusually functionalized FA derivatives of podophyllotoxin were synthesized (Scheme 1), and spectroscopic data established their chemical structures. The novel $C_4\alpha$-FA analogs were assayed for their *in vitro* antitumor activity against a panel of four human solid tumor cell lines, SK-MEL, KB, BT-549, SK-OV-3, and one human leukemia cell line, HL-60. To compare their tumor selectivity over normal cell lines, VERO cells were also included.

EXPERIMENTAL PROCEDURES

The synthesis of 4-*O*-podophyllotoxinyl 12-hydroxy-octadec-*Z*-9-enoate **2** and all the experimental procedures used are as described previously (21). The palladium (10% on activated carbon powder, standard, reduced, normally 50% water wet) was purchased from Alfa Aesar (Ward Hill, MA). All other reagents were obtained from Aldrich Chemicals (Milwaukee, WI) and used without further purification.

(i) 4-O-Podophyllotoxinyl 12-hydroxy-octadecanoate 3. Compound **2** (100 mg) was dissolved in ethyl acetate (20 mL), and 10% Pd/C (10 mg) was added and hydrogenated for 8 h under a pressure of 45 psi. The solution was filtered and rotary-evaporated under reduced pressure at 20°C. The crude material was passed through a silica gel column (J.T.Baker, Phillipsburg, NJ; *n*-hexane/ethyl acetate, 1:1, vol/vol; R_f: 0.70) to obtain a sticky and viscous colorless oily form of **3** (yield: 99%). IR (CHCl$_3$, cm^{-1}): 3530, 1776, 1735, 1586, 1506, 1483, 1419, 1240, and 1122; ^{1}H NMR (CDCl$_3$, δ_H): 0.87 (*t*, *J* = 7.0 Hz, terminal methyl of the FA chain, 3H), 1.36–1.26 (*br m*, 11 × C$\underline{H}_2$ groups of the FA methylene chain, 22H), 1.40 (*m*, 11-C$\underline{H}_2$, 13-C$\underline{H}_2$, 4H), 1.68 (*m*, 2H), 2.43 (*m*, 2-C$\underline{H}_2$, 2H), 3.58 (*m*, 12-C$\underline{H}$-OH, 1H); ^{13}C NMR (CDCl$_3$, δ_C): 14.47 (C-18), 23.00 (C-17), 25.39 (C-16), 26.02, 29.61, 29.79, 29.96, 30.08 (C-11 & C-13), 32.23, 34.78 (C-2), 174.09 (ester carbonyl, C-1). The various resonances originating from the podophyllotoxin nucleus were as follows: ring A: δ_H 5.98 (*d*, *J* = 2.50 Hz, 1H) and 5.99 (*d*, *J* = 2.50 Hz, 1H), δ_C 101.97; ring B: δ_H 6.54 (*s*, 8-H), δ_C 110.09 (C-8); δ_H 6.76 (*s*, 5-H, 1H), δ_C 107.38 (C-5); ring C: δ_H 4.61 (*d*, $J_{1,2}$ = 4.50 Hz, 1-H, 1H), δ_C 44.29 (C-1); δ_H 2.92 (*dd*, $J_{1,2}$ = 4.60 Hz, $J_{2,3}$ =14.60 Hz, 2-H, 1H), δ_C 39.17 (C-2); δ_H 2.83 (*m*, 3-H, 1H), δ_C 45.95 (C-3); δ_H 5.89 (*d*, $J_{3,4}$ = 8.70 Hz, 4-H, 1H), δ_C 73.76 (C-4); ring D: two protons of 11-C$\underline{H}_2$ signals split into two, δ_H 4.23 (*t*, *J* = 10.0 Hz, 11-H, 1H) and δ_H 4.35 (*dd*, *J* = 7.0 Hz, *J* = 7.0 Hz, 11-H, 1H), δ_C 71.81 (C-11); ring E: δ_H 3.76 (*s*, 3′-H, 3′C-OC$\underline{H}_3$, 5′-H, 5′C-OC$\underline{H}_3$, 6H), 56.51 (C-3′, C-5′); δ_H 3.82 (*s*, 4′-H, 4′C-OC$\underline{H}_3$, 3H), δ_C 61.12 (C-4′); δ_H 6.40 (*s*, 2′-H, 6′-H, 2H), δ_C 108.49 (C-2′, C-6′); quaternary carbons of podophyllotoxin: 128.83, 132.72, 135.23, 137.52, 147.97, 148.49, 153.01, and 174.66 (lactone carbonyl in the D ring of podophyllotoxin); EI-MS found [M + H] 697.3952; C$_{40}$H$_{57}$O$_{10}$ [M + H]$^+$ requires 697.39517.

(ii) 4-O-Podophyllotoxinyl 12-fluoro-octadec-Z-9-enoate 4. Compound **2** (0.24 mmol) was dissolved in dry methylene chloride (3 mL) and to this solution, diethylaminosulfur trifluoride (DAST) (0.24 mmol) was added at −78°C (dry ice/acetone) under nitrogen. The reaction was warmed to room temperature and stirred for 1 h. Progress of the reaction was monitored by TLC. The complete conversion of **2** into the desired product was achieved in 1 h. The reaction mixture was diluted with methylene chloride (10 mL), washed with brine and water, dried over Na$_2$SO$_4$, and concentrated to dryness under reduced pressure at 20°C to obtain a crude reaction product. A silica gel flash column (*n*-hexane/ethyl acetate, 2:1, vol/vol; R_f: 0.90) was used to purify **4**. The isolated yield of a colorless, viscous oily product was 98.5%. IR (CHCl$_3$, cm^{-1}): 1777, 1732, 1587,

1481, 1420, 1329, 1235, 1125, 1038, 1000, 931, 862, and 772; ^{1}H NMR (CDCl$_3$, δ_H): 0.86 (*t*, *J* = 6.50 Hz, terminal methyl of the FA chain, 3H), 1.48 (*br m*, 8-C$\underline{H}_2$ was merged, 8 × C$\underline{H}_2$ groups of the FA methylene chain, 18H), 1.66–1.56 (*m*, 3-C$\underline{H}_2$, 13-C$\underline{H}_2$, 4H), 2.00 (*m*, 11-C$\underline{H}_2$, 2H), 2.38 (*m*, 2-C$\underline{H}_2$, 2H), 3.71 (*m*, 12-C$\underline{H}$-F, 1H), 5.40 (*m*, 9-H, 1H), 5.47 (*m*, 10-H, 1H); ^{13}C NMR (CDCl$_3$, δ_C): 14.49 (C-18), 23.04 (C-17), 25.36 (C-3), 25.51 (C-8), 29.55, 29.71, 32.25, 34.73 (C-2), 35.60 (C-11), 97.85 (C-12), 125.81 (C-9),132.78 (C-10), and 174.06 (ester carbonyl, C-1); EI-MS found [M + Na] 719.3576; C$_{40}$H$_{53}$O$_9$FNa [M + Na]$^+$ requires 719.3571.

(iii) 4-O-Podophyllotoxinyl 12-[3′-(3″, 4″, 5″-trimethoxy-phenyl)propionyloxy]octadec-Z-9-enoate 5. Equimolar amounts of 3-(3,4,5-trimethoxyphenyl)propionic acid and **2** were reacted to produce **5** by a method adopted earlier (21). The isolated (*n*-hexane/ethyl acetate, 1:1, vol/vol, R_f: 1.0) yield of this viscous colorless oil was 99%. IR (CHCl$_3$, cm^{-1}): 1779, 1733, 1587, 1464, 1235, 1123, and 1001; ^{1}H NMR (CDCl$_3$, δ_H): 0.90 (*t*, *J* = 7.0 Hz, terminal methyl of the FA chain, 3H), 1.34–1.27 (*br m*, 8 × C$\underline{H}_2$ groups of the FA methylene chain, 16H), 1.54 (*m*, 2H), 1.70 (*m*, 2H), 2.03 (*m*, 8-C$\underline{H}_2$, 2H), 2.31 (*m*, 2H), 2.42 (*m*, 2-C$\underline{H}_2$, 2H), 2.62 (*m*, 3′-C$\underline{H}_2$, 2H), 2.83 (*m*, 11-C$\underline{H}_2$, 2H), 2.97–2.91 (*m*, 2-H of podophyllotoxin, 2′-C$\underline{H}_2$, 3H), 4.91 (*m*, 12-H, 1H), 5.32 (*m*, 9-H, 1H), 5.46 (*m*, 10-H, 1H); ^{13}C NMR (CDCl$_3$, δ_C): 14.46 (C-18), 22.97 (C-17), 25.41, 25.71, 27.72 (C-8), 29.52, 29.91, 31.83, 32.11, 32.33 (C-3′), 33.01 (C-11), 34.74 (C-2), 36.64 (C-2′), 74.53 (C-12), 124.63 (C-9), 132.71 (C-10). Two ester carbonyls appeared at δ_C 172.96 (C-1′) and 174.10 (C-1). The NMR signals associated with two sets of three methoxy groups were as follows: δ_H 3.78 (*s*, 6H) and 3.83 (*s*, 6H) for 3′OC$\underline{H}_3$, 5′OC$\underline{H}_3$, 3″OC$\underline{H}_3$, and 5″OC$\underline{H}_3$; correlations at δ_C 56.43, 56.52 for C-3′, C-5′, C-3″ and C-5″; 3.86 (*s*, 6H) for 4′OC$\underline{H}_3$ and 4″OC$\underline{H}_3$; correlations at δ_C 61.14, and 61.21 (C-4′, C-4″). The equivalent aromatic protons 2′-H and 6′-H (podophyllotoxin ring E) appeared at δ_H 6.41 (*s*) and correlated at δ_C 108.50. Similar protons (2″-H and 6″-H) of the trimethoxyphenyl propionate moiety were deshielded to appear slightly downfield at δ_H 6.44 (*s*) and correlated at δ_C 105.56 (C-2″, C-6″). The quaternary carbons of both podophyllotoxin and the trimethoxyphenyl propionate moiety were recorded at δ_C 128.0, 132.91, 135.25, 136.80, 137.52, 147.98, 148.50, 153.02, 153.60; EI-MS found [M + H] 917.4676; C$_{52}$H$_{69}$O$_{14}$ [M + H]$^+$ requires 917.4687.

(iv) 4-O-Podophyllotoxinyl 12-(phenoxycarbonyloxy)oc-tadec-Z-9-enoate 6. First pyridine (1.80 mmol) and then phenyl chloroformate (1.80 mmol) were added to a dry methylene chloride (10 mL) solution of **2** (0.75 mmol) under a nitrogen atmosphere with stirring at 0°C. The reaction mixture turned yellow as soon as the phenyl chloroformate was added, and this was allowed to stir at room temperature. Phenoxy ester formation was completed in 30 min as revealed by TLC. After the usual workup, a crude product was obtained, which on purification by silica gel column chromatography (*n*-hexane/ethyl acetate, 1:1, vol/vol; R_f: 1.0) produced **6** as a yellowish oil. The isolated yield was 98.5%. IR (CHCl$_3$, cm^{-1}): 1755, 1731, 1588, 1483, 1329, 1243, 1210, 1125, 1036, 999, and 866; ^{1}H NMR

(CDCl$_3$, δ$_H$): 0.87 (*t*, *J* = 6.80 Hz, terminal methyl of the FA chain, 3H), 1.31–1.28 (*br m*, 8 × C$\underline{H}_2$ groups of the FA methylene chain, 16H), 1.64 (*m*, 4H), 2.05 (*m*, 8-C$\underline{H}_2$, 2H), 2.23 (*m*, 2-C$\underline{H}_2$, 11-C$\underline{H}_2$, 4H), 4.79 (*m*, 12-H, 1H), 5.38 (*m*, 9-H, 1H), 5.54 (*m*, 10-H, 1H), 7.15 (*m*, 3′′-H and 5′′-H, two *meta* protons, 2H), 7.22 (*m*, 4′′-H, one *para* proton, 1H), and 7.36 (*m*, 2′′-H and 6′′-H, two *ortho* protons, 2H); ^{13}C NMR (CDCl$_3$, δ$_C$): 14.43 (C-18), 22.93 (C-17), 25.34, 25.61, 27.68 (C-8), 29.46, 29.84, 32.06, 32.27, 33.89 (C-11), 34.69 (C-2), 79.85 (C-12), 121.43 (C-2′′, C-6′′), 124.04 (C-4′′), 126.19 (C-9), 129.75 (C-3′′, C-5′′), 132.71 (C-10), 133.58 (C-1′′, quaternary carbon), 152.97 (phenoxy carbonyl at C-12 of the FA), and 174.02 (ester carbonyl, C-1); EI-MS found [M + H] 815.3976; C$_{47}$H$_{59}$O$_{12}$ [M + H]$^+$ requires 815.40065.

(v) 4-O-Podophyllotoxinyl 12-[4′-(2′′-hydroxyethyl)piperazinecarbonyloxy]octadec-Z-9-enoate **7**. To a solution of **6** (1 mmol) in dry methylene chloride (5 mL) was added 1-(2-hydroxyethyl)piperazine (2 mmol) under nitrogen. After being stirred at room temperature for 24 h, the reaction mixture was diluted with methylene dichloride (10 mL), washed with brine and water, and dried. The organic layer was rotary-evaporated, and the viscous residue was chromatographed on a silica gel column (ethyl acetate/methanol, 9:1, vol/vol, *R$_f$*: 0.70) to afford a viscous colorless and sticky oily product, **7**, in 90% isolated yield. IR (CHCl$_3$, cm^{-1}): 3472, 1773, 1733, 1692, 1589, 1459, 1425, 1240, 1127, 1036, and 872; ^{1}H NMR (CDCl$_3$, δ$_H$): 0.88 (*t*, *J* = 6.30 Hz, terminal methyl of the FA chain, 3H), 1.32–1.28 (*br m*, 17-C$\underline{H}_2$, 7-C$\underline{H}_2$, 6 × C$\underline{H}_2$ groups of the FA methylene chain, 16H), 1.60 (*m*, 3-C$\underline{H}_2$, 13-C$\underline{H}_2$, 4H), 2.01 (*m*, 8-C$\underline{H}_2$, 2H), 2.23 (*m*, 2-C$\underline{H}_2$, 2H), 2.31 (*m*, 11-C$\underline{H}_2$, 2H), 2.55 (*m*, 3′-C$\underline{H}_2$, 5′-C$\underline{H}_2$, 4H), 2.62 (*t*, *J* = 5.22 Hz, 2′′-C$\underline{H}_2$, 2H), 2.96 (*m*, 2′-C$\underline{H}_2$, 6′-C$\underline{H}_2$, 4H), 3.68 (*t*, *J* = 5.22 Hz, 2′′-C$\underline{H}_2$, 2H), 3.53 (unresolved signal, D$_2$O exchangeable, O$\underline{H}$, 1H), 4.78 (*m*, 12-H, 1H), 5.36 (*m*, 9-H, 1H), 5.47 (*m*, 10-H, 1H); ^{13}C NMR (CDCl$_3$, δ$_C$): 14.43 (C-18), 22.94 (C-17), 25.22 (C-3), 25.73, 27.73 (C-8), 29.47, 29.56, 29.91, 32.12 (C-13), 32.51 (C-11), 34.14 (C-2), 40.24 (C-2′, C-6′), 53.15 (C-3′, C-5′), 58.10 (C-2′′), 59.99 (C-1′′), 75.65 (C-12), 126.84 (C-9), 132.71 (C-11), 155.60 (carbamate carbonyl attached to C-12 of the FA), and 173.75 (ester carbonyl, C-1); EI-MS found [M + H] 851.4689; C$_{47}$H$_{67}$O$_{12}$N$_2$ [M + H]$^+$ requires 851.4694.

(vi) 4-O-Podophyllotoxinyl 12-{4′-[2′′-(hydroxyethoxy)-ethyl]piperazinecarbonyloxy} octadec-Z-9-enoate **8**. The procedure was the same as described for **7** except that 1-[2-(2-hydroxyethoxy)ethyl] piperazine was used as a reagent. A colorless, viscous, and sticky oily, **8**, was obtained in 92% yield on isolation (ethyl acetate/methanol, 9:1, vol/vol, *R$_f$*: 0.60). IR (CHCl$_3$, cm^{-1}): 3450, 1774, 1731, 1692, 1589, 1459, 1425, 1244, 1126, 1037, 930, 867, and 733; ^{1}H NMR (CDCl$_3$, δ$_H$): 0.84 (*t*, *J* = 6.80 Hz, terminal methyl of the FA chain, 3H), 1.31–1.23 (*br m*, 6 × C$\underline{H}_2$ groups of the FA methylene chain, 12H), 1.52 (*m*, 3-C$\underline{H}_2$, 17-C$\underline{H}_2$, 4H), 1.64 (*m*, 13-C$\underline{H}_2$, 2H), 1.98 (*m*, 8-C$\underline{H}_2$, 2H), 2.21 (*m*, 2H), 2.24 (*m*, 11-C$\underline{H}_2$, 2H), 2.40 (*m*, 2-C$\underline{H}_2$, 2H), 2.51 (*m*, 3′-C$\underline{H}_2$, 5′-C$\underline{H}_2$, 4H), 2.61 (*m*, 1′′-C$\underline{H}_2$, 2H), 3.51 (*m*, 2′-C$\underline{H}_2$, 6′-C$\underline{H}_2$, 4H), 3.58 (*m*, 1′′′-C$\underline{H}_2$, 2H), 3.65 (*m*, 2′′-C$\underline{H}_2$, 2′′′-C$\underline{H}_2$, 4H), 3.72 (unresolved signal,

D$_2$O exchangeable, O$\underline{H}$, 1H), 4.73 (*m*, 12-H, 1H), 5.33 (*m*, 9-H, 1H), 5.41 (*m*, 10-H, 1H); ^{13}C NMR (CDCl$_3$, δ$_C$): 14.06 (C-18), 22.60 (C-17), 25.29 (C-3), 27.32 (C-8), 29.17, 29.50, 32.11 (C-13), 34.23 (C-2), 43.71 (C-2′, C-6′), 53.11 (C-3′, C-5′), 57.93 (C-1′′), 61.75 (C-2′′′), 67.23 (C-2′), 72.43 (C-1′′′), 75.21 (C-12), 126.42 (C-9), 132.30 (C-10), 155.25 (carbamate carbonyl attached to C-12 of the FA), and 173.42 (ester carbonyl, C-1); EI-MS found [M + H] 895.4909; C$_{49}$H$_{71}$O$_{13}$N$_2$ [M + H]$^+$ requires 895.4956.

(vii) 4-O-Podophyllotoxinyl undec-10-enoate **9**. Compound **9** was prepared by the reaction of podophyllotoxin and undec-10-enoic acid; the method is described in an earlier publication (21). Isolated (*n*-hexane/ethyl acetate, 1:1 vol/vol, *R$_f$*: 1.0) yield of a colorless oil was 99%. IR (CHCl$_3$, cm^{-1}): 1777, 1732, 1640, 1481, 1377, 1330, 1236, 1125, 997, and 862; ^{1}H NMR (CDCl$_3$, δ$_H$): 1.36–1.22 (*br m*, 4 × C$\underline{H}_2$ groups of FA methylene chain, 8H), 1.65 (*m*, 2H), 2.03 (*m*, 3-C$\underline{H}_2$, 9-C$\underline{H}_2$, 4H), 2.42 (*m*, 2-C$\underline{H}_2$, 2H), 4.94 (*m*, 11-C$\underline{H}_2$, 2H), 5.81 (*m*, 10-H, 1H); ^{13}C NMR (CDCl$_3$, δ$_C$): 24.50, 27.11, 28.85, 29.05, 29.15, 29.28, 33.77, 34.39 (C-2), 38.77, 114.29 (C-11), 139.15 (C-10), and 173.71 (ester carbonyl, C-1); EI-MS found [M + H] 581.2721; C$_{33}$H$_{41}$O$_9$ [M + H]$^+$ requires 581.2750.

(viii) 4-O-Podophyllotoxinyl 11-(2′-hydroxyethylthio)undecanoate **10**. 2-Mercaptoethanol (1.20 mmol) is added to a stirred solution of **9** (1 mmol) in dry methylene chloride (5 mL) and stirring is continued for 24 h under nitrogen at room temperature. Methylene chloride was rotary-evaporated, and silica gel chromatography (*n*-hexane/ethyl acetate, 1:1, vol/vol, *R$_f$*: 0.80) of the residue gave a colorless and sticky oily form of **10**. The isolated yield was recorded as 95%. IR (CHCl$_3$, cm^{-1}): 3507, 1778, 1733, 1588, 1484, 1420, 1331, 1239, 1171, 1127, 1038, 999, 866, and 735; ^{1}H NMR (CDCl$_3$, δ$_H$): 1.32–1.26 (*br m*, 6 × C$\underline{H}_2$ groups of the FA methylene chain, 12H), 1.55 (*m*, 2H), 1.65 (*m*, 2H), 2.25 (unresolved signal, O$\underline{H}$, D$_2$O exchangeable, 1H), 2.40 (*m*, 2-C$\underline{H}_2$, 2H), 2.51 (*t*, *J* = 7.60 Hz, 11-C$\underline{H}_2$, 2H), 2.68 (*t*, *J* = 6.0 Hz, 1′-C$\underline{H}_2$, 2H), 3.68 (*t*, *J* = 6.0 Hz, 2′-C$\underline{H}_2$, 2H); ^{13}C NMR (CDCl$_3$, δ$_C$): 24.96, 28.76, 29.12, 29.16, 29.31, 29.37, 29.70, 31.69, 33.87, 34.35 (C-2), 35.12 (C-1′), 60.40 (C-2′), and 173.74 (ester carbonyl, C-1); EI-MS found [M + Na] 681.2713; C$_{35}$H$_{46}$O$_{10}$SNa [M + Na]$^+$ requires 681.2709.

(ix) 4-O-Podophyllotoxinyl 11-(2′,3′-dihydroxypropylthio)-undecanoate **11**. To a stirred solution of **9** (1 mmol) in dry methylene chloride (5 mL) was added 3-mercapto-1,2-propanediol (1.20 mmol) under a nitrogen atmosphere. The reaction mixture was stirred at room temperature for 24 h. The organic solvent was rotary-evaporated, and the crude product was purified on a silica gel column (J.T.Baker; *n*-hexane/ethyl acetate, 1:2, vol/vol, *R$_f$*: 0.70) to produce **11**. The isolated yield of the viscous, colorless, and sticky oily product was 91%. IR (CHCl$_3$, cm^{-1}): 3425, 1776, 1731, 1653, 1588, 1481, 1419, 1236, 1169, 1124, 1038, and 864; ^{1}H NMR (CDCl$_3$, δ$_H$): 1.30–1.23 (*br m*, 6 × C$\underline{H}_2$ groups of the FA methylene chain, 12H), 1.55 (*m*, 2H), 1.65 (*m*, 2H), 2.45 (*m*, 2-C$\underline{H}_2$, 2H), 2.52 (*m*, 11-C$\underline{H}_2$, 2H), 2.62 (unresolved signal, D$_2$O exchangeable, 2 × O$\underline{H}$), 2.76 (*m*, 1′-C$\underline{H}_2$, 2H), 3.54 (*m*, one of the protons of 3′-C$\underline{H}_2$, 1H), 3.70 (*m*, second proton of 3′-C$\underline{H}_2$, 1H), 3.77 (*m*,

2′-H, 1H); ^{13}C NMR (CDCl$_3$, δ$_C$): 25.0, 28.98, 29.33, 29.32, 29.38, 29.52, 29.60, 29.89, 32.60 (C-11), 34.60 (C-2), 36.10 (C-1′), 65.63 (C-3′), 70.25 (C-2′), and 173.95 (ester carbonyl, C-1); EI-MS found [M + H] 689.3010; C$_{36}$H$_{49}$O$_{11}$S [M + H]$^+$ requires 689.2995.

Assay for in vitro anticancer activity. Compounds **1–11** were tested for their *in vitro* anticancer activity against a panel of human cancer cell lines, including SK-MEL (malignant, melanoma), KB (epidermal carcinoma, oral), BT-549 (ductal carcinoma, breast), SK-OV-3 (ovary carcinoma) and HL-60 (human leukemia) as well as for cytotoxicity in noncancerous VERO cells (African green monkey kidney fibroblast) as described previously (21). The highest concentration tested was 15 μM, and DMSO (0.5%) was used as a solvent control.

RESULTS AND DISCUSSION

Previous research (24–26) has suggested that FA in general, and PUFA in particular, have preventive and therapeutic potential against cancer. Results of our previous cytotoxicity studies on podophyllotoxin derivatives (C$_4$α-FA) involving natural FA of varying degrees of unsaturation, ω-hydroxyl FA, and 12-hydroxy-Z-9-ene FA demonstrated tumor selectivity over normal cells *in vitro* (21–23). A number of studies have concluded that chemically modified FA molecules possess more specific and potent biological activity with possible changes in their therapeutic targets (27). The present work is based on the chemically transformed FA analogs of podophyllotoxin **1**.

As part of our search for potential analogs of **1**, functionalities on FA side chains of an anticancer candidate, 4-*O*-podophyllotoxinyl 12-hydroxy-octadec-Z-9-enoate **2**, were chemically modified to generate first F- and N-containing analogs and then other products, 4-*O*-podophyllotoxinyl 12-hydroxy-octadecanoate **3**, 4-*O*-podophyllotoxinyl 12-fluoro-octadec-Z-9-enoate **4**, 4-*O*-podophyllotoxinyl 12-[3′-(3″,4″,5″-trimethoxyphenyl) propionyloxy]octadec-Z-9-enoate **5**, 4-*O*-podophyllotoxinyl 12-(phenoxycarbonyloxy)octadec-Z-9-enoate **6**, 4-*O*-podophyllotoxinyl 12-[4′-(2″-hydroxyethyl)-piperazinecarbonyloxy]octadec-Z-9-enoate **7**, and 4-*O*-podophyllotoxinyl 12-{4′-[2″-(hydroxyethoxy)ethyl]piperazinecarbonyloxy}octadec-Z-9-enoate **8** (Scheme 1) by adopting different synthetic strategies.

Compounds **3–5** were obtained directly from **2** by hydrogenation of the FA Z-double bond (C-9/10) *via* substitution of the FA 12C–OH by the F atom and by using the FA 12C–OH to esterify the carboxylic acid of a trimethoxy aromatic acid, respectively. The formation of podophyllotoxin FA carbamates **7** and **8** at C-12 of the FA chain was achieved in two steps: first, the conversion of **2** into its phenoxy ester **6**, followed by the reaction of **6** with two different functional piperazines.

Two *S*-ethers (thioethers), 4-*O*-podophyllotoxinyl 11-(2′-hydroxyethylthio)undecanoate **10** and 4-*O*-podophyllotoxinyl 11-(2′,3′-dihydroxypropylthio)undecanoate **11**, were synthesized from a new molecule, 4-*O*-podophyllotoxinyl undec-10-enoate **9** (Scheme 1). The hydroxy group (C$_4$α) of podophyllotoxin **1** was esterified with undec-10-enoic acid to give **9**

(Scheme 1). The chemical structures of **3–11** were established with the help of their spectroscopic data. In signals associated with the FA, with podophyllotoxin, and in compounds **5–8**, **10**, and **11**, with additional signals arising from the introduction of aromatic rings, N- and S-possessing moieties were adequately assigned in their respective IR, ^{1}H NMR, and ^{13}C NMR spectra and were confirmed by ^{13}C–^{1}H COSY correlation and distortionless enhancement by polarization transfer 135, 90, and 45 techniques. The high-resolution mass (electrospray ionization) spectral studies confirmed their elemental composition. A detailed spectroscopic characterization of **2** was discussed previously (21). Full spectroscopic values of **3** are given in the Experimental Procedures section because of its close structural resemblance to **2**. The NMR resonances related to the podophyllotoxin nucleus in the remaining compounds, **4–11**, were omitted as no appreciable difference was detected between these values and the ones we reported previously (21,22) for C$_4$α-FA derivatives.

The *Z*-double bond (C-9/10) in the FA side chain of compound **2** was hydrogenated under 45 psi (10% Pd/C) and yielded **3** as a completely hydrogenated product in high purity, as confirmed by its NMR analysis. The GLC and NMR spectra of aliquots taken at different time periods monitor the progress of the reaction and show the time required for complete hydrogenation. The reaction was repeated three times under similar reaction conditions, and the average time for complete hydrogenation of Z-9-ene was 8 h, when olefin signals were no longer detected in the NMR spectrum of the product.

The 12-fluoro derivative **4** was synthesized by fluorinating 12-C–OH of **2** with an equimolar amount of both **2** and DAST (source of fluorine) at −78°C under nitrogen for 1 h. The reaction proceeded cleanly under mild reaction conditions and produced only the desired product **4**. Compound **2** contained one trimethoxyphenyl group in its podophyllotoxin nucleus (ring E), and we introduced a second such moiety at C-12 in the FA chain to study the anticancer activity of the new molecule. The carboxylic acid group of 3-(3,4,5-trimethoxyphenyl)propionic acid was esterified with the 12-hydroxy group of **2** with dicyclohexylcarbodiimide (DCC)/dimethyl aminopyridine (DMAP) to achieve a quantitative amount of ditrimethoxy-phenyl-containing compound **5**. Podophyllotoxin C$_4$α-FA carbamates **7** and **8** were formed through phenoxy ester **6**, which was readily prepared quantitatively by treating **2** under anhydrous conditions with phenyl chloroformate and pyridine first at 0°C and then at room temperature for 30 min. A methylene chloride solution of phenoxy ester **6** was treated with 2 equiv of 1-(2-hydroxyethyl)piperazine under nitrogen at room temperature for 24 h to produce **7**. The chemical composition of compound **7** consisted of three nuclei. The FA formed an ester bond at C$_4$α of podophyllotoxin, and hydroxyethylpiperazine formed a carbamate at C-12 on the FA chain. Similarly, compound **8** was prepared when a solution of **6** was stirred with 2 equiv of 1-[2-(2-hydroxyethoxy)ethyl]piperazine at room temperature for 24 h. Compound **8** was slightly more functionalized than **7**. The spectroscopic data of this molecule were almost similar to **7** as far as the NMR signals related to the podophyllotoxin and FA

units were concerned, but differed in signals related to the piperazine moieties.

4-*O*-Podophyllotoxinyl undec-10-enoate **9** was used as an intermediate for synthesis of the S-ether analogs **10** and **11** and formed readily when DCC/DMAP were used to esterify the 4α-hydroxy group of **1** with the carboxylic acid group of FA, undec-10-enoic acid. The terminal double bond (C-11/10) in the FA side chain of **9** underwent an efficient addition reaction at C-11 when treated with a slight excess of 2-mercaptoethanol to give a saturated thioether-incorporated analog, **10**. The chemical composition of the FA part of **10** was very similar to the ω-hydroxy FA except that this FA contained an S atom to form a thioether moiety. Similarly, when compound **9** was reacted with 3-mercapto-1,2-propanediol, an addition reaction at C-11 afforded a saturated *S*-ether FA analog **11** of podophyllotoxin. Compound **11** possessed a FA that was bifunctional, as it had a vicinal diol (C-2′, C-3′) function beside a thioether group present at C-11 of the FA chain.

Configurations of two stereogenic/chiral centers, at which reactions occurred, are depicted in Scheme 1. The stereochemistry of both stereogenic centers, C-4 of podophyllotoxin and C-12 of the FA chain in compound **5**, at which coupling reactions took place, was retained. The reaction mechanism shows that the coupling reactions did not alter the configurations of the stereogenic centers (21,22). Similarly, the *R*-configuration at C-4 of the podophyllotoxin was retained in compounds **2–11**. The *R*-configuration of the stereogenic center (C-12) in the hydrogenated product **3** remained intact because three different groups and the lone hydrogen atom attached to it retained their respective priorities as those in compound **2**. According to the sequence rule, a change in the priorities of substituents changes the absolute configuration of the stereogenic center even without its participation in a reaction. It is well established that the fluorinating reagents, particularly DAST, replace the hydroxy group with fluorine stereospecifically to produce a product of

inverted configuration with the highest optical purity (28–30). Compound **4** might have the inversion of an *R*- to *S*-configuration at C-12 to which the fluorine is bonded. Since stereochemistry was not studied, we preferred to show the bonding of fluorine at C-12 as a mixture of isomers (Scheme 1). The phenoxy ester, **6**, was formed from compound **2** when the lone pair of electrons on the oxygen of the hydroxy group of the stereogenic carbon (C-12) attacked the carbonyl carbon of the phenyl chloroformate. This explains the retention of the *R*-configuration at C-12, as shown in Scheme 1. The retention of the R-configuration at C-12 in carbamates **7** and **8** was attributed to noninvolvement of the stereogenic carbon in the reaction, as these products were formed through the reactions of the carbonyl carbon of the phenoxy ester moiety of **6** with piperazines.

In vitro anticancer activity. Compounds **3–11** were assayed *in vitro* against four human solid tumors—SK-MEL (malignant, melanoma), KB (epidermal carcinoma, oral), BT-549 (ductal carcinoma, breast), and SK-OV-3 (ovary carcinoma)—and human leukemia (HL-60) and noncancerous VERO (African green monkey kidney fibroblast) cell lines. Their growth inhibition activities are listed in Table 1. Compounds **3–5** were chemically modified products of **2** and lacked a methylene-interrupted hydroxy-*Z*-ene (12-hydroxy-Z-9-ene) system in their FA side-chain moiety. Results of cytotoxicity testing indicated that probably the "12-hydroxy-Z-ene" system was important for these compounds to be active against the present panel of human neoplastic cell lines. Saturation of *Z*-unsaturation (C-9/C-10) in the FA chain of **2** decreased the activity of **3** against all four solid tumor cell lines. However, increased activity was recorded in HL-60 cells as compared with **2**. Similarly, a loss of activity against solid tumors was observed when the C-12 hydroxy group was substituted by the F atom in compound **4**, whereas almost the same potency against HL-60 was maintained. The loss of activity against certain cell lines may be attributed to inversion of the configuration at the stereogenic

TABLE 1
Cytotoxicity of Compounds in a Panel of Cancer Cell Lines and Kidney Fibroblast Cells[a]

[a]Values are IC_{50} in μM.
[b]The highest concentration tested was 15 μM. IC_{50}, concentration that causes 50% growth inhibition; NA, not active; SK-MEL, human malignant melanoma; KB, human epidermal carcinoma, oral; BT-549, human ductal carcinoma, breast; SK-OV-3, human ovary carcinoma; HL-60, human leukemia; VERO, monkey kidney fibroblast. Paclitaxel and doxorubicin were used as positive controls.

center (C-12) or to the optical impurity of **4**. The FA carbamate (at C-12) derivatives **7** and **8** were uniformly active throughout five cancer cell lines, although they were more effective toward the HL-60-like compounds **2–4**. Compound **5** was inactive against all cell lines despite the presence of an additional 3,4,5-trimethoxy aromatic functionality (at C-12) in addition to one that was already in the main podophyllotoxin structure.

Compound **9** possessed a terminal unsaturated (11:1) FA chain at $C_4\alpha$ of the podophyllotoxin and was the first monoene FA analog that was found to be active against two solid tumor cell lines, KB and BT-549. It showed significantly high growth inhibition activity in the HL-60 (leukemia) cell line. Earlier investigations on the derivatives of FA internal *Z*-monoenes (20:1, Δ^{11}) *in vitro* against similar cell lines (21) and *in vivo* (18:1, Δ^9) against P388 lymphocytic leukemia (19) have failed to report any anticancer activity. The FA *S*-ether analogs **10** and **11**, derived from **9**, showed promising activities against all five cancer cell lines, except that **11** was not active against ovary carcinoma (SK-OV-3) cells. Analog **10** was functionalized with a FA moiety (C_{11}) at $C_4\alpha$ of podophyllotoxin, which has a close resemblance to the chemical structure of ω-hydroxy FA, and its extent of growth inhibition was the same as that recorded for a C_{10} ω-hydroxy FA $C_4\alpha$-analog against the same panel of human cancer cell lines (21). Both **10** and **11** were excellent growth inhibitors of HL-60 (leukemia cells). Unlike podophyllotoxin **1**, none of its new derivatives (2–11) were toxic toward normal mammalian cells. The present *in vitro* evaluation revealed that structural modifications of **2**, even by incorporation of the F atom or N-containing moieties and FA thioether derivatives, resulted in analogs that were nontoxic to noncancerous VERO cells (Table 1). This feature places these products into the class of anticancer agents that possess selectivity toward cancer cells over normal cells.

The main problem of podophyllotoxin and many of its analogs, which has substantially reduced their therapeutic usefulness, is their scant selectivity, because these molecules target both cancer and normal cells alike. This study involving FA-derived products has indicated promising results to address this problem at the present stage of *in vitro* testing. Further investigation of these molecules may provide useful leads in the development of new and effective pharmaceutical products.

METHODS

The Bottom-Up Solution to the Triacylglycerol Lipidome Using Atmospheric Pressure Chemical Ionization Mass Spectrometry

William Craig Byrdwell*

Department of Chemistry & Biochemistry, Florida Atlantic University, Boca Raton, Florida 33431

ABSTRACT: Presented here is an approach to representing the data from atmospheric pressure chemical ionization (APCI) mass spectrometry (MS) of triacylglycerols (TAG) using a set of one, two, or three Critical Ratios. These Critical Ratios may be used directly to provide structural information concerning the regioisomeric composition of the triacylglycerols (TAG), and about the degree of unsaturation in the TAG. An AAA-type, or Type I, TAG has only one Critical Ratio, the ratio of the protonated molecule, $[M + H]^+$, to the DAG fragment ion, $[AA]^+$. The Critical Ratio for a Type I TAG is $[MH]^+/\Sigma[DAG]^+$, and the mass spectrum of a Type I TAG can be reproduced from only this one ratio. An ABA/AAB/BAA, or Type II, TAG has two Critical Ratios, the $[MH]^+/\Sigma[DAG]^+$ ratio and the $[AA]^+/[AB]^+$ ratio. The $[AA]^+/[AB]^+$ ratio for a single TAG or TAG mixture can be compared with the $[AA]^+/[AB]^+$ ratios of pure regioisomeric standards, and the percentage of each regioisomer can be estimated. The abundance of the protonated molecule and the abundances of the two $[DAG]^+$ fragment ions can be calculated from the two Critical Ratios for a Type II TAG. To calculate the abundances, the Critical Ratios are processed through the Bottom-Up Solution to the TAG lipidome. First, Critical Limits are calculated from the Critical Ratios, and then the Critical Ratios are classified into Cases by comparison with the Critical Limits. Once the Case classification is known, the equation for the abundance of each ion in the mass spectrum is given by the Bottom-Up Solution. A Type III TAG has three different FA and three Critical Ratios. The $[MH]^+/\Sigma[DAG]^+$ ratio is the first Critical Ratio, the $[AC]^+/([AB]^+ + [BC]^+)$ ratio is the second Critical Ratio, and the $[BC]^+/[AB]^+$ ratio is the third Critical Ratio. The second critical ratio for a Type III TAG can be compared with regioisomeric standards to provide an estimate of the percentage composition of the regioisomers. The three Critical Ratios for a Type III TAG can be processed through the Bottom-Up Solution to calculate the four ion abundances that make up the APCI-MS mass spectrum. The Critical Ratios constitute a reduced data set that provides more information in fewer values than the raw abundances.

an instrumental technique capable of accomplishing qualitative and quantitative analyses of complex mixtures of many classes of lipids. HPLC/APCI-MS is useful for qualitative and/or quantitative analysis of FA (1–4), TAG (5–11), phospholipids (12–16), ceramides (17), carotenoids (18–22), steroids (23–25), and others. Reviews of the applications of APCI-MS for lipid analysis have been published in recent years (26–29).

An important aspect of TAG analysis is the determination of the positional placement of the FA on the glycerol backbone (30). Plants synthesize lipids with structural specificity, namely, saturated FA are most often preferentially located on the *sn*-1 and *sn*-3 positions of the glycerol backbone, and PUFA are preferentially found in the *sn*-2 position. TAG are metabolized by enzymes in the human digestive system with structural specificity, with FA in the *sn*-1 and *sn*-3 positions being removed from the glycerol backbone first. Furthermore, enzymatic synthesis of TAG can be used to produce structured TAG with particular FA located in regiospecific locations (31). Therefore, knowledge of the composition of molecular species in a mixture of TAG, and of the regioisomeric configurations of selected TAG for which standards are available, could provide valuable information to be considered in the planning of dietary, nutritional, metabolic, and related studies. It has been demonstrated by a growing literature precedent that APCI-MS, preceded by a variety of HPLC or supercritical fluid chromatography (SFC) techniques, or simply by direct infusion, provides much of the information sought by those engaged in dietary studies of natural and/or synthetic TAG.

We have been interested in the qualitative and quantitative analysis of TAG. In 1995, we reported the first applications of reversed-phase (RP)-HPLC/APCI-MS to a mixture of synthetic TAG (6). In that initial work, we described basic characteristics of APCI-MS mass spectra of TAG and showed that APCI-MS mass spectra of TAG molecules exhibited primarily two types of ions. One is the protonated molecule and the other is DAG-like ions. We noted that the amount of the protonated molecule depends on the number of sites of unsaturation in the molecule. TAG with more sites of unsaturation form larger protonated molecule abundances (and small $[DAG]^+$ abundances), whereas those TAG with few sites of unsaturation form only small abundances of the protonated molecule (and large abundances of $[DAG]^+$). In summary, the abundance of the protonated molecule in a mass spectrum obtained by APCI-MS is proportional to (increases with) the amount of unsaturation in a TAG molecule and is inversely proportional to the abundances

of the [DAG]+ fragment ions. Although proportional in some way, the relationship between the degree of unsaturation and the abundance of the protonated molecule is not simply linear. The nature of the relationship remains to be characterized.

APCI-MS of TAG

Early reports. Shortly after the first report (6), we studied several qualitative applications of RP-HPLC/APCI-MS to TAG in normal and genetically modified seed oils (32) and in industrial seed oils containing epoxide and alkyne functional groups (33). We went on to study the quantitative analysis of TAG using response factors and have presented these results in several reports (7,34,35).

Meanwhile, other researchers used APCI-MS for qualitative analysis of TAG, with an emphasis on the identification of regioisomers. Laakso and Voutilainen (8) used silver-ion (argentation) chromatography with APCI-MS for analysis of 10 structurally specific regioisomers of TAG. The authors combined the partial separation of isomers of polyunsaturated TAG by the silver-loaded column with the detection ability of APCI-MS. The authors presented data for several di-acid TAG, which contain two different FA, A and B, to form three possible TAG regioisomers: ABA, AAB, or BAA. The authors showed that the DAG-like fragment ions, [DAG]+, seen in the APCI-MS mass spectrum of a di-acid TAG were formed in proportions that were other than statistically expected, which led to the understanding that the ratio of the abundances of the fragment ions, [AA]+/[AB]+, can be correlated with the identities of specific regioisomers. They showed that the [DAG]+ fragment ion formed by the loss of the FA chain in the *sn*-2 position was less abundant than the [DAG]+ formed by loss of the *sn*-1 or *sn*-3 FA. This demonstrated that the relative amounts of the fragment ions could potentially be used to identify the positional isomers present in a mixture of TAG. Also in 1996, Laakso (36) applied RP-HPLC/APCI-MS to the analysis of berry oils. Although the chromatographic behavior of the isomeric TAG was reversed on the RP column compared with the silver-loaded column, the APCI-MS mass spectra exhibited the same trends as described above. Manninen and Laakso (37) later applied SFC coupled with APCI-MS for analysis of regioisomers in berry oils.

In 1996, Mottram and Evershed (10) also demonstrated that the loss of the acyl chain from the *sn*-1 or *sn*-3 position was energetically favored over loss from the *sn*-2 position. These authors, in collaboration with other colleagues, went on to report the identities of regioisomers in a variety of vegetable oils (11) and in animal fats (38). Both Mottram and Evershed and colleagues (10,11,38), and Laakso and coworkers (8,36,37) reported several important qualitative trends. First, they agreed that the DAG-like ion, [DAG]+, formed by loss of the FA chain in the *sn*-2 position was less abundant than the [DAG]+ formed by loss of the *sn*-1 or *sn*-3 FA for di-acid TAG. Mottram and Evershed (10) were the first to mention that the APCI-MS mass spectrum of a TAG having three different FA, a tri-acid TAG, showed three [DAG]+ fragments, and that the [DAG]+ ion that had the lowest abundance was the *sn*-1,3 [DAG]+ fragment formed by loss of

the *sn*-2 FA chain. A TAG having three different FA is referred to as an ABC TAG; alternatively, it is termed a Type III TAG. Unless further specified, an ABC-type TAG can have six possible structures: ABC, BAC, BCA, CBA, CAB, and ACB. However, the *sn*-1 and *sn*-3 regioisomers cannot be distinguished by on-line APCI-MS without derivatization. To simplify reference to ABC-type TAG, they can be considered as ABC, BAC and BCA, with the understanding that the *sn*-1 and *sn*-3 positions can be reversed. So simply referring to a TAG as ABC cannot be assumed to represent one specific regioisomer having A at *sn*-1, B at *sn*-2, and C at *sn*-3. Because of the inherent ambiguity in the label ABC, we refer to this type of TAG as a Type III TAG herein, because no regiospecificity is inherently implied, and thus there is no inherent ambiguity.

The results of Laakso (36), Laakso and Voutilainen (8), Mottram, Evershed, and colleagues (10,11,38), and Laakso and Manninen (9) revealed that the [DAG]+ fragment ions formed by the loss of the *sn*-2 FA had the lowest abundance of the [DAG]+ fragment ions. Thus, the specific *sn*-1,3 [DAG]+ fragment could be identified. They also indicated that no preference for the *sn*-1 vs. *sn*-3 positions on the glycerol backbone of the TAG was observed. A preference was reported by Laakso and Voutilainen (8), Manninen and Laakso (37), and Laakso (36) that indicated that, for PUFA, a closer proximity of the double bonds to the glycerol backbone led to a larger abundance of the fragment formed by loss of the PUFA than when the double bonds were further away. Specifically, when γ-linolenic (n-6) acid (Ln) was compared with α-Ln (n-3), the former showed a more abundant [*sn*-1,3-DAG]+ fragment ion than the latter when the PUFA was in the *sn*-2 position.

Herein, when the APCI-MS data are used to specify the regiospecific structure of a TAG, the name of the TAG is placed in bold, as in **OPS**, compared with OPS, POS, or PSO (where S = stearic acid, P = palmitic acid, and O = oleic acid). This indicates that the *sn*-1,3 [DAG]+ (e.g., [**OS**]+) has been identified by its minimal abundance in an APCI-MS mass spectrum. Of course, these are also equal to **SPO**, compared with SPO, SOP, or OSP, all else being equal. This will be discussed further below.

Statistical and nonstatistical considerations for Type II TAG. A TAG having two different FA chains is referred to herein as a Type II TAG. It is also referred to as an ABA/AAB TAG. Of course, this is equal to ABA/BAA. These possibilities can also be referred to as ABA/(AAB/BAA). Since Type II TAG have two of one FA, A, and one of the other FA, B, there is a likelihood of 2/3 (= 66.67% statistical probability) that any [DAG]+ fragment would contain one A FA combined with a B FA, which would give either an [AB]+ or [BA]+ fragment ion, which are two possibilities with equivalent mass, in contrast to [AA]+. Since the [AB]+ and [BA]+ ions have the same mass, they are indistinguishable by APCI-MS, so these two ions may be considered as a single group and should represent 66.67% of the abundances of all [DAG]+ fragment ions, all else being equal. On the other hand, there is a 1/3 chance (= 33.33% statistical probability) that any [DAG]+ that is observed would contain two A FA, which would give the [AA]+ fragment, out of the three possible [DAG]+ fragment structures.

Statistical considerations can be used for determining what relative abundances of the [DAG]$^+$ fragment ions could be expected in an APCI-MS mass spectrum of a TAG. Based solely on statistical considerations, all Type II TAG contain two A FA and one B FA and so should give a ratio of abundances [AA]$^+$/([AB]$^+$ + [BA]$^+$) equal to (1/3)/(2/3) = 1/2, or 0.5. Regardless of their absolute abundances, from 100% to less than 1.00%, the ratio of the abundances of the [AA]$^+$ and [AB]$^+$ fragment ion *m/z* values should be 0.5. Observed conditions can lead to nonstatistical abundances of [AA]$^+$ and [AB]$^+$ [DAG]$^+$ fragment ions in APCI-MS mass spectra.

The [AA]$^+$ ion that is observed at a given *m/z* value will represent [*sn*-1,3-AA]$^+$, [*sn*-1,2-AA]$^+$, and [*sn*-2,3-AA]$^+$. Similarly, the [AB]$^+$ ion at a particular *m/z* value will represent [*sn*-1,3-AB]$^+$, [*sn*-1,2-AB]$^+$, and [*sn*-2,3-AB]$^+$, and also [*sn*-1,3-BA]$^+$, [*sn*-1,2-BA]$^+$, and [*sn*-2,3-BA]$^+$.

By using APCI-MS mass spectra of the pure regioisomers of *sn*-1,3 ABA TAG vs. *sn*-1,2 AAB TAG, it has been shown that the abundance of the [DAG]$^+$ fragment ion formed as [*sn*-1,3-AA]$^+$ from [**ABA** + H]$^+$ is smaller than that formed as [*sn*-1,2-AA]$^+$ from [**AAB** + H]$^+$, even though these ions are expected with equal statistical probability. Mottram and Evershed (10) and Hsu and Turk (39) mentioned that this indicated that the formation of the [*sn*-1,3-AA]$^+$ ion was energetically disfavored, because it involves loss of the *sn*-2 FA instead of one of the more labile *sn*-1 or *sn*-3 chains. Hsu and Turk (39), who used electrospray ionization (ESI) MS of TAG as their lithiated adducts, proposed that the *sn*-1 and *sn*-3 chains are promoted to leave by participation of the labile α-hydrogens of the neighboring FA. They suggest that the α-hydrogens of the middle FA are more labile than the α-hydrogens of the *sn*-1 or *sn*-3 chains and so help the *sn*-1 or *sn*-3 chains to leave more readily. Regardless of the specific mechanism that is assumed to operate, the observed ratios of [AA]$^+$/[AB]$^+$ are different for the different pure isomers of regiospecific TAG.

Table 1 shows the [AA]$^+$/[AB]$^+$ ratios for a variety of pure isomers, most of them commercially available. It is notable that the [AA]$^+$/[AB]$^+$ ratios of the two isomers are not equal for any

TAG. The two pure isomers each give different characteristic ion abundance ratios [AA]⁺/[AB]⁺, and these are almost all at nonstatistically expected ratios. The variation of the [AA]⁺/[AB]⁺ ratio with different regioisomers demonstrates that the positional placement of the FA on the glycerol backbone exerts a nonstatistical effect on the abundances of the ions formed by APCI-MS.

When comparing APCI-MS spectra of TAG, one must differentiate between (i) the APCI-MS mass spectrum of an individual TAG with unknown regiospecificity; (ii) the APCI-MS mass spectrum of a pure positional isomer of a TAG; (iii) a mass spectrum of a mixture of pure positional isomers; (iv) a mass spectrum of mixtures of several isomers in synthetic mixtures; and (v) mass spectra of combinations of TAG in natural mixtures. Knowing the type of sample being examined is essential to proper use of the [AA]⁺/[AB]⁺ ratio obtained from the sample. The actual [AA]⁺/[AB]⁺ ratio observed for any TAG or mixture of TAG is due to nonstatistical effects acting in combination with the expected ratio of 0.5. When considering the variety of pure TAG and TAG mixtures, the nonstatistical effects on the [AA]⁺/[AB]⁺ ratio can include: (i) differences in composition from 100% isomers to combinations of TAG regioisomers in TAG mixtures; (ii) formation of the *sn*-1,3 isomer, which is energetically disfavored under APCI-MS conditions, leading to a lower [AA]⁺/[AB]⁺ ratio when [AA]⁺ is the *sn*-1,3 isomer; and (iii) a disparity in the amount of unsaturation in FA A vs. B, and (iv) differences in the positions of the sites of unsaturation in the FA chains.

Characterization of the relationship between the identities of TAG structures and the [DAG]⁺ fragment ions in the APCI-MS mass spectra of TAG has been the subject of primarily qualitative investigations of regioisomers of TAG. Such studies have shown that each of the foregoing categories of TAG and TAG mixtures gives different [AA]⁺/[AB]⁺ ratios, based on the structure(s) of the TAG. Pure regioisomers give [AA]⁺/[AB]⁺ ratios that represent the upper and lower boundaries of the [AA]⁺/[AB]⁺ ratio that should be obtained by any mixture of regioisomers of a particular TAG.

Using APCI-MS mass spectra for qualitative analysis of TAG regioisomers. As mentioned, Laakso and Voutilainen (8), Mottram and Evershed and colleagues (10,11), and Laakso (36) showed that the [DAG]⁺ fragment ions formed by the loss of the *sn*-2 FA chain have the lowest abundance of the [DAG]⁺ fragment ions. The APCI-MS mass spectra of pure TAG isomers reported by the above authors demonstrated that the ion abundances and, more conveniently, the ratio of the ion abundances, [AA]⁺/[AB]⁺, are expected to change with the regioisomeric composition of a mixture of TAG regioisomers. These authors reported that if the FA A chains in an ABA/AAB/BAA TAG are located in the *sn*-1,3 positions, i.e., [*sn*-1,3-AA]⁺, the [DAG]⁺ fragment ion has a lower abundance than the 0.5 ratio statistically expected.

This tendency was used by Laakso (36) and Manninen and Laakso (37) to describe, in a semiquantitative way, the compositions of regioisomers in natural berry and other oils. This represented an early attempt at quantitative analysis of the relative

amounts of regioisomers. These articles described another interesting observation that must be taken into consideration. They showed that the positions of the double bonds in polyunsaturated TAG had a substantial impact on the relative abundances of [AA]⁺ and [AB]⁺ fragment ions. This trend can clearly be seen in Table 1 by comparing the [AA]⁺/[AB]⁺ ratios of the O(n-6)LnO and O(n-3)LnO regioisomers [where O = oleic acid, (n-6)Ln = γ-linolenic acid, and (n-3)Ln = α-linolenic acid]. The O(n-3)LnO isomer has a low [AA]⁺/[AB]⁺ ratio (= 0.17) typical of most pure *sn*-1,3 isomers. On the other hand, the O(n-6)LnO isomer has [AA]⁺/[AB]⁺ ratios (= 0.63 to 0.90) that are higher than the 0.5 that is statistically expected, and the OO(n-6)Ln isomer gives an even higher [AA]⁺/[AB]⁺ ratio. Observations such as these constitute the trends that can be correlated with certain ratios.

In addition to the observations previously mentioned, Table 1 shows several other trends. First, every ABA TAG gave an [AA]⁺/[AB]⁺ ratio that was smaller than the ratio from the corresponding AAB TAG. This, of course, reflects the fact that the loss of *sn*-2 chain is energetically disfavored. When the [AA]⁺ corresponds to the *sn*-1,3 isomer, its abundance is diminished. Another trend is that the [AA]⁺/[AB]⁺ ratio for almost all *sn*-1,3 isomers, ABA, is substantially below the statistically expected value of 0.5. The isomer that contained the (n-6)Ln was the exception to this trend. It can also be seen in Table 1 that most, but not all, AAB isomers gave [AA]⁺/[AB]⁺ ratios larger than the statistically expected value of 0.5. Hence, the [AA]⁺/[AB]⁺ ratio may by more useful for identifying some AAB TAG (e.g., PPO, where P = palmitic acid) than others (e.g., OOP).

Recent articles allow us to move toward a more numeric and quantitative method for analysis of TAG regioisomers. Articles cited below describe approaches that have been demonstrated to be useful to obtain a quantitative estimation of the percentage compositions of any regioisomers for which calibration standards are available. However, three other qualitative considerations should be mentioned. First, the [DAG]⁺ fragment ions that are produced by APCI-MS are isobaric with a normal intact DAG minus a water group. In the process of leaving, the R$_x$COO that is lost from a TAG in the APCI source takes the glycerol oxygen with it to form an [M + H − RCOOH]⁺ ion. These same [DAG]⁺ fragment ions are formed during ESI-MS/MS of TAG. According to Hsu and Turk (39), who performed deuterium-labeled experiments on lithiated TAG by ESI-MS, the carbonyl oxygen of the FA neighboring the one that is lost carries out nucleophilic attack on the glycerol carbon atom that contains the leaving group, forming a five- or six-membered ring, with the participation of the α-hydrogen of the ring-attached FA chain.

Second, plants produce TAG with regiospecificity as well as single enantiomers of asymmetric TAG having the L configuration. TAG that are produced by the chemical interesterification of glycerol and FA, such as the 35-TAG mixture used as an example herein, are a mixture of enantiomers.

Third, the integrated areas under the ion chromatograms of the [M + H]⁺ ion and of [DAG]⁺ fragment ions over a specific time range can be used to produce a mass spectrum that appears

the same as an averaged mass spectrum across the same time range. Since all [DAG]$^+$ fragments originate in the APCI source, all fragments that occur from a particular TAG must occur at the retention time associated with that TAG. So integrated areas under ion chromatograms corresponding to the fragments will be in the same proportions as the ion abundances in an averaged mass spectrum across the same time range. Therefore, quantitative estimation of the regioisomeric composition based on the [AA]$^+$/[AB]$^+$ ratio can use either integrated areas under ion chromatograms or abundances in an average mass spectrum across the chromatographic peak. The method for the quantitative analysis of TAG molecular species that we developed and have reported extensively before (7,34,35) uses the areas under ion chromatograms for quantitative analysis of TAG molecular species. These same data will also be used to construct the [AA]$^+$/[AB]$^+$ ratio and other ratios presented herein. Fauconnot *et al.* (40) also used areas under ion chromatograms for quantitative analysis of TAG regioisomers. The areas under the peaks of the [M + H]$^+$ and [DAG]$^+$ fragment ions determined by APCI-MS were used to calculate the Critical Ratios given in Table 2.

Using APCI-MS mass spectra for quantitative analysis of TAG regioisomers. In 2003, Byrdwell (29) cited the need for improved methods for quantitative analysis of regioisomers. In discussing the quantification of TAG positional isomers, he said:

A comprehensive study using the greatest possible number of positional isomers with disparate amounts of unsaturation needs to be undertaken for both APCI-MS and ESI-MS/MS. In our initial work, we did not address this issue because we felt that it would require lengthy quantification of the abundances of DAG fragment ions from a large series of standards to address the issue adequately. We believed that the proper approach would be to perform APCI-MS of a wide range of structured lipids, determine the ratios of DAG fragment ions that are produced, and then interpolate between the ratios for the 1,2- versus the 1,3- isomers to get a quantitative estimation of the relative amounts of each of these isomers in real samples. Unfortunately, only a limited number of structured lipids are commercially available, so full treatment of this subject will require synthesis of an array of structured lipids, followed by their analysis. Until then, great care must be exercised in using APCI-MS for positional isomer identification, especially for polyunsaturated TAG (41).

A recent article by Jakab, Jablonkai, and Forgacs (42) constitutes the first example of the process described above. Jakab *et al.* (42) described the use of APCI-MS for analysis of mixtures of pure positional isomers of LOL/LLO (where L = linoleic acid). They demonstrated that a calibration curve could be constructed that plotted the ratio of abundances of [DAG]$^+$ fragment ions vs. the percentage of the LLO isomer (the LOL isomer percentage could just as easily be plotted). This calibra-

tion curve, reproduced in Figure 1, accomplished quantification of the relationship between the abundances of ions in APCI-MS mass spectra and, more specifically, the ratio of abundances, [AA]$^+$/[AB]$^+$ (i.e., [LL]$^+$/[LO]$^+$), to the relative amount of the **ABA** isomer, i.e., the LOL isomer.

The equation shown by Jakab *et al.* (42) and seen in Figure 1 is the least-squares best-fit line equation, based on 11 mixtures representing the concentration range from 0% LOL/(LLO + OLL) to 100% LOL/(LLO + OLL). Of course, 0% LOL represents 100% (LLO + OLL), and, conversely, 100% LOL represents 0% (LLO + OLL). Any mixture of TAG should contain an amount of the ABA isomer somewhere between 0 and 100%, so this calibration line should apply to any mixture of these TAG, to correlate the amount of the [*sn*-1,3-AA]$^+$ isomer with the [AA]$^+$/[AB]$^+$ ratio.

These authors (42) simplified the complex situation mentioned by Byrdwell (41) by examining only the two isomers of one TAG. Nevertheless, they clearly demonstrated that the approach—of determining the DAG fragment ratios for a series of standard solutions and then interpolating the ratio of positional isomers from the DAG fragment ratios of actual samples—is effective for determining the relative amounts of two isomers. Of course, every TAG for which positional isomers are to be determined requires isomeric standards and multiple solutions of each standard pair of isomers to be quantified. As Figure 1 shows, Jakab *et al.* (42) used 11 solutions to cover the range from 0 to 100%, inclusive, by 10% increments. Five replicate measurements of each of these standard solutions represent at least 55 experiments that were performed to produce the calibration line shown in Figure 1. These experiments would need to include a larger number of pure regiospecific standards to be more widely applicable. Nevertheless, the approach taken by Jakab *et al.* (42) appears to be the most appropriate approach for accurate quantitative estimation of the relative amounts of regioisomers.

The full set of standard solutions serves to demonstrate that there is an approximately linear relationship ($r^2 = 0.9884$) between the [AA]$^+$/[AB]$^+$ ratio and the percent composition of regioisomers. One could say that the [AA]$^+$/[AB]$^+$ ratio can be used as a Critical Ratio for the determination of the percentage composition of mixtures of regioisomeric standards. Therefore, the question arises: Can this accurate quantitative analysis of TAG regioisomers be accomplished with fewer experimental data? Can one derive the same or similar results from a less extensive set of experiments? If so, then this would be an advantage. The first simplification would be to construct a line directly between the two end points of the line. This is experimentally equal to determining only the mass spectra and therefore the [AA]$^+$/[AB]$^+$ ratios for 100% pure **LLO** (0% **LOL**) and for 100% pure **LOL** (0% **LLO**). The equation for the line formed between the two average ($n = 5$) end point values in Figure 1 can be compared with the line formed by the least-squares best-fit line end points.

For instance, in the data presented by Jakab *et al.* (42), the observed extremes had average [AA]$^+$/[AB]$^+$ ratios of 0.7028 and 0.2289, for 100% **LLO** (= 0% **LOL**) and 100% **LOL** (= 0%

[a]ECN, equivalent carbon number = # carbon atoms in FA chains – (2 × # sites of unsaturation); Ln, 18:3, linolenic acid; L, 18:2, linoleic acid; O, 18:1, oleic acid; S, 18:0, stearic acid; P, 16:0, palmitic acid. The statistical composition is the composition calculated based on the FA composition. The adjusted APCI-MS composition is the composition determined by three replicate chromatographic runs, adjusted using response factors calculated from the FA composition (35). SD2, simple standard deviation of the three numberic $[AA]^+/[AB]$ ratio values. For other abbreviations see Table 1.

LLO), respectively. These values are shown in Table 1. Similarly, each set of $[AA]^+/[AB]^+$ ratios of TAG positional isomers in Table 1 defines the range of DAG fragment ion ratios that should be encountered in APCI-MS (as well as some ESI-MS) mass spectra of TAG. An equation of the line that approximately describes the $[AA]^+/[AB]^+$ ratio for any combination of TAG positional isomers can be constructed from these two end points. If one puts the line in Figure 1 in the form of $y = mx + b$, then $y = ([AA]^+/[AB]^+) = m \cdot (\% \textbf{LOL}) + b$. In this equation, b would equal the $([AA]^+/[AB]^+)$ ratio at 0% **LOL**. In terms of x and y, the coordinates of the two end points would be (0% **LOL**, $([AA]^+/[AB]^+)_{AAB}$) and (100% **LOL**, $([AA]^+/[AB]^+)_{ABA}$), where the subscripts represent the $([AA]^+/[AB]^+)$ ratios of pure standards of AAB and ABA, i.e., **LLO** (= 0% **LOL**) and **LOL**, which would be explicitly: (0%, 0.7028), (100%, 0.2289). The equation of the line constructed from these end points would be: $m = (\Delta y)/(\Delta x) = (y_2 - y_1)/(x_2 - x_1) = ((([AA]^+/[AB]^+)_{ABA} -$

$([AA]^+/[AB]^+)_{AAB}))/(100 - 0)$ and $b = ([AA]^+/[AB]^+)_{AAB}$. In terms of the data reported by Jakab *et al.* (42), this gives: $m = (\Delta y)/(\Delta x) = (y_2 - y_1)/(x_2 - x_1) = ((([LL]^+/[OL]^+)_{LOL}) - ([LL]^+/[OL]^+)_{LLO}))/(100 - 0) = (0.2289 - 0.7028)/(100 - 0) = (-0.4739)/(100) = -0.004739$; and $b = ([LL]^+/[OL]^+)_{LLO} = 0.7028$. From this line comes the relationship:

$$\left(\frac{[LL]^+}{[LO]^+}\right) = (-0.004739)\cdot(\%\textbf{LOL}) + 0.7028$$

This equation can be seen to be in the general form:

$$\left(\frac{[AA]^+}{[AB]^+}\right)_{Obs} = \left(\left(\frac{[AA]^+}{[AB]^+}\right)_{ABA} - \left(\frac{[AA]^+}{[AB]^+}\right)_{AAB}\right)\cdot\left(\frac{\%\textbf{ABA}}{100}\right) + \left(\frac{[AA]^+}{[AB]^+}\right)_{AAB} \quad [1]$$

To get a line with a positive slope, the y values, $([AA]^+/[AB]^+)$, can be arranged from lowest to highest, which means that the x values should be put in terms of % LLO to make x also go from low to high as $([AA]^+/[AB]^+)$ goes from low to high. The
FIG. 1. Ratio of the $[LL]^+$ and $[LO]^+$ fragment ions (%) in mixtures of LOL and LLO at various percentages (calibration curve). L, linoleic acid; O, oleic acid. From A. Jakab, I. Jablonkai, and E. Forgacs, *Rapid Commun. Mass Spectrom. 17*, 2295–2302 (2003). Copyright John Wiley & Sons Ltd. Reprinted with permission.

equivalent points that would give a positive slope would be: $(x_1, y_1), (x_2, y_2) = (0\% \text{ LLO}, ([AA]^+/[AB]^+)_{ABA})$, (100% LLO, $([AA]^+/[AB]^+)_{AAB})$, or (0, 0.2289), (100, 0.7028). In terms of the average end point data by Jakab *et al*. (42), this would be a line having the equation:

$$\left(\frac{[LL]^+}{[LO]^+}\right) = (0.004739) \cdot (\% \text{ \textbf{LLO}}) + 0.2289$$

This equation can be written in a general form as:

$$\left(\frac{[AA]^+}{[AB]^+}\right)_{Obs} = \left(\left(\frac{[AA]^+}{[AB]^+}\right)_{AAB} - \left(\frac{[AA]^+}{[AB]^+}\right)_{ABA}\right) \cdot \left(\frac{\%\textbf{AAB}}{100}\right) + \left(\frac{[AA]^+}{[AB]^+}\right)_{ABA} \quad [2]$$

One can solve Equations 1 and 2 for the following relationships.

One may rearrange Equation 1 (and multiply by $(-1)/(-1)$) to solve for the % **ABA** as follows:

$$(\% \textbf{ABA}) = \left[\frac{\left(\frac{[AA]^+}{[AB]^+}\right)_{AAB} - \left(\frac{[AA]^+}{[AB]^+}\right)_{Obs}}{\left(\frac{[AA]^+}{[AB]^+}\right)_{AAB} - \left(\frac{[AA]^+}{[AB]^+}\right)_{ABA}}\right] x100 \quad [3]$$

Similarly, one may rearrange Equation 2 to solve for the % **AAB** as follows:

$$(\% \textbf{AAB}) = \left[\frac{\left(\frac{[AA]^+}{[AB]^+}\right)_{Obs} - \left(\frac{[AA]^+}{[AB]^+}\right)_{ABA}}{\left(\frac{[AA]^+}{[AB]^+}\right)_{AAB} - \left(\frac{[AA]^+}{[AB]^+}\right)_{ABA}}\right] x100 \quad [4]$$

And these two percentages share the relationship that % **LOL** + % LLO (= **LLO** + **OLL**) = 100%.

Therefore, whenever one percentage is known, % ABA or % AAB, the other may be known as % AAB (= % **AAB** + % **BAA**) = 100 − % **ABA** or % **ABA** = 100 − % AAB, respectively.

Equations 3 and 4 allow the direct calculation of the percentage composition of either one regiospecific isomer, % **ABA**, or the sum of two isomers, % AAB (= % **AAB** + % **BAA**). Of course, the $([AA]^+/[AB]^+)$ ratios of pure known standards of each individual TAG must be determined for each TAG for which quantification is sought. These $([AA]^+/[AB]^+)$ ratios of pure known standards potentially can be tabulated. We have compiled the $([AA]^+/[AB]^+)$ ratios of pure known standards before and have noted the references that allow the instrument type and conditions under which these values were obtained to be determined. If a researcher has a similar instrument and obtains $([AA]^+/[AB]^+)$ ratios of pure known standards on his or her instrument that are similar to those of the tabulated values, then these results lend credibility to the possibility that tabulated values might be helpful in assessing the percentages of regioisomers in a TAG mixture of unknown composition. The minimal approach to linear interpolation would require the analysis of two pure regioisomeric standards, and then the $([AA]^+/[AB]^+)_{Obs}$ ratio of a mixture of unknown regioisomeric content might be interpolated between the $([AA]^+/[AB]^+)$ ratios obtained for pure isomers, and a quantitative estimate of the % **ABA** or % AAB could be obtained with relative ease.

For example, Table 1 shows the ratio of $[PP]^+/([PO]^+,[OP]^+)$, which is more simply referred to as the $[PP]^+/[PO]^+$ ratios for two commercially available regiospecific isomers, POP and PPO. Four out of five authors using APCI-MS have reported low values for the $[PP]^+/[PO]^+ = [AA]^+/[AB]^+$ ratio, in the range of 0.20 to 0.34 (8,10,40,43). Three of four of those authors reported $[AA]^+/[AB]^+$ ratios between 0.87 and 0.95 for pure PPO, by APCI-MS. The fourth example of POP/PPO data in Table 1 had a higher $[AA]^+/[AB]^+$ ratio for POP (= 0.41) and a lower value for PPO (= 0.79) (37). Our reports and those of many others have been obtained on TSQ 700 and 7000 tandem triple-stage quadrupole instruments. The data by Fauconnot *et al*. (40) included in Table 1 were obtained on a tandem sector quadrupole instrument with a Z-spray interface. Unlike collision-induced dissociation (CID), which exhibits differences between TSQ and ion-trap MS (ITMS) instruments in fragment ions formed, full-scan APCI-MS mass spectra on a TSQ instrument can appear nearly identical to an APCI-MS mass spectrum obtained on an ITMS instrument. The reason for this is that fragmentation occurs in the ionization source, so the $[DAG]^+$ fragment ions are formed before they reach the first or subsequent mass analyzers, whether quadrupole or ion trap. In fact, the APCI ionization heads on the TSQ 700 and LCQ Deca instruments in our laboratory are nearly identical and have interchangeable parts but are not themselves interchangeable between instruments. This is in contrast to CID, which exhibits different ratios of fragment ions in TSQ vs. ITMS instruments. Hsu and Turk (44) reviewed the mechanisms of fragmentation of phospholipids and TAG by ESI-MS/MS in their recent book chapter.

The equations above, which are based on only two pure regioisomers, must be compared with the more accurate line described by the full set of standards analyzed by Jakab *et al*. (42). The equation for the best-fit line given in Figure 1 is $y = 0.4906 \cdot x + 69.83$, but the y axis gives $[AA]^+/[AB]^+$ as a percentage. The

equation of the line for the $[AA]^+/[AB]^+$ as a pure ratio (not a percentage) would therefore be:

$$\left(\frac{[LL]^+}{[LO]^+}\right) = (-0.004906) \cdot (\% \, \textbf{LOL}) + 0.6983$$

The best-fit line gives an $([AA]^+/[AB]^+)$ ratio of 0.6983 for 0% LOL and 0.2077 for 100% LOL.

These best-fit values for the pure positional isomers can be inserted into Equation 3 to give the following equation:

$$(\% \, \textbf{LOL}) = \left(\frac{0.6983 - \left(\frac{[AA]^+}{[AB]^+}\right)_{Obs}}{0.6983 - 0.2077}\right) x100$$

This can be used to calculate the % LOL from the $([AA]^+/[AB]^+)_{Obs}$ ratio for a mixture. For instance, a hypothetical $[AA]^+/[AB]^+$ ratio of 0.5348 would give a calculated % LOL of 33.33%. This is the $[AA]^+/[AB]^+$ ratio that would be expected from a statistically randomly distributed combination of two FA, L and O, onto the three possible positions of the glycerol backbone of a TAG, on the instrument and under the conditions reported by Jakab *et al.* (42). Thus, nonstatistical influences on the abundances of the $[DAG]^+$ fragments formed shift the $[AA]^+/[AB]^+$ ratio from the statistically expected value of 0.5 to a hypothetical $[AA]^+/[AB]^+$ ratio of 0.5348, calculated from the best-fit line using 11 standard solutions.

For comparison, the equation based only on the average values of the two pure standards, given in the form of Equation 3 above, is:

$$(\% \, \textbf{LOL}) = \left(\frac{0.7028 - \left(\frac{[AA]^+}{[AB]^+}\right)_{Obs}}{0.7028 - 0.2289}\right) x100$$

This equation gives a calculated % LOL of 35.45% from the same $([AA]^+/[AB]^+)_{Obs}$ ratio of 0.5438. Although this is not identical to the 33.33% obtained from the best-fit line made from 11 standards, it is a good approximation of the more accurate value and can be obtained with only two authentic standards, instead of a large number of mixtures containing various compositions. Certainly in the range 0 to 100%, narrowing the composition down to 35.45% LOL would represent a good approximation of 33.33%, but with much less data required. Of course, if greater accuracy is required for a particular application, more standards can be analyzed, and the same equations can be used with the slope and intercept calculated from the best-fit line.

The above equations allow one to quantify the relative amounts of positional isomers in a mixture. It is expected that the $[AA]^+/[AB]^+$ ratios of a greater variety of regiospecific isomers will be reported and compared, and this method will be applied to a greater variety of TAG mixtures. These equations also demonstrate the utility of the $[AA]^+/[AB]^+$ ratio for determination of the regiospecific composition of a TAG mixture. This ratio allows one to move from qualitative analysis of TAG to a more quantitative approximation of the composition of TAG regioisomers.

Even more recently, another article appeared that describes the linear relationship between the abundances of $[AA]^+$ and $[AB]^+$ fragments and the compositions of known standard mixtures of TAG regioisomers. Fauconnot *et al.* (40) reported calibration curves for regioisomers of seven pairs of Type II TAG standards. The authors showed the growing importance of the $[AA]^+/[AB]^+$ ratio in their statement: "Identification of the major regioisomers of an AAB/ABA pair of TGs was shown to be enabled by comparing the ratios of abundances of $c(AA^+)/c(AB^+)$ with the statistically expected value of 0.5."

In their calibration curves, though, they plotted what they called the *regioisomeric purity*, r_{AA}, which they defined as:

$$r_{AA} = \frac{100\% c(AA^+)}{c(AA^+) + c(AB^+)}$$

This equation can be shown to be equivalent to

$$r_{AA} = \frac{1}{1 + \frac{1}{\frac{(AA^+)}{(AB^+)}}} x100$$

It is much more convenient and useful to use the ratio $[AA]^+/[AB]^+$ directly. This is a simpler ratio, which can be used directly with Equations 3 and 4 to calculate the relative percentages of the regioisomers. This is also the approach used by Jakab *et al.* (42). Nevertheless, the data by Fauconnot *et al.* (40) also demonstrated the linear relationship between the $[AA]^+/[AB]^+$ ratio and the percent composition of the regioisomers.

CONSTRUCTION OF THE CRITICAL RATIOS

Construction and use of the $[AA]^+/[AB]^+$ ratio for a Type II TAG. If the APCI-MS or ESI-MS mass spectrum of a Type II TAG exhibits a ratio of ion abundances other than 0.50, then it is due to nonstatistical influences. Several of the nonstatistical influences already have been mentioned, but another nonstatistical influence that has been observed deserves further discussion. Laakso and Voutilainen (8), Manninen and Laakso (37), and Laakso (36) reported results for the effect of unsaturation on the abundances of $[DAG]^+$ fragment ions and showed that O(n-3)LnO behaved much like a normal, less unsaturated TAG, by exhibiting a low $[AA]^+/[AB]^+$ ratio of 0.17 (Table 1), owing primarily to the well-reported effect of being the $[DAG]^+$ fragment formed by loss of the *sn*-2 chain. Conversely, they showed that when the double bonds were closer to the carbonyl end of the chain, i.e., n-6 vs. n-3, a much greater amount of the $[sn\text{-}1,3\text{-}AA]^+$ fragment was formed, which led to a larger $[AA]^+/[AB]^+$ ratio, which had a larger value than the 0.5 that was statistically expected. The authors attributed the difference in the n-6 polyunsaturated TAG to the fact that the proximity of the double bonds to the carbonyl end of the chain helped make the PUFA a better leaving group. This made the polyunsaturated group, even in the *sn*-2 position, easily lost. This was reflected in the higher $[AA]^+/[AB]^+$ ratio for all of the n-6 FA, which, for the ABA isomer, was higher than statistically expected, and which, for the

AAB/BAA isomers, was higher than 1. Thus, more information could potentially be derived from the [AA]$^+$/[AB]$^+$ ratio.

The only reported [AA]$^+$/[AB]$^+$ ratio greater than 1 for a pure synthetic [*sn*-1,3-AA]$^+$ isomer was for *sn*-1,3-PAP (di-palmitoyl, arachidonyl TAG, 16:0, 20:4, 16:0) by Fauconnot *et al.* (40), seen in Table 1. The authors used an instrument with a Z-spray interface, whereas most other reports were based on data from ThermoFinnigan TSQ or LCQ instruments. Several values obtained on this instrument and shown in Table 1 were higher than the values obtained by other instruments, and many were much higher than the statistically expected value of 0.5. A notable exception was the TAG regioisomer pair APA/AAP. These both gave a virtually nonexistent [AA]$^+$ ion, the di-arachidonyl [DAG]$^+$ fragment, apparently because the arachidonic chain is lost so easily that two of them cannot both re-main attached. Arachidonic acid is an n-6 FA, like the (n-6)Ln in the OLnO/OOLn pair that Laakso and Voutilainen (8) and Manninen and Laakso (37) reported. The proposition that n-6 arachidonic acid is more easily lost would also explain why the [AA]$^+$/[AB]$^+$ ratios of the PAP/PPA isomer standards were much higher than statistically expected. If the arachidonic chain is lost easily from the TAG PAP because it is an n-6 FA, this would explain why a higher than expected abundance of the [PP]$^+$, dipalmitoyl DAG fragment ion, was observed. This again demonstrates that the [AA]$^+$/[AB]$^+$ Critical Ratio can be used to correlate observations in mass spectra with structural characteristics.

Another benefit to constructing the [AA]$^+$/[AB]$^+$ ratio is that two abundances, [AA]$^+$ and [AB]$^+$, which are two separate numbers, can now be represented by only one number, the nu-meric ratio [AA]$^+$/[AB]$^+$. It will be demonstrated that, using the [AA]$^+$/[AB]$^+$ Critical Ratio, both abundances can be accu-rately reconstructed from this one number when classified cor-rectly. This means that the same amount of information can be conveyed in less space, one number instead of two. When this number and one other number are processed through the Bot-tom-Up Solution (BUS), the complete mass spectrum of a Type II TAG can be reproduced and would exhibit two [DAG]$^+$ frag-ment ion abundances, [AA]$^+$ and [AB]$^+$, and a protonated mol-ecule abundance, for three abundances. These three ions con-stitute all of the primary peaks that provide the M.W. and DAG fragment structural information. The [AA]$^+$/[AB]$^+$ ratio can be used to store two of the three numbers for that mass spectrum as one ratio. Then a second ratio is used to provide the third value, and the relationship between the third value and the first two. The second ratio is the [MH]$^+$/Σ[DAG]$^+$ ratio, which pro-vides information for the value of [M + H]$^+$ and its relationship to [AA]$^+$ and [AB]$^+$. This ratio will be discussed shortly. Masses for each of these ions are specified by the *m/z* value from which came each peak area integrated over time. The known masses are compared with tabulated values, and all pos-sible identities for each mass are known, including isobaric species. Chromatographic information is used with the mass information to identify and differentiate isobaric species (7,34,35).

The [AA]$^+$/[AB]$^+$ ratio as provided at face value can be used

in Equations 3 and 4 to provide direct information regarding the percent compositions of regioisomers, compared with stan-dard solutions. This Critical Ratio, along with one other num-ber (the [MH]$^+$/Σ[DAG]$^+$ ratio), can be used with the BUS to accurately reproduce the exact three abundances that represent the mass spectrum. These characteristics of the BUS—of sav-ing space and providing more information in fewer values— will be seen with the other Critical Ratios as well. All Critical Ratios provide more information than the raw abundances, but the raw abundances can be reconstructed at will by processing them through the BUS.

Construction of the [MH]$^+$/Σ[DAG]$^+$ ratio for all TAG. During the preparation of a recent review (45), Byrdwell sought quantifiable numerical values that could be related to observed mass spectrometric fragmentation characteristics. Some empirically determined Critical Ratios were sought that could be used to describe, in a more quantitative way, the char-acteristics that were ascribed to APCI-MS mass spectra in that chapter. Among the fragmentation characteristics was the de-pendence of the abundance of the protonated molecule, [M + H]$^+$ or [MH]$^+$, on the amount of unsaturation in the TAG FA. TAG containing numerous sites of unsaturation have a proton-ated molecule, [M + H]$^+$ as the base peak, whereas TAG with fewer sites of unsaturation give a [DAG]$^+$ fragment as the base peak. Saturated TAG give a [DAG]$^+$ fragment as the base peak, with no or practically no [M + H]$^+$ abundance. This depen-dence of [M + H]$^+$ abundance on the amount of unsaturation often has been noted and was observed in our first report on the HPLC/APCI-MS analysis of TAG (6). Since that first report, we have sought ways to describe this undefined relationship in a qualitative or quantitative way. In 1997 (34), the relationship between the ratio of the abundance of the [M + H]$^+$ ion of a TAG to the sum of all ions, [M + H]$^+$ plus [DAG]$^+$, was mod-eled as using:

$$\frac{[TAG]^+}{[TAG]^+ + \Sigma[DAG]^+}$$

An equation was shown, referred to as *the TAG quotient 1/3 power fit*, that was an approximate representation of the curve described when this ratio was plotted vs. the number of sites of unsaturation in the TAG. This ratio has now been calculated to equal the following:

$$\frac{[TAG]^+}{[TAG]^+ + \Sigma[DAG]^+} = \frac{1}{1 + \dfrac{1}{\dfrac{[TAG]^+}{\Sigma[DAG]^+}}}$$

It is simpler, and is preferred, to use the [MH]$^+$/Σ[DAG]$^+$ ratio instead of the inverse of its inverse.

The ratio of the TAG protonated molecule, [TAG + H]$^+$, [M + H]$^+$, or [MH]$^+$, to Σ[DAG]$^+$ is referred to in the BUS as the [MH]$^+$/Σ[DAG]$^+$ ratio.

One important aspect of the relationship between the [M + H]$^+$ ion and the sum of the [DAG]$^+$ fragment ions is that they are inverses: When one goes up, the other goes down. This dependence is not linear, but it is inverse in some way. Since

one value goes up and one goes down, the ratio of these two values highlights, or accentuates, the dependence of $[M + H]^+$ on the degree of unsaturation. This ratio will show more movement in its numeric value than the abundance alone as the number of sites of unsaturation changes, since the ratio contains two abundances that have an inverse relationship. Therefore, the dependence of the abundance of the protonated molecule, $[M + H]^+$, on the degree of unsaturation is best reflected in the ratio of the protonated molecule, $[MH]^+$, to the sum of the DAG fragment ion abundances, $\Sigma[DAG]^+$, to give $[MH]^+/\Sigma[DAG]^+$. This ratio can be used as a Critical Ratio to provide information regarding the number of sites of unsaturation in the molecule, which determines whether the $[M + H]^+$ or a $[DAG]^+$ is the base peak. TAG containing numerous sites of unsaturation have an $[MH]^+/\Sigma[DAG]^+$ larger than 1, and thus have a $[M + H]^+$ base peak. TAG with few sites of unsaturation have a low $[MH]^+/\Sigma[DAG]^+$ ratio, and a $[DAG]^+$ base peak. Saturated TAG are expected to have an $[MH]^+/\Sigma[DAG]^+$ ratio of zero, because they often give no $[M + H]^+$ ion.

An important aspect of the BUS construct is that the Critical Ratios are chosen, or constructed, based on observations in APCI-MS mass spectra, and keep them from going to catastrophic values. It has been observed that the $[M + H]^+$ ion can be zero for saturated TAG, so if this number were alone in the denominator of a ratio, then the ratio would take a value of 1/0 for saturated TAG and would become unsolvable. Since it is known that the $[M + H]^+$ ion goes to zero for some TAG, but that $\Sigma[DAG]^+$ never goes to zero, one can choose to calculate the $[MH]^+/\Sigma[DAG]^+$ ratio instead of the $\Sigma[DAG]^+/[MH]^+$ ratio, so that the number that can go to zero is in the numerator. Thus, judicious selection of the ratio that is constructed can keep the system completely bounded in all observed circumstances. The $[MH]^+/\Sigma[DAG]^+$ ratio can be classified into one of two cases: $[MH]^+/\Sigma[DAG]^+ \leq 1$, or $[MH]^+/\Sigma[DAG]^+ > 1$. The case when $[MH]^+/\Sigma[DAG]^+ = 0$ is a subset of the case when $[MH]^+/\Sigma[DAG]^+ \leq 1$, so a special case for $[M + H]^+ = 0$ is not required. Therefore, selecting the $[MH]^+/\Sigma[DAG]^+$ ratio as the Critical Ratio to represent the abundance of the $[M + H]^+$ ion and its relationship to the $[DAG]^+$ fragment ions is the better choice, because it leads to a simpler construct, which requires only two cases and remains bounded in all observed circumstances. In all instances, the Critical Ratios, which are the primary elements in the BUS construct, have been chosen to be as simple as possible and yet still convey more information in fewer variables than the raw mass spectrum.

There is another consideration and guiding principle that is inherent in the BUS. Since the BUS is a construct based on data from MS, it inherently incorporates and reflects the two important rules for data from MS: (i) All relative abundances are limited to a maximum individual value of 100%, and (ii) one ion abundance must be 100%. Since the tallest peak in a mass spectrum is normalized to 100%, one peak always represents 100%. The BUS ensures that all calculated values are less than or equal to 100%, since this is the limit imposed by MS. And the BUS determines which peak is the tallest and establishes it as

100%. Of course, 100 per*cent* (one hundred per hundred) as a pure ratio is 1.00. The Critical Limits within the BUS are what keep all values limited to being within the two rules imposed by MS. The value of 1.00 for several of the ratios also has other inherent meanings that provide structural information regarding the TAG (for instance, if $[AA]^+/[AB]^+ > 1$ for a Type II TAG, this provides structural information regarding the identity of the regioisomers).

For a Type II TAG, only the first two Critical Ratios mentioned earlier are necessary to specify the appearance of the mass spectrum. The $[AA]^+/[AB]^+$ ratio is used at face value in Equations 3 and 4 to provide information on the composition of the regioisomers of the TAG. The other Critical Ratio, $[MH]^+/\Sigma[DAG]^+$, may be used to provide insight into the degree of unsaturation in the TAG. These two numbers, the two Critical Ratios for a Type II TAG, provide more information in fewer values than the three raw abundances that constitute the raw mass spectrum. The mass spectrum of a Type III TAG contains four primary peaks and so requires three critical ratios. However, the $[MH]^+/\Sigma[DAG]^+$ ratio provides the same kind of information about a Type III TAG as it does for a Type II TAG. The $[MH]^+/\Sigma[DAG]^+$ ratio provides information to correlate the total amount of unsaturation in the three FA to the abundance of the protonated molecule. For a Type I TAG, the mass spectrum contains only two peaks, which are the $[M + H]^+$ peak and one single $[DAG]^+$ fragment ion. For a Type I TAG, the BUS requires only the $[MH]^+/\Sigma[DAG]^+$ ratio to reproduce the mass spectrum, and it also provides information regarding the number of sites of unsaturation in the TAG molecular species. This critical ratio provides information regarding the abundance of the $[M + H]^+$ ion, when properly classified, and also provides information to relate the abundance of this ion to the $[DAG]^+$. So with the $[MH]^+/\Sigma[DAG]^+$ ratio, as with the $[AA]^+/[AB]^+$ ratio already discussed, more information is provided in this Critical Ratio than in the raw abundances. The proper selection of the complete set of Critical Ratios for Types I, II, and III TAG, of which the first Critical Ratio is the $[MH]^+/\Sigma[DAG]^+$ ratio, allows the BUS to be completely self-contained and to operate within the rules imposed by MS in all observed circumstances.

Construction of the $[AC]^+/([AB]^+ + [BC]^+)$ ratio for a Type III TAG. A Type III TAG has three different FA, ABC, and these produce three possible $[DAG]^+$ fragment ions, $[AB]^+$, $[BC]^+$, and $[AC]^+$. These fragment ions may contain A, B, and C in any combination of *sn*-1, *sn*-2, and *sn*-3 positions, and in a randomized mixture, these are observed to be statistically distributed throughout all positions (7). Statistically speaking, the abundances of all three ions, $[AB]^+$, $[BC]^+$, and $[AC]^+$, should be identical in the absence of nonstatistical influences. However, fragment ions are not observed with equal abundance in APCI-MS or ESI-MS/MS mass spectra. It has been observed (10,11) that the abundance of the ion formed from loss of the FA in the *sn*-2 position, which gives the $[sn-1,3-AC]^+$ fragment, is the lowest of the three possible $[DAG]^+$ fragment ions. With this rule, all Type III TAG could be categorized, and the identities of the FA in the *sn*-2 position known. All four possibilities for the

A and C FA with B still remain: $[sn\text{-}1,2\text{-}AB]^+$ and $[sn\text{-}2,3\text{-}BC]^+$ or $[sn\text{-}1,2\text{-}CB]^+$ and $[sn\text{-}2,3\text{-}BA]^+$. But the $[sn\text{-}1,3\text{-}AC]^+$ isomer can be identified as the ion with the lowest abundance, so a piece of structural information may be known from the ion having the lowest abundance.

For simplicity, the isobaric $[sn\text{-}1,3\text{-}AC]^+$ or $[sn\text{-}1,3\text{-}CA]^+$ regioisomers are usually referred to more briefly as $[sn\text{-}1,3\text{-}AC]^+$, with the understanding that APCI-MS cannot distinguish between the $[sn\text{-}1,3\text{-}AC]^+$ and $[sn\text{-}1,3\text{-}CA]^+$ isomers, and so both possibilities are always implied herein. By putting the $[sn\text{-}1,3\text{-}AC]^+$ abundance alone in the numerator of the second Critical Ratio of the Type III TAG (the $[MH]^+/\Sigma[DAG]^+$ ratio is the first Critical Ratio for all TAG), the second Critical Ratio can be used to reflect the trend in the $[sn\text{-}1,3\text{-}AC]^+$ abundance with regioisomeric structure. This is analogous to the way the $[AA]^+/[AB]^+$ ratio is used to provide structural information for a Type II TAG, except the means for quantitative analysis of the regioisomers of Type III TAG have not yet been developed as thoroughly as the quantification of Type II TAG has (see Jakab *et al.* (42) and Eqs. 3 and 4).

Thus, the Critical Ratio $[AC]^+/([AB]^+ + [BC]^+)$ for a Type III TAG first provides a piece of information, which is the identity of the $[sn\text{-}1,3\text{-}AC]^+$ isomer, and then allows the abundance of the $[sn\text{-}1,3\text{-}AC]^+$ isomer to be calculated, when properly classified by the Critical Limits. This Critical Ratio also contains information to relate the $[AC]^+$ ion abundance to the two other ions that make up the mass spectrum.

In a complex mixture of TAG, the complete identification of all TAG molecular species requires the chromatographic information provided by the on-line separation, in addition to the masses provided by APCI-MS, to differentiate the many isobaric molecular species having overlapping masses, such as $[OO]^+$ and $[SL]^+$, $[OL]^+$ and $[SLn]^+$, etc. $[OO]^+$ and $[SL]^+$ are separated by a good chromatographic method (35), and so these can be differentiated and the characteristic Critical Ratios for each TAG molecular species can be constructed.

For a Type III TAG, if all FA in a TAG were distributed statistically and there was no influence by different levels of unsaturation or preferential loss, then the $[AC]^+$, $[AB]^+$, and $[BC]^+$ fragment abundances should all be equal, and the $[AC]^+/([AB]^+ + [BC]^+)$ ratio would be 0.5. An $[AC]^+/([AB]^+ + [BC]^+)$ ratio other than 0.5 indicates that nonstatistical influences are affecting the abundances. An $[AC]^+/([AB]^+ + [BC]^+)$ ratio greater than 1 would certainly indicate a preference for $[AC]^+$. According to literature precedent, one should be able to identify the $[sn\text{-}1,3\text{-}AC]^+$ fragment as the fragment with the lowest $[AC]^+/([AB]^+ + [BC]^+)$ ratio, and thus have a substantial piece of information regarding the TAG, which came from just this one Critical Ratio. Thus, one should choose to construct the $[AC]^+/([AB]^+ + [BC]^+)$ ratio using the smallest abundance in the numerator, since this has been correlated (10,11) with being the $[sn\text{-}1,3\text{-}AC]^+$ isomer.

Throughout this work, the identities of A, B, and C are irrespective of mass but reflect only the regioisomeric position of the FA on the backbone. This is analogous to the Type II TAG, in which, for OPO, the FA represented by A, out of ABA, has

a larger mass than the FA in the B position. On the other hand, in POP, the A FA has a mass that is lower than the FA in the B position. ABC refers to the regioisomeric positions of FA, when properly assigned, whereas the identities of the $[DAG]^+$ are characterized first by mass, then by their chromatographic elution at that mass, and then by comparison with tabulated masses (11). With this approach, the A and C can be identified and labeled specifically, and the FA in the $sn\text{-}2$ position can be identified.

With the FA in the $sn\text{-}2$ position known, the identities of the FA in the $sn\text{-}1$ and $sn\text{-}3$ positions are known to constitute the isobaric $[DAG]^+$ fragment possibilities, $[sn\text{-}1,2\text{-}AB]^+$ and $[sn\text{-}2,3\text{-}BC]^+$, or $[sn\text{-}1,2\text{-}BA]^+$ and $[sn\text{-}2,3\text{-}CB]^+$. No definitive trend has yet been reported to distinguish between $[sn\text{-}1,2\text{-}AB]^+$ and $[sn\text{-}2,3\text{-}BA]^+$ or between $[sn\text{-}2,3\text{-}BC]^+$ and $[sn\text{-}1,2\text{-}CB]^+$. It is reasonable to expect that, after the $[AC]^+/([AB]^+ + [BC]^+)$ ratios of a sufficient number of Type III TAG have been tabulated, trends in this ratio will be observable and will be correlated with the regioisomeric structures of the TAG.

The literature precedent for APCI-MS analysis of Type III TAG is currently based on a limited number of observations (10,11). Because of this, the ability to use the $[AC]^+/([AB]^+ + [BC]^+)$ ratio for identification of regioisomers in complex mixtures of TAG has not yet been developed. Also, not all nonstatistical influences have been characterized. The influence of the number of double bonds and their positions in the fatty chain (n-6 vs. n-3) has already been discussed herein in detail for a Type II TAG, and so it is reasonable to expect that similar trends, relating increased levels of polyunsaturation to increased abundances of ions containing the FA with more double bonds, will be observed for Type III TAG. Furthermore, the positions of the double bonds were shown to have an influence on Type II TAG, as discussed herein, so the positions of the double bonds in the FA of Type III TAG could also be expected to exert an influence on the abundances of ions observed in APCI-MS mass spectra. If the $[AC]^+/([AB]^+ + [BC]^+)$ ratios of numerous Type III TAG from different mixtures of TAG having known compositions of regioisomers are accumulated and tabulated (as is done with Type II TAG), it may be possible to move toward a more quantitative interpretation of this Critical Ratio. For now, some expected and probably some unexpected nonstatistical influences remain to be characterized. Regardless of how specifically information from this Critical Ratio can be derived at this time, it is clear that the $[AC]^+/([AB]^+ + [BC]^+)$ ratio as a single number already provides more information than the raw abundance alone. The $[AC]^+$ abundance must be compared with the other abundances to know whether it is the smallest and whether it is therefore the $[sn\text{-}1\text{-}AC]^+$. The abundance does not provide the desired information if used by itself. It provides the desired information regarding the regiospecific identity of the ion exhibiting that abundance only if it is taken as a ratio to the other ions. As with the other Critical Ratios, the numerator provides the abundance of one ion directly, when classified correctly in the BUS, and the ratio provides information to relate this ion to the other ions.

So while it remains to be further characterized, this Critical

Ratio as a single numeric value for a Type III TAG provides not only the same, but more information, when used with the BUS, than the original raw abundance of [AC]$^+$ as a single number.

Construction of the [BC]$^+$/[AB]$^+$ ratio. No distinctive preference for the [*sn*-1,2-AB]$^+$ position compared with the [*sn*-2,3-BC]$^+$ position has been reported using APCI-MS data. There appears to be minimal difference energetically, in an APCI source, between loss of the FA in the *sn*-1 position and loss of the FA in the *sn*-3 position. Nevertheless, if there is any *sn*-1,2 vs. *sn*-2,3 preference, this would be reflected in the ratio [BC]$^+$/[AB]$^+$, if [BC]$^+$ is the abundance of the *sn*-2,3 isomer and [AB]$^+$ is the abundance of the *sn*-1,2 isomer, regardless of mass. The ratio [BC]$^+$/[AB]$^+$ would constitute the Critical Ratio necessary to specify any [*sn*-1,2-AB]$^+$ vs. [*sn*-2,3-BC]$^+$ preference (or vice versa). Based on previous reports, at this time no observed trends that correlate regioisomeric structures of Type III TAG with different amounts of unsaturation in the [*sn*-1,2-AB]$^+$ vs. [*sn*-2,3-BC]$^+$ FA can be cited. However, several expected trends can be discussed.

Just as was observed with Types I and II TAG, the amount of unsaturation in the FA should have an influence on the abundances of the [DAG]$^+$ fragment ions that contain the FA. Since there appears to be minimal influence due to the regioisomeric position of the FA in the TAG at the *sn*-1,2 vs. *sn*-2,3 positions, the degree of unsaturation in the fragment [AB]$^+$, compared with the unsaturation in [BC]$^+$, may exhibit a greater influence on the [BC]$^+$/[AB]$^+$ ratio than the unreported influence due to the regioisomeric identity. Of course, the locations and number of the double bonds were of primary importance in determining the effect of the double bonds on the ion abundances for Type II TAG and therefore should be expected to exert a similar influence on Type III TAG that contain PUFA.

Although the amount of information that can be derived from the [BC]$^+$/[AB]$^+$ ratio is currently limited, it does provide one piece of information at face value. This information is found by comparing the [BC]$^+$/[AB]$^+$ ratio to its inherent Critical Value of 1. If the [BC]$^+$/[AB]$^+$ ratio is greater than 1, the [BC]$^+$ ion is larger than [AB]$^+$ ion, but if this third Critical Ratio for a Type III TAG is less than 1, [AB]$^+$ is larger than [BC]$^+$. It can be seen that this third Critical Ratio for a Type III TAG can be used with the BUS, which incorporates the rules of MS, to provide the two numerical values that are the raw abundances of the [BC]$^+$ and [AB]$^+$ fragment ions from the one numerical value. Thus, this Critical Ratio provides the same information (two abundances) in less space (one number instead of two) than the raw abundances. Whether more information can be derived from this ratio will be determined by future reports.

Summary of the construction of the Critical Ratios. The Critical Ratios just described can be constructed and directly interpreted at face value to provide information regarding structural trends. These ratios provide a method for visualizing trends that is more direct than using the raw abundances alone. The trends are not as apparent in the raw data as they are in the Critical Ratios. Therefore, is it useful to construct these Critical Ratios as an aid to qualitative analysis of TAG.

Not only do these Critical Ratios highlight structural trends, but also they constitute a reduced data set from which the mass spectrum of any TAG can be reconstructed in its entirety. The Critical Ratios can be used with inherent Critical Values and calculated Critical Limits to classify all TAG into Cases. The Case into which a TAG is classified provides all of the equations necessary to calculate the abundances of every ion in the mass spectrum as well as the sum of all ions. This report will present the basic equations that encompass every structural possibility within the TAG Lipidome. The solution to the *Triacylglycerol Lipidome* comes in the form of the Critical Ratios operated into the BUS, to accomplish the classification of the TAG into the proper Cases, based on the Critical Values and Critical Limits. The ratios are applied with an interpretation matrix that provides structural information from the Critical Ratios as they operate through the Critical Values and Critical Limits. Once a TAG is properly classified by its Critical Ratios, the Case indicates the correct equations to use for the solution of all ion abundances. This combination of Critical Ratios with Critical Values and Critical Limits used to define the Cases, along with the interpretation matrix and the equations for each Case constitutes the BUS to the TAG Lipidome. This solution allows the primary ions in the mass spectrum of any TAG to be reproduced, and the Critical Ratios can be used for a quantitative description for the set of structural possibilities exhibited by the TAG.

Method for quantitative analysis based on ion abundances determined by APCI-MS. During the routine processing of data from LC/APCI-MS using the quantitative method of Byrdwell *et al*. (7,34,35), the area under every peak is integrated in every extracted ion chromatogram (EIC) of each *m/z* value for every [DAG]$^+$ fragment ion and protonated molecule, [M + H]$^+$. The peaks that gave the areas of [DAG]$^+$ fragment ions and protonated molecules, [M + H]$^+$, that come from a particular TAG must elute at the same specific retention time, since they come from the same TAG. Therefore, the areas under the fragment ion and protonated molecule chromatographic peaks constitute an average mass spectrum across the retention time window used for integration. The average mass spectrum is calculated as the normalized percent composition of the areas of the fragment ions and the protonated molecule across the integrated chromatographic retention time window for a particular TAG. Small differences in retention times at the beginning and end of the fragment peaks have no substantial impact on the integrated area of each peak. The integrated areas provide a good representation of the mass spectrum averaged across a chromatographic peak. Typical ion chromatograms that are integrated to give peak areas are shown and discussed in the subsequent section entitled Implementation of the BUS. All solutions provided herein work equally well on an average mass spectrum that is produced from integrated peak areas or from manual qualitative analysis, or from a single mass spectrum manually acquired. Of course, there is some variability in abundances between single replicate mass spectra, and this variability is greater for TAG present at low levels. Whichever abundances

are used to produce the Critical Ratios, the mass spectrum from which they come is exactly reproduced by the BUS.

As mentioned, the first Critical Ratio is the ratio of the percent abundance of the protonated molecule as a ratio to the sum of all [DAG]⁺ fragment ions:

$$\text{Critical Ratio 1} = \left(\frac{[MH]^+}{\sum [DAG]^+} \right) \qquad [5]$$

Table 2 lists the Critical Ratios for a 35-TAG mixture of synthetic TAG. The critical ratios are listed as a percentage simply for the most convenient display of four (or five) significant figures, with up to two decimal places. This is the same method of representation that Jakab *et al.* (42) used in their analysis of the [AA]⁺/[AB]⁺ ratio for characterization of mixtures of LOL/LLO. It is important to realize that the Critical Ratios as percentages must be converted to pure ratios (fractions), by dividing by 100, before they are used in the equations below. Throughout the following discussion, all ratios are expressed in pure fraction form, not percentage form. As a fraction, 100% equals 1.00, so 1.00 is the upper limit in the equations below. In the spreadsheet formulas used for the automated implementation of the BUS, the division of the ratio by 100 is incorporated into the formulas.

As already discussed, the first Critical Ratio can be used to define the overall unsaturation of a molecule. It is well known that saturated TAG have a [MH]⁺/Σ[DAG]⁺ ratio that is either very low or zero. The polyunsaturated TAG have large values of the [MH]⁺/Σ[DAG]⁺ ratio. The [MH]⁺/Σ[DAG]⁺ ratio for OOO is a very low value of 0.0324, and so for this Type I TAG (a mono-acid TAG), a [DAG]⁺ is the base peak, and the protonated molecule abundance is simply the [MH]⁺/Σ[DAG]⁺ ratio, expressed as a percentage, 3.24%. For LLL and LnLnLn, the large [MH]⁺/Σ[DAG]⁺ ratio indicates that [M + H]⁺ is the base peak, and the [DAG]⁺ abundance is easily calculated from the inverse of the [MH]⁺/Σ[DAG]⁺ ratio.

The second Critical Ratio depends on whether the molecule is a Type II or Type III TAG. For a Type II TAG, the second Critical Ratio is [AA]⁺/[AB]⁺. For a Type III TAG, the second Critical Ratio is ([AC]⁺/([AB]⁺ + [BC]⁺)):

Type II :
$$\text{Critical Ratio 2} = \left(\frac{[AA]^+}{[AB]^+} \right) \qquad [6a]$$

Type III :
$$\text{Critical Ratio 2} = \left(\frac{[AC]^+}{([AB]^+ + [BC]^+)} \right) \qquad [6b]$$

This second Critical Ratio has an obvious relationship to the positional preference of a TAG. It is expected that the ([AA]⁺/[AB]⁺) ratio should always be less than 1, unless there is a strong [AA]⁺ positional preference. Likewise, the ratio ([AC]⁺/([AB]⁺ + [BC]⁺)) should be less than 1 unless there is a strong [AC]⁺ positional preference. But the degree of unsaturation in the [AB]⁺ or [AC]⁺ fragment also has an effect on this ratio. Deconstruction of the second Critical Ratio of an ABC TAG into the two components of positional preference and de-

gree of unsaturation remains to be accomplished. For now, this ratio can simply be compared to positional isomer standards.

The third Critical Ratio is only observed from Type III TAG. It is the ratio of [BC]⁺/[AB]⁺, or the ratio of the *sn*-2,3 [DAG]⁺ to the *sn*-1,2 [DAG]⁺. For now, it is assumed that there is no particular preference between these two, but evidence at a future date may allow quantification of a preference for the *sn*-1,2 [DAG]⁺ peak over the *sn*-2,3 [DAG]⁺ peak or vice versa. All else being equal, a [BC]⁺/[AB]⁺ of ≤1 is used herein as the default assumption (assume [AB]⁺ ≥ [BC]⁺). The reason for this is discussed shortly. In the absence of any preference or assumption, the [BC]⁺/[AB]⁺ ratio may be less than one or greater than 1 with equal statistical probability, thereby giving an equal probability of Case 5 or Case 6.

THE BUS

The BUS for a Type I TAG. Now that the critical ratios have been defined, it is useful to examine the visualization approach that led to the definition of the Cases. Figure 2 shows the appearance of idealized APCI-MS mass spectra of TAG. The axes in these figures have a maximum value of 1, representing 100% as a pure ratio. AAA TAG are shown first in this figure.

Since an AAA TAG has only one [DAG]⁺ and the [M + H]⁺, it is obvious that the Critical Value that determines which peak is the base peak occurs when both [AA]⁺ and [MH]⁺ have their maximal values, and [MH]⁺/Σ[DAG]⁺ is equal to 1. The Critical Value for an AAA TAG is depicted in the upper right panel of Figure 2, Part I. From this Critical Value of [MH]⁺/Σ[DAG]⁺ = 1, if the [MH]⁺ were to diminish by the least amount, the [MH]⁺/Σ[DAG]⁺ ratio would be less than 1 and [AA]⁺ would be the base peak. This is referred to as Case 1, and the solution would use the equation shown in Scheme 1, Part I, for Case 1.

On the other hand, if the [DAG]⁺ were to diminish by the least amount, then the [MH]⁺/Σ[DAG]⁺ ratio would be larger than 1 and [M + H]⁺ would be the base peak. This is referred to as Case 2, and the solution would use the equation listed in Scheme 1, Part I, for Case 2. No other Critical Limit is necessary to specify the Case for a Type I TAG. Once the case has been specified, the actual percentages of [M + H]⁺ and the [AA]⁺ abundances are given by the equations in Scheme 1, Part I, for either the Case 1 solution [AA]⁺ base peak) or the Case 2 solution [M + H]⁺ base peak). The value of 1 serves as a Critical Value for all Types I, II, and III TAG. If the [MH]⁺/Σ[DAG]⁺ ratio is greater than 1 for any TAG, this automatically means that [M + H]⁺ is the base peak and specifies a Case 2 solution. More generally, if any Critical Ratio has a value greater than 1, the numerator is automatically the largest peak of the peaks used to construct the ratio.

Using a Type I TAG as an example, the pattern in the equations in the BUS can now be described. The sum of all ions can be referred to as the Σ(I⁺) for any TAG. For a Type I TAG, the sum of all ions, Σ(I⁺), is simply equal to the sum of the protonated molecule ion and the single [DAG]⁺ fragment ion, Σ([MH]⁺ + [DAG]⁺). Thus, Σ(I⁺) = Σ([MH]⁺ + [DAG]⁺). Similarly, the sum of all ions for any TAG is equal to the sum

I) 'AAA' TAG   Critical value = 1.0   **Critical Value :**

Case 1 $[AA]^+$ $[MH]^+$

Case 2 $[MH]^+$ $[AA]^+$

$[AA]^+$ $[MH]^+$

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{100\%}{100\%} = \frac{1.00}{1.00} = 1$$

II) 'ABA/AAB' TAG   Critical value = 0.5

Case 1.0 $\Sigma[DAG]^+$ $[MH]^+$

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{100\%}{200\%} = 1/2$$

Case *n.n.n* $\Sigma[DAG]^+$ $[MH]^+$

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{100\%}{300\%} = 1/3$$

Critical Limits :

Case *n.3* $\Sigma[DAG]^+$ $[AB]^+$ $[MH]^+$ $[AA]^+$

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{1}{1+\frac{[AA]^+}{[AB]^+}}$$

Case *n.4.n* $\Sigma[DAG]^+$ $[AC]^+[MH]^+$

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{1}{1+\frac{1}{\frac{[AC]^+}{([AB]^+ +[BC]^+)}}}$$

FIG. 2. Generalized representations of mass spectra used to calculate Critical Ratios. Also, generalized mass spectra that demonstrate Critical Values and Critical Limits are shown.

of the protonated molecule plus the sum of the $[DAG]^+$ fragment ions: $\Sigma(I^+) = \Sigma([MH]^+ + \Sigma[DAG]^+)$. The BUS for a Type I TAG shows that if the $[MH]^+/\Sigma[DAG]^+$ ratio is less than the Critical Value of 1, then the solution obeys Case 1. According to Case 1, the $[DAG]^+$ fragment is the base peak and has an abundance of 100% (= 1.00 as a pure ratio). In such a case, the sum of the ions $\Sigma(I^+)$ is $(1 + ([MH]^+/\Sigma[DAG]^+))$. For instance, OOO has an $[MH]^+/\Sigma[DAG]^+$ ratio of 0.0324. This ratio is less than 1, so OOO is solved using Case 1.

Classifying this TAG as a Case 1 TAG first provides a piece of information, which is that the $[DAG]^+$ fragment is the base peak, and then it provides the equation to use to calculate the abundance of the $[M + H]^+$ ion. The percent abundance of the

$[M + H]^+$ ion is given by $([MH]^+/\Sigma[DAG]^+) \times 100$, as shown in Scheme 1 Part I, or $(0.0324 \times 100) = 3.24\%$. Then the sum of all ions is $\Sigma(I^+) = \Sigma([DAG]^+ + [MH]^+) = 100\% + 3.24\% = 103.24\%$, which is 1.0324 as a pure ratio. Thus, for this Case 1 TAG, the following equivalences are true:

$$\sum(I^+) = \sum\left([MH]^+ + [DAG]^+\right) = \left(1 + \left(\frac{[MH]^+}{\sum[DAG]^+}\right)\right) = (1+.0324) = 1.0324, \text{ or } = 103.24\%$$

On the other hand, a TAG such as LLL has an $[MH]^+/\Sigma[DAG]^+$ ratio of 1.2007. This is greater than 1, and so Scheme 1, Part I, shows that this would be classified as a Case 2 solution. This classification immediately provides a piece of information, which is that the protonated molecule, $[M + H]^+$, is the base

peak, and then it provides the equation used to calculate the abundance of the [DAG]$^+$ fragment ion. The [DAG]$^+$ ion abundance (%) is given by $(1/([MH]^+/\Sigma[DAG]^+)) \times 100$, or $(1/1.2007) \times 100$, which equals 0.8328×100, or 83.28%. Thus, the base peak is known by the classification process, and the other abundance is given by the equation dictated by the classified BUS. The sum of the ions in the mass spectrum is $100 + 83.28\% = 183.28\%$, or 1.8328 as a pure ratio. The second solution can be seen to give the following equivalences:

$$\sum(I^+) = \sum([MH]^+ + [DAG]^+) = \left(1 + \frac{1}{\dfrac{[MH]^+}{\sum[DAG]^+}}\right) = \left(1 + \frac{1}{1.2007}\right) = 1.8328 \text{, or } = 183.28\%$$

There are only two possible solutions for a Type I TAG, and these may be summarized by the equivalence:

$$\sum(I^+) = \sum([MH]^+ + [DAG]^+) = \left\{\underset{\text{Case 1}}{\left(1 + \left(\frac{[MH]^+}{[DAG]^+}\right)\right)} \text{ or } \underset{\text{Case 2}}{\left(1 + \frac{1}{\left(\frac{[MH]^+}{[DAG]^+}\right)}\right)}\right\}$$

This equation shows that the sum of all ions is equal to the sum of the protonated molecule plus the one [DAG]$^+$ fragment ion, and this is equal to one of two possibilities, depending on whether it is a Case 1 or a Case 2 solution, as determined by whether the [MH]$^+$/Σ[DAG]$^+$ ratio is less than the Critical Value of 1 or larger than 1. Scheme 1, Part I, shows the equivalence just given. The foregoing two examples, for OOO and LLL, demonstrate that this equivalence is true for Type I TAG having an [MH]$^+$/Σ[DAG]$^+$ ratio less than 1 (OOO), or a ratio greater than 1 (LLL).

The BUS for a Type II TAG. For Types II and III TAG, a [MH]$^+$/Σ[DAG]$^+$ ratio greater than 1 certainly indicates that [M + H]$^+$ is the base peak, but an [MH]$^+$/Σ[DAG]$^+$ ratio less than 1 does not, by itself, indicate that [M + H]$^+$ is not the base peak. Thus, for Types II and III TAG, an [MH]$^+$/Σ[DAG]$^+$ ratio greater than 1 is sufficient, but not necessary, to define [M + H]$^+$ as the base peak for any TAG. Types II and III TAG have other Critical Values inherent in the construction of the ratios. The same logic demonstrated for AAA TAG of setting all peaks equal to 1 at the Critical Value and comparing the observed Critical Ratio to this Critical Value to determine the identity of the base peak is also applicable to Types II and III TAG.

The Critical Value for a Type II TAG is depicted in the fourth panel down in Figure 2. At the Critical Value for a Type II TAG, the [M + H]$^+$ and both [DAG]$^+$ have their maximum values of 1.00, or 100%. This circumstance is rarely, if ever, actually observed, but it serves as an inherent arithmetic equivalence point for TAG that fragment to produce two different [DAG]$^+$ ions. For any Type I, II, or III TAG, the Critical Value, at which all ions, $\Sigma(I^+)$, are at their maximum values, produces the limit that represents the minimum [MH]$^+$/Σ[DAG]$^+$ ratio that the TAG could have and still give a protonated molecule, [MH]$^+$. At the Critical Value for the [MH]$^+$/Σ[DAG]$^+$ ratio, if any [DAG]$^+$ fragment were to decrease by the least amount, the Σ[DAG]$^+$ would decrease, and the [MH]$^+$/Σ[DAG]$^+$ ratio would increase, and so this value represents the minimum of the ratio. If the [M + H]$^+$ abundance were to decrease by the least amount, it would not be the base peak, and so a piece of information would be known.

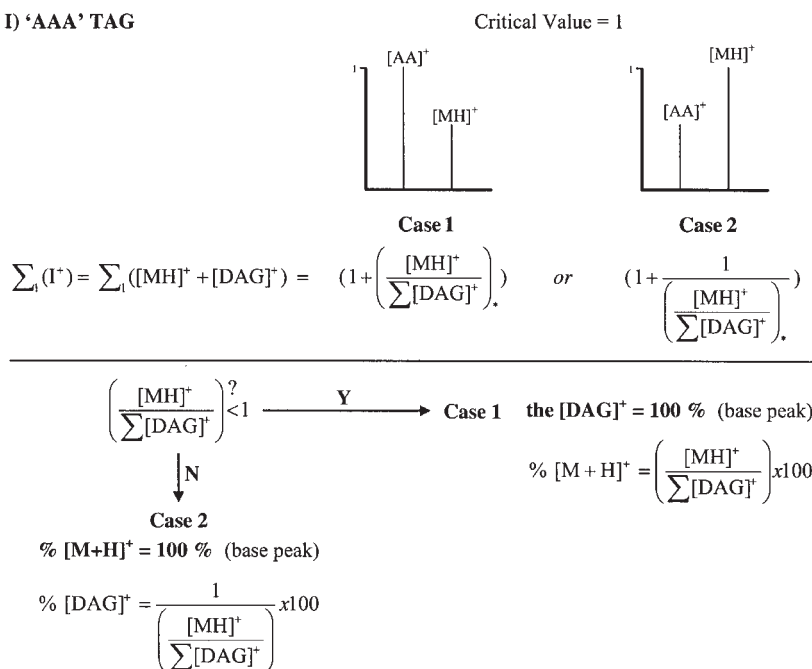

SCHEME 1, PART I. Equations to calculate the relative abundances of the [M + H]$^+$ and the [DAG]$^+$ fragment ion for an AAA TAG using the [MH]$^+$/Σ[DAG]$^+$ Critical Ratio from atmospheric pressure chemical ionization (APCI)-MS data (Table 2).

The Critical Value of the $[MH]^+/\Sigma[DAG]^+$ ratio for a Type II TAG, or ABA/AAB TAG, is 1/2, or 0.5, as shown in the fourth panel down in Figure 2. A mass spectrum with a $[MH]^+/\Sigma[DAG]^+$ ratio less than the Critical Value cannot have a protonated molecule base peak. But a $[MH]^+/\Sigma[DAG]^+$ ratio greater than the Critical Value does not immediately indicate that the protonated molecule is the base peak. The Critical Ratio must be further tested with another limit to determine whether the $[M + H]^+$ is the base peak. The Critical Value serves as the lower limit for the possibility of having a protonated molecule base peak. If the $[MH]^+/\Sigma[DAG]^+$ ratio is greater than the Critical Value, then the next limit to which it is compared is the Critical Limit, discussed next, which is the limit of the $[MH]^+/\Sigma[DAG]^+$ ratio, based on actual $[DAG]^+$ abundances, that defines whether the $[M + H]^+$ is the base peak or a $[DAG]^+$.

The Critical Limit for a Type II TAG. The Critical Limit for a Type II TAG makes use of the inherent limitations imposed by the MS construct, within which all abundances must operate. If it is known by classification that a TAG is Case 1, then a $[DAG]^+$ is known to be the base peak, and, for a Type II TAG, the possibilities for the base peak are narrowed down to two: (i) $[AB]^+$ is larger than $[AA]^+$, and so $[AB]^+$ is the base peak and has an abundance of 100%; or (ii) $[AA]^+$ is larger than $[AB]^+$, and so $[AA]^+$ is the base peak and has an abundance of 100%. In the first case, $[AB]^+$ is larger than $[AA]^+$, and so $[AB]^+$ is 100%, or is 1.00 as a pure ratio; thus, since $[AB]^+ = 1$, $[AA]^+/[AB]^+$ becomes equal to $[AA]^+/(1)$, and so $[AA]^+ = [AA]^+/[AB]^+$. In this case, the sum of the $[DAG]^+$ fragment ions is $[AB]^+ + [AA]^+ = (1.0000 + [AA]^+/[AB]^+)$. This may be summarized as:

$$\Sigma[DAG]^+(\text{ratio}) = \left(1.0000 + \frac{[AA]^+}{[AB]^+}\right) \quad or \quad \Sigma[DAG]^+(\%) = \left(1.0000 + \frac{[AA]^+}{[AB]^+}\right)x100$$

For instance, in the case of OOP, Table 2 gives an $[AA]^+/[AB]^+$ ratio of 0.3612, and since this value is less than 1, it is classified as Case 3. Along with the knowledge of the fact that there is a $[DAG]^+$ base peak, from classifying the $[MH]^+/\Sigma[DAG]^+$ ratio as Case 1, a Case 1.3 solution is dictated. In this case, $[AB]^+ = 100\%$, and so $[AA]^+ = ([AA]^+/[AB]^+) \times 100 = 0.3612 \times 100 = 36.12\%$. Then the sum of the $[DAG]^+$ ions is $1.0000 + 0.3612 = 1.3612$ as a ratio, or 136.12% as percent abundance.

On the other hand, if the ratio $[AA]^+/[AB]^+$ is greater than 1, and so is a Case 1.4 solution, then $[AA]^+$ is the base peak and has an abundance of 100% (= 1.0000). Then, since $[AA]^+ = 1$, $[AB]^+ = (1/[AA]^+/[AB]^+)) = (1/(1)/[AB]^+))$. This may be summarized as follows:

$$\Sigma[DAG]^+(\text{ratio}) = \left(1.0000 + \frac{1}{\frac{[AA]^+}{[AB]^+}}\right) \quad or \quad \Sigma[DAG]^+(\%) = \left(1.0000 + \frac{1}{\frac{[AA]^+}{[AB]^+}}\right)x100$$

Of course, since loss of the B chain in an **ABA** TAG is energetically disfavored, the $[sn\text{-}1\text{-}AA]^+$ fragment is expected and is normally observed to have a low abundance. It is most often observed as a ratio that is not only less than 1, but is often less than the 0.5 that is statistically expected. And so an $[AA]^+/[AB]^+$ ratio greater than 1 normally provides a piece of information, which is that there is a strong nonstatistical influence. This influence may be due to a structural characteristic of the FA (amount and location of unsaturation), which renders the $sn\text{-}2$ FA easily lost and gives an $[AA]^+/[AB]^+$ ratio that is larger than expected. Other nonstatistical influences may be involved that have not yet been elucidated.

To summarize the two preceding pairs of equations, if the Type II TAG is Case 1, then one of the $[DAG]^+$, $[AA]^+$ or $[AB]^+$, would be 1.00, and the sum of the $[DAG]^+$ fragment ions could be calculated as one of either of two possibilities:

$$\Sigma[DAG]^+ = \Sigma([AA]^+ + [AB]^+) = \left\{ 1 + \frac{[AA]^+}{[AB]^+} \quad or \quad 1 + \frac{1}{\frac{[AA]^+}{[AB]^+}} \right\}$$
$$\text{Case 3} \qquad\qquad \text{Case 4}$$

On the other hand, if the $[MH]^+/\Sigma[DAG]^+$ ratio is greater than the Critical Limit, then it would be a Case 2 solution, and the $[M + H]^+$ is the base peak. The equations for the $[AA]^+$ and $[AB]^+$ percent relative abundances would then be calculated using the inverses of the preceding two equations. These equations appear in the denominator of the Case 2 solutions. Likewise, these equations for the $\Sigma[DAG]^+$ appear as the denominator of the Critical Limit for a Type II TAG. At this Critical Limit, one of the $[DAG]^+$ fragment ions is 100%, or 1.00, and the other is less than 100%, based on its proper proportion, as given by either the $[AA]^+/[AB]^+$ ratio (Case 3), or $1/([AA]^+/[AB]^+)$ (Case 4). At this Critical Limit, $[MH]^+$ is also 100%, because it is the numerator of the ratio, $[MH]^+/\Sigma[DAG]^+$, for which this is the Critical Limit. The Critical Limit for a Type II TAG is pictured in the fifth (bottom) panel of Figure 2. In the hypothetical spectrum shown, one $[DAG]^+$ fragment is 1 and $[MH]^+$ is 1. From this point, if the $[MH]^+$ were to decrease by the least amount, the $[DAG]^+$ would be the base peak, whereas if the $[DAG]^+$ were to decrease by the least amount, the $[MH]^+$ would be the base peak. Hence, based on a particular $[AA]^+/[AB]^+$ ratio, the Critical Limit is the point that determines whether $[MH]^+$ or a $[DAG]^+$ is the base peak. The Critical Limit, with $[MH]^+ = 1$ and a $[DAG]^+ = 1$, is shown in Figure 2 and can be summarized in this equation:

$$\left(\frac{[MH]^+}{\Sigma[DAG]^+}\right)_{\substack{Critical \\ Limit}} = \frac{1}{1 + \frac{[AA]^+}{[AB]^+}} \quad or \quad \frac{1}{1 + \frac{1}{\frac{[AA]^+}{[AB]^+}}}$$
$$\text{Case } n.3 \qquad\qquad \text{Case } n.4$$

The area bounded by the equation set in the BUS for a Type II TAG can be envisioned as the structure shown in Figure 3, where the primary vertical axis is the $[MH]^+/\Sigma[DAG]^+$ ratio. The axis needs only to go to 1 in the figure, since anything above 1 automatically means an $[MH]^+$ base peak, and then the $\Sigma[DAG]^+$ is given by $1/[MH]^+/\Sigma[DAG]^+$, the inverse of the $[MH]^+/\Sigma[DAG]^+$ ratio. The $[MH]^+/\Sigma[DAG]^+$ ratio for a Type
FIG. 3. The shape of the Triacylglycerol Lipidome for a Type II TAG. The Critical Value and the Critical Limit determine whether the [M + H]$^+$ or a [DAG]$^+$ fragment is the base peak. The [AA]$^+$/[AB]$^+$ ratio can be compared with regioisomeric standards for quantitative analysis of the amounts of regioisomers of calibrated TAG. The statistically expected value for the [AA]$^+$/[AB]$^+$ Critical Ratio = 1/2 = 0.5, Case 1.3 and Case 2.3, is not shown on the equatorial axis.

II TAG has an inherent Critical Value = 0.5, which is the minimum [MH]$^+$/Σ[DAG]$^+$ ratio that a TAG could have and still give an [MH]$^+$ base peak. This Critical Value of 0.5 is inherent in the MS construct pertaining to TAG. The Critical Value can be seen at the intersection of the vertical and equatorial axes in Figure 3. At the Critical Value, both of the [DAG]$^+$ were set to 100% to calculate the minimum possible [MH]$^+$/Σ[DAG]$^+$ ratio that could possibly give an [MH]$^+$ base peak. In real circumstances, [AA]$^+$ and [AB]$^+$ are rarely both equal to 100%, as they are at the theoretical Critical Value. In the rare case where [AA]$^+$ exactly equals [AB]$^+$ (whether 100% or not), either Case 3 or Case 4 could be used for the solution. The "less than" sign is used for Cases 1, 3, and 5, to produce a decision, but at the Critical Values and Critical Limits both Cases are equal.

The Critical Limit for a Type II TAG occurs when the larger of the two [DAG]$^+$ fragment ions is set to 100%, and the [MH]$^+$ is set to 100%, such that a decrease in either value will determine the base peak. The Critical Limit is based on the maximum hy-

pothetical Σ[DAG]$^+$ that could be obtained by an observed [AA]$^+$/[AB]$^+$ ratio. In real circumstances, the [AA]$^+$/[AB]$^+$ ratio that is observed is often less than the statistically expected value of 0.5, because of the trends already discussed regarding formation of the [sn-1,3-AA]$^+$ fragment in the APCI-MS source. For instance, the Critical Limit for the Type II TAG OPO/OOP can be calculated using the [AA]$^+$/[AB]$^+$ ratio of 0.3612 from Table 2, as follows: *Critical Limit* = 1/(1 + 0.3612) = 1/1.3612 = 0.7346. Of course, in the case of OPO/OOP, the [MH]$^+$/Σ[DAG]$^+$ could be seen to be less than the Critical Value of 0.5, so construction of the Critical Limit would not be necessary to classify it as Case 1, if classifying it manually. In contrast, if the observed [MH]$^+$/Σ[DAG]$^+$ ratio is greater than or equal to the Critical Limit, then it is Case 2, so the [MH]$^+$ is equal to 100%. For instance, the Critical Limit for the Type II TAG LnSLn/LnLnS can be calculated using the [AA]$^+$/[AB]$^+$ ratio of 0.9510 from Table 2 as follows: *Critical Limit* = 1/(1 + 0.9510) = 0.5126. This Critical Limit for LnSLn/LnLnS is seen in Table 3. The observed [MH]$^+$/Σ[DAG]$^+$ ratio from this TAG, given in

[a]The Critical Limit is given as a percentage to two decimal places but is used as a pure ratio. For abbreviations see Table 1.

Table 2, is 0.6131. Since the observed $[MH]^+/\Sigma[DAG]^+$ ratio is greater than the Critical Limit, it is classified as Case 2, and this ratio indicates that this TAG gave an $[MH]^+$ base peak. The $[DAG]^+$ abundances then are calculated using the Case 2.3 equations given in the BUS. The Critical Limit is seen as the upper circular limit on the main axis in Figure 3.

Two notes must be considered regarding the Critical Limit for a Type II TAG: First, in the automated spreadsheet implementation given below, only the Critical Limit is calculated and used, because it is sufficient to classify Case 1 or 2. The Critical Value for a Type II TAG is not required in the automated implementation. Second, in the rare case where the $[MH]^+/\Sigma[DAG]^+$ ratio exactly equals the Critical Limit, either a Case 1 or a Case 2 solution may be used.

During the process of calculating the Critical Limit and classifying the base peak as Case 1 or Case 2, the identity of Case 3 or Case 4 is found. For Case 1.n, when Case 3 or 4 is known, the $\Sigma[DAG]^+$ can be calculated using the Critical Ratio $[AA]^+/[AB]^+$

or its inverse, $1/[AA]^+/[AB]^+$. For all Cases, the observed $([AA]^+/[AB]^+)_{Obs}$ ratio of the sample can be compared with the $[AA]^+/[AB]^+$ ratios of regiospecific standards through Equations 3 and 4 above. The linear interpolation of the $([AA]^+/[AB]^+)_{Obs}$ ratio, between the $[AA]^+/[AB]^+$ ratios of standards, $([AA]^+/[AB]^+)_{ABA}$ and $([AA]^+/[AB]^+)_{AAB}$, is depicted on the equatorial lines in Figure 3. The circles around the equatorial lines represent the $([AA]^+/[AB]^+)_{Obs}$ ratios of pure regioisomeric standards, such as those given in Table 1. Figure 3 shows $([AA]^+/[AB]^+)_{Obs}$ ratios between 0 and 1, which is the most common case. This is the Case 1.3 or Case 2.3 solution. The BUS works equally well for $([AA]^+/[AB]^+)_{Obs}$ ratios greater than 1, and those instances give a Case 1.4 or Case 2.4 solution. The BUS does not depend on the linear interpolation given by Equations 3 or 4. The use of the $([AA]^+/[AB]^+)_{Obs}$ ratio for calculation of the regioisomeric composition is separate from the BUS.

The equations in the BUS can be demonstrated using the data from the synthetic mixture of 35 TAG made from five FA

SCHEME 1, PART II. Equations to calculate the relative abundances of the $[M + H]^+$ and $[DAG]^+$ fragment ions for ABA/AAB TAG using Critical Ratios from APCI-MS data (Table 2). For abbreviation see Scheme 1, Part I.

randomly distributed among the three positions on the glycerol backbone, given in Table 2. For example, this synthetic mixture contains oleic, palmitic, linoleic, linolenic, and stearic acids, so the TAG made from these FA include POP, for which standards of pure regioisomers have been run on the same instrument, as given in Table 1. The Type II TAG POP/PPO from the synthetic mixture gave the $([AA]^+/[AB]^+)_{Obs}$ ratio of 0.6528 in Table 2, as a pure ratio, and an $[MH]^+/\Sigma[DAG]^+$ ratio of

0.0055, as a pure ratio. These ratios are processed through the BUS, Scheme 1, Part II, as follows: the $[MH]^+/\Sigma[DAG]^+$ ratio is less than 1 and is also less than the Critical Value of 0.5. This allows classification of the solution for this TAG as being a Case 1 solution. There is no need to construct the Critical Limit, because the $[MH]^+/\Sigma[DAG]^+$ ratio is less than the Critical Value. Nevertheless, the Critical Limit can still be calculated as an example. For instance, the $([AA]^+/[AB]^+)_{Obs}$ ratio

of 0.6528 for POP/PPO in Table 1 is less than 1, so it indicates a case *n*.3 solution. The Critical Limit can be calculated as:

$$\left(\frac{[MH]^+}{\Sigma[DAG]^+}\right)_{\substack{Critical \\ Limit}} = \frac{1}{1+\dfrac{[AA]^+}{[AB]^+}} = \frac{1}{1+0.6528} = 0.6050$$

As expected, the $[MH]^+/\Sigma[DAG]^+$ ratio is less than the Critical Limit, so the solution for this TAG is categorized as a Case 1.3 solution. The Case 1.3 solution indicates that $[AB]^+$ is the base peak, equaling 100%, and the percent $[AA]^+$ is given as $[AA]^+ = (([AA]^+/[AB]^+)_{Obs} \times 100)$ ratio, or $0.6528 \times 100 = 65.28\%$. Finally, the $[MH]^+$ is calculated as $[MH]^+ (\%) = ([MH]^+/\Sigma[DAG]^+) \times (1 + 1/([AA]^+/[AB]^+)_{Obs}) \times 100 = (0.0055)(1 + 0.6528) \times 100 = 0.91\%$ abundance. This abundance is seen in the tabulated mass spectral data in Table 4. This small abundance is exactly as expected from a TAG with only one site of unsaturation. It can be seen from this example that the three abundances that make up the mass spectrum can be calculated from only the two Critical Ratios. Other example solutions are shown below.

As these examples demonstrate, the two Critical Ratios for a Type II TAG can be used to calculate the three abundances of the ions in the mass spectrum. Then the second Critical Ratio may also provide information regarding the percentage composition of regioisomers in the mixture. When the $([AA]^+/[AB]^+)_{Obs}$ ratio of 0.6528 for POP/PPO from the synthetic TAG mixture is inserted into Equation 3, with the ratios $([AA]^+/[AB]^+)_{ABA} = 0.29$ and $([AA]^+/[AB]^+)_{AAB} = 0.87$ for the pure regioisomeric standards from Table 1 [based on the report of Byrdwell and Neff (43)], the calculated % ABA is given as:

$$\%ABA = \frac{\left(\dfrac{[AA]^+}{[AB]^+}\right)_{AAB} - \left(\dfrac{[AA]^+}{[AB]^+}\right)_{Obs}}{\left(\dfrac{[AA]^+}{[AB]^+}\right)_{AAB} - \left(\dfrac{[AA]^+}{[AB]^+}\right)_{ABA}} x100 = \frac{0.87 - 0.6528}{0.87 - 0.29} x100 = 37.45\%$$
$$\text{from}$$
$$\text{Table 1}$$

This calculation indicates that the mixture appears to contain 37.45% POP. Since the FA in this mixture are statistically distributed among all possible positions on the glycerol backbone, the POP isomer would be expected to be present in an amount equal to one-third, or 33%, with PPO and OPP making up the other two-thirds. This synthetic mixture had previously been subjected to lipase hydrolysis, and it was determined that the FA were approximately statistically distributed (7), so it is not surprising that the $[AA]^+/[AB]^+)_{Obs}$ ratio for the POP in the synthetic mixture gives a percentage that is close to the expected value of 33%, even using tabulated values for regioisomeric standards. It must be noted that the tabulated values were obtained on the same instrument. Of course, when accurate quantification is sought, fresh standards should be analyzed. From the preceding discussion and examples below, one can see that, by using the Critical Ratios, the BUS provides the abundances that make up the mass spectrum, and one of the Critical Ratios may provide additional information regarding the composition of regioisomers.

The BUS for a Type III TAG. As already discussed, Type II TAG have a Critical Value and a Critical Limit for the $[MH]^+/\Sigma[DAG]^+$ ratio, which determine the identity of the base peak. Also, the number 1 serves as the Critical Value for the $[AA]^+/[AB]^+$ ratio to determine whether $[AA]^+$ or $[AB]^+$ is larger. Type III TAG have a Critical Value and a Critical Limit for the $[MH]^+/\Sigma[DAG]^+$ ratio, and a Critical Value and

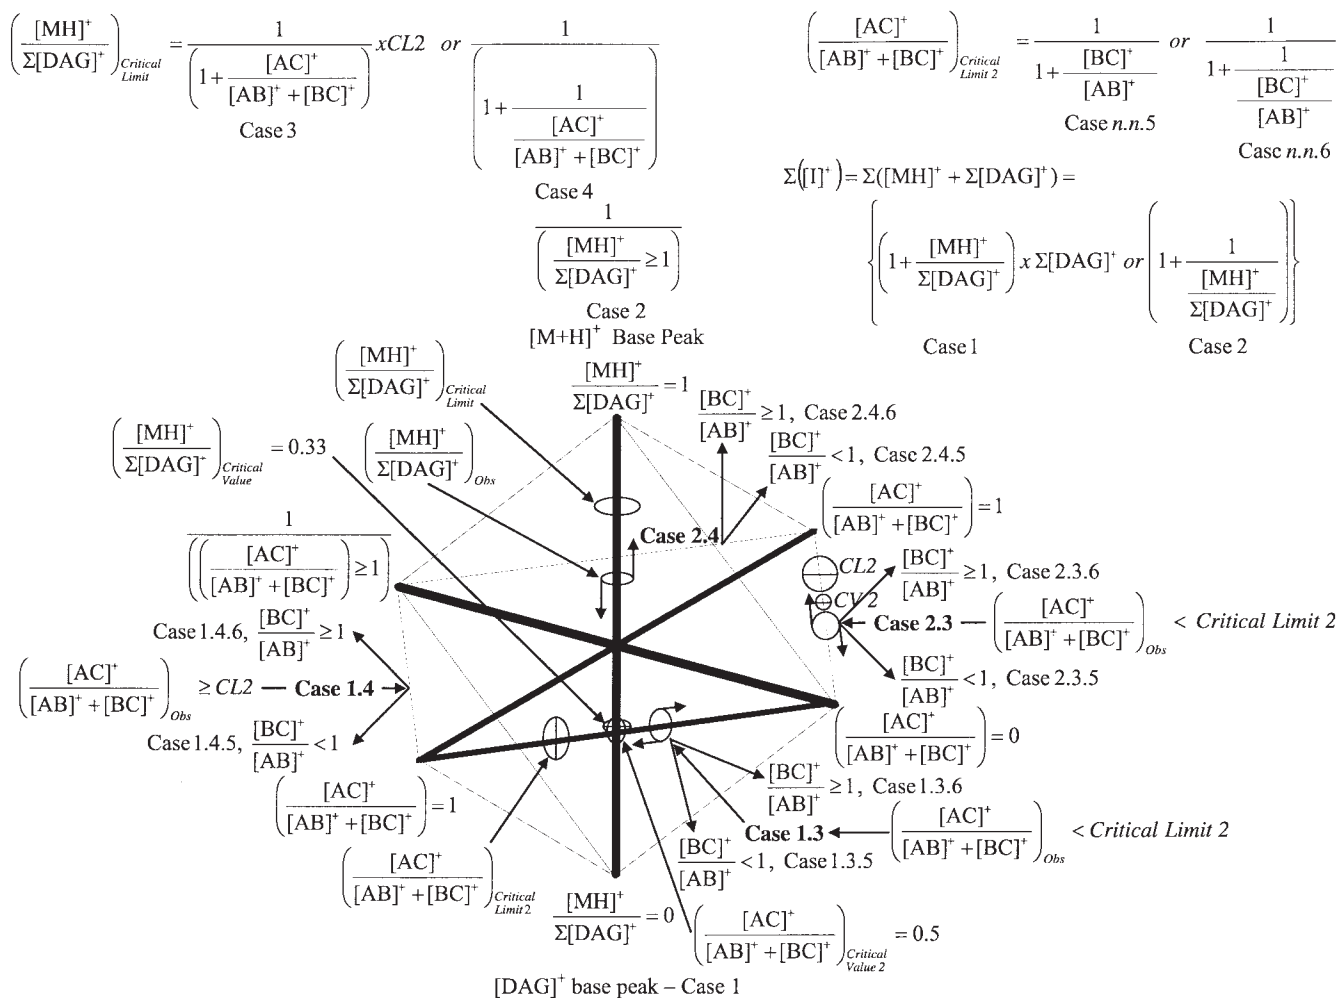
TABLE 4
Spreadsheet Formulas for the Implementation of the Bottom-Up Solution[a]

The spreadsheet formulas, listed by TAG type, are as follows:

Type I:
$[MH]^+$: = IF(Q2=**1**,(E2),(100))
$[AA]^+$: = IF(Q2=**1**,(100),(100/(E2/100)))

Type II:
$[MH]^+$: = IF(Q7=**1**,(IF(R7=**3**,(E7*(1+(G7/100))),(E7*(1+(100/G7))))),(100))
$[AA]^+$: = IF(Q7=**1**,IF(R7=**3**,G7,100),(100/((E7/100)*(1+(1/(G7/100))))))
$[AB]^+$: = IF(Q7=**1**,IF(R7=**3**,100,G7),(100/((E7/100)*(1+(G7/100)))))

Type III:
$[MH]^+$: = IF(Q27=**1**,IF(R27=**3**,(IF(S27=**5**,(E27*(1+(G27/100))*(1+(I27/100))),(E27*(1+(G27/100))*(1+(100/I27))))),(E27*(1+(100/G27)))),100)
$[AC]^+$: = IF(Q27=**1**,IF(R27=**3**,(IF(S27=**5**,(G27*(1+(I27/100))),(G27*(1+(100/I27))))),(100)),(100/((E27/100)*(1+(100/G27)))))
$[AB]^+$: = IF(Q27=**1**,(IF(R27=**3**,(IF(S27=**5**,(100),(100/(I27/100)))),(1/((G27/100)*(1+(I27/100)))))),(100/((E27/100)*(1+(G27/100))*(1+(I27/100)))))
$[BC]^+$: = IF(Q27=**1**,(IF(R27=**3**,(IF(S27=**5**,((I27/100)*100),(100))),(1/((G27/100)*(1+(100/I27)))))),(100/((E27/100)*(1+(G27/100))*(1+(100/I27)))))

[a]Assume the columns in Table 2 were labeled A through J, and the rows were numbered from 1 to 37; then the Critical Ratios would be in columns E, G, and I, and the data would be in rows 2 to 36. Imagine the Case classification in Table 3 is in columns Q, R, and S, with the same rows as Table 2.


$$\left(\frac{[MH]^+}{\Sigma[DAG]^+}\right)_{\substack{Critical \\ Limit}} = \frac{1}{\left(1 + \frac{[AC]^+}{[AB]^+ + [BC]^+}\right)} x CL2 \quad or \quad \frac{1}{\left(1 + \frac{1}{\frac{[AC]^+}{[AB]^+ + [BC]^+}}\right)}$$

FIG. 4. The Shape of the Triacylglycerol Lipidome for a Type III TAG.

a Critical Limit for the $[AC]^+/([AB]^+ + [BC]^+)$ ratio, and the value 1 serves as the Critical Value for the $[BC]^+/[AB]^+$ ratio.

The first Critical Value for a Type III TAG is the Critical Value for the $[MH]^+/\Sigma[DAG]^+$ ratio, based on all ions being equal to 1. The Critical Value for the $[MH]^+/\Sigma[DAG]^+$ ratio of a Type III TAG is depicted in the right side of the fourth panel down in Figure 2. The Critical Value of the $[MH]^+/\Sigma[DAG]^+$ ratio for an ABC TAG is 1/3, or 0.33, as shown in Figure 2. A TAG with an $[MH]^+/\Sigma[DAG]^+$ ratio less than the Critical Value cannot have a protonated molecule base peak. The Critical Value for the $[MH]^+/\Sigma[DAG]^+$ ratio is depicted as the lower horizontal ring on the vertical axis in Figure 4. The Critical Values of TAG are inherent values based on the definition of the scale (= 100%) and do not depend on a particular Critical Ratio. An $[MH]^+/\Sigma[DAG]^+$ ratio greater than the Critical Value does not immediately indicate a protonated molecule base peak. The Critical Ratio must be further tested with another limit to determine whether the $[M + H]^+$ is the base peak. As with Type II TAG, the Critical Value serves as the lower limit for the possibility of having a protonated molecule base peak. The $[MH]^+/\Sigma[DAG]^+$ ratio may be above the Critical Value, yet still

not be the base peak, since the Critical Value is based on all $[DAG]^+$ being at their maximum values, which is not usually the case. A Critical Limit, on the other hand, is based on observed Critical Ratios from data. Critical Limits used for Type III TAG, including the limit of the $[MH]^+/\Sigma[DAG]^+$ ratio that defines whether the $[M + H]^+$ is the base peak, are discussed below.

(i) Critical Limit 1 for a Type III TAG. Critical Limit 1 is used to determine whether the $[M + H]^+$ or a $[DAG]^+$ fragment ion is the base peak. Just as the $[AA]^+/[AB]^+$ ratio for a Type II TAG was used to calculate the Critical Limit for a Type II TAG, the $[AC]^+/([AB]^+ + [BC]^+)$ ratio is used in an analogous way to calculate Critical Limit 1 for a Type III TAG. The $[AC]^+/([AB]^+ + [BC]^+)$ ratio is similar to the $[AA]^+/[AB]^+$ ratio in another way, which is that both have a statistically expected value of 0.5. The $[AC]^+$ fragment is one of three possible $[DAG]^+$ fragments, and is taken as a ratio to the other two, so the ratio $[AC]^+/([AB]^+ + [BC]^+)$ has a statistically expected value of 1/2, or 0.5. Also in an analogous way, the $[AC]^+/([AB]^+ + [BC]^+)$ ratio defines the Case 3 and Case 4 possibilities for a Type III TAG, as the $[AA]^+/[AB]^+$ ratio did for

A)

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{100}{95} = \frac{20}{19}$$

$$\frac{[AA]^+}{[AB]^+} = \frac{40}{55} = \frac{8}{11}$$

e.g.- LnPLn/LnLnP

$$\frac{[MH]^+}{\sum[DAG]^+} > 1, \quad \text{so} \ [MH]^+ = 100\% \ \text{and Case } \mathbf{2}.n$$

$$\text{Critical Limit} = \frac{1}{1+\frac{8}{11}} = \frac{1}{\frac{19}{11}} = \frac{11}{19} = 0.579$$

$$\left(\text{Not Used since} \ \frac{[MH]^+}{\sum[DAG]^+} > 1\right)$$

$$\frac{[AA]^+}{[AB]^+} < 1, \ \text{so Case } 2.\mathbf{3}$$

Case 2.3

$$\%[AB]^+ = \frac{1}{\left(\frac{20}{19}\right)\left(1+\frac{8}{11}\right)} \times 100 = \frac{1}{\left(\frac{20}{19}\right)\left(\frac{19}{11}\right)} \times 100 = \frac{1}{\frac{20}{11}} \times 100 = \frac{11}{20} \times 100 = 11 \times 5 = 55\%$$

$$\%[AA] = \frac{1}{\left(\frac{20}{19}\right)\left(1+\frac{1}{\frac{8}{11}}\right)} \times 100 = \frac{1}{\left(\frac{20}{19}\right)\left(1+\frac{11}{8}\right)} \times 100 = \frac{1}{\left(\frac{20}{19}\right)\left(\frac{19}{8}\right)} \times 100 = \frac{1}{\frac{20}{8}} \times 100 = \frac{8}{20} \times 100 = 8 \times 5 = 40\%$$

B)

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{100}{145} = \frac{20}{29}$$

$$\frac{[AA]^+}{[AB]^+} = \frac{75}{70} = \frac{15}{14}$$

$$\text{Critical Limit} = \frac{1}{1+\left(\frac{1}{\frac{15}{14}}\right)} = \frac{1}{1+\frac{14}{15}} = \frac{1}{\frac{29}{15}} = \frac{15}{29} = .517$$

$$\frac{[MH]^+}{\sum[DAG]^+}\left(=\frac{20}{29}\right) \geq \text{Critical Limit}\left(=\frac{15}{29}\right),$$

$$\text{so} \ [M+H]^+ = 100\% \ \text{and Case } \mathbf{2}.n$$

$$\frac{[AA]^+}{[AB]^+} \geq 1, \ \text{so Case } 2.\mathbf{4}$$

Case 2.4

$$\%[AB]^+ = \frac{1}{\left(\frac{20}{29}\right)\left(1+\frac{15}{14}\right)} \times 100 = \frac{1}{\left(\frac{20}{29}\right)\left(\frac{29}{14}\right)} \times 100 = \frac{1}{\frac{20}{14}} \times 100 = \frac{14}{20} \times 100 = 14 \times 5 = 70\%$$

$$\%[AA]^+ = \frac{1}{\left(\frac{20}{29}\right)\left(1+\frac{1}{\frac{15}{14}}\right)} \times 100 = \frac{1}{\left(\frac{20}{29}\right)\left(1+\frac{14}{15}\right)} \times 100 = \frac{1}{\left(\frac{20}{29}\right)\left(\frac{29}{15}\right)} \times 100 = \frac{1}{\frac{20}{15}} \times 100 = \frac{15}{20} \times 100 = 15 \times 5 = 75\%$$

FIG. 5. Examples of the Bottom-Up Solution (BUS) to the Triacylglycerol Lipidome, using abundances to the nearest 5%.

the Type II TAG. Because of these similarities, the shape of the area bounded by the $[MH]^+/\Sigma[DAG]^+$ ratio and the $[AC]^+/([AB]^+ + [BC]^+)$ ratio, which are the first two Critical Ratios for a Type III TAG, is similar to the shape of the Type II TAG Lipidome pictured in Figure 3. In the diagram of the shape of the Lipidome for a Type III TAG, the $[AC]^+/([AB]^+ +$

$[BC]^+)$ ratio is on the equatorial axis instead of the $[AA]^+/[AB]^+$ ratio, as shown in Figure 4.

The $[AC]^+/([AB]^+ + [BC]^+)$ ratio has a Critical Value of 0.5 that represents the minimum value that the ratio can have and still have an $[AC]^+$ abundance larger than or equal to the $[AB]^+$ and $[BC]^+$ abundances. If the $[AC]^+/([AB]^+ + [BC]^+)$ ratio has

C)

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{100}{200} = \frac{1}{2}$$

$$\frac{[AC]^+}{([AB]^+ + [BC]^+)} = \frac{55}{145} = \frac{11}{29}$$

$$\frac{[BC]^+}{[AB]^+} = \frac{60}{85} = \frac{12}{17}$$

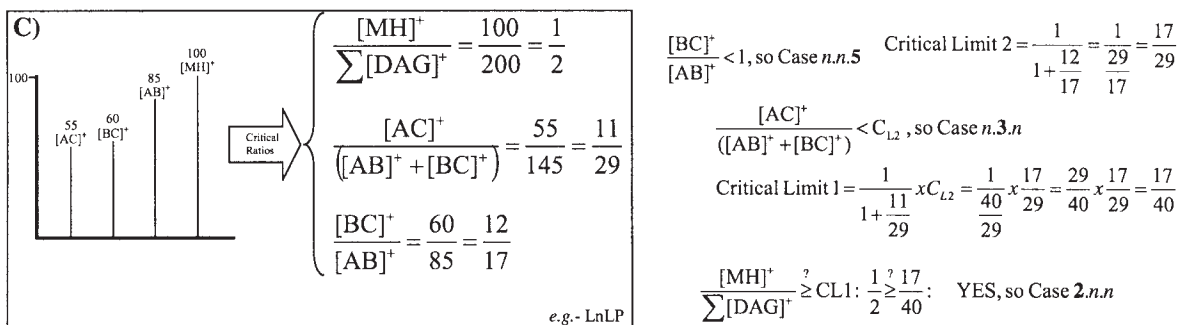
e.g.- LnLP

$\frac{[BC]^+}{[AB]^+} < 1$, so Case *n.n.***5**

$$\text{Critical Limit 2} = \frac{1}{1 + \frac{12}{17}} = \frac{1}{\frac{29}{17}} = \frac{17}{29}$$

$\frac{[AC]^+}{([AB]^+ + [BC]^+)} < C_{L2}$, so Case *n.***3**.*n*

$$\text{Critical Limit 1} = \frac{1}{1 + \frac{11}{29}} x C_{L2} = \frac{1}{\frac{40}{29}} x \frac{17}{29} = \frac{29}{40} x \frac{17}{29} = \frac{17}{40}$$

$$\frac{[MH]^+}{\sum[DAG]^+} \overset{?}{\geq} CL1: \frac{1}{2} \overset{?}{\geq} \frac{17}{40}: \quad \text{YES, so Case } \mathbf{2}.n.n$$


Therefore: Case 2.3.5

Case 2.3.5

Case 2, so [M+H]⁺ = 100 % (base peak)

$$\%[AC]^+ = \frac{1}{\left(\frac{1}{2}\right)\left(1 + \frac{1}{\frac{11}{29}}\right)} x100 = \frac{1}{\left(\frac{1}{2}\right)\left(1 + \frac{29}{11}\right)} x100 = \frac{1}{\left(\frac{1}{2}\right)\left(\frac{40}{11}\right)} x100 = \frac{1}{\frac{20}{11}} x100 = \frac{11}{20} x100 = 55\%$$

$$\%[AB]^+ = \frac{1}{\left(\frac{1}{2}\right)\left(1 + \frac{11}{29}\right)\left(1 + \frac{12}{17}\right)} x100 = \frac{1}{\left(\frac{1}{2}\right)\left(\frac{40}{29}\right)\left(\frac{29}{17}\right)} x100 = \frac{1}{\frac{40}{34}} x100 = \frac{17}{20} x100 = 17x5 = 85\%$$

$$\%[BC]^+ = \frac{1}{\left(\frac{1}{2}\right)\left(1 + \frac{11}{29}\right)\left(1 + \frac{1}{\frac{12}{17}}\right)} x100 = \frac{1}{\left(\frac{1}{2}\right)\left(\frac{40}{29}\right)\left(1 + \frac{17}{12}\right)} x100 = \frac{1}{\left(\frac{1}{2}\right)\left(\frac{40}{29}\right)\left(\frac{29}{12}\right)} x100 = \frac{1}{\frac{40}{24}} x100 = \frac{3}{5} x100 = 60\%$$

D)

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{20}{265} = \frac{4}{53}$$

$$\frac{[AC]^+}{([AB]^+ + [BC]^+)} = \frac{80}{185} = \frac{16}{37}$$

$$\frac{[BC]^+}{[AB]^+} = \frac{85}{100} = \frac{17}{20}$$

e.g.- LOS

$\frac{[BC]^+}{[AB]^+} < 1$, so Case *n.n.***5**

$$\text{Critical Limit 2} = \frac{1}{1 + \frac{17}{20}} = \frac{1}{\frac{37}{20}} = \frac{20}{37}$$

$\frac{[AC]^+}{([AB]^+ + [BC]^+)} < C_{L2}$, so Case *n.***3**.*n*

$$\text{Critical Limit 1} = \frac{1}{1 + \frac{16}{37}} x C_{L2} = \frac{1}{\frac{53}{37}} x \frac{20}{37} = \frac{37}{53} x \frac{20}{37} = \frac{20}{53}$$

$$\frac{[MH]^+}{\sum[DAG]^+} \overset{?}{\geq} CL1: \frac{4}{53} \overset{?}{\geq} \frac{20}{53}: \quad \text{NO, so Case } \mathbf{1}.n.n$$

Therefore: Case 1.3.5

Case 1.3.5

Case 1.3.5, so [AB]⁺ = 100 % (base peak)

$$\%[BC]^+ = \frac{17}{20} x100 = 17x5 = 85\%$$

$$\%[AC]^+ = \left(\frac{16}{37}\right)\left(1 + \frac{17}{20}\right)x100 = \left(\frac{16}{37}\right)\left(\frac{37}{20}\right)x100 = \frac{16}{20} x100 = 16x5 = 80\%$$

$$\%[MH]^+ = \left(\frac{4}{53}\right)\left(1 + \frac{16}{37}\right)\left(1 + \frac{17}{20}\right)x100 = \left(\frac{4}{53}\right)\left(\frac{53}{37}\right)\left(\frac{37}{20}\right)x100 = \frac{4}{20} x100 = 4x5 = 20\%$$

Continued

FIG. 5. (Continued)

E)

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{25}{250} = \frac{1}{10}$$

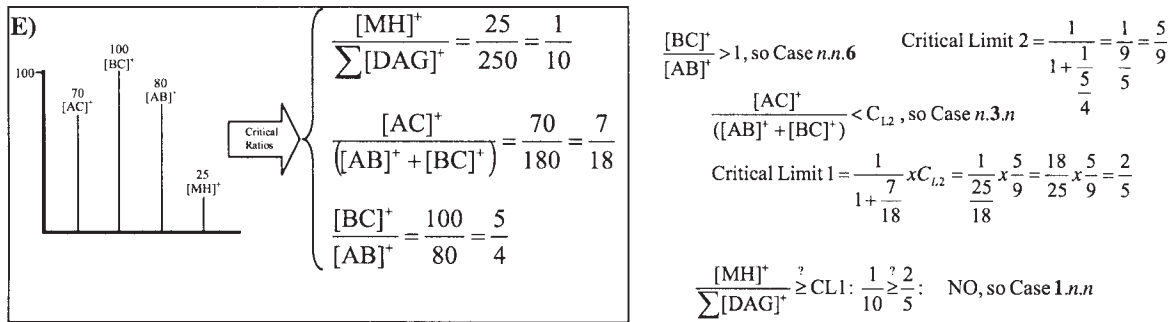
$$\frac{[AC]^+}{([AB]^+ + [BC]^+)} = \frac{70}{180} = \frac{7}{18}$$

$$\frac{[BC]^+}{[AB]^+} = \frac{100}{80} = \frac{5}{4}$$

$\frac{[BC]^+}{[AB]^+} > 1$, so Case $n.n.\mathbf{6}$ Critical Limit 2 $= \dfrac{1}{1+\dfrac{1}{\dfrac{5}{4}}} = \dfrac{1}{\dfrac{9}{5}} = \dfrac{5}{9}$

$\dfrac{[AC]^+}{([AB]^+ + [BC]^+)} < C_{L2}$, so Case $n.\mathbf{3}.n$

Critical Limit 1 $= \dfrac{1}{1+\dfrac{7}{18}} \times C_{L2} = \dfrac{1}{\dfrac{25}{18}} \times \dfrac{5}{9} = \dfrac{18}{25} \times \dfrac{5}{9} = \dfrac{2}{5}$

$\dfrac{[MH]^+}{\sum[DAG]^+} \overset{?}{\geq} CL1: \quad \dfrac{1}{10} \overset{?}{\geq} \dfrac{2}{5}: \quad$ NO, so Case $\mathbf{1}.n.n$


Therefore: Case 1.3.6

Case 1.3.6

Case 1.3.6, so $[BC]^+ = 100\,\%$ (base peak)

$$\%[AB]^+ = \frac{1}{\left(\dfrac{5}{4}\right)} x100 = \frac{4}{5} x100 = 4 x 20 = 80\%$$

$$\%[AC]^+ = \left(\frac{7}{18}\right)\left(1+\frac{1}{\dfrac{5}{4}}\right) x100 = \left(\frac{7}{18}\right)\left(\frac{9}{5}\right) x100 = \frac{7}{10} x100 = 70\%$$

$$\%[M+H]^+ = \left(\frac{1}{10}\right)\left(1+\frac{7}{18}\right)\left(1+\frac{1}{\dfrac{5}{4}}\right) x100 = \left(\frac{1}{10}\right)\left(\frac{25}{18}\right)\left(\frac{9}{5}\right) x100 = \frac{5}{20} x100 = 5 x 5 = 25\%$$

F)

$$\frac{[MH]^+}{\sum[DAG]^+} = \frac{70}{270} = \frac{7}{27}$$

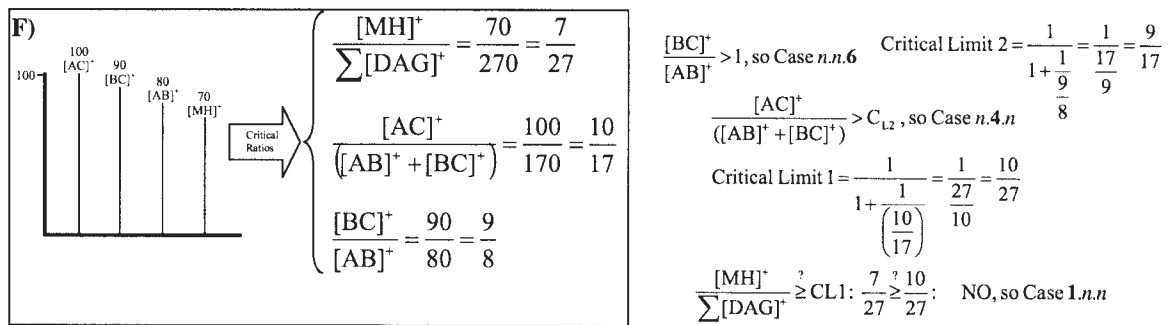
$$\frac{[AC]^+}{([AB]^+ + [BC]^+)} = \frac{100}{170} = \frac{10}{17}$$

$$\frac{[BC]^+}{[AB]^+} = \frac{90}{80} = \frac{9}{8}$$

$\frac{[BC]^+}{[AB]^+} > 1$, so Case $n.n.\mathbf{6}$ Critical Limit 2 $= \dfrac{1}{1+\dfrac{1}{\dfrac{9}{8}}} = \dfrac{1}{\dfrac{17}{9}} = \dfrac{9}{17}$

$\dfrac{[AC]^+}{([AB]^+ + [BC]^+)} > C_{L2}$, so Case $n.\mathbf{4}.n$

Critical Limit 1 $= \dfrac{1}{1+\dfrac{1}{\left(\dfrac{10}{17}\right)}} = \dfrac{1}{\dfrac{27}{10}} = \dfrac{10}{27}$

$\dfrac{[MH]^+}{\sum[DAG]^+} \overset{?}{\geq} CL1: \quad \dfrac{7}{27} \overset{?}{\geq} \dfrac{10}{27}: \quad$ NO, so Case $\mathbf{1}.n.n$


Therefore: Case 1.4.6

Case 1.4.6

Case 1.**4**.n, so $[AC]^+ = 100\,\%$ (base peak)

$$\%[M+H]^+ = \left(\frac{7}{27}\right)\left(1+\frac{1}{\dfrac{10}{17}}\right) x100 = \left(\frac{7}{27}\right)\left(\frac{27}{10}\right) x100 = \frac{7}{10} x100 = 70\%$$

$$\%[AB]^+ = \frac{1}{\left(\dfrac{10}{17}\right)\left(1+\dfrac{9}{8}\right)} x100 = \frac{1}{\left(\dfrac{10}{17}\right)\left(\dfrac{17}{8}\right)} x100 = \frac{1}{\dfrac{10}{8}} x100 = \frac{8}{10} x100 = 80\%$$

$$\%[BC]^+ = \frac{1}{\left(\dfrac{10}{17}\right)\left(1+\dfrac{1}{\dfrac{9}{8}}\right)} x100 = \frac{1}{\left(\dfrac{10}{17}\right)\left(\dfrac{17}{9}\right)} x100 = \frac{1}{\dfrac{10}{9}} x100 = \frac{9}{10} x100 = 90\%$$

FIG. 5. (Continued)

a value less than 0.5, then $[AC]^+$ must be smaller than $[AB]^+$ or $[BC]^+$, and so is a Case $n.3.n$ solution. Coincidentally, this second Critical Value for a Type III TAG also equals the statistically expected value of this Critical Ratio. The Critical Value of this Critical Ratio is seen in Scheme 1, Part III, and it is shown as Critical Value 2 on the equatorial axis in Figure 4.

If the ratio $[AC]^+/([AB]^+ + [BC]^+)$ is greater than 1, then $[AC]^+$ is automatically known to be larger than $[AB]^+$ and $[BC]^+$, and Critical Limit 1 can be constructed based only on $[AC]^+/([AB]^+ + [BC]^+)$. Furthermore, if $[AC]^+/([AB]^+ + [BC]^+)$ is greater than 1, this indicates a Case $n.4.n$ solution. For a Case $n.4.n$ solution, the value of Critical Limit 1 is given as:

$$\text{Critical Limit}\,1 = \frac{1}{1 + \frac{1}{\left(\frac{[AC]^+}{([AB]^+ + [BC]^+)}\right)}} \quad [7]$$

When the solution is classified as Case $n.4.n$ solution, $[AC]^+ = 100\%\ (= 1.00)$ at Critical Limit 1, because it is larger than $[AB]^+$ and $[BC]^+$, and so it is the peak against which the $[M + H]^+$ must be compared to determine the base peak. This is shown in the bottom panel of Figure 2.

When the $[AC]^+/([AB]^+ + [BC]^+)$ ratio is less than 1 but greater than 0.5, it must be compared with Critical Limit 2 to determine whether it is Case 3 or Case 4. The equation for Critical Limit 2 requires the use of the $[BC]^+/[AB]^+$ ratio, and so this ratio is first classified as either Case 5, in which the $[BC]^+/[AB]^+$ ratio is < 1, or Case 6, in which the $[BC]^+/[AB]^+$ ratio is ≥ 1. Knowing the Case for the third Critical Ratio for a Type III TAG allows Critical Limit 2 for the TAG to be calculated, which is:

$$\left(\frac{[AC]^+}{[AB]^+ + [BC]^+}\right)_{\substack{Critical \\ Limit\,2}} = \frac{1}{1 + \frac{[BC]^+}{[AB]^+}} \ or\ \frac{1}{1 + \frac{1}{\frac{[BC]^+}{[AB]^+}}}$$

$$\text{Case 5} \qquad\qquad \text{Case 6}$$

Then, to fully calculate Critical Limit 1 for a Case $n.3.n$ Type III TAG, both Critical Ratio 2 and Critical Ratio 3 are used. The complete equation for Critical Limit 1 for a Case $n.3.n$ solution is given as follows:

For Case 5:

$$\left(\frac{[MH]^+}{\Sigma[DAG]^+}\right)_{\substack{Critical \\ Limit\,1}} = \frac{1}{1 + \frac{[AC]^+}{[AB]^+ + [BC]^+}} \times \frac{1}{1 - \frac{[BC]^+}{[AB]^+}} = \frac{1}{\left(1 + \frac{[AC]^+}{[AB]^+ - [BC]^+}\right)\left(1 + \frac{[BC]^+}{[AB]^+}\right)} = \frac{1}{1 + \frac{[AC]^+}{[AB]^+ + [BC]^+}} \times CL2$$

or, for Case 6:

$$\left(\frac{[MH]^+}{\Sigma[DAG]^+}\right)_{\substack{Critical \\ Limit\,1}} = \frac{1}{1 - \frac{[AC]^+}{[AB]^+ + [BC]^+}} \times \frac{1}{1 - \frac{1}{\frac{[BC]^-}{[AB]^+}}} = \frac{1}{\left(1 - \frac{[AC]^+}{[AB]^+ + [BC]^+}\right)\left(1 + \frac{1}{\frac{[BC]^-}{[AB]^+}}\right)} = \frac{1}{1 + \frac{[AC]^+}{[AB]^+ - [BC]^+}} \times CL2$$

(ii) Critical Limit 2 for a Type III TAG. As seen above, Critical Limit 2 is necessary to calculate Critical Limit 1 when the $[AC]^+/([AB]^+ + [BC]^+)$ ratio is Case 3. This is the statistically expected normal circumstance. As already mentioned, the statistically expected $[AC]^+/([AB]^+ + [BC]^+)$ ratio is 0.5. To determine whether the $[AC]^+$ abundance is less than $[AB]^+$ or $[BC]^+$, or whether it is greater than $[AB]^+$ and $[BC]^+$, the $[AC]^+/([AB]^+ + [BC]^+)$ ratio must be compared with Critical Limit 2. This determines whether $[AC]^+/([AB]^+ + [BC]^+)$ obeys a Case 3.0 or a Case 4.0 solution. Critical Limit 2, in turn, depends on whether the third Critical Ratio, $[BC]^+/[AB]^+$, is greater than or less than 1.

Critical Limit 2 is calculated as follows:

$$\text{if}\left(\frac{[BC]^+}{[AB]^-}\right) < 1.0, \text{then } Critical\ Limit\ 2 = \frac{1}{1 + \frac{[BC]^-}{[AB]^+}}, \text{Else } Critical\ Limit\ 2 = \frac{1}{1 + \frac{1}{\left(\frac{[BC]^-}{[AB]^-}\right)}} \quad [8]$$

$$\text{Case } n.n.5 \qquad\qquad \text{Case } n.n.6$$

When this *Critical Limit 2* has been calculated, it is then used to calculate *Critical Limit 1*:

$$\text{if}\left(\frac{[AC]^-}{([AB]^+ + [BC]^-)}\right) < Critical\ Limit\ 2, \text{then } Critical\ Limit\ 1 = \frac{1}{1 + \left(\frac{[AC]^+}{([AB]^- + [BC]^-)}\right)} \times Critical\ Limit\ 2;$$

$$\text{Else } Critical\ Limit\ 1 = \frac{1}{1 + \frac{1}{\left(\frac{[AC]'}{([AB]^- + [BC]')}\right)}} \quad [9]$$

Critical Limit 1 is used to specify whether $[M + H]^+$ is the base peak, which determines either Case 1.0 or Case 2.0. Critical Limit 2 is used to specify whether $[AC]^+$ is larger than $[AB]^+$ and $[BC]^+$, which specifies either Case 3.0 or 4.0. The $[BC]^+/[AB]^+$ ratio alone (<1 or ≥1) specifies either Case 5 or 6. Thus, the complete Case classification can be given by comparison of the three Critical Ratios to Critical Limit 1, Critical Limit 2, and 1 (= Critical Value 3).

Once the Case has been classified, the complete set of equations necessary to calculate the abundance of every ion is given in Scheme 1, Part IIIA or IIIB, for the Case 1 or Case 2 solutions, respectively. Up to five specific values can be calculated from three Critical Ratios: (i) the abundance of the protonated molecule, (ii) the abundances of each of the three $[DAG]^+$ fragment ions, and (iii) the sum of all the ions. Three critical ratios are required to specify the four primary ions in an APCI-MS mass spectrum of an ABC-type TAG, plus the sum of all ions. Only two critical ratios are required to fully describe the three primary ions in the mass spectrum of an ABA/AAB-type TAG. Four specific values may be calculated for the mass spectrum of a Type II TAG: (i) the abundance of the protonated molecule, (ii) the abundances of each of the two $[DAG]^+$ fragment ions, $[AA]^+$ and $[AB]^+$, and (iii) the sum of all ions. Only one single Critical Ratio is necessary to describe an AAA, or Type I TAG. That one ratio specifies that one peak is the base peak and the other is a ratio to the first, and the sum of the ions is then given.

IMPLEMENTATION OF THE BUS

The Critical Ratios are the key elements of the BUS to the TAG Lipidome. During the process of investigating the relationships between the Critical Ratios and the structural information that they provide, it was observed that the Critical Ratios contained all of the information necessary to reconstruct the mass spectrum from which they came. Thus, the starting point for the BUS for TAG is the construction of the Critical Ratios for the TAG. The reasons for the identities of the Critical Ratios were given in the section entitled Construction of the Critical Ratios. The Critical Ratios may be constructed from abundances or areas in several ways. They may be constructed either from the abundances from a single mass spectrum or from an averaged mass spectrum obtained by averaging individual mass spectra over time from data obtained by infusion of an analyte solution

at a constant rate, or from data by injection of analyte into an infused solvent flow. Further still, the mass spectrum used to construct the Critical Ratios may be an averaged-in-time mass spectrum across a chromatographic peak, or it may be constructed from the integrated-in-time normalized relative area abundances. For mass spectra across a chromatographic peak, the abundances are different in the middle, front, and back portions of the peak, as was mentioned by Mottram *et al.* (11) and in a recent review (45). For Type II TAG, it appears that the regioisomers may be partially separated across the breadth of the

peak. Construction of the Critical Ratios for the first, middle, and last portions of the chromatographic peaks may help to make more trends apparent. For polyunsaturated TAG, the [AA]$^+$/[AB]$^+$ ratio is higher than other TAG and is often greater than 1.

The averaged mass spectrum across a chromatographic peak shows all ions eluted at that particular time. Similarly, a plot of the areas under integrated peaks in ion chromatograms at a particular retention time, normalized to 1 (or 100%), appears the same as a mass spectrum averaged across that time window. The

averaged mass spectrum of each TAG of the 35-TAG mixture given in Table 5 is an average of the three sets of mass spectra given by the (abundance × time) integrated peak areas of each of three chromatographic runs, in which complete chromatographic resolution was achieved between almost all TAG molecular species. Peaks that appear to overlap in the total ion current chromatogram (TIC) are resolved in ion chromatograms of [DAG]$^+$ fragments that are extracted out of the TIC, to form extracted ion chromatograms (EIC). Any overlapped peaks are apportioned as has been described previously (7,34). In the data set used herein, the only chromatographic peak that required apportionment was the P peak of OL and the O peak of SLn in the *m/z* 601.5 EIC, marked with an asterisk in Figure 6E. In whichever manner the percent relative abundances are obtained that represent the mass spectrum, the Critical Ratios can be calculated from the abundances or areas. One need not convert integrated peak areas to percent relative abundances, since the critical ratios can be calculated directly from the integrated areas as long as they are properly grouped by retention time for each TAG. However,

when averaging several runs, calculations should be based on normalized area percentages.

Error propagation in the Critical Ratios must be mentioned. In Table 2, the SD are not simply the SD of the three numerically calculated ratio values. Since the Critical Ratios are ratios of average abundances that each have a SD, error propagation is more correctly calculated as the square root of the sum of the squares of the percent relative SD of the abundances involved in the construction of the ratios. Table 2 shows the SD calculated in this way. When a ratio has been shown to have a linear relationship, such as the [AA]$^+$/[AB]$^+$ ratio for regioisomers, it may be appropriate to express the simpler SD in the ratio itself. In Table 2, the simple SD of the three numeric [AA]$^+$/[AB]$^+$ ratio values has been shown as SD2. In most cases, the peak that is the base peak in an averaged mass spectrum is the base peak in each of the averaged spectra, and so that abundance has a 0% SD from spectrum to spectrum. In the cases of highly unsaturated TAG, the error expressed as the square root of the sum of the squares of the SD of the abundances was larger than for TAG containing

[a]This is an exact reproduction of the average mass spectrum obtained as an average of three chromatographic runs. I, ion abundance; for other abbreviations see Table 1.

FA with fewer sites of unsaturation. TAG. Although the approach used to obtain an averaged mass spectrum affects the SD of the abundances, the BUS does not depend on the approach used to obtain the mass spectrum.

Figures 5A through 5F show examples of mass spectra and the construction of the Critical Ratios. For Type II TAG, the $[AA]^+/[AB]^+$ ratio can be used to assess the amounts of regioisomers; so instead of providing abundances, which would then need to be converted into the ratio that is compared to regioisomeric standards, one could provide the desired ratio directly, along with one or two other ratios, which constitute the set of Critical Ratios. These ratios can be tabulated in fewer values than the raw abundances. The ratios therefore are a more efficient means of storing information. They provide more information in fewer values.

Automated spreadsheet implementation of the BUS starts with the classification of the Critical Ratios into Cases. The classification can be accomplished using only the Critical Limits. The Critical Values do not need to be used in the automated implementation. If the columns in Table 2 were labeled A through J, and the rows were numbered from 1 to 37, then the Critical Ratios would be in columns E, G, and I, and the data would be in rows 2 to 36. Based on Table 2 numbered as mentioned, the following formulas allow the calculation of the Critical Limits:

Type II: J7: =
   IF(G7<100,(100/(1+(G7/100))),(100/(1+(100/G7))))
                                                   Critical Limit

Type III: J27: =
   IF(G27<M27,(100/(1+(G27/100))*(M27/100)),(100/(1+
   (100/G27))))
                                                   Critical Limit 1

M27: = IF(I27<100,(100/(1+(I27/100))),(100/(1+(100/I27))))
                                                   Critical Limit 2

G7–36: = Critical Ratio $[AA]^+/[AB]^+$ (Type II TAG)
   or $[AC]^+/([AA]^+ + [AB]^+)$ (Type III)

I27–36: = Critical Ratio $[BC]^+/AB]^+$ (Type III TAG)

These formulas are the implementation of the equations for the Critical Limits that were given in the closed boxes in Scheme I, Parts II and III, and in Equations 7–9. These formulas may be pasted down the column for all TAG of each type, to automatically calculate the Critical Limits for all TAG. Notice that Critical Limit 1 for a Type III TAG depends on Critical Limit 2.

Notice that the formula for Critical Limit 2 for a Type III TAG is in the same form as the formula for the one Critical Limit of a Type II TAG. Once the Critical Limits have been calculated, then the Case classification can also be automated. The Critical Limits calculated from the Critical Ratios in Table 2 are given in Table 3, along with the Critical Values. Examples in the preceding text and in Figure 5 demonstrate calculation of the Critical Limit.

In the spreadsheet implementation for Type I TAG, the $[MH]^+/\Sigma[DAG]^+$ ratio is simply compared with 1, so the classification is =IF(E2<100,**1**,**2**), where **1** and **2** are Case 1 and Case 2. For both Types II and III TAG, the $[MH]^+/\Sigma[DAG]^+$ ratio is compared with the first Critical Limit (formulas just shown) and is given by: =IF(E7<J7,**1**,**2**), where **1** and **2** are Case 1 and Case 2, with the Critical Limit in column J. Next, Case 3 and Case 4 are determined. For the Type II TAG, the $[AA]^+/[AB]^+$ ratio is simply compared with 1, so the classification formula is: =IF(G7<100,**3**,**4**), where **3** and **4** are Case 3 and Case 4. For a Type III TAG, the $[AC]^+/([AB]^++[BC]^+)$ ratio is compared with Critical Limit 2, so the classification formula is: =IF(G27<M27,**3**,**4**), where Critical Limit 2 is in column M. Finally, Case 5 and Case 6 are determined. The $[BC]^+/[AB]^+$ ratio is simply compared with 1 for this determination, so the classification formula in spreadsheet notation is =IF(G27<100,**5**,**6**).

From these formulas, the TAG are classified into their complete Case classifications. The case classifications for the 35-TAG mixture, for which Critical Ratios are given in Table 2, are shown in Table 3. Once they are classified, the solution equations are given in Scheme 1 of the BUS. Since they may not be obvious and might seem daunting at first, the formulas will be given here by which the entire BUS can be implemented. This actually requires only a few nested spreadsheet formulas. To exemplify this, imagine that the case classification in Table 3 is in columns Q, R, and S of the same spreadsheet as that envisioned for Table 2. Keeping the same row numbers (2 through 36), the following formulas use the Cases defined in Table 3 with the Critical Ratios given in Table 2 to calculate the abundances of all ions in the original mass spectra.

In the implementation in a spreadsheet, the comparison of the $[MH]^+/\Sigma[DAG]^+$ ratio to 1 and to its Critical Value can be skipped, since the Critical Limits are sufficient to determine which peak is the base peak. The comparison with 1 and with the Critical Value is done when the BUS is being used manually (not in a spreadsheet), to accomplish the case classification of the TAG with these simple values if possible, to save time and avoid calculation of the more complicated Critical Limit(s).

When the spreadsheet is used, the formulas given above can be typed in and then pasted down the column, so calculation of the Critical Limits requires minimal effort. Therefore, these formulas for the Critical Limits can be used without first testing the $[MH]^+/\Sigma[DAG]^+$ ratio with the Critical Value and 1.

Similarly, for a Type III TAG, Critical Limit 1 depends on Critical Limit 2. Since the spreadsheet calculates both of these values easily from the formulas for the Critical Limits given, Critical Limit 2 is easily determined without first testing the $[AC]^+/([AB]^+ + [BC]^+)$ ratio using its Critical Value of 0.5. The $[AC]^+/([AB]^+ + [BC]^+)$ ratio can simply be compared with Critical Limit 2 using the automated classification formulas just given, to arrive at the Case classification for Case 3 or Case 4.

Thus, the whole Critical Limit calculation process is accomplished with only the three formulas given, and these are used with the Critical Ratios to accomplish the complete Case
FIG. 6. Total ion current chromatogram (TIC), evaporative light-scattering detector (ELSD) chromatogram, and extracted ion chromatograms (EIC) of [DAG]+ fragment ion masses. S, stearic acid; Ln, linolenic acid; for other abbreviations see Figure 1.

classification of the TAG. Once the Case classification is accomplished, the BUS shows which equations to use to calculate the ion abundances for every TAG of every case. In looking at Scheme 1, it might appear difficult to implement the system of equations given in the BUS. However, the whole solution for every TAG can be implemented in only nine formulas that contain nested "if (*x*, then *y*, else *z*)" spreadsheet formulas, in which *x* is the case classification given in Table 3. There are nine types of $[MH]^+$ or $[DAG]^+$ fragment ions that can be produced from a Type I, II, or III TAG. The nine spreadsheet formulas necessary to calculate the abundance of every possible ion are provided in Table 4. These can be entered into the spreadsheet and then pasted down the column for each TAG type. Since there are only two possible cases for each Critical Ratio, the "if (*x*, then *y*, else *z*)" statement can be tested using Cases **1**, **3**, and **5** as *x*, and if any of the tests fails, then the inherent "else *z*" is the Case **2**, **4**, or **6** solution, respectively, by default. This is why, for a Type III TAG, only the values **1**, **3**, and **5** appear at the beginning of each "if (*x*, then *y*, else *z*)" statement. Notice in Table 4 that, for a Type III TAG, the "if (*x*, then *y*, else *z*)" statements are nested three levels deep, whereas for a Type II TAG, they are nested two levels deep. The spreadsheet formulas in Table 4 allow the abundances for every $[MH]^+$ ion and $[DAG]^+$ fragment from every TAG to be calculated based on the Critical Ratios tabulated in Table 2, using the Critical Limits and Case classification shown in Table 3. The abundances calculated from the spreadsheet formulas in Table 4 are given in Table 5.

Table 5 represents an average mass spectrum obtained from three chromatographic runs. The average mass spectrum was used to calculate the Critical Ratios. The values in Table 5 were calculated from the Critical Ratios in Table 2 processed through the equations in Table 4 and are exactly equal to the average mass spectrum to the number of significant figures given. In the spreadsheet, where many decimal places can be kept, the BUS reproduces the original mass spectrum to as many decimal places as desired. Figure 5 demonstrates that when theoretical Critical Ratios with infinite precision (perfect integer ratios) are used, the abundances are calculated with infinite precision. The abundances calculated and shown in Table 5, which are given by the BUS using the Critical Ratios in Table 2, are an exact reproduction of the average mass spectrum obtained from the average of three chromatographic runs, to two decimal places. The reproduced mass spectrum in Table 5 gives the Critical Ratios shown in Table 2. It should be noted that, since the abundances calculated from the BUS, shown in Table 5, required rounding to two decimal places, rounding error would occur each time the spectrum is reproduced from the Critical Ratios of a reproduced spectrum. In situations where the Critical Ratios are pure integer ratios, as shown in Figure 5, there is no error; and the Critical Ratios can be used to calculate the reproduced mass spectrum, and the Critical Ratios from the reproduced mass spectrum give the exact same Critical Ratios, with infinite precision. Just like the average mass spectra shown in Table 5, the abundances that

make up any individual APCI-MS mass spectrum can be exactly reproduced by the BUS. The Critical Ratios for any individual mass spectrum are processed through the BUS, and the abundances from which they came are reproduced to as many significant figures as were given for the Critical Ratios.

The structural trends that have been reported, as discussed in the foregoing sections, make up part of the Interpretation Matrix that is used to interpret information from the Critical Ratios. But the Interpretation Matrix is also used, if literature precedent has been reported, to make structural assignments that affect the Critical Ratios. The structural trends can be seen in the way the fragment ions are arranged in Table 5. It has already been discussed that the statistically expected $[AA]^+/[AB]^+$ ratio is 0.5. Thus, the $[AA]^+$ ion abundance is always expected to be smaller than the $[AB]^+$ abundance. It can be seen in Table 5 that the $[AA]^+$ ion abundance (identified as the $[AA]^+$ fragment by *m/z* value) is smaller than the $[AB]^+$ abundance for every TAG. With Type II TAG, there is no selection to be made regarding the identities of A and B, because whichever $[DAG]^+$ fragment has two of the same FA is the $[AA]^+$ fragment, and whichever $[DAG]^+$ fragment has two different FA is the $[AB]^+$. The 35-TAG mixture theoretically has equimolar amounts of regioisomers, since the FA are randomly distributed.

Based on linear interpolation of the $([AA]^+/[AB]^+)_{Obs}$ ratio between the $([AA]^+/[AB]^+)_{ABA}$ and $([AA]^+/[AB]^+)_{AAB}$ ratios of pure standards, the $[AA]^+/[AB]^+$ ratio for the 35-TAG mixture should give an $[AA]^+/[AB]^+$ ratio that is ~1/3 of the way between the $[AA]^+/[AB]^+$ ratio of the ABA isomer and the $[AA]^+/[AB]^+$ ratio of the AAB/BAA isomer pair. The $[AA]^+/[AB]^+$ ratios of many TAG regioisomers have not yet been reported. Table 2 represents one point, obtained from a randomized mixture, on the line interpolated between the two regioisomeric standards. The $[AA]^+/[AB]^+$ ratios in Table 2 theoretically represent approximately the one-third (1/3) point on the line interpolated between the $[AA]^+/[AB]^+$ ratios of the ABA isomer and the AAB/BAA isomer pair. As already mentioned, the 35-TAG synthetic mixture for which Critical Ratios were given in Table 2 represents a mixture of regioisomers, and each of these is present as a racemic mixture of enantiomers.

The $[AA]^+/[AB]^+$ ratios in Table 2 show that the TAG that contained the diolein DAG combined with a saturated FA had some of the lowest $[AA]^+/[AB]^+$ ratios. Polyunsaturated TAG, containing linoleic and linolenic acids, gave the highest $[AA]^+/[AB]^+$ ratios, especially from the TAG containing one saturated FA. Perhaps construction of the $[AA]^+/[AB]^+$ ratios from a larger number of TAG mixtures and TAG standards will lead to a greater understanding of the effects of unsaturation in the FA, and of the regioisomeric placement of the FA, on the relative abundances of the $[DAG]^+$ fragment ions formed from Type II TAG.

Unlike Type II TAG, for Type III TAG the identities of the FA A, B, and C are not automatically known. However, the trends reported from APCI-MS data provide information to be able to classify the FA and deduce the structure of $[AC]^+$ and

therefore to know the identity of the B FA in the *sn*-2 position. As discussed in the preceding sections, the *sn*-1,3 [DAG]$^+$ fragment has been reported to be energetically disfavored, and has been reported to exist in the least abundance (10,11) of the three [DAG]$^+$ fragments that come from a Type III TAG. Based on this reported trend, the abundances of Type III TAG in Table 5 have been arranged such that the [AC]$^+$ fragment is selected as the peak with the lowest abundance. Aligning the identity of [AC]$^+$ as the ion with the smallest abundance implies that it is the [*sn*-1,3-AC]$^+$ fragment. For instance, for OPS, the lowest [DAG]$^+$ abundance was observed from the [OS]$^+$ fragment (=[SO]$^+$), so the [OS]$^+$ fragment is labeled as the [AC]$^+$ fragment. In this way, the previous structural trends that have been reported for TAG can be used for identification of at least one of the three possible regioisomers for a Type III TAG. Before constructing the Critical Ratios (such as in Table 2), the lowest [DAG]$^+$ abundance should be properly identified as [AC]$^+$, so that the [AC]$^+$/([AB]$^+$ + [BC]$^+$) ratio will have its minimum value when the [AC]$^+$ fragment is properly assigned. Of course, the equations of the BUS operate properly whether the ions have been assigned properly or not, but proper construction of the Critical Ratios allows additional structural information to be derived and trends observed. In Table 5, one can observe that all [AC]$^+$ fragments have the lowest abundances of the three [DAG]$^+$ fragments for each TAG. However, the trend reported for Type III TAG was based on a limited number of Type III TAG; therefore, this trend needs to be further verified with additional Type III TAG standards. Regardless of how the Critical Ratios are used to derive regiospecific structural information, the BUS works with all values of all Critical Ratios.

No definitive trend has been reported for [AB]$^+$ vs. [BC]$^+$ fragments. All else being equal, the [AB]$^+$ vs. [BC]$^+$ fragments are interchangeable. Thus, it is equally likely that a TAG could represent a Case 5 vs. a Case 6 solution. In the absence of a definitive trend, the data can be used to try to elucidate any subtle trends that may not be readily apparent. If one chooses to set the [BC]$^+$ fragment equal to the smaller of the two possible abundances for [AB]$^+$ or [BC]$^+$, then perhaps the ratios will indicate some structural trends. For instance, in Table 5, the [BC]$^+$ fragment is chosen so that the [BC]$^+$ fragment is smaller than abundances for [AB]$^+$. By doing this, one can observe that every Type III TAG in the mixture that has less than two saturated FA had the least saturated chain in the C, or *sn*-3, position. Seven of the ten Type III TAG in the 35-TAG mixture had one or no saturated FA. All seven of these TAG gave a lower abundance for the [BC]$^+$ fragment than the [AB]$^+$ fragment when the single saturate or monounsaturate (for LLnO) was in the *sn*-3 position. Of course, the *sn*-1 and *sn*-3 positions could be reversed, and all Type III TAG would have the [BC]$^+$ fragment larger than the [AB]$^+$ fragment. But whichever way they are labeled, it reveals a trend that the [DAG]$^+$ fragment with more unsaturation is the larger fragment, in most cases, giving a [BC]$^+$/[AB]$^+$ ratio less than one, when the unsaturated TAG is labeled as the A, or *sn*-1, FA. Additional data from regioisomeric standards of Type III TAG will reveal which is the correct assignment. With the BUS, the mechanism, or the construct, is now in place to be able to

more easily identify and interpret structural trends, as they are reflected in the abundances of the [DAG]$^+$ fragment ions in APCI-MS mass spectra, and the Critical Ratios made from the raw abundances. Regardless of whether the [BC]$^+$ fragment is less than the [AC]$^+$ fragment or vice versa, the BUS accurately calculates the abundances of each ion whether the [BC]$^+$/[AB]$^+$ ratio is larger than 1 or less than 1.

In a way analogous to proteomics, the sum of all possible species and structures of lipid molecules may referred to as the *lipidome*, and the study of the lipidome is referred to as *lipidomics* (46). The sum of all possible structures of TAG may be referred to as the TAG Lipidome. There is not a single TAG that cannot be represented by its Critical Ratios, and from these Critical Ratios, all abundances of ions may be reproduced. Thus, Scheme 1 represents the complete boundary to the solution of the TAG Lipidome, based on data from APCI-MS mass spectra. There is no TAG that cannot be represented within this construct. The structural trends that have just been mentioned, which were correlated to values or trends in the Critical Ratios, constitute the Interpretation Matrix that is part of the BUS. These correlations are not written here in a single table but have been discussed in detail. In the future, further information may be added to the Interpretation Matrix to allow a preference for [BC]$^+$ vs. [AB]$^+$ to be further described, or other information may be added to allow more information to be interpreted from the Critical Ratios. But, whereas this may provide incremental additional information, the essential construct of the BUS to the TAG Lipidome is complete in its entirety as given in Scheme 1, and the mass spectrum of any TAG may be reproduced from its equations. The BUS constitutes the first full solution to the TAG Lipidome.

FUTURE DIRECTIONS

Critical Ratios and their use in the BUS have been demonstrated using APCI-MS of TAG. This solution is also applicable to data obtained by ESI-MS. Since ESI-MS produces mostly the protonated molecule, with small abundances of [DAG]$^+$ fragment ions, the [MH]$^+$/Σ[DAG]$^+$ ratio is, of course, higher for ESI-MS data, but as long as the Σ[DAG]$^+$ is nonzero, the BUS may be applied to the same Critical Ratios calculated from ESI-MS data as from APCI-MS data. Alternatively, since ESI-MS mass spectra never give a zero abundance of protonated molecule (whereas APCI-MS spectra do), the completely bounded solution to the TAG lipidome by ESI-MS would best be constructed using the (Σ[DAG]$^+$/[MH]$^+$) ratio. This will give essentially the same construct as the TAG lipidome by APCI-MS, but with the (Σ[DAG]$^+$/[MH]$^+$) ratio having an inverse relationship to the [MH]$^+$/Σ[DAG]$^+$ ratio. Nevertheless, as long as the Σ[DAG]$^+$ fragments is not zero, the same set of ions (an [MH]$^+$ and up to three [DAG]$^+$ fragment ions) can be used with the BUS for TAG analysis by ESI-MS as was used for analysis by APCI-MS. Furthermore, as several values obtained by ESI-MS in Table 1 show, the [AA]$^+$/[AB]$^+$ ratio obtained by ESI-MS may be useful for characterization of the regioisomers, just like the [AA]$^+$/[AB]$^+$ ratio obtained by APCI-MS.

Glycerophospholipids have some structural similarity to TAG, because both classes of molecules have a three-carbon glycerol backbone. This similarity is seen in the mass spectra of glycerophospholipids. Most glycerophospholipids produce a protonated molecule and one [DAG]⁺ fragment, which is the same type of DAG fragment that is produced by TAG. It should be obvious that these two ions could be represented by the ([MH]⁺/[DAG]⁺) ratio, and the abundances of the two ions could be found using Scheme 1, Part I, just like a Type I TAG. Furthermore, glycerophospholipids produce fragments ions by loss of one fatty acyl chain as either an acid or a ketene (44). Phospholipid fragments containing one FA, formed by loss of one fatty acyl chain as an acid or a ketene (44), are analogous to the [AA]⁺ or [AB]⁺ fragments from a Type II TAG, in that the fragments provide information to allow identification of regioisomers. It will be a very straightforward extension of the BUS to construct Critical Ratios from phospholipids and process them through a solution that will be very similar to this original BUS, but that will be customized to identify the ions observed from phospholipids.

This solution to the TAG lipidome was referred to as the BUS because it was accomplished through manual solutions to every possible case. Once the complete solution was accomplished, trends within the equations were observed, and the mathematical function behind those equations was developed. The new function that describes all possible combinations of two variables (abundances) interacting with each other is defined as the Unit Simulacrum. Once the patterns within the equations were recognized and the equations behind the equations were found, two more mathematically equivalent solutions to the TAG lipidome were produced, which are referred to as the term-wise simulacrum solution and the nested simulacrum solution. Since these other solutions were arrived at by using the equations behind the equations, it may be said that these solutions were developed using a "top-down" approach. These other solutions will be presented in another report. The masses of the fragments have not been discussed, since they are constant and are dictated by the identity of the TAG. For instance, it is automatically known that the TAG POL will produce a [PO]⁺ fragment having *m/z* 577.5, a [PL]⁺ fragment having *m/z* 575.5, an [OL]⁺ fragment having *m/z* 601.5, and a [POL + H]⁺ ion having *m/z* 857.8. These *m/z* values do not change and so do not need to be reiterated. It is the abundances of the protonated molecule and the [DAG]⁺ fragment ions that change and that are affected by unsaturation and by positional placement of the FA on the glycerol backbone. It is these structural features that the Critical Ratios elucidate. As demonstrated, these Critical Ratios can then be used to reconstruct the appearance of the APCI-MS mass spectrum of any TAG.

CONCLUSION

The BUS represents the first complete solution to the TAG lipidome. Critical Ratios have been defined that, used by themselves, provide direct information regarding the structural characteristics of TAG (e.g., amount of unsaturation and positional

isomer distribution). Furthermore, these Critical Ratios constitute a reduced data set from which the mass spectrum of any TAG can be reproduced in its entirety. This reduced data set has potential advantages for storage of library spectra. Normally, the abundances of all four ions in the mass spectrum of a TAG would be presented in tabular form to represent a mass spectrum. In using the BUS, only three pieces of data are required (the three Critical Ratios). This represents a saving of 25% (three values needed instead of four) for ABC TAG. For ABA/AAB TAG, only two critical ratios are necessary to provide all of the information necessary to reproduce the mass spectrum, compared with three abundance values that would be used to tabulate the spectrum. This constitutes a data storage reduction by 33% (two values needed instead of three) for ABA/AAB TAG. Since only one critical ratio is necessary to describe the mass spectral abundances of an AAA TAG completely, the BUS provides a 50% saving in data storage space required (one value needed instead of two). The benefit of reduced data storage requirements is in addition to the benefits of being able to use the Critical Ratios directly to determine the distribution of regioisomers and the degree of unsaturation.

In the past, articles often presented tabulated abundances of mass spectral ions (8,32,33,36,37), which could later be used to calculate the ratio of [AA]⁺/[AB]⁺ abundances to allow the positional isomer preference to be assessed (45). It has now been demonstrated that it is possible to list Critical Ratios that can be used directly to provide structural information (e.g., assessing the degree of unsaturation or assigning positional isomers) and that constitute a reduced data set that uses fewer values and therefore takes less space than conventional tabulated mass spectra. It has been demonstrated that the mass spectrum of any TAG can be reproduced from the Critical Ratios using the BUS, which uses Critical Values and Critical Limits, and an Interpretation Matrix, to define the Case of a TAG. Once the Case of the TAG is defined, the exact equations used to calculate the abundance of every ion in the mass spectrum are given by the BUS. Finally, all of the spreadsheet formulas that are necessary to implement the BUS have been provided. For the automated spreadsheet implementation, the following spreadsheet formulas are given: three formulas for Critical Limits, five formulas for the Case classification process, and nine formulas to calculate every possible [MH]⁺ or [DAG]⁺ fragment, which represent the primary ions in an APCI-MS mass spectrum, for a Type I, II, or III TAG.

ABSTRACT: The determination of FAME by GC is among the most commonplace analyses in lipid research. Quantification of FAME by GC with FID has been effectively performed for some time, whereas detection with MS has been used chiefly for qualitative analysis of FAME. Nonetheless, the sensitivity and selectivity of MS methods advocate a quantitative role for GC–MS in FAME analysis—an approach that would be particularly advantageous for FAME determination in complex biological samples, where spectrometric confirmation of analytes is advisable. To assess the utility of GC–MS methods for FAME quantification, a comparative study of GC–FID and GC–MS methods has been conducted. FAME in prepared solutions as well as a biological standard reference material were analyzed by GC–FID and GC–MS methods using both ion trap and quadrupole MS systems. Quantification by MS, based on total ion counts and processing of selected ions, was investigated for FAME ionized by electron impact. Instrument precision, detection limits, calibration behavior, and response factors were investigated for each approach, and quantitative results obtained by each technique were compared. Although there were a number of characteristic differences between the MS methods and FID with respect to FAME analysis, the quantitative performance of GC–MS compared satisfactorily with that of GC–FID. The capacity to combine spectrometric examination and quantitative determination advances GC–MS as a powerful alternative to GC–FID for FAME analysis.

Paper no. L9654 in *Lipids* 40, 419–428 (April 2005)

The first of many important advances in the early development of GLC for analytical purposes was the separation and determination of FA reported by James and Martin in 1952 (1). Soon after, the analytical separation of FAME by vapor-phase chromatography was described by Cropper and Heywood (2). Since then, the characterization of FA composition by esterification to FAME and subsequent determination by GC has become one of the most widely performed analyses in lipid research laboratories and has found broad application to biochemical, biomedical, microbiological, agricultural, and ecological research.

Presently, a large number of lipid analysts use the FID to measure FAME separated by GC. Although FID has proven to be a robust tool for FAME determination, the lack of any selectivity can limit the usefulness of this detector when applied to complicated samples, since only instrument response and retention time information may be gathered. Owing in large part to this limitation, misidentification of FAME in the presence of contaminants, artifacts, or coeluting compounds is still of concern when using FID (3–5). Thus, much work has been done to maximize the usefulness of retention time for FAME identification through methods such as retention time locking, retention time prediction, and the dependence of retention time on FAME equivalent chain lengths (6–8); however, FAME identities assigned by such methods are generally considered tentative (9). Hence, FID analysis of complex biological extracts may prove inadequate in some situations, particularly for FAME of relatively low abundance (10).

With the coupling of MS methods to GC, much has been accomplished in the area of qualitative characterization of FAME mixtures. Since GC–MS provides spectrometric information on separated compounds, it provides a means of analyte selectivity; thus, detection with MS also represents a potentially powerful tool for quantitative analysis of FAME, especially in the presence of a convoluted biochemical background. Despite the prospective benefits of GC–MS methodologies for quantitative FAME analysis, the more familiar FID is still favored in many laboratories, particularly among lipid specialists.

GC–MS offers a host of tools for qualitative characterization of FA. For example, standard 70 eV EI ionization of picolinyl, dimethyloxazoline, pyrrolidide, pentafluorodimethylsilyl, and trimethylsilyl derivatives of FA has been extensively studied for the purpose of structural determination (11–17). EI ionization of these less common FA derivatives yields fragments of diagnostic value in locating the positions of branching and in some cases the positions of unsaturation in FA (although the geometric configuration of the double bond is not forthcoming).

The simplest method of FAME quantification by EI–MS may be carried out by monitoring a range of mass-to-charge (*m/z*) values that will encompass the fragments expected of the analytes, then determining amount based on integration of

peaks in the total ion count (TIC) chromatogram. If the identity and retention time of a given analyte have been established, the sensitivity and specificity of EI–MS can be extended through the use of selective ion monitoring (SIM), which involves the exclusive acquisition of a specified ion or group of ions during a given time frame. When SIM is used in concert with EI, an analyte peak area can be measured reliably regardless of high background or coeluting peaks, provided that ions unique to the analyte are monitored. Ideally, a fragment or fragments of relatively high abundance and characteristic *m/z* would be monitored. When entire mass spectra are acquired, benefits similar to those offered by SIM may be gained through quantification based on only a subset of the acquired ions extracted from the TIC. This selected ion extraction (SIE) allows complete spectra to be recorded and permits the exclusion of undesirable masses for purposes of quantification. Both approaches generally involve the use of relatively few ions for quantification; thus, significant numbers of analyte ions are disregarded and a corresponding loss of signal is experienced. Nonetheless, the net result is an enhancement of the signal-to-noise ratio by elimination of most nonanalyte response from the signal.

An investigation of the performance of FID vs. MS in quantifying FAME separated by GC has not been conducted since the work of Koza *et al.* in 1989 (18). These authors compared FID response factors (RF) of FAME with those obtained using EI in quadrupole (QP) as well as sector-type mass spectrometers. Unfortunately, only seven FAME were examined, none of which was polyunsaturated. In addition, the study provided no

information to users of ion trap (IT) MS systems (since this form of MS was still a relatively recent development at that time). Limits of detection (LOD), calibration behavior, and reproducibility of the instrumental methods were not addressed.

The present study provides a comparison of GC–FID and GC–MS techniques for quantitative FAME analysis. Using both IT and QP MS systems, quantification methods based on the TIC and selected ion techniques were applied to FAME ionized by EI. LOD, calibration characteristics, RF, and method precision for determination of a broad range of FAME were assessed by analysis of standard mixtures with each detection method. To determine the applicability of each approach to the analysis of a biological sample, FAME were prepared from a standard reference fish tissue homogenate with certified values for a group of individual FA [NIST Standard Reference Material (SRM) 1946] (19).

EXPERIMENTAL PROCEDURES

Calibration standards. A series of standard mixtures, including all FAME listed in Table 1, was prepared in residue analysis-grade hexane (EM Science, Gibbstown, NJ). These FAME were selected for calibration because of their prevalence in the tissues of fish and marine animals. The FAME were obtained from Sigma-Aldrich (St. Louis, MO), Supelco (Bellefonte, PA), Matreya (State College, PA), and Nu-Chek-Prep (Elysian, MN), and were of the highest purity available. For each level of calibration, all FAME were present at equal concentrations,

TABLE 1
Analyte FAME Present in the Calibration Standards and Their Order of Elution[a]

Elution order	FAME carbon numer	Systematic name	Common name
1	14:0	Tetradecanoic acid, methyl ester	Methyl myristate
2	16:0	Hexadecanoic acid, methyl ester	Methyl palmitate
3	16:1n-7	*cis*-9-Hexadecenoic acid, methyl ester	Methyl palmitoleate
4	17:0	Heptadecanoic acid, methyl ester	Methyl margarate
5	18:0	Octadecanoic acid, methyl ester	Methyl stearate
6	18:1n-9	*cis*-9-Octadecenoic acid, methyl ester	Methyl oleate
7	18:1n-7	*cis*-11-Octadecenoic acid, methyl ester	Methyl *cis*-vaccenate

[a]The FAME of 21:0 was added pre-analysis as an internal standard.

ranging from 0.02 to 100.0 μg/mL across the series. As an internal standard, 21:0 FAME was added to each mixture at a concentration of 50.0 μg/mL. All standards were analyzed in quadruplicate by GC–FID and each of the GC–MS methods.

RF standard. A commercially available standard mixture of 37 FAME (Supelco) was used in the determination of RF. The original solution was diluted 10-fold to give a final concentration of 1.0 mg/mL total FAME. The RF standard was also spiked with the FAME of 21:0 to obtain a 50.0 μg/mL internal standard concentration. This preparation was then analyzed in quadruplicate by GC–FID and all GC–MS methods under study.

NIST SRM. The NIST SRM 1946 (Gaithersburg, MD), Lake Superior fish tissue homogenate, was used to evaluate the usefulness of each method in analysis of a realistic sample (19). The tissue homogenate was extracted using a Dionex ASE 200 accelerated solvent extractor (Sunnyvale, CA) (20). Conditions similar to those previously described for lipid extraction were used (21–27).

To prepare for extraction, the sample was removed from −80°C storage and allowed to thaw. A 100-mg portion of the tissue homogenate was weighed and combined with approximately 1 g hydromatrix drying agent (Varian, Walnut Creek, CA). The tissue and hydromatrix mixture were transferred to an 11-mL stainless steel extraction cell fitted with three cellulose filters, and additional hydromatrix was added to fill the cell. The sample was then extracted with 60% chloroform/40% methanol (obtained, respectively, from EM Science and Fisher Scientific, Fair Lawn, NJ) at 100°C and 13.8 MPa. Two static extraction cycles were carried out, each 5 min in duration. Both extraction solvents were residue-analysis grade and were treated with 100 mg/L BHT as an antioxidant (Sigma). The crude extract was dried by pouring it through a sintered glass funnel containing several grams of anhydrous sodium sulfate (J.T.Baker, Phillipsburg, NJ). This was followed by thorough rinsing of the funnel with chloroform. The pooled dried extract and rinsing were then concentrated to approximately 1 mL under a stream of nitrogen using a TurboVap apparatus set at a bath temperature of 50°C (Zymark, Hopkinton, MA). The extract concentrate was transferred to a round-bottomed reaction vessel, and the remaining solvent was evaporated by impinging with nitrogen. The recovered lipids were reconstituted in 1 mL 0.5 M methanolic KOH (VWR, West Chester, PA) and hydrolyzed at 80°C for 30 min. Once the reaction mixture had cooled to room temperature, 1 mL of freshly opened 10% BF_3 in methanol was added (Supelco). Transesterification was performed at 100°C for 10 min. After cooling, 1 mL of distilled water and 2 mL of hexane were added to the sample with vortexing. Following phase separation, the organic phase was collected and transferred to a new vessel. The solvent exchange was repeated with a fresh 2-mL portion of hexane. The recovered organic phases were pooled, spiked with the methyl ester of 21:0 to result in a final concentration of 50.0 μg/mL, and diluted to a total final volume of 10 mL with hexane. This sample was analyzed in quadruplicate by each detection method.

Instrumentation, chromatography, and detection methods. FID analyses were performed with an HP 5890 Series II Plus GC–FID system (Hewlett-Packard, Palo Alto, CA). The detector temperature was held at 300°C, and the flame was maintained with 30 mL/min H_2 and 300 mL/min air. Helium was used as the detector auxiliary gas at a flow of 30 mL/min. The same GC system was also used for QP EI-MS analyses by equipping the GC instrument described above with an HP 5970 MS. IT EI-MS analyses were carried out on a Varian CP-3800 GC equipped with a Varian Saturn 2200 MS. A 10-min solvent delay was applied to all detection methods. On both GC instruments, chromatography was carried out using a 60 m × 0.25 mm DB-23 capillary column with a film thickness of 0.25 μm (Agilent Technologies, Wilmington, DE). Helium was used as the carrier gas at a flow rate of 1.0 mL/min with constant flow compensation. GC inlets were held at a temperature of 300°C, and MS transfer lines were maintained at a temperature of 250°C. Sample injections of 1 μL were performed without split for 30 s, followed by a 10:1 split ratio for the remainder of the analysis. The oven temperature was programmed from 125 to 240°C at a rate of 3°C/min with a final hold of 1.67 min (the total analysis time was 40.00 min).

IT GC–MS was carried out using 70 eV EI, and these data were evaluated using both TIC and SIE. Additionally, QP GC–MS with 70 eV EI was carried out in full-scan acquisition (with quantification based on the TIC) as well as in SIM mode. All mass spectra were acquired over the *m/z* range of 40—400 except during SIM. A dwell time of 100 ms was used for all SIM ions. Ions acquired during QP-SIM or processed in IT-SIE are listed in Table 2. In all cases, the three most abundant ions were monitored (SIM) or extracted (SIE) from the complete spectrum.

RESULTS

Reproducibility, calibration, and LOD. Typical chromatograms of a FAME calibration standard obtained by each instrumental approach are shown in Figure 1. Although retention times and chromatographic resolution are slightly different among the methods (likely owing to the differing inlets, detector interfaces, and column ages involved), all analytes eluted under comparable conditions regardless of the instrument involved.

To compare the precision of each detection technique, the mean area ratio (AR) of each analyte FAME with respect to the internal standard was calculated based on the quadruplicate analyses of a FAME standard of intermediate concentration (10 μg/mL). The variability about each mean was computed and expressed as the relative SD (RSD). These results are provided in Table 3 for a representative suite of FAME. The greatest reproducibility was consistently achieved with detection by FID and QP-SIM, with both techniques giving AR with variabilities of less than 1% RSD for most FAME. Notable gains in precision were afforded by QP-SIM as compared with QP-TIC (on average, about 0.9% RSD as compared with about 3% RSD); however, this degree of precision enhancement was not fully realized when IT-SIE was compared with IT-TIC. Although

[a]FAME listed here but absent from Table 1 were unique to the response factor standard. SIM, selective ion monitoring; SIE, selected ion extraction; QP, quadrupole; IT, ion trap.

there are obvious differences in the response reproducibilities among the different detection methods, essentially all of the results in Table 3 fall within a range of only a few percent RSD.

For each quantification method, calibration curves for all FAME were compiled by plotting the mean AR for the quadruplicate analyses as a function of FAME concentration. As a representative example, the calibration curves for the 18:0 FAME are shown in Figure 2. Whereas the FID exhibited a linear response over the entire concentration range examined, each of the MS methods was characteristically nonlinear to varying degrees. The MS method typically yielding the most nearly linear calibrations was QP-MS, where the range of linear response was extended with the use of SIM. The IT-MS methods demonstrated more pronounced departures from linearity under most conditions. This was not unexpected, as ion losses are well known to occur as a consequence of space charging when ions are present in the trap at high concentration. For quantification in subsequent experiments, a quadratic regression was used to

establish the nonlinear calibrations, whereas linear regressions were used for calibration where appropriate.

The LOD was calculated for each calibrated FAME, based on linear regression analysis of the AR vs. FAME concentration relationship. In this context, the LOD expressed in terms of instrumental response, LOD_R, is given by:

$$LOD_R = b + 3s_b \quad [1]$$

where b is the y-intercept of the linear regression line and s_b is the SE of the intercept (28). Rewriting Equation 1 to give LOD in terms of analyte concentration, LOD_C, and making the approximation that b approaches zero (which was, in fact, observed in practice), we have:

$$LOD_c = \frac{3s_b}{m} \quad [2]$$

where m is the slope of the linear fit. Since second-order regression was used to fit a number of the MS calibrations, the LOD for all FAME were based on first-order regression of the low concentration portions of all standard curves (i.e., the first four standard levels detectable by a given method), a region in which linear response was observed regardless of detection method.

The resultant LOD values for a number of analyte FAME are given in terms of both solution concentration and the corresponding number of picomoles (Table 4). Each of the quantification methods is fully capable of detecting low-picomole amounts of a variety of FAME. Detection of subpicomole quantities of almost all the FAME in Table 4 is readily accomplished by FID, with remarkably similar LOD observed for all FAME considered; in general, however, MS quantification methods proved to have LOD that were more sensitive to the identity of the FAME being detected. Of the MS-based quantification methods, QP-TIC generally had the highest LOD; however, when this instrument was operated in SIM mode, LOD were much improved (by as much as a factor of five), rivaling those of any other method. Figure 3 serves to underscore the advantage of quantification by SIM as opposed to TIC when using the QP instrument. For the IT instrument, however, similar improvements in LOD were not achieved in SIE vs. TIC modes. Thus, whereas quantification based on SIE in this case yields marginal improvement in LOD as compared with the TIC and still allows full-scan mass spectra to be acquired, SIM offers much more significant improvements in the LOD while precluding the acquisition of full-scan mass spectra.

RF. To investigate the response dependence of each method on the number of unsaturations as well as the FAME carbon number, the mean response of each analyte with respect to the internal standard was used to calculate the analyte RF according to Equation 3:

$$RF_a = \frac{R_a C_s}{R_s C_a} \quad [3]$$

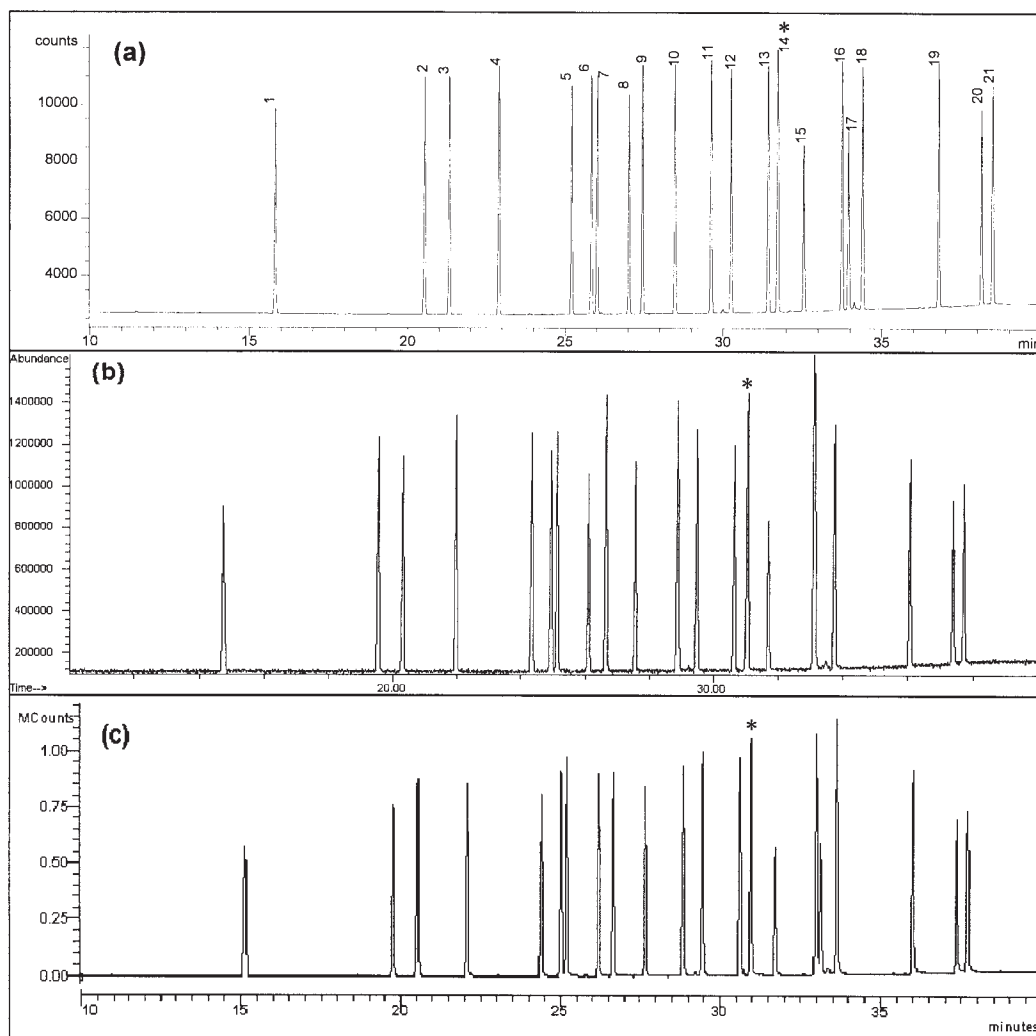
where the RF of an analyte (RF_a) is given in terms of the analyte response (R_a), the internal standard response (R_s), and the


FIG. 1. Gas chromatograms of a FAME calibration standard with detection by FID (a), quadrupole (QP) MS (b), and ion trap (IT) MS (c). For (b) and (c), the total ion counts (TIC) are shown for m/z 40–400. All FAME were present at 50.0 μg/mL. The peaks numbered in (a) correspond to the compounds listed in Table 1. The same order of elution applies to (b) and (c). The internal standard is labeled with an asterisk.

concentrations of the analyte and the internal standard (C_a and C_s, respectively). RF for a representative sampling of FAME are shown for each instrumental approach in Figure 4.

An often-held assumption among lipid analysts is that, in an FID chromatogram, the peak area of an analyte FAME (A_{FAME}) divided by the total peak area of all FAME (ΣA_{FAME}) is equal to the ratio of the corresponding analyte FA mass (m_{FA}) to the total mass of FA present in the sample (Σm_{FA}):

$$\frac{A_{FAME}}{\Sigma A_{FAME}} = \frac{m_{FA}}{\Sigma m_{FA}} \qquad [4]$$

This statement is clearly based on a number of assumptions, not the least of which is that for the FID, the relative responses toward all FAME are equal. The present results, however, are in agreement with a number of contrary findings that attest to the questionable legitimacy of Equation 4 (29–31). That the

FID responses toward all FAME cannot be assumed equivalent may be argued strictly in terms of the mechanism of detection. In FID, the production of CHO^+ ions, which are collected by the cathode and thus generate the detected current, is proportional to the number of carbon–hydrogen bonds introduced to the flame. Since carbonyl carbons are not FID susceptible, it would follow that for an equal mass of two different FAME, the FAME of lower carbon number would have the smaller RF owing to a higher proportion of FID-inactive carbon. Hence, the FID RF for FAME are expected to depend on both the carbon number and the number of unsaturations of the analyte FAME in question. The FID RF shown in Figure 4 reinforce this point, clearly illustrating the predicted relationships. In practice, a number of additional factors prevent the FAME area percentage from equating to mass percentage; for example, injector bias results in a lesser percentage of more volatile com-

[a]In all cases, the mean area ratio (AR) vs. the internal standard and relative standard deviation (RSD) of the AR are based on quadruplicate analyses of a 10 µg/mL standard FAME mixture. TIC, total ion counts; for other abbreviations see Table 2.

pounds being successfully loaded on-column (9,30,32). This phenomenon was likely responsible for the reduced FID RF for the 20:0 FAME seen in Figure 4(a).

Unsurprisingly, the MS detectors also have RF that are sensitive to the identity of the analyte, albeit in these cases the relationships between RF and carbon number or unsaturation number are more varied. The QP RF, for example, showed relatively little variability as a function of carbon number and had less scatter than FID; in the case of QP-SIM, the RF were reproduced with exceptional precision. The QP RF, however, experienced a steep reduction with the addition of even a single double bond, with additional but smaller reductions following with additional degrees of unsaturation. The only significant difference between QP-TIC and QP-SIM appeared to be a matter of precision. For IT-TIC, as in FID, the RF were directly proportional to carbon number and were diminished with increasing unsaturation number, although the range of RF was broader (about 0.6 to 1.1 for IT-SIE as opposed to a range of roughly 1.0 to 1.2 for FID). The RF for IT-SIE, though, did not

appear to be predictably dictated by either carbon number or degrees of unsaturation. Interestingly, the same ions were extracted to produce the IT-SIE data as were monitored by QP-SIM, but very different trends in RF were observed, illustrating the impact that continuously sorted ions (QP-SIM) vs. selected extraction of trapped and sequentially released ions (IT-SIE) can exert upon quantification.

NIST SRM. The analyte concentrations determined in the quadruplicate analyses of the NIST SRM extract were averaged, and the FA quantities were expressed in terms of the TG mass percentage in tissue such that direct comparison of the present results with the standard reference values reported by NIST was possible. These results for each detection technique are summarized in Figure 5. For the majority of the analytes (of which the NIST-certified FA are shown in Fig. 5), most FID and MS results were found to be in good agreement with the NIST SRM values (i.e., to within the SE of the measurements).

The procedure used for extraction of the SRM was significantly different from that used by NIST to characterize the

sample. The present method made use of high-pressure, high-temperature accelerated solvent extraction with chloroform/methanol, employing less than 20 mL of solvent to extract 100 mg of tissue homogenate in roughly 20 min. By contrast, the SRM values were determined by 18–24 h Soxhlet extractions of 2.5 g tissue homogenate samples with hexane/acetone. Although the performance of accelerated solvent extraction for lipid extraction has been addressed elsewhere and deemed sat-

isfactory (21–27), these different approaches may be partly responsible for some of the minor discrepancies between the present results and the NIST SRM certified values; however, since the same extract was analyzed by all methods, the results are indeed suitable for direct comparison among the various quantification methods.

Overall, these results demonstrate that appropriately chosen and properly calibrated MS detection methods are capable of producing accurate quantitative results for FAME in a biological sample that are of comparable quality to those produced by the more traditional FID.

DISCUSSION

The present findings demonstrate that, although FID and various MS techniques exhibit distinct behavior where response to FAME for quantification is concerned, the use of calibration with internal standardization allows the application of MS to quantitative FAME analysis with adequate precision, low LOD, and accurate quantitative results. The hallmarks of FID performance in FAME quantification include a broad range of linear response, excellent precision, and subpicomole LOD. Of course, the main limitation of this detector is that the response is nonspecific and provides no information on the identity of the analyte.

Overall, the best MS performance was obtained using the QP instrument operated in SIM mode. Although some selectivity was afforded by virtue of the monitoring of selected ions, the ability to acquire complete mass spectra was precluded. Whereas this may be satisfactory for quantitative analysis of well-characterized samples, samples of unknown FAME composition should be screened with full-scan MS prior to SIM analysis for quantification. QP-SIM allowed better linearity of response and better precision when compared with acquisition of TIC on the same instrument and when compared with the IT instrument. Subpicomole LOD were also obtainable in SIM mode, a marginal improvement in the TIC LOD (typically, a few picomoles). Even so, it should be noted that the majority of these results occur within a rather small range regardless of detection method, with each method being capable of a level of performance that is acceptable for many applications.

The response of the IT instrument was less linear and, as has been reported, gave slightly different spectra from those produced using QP instruments (33). The main advantage of the IT instrument was that acquisition of full-scan mass spectra (IT-TIC) gave better quantitative performance than the QP-TIC; thus, although QP-SIM offered the best MS performance overall, IT-TIC was superior to QP-TIC for quantification with full-scan acquisition. The IT-MS analysis also afforded the ability to collect full spectra, yet still offered the capability to extract ions for a given analyte later if enhanced signal-to-noise was needed. Indeed, SIE of FAME chromatograms did allow some improvement in LOD and method precision.

These results also support the need for rigorous calibration, irrespective of the detection method chosen. Whereas appropriate calibration is particularly critical for MS work, the assumption of uniform FID RF is also inadequate for precise
FIG. 3. Expanded chromatograms at the retention time of 18:0 FAME with detection by QP-MS showing the TIC (a) and SIM of *m/z* 43 + 74 + 87 (b). Approximately 20 pg of the 18:0 FAME was injected in both cases. For abbreviations see Figures 1 and 2.

quantitative work. If this approach is used, determinant errors are introduced that may be significant depending on the application.

The sensitivity and selectivity of GC–MS make it an advantageous platform for FAME quantification, despite its obvious absence from discussions on FAME quantification in even relatively recent reviews on the subject of FA analysis (9,29,34). In addition to providing several acceptable options for quantification of FAME, GC–MS offers two powerful advantages over FID: the ability to confirm the identity of analytes based on spectral information in addition to retention time, and the ability to separate peaks from a noisy background or coeluting peaks if unique ions are available. These characteristics, taken together with good quantitative performance and the widespread availability of GC–MS instruments such as those described here, offer compelling motivation to predict that GC–MS will eventually become a far more widely exploited alternative to GC-FID for FAME analysis, both quantitative and qualitative.

Application of Supercritical Fluid Chromatography in the Quantitative Analysis of Minor Components (carotenes, vitamin E, sterols, and squalene) from Palm Oil

Yuen May Choo[a],*, **Mei Han Ng[a], Ah Ngan Ma[a],**
Cheng Hock Chuah[b], and Mohd. Ali Hashim[c]

[a]Malaysian Palm Oil Board (MPOB), No. 6, Persiaran Institusi, Bandar Baru Bangi, 43000 Kajang, Selangor, Malaysia, and Departments of [b]Chemistry and [c]Chemical Engineering, University of Malaya, Kuala Lumpur, Malaysia

ABSTRACT: The application of supercritical fluid chromatography (SFC) coupled with a UV variable-wavelength detector to isolate the minor components (carotenes, vitamin E, sterols, and squalene) in crude palm oil (CPO) and the residual oil from palm-pressed fiber is reported. SFC is a good technique for the isolation and analysis of these compounds from the sources mentioned. The carotenes, vitamin E, sterols, and squalene were isolated in less than 20 min. The individual vitamin E isomers present in palm oil were also isolated into their respective components, α-tocopherol, α-tocotrienol, γ-tocopherol, γ-tocotrienol, and δ-tocotrienol. Calibration of all the minor components of palm as well as the individual components of palm vitamin E was carried out and was found to be comparable to those analyzed by other established analytical methods.

Paper no. L9679 in *Lipids 40*, 429–432 (April 2005).

Crude palm oil (CPO) consists of mainly glycerides (TG, >90%; DG, 2–7%; and MG, <1%), FFA (3–5%), and about 1% minor components such as carotenoids (500–700 ppm), vitamin E (600–1000 ppm), sterols (250–620 ppm), and squalene (200–600 ppm) (1). These minor components are also present in palm fiber oil (PFO) but in a much higher concentration: carotenoids (4000–6000 ppm), vitamin E (2000–4000 ppm), sterols (4000–6500 ppm) (2). All these components have important physiological properties, such as being antioxidative, anticareinogenic, and hypocholesterolemic (3–12).

Various chromatographic and analytical techniques have been reported for the isolation and analysis of these minor components: vitamin E by HPLC using fluorescence detection, squalene and sterols by GC-FID after saponification, and total carotenes by UV-vis spectrophotometry (5,13–16). Chromatographic isolations, e.g., by HPLC and GC, of similar compounds from sources other than palm oil also have been reported (5,13–16).

Although supercritical fluid chromatography (SFC) was reported more than 20 years ago, its advantages have only recently been realized. The unique properties of supercritical fluid as a mobile phase in SFC overcome the difficulties of solute thermal instability and volatility encountered in GC and also shorten the relatively longer analysis times of HPLC separations (17). The comparatively lower operating temperature of SFC over GC gives the advantage of preserving the heat-labile compounds in palm oil. Thus, the deterioration of minor components in palm oil caused by thermal degradation can be minimized or avoided. The growth in popularity of SFC as an analytical tool has been slow because some technical deficiencies, such as injection methods, flow restrictors, and interfaces between the supercritical fluid chromatograph and detectors, needed be addressed before it could be more widely used.

Although the SFC of carotenes, vitamin E, and sterols has been reported in the past, it should be noted that most of these separations were carried out using model mixtures, thereby eliminating interference from other compounds that would be present should a real sample matrix be used (18,19). Moreover, successful SFC separations of real samples also differed from one type of oilseed to another, as the types of minor components present were not similar. In addition, the choice of a capillary or packed column influences the choice for SFC as a separation tool. Packed-column SFC has only recently gained popularity because of the rapid development of packed-column technologies in recent years.

The detection of solutes from SFC separations has been reported using detectors such as flame ionization, NMR, evaporative light-scattering, and IR (17–19). However, a UV variable-wavelength detector was chosen in this study, as the λ_{max} of the solutes indicates the identity of the minor components eluted. This is because the minor components in palm absorb UV at different wavelengths: carotenes at 446 nm, vitamin E at 291 nm, sterols at 220 nm, and squalene at 220 nm.

Previously, Ng and fellow researchers (20) reported the SFC separation of tocols from palm oil using both silica and diol columns. To date, a successful single SFC separation of carotenes, vitamin E, sterols, and squalene from any real sample matrix has not been reported. This paper now reports the SFC separation and quantification of these four minor oilseed components from both CPO and PFO.

EXPERIMENTAL PROCEDURES

Apparatus. A JASCO Model SUPER-200 SFC system with a UV-970 variable-wavelength UV/vis detector equipped with high-pressure flow cells was used.

Materials. CPO was obtained from Keck Seng (Malaysia) Berhad (Johor, Malaysia). Palm pressed fiber was obtained from the MPOB Experimental Mill (Negri Sembilan, Malaysia). The fiber was extracted for its oil by soaking it in hexane for 16 h.

All solvents used were of either chromatography or analytical grade and were purchased from Merck (Darmstadt, Germany), J.T.Baker (Phillipsburg, NJ), or HmBG (Hamburg, Germany). Solvents used for chromatography were degassed before use. CO_2 (99.995%) was purchased from Malaysian Oxygen Berhad (Kuala Lumpur, Malaysia).

Squalene, β-carotene, β-sitosterol, and α-tocopherol standards were purchased from Sigma-Aldrich (St. Louis, MO). Tocotrienol standards were obtained from Calbiochem (San Diego, CA).

Preparation of the unsaponifiable sample. Approximately 5 g of CPO was saponified with 5 mL of 50% ethanolic KOH and 1 g of pyrogallol (which acts as an antioxidant) by heating it in the dark under nitrogen flushing using a steam bath for 1 h. The saponified sample was then cooled to room temperature and extracted using a 50-mL portion of a single-phase system of 10% distilled water in *n*-hexane until the supernatant turned colorless. The pooled hexane extracts were washed with 50-mL portions of 10% ethanol in distilled water until the washed water turned neutral. The extract was then taken to dryness using a rotary evaporator and was further dried under vacuum.

The same saponification procedure was repeated using 3 g of PFO.

The yield of unsaponifiable sample from 5 g of CPO was 0.1 g, or 2%, whereas the yield from 3 g of PFO was 0.08 g, or 2.7%. Each unsaponifiable sample from CPO and PFO was dissolved in dichloromethane and injected into a supercritical fluid chromatograph, a high-performance liquid chromatograph, or a gas chromatograph after silylation for further analysis of sterols. Wavelengths for the detection of minor components were: carotenes, 446 nm; vitamin E, 291 nm; sterols, 220 nm; and squalene, 220 nm.

SFC. SFC was carried out using a 5-μm, 4.6 × 250 mm LiChrosorb® 60A Silica analytical column (Merck), with a flow rate of 3.12 mL/min CO_2 with 4% ethanol as entrainer under 180 kg/cm² pressure at 50°C. The loop at the injector port was 20 μL.

HPLC. Analysis of vitamin E was also carried out using HPLC coupled with a fluorescence detector (λ_{ex}: 295 nm; λ_{em}: 325 nm) to compare the results obtained by SFC. A LiChrosorb® 60A Silica analytical column (Merck), 4.6 mm i.d. × 250 mm length, was used. The mobile phase was hexane/THF/isopropanol (1000:60:4) at 1 mL/min.

GC. Results obtained from the analysis of squalene and sterols using SFC were compared with those obtained using a known GC method. Samples for GC analyses were prepared by adding 0.3 mL of 30% *N,O*-bis(trimethylsilyl) trifluoro-acetamide in dichloromethane to a weighed sample (*ca.* 0.02 g). The solution was brought up to 1.5 mL using dichloromethane. Thereafter, the sample mixture was heated at 60°C for 2 h before injection into the gas chromatograph-FID.

A Hewlett-Packard 5890 Series II Plus gas–liquid chromatograph was used. The column used was an SGE 15 m × 0.32 mm i.d. BPX5 0.25 μm capillary column (SGE, Melbourne, Australia); the initial oven temperature was set at 100°C for 1 min and increased to 400°C at the rate of 10°C/min. The injector and detector temperatures were set at 370°C. The oven equilibrium time was 3 min under a pressure of 6.60 psi. The carrier gas (helium) was set at flow velocity ranges of 1.99–2 mL/min/cm/s. The range of split ratio between the compressed air and H_2 gas was 0.0–1.

Quantification of carotene, vitamin E, sterols, and squalene. Standard curves of the vitamin E standards (α-tocopherol, α-tocotrienol, γ-tocopherol, γ-tocotrienol, and δ-tocotrienol) were obtained by injecting different concentrations of the standard into the supercritical fluid chromatograph. Peak areas were obtained, and calibration graphs were then plotted.

Similar steps were applied for the squalene and sterols, which were calibrated as β-sitosterol. Statistical data from the analysis were obtained based on the results of 15 repetitive analyses.

The total carotene content was confirmed using the established method of UV-vis spectrophotometry, by which its spectra and absorbance were obtained at 446 nm.

RESULTS AND DISCUSSION

The isolation of minor components of palm using SFC is a more straightforward method than other procedures. Conventional analyses of palm minor components are tedious, as different techniques such as UV-vis spectrophotometry, HPLC, and GC are necessary to quantify all four minor components of palm in just one sample. Because different analyses require different sample preparations, such as silylation, to convert the nonvolatile compounds to their more volatile derivatives for GC analyses, the whole procedure is time-consuming and labor-intensive. Using SFC, sample preparation, which takes less than 5 min, is carried out only once, thus saving time and labor. Moreover, isolation of the minor components of palm oil by SFC can be accomplished in less than 20 min (Fig. 1). This is much shorter than HPLC and GC, which takes 45 min to complete.

Figure 1 shows the SFC chromatograms of carotenes, vitamin E, sterols, and squalene in CPO and PFO, respectively. Squalene was eluted first, as observed at a wavelength of 220 nm. The amounts of squalene in CPO and PFO were 600 ± 10 and 1730 ± 30 ppm, respectively. The results obtained by the SFC analysis were comparable to those obtained by GC.

Carotenes were eluted as total carotenes, as observed at 446 nm. This was chosen as the wavelength of palm carotenes since it corresponds to the wavelength with maximal absorption in the UV. The amount of carotenes in palm oil was calibrated as
FIG. 1. Supercritical fluid chromatogram of crude palm oil (CPO) and palm fiber oil (PFO) unsaponifiable matter at 210 nm. CPO (A) and PFO (B) unsaponifiable matter was separated by supercritical fluid chromatography (SFC) with a LiChrosorb® 60A Silica column (4.6 mm i.d. × 250 mm length; Merck, Darmstadt, Germany) at 180 kg/cm² and 50°C. The compounds separated were: 1, squalene; 2, carotenes; 3, vitamin E; and 4, sterols.
FIG. 2. Supercritical fluid chromatogram of vitamin E in CPO and PFO at 291 nm. Vitamin E in CPO (A) and PFO (B) was separated by SFC with a LiChrosorb 60A Silica column (4.6 mm i.d. × 250 mm length; Merck) at 180 kg/cm² and 50°C. α-T, α-tocopherol; α-T₃, α-tocotrienol; γ-T, γ-tocopherol; γ-T₃, γ-tocotrienol, and δ-T₃, δ-tocotrienol. For other abbreviations see Figure 1.

total β-carotene since it is the major carotene present in palm oil. The total carotenes in CPO were 550 ± 10 ppm, whereas they were 2400 ± 30 ppm in PFO. Using UV-vis spectrometry, the total carotenes in CPO and PFO were 600 ± 20 and 2290 ± 190 ppm, respectively. These results are in agreement with the results obtained by SFC.

Since vitamin E isomers have their maximal absorbance (fluorescence) at 291 nm, this wavelength was chosen for quantification of the vitamin E isomers. At 291 nm, the vitamin E isomers in palm oil were separated into five components, with α-tocopherol as the first vitamin E isomer to be eluted, followed by α-tocotrienol, γ-tocopherol, and γ-tocotrienol, with δ-tocotrienol as the last. Figure 2 shows the SFC chromatograms of vitamin E isomers in the CPO and PFO unsaponifiable samples at 290 nm. The concentrations of the five types of

vitamin E isomers detected in CPO and PFO are presented in Table 1 and compared with HPLC analyses. There was a distinct difference in the concentrations of the vitamin E isomers analyzed by SFC and HPLC. Analyses carried out using SFC gave higher concentrations than those by HPLC. This can be attributed to the fact that in HPLC, vitamin E is destroyed due to prolonged exposure to organic solvents. Because SFC uses supercritical carbon dioxide (SC-CO₂) as the mobile phase, the oxidation of minor components of palm (especially vitamin E isomers) is avoided because SC-CO₂ is nondestructive. Other organic solvents used with HPLC or other chromatographic methods have been shown to degrade the tocols.

Sterols were the last to be eluted by SFC and were quantified as total β-sitosterol, as this is the major sterol present in palm oil. The concentrations of total sterols in CPO and PFO

	SFC		HPLC	
	PFO	CPO	PFO	CPO
α-Tocopherol	1260 ± 50	300 ± 40	1250 ± 70	310 ± 70
α-Tocotrienol	260 ± 10	230 ± 20	230 ± 40	240 ± 5
γ-Tocopherol	80 ± 5	20 ± 5	100 ± 20	10 ± 10
γ-Tocotrienol	480 ± 30	540 ± 30	350 ± 30	460 ± 30
δ-Tocotrienol	200 ± 50	90 ± 10	160 ± 10	100 ± 70
Total	2280 ± 145	1180 ± 105	2090 ± 170	1120 ± 185

[a]Results obtained by calibration with authentic standards using both supercritical fluid chromatography (SFC) and HPLC.

TABLE 2
Concentration of Individual Sterols Analyzed by GC^a

	Concentration (ppm)	
	CPO	PFO
Cholesterol	60	620
Stigmasterol	30	340
β-Sitosterol	60	300
Campesterol	80	990
Total	230	2250

^{a}Breakdown of the sterol composition of CPO and PFO as analyzed by GC. In contrast, the composition of sterols for SFC is reported in this paper as total sterols. For abbreviations see Table 1.

were 180 ± 10 and 2410 ± 50 ppm, respectively. GC-FID is an established method for the quantification of sterols by which the individual sterols can be calibrated (2). Table 2 shows GC results for the quantification of individual sterols. The results obtained by SFC for the determination of total sterols were comparable to those obtained by GC.

In conclusion, SFC can be applied for the isolation of minor components of palm oil, as SFC results for the isolation of these compounds are comparable to those obtained by known methods.
