ABSTRACT: The overall objective is to test the hypothesis that conjugated linoleic acid (CLA) has beneficial effects in Atlantic salmon as a result of affecting lipid and FA metabolism. The specific aims of the present study were to determine the effects of CLA on some key pathways of FA metabolism, including FA oxidation and highly unsaturated FA (HUFA) synthesis. Salmon smolts were fed diets containing two levels of fish oil (low, ~17%, and high, ~34%) containing three levels of CLA (a 1:1 mixture of *cis*-9,*trans*-11 and *trans*-10,*cis*-12 at 0, 1, and 2% of diet) for 3 mon. The effects of dietary CLA on HUFA synthesis and β-oxidation were measured, and the expression of key genes in the FA oxidation and HUFA synthesis pathways, and the potentially important transcription factors peroxisome proliferators activated receptors (PPAR), were determined in selected tissues. Liver HUFA synthesis and desaturase gene expression was increased by dietary CLA and decreased by high dietary oil content. Carnitine palmitoyltransferase-I (CPT-I) activity and gene expression were generally increased by CLA in muscle tissues although they were relatively unaffected by dietary oil content. In general CPT-I activity or gene expression was not correlated with β-oxidation. Dietary CLA tended to increase PPARα and β gene expression in both liver and muscle tissues, and PPARγ in liver. In summary, gene expression and activity of the FA pathways were altered in response to dietary CLA and/or oil content, with data suggesting that PPAR are also regulated in response to CLA. Correlations were observed between dietary CLA, liver HUFA synthesis and desaturase gene expression, and liver PPARα expression, and also between dietary CLA, CPT-I expression and activity, and PPARα expression in muscle tissues. In conclusion, this study suggests that dietary CLA has effects on FA metabolism in Atlantic salmon and on PPAR transcription factors. However, further work is required to assess the potential of CLA as a dietary supplement, and the role of PPAR in the regulation of lipid metabolism in fish.

Abbreviations: CPT-I, carnitine palmitoyl transferase-I; HUFA, highly unsaturated FA; PPAR, peroxisome proliferator-activated receptor; rtqPCR, real-time quantitative polymerase chain reaction; SCD, stearoyl CoA desaturase; SGR, specific growth rate; SREBP, steryl regulatory element binding protein.

Conjugated linoleic acid (CLA) refers to conjugated isomers of linoleic acid (18:2n-6); the two main naturally occurring isomers are *cis*-9,*trans*-11 and *trans*-10,*cis*-12. In mammals, dietary CLA has been shown to have a number of physiological effects and health benefits, including anticarcinogenic and immune enhancing properties (1). In addition, CLA has several beneficial effects on lipid metabolism in mammals, including altering body composition (2). Specifically, CLA has been shown to decrease body fat and increase lean body mass in mice, rats, and pigs (2). Decreased body fat has also been observed in human studies, although the effect was much less than that observed with mice (3). CLA is also known to decrease the activity and gene expression of mammalian stearoyl CoA Δ9 desaturase (4), and may also suppress Δ6 and Δ5 desaturase (5) and elongase (6).

There is accumulating evidence that some of the effects of CLA may be mediated through transcription factors such as peroxisome proliferator activated receptors (PPAR) or sterol regulatory element binding proteins (SREBP). Specifically CLA isomers are ligands and activators of both PPARα (7) and PPARγ (8), which in mammals are known to regulate the expression of genes of FA oxidation and lipid deposition in liver and adipose tissue, respectively (9). Dietary CLA also influenced the expression of SREBPs in ob/ob mice (10). Both PPARs and SREBPs are involved in the control of FA desaturation and elongation, with PPARα and SREBP-1 both affecting Δ6 and Δ5 activities (11), and SREBP-1 also regulating elongase activities (12). Therefore, CLA via PPARs and/or SREBPs may affect lipid contents and FA compositions in a variety of ways including selectivity in oxidation and deposition of specific FA and modulation of FA desaturation and elongation.

The overall objective is to test the hypothesis that CLA has beneficial effects in Atlantic salmon as a result of affecting lipid and FA metabolism. The specific aims of the present study were to determine the effects of CLA on some key pathways of FA metabolism, including FA oxidation and highly unsaturated FA (HUFA) synthesis via desaturation and elongation. To this end, salmon smolts were fed diets containing two levels of fish oil (low, ~17%, and high, ~34%) containing three levels of CLA (a 1:1 mixture of the two main isomers

present in nature, *cis*-9,*trans*-11 and *trans*-10,*cis*-12, at 0, 1, and 2% of diet) for 3 mon. The effects of dietary CLA on the expression of key genes of FA oxidation and HUFA synthesis, and on the enzymatic activities of the pathways were determined. In addition, the effect of CLA on the expression of potentially important transcription factors, PPAR, was determined in selected tissues.

EXPERIMENTAL PROCEDURES

Diets and animals. Atlantic salmon smolts (S1/2) were obtained from a commercial salmonid farm (Howietoun Fish Farm, Sauchieburn, Scotland) in late October and transported to Stirling University, Institute of Aquaculture, Marine Environmental Research Laboratory, Machrihanish, Scotland. The fish were maintained in stock tanks for 3 wk at ambient water temperature of about 10–11°C to acclimatize, during which time the fish were fed standard salmon diet, before being randomly distributed between 18 indoor, round, conical tanks of 1.5 m^3 volume (1.72 m diameter). The initial stocking density was 100 fish of average fish weight 87.5 ± 1.6 g per tank (5.8 kg/m^3). Water temperature was maintained at 12 ± 1°C throughout the trial, with a light regime of 12 h light:12 h dark. Six experimental diets were fed to triplicate tanks for 3 mon, with feed supplied to appetite manually. The experimental diets were formulated to satisfy the nutritional requirements of salmonid fish (13), and were formulated and manufactured by BioMar A/S (Brande, Denmark). The trial had a 3×2 factorial design with CLA added at three concentrations to diets with two oil contents (low and high). Thus diets were produced with 0, 1, and 2% CLA replacing standard Northern hemisphere fish oil in smolt feeds containing either 17 or 34% total lipid. The low-oil diets contained 17% total lipid with 0 (L0), 1 (L1), and 2% (L2) CLA. The high-oil diets, labeled H0, H1, and H2, contained 34% total lipid. Diets were formulated to be isonitrogenous; protein content was constant between diets of different oil content (Table 1). Diets within the low or high oil groups were identical in formulation other than FA composition, with CLA (LUTA-CLA™ 60, containing 60% CLA methyl esters as a 50:50 mixture of *cis*-9,*trans*-11 and *trans*-10,*cis*-12 isomers; BASF AG, Ludwigshafen, Germany) balanced by fish oil (capelin oil, Norsemeal Ltd., London, United Kingdom). The FA compositions of the diets are presented in Table 2.

Sampling protocols. At the termination of the trial, 10 fish per dietary treatment (3–4/tank) were individually weighed and eviscerated, and hepato- and viscero-somatic indices were determined. Samples of 0.5 g of liver, white muscle, and red muscle were rapidly dissected from six of the fish (2/tank) and immediately frozen in liquid nitrogen for RNA analyses. In addition, samples of 1–2 g of liver, white muscle, and red muscle for biochemical analyses were collected from the same fish and immediately frozen in liquid nitrogen. All samples were subsequently stored at –80°C prior to analysis.

RNA extraction and real-time quantitative polymerase chain reaction (rtqPCR). Total RNA was isolated from 100–500 μg (depending upon tissue) of pooled (2 fish) tissue by the standard TRIzol method (Invitrogen Ltd, Paisley, United Kingdom), and DNA was removed using DNA-*free*™ DNase treatment (Ambion Inc., Austin, TX). Total RNA (5 μg) was reverse transcribed into cDNA using M-MLV reverse transcriptase first strand cDNA synthesis kit (Promega UK, Southampton, United Kingdom). The PCR primers were designed according to the salmon cDNA sequences for Δ6 desaturase (accession no. AY458652), Δ5 desaturase (accession no. AF478472), CPT-I, PPARα (M.J. Leaver, personal communication), PPARβ (accession no. AJ416953), and PPARγ (accession no. AJ416951). Primer sequences and PCR product sizes are given in Table 3. The linearized plasmid DNA containing the target sequence for each gene was quantified to generate a standard curve of known copy number. Amplification of cDNA samples and DNA standards was carried out using the SYBR Green PCR Kit (Applied Biosystems, Foster City, CA) with the following conditions: denaturation for 15

TABLE 1

min at 95°C followed by 45 cycles of 15 s at 95°C, 15 s at 56°C, and 30 s at 72°C, followed by product melting to check purity of PCR product. Thermal cycling and fluorescence detection were conducted using the Rotor-Gene 3000 system (Corbett Research, Cambridge, United Kingdom). Expression of target genes was normalized using a Quant-iT™ high-sensitivity DNA assay kit containing PicoGreen reagent, (Molecular Probes, Rijinsburgerweg, the Netherlands) using a modified version of the manufacturer's protocol (14). All reactions were carried out in duplicate and a linear standard curve was drawn, plotting the average absorbance values obtained for the Quant-iT DNA values against the standard DNA concentration, with the concentration of total cDNA calculated from the linear equation.

FA desaturation and elongation (HUFA synthesis) in liver microsomes. Portions of frozen liver were homogenized to 10% (w/v) in 0.25 M sucrose in 40 mM phosphate buffer (pH 7.4) containing 1 mM EDTA, 0.15 M KCl, 40 mM KF, and 1 mM *N*-acetyl cysteine. The homogenate was centrifuged at 25,000*g* for 15 min at 4°C, the floating fat layer removed by aspiration, and the remaining supernatant centrifuged at 105,000*g* for 60 min at 4°C. The floating fat layer was aspirated and the supernatant decanted. The pelleted microsomal fraction was resuspended in 1 mL of sucrose buffer, and 50 μL was taken for protein determination following the procedure of Lowry *et al.* (15) after incubation with 0.45 mL of 0.25% (w/v) SDS/1 M NaOH for 45 min at 60°C. The assay mixture, in sucrose buffer (pH 7.4), contained 5 mM $MgCl_2$, 1.5 mM glutathione, 0.5 mM nicotinamide, 1 mM NADH, 100 μM coenzyme A, and 5 mM ATP in a total volume of 0.75 mL. Fifty μL of [1-^{14}C]18:3n-3 (0.25 μCi, 5 μM final concentration), as a fatty acid-free (FAF) BSA complex, was added and the reaction initiated by the addition of 200 μL of microsomes. Incubation continued for 1 h at 20°C, and the reaction was stopped by the addition of 5 mL of chloroform/methanol (2:1, vol/vol) containing 0.01% BHT, and total lipid was extracted, transmethylated, and FAME prepared as described previously (16). FAME were separated by argentation TLC and visualized by autoradiography; radioactivity was determined by scintillation counting as described previously (17).

Assay of carnitine palmitoyltransferase I (CPT-I) and FA β-oxidation in tissue homogenates. Liver, red muscle, and white muscle were weighed, diced, and homogenized to 20%

(w/v) in 0.25 M sucrose in 10 mM HEPES buffer and 1 mM EDTA at pH 7.4. The homogenates were centrifuged at 1880*g* for 10 min at 4°C, the floating fat layer was aspirated, the postnuclear fractions were collected, and 50 μL was taken for protein determination as above. Portions were used immediately for determination of enzyme activities. CPT-I activity was estimated by determining the production of palmitoyl[^{3}H]carnitine from palmitoyl CoA and [^{3}H]carnitine essentially as described by Saggerson and Carpenter (18). FA β-oxidation was estimated by determining radioactivity in acid-soluble products derived from the oxidation of [1-^{14}C]palmitoyl-CoA as described by Torstensen *et al.* (19).

Materials. [1-^{14}C] Palmitoyl CoA (50–55 mCi/mmol) and [methyl-^{3}H] L-carnitine hydrochloride (60–86 Ci/mmol) were obtained from GE Healthcare Bio-Sciences (Little Chalfont, Bucks, United Kingdom), and [1-^{14}C]18:3n-3 (50–55 mCi/mmol) was obtained from NEN (PerkinElmer LAS UK Ltd., Beaconsfield, United Kingdom). BHT, carnitine, FAF-BSA, HEPES, palmitoyl-CoA, silver nitrate, and TriReagent were obtained from Sigma Chemical Co. (Poole, United Kingdom). TLC (20 cm × 20 cm × 0.25 mm) plates, precoated with silica gel 60 (without fluorescent indicator) were obtained from Merck (Darmstadt, Germany). All solvents were HPLC grade and were obtained from Fisher Scientific UK (Loughborough, United Kingdom).

Statistical analysis. All data are presented as means ± SD (*n* value as stated). Percentage data and data that were identified as nonhomogeneous (using Bartlett's test) were subjected to arcsine transformation before analysis. The effects of dietary CLA and oil content were determined by two-way ANOVA with Bonferroni posttests to determine significance of differences due to CLA. Differences were regarded as significant when $P < 0.05$ (20).

RESULTS

Diet composition, growth, and biometry. Inclusion of CLA in the low-oil diets resulted in levels of total CLA of 5.9 and 9.5% of total FA at the 1 and 2% inclusion levels, respectively (Table 2). Obviously, in the high-oil diets, inclusion of CLA at 1 and 2% resulted in lower levels of total CLA, at 3.3 and 5.8% of total FA, respectively. The levels of CLA in relative terms were identical in the L1 and H2 diets, with an overall rank order for CLA content of L2 > L1 = H2 > H1 > L0 = H0. There were no effects of diet on growth parameters, with no significant effects of CLA or oil content on final weights or specific growth rate (SGR) (Table 4).

Tissue enzyme activities. HUFA synthesis in liver microsomes, as measured by the recovery of radioactivity in the summed Δ6 and Δ5 desaturated products (18:4, 20:4, 20:5, and 22:5) of [1-^{14}C]18:3n-3, was significantly affected by both dietary oil content and CLA content as determined by two-way ANOVA (Table 5). However, there was significant interaction between the variables, as activity was significantly higher in fish fed 2% CLA compared to fish fed fish oil alone at the low-oil level, whereas the opposite trend was observed at the high-oil level (Fig. 1). HUFA synthesis activity in liver was significantly lower in fish fed the high-oil diet (Table 5, Fig. 1).

Dietary CLA did not significantly increase β-oxidation activity in white muscle irrespective of dietary oil content (Table 5, Fig. 2). There was a trend suggesting CLA may increase β-oxidation in red muscle in fish fed high dietary oil, but the high variation made this nonsignificant. Liver β-oxidation was significantly lower in fish fed the high-oil diet, but dietary CLA had no effect on β-oxidation in liver (Table 5, Fig. 2). Dietary oil content had no effect on β-oxidation activities in either muscle tissue.

CPT-I activity was significantly increased by dietary CLA in white muscle, and also in red muscle, particularly in fish fed the high-oil diets (Table 5, Fig. 3). CPT-I activity in white

TABLE 4
Final Weights of Atlantic Salmon (*Salmo salar*) Fed Diets Containing CLA

Diet	Initial weight (g)	Final weights (g)	SGR
L0	87.8 ± 1.5	256.3 ± 18.7	1.31
L1	87.4 ± 0.5	236.3 ± 17.6	1.21
L2	87.9 ± 2.2	236.7 ± 18.4	1.21
H0	85.5 ± 1.5	245.4 ± 12.1	1.29
H1	89.3 ± 0.9	260.8 ± 13.1	1.31
H2	86.9 ± 0.6	260.4 ± 5.4	1.34

Data are presented as means ± SD (n = 100 and 10 for initial and final weights); SGR, specific growth rate (%/day) = 100 × [(ln weight$_{final}$ – ln weight$_{initial}$) × days^{-1}]; L0, L1, and L2, low-lipid diets with 0, 1, and 2% CLA; H0, H1, and H2, high-lipid diets with 0, 1, and 2% CLA. There were no significant differences between dietary treatments as determined by two-way ANOVA.

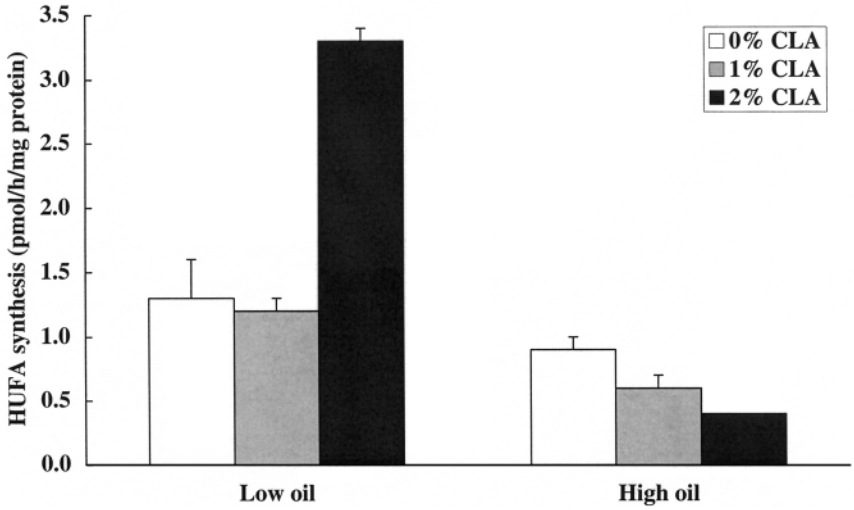

FIG. 1. Effects of dietary oil content and CLA on HUFA synthesis in the liver microsomes. Specific activities are presented as means ± SD (n = 3) and were determined as described in the text.

muscle was also significantly increased by high dietary oil. In contrast, hepatic CPT-I activity was unaffected by dietary oil content, but there was a trend for it to be decreased by dietary CLA in the low-oil group (Table 5, Fig. 3).

Tissue enzyme expression. The expression of FA Δ6 and Δ5 desaturases in liver was significantly affected by both dietary CLA and oil content (Table 5). Specifically, expression of both desaturases was increased by dietary CLA and reduced by high dietary oil content (Fig. 4). CPT-I expression in all three tissues, red and white muscle and liver, was significantly increased by dietary CLA (Table 5, Fig. 5). However, CPT-I expression was not affected by dietary oil content in either muscle tissue, although it was increased in liver tissue, at least in fish also being fed CLA (Table 5, Fig. 5).

Tissue PPAR expression. The expression of all PPAR subtypes was significantly affected by both dietary CLA and oil content (Table 5). Dietary CLA increased PPARα expression in liver and, to a lesser extent, white muscle (Fig. 6). In red muscle, there was a strong interaction between dietary CLA and oil content such that CLA increased expression at low oil content, but the opposite was true at high dietary oil content. High oil content may have induced increased expression of PPARα in red muscle, although the interaction also made this difficult to interpret. PPARβ expression in the muscle tissues was similar to that for PPARα in these tissues. Thus the expression of PPARβ was increased by dietary CLA in white muscle, whereas there was a significant interaction between CLA and dietary oil in red muscle, which made the effects of CLA difficult to interpret (Table 5). However, PPARβ expression was increased by high dietary oil, but dietary CLA decreased PPARβ expression in red muscle in fish fed high dietary oil (Fig. 7). The expression of PPARβ in liver was greatest in fish fed 1% CLA (Table 5, Fig. 7). Expression of PPARγ in liver was significantly increased by dietary CLA, but dietary oil content had no significant effect (Table 5, Fig. 8). PPARγ expression in muscle tissues was too low to be reliably determined.

DISCUSSION

CLA has the capacity to exert both agonistic and antagonistic effects on a wide variety of lipid metabolic factors. These effects depend on the pattern of lipid metabolism, which itself varies with species, tissue type, and age, and dietary factors, including lipid content, CLA isomer composition, and duration of supplementation. Thus, it is difficult to define a specific biochemical mechanism of action. However, the view that CLA can affect lipid accumulation both by decreasing *de novo* FA synthesis and by increasing oxidation is well established, at least in mammals. For example, CLA inhibits FA synthetase activity in rat liver (21), and suppresses TAG accumulation and increases FA oxidation in 3T3-L1 adipocytes (22). It is hypothesized that CLA exerts such effects on lipid metabolism at the transcriptional level by altering gene expression of key regulatory proteins and enzymes mediated, in part, by PPAR. However, it was unclear whether CLA have the ability to alter lipid metabolism in fish in a manner similar to that of mammalian models (23).

In the present study, salmon fed CLA exhibited increased expression of Δ5 and Δ6 FA desaturases in liver; this was particularly evident in the low-oil diet, which displayed an approximately twofold increase in expression of Δ5 and Δ6 at 2% inclusion of CLA. This was at least partly reflected in HUFA synthesis activity, which increased in fish fed 2% CLA at the low dietary oil content. Analogously, Δ5 and Δ6 FA desaturase expression was increased in mice fed CLA (24), whereas the amount of HUFA, EPA, and DHA increased in hybrid striped bass *Morone chrysops, saxatilis* in response to dietary CLA (25). One explanation may be that transcription factors equivalent to mammalian PPARα and SREBP-1c are directly involved in regulating Δ6 and Δ5 desaturases in fish via a feedback mechanism. A similar mechanism for the regulation of desaturase gene expression has been proposed in mammals, whereby Δ6 desaturase gene expression is partly

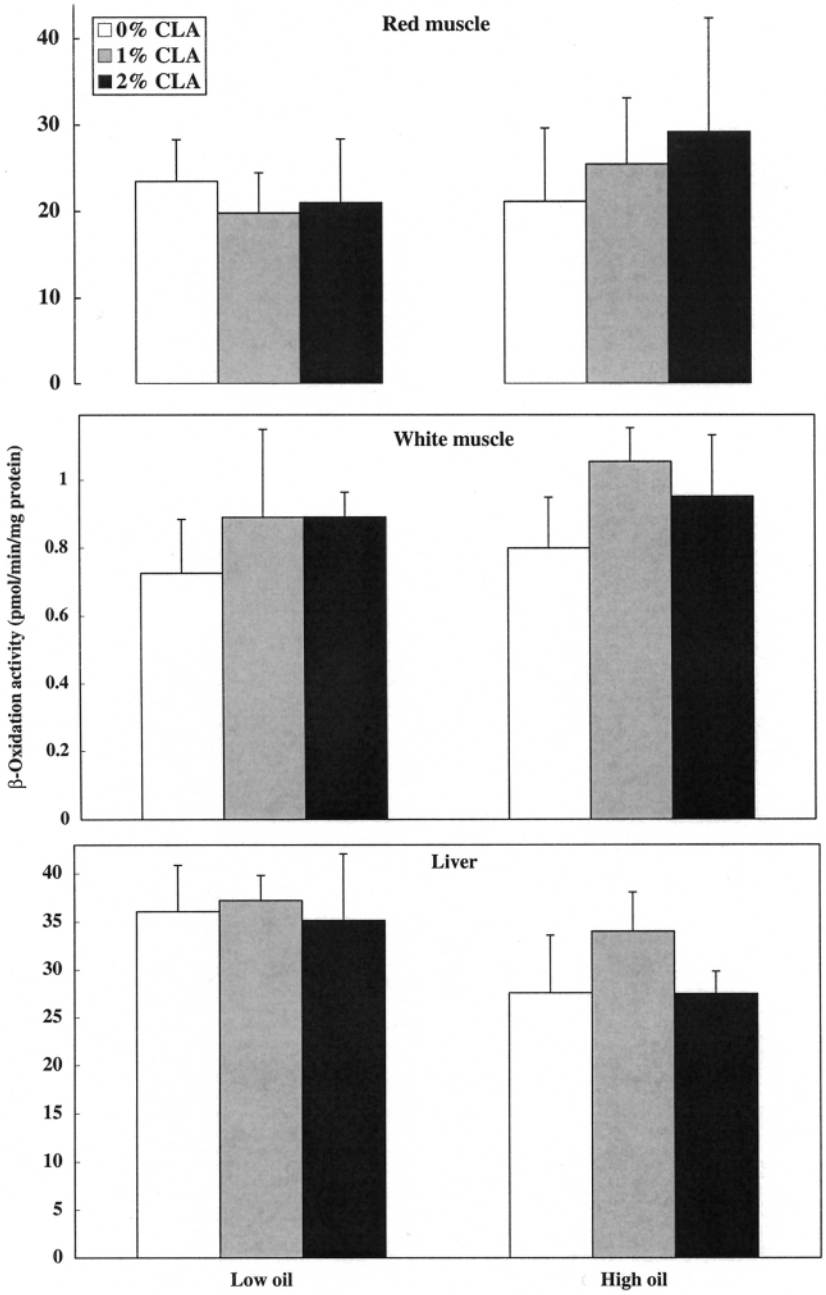

FIG. 2. Effects of dietary oil content and CLA on total β-oxidation activities in tissue homogenates of red and white muscle and liver. Specific activities are presented as means ± SD (n = 3) and were determined as described in the text.

regulated by PPARα (26). It was shown that ligand activation of PPARα via peroxisome proliferators may result in upregulation of Δ5 and Δ6 desaturase, and that high PUFA feeding downregulated these genes in a SREBP-1–dependent mechanism (11). In salmon liver, CLA feeding was associated with increases in Δ5 and Δ6 desaturase expression and HUFA synthesis in low-oil treatments, which might be indicative of a role for ligand activation of PPARα by CLA. In contrast, in high-oil diets, Δ5 and Δ6 expression and HUFA synthesis were repressed, even in the presence of similar amounts of CLA, possibly indicating a role for SREBP-1 proteins. Interestingly, CLA feeding also increased the levels of PPARα, providing some further support for this mechanism of regulation in salmon liver.

Previously, however, we reported that dietary CLA had no significant effect on either liver or flesh (muscle) FA compositions in salmon; thus it appears that the increased FA desaturase expression and HUFA synthesis activity does not have a major physiological consequence in terms of gross FA compositions (16). That alterations in desaturase gene expression

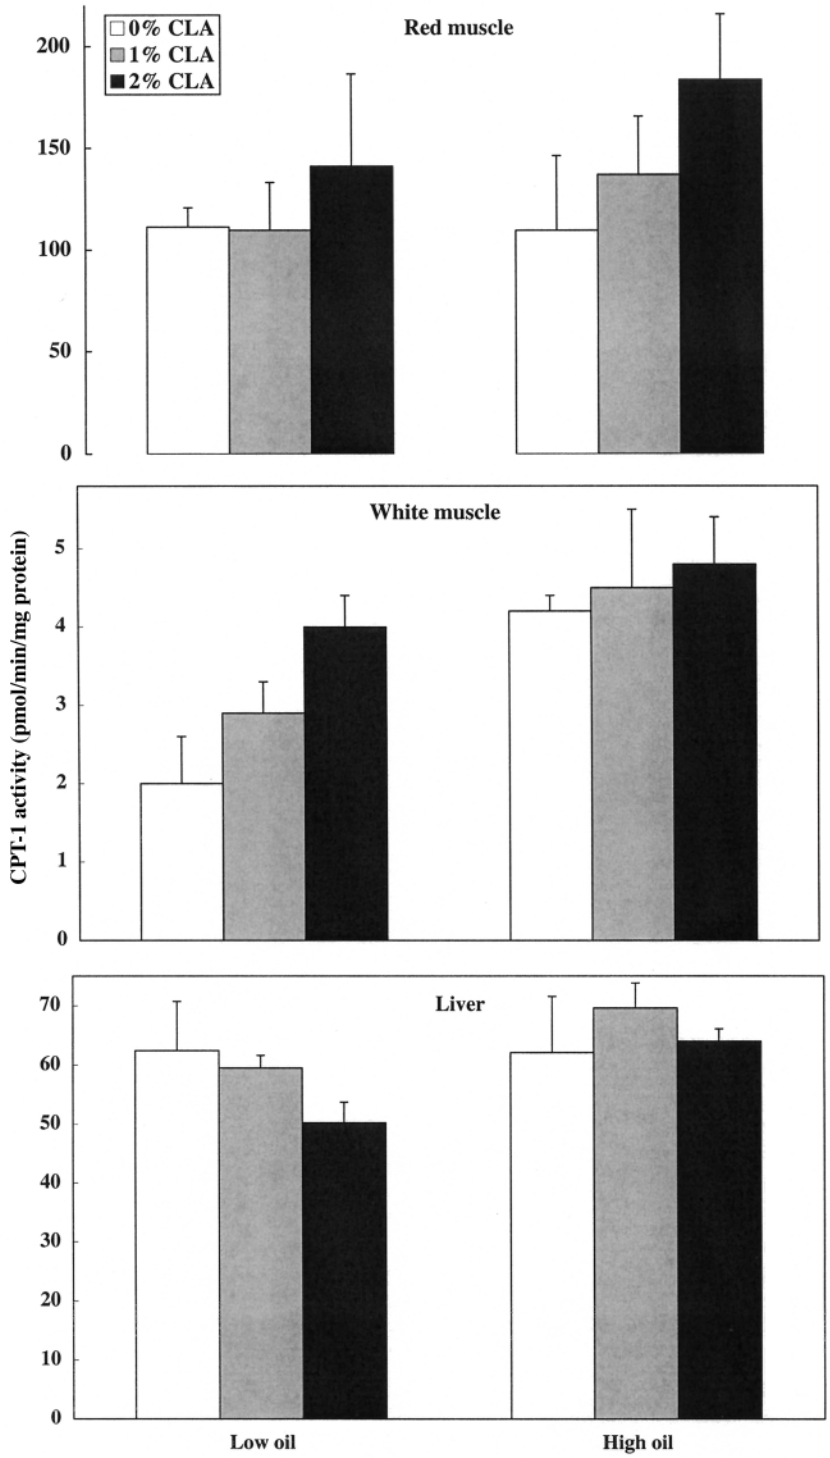

FIG. 3. Effects of dietary oil content and CLA on CPT-I activities in tissue homogenates of red and white muscle and liver. Specific activities are presented as means ± SD (n = 3) and were determined as described in the text.

and HUFA synthesis activity in liver can have relatively little effect on tissue FA compositions has been demonstrated previously in several trials in which salmon have been fed vegetable oils (see 27). The data from the present trial also show a correlation between desaturase expression and HUFA synthesis activity, and dietary oil content, with diets containing high oil conferring significantly lower levels of desaturase expression and HUFA synthesis activity compared to low-oil diets. In addition to effects on HUFA synthesis, it is well established that there is a reduction in FA synthesis (lipogene-

sis) as a result of high dietary oil levels, as demonstrated in Atlantic salmon and other fish species (28).

β-Oxidation is the principal means of FA catabolism in vertebrates. The basic mechanism of the pathway, and possibly regulation, appear to be highly conserved in mammals and fish (29). Recently, it has been suggested that CLA can increase mitochondrial β-oxidation in a variety of tissues in rats via an increase in CPT-I (30). Moreover, evidence of increased FA oxidation after CLA supplementation is presented in similar studies, which indicated that CLA increases gene expression and activity of CPT-I in mouse liver (31). However, in the present trial, β-oxidation capacity was not significantly affected in red or white muscle tissue of fish fed dietary CLA, despite mitochondrial β-oxidation predominating over peroxisomal β-oxidation in salmon red and white muscle (32). In contrast, CLA significantly increased both CPT-I expression and activity in these tissues. The reasons for the lack of association of CPT-I with β-oxidation are unclear. Increased CPT-I activities in liver and red muscle of hamsters fed CLA was not correlated with increased FA oxidation (33). The authors speculated that this may have been due to increased sensitivity of CPT-I to malonyl-CoA in animals fed CLA (33). As in mammals, malonyl-CoA is an inhibitor of CPT-I in Atlantic salmon, but it is not known if CLA can affect its potency (34). There are few data in fish species to compare the present data with. However, dietary lipid level did not alter β-oxidation activity in the muscle of haddock *Melanogrammus aeglefinus* L. fed graded levels of oil (29). In the present study, dietary oil content had no major effect on β-oxidation activity or CPT-I mRNA levels in either red or white muscle, or CPT-I activity in red muscle, although CPT-I activity was increased by dietary oil content in white muscle.

Previous studies in rodents showed that CPT-I mRNA level was elevated in liver in response to dietary CLA (31). In the present study and similar to results in muscle, CPT-I gene expression was found to be upregulated in salmon liver in response to dietary CLA, although this was not accompanied by

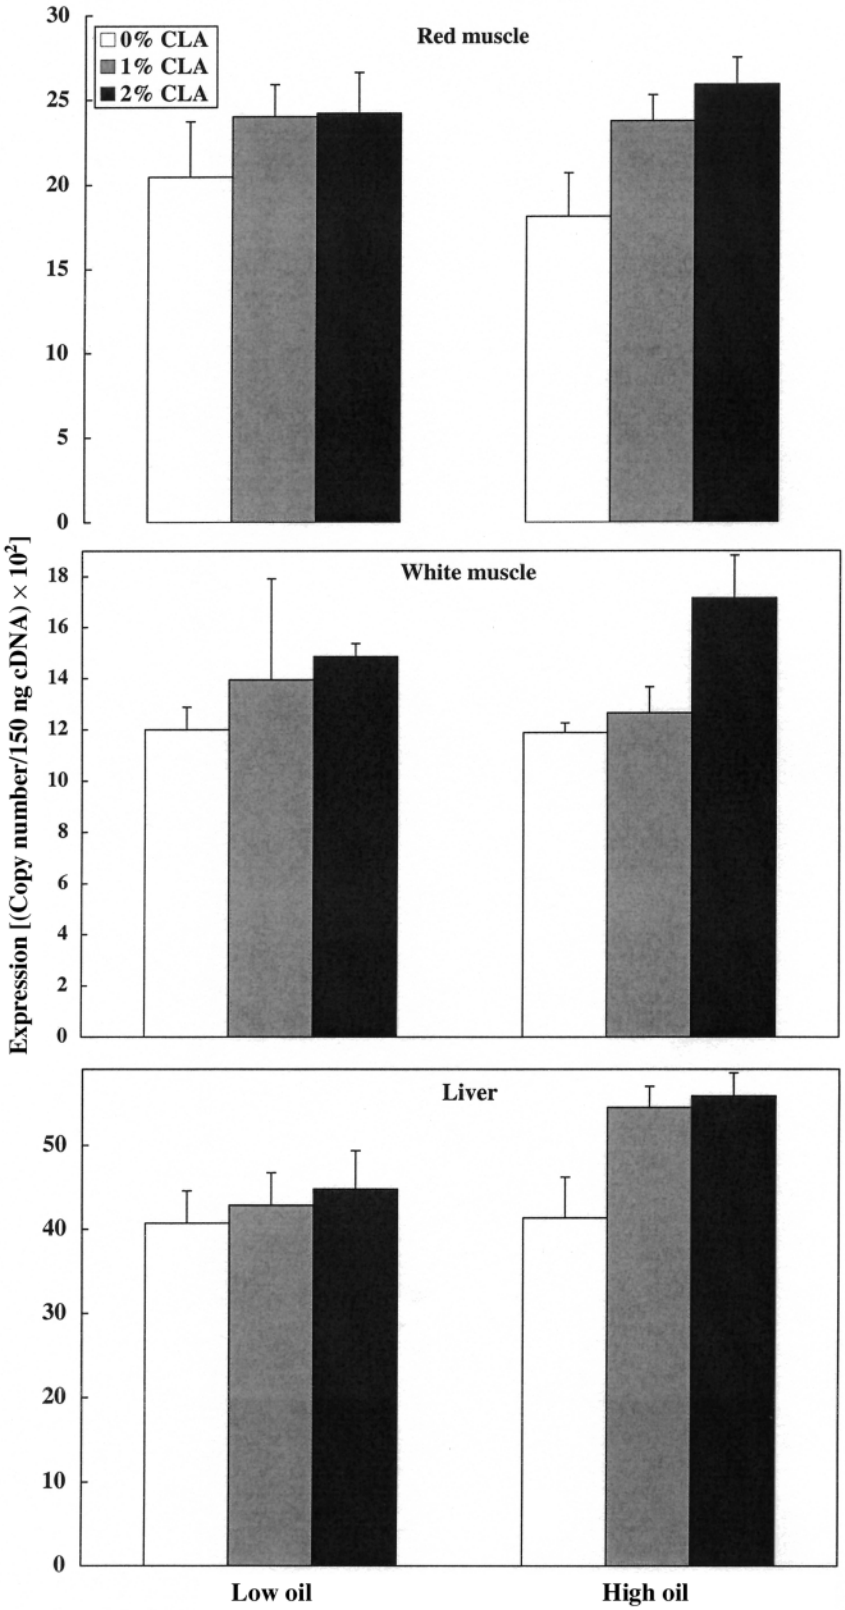

FIG. 5. Effects of dietary oil content and CLA on the expression of CPT-I in the liver, red muscle, and white muscle. Genes were determined by rtqPCR and normalized relative to total RNA, determined by fluorescent assay. Results are presented as means ± SD (n = 3).

increased CPT-I or β-oxidation activities. Furthermore, CPT-I expression was higher in salmon liver in fish fed the high-oil diet when fed in combination with CLA. Consistent with this, it appeared that in fish fed CLA, CPT-I activity was lower in fish fed the low-oil diet compared with fish fed the high-oil diet. However, these effects on CPT-I expression and activity

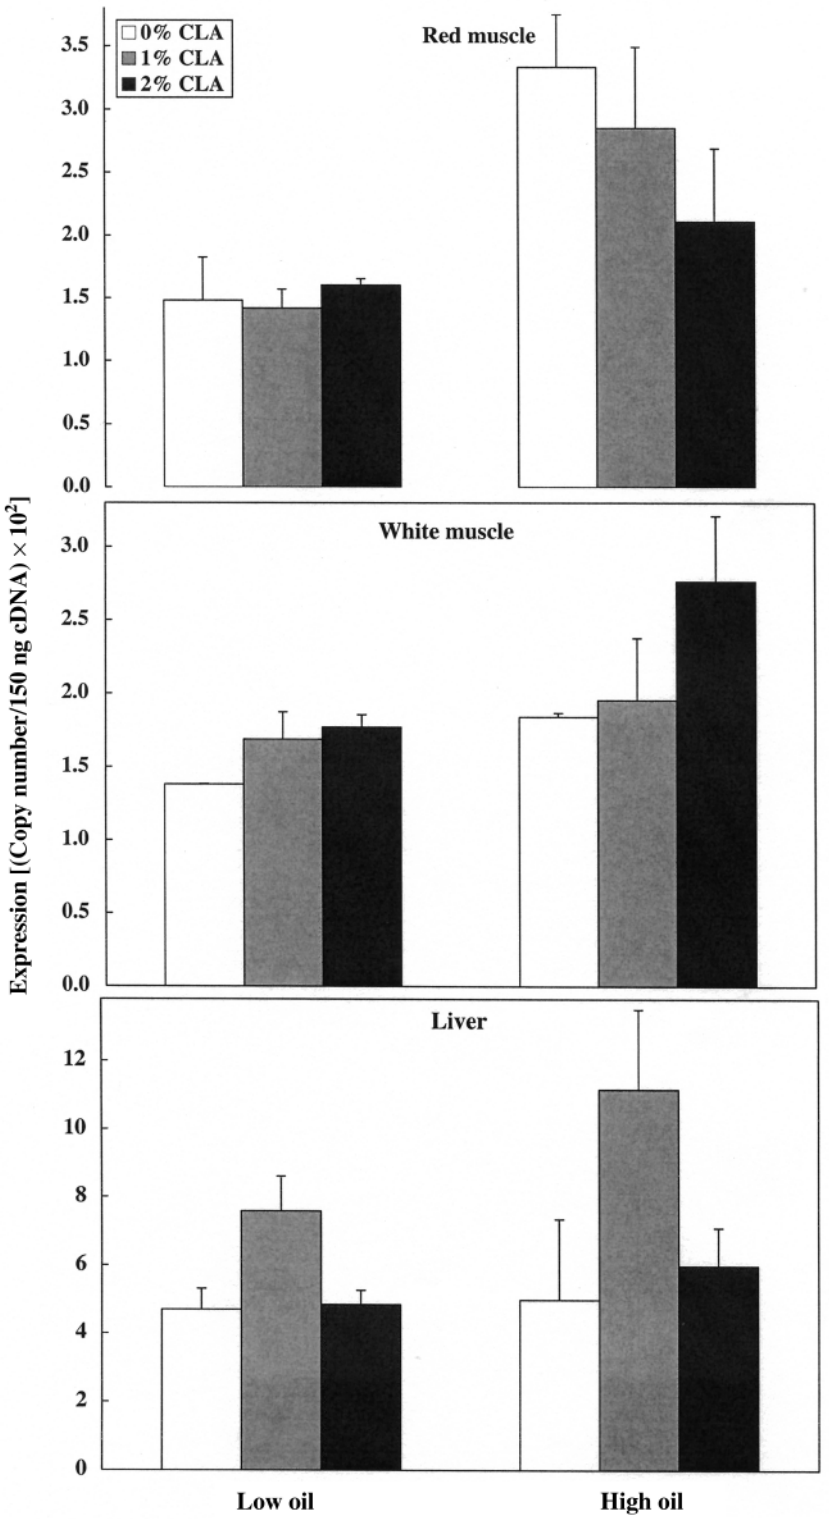

FIG. 7. Effects of dietary oil content and CLA on the expression of PPARβ in the liver, red muscle, and white muscle. Genes were determined by rtqPCR and normalized relative to total RNA, determined by fluorescent assay. Results are presented as means ± SD (n = 3).

in liver were not reflected in β-oxidation activity, which surprisingly was reduced in fish fed the high-oil diet. These results seem contradictory considering that the *in vivo* rate of FA oxidation should be associated with *in vitro* CPT-I activity (35). Nevertheless, studies determining changes in energy metabolism in hamsters fed CLA also found disparities between the

activity of CPT-I and lipid oxidation in the liver (33). Pertinent to this lack of correlation between CPT-I expression and activity and β-oxidation activity in liver is the fact that, with Atlantic salmon of similar age and size, catabolism of FA in liver was reported to be principally due to peroxisomal, rather than mitochondrial, β-oxidation (32). Consequently, CPT-I may not have a prominent role as a regulatory element of FA oxidation in salmon smolt liver, considering it is primarily involved in mitochondrial metabolism (36). This may be relevant in the present study, as it clearly provides a mechanism whereby changes in CPT-I expression and/or activity can be unrelated to β-oxidation activity in liver. This remains the case even considering that, in the present study, only total β-oxidation, combining mitochondrial and peroxisomal β-oxidation, was determined. Clearly, however, it also suggests that peroxisomal β-oxidation in salmon liver was unaffected by dietary CLA, and was actually decreased by high dietary oil. In comparison, graded levels of dietary lipid showed no significant differences in β-oxidation activity in liver of haddock (29).

There is consolidating evidence that lipid homeostasis is, at least in part, modulated through the PPAR transcription factors in mammals. Recent studies suggest that CLA could mediate this activation by acting as high-affinity ligands for a number of PPAR isotypes, particularly PPARα (7). PPARα is intimately involved in the regulation of genes involved in mitochondrial FA oxidative processes in mammals (37), whereas PPARγ is primarily involved in lipid deposition via preadipocyte differentiation and lipogenesis (38). Very recent work has elucidated that marine fish also share homologous gene sequences, with similar phylogenetic characteristics to the mammalian PPAR counterparts, possibly also suggesting similar molecular roles (39,40). However, Atlantic salmon may possibly contain up to five PPAR genes, as opposed to three in mammals, and therefore the precise role of piscine PPARs have not been conclusively defined (40).

The effects of CLA on mammalian PPAR gene expression are ambiguous and seem to be dependent partly on species, partly on tissue type, and partly on CLA isomer. The majority of studies describe a decrease in PPARγ mRNA in isolated adipocytes, or in adipose tissue from mice treated with *trans*-10,*cis*-12 CLA or a 1:1 mixture of the two predominant CLA isomers (41,42). Conversely, CLA has also been reported to increase expression of PPARγ in liver of mice, and in white adipose tissue of rats (43,44). *Trans*-10,*cis*-12 CLA downregulated PPARα in mice (45); however, there was no change in PPARα expression in liver of hamsters fed diets containing *trans*-10,*cis*-12 or *cis*-9,*trans*-11 CLA (46). In the present study, there was a trend for PPARα expression to be increased by dietary CLA in liver, red muscle, and white muscle of fish fed the low-oil diets. In addition, upregulation of PPARα in response to dietary CLA was also observed in white muscle and liver in fish fed the high-oil diets. As previously mentioned, activation of PPARα (via peroxisome proliferators) can induce β-oxidation through upregulation of key enzymes such as CPT-I in mammals (37). The data in the present trial suggest that PPARα may also be implicated in the action of CLA. In general, CLA increased the levels of both CPT-I mRNA and PPARα, and in some cases PPARβ mRNA. The exceptions to this were PPARα and PPARβ expression in red muscle from fish fed high oil, which tended to decrease with dietary CLA inclusion, and at high CLA inclusion liver PPARβ was decreased. It has been shown in PPARα-knockout mice that the effects of CLA on body fat distribution and mitochondrial lipid catabolism genes are not mediated by PPARα, but that the peroxisomal β-oxidation gene acyl CoA oxidase is regulated by a PPARα-dependent mechanism (47).

Acyl CoA oxidase shows high activity in salmon liver, but much lower activity in red muscle and very low activity in white muscle (34). Thus, it is possible that effects on mitochondrial lipid catabolic genes such as CPT-I could be mediated through PPARβ subtypes. However, PPARα expression exceeds that of PPARβ by an order of magnitude in muscle tissues, suggesting that PPARα would have the predominant regulatory role. Of course, it is not the absolute amount of PPAR that is important for target gene activation, but rather the binding of activating ligand.

Of the tissues investigated in salmon, PPARγ expression was only detected in liver. However, in agreement with work carried out in mice (43), PPARγ mRNA levels increased in liver of salmon fed CLA, and CLA have been reported to cause fatty liver in mice (43). However, PPARγ in fish does not share the same ligand activation profile as PPARγ in mammals (40). Fish PPARγ does not respond to FA and has specific amino acid differences compared to the mammalian form, which explains lack of activation, suggesting that it is unlikely, despite increases observed in liver, that CLA would mediate its effects through this transcription factor. Indeed, neither liver size nor lipid content was increased in salmon fed CLA (16).

In summary, gene expression and activity of various lipid metabolic factors were altered in response to graded levels of CLA and/or dietary oil content in Atlantic salmon smolts. Specifically, some association was observed between dietary CLA, liver HUFA synthesis and desaturase gene expression, and liver PPARα expression, although this varied with dietary oil content. In addition, some association between dietary CLA, CPT-I expression and activity, and PPARα expression was observed in muscle tissues. However, the magnitude of the changes in FA metabolism observed was not sufficient to bring about major changes in the whole body lipid and FA composition of the fish (16). In conclusion, this study has presented evidence that dietary CLA have effects on FA metabolism in Atlantic salmon, but that there is little evidence of a direct mechanism involving PPAR transcription factors. However, considering the importance of dietary lipid in aquaculture, further work is required to assess the potential of CLA as a dietary supplement, and the role of PPAR in the regulation of lipid metabolism in fish.

ABSTRACT: More than half of the U.S. population has a body mass index of 25 kg/m^2 or more, which classifies them as overweight or obese. Obesity is often associated with comorbidities such as diabetes, cardiovascular diseases, and cancer. CLA and chromium have emerged as major dietary supplements that reduce body weight and fat mass, and increase basal metabolic rate in animal models. However, studies show that CLA induces insulin resistance in mice and in humans, whereas Cr improves insulin sensitivity. Hence, we designed the present study to examine the combined effect of CLA and Cr on body composition and insulin sensitivity in a Balb/c mice (n = 10/group) model of high-fat-diet–induced obesity. CLA alone lowered body weight, total body fat mass, and visceral fat mass, the last of which decreased further with the combination of CLA and Cr. This effect was accompanied by decreased serum leptin levels in CLA-fed and CLA + Cr–fed mice, and by higher energy expenditure (EE) and oxygen consumption (OC) in CLA + Cr–fed mice. Serum levels of glucose, insulin, the pro-inflammatory cytokines, tumor necrosis factor-α (TNF-α), and interleukin-6 (IL-6), as well as insulin resistance index (IRI), decreased with CLA, whereas CLA and Cr in combination had significant effects on insulin and IL-6 concentrations and IRI. In summary, CLA + Cr decreased body weight and fat mass in high-fat-diet–fed mice, which may be associated with decreased leptin levels and higher EE and OC.

Paper no. L9861 in *Lipids 41,* 437–444 (May 2006).

Obesity is one of the major avoidable risk factors for mortality and morbidity, and increases the risk for type 2 diabetes, cancer, diseases associated with the cardiovascular system, and osteoarthritis in weight-bearing joints (1), leading to an enormous increase in health care costs. Decrease in energy expenditure (EE) associated with lack of physical activity has been identified as one of the major reasons for the spread of this epidemic (2–5). Obesity is usually accompanied by abnormalities in leptin and insulin secretion and their action, together with defects in lipid and carbohydrate metabolism (6,7).

CLA refers to a group of polyunsaturated FA that are positional and stereoisomers of octadecadienoic acid (linoleic acid, LA, 18:2n-6, double bonds at position 9 and 12). They are found naturally in ruminant food products such as beef, lamb, and dairy products containing approximately 80% *cis*-9, *trans*-11 (c9t11) isomer and 10% *trans*-10, *cis*-12 (t10c12) isomer (8,9). CLA is available commercially as a mixture of c9t11 and t10c12 isomers present in equal amounts (~35%), and has significant antiadipogenic, anticarcinogenic, antiatherosclerotic, antiinflammatory, antidiabetic, and antihypertensive properties in animal models (10–18). Some recent studies also indicate that CLA reduces body fat mass (BFM) in humans (19,20). However, evidence derived from studies in mice and humans suggest that intake of CLA or t10c12 isomer alone may induce hyperglycemia, hyperinsulinemia, and insulin resistance (IR) (16,21–25). In a recent study in human mature adipocytes, t10c12 isomer activated nuclear factor-kappaB (NF-κB) and ERK1/2-dependent tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6) production, which suppressed peroxisome proliferator-activated receptor-γ (PPAR-γ), leading to impaired glucose uptake. This provided supportive evidence that the t10c12 isomer induces IR (26).

Chromium is an important trace element essential for normal fat, carbohydrate, and protein metabolism (27). Chromium intake increases lean mass and decreases body weight and fat mass in animal studies and in humans (27,28). Moreover, it improves serum lipid levels and glucose tolerance in rodents and in humans, and increases or potentiates insulin's effects on glucose uptake and utilization (29–33) and decreases IR (34,35).

It is well established that rodents on a high-fat diet develop obesity and IR, similar to the effect of Western—style diet in humans (36–38). Because CLA and Cr have beneficial effects on body composition, we hypothesized that intake of a low dose of CLA and Cr, in combination, would decrease fat mass in a mouse model of high-fat-diet–induced obesity. We also hypothesized that CLA could induce hyperinsulinemia and hyperglycemia in this mouse model, which may be amelio-

Abbreviations: AKP, alkaline phosphatase; BFM, total body fat mass; BLM, total body lean mass; CO, corn oil; c9t11, *cis*-9, *trans*-11; DEXA, dual energy x-ray absorptiometry; EE, energy expenditure; IL, interleukin; IR, insulin resistance; IRI, insulin resistance index; IRK, insulin receptor kinase; IRTP, insulin receptor tyrosine phosphatase; IS, insulin sensitivity; LA, linoleic acid; NF-κB, nuclear factor-kappaB; OC, oxygen consumption; PPAR-γ, peroxisome proliferator-activated receptor-γ; SFO, safflower oil; t10C12, *trans*-10, *cis*-12; TNF, tumor necrosis factor; UCP2, uncoupling protein 2; VFM, visceral fat mass.

rated by Cr intake. To establish this hypothesis, we conducted the present study in Balb/c mice on a high-fat diet (20% corn oil [CO], ~35% kcal) that induced obesity. Balb/c mice significantly gain body weight and fat mass in response to high-fat diet (39). We performed a longitudinal study to measure the interaction of CLA and Cr in their effects on body composition utilizing dual-energy x-ray absorptiometry (DEXA) technology. We measured serum levels of glucose, insulin, leptin, adiponectin, the proinflammatory cytokines, IL-6, and TNF-α, and insulin resistance index (IRI). Because CLA increases EE (40,41), we also measured parameters of metabolic rate to determine whether any CLA + Cr–mediated decrease in fat mass is associated with higher EE and oxygen consumption (OC).

EXPERIMENTAL PROCEDURES

Animals and experimental diets. Six-week-old male Balb/c mice were obtained from Harlan (Indianapolis, IN). Weight—matched mice were housed in a laboratory animal care facility in cages (5 mice/cage) and fed standard lab chow diet. At 8 wk of age, animals were divided into different groups and provided with semipurified AIN-93M diets containing 0.5% safflower oil (SFO) or 0.5% CLA (Clarinol powder, Loders Croklaan, Channahon, IL). Each group was further divided into Cr and non-Cr groups of 10 mice each, thus resulting in four treatment groups: SFO, SFO + Cr, CLA, and CLA + Cr . The diets contained 20% CO by weight. The composition of the semipurified diets is provided in Table 1. The composition of the oil extracted from the Clarinol powder was: c9t11, 36.9%; t10c12, 37.4%; total trans, 2.7%. The total CLA content of the oil was 80.9%, with the main isomers accounting for 74.4%. Like CO, SFO contains 18:2n-6 (LA) as the major FA component. Cr was provided as chromium tricarnosinate at 22.77 g/kg diet (3.4% chromium and 89.3% carnosine, FutureCeutical Carnochrome, VDF FutureCeuticals, Momence, IL). Fresh diet was prepared weekly, stored in aliquots at –20ºC, and provided daily *ad libitum*. Body weight was monitored biweekly. Animals were maintained on a 12—hr light/12—hr dark cycle in an ambient temperature of 22–25ºC at 45% humidity. NIH guidelines (42) were strictly followed; and the Institutional Laboratory Animal Care and Use Committee of the University of Texas Health Science Center at San Antonio approved all studies.

TABLE 1
Composition of Experimental Diets

Ingredients (g/kg)	SFO	CLA	SFO + Cr	CLA + Cr
Casein	248	248	248	248

Corn oil	200	200	200	200
Total	1000	1000	1000	1000

[a]Contains 74% CLA.
[b]CarnoChrome (chromium tricarnosinate), 3.14% (wt/wt); chromium mixed 3 mg/10 g in cerelose.

Collection of tissues and blood serum. Blood was collected after overnight fasting under anesthesia by retro-orbital bleeding 3 d before the end of the experiment, and serum was obtained by centrifugation at 3000 rpm for 15 min at 4°C for the determination of glucose and insulin. At the termination of the study, mice were sacrificed by cervical dislocation, and serum was collected for all the other assays.

Measurement of fat mass and lean mass. BFM and total body lean mass (BLM) were measured by DEXA using a Lunar PIXImus mouse bone densitometer (GE**,** Madison, WI), and data were analyzed with PIXImus software (43—45). Before scanning was performed, mice were anesthetized with an intramuscular injection of 0.1 mL/100 g body weight of mouse cocktail containing ketamine/S.A. rompun/NaCl (3:2:5, by vol). BFM and BLM were obtained for the entire body, excluding the head. Visceral fat mass (VFM) was determined manually using DEXA. Scanning was performed first at baseline and again at the end of 14 wk of the study diet.

Serum metabolites. Insulin was analyzed using a rat/mouse insulin ELISA kit from Linco Research (St Charles, MO). Glucose was analyzed spectrophotometrically using Sigma Diagnostics glucose (Trinder) reagent (Sigma Diagnostics, St Louis, MO). Adiponectin was assayed using mouse adiponectin Quantikine immunoassay kit from R&D Systems (Minneapolis, MN). Leptin was assayed using an active murine leptin kit from Diagnostic Systems Laboratories (Webster, TX).

IRI. IRI was calculated by the following formula: [fasting serum insulin (ng/mL) × fasting serum glucose (mM)]/22.5. A high IRI denotes low insulin sensitivity (IS) (46).

Serum proinflammatory cytokines. TNF-α and IL-6 were measured by using BD OptEIA™ ELISA kits from BD Biosciences Pharmingen (San Diego, CA) (43). Sensitivity of the assays was approximately 1 pg/mL. In brief, each well of flat-bottom 96-well microtiter plates was coated with 100 µl of purified anti-TNF-α and anti-IL-6 antibodies (4 µg/mL in binding solution) overnight at 4°C. The plates were rinsed four times with washing buffer, and diluted serum was added, followed by incubation for 2 h at room temperature. The plates were washed four times with washing buffer, followed by the addition of biotinylated anticytokine antibodies. The plates were incubated in room temperature for 1 h and then washed four times with washing buffer. Streptavidin-alkaline phosphatase conjugate was added, and the plates were incubated for 30 min at room temperature. The plates were again washed four times with washing buffer, and the chromogen substrate was added. The plates were then incubated at room temperature to achieve the desired maximum absorbance and were read at 410 nM in an ELISA reader (Dynex Technologies, Worthington, West Sussex, United Kingdom).

Metabolic rate. Metabolic rate was measured indirectly by

drawing air through sealed rodent cages and monitoring the partial pressures of oxygen and carbon dioxide of the air entering and leaving the cage, as described in several earlier studies (47). In brief, gas composition was measured using a zirconia cell O_2 detector and an infrared CO_2 analyzer (Applied Electrochemistry models S-3A and CD-3A, respectively; Ametek, Paoli, PA), with flow regulated by a mass flow controller (Linde model FM4570; Ontario, Canada). Gas pressures, airflow, cage temperature, ambient air temperature, pressure, and humidity were digitized, recorded every 10 s, and averaged on an hourly basis. Each mouse was monitored between 0800 and 1200 h for 3 h. Mice were acclimated to the flowthrough system for 24 h before measurement of metabolic rate. During the time of measurement, air was also sampled from an empty cage situated adjacent to the experimental cage, as a control. The rate of O_2 consumption was calculated using the equations of Consolazio et al. (48). The metabolic rate was then calculated in kJ/min using these values and an energy equivalent of 1 L of oxygen per 4.76 kJ. This assumes that the fuel combusted *in vivo* is the same as that of the food ingested; only small errors are introduced if the fuel mix metabolized at a given time deviates from this value.

Statistical analysis. Results are expressed as means ± SEM. Data were analyzed statistically by two-way ANOVA or repeated-measures ANOVA using Graphpad Prism 4 software. The Newman-Keuls multiple comparison test was used to test the differences among groups. Differences were considered significant at $P < 0.05$.

RESULTS

Body composition and liver weight. Body weight initially increased in all the dietary groups until 6 wk of age. Thereafter, body weight increased maximally in SFO-fed mice, whereas body weight decreased in CLA + Cr–fed mice (Fig. 1). Body weight was significantly lowered in CLA-fed mice, compared with SFO-fed mice ($P < 0.001$). Cr decreased body weight in both SFO-fed and CLA-fed mice but more significantly in CLA + Cr–fed mice. Body weight in SFO + Cr–fed mice was comparable to CLA-fed mice. CLA-fed mice showed lower fat mass that decreased further in CLA + Cr–fed mice ($P < 0.05$) compared with SFO-fed mice. VFM is the sum of the weights of the mesenteric, epididymal, and retroperitoneal fat depots. VFM was significantly lowered in CLA-fed mice compared with SFO-fed mice, and decreased further in CLA + Cr–fed mice ($P < 0.05$). There was no difference in liver weights between the different dietary groups (Table 2). Lean mass was higher in CLA-fed mice compared with SFO + Cr–fed and CLA + Cr–fed mice but not SFO-fed mice (Table 2).

Serum metabolites. Leptin was lowered in CLA-fed and CLA + Cr–fed mice compared with SFO-fed and SFO + Cr–fed mice but there was no effect of Cr supplementation ($P < 0.001$). Serum adiponectin levels were unaltered by CLA or Cr. Glucose concentrations was lowered in CLA-fed mice

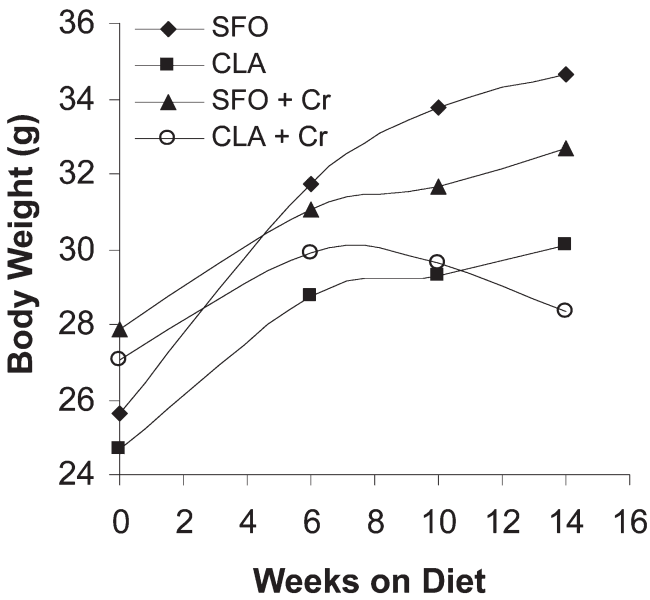

FIG. 1. Body weight curves for safflower oil (SFO) control, conjugated linoleic acid (CLA)–treated, SFO and chromium (Cr) (SFO + Cr)–treated, and CLA and Cr (CLA + Cr)–treated mice ($n = 10$/group). Day 0 was the first day mice were placed on different diets. Both CLA and Cr significantly suppressed body weight (CLA: $P < 0.0001$; Cr: $P < 0.05$).

compared with SFO-fed and SFO + Cr–fed mice ($P < 0.05$). However, glucose level in the CLA + Cr group was comparable to that in all the other dietary groups. Analysis by two-way ANOVA for main effects revealed that the only statistically significant effect of CLA was on glucose level. Insulin levels decreased in SFO + Cr–fed, CLA-fed, and CLA + Cr–fed mice compared with SFO-fed mice. Analyzing the data by two-way ANOVA for main effects showed that CLA and the combination of CLA and Cr had significant effects on insulin levels. Insulin sensitivity was estimated by several indices, including the homeostasis model assessment, l/insulin, and glucose/insulin. A higher IRI reflects low IS; IRI was lowered in all the other dietary groups compared with SFO-fed mice. However, the decrease was much higher in CLA-fed and CLA + Cr–fed mice. Analyzing the data by two-way ANOVA for main effects showed significant effects of CLA, Cr, and their interaction on IRI (Table 3).

Serum proinflammatory cytokines. Serum TNF-α levels were lowered in CLA-fed and CLA + Cr–fed mice compared with SFO-fed and SFO + Cr–fed mice ($P < 0.05$), but there was no additional effect of Cr. Two-way ANOVA for main effects revealed that the only statistically significant effect of CLA was on TNF-α, whereas interaction of CLA and Cr was close to being statistically significant. Serum IL-6 levels were decreased in SFO + Cr–fed, CLA-fed, and CLA + Cr–fed mice compared with SFO-fed mice. Cr lowered IL-6 in SFO-fed mice but there was no additional effect of Cr in CLA-fed mice. Analyzing the data by two-way ANOVA for main effects found significant effects of CLA and interaction of CLA and Cr on IL-6 activity (Table 3).

OC and EE. OC and EE did not differ between SFO-fed

and CLA-fed mice. However, both OC and EE were higher ($P < 0.05$) in CLA + Cr–fed mice than in SFO-fed mice. Analyzing the EE data by two-way ANOVA for main effects revealed statistically significant effects of CLA alone and Cr alone but not in combination (Table 4).

DISCUSSION

High-fat—diet–induced obesity is often associated with IR, which is a major risk factor for diabetes (49,50). Visceral obesity, in particular, has a strong correlation with IR and onset of glucose intolerance (51). Rats and mice fed a high-fat diet have increased VFM, whole body and muscle IR, and hyperinsulinemia within 4 wk, whereas continuous feeding of a high-fat diet for 8–12 wk develops severe visceral obesity, diabetes or impaired glucose tolerance, and plasma lipid and lipoprotein abnormalities (38). In the present study, CLA decreased body weight, BFM, and VFM, the last of which decreased further with the combination of CLA and Cr. Previous studies in animals fed CLA or the t10c12 isomer have shown decreased body weight and fat mass compared with control animals (40,52—54). Cr alone decreased body weight and fat mass in our study in accordance with previous studies (27). This is the first observation to show that Cr has beneficial effects on body composition in high-fat-diet–fed mice.

The antiadiposity effect of CLA has been ascribed, in part, to its ability to alter energy balance. Some studies in mice have shown that decreased energy intake may be insufficient to account for CLA—mediated dramatic loss of fat mass, implying that other mechanisms may be involved (40,41,52). Increased

[b]From two-way ANOVA.

EE has increasingly been proposed to be one of the mechanisms for the antiadiposity effects of CLA and particularly with the use of t10c12 isomer (40,41). Research suggests that uncoupling protein 2 (UCP2) expressed in white and brown adipose tissues may play a significant role in regulation of EE by CLA. UCP2 mRNA expression was shown to be augmented by CLA and t10c12 isomer in white adipose tissues from mice and rats, and in cultured adipocytes (21,22,52). We observed higher EE and OC in CLA + Cr–fed mice compared with control diet–fed mice, suggesting that CLA + Cr–mediated loss of fat mass may be associated, in part, with increased EE and OC.

Leptin, a product of the obese gene, is secreted primarily by adipocytes and plays an important role in regulating energy balance. Circulating leptin is highly correlated with general adiposity in obese rodents and individuals exhibiting higher plasma leptin levels (55,56)**.** Decreased leptin levels in CLA-fed mice were correlated with decrease in fat mass in the present study, suggesting that this may be one of the mechanisms involved in the observation. Because Cr did not lower circulating leptin levels in our study, Cr—induced loss of fat mass may be independent of leptin concentration. CLA and Cr have been reported to decrease serum leptin levels in animal studies (57,58). We have previously shown that CLA decreases leptin mRNA expression in peritoneal fat tissues, and CLA also decreases circulating leptin levels in high-fat-diet–fed mice (44).

In the present study, decreased glucose, insulin, and IRI were observed in CLA-fed mice, indicating a beneficial effect on IS. This is indeed an interesting finding considering that CLA and t10c12 isomer alone induced hyperinsulinemia, hyperglycemia, and IR in most of the studies in mice (21,22,59) and in humans (23–25). Studies suggest that PPAR-γ may be one of the key modulators of IR by CLA (more predominantly by the t10c12 isomer). PPAR-γ is downregulated in both adipose tissues from CLA-fed mice and cultured adipocytes. Downregulation of PPAR-γ contributes to loss of adiposity and decreased IS (21,60). Recently, Chung *et al*. found that t10c12 isomer decreases PPAR-γ expression in human adipocytes through NF-κB activation (26). This study provides evidence that inhibition of PPAR-γ in human adipocytes by CLA and/or t10c12 isomer may be a key mechanism involved in IR in humans. Interestingly, studies in normal and diabetic rats indicate beneficial effects of CLA and t10c12 isomer on glucose and insulin levels, glucose tolerance, and IS (52,61,62), which could be related to activation of PPAR-γ in these studies (61,63). Thus, the effect of CLA on IR seems to be dependent partly on species, metabolic state of the animal, and response of PPAR-γ to CLA, more specifically the t10c12 isomer. Wargent *et al*. recently demonstrated increased glucose and insulin levels, and exacerbated glucose tolerance, in genetically obese (lep^{ob}/lep^{ob}) mice fed CLA or t10c12 isomer–enriched CLA for 2 wk. However, long-term CLA intervention (10 wk) had beneficial effects on glucose, insulin, and IRI levels (64). This study and long-term studies in humans suggest that the detrimental effect of CLA on IR may be a transient effect seen in short-term studies; long-term studies did not show any adverse effects on glucose and insulin levels (19,20). However, these findings need to be confirmed with more long-term studies in rodents and humans using purified isomers. Cr alone significantly decreased insulin level and IRI in our study, in accordance with previous studies (34,57). Our results further suggest that CLA + Cr may have additive beneficial effects on insulin level and IRI in high-fat-diet–fed mice. Although the results from the present study are encouraging and suggest a beneficial effect of CLA + Cr on IS, more mechanistic studies in animal models need to be pursued to establish the efficacy of CLA + Cr supplementation on IR and body composition. Cr has been shown to activate insulin receptor kinase (IRK) but to downregulate insulin receptor tyrosine phosphatase (IRTP) (33). The activation of IRK and inhibition of IRTP may lead to increased phosphorylation of the insulin receptor and improved IS. Because PPAR-γ is an important target for CLA, studying the effect of Cr on PPAR-γ in adipocytes derived from rodents and humans may be of interest to establish the beneficial effect of Cr on IR in mice fed CLA.

Adiponectin is secreted by fat cells and enhances insulin action by suppressing hepatic glucose production and glucose uptake by skeletal muscles (65). In human studies, adiponectin levels are negatively correlated with fat mass (65,66). However, in a recent study in PPAR-γ adipose knockout mice, improved IS was observed along with decreased adipose tissue expression and lower plasma levels of adiponectin, suggesting that adiponectin produced by fat may not completely account for the improved IS (67). Moreover, Baratta *et al*. reported that the plasma adiponectin level was independent of fat mass in nondiabetic and diabetic patients (68). CLA and Cr alone or in combination had no effect on

serum adiponectin levels in the present study. Our previous study on the effects of CLA and exercise interaction in high-fat-diet–fed mice also did not show any effect on serum adiponectin levels or adiponectin mRNA expression in peritoneal fat pads derived from these mice (44). Adiponectin has been shown to be increased in CLA—fed diabetic rats but decreased in mice, which was associated with decreased IR (69—71). Improved IS without enhanced serum adiponectin levels in our study suggest that beneficial effects of CLA may be independent of adiponectin concentrations in this mouse model.

CLA alone and in interaction with Cr had beneficial effects on serum TNF-α and IL-6 levels in the present study. Our previous study in peritoneal fat derived from high-fat-diet–fed mice clearly indicated a statistically significant effect of CLA on TNF-α mRNA expression, which suggests that inhibition may occur at the adipose tissue level (44). CLA has been previously shown to decrease TNF-α and IL-6 in serum and macrophages derived from rats and mice (58,63,70,72), whereas other studies have reported either no effect or significant elevation of these cytokines in cultured cells from mice and humans (73,74). Cr has been reported to inhibit endotoxin—mediated inflammatory cytokine production in swine (75) and phytohemagglutinin—stimulated human peripheral blood mononuclear cells (76). The present data suggests that CLA and Cr may have additive effects in decreasing TNF-α and IL-6 in high-fat-diet–fed mice, which, in part, could explain improved IS in these mice.

We did not observe any enlarged livers in CLA—fed mice, although there was a dramatic decrease in fat mass. Previous studies show that CLA and t10c12 isomer increase liver weight in mice due to increased fat deposition (21,59). However, when CLA was supplemented with a high-fat diet, the mice did not show higher liver weight compared with control mice (77). A similar phenomenon may have influenced liver weights in this study.

In conclusion, the present study suggests that the combination of CLA and Cr lowers body weight and VFM, and may have a beneficial effect on IS in high-fat—diet–fed mice. More studies in different strains of mice and other species are warranted before the combination of CLA and Cr may be recommended to be beneficial in human health.

Effect of Species and Genotype on the Efficiency of Enrichment of Poultry Meat with n-3 Polyunsaturated Fatty Acids

C. Rymer* and D.I. Givens

Animal Science Research Group, University of Reading, Reading, RG6 6AR, United Kingdom

ABSTRACT: The effect of poultry species (broiler or turkey) and genotype (Wrolstad or BUT T8 turkeys and Ross 308 or Cobb 500 broilers) on the efficiency with which dietary long-chain n-3 PUFA were incorporated into poultry meat was determined. Broilers and turkeys of both genotypes were fed one of six diets varying in FA composition (two replicates per genotype × diet interaction). Diets contained 50 g/kg added oil, which was either blended vegetable oil (control), or partially replaced with linseed oil (20 or 40 g/kg diet), fish oil (20 or 40 g/kg diet), or a mixture of the two (20 g linseed oil and 20 g fish oil/kg diet). Feeds and samples of skinless breast and thigh meat were analyzed for FA. Wrolstad dark meat was slightly more responsive than BUT T8 ($P = 0.046$) to increased dietary 18:3 concentrations (slopes of 0.570 and 0.465, respectively). The Ross 308 was also slightly more responsive than the Cobb 500 ($P = 0.002$) in this parameter (slopes of 0.557 and 0.449). There were no other significant differences between the genotypes. There was some evidence (based on the estimates of the slopes and their associated standard errors) that white turkey meat was more responsive than white chicken meat to 20:5 (slopes of 0.504 and 0.289 for turkeys and broilers, respectively). There was no relationship between dietary 18:3 n-3 content and meat 20:5 and 22:6 contents. If birds do convert 18:3 to higher FA, these acids are not then deposited in the edible tissues.

Paper no. L9949 in *Lipids 41,* 445–451 (May 2006).

The health benefits associated with increased consumption of EPA (C20:5) and DHA (C22:6) as found in fish oil are well established. A meta-analysis of 26 studies by Friedberg *et al.* in 1998 (1) demonstrated that supplementing the diet with fish oil reduced serum concentration of triacylglycerols, and this effect was even more marked in individuals with Type 2 diabetes. Increasing consumption of EPA and DHA would therefore contribute to a reduction in the incidence of metabolic syndrome, which is characterized by obesity, insulin resistance, or Type 2 diabetes and dyslipidemia (2). However, although recommended minimum intakes of EPA plus DHA are, for example, in the UK, 450 mg/d (3), actual mean consumption in the UK is apparently only about 244 mg/d. Closer analysis of dietary survey data (4) reveals that consumption is in fact lower still, at approximately 113 mg/d (5), as only 27% of the UK population consume any oily fish at all. In this scenario, poultry meat contributes approximately 23% of the EPA and DHA that is consumed (5). This pattern is also observed throughout northern Europe (6). Clearly, from a public health perspective, the consumption of EPA and DHA needs to increase, but efforts to encourage the consumption of oily fish or even fish oil capsules have largely failed. An alternative approach is to increase the EPA and DHA content of those foods (such as poultry meat) that are consumed and already contribute to EPA and DHA intake. The n-3 PUFA content of poultry meat can be readily increased by increasing the n-3 PUFA content of poultry diets (7–10). However, a review of several papers that reported such increases (11) noted that the response, particularly to EPA and DHA, was highly variable. Some of this variability may be due to differences in the species and genotype of bird used, but few data examining these relationships are available. The objective of this study was therefore to determine the effect of different species and genotypes of poultry on their response (as measured by increases in the n-3 PUFA content of their edible tissues) to increased concentrations of n-3 PUFA in their diet. Skinless meats were studied in this experiment, as these are more homogenous than meats with skin on, and also represent more closely what is actually consumed (at least in Europe and North America). Poultry meat is regarded as a low-fat food, and much of the fat that is present is trimmed off either before or after cooking. Thus by studying skinless meat, the impact on human nutrition of altering the FA composition of poultry tissues that are actually consumed could be determined.

EXPERIMENTAL PROCEDURES

Birds. The species and genotypes of poultry investigated were turkeys (using the bronze Wrolstad and white BUT T8 genotypes) and broilers (using the Ross 308 and Cobb 500 genotypes). These genotypes were selected to be indicative of those commonly consumed in Europe, except for the Wrolstad, which is reared for a more specialized niche Christmas market. Male turkey poults, 100, were purchased as day-old birds; half of them were Wrolstad (Kelly Turkeys, Danbury, Essex, United Kingdom) and the other half were BUT T8 (SCF Turkeys, Liverpool, United Kingdom). On arrival, they were brooded together for 8 wk in separate pens (divided by genotype) and fed a proprietary feed for turkey poults with clean, fresh water always available. Male broiler chicks, 120,

Abbreviations: ALA, alpha-linolenic acid; LA, linoleic acid; LC n-3 PUFA, long-chain n-3 PUFA.

were also purchased as day-old birds (Anglia Chicks, Fakenham, Norfolk, United Kingdom); half of these were of the genotype Ross 308 and the other half were Cobb 500. On arrival they were brooded together for 3 wk in separate pens (again divided by genotype) and fed a proprietary chick crumb with clean, fresh water always available.

When the turkeys were 8 wk old and the broilers 3 wk old, they were randomly allocated to one of 24 pens (turkeys) or one of 24 cages (broilers). There were four turkeys per pen and six broilers per cage, and all the birds in one pen or cage were of the same genotype. The birds were then fed one of six experimental diets *ad libitum* with clean, fresh water always available. There were two replicates for each genotype × diet interaction. In the first week following allocation to the pens, the experimental diet was mixed on a 50:50 (fresh weight) basis with the proprietary starter pellet that the birds had been fed prior to allocation to the pens.

When the broilers were 42 d old and the turkeys 16 wk old, they were humanely slaughtered, bled, plucked, and eviscerated. The head and feet were removed and carcasses were then stored at <5°C in labeled plastic bags. After 7 d, one carcass from each pen was carefully dissected to separate the breast and thigh meat. Samples of skinless breast and thigh meat were placed in clean labeled plastic bags and stored at –20°C pending analysis.

Diets. Six different diets were fed to the birds, varying in their proportion of α-linolenic acid (ALA), EPA, and DHA. All diets contained 70 g/kg (fresh weight) ether extract, with 50 g of this ether extract coming from added oil. In the control diets, all the oil was in the form of blended vegetable oil. In diets Lolin and Hilin, the vegetable oil was partially substituted with linseed oil, such that the diets contained 20 and 40 g/kg (fresh weight) linseed oil respectively. In diets Lofish and Hifish, the vegetable oil was partially substituted with fish oil, such that the diets contained 20 and 40 g/kg (fresh weight) fish oil respectively. In diet Linfish, the diet contained 20 g/kg linseed oil and 20 g/kg fish oil (fresh weight basis). Details of the composition of the diets used, and their calculated nutrient compositions, are provided in Tables 1 and 2. The antioxidant used was predominantly vitamin E, which was included in all diets at a rate of 100 mg DL-α-tocopherol acetate/kg diet as fed. In the turkey diets, BHT was also included in the vitamin/mineral mix that was used, and was present in the diets at a concentration of 20 mg/kg (as fed).

Analysis. The feeds and the samples of white and dark meat taken from the birds were analyzed for long-chain FA. Lipids were extracted from samples of feed (3 g) or grated frozen meat tissue (20 g) using the method of Folch *et al*. (12). Samples were then methylated by drying the lipid extract under a stream of nitrogen and then dissolving the residue in dried toluene (1 mL) and sodium methoxide (2.7 g dry sodium methoxide in 100 mL methanol, 2 mL). Glacial acetic acid (0.1 mL) and hexane (2 mL) were added and mixed, followed by water (5 mL). The hexane layer containing the FAME was then separated off and analyzed using a gas chromatograph-mass spectrometer (Hewlett Packard GCD Series 2). Samples were injected (split injection) onto a capillary column (60 m, 0.32 mm diameter) with helium (flow rate 1 mL/min) used as the carrier gas. The column was held at 70°C for 2 min before being raised to 165°C (5°C/min) for 5 min. It was then raised to 180°C (6°C/min) for 10 min and then 230°C (3°C/min) for 3 min. The inlet temperature was 260°C and the detector temperature 250°C. FAME were identified by comparing retention times with those of standards and quantification was done by normalizing the areas under the curve. FA concentrations were calculated in terms of % wt/wt total FA detected. Mean concentrations (mg/100 g fresh meat tissue) of total FA were calculated for each of the four meats (white chicken, dark chicken, white turkey, and dark turkey). From these estimates, the concentrations of individual FA in each poultry meat were calculated and expressed as mg/100 g edible portion.

Statistical analysis. ANOVA was used to determine the ef-

fect of genotype, diet, and the interaction between genotype and diet on the FA content of the different poultry tissues. The FA contents of white and dark meat were compared using a paired student's t-test. To consider the efficiency with which FA were enriched in poultry meat, a linear model was used to test the hypothesis of a straight-line relationship between the concentration of an individual FA in the diet (% wt/wt total FA) and its concentration (% wt/wt total FA) in edible tissue (either white or dark meat). The interaction between this estimate of slope and the genotype of the bird was also examined. A linear mixed model was then used to determine whether there was a significant difference between tissues (and a significant interaction with genotype of bird) in the response to increased dietary concentrations of an individual FA. Statistical comparisons were made using SAS (SAS Institute Inc., Cary, NC). In the case of turkeys, the concentrations of dietary FA used were those estimated in the diets fed to the turkeys from 13 to 16 wk of age. No direct statistical comparisons between species of birds could be made, as they were reared for different times, in different houses, and on slightly different diets. However, the slopes and standard errors of the responses to increased dietary concentrations of FA were compared to determine whether there was any evidence of a difference between species in their response to dietary FA concentrations.

To ascertain whether there was any difference between genotypes in increased meat concentrations of EPA and DHA resulting from an increased supply of dietary ALA, the linear relationship between diet ALA content and meat EPA or DHA content was estimated using a linear model for each tissue. Data from birds fed Lofish, Hifish, or Linfish were excluded from this analysis as the EPA and DHA present in these diets would have confounded the estimation.

RESULTS

The concentrations of FA in the different diets are presented in Table 3. Increasing the linseed oil content of the diet increased the ALA content of the diet. Adding fish oil to the diet increased the EPA and DHA content of the diet but had a negligible effect on the ALA content. Compared with the controls, all diets had lower concentrations of 18:2 (LA), and lower ratios of n-6:n-3 FA.

FA content of edible tissues. Regarding the concentrations of FA in both white and dark meat, there were no significant interactions (with either broilers or turkeys), between diet and the genotype of bird for the concentrations of FA in either white or dark meat (Tables 4–7). The Lofish and Hifish diets increased the 16:0 content of both white and dark meat. The 18:1 n-9 content of Wrolstad dark meat was approximately 12% greater ($P = 0.044$) than that of BUT T8 dark meat (Table 7).

The LA content of meat was not affected by the genotype of bird (be it turkey or broiler), but there was a significant reduction in LA content as vegetable oil was replaced by either linseed oil or fish oil, except in the case of turkey white meat. Conversely, there was a highly significant ($P < 0.001$) increase in ALA content of all meats when linseed oil was included in the poultry diets, with the genotype of bird having

[a]For diet oil content and abbreviations, see Tables 4 and 6.

no significant effect. Replacing vegetable oil with n-3–rich oils reduced the 20:4 content of white chicken meat (P = 0.004), and Ross 308 white meat had a lower concentration of 20:4 than Cobb 500 white meat (P = 0.013).

With regard to the long–chain (LC) n-3 PUFA, increasing the concentration of fish oil in the diet resulted in significant increases in the concentration of both EPA and DHA in all meats. White Cobb 500 meat tended (P = 0.053) to have a higher concentration of DHA than Ross 308 meat, but otherwise there was no effect of poultry genotype. The EPA content of turkey meat was increased by a factor of approximately 2.8 when Hifish was fed instead of control, and the DHA content was also nearly doubled. The DHA content of white chicken meat was trebled, and that of dark chicken meat nearly quadrupled by feeding Hifish instead of control. The most dramatic increases were observed with the EPA content of chicken meat, however, which was increased by a factor of six in the dark meat when Hifish was fed instead of control. The amount of EPA + DHA that might be consumed by eating 100 g portions of poultry fed with Hifish compared with control was doubled in turkeys (from 57 to 114 mg in white meat, and from 89 to 192 mg in dark meat). In broilers, the increase was 226% in white meat (from 46 to 151 mg) and 340% in dark meat (from 27 to 117 mg).

The FA content of dark meat was in all cases greater than that of white meat ($P < 0.001$), except for EPA in chicken meat, in which there was no significant difference, and for 20:4 and DHA in chicken meat, in which the white meat was a richer source than dark meat.

Response to dietary concentrations of LNA, EPA, and DHA. Increasing the dietary concentration of LNA, EPA, or DHA resulted in significant ($P < 0.001$) linear increases in the concentration (% wt/wt total FA) of these acids in poultry meat (Table 8). Generally, there was no significant difference

between the two turkey genotypes in their response to these acids, but Wrolstads did show a greater response to ALA in their dark meat compared with BUT T8. Similarly, the only significant difference between broiler genotypes in their response to these FA was the response in dark meat to ALA, with Ross 308 being more responsive than Cobb 500. There was no significant difference between white and dark meat in terms of its responsiveness to increased concentrations of dietary ALA or EPA in turkeys, but there was a tendency (P = 0.079) for white meat to be more responsive than dark meat to DHA. In broilers, there was a tendency (P = 0.078) for dark meat to be more responsive than white meat to ALA, and although there was no significant difference in their responsiveness to EPA, the response to DHA was much greater (P = 0.001) in white meat compared with dark meat. There was no difference between the broiler genotypes in this differential response by different tissues. Based on the evidence of the coefficients and their standard errors, there was some evidence that turkey white meat may be more responsive than broiler white meat to increased dietary concentrations of EPA, but otherwise there was no evidence of any difference in efficiency between the two species.

There was no evidence of a linear relationship between dietary ALA content and the concentration of EPA or DHA in the meat (Table 9). There was also no difference between either broiler or turkey genotypes in this parameter, and no evidence of a difference between the species of poultry. In all cases, the coefficient describing the relationship was ≤0.1, and in some cases was negative.

DISCUSSION

Enrichment of poultry meat with n-3 PUFA. The levels of enrichment observed in this experiment with white chicken meat were similar to those reported when broilers were fed a stabilized fishmeal formulation comprising 200 g/kg of the diet (13) or a diet comprising 120 g/kg redfish meal (8). For dark meat, our results were very similar to those observed from feeding 120 g/kg redfish meal (8) or 40 g/kg fish oil (14) to broilers. However, the experiment reported by Howe *et al*. in 2002 (13) achieved much greater enrichment of dark meat by feeding a stabilized fishmeal formulation, and our results were equivalent to their feeding just 50 g/kg of this formulation. Much greater degrees of enrichment in white and dark meat were reported by Gonzalez-Esquerra and Leeson (15) when they fed broilers a diet comprising just 15 g/kg menhaden oil, but in this case the FA content was measured in cooked meat and Howe *et al*. (13) demonstrated that cooking can more than double the FA content in the tissue, presumably because of moisture loss. The LC n-3 PUFA content observed by Gonzalez-Esquerra and Leeson (15) is therefore likely, in the fresh tissue, to be similar to that observed in this experiment, although it is remarkable that such a high degree of enrichment could be obtained by them with such a low level of inclusion of the fish oil in the diet. This serves to illustrate the variability in the LC n-3 PUFA content of different fish oils, and does explain, in part, the variability in enrichment observed when similar quantities of fish oil are fed. For example, Zanini *et al*., in 2004, fed broilers diets com-

prising 60 g/kg fish oil yet only achieved LC n-3 PUFA contents of 54 mg/100 g in white meat and 42 mg/100 g in dark meat (16). Similarly, feeding broilers diets comprising 55 g/kg marine algae resulted in the LC n-3 PUFA content of the white meat being just 20 mg/100 g (17).

Although conventional poultry meat contributes relatively little LC n-3 PUFA (a 100-g serving of the meat produced in this study would contribute just 12% of the recommended minimum daily intake), poultry meat enriched by dietary means with LC n-3 PUFA does result in meat with a nutritionally meaningful LC n-3 PUFA content. In this experiment, 100 g servings of either chicken or turkey meat (be it white or dark) would contribute approximately 32% of the recommended minimum daily intake of 450 mg LC n-3 PUFA.

Effect of poultry species and genotype on enrichment efficiency. The results of this experiment demonstrated that, in modern broiler genotypes, there was no significant difference in the efficiency with which LC n-3 PUFA were incorporated into edible tissue. Even the more genetically diverse white and bronze genotypes of turkey showed a difference only in the incorporation of ALA into dark meat (as did the broilers). This limited difference may still suggest that there is some scope for selecting birds on the basis of their efficiency of transferring dietary n-3 PUFA to their meat tissues, but such selection cannot be at the cost of meat growth potential if this approach is to be viable. There is little evidence from this experiment (and from comparing data from the literature) to suggest that there is any inherent difference between broilers and turkeys in their ability to incorporate n-3 PUFA in their edible tissues, except perhaps for EPA in white meat.

The evidence that white chicken meat is a richer source of DHA than dark meat and also has a greater enrichment efficiency than dark meat for DHA is promising, particularly from the European Union viewpoint, since the consumption of white poultry meat far outweighs the consumption of dark meat in the EU. It is not a surprising finding, as the LC n-3 PUFA preferentially accumulate in the phospholipids, which are much more prevalent in the white meat compared with the dark meat (7).

The enrichment of EPA and DHA that was achieved in the white and dark meat with the Hifish diet amounted to (mean wt/wt total FA) 3.1% EPA and 8.8% DHA. It is not known what the maximum possible degree of EPA and DHA enrichment in poultry meat is, but it is perhaps worth noting that the skeletal muscle of the king penguin chick, which is hatched from eggs containing the highest known DHA content and which then feeds exclusively on fish, was quite refractory to changes in dietary EPA and DHA content (18). Indeed, although the EPA and DHA content of adipose tissue in the first month of growth increased rapidly and by the time of thermal emancipation was essentially identical to that of the diet, the DHA content of muscle phospholipid in particular remained remarkably constant at about 11.5% (18). There may of course be species differences, but these data may suggest that the maximum degree of enrichment of DHA that may be possible in poultry meat is around 12% wt/wt total FA. This was the degree of enrichment achieved in white chicken meat with the Hifish diet, and would be equivalent to approximately 113 mg DHA/100 g white poultry meat and 189 mg DHA/100 g dark poultry meat.

Enrichment of poultry meat with EPA and DHA in response to dietary LNA. If sources other than marine oils are to be used to enrich poultry meats with LC n-3 PUFA, then a disappointing result was the lack of relationship between the dietary ALA content and the EPA and DHA content of the meat. This relationship was calculated after data that involved feeding EPA and DHA to poultry were excluded. It therefore examined the birds' ability to convert dietary ALA to EPA and DHA and then deposit these LC n-3 PUFA in the edible tissues. The evidence from this experiment is that such a process is extremely limited, and this was also the conclusion of López-Ferrer *et al*. in 2001 (19). Their work suggested that although the birds may be capable of converting ALA to EPA and DHA to some extent, these acids were not then deposited in skeletal muscle but rather sequestered in the liver or transported to other tissues. It is not clear what mechanisms control the transport and distribution of EPA and DHA within the bird, but developing a means of controlling and manipulating such pathways would be an extremely valuable means of increasing the impact of measures to enrich poultry meat with the nutritionally valuable LC n-3 PUFA, without reliance on fish oils.

[a]Advanced Medical Research, Madison, Wisconsin, 53719, [b]Department of Basic Medical Science, School of Medicine, Shock/Trauma Research Center, 2411 Holmes Street, University of Missouri, Kansas City, Missouri, 64108, [c]Palm Oil Research Institute of Malaysia, Kuala Lumpur, Malaysia, and [d]American River Nutrition, Inc. 31 Campus Plaza Road, Hadley, Massachusetts, 01035.

ABSTRACT: The cholesterol-suppressive action of the tocotrienol-rich-fraction (TRF) of palm oil may be due to the effect of its constituent tocotrienols on β-hydroxy-β-methylglutaryl coenzyme A (HMG-CoA) reductase activity. The tocotrienols modulate HMG-CoA reductase activity via a post-transcriptional mechanism. As a consequence small doses (5–200 ppm) of TRF-supplemented diets fed to experimental animals lower serum cholesterol levels. These findings led us to evaluate the safety and efficacy of large supplements of TRF and its constituents. Diets supplemented with 50,100, 250, 500, 1,000, or 2,000 ppm of TRF, α-tocopherol, α-tocotrienol, γ-tocotrienol, or δ-tocotrienol were fed to chickens for 4 wk. There were no differences between groups or within groups in weight gain, or in feed consumption at the termination of the feeding period. Supplemental TRF produced a dose-response (50–2,000 ppm) lowering of serum total and LDL cholesterol levels of 22% and 52% ($P < 0.05$), respectively, compared with the control group. α-Tocopherol did not affect total or LDL-cholesterol levels. Supplemental α-tocotrienol within the 50–500 ppm range produced a dose-response lowering of total (17%) and LDL (33%) cholesterol levels. The more potent γ and δ isomers yielded dose-response (50–2,000 ppm) reductions of serum total (32%) and LDL (66%) cholesterol levels. HDL cholesterol levels were minimally impacted by the tocotrienols; as a result, the HDL/LDL cholesterol ratios were markedly improved (123–150%) by the supplements. Serum triglyceride levels were significantly lower in sera of pullets receiving the higher supplements. The safe dose of various tocotrienols for human consumption might be 200–1,000 mg/d based on this study.

Paper no. L9876 in *Lipids 41,* 453–461 (May 2006).

Hypercholesterolemia and inflammation of coronary arteries are major factors in the development of coronary heart disease in humans (1,2). Recently, inflammation has been implicated in the pathogenesis of atherosclerosis, cancer, stroke, and diabetes in human subjects (3–5). The major risk factors for atherosclerosis are elevated levels of serum total cholesterol and LDL cholesterol and inflammation of coronary arteries caused by increased levels of C-reactive protein (CRP; 6–9). CRP is now considered the best indicator for the risk of coronary heart disease (6,7). However, physiological and genetic factors also contribute to the progression of heart disease (10). The treatment of hypercholesterolemia with exercise, diet, and lipid-lowering agents has been the mainstay for treatment of atherosclerosis (11–15).

Dietary modifications recommended for the modulation of serum cholesterol levels are generally based on approaches that reduce cholesterol and saturated FA intake, reduce cholesterol absorption, and increase the excretion of cholesterol metabolites (16). Our research has roots in the anomalous finding that animals fed palm oil, a tropical oil rich in palmitic acid, had lower than predicted serum cholesterol levels (17,18). Our subsequent studies have identified tocotrienol-rich fraction (TRF) of palm oil as the source responsible for lowering serum cholesterol levels in experimental animal models (19). TRF consists of a mixture of α-tocopherol, α-tocotrienol, γ-tocotrienol, and δ-tocotrienol. However, only the unsaturated analogues, α-tocotrienol, γ-tocotrienol, and δ-tocotrienol, are responsible for hypocholesterolemic properties (20,21). The tocotrienols, with varying levels of efficacy, regulate cholesterol synthesis via a post-transcriptional mechanism, which leads to down-regulation of β-hydroxy-β-methylglutaryl coenzyme A (HMG-CoA) reductase activity (22). Mevalonic acid, the product of this reaction, is considered to be the rate-limiting substrate for the synthesis of cholesterol in the body (23). A decrease in serum total cholesterol, a response consistent with the tocotrienol-mediated down-regulation of HMG-CoA reductase activity, has been reported by a number of other investigators (24–28).

We have recently reported a number of biological activities of tocotrienols, which interfere with the formation of atherosclerotic plaque, including hypercholesterolemic, antioxidant, anti-inflammatory, and antiproliferation properties (29). Tocopherols, as well as tocotrienols, are classified as "generally regarded as safe" (GRAS) compounds by the U.S. Food and Drug Administration in small doses for human consumption and are remarkably free of any adverse effects (30). In earlier studies, experimental animal models were fed respective commercial diets supplemented with smaller doses of 5–200 ppm α-tocopherol, α-tocotrienol, γ-tocotrienol, δ-tocotrienol, or TRF for 4–6 wk (24–29,31,32). The effects of feeding higher levels of TRF or tocotrienols (50–2,000 ppm) on body weight gain and serum lipid parameters have not previously been determined. However, weight gain by male Fis-

Abbreviations: α-TTP, α-tocopherol transfer protein; CRP, C-reactive protein; HMG-CoA, β-hydroxy-β-methylglutaryl coenzyme A; TRF, tocotrienol-rich fraction.

cher 344 rats was suppressed by feeding a diet supplemented with 4,000 ppm of α-tocotrienol (33).

In order to determine the safety and efficacy of TRF and its constituent tocols (mixture of tocopherol plus tocotrienols), the present study was carried out to examine the effects of large dietary supplementation of TRF, α-tocopherol, α-tocotrienol, γ-tocotrienol, and δ-tocotrienol on weight gain, organ weights (liver, lungs, pancreas, heart, and kidneys), and serum lipid parameters (total cholesterol, HDL cholesterol, LDL cholesterol, and triglycerides) of chickens fed diets supplemented with 50, 100, 250, 500, 1,000, or 2,000 ppm of the aforementioned agents for 4 wk. Earlier findings show that the lipogenic activities of avians (34) and humans (35) are predominantly located in the liver, whereas the lipogenic activities of rodents are shared between liver and adipose tissue. Moreover, the levels of HDL and LDL cholesterol are similar in avians and humans (1.3 and 3.9 mmol/L for HDL and LDL, respectively), but differ in rodents (4.1 and 1.4 mmol/L for HDL and LDL, respectively). These factors led us to employ chickens for the present study (34,35). The young chickens (1 wk old) were chosen for the present study due to lack of pure large quantities of individual tocotrienols.

EXPERIMENTAL PROCEDURES

Materials. Sources of all chemicals, substrates, and diagnostic kits have been identified previously (29,31,32). Chemicals and solvents were of analytical grade. The commercially available TRF isolated from palm oil is a blend of α-tocopherol (25%), α-tocotrienol (25%), γ-tocotrienol (25%) and δ-tocotrienol (5%). After purification, in our laboratory, the TFR contained α-tocopherol (16.8%), α-tocotrienol (26.5%), γ-tocotrienol (42.5%) and δ-tocotrienol (14.1%). The ratio of tocotrienols vs tocopherols is important for the effects observed with tocotrienols, and these ratios can vary significantly from 1–5 in various preparations of TRF. Purified α-tocopherol, α-tocotrienol, γ-tocotrienol, and δ-tocotrienol were provided by Palm Oil Research Institute of Malaysia (PORIM, Kuala Lumpur, Malaysia). The individual components of TRF were purified as described in detail in our recent paper (29). The purities of α-tocopherol and individual tocotrienols were established by HPLC and MS as reported earlier (29). The tocols of corn oil were removed by extracting the oil with ethyl alcohol.

Effects of different doses of tocotrienols on gain in body weight and lipid parameters in 5-wk-old female chickens. White Leghorn 1-wk-old female chickens were supplied by the Poultry Research Laboratory, University of Wisconsin—Madison, and weighed 40–50 g. The chickens were divided into 34 groups of 6 each. Each group was housed in a single brooder at the University of Wisconsin—Madison's Poultry Research Laboratory with 24 h light and free access to water and a cholesterol-free corn–soy meal diet for a 4-wk period. The control group for each series of treatments was fed the unsupplemented diet for 4 wk.

The diet consists of corn (8.8% protein, 615 g), soybean meal (44% protein, 335 g), tocol-stripped corn oil (10 g), calcium carbonate (10 g), dicalcium phosphate (20 g), iodized salt (5 g), and mineral and vitamin mixtures (2.5 g of each), which provided the following per kg feed: zinc sulfate·H_2O, 110 mg; manganese sulfate·$5H_2O$, 70 mg; ferric citrate·H_2O, 500 mg; copper sulfate·$5H_2O$, 16 mg; sodium selenite, 0.2 mg; DL-methionine, 2.5 mg; choline chloride (50%), 1.5 g; ethoxyquin, 125 mg; thiamine HCl, 1.8 mg; vitamin A, 1,500 IU; vitamin D3, 400 IU; vitamin E (D-tocols of corn, a mixture of 12% α-tocopherol, 3% α-tocotrienol, 7% β-tocotrienol, 70% γ-tocopherol, 6% γ-tocotrienol, and 2% δ-tocopherol), 10 IU (10 ppm, 23 μmol); riboflavin, 3.6 mg; calcium pantothenate, 10 mg; niacin 25 mg; pyridoxine HCl, 3 mg; folacin, 0.55 mg; biotin, 0.15 mg; vitamin B_{12} 0.01 mg; and vitamin K, 0.55 mg. Six experimental groups were fed diets supplemented with 50, 100, 250, 500, 1,000, or 2,000 ppm of the TRF isolated from palm oil. TRF consists of a blend of α-tocopherol (16.8%), α-tocotrienol (26.5%), γ-tocotrienol (42.0%), and δ-tocotrienol (14.1%). The tocotrienols account for 82.6% of the TRF. Diets for the remaining experimental groups were supplemented with 115 (50 ppm), 230 (100 ppm), 575 (250 ppm), 1,150 (500 ppm), 2,300 (1,000 ppm), or 4,600 (2,000 ppm) μmol of α-tocopherol, α-tocotrienol, γ-tocotrienol, or δ-tocotrienol per kg diet.

The required amount of each tocol or TRF was dissolved in hexane (50 mL) and mixed with the commercial diet (10 kg) for 30 min permitting the evaporation of hexane. The experimental diets were stored at 4°C throughout the feeding period.

Chickens and diets were weighed at the start and end of the 4-wk test. At the end of the feeding period, the birds were fasted for 12 h prior to sacrifice to facilitate chylomicron and VLDL clearance. The birds were sacrificed in three sets, each having its own control, by severing their carotid arteries. The collected sera were stored at –20°C for pending analyses. Organs were removed, blotted, and weighed. Feed consumption and efficiency were calculated from body and feed weights taken at the start and end of the test.

The protocol was reviewed and approved by the University of Wisconsin—Madison College of Agriculture and Life Sciences Animal Care Committee. The study was carried out under the supervision of Z.A. Din (DVM, M.Sc.), and S.G. Yu, (MD, PhD). The study was carried out under FDA-approved IND number 36906.

Assays of serum lipid parameters. The analyses of the coded samples were performed as described in detail recently (29) at Advanced Medical Research (Madison, WI). The serum total cholesterol, HDL cholesterol, and triglyceride concentrations were estimated by using kits 352 and 336, respectively, from Sigma Chemical Co. (St. Louis, MO). Serum LDL cholesterol was precipitated from 200 μL of serum with 25 μL of a mixture of 9.7 mM phosphotungstic acid and 0.4 M $MgCl_2$. The preparation was mixed for 10 min at room temperature and then was centrifuged at 12,000 × *g* for 20 min. The supernatant was decanted and analyzed for HDL cholesterol. The remaining precipitate was dissolved in 200 μL of 0.1 M sodium citrate, and the concentration of LDL cholesterol was estimated as described for total cholesterol (29). All assays for each treatment were carried out at the same time under similar conditions to minimize standard deviation.

Statistical analysis. The overall analyses identified significant main effects and interactions for all serum lipid parameters between the groups evaluated. StatView software (version 4.01, Abacus Concepts, Berkeley, CA) was used for the analyses of treatment-mediated effects as compared with respective control groups. Treatment-mediated differences in serum lipid (total cholesterol and LDL cholesterol) variables were identified with a two-way ANOVA, and when the F test indicated a significant effect, the differences between the means were analyzed by a Fisher's protected least significant difference test. Data were reported as mean ± SD in the text and tables. The statistical significance level was set at 5% ($P < 0.05$). The reductions achieved with the supplements at specified dose levels were also evaluated.

RESULTS

Effects of TRF, α-tocopherol, and α-, γ-, and δ-tocotrienols on serum lipid parameters in 5-wk-old female chickens. The previously reported cholesterol-suppressive action of TRF (19–21) is confirmed by plots of the data, which show the significant dose-dependent impact of TRF on serum total cholesterol (Fig. 1) and LDL cholesterol levels (Fig. 2). The maximum lowering of both parameters, a 22% reduction in total cholesterol and a 50% ($P < 0.05$) lowering of LDL cholesterol, was achieved with 1,000 ppm TRF. Increasing the α-tocopherol content of the diet by 5- to 200-fold (50-2,000 ppm) had no impact on serum total cholesterol level (Fig. 1) and yielded a modest lowering of LDL cholesterol (6%) only when present at supranormal (2,000 ppm) levels (Fig. 2).

Consistent with findings that the tocotrienol isomers have differential effects on HMG CoA reductase activity (25,29), α-tocotrienol was less effective than either γ-tocotrienol or δ-tocotrienol in lowering serum total (Fig. 3) and LDL (Fig. 4) cholesterol levels in the present study. A 500 ppm supplement of α-tocotrienol yielded the maximum response, a 17% reduction, whereas significant dose-dependent impacts of γ-tocotrienol and δ-tocotrienol were achieved ($P < 0.05$); for these isomers, 2,000 ppm supplements effected modest but significantly greater reductions than those attained with1,000 ppm supplements (Fig. 3). As shown in Figures 3 and 4, 500 ppm/kg diet supplementation of α-tocotrienol, γ-tocotrienol, and δ-tocotrienol effected 17%, 20%, and 27% ($P < 0.05$) reductions in serum total cholesterol levels, respectively. The serum total cholesterol level was decreased with TRF, 17% at 500 ppm/kg diet, which falls close to the average value of 17% recorded for its individual tocols: α-tocopherol (3%), α-tocotrienol (17%), γ-tocotrienol (20%), and δ-tocotrienol (27%), at 500 ppm/kg diet of each supplement (Figs. 1 and 2).

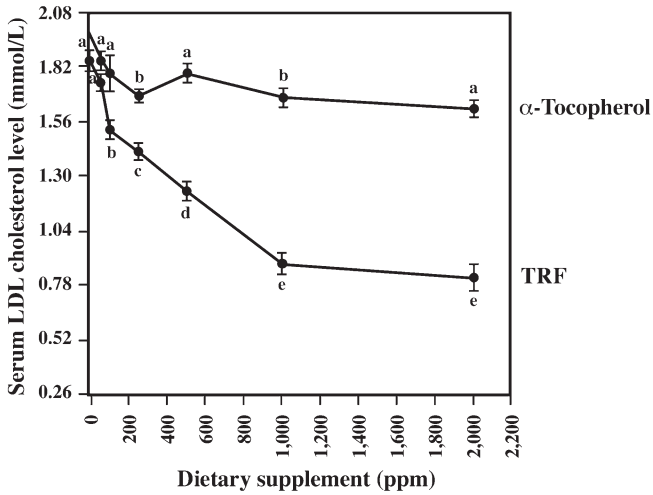

FIG. 2. Dose-dependent impacts of the TRF from palm oil and α-tocopherol on the serum LDL cholesterol levels of pullets. Values are means ($n = 6$); standard error is shown by bars. Points on a line not sharing a common letter are significantly different ($P < 0.05$).

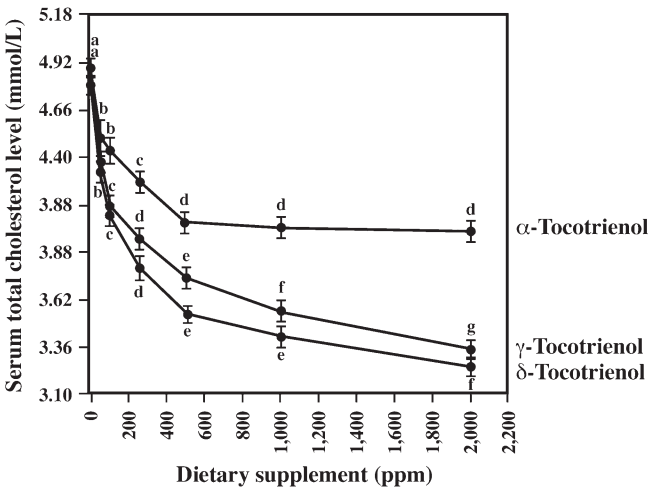

FIG. 3. Dose-dependent impacts of the tocotrienol isomers on the on the serum cholesterol levels of pullets. Values are means ($n = 6$); standard error is shown by bars. Points on a line not sharing a common letter are significantly different ($P < 0.05$).

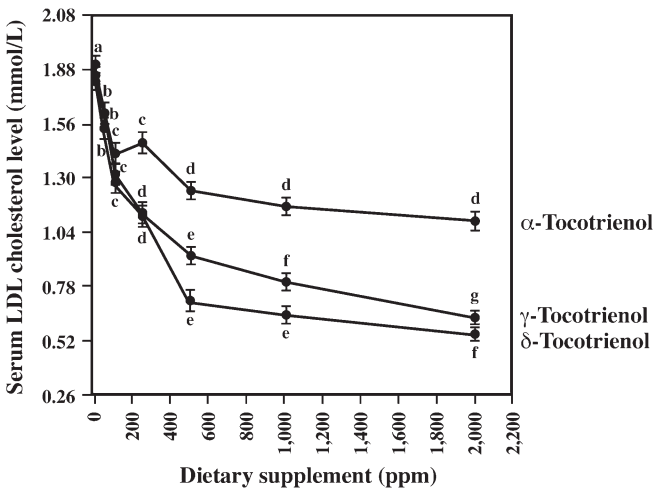

FIG. 4. Dose-dependent impacts of the tocotrienol isomers on the serum LDL cholesterol levels of pullets. Values are means ($n = 6$); standard error is shown by bars. Points on a line not sharing a common letter are significantly different ($P < 0.05$).

As noted in the experimental section, TRF consists of a blend of 16.8% α-tocopherol, 26.5% α-tocotrienol, 42.0% γ-tocotrienol, and 14.1% δ-tocotrienol. The 21% reduction in serum total cholesterol level obtained with a 2,000 ppm supplement of TRF is in agreement with the sum (22.1% reduction) of proportional impacts of the individual constituents.

The α-tocopherol supplement produced a significant, dose-dependent elevation of HDL cholesterol, confirming the finding reported by others (36–38); other supplements had less impact on HDL levels (Table 1). Although no supplement-mediated trends in triglyceride levels were observed, the levels in all supplemented groups receiving α-tocopherol, TRF, and δ-tocotrienol were significantly lower than the control value, as were the levels of the groups receiving the highest supplements of α- and γ-tocotrienols (Table 2). Weight gains were not impacted by the supplements; within each supplement grouping the weight gain by the group receiving the 2,000 ppm supplement matched that of the control. Similarly, differences in values for other parameters, such as feed consumption, body weight at sacrifice, and weights of liver, lungs, pancreas, kidneys, and heart, did not differ between treatments or within treatments (data not shown).

Figures 5 and 6 show the changes from control in total and LDL cholesterol levels produced by 500 ppm of each of the individual supplements. The various supplementation levels (50–1,000 ppm) of α-tocopherol did not reduce serum total (Fig. 5) or LDL (Fig. 6) cholesterol levels. On the other hand, 500 ppm supplementation of TRF or α-, γ-, or δ-tocotrienol caused significant lowering of serum total and LDL cholesterol

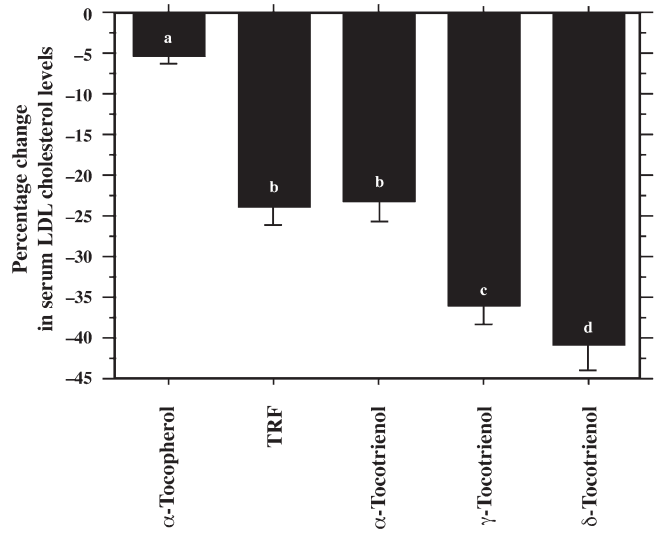

FIG. 6. Changes from control in serum LDL cholesterol levels of pullets receiving a 500 ppm supplement of TRF or its constituent tocols. Values are means ($n = 6$); standard error is shown by bars. Columns not sharing a common letter are significantly different ($P < 0.05$).

levels (Figs. 5 and 6). TRF and α-tocotrienol were effective in lowering these parameters; the reductions in the total and LDL cholesterol levels achieved with the γ-tocotrienol supplement were significantly greater than those achieved with the TRF and α-tocotrienol supplements, and they were significantly less than those achieved with the δ-tocotrienol supplement (Figs. 5 and 6). Supplementation with higher concentrations (1,000 ppm or 2,000 ppm) of these tocotrienols did not show the profound reductions in total and LDL cholesterol levels compared with control values that were found with 500-ppm supplementation.

DISCUSSION

The absence of a supplement-induced change in weight gain, weight of organs, or feed consumption suggests that the elevated levels of TRF and its constituent tocols were free of toxic effects. Consistent with widely published reports (19–22,24–29), the unsaturated tocol analogues and TRF supplements produced a significant dose-dependent lowering of total (Fig. 1) and LDL (Fig. 2) cholesterol levels. A lowering of LDL cholesterol was achieved with higher levels of α-tocopherol; 2,000 ppm showed a modest response compared with responses to TRF and the individual tocotrienols (Fig. 4), yielding a 6% reduction (Fig. 2). The relative impacts of the tocotrienol isomers on serum LDL cholesterol levels (Fig. 4) were parallel with but substantially greater than those recorded for total cholesterol levels (Fig. 3). The 55% reduction in LDL cholesterol level obtained with a 2,000-ppm supplement of TRF is modestly greater than the sum, a 50% reduction in the LDL cholesterol level, of the proportional impacts of the individual constituents.

These results show that the serum total and LDL cholesterol levels were decreased significantly ($P < 0.05$) in a dose-dependent (50–2,000 ppm) manner by individual tocotrienols (Figs. 1–4). These decreases in cholesterol levels induced by tocotrienols were due to down-regulation of HMG-CoA reductase activity by a novel post-transcriptional mechanism, which results in decreased protein synthesis of HMG-CoA reductase, while increasing the degradation of the reductase protein (22). Therefore, cholesterol synthesis *in vivo* was suppressed, and concomitantly, the levels of total and LDL cholesterol were decreased. The pure individual tocotrienols were more effective in lowering the serum total and LDL cholesterol levels as compared with TRF, which typically contains 16% to 45% α-tocopherol in various preparations of palm oil or rice bran oil (39,40). As pointed out earlier, tocotrienols act by inhibiting the enzymic activity of HMG-CoA reductase; however, α-tocopherol induces HMG-CoA reductase activity in the liver without affecting serum cholesterol levels (39,40).

The α-tocopherol supplements, in contrast with the TRF and tocotrienol supplements, tended to raise HDL cholesterol levels. Nevertheless, the HDL/LDL ratio remained constant across the dose range for the α-tocopherol supplements, whereas the ratio improved dramatically in a dose-response relationship for TRF and tocotrienol supplements (Fig. 7). Therefore, the individual tocotrienols not only lower LDL cholesterol, but also improve the ratios of HDL cholesterol to total cholesterol and LDL cholesterol significantly, 200–300% (Fig. 7).

The present findings indicate that supplementation of 500 ppm of α-tocotrienol, γ-tocotrienol, and δ-tocotrienol will yield a reduction of 0.47, 0.62, and 0.74 mmol/L, respectively, in serum total cholesterol levels. The supplementation at the 50 ppm level caused decreases of 0.36, 0.44, and 0.57 mmol/L (Fig. 3). This differential impact of the individual tocotrienols on serum total cholesterol levels parallels their differential impacts *in vitro* on hepatic HMG-CoA reductase activity (25,29).

Tocotrienols show significant lowering of serum total cholesterol level in all animal models (19,22,24–29,31,32,39,40). On the other hand, human studies have yielded conflicting results; some studies indicate significant lowering of cholesterol

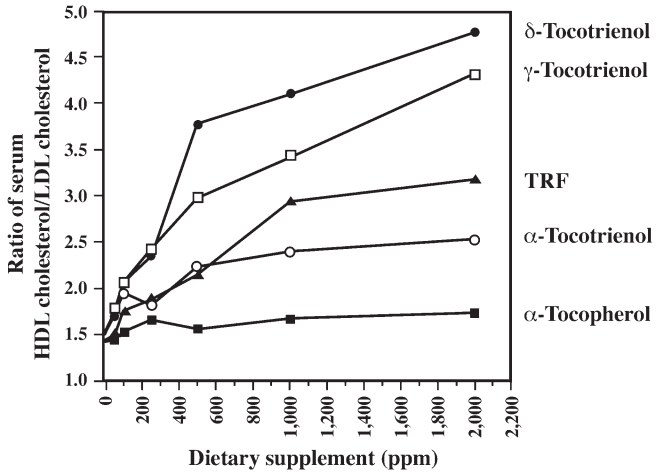

FIG. 7. Dose-dependent impacts of the TRF from palm oil and α-tocopherol on the HDL/LDL ratios of pullets.

levels (20,41–44), whereas in other studies, no response was detected (45–49). The differences observed in the human studies were partly due to the use of various doses and sources of TRF and tocotrienols. In order to compare the results of animal and human studies, Raederstorff *et al.* studied steady-state plasma γ-tocotrienol levels and plasma cholesterol levels in hamsters (50). They observed that the maximum effect of γ-tocotrienol was reached after 2 wk with the highest dose (263 mg/d/kg body weight); thereafter, the effect on cholesterol was plateaued. However, the cholesterol level continued to decrease after week 2 with the intermediate dose (58 mg/d/kg body weight). The lowest dose (23 mg/d/kg body weight) did not lower total cholesterol levels in their study, as was also reported by Hayes *et al.* (51), due to the presence of very low plasma level of tocotrienols (1 μmol/L). The only significant decrease in plasma cholesterol levels, in the hamster model, was seen when plasma tocotrienols levels were above 15 μmol/L with a dose of 58 mg/kg body weight (50).

The plasma levels of tocotrienols were 5–8 μmol/L (200 mg/d) in our first human study (20). On the other hand, the plasma levels of tocotrienols were 0.2 μmol/L and 1 μmol/L in the Mensik *et al.* (47) and O'Byrne *et al.* (48) studies, as pointed out by Raederstorff *et al.* (50). Therefore, it seems that in several well-designed human studies, pharmacologically effective plasma levels of tocotrienol were not reached, which could explain the inconsistent effects observed in various human studies (45–49), including some nonrespondents in our studies (20,42–44). The second possible explanation of reported inability of tocotrienols to lower serum total and LDL cholesterol levels in hypercholesterolemic human subjects is the presence of higher percentages of tocopherols (>30%) in the TRF used by various investigators (45–49).

As mentioned earlier, α-tocopherol appears to attenuate the tocotrienol effect *in vivo* but not in isolated liver cells (25). These findings suggest that transport systems may play a role in the biological activities of tocols. The differences in the transport and tissue uptake of the saturated (α-, γ-, and δ-tocopherols) and unsaturated (α-, γ-, and δ-tocotrienols) tocols have been reported by various investigators (51–54). The preferential transport of α-tocopherol by α-tocopherol transfer protein (α-TTP) in serum lipoproteins was reported by Traber *et al.* (52). A hepatic binding protein with high specificity for α-tocopherol in the liver results in the subsequent enrichment of α-tocopherol in the VLDL and LDL moieties (52–54). The tocotrienols, on the other hand, are transported nonspecifically like other lipid-soluble compounds, and are found in much higher levels in the HDL moiety (42). α-Tocotrienol has preferential absorption compared with γ- or δ-tocotrienol in rat LDL moiety due to low affinity by hepatic α-TTP (55), and these tocotrienols also might be competing with α-tocopherol in the TRF supplements used by others in their studies (56). Moreover, these various tocotrienol isomers may have been retained in tissues to different extents (56). The tocotrienols cleared rapidly from plasma due to low affinity of tocotrienols to hepatic α-TTP, which may also account for the ambiguous findings by various investigators (56). In this respect, a recently published human study investigating the pharmacokinetics of a 300-mg dose is of relevance (57). The pharmacokinetics and bioavailability of various tocotrienols in postprandial and fasting humans were reported (57). The absorption of each tocotrienol was 100% greater in the fed state, and their elimination half-life ($t_{1/2}$) was found to be relatively short compared with tocopherol. The plasma levels of all tocotrienols were markedly increased in the fed state and were achieved between 3 and 5 h. The experimental values of various tocotrienols compared with the pharmacokinetic results of α-tocopherol were described in detail (57).

Thus, in chickens, palm oil preparations containing at least 30% α-tocopherol and 45% γ-tocotrienol seem to be less effective in lowering cholesterol than preparations containing 15–20% α-tocopherol and 60% γ-tocotrienol (39). Similarly, lower bioavailability of tocotrienyl acetates compared with the phenolic forms may have contributed to the lack of effect in the O'Byrne *et al.* human study (48). It should be noted that only clinical trials with duration of less than 35 d have provided evidence that γ-tocotrienol or mixed tocotrienols/tocopherol preparations lower serum total and LDL cholesterol levels, suggesting that tocotrienols have only short-term inhibitory effects on cholesterol synthesis (42–44).

The third possible reason of the inability of tocotrienols to lower serum total and LDL cholesterol levels in hypercholesterolemic human subjects might be due to the presence of higher percentages of tocopherols (>30%) in TRF used by various investigators (45–47,49). Khor *et al.* (58) have reported that a tocopherol-free TRF preparation caused a dose-dependent increase in the α-tocopherol content of guinea pig liver and serum, which confirmed our earlier findings that dietary TRF or γ-tocotrienol causes an increase in serum α-tocopherol levels in hypercholesterolemic humans (42–44). The failure of large doses of tocotrienols as effective hypocholesterolemic agents in all of these studies might be due to their

conversion to α-tocopherol *in vivo*, because the level of α-tocopherol in serum of TRF- or pure tocotrienol–treated subjects is substantially higher (2- to 4-fold) compared with the placebo group, as reported also by other investigators (20,45–47,49,50,58). This bioconversion of γ-tocotrienol to α-tocopherol was confirmed by feeding radioactive γ-[4-^{3}H]-tocotrienol to chickens for 4 wk, followed by the separation of various tocols from serum by HPLC. The radioactivity was found only in α-tocopherol, α-tocotrienol, and γ-tocotrienol, but not in δ-tocopherol or δ-tocotrienol (43). These findings were further supported by other investigators (27,37,50,58).

The recent studies show that CRP (associated with inflammation) is playing a more important role in the development of atherosclerosis than the previously established lipid parameters, total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides (4,5). Preliminary data in an ongoing open human study (5 hypercholesterolemic subjects) shows a decrease (11%) in CRP after feeding δ-tocotrienol (100 mg/d) for 4 wk (unpublished results). Atherosclerosis is a disease of chronic inflammation and accumulation of cholesterol and foam cells within the arterial wall (1–3). Our recent studies indicate that tocotrienols reduce the induction of tumor necrosis factor-α (TNF-α) in response to lipopolysaccharide (Re-LPS) challenge in mice and macrophages (59). δ-Tocotrienol also blocks LPS-induced gene expression of TNF-α, IL-β, IL-6, and iNOS in thioglycolateelicited peritoneal macrophages prepared from BALB/c, C57BL/6N, and PPAR-α mice (data not shown). Tocotrienols also prevent atherosclerotic lesions in apo-E–deficient mice and rabbits due to reduction of inflammation (32,60).

Tocotrienols in various human studies (consuming doses of 50–200 mg/d) were not very effective for lowering serum total cholesterol levels in all hypercholesterolemic subjects, with 20–25% nonrespondent (20,42–44). Therefore, a higher oral dose of tocotrienols might be required to reach an effective level in plasma to suppress cholesterol synthesis. A high level of tocotrienols or α-tocopherol (200–1,000 mg/d) could safely be consumed by humans on the basis of the present study; however, one should exercise care in extrapolating the studied high doses of tocotrienols for human consumption.

ACKNOWLEDGMENTS

The authors thank Ms. L. He, Dr. H.B. Mo, and Dr. Z.A. Din for their technical assistance, literature search, and helpful discussion. We greatly appreciate the editing of this paper by Dr. C.E. Elson (Department of Nutrition, University of Wisconsin—Madison). We also thank PORIM for supplying TRF and its purified components (α-tocopherol and α-, γ-, and δ-tocotrienols). The study was funded by Advanced Medical Research, Madison, Wisconsin. Statistic analyses were carried out by Dr. C.E. Elson and Keith Gilchrist.

Influence of Diet on Fatty Acids and Tocopherols in *M. Longissimus Dorsi* from Reindeer

S. Sampels*, E. Wiklund, and J. Pickova

Swedish University of Agricultural Sciences, Department of Food Science, Uppsala, Sweden

ABSTRACT: Our aim was to compare the effects of two pelleted diets containing differing FA composition with natural lichen pasture on reindeer's meat FA composition. In addition we wanted to increase the knowledge about reindeer FA metabolism and the effect of animal sex and age on FA composition in reindeer muscle.

The trial included five reindeer groups: three grazing, consisting of adult males, adult females, and calves; and two groups of calves fed conventional pellets (CPD) and pellets containing crushed linseed (LPD), respectively, for two months before slaughter. Differences between male and female animals were mainly found in the neutral lipid fraction and related to fatness. Calves differed significantly from adult males and females in FA and lipid class composition. CPD led to a higher ratio of n-6 to n-3 FA compared with grazing. The ratio n-6/n-3 in the polar lipid (PL) fraction of the animals fed LPD was slightly, but not significantly, higher than that in the grazing reindeer. LPD-fed animals had lower proportions of long-chain polyunsaturated FA (LCPUFA), namely 20:4n-6, 22:5n-3, and 22:6n-3, in the PL fraction compared with the grazing animals due to the content of these FA in the natural feed. The animals seemed unable to elongate dietary FA in significant amounts. We conclude that by adding crushed linseed to the pellets it was possible to keep the favorable FA composition of meat from grazing reindeer with regard to the n-6/n-3 ratio but not in LCPUFA.

Paper no. L9940 in *Lipids 41,* 463–472 (May 2006).

A diet rich in polyunsaturated FA (PUFA), especially n-3 FA, has beneficial effects on human health (1). Today's Western diets have an n-6/n-3 ratio between 15 and 20, whereas it is assumed that it was close to 1 during human evolution (2,3). Because from a human nutritional point of view it is suggested that the n-6/n-3 ratio in the diet should be below 4, it is important to include sources rich in n-3 PUFA in the daily diet. There is an interest and a need to improve FA composition of meat and to produce healthier meat (4). The FA composition of the animal's diet influences the FA composition of the meat (4). Meat from grazing reindeer has been suggested to be nutritionally valuable because of its low fat content and moderate proportion of n-3 PUFA (5).

Abbreviations: CPD, conventional pellets; GLM, general linear model; HIP, hexan-isopropanol; LCPUFA, long-chain polyunsaturated FA; LPD, linseed pellets; MUFA monounsaturated FA; NL, neutral lipid fraction; PL, polar lipid fraction; SFA, saturated FA; SPE, solid phase extraction.

Reindeer are among the northernmost freely ranging ruminants in Scandinavia, and are well adapted to their habitat, which has a cold climate and snow during the main part of the year. In Sweden all reindeer are semidomesticated, and reindeer husbandry is based on utilization of natural pastures all year round. The reindeer migrate from pastures on the mountain tundra in the summer months to winter pastures in the valleys and forests, so their diet changes markedly over the year (6). The main diet for reindeer during winter before slaughter consists normally of wintergreen plants and lichens (7). However, occasionally, an increased number of reindeer are fed commercial pellets before slaughter, during winter. The main reason to feed pellets is to reduce radioactive cesium (Cs) in the meat of reindeer that have been winter grazing in certain contaminated areas (8). Partly, feeding is also used to improve the nutritional status (9) and enable weight gain of the animals, because reindeer normally do not gain weight at winter pastures (10).

Taugbøl and Mathiesen (11) found changes in the FA composition of total lipids of reindeer meat due to variation in feed composition, and Wiklund *et al.* (5) showed a difference in the FA profile in neutral lipids (NL) and polar lipids (PL) between different feeding groups. FA composition of ruminant tissues is in general less influenced by the feed than that of monogastric animals (12). In ruminants a high proportion of C18 unsaturated FA are hydrogenated in rumen by microorganisms if they are not naturally protected by cell walls as in plants or by synthetic coatings (13). Because of this hydrogenation, feeding of concentrates to ruminants usually leads to lower proportions of PUFA in the meat compared with monogastric animals fed on the same diet (12). This effect can be suppressed by adding whole or crushed seeds, instead of oils, to feeds (13,14). In addition, intensive feeding with pellets leads to a higher n-6/n-3 ratio in the meat because concentrates are often based on grains that are rich in n-6 FA, whereas grass and other green plants are rich in n-3 FA (14). It has also been suggested that a higher intake of 18:3n-3 could enhance *de novo* synthesis of longer-chain n-3 PUFA, such as 20:5n-3 and 22:5n-3 (15) (cattle).

The purpose of this study was to investigate the possibility of improving the FA composition of the meat from pellet-fed reindeer. To achieve a more nutritionally favorable composition in the pellets, linseed, a rich source of 18:3n-3, was added, mimicking the FA composition of natural green forage in terms of n-6/n-3 ratio. Meat lipids were separated into

NL and PL fractions because a variation of total lipid content will lead to different proportions of these fractions. NL represents the storage lipids, which are mainly used as a depot for energy sources, whereas PL refers to the membrane lipids, which represent a relatively stable amount (15). Studies on different species exemplify that age and sex might influence lipid metabolism and thereby FA composition in the muscle (16–19) (goats, pigs, and cattle). We therefore chose to include animals of different age and sex in this study. However, because earlier results showed that FA composition of meat did not differ between male and female reindeer calves (20), calves were not separated by sex.

In addition, we studied how diet, age, and sex affected tocopherol and retinol content in the meat, because tocopherol is an important antioxidant preventing oxidation of FA.

EXPERIMENTAL PROCEDURES

Animals. A total of 38 reindeer (7 males and 7 females aged 2 yr and older, and 24 calves aged about 10 mon) were included in the study. Age was determined at slaughter by body size and the color of the knee conjunction. Animals 2 yr and older were considered as adult animals. The older animals and a group of 7 calves were previously grazing winter pasture, whereas the other calves were divided in two groups ($n = 10$ and $n = 7$, respectively) that were fed two different pelleted feed mixtures as complete feeds *ad libitum*. One of these latter groups was fed a conventional pellet diet (CPD), and the other was fed pellets enriched with 6% crushed linseed (linseed pellet diet, LPD) (Table 1) (21) for two months before slaughter. In addition a small amount of hay was offered as roughage. All animals were slaughtered in early April, following the common procedures at the abattoirs (Grundnäs Kött AB, Grundnäs and Arvidsjaur Renslakt AB, Arvidsjaur, Sweden). All animals were in good condition; slaughter weights and classification were presented previously in the literature (22). Fresh meat samples were taken directly after slaughter (about 45 min *post mortem*) from the *M. longissimus dorsi*. All samples were frozen at –20°C and finally stored at –80°C until analysis.

TABLE 1
Industrial Nutrient Declaration for Renfor Bas and Renfor Bas Enriched with Crushed Linseed (21)

Nutrient content	Renfor Bas (CPD)	Renfor Bas plus 6% linseed (LPD)
Crude protein, %	10.0	10.4
Energy, MJ/kg	10.0	10.0
Fiber, %	15.0	14.6
Crude fat, %	3.0	3.05
Water, %	12.0	12.0
Vitamin A, IU/kg	9,000 (2.7 mg/kg)	9,000 (2.7 mg/kg)
Vitamin D_3, IU/kg	3,000 (0.075 mg/kg)	3,000 (0.075 mg/kg)
Vitamin E, mg/kg	60	60
Calcium, %	0.8	0.8
Phosphate, %	0.4	0.4
Magnesium, %	0.3	0.3
Selenium, %	0.6	0.6

Feed samples. Samples of the pellets and different lichens (*Cladina arbuscula*, *Cetraria islandica*, *Cladina stellaris*, and *Cladina mitis*) from the grazing area were collected. The dry lichens were stored at –80°C until analyzed.

Extraction of lipid from the meat. The lipid extraction was performed according to Hara and Radin (23), with slight modifications as described by Pickova *et al.* (24). Connective tissue and visible fat were removed, the semifrozen samples were minced, and a subsample of approximately 5 g muscle tissue was taken for extraction. The samples were homogenized for 3 × 30 s in 70 mL hexane/isopropanol (HIP) (3:2, vol/vol) using an Ultra Turrax (T25, Janke and Kunkel, IKA Werke, Germany), and 30 mL Na_2SO_4 solution (0.47 M) was added. The homogenate was centrifuged for 5 min at 4000 rpm (2103 rcf) (Sorvall Super T21; Sorvall Products L.P., Newton, CT) and the upper phase was transferred to a new flask and evaporated under nitrogen. The lipid content of the meat was determined gravimetrically from this total extracted lipid, which was then dissolved in 2 mL chloroform. The samples were stored at –80°C in normal atmosphere until further analyses.

Extraction of lipid from the feed. The different feed samples were extracted according to Folch *et al.* (25), with slight modifications. Lichens and pellets were milled, and subsamples of 2 g dry material were soaked in 8 mL H_2O. The samples were then homogenized for 3 × 30 s in 150 mL chloroform/methanol (2:1, vol/vol) using an Ultra Turrax (T25, Janke and Kunkel). The samples were transferred to a separatory funnel and 40 mL KCl solution (0.11 M) was added. The lower phase, containing the lipids, was transferred to a new flask and evaporated. The lipid content from the lichens and the pellets was determined from this total extracted lipid, which was then dissolved in 2 mL chloroform. The samples were stored at –80°C in normal atmosphere until further analyses.

Separation of the meat lipids. Total lipids from the meat were separated on prepacked 6-mL solid-phase-extraction (SPE) columns (Isolute SI 500 mg, IST, United Kingdom) into NL and PL fractions according to Prieto *et al.* (26) with slight modifications. The samples were dissolved in 2 mL diethylether/acetic acid (100:0.2, vol/vol) and applied on the columns, which were activated previously with 6 mL hexane. NL were eluted with 18 mL hexane/diethylether (200:3, vol/vol) and the PL fraction with 6 mL methanol/acetonitrile (65:35, vol/vol). After evaporating the solvent, the lipids were dissolved in 0.5 mL hexane and stored under normal atmospheric pressure at –80°C until further analysis.

Preparation of FAME of PL and NL. FA from the NL and PL fractions were methylated according to Appelqvist (27). To each sample, 2 mL of a 0.01 M solution of NaOH in dry methanol was added, after which the samples were heated for 30 min at 60°C. Thereafter 2 mL of a solution of $NaHSO_4$ and NaCl in water (4.16 and 4.27 M, respectively) was added. After cooling the samples under running water, 3 mL water was added and the FAME were extracted with 2 mL hexane, transferred to a new tube, evaporated, dissolved again, and

stored under normal atmosphere at –20°C for a maximum of 1 wk until analysis.

Preparation of FAME of total lipids from feed samples. FA from total lipids of lichens and pellets were methylated according to Appelqvist (27). To each sample, 2 mL of a 0.01 M solution of NaOH in dry methanol was added, and the samples were then heated for 10 min at 60°C. Next, 3 mL of BF_3 reagent (boron trifluoride-methanol complex) was added and the samples were reheated at 60°C for 10 min. Thereafter the tubes were cooled under running cold water and 2 mL of a 3.42 M NaCl solution in water was added to all tubes. The FAME were extracted with 2 mL hexane, and the upper layer was transferred to a new tube and evaporated under nitrogen gas to dryness. The lipids were dissolved in 0.5 mL hexane and stored under normal atmospheric pressure at –20°C for a maximum of 1 wk until GC analysis.

Capillary GC. The completeness of FA methylation was checked by analytical TLC using hexane/diethyl ether/acetic acid (85:15:1, by vol) as solvent. The plates were developed by spraying with a mixture of 10% phosphomolybdic acid in ethanol:diethylether (1:1, vol/vol) and drying for 15 min at 100°C. The FAME were analyzed with a gas chromatograph (CP9001, Chrompack, Middelburg, The Netherlands) equipped with an FID and split injector as described by Pickova *et al.* (24) using a BPX 70 column (SGE, Austin, TX) with length 50 m, i.d. 0.22 mm, and film thickness 0.25 μm. The GC was programmed to start at 158°C, with a rate of temperature increase of 2°C/min to 220°C and a final constant time of 13 min at 220°C. Helium was used as carrier gas at a flow rate of 0.8 mL/min. Makeup gas was nitrogen. The peaks were identified by comparing their retention times with those of the standard mixture GLC-68A (Nu-Chek-Prep, Elysian, MN) and other authentic standards. The response factors were also evaluated by comparing with the GLC-68A standard. An average of 95.6% of the peak areas could be identified. The percentages of FA were calculated as 100% from the FA identified. The unknown peaks in both NL and PL fractions, including the dimethyl acetals from the phospholipid plasmalogens (28), were subtracted before addition due to the high SD, which otherwise might have disturbed the calculation of the percentage of the other FA. The proportion of excluded unknowns was on average 10.2% of the identified FA in PL fraction and 2.2% of the identified FA in NL fraction.

Vitamin analysis. For the analysis of retinol and tocopherols in meat, pellets, and lichens a method described by Jensen *et al.* (29), slightly modified, was used as follows: 2 × 1 g muscle (0.5 g for pellets and lichens) was ground and homogenized in two tubes together with 1.2 mL 20% ascorbic acid solution, 0.6 mL methanol, and 1.2 mL 17.8 M KOH. After saponification and cooling, tocopherols and retinol were extracted with 2 × 4 mL hexane. The hexane-vitamin solution was evaporated under nitrogen gas and diluted with the mobile phase. The mobile phase used consisted of 95% methanol:acetonitrile (1:1, vol/vol) and 5% chloroform pumped at a flow rate of 1.2 mL/min. Analyses were carried out with a Merck Hitachi L7100 pump, an FL-7485 detector, and an L-7200 auto sampler (Merck Hitachi, Eurolab, Darmstadt, Germany). The HPLC column was a 4.0 × 250 mm RP-18 LiChroCART (Merck KGaA, Darmstadt, Germany).

Identification and quantification were done by external standards. Retinol was detected with an excitation wavelength of 344 nm and emission wavelength of 472 nm; γ-tocopherol and α-tocopherol were detected with excitation wavelengths of 290 and 260 nm, respectively, and with an emission wavelength of 327 nm.

Statistical analysis. The statistical analyses were carried out with the Statistical Analysis System (30) using the general linear model (GLM) procedure. The models for comparing fat content, FA, and vitamins included age, gender, and the treatment of the animals as fixed factors.

RESULTS

*Composition of the feed***.** The content of retinol and tocopherols was higher in the pellets than in the lichens. The content of tocopherol acetate in the CPD was slightly higher than in the LPD (Table 2).

The pelleted feed contained more saturated FA (SFA), especially 12:0, compared to the lichens, due to the use of palm-expeller in the pellets (Table 2). The n-6/n-3 ratio in the lichens was around 5.3–5.8 except for *Cetraria islandica*, which had a lower ratio of 2.7. The pelleted feed had an n-6/n-3 ratio of 4.3 for the CPD and 2.6 for the LPD.

Fat content of different lichens was lower than the fat content of the pellets except for *Cetraria islandica*, which had a higher fat content than the pellets.

Fat content and FA composition of the meat. The adult females had the highest fat contents, followed by the males, whereas the pellet-fed calves had a slightly but not significantly higher fat content compared with the grazing calves, which had the lowest fat content (Tables 3 and 4).

Effect of age and sex on meat FA composition. FA composition in both PL and NL fractions differed only slightly between grazing calves and the grazing adult animals (Table 3, Fig. 1). Calves had a significantly lower proportion of 16:0 in both PL and NL and significantly higher proportions of 18:1n-9 and monounsaturated FA (MUFA) in the NL fraction than the adult animals. In the PL the proportions of SFA and MUFA were lowest in the calves, whereas n-3 PUFA was higher in these samples, compared with the adult animals. In the NL fraction SFA was significantly lower in the meat from the calves, whereas n-3 and n-6 PUFA were significantly higher compared with the adult animals. The n-6/n-3 ratio was significantly lower in the NL fraction of the calves compared with the males. No 22:6n-3 was found in NL fractions.

Effect of the different diets on meat FA composition. In spite of the high content of 12:0 in the pelleted feed, this FA is not detectable in significant amounts in either lipid fraction (Table 4).

The main differences in FA composition were found in the PL fraction of meat from animals fed different diets (Table 4, Fig. 2). In the meat from reindeer fed LPD the proportion of

[a]Values reported are means of duplicate values. FA are presented if at least one group had values ≥ 0.16%. In total 32 FA were identified. Abbreviations: n.d., not detected; SFA, saturated FA; MUFA, monounsaturated FA; PUFA, polyunsaturated FA.
[b]Tocopherol acetate in pellets.

20:4n-6 was significantly lower compared with the grazing animals, while 18:2n-6 was higher. The meat from grazing animals contained more long-chain PUFA (LCPUFA, C20 and longer FA), both n-3 and n-6. Also significantly more 18:1n-9 was found in meat PL of this group, compared with both pellet-fed groups. The content of n-3 PUFA in muscle PL fraction of pellet-fed animals did not differ between CPD- and LPD-fed animals. However n-3 in the PL fraction from the CPD-fed group differed from that of the grazing animals, and LPD-fed animals had an intermediate value.

In NL the main FA, 16:0, 18:0, and 18:1n-9, did not differ between treatments. A lower proportion of n-3 was found in muscle of animals fed LPD than those grazing ($P = 0.010$). Even if the proportion of n-3 in NL did not differ between CPD- and LPD-fed reindeer in this study, the ratio of n-6/n-3 was significantly lower in the LPD-fed animals compared with the animals fed CPD. However the n-6/n-3 ratio in the meat of grazing animals was still lowest.

Vitamin content. The calves had significantly more α-tocopherol compared with the adult animals (Table 5) among the grazing animals, whereas retinol and γ-tocopherol were not affected by age or sex. There was more retinol and γ-tocopherol in the meat of the pellet-fed animals compared with the grazing animals (Table 6).

DISCUSSION

The analyzed composition of vitamins in the pellets (Table 2) corresponded well with the industrial nutrient declaration (Table 1). The amount of tocopherol acetate was slightly lower in the LPD compared with LPD, which suggests that LPD were more prone to oxidation due to the higher content of n-3 PUFA, and that some of the antioxidants were used during feed storage.

The fat content of the lichens was comparable to results in earlier studies; the values varied from 2.9 to 4.5% for differ-

[a]Means with different superscripts within a row differ significantly ($P < 0.05$). FA are presented if at least one group had values > 0.15%. In total 32 FA were identified.

ent *Cladina* spp. from Finland (7) and were slightly lower in a Norwegian study (31). The FA composition of the lichens was different to that found by Soppela *et al.* (32); in particular, we found twice as much 18:2n-6. This variation could depend on both species and environmental differences. Storeheier *et al.* (31) showed that the nutritive value of lichens can differ greatly between species and within genera. Even though the lichens contained more n-3 LCPUFA than the pellets, the ratio of n-6/n-3 was relatively high due to a high proportion of 18:2n-6 in the lichens.

Earlier studies have shown that sex hormone status influenced FA composition in both adipose tissue and phospholipids (33,34) (reindeer and cattle). The present study however, showed in general no important effects of sex or age on the FA composition in the meat; indeed, we suggest the main differences depend on fatness, which is expressed by higher proportions of SFA in adult reindeer and lower proportions of PUFA in the calves.

In our reindeer study the proportions of both PL n-3 and n-6 PUFA do not differ between male and female animals, whereas the proportion of 22:6n-3 is significantly lower in female reindeer compared with males. However, the major differences in PL can be seen between males and calves in our study. In contrast to the findings in cows and yearlings of Malau-Aduli *et al.* (33), who analyzed phospholipids, we found higher proportions of PL n-3 in the meat from reindeer calves. The generally higher proportion of 22:5n-3 in PL fraction from calves could be a sign that calves accumulate this FA to a greater extent. Because 22:5n-3 is also increased in NL fraction from calves, this suggests a surplus intake and possibly also desaturation and elongation.

The higher proportion of NL PUFA in calves might be a

[a]Means with different superscripts within a row differ significantly ($P < 0.05$). FA are presented if at least one group had values > 0.15%. In total 32 FA were identified.

result of less dilution in adult animals by lower *de novo* synthesis of PUFA. Also, due to the higher demand for energy due to growth, lower proportions of SFA are deposited in calves. Similar results have also been reported in lambs; older lambs had higher SFA and lower n-6 content in total lipids compared with younger ones (35). However, differences in FA composition were correlated with higher fatness in females compared with males and with increasing age (36) (pigs, cattle, and lamb).

The fact that 12:0 was found in relatively high proportions in the pellets (7.05% in CPD and 6.08% in LPD), but not in the meat lipids, indicates that the reindeer use this FA as an energy source or store it in the adipose tissue and do not store it in the muscles. The differences in n-6, SFA, and MUFA in the PL fraction between the pellet-fed and the grazing animals are probably due to the different proportion of these FA in the pellets compared to the lichens and the other feed items consumed. This is especially true for the LCPUFA 20:4n-6, 20:5n-3, 22:5n-3, and 22:6n-3, which are not present in the pellets. The natural feed of grazing animals significantly affects the composition of the PL, which is exhibited by the FA mentioned above. These FA are significantly higher in the PL fraction of meat from the grazing animals compared with the pellet-fed animals. It is suggested that this difference is caused by the difference in feed composition. Similar results have been found in an earlier study on grazing and pellet-fed reindeer (5).

However, some lichen FA were not reflected in the meat in the same proportions as the pellet FA were. For example, 18:2n-6 was lower in meat from grazing reindeer than pellet-

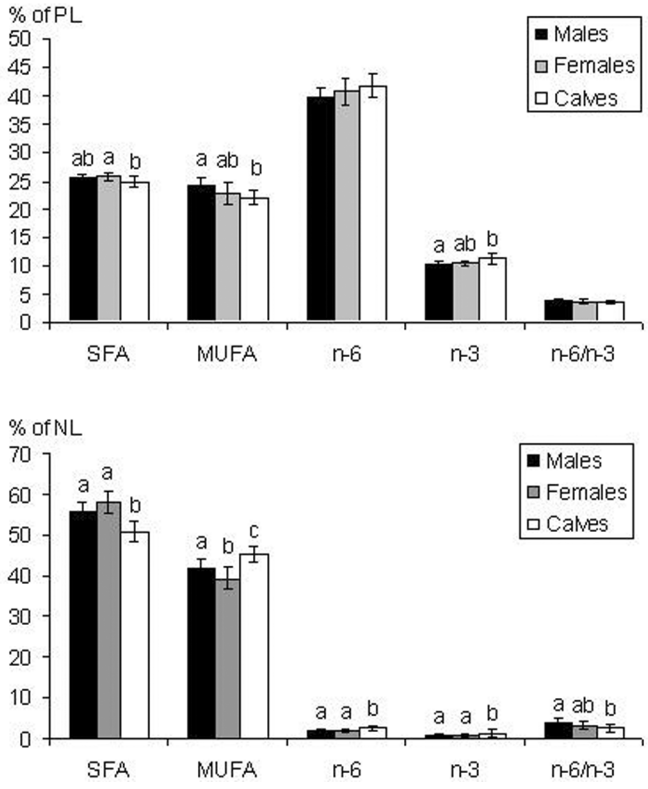

FIG. 1. FA composition of free-ranging reindeer of different age and sex (percent of total identified FA; mean values and standard deviation) presented as sums of saturated and unsaturated FA. Means with different superscripts within a row differ significantly ($P < 0.05$).

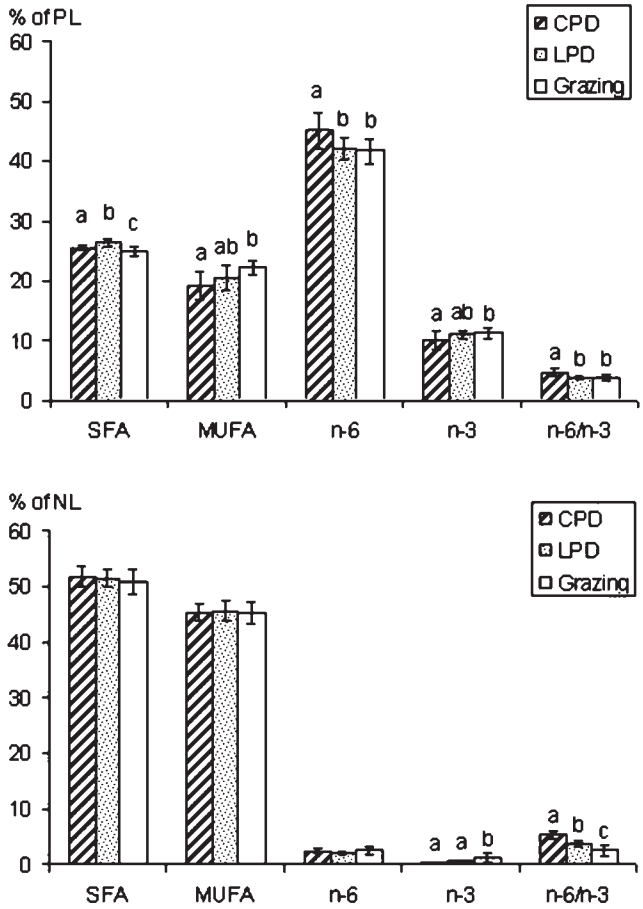

FIG. 2. FA composition of reindeer calves fed different types of pellets compared with free-ranging calves (percent of total identified FA; mean values and standard deviation) presented as sums of saturated and unsaturated FA. Means with different superscripts within a row differ significantly ($P < 0.05$).

fed ones in spite of the higher proportion in the analyzed lichens compared with the pellets. Grazing of green plants other than lichens possibly caused a lower intake of 18:2n-6. Lichens are estimated to contribute to 13–56% (31,37–39) or even 50–80% (40) of the winter diet. Green feed, such as grass, contains 14.7% 16:0 and 10% 18:2n-6, but up to 68% 18:3n-3 (41). This composition illustrates well the general green plant FA profile.

As the PL have a relatively stable composition due to their functionality, they are in general less affected, but variation can be found within the groups of SFA and unsaturated FA, for example, if one PUFA is increased another similar one will be decreased to balance this (15,42) (fish, cattle). Nonetheless the significantly higher proportion of 18:3n-3 in the LPD is reflected in the PL fraction in addition to a significantly higher proportion of 18:2n-6. In the present study the higher proportions of 18:2n-6 and 18:3n-3 in LPD-fed reindeer are probably balanced by lower contents of 20:4n-6 and 22:5n-3 as argued by Scollan *et al.* (15) (cattle).

The increased amount of 20:5n-3 in the meat of the LPD-fed animals compared with the CPD-fed reindeer group indicates an enhanced synthesis from 18:3n-3; similar results were also found in a study of beef (15). However, this does not apply for 22:5n-3 and 22:6n-3 in the LPD-fed animals. The n-3 LCPUFA were still somewhat lower in the LPD-fed reindeer compared with the grazing reindeer, even though the total n-3 in PL of the meat from the animals fed LPD did not differ significantly from the grazing animals. This suggests either that the increase of 18:3n-3 was still too small to enhance the synthesis of longer-chain FA or that the animals are not able to elongate and desaturate these FA in significant amounts. A similar limited elongation and desaturation is found in pigs (43) and rats (44). This lack of elongation and the fact that 22:6n-3 competes poorly against 20:5n-3 for incorporation into PL indicates that the reindeer need to ingest LCPUFA *via* the diet. It can be argued that even a low amount of essential FA and their elongated and desaturated derivatives are accumulated in the food chain and therefore of significant importance.

The grazing reindeer had a slightly lower content of retinol than the pellet-fed animals, but the difference was not as large as the difference in the feed, which suggests that the animals are not able to take up and metabolize higher amounts of retinol.

γ-Tocopherol was significantly higher in the pellet-fed reindeer, which correlates with the significantly higher

TABLE 5
Vitamin Content (μg/g) in Meat from Free-Ranging Reindeer of Different Age and Sex[a]

	Males (n = 7)	SE	Females (n = 6)	SE	Calves (n = 7)	SE	P
Retinol	0.026	0.003	0.030	0.003	0.029	0.003	0.648
γ-Tocopherol	0.035	0.005	0.031	0.005	0.025	0.005	0.441
α-Tocopherol	4.47[a]	0.288	4.90[a,b]	0.311	5.67[b]	0.288	0.028

[a]Values reported are least-square means and standard errors. Means with different superscripts within a row differ significantly ($P < 0.05$).

γ-Tocopherol	0.055[a]	0.009	0.067[a]	0.007	0.025[b]	0.009	0.002
α-Tocopherol	5.50	0.293	5.36	0.245	5.67	0.293	0.722

[a]Values reported are least-square means and standard errors. Means with different superscripts within a row differ significantly ($P < 0.05$). CPD, conventional pellet diet; LPD, linseed pellet diet.

amount of γ-tocopherol in the pellets compared to the analyzed lichens. In the lichens γ-tocopherol was only detected in small amounts in *Cladina mitis*; it was not detectable in the other lichen species included in this study.

Otherwise, the difference in tocopherols between the pellets, which contain 56.5 and 48.4 μg/g tocopherol acetate in CDP and LDP, respectively, and the lichens, which contain much lower amounts of total tocopherols (9.4–15.8 μg/g α-tocopherol), is not reflected in the meat. This can be explained by several mechanisms. First, it might be that the animals reach a saturation level as shown for cattle (45). Also Jensen *et al.* (46) present data from several trials on pigs and poultry in which vitamin E increases only slightly with increased supplementation. Second, it is possible that some substances in the lichens increase tocopherol bioavailability, as it was suggested that phenolic compounds affect tocopherol levels in tissues (47) (rats and humans).

In addition, the natural antioxidants can have an additive value for the total antioxidant capacity. These mechanisms are still very much unknown. Gülçin *et al.* (48) showed that aqueous lichen extract inhibited lipid peroxidation to a higher extent than α-tocopherol in a linoleic acid emulsion, which indicates that one or more other compounds with antioxidant function might be found in lichens. Therefore we suggest that α-tocopherol might accumulate in the meat because it is not affected by nonenzymatic oxidation.

The consumption of reindeer meat is traditionally relatively high among Sami reindeer herders compared with people of Swedish, Finnish, and Norwegian origin living in the same areas (49,50). Reindeer meat FA composition is suggested to influence the n-6/n-3 ratio and the intake of LCPUFA and thereby affect health. Studies of health among reindeer herders showed a significantly lower incidence of ischemic heart disease in Finnish Sami compared with Finns (51), which could be related to diet, but may also depend on other lifestyle factors. These results were suggested to be related to the diet, especially the consumption of reindeer meat. The high content of tocopherol increased serum α-tocopherol, and the FA composition was suggested to beneficially affect thrombogenesis and reduce atherogenicity (51).

CONCLUSION

Effects on FA composition of reindeer meat were found to be mainly diet dependent. Tocopherol and retinol contents were only slightly affected by different feeding regimen or sex.

Feeding reindeer pelleted feed containing crushed linseed positively affects the FA composition and decreases the n-6/n-3 ratio. It is possible through the feed to influence the FA composition of the meat toward a more nutritionally valuable composition. The animals are not able to fully elongate and desaturate linolenic acid toward 22:5n-3 and 22:6n-3, which indicates that reindeer need to ingest these FA via the diet.

ACKNOWLEDGMENTS

The authors wish to thank Svenska Lantmännen and their representatives Sven Hellberg and Åke Strömberg for the production of the pellets, financial support, and advice during the study. We are grateful to the staff at Grundnäs Kött AB and Arvidsjaur Renslakt AB for their assistance in connection with the collection of samples, and to reindeer herder Peter Omma for all practical work associated with feeding of the reindeer. We also want to thank René Tischer for parts of the FA analyses and Dr. Birgitta Åhman for collecting the lichens.

Year-round High Arachidonic Acid Levels in Herbivorous Rabbit Fish *Siganus fuscescens* Tissues

Kazufumi Osako[a,*], Hiroaki Saito[b], Koichi Kuwahara[a], and Akira Okamoto[a]

[a]Food Science and Technology Section, Nagasaki Prefectural Institute of Fisheries, 1551-4 Taira-machi Nagasaki 851-2213, Japan and [b]National Research Institute of Fisheries Science, Yokohama-shi 236-8648, Japan

ABSTRACT: To identify a stable resource of 20:4 n-6 (arachidonic acid, AA) in marine fish tissues, the lipid profiles of *Siganus fuscescens* organs (muscle, liver, and other viscera) and stomach contents were examined throughout the year. Crude total lipid (TL) contents in respective organs showed seasonal variations and were high in winter and low in summer. The main FA in TL were 16:0, 18:0, 16:1n-7, 18:1n-9, AA, and 22:6n-3 (DHA). These FA were those generally observed in marine fish lipids, except for comparatively high levels of AA. In TL of muscle and liver, AA showed relatively high values during the period from late May to August (muscle, 4.6–13.1%; liver, 4.5–9.1%), compared with other seasons (muscle, 4.3–9.5%; liver, 3.6–8.4%). The AA levels in TL of other viscera and stomach contents fluctuated (other viscera, 2.0–10.7%; stomach contents, 7.6–26.7%). Regardless of the fishing season, each organ contained a higher level of AA in polar lipids (PL) than in neutral lipids. It was concluded that the fish contain comparatively high levels of AA in their TL throughout the year, and they accumulate AA characteristically in their tissue PL, probably from dietary food sources. Moreover, it was suggested that *S. fuscescens* has potential utility as a natural marine source of nutritional lipids, because the fish contain comparatively high levels of DHA and AA.

Paper no. L9917 in *Lipids 41*, 473–489 (May 2006).

The desirable biochemistry of fish lipids as part of the human diet has been confirmed. In particular, many reports indicate that n-3 series PUFA are useful for suppressing increases in plasma cholesterol (1,2), preventing cardiovascular diseases (3–5), and improving learning ability and visual function (6,7). Consequently, for the purpose of developing sources of n-3 series PUFA, especially DHA, scientists have been studying the chemistry of fish lipids.

Generally, human beings are able to synthesize arachidonic acid (AA) or DHA by chain elongation and desaturation from linoleic acid (18:2n-6) or alpha-linolenic acid, but this process is inefficient, particularly in infants (8,9).

The importance of the intake balance of DHA and AA for human health, especially for the growth of infants, has only recently been clarified (10–12). Therefore, intake of AA with DHA is presumed to be essential for the growth of infants.

E-mail: osako@marinelabo.nagasaki.nagasaki.jp

Abbreviations: AA, arachidonic acid; DMOX, 4, 4-dimethyloxazoline; GSI, gonadsomatic index; MUFA, monounsaturated FA; NL, neutral lipids; PL, polar lipids; SFA, saturated FA; ST, sterols; TFA, total FA; TL, total lipids; WE, wax esters.

The marine resource of DHA has been gradually identified, and an industrial supply system has been established. Nevertheless, no information is available on AA from the viewpoint of natural resources.

Industrially, AA is produced by extracting oil from the bacterium *Mortierella alpina* (13), and is used as a dietary supplement or food additive. However, in Japan, AA produced by this method has not been allowed for use as an additive in infant formula (modified milk) by the Ministry of Health, Labour and Welfare. Therefore, a natural, stable resource of AA is needed.

Generally, freshwater fish have high levels of n-6 PUFA in their lipids, from terrestrial prey rich in n-6 PUFA that they commonly consume (14–16). In contrast, marine fish lipids contain n-3 PUFA originating from phytoplankton through the marine food chain, whereas the levels of n-6 PUFA, such as AA, in their lipids are undetectable or negligible. However, there are several marine species whose lipids contain comparatively high levels of n-6 PUFA, including some kinds of algae, abalone, and fish (17–22).

Herbivorous species (including omnivorous species) reportedly contain high levels of AA (23–25). Moreover, carnivorous fishes that feed on macro-algae-consuming sea urchins and sea snails are also known to have high levels of AA (25). The high levels of AA observed in these species may originate in macroalgae, which generally contain high levels of AA. However, there are no reports that discussed the relationships between AA levels in fish organs and their diets, except for the report by Saito *et al.* (22).

Siganus fuscescens (Houttuyn, 1782) is one of the most common herbivorous fish species in Japan. This fish is abundantly caught as a by-catch species year-round, and their excessive consumption of algae is known as the main cause of the subtidal barren observed at the Japanese offshore line (26–29). This fish could be useful as a natural, stable source of both AA and DHA if it contains both of these PUFA abundantly in its tissues.

It has been reported that the total FA (TFA) composition of several fish species varies from season to season due to environmental conditions, including its natural cycle, maturity stage, geographic location, and other factors (30–37). However, there are no reports on seasonal variations in the FA composition of herbivorous fish such as *S. fuscescens*.

We assessed the FA composition of a typical herbivorous fish, *S. fuscescens*, throughout the year to analyze seasonal variations.

EXPERIMENTAL PROCEDURES

Fish. S. fuscescens were caught using set nets between April 11, 2002, and September 29, 2004, in the Nagasaki offshore (33°19'N, 129°02'E), Japan, and transported to our laboratory under ice-storage condition. The fork length and body weight of the fish were 24.9–34.7 cm and 273.4–502.2 g, respectively.

Preparation of sample for lipid analyses. The fish were measured for fork length and body weight. Dorsal ordinary muscles, liver, and other viscera (without stomach contents, includes stale tissues) were then cut out using a scalpel after wiping. The stomach contents were then removed and used as samples.

Lipid extraction and analyses of lipid classes. Individual tissue samples were minced and homogenized with a mixture of chloroform/methanol (2:1, vol/vol). A portion of the homogenized sample was extracted according to the procedure of Folch et al. (38). The total lipids (TL) of specimens collected on November 27, 2002; July 30, 2003; and August 1, 2003 were separated into classes on silicic acid columns, and the constituent lipids were quantified by gravimetric analyses of column chromatographic fractions. The first eluate (dichloromethane/ether, 9:1, vol/vol) was used to collect the neutral lipids (NL). The second elute (dichloromethane/methanol, 10:1, vol/vol) from the column contained the free FA (FFA). This was followed with dichloromethane/methanol (1:20, vol/vol), eluting polar lipids (PL). Individual lipids, separated from each lipid class, were identified by comparing with standard samples using TLC (thickness of 0.25 mm for analysis, Kiesel gel 60, Merck and Co., Ltd., Darmstadt, Germany). All sample lipids were dried under nitrogen at room temperature and stored at –70°C with a small amount of dichloromethane.

The preparation of methyl esters and GLC of the esters. The TL, NL, and PL fractions were directly transesterified with boiling methanol containing 1% of concentrated hydrochloric acid under reflux for 1.5 h to produce the FAME (39). These methyl esters were purified using silica gel column chromatography by elution with dichloromethane.

Analysis of the FAME was performed on a gas chromatograph (GC–17A, Shimadzu Seisakusho Co., Ltd., Kyoto, Japan) equipped with a capillary column (Omegawax–250, 30 m × 0.25 mm i.d., 0.25 μm film thickness; split ratio 10:1; Supelco Japan Co., Ltd., Tokyo, Japan). The temperatures of the injector, column, and detector were maintained at 290, 205, and 290°C, respectively. Helium was used as the carrier gas at a constant inlet rate of 17 mL/min.

Quantitation of individual components was performed by means of Shimadzu Model C-R7A (Shimadzu Seisakusho Co. Ltd.) electronic integrator. The weight percentages of individual components in the lipids were expressed as relative percentage of peak area to total peak area.

The preparation of 4,4-dimethyloxazoline (DMOX) derivatives and analysis by GC–MS. The DMOX derivatives were prepared by adding excess 2-amino-2-methylpropanol to a small amount of the FAME in a test tube under nitrogen atmosphere. The mixture was heated at 180ºC for 18 h. The reaction mixture was cooled and poured onto saturated brine and extracted with n-hexane. Triplicate extraction with n-hexane was carried out, and the extract was washed with saturated brine, and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure, and samples were dissolved again in n-hexane for analysis by GC–MS (40).

Analysis of the DMOX derivatives was performed on a GC-MS QP 2010 (Shimadzu Seisakusho Co., Ltd.) gas chromatograph–mass spectrometer equipped with the same capillary column described in the previous section. The temperatures of the injector and the column were held at 240 and 210ºC, respectively. The split ratio was 1:76, and the ionization voltage was 70 eV. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min.

FAME were identified (i) using marine lipid methyl esters as standards (Supelco 37 Component FAME Mix, Supelco Japan Ltd.), and (ii) by comparison of mass spectral data obtained by GC–MS.

Statistical analyses. Averages were compared based on one-way ANOVA (Statview, Version 5, SAS Institute Inc., Cary, NC). Values were considered statistically different at $P < 0.05$.

RESULTS AND DISCUSSION

Seasonal variations in gonadsomatic index (GSI) and TL in respective tissues. The body size, GSI, and lipid content of respective organs of sampled fish are presented in Table 1. The high GSI values from June to August (2.7–10.2) compared with other seasons (0.6–1.7) indicated that the spawning period of the fish occurs during June to August. A previous report on the spawning season of the species for the same area confirmed this finding (41).

Muscle TL levels showed seasonal variation, with relatively high values (1.7 ± 0.5%) from September to January, and low values (1.1 ± 0.4%) from February to August, although the variations were not as clear as those in visceral TL. The levels of TL in both liver and other viscera varied seasonally in a clear manner, with high values in October and November (liver, 7.0–18.0%; other viscera, 25.1–37.3%), decreased values from November to late May (liver, 4.9–18.0%; other viscera, 4.1–37.3%), and low values from June to August (liver, 2.2–4.8%; other viscera, 1.3–6.0%). Generally, muscle TL of pelagic fishes varies widely, because they store their depot lipids in this tissue (42,43), whereas demersal fishes use viscera as a lipid storage site (44,45). *S. fuscescens* shows the typical character of demersal species.

Sexual maturation has been found to reduce lipids stored in the body of salmon because this species stops feeding during maturation and uses stored lipid as an energy source for spawning (46). Other studies showed that reduced feeding level and sexual maturation contribute to reduced lipid levels (47). Many marine fish species tend to reduce their food intake during sexual maturation; lipids and other nutrients needed for gonadal growth are presumed to be taken from the reserves in their bodies.

TABLE 1

[a]Lipid contents are expressed as weight percentage of wet tissues.
[b]Data are mean ± SE.
[c]GSI is the mean percentage of gonad weight to body weight.

In individuals caught off the Japanese coast in the Nagasaki district, the minimum levels of lipid observed in summer may indicate reduced feeding and lipid consumption as an energy source for spawning. The increase of lipid level in winter may be explained by enhanced feeding activity for recovery and growth.

FA composition of TL in tissues and stomach contents. FA compositions of TL in specific organs are presented in Tables 2–4. The FA compositions were almost the same among the organs, and the major components (>5% in annual average) of muscle were 16:0 (muscle, 21.2–30.7%; liver, 25.0–36.6%; other viscera, 22.9–34.0%), 18:0 (muscle, 5.2–9.3%; liver, 4.4–9.0%; other viscera, 5.0–8.2%), 16:1n-7 (muscle, 2.7–15.4%; liver, 4.3–13.9%; other viscera, 4.5–16.6%), 18:1n-9 (muscle, 7.0–15.8%; liver, 5.6–18.5%; other viscera, 8.0–20.2%), 20:4n-6 (AA; muscle, 4.3–13.1%; liver, 3.6–9.1%; other viscera, 2.0–10.7%), and 22:6n-3 (DHA; muscle, 8.0–22.4%; liver, 7.7–22.1%; other viscera, 2.9–17.1%). Moderate amounts (>2% in annual average) of other FA, such as n-6 PUFA 22:5 n-6 (muscle, 1.4–4.1%; liver, 1.1–3.7%; other viscera, 0.6–2.9%), n-3 PUFA 20:5n-3 (muscle, 1.2–4.2%; liver, 0.4–3.1%; other viscera, 0.5–3.7%), and 22:5n-3 (muscle, 2.5–6.2%; liver, 1.3–5.0%; other viscera, 1.6–6.6%), were also detected.

The comparatively high AA levels in *S. fuscescens* organs were similar to those reported in other herbivorous species including *Caesio diagramma*, *C. tile*, and *S. canaliculatus*, as reported by Saito *et al.* (22). Thus, the comparatively high levels of AA may be a specific characteristic of herbivorous species. The FA compositions in stomach contents are shown in Table 5. The stomach contents were a mixture of small pieces of seaweed, mucoid substance, sludge, and other components. The major FA in stomach contents TL were 16:0 (12.5–27.2%), 18:0 (6.6–14.8%), 18:1n-9 (3.5–9.8%), AA (7.6–26.7%), and DHA (8.8–20.3%), similar to those in the tissue TL of *S. fuscescens*. These findings suggest that the high levels of AA in *S. fuscescens* originated from their food sources.

Seasonal variations in the FA composition of TL in tissues and stomach contents. In the muscle TL, the total SFA levels showed constant values of 37.1 ± 0.5% (annual average ± SE) throughout the year, and those of MUFA differed somewhat between late May to August (13.6–29.0%) and other seasons (17.9–34.9%). Total PUFA levels showed seasonal tendencies opposite to those of total MUFA levels. In the liver TL, total SFA levels were almost constant throughout the year at 40.4 ± 0.8%. Similar seasonal variations to those in muscle TL were found in liver TL, where total MUFA levels were low from late May to August (13.3–21.9%) and higher during the rest of the

TABLE 6
NL and PL in Muscle, Liver, and Other Viscera of *S. fuscescens*[a,b]

		Muscle	Liver	Other viscera
Fatty[c] (*n* = 10)	NL[d]	1,407.4 (80.0 ± 137.8)[e]	8,607.9 (68.2) ± 2,888.9	32,127.5 (93.6) ± 3,948.3
	FFA	46.6 (2.6) ± 6.0	2,400.1 (19.0) ± 388.6	1,903.1 (5.5) ± 184.4
	PL[f]	305.7 (17.4) ± 46.6	1,611.0 (12.8) ± 420.6	291.9 (0.9) ± 76.0
Lean[g] (*n* = 11)	NL[d]	527.7 (66.8) ± 158.7	1,301.1 (35.1) ± 361.1	2,491.4 (67.5) ± 631.7
	FFA	43.7 (5.5) ± 3.3	1,384.1 (37.4) ± 226.0	789.3 (21.4) ± 177.9
	PL[f]	218.9 (27.7) ± 23.0	1,019.5 (27.5) ± 111.6	410.3 (11.1) ± 45.8

[a]Results are expressed as contents (mg) in 100 g of respective tissues.
[b]Data are mean ± SE.
[c]Fatty indicates the fish samples collected on November 27, 2002, and November 18, 2003.
[d]There are significant differences ($P < 0.05$) in the actual NL values (mg/100 g) of each organ between fatty fish and lean fish.
[e]Numerals in parenthesis are weight percentage of total lipids.
[f]There are no significant differences ($P > 0.05$) in the actual PL values (mg/100 g) of each organ between fatty fish and lean fish.
[g]Lean indicates fish collected on July 9, 2002, August 1, 2003, and July 30, 2004.

year (17.5–33.7%). Characteristic seasonal changes could not be found, however, in the FA compositions of other viscera and stomach contents. In the other viscera TL, the total SFA levels were almost constant throughout the year at 40.8 ± 0.6%. Total MUFA levels fluctuated widely (18.4–40.5%), with lower values (18.4–21.4%) obtained on May 25, July 9, August 1, and August 7, 2002; August 1, 2003; and June 18 and July 30, 2004, compared with other samples (26.5–40.5%). In the stomach contents, total SFA levels were almost constant at 35.5 ± 0.8%, except for lower values observed in samples obtained on May 25 (23.9 ± 7.1%) and August 1, 2002 (27.6 ± 5.7%). Similar to MUFA of other viscera, total MUFA levels in stomach contents fluctuated widely (7.4–24.0%), with lower values observed on August 7, 2002 (10.7 ± 0.4%); August 1, 2003 (7.4 ± 0.9%); and July 30, 2004 (9.6 ± 0.4%).

MUFA levels in TL of muscle and liver varied in accordance with their TL levels, indicating that seasonal variations in TL were largely due to those of MUFA. No seasonal changes existed in the MUFA levels of stomach content lipids, as already mentioned. Moreover, the annual average total MUFA level of stomach contents (15.0 ± 0.8%) was significantly lower than those of muscle (24.0 ± 1.1%) or liver (21.6 ± 1.1%). These findings suggest that *S. fuscescens* seasonally stores MUFA selectively in muscle and liver as depot fats.

In TL of muscle and liver, the AA levels varied in accordance with total PUFA levels, and relatively high values of AA were observed between late May and August (muscle, 4.6–13.1%; liver, 4.5–9.1%) compared with other times of the year (muscle, 4.3–9.5%; liver, 3.6–8.4%). The AA levels in TL of other viscera fluctuated year-round (2.0–10.7%), with higher values in the samples obtained on July 9, August 1, and August 7, 2002; August 1, 2003; and June 18 and July 30, 2004 (7.0–10.7%). Similar to the situation in other viscera, the AA levels in stomach contents on August 1, 2002; August 1, 2003; and July 30, 2004 showed higher values (16.3–26.7%) compared with other samples (7.6–14.1%). This indicates that visceral FA compositions are directly influenced by those of lipids derived from food sources.

The FA composition of NL and PL of S. fuscescens *tissues*. To compare characteristics of the lipids of fatty fish (obtained on November 27, 2002, and November 18, 2003) and lean fish (obtained on July 9, 2002; August 1, 2003; and July 30, 2004), the NL and PL contents and their FA compositions were analyzed (Tables 6–9). In the NL, steryl esters, triacylglycerols, diacylglycerols, and sterols were detected. Phosphatidylethanolamine and phosphatidylcholine were observed in the PL. The contents (mg/100 g) of NL from each organ differed between fatty fish (muscle, 1,407 mg/100 g; liver, 8,608 mg/100 g; other viscera, 32,130 mg/100 g) and lean fish (muscle, 527.7 mg/100 g; liver, 1,301 mg/100 g; other viscera, 2,491 mg/100 g). However, the values for PL were similar between fatty fish (muscle, 305.7 mg/100 g; liver, 1,011 mg/100 g; other viscera, 291.9 mg/100 g) and lean fish (muscle, 218.9 mg/100 g; liver, 1,020 mg/100 g; other viscera, 410.3 mg/100 g). This indicates that the seasonal variations in the TL content were influenced by changes in NL.

The FA composition in NL were similar between organs; the major components were 16:0 (muscle, 24.4–30.1%; liver, 25.9–27.8%; other viscera, 21.6–30.4%), 18:0 (muscle, 4.5–5.3%; liver, 4.8–6.4%; other viscera, 4.7–5.9%), 16:1n-7 (muscle, 10.9–11.7%; liver, 8.6–10.2%; other viscera, 8.9–10.9%), 18:1n-9 (muscle, 10.9–11.7%; liver, 8.6–10.2%; other viscera, 8.9–10.9%), and 22:6n-3 (muscle, 7.0–8.9%; liver, 8.1–13.9%; other viscera, 5.5–12.1%). Lower relative levels of other FA, such as 20:4n-6 (muscle, 2.6–3.8%; liver, 3.8–7.0%; other viscera, 2.6–7.6%) and the n-3 PUFA 20:5n-3 (muscle, 1.4–2.6%; liver, 0.8–2.8%; other viscera, 1.2–3.1%) and 22:5n-3 (muscle, 2.7–5.8%; liver, 2.8–4.5%; other viscera, 2.5–6.3%) were detected.

The major components in PL were 16:0 (muscle, 8.4–15.1%; liver, 17.8–20.3%; other viscera, 17.0–17.4%), 18:0 (muscle, 16.4–19.3%; liver, 13.9–14.0%; other viscera, 11.4–13.7%), 18:1n-9 (muscle, 3.7–5.6%; liver, 3.1–4.5%; other viscera, 4.4–8.2%), the n-6 PUFA 20:4n-6 (muscle, 13.1–14.2%; liver, 12.0–13.6%; other viscera, 7.2–11.9%), and the n-3 PUFA 22:6n-3 (muscle, 26.8–30.5%; liver, 26.6–31.1%; other viscera, 13.2–26.0%). Lower levels of the

[a]Results are expressed as weight percentage of total FA. Data are mean ± SE.
[b]Different letters in the lines of arachidonic acid in Tables 7 and 8 indicate statistical differences ($P < 0.05$).

n-6 PUFA 22:5n-6 (muscle, 4.4%; liver, 2.9–5.4%; other viscera, 3.6–4.3%) and the n-3 PUFA 20:5n-3 (muscle, 1.6–2.2%; liver, 1.0–1.4%; other viscera, 0.9–2.1%) and 22:5n-3 (muscle, 4.2–6.3%; liver, 2.8–3.3%; other viscera, 2.6–6.0%) were detected.

PL contained higher levels of AA than NL throughout the year, indicating that *S. fuscescens* selectively accumulate AA in their PL, as herbivorous fishes do (22).

In both muscle NL and PL, there were no significant differences in AA levels between fatty fish (NL, 2.6 ± 0.4%; PL, 14.2 ± 0.9%) and lean fish (NL, 3.8 ± 0.5%; PL, 13.1 ± 0.6%), indicating that the seasonal difference of AA levels in muscle TL might depend only on the variations in PL. Comparatively high levels of AA and PL with low levels of TL were observed in summer, and lower levels of AA in TL were found with higher levels of TL in winter. This also indicates that AA in NL is utilized with other FA at the same level when the fish is starved, whereas AA in PL is maintained at comparatively high levels regardless of the fish's condition.

In liver, the AA levels in NL of the lean fish (7.0 ± 1.1%) were significantly higher than those in fatty fish (3.8 ± 0.6%), indicating that the seasonal variations in AA levels observed in liver TL depend on the changes of AA levels in NL. PL in contrast contains comparatively high and constant levels of AA. The absolute values of AA in liver NL of lean fish and fatty fish were 74.2 ± 12.6 mg/100 g and 236 ± 65.1 mg/100 g, respectively, indicating that 69% of AA was consumed during the period from winter to summer. However, the liver NL contents decreased 85% from 8,608 ± 2,889 mg/100 g to 1,301 ± 361.1 mg/100 g during the same period. In the PL, there were no significant differences in AA levels (fatty fish, 13.6 ± 1.0%; lean fish, 12.0 ± 0.8%) and actual values (fatty fish, 238.7 ± 69.2 mg/100 g; lean fish, 120.9 ± 17.4 mg/100 g) between fatty and lean fish. This suggests that AA in the liver PL were maintained

[a]For footnotes, see Table 7
[b]Different letters in the lines of arachidonic acid in Tables 7 and 8 indicate statistical differences ($P < 0.05$).

at comparatively high levels regardless of the condition of the fish, similar to those in muscle PL.

In other viscera, the AA contents in NL from fatty fish (748.5 ± 135.0 mg/100 g) were approximately sixfold higher than those from lean fish (125.5 ± 20.7 mg/100 g). However, NL in fatty fish (32,130 ± 3,948 mg/100 g) was 13-fold higher than in lean fish (2,491 ± 631.7 mg/100g). Consequently, AA levels in NL from lean fish (7.6 ± 1.6%) were significantly higher than those from fatty fish (2.6 ± 0.5%). These results indicate that AA is inferior to other FA, such as MUFA or SFA, as an energy source, and remains unused during the months from winter to summer. Or, AA may be being spared for other roles and functions; the important roles of AA for fish growth have been gradually clarified (48,49). Alternatively, the FA composition in NL of other viscera may be largely influenced by the fish's food sources. In PL, the AA levels fluctuated and were present at higher levels in lean fish (11.9 ± 1.2%) than in fatty fish (7.2 ± 0.6%). This may indicate that the lipids in other viscera, even if they are PL, are influenced by the lipid content of food sources.

Comparative high levels of AA in S. fuscescens *tissues*. In general, n-6 series PUFA, such as AA, are present in undetectable or negligible amounts in marine fish lipids, whereas n-3 series PUFA, such as EPA and DHA, are abundant. These n-3 series PUFA have an important role for membrane fluidity (50), and dominate approximately 50% of TFA in PL (39,51,52). Thus, it is well known that n-3 series PUFA are essential for all marine fish (53–59). These fish may obtain a large part of their n-3 PUFA through the marine food chain, as has been reported for DHA (60–62), because marine fish lack the Δ4- and Δ5-desaturases (53,54). Similar to other marine fishes, *S. fuscescens* contained comparatively high levels of n-3 series PUFA, such as EPA and DHA, in their tissues. These PUFA are probably sourced from the lipids of their diets. *S. fuscescens* tissues also contained high levels of the n-6 series PUFA, AA.

Herbivorous species (including omnivorous species), such

as *Eubalichthys mosaicus*, *Meuschenia freycineti*, *Thamnaconus degeni*, *M. scaber*, and *Pentaceropsis recurvirostris* were also reported to contain high levels of AA (7.4–14.9%) in their muscle TL by Dunstan *et al.* (25). Moreover, they reported that carnivorous *Heterodontus portusjacksoni*, which feed on the macro-algae-consuming sea urchins and sea snails, also contained high levels of AA (13.8%) in their muscle TL (25). A few other reports also suggested that in fishes containing high levels of AA, the AA levels are influenced by dietary lipids (22–25).

Our finding that *S. fuscescens* contained high levels of AA in both organs and stomach contents supports these findings.

From the previous findings and ours, it appears that comparatively high levels of AA observed in those fishes may originate from macro-algae through the marine food chain.

We have only a few reports of the functions of AA in marine fish tissues (48,49). AA may be an essential FA for *S. fuscescens*. They accumulate AA in PL more than in NL, and AA in PL of both muscle and liver was maintained at high levels regardless of the condition of the fish, such as fatty or lean.

S. fuscescens tissues contained high amounts of AA and DHA throughout the year. This suggests that the fish is an available and desirable source for infant food to meet the recently confirmed requirements of both n-3 PUFA and n-6 PUFA for infant growth (8,9,63). Those PUFA were reported to affect neural development and maturation of sensory systems of infants (8,63). Moreover, an increase in the dietary n-3/n-6 FA ratio is desirable to help reduce the risk of cardiovascular disease (64). It is thus important for human health to increase the consumption of n-3 FA. Although there is no officially recommended n-3/n-6 ratio, the suggested ratio is 1:1 from evidence in wild animals and estimated nutrient intake during human evolution (65). The present study shows that the n-3/n-6 ratios of *S. fuscescens* were 1.3–2.5 in muscle, 1.1–2.9 in liver, and 1.0–2.6 in other viscera, indicating that *S. fuscescens* can provide the suggested ratio suitable for the human diet throughout the year.

cis-4,7,10,*trans*-13-22:4 Fatty Acid Distribution in Phospholipids of Pectinid Species *Aequipecten opercularis* and *Pecten maximus*

Edouard Kraffe[a], Philippe Soudant[b], and Yanic Marty[a,*]

[a]Unité mixte Centre National de la Recherche Scientifique (CNRS) 6521, Université de Bretagne Occidentale, CS 93837, 29238 Brest Cedex 3, France, and [b]Unité mixte CNRS 6539, IUEM, Université de Bretagne Occidentale, 29280 Plouzané, France

ABSTRACT: The distribution of *cis*-4,7,10,*trans*-13-docosatetraenoic (*c*4,7,10,*t*13-22:4), a peculiar FA previously isolated in the glycerophospholipids of some pectinid bivalves, was investigated in glycerophospholipid classes and subclasses of separated organs (gills, mantle, gonads, and muscle) of the queen scallop *Aequipecten opercularis* and the king scallop *Pecten maximus*. Plasmalogen (Pls) and diacyl + alkyl (Ptd) forms of serine, ethanolamine, and choline glycerophospholipids were isolated by HPLC and their FA compositions analyzed by GC-FID. Pls and Ptd forms of serine glycerophospholipids (PlsSer and PtdSer), and to a lesser extend the Pls form of ethanolamine glycerophospholipids (PlsEtn), were found to be specifically enriched with *c*4,7,10,*t*13-22:4. This specificity was found to decrease in the tested organs in the following order: gills, mantle, gonad, and muscle. In gills, *c*4,7,10,*t*13-22:4 was shown to be the main unsaturated FA of serine glycerophospholipids in both Pls and Ptd forms (23.8 and 19.4 mol%, respectively, for *A. opercularis*, and 21.0 and 26.2 mol% for *P. maximus*). These results represent the first comprehensive report on the FA composition of plasmalogen serine subclass isolated from pectinid bivalves. The specific association of the PlsSer with the *c*4,7,10,*t*13-22:4 for the two pectinid species can be paralleled to the specific association of the PlsSer with the non–methylene interrupted (NMI) FA and 20:1(n-11) observed in mussels, clams, and oysters (Kraffe, E., Soudant, P., and Marty, Y. (2004) Fatty Acids of Serine, Ethanolamine and Choline Plasmalogens in Some Marine Bivalves, *Lipids 39*, 59–66.) This, led us to hypothesize a similar functional significance for *c*4,7,10,*t*13-22:4, NMI FA, and 20:1(n-11) associated with PlsSer subclass of bivalves.

Paper no. L9913 in *Lipids 41*, 491–497 (May 2006).

In *Pecten maximus* larvae and adults (family Pectinidae, class Bivalvia), a new C_{22} PUFA was reported in significant amounts (1–5). This PUFA was later characterized in *P. maximus* and *Argopecten purpuratus* as a new *cis*-4,7,10,*trans*-13-docosatetraenoic FA (*c*4,7,10,*t*13-22:4) (6). This *c*4,7,10,*t*13-22:4, found mainly in glycerophospholipids (Gpl), appeared to be specifically associated with the phosphatidylserine (SerGpl).

The same investigations have also shown that non–methylene-interrupted (NMI) FA were present in only trace amounts in the studied species. Although these NMI FA are seemingly ubiquitous mollusk components (see Ref. 8 for an early review), they were always found in low levels in scallops in comparison with other bivalve mollusks (7–9). Experiments conducted on the mollusks *Scapharca broughtoni* and *Callista brevisiphonata* and the mussel *Mytilus edulis* have shown that marine bivalve mollusks were able to synthesize *de novo* the NMI FA 7,15-22:2 and 7,13-22:2 from carbon-labeled acetate (10,11), whereas it is also established that they have limited or no ability to synthesize PUFA (12–14).

In parallel, it is well established that marine invertebrates are an especially rich source of 1-alkenyl-2-acyl Gpl, commonly called plasmalogens (Pls) (7,15). The presence of a Pls serine subclass (PlsSer), found only in mollusks among all winter-collected invertebrates studied, was first described by Dembitsky and Vaskovsky (16), and confirmed on summer-collected animals by Dembitsky (17). Very little information is available on the FA composition of Pls subclasses from marine bivalves. Only two studies described the FA composition of PlsEtn and PlsCho of *Crassostrea gigas* (18,19), and the PlsSer FA composition was never studied until recently (20). In the present study, the analysis of the FA profiles of both 1-alkenyl-2-acyl (Pls) and 1,2-diacyl + 1-alkyl-2-acyl (Ptd) analogues of Gpl, obtained from the oyster *C. gigas*, the mussel *M. edulis*, and the clam *Ruditapes philippinarum* showed a very consistent high specificity of the aminoplasmalogens PlsSer and PlsEtn, for the NMI and for the 20:1(n-11).

Considering the former results, on the one hand, high levels of NMI were always found in bivalve mollusks except in scallops, and a good specificity of aminoplasmalogens for NMI was shown in mussels, clams, and oysters (which belong to Mytilidae, Ungulinidae, and Ostreidae families, respectively). On the other hand, the peculiar presence of *c*4,7,10,*t*13-22:4 in some scallops, *A. opercularis*, *P. maximus*, and *A. purpuratus* could be associated with very low levels of NMI FA in these species, which belong to the Pectinidae family. The objective of the pre-

Abbreviations: *c*4,7,10,*t*13-22:4, *cis*-4,7,10,*trans*-13-docosatetraenoic FA; Gpl, glycerophospholipid; LysoPtdCho, natural lysophosphatidylcholine compound (FA in *sn*-1 position); MUFA, monounsaturated FA; NMI, non–methylene interrupted (concerning the present results NMI refers to the sum of *c*5,13-20:2, *c*5,11-20:2, *c*7,15-22:2, *c*7,13-22:2, and *c*7,13,16-22:3); Pls, plasmalogen; PlsCho, 1-alkenyl-2-acyl-glycerophosphatidylcholine; PlsEtn, 1-alkenyl-2-acyl-glycerophosphatidylethanolamine; PlsSer, 1-alkenyl-2-acyl-glycerophosphatidylserine; Ptd, diacyl + alkyl; PtdCho, [1,2-diacyl- + 1-alkyl-2-acyl-] glycerophosphatidylcholine; PtdEtn, [1,2-diacyl- + 1-alkyl-2-acyl-] glycerophosphatidylethanolamine; PtdSer, [1,2-diacyl- + 1-alkyl-2-acyl-] glycerophosphatidylserine; SFA, saturated FA.

sent study was to investigate the repartition of the *c*4,7,10,*t*13-22:4 among the Gpl classes of the different organs of the two scallop species *A. opercularis* and *P. maximus,* (family Pectinidae, class Bivalvia), taking into account the detailed FA composition of the Pls forms of EtnGpl, SerGpl, and ChoGpl.

MATERIALS AND METHODS

Chemicals. Boron trifluoride (BF_3, 10% by wt in methanol) was obtained from Supelco (Saint-Quentin Fallavier, France). Other described reagents and solvents were purchased from Merck (Darmstadt, Germany).

Sample preparation and lipid extraction. Adult *A. opercularis* and *P. maximus* scallops were collected from the Bay of Brest during spring 2001 (between 10 and 20 m depth). The digestive tract was first removed to limit contamination by ingested algae. Then mantle, gills, adductor muscle, and gonads were excised, pooled, weighed, and homogenized with a Dangoumeau homogenizer at –180°C. Three pools of three individuals were analyzed for each of the two species. Lipid extraction was conducted on tissue homogenates with a mixture of $CHCl_3$/MeOH (2:1, vol/vol) following a procedure in the literature (21), modified. To ensure the complete extraction of tissue lipids, a solvent-to-tissue ratio of 70:1 (wt/wt) was used as described by Nelson (22). After removing the organic phase, the residue was re-extracted with a mixture of $CHCl_3$/MeOH (2:1, vol/vol). The final lipid extract was stored at –20°C under nitrogen after 0.01 wt% BHT (antioxidant) was added.

Separation of polar lipids on a silica gel microcolumn. An aliquot of the lipid extract was evaporated to dryness, and lipids were recovered with three washings of 500 µL of $CHCl_3$/MeOH (98:2, vol/vol) and deposited at the top of a silica gel microcolumn (30 × 5 mm i.d., packed with Kieselgel 60 (70-230 mesh, Merck) previously heated at 450°C and deactivated with 6 wt% H_2O (1). Neutral lipids were eluted with 10 mL of $CHCl_3$/MeOH (98:2, vol/vol). The polar lipid fraction was recovered with 20 mL of MeOH and stored at –20°C for later phospholipid class separation by HPLC and FA composition analysis by GC.

Separation of glycerophospholipid classes and FA analysis. Separation of the Gpl classes and subclasses was achieved according to the method previously described (20) using a combination of two successive HPLC separations with two different mobile phases.

(i) Non-acid HPLC separations. A rapid gradient elution separation was achieved on a Merck HPLC system (UV detection at 206 nm) equipped with a Diol phase column (OH-bound silica gel column, Lichrosorb Diol 5 µm, 250 × 4 mm i.d., Merck). An isocratic 9:1 ratio of solvent A (*n*-hexane/2-propanol/water, 40:52:1, by vol) and solvent B (*n*-hexane/2-propanol/water, 40:52:8, by vol) was run for 11 min. This solvent ratio was then followed by a 1-min linear gradient to 100% solvent B. The column was maintained on solvent B for 18 min to complete the separation, then reactivated with 20 min of the initial 9:1 ratio of solvent A to B. The solvent flow rate was 1 mL/min during the entire elution program. This separation allowed the collection of a first fraction (within 3–19 min) containing EtnGpl (1,2-diacyl + 1-alkyl-2-acyl + 1-alkenyl-2-acyl [Pls] Gpl forms) and ChoGpl (1,2-diacyl + 1-alkyl-2-acyl + 1-alkenyl-2-acyl [Pls] Gpl forms), and a second fraction (within 19–25 min) containing cardiolipin, phosphatidylinositol, lysophosphatidylcholine (LysoPtdCho), and SerGpl (1,2-diacyl + 1-alkyl-2-acyl + 1-alkenyl-2-acyl [Pls] Gpl forms).

(ii) Acidic HPLC separations. After evaporation to dryness under nitrogen, first or second fractions were recovered with two washings of 50 µl each of $CHCl_3$/MeOH (98:2, vol/vol) before being manually injected in the 200-µl loop of the second HPLC system. The separation was achieved as previously described (20). This method, based on the use of an acidic mobile phase, allows the hydrolysis of the vinyl ether bond at the *sn*-1 position of the glycerol backbone of the Pls form (4), which creates lyso analogs that elute later than the intact diacyl + alkyl-acyl (Ptd) forms. This offers the possibility of analyzing separately Ptd and Pls subclasses of EtnGpl and ChoGpl from the first fraction, and Ptd and Pls subclasses of SerGpl from the second fraction. Each SerGpl, EtnGpl, and ChoGpl subclass, jointly with cardiolipin, phosphatidylinositol, and LysoPtdCho, was collected and, after transesterification ($MeOH/BF_3$), analyzed by GC for FA composition. FAME obtained were identified and quantified using both polar (CPWAX 52 CB, 50 m × 0.25 mm i.d., 0.2 µm thickness) and nonpolar (CP-Sil 8 CB, 25 m × 0.25 mm i.d., 0.25 µm thickness) capillary columns. FA were expressed as molar percentage of the total FA content of each class or subclass. For PlsSer, PlsEtn, and PlsCho subclasses, the total percentage was adjusted to 50% to take into account the alkenyl chains of the *sn*-1 position hydrolyzed by the acid mobile phase. The quantities of each class and subclass of Gpl were determined from their respective quantitative spectrum of FA obtained by GC. To obtain the molar content of each analyzed fraction, a corrective factor was applied to their respective total FA molar contents: ×1 for the PlsSer, PlsEtn, and PlsCho fractions and for the natural lysoPtdCho fraction; ×1/2 for the PtdEtn, PtdCho, PtdSer, and phosphatidylinositol fractions, and ×1/4 for the cardiolipin fraction. The Ptd fractions were, in that case, assimilated to diacyl fractions.

RESULTS

Gpl composition and Pls content of gills, mantle, gonads and muscle. The detailed Gpl composition of gills, mantle, gonads (male + female), and adductor muscle obtained from *A. opercularis* and *P. maximus* are presented in Table 1. The Gpl subclass compositions of each organ were very similar in *A. opercularis* and *P. maximus.* In gills of the two scallop species the most abundant Gpl subclasses were PlsEtn and PtdCho, respectively 37.6 and 31.7% of the total Gpl in *A. opercularis*, and 34.2 and 33.2% in *P. maximus*. The highest percentage of total plasmalogens (PlsEtn + PlsSer + PlsCho) was found in gills, accounting for 43.3% in *A. opercularis* and 40.4% in *P. maximus*. In mantle, although present at a lower level, Pls totaled respectively 37.4 and 35% of Gpl. In gonads, PlsEtn decreased at the expense of PtdCho, but both remained the most promi-

[a]Expressed as mol % of total moles of glycerophospholipids, calculated as indicated in text. Results are mean ± SD (n = 3).
[b]EtnGpl (or SerGpl or ChoGpl) refers to the pool of the [diacyl + alkyl acyl + alkenyl acyl (plasmalogen)] forms of glycerophosphatidylethanolamine (or serine or choline) class.
[c]« Ptd » refers to diacyl form + alkyl acyl form (see text).
[d]« Pls » refers to alkenyl acyl (plasmalogen) form.
[e]Proportion of the plasmalogen form relatively to the whole of a same class forms.

nent Gpl components, respectively 23.4 and 41.8% in *A. opercularis*, and 25.5 and 45.1% in *P. maximus*. In the adductor muscle this tendency was accentuated and PtdCho amounted to approximately half of the Gpl content, while total Pls accounted only for 19.8% in *A. opercularis* and 14.4% in *P. maximus*. In parallel, and for both species, highest Pls proportions in EtnGpl, SerGpl, and ChoGpl were found in gills, accounting for more than 86.0, 29.5, and 4.9%, respectively. These values decreased in mantle and gonads, and the lowest percentages were observed in the muscle, for both species.

FA composition of the different forms of EtnGpl, SerGpl, and ChoGpl of gills, mantle, gonads, and muscle. In separated organs of the two pectinid species, five major FA (16:0, 18:0, 20:4(n-6), 20:5(n-3), 22:6(n-3), and *c*4,7,10,*t*13-22:4) represented 70–90% of the total FA in the Pls (*sn*-2 position) and Ptd forms (*sn*-1 and *sn*-2 positions) of ethanolamine, serine, and choline Gpl (Tables 2 and 3). Total saturated FA (SFA) content was found to be very low in PlsEtn and slightly higher in PlsSer (respectively <2.8 and <18% in *A. opercularis*, and <2.1 and <15.0% in *P. maximus*), whereas it was higher in PlsCho for all organs <30.4% in *A. opercularis* and <22.1% in *P. maximus*. In Ptd fractions of EtnGpl, SerGpl, and ChoGpl, SFA content ranged from 28.4 to 46.7%. SFA were dominated by the 16:0 and 18:0 in all fractions. Total monounsaturated FA (MUFA) were low in Pls fractions of all organs, <5.8% in *A. opercularis* and <5.1% in *P. maximus*, and in Ptd fractions they were <12.1% in *A. opercularis* and <14.9% in *P. maximus*. Long-chain PUFA with 20 and 22 carbons were found to be the dominant PUFA in the Pls and Ptd fractions. They were mainly constituted by 20:4(n-6), 20:5(n-3), 22:6(n-3), and *c*4,7,10,*t*13-22:4. Only very low levels of NMI FA were detected among the different organs of the two species (Tables 2 and 3).

c4,7,10,t13-22:4 distribution in Gpl and in the different forms of EtnGpl, SerGpl, and ChoGpl. The content of *c*4,7,10,*t*13-22:4 in Gpl was found to range from the highest value in gills (9.9 and 9.3% in *A. opercularis* and *P. maximus*, respectively) to the lowest value in muscle (1.2 and 1.3% in *A. opercularis* and *P. maximus*, respectively) (Table 4). For all organs tested, the *c*4,7,10,*t*13-22:4 FA was found to be preferentially located in SerGpl, EtnGpl, and ChoGpl, whereas it was detected in only trace amounts in the other analyzed Gpl classes, phosphatidylinositol, cardiolipin, and lysoPtdCho (data not shown). Variations of *c*4,7,10,*t*13-22:4 proportions in the Pls and Ptd forms of SerGpl, EtnGpl, and ChoGpl among the different organs of *A. opercularis* and *P. maximus* are summarized in Figure 1. In all organs of both species the highest proportions of *c*4,7,10,*t*13-22:4 were found in PtdSer and PlsSer fractions. When comparing organs, gills showed the highest percentages of *c*4,7,10,*t*13-22:4, similarly in Pls and Ptd forms, reaching 19.4 and 23.8% of total FA, respectively, for PtdSer and PlsSer fractions in *A. opercularis,* and 26.2 and 21.0% in *P. maximus*. In the mantle, equivalent levels of *c*4,7,10,*t*13-22:4

[a]For abbreviations see Table 1.
[b]Results expressed as mol % are mean ± SD (n = 3).
[c]« Ptd » refers to both *sn*-1 and *sn*-2 fatty acyl chains of the diacyl form + *sn*-2 fatty acyl chains of the alkyl form.
[d]« Pls » refers to *sn*-2 fatty acyl chains of the plasmalogen form, and total percent was adjusted to 50% to take into account the alkenyl chains of the *sn*-1 position hydrolyzed by the acid mobile phase as described in text.
[e]« NMI » refers to sum of all non-methylene-interrupted FA: 5,13-20:2; 5,11-20:2; 7,15-22:2; 7,13-22:2; 7,13,16-22:3.

were also found between PtdSer and PlsSer, but these proportions were lower than in gills (about 9 and 13%, respectively, in *A. opercularis* and *P. maximus*). Similar levels of *c*4,7,10,*t*13-22:4 were also found in gonad and muscle, but in PtdSer only (from 7.1 to 9.5% in PtdSer of both species). Lower percentages of *c*4,7,10,*t*13-22:4 were found in PlsSer of these organs (between 2.6 and 4.8% in both species). In addition, noticeable levels of *c*4,7,10,*t*13-22:4 were found in gill PlsEtn (10.3 and 7.7% in *A. opercularis* and *P. maximus*, respectively).

DISCUSSION

Examination of the *c*4,7,10,*t*13-22:4 repartition within the Pls and Ptd forms of SerGpl, EtnGpl, and ChoGpl let us to report on the specific distribution of this FA in these Gpl subclasses. The *c*4,7,10,*t*13-22:4 has been shown to be especially concentrated in PlsSer and PtdSer, and to a lesser extent in PlsEtn. This specific association was evidenced in all tissues analyzed, but proportions of the *c*4,7,10,*t*13-22:4 in these subclasses were the highest in gills and the lowest in the adductor muscle. In gills, the *c*4,7,10,*t*13-22:4 was shown to be the main unsaturated FA of the SerGpl class, both in Pls and Ptd forms. To date, very little information was available on the FA composition of Pls subclasses from marine bivalves, and particularly on the FA composition of the PlsSer detected only in mollusks (18). Indeed, this is the first study reporting on the FA composition of PlsSer subclass in pectinid bivalves.

Using the same methodology, a previous analysis of the oyster *C. gigas*, the mussel *M. edulis*, and the clam *R. philip-*

[a–e]For footnotes see Table 2.

pinarum indicated that Pls forms of EtnGpl and SerGpl were found to be specifically enriched with NMI FA and 20:1(n-11) (20). Interestingly, this trend was particularly obvious in PlsSer, in which NMI FA and 20:1(n-11) were found to be, respectively, the predominant PUFA and monounsaturated FA for the three species. Moreover, this specificity was observed in all the analyzed organs of the clams, with the highest levels measured in gills, and the lowest measured in the muscle (20). Consequently one can draw a parallel between the specific FA pattern of PlsSer subclass enriched with NMI FA and 20:1(n-11) in gills of the clams, and with that of the pectinid species *A. opercularis* and *P. maximus* enriched with *c*4,7,10,*t*13-22:4 (present study). Several investigations showed that bivalve species, including mussels, clams, and oysters, generally contain significant amounts of 22:2 NMI FA (7,15-22:2 and 7,13-22:2), and to a lesser extent 20:2 NMI (5,13-20:2 and 5,11-20:2) (23–26). On the other hand, reports on scallop FA compositions (8,9) indicated that the levels of NMI FA were very low in pectinids in comparison with other members of the class Bivalvia. Moreover, *c*4,7,10,*t*13-22:4 found in scallops *A. purpuratus* and *P. maximus* was not detected in the non-pectinid bivalve species such as *Glycymeris glycymeris*, *M. edulis*, *Ostrea edulis*, *C. gigas*, *Tapes decussatus*, and *Crassostrea edule* (6, 20). This suggests some functional and/or structural analogies

TABLE 4
4,7,10,*t*13-22:4 Content in Glycerophospholipids of Separated Organs of *A. opercularis* and *P. maximus* (in mol % of the Total FA of Glycerophospholipid)

	Gills	Mantle	Gonads	Muscle
A. opercularis	9.9 ± 1.4	3.5 ± 0.2	2.0 ± 0.1	1.2 ± 0.1
P. maximus	9.3 ± 0.1	4.7 ± 1.0	1.7 ± 0.5	1.3 ± 0.3

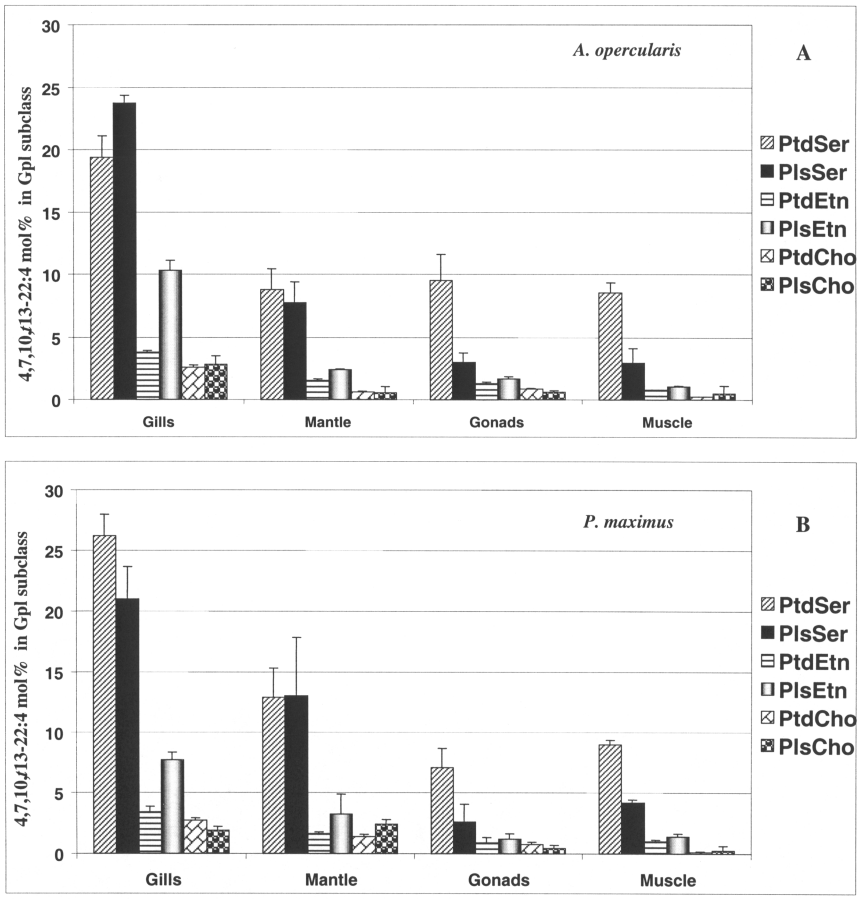

FIG. 1. Percent composition of *c*4,7,10,*t*13-22:4 (in mol%, mean ± SD, $n = 3$) from serine (Ser), ethanolamine (Etn), and choline (Cho) glycerophospholipid subclasses of (A) *A. opercularis* and (B) *P. maximus* organs.

between NMI FA in non-pectinid bivalves and *c*4,7,10, *t*13-22:4 in pectinid bivalves.

In addition, we are also proposing that these peculiar FA (NMI, 20:1(n-11), and *c*4,7,10,*t*13-22:4) may be of endogenous origin even though biosynthesis of long-chain PUFA is considered to be nonexistent or limited in mollusks (12,14). Indeed, as first proposed by Ackman and Hooper (23), and demonstrated by Zhukova and Svetashev (27), and Zhukova (11), on *S. broughtoni* and *M. edulis*, bivalve mollusks are able to synthesize NMI FA. The possibility that 20:1(n-11) and *c*4,7,10,*t*13-22:4 could also be of endogenous origin must be considered, as previously evoked and discussed (6,20). Unfortunately, there is not yet demonstration of that in literature.

In both pectinid bivalves analyzed in the present study, the highest level of *c*4,7,10,*t*13-22:4 was found in gills. Previous investigations on NMI FA distribution in various tissues of bivalve mollusks have indicated the same uneven distribution with highest levels found in gills (7,20,26). Thus, the requisite presence of a high level of *c*4,7,10,*t*13-22:4 or NMI, and 20:1(n-11), in bivalve gills in comparison with muscle, must be further questioned and investigated in terms of functional and structural roles. Nevertheless, some differences between pectinid and non-pectinid species can also be noticed. In *A. opercularis* and *P. maximus* *c*4,7,10,*t*13-22:4 was found to be highly associated with PtdSer. In comparison, in the non-pectinid species analyzed, NMI FA and 20:1(n-11) were mainly associated with PlsSer, and PlsEtn. In pectinids, the greater association of *c*4,7,10,*t*13-22:4 with the serine polar head, in comparison with non-pectinids, is still unclear. However, because the specific association of the peculiar FA with an aminoglycerophospholipid is conserved for all studied bivalve species, one may conclude that *c*4,7,10,*t*13-22:4, NMI FA, and 20:1(n-11) are asymmetrically distributed in the lipid bilayer, and are involved in specific cellular function of the inner membrane. Although these peculiar FA are structurally different, they could play a similar role in membrane functions of different bivalve species.

METHOD

Synthesis of 3-Oxalinolenic Acid and β-Oxidation-Resistant 3-Oxa-oxylipins

ABSTRACT: 3-Oxalinolenic acid (3-oxa-9(*Z*),12(*Z*),15(*Z*)-octadecatrienoic acid or (6(*Z*),9(*Z*),12(*Z*)-pentadecatrienyloxy)acetic acid) was synthesized from 5(*Z*),8(*Z*),11(*Z*),14(*Z*),17(*Z*)-eicosapentaenoic acid by a sequence involving the C15 aldehyde 3(*Z*),6(*Z*),9(*Z*),12(*Z*)-pentadecatetraenal as a key intermediate. Conversion of the aldehyde by isomerization and two steps of reduction afforded 6(*Z*),9(*Z*),12(*Z*)-pentadecatrienol, which was coupled to bromoacetate to afford after purification by HPLC >99%-pure 3-oxalinolenic acid in 10–15% overall yield. 3-Oxalinolenic acid was efficiently oxygenated by soybean lipoxygenase-1 into 3-oxa-13(S)-hydroperoxy-9(*Z*),11(E),15(*Z*)-octadecatrienoic acid, and this hydroperoxide could be further converted chemically into 3-oxa-13(S)-hydroxy-9(*Z*),11(E),15(*Z*)-octadecatrienoic acid and 3-oxa-13-oxo-9(*Z*),11(E),15(*Z*)-octadecatrienoic acid. The 3-oxa-hydroperoxide also served as the substrate for the plant enzymes allene oxide synthase, divinyl ether synthase, and hydroperoxide lyase to produce 3-oxa-12-oxo-10,15(*Z*)-phytodienoic acid and other 3-oxa-oxylipins that were characterized by MS. 3-Oxalinolenic acid was not oxygenated by 9-lipoxygenase from tomato but was converted at a slow rate into 3-oxa-9(S)-hydroperoxy-10(E),12(*Z*),15(*Z*)-octadecatrienoic acid by recombinant maize 9-lipoxygenase. Recombinant α-dioxygenase-1 from *Arabidopsis thaliana* catalyzed the conversion of 3-oxalinolenic acid into a 2-hydroperoxide, which underwent spontaneous degradation into a mixture of 6,9,12-pentadecatrienol and 6,9,12-pentadecatrienyl formate. A novel α-dioxygenase from the moss *Physcomitrella patens* was cloned and expressed and was found to display the same activity with 3-oxalinolenic acid as *Arabidopsis thaliana* α-dioxygenase-1. Lipoxygenase-generated 3-oxa-oxylipins are resistant toward β-oxidation and have the potential for displaying enhanced biological activity in situations where activity is limited by metabolic degradation.

Paper no. L9993 in *Lipids 41*, 499–506 (May 2006).

FA hydroperoxides can be enzymatically produced in plants by lipoxygenase- or α-dioxygenase-catalyzed oxygenations (1,2). Further conversion by secondary enzymes such as allene oxide synthase, allene oxide cyclase, divinyl ether synthase, and hydroperoxide lyase results in an array of oxygenated derivatives collectively called oxylipins. Interest in oxylipins stems from their involvement in plant development and their role as defensive agents in plants attacked by fungi, insects, and bacteria (3,4). Assays of the growth-inhibitory actions of oxylipins on fungi and bacteria have shown impressive effects in many studies (5–7); however, interpretation of the results is often complicated by the fact that active oxylipins have limited stability (6,7). Degradation of certain oxylipins, such as hydroperoxides, can be attributed to inherent chemical instability, whereas others, such as ketodienes and ketotrienes, react chemically with glutathione and other biomolecules, and in this way escape from the test system. Furthermore, a large group of oxylipins are actively metabolized by the microorganism under study. In recent work on the *in vitro* antimicrobial effects of oxylipins, the β-oxidation system for degradation of the carbon chain of FA and FA derivatives was identified as an important pathway for inactivation of exogenously added oxylipins (7). Substitution of the β-methylene group of FA with oxygen (forming 3-oxa FA) affords derivatives that cannot be degraded by mitochondrial or peroxisomal β-oxidation (8,9). The present work describing synthesis of 3-oxalinolenic acid and 3-oxa-oxylipins was carried out with the goal of generating oxylipin analogs resistant to β-oxidation and therefore potentially displaying enhanced biological activity.

EXPERIMENTAL PROCEDURES

FA and reference oxylipins. 5(*Z*),8(*Z*),11(*Z*),14(*Z*),17(*Z*)-Eicosapentaenoic acid was purchased from Nu-Chek-Prep (Elysian, MN). The oxylipins used in the present work, including linoleic and linolenic acid hydroperoxides, divinyl ether FA, and 12-oxo-10,15(*Z*)-phytodienoic acid (12-oxo-PDA), were purchased from Larodan Fine Chemicals (Malmö, Sweden).

*Methyl 5,6-dihydroxy-8(Z),11(Z),14(Z),17(Z)-eicosatetraenoate (**2**).* The procedures described previously by Skattebol and others (10,11) were used with slight modifications. In a typical run, 5(*Z*),8(*Z*),11(*Z*),14(*Z*),17(*Z*)-eicosapentaenoic acid (**1**; 1.6 g; 5.3 mmol) in THF (80 mL) was treated

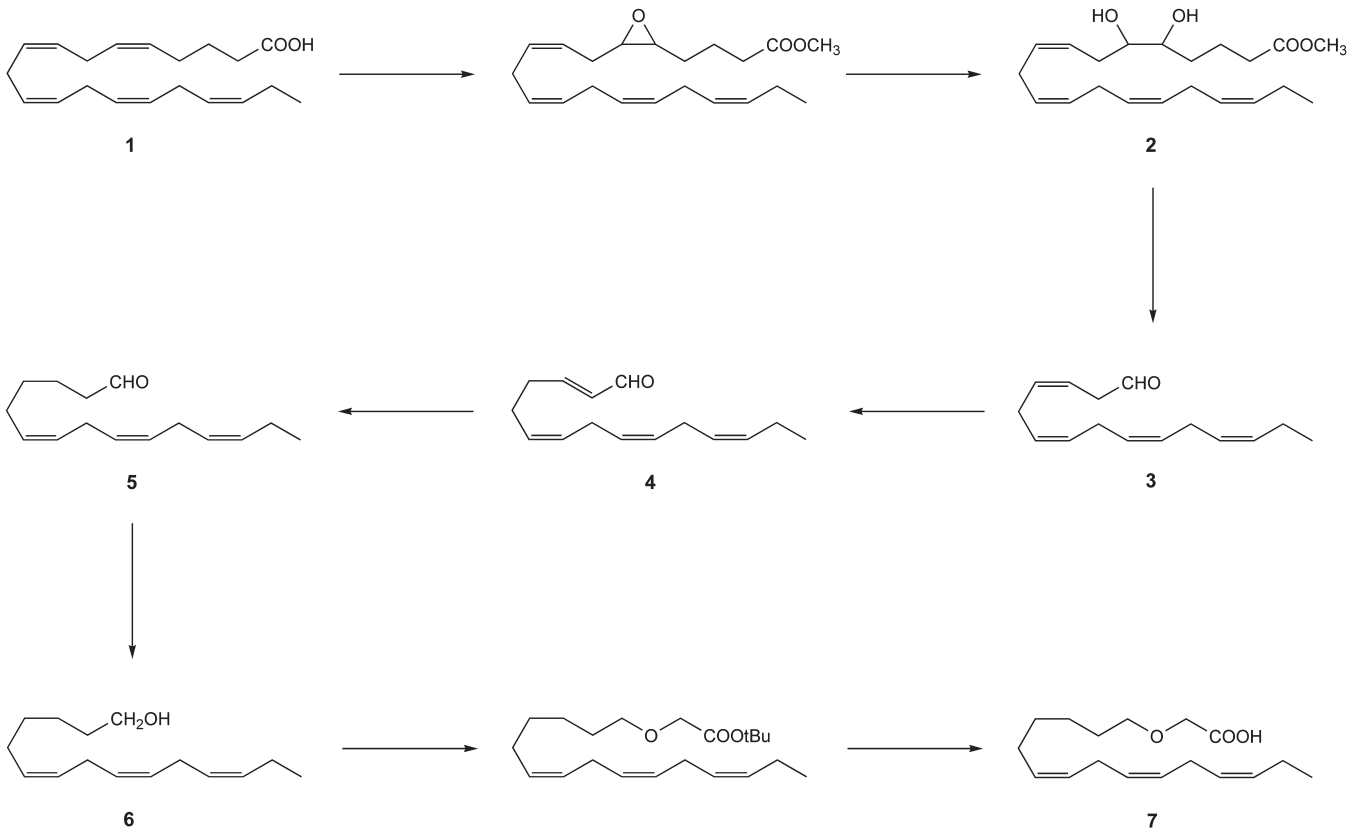
Abbreviations: At-DOX1, recombinant α-dioxygenase-1 from *Arabidopsis thaliana*; 12-oxo-PDA, 12-oxo-10,15(*Z*)-phytodienoic acid; Pp-DOX, recombinant α-dioxygenase from *Physcomitrella patens*.

at 0°C with $KHCO_3$ (3.8 g in 132 mL of water) and sodium iodide and iodine (5.6 g and 9.4 g, respectively, in 80 mL of THF). After adding a few crystals of BHT and purging with argon, the solution was stirred at 23°C for 22 h. The iodolactone obtained by extraction with diethyl ether was dissolved in THF (160 mL) and treated with LiOH (1.4 g) in 108 mL of water. After stirring at 23°C for 1 h, crude *cis*-5,6-epoxy-8(*Z*),11(*Z*),14(*Z*),17(*Z*)-eicosatetraenoic acid was isolated by extraction with diethyl ether, and its methyl ester was prepared by treatment with diazomethane. Conversion of the epoxyester into the corresponding 5,6-diol (Scheme 1) was effected by treatment with formic acid/acetic anhydride followed by K_2CO_3 in methanol as described (11). Purification by open column silicic acid chromatography (elution with diethyl ether/hexane [8:2, vol/vol]) afforded methyl 5,6-dihydroxy-8(*Z*),11(*Z*),14(*Z*),17(*Z*)-eicosatetraenoate as a colorless oil (1.2 g; yield, 64%). Analysis of the Me_3Si derivative by GC-MS showed a single eluted peak. MS showed fragments at *m/z* 494 (6%, M^+), 463 (4; $M^+ - 31$; loss of OMe), 305 (23; Me_3SiO^+=CH-CH($OSiMe_3$)-$(CH_2)_3$-COOMe), 215 (37; 305-90), 203 (76; Me_3SiO^+=CH-$(CH_2)_3$-COOMe), and 73 (100; Me_3Si^+).

*2(E),6(Z),9(Z),12(Z)-Pentadecatetraenal (**4**).* The previous product **2** (1.2 g; 3.4 mmol) in acetone (120 mL), water (30 mL), and glacial acetic acid (9 mL) was treated with sodium periodate (3.6 g) at 23°C under magnetic stirring for 1 h. Extraction with hexane afforded 3(*Z*),6(*Z*),9(*Z*),12(*Z*)-pentadecatetraenal (**3**) as an oil producing a single peak upon GC-MS analysis. MS analysis gave *m/z* 218 (<1%; M^+), 189 (1; $M^+ - 29$; loss of C_2H_5), 135 (6), 122 (16), 105 (24), 93 (49), 91 (55), and 79 (100). The aldehyde was dissolved in THF (60 mL) and isomerized by treatment with 70% perchloric acid (2 mL) at 23°C for 1 h. Diethyl ether was added, and the solution was washed with water and dried over $MgSO_4$. The oil (0.86 g) obtained after evaporation of the solvent was characterized as the title compound on the basis of GC-MS analysis, in which peaks were seen at *m/z* 218 (<1%; M^+), 189 (1; $M^+ - 29$; loss of C_2H_5), 148 (14), 119 (13), 105 (21), 93 (60), 91 (56), and 79 (100), UV (λ_{max} [EtOH] 219 nm), and FT-IR, which gave bands at 1696 (aldehyde carbonyl), 1128, and 972 cm^{-1} (*E*-double bond).

*6(Z),9(Z),12(Z)-Pentadecatrienal (**5**).* A mixture of diisobutylaluminium hydride (20 mmol), hexamethylphosphoric triamide (10 mL; distilled fom calcium hydride), and CuI (200 mg) in 45 mL of dry THF was stirred under argon at 0°C for 20 min. Aldehyde **4** (0.86 g) in 15 mL of THF was added, and the mixture was stirred at 0°C for 1 h. Extraction with hexane provided **5** (0.66 g) as an essentially colorless oil showing *m/z* 220 (1%; M^+), 191 (1; $M^+ - 29$; loss of C_2H_5), 164 (6), 108 (19), and 79 (100).

*6(Z),9(Z),12(Z)-Pentadecatrienol (**6**).* The above-mentioned aldehyde **5** (0.66 g) was dissolved in 20 mL of methanol and cooled to 0°C. Sodium borohydride (500 mg) was added during 10 min under stirring. After further 20 min



SCHEME 1

at 23°C, water was added and the solution extracted with diethyl ether. Alcohol **6** thus obtained (0.63 g, purity ca. 95%) showed *m/z* 222 (4%; M^+), 166 (2), 108 (23), 93 (44), 91 (40), and 79 (100). FTIR (film) showed bands at 3351 (alcohol), 1456, 1055, and 714 cm^{-1}.

*3-Oxalinolenic acid (**7**).* To a solution of alcohol **6** (0.63 g) in toluene (26 mL) were added tetrabutylammonium chloride (187 mg), *tert*-butyl bromoacetate (2.85 g), and 8.75 g of a 50% (wt/vol) solution of NaOH in water. After addition of a crystal of BHT antioxidant and purging with argon, the mixture was stirred at room temp for 24 h. The *tert*-butyl ester of **7** obtained after extraction with diethyl ether was hydrolyzed by treatment with trifluoroacetic acid (4 mL) in dichloromethane (8 mL) at room temperature for 1 h. Purification by silicic acid column chromatography (elution with diethyl ether/hexane (3:7, vol/vol)) afforded **7** (0.47 g; purity, ca. 90%; yield from **1**, 32%). Final purification by RP-HPLC using solvent system A afforded >99% pure 3-oxalinolenic acid (0.18 g [0.64 mmol]; yield from **1**, 12%) as a colorless oil. Analysis of the methyl ester derivative by GC-MS using capillary columns of phenylmethylsilicone or Supelcowax showed single peaks having retention times corresponding to C-17.71 and C-20.58, respectively, and a mass spectrum showing *m/z* 294 (2%; M^+), 265 (1; $M^+ - 29$; loss of C_2H_5), 204 (2; $M^+ - 90$; loss of $OCH_2COOMe + H$), 175 (3), 108 (26), and 79 (100). The proton NMR (400 MHz, $CDCl_3$) spectrum showed signals at δ 0.97 ppm (t, J = 7.4, H-18), 1.35–1.47 (m, H-6 and H-7), 1.60–1.68 (m, H-5), 2.02–2.11 (m, H-8 and H-17), 2.78–2.83 (m, H-11 and H-14), 3.56 (t, J = 6.6, H-4), 4.10 (s, H-2), and 5.27–5.43 (m, H-9, H-10, H-12, H-13, H-15, H-16). That the *cis* configuration of the double bonds of **1** was retained in **7** was shown by the FTIR spectrum, which showed the absence of an absorption band at ca. 970 cm^{-1} typical for *trans* unsaturation.

*3-Oxa-13(S)-hydroperoxy-9(Z),11(E),15(Z)-octadecatrienoic acid (**8**).* 3-Oxalinolenic acid **7** (2.4 mM) in 15 mL of sodium borate buffer pH 10.4 was stirred for 15 min at 0°C under oxygen atmosphere in the presence of soybean lipoxygenase-1 (170,000 units). The product was isolated by extraction with diethyl ether and subjected to open column silicic acid chromatography. Elution with diethyl ether-hexane (3:7, vol/vol) afforded the title compound in 90% yield showing UV absorption with λ_{max} (EtOH) 234 nm. An aliquot was subjected to catalytic hydrogenation using platinum catalyst to provide 3-oxa-13-hydroxystearic acid (mass spectrum of methyl ester/Me_3Si derivative: *m/z* 373 (1%; $M^+ - 15$), 317 (71; $M^+ - (CH_2)_4\text{-}CH_3$), 288 (39; rearrangement with loss of $OCH\text{-}(CH_2)_4\text{-}CH_3$), 173 (100; $Me_3SiO^+{=}CH\text{-}(CH_2)_4\text{-}CH_3$), 147 (61), and 73 (91; Me_3Si^+).

*3-Oxa-13(S)-hydroxy-9(Z),11(E),15(Z)-octadecatrienoic acid (**9**).* The hydroperoxide **8** (10 mg) was dissolved in 3 mL of ice-cold methanol and treated with 30 mg of $NaBH_4$ at 0°C for 15 min to provide the title compound in essentially quantitative yield. The UV spectrum showed λ_{max} (EtOH) = 233 nm and the mass spectrum of the methyl ester/Me_3Si derivative showed prominent ions at *m/z* 382 (1%; M^+), 323 (1; $M^+ - 59$; loss of COOMe), 313 (100; $M^+ - 69$; loss of $CH_2\text{-}CH{=}CH\text{-}CH_2\text{-}CH_3$), 223 (11; 313-90), 133 (39), and 73 (99; Me_3Si^+).

*3-Oxa-13-oxo-9(Z),11(E),15(Z)-octadecatrienoic acid (**10**).* To hydroperoxide **8** (20 mg) was added an ice-cold mixture of acetic anhydride (0.25 mL) and pyridine (0.2 mL). After 13 min at 0°C, water (0.5 mL) was added, and the mixture was stirred for 30 min at 23°C. Purification by RP-HPLC using solvent system B provided **10** (effluent volume, 47.7–50.0 mL; 13.9 mg; 74% yield). The UV spectrum showed λ_{max} (EtOH) = 280 nm and the mass spectrum of the methyl ester showed prominent ions at *m/z* 308 (17%; M^+), 239 (59; $M^+ - 69$; loss of $CH_2\text{-}CH{=}CH\text{-}CH_2\text{-}CH_3$), 149 (91; $[CH{=}CH\text{-}CH{=}CH\text{-}CO\text{-}CH_2\text{-}CH{=}CH\text{-}CH_2\text{-}CH_3]^+$), 121 (76), 107 (100), and 79 (91).

*3-Oxa-12-oxo-10,15(Z)-phytodienoic acid (**11**).* Product **8** (75 mg, 300 μM) was stirred at 23°C for 20 min with an acetone preparation of flaxseed (12) resuspended in the 100,000 × *g* supernatant of homogenate of potato tuber (13) as sources of allene oxide synthase and allene oxide cyclase, respectively. The product was subjected to RP-HPLC using solvent system C to provide **11** as a colorless oil (effluent volume, 59.5–62.8 mL; 15 mg, 21% yield). The UV spectrum showed λ_{max} (EtOH) = 220 nm, and the mass spectrum of the methyl ester showed prominent ions at *m/z* 308 (23%; M^+), 279 (12; $M^+ - 29$; loss of C_2H_5), 249 (7; $M^+ - 59$; loss of COOMe), 240 (34; $M^+ - 68$; β-cleavage with loss of $CH_2\text{-}CH{=}CH\text{-}C_2H_5$), 235 (16; $M^+ - 73$; loss of $CH_2\text{-}COOMe$), 218 (8; $M^+ - 90$; loss of $OH\text{-}CH_2\text{-}COOMe$), 149 (58; $M^+ - 159$; loss of $(CH_2)_5\text{-}O\text{-}CH_2\text{-}COOMe$), 107 (90), and 95 (100).

Incubations with 9-lipoxygenases. Recombinant maize 9-lipoxygenase was obtained following expression of the maize lipoxygenase gene (cssap92) in *E. coli* as described in the literature (14). The products formed after incubation of **7** (36 μM) with maize lipoxygenase in Tris buffer pH 7.0 at 23°C for 20 min under oxygen atmosphere were treated with sodium borohydride in methanol. The reduced material was derivatized by methyl-esterification and trimethylsilylation and analyzed by GC-MS. Incubations of **7** with tomato lipoxygenase (15) were carried out in potassium phosphate buffer pH 6.0 under oxygen, and aliquots of the mixture were removed for UV spectroscopic analysis.

Cloning and expression of Physcomitrella patens α-dioxygenase and Arabidopsis thaliana α-dioxygenase-1. Recombinant baculoviruses expressing *Arabidopsis thaliana* α-dioxygenase-1 (At-DOX1) or *Physcomitrella patens* α-dioxygenase (Pp-DOX) were generated using the Bac-to-Bac baculovirus expression system (InVitrogen, Paisley, UK). The generation of At-DOX1 baculovirus has been described previously (16). A 2.3-kb DNA fragment containing the entire cDNA for a *Physcomitrella patens* α-dioxygenase (*cf.* ref. 2) was obtained from an EST database (http://moss.nibb.ac.jp) (17). The Pp-DOX cDNA was excised from its host plasmid RAFL 12-25 with Sfi1, blunt-ended with T4 DNA polymerase, and ligated into the Stu1 restriction site of the pFastBac vector. Correct cloning of the insert was verified by restriction analysis. The recombinant plasmid was transferred

into DH10Bac *E. coli* cells containing the baculovirus shuttle vector bMON14272 and the helper plasmid pMON7124. Recombinant bacmid DNA was prepared from positive bacterial clones, and recombinant baculovirus was obtained by transfecting the bacmid into High Five insect cells according to manufacturer's instructions.

α-Dioxygenase expression was performed by infecting High Five insect cell cultures grown at 28°C in Tc100 medium supplemented with 10% fetal calf serum with the recombinant viruses. At 48 h (At-DOX1 expression) or 72 h (Pp-DOX expression) after infection, cells were collected by centrifugation (5 min, 3000 g), washed twice with Dulbecco's phosphate-buffered saline (pH 7.4), divided in aliquots and pelleted by centrifugation (5 min, 3000 g). Cell pellets were stored at –80°C until analysis. Total protein extracts of α-dioxygenase-expressing cells were separated by gel-electrophoresis and visualized by Coomassie Brilliant Blue staining.

Incubations with α-dioxygenases. High Five cells expressing Pp-DOX and At-DOX1 (190 and 470 μg total protein, respectively) were briefly sonicated on ice (3 × 0.3 s at 35 W) in 0.1 M Tris pH 7.4 and immediately incubated for 30 min at room temperature with **7** (100 μM) in a total volume of 3 mL of oxygenated 0.1 M Tris buffer at pH 7.4 containing 100 μM $CaCl_2$. The products were extracted with diethyl ether, derivatized, and analyzed by GC-MS.

Incubations with hydroperoxide-metabolizing enzymes. For studies of **8** as a precursor of cyclopentenone and ketol derivatives, an acetone powder preparation of allene oxide synthase from flaxseed (12) suspended in a 100,000 × *g* supernatant from potato homogenate containing allene oxide cyclase (13) were stirred with 300 μM **8** at 23°C for 20 min. The product was methyl-esterified and trimethylsilylated and analyzed by GC-MS. Metabolism of **8** by guava hydroperoxide lyase (18) and divinyl ether synthases from garlic (19) or *Ranunculus acris* (20) was studied under incubation conditions described as indicated. The reaction products isolated by extraction with diethyl ether were derivatized and analyzed by GC-MS.

Chemical, chromatographical, and instrumental methods. RP-HPLC was carried out with a column of Nucleosil C_{18} 100-7 (250 × 10 mm; Macherey-Nagel, Düren, Germany) and solvent systems of acetonitrile-water-acetic acid in proportions 60:40:0.005, by vol (solvent system A), 55:45:0.005, by vol (solvent system B), or 45:55:0.005, by vol (solvent system C) at a flow rate of 4 mL/min. The effluent was led to a Bischoff model DAD-100 diode-array detector (Bischoff Chromatography, Leonberg, Germany).

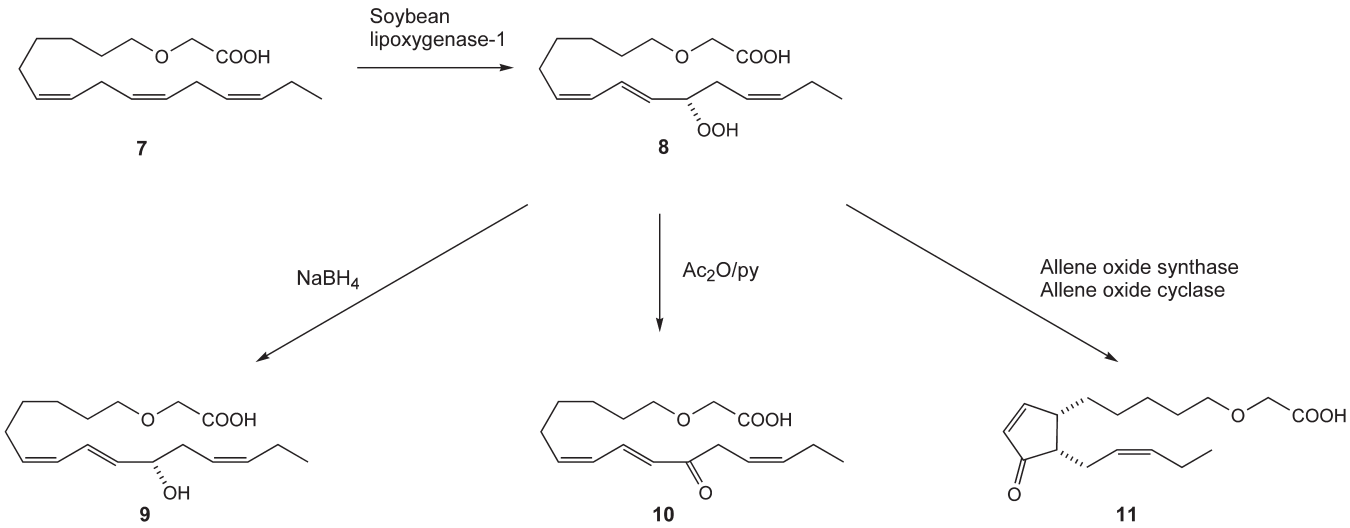
GLC with flame ionization detection was performed using a Hewlett-Packard (Avondale, PA) model 5890 gas chromatograph using either a methylsilicone capillary column (length 25 m, film thickness 0.33 μm) or a Supelcowax capillary column (length 30 m, film thickness 0.25 μm). Helium at a flow rate of 25 cm/s was used as the carrier gas. C-values recorded during gas chromatography were calculated from diagrams constructed by plotting the retention times of standard saturated FAME on a logarithmic scale vs. the number of carbon atoms of the carbon chains on a linear scale. GC-MS was carried out with a Hewlett-Packard model 5970B mass-selective detector connected to a Hewlett-Packard model 5890 gas chromatograph. UV spectra were recorded with a Hitachi (Tokyo, Japan) model U-2000 UV/vis spectrophotometer. FT-IR spectrometry was carried out using a PerkinElmer (Norwalk, CT) model 1650 FT-IR spectrophotometer. NMR spectra were recorded on a Varian Mercury plus spectrometer at 400 MHz. Samples were dissolved in deuteriochloroform, and chemical shifts are reported as δ values (ppm) and indirectly referenced to tetramethylsilane via the residual solvent signal ($CHCl_3$ in $CDCl_3$).

RESULTS AND DISCUSSION

3-Oxalinolenic acid (7). Synthesis of **7** was achieved by an eight-step sequence starting with 5(*Z*),8(*Z*),11(*Z*),14(*Z*),17(*Z*)-eicosapentaenoic acid, a cheap and readily available natural product (Scheme 1). Iodolactonization and hydrolysis as originally described by Corey *et al*. (21) provided the 5,6-epoxide derivative of eicosapentaenoic acid. Further conversion by hydrolysis and periodate cleavage afforded tetraenal **3**, the β,γ-double bond of which was removed by isomerization into the α,β-position followed by selective reduction using diisobutyl aluminium hydride. Aldehyde **3** has been previously prepared by Skattebol and coworkers (10,11) and been further elaborated to sulfur- and oxygen-containing PUFA (10) as well as polyunsaturated trifluoromethyl ketones (11). Indeed aldehyde **3** and its isomerized and saturated analogs **4** and **5**, as well as other aldehydes derived from 5,8,11,14,17-eicosapentaenoic acid (22), appear to be useful starting materials for a range of ω-3 FA, and can also be used for the preparation of ω-3 FA isotopically labeled in the carboxyl end.

To the best of our knowledge, this study describes the first synthesis of 3-oxalinolenic acid, although the 3-oxa and 3-thia analogs of the related 6,9,12,15-octadecatetraenoic acid (stearidonic acid) have been prepared (10). 3-Oxa FA prepared in other studies are "unnatural" in the sense that their chain lengths consist of an odd number of atoms. Such FA include 3-oxa-6,9,12,15,18-heneicosapentaenoic acid (10) as well as 3-oxa-heneicosatrienoic acid, 3-oxa-heneicosatetraenoic acid, and 3-oxa-tricosatetraenoic acid (9,23,24). Among oxylipins, 3-oxa analogs of 10,11-dihydro-13-epi-12-oxo-PDA (25) and tetrahydrodicranenone B (26) have been prepared. Furthermore, β-oxidation–resistant 3-oxa analogs of the eicosanoid lipoxin A_4 have been synthesized (27).

3-Oxalinolenic acid was oxygenated by soybean lipoxygenase-1 to provide the corresponding 13(*S*)-hydroperoxide, and this compound could be further elaborated into 13-hydroxy or 13-oxo derivatives by reduction or dehydration, respectively (Scheme 2). On the other hand, no conversion of 3-oxalinolenic acid by tomato 9-lipoxygenase could be observed. In an earlier study, 2-hydroxylinolenic acid was found not to be a substrate for this enzyme (28). Taken together, these observations suggest that binding of the carboxyl end



SCHEME 2

plays an important role in the tomato 9-lipoxygenase-catalyzed oxygenation of FA. In previous studies, replacement of the carboxyl group of substrates for 9-lipoxygenases with nonionizable groups was found to affect the rate of oxygenation as well as the regiospecificity (29,30).

*Oxygenation of **7** by recombinant maize 9-lipoxygenase*. In contrast to tomato lipoxygenase, recombinant maize lipoxygenase catalyzed oxygenation of **7**, albeit at a slow rate (8% of the rate of linolenic acid oxygenation). The mass spectrum of the reduced and derivatized hydroperoxide product showed prominent ions at *m/z* 382 (1%; M^+), 313 (4; $M^+ - CH_2$-CH=CH-CH_2-CH_3), 292 (9; $M^+ - 90$), 223 (16; Me_3SiO^+=CH-(CH=CH)$_4$-CH_2-CH=CH-CH_2-CH_3), 151 (7), 133(14), 131 (11), 75 (100; $Me_2Si=O^+H$), and 73 (51; Me_3Si^+). In another experiment, the 3-oxa-9-hydroperoxide was converted into the saturated 3-oxa-9-hydroxystearate by sodium borohydride reduction followed by catalytic hydrogenation. The mass spectrum of the methyl ester/Me_3Si derivative of this compound showed prominent ions at *m/z* 373 (0.2%; $M^+ - CH_3$), 261 (53; Me_3SiO^+=CH-$(CH_2)_5$-O-CH_2-$COOCH_3$), 232 (29; $M^+ - 56$; rearrangement with loss of OHC-$(CH_2)_8$-CH_3), 229 (72; Me_3SiO^+=CH-$(CH_2)_8$-CH_3), 147 (39), and 73 (100; Me_3Si^+).

*Oxygenation of **7** by α-dioxygenases*. The effect of the 3-oxa substitution in **7** on the dioxygenation of the vicinal α-carbon by α-dioxygenases (2) was studied using recombinant enzymes from *Arabidopsis thaliana* and the moss *Physcomitrella patens*, At-DOX1 and Pp-DOX. These proteins were expressed in High Five insect cells following infection with recombinant baculoviruses containing the At-DOX1 or Pp-DOX pFastBac constructs, respectively (Fig. 1). The molecular masses of the expressed proteins were approximately 75 kDa and 70 kDa, respectively, in accordance with the size predicted for both proteins. The two α-dioxygenases were not expressed when insect cells were infected with baculovirus prepared from empty pFastBac vector.

The product **7** was oxygenated by At-DOX1 at a rate 25% of that of linolenic acid oxygenation. GC-MS analysis of the derivatized reaction products revealed comparable amounts of two main products identified as 6,9,12-pentadecatrienol and 6,9,12-pentadecatrienyl formate (Scheme 3). The mass spectrum of the first-mentioned compound was identical to that of authentic 6,9,12-pentadecatrienol (**6**), and the spectrum of the corresponding Me_3Si derivative showed ions at *m/z* 294 (3%; M^+), 175 (5), 129 (16; Me_3SiO^+=CH-CH=CH_2), 108 (39), 93 (48), 79 (100), and 73 (63; Me_3Si^+). As expected, catalytic hydrogenation afforded pentadecanol. The second product showed *m/z* 250 (4%; M^+), 221 (1; $M^+ - C_2H_5$), 194 (7), 135 (8), 93 (49), 79 (100), and 67 (67). Mild alkaline hydrolysis (0.3 M NaOH in 43% aqueous ethanol, 1

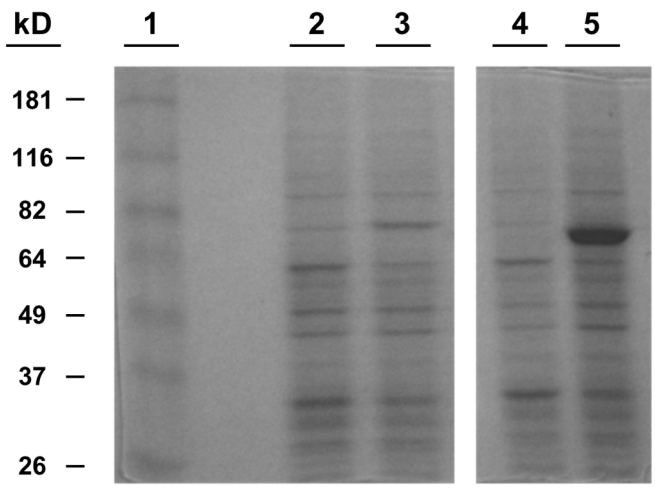


FIG. 1. SDS-polyacrylamide gel electrophoresis illustrating the expression of At-DOX1 and Pp-DOX in High Five insect cells infected with recombinant baculoviruses. Lane 1, molecular mass markers (indicated in kDa); lanes 2 and 4, cells infected with baculovirus without transposed gene; lane 3, cells infected with recombinant pFastBac/At-DOX1 baculovirus (48 h); lane 5, cells infected with recombinant pFastBac/Pp-DOX baculovirus (72 h). Each lane corresponds to protein lysates derived from approximately 125,000 cells.

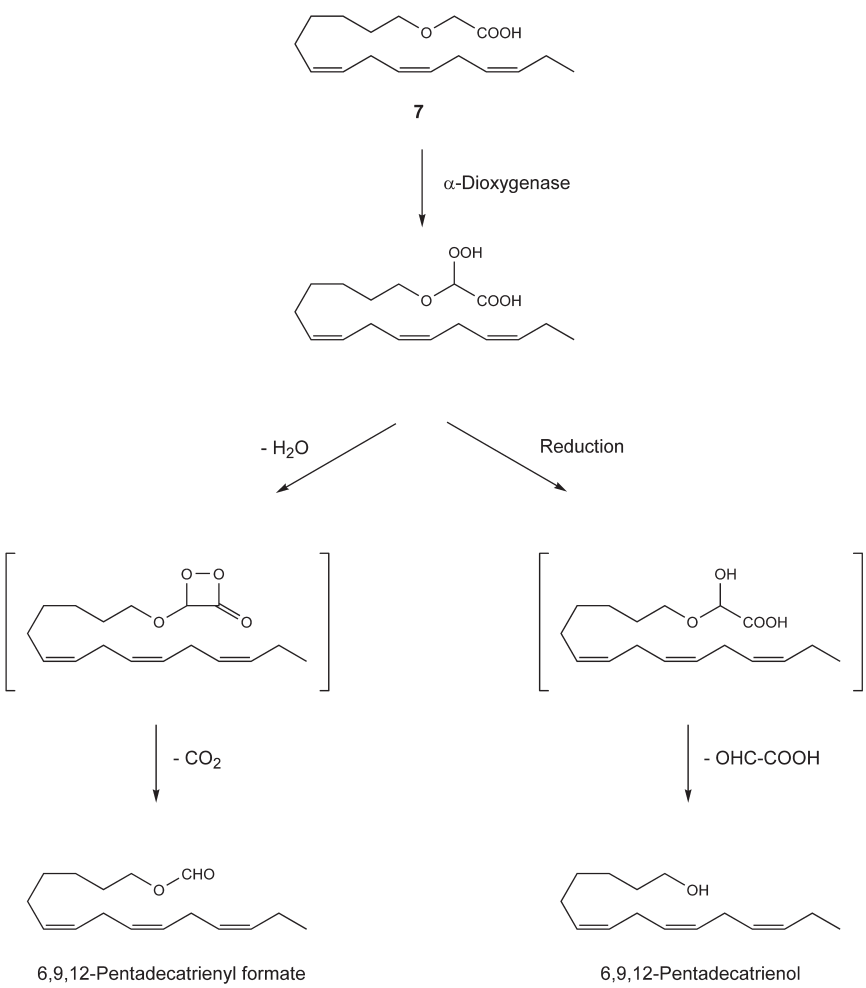

SCHEME 3

h at 37°C) converted the product into 6,9,12-pentadecatrienol, indicating its identity with the formate ester of this alcohol. In previous work using pea α-dioxygenase, a 4-oxa FA (4-oxadodecanoic acid) was found not to serve as a substrate whereas a 5-oxa substituted FA (5-oxapentadecanoic acid) was efficiently oxygenated (31).

Pp-DOX was ca. 20% more active than At-DOX1 in oxygenating **7** and produced the same set of compounds. The mode of formation of these products can be rationalized in terms of the mechanism of α-dioxygenases and the known instability of 2-hydroperoxy FA (32). Thus, part of the α-dioxygenase product 3-oxa-2-hydroperoxylinolenic acid will decarboxylate to produce the formate ester of 6,9,12-pentadecatrienol, a process that probably takes place via a peroxylactone intermediate (Scheme 3). Another part will be reduced into the corresponding hydroxide prior to decarboxylation and produce a highly unstable hemiacetal that will rearrange spontaneously into 6,9,12-pentadecatrienol and glyoxylic acid.

*Conversion of **8** by allene oxide synthase/allene oxide cyclase*. GC-MS analysis of the derivatized products formed upon incubation of **8** (300 μM; 23°C, 20 min) with a preparation of flax allene oxide synthase and potato allene oxide cyclase showed the absence of remaining hydroperoxide and the presence of two main products formed in ca. 1:1 ratio. The earlier-eluting derivative was identified as the methyl ester of 3-oxa-12-oxo-PDA (**11**). The second derivative eluted just before the Me_3Si derivative of the methyl ester of 13-hydroxy-12-oxo-9(*Z*),15(*Z*)-octadecadienoic acid. On the basis of its mass spectrum, which showed prominent ions at *m/z* 383 (4%; $M^+ - 15$; loss of CH_3), 339 (1; $M^+ - 59$; loss of COOMe), 329 (2; $M^+ - 69$; loss of CH_2-CH=CH-C_2H_5), 272 (50; $M^+ - 126$; rearrangement of Me_3Si with loss of CO(O)CH-CH_2-CH=CH-C_2H_5 or its equivalent), 249 (1; 339-90), 171 (100; Me_3SiO^+=CH-CH_2-CH=CH-C_2H_5), 129 (29; Me_3SiO^+=CH-CH=CH_2), and 73 (88; Me_3Si^+), it was tentatively identified as the Me_3Si derivative of the methyl ester of 3-oxa-13-hydroxy-12-oxo-9(*Z*),15(*Z*)-octadecadienoic acid.

*Conversion of **8** by garlic and* Ranunculus *divinyl ether synthases*. The products obtained after incubation of **8** (300 μM; 23°C for 15 min) with whole homogenate preparations of garlic tuber (19) or leaves from *Ranunculus acris* (20) were methyl-esterified, trimethylsilylated, and subjected to GC-MS. This analysis showed the absence of derivatives of the methyl esters of **9** or **10** (on-column degradation products of

hydroperoxide, *cf*. ref. 33), thus indicating that hydroperoxide **8** had been completely consumed in the divinyl ether synthase reactions. Instead, major peaks eluting close to the divinyl ether etherolenic acid (garlic incubation) and ω-5(*Z*)-etherolenic acid (*Ranunculus* incubation) appeared. The identity of these materials with 3-oxa-etherolenic acid and 3-oxa-ω-5(*Z*)-etherolenic acid, respectively, was supported by mass spectrometry, which showed prominent ions at *m/z* 308 (72%; M^+), 292 (6), 241 (9), 189 (8), 171 (15), 133 (44), and 79 (100), and 308 (63%), 279 (3), 189 (7), 171 (14), 149 (28), and 79 (100), respectively. Although this experiment proved that **8** served as the substrate for garlic and *Ranunculus* types of divinyl ether synthases, no attempts were made to verify the double bonds of the resulting divinyl ethers with regard to position or configuration.

*Conversion of **8** by guava hydroperoxide lyase*. Incubation of **8** (300 μM; 23°C for 10 min) with a whole homogenate preparation of guava fruit (18) led to a product that was methyl-esterified, trimethylsilylated, and analyzed by GC-MS. As was the case with the divinyl ether synthase incubations, derivatives of the hydroperoxide degradation products **9** or **10** could not be detected, thus indicating a complete consumption of **8**. In another experiment, the incubation mixture was treated with an equal volume of 30 mM methoxyamine hydrochloride in methanol in order to facilitate detection of the expected aldehyde product. One major peak appeared showing the following prominent mass spectral ions: *m/z* 257 (2%; M^+), 226 (9; M^+ – OMe), 198 (6; M^+ – COOMe), 184 (30; M^+ – CH_2-COOMe), 93 (61), 80 (100), and 67 (99). The identity of the parent aldehyde with 3-oxa-12-oxo-9-dodecenoic acid was supported by an additional experiment, in which the incubation mixture was treated with an excess of sodium borohydride in methanol. The resulting major product was tentatively identified as 3-oxa-12-hydroxy-9-dodecenoic acid on the basis of its mass spectrum (methyl ester – Me_3Si derivative), which showed *m/z* 302 (0.3%; M^+), 272 (5), 212 (3; M^+ – Me_3SiOH), 147 (34), 103 (72; $Me_3SiO^+=CH_2$), and 73 (100; Me_3Si^+).

Conclusion. 3-Oxa-linolenic acid, a β-oxidation–resistant analog of linolenic acid, was synthesized in 10–15% yield starting with the easily accessible FA 5,8,11,14,17-eicosapentaenoic acid. 3-Oxalinolenic acid was found to be oxygenated by both lipoxygenases and α-dioxygenases. In agreement with a previous study using 3-oxa FA having acyl chains composed of an odd number of atoms (22), 3-oxalinolenic acid served as a good substrate for soybean lipoxygenase. The resulting 3-oxa-13-hydroperoxide was convertible chemically or by secondary enzymes into a range of 3-oxa oxylipins including 3-oxa-12-oxo-PDA. The biological activities of such oxylipin analogs are presently being explored.

ACKNOWLEDGMENTS

The expert technical assistance of Mrs. G. Hamberg and Mr. Tomás Cascón Vázquez is gratefully acknowledged. 2,6-Hexadecadiynoic Acid and 2,6-Nonadecadiynoic Acid: Novel Synthesized Acetylenic Fatty Acids as Potent Antifungal Agents

Néstor M. Carballeira[a,*], David Sanabria[a], Clarisa Cruz[a], Keykavous Parang[b], Baojie Wan[c], and Scott Franzblau[c]

[a]Department of Chemistry, University of Puerto Rico, San Juan, Puerto Rico, 00931-3346, [b]Department of Biomedical and Pharmaceutical Sciences, College of Pharmacy, University of Rhode Island, Kingston, Rhode Island, 02881, and [c]Institute for Tuberculosis Research, College of Pharmacy, The University of Illinois at Chicago, Chicago, Illinois, 60612-7231

ABSTRACT: The hitherto unknown 2,6-hexadecadiynoic acid, 2,6-nonadecadiynoic acid, and 2,9-hexadecadiynoic acid were synthesized in two steps and in 11–18% overall yields starting from either 1,5-hexadiyne or 1,8-nonadiyne. Among all the compounds 2,6-hexadecadiynoic acid displayed the best overall antifungal activity against both the fluconazole-resistant *Candida albicans* strains ATCC 14053 and ATCC 60193, with a minimum inhibitory concentration (MIC of 11 μM), and against *Cryptococcus neoformans* ATCC 66031 (MIC < 5.7 μM). 2,9-Hexadecadiynoic acid did not display any significant cytotoxicity against the fluconazole-resistant *C. albicans* strains, but it showed fungitoxicity against *C. neoformans* ATCC 66031 with a MIC value of < 5.8 μM. Other FA, such as 2-hexadecynoic acid, 5-hexadecynoic acid, 9-hexadecynoic acid, and 6-nonadecynoic acid were also synthesized and their antifungal activities compared with those of the novel acetylenic FA. 2-Hexadecynoic acid, a known antifungal FA, exhibited the best antifungal activity (MIC = 9.4 μM) against the fluconazole-resistant *C. albicans* ATCC 14053 strain, but it showed a MIC value of only 100 μM against *C. albicans* ATCC 60193. 2,6-Hexadecadiynoic acid and 2-hexadecynoic acid also displayed a MIC of 140–145 μM toward *Mycobacterium tuberculosis* $H_{37}Rv$ in Middlebrook 7H12 medium. In conclusion, 2,6-hexadecadiynoic acid exhibited the best fungitoxicity profile compared with other analogues. This diynoic FA has the potential to be further evaluated for use in topical antifungal formulations.

Paper no. L9921 in *Lipids 41*, 507–511 (May 2006).

The 2-alkynoic FA have been known to be fungitoxic (1–2). The fungal activity of these compounds depends on the FA chain length and pH of the medium (1–2). The optimal chain lengths (between 8 and 16 carbons) have been established for the 2-alkynoic FA to exert maximum fungistatic effects (2). Among the 2-alkynoic FA 2-hexadecynoic acid has received the most attention for its antifungal, antimicrobial, and cytotoxic properties (3–5). The bioactivity of 2-hexadecynoic acid has been ascribed to its ability to inhibit the elongation of saturated and unsaturated FA as well as its potential to inhibit the FA acylation process, particularly triglyceride synthesis (4–5).

Other isomeric alkynoic FA, in particular the 6-alkynoic FA, are also fungistatic. For example, when an unsaturation is introduced between C-6 and C-7 in a fatty acyl chain, the FA displays good fungitoxicity. It is shown that 6-hexadecynoic acid is a good substrate for the enzyme myristoyl-CoA:protein *N*-myristoyltransferase from *Saccharomyces cerevisiae*, an important enzyme for fungal growth and a good target for antifungal therapy (6). Furthermore, 6-nonadecynoic acid, recently isolated from the roots of *Pentagonia gigantifolia*, is reported to be fungistatic against some fungal strains of fluconazole-resistant *Candida albicans* (7) as well as against *Cryptococcus neoformans* (8). *C. albicans* and *C. neoformans* are pathogenic fungi of concern in immunocompromised patients. 6-Alkenoic FA have also been evaluated. For example, 6-hexadecenoic acid is antimicrobial to gram-positive bacteria (MIC of 10–20 μg/mL) and blocks the adherence of *C. albicans* to porcine stratum corneum (9).

With this information at hand regarding the antifungal activities of 2-alkynoic and 6-alkynoic FA, we envisaged the possibility of combining in a single molecule the C-2 and C-6 ynoic functionalities by synthesizing 2,6-diynoic FA and evaluating their antifungal properties. It was expected that novel 2,6-diynoic FA would have a better antifungal profile than either of its parent 2-alkynoic or 6-alkynoic FA. The synthesis of 2,6-octadecadiynoic acid as a precursor to furan-containing FA has been previously reported by Lie Ken Jie *et al.* (10–11). However, to the best of our knowledge, the FA 2,6-hexadecadiynoic acid (**3a**) and 2,6-nonadecadiynoic acid (**3c**) are novel. We describe the synthesis of the dimethylene-interrupted diynoic FA **3a** and **3c**, as well as the synthesis of 2,9-hexadecadiynoic acid (**3b**). Comparative antifungal activities of the compounds indicate that **3a** has the best fungitoxicity profile among the studied compounds and the known 2-hexadecynoic acid.

EXPERIMENTAL PROCEDURES

Instrumentation. ^1H and ^{13}C NMR spectra were recorded on either a Bruker DPX-300 or a Bruker DRX-500 spectrometer. ^1H NMR chemical shifts are reported with respect to internal

Abbreviations: AMB, amphotericin B; FLC, fluconazole; LORA, low oxygen recovery assay; MABA, microplate alamar blue assay; MIC, minimum inhibitory concentration; NCCLS, National Committee for Clinical Laboratory Standards; SDA, Sabouraud dextrose agar; SDB, Sabourand dextrose broth.

Me_4Si, and chemical shifts are given in parts per million (ppm) relative to $CDCl_3$ (77.0 ppm). Mass spectral data were acquired on a GC–MS (Hewlett-Packard 5972A MS ChemStation) instrument at 70 eV, equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS) of polymethylsiloxane crosslinked with 5% phenyl methylpolysiloxane. Infrared spectra were recorded on a Nicolet 600 FT-IR spectrophotometer.

Microorganisms. C. albicans ATCC 60193, *C. albicans* ATCC 14053, and *C. neoformans* ATCC 66031 were obtained from American Type Culture Collection (Manassas, VA). Stock cultures were kept on Sabouraud dextrose agar (SDA; Becton-Dickinson and Co., Sparks, MD). Subcultures were prepared on SDA at 35–37°C. Suspension cultures were prepared by inoculation of single colonies in 7 mL of normal saline solution. Prior to preparation of susceptibility assays, yeast cells were resuspended in normal saline to yield a transmittance of 73–75% at 530 nm, which provided an equivalent concentration of 10^6 cells/mL. The medium was Sabourand dextrose broth (SDB; Becton Dickinson and Co.).

Chemicals and antifungal agents. Amphotericin B (AMB) was purchased from Acros Organics (Geel, Belgium), and was kept as a 5-mM stock in DMSO at 0°C and used within 1 wk of preparation. Fluconazole (FLC) was purchased from Medisa Inc. (New York, NY), or was provided from Vera Laboratories Ltd. (Hyderabad, India), and was kept as a 20-mM stock solution at 0°C. Working dilutions were made in SDB medium. Higher concentrations of compounds were used for those with weak antifungal activities. The final maximum concentration of DMSO in the assays was 5% (vol/vol). DMSO was not inhibitory to the organisms tested.

Susceptibility testing. Microdilutions for control experiments with *C. albicans* and *C. neoformans* were performed according to the modified method of the National Committee for Clinical Laboratory Standards (NCCLS) as described by Galgiani (12) and according to the more recent NCCLS M27-A microdilution methods as described previously (13–14). Dilutions were prepared in 0.1 mL of SDB; the inocula were 10^4 cells of either *C. albicans* or *C. neoformans*. The tubes were incubated for 24–48 h at 36 ± 1°C, and turbidity was read visually. MIC were calculated in comparison with growth control as the lowest concentration that showed inhibition for AMB, FLC, and the test compounds.

General procedure for the monoalkylation of the diynes. To a stirred solution of the diyne (8.3–12.8 mmol) in dry THF (20–25 mL), *n*-Buli (2.5 M, 7.5–11.5 mmol) in dry hexane (3.0–5.0 mL) was added dropwise while keeping the temperature at –78°C. After 45 min, hexamethylphosphoramide (HMPA) (3.0–5.0 mL) and the bromoalkane (7.7–11.5 mmol) were added dropwise to the reaction mixture while maintaining the temperature at –78°C. After 24 h, the reaction mixture was worked up by pouring into a large volume of water, and extracting with diethyl ether (2 × 20 mL). The organic layer was washed with brine (1 × 20 mL) before drying ($MgSO_4$). Filtration, rotoevaporation of the solvent, and fractional distillation afforded the monoalkylated diynes **2a**–**2c** in 21–47% yields after purification by Kugel-Rohr distillation (60–100°C and 3 mm Hg) of the impurities.

(i) 1,8-Pentadecadiyne (***2b***). 1,8-Pentadecadiyne (**2b**) was obtained in a 21% yield as a viscous oil from the reaction of 1.22 mL of 1,8-nonadiyne (1.00 g, 8.32 mmol) and 1.16 mL of 1-bromohexane (1.37 g, 8.32 mmol) according to the general procedure described above. IR (neat) ν_{max} 3311, 2932, 2859, 2118, 1463, 1332, 1192, 1100, 629 cm^{-1}; ^1H NMR ($CDCl_3$, 500 MHz) δ 2.19 (2H, *dt*, *J* = 2.6 and 6.9 Hz, H-10), 2.13 (4H, m, H-3, H-7), 1.93 (1H, *t*, *J* = 2.6 Hz, H-1), 1.57–1.24 (14H, m, CH_2), 0.88 (3H, *t*, *J* = 7.0 Hz, H-15); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 84.53 (*s*, C-2), 80.48 (*s*), 79.84 (*s*), 68.15 (*d*, C-1), 31.36 (*t*, C-13), 29.10 (*t*), 28.61 (*t*), 28.53 (*t*), 28.04 (*t*), 27.95 (*t*), 22.56 (*t*, C-14), 18.73 (*t*), 18.69 (*t*), 18.33 (*t*), 14.04 (*q*, C-15); GC–MS *m/z* (relative intensity) M^+ 204 (0.1), 189 (1), 175 (4), 161 (4), 147 (14), 133 (28), 119 (32), 107 (11), 105 (54), 95 (13), 91 ($C_7H_7^+$, 100), 81 (30), 79 (61), 67 (51), 55 (31).

(*ii*) *1,5-Pentadecadiyne* (***2a***). 1,5-Pentadecadiyne (**2a**) was obtained in a 40% yield as a viscous oil from the reaction of 2.5 mL of 1,5-hexadiyne (1.00 g, 12.80 mmol) and 2.2 mL of 1-bromononane (2.38 g, 11.50 mmol) according to the general procedure described above. IR (neat) ν_{max} 3313, 2926, 2855, 2122, 1466, 1338, 1257, 635 cm^{-1}; ^1H NMR ($CDCl_3$, 500 MHz) δ 2.38 (4H, *m*, H-3, H-4), 2.14 (2H, *brt*, *J* = 7.0 Hz, H-7), 2.00 (1H, *t*, *J* = 2.0 Hz, H-1), 1.52–1.27 (14H, *m*, CH_2), 0.88 (3H, *t*, *J* = 6.9 Hz, H-15); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 83.11 (*s*, C-2), 81.61 (*s*), 78.09 (*s*), 68.94 (*d*, C-1), 31.89 (*t*, C-13), 29.50 (*t*), 29.28 (*t*), 29.16 (*t*), 28.97 (*t*), 28.83 (*t*), 22.67 (*t*, C-14), 19.18 (*t*), 18.93 (*t*), 18.71 (*t*), 14.09 (*q*, C-15); GC–MS *m/z* (relative intensity) M^+ 204 (0.1), 161 (1), 147 (3), 133 (13), 119 (19), 109 (6), 105 (31), 95 (16), 91 ($C_7H_7^+$, 100), 81 (22), 79 (31), 67 (32), 65 (20), 55 (29).

(*iii*) *1,5-Octadecadiyne* (***2c***). 1,5-Octadecadiyne (**2c**) was obtained as a viscous oil in a 47% yield from the reaction of 2.5 mL of 1,5-hexadiyne (2.00 g, 12.80 mmol) and 1.8 mL of 1-bromododecane (1.87 g, 7.70 mmol) according to the general procedure described above. IR (neat) ν_{max} 3313, 2925, 2854, 2122, 1466, 1338, 1257, 635 cm^{-1}; ^1H NMR ($CDCl_3$, 500 MHz) δ 2.38 (4H, *m*, H-3, H-4), 2.14 (2H, *brt*, *J* = 6.9 Hz, H-7), 2.00 (1H, *m*, H-1), 1.55–1.26 (20H, *m*, CH_2), 0.88 (3H, *t*, *J* = 6.8 Hz, H-18); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 83.11 (*s*, C-2), 81.62 (*s*), 78.09 (*s*), 68.93 (*d*, C-1), 31.92 (*t*, C-16), 29.67 (*t*), 29.64 (*t*), 29.63 (*t*), 29.55 (*t*), 29.35 (*t*), 29.16 (*t*), 28.97 (*t*), 28.83 (*t*), 22.68 (*t*, C-17), 19.18 (*t*), 18.93 (*t*), 18.71 (*t*), 14.10 (*q*, C-18); GC–MS *m/z* (relative intensity) M^+ 246 (0.1), 175 (1), 161 (2), 147 (8), 133 (27), 119 (27), 105 (38), 95 (16), 91 ($C_7H_7^+$, 100), 81 (20), 79 (35), 67 (28), 65 (24), 55 (29).

General procedure for the carboxylation of the alkylated diynes. To a stirred solution of the alkylated diynes (**2a**–**2c**, 1.7–4.6 mmol) in dry THF (17–46 mL), *n*-Buli (2.5 M, 2.6–7.2 mmol) in dry hexane (1–3 mL) was added dropwise while keeping the temperature approximately at –78°C. After 45 min the reaction mixture was treated with dry CO_2 (by passing the CO_2 through sulfuric acid) and left stirring for 24 h. The reaction mixture was then worked up by pouring into a large volume of a saturated solution of ammonium chloride followed by extraction with diethyl ether (3 × 20 mL). Rotoevaporation of the solvent afforded the diynoic acids **3a**–**3c** in 28–52% yields

after purification by Kugel-Rohr distillation (60–100°C and 3 mm Hg) of the impurities. The higher yield (52%) was obtained for 2,9-hexadecadiynoic acid (**3b**).

*(i) 2,9-Hexadecadiynoic acid (**3b**).* 2,9-Hexadecadiynoic acid (**3b**) was obtained as an oil in a 52% yield from the reaction of 1,8-pentadecadiyne (0.35 g, 1.70 mmol) and excess dry CO_2 (by passing the CO_2 through sulfuric acid) according to the general procedure described above. IR (neat) ν_{max} 3400–2900 (*br*), 2932, 2859, 2238, 1688, 1462, 1410, 1332, 1279, 1076 cm^{-1}; ^1H NMR ($CDCl_3$, 500 MHz) δ 2.36 (2H, *t*, *J* = 7.1 Hz, H-4), 2.14 (4H, *m*, H-8, H-11), 1.62–1.23 (14H, *m*, CH_2), 0.88 (3H, *t*, *J* = 7.0 Hz, H-16); ^{13}C NMR ($CDCl_3$,125 MHz) δ 157.08 (*s*, C-1), 92.01 (*s*, C-3), 81.24 (*s*), 80.71 (*s*), 72.69 (*s*, C-2), 31.35 (*t*, C-14), 29.08 (*t*), 28.54 (*t*), 28.43 (*t*), 27.96 (*t*), 26.98 (*t*), 22.56 (*t*, C-15), 18.72 (*t*), 18.69 (*t*), 18.55 (*t*), 14.04 (*q*, C-16).

*(ii) 2,6-Hexadecadiynoic acid (**3a**).* 2,6-Hexadecadiynoic acid (**3a**) was obtained as a white solid in a 45% yield from the reaction of 1,5-pentadecadiyne (0.94 g, 4.60 mmol) and excess dry CO_2 (by passing the CO_2 through sulfuric acid) according to the general procedure described above. M.p. 48–50°C, IR (neat) ν_{max} 3400–2900 (*br*), 2953, 2915, 2848, 2246, 1674, 1469, 1425, 1300, 1276, 1075, 890, 608 cm^{-1}; ^1H NMR ($CDCl_3$, 500 MHz,) δ 2.54 (2H, *brt*, *J* = 7.3 Hz, H-4), 2.44 (2H, *m*, H-5), 2.14 (2H, *tt*, *J* = 2.2 and 7.1 Hz, H-8), 1.47 (2H, *m*, H-9), 1.40–1.27 (12H, *m*, CH_2), 0.88 (3H, *t*, *J* = 6.9 Hz, H-16); ^{13}C NMR ($CDCl_3$, 125 MHz) δ 156.58 (*s*, C-1), 90.10 (*s*, C-3), 82.44 (*s*), 77.10 (*s*), 73.14 (*s*, C-2), 31.83 (*t*, C-14), 29.48 (*t*), 29.29 (*t*), 29.15 (*t*), 28.86 (*t*), 28.83 (*t*), 22.67 (*t*, C-15), 19.51 (*t*, C-4), 18.67 (*t*, C-8), 17.94 (*t*, C-5), 14.08 (*q*, C-16). Anal. calcd. for $C_{16}H_{24}O_2$: C, 77.38%; H, 9.74%. Found: C, 76.17%; H, 10.19%.

*(iii) 2,6-Nonadecadiynoic acid (**3c**).* 2,6-Nonadecadiynoic acid (**3c**) was obtained as a white solid in a 28% yield from the reaction of 1,5-octadecadiyne (0.89 g, 3.60 mmol) and excess dry CO_2 (by bubbling the CO_2 through sulfuric acid) according to the general procedure described above. M.p. 62–64°C, IR (neat) ν_{max} 3400–2900 (*br*), 2953, 2916, 2848, 2245, 1671, 1422, 1280, 912, 720 cm^{-1}; ^1H NMR ($CDCl_3$, 500 MHz) δ 2.54 (2H, *brt*, *J* = 7.4 Hz, H-4), 2.44 (2H, *m*, H-5), 2.14 (2H, *tt*, *J* = 2.3 and 7.1 Hz, H-8), 1.47 (2H, *m*, H-9), 1.38–1.25 (18H, *m*, CH_2), 0.88 (3H, *t*, *J* = 6.9 Hz, H-19); ^{13}C NMR ($CDCl_3$, 75 MHz) δ 156.96 (*s*, C-1), 90.33 (*s*, C-3), 82.44 (*s*), 77.21 (*s*), 73.06 (*s*, C-2), 31.91 (*t*, C-17), 29.64 (*t*), 29.53 (*t*), 29.35 (*t*), 29.14 (*t*), 28.84 (*t*), 22.68 (*t*, C-18), 19.49 (*t*, C-4), 18.66 (*t*, C-8), 17.91 (*t*, C-5), 14.11 (*q*, C-19). Anal. calcd. for $C_{19}H_{30}O_2$: C, 78.57%; H, 10.41%. Found: C, 77.14%; H, 10.40%.

RESULTS AND DISCUSSION

Seven acetylenic FA were synthesized and evaluated for antifungal activities against *C. albicans* and *C. neoformans*. The acetylenic FA 2-hexadecynoic acid, 5-hexadecynoic acid, 9-hexadecynoic acid, and 6-nonadecynoic acid were synthesized according to the previously described procedures (1,8,15). Despite the fact that 2,6-octadecadiynoic acid has been previously synthesized (10–11), there are no reported syntheses for acids **3a**–**3c**. Therefore, a simple synthetic methodology for the preparation of novel FA **3a**–**3c** was developed based on two consecutive acetylide coupling reactions.

The synthesis of the dimethylene-interrupted 2,6-hexadecadiynoic acid (**3a**) and 2,6-nonadecadiynoic acid (**3c**) was conveniently accomplished using 1,5-hexadiyne (50% in pentane) as the starting material (Scheme 1). In the preparation of **3a**, 1,5-hexadiyne was coupled with 1-bromononane using *n*-BuLi in THF/HMPA at –78°C, which afforded 1,5-pentadecadiyne (**2a**) in a 40% yield. Likewise, for the synthesis of acid **3c**, 1,5-hexadiyne was coupled with 1-bromododecane using the same acetylide coupling conditions, which afforded 1,5-octadecadiyne (**2c**) in a 47% yield after final purification (Scheme 1). Coupling of the lithium acetylides of 1,5-pentadecadiyne (**2a**) or 1,5-octadecadiyne (**2c**) with carbon dioxide and subsequent protonation with ammonium chloride afforded 2,6-hexadecadiynoic acid (**3a**) or 2,6-nonadecadiynoic acid (**3c**) in 28–45% yields after final purification (Scheme 1). The overall yields for these two two-step syntheses ranged between 13 and 18%.

DMSO	>5,000	>5,000	>5,000

[a]The results are the average of three separate experiments. SDB, Sabourand dextrose broth; FLC, fluconazole; AMB, amphotericin B.

The preparation of 2,9-hexadecadiynoic acid (**3b**) followed a similar synthetic strategy, with the exception that this synthesis started with the 1,8-nonadiyne. The diyne was coupled with 1-bromohexane using again *n*-BuLi in THF/HMPA at –78°C, which afforded 1,8-pentadecadiyne (**2b**) in a 21% yield after final purification. Final coupling of the lithium acetylide of 1,8-pentadecadiyne (**2b**) with carbon dioxide and subsequent protonation with ammonium chloride afforded the desired 2,9-hexadecadiynoic acid (**3b**) in a 52% yield after final purification (Scheme 1). The overall yield for this two-step synthesis was 11%.

The antifungal activity of the synthesized acetylenic FA against *Candida albicans* strains ATCC 14053 and ATCC 60193, and *Cryptococcus neoformans* ATCC 66031 in SDB were determined using a modified method of the National Committee for Clinical Laboratory Standards (NCCLS) as described by Galgiani and the more recent NCCLS M27-A microdilution methods as described previously (12–13) (Table 1). AMB and FLC were used as positive controls. Among the monoynoic FA, 2-hexadecynoic acid exhibited the best MIC values against FLC-resistant *C. albicans* ATCC 14053 and ATCC 60193 strains; these MIC values were 9.4 and 100 μM, respectively. However, as we have previously reported (8), 6-nonadecynoic acid showed the best MIC value (<4.3 μM) against *C. neoformans* ATCC 66031, but it was not very effective against the FLC-resistant *C. albicans* strains studied herein (8). Therefore, introduction of a triple bond at either C-2 or C-6 in the alkyl chain was effective in increasing the fungitoxicity of the FA. However, a triple bond at either C-5 or C-9 in the alkyl chain was not particularly effective in increasing the fungitoxicity of the FA.

Among the studied diynoic FA, 2,6-hexadecadiynoic acid (**3a**) displayed the best MIC values against both FLC-resistant *C. albicans* strains, ATCC 14053 and ATCC 60193, with MIC values of 11.5 μM. However, 2,6-nonadecadiynoic acid (**3c**) displayed the best MIC value (<5.0 μM) among the diynoic acids against *C. neoformans* ATCC 66031, but it displayed modest activity against the studied FLC-resistant *C. albicans* strains, with MIC values between 20 and 80 μM (Table 1). A comparison of the bioactivity of **3a** with that of the 2-hexadecynoic acid reveals that introduction of a second triple bond at C-6 increases the fungitoxicity of the acid toward *C. albicans* ATCC 60193 (MIC = 11.5 μM) approximately 9-fold compared with 2-hexadecynoic acid (MIC = 100 μM). Therefore, the diynoic acid **3a** has the potential of displaying a broader antifungal profile than the parent 2-hexadecynoic acid.

The acid 2,9-hexadecadiynoic acid (**3b**) was also studied, and it was not particularly effective against the FLC-resistant *C. albicans* strains studied herein, but it displayed fungitoxicity against *C. neoformans* ATCC 66031 with a MIC of < 5.8 μM. A comparison of the bioactivity of **3b** with that of the 9-hexadecynoic acid reveals that introduction of a second triple bond at C-2 increases the fungitoxicity of the parent 9-hexadecynoic acid against the three fungal strains studied, but the bioactivity of **3b** was still poor as compared with that of either **3a** or **3c**.

In order to determine the selectivity of the 2,6-hexadecadiynoic acid (**3a**) toward fungi (eukaryotic pathogens) vs. bacteria we chose to explore the antimycobacterial activity of both **3a** and 2-hexadecynoic acid toward *Mycobacterium tuberculosis* $H_{37}Rv$ following a procedure previously described (16). We decided on *M. tuberculosis* because there is a recent literature report indicating that 2-hexadecynoic acid can be toxic (MIC ~ 10–20 μM in Sauton's medium) to mycobacteria by the accumulation of two metabolites, specifically, 3-ketohexadecanoic acid, which blocks FA biosynthesis, and 3-hexadecynoic acid, an inhibitor of FA β-oxidation

TABLE 2
MIC of 2,6-Hexadecadiynoic Acid and 2-Hexadecynoic Acid Against *Mycobacterium tuberculosis* $H_{37}Rv$[a]

Compound	MIC (μM)	
	MABA	LORA
2,6-Hexadecadiynoic (**3a**)	145	>300
2-Hexadecynoic	141	>300
Rifampin	0.08	1.5

[a]MABA, microplate alamar blue assay; LORA, low oxygen recovery assay.

(17). 2-Hexadecynoic acid, therefore, can inhibit mycolic acid biosynthesis, FA biosynthesis, and FA degradation (β-oxidation) pathways of importance for mycobacteria (17).

Our antimycobacterial results are shown in Table 2. Two assays were used to study the antimycobacterial activity of the acetylenic FA: the microplate alamar blue assay (MABA) and the low oxygen recovery assay (LORA). The MABA is the "normal" MIC determination against replicating *M. tuberculosis* under aerobic conditions for 8 d. On the other hand, the LORA utilizes *M. tuberculosis* under anaerobic nonreplicating conditions for 11 d. As can be seen from Table 2, both acetylenic FA displayed similar MIC of around 140–145 μM (in Middlebrook 7H12 medium) against *M. tuberculosis* using the MABA assay, but also both acids were not inhibitory to nonreplicating and persistent *M. tuberculosis*, as determined by the LORA assay (16). From these experiments we can conclude that the additional Δ6 triple bond in **3a** does not help in increasing its antimycobacterial activity as compared with the 2-hexadecynoic acid, a fact that supports its postulated mechanism of action (17). However, it is evident that **3a** is a better antifungal agent than antimycobacterial agent due to its specificity toward fungal cells, because the additional Δ6 triple bond in **3a** makes a difference in the antifungal activity.

With respect to the toxicity of the 2-alkynoic acids it was recently demonstrated that 2-alkynoic acids could be used specifically against bacteria without toxicity to their host due to the fact that the FASI complex in microsomal systems is not inhibited by the 2-alkynoic acids (17). In addition, it was previously reported that despite the fact that 2-hexadecynoic acid inhibits the growth of HeLa cells, the simultaneous addition of palmitic acid to the culture medium reverses the growth inhibition observed in HeLa cells, thus implying that toxicity would not occur in animals consuming a normal diet (3).

Further experiments are required to determine the mechanism of antifungal activities by these novel 2,6-diynoic FA. One possible mechanism of action for the 2,6-diynoic FA is isomerization to a 2,3-allene (as the CoA derivative) and subsequent inhibition of the biosynthesis of the fungal FA as shown for the 2-hexadecynoic acid in intact animals (4). Likewise, also analogous to the suspected mechanism of action for 6-nonadecynoic acid, the 2,6-diynoic FA could also inhibit sphingolipid biosynthesis in these fungi (7). Both mechanisms of lipid biosynthesis inhibition could also be operative, thus explaining the enhanced activity of **3a**. Compound **3a** has the potential for further evaluation in topical formulations for the treatment of fungal infections, as an antifungal in wound dressings, or as a preservative in skin and hair care products.

ABSTRACT: The additional mass associated with ^{13}C in metabolic tracers may interfere with their metabolism. The comparative isomerization and biohydrogenation of oleic, [1-^{13}C]oleic, and [U-^{13}C]oleic acids by mixed ruminal microbes was used to evaluate this effect. The percent of stearic, *cis*-14 and -15, and *trans*-9 to -16 18:1 originating from oleic acid was decreased for [U-^{13}C]oleic acid compared with [1-^{13}C]oleic acid. Conversely, microbial utilization of [U-^{13}C]oleic acid resulted in more of the ^{13}C label in *cis*-9 18:1 compared with [1-^{13}C]oleic acid (53.7 vs. 40.1%). The isomerization and biohydrogenation of oleic acid by ruminal microbes is affected by the mass of the labeled tracer.

Paper no. L9963 in *Lipids 41*, 513–517 (May 2006).

Metabolic studies often use chemical tracers to evaluate *in vivo* events. A common method to create metabolic tracers is to replace an atom of the tracee molecule with a radioactive or stable isotope of that atom. These types of isotopes are less abundant in nature and are therefore easily distinguished from the isotope that is naturally more abundant (1). A summary of several studies has established that the use of tracer and higher doses of stable isotopes *in vivo* present no identifiable risk to human subjects (2). Therefore, *in vivo* measurements of FA metabolism may be obtained from the analysis of ^{13}C-labeled FA. Today, the use of stable isotopes to evaluate FA metabolism in humans is not uncommon (3,4). However, there is concern that not all isotopically labeled molecules are utilized equally. For example, different isotopically labeled glucose molecules are metabolized to varying extents (5,6). Furthermore, position and number of ^{14}C in labeled FA has been found to impact the extent of β-oxidation (7).

Previous research (8) has illustrated that [1-^{13}C]oleic acid is isomerized and biohydrogenated by ruminal microbes. Using these results as a model, it was hypothesized that there was no difference in the utilization of unlabeled oleic, [1-^{13}C]oleic, and [U-^{13}C]oleic acids by ruminal microbes despite the increased mass of the ^{13}C-labeled oleic acid molecules. Mixed ruminal microbes are necessary to carry out all possible isomerization and biohydrogenation processes (9). Additionally, ruminal microbes do not catabolize, elongate, or desaturate external FA to any great extent (10). Therefore, this model will only focus on differences in the isomerization and biohydrogenation of the treatment FA of differing masses without altering the isotope distribution in other metabolic pools.

EXPERIMENTAL PROCEDURES

Reagent grade oleic acid (97%) was purchased from Acros Organics (Geel, Belgium). [1-^{13}C]Oleic acid (99%) and [U-^{13}C]oleic acid (99%) were purchased from Cambridge Isotope Laboratories, Inc. (Andover, MA). All solvents were HPLC or GC grade. Dimethyl disulfide (DMDS) was purchased from Sigma-Aldrich Chemical Company (St. Louis, MO). Anhydrous ethyl ether, iodine, and sodium thiosulfate were purchased from Fisher Scientific (Pittsburgh, PA).

Microbial biohydrogenation of oleic acid was studied in cultures of microbes taken from the rumen of cattle as previously described (8). Cultures containing unlabeled, [1-^{13}C]-labeled, or [U-^{13}C]-labeled oleic acid were run in triplicate at 39°C under anaerobic conditions. Samples (5 mL) were taken from each culture at 0 and 48 h and immediately frozen. The samples were freeze-dried and then methylated using a two-step sodium methoxide and methanolic HCl procedure (11).

DMDS adducts of the FAME were prepared (8). The FAME and DMDS were analyzed by GC-MS (Agilent Technologies 6890N GC equipped with a 30 m × 0.25 mm with 0.2-μm film DB-225ms capillary column [Agilent J&W Scientific] and a 5973 inert series quadrupole mass-selective detector controlled by MSD ChemStation software [D.01.02.16] in the scan mode). For the FAME samples, column temperature was programmed from 50°C to 220°C at a rate of 6°C/min and held for 15 min. For the DMDS samples, column temperature was programmed from 195°C to 230°C at a rate of 0.5°C/min. Additionally, FAME were analyzed on a GC to determine the FA profile (12).

In order to measure the change in the ratio of ^{13}C to ^{12}C, the tracer (^{13}C) to tracee (^{12}C) ratio (TTR) for each FA was calculated from the mass abundance of the ^{13}C ($M + n$) and ^{12}C (M)

Abbreviations: DMDS, dimethyl disulfide; E, enrichment; TTR, tracer to tracee ratio.

fragments using the equation TTR = $(M + n)/M$, where n is the number of ^{13}C atoms present in the fragment (1). In order to account for the natural levels of ^{13}C, the average TTR of samples taken from the unlabeled oleic acid cultures was subtracted from the TTR of samples from the ^{13}C-labeled oleic acid cultures, and the result was then adjusted for spectrum skew (1).

ANOVA using the GLM procedure of SAS (v. 9.1, SAS Institute, Inc., Cary, NC) was utilized to evaluate the ^{13}C enrichments at 0 and 48 h. Also, in an effort to evaluate the response to isotopic label, the degrees of freedom were partitioned into linear contrasts. All results are expressed as least square means. Additionally, ANOVA with the main effect of time on the percentage of each FA originating from oleic acid at 48 h and the distribution of the ^{13}C label at 48 h was evaluated for the [1-^{13}C]oleic and [U-^{13}C]oleic acid treatments. Least square means for each FA by treatment were analyzed for differences using Fisher's least significant difference with significance declared at $P \leq 0.05$.

RESULTS

Oleic acid was isomerized to a variety of *cis*- and *trans*-18:1 isomers and biohydrogenated to stearic acid (18:0) at the end of 48 h (Fig. 1). The other sources of oleic acid and its isomerization and biohydrogenation products in the microbial cultures (from the rumen inoculum and hay substrate) were minimal, and only linoleic (18:2 n-6) and linolenic (18:3 n-3) acids were considered in the data analysis. As expected, no enrichment was detected at either 0 or 48 h in the unlabeled oleic acid treatment. Excluding the minor contamination of [1-^{13}C]*trans*-9 18:1 (<1%) in the [1-^{13}C]oleic acid treatment and [U-^{13}C]*cis*-11 18:1 (5.5%) in the [U-^{13}C]oleic acid treatment, only oleic acid was enriched at 0 h in these two treatments (data not shown). Enrichment of *cis*-11 18:1 only occurred in the [U-^{13}C]oleic acid treatment. Therefore, only the change in weight percentage of *cis*-11 18:1 was evaluated.

The percentage of 18:0 and 18:1 isomers originating from oleic acid at 48 h was also evaluated. Excluding *cis*-9 and *cis*-

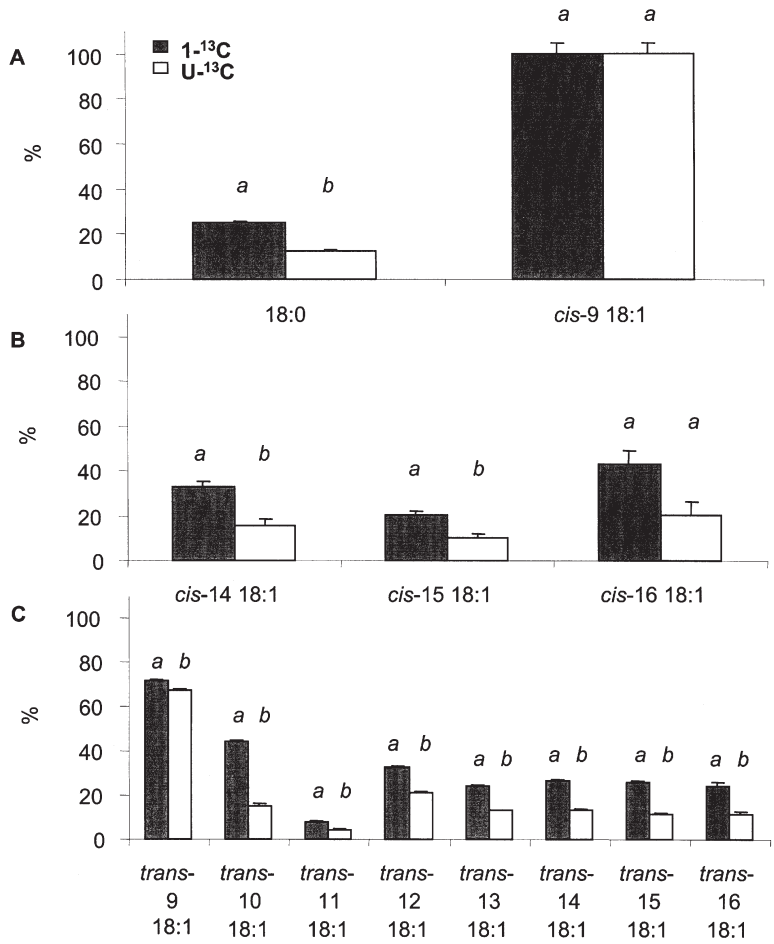

FIG. 1. Percent of (A) stearic and oleic, (B) *cis*-18:1, and (C) *trans*-18:1 FA originating from stably labeled oleic acid in microbial cultures. Determination occurred 48 h after [1-^{13}C]oleic (1-^{13}C) or [U-^{13}C]oleic (U-^{13}C) acid was added (25 mg per culture) to flasks. Values are mean ± SEM ($n = 3$). The SEM for 18:0 and *trans*-13 18:1 are too small to be viewed on figure. Columns with different letters differ ($P < 0.05$) within each FA variable.

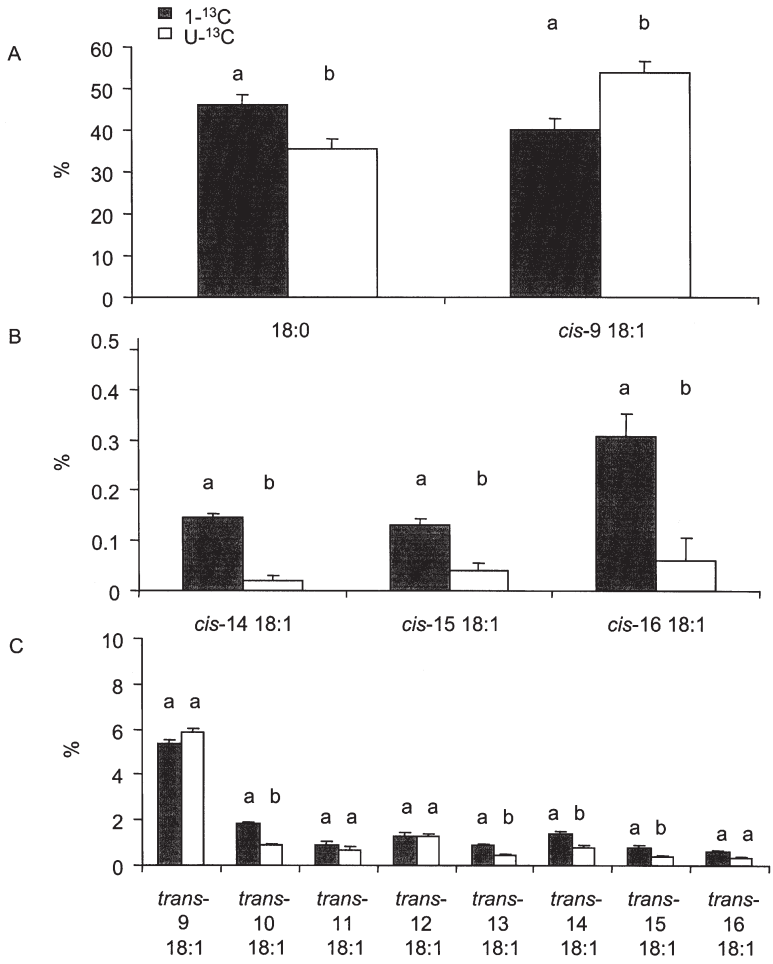

FIG. 2. Relative distribution of ^{13}C label from oleic acid in (A) stearic and oleic, (B) *cis*-18:1, and (C) *trans*-18:1 FA in microbial cultures 48 h after addition of [1-^{13}C]oleic (1-^{13}C) or [U-^{13}C]oleic (U-^{13}C) acid (25 mg per culture) to flasks. Values are mean ± SEM (n = 3). Columns with different letters differ ($P < 0.05$) within each FA variable.

16 18:1 isomers, there was a lower percentage of all other FA originating from oleic acid at 48 h for the [U-^{13}C]oleic acid treatment compared with the [1-^{13}C]oleic acid treatment (Fig. 1). Furthermore, when the overall distribution of the ^{13}C label was examined, treatment differences were observed (Fig. 2). A greater percentage of label remained in *cis*-9 18:1 in the [U-^{13}C]oleic acid treatment, whereas more of the label was detected in 18:0 and 18:1 isomers (*cis*-14, *cis*-15, *cis*-16, *trans*-10, *trans*-13, *trans*-14, and *trans*-15) in the [1-^{13}C]oleic acid treatment.

At 48 h, the weight percentage of 18:0 and most *cis*- and *trans*-18:1 FA increased (Table 1). The starting proportions of 18:0 in the cultures were variable among cultures; but no significant effect of isotopic label was detected. The *cis*-9 18:1 (oleic acid) weight percentage decreased over time; however, this was only a tendency when the singly and uniformly labeled oleic acid treatments were compared. The variation resulting from the contamination of the [U-^{13}C]oleic acid treatment with [U-^{13}C] *cis*-11 18:1 resulted in no differences observed when the unlabeled treatment was compared with the isotopically labeled treatments. However, when the isotopically labeled treatments were compared, differences in the concentration of [U-^{13}C]*cis*-11 18:1 were detected. Furthermore, differences due to addition of isotopic label and number of isotopes resulted in changes in the concentrations of several of the *cis*- and *trans*-18:1 FA (Table 1).

DISCUSSION

In our experiment, oleic acid was converted to stearic acid and a multitude of *cis*- and *trans*-18:1 isomers as previously described (8). Despite contamination of the ^{13}C FA sources, the formation of *trans*-18:1 monoenes from oleic acid is in agreement with previous research (8). It is unknown whether the *cis*- and *trans*-18:1 monoenes that are formed from oleic acid are intermediates or if they are end products of microbial manipulation of oleic acid. However, *trans*-9 18:1 was extensively intra-isomerized to other *cis*- and *trans*-18:1 and hydrogenated to stearic acid (13). Therefore, isomerization of oleic acid may be followed by further isomerization or hydrogenation to stearic acid.

TABLE 1
Proportions of Stearic Acid (18:0) and 18:1 FA Detected at 0 and 48 h when Oleic, [1-^{13}C]Oleic, or [U-^{13}C]Oleic Acids Were Added (25 mg) to Microbial Cultures[a]

[a]The quantity of each FA is given as mg/100 mg of the FA presented. Values are the mean of three replicates at each time.
[b]1, oleic acid vs. the mean of [1-^{13}C]oleic acid and [U-^{13}C]oleic acid treatments; 2, [1-^{13}C]oleic acid vs. [U-^{13}C]oleic acid treatment; NS, nonsignificant.

Uniform, multiple, or single isotopically labeled FA are used to examine FA metabolism *in vivo* in humans and animals. Early milk fat researchers used isotopically labeled FA to examine the contribution of dietary FA to milk fat (14,15). Additionally, ^{2}H-labeled FA have been used to investigate the flow of FA through various plasma lipid classes in lactating women (16) and to determine the impact of FA position and structure of dietary triglycerides on absorption (17). However, there is limited research on the comparative utilization of stably labeled lipid and FA tracers of varying mass. When [23,24,25,26,27-^{13}C]cholesterol, [26,26,26,27,27,27-^{2}H]cholesterol, and [4-^{14}C]cholesterol were given intravenously and orally to healthy adult men and women, no differences in metabolism were observed (18). Similarly, when sample dilution correction factors were applied, no differences were detected in utilization of [17,17,18,18,18-^{2}H]linolenic, [U-^{13}C]linolenic, [17,17,18,18,18-^{2}H]linoleic, and [U-^{13}C]linoleic acids after simultaneous oral administration to rats (19). However, in isolated mitochondria, β-oxidation of [16-^{14}C]palmitic and [U-^{14}C]palmitic acids was reduced compared with [1-^{14}C]palmitic acid (7). Using mixed microbial cultures, slight differences were observed between the metabolism of unlabeled and isotopically labeled oleic acid. Furthermore, differences were also observed when singly or uniformly labeled oleic acid were compared (Table 1). These alterations in metabolism of isotopically labeled oleic acid by mixed ruminal microbes may be simply due to increases in the mass of the molecule or possibly due to some other isotope effect.

Despite differences in the extent of isomerization and biohydrogenation between the [1-^{13}C]oleic and [U-^{13}C]oleic acids, the same FA were enriched with ^{13}C. Additionally, the spectral shift associated with the use of [U-^{13}C]oleic acid is detected with less difficulty, as the mass fragments produced by MS analysis do not occur in the unlabeled oleic acid, but those produced by [1-^{13}C]oleic acid do occur. For example, the major spectral fragments 217 and 218 are used to identify FAME-DMDS derivatives of oleic and [1-^{13}C]oleic acids, respectively. Both of these fragments occur in the mass spectra of the FAME-DMDS derivative of unlabeled oleic acid. However, the major spectral fragment of [U-^{13}C]oleic acid is 226, which is a negligible fragment of oleic and [1-^{13}C]oleic acid. Furthermore, the detection of isotope discrimination may be trivial in mechanistic evaluations due to the relatively small differences observed. In the current study the entire FA pool is saturated with the labeled isotope, resulting in enrichment values of ^{13}C based on TTR calculations >100%. This large incorporation of labeled mass into the FA pool is not considered a tracer dose. For example, average *in vivo* measures of enrichment based on the TTR calculation in one study were <10% (12) when tracer doses of the labeled FA are used. Thus, there would be a considerable shift in the isotopic pool size being measured in the current study compared with other *in vivo* experiments.

The use of isotopically labeled FA has proven beneficial to research in lipid metabolism. The development of stable isotope tracers is necessary to safely study *in vivo* FA utilization in humans and other animals. However, researchers should consider the possible alterations in substrate utilization that result from some isotopically labeled compounds.

ABSTRACT: The *in vitro* relationship between human p53 DNA binding domain (p53 DBD) and FA was investigated. We found that saturated and monounsaturated long-chain FA inhibited the double-stranded DNA (dsDNA) binding activity of p53 DBD. The strongest inhibitors of saturated and unsaturated FA were docosanoic acid (22:0) and *cis*-12-heneicosenoic acid (21:1n-9), respectively. *n*-Octadecane, *trans*-unsaturated FA, and FAME had no influence on the binding activity of p53 DBD, showing that the FA structures such as one or no double bond of *cis* configuration, hydrocarbon chain of length C_{20} to C_{22}, and free carboxyl groups are important for the inhibition. The inhibitory effect of the R248A mutant of p53 DBD by saturated FA was as strong as that for wild-type p53 DBD. On the other hand, the inhibition of dsDNA binding activity of the same mutant by the *cis*-configuration of monounsaturated FA was weaker than that for the wild type. These results suggest that R248 in p53 DBD is important for binding to monounsaturated FA. This is the first report that long-chain FA act as a dsDNA binding inhibitor of p53, and it could be considered that FA in the cell membrane might regulate the activity of p53 for cell division, cell-cycle checkpoint, and tumor suppression.

Paper no. L9978 in *Lipids 41,* 521–527 (June 2006).

The tumor suppressor protein p53 (393 amino acids) is a transcription factor that functions to maintain the integrity of the genome (1). On its induction in response to DNA damage, p53 promotes cell-cycle arrest in the G1 phase (2) and apoptosis if DNA repair is not possible (3). The p53 gene encodes a protein with a central DNA binding domain (DBD) comprising residues 102–292, flanked by an N-terminal transactivation domain and a C-terminal tetramerization domain (4). The crystal structure of the core domain (i.e., p53 DBD) bound to DNA has been determined (5). The structure of the DNA binding domain consists of a large β-sandwich that acts as a scaffold for three loop-based elements that contact the DNA (5). Importantly, the residues most frequently mutated in cancers are all at or near the protein-DNA interface, and over two-thirds of the missense mutations are within the DNA binding loops (6). Although it is clear that tumorigenic p53-DBD mutations act by diminishing the DNA binding activity of p53 (7,8), the mechanisms are not fully understood.

We have been screening the products of microbial fermentation for compounds that inhibit the double-stranded DNA (dsDNA) binding activity of human p53-DBD, because the inhibitor can elucidate the structure and function of p53. Recently, we found an inhibitor from a basidiomycete (*Ganoderma lucidum*), a well-known FA, stearic acid (18:0). Subsequently, we investigated the effects of many commercially available FA on the activity of p53. We found that several FA interact with p53-DBD and strongly suppress the activity. In this paper, we discuss the effects of FA on the activity of p53. This study of FA may help to clarify the structure and function of p53-DBD.

EXPERIMENTAL PROCEDURES

Fatty acids. The following FA were purchased from Sigma (St. Louis, MO): saturated FA including hexadecanoic acid (palmitic acid, 16:0), octadecanoic acid (stearic acid, 18:0), nonadecanoic acid (19:0), eicosanoic acid (arachidic acid, 20:0), heneicosanoic acid (21:0), docosanoic acid (behenic acid, 22:0), tricosanoic acid (23:0), tetracosanoic acid (lignoceric acid, 24:0), hexacosanoic acid (26:0), methyl octadecanoate (methyl-18:0), and 12-hydroxy-octadecanoic acid (12-hydroxy-18:0), and unsaturated FA including *cis*-9-hexadecenoic acid (palmitoleic acid, 16:1n-7), *cis*-9-octadecenoic acid (oleic acid, 18:1n-9), *cis*-10-nonadecenoic acid (19:1n-9), *cis*-11-eicosenoic acid (gadoleic acid, 20:1n-9), *cis*-13-docosenoic acid (erucic acid, 22:1n-9), *cis*-14-tricosenoic acid (23:1n-9), *cis*-15-tetracosenoic acid (24:1n-9), *trans*-9-octadecenoic acid (elaidic acid, 18:1n-9), and 12-hydroxy-*cis*-9-octadecenoic acid (12-hydroxy-18:1n-9). *n*-Octadecane was also purchased from Sigma. *cis*-9,12-Octadecedienoic acid (linoleic acid, 18:2n-6), *cis*-9,12,15-octadecatrienoic acid (α-linolenic acid, 18:3n-3), *cis*-6,9,12,15-octadecatetraenoic acid (parinaric acid, 18:4n-3), and *cis*-12-heneicosenoic acid (21:1n-9) were obtained from Nu-Chek Prep Inc. (Elysian, MN). To avoid oxidation, these compounds were dissolved in DMSO and stored under nitrogen.

Materials. Supercoiled pBR322 plasmid dsDNA was obtained from Takara Bio Inc. (Kyoto, Japan). All other reagents

were of analytical grade and purchased from Nacalai Tesque (Kyoto, Japan).

Expression and purification of the human p53 DBD. The human p53-DNA binding domain (p53 DBD) gene (residues 92–292) was cloned into pET28b between *Nde*I and *Xho*I sites. The histidine-tagged protein was overexpressed in *Escherichia coli* strain BL21(DE3) harboring the expression plasmid constructed in our laboratory. The expression vector of the mutant protein (i.e., R248A) was constructed by a QuikChange site-directed mutagenesis kit (Stratagene, Ladolla, CA) and fully sequenced. The mutant protein of p53 DBD was overexpressed in *Escherichia coli* strain BL21(DE3) harboring the expression plasmid pET28b. After Ni-NTA column (Qiagen, Hilden, Germany) purification, following the procedure recommended by the manufacturer, the mutant proteins were purified on a heparin column (GE Health Care Bio-Sciences, Little Chalfant, UK) by elution with a concentration gradient of 0–1 M potassium chloride.

Gel mobility shift assay. The gel mobility shift assay was carried out as described by Casas-Finet *et al*. (9). The standard binding mixture (a final volume of 20 µl) contained 20 mM Tris-HCl, pH 7.5, 10% glycerol, 10% DMSO, 1 mM EDTA, 0.20 pmol pBR322 dsDNA (i.e., 870 pmol nucleotide), and 30.0 pmol (1.50 µM) human p53 DBD. The mixture was incubated for 20 min on ice. Samples were run on a 1.0% agarose gel in 0.1 M Tris-acetate, pH 8.3, containing 5 mM EDTA at 100 V for 1 h. The agarose gels were stained with ethidium bromide and dsDNA was visualized on a UV transilluminator. The gel mobility shift length of pBR322 dsDNA was measured with computer software (Zero-D scan, version 1.0, M&S Instruments Trading, Tokyo, Japan).

Surface plasmon resonance. Human p53 DBD and FA binding analyses were performed using a Biosensor BIAcore instrument (BIACORER X) (BIAcore, Uppsala, Sweden). CM5 research grade sensor chips (BIAcore) were used. All buffers were filtered before use. Human p53 DBD (25.5 kDa, 480 µg/ml, 30 µL, i.e., 565 pmol) in coupling buffer (10 mM sodium acetate, pH 4.7) was injected over a CM5 sensor chip at 20 µL/min to capture the protein to the carboxymethyl dextran matrix of the chip by NHS/EDC coupling reaction (60 µL of mix) as described (10). Unreacted *N*-hydroxysuccinimide ester groups were inactivated using 1 M ethanolamine-HCl (pH 8.0). This reaction immobilized about 5,000 response units (RU) of the protein. Binding analysis of FA was performed in running buffer including FA (5 mM potassium phosphate buffer (pH 7.0) and 10% DMSO) at a flow rate of 20 mL/min at 25°C. Kinetic parameters were determined using BIA evaluation 3.1 software.

Structural models of the complex. Molecular docking of human p53 DBD and FA was performed using the Affinity program within the Insight II software (Accelrys, San Diego, CA). The coordinates of human p53 DBD (Protein Data Bank (PDB) ID: 1TUP) were obtained from PDB. The initial position of FA was determined based on the result of the dsDNA gel mobility shift assay with the mutant p53 DBD and the protein surface of hydrophobicty. The calculation used a CVFF force field in the Discovery program (Accelrys).

RESULTS AND DISCUSSION

Analysis of the dsDNA binding activity of human p53 DBD. We first established the assay method of the dsDNA binding activity of human p53 DBD, which is the central region of p53, using agarose gel electrophoresis. As shown in Fig. 1A, 30.0 pmol of p53 DBD bound to pBR322 dsDNA, and the complex of p53DBD and dsDNA was performed, and the dsDNA stained with ethidium bromide was shifted to the

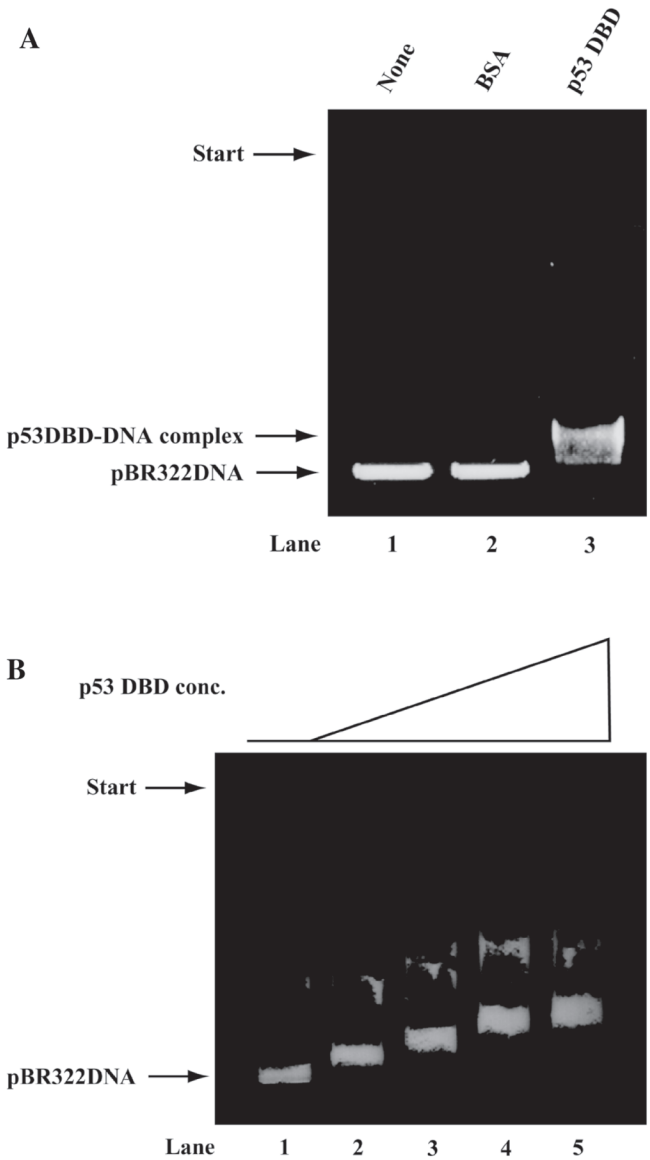

FIG. 1. The dsDNA binding activity of human p53 DBD. (A) Gel mobility shift assay of binding between pBR322 plasmid dsDNA (0.20 pmol; 870 pmol of nucleotide) and BSA (30.0 pmol, lane 2) or p53 DBD (30.0 pmol, lane 3). Lane 1 contained no proteins. (B) Gel mobility shift assay of binding between pBR322 dsDNA and p53 DBD. Lanes 1–5, purified p53 DBD at amounts of 0, 15.0, 30.0, 45.0, and 60.0 pmol, respectively. A photograph of an ethidium bromide-stained gel is shown.

upper side (lane 3). Because the same amount of BSA (bovine serum albumin) instead of p53 DBD did not shift at all (lane 2), dsDNA binding activity could occur selectively to a specific site on p53 DBD. The activity of p53 DBD was dose-dependent, and the distance of the stained and shifted band could be proportional to the dsDNA binding activity (Fig. 1B). We decided the activity by the shifted distances of the band, and 30.0 pmol of p53 DBD (i.e., 1.50 μM, lane 3) was used in the experiments below in this study.

Inhibitory effects of FA on the activity of human p53 DBD. As described earlier, the inhibitor of dsDNA binding activity of human p53 DBD was screened from the natural sources, and we found that a major FA, stearic acid (18:0), from a basidiomycete (*Ganoderma lucidum*), inhibited the activity. Since stearic acid is a C_{18} FA, inhibition of the activity of p53 DBD with commercially purchased C_{18} FA and related compounds was investigated (Fig. 2A). The 1.20 nmol (i.e., 60.0 μM) of the compound in the reaction mixture was 40-fold higher than that of the p53 DBD molecule (i.e., the amount of p53 DBD was 30.0 pmol). Stearic acid and oleic acid (*cis*-18:1n-9), which have a free-carboxyl group, inhibited the activity of p53 DBD, and the inhibitory effect of oleic acid was stronger than that of stearic acid. Other compounds such as *trans*-9-octadecenoic acid (elaidic acid: *trans*-18:1n-9), 12-hydroxy-octadecanoic acid (12-hydroxy-18:0), 12-hydroxy-*cis*-9-octadecenoic acid (12-hydroxy-18:19) and methyl octadecanoate (methyl-18:0) had no influence on the activity of p53 DBD, and the inhibition was less than 50%. Therefore, *trans*-configuration of the double bond, hydroxyl group and ester of the carboxyl group in C_{18} FA suggested the suppression of the inhibition.

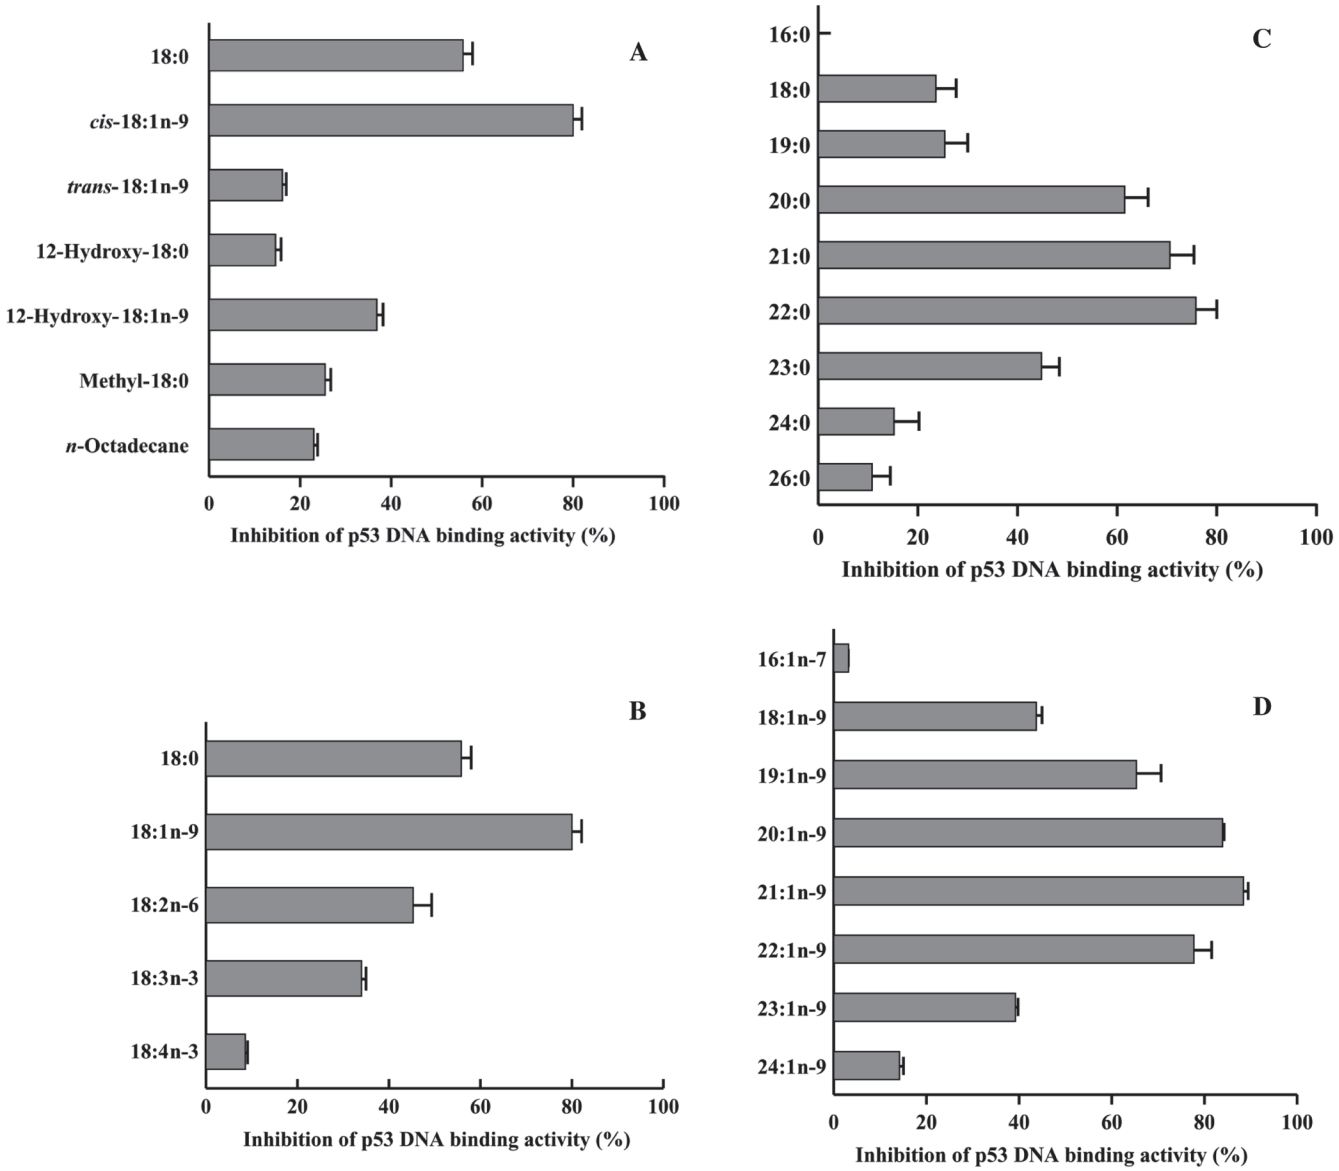

FIG. 2. Inhibitory effect of FA (1.20 nmol each) on the dsDNA binding activities of human p53 DBD. (A) C_{18} FA and related compounds, (B) C_{18} PUFA, (C) $C_{16\text{-}26}$ saturated FA, and (D) monounsaturated FA of *cis*-type (16:1 to 24:1). The dsDNA binding activity of p53 DBD (30.0 pmol) in the absence of FA was taken as 0%. Data are shown as the means ± SEM for four independent experiments.

As *n*-octadecane had no effect on the activity, the free carboxyl moiety of FA is important for the inhibition of the dsDNA binding activity of p53 DBD. Among the *cis*-configuration of polyunsaturated C_{18} FA (1.20 nmol each) tested, oleic acid had the strongest inhibitory activity, the second strongest inhibitor was stearic acid, and the weakest was parinaric acid (18:4n-3) (Fig. 2B). These results suggested that PUFA, which have two or more double bonds, did not influence the activity.

To know the inhibitory effects of the hydrocarbon chain length of FA, C_{16} to C_{26}-saturated FA were investigated. As shown in Fig. 2C, the FA (1.20 nmol each) with more than 50% inhibitory activity were eicosanoic acid (20:0), heneicosanoic acid (21:0) and docosanoic acid (22:0), and the strongest inhibitor was docosanoic acid. Among C_{16} to C_{24}-monounsaturated FA (*cis*-type), 1.20 nmol of four FA such as *cis*-10-nonadecenoic acid (19:1n-9), *cis*-11-eicosenoic acid (gadoleic acid: 20:1n-9), *cis*-12-heneicosenoic acid (21:1n-9) and *cis*-13-docosenoic acid (erucic acid: 22:1n-9) inhibited the activity more than 50%, and *cis*-12-heneicosenoic acid had the strongest activity of p53 DBD inhibition (Fig. 2D). It was considered that there are suitable hydrocarbon lengths of FA for inhibition; in particular, the lengths of saturated and monounsaturated FA were C_{20} to C_{22} and C_{19} to C_{22}, respectively. Therefore, we concentrated on the properties of docosanoic acid and *cis*-12-heneicosenoic acid, which are the strongest saturated and monounsaturated FA inhibitors, respectively, in the latter part of this study.

To determine whether the FA resulted in binding to DNA or p53 DBD, the interaction of FA with dsDNA was investigated based on the thermal transition of dsDNA with or without FA. The melting temperature (Tm) of dsDNA with an excess amount of docosanoic acid or *cis*-12-heneicosenoic acid (100 μM) was measured using a spectrophotometer equipped with a thermoelectric cell holder. In the concentration range used, no thermal transition of Tm was observed, whereas ethidium bromide used as a positive control, a typical intercalating compound, produced a clear thermal transition. These results indicated that these compounds did not intercalate to dsDNA, and FA might directly bind to p53 DBD and inhibit its activity.

Effects of reaction conditions on long-chain FA inhibition. To determine the effects of a non-ionic detergent on the binding of docosanoic acid, *cis*-12-heneicosenoic acid and p53 DBD, Nonidet P-40 (NP-40) was added to the reaction mixture at various concentrations. The inhibitory effect of *cis*-12-heneicosenoic acid in the ranges of 0.60 nmol (i.e., 30.0 μM) on p53 DBD had no influence with the addition of NP-40 (Fig. 3); however, the p53 DBD inhibitory effect of docosanoic acid at 0.60 nmol was significantly reversed by the addition of NP-40 to the reaction mixture. The inhibitory reversion by NP-40 was concentration dependent, suggesting that docosanoic acid interacts with the hydrophobic region of p53 DBD protein. These results also suggested that the molecular binding mechanism of *cis*-12-heneicosenoic acid–p53 DBD binding was different from that of docosanoic acid–p53 DBD.

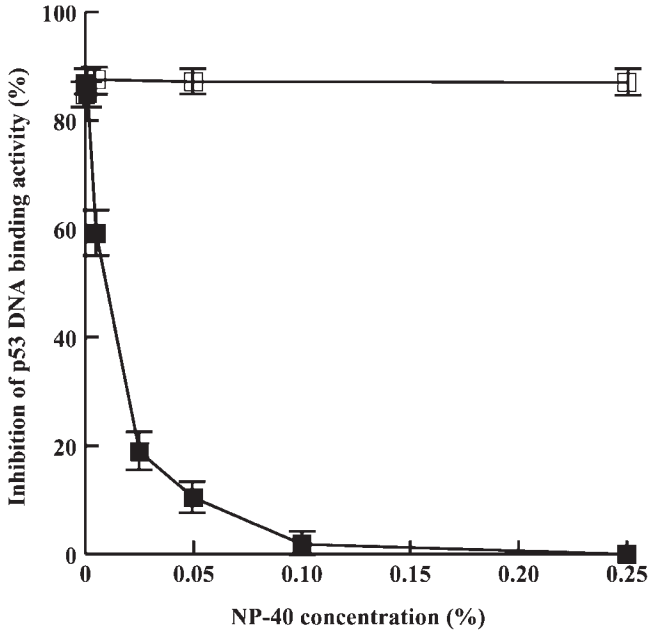

FIG. 3. Effect of detergents on the inhibition of human p53 DBD activities by FA. Nonidet P-40 (NP-40) was added to the reaction mixture at 0–0.25%. Docosanoic acid (22:0) (closed square) and *cis*-12-heneicosenoic acid (21:1n-9) (open square) were present at a concentration of 0.60 nmol. The dsDNA binding activity of p53 DBD (30.0 pmol) in the absence of FA was taken as 0%. Data are shown as the means ± SEM for three independent experiments.

We also tested whether an excess amount of a DNA analog, poly(rC) (2.00 pmol), or a protein, BSA (12.5 μM, 250 pmol), could prevent the inhibitory effects of FA. If FA bind to p53 DBD by non-specific adhesion, the addition of a nucleic acid and/or protein would be expected to reduce inhibitory activity. The fact that neither poly(rC) nor BSA influenced the inhibitory effects of FA suggests that the compound occurs selectively or binds to a specific site on p53 DBD and not to the nucleic acid.

Binding analysis of FA and human p53 DBD using surface plasmon resonance. To confirm the direct binding between FA and human p53 DBD, the kinetic parameters for docosanoic acid/*cis*-12-heneicosenoic acid and binding were determined using p53 DBD immobilized to the sensor chip in a BIAcore. Four different concentrations of docosanoic acid or *cis*-12-heneicosenoic acid (50 to 400 pmol, i.e., 1.25 to 10.0 μM) were used for the binding analysis. Because p53 DBD (565 pmol) was conjugated to the CM5 sensor chip, and then docosanoic acid or *cis*-12-heneicosenoic acid was added to the conjugated proteins, the response differences for the binding of docosanoic acid and *cis*-12-heneicosenoic acid to the protein were the same, approximately 200 RU (Fig. 4A and B). These FA dissociated very slowly from p53 DBD. The dissociation constants (K_D) of the binding of docosanoic acid and *cis*-12-heneicosenoic acid to the protein were determined to be 12.0 nM and 10.8 nM, respectively, from these data. The kinetic studies supported the suggestion that FA interact with p53 DBD directly.

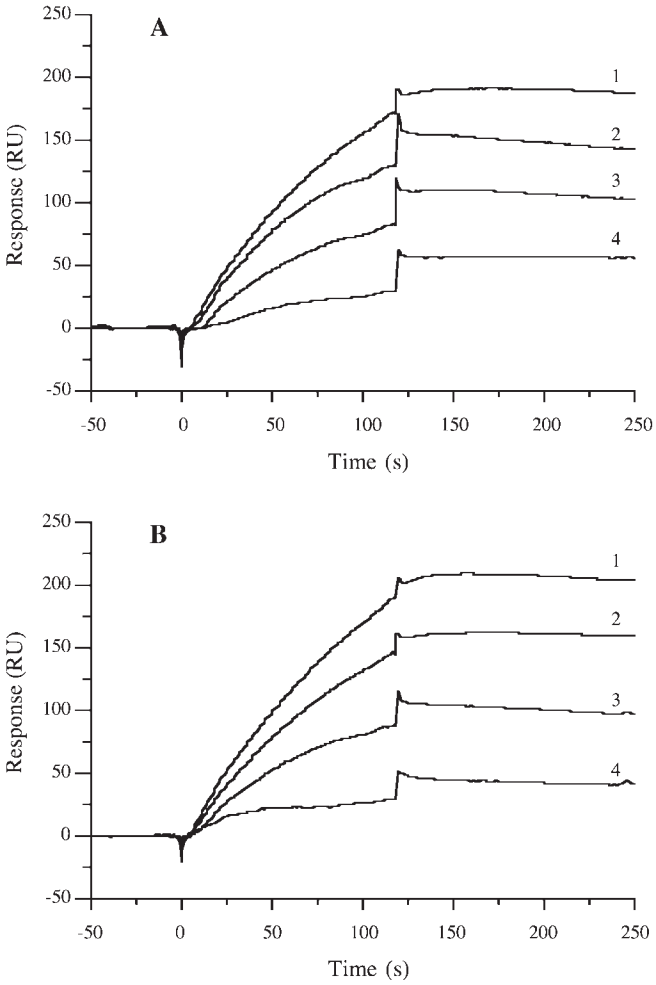

FIG. 4. BIAcore analysis of the binding of FA to immobilized human p53 DBD. p53 DBD (565 pmol) binding to docosanoic acid (22:0) (A) and *cis*-12-heneicosenoic acid (21:1n-9) (B) was detected by surface plasmon resonance signal (BIAcore, see Experimental procedures) and is indicated in response units. Four different concentrations of FA (curve 1, 10 μM (400 pmol); curve 2, 5 μM (200 pmol); curve 3, 2.5 μM (100 pmol); curve 4, 1.25 μM (50 pmol)) were injected over the protein for 120 S at 20 μl/min and dissociated for 130 S at 20 μl/min. The background resulting from the injection of running buffer alone was subtracted from the data before plotting.

Inhibitory effect of FA on the dsDNA binding activity of the mutant of human p53 DBD. Sequencing of the p53 gene in mammals, amphibians, birds, and fish has revealed five highly conserved domains, four of which fall within exons 5 through 8 (11): domain II (residues 117-142), domain III (residues 171-181), domain IV (residues 234-258), and domain V (residues 270-286). p53 is mutated in over half of all tumors. The overwhelming majority of these changes are found in the central DNA binding domain (i.e., p53 DBD) comprised of residues 94–312, which consists of domains II to V (5). Six tumorigenic mutations (R175, G245, R248, R249, R273 and R282) are most prevalent in the general population (5, 12), and these positions account for 22% of the 15,000 p53 mutations identified from human tumors and cell lines according to the database compiled by the Institut Curie (http://p53.free.fr/). In particular, R248 in domain IV is the most common mutation (13), therefore, an R248A mutant of human p53 DBD was prepared, and the inhibitory effect of FA was investigated as compared with the wild-type.

Figure 5 shows the inhibition dose-response curves of docosanoic acid and *cis*-12-heneicosenoic acid against the wild-type and R248A mutant of human p53 DBD (30.0 pmol).

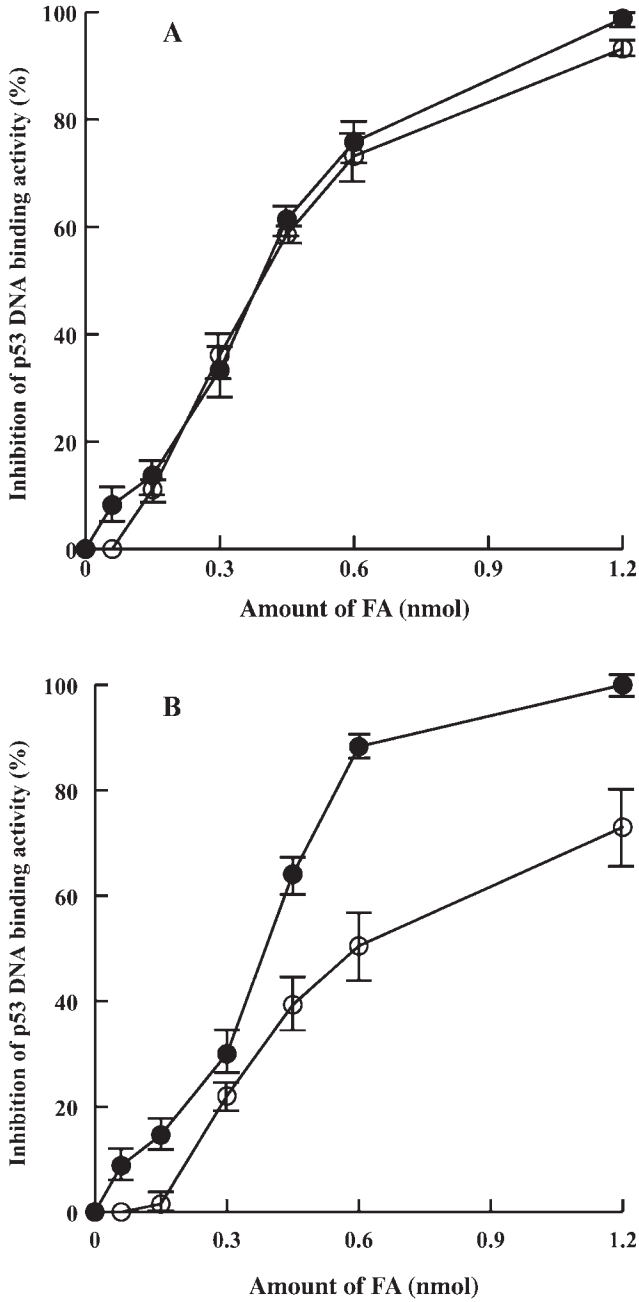

FIG. 5. Effect of FA on the inhibition of the R248A mutant of human p53 DBD activity. Inhibitory dose-response curves of docosanoic acid (22:0) (A) and *cis*-12-heneicosenoic acid (21:1n-9) (B) for the dsDNA binding activities of p53 DBD wild-type (30.0 pmol, closed circle) or R248A mutant (30.0 pmol, open circle). The dsDNA binding activity of p53 DBD (30.0 pmol) in the absence of FA was taken as 0%. Data are shown as the means ± SEM for three independent experiments.

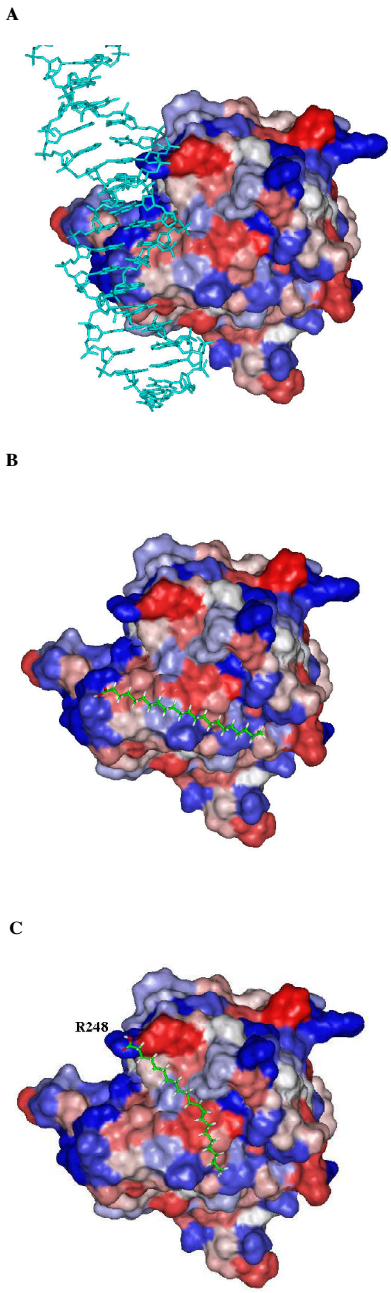

FIG. 6. Simulation of the long-chain FA interaction interface on human p53 DBD. (A) The complex of dsDNA and p53 DBD. (B) The complex of docosanoic acid (22:0) and p53 DBD. (C) The complex of *cis*-12-heneicosenoic acid (21:1n-9) and p53 DBD. Connolly surface and electrostatic potential of p53 DBD are shown, blue is a positive charge, and red is a negative charge. The carbons, oxygens and hydrogens of the structure of FA are indicated in green, red and white, respectively. The molecular docking of the DNA binding domain of human p53 DBD (PDB: 1TUP) was performed using the Affinity program within the Insight II software (Accelrys, San Diego, CA). The calculation used a CVFF force field in the Discovery program (Accelrys).

Both docosanoic acid (Fig. 5A) and *cis*-12-heneicosenoic acid (Fig. 5B) were effective at inhibiting the dsDNA binding activity of wild-type p53 DBD, with 50% inhibition observed at 0.41 and 0.36 nmol, respectively. The inhibitory effect of docosanoic acid on the activities of R248A mutant p53 DBD was almost as strong as that of the wild-type (Fig. 5A). On the other hand, inhibition of the activity of mutant p53 DBD by *cis*-12-heneicosenoic acid was 1.7-fold weaker than that of the wild-type (Fig. 5B). These results suggested that the p53-binding surface of docosanoic acid was different from that of *cis*-12-heneicosenoic acid; in particular, *cis*-12-heneicosenoic acid must bind to or interact with R248 in p53 DBD, but docosanoic acid might not influence R248.

Simulation of the docking of human p53 DBD with FA. As described above, the three-dimensional structure of human p53 DBD with or without FA such as docosanoic acid and *cis*-12-heneicosenoic acid was studied (Fig. 6). The crystal structure of the human p53 DBD in complex with consensus dsDNA is shown in Fig. 6A. A large immunoglobulin-like β-sandwich, forming a compact barrel-like structure, provides the basic scaffold for the conserved DNA binding surface (the blue area of p53 DBD in Fig. 6). This extended surface, rich in basic amino acids, consists of a loop-sheet-helix motif and two large loops (L2 and L3).

The docosanoic acid-binding site of p53 DBD was refined using Insight II / Discovery (Accelrys Inc.) (Fig. 6B). A cavity with a space (grid size, site of open size and site of cutoff size were 2.54 Å, 2.54 Å and 28.41 Å, respectively) where docosanoic acid, which is a linear carbon chain, can bind was searched for on the surface of the protein, and found in the hydrophobic area. Docosanoic acid was suggested to interact with the hydrophobic region of p53 DBD, because the complex of docosanoic acid and p53 DBD was reversed by a neutral detergent, NP-40 (Fig. 3). In these simulation results, the carboxyl end of docosanoic acid on p53 DBD was the same position as the minor groove of dsDNA on p53 DBD, because the free carboxyl group of FA was required for the inhibition of dsDNA binding activity (Fig. 2A).

The docking simulation of *cis*-12-heneicosenoic acid and p53 DBD is shown in Fig. 6C. As the inhibitory effect of *cis*-12-heneicosenoic acid on the R248A mutant of p53 DBD was weaker than that on the wild-type (Fig. 5), the carboxyl group of *cis*-12-heneicosenoic acid could interact with the residue of R248, and the V-like-shaped alkyl chain region interacted with the hydrophobic surface of p53. It was suggested that *cis*-12-heneicosenoic acid bound to the residue of R248 of p53 DBD and inhibited dsDNA-binding activity by competing with dsDNA. Since the molecular shape of *cis*-12-heneicosenoic acid (grid size, site of open size and site of cutoff size were 2.54 Å, 6.25 Å and 25.35 Å, respectively) is different from docosanoic acid, it might be considered that there are two FA-binding pockets in p53 DBD. The size of the pockets may be a key to explain these inhibition characteristics by FA. This is the first report to find that C_{20} to C_{22} long-chain FA could bind to human p53 directly, and inhibit or regulate the dsDNA binding activity of p53.

Free FA play important physiological roles in many tissues. For example, the impairment of insulin-mediated glucose uptake and glycogen synthesis in muscle and the potentiation of

glucose-stimulated insulin secretion in pancrearic islets have been considered as a result of the intracellular metabolism of free FA to long-chain acyl-CoA esters. However, it is also suggested that free FA may act as ligands for cell-surface receptors because FA derivatives, such as prostaglandins and leukotrienes, have specific cell-surface G protein-coupled receptors. PUFA has been shown to promote apoptosis in pancreatic cancer cells (14), and in fibroblast and lymphoblastoid cell lines (15). However, our results suggested that saturated and monounsaturated FA might act as regulators or inhibitors of transcription by p53. It was considered that apoptosis induced by FA might be independent of the p53 pathway.

The p53 tumor suppressor protein responds to a variety of cellular stresses, including DNA damage, UV irradiation, hypoxia and aberrantly activated oncogenes, and may induce cell-cycle arrest or apoptosis (16–18). However, the molecular mechanisms of the various biological activities of p53 have not been characterized. In this study, we found that saturated and monounsaturated (*cis*-type) long-chain FA such as docosanoic acid and *cis*-12-heneicosenoic acid strongly inhibited the dsDNA binding activity of human p53 DBD. Since these FA are present in the inner membrane of human cells (19), FA might regulate the biological activities of p53 to achieve complexes of FA and p53 *in vivo*. The *in vivo* regulation mechanism of p53 by FA will be a future study.

Low-Density Lipoproteins Are More Electronegatively Charged in Type 1 Than in Type 2 Diabetes Mellitus

R. Gambino, E. Pisu, G. Pagano, and M. Cassader

Department of Internal Medicine, University of Turin, Italy

ABSTRACT: Multifactorial etiology is involved in premature atherosclerosis related to diabetes. Most of the mechanisms that are responsible for the etiology in diabetes have remained unsolved so far. Type 1 diabetes is associated with a favorable lipid pattern and with microangiopathy, which is not true for type 2 diabetes, which is related to dyslipidemia and macroangiopathy. The aim of this work was to evaluate the degree of LDL modification related to the types of diabetes. The question is whether the LDL could be differently modified since the pathogenesis of type 1 and type 2 diabetes is different. Thirty-one type 1 (19 male and 12 female) and thirty type 2 (18 male and 12 female) diabetic patients were included in this study. Isolated LDL was analyzed by capillary electrophoresis for diene conjugate content and for electronegativity. LDL from type 1 diabetes subjects showed the highest electrophoretic mobility (P = 0.000). Instead, the diene conjugates contents were higher in the type 2 patients with HbA1c levels >8 % (P = 0.007). In conclusion, the increased diene content in type 2 diabetic subjects in poor glycemic control and the highest LDL mobility found in type 1 subjects show that the LDL undergoes different modifications. In type 2 patients, electronegative LDL are in a state of higher susceptibility to oxidation, whereas in type 1 subjects the finding of electronegative lipoproteins could provide an index of the relative atherogenicity of circulating LDL, especially as LDL has higher electrophoretic mobility than normal subjects.

Paper no. L9950 in *Lipids 41*, 529–533 (June 2006).

Multifactorial etiology is involved in premature atherosclerosis related to diabetes. Most of the mechanisms that are responsible for the etiology in diabetes have remained unsolved so far. Without any doubt, a major factor is an impaired lipoprotein metabolism. Hypertriglyceridemia, increased postprandial lipemia, and the presence of small dense LDL and decreased HDL levels (1–4) are the common abnormalities that often occur in diabetes. Focus has therefore turned to qualitative changes in lipoprotein metabolism rather than simply lipoprotein concentrations. Modified or aberrant forms of lipoproteins, including glycated lipoproteins, favor the progression of atherosclerosis (5). LDL is the lipoprotein component responsible for transferring either exogenous or endogenous lipids to peripheral tissues. Oxidation of the LDL particles enhances its atherogenicity (6), and the interaction of oxidation and the excess glycosylation seen in diabetes (7) may be the source of the cardiovascular risk (8). The oxidative modification of LDL can exert cytotoxic and immunogenic effects (9). Additionally, oxidized LDL contributes to atherogenesis by its ability to trigger an immune response leading to the formation of immune complexes (10). The electrophoretic mobility linked to the measure of the amount of baseline diene conjugation (BDC) in LDL is one of the more reliable indicators of LDL modification (11). The measure of BDC in LDL is a clinically applicable method to estimate *in vivo* LDL oxidation (12). Strong correlation between the titer of autoantibodies against oxidized LDL and results of HPLC and NMR studies indicated that BDC-LDL was a specific measure of oxidized LDL *in vivo* (13).

Oxidation, like glycosylation, is a process that increases the negative charge of LDL (14). Modifications that increase the net negative charge may have important metabolic consequences (15,16). The advanced glycation end-products (AGE) process is one of the main pathogenic mechanisms linked to the development of diabetic complications (17), and both oxidized LDL and AGE-LDL have been detected (18) in diabetes.

This study was undertaken with the aim of evaluating the degree of LDL modification related to the types of diabetes. Type 1 diabetes has a different pathogenesis from type 2 diabetes, and although there are similarities between the diseases such as hyperglycemia, inferences cannot be made from one type to the other for all risk factors, such as lipids and obesity (19). Type 1 diabetes is associated with a favorable lipid pattern and with microangiopathy; this is not true for type 2 diabetes, which is related to dyslipidemia and macroangiopathy (20). The question is whether the LDL could be differently modified because the pathogenesis of type 1 and type 2 diabetes is different. To this purpose, we have measured the electronegativity and diene conjugates content in LDL isolated in two groups of diabetic subjects.

EXPERIMENTAL PROCEDURES

Study subjects. Thirty-one type 1 (19 male and 12 female) and thirty type 2 (18 male and 12 female) diabetic patients were included in this study. They were recruited from the diabetes clinic at the San Giovanni Battista Hospital in Turin (Italy). They were enrolled based on good (glycated hemoglobin [HbA_{1c}] < 8%) and poor (HbA_{1c} > 8%) glycemic control. Di-

Abbreviations: AGE, advanced glycation end-products; BDC, baseline diene conjugation; BMI, body mass index; CE, capillary electrophoresis; EOF, electroendosmotic flow; glyc-LDL, glycosylated LDL.

abetes was defined according to the National Diabetes Data Group criteria (21). For the type 1 diabetic subjects mean age was 42 ± 15.7 yr, body mass index (BMI) was 25 ± 3.9 kg/m^2, and known diabetes duration was 20 ± 10.5 yr. For the type 2 diabetic subjects control mean age was 61 ± 10.5 yr, BMI was 28 ± 5.3 kg/m^2, and known diabetes duration was 9.2 ± 7.3 yr. Antropometric characteristics, glycemic control parameters, and lipid profiles of type 2 diabetic patients are shown in Table 1.

All the type 2 diabetic patients were on hypoglycemic oral agents, and insulin therapy was administered to type 1 diabetic patients. None of the patients were taking any other drugs or vitamins, or had any disease known to influence lipoprotein metabolism. To exclude an influence of the diet on LDL mobility, all the subjects were given a common standard diet 3 mon before blood drawing.

The type 1 diabetic subjects with a value of Lp(a) exceeding 15 mg/dL were excluded.

Informed consent has been obtained from all the enrolled subjects and the reported investigations have been carried out in accordance with the principle of the Declaration of Helsinki (22).

Blood samples were collected from all participants in the fasting period.

Twenty-six healthy subjects matched for gender (17 males and 9 females) and with a normal lipid profile were enrolled as control group.

Biochemical analyses. Glucose was determined by a standardized automatized enzymatic method, glucose oxidase (Sentinel CH, Milan, Italy), adapted to a Hitachi 911 autoanalyzer. Cholesterol and triglyceride concentrations were determined from plasma and lipoprotein fraction by enzymatic methods (Sentinel CH) adapted to a Hitachi 911 autoanalyzer.

Isolation of LDL. Venous blood was collected from all participants into EDTA-containing Vacutainer tubes, and plasma was separated by low-speed centrifugation for 15 min at 4°C. LDL was isolated by preparative sequential ultracentrifugation (23) in a Beckman L8-70M ultracentrifuge (Beckman Instruments Inc., Fullerton, CA). Plasma was adjusted to a density of 1.019 kg/L with KBr solution and ultracentrifuged at 121,000 g for 20 h at 18°C in a Beckman 70.1 rotor. After centrifugation, the VLDL fraction was removed by the tube slicing and the infranate was adjusted to a density of 1.063 kg/L and ultracentrifuged at 148,000 g for 21 h at 18°C. To avoid oxidative modification of lipoproteins, 1 mmol/L EDTA was added to all KBr solutions in the two sequential ultracentrifugations. The fraction containing LDL was removed by tube slicing and dialyzed through Sephadex G-25 columns (Pharmacia, Uppsala, Sweden) against buffers used in the subsequent experiment.

In order to rule out the presence of Lp(a) in the samples containing LDL, we performed a Lp(a) determination in all the fractions with an immuno-nephelometric method (Behring, Italy).

Chromatographic assays. HbA_{1c} was routinely determined by standardized affinity HPLC (Bio Rad, Milan, Italy). The reference range in our laboratory is 4.0–5.8%.

Capillary electrophoresis. Capillary electrophoresis (CE) was performed with a Beckman P/ACE 5510 system fitted with a diode array detector. An untreated fused silica capillary tube with a 75 µm i.d. was used. The total length of the capillary tube was 57 cm (50 cm to the detector). The capillary was operated at 20°C. An applied voltage of 350 V/cm was used in all CE separations. CE was performed as described by Stocks *et al.* (11). The cathode and anode electrolytes and the capillary run buffer were 40 mM methylglucamine-Tricine, pH 9.0. LDL samples were injected by low pressure for 4 s. Dimethylformamide was injected as an electroendosmotic flow (EOF) marker for 1 s. A voltage of 24 kV was applied ramping over 0.8 min. Migration of LDL particle was monitored at 200 and 234 nm. The amount of conjugated dienes is obtained from the percentage of the height of LDL peak at 234 nm related to the height of LDL peak at 200 nm.

Calculation of electrophoretic mobility. The electrophoretic mobility of LDL (µ) was calculated using the following equation (24): $\mu = L_c L_d / U(1/t_{sample} - 1/t_{EOF})$, where L_c is the total length of the capillary (cm), L_d is the length of the capillary from injector to detector (cm), U is the applied voltage (V), t_{sample} is the migration time of LDL (s), and t_{EOF} is the migration time of the EOF marker (s). The higher the migration rate of LDL is, the more negative is the result. The negative result mirrors the net charge of the molecule, which is, of course, negative.

Statistical analysis. Data were expressed as means ± SD unless otherwise indicated. Student's *t*-test was used to compare groups when variables were normally distributed. Pearson's correlation coefficients were used to describe relationships between variables. In all cases, *P* less than 0.05 was considered statistically significant. Triglyceride values were log-transformed before analyses.

HDL cholesterol (mg/dL)	59 ± 15	50 ± 20	0.086

RESULTS

Anthropometric characteristics, glycemic control parameters, and lipid profiles of type 1 and 2 diabetic subjects are shown in Table 1. Type 1 and 2 diabetic patients had $HbA1_c$ levels of 7.70 ± 1.56% and 8.04 ± 2.04%, respectively. Type 2 dia-

betic patients had a higher BMI value and shorter diabetes duration than type 1 diabetic patients.

The LDL electrophoretic mobility mean for the type 1 diabetic group was higher than that for the type 2 diabetic group ($-1.2669 \pm 0.056 \times 10^{-4}$ vs. $-1.0905 \pm 0.0724 \times 10^{-4}$ cm^2 V^{-1} s^{-1}, respectively, $P = 0.000$; Table 2). In both diabetic groups, LDL electrophoretic mobility and the content of conjugated dienes were significantly higher than that found in the control group ($P < 0.001$, data not shown). No significant difference in diene conjugated was observed in the LDL isolated from type 1 and 2 diabetic patients ($P = 0.293$).

The diabetic subjects were further divided according to their $HbA1_c$ levels in two subgroups. The $HbA1_c$ cut-off value was set at 8.0%. In diabetic subjects with $HbA1_c$ < 8.0%, only the electrophoretic mobility of isolated LDL in the type 1 diabetic subjects was higher than that observed in the type 2 subjects ($-1.272 \pm 0.06 \times 10^{-4}$ vs. $-1.077 \pm 0.053 \times 10^{-4}$ cm^2 V^{-1} s^{-1}, respectively, $P = 0.000$). The diene conjugates contents were similar (6.76 ± 1.01% for type 1 diabetes vs. 6.69 ± 0.93% for type 2 diabetes, $P = 0.833$; Table 3).

Similarly, when LDL isolated from type 1 and 2 diabetic subjects with $HbA1_c$ > 8.0% was compared, the electrophoretic mobility was increased in the type 1 diabetic group (-1.259 ± 0.05 ? 10^{-4} vs. $-1.1034 \pm 0.088 \times 10^{-4}$ cm^2 V^{-1} s^{-1}). On the contrary, the diene conjugates contents were higher in the type 2 patients (5.81 ± 0.39% for type 1 diabetes vs. 6.60 ± 0.87% for type 2 diabetes). In both cases the statistical difference was reached ($P = 0.000$ for the electrophoretic mobility, and $P = 0.008$ for diene conjugates; Table 4).

After splitting each diabetic group into two subgroups on the basis of the hemoglobin levels, it was observed that among type 1 patients the diene conjugates of LDL were higher in the subjects who had $HbA1_c$ < 8.0% (6.76 ± 1.01% vs. 5.81 ± 0.39%, $P = 0.0045$).

The electrophoretic mobility and the diene content of LDL isolated from subjects with type 2 diabetes mellitus were not statistically different.

DISCUSSION

Our study was designed to highlight the electrophoretic characteristics of LDL isolated from subjects affected by diabetes and to determine whether the susceptibility to oxidation of the lipoprotein particle could be modified by a glucose-rich environment and other factors related to diabetes. We expected to find some differences in the quality of LDL according to the type of diabetes, because the pathogenesis and the duration (Table 1) of the two diseases are different.

Our work highlights two important phenomena: an increased electrophoretic mobility of LDL in type 1 diabetic patients relative to type 2 diabetic subjects, and an increased diene conjugates content in LDL of type 2 diabetic subjects in poor glycemic control relative to those affected with type 1 diabetes. Furthermore, the diabetic disease modifies the circulating LDL, in accordance to what was found in the control group, whose LDL had electrophoretic mobility and conjugated dienes far lower than in diabetic subjects. The electrophoretic mobility is one of the more reliable indicators of LDL modification. The more electronegative mobility found in LDL isolated from type 1 diabetic subjects agrees with our previous work (25), in which they were related to the increase of the so-called LDL(-) (26), which is also detectable in normal subjects, although in small amounts (27). One can argue that diene conjugates is the major determinant of electrophoretic mobility in type 1 diabetes. Instead, diene conjugates in type 1 diabetes are similar to those in type 2 diabetes. In other words, factors other than glucose having capability in modifying lipoproteins should be implicated.

In type 1 diabetes the diene conjugates decreased with the impairment of the glucose metabolism. That is, at high values

Electrophoretic Mobility and Diene Conjugates of LDL in Type 1 and 2 Diabetes Mellitus with Hb1c > 8%

	Type 1 diabetic subjects ($n = 12$)	Type 2 diabetic subjects ($n = 15$)	P
Electrophoretic mobility ($\times 10^{-4}$ cm^2 V^{-1} s^{-1})	–1.258 ± 0.049	–1.103 ± 0.087	0.000
Diene conjugates (%)	5.81 ± 0.39	6.60 ± 0.87	0.007

of HbA1c we observed a trend toward low levels of dienes (from 5.81 ± 0.39% to 6.77 ± 1.01%, $P = 0.0045$ for type 1 diabetes). In agreement with that, the negative correlation found between HbA1c and diene conjugates explains that glycosylation can offer lipoproteins more resistance to the further oxidation process as other authors have suggested (28).

At a value of HbA1c > 8% type 2 diabetic patients had a significantly higher diene conjugates level than type 1 subjects. The diene conjugates play a major role in type 2 diabetic patients, who often have dyslipidemia, which provides excellent substrates for lipid peroxidation. Therefore, the increased diene contents in type 2 diabetes LDL isolated from subjects in bad glucose control could be due to the metabolic alterations, which are typical of type 2 diabetes. The measure of conjugated dienes in circulating LDL is an indicator of oxidized LDL *in vivo* (12), which in type 2 subjects are related to the demonstrated higher prevalence of subjects of a more atherogenic LDL phenotype (29), because small dense LDL particles are more susceptible to oxidation (30). Oxidizability of plasma lipoproteins in diabetic patients not due to glycation (31) was investigated by M. Kalousová *et al.* (32), who found that both AGE and advanced oxidation protein products are elevated in patients with diabetes mellitus, with marked differences between patients with diabetes mellitus type 1 and type 2. The increase of both parameters is more pronounced in patients with type 2 diabetes mellitus. This might indicate the presence of oxidative stress in both types of diabetes mellitus with its increase in type 2. Oxidative stress probably also plays a more important role in AGE formation in diabetes mellitus type 2 than in type 1, where AGE formation depends more on the compensation of the disease.

In conclusion, the finding of more electronegative LDL assumes different meanings according to the type of diabetes. In type 2 patients electronegative LDL are in a state of higher susceptibility to oxidation, whereas in type 1 subjects the finding of electronegative lipoproteins could provide an index of the relative atherogenicity of circulating LDL, especially as LDL has higher electrophoretic mobility than normal subjects. The increased negative charge of type 1 diabetic LDL could be related to underlying atherosclerosis-related complications developed during long-duration diabetes or to compositional abnormalities. Structural endothelial proteins become modified by AGE and trap circulating lipoproteins (33). Modifications of lipoproteins enhance their atherosclerotic behavior.

ABSTRACT: The purpose of this study was to evaluate the effects of four isoenergetic diets of differing fat composition on blood lipid profile and adiposity in young rats. Diets containing different lipid sources—partially hydrogenated vegetable oil (PHVO), palm oil (PO), canola oil (CO), and soy oil (SO)—were fed to lactating rats during the 21 days of lactation, and then fed to young males following weaning until the 45th day of life. *In vivo* lipogenesis rate (LR), lipid content (LC), relative level of FA, and the activity of lipoprotein lipase (LPL) enzyme were measured in epididymal adipose tissue (EPI). Fasting blood lipoproteins and LC in the carcass were also appraised. Body weight of PO and PHVO groups was significantly higher than CO and SO groups from day 14 of lactation to day 45, despite the lower food intake in the PHVO group. PO and PHVO groups presented higher LR and LC in EPI than SO and CO groups. Carcass fat content was significantly higher in PHVO and PO groups than in CO and SO groups. The LPL activity in EPI was unaffected by dietary lipids. PHVO group had increased total cholesterol and TAG concentrations in comparison with the PO group, and significantly lower HDL level compared with the other groups. These results show that the kind of FA in the dietary lipid offered early in life can affect lipid metabolism and adiposity.

Paper no. L9881 in *Lipids 41*, 535–541 (June, 2006)

In past years, considerable interest has focused on dietary fat, an essential nutrient that can increase the risk of certain chronic diseases if consumed in excess (1). Several studies have been conducted in a search for possible effects of the level of dietary fat, fat type (animal vs. vegetable), and FA classes (e.g., saturated, monounsaturated *cis* and *trans*, and polyunsaturated) on various chronic diseases (2,3,4). More recently, interest has focused on the FA composition of dietary fats early in life with a view toward preventing a further increase of childhood obesity in future generations (5).

White adipose tissue is the most important extrahepatic site regulating *in vivo* lipid metabolism. TAG deposition in this tissue is related to the *in situ de novo* synthesis, the uptake of FA from lipoproteins derived from dietary lipids and liver, and the lipolysis rate (6). Some studies have demonstrated that the dietary FA type can influence the metabolism of adipose tissue (6,7). Doucet *et al.* (8) observed that diets rich in saturated FA (SFA) and monounsaturated FA (MUFA) lead to a higher body adiposity than those rich in PUFA. Only one study, performed on rats during the gestation/lactation period, and subsequently on post-weaning pups eating the same diet their mother had consumed, has emphasized the sensitivity of adipose tissue to the FA composition of ingested fats (9).

The question of how the lipid composition of the diet can affect body adiposity early in life is still controversial, particularly in studies with normolipidic diets containing different compositions of FA.

Taking into consideration that there are only a few studies on the metabolic effects of the FA during the period of growth and development, particularly involving *trans* FA (tFA), whose dietary consumption has been increasing in recent years, we aimed to investigate the possible metabolic effects of different sources of dietary fats. We compared omega-6 PUFA, MUFA, SFA, and tFA on lipid levels and adipose tissue metabolism of young rats.

MATERIALS AND METHODS

Animals, diets, and general procedures. Pregnant female Wistar rats weighing 180–220 g, obtained from the animal breeding unit of the Institute of Nutrition of the Federal University of Rio de Janeiro, were maintained under controlled conditions (24 ± 1°C and 12 h light/12 h dark cycle). On the parturition day (day 0 of lactation), litters were weighed and adjusted to six male pups per dam. The lactating dams and their respective litters were divided into four groups according to the experimental diets, which were isocaloric (all diets provided 4.1 kcal/g of dry diet) but differed in the FA profile. After weaning (day 21 of life), the pups received the same diets as their mothers until the 45th day of life. The soy oil (SO) group received a diet containing 7% soy oil; the partially hydrogenated vegetable oil (PHVO) group received 6% partially hydrogenated vegetable oil plus 1% soy oil; the palm oil (PO) group received 5% palm oil plus 2% soy oil, and the canola oil (CO) group received 6% canola oil plus 1% soy oil. Soy oil was included in each diet to adjust the diet to the requirement for essential FA. The composition of each diet com-

[a]Soy oil and hydrogenated fat were obtained from Lisa/Ind. Brazil.
[b]Hydrogenated vegetable oil was obtained from Gessy Lever, São Paulo, Brazil.
[c]Vitamin mix contents (g/kg diet): thiamin HCl, 0.6; riboflavin, 0.6; pyridoxine HCl, 0.7; niacin, 3.0; calcium pantothenate, 1.60; folic acid, 0.20; biotin, 0.02; vitamin B12, 2.5; vitamin A palmitate (500.0 IU/g), 0.80; vitamin E acetate (500 IU/g), 15.0; vitamin D3 (400.000 IU/g), 0.25; vitamin K1, 0.75. AIN-93 vitamin mix, DYETS 310025, obtained from Dyets Inc., Bethlehem, PA.
[d]Mineral mix provided (g/kg): calcium, 357.0; phosphorus, 250.0; potassium, 74.6; sodium, 74.0; sulfur, 300; magnesium, 24.0; iron, 5.21; copper, 0.3; manganese, 0.63; zinc, 1.65; chromium, 0.27; iodine, 0.01; selenium, 0.01; boron, 0.08; molybdenum, 0.01; silicon, 1.45; nickel, 0.03; lithium, 0.02; vanadium, 0.007. AIN-93 mineral mix, DYETS 210025, obtained from Dyets Inc.. SO, 7.0% soy oil (AIN-93); PHVO, 6.0 % partially hydrogenated vegetable oil plus 1% soy oil (AIN-93); CO, 6% canola oil plus 1% soy oil (AIN-93); PO, 5.0% palm oil plus 2% soy oil (AIN-93).

plied with the American Institute of Nutrition (10) recommendation and is shown in Table 1. The FA composition of the diets is summarized in Table 2. Diets were prepared as pellets and stored at 4°C until use. Rats had free access to diet and water throughout the experimental period. Food consumption was measured daily and body weight weekly from day 1 to 45 of life. The young male rats were killed on the 45th day of life according to two different procedures: (a) six rats in each group were killed after an overnight fast, between 10:00 and 12:00 a.m., by guillotine. Immediately after decapitation, the blood was collected in tubes containing EDTA (1 mmol/L) and used for plasma metabolite measurements. Samples of epididymal white adipose tissue (EPI) were quickly extracted and stored at –70°C for determination of lipoprotein lipase (LPL) activity. The carcasses were stored at –70ºC for later lipid analysis; (b) the other six rats were decapitated 1 h after intraperitoneal administration of 3 mCi of ^3H_2O, and the EPI was removed and stored at –70ºC for later measurement of LR and LC. All experimental protocols and procedures were approved by the University's Experimental Research Committee.

FA analysis. Lipid extraction, saponification, and methylation of FA in the experimental diets and EPI were performed in duplicate using 0.5-g samples according to the method of Lepage and Roy (11), which includes treatment with 2 mL of 4:1 (vol/vol) methanol:benzene solution and addition of 200 µL of acetyl chloride under light agitation. FAME were quantified with GLC in a Perkin Elmer autosystem XL chromatograph with an ionizable flame detector and Turbochrom software (PerkinElmer, Norwalk, CT). FA were separated on a 100-m × 0.25-mm × 0.20-µm capillary column (SP2560, Supelco, Bellefonte, PA). Hydrogen was used as carrier gas. Injection and detection temperatures were 260°C and 280°C, respectively. The run temperature was programmed to start at 135°C for 5 min, with a 2°C increase per minute up to 195°C. Thereafter, the temperature increased 4°C per minute up to 240°C and was kept at this level for 2.5 min. Total run time was 45 min. The carrier gas pressure was 32 psi. The split ratio was 1:70. Esters were identified by comparing their retention times with those of standard FA. Results are expressed as percentage of total FA.

Measurements of LPL activity and protein content. LPL activity in epididymal adipose tissue was measured using the method of Nilsson-Ehle and Chotz (12) as modified by Llobera *et al.* (13). Tissue protein content was determined as described by Lowry *et al.* (14).

Measurements of in vivo lipogenesis and fat content. For measuring the *in vivo* lipogenesis rate, ^3H_2O (3 mCi) was injected intraperitoneally and the rats were killed by decapitation 1 h later. The EPI was removed and weighed, and 1-g aliquots were saponified in 3 mL 30% KOH. Lipids were extracted in petroleum ether for lipid extraction (15) and the radioactivity in the lipid fraction was measured. The LR was estimated as described by Robinson and Williamson (16). Carcasses were shaved, softened, and homogenized after removal of the gastrointestinal tract (17) to determine the carcass lipid content. Lipid was extracted from 3-g aliquots with petroleum ether and determined gravimetrically (15). Lipid content was determined as the difference between the weight of the vial containing the dry sample and the weight of the empty dry vial.

Plasma metabolites. Blood samples were taken by decapitating rats after an overnight fast of 12 h. Blood was collected in tubes containing EDTA (1 mmol/L), and plasma was separated immediately by centrifugation. Plasma total cholesterol (TC), HDL cholesterol, and TAG concentrations were determined by enzymatic methods with commercial kits (Gold Analisa Diagnóstica Ltda, Belo Horizonte, MG, Brazil).

Statistical analysis. The results were expressed as mean ± SEM, and statistical comparison among groups was done by a one-way ANOVA. Differences between means were tested for significance by Duncan's multiple range test ($P \leq 0.05$).

RESULTS

No significant differences were observed in maternal food intake and body weight of the experimental groups during lactation (data not shown). Evaluation of the post-weaning food intake (in g/100 g body weight) revealed that, immediately after weaning, the PO group consumed a significantly greater amount of food, followed by SO and CO groups. From the second post-weaning day onward, food intake was significantly lower in the PHVO group than in the other groups. However, from day 42 on, no significant differences were found among the dietary groups (Fig. 1). Regarding body weight, pups of PO and PHVO groups showed a significantly higher body weight than the others from day 14 on, and these differences persisted after weaning until the end of the experimental period (day 45) (Fig. 2). In contrast, no significant difference was observed between the SO and the CO groups. The carcass fat content (g/100 g) was significantly higher in the PO (8.97 ± 0.32) and PHVO (9.43 ± 0.88) groups compared with CO (3.67 ± 0.10) and SO (4.91 ± 0.48) groups.

The FA composition of EPI is summarized in Table 3. It is readily apparent that the FA composition of the EPI varied with

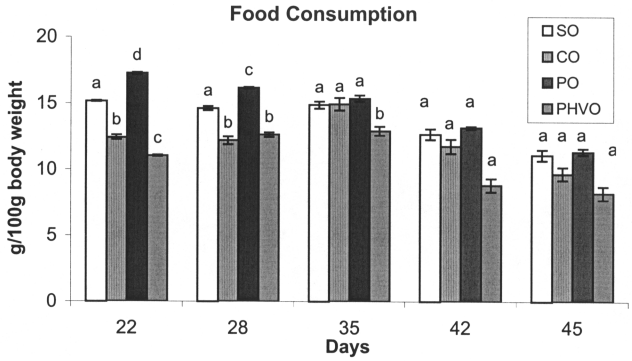

FIG. 1. Effects of dietary fat on food consumption in rats fed SO, CO, PHVO, or PO diets for 45 d. Values are mean ± SEM of six rats per group. Different superscript letters indicate significant differences from one another on the same day at $P \leq 0.05$ as determined by Duncan's test. SO, 7% soy oil; CO, 6% canola oil plus 1% soy oil; PHVO, 6% partially hydrogenated vegetable oil plus 1% soy oil; PO, 5% palm oil plus 2% soy oil.

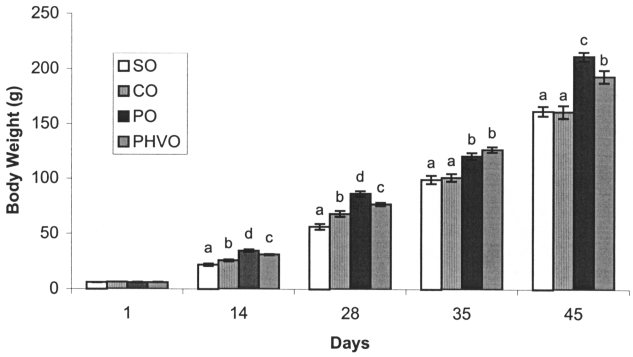

FIG. 2. Body weight (g) of the male pups during lactation (1 and 14 d) and after weaning (21–45 d). Values are mean ± SEM of six rats per group. Different superscript letters indicate significant differences from one another on the same day at $P \leq 0.05$ as determined by Duncan's test. SO, 7% soy oil; CO, 6% canola oil plus 1% soy oil; PHVO, 6% partially hydrogenated vegetable oil plus 1% soy oil; PO, 5% palm oil plus 2% soy oil.

[a]Values are mean ± SEM for six animals per group. Different superscript letters indicate significant differences from one another at $P \leq 0.05$ as determined by Duncan's test. For abbreviations, see Table 1.
[b]Includes all positional cis-isomers of 18:1 except 18:1n-9.

the type of dietary fat. The proportion of SFA was higher in the PO group than in the other groups. The content of MUFA was significantly higher in the CO group than in the SO, PHVO, and PO groups. Higher levels of linoleic acid (18:2n-6) were detected in EPI of the SO group compared with that of the remaining groups. It is relevant to note that tFA were only incorporated into EPI lipids of the PHVO group, which received a diet rich in these isomers. When the essential PUFA were evaluated, a significant decrease was observed in the percentage of linoleic and linolenic (18:3n-3) FA in EPI of PHVO and PO groups compared with SO and CO groups. It can also be observed that the amount of longer-chain metabolites of n-3 and n-6 PUFA—such as arachidonic acid (AA), EPA, and DHA—was less than 1% of the total lipid in the EPI of all groups. However, the AA levels in adipose tissue of all dietary groups were (slightly) higher than EPA and DHA. Both PO and PHVO groups had lower AA and DHA levels in EPI than SO and CO groups. Moreover, DHA and EPA were more abundant in the CO group than in the other three groups.

The fat content and LR in EPI on the 45th day of postnatal life are listed in Table 4. The results show that the PO and PHVO diets increased the relative weight of EPI, the LR, and the lipid content in this tissue, in comparison with the SO and CO groups. Moreover, the PO group had a significant increase in LR and in lipid content in EPI compared with PHVO.

The protein content (mg/100 mg) of EPI was not affected by the different experimental diets (SO: 21.88 ± 0.51; CO: 21.16 ± 0.81; PO: 23.34 ± 0.84; PHVO: 23.70 ± 0.71). As well, no significant differences in LPL activity (μM/min/g protein) were observed among the dietary groups (SO: 237.12 ± 8.65; CO: 234.08 ± 7.50; PO: 244.70 ± 6.77; PHVO: 245.25 ± 11.56).

Table 5 shows the mean plasma concentrations of TC, HDL cholesterol, TAG, and glucose according to diet. TAG level was significantly lower in the PO group compared with the other groups. Total cholesterol was significantly higher in the PHVO group than the PO group, which showed a lower concentration of TC than the CO group. HDL cholesterol of the PHVO group was lower than that of the remaining groups. Plasma glucose concentration was similar for the various experimental groups.

TABLE 4
Weight, Lipid Content, and Lipogenesis Rate in Epididymal Adipose Tissue[a]

[a]Values are mean ± SEM for six animals per group. Different superscript letters indicate significant differences from one another at $P \leq 0.05$ as determined by Duncan's test. For abbreviations, see Table 1.

DISCUSSION

In the present study, we documented that diets rich in palmitic acid (PO) or *trans* isomers (PHVO), in spite of being normolipidic diets, caused greater body weight gain at a young age (14 and 45 d) than those rich in PUFA (SO) or MUFA (CO). The literature shows controversial results concerning the relationship between the intake of palm oil—a saturated fat—and obesity. Loh *et al.* (18) showed that body weight gain and carcass lipid content were greater in obese rats fed the high-fat palm olein diet than in those fed soybean diet. In addition, Lemmonnier *et al.* (19) reported that both epididymal and perirenal depots had more fat cells in male rats fed high-fat diets with palm oil than in those fed corn oil. Moreover, Shillabeer and Lau (20) demonstrated that diets rich in saturated fat promoted adipocyte replication. In this context, an understanding of the ability of FA to regulate factors such as adipocyte size and number, or lipid metabolism (adipogenesis and fat oxidation), particularly in young animals, would be of great interest to better understand human obesity.

In humans, long-term tFA intake has been shown to positively correlate with body mass index (21). In cells cultured in the presence of tFA, some studies demonstrated a lower fat accumulation in adipocytes (22). On the other hand, adult male rats fed a hyperlipidic diet containing partially hydrogenated fat showed no significant difference in body weight (23). Although these studies correlate the increase of adiposity with the type of FA consumed, all of the diets tested were hyperlipidic. An original aspect of the present study is that all diets were normolipidic, differing only in the FA sources. Thus, some of the discrepancies between the present study and the literature can be explained by differences in important variables such as the overall amount of fat in the diet, the age of the animals at the beginning of the study and the feeding period.

Alterations in dietary fat type have been shown to influence membrane composition, function, and metabolic processes in many tissues (24). Changes in body weight and carcass fat content of PHVO and PO groups may also be due to differences in energy retention as a result of changes in metabolism or food intake. Immediately after weaning, we observed that the PO group presented the highest food intake, whereas the PHVO had the lowest, although during the final period of the study no significant differences were detected among the groups. It is interesting to note that the differences in food intake observed in the PHVO group are opposite to the ones observed in body weight, suggesting that the higher body weight in this group is due to differences in energy retention, probably due to a greater metabolic efficiency, particularly during the perinatal period, which involves several metabolic and physiological adaptations (25).

There is little definitive information on the effects of the type of dietary fat on lipid metabolism of adipose tissue. We observed an increase in *de novo* synthesis of FA in the epididymal adipose tissue of the PHVO and PO groups, and there was more fat in this tissue in comparison with the other groups. Moreover, the rate of FA synthesis in the PO group was approximately 45% higher than in PHVO. This means that different dietary FA will have different effects on *de novo* FA synthesis in adipose tissue in the young rats, which might contribute to their selective storage in adipose tissue as well as to the development of obesity. On the other hand, if different types of dietary fat affect FA synthesis in adipose tissue in different ways, it would be interesting to know how the body metabolizes specific FA, including differences in their propensity for direct incorporation into adipose tissue triglyceride, whether they must first be metabolized prior to deposition, and whether they are oxidized at different rates or mobilized from fat cells more readily than others (26). These seem to be relevant issues, which may partly explain some conflicting results of the present study regarding the increase in *de novo* FA synthesis and in the total lipid content of EPI in the PO group.

Adipose tissue lipoprotein lipase (LPL) plays an important role in recruitment of circulating fat into adipocyte stores (27). In the present study, no significant differences were observed in the LPL activity of the epididymal adipose tissue among the different groups. Similar results were reported by Takeuchi *et al.* (28) in a study with rats fed diets containing different types of lipids (saturated and unsaturated). Thus, these results indicate that the increase in adiposity of PO and PHVO groups was not due to greater uptake by the adipose tissue of FA coming from the diet in the form of chylomicrons, or released by the liver into the blood, in the form of VLDL.

Upon evaluating the FA composition of EPI, we observed that it reflects primarily the specific FA content of the experimental diet. Our results on FA profile in adipose tissue are in agreement with previous reports (23,29). The amount of tFA incorporated into adipose tissue of animals fed partially hydrogenated fat (PHVO) follows the dietary FA profile, because these FA are not synthesized by nonruminant animals (23). Furthermore, it has been reported that the composition of adipose tissue is a suitable biomarker of dietary FA intake, particularly for tFA, n-3, and n-6 FA (30).

In the present study, groups PO and PHVO presented lower levels of AA (20:4n-6) and DHA (22:6n-3) in EPI than groups SO and CO. EPA and AA are both precursors of eicosanoids, which have been demonstrated to be related to adiposity (26,31). Recently, prostaglandins I2 and J2 have been shown to induce adipocyte differentiation (32,33), whereas prostaglandins E2 and F2α are described as inhibitors of the adipogenic process (33,34). Moreover, prostaglandin E2 produced in adipose tissue may affect lipolysis (34).

Studies suggest that dietary FA have a significant impact on the circulating lipid levels. Our findings confirm previous studies conducted by other authors who observed the harmful effects of hydrogenated fat on the increase in total cholesterol levels, and a decrease of the circulating HDL levels (35,36), as well as beneficial effects of palm oil on the circulating lipid levels (37). In humans, the effect of feeding palm oil on serum cholesterol was similar to that observed when feeding olive oil (38) or canola oil (39). Various hypotheses have been formulated to attempt to explain the hypocholesterolemic effect of palm oil. One proposal take into account the high proportion of MUFA in palm oil, which has been associated with improvements in the lipoprotein profile (40). Another proposal attributes it to the presence in palm oil of natural antioxidants such as tocotrienols, vitamin E, and carotenoids (37).

In the present study no significant differences among groups were found in LPL activity in the adipose tissue. However, a reduction in circulating TAG was found in the PO group, in comparison with the other groups. At this point we note that there is evidence that the metabolic effects of dietary TAG depend not only on their FA composition but also on the stereochemical configuration of specific FA in the TAG molecule (41). Diets containing palmitic acid in the *sn*-2 position have caused higher plasma TAG values than diets containing palmitic acid in the *sn*-1/3 positions both in rats (41) and in human infants (42). Palm oil contains about 40% palmitic acid, but only about 3% of it is in the *sn*-2 position. This could explain the reduced blood TAG levels observed in the PO group.

The hypotriglyceridemic effect of palm oil may also be related to the rate of oxidation. Leyton *et al.* (43) fed rats FA of different chain lengths and degrees of saturation and reported varied oxidation rates, with unsaturated FA showing higher oxidation rates than SFA. Although more direct experiments are required, it is possible that the palm oil FA, due to its higher proportion of unsaturated FA chains in position 2 of the TAG molecule (41), can be quickly oxidized, resulting in reduced TAG levels in rats fed a palm oil diet.

In conclusion, our study shows a difference in effect on lipid metabolism when various dietary fats are given to male rats during lactation and up to 45 d. The results suggest that an unsaturated FA-rich diet promotes less body weight gain and fat deposition than an SFA-rich diet; a diet rich in tFA increases plasma concentrations of cholesterol and decreases HDL cholesterol; and a diet rich in palmitic FA decreases TAG levels, whereas both palmitic acid and tFA-rich diets raise the lipogenesis rate in epididymal adipose tissue, leading to increased fat content of this tissue and increased body weight, these effects being more pronounced in rats fed a palmitic FA-rich diet.

Mice Raised on Milk Transgenically Enriched with n-3 PUFA Have Increased Brain Docosahexaenoic Acid

Beth T. Kao, Edward J. DePeters, and Alison L. Van Eenennaam*

Department of Animal Science, University of California, Davis, CA, 95616, USA

ABSTRACT: The brain contains high levels of the long-chain n-3 FA DHA(22:6n-3), mainly in the gray matter and synaptosomes. Adequate intake of DHA is crucial for optimal nervous system function, particularly in infants. Supplementation of infant formulas with DHA at levels similar to human breast milk is recommended for biochemical and functional benefits to neonates. We generated transgenic mice that produce elevated levels of n-3 PUFA in their milk by expressing the *Caenorhabditis elegans* n-3 FA desaturase under the control of a lactation-induced goat beta-casein promoter. To examine the postnatal effects of consuming the n-3-enriched milk, we compared the growth and brain and plasma FA composition of mouse pups raised on milk from transgenic dams with those observed for pups raised on milk from nontransgenic dams. A significant decrease in arachidonic acid (ARA, 20:4n-6) and concomitant increases in n-3 PUFA were observed in the phospholipid fraction of transgenic mouse milk. The n-6:n-3 FA ratios were 4.7 and 34.5 for the transgenic and control milk phospholipid fractions, respectively. DHA and DPA (22:5n-6) comprised 15.1% and 2.8% of brain FA from weanling mice nursed on transgenic dams, as compared with 6.9% and 9.2% for weanling mice nursed on control dams, respectively. This transgenic mouse model offers a unique approach to disassociate the effects and fetal programming resulting from a high n-6:n-3 FA ratio gestational environment from the postnatal nutritional effects of providing milk with differing n-6:n-3 FA ratios.

Paper no. L9994 in *Lipids 41*, 543–549 (June 2006).

The long-chain n-3 FA DHA (22:6n-3) is an essential component in neuronal tissues (1). Results from numerous studies have demonstrated the involvement of DHA in the normal function and development of the central nervous system (2–4). Mammals are unable to synthesize n-3 FA *de novo,* hence DHA or its 18-carbon-chain precursor, alpha-linolenic acid (ALA, 18:3n-3), must be obtained from dietary sources. Adequate intake of dietary DHA is crucial, particularly in infants, because data indicate that conversion of ALA to DHA by the endogenous desaturation-elongation pathway may not be sufficient to support the needs of growing infants (5,6). Human breast milk contains 0.05–1.4% DHA of total FA by weight, depending upon the maternal diet and stage of lactation (7). Until 2002, infant formulas in North America did not contain preformed DHA, but rather contained n-3 FA in the form of ALA (8).

Abbreviations used: ALA, alpha-linolenic acid; ARA, arachidonic acid; LA, linoleic acid, LC-PUFA, long-chain PUFA.

Different sources of preformed DHA are currently available to supplement infant formula: TG extracted from algae or fish, and phospholipids extracted from egg yolks. The parent molecule that is used to deliver FA in the diet can have important effects on the extent of FA bioavailability and transport to specific tissues (9). TG structure, that is, the FA position on the glycerol molecule, affects digestion, absorption, and FA metabolism. Likewise, phospholipid species and FA profile can influence gastric lipase activity, plasma accretion, and tissue distribution (9,10). The acyl lipids in milk fat comprise a large number of different FA and give rise to one of the most complex naturally occurring fats. In human milk, long-chain PUFA (LC-PUFA) are more highly concentrated in phospholipids, so that although phospholipids make up only 0.08% of total milk fat, they carry 15% of LC-PUFA. The remaining 85% of LC-PUFA are in the form of TG (11). If a given lipid class, species, or structure is a more available source of DHA for developing neural structures, this would have important nutritional, economic, and industrial implications for the supplementation of infant formulas.

The nematode *Caenorhabditis elegans* is able to synthesize ALA by virtue of an endogenous n-3 FA desaturase that recognizes a range of 18- and 20-carbon n-6 substrates (12) (Fig. 1). Unlike mammalian desaturases that act on FA esterified to coenzyme A, the *C. elegans* n-3 desaturase is hypothesized to be an acyl-lipid desaturase, meaning that it desaturates lipid-bound FA (13). Acyl-lipid desaturases from lower

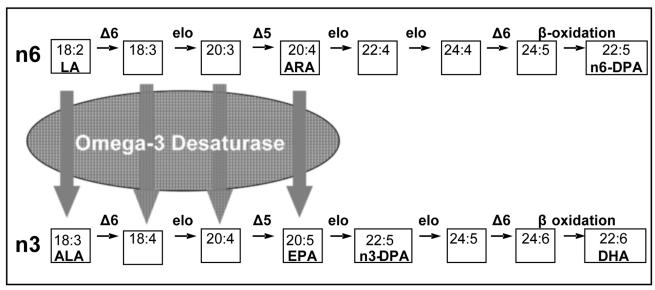

FIG. 1. Biosynthetic pathways of n-6 and n-3 LC-PUFA in mammals. FA elongases (elo) and desaturases (Δ5, Δ6) are capable of acting on either n-6 or n-3 FA to convert linoleic acid (LA) and alpha-linolenic acid (ALA) into LC-PUFA of the n-6 and n-3 families, respectively. The *C. elegans* n-3 FA desaturase recognizes a range of 18- and 20-carbon n-6 substrates. The synthesis of n-6- DPA and DHA requires a chain shortening brought about by one cycle of ,-oxidation in the peroxisome. ARA = arachidonic acid, EPA = eicosapentaenoic acid, DPA = docosapentaenoic acid, DHA = docosahexaenoic acid.

plants and microorganisms operate on acyl groups that are esterified to phospholipids, predominately at the *sn*-2 position (14). Constitutive expression of the *C. elegans* n-3 desaturase under the control of the chicken beta-actin promoter in transgenic mice was found to significantly increase the proportion of n-3 PUFA in total lipids of muscle, milk, brain, heart, erythrocytes, liver, lung, and spleen relative to the control mice (15).

We were interested in directing the expression of this transgene to the mammary gland during lactation as an approach to produce milk with elevated levels of n-3 FA. Transgenic mice expressing the *C. elegans* omega-3 desaturase under the control of the goat beta-casein lactation-induced mammary gland promoter were generated previously. This promoter has been found to direct transgene expression primarily in the lactating mammary gland of transgenic mice (16). These mice produce milk with elevated levels of n-3 FA, especially ALA and EPA (20:5n-3), with the most significant increase being observed in the LC-PUFA–rich phospholipid fraction (17). Several studies have suggested that the balance between n-6 and n-3 PUFA during the perinatal development has long-lasting effects on a number of metabolic parameters into adulthood (18–20). n-6 PUFA promote adipogenesis, and the increasing ratio of n-6:n-3 FA in the Western diet, particularly during fetal life and infancy, may be associated with increased adipogenesis and subsequent obesity (21). This transgenic model provides a way to transgenically decrease the n-6:n-3 FA ratio of milk from animals fed a high n-6:n-3 diet, and disassociate postnatal nutrition effects on programming (22), from those that result from a high n:6:n-3 gestational environment.

In this study we placed n-3 desaturase transgenic and control female mice on a high–n-6 FA diet at breeding and examined the neonatal growth and FA composition of their offspring after being raised on either control milk or milk transgenically enriched with n-3 FA.

EXPERIMENTAL PROCEDURES

Transgenic mice. Transgenic mice (C57/BL6 × DBA) were generated at the UC Davis Murine Targeted Genomics Laboratory by pronuclear microinjection of the *C. elegans* omega-3 FA desaturase (GenBank accession number L41807) under the control of the goat beta-casein promoter of the pBC1 mammary expression vector (Invitrogen, Carlsbad, CA) as detailed in Kao *et al*. (17). The animal experimentation was carried out in accordance with the regulations of the American Association for Accreditation of Laboratory Animal Care in fully accredited facilities at Cole B Vivarium of the UC Davis Department of Animal Science. Eight heterozygous transgenic and eight null (non-transgenic) full-sib control females were placed on a high-safflower mouse diet (Table 1, Diet D03092902, Research Diets, New Brunswick, NJ) at pairing with C57/BL6 males and maintained on this diet for the duration of the study. Pups were weaned to the experimental diet of the dam. Thirty-three pups from six litters per lactational group (ranging from 2 to 8 pups per litter) were nursed on these dams and weighed at days 10 and 21 postpartum. Toe clips from potential transgenic pups were added to 100 µL of lysis buffer [10 mM Tris-HCl, pH 8.0, 50 mM KCl, 20 g proteinase K (EM Science, Darmstadt, Germany), 0.5% Nonidet P-40 substitute (Calbiochem, San Diego, CA), and 0.5% Tween] and incubated at 55°C for 3 h, agitating every 1 h. Toe samples were then heated to 95°C for 10 min to denature the proteinase K, and DNA in the lysate was used as a template for PCR using the n-3 desaturase forward and reverse primers (5′GTCGACCATGGTCGCTCATTCCTCAG3′; 5′GTCGACTTACTTGGCCTTTGCCTTC3’). Transgenic pups were identified by the presence of a 1,444-bp PCR product.

Milk collection and analysis. Duplicate milk samples were collected from the 16 dams during peak lactation (days 10 and 12 postparturition). Phospholipid (polar lipids) and TAG (nonpolar lipids) fractions of the milk fats were separated using Sep-pak silica cartridges WAT051900 (Waters, Milford, MA). The TAG fraction was eluted with hexane:ethyl ether (1:1, vol/vol), and the phospholipid fraction was eluted with

methanol and chloroform:methanol:water (3:5:2, by vol) according to Bitman *et al.* (23). Both fractions were methylated by adding 10% acetyl chloride and incubated at 100°C for 1 h, followed by the addition of 6% K_2CO_3 and hexane. The samples were centrifuged for 5 min at 1,800 rpm, and the upper solvent layer was collected, evaporated under nitrogen, and resuspended in hexane (17). The resulting FAME were then resolved by GC (Hewlett Packard 5890 gas chromatograph). FA were identified by comparison of retention times to known standards (NuChek Prep, Elysian, MN) including 18:1, (18:2, 20:4, 22:5) n-6 FA, and (18:3, 20:5, 22:5, 22:6) n-3 FA, and expressed as g/100 g FA.

Brain and plasma collection and analysis. Whole brains were harvested from pups at 0 d (n = 7 from a control dam), 12 d (n = 7 per lactational group), 21 d (n = 33 per lactational group), and 42 d (n = 7 per lactational group). Brain samples were stored at –80°C until further analysis. For plasma collection, whole blood was collected by cardiac puncture of 21 d pups (n = 33 from 6 litters per lactational group). Blood samples from all pups in each litter were pooled to obtain adequate plasma for FA analysis and placed in a 1.5-mL tube containing 20 μL of 0.5 M EDTA to prevent blood coagulation. To separate the plasma from the erythrocytes, whole blood samples were centrifuged at 3,000 rpm at 4°C for 10 min, and plasma was stored at –20°C until further analysis.

To extract the total lipids, brain samples were homogenized with 0.5 mL of phosphate buffered saline. The brain homogenate samples were methylated with 2 mL 2% H_2SO_4 in methanol at 90°C for 30 min, and the solution was cooled to room temperature and neutralized with 10 mL of 6% K_2CO_3. The samples were vortexed, and 3 mL of hexane and 1 mL of water were added to the solution. The samples were vortexed again and centrifuged at 1,800 rpm for 5 min. The top organic layer was removed and evaporated under nitrogen and resuspended in 100 μL of iso-octane. Total lipids from plasma samples were methylated using the same method, and FA composition was analyzed by GC as previously described (17).

Statistical analysis. Values reported are means ± SEM. Milk, brain, and plasma FA composition and pup weight data analyses were performed using SAS statistical analysis software (SAS Institute, Cary, NC). The procedure MIXED was used to perform an ANOVA to test for differences between data from transgenic and control treatment groups. The differences between the DHA, n-6 DPA (22:5n-6), and total 22-carbon polyene (DHA + DPA) brain FA content of the pups nursed on transgenic dams over time (days 0, 12, 21, and 42 postpartum) were analyzed using a two-way ANOVA. Differences were considered significant if $P < 0.05$.

RESULTS

Milk FA analysis. The FA profiles of TAG and phospholipid fractions of milk produced by n-3 desaturase transgenic dams (n = 8) were compared with those from non-transgenic full-sib control (n = 8) dams when fed a high–linoleic acid (LA, 18:2n-6) diet (Table 2). A significant decrease ($P < 0.001$) in ARA and increases in the n-3 PUFA ALA ($P < 0.001$), EPA ($P < 0.001$), and DHA ($P < 0.05$) were observed in the phospholipid fraction of milk. The n-6:n-3 FA ratios were 4.7 and 34.5 for the transgenic and control milk phospholipid fractions, respectively. In the milk TAG fraction, a significant decrease was observed in ARA ($P < 0.01$), and increases were observed in EPA ($P < 0.001$) and n-3 DPA ($P < 0.01$). The n-6:n-3 FA ratios were 32.2 and 43.5 for the transgenic and control milk TAG fractions, respectively.

Pup plasma FA analysis. The blood from 21-d-old pups nursed on transgenic or non-transgenic full-sib dams was pooled within litter, and plasma FA composition was analyzed (Table 2). The n-6 DPA level was decreased ($P < 0.001$) and n-3 PUFA (EPA, n-3 DPA, and DHA) and stearic acid (18:0) levels were increased ($P < 0.01$–0.001) in plasma from pups nursed on transgenic dams.

Pup brain FA analysis. The FA composition of total brain lipids from 21-d-old pups nursed on n-3 desaturase transgenic and non-transgenic full-sib control dams were analyzed by GC (Table 2). Decreased ($P < 0.001$) levels of myristic acid (14:0), palmitic acid (16:0), ARA, and n-6 DPA (22:5n-6), and increased levels ($P < 0.01$–0.001) of ALA, EPA, n-3 DPA, and DHA were observed in the brains of 21-d-old pups nursed on transgenic dams, compared with the pups nursed on control dams. Twelve-day-old pups nursed on transgenic dams also showed less stearic acid, ARA, and n-6 DPA ($P < 0.01$–0.001) in their brains, and more DHA ($P < 0.01$) as compared with control-reared pups (Table 2). A rapid increase in the proportion of DHA and a decrease in n-6 DPA were observed over time in the brains of pups raised on transgenic dams. In contrast, the proportion of n-6 DPA in the brain increased over time in the pups raised on non-transgenic dams (Fig. 2). There was no effect of pup genotype (heterozygous versus full-sib null) on pup brain FA composition derived from pups nursed on heterozygous transgenic females (data not shown).

Pup weight analysis. The average weight of pups nursed on n-3 desaturase transgenic dams, 4.66 ± 0.11 g and 6.50 ± 0.19 g at day 10 and day 21 postpartum, respectively, did not differ from the average weight of pups nursed on control dams, 4.78 ± 0.17 g and 7.35 ± 0.15 g at day 10 and day 21 postpartum, respectively. Transgenic pups weighed an average of 4.30 ± 0.14 g and 6.23 ± 0.35 g at day 10 and day 21 postpartum, respectively, and this did not differ significantly from the average weights of nontransgenic pups, 4.73 ± 0.11 g and 6.77 ± 0.14 g.

DISCUSSION

Expression of the n-3 desaturase in the mammary gland had a significant effect on the FA composition of milk lipids in agreement with previous work (17). This effect was most striking in the milk phospholipid fraction, where there were 5-, 23-, and 3-fold increases in ALA, EPA, and DHA, respectively, relative to milk phospholipids from nontransgenic controls on the same

diet (Table 2). In the TG fraction of transgenic milk, the increases in EPA and n-3 DPA were 24- and 5-fold, respectively. These increases were accompanied by concomitant decreases in n-6 FA.

Weanlings (21 d) raised on milk from transgenic dams had elevated levels of EPA, n-3 DPA, and DHA in plasma lipids, and ALA, n-3 DPA, and DHA (~ 2-fold increase) in brain lipids (Table 2). Conversely, weanlings nursed on control dams had elevated levels of n-6 DPA in both plasma and brain lipids, despite the fact that the proportion of n-6 DPA in milk FA was not significantly different between milk derived from transgenic and control dams. Many other studies with n-3–deficient diets have reported that a decrease in DHA is accompanied by an increase in n-6 DPA, and the DHA:n-6 DPA ratio can be used as an indicator of n-3 FA deficiency (24). This ratio was 0.75 for the control pups' brains, as compared with 5.39 for the brains of pups nursed on transgenic dams. It has been demonstrated that n-6 DPA is not equivalent to DHA for optimum brain function (25,26), suggesting that the brain has a highly specific structural requirement for DHA. Phosphatidylserine is one of the major phospholipids in many eukaryotic membranes. Neuronal tissues are especially rich in phosphatidylserine, which may contain a high proportion (up to 35%) of DHA (27,28). The loss of DHA due to n-3 PUFA deficiency decreases the phosphatidylserine content in neuronal membranes, which could lead to alterations in membrane properties and adverse functional consequences (29), such as learning disturbances (30,31), olfactory discrimination deficits(32,33), and reduced visual acuity (34).

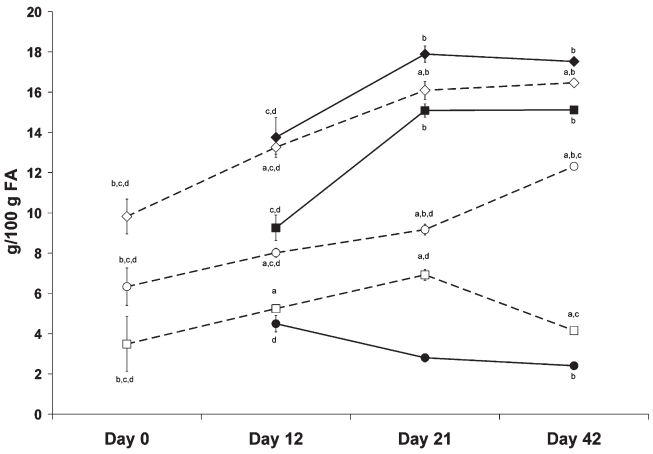

FIG. 2. Time course of 22-carbon polyene levels in the brains of young mice raised on milk from n-3 desaturase transgenic and control dams. DHA (□), n-6- DPA (○), and DHA + n-6 DPA (◇) g/100 g FA from pups ($n = 7$, 14, 66, and 21 at day 0, 12, 21, and 42, respectively) raised on milk from transgenic dams ($n = 8$; solid symbols and line) expressing an n-3 FA desaturase gene in the mammary gland during lactation, or from non-transgenic full-sib control dams ($n = 8$; open symbols and dashed line). Error bars represent SEM; a, b, c, and d denote significantly different ($P < 0.05$) from day 0, 12, 21, and 42 values for the same FA and treatment group, respectively.

The levels of DHA and n-6 DPA in the pup brains were divergent by 12 d postpartum (Fig. 2). An increase in pup brain DHA levels and a concomitant decrease in n-6 DPA levels were observed from 12 d postpartum until pups were weaned from transgenic dams (21 d). In pups raised on non-transgenic dams, the brain n-6 DPA level increased continuously over time, whereas the DHA level increased slowly until weaning and then decreased. Maternal body stores can be a significant source of DHA during lactation (8). The sum of DHA + n-6 DPA in the brains of pups raised on control dams fell behind

that of pups consuming transgenic milk during postnatal development. The "reciprocal replacement" of DHA by n-6 DPA in the brain that is associated with n-3 FA deficiency (35) is incomplete in young animals (36). Therefore, the total proportion of DHA and n-6 DPA 22-carbon polyenes in the brain declines when animals face n-3 FA deficiency during early development.

The inheritance of the transgene itself did not impact the brain FA, as evidenced by the fact that there was no significant effect of pup genotype (heterozygous versus null) in the statistical model (data not shown). This was predicted based on the nearly exclusive expression of the goat beta-casein promoter in the lactating mammary gland. Although discreet amounts of goat beta-casein expression have been observed in the skin and skeletal muscle of transgenic mice, no expression has been observed in the brain (16,17).

The molecular mechanism underlying the accretion of high concentrations of DHA in the brain is unknown (37). Despite the fact that the absolute levels of DHA and n-6 DPA relative to the total FA in milk were not greatly altered by transgenic expression of the n-3 FA desaturase, highly significant differences were observed in the FA composition of weanling brains. The brain rapidly accretes DHA during intrauterine growth and early postnatal "brain growth spurt." Afterward, the adult brain has been described as tenaciously retaining DHA, even during n-3 FA dietary deficiency (26,38). The continued divergence of brain DHA levels observed at day 42 (21 d after weaning) of 15.1% in transgenic-reared pups, as compared with 4.2% in control-reared pups, supports the contention that the brain retains DHA (Fig. 2). Mechanisms exist to minimize DHA loss from the brain during periods of n-3 FA deficiency (39), although it should be noted that the already low brain DHA levels in control-reared pups further declined from 6.9 to 4.2% in this post-weaning period.

Results from studies examining the effects of dietary source on PUFA availability and accumulation in the brain have been contradictory. Some researchers have reported that absorption (7) and brain accretion (37,40) of LC-PUFA are greater from phospholipid sources of LC-PUFA than TG sources, whereas others have concluded the reverse (41), or that the form of the dietary LC-PUFA does not influence their bioavailability (42,43). One explanation that has been put forward to address this apparent paradox is the questionable validity of extrapolating blood plasma FA composition data to estimate the essential FA status of the brain (37). It has been shown that, although plasma phospholipids are good indicators for liver and bile phospholipid FA status, they are not predictive of brain FA composition (37,44). Although our results agree with these findings in that there were no predictable associations between milk and pup plasma or brain FA compositions, this explanation does not resolve the fact that two animal studies found no effect of the form of dietary LC-PUFA on direct measurements of brain FA composition (45,46).

The weights of the pups raised on the transgenic milk were not significantly different from those of the pups raised on control milk, although there was a trend for the pups raised on control milk to be heavier. Other studies have shown that decreasing the n-6:n-3 FA ratio of milk fat, as was effected in the milk derived from the transgenic dams, decreases growth rate, reduces adipose tissue mass, and lowers serum leptin levels in nursing offspring (47,48).

The endogenous mammary gland production of n-3 FA in the transgenic mammalian model described in this study offers a

unique opportunity to examine the growth and development effects of decreasing the n-6:n-3 ratio of maternally-derived FA between gestation and lactation. It may be particularly valuable in isolating the effect of varying the n-6:n-3 FA ratio of milk on adipogenesis and the development of obesity. It is also well suited to answer questions related to the contribution of milk lipids to DHA accretion in the neonatal brain. The relative bioavailability of LC-PUFA associated with different species of milk phospholipids (phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine) could be examined, along with further exploration as to whether the form of LC-PUFA in milk impacts brain FA profiles in suckling neonates. This question has obvious practical relevance in that most infant formulas are currently being supplemented with an algal TAG source of n-3 LC-PUFA. This model may also be of utility to researchers working to further understand the effects of neonatal n-3 LC-PUFA nutrition on visual acuity, brain function, and behavioral development.

ABSTRACT: Intestinal absorption of various plant sterols was investigated in thoracic duct–cannulated normal rats. Lymphatic recovery was the highest in campesterol, intermediate in brassicasterol and sitosterol, and the lowest in stigmasterol and sitostanol. Higher solubility in the bile salt micelle was observed in sitosterol, campesterol, and sitostanol than in brassicasterol and stigmasterol. The solubility of the latter two sterols was extremely low. When the affinity of plant sterols for the bile salt micelle was compared in an *in vitro* model system, which assessed sterol transfer from the micellar to the oil phase, the transfer rate was the highest in brassicasterol, intermediate in campesterol and stigmasterol, and lowest in sitosterol and sitostanol. Although no significant correlations between lymphatic recovery of plant sterols and their micellar solubility or transfer rate from the bile salt micelle were observed, highly positive correlation was obtained between the lymphatic recovery and the multiplication value of the micellar solubility and the transfer rate. These observations strongly suggest that both solubility in and affinity for the bile salt micelle of plant sterols are important determinants of their intestinal absorption in rats.

Paper no. L9965 in *Lipids 41*, 551–556 (June 2006).

Although plant sterols have similar chemical structures to cholesterol (Fig. 1), they are less absorbable than the latter in experimental animals and humans (1). It has been known that absorption rates of various plant sterols are also different from each other (1). However, precise mechanisms of their differential absorption are not understood in detail. Recently, Altmann *et al.* (2) and Davis *et al.* (3) reported that Niemann-Pick C1 Like 1 protein (NPC1L1) is involved in intestinal uptake of cholesterol and plant sterols. However, factors other than NPC1L1 may participate in sterol absorption, because about half of cholesterol and plant sterols was absorbed in NPC1L1-deficient mice compared with wild-type mice (2,3).

Another determinant for differential absorption of plant sterols is differences in efflux from the enterocyte by ATP-binding cassette transporter G5 (ABCG5) and ATP-binding cassette transporter G8 (ABCG8). ABCG5 and ABCG8 work as a heterodimer and secrete absorbed cholesterol and plant sterols from the enterocyte to the intestinal lumen (4). Several mutations of ABCG5 or ABCG8 were found in sitosterolemic patients, who deposit plant sterols in the body and have higher absorbability of plant sterols than normal subjects (5,6). There is a possibility that ABCG5 and ABCG8 might discriminate structural differences in various plant sterols. However, in ABCG5/ABCG8-deficient mice, differential absorption between sitosterol and campesterol was observed (7). Yu *et al.* also showed that when ezetimibe, a potential inhibitor of the NPC1L1 sensing pathway, was given to mice lacking ABCG5 and ABCG8, sterol absorption was reduced, but it was not negligible (8). These observations suggest that factors other than NPC1L1 and ABCG5/ABCG8 are also involved in intestinal absorption of plant sterols.

We previously showed a possibility that intestinal absorption of various plant sterols partly depend on their affinity for the bile salt micelle (9). Sitosterol and stigmasterol, less absorbable plant sterols, had higher affinity for the bile salt micelle than campesterol, which is more absorbable than the former sterols (9). Micellar solubilization of sterols is also essential for sterol absorption (10). Although some studies showed that the solubility of sitosterol in the bile salt micelle was lower than that of cholesterol (11,12), systematic studies by using various plant sterols have never been conducted.

In the present study, to reveal factors participating in plant sterol absorption, lymphatic absorption of various plant sterols in rats, as well as their micellar solubility and affinity for the bile salt micelle, were studied. In most of the studies on plant sterol absorption, plant sterol mixtures were given to animals and humans. Because each plant sterol inhibits intestinal absorption of other plant sterols, accurate comparison among their absorption is impossible. Therefore, we used purified plant sterols in the present study.

EXPERIMENTAL PROCEDURES

Materials. Brassicasterol (purity 93.5%), campesterol (94.4%), stigmasterol (97.7%), and sitosterol (98.6%) were kindly provided by Tama Biochemical Co., Ltd. (Tokyo, Japan). Cholesterol

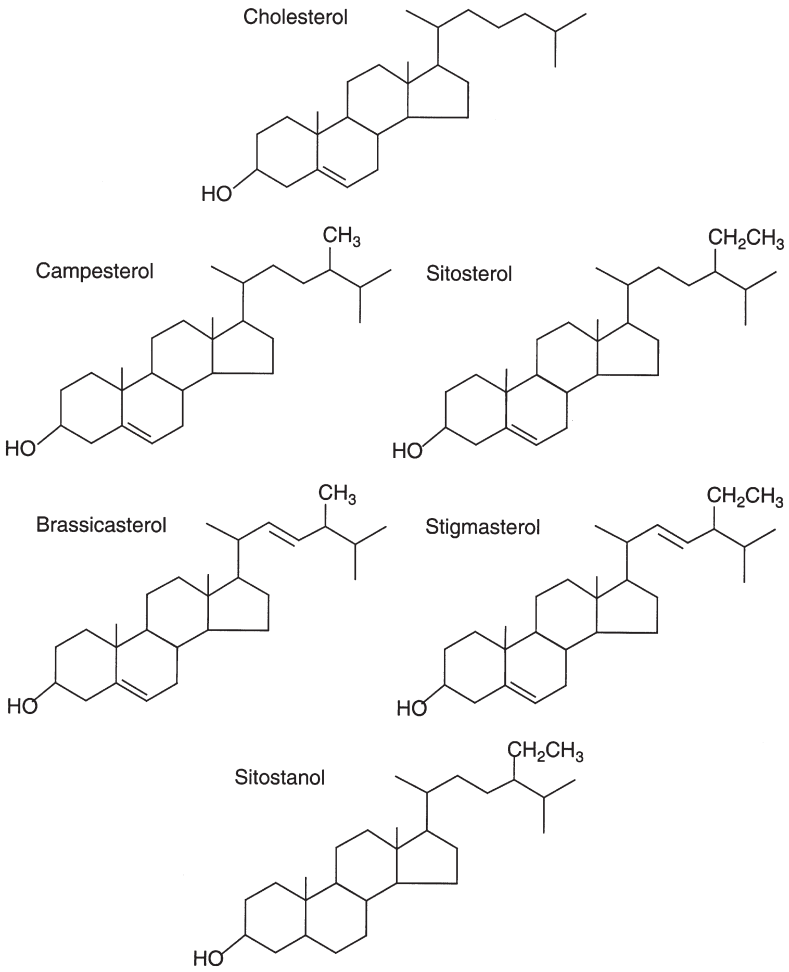

FIG. 1. Chemical structures of plant sterols and cholesterol.

(>99%), sitostanol (95.9%), oleic acid, 1-monooleoyl-rac-glycerol (1-monoolein), L-α-phosphatidylcholine, and triolein were purchased from Sigma (Tokyo, Japan). Sodium taurocholate (>97%) was purchased from Nacalai Tesque (Kyoto, Japan).

Lymphatic absorption of purified plant sterols in rats. Four-week-old male Wistar rats (n = 35) (Seac Yoshitomi, Fukuoka, Japan) were fed an AIN-93G purified diet containing 10% lard for 4 wk *ad libitum*. Because plant sterol content in lard was extremely low, plant sterol concentration in lymph of Wistar rats became almost negligible. These rats were subjected to surgery. Average body weight at surgery was 362 g. The left thoracic lymphatic duct cephalad to the cisterna chili was cannulated as described previously (13). A second indwelling catheter was placed in the stomach for administration of emulsion. After surgery, animals were placed in restraining cages and intragastrically given a continuous infusion of a solution containing 139 mM glucose and 85 mM NaCl at a rate of 3.4 mL/h until the end of experiment. The same solution was given as drinking water. The next morning, animals with a constant lymph flow rate were divided into five groups (n = 6–7 rats per group) to evaluate lymphatic absorption of different plant sterols. Lipid emulsions composed of 67 mg sodium taurocholate, 17 mg FA-free BSA fraction V (Serologicals, Kankakee, IL), 67 mg triolein, and 6.67 mg of a purified plant sterol in 1 mL were prepared by sonication and one of the emulsions was administered into the stomach for 1 mL at 100 g body weight. In this study, five types of purified plant sterols, specifically brassicasterol, campesterol, stigmasterol, sitosterol, and sitostanol, were used for preparing test emulsions. Lymph was collected on ice-chilled tubes containing EDTA for 24 h, and aliquots were served to sterol analysis. In a separate study, lymphatic recovery of cholesterol was also evaluated in the same experimental condition (n = 6, average body weight 303 g). Because cholesterol and trace amounts of plant sterols were detected in lymph before the infusion of a test emulsion, the amounts of cholesterol and plant sterols in lymph before administration were used as the baseline. All animal studies were carried out under the guidelines for animal experiments of the Faculty of Agriculture, Graduate School, Kyushu University, and Law 105 and Notification 6 of the government of Japan.

Micellization of purified plant sterols in vitro. Lipid emulsions containing 10.8 mM oleic acid, 10.8 mM triolein, 5.4 mM

TABLE 1
Lymphatic Absorption, Micellar Solubility, and Transfer Rate to Triolein of Purified Plant Sterols

[a]Data on cholesterol were obtained in separate studies. Therefore, the data were not subjected to statistical analyses.
[b]Data are mean ± SE of 6 to 7 rats per group.
[c]Data are mean ± SE of 3 determinations.
[d]Data are mean ± SE of 4 determinations.
[a,b,c]Different letters show significant differences among plant sterols at $P < 0.05$ in the Tukey-Kramer test.

1-monoolein, 6 mM sodium taurocholate, and 0.5 to 8 mM of a purified plant sterol, either brassicasterol, campesterol, stigmasterol, sitosterol, or sitostanol, were prepared in 150 mM sodium phosphate buffer (pH 7.0) by sonication. The emulsions thus obtained were kept at 37°C and transferred to a Beckman Quick Seal tube and ultracentrifuged at 100,000 × *g* for 1 h at 37°C (Optima TL Ultracentrifuge, Beckman, Palo Alto, CA) to separate the micellar phase from the emulsion. Aliquots of the clear micellar solution and the emulsion were served to sterol analysis by GLC. Micellar solubility of cholesterol was also examined at 8 mM in a separate study.

Transfer of purified plant sterols from the bile salt micelle to triolein. Micellar solutions containing 6.6 mM sodium taurocholate, 0.6 mM phosphatidylcholine, 0.1 mM of a purified plant sterol, either brassicasterol, campesterol, stigmasterol, sitosterol, or sitostanol, and 132 mM NaCl in 15 mM sodium phosphate buffer (pH 7.4) were prepared. The micelles then passed through a 0.2-μm syringe filter (25 mm, GD/X, Whatman, Inc., Clifton, NJ) and kept at 37°C overnight. The next morning, 1.5 mL of a micellar solution and 0.5 mL of triolein were placed in a plastic tube, flushed with N_2, and sealed. The tubes were incubated at 37°C in an oscillating water bath for 6 h (190 oscillations/min), at which time the rate of sterol transfer from the micellar solution to triolein was linear. At the end of the incubation, the contents of each tube were transferred to a Beckman Quick Seal tube, and the oil and aqueous phases were separated by ultracentrifugation (Beckman) at 100,000 × *g* for 1 h at 37°C. The oil and micellar phases were collected and sterol concentrations were analyzed by GLC (9). Transfer of cholesterol from the bile salt micelle to triolein was also examined under the same experimental conditions.

Sterol analysis. Total lipids were extracted and purified by the method of Folch *et al.* (14). After saponification of total lipids, unsaponifiable matters collected were derivatized to trimethylsilylethers and were quantified by GLC using a SPELCO SPB-1™ column (0.25 mm × 60 m, 0.25-μm film thickness, Sigma-Aldrich, Tokyo, Japan) and 5α-cholestane (Sigma) as an internal standard.

Statistics. All data were expressed as mean ± SE. The Tukey-Krammer test was performed, and $P < 0.05$ was considered significant.

RESULTS

Lymphatic absorption of purified plant sterols in Wistar rats. The lymphatic 24-h recovery of campesterol was the highest among the five types of plant sterols, and stigmasterol and sitostanol were the lowest (Table 1). Lymphatic recoveries of brassicasterol and sitosterol were intermediate. The lymphatic 24-h recovery of cholesterol was 59.2 ± 5.2% under the same experimental conditions.

Micellar solubility of purified plant sterols in vitro. Micellar concentrations of purified plant sterols proportionally increased with the increase of their concentration from 0.5 to 6 mM in test emulsions. The micellar concentration of each plant sterol reached plateau when the concentration in emulsion was 8 mM. Therefore, we thought that maximal solubility of each plant sterol was obtained at 8 mM in test emulsion under our experimental conditions. Among the five types of purified plant sterols, the solubility of brassicasterol and stigmasterol were extremely low (Table 1). Micellar solubilities of campesterol, sitosterol, and sitostanol were 3.5–4.5 times higher than those of brassicasterol and stigmasterol. Micellar concentration of cholesterol in the 8 mM emulsion was 5.21 ± 0.07 mM in a separate study.

Transfer of micellar plant sterols to triolein. We investigated the transfer rates of purified plant sterols from the bile salt micelle to triolein at 37°C *in vitro*. In this condition, it is thought that degrees of movement of micellar sterols to the oil phase depend on affinity of sterols for the bile salt micelle (9), that is, the higher the sterol transfer to triolein, the lower the affinity of the sterol for the bile salt micelle. The transfer rate of plant sterols was the highest in brassicasterol and the lowest in sitostanol among the five types of plant sterols tested (Table 1). The order of transfer rates of each plant sterol was as follows: brassicasterol > campesterol > stigmasterol > sitosterol > sitostanol. The transfer rate of cholesterol was comparable to that of brassicasterol.

Correlation between lymphatic recovery of sterols and their micellar solubility or transfer rate. There was no positive correlation between micellar solubility and lymphatic recovery of plant sterols ($r = +0.41$, $P = 0.50$), or between transfer rate of micellar plant sterols to triolein and lymphatic recovery of plant sterols ($r = +0.21$, $P = 0.74$). However, a

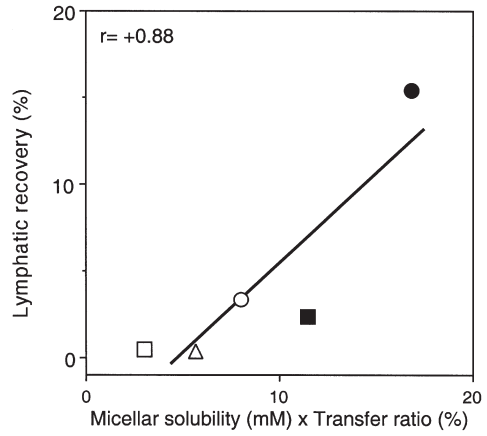

FIG. 2. Correlation between lymphatic recovery of plant sterols and multiplication value of micellar solubility and transfer rate of micellar sterol to triolein. ○, Brassicasterol; ●, campesterol; □, stigmasterol; ■, sitosterol; △, sitostanol.

highly positive correlation was observed (Fig. 2) between lymphatic recovery of plant sterols and multiplication value of micellar solubility and transfer rate ($r = +0.88$, $P < 0.05$). When data for cholesterol, collected in separate studies, were included, the correlation coefficient between these parameters was $r = +0.99$, $P < 0.001$.

DISCUSSION

In the present study, we measured absorption rates of sterols by the lymphatic recovery method. Absorption rates measured by the intestinal perfusion method and the fecal recovery must be lower than those measured in the lymphatic recovery method, because in intact animals, a part of absorbed sterols is excreted via bile into intestinal lumen and then into feces. Absorption rates excluding influence of biliary excretion of sterols may be important to consider the relationship between absorption rates of sterols and micellar solubility and affinity for the bile salt micelle of sterols.

We compared lymphatic absorption of various purified plant sterols in rats and showed that intestinal absorption rates of various plant sterols vary widely. Lymphatic 24-h recovery of campesterol was about 50 times higher than that of sitostanol, the least absorbable sterol (Table 1). The recovery of stigmasterol was almost comparable to that of sitostanol. Sitosterol and brassicasterol were more absorbable than sitostanol and stigmasterol, and less absorbable than campesterol.

We previously showed that fecal output of dietary sitostanol in rats was almost quantitative (15). When fecal output of ^{14}C-sitostanol was assessed in rats, more than 97% was recovered in feces (16). Hassan and Rampone showed that lymphatic absorption of trace amounts of ^{3}H-sitostanol in 24 h was 2.2% in rats (17). In the present study, lymphatic recovery of sitostanol was only 0.3%, and therefore it is clear that sitostanol absorption is extremely low.

It has been reported that sitosterol is more absorbable than sitostanol (16). Sitosterol absorption rate has been measured in many studies and reported to be 5–32% in humans and rats (18). According to relatively reliable observations, sitosterol absorption may be around 5% in rats and humans (19–23). Although intestinal absorption of campesterol has been suggested to be higher than sitosterol, only two previous studies showed preferential absorption of campesterol over sitosterol. Heinemann *et al.* reported that intestinal absorptions of campesterol and sitosterol were estimated to be 9.6% and 4.2%, respectively, in healthy humans measured by an intestinal perfusion technique (23). Lütjohann *et al.* showed that absorptions of campesterol and sitosterol were estimated to be 16% and 5% in normal subjects by measuring fecal output of deuterium-labeled sterols (22). However, there is no precise observation of campesterol absorption rate in rats. In the present study, higher absorbability of campesterol than sitosterol was proved in rats. Bhattacharyya measured uptake of campesterol and sitosterol by rat small intestine *in vivo* (24). The amounts incorporated into intestinal mucosa were higher in campesterol than in sitosterol.

The results on intestinal absorption of stigmasterol and brassicasterol are controversial. Heinemann *et al.* observed almost comparable absorption of stigmasterol to that of sitosterol in humans (23). Vahouny also observed lymphatic 24-h recoveries of stigmasterol and sitosterol were 4.3% and 3.1%, respectively, in rats (25). These observations suggest that absorption of stigmasterol is comparable to that of sitosterol. In contrast, Bhattacharyya showed extremely lower incorporation of stigmasterol than sitosterol into the small intestine in rat (24). In the present study, the rate of stigmasterol absorption was extremely low and comparable to that of sitostanol absorption. Vahouny showed that lymphatic absorption of brassicasterol included in oyster sterols was 5.4% for 12 h in rats (26). Gregg *et al.* reported that absorption of brassicasterol (given as shellfish sterols) was 4.8% in normal subjects (27). The values seem to be higher than the absorption rate of brassicasterol in the present study. Because studies on absorption of stigmasterol and brassicasterol are scarce, more research is necessary.

To clarify the involvement of micellar solubility and affinity for the bile salt micelle of various plant sterols, these parameters were measured. The micellar solubility of plant sterols increased in the following order: stigmasterol = brassicasterol < sitostanol < campesterol < sitosterol. There was no significant correlation between micellar solubility and lymphatic recovery of plant sterols ($r = +0.41$). The affinity of plant sterols for the bile salt micelle was assessed by measuring their transfer from the bile salt micelle to triolein. In our previous study, the transfer of sterols classified as absorbable (cholesterol, campesterol, 7-dehydrocholesterol) was higher than that of sterols known to be less absorbable (sitosterol, stigmasterol, fucosterol) (9). Therefore, we concluded that intestinal absorption of sterols depends on the affinity for the bile salt micelle. In the present study, when we reevaluated the transfer of five types of plant sterols, newly including brassicasterol and sitostanol, the transfer rate increased in the following order: sitostanol < sitosterol < stigmasterol < campesterol < brassicasterol. No positive correlation was observed between their transfer rate and lymphatic absorption ($r = +0.21$). In contrast

to our previous study, the results in the present study suggest that affinity to the bile salt micelle is not a sole determinant of plant sterol absorption. Hence, we thought that both micellar solubility and affinity for the bile salt micelle must relate to intestinal absorption of plant sterols. We multiplied amounts of plant sterols solubilized in the bile salt micelle by transfer rate from the bile salt micelle and found that there is a highly positive correlation between lymphatic absorption rate and the multiplicative product of micellar solubility and transfer rate (r = +0.88). When results obtained from separate experiments using cholesterol were included, correlation coefficient was r = +0.99. The observation strongly suggests that both micellar solubility and transfer rate are involved in differential absorption rate of plant sterols and cholesterol.

It has been reported that NPC1L1 is involved in intestinal uptake of cholesterol and plant sterols (2,3). Ezetimibe, a potential inhibitor of the NPC1L1 sensing pathway, reduced their absorption. Davis *et al.* reported that the uptake of sitosterol into the intestine of NPC1L1-deficient mice and normal mice given ezetimibe was reduced by around 50% (3). Yu *et al.* also reported that absorption of campesterol and sitosterol in normal mice was reduced by the administration of ezetimibe roughly to one-half (8). These observations suggest that 50% of incorporation of sterols into intestinal epithelial cells is dependent on the pathway through NPC1L1. We think that micellar solubility and affinity for the bile salt micelle participate in the remaining part (about 50%) of uptake of plant sterols into the intestine. However, we will have to examine a possibility that NPC1L1 contributes to differential absorption of plant sterols.

There is a possibility that ABCG5 and ABCG8 also participate in differential absorption of plant sterols. Igel *et al.* proposed a hypothesis that the uptake of sterols and their corresponding stanols into the intestinal mucosal cell are extremely rapid and unselective process, hence, discrimination takes place on the level of reverse transport back into the gut lumen by ABCG5 and ABCG8 (28). However, Yu *et al.* observed that although intestinal absorptions of cholesterol, campesterol, and sitosterol in AGCG5/ABCG8-deficient mice were higher than those in the wild-type mice, the rank order of absorption rate was cholesterol > campesterol > sitosterol in both mice (7). Therefore, they described that differential absorption of plant sterols is largely independent of ABCG5 and ABCG8 (7). Further investigation is necessary to clarify whether the rates of efflux of various plant sterols by ABCG5 and ABCG8 are different.

In the present study, we showed that solubility in and affinity for the bile salt micelle of plant sterols are important determinants of their intestinal absorption. The extent of contribution of these parameters, the incorporation by NPC1L1, and the efflux by ABCG5 and ABCG8 on plant sterol absorption remain to be solved.

Diacylglycerol Acyltransferases from *Vernonia* and *Stokesia* Prefer Substrates with Vernolic Acid

Keshun Yu, Charles T. McCracken, Jr., Runzhi Li, and David F. Hildebrand*

Department of Plant and Soil Sciences, University of Kentucky, Lexington, Kentucky, 40546

ABSTRACT: Genetic engineering of common oil crops for industrially valuable epoxy FA production by expressing epoxygenase genes alone had limited success. Identifying other key genes responsible for the selective incorporation of epoxy FA into seed oil in natural high accumulators appears to be an important next step. We investigated the substrate preferences of acyl CoA:diacylglycerol acyltransferases (DGAT) of two natural high accumulators of vernolic acid, *Vernonia galamensis* and *Stokesia laevis*, as compared with a common oilseed crop soybean. Developing seed microsomes were fed with either [^{14}C]oleoyl CoA or [^{14}C]vernoloyl CoA in combinations with no exogenous DAG or with 1,2-dioleoyl-*sn*-glycerol, 1-palmitoyl-2-vernoloyl-*sn*-glycerol, 1,2-divernoloyl-*sn*-glycerol, 1,2-dioleoyl-*rac*-glycerol, or 1,2-divernoloyl-*rac*-glycerol to determine their relative incorporation into TAG. The results showed that in using *sn*-1,2-DAG, the highest DGAT activity was from the substrate combination of vernoloyl CoA with 1,2-divernoloyl-*sn*-glycerol, and the lowest was from vernoloyl CoA or oleoyl CoA with 1,2-dioleoyl-*sn*-glycerol in both *V. galamensis* and *S. laevis*. Soybean DGAT was more active with oleoyl CoA than vernoloyl CoA, and more active with 1,2-dioleoyl-*sn*-glycerol when oleoyl CoA was fed. DGAT assays without exogenous DAG, or with exogenous *sn*-1,2-DAG fed individually or simultaneously showed consistent results. In combinations with either oleoyl CoA or vernoloyl CoA, DGAT had much higher activity with *rac*-1,2-DAG than with their corresponding *sn*-1,2-DAG, and the substrate selectivity was diminished when *rac*-1,2-DAG were used instead of *sn*-1,2-DAG. These studies suggest that DGAT action might be an important step for selective incorporation of vernolic acid into TAG in *V. galamensis* and *S. laevis*.

Paper no. L9987 in *Lipids 41*, 557–566 (June 2006).

Epoxy FA such as vernolic acid have many industrial applications including in plasticizers (1), coatings (2), and resins (3). A few plant species such as *Vernonia galamensis* (2) and *Stokesia laevis* (4) accumulate vernolic acid as their major FA in their seed oils. However these plants, in their present form, cannot readily be grown to produce seed efficiently on an industrial scale. Soybean and linseed oil are currently utilized to produce epoxidized oil using a chemical process. Epoxygenase genes that are responsible for epoxidizing linoleic acid while in the *sn*-2 position of phospholipids such as PC (5) have been cloned from several accumulators of vernolic acid (6–9). However, expressing *V. galamensis* epoxygenase in soybean seeds resulted in an accumulation of only 8% vernolic acid of the total FA of the seed oil (10), which is not high enough to be commercially viable. Similar results were found with arabidopsis seeds (9). Thus, other key enzymes in seed oil biosynthesis need to be identified in high accumulators of epoxy FA to achieve greater epoxy FA accumulation in transgenic oilseeds. Three enzymes, namely acyl CoA:diacylglycerol acyltransferase (DGAT, EC 2.3.1.20), phospholipid:diacylglycerol acyltransferase (EC 2.3.1.158), and diacylglycerol transacylase, are known to be able to carry out the final step in TAG synthesis in developing seeds (11). These enzymes may play an important role for the selective incorporation of unusual FA into TAG in natural high accumulators of unusual FA. For example, the DGAT of castor (*Ricinus communis*), an accumulator of ricinoleic acid, has been shown to favor diricinoleoylglycerol and ricinoleoyl CoA incorporation into TAG (12–14).

In the present study we test the hypothesis that *V. galamensis* and *S. laevis* DGAT but not soybean DGAT might be able to preferentially incorporate vernolic acid into TAG. We also demonstrate that the DGAT studied have higher activity when acyl-CoA are fed with *rac*-1,2-DAG than with their corresponding *sn*-1,2-DAG.

EXPERIMENTAL PROCEDURES

Materials. All solvents (HPLC grade or anhydrous), Na, KCl, NaOH, HCl, H_2O_2 (30%), $MgCl_2$, MOPS, DTT, ammonium acetate, glacial acetic acid, Triton X-100, *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide (Diazald®), boiling chips, Whatman No. 1 filter paper, and Whatman TLC plates were purchased from Fisher Scientific (Fair Lawn, NJ). [1-^{14}C]Linoleic acid (55 mCi mmol^{-1}) was purchased from Amersham Biosciences (Piscataway, NJ). [1-^{14}C]Oleoyl CoA (18:1-CoA, 55 mCi mmol^{-1}) supplied in 10 mM sodium acetate (pH 5.2):ethanol (1:1) was purchased from American Radiolabeled Chemicals Inc. (St. Louis, MO). It was diluted about 60-fold with methanol prior to use and stored at –80ºC under argon. 1,2-Dioleoyl-*sn*-glycerol (*sn*-DODAG), 1,2-dioleoyl-*rac*-glycerol (*rac*-DODAG), 1,3-specific lipase (Palatase 20000 L, L4277) from *Rhizomucor miehei*, acyl-

Abbreviations: 18:1-CoA, oleoyl CoA; DGAT, acyl-CoA:diacylglycerol acyltransferase; *rac*-DODAG, 1,2-dioleoyl-*rac*-glycerol; *sn*-DODAG, 1,2-dioleoyl-*sn*-glycerol; DV, divernolin; *rac*-DVDAG, 1,2-divernoloyl-*rac*-glycerol; *sn*-DVDAG, 1,2-divernoloyl-*sn*-glycerol; MTBE, methyl tertiary butyl ether; MV, monovernolin; *sn*-MVDAG, 1-palmitoyl-2-vernoloyl-*sn*-glycerol; TV, trivernolin; Va-CoA, vernoloyl CoA.

CoA synthetase (A3352), lipase acrylic resin (Novozyme 435, L4777), phospholipase C (P7633), phospholipase A_2 (P0861), 4-Å molecular sieves, antipain, catalase, protease inhibitor cocktail for plant cell and tissue extracts (P9599), diheptadecanoyl PC, ATP, CoASH, ethyl chloroformate, triethylamine, *N*,*N*-4-dimethylaminopyridine, dicyclohexylcarbodiimide, trifluoroacetic anhydride, *sn*-glycero-3-phosphocholine:cadmium chloride adduct (1:1), primulin, Folin & Ciocalteu's phenol reagent (2 N, F9252), and lipid standards other than triacylglyceride (which was from soybean oil [Crisco] purchased from a local grocery store), were purchased from Sigma Chemical Co. (St. Louis, MO). 1-Palmitoyl-2-hydroxy- *sn*-glycero-3-lysophosphatidylcholine was purchased from Avanti Polar Lipids, Inc. (Alabaster, AL). Ag 501-X8 resin was purchased from Bio-Rad (Hercules, CA). NH_2 columns (35 mg) were purchased from J.T. Bakers (Phillipsburg, NJ). Sep-Pak tC_{18} cartridges were purchased from Waters (Milford, MA). Silica solid phase extraction columns were purchased from J & W Scientific (Folsom, CA). Liquid scintillation cocktail and 20-mL glass storage vials were purchased from Research Products International Corp. (Mount Prospect, IL). *V. galamensis* oil was purchased from VerTech, Inc. (North Bethesda, MD). Dry hexane and toluene were obtained by adding molecular sieves to HPLC-grade hexane in a 20-mL screw-capped storage vial. Sodium methoxide (4.2%, wt/vol) was made by slowly adding 1.8 g of sodium, which was cut into small pieces when submerged in toluene, into 100 mL methanol under a stream of argon. Diazomethane was synthesized from *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide using Mini Diazald® Apparatus according to Aldrich Technical Information Bulletin No. AL-121.

Chemical syntheses. Trivernolin was purified by repeated recrystallization in hexane at –20°C. 1,2-Divernoloyl-*rac*-glycerol (*rac*-DVDAG) was from partial hydrolysis of trivernolin using Palatase (Sigma) and purified by column chromatography. Vernolic (12,13-epoxy-9-octadecenoic) acid was synthesized from saponification of trivernolin with ethanolic NaOH. Briefly, 30 g of trivernolin, 10 g NaOH, and 150 mL of water:ethanol (1:2) were mixed in a 1-L flask and boiled on a hot plate with constant stirring with a magnetic stirrer for 20 min. Ethyl acetate (about 300 mL) was added to the reaction mixture. Subsequently glacial acetic acid was added to neutralize the base to a pH of 5. The ethyl acetate was removed using a separatory, funnel and the water phase was extracted with ethyl acetate two more times. The extracts were combined, washed with water, dried with anhydrous sodium sulfate, and filtered with Whatman No. 1 filter paper. The solvent was evaporated with a rotary evaporator (Buchler Instruments, Fort Lee, NJ). The vernolic acid was purified using column chromatography. Vernolic anhydride was synthesized from vernolic acid using ethyl chloroformate according to Subramanian *et al.* (15) except that methyl tertiary butyl ether (MTBE) was used instead of ether. 1-Palmitoyl-2-vernoloyl-*sn*-glycero-3-phosphocholine and 1,2-divernoloyl-*sn*-glycero-3-phosphocholine were synthesized from vernolic anhydride with 1-palmitoyl-2-hydroxyl-*sn*-glycero-3-phosphocholine and *sn*-glycero-3-phosphocholine:cadmium adduct, respectively, according to Subramanian *et al.* (15) with some modifications. Argon was used for degassing instead of nitrogen. The reaction mixture included both dimethylaminopyridine and dicyclohexylcarbodiimide at a similar molar ratio. 1-Palmitoyl-2-vernoloyl-*sn*-glycerol (*sn*-MVDAG) and 1,2-divernoloyl-*sn*-glycerol (*sn*-DVDAG) were synthesized from their respective PC using phospholipase C according to the manufacturer's activity testing procedure, and the compounds were purified by TLC using the solvent system of hexane/MTBE (60:40, vol/vol). All DAG used for enzyme activity assays were examined via TLC and *sn*-1,3-DAG levels were very low.

[1-^{14}C]Vernolic acid was synthesized by a modified reaction (16) using Novozyme 435 (Sigma). Briefly, [^{14}C]linoleic acid (100 mCi) was dried under a stream of nitrogen and resuspended in 2 mL of toluene. Novozyme 435 (2 mg) and 20 mL of 30% H_2O_2 were added. The reaction mixture was shaken for 4 h at 800 rpm on a VXR orbital shaker (Type VX 7, Janke & Kunkel, Staufen, Germany) at room temperature. A small sample of the reaction mixture was tested on TLC after methylation with diazomethane using a solvent system of hexane/MTBE/acetic acid (85:15:1, by vol) to view the reaction progress. The reaction mixture was kept at –20ºC. This process was repeated until maximum yield was obtained (~40% vernolic acid). The reaction mixture was dried under a stream of nitrogen and methylated with diazomethane. [^{14}C]Methyl vernolate was purified by TLC using a solvent system of hexane/MTBE (88:12, vol/vol). The [^{14}C]vernolic acid methyl ester was saponified with 1 mL of ethanol:2 N NaOH (9:1, vol/vol) at 80°C refluxing under argon for 1 h and extracted with ethyl acetate immediately after acidification by about 0.42 mL 1 N HCl. [^{14}C]Vernoloyl-CoA (Va-CoA) was synthesized using acyl-CoA synthetase (Sigma) according to Taylor *et al.* (17). The Va-CoA was then purified by Sep-Pak tC_{18} cartridges (Waters) according to Gang *et al.* (18) except that the Va-CoA was finally eluted with two volumes of methanol followed by two volumes of butanol. The methanol was evaporated with a stream of nitrogen. The Va-CoA was extracted with butanol and combined with the previous butanol elution. The Va-CoA in butanol was further purified on normal phase silica column using butanol and butanol/water (79:21, vol/vol). The Va-CoA showed a single band on reverse phase TLC using a solvent system of butanol/acetic acid/water (63:10:27, by vol).

Mixed [^{14}C]linoleic acid anhydrides were synthesized from [^{14}C]linoleic acid and trifluoroacetic anhydride in dry hexane at refluxing temperature; the solvent was allowed to leak out of the screw-capped test tube over a period of about 1 h. In detail, [^{14}C]linoleic acid (1 µmol, 55 µCi/µmol) was placed in a 10-mL screw-capped test tube. The solvent was removed under a stream of nitrogen gas and 1 mL of dry hexane was added. To the solution 20 µL trifluoroacetic anhydride was added, and the test tube was flushed with argon and closed. The test tube was placed in boiling water, and the sample was refluxed and hexane was allowed to slowly leave

the test tube over about 1 h. The release of hexane was controlled by slightly loosening the screw cap from the test tube. The sample was resuspended in 1 mL of dry hexane. The yield of [^{14}C]linoleic trifluoroacetic anhydride was checked by TLC using the solvent system hexane/MTBE/acetic acid (85:15:1, by vol). The mixed anhydride ran much higher than linoleic acid on the TLC plate but below linoleic anhydride. If the yield was not satisfactory, the reaction could be repeated until a high yield (over 80%) was obtained.

Vernolic acid is very sensitive to acids, so the method used for mixed linoleic acid anhydride cannot be used for mixed vernolic acid anhydride. Mixed [^{14}C]vernolic anhydride was synthesized by reacting [^{14}C]vernolic acid with an excess of ethyl chloroformate in the presence of triethylamine at room temperature. Briefly, [^{14}C]vernolic acid was dissolved in 1 mL of dry hexane in a 10-mL screw-capped test tube. To the solution 5 μL of 5% triethylamine and 5 μL of 5% ethyl chloroformate were added in dry hexane. The solution was flushed with argon, tightly closed, and shaken at 800 rpm at room temperature for 1.5 h. The reaction mixture was brought to dryness with a stream of nitrogen gas and resuspended in 1 mL dry hexane. The solution was again brought to dryness under a stream of nitrogen gas. The mixed [^{14}C]vernolic anhydride was checked on TLC using a solvent system of hexane/MTBE/acetic acid (85:15:1, by vol).

The procedure for synthesis of [^{14}C]PC was derived from Subramanian *et al.* (15) and Ramstedt and Slotte (19). The labeled mixed FA anhydrides were reacted with an excess of 1-palmitoyl-2-hydroxy-*sn*-glycero-3-lysophosphatidylcholine in the presence of dimethylaminopyridine and dicyclohexylcarbodiimide at room temperature. In detail, the mixed [^{14}C]linoleic acid anhydride or mixed [^{14}C]vernolic anhydride (55 μCi, 1 μmol) synthesized as described above was placed in a 15-mL screw-capped conical test tube and brought to dryness under a stream of nitrogen gas. To the test tube were added 1-palmitoyl-2-hydroxy-*sn*-glycero-3-lysophosphatidylcholine (991 μg, 2 μmol), dimethylaminopyridine (1.22 mg, 10 μmol) and dicyclohexylcarbodiimide (2.06 mg, 10 μmol), all in dry chloroform. The solution was again brought to dryness under a stream of nitrogen gas and resuspended in 40 μL of dry toluene. The sample was flushed with argon and closed tightly with a screw cap. The test tube was shaken for 24 h at 800 rpm at room temperature. The reaction progress was assayed by TLC along with *sn*-1,2-dioleoyl-PC as a standard using solvent systems of chloroform/methanol/water (65:25:4, by vol) and hexane/MTBE (75:25, vol/vol). [^{14}C]PC were synthesized with up to 36% yield for [^{14}C]vernoloyl-PC and 40% for [^{14}C]linoleoyl-PC relative to the labeled mixed FA anhydrides added based on the quantitative analysis using ImageQuant (version 5.2, Amersham Biosciences).

For the analyses of the positional distribution of labeled FA of the [^{14}C]PC, small samples of the labeled PC (0.01 μCi) synthesized as described above were digested with 10 μL phospholipase A_2 (100 units) for 30 min at room temperature in a buffer (100 μL) as described by Egger *et al.* (20) except that the pH was 7.5 instead of 8. The lipids were extracted into chloroform according to Bligh and Dyer (21) and analyzed by TLC using corresponding unlabeled free FA and 1-oleoyl-2-hydroxyl-*sn*-glycero-3-lysophosphatidylcholine as standards. The TLC plates were visualized by phosphorimaging (Amersham). Free FA and lysophosphatidylcholine bands were scraped off the TLC plate and analyzed by a liquid scintillation analyzer (PerkinElmer, Wellesley, MA). The results showed that the digestion went to completion and the percentage of labeled FA located at *sn*-1 and *sn*-2 were 60% and 40% for the palmitoyl-[^{14}C]vernoloyl-PC and 41% and 59% for the palmitoyl-[^{14}C]linoleoyl-PC, respectively. These results indicate that significant acyl exchange between *sn*-1 and *sn*-2 positions occurred during the [^{14}C]PC synthesis reactions.

Microsomal preparations. *V. galamensis* and *S. laevis* were grown in a soil bed outdoors in Lexington, KY. Soybeans (*Glycine max* cv. Jack) were grown in a greenhouse. Microsomes from developing seeds of *V. galamensis*, *S. laevis*, and soybean at a stage of rapid growth and high triglyceride biosynthesis were prepared according to Bafor *et al.* (5), with antipain (5 mg/mL buffer) added according to Lin *et al.* (22). For *V. galamensis* and *S. laevis*, developing seeds used were soft and white after seed coats were removed. Soybean developing seeds used were 9–11 mm in length, and their seed coats were also removed. Protease inhibitor cocktail (33.3 μL g^{-1} of tissue) was added just before tissue homogenation for *V. galamensis* and *S. laevis* but not for soybean since its developing seeds are known to contain large amounts of protease inhibitors that can be released quickly (23). The microsomal pellets were resuspended in a buffer at approximately 1 mL/g tissue. The resuspension buffer was 100 mM potassium phosphate buffer (pH 7.2), 0.1% (wt/vol) of BSA (FA-free), 1,000 units/mL of catalase, and 5 μg/mL of antipain. Aliquots of the microsomal fractions were flash frozen with liquid nitrogen and stored at –80°C. The microsomal PC concentrations were determined in triplicate by GC (Model 5890, Hewlett Packard) using diheptadecanoyl PC as an internal standard according to Christie *et al.* (24). Thirty microliters of microsomal suspension was mixed with 5 μg of diheptadecanoyl PC. The lipids were extracted into chloroform according to Bligh and Dyer (21) and separated on TLC along with 50 μg of soy lecithin as a standard using a solvent system of chloroform/methanol/acetic acid/water (85:17:10:3.5, by vol). The lipid bands were visualized under ultraviolet light after spraying with 0.005% primulin in acetone/water (4:1, vol/vol). The band corresponding to PC was scraped off the plate, and the lipid was methylated with 0.5 mL of sodium methoxide (4.2%, wt/vol) with shaking at 800 rpm for 45 min. One milliliter of hexane was used to extract the FAME, and this was repeated once. The hexane extracts were combined and then washed with 1 mL of 0.9% KCl. The FAME in hexane was brought down to 0.5 mL and analyzed by GC. The area units of the methyl esters of five common FA (palmatic, stearic, oleic, linoleic, and linolenic) were combined for the calculation of microsomal PC levels as compared with those of methyl heptadecanoate. The microsomal

protein concentrations were determined by a modified Lowry method according to Wang (25).

Microsomal assays. Microsomal assay conditions were modified from the DGAT assay as described by Jako *et al.* (26). Microsomal fractions (0.5 nmol PC eq.) were fed with 5 μM [^{14}C]18:1-CoA or [^{14}C]Va-CoA in combinations with *sn*-DODAG, *sn*-MVDAG, *sn*-DVDAG, *rac*-DODAG, *rac*-DVDAG, or no exogenous DAG in a total reaction volume of 200 μL. The *sn*-1,2-DAG were either fed individually or simultaneously. The reaction mixture was in 100 mM potassium phosphate buffer (pH 7.2) containing 1 mM $MgCl_2$, 0.5 mM ATP, 0.5 mM CoASH, and 20% glycerol (vol/vol). The reaction mixture was incubated at 30°C in an incubator with shaking at 100 rpm for 30 min. The microsomal assay reactions were stopped by placing them in ice, which was immediately followed by addition of 1 mL of chloroform/methanol (2:1, vol/vol) containing 50 μg TAG. After vortexing vigorously, 300 μg *V. galamensis* oil was added.

The lipids from microsomal assay reactions were extracted into chloroform according to Bligh and Dyer (21), blown dry, and resuspended in 1 mL ethyl acetate. The ethyl acetate extract was passed through an NH_2 column to removed free FA. Lipids were eluted with a total of 6 mL of ethyl acetate, which was blown down with a stream of nitrogen and loaded onto a Whatman silica gel channel plate with appropriate standards. The TLC was run with hexane/MTBE/acetic acid (75:25:1, by vol) to full length. The nonradioactive compounds were visualized under ultraviolet light after spraying with 0.005% primulin in acetone/water (4:1, vol/vol). Marked radioactive dots were added to the plate to locate the bands precisely. The radioactive bands and dots were visualized using a phosphorimager (Amersham Biosciences), and the bands of interest were scraped off the plates and quantified by a liquid scintillation analyzer (PerkinElmer). The assays had two replicates for each treatment and the experiment was performed three times. Statistical analyses were performed using Statistical Analysis System (SAS Institute, Cary, NC) using GLM procedure with each pair of means analyzed separately, and the significance level was $P < 0.05$.

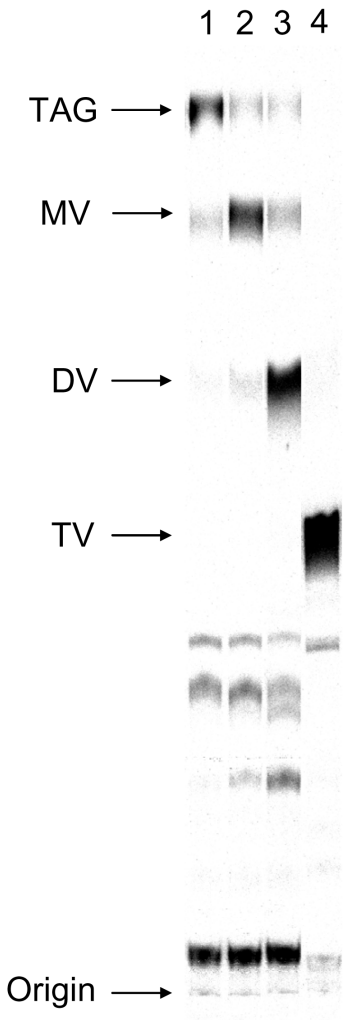

FIG. 1. TLC separation of radiolabeled TAG, monovernolin (MV), divernolin (DV), and trivernolin (TV). The solvent system used was hexane/MTBE/acetic acid (75:25:1, by vol), and the full length was run using a channeled silica gel 60-Å plate. The TLC origin and phosphorimage bands corresponding to the TAG species formed from *V. galamensis* microsomal DGAT assays using fed substrates (lane 1: [^{14}C]oleoyl-CoA and 1,2-dioleoyl-*sn*-glycerol; lane 2: [^{14}C]vernoloyl-CoA and 1,2-dioleoyl-*sn*-glycerol; lane 3: [^{14}C]vernoloyl-CoA and 1-palmitoyl-2-vernoloyl-*sn*-glycerol; lane 4: [^{14}C]vernoloyl-CoA and 1,2-divernoloyl-*rac*-glycerol) are shown. The free FA were removed by passing the sample through an NH_2 column.

RESULTS

To evaluate factors affecting the accumulation of industrially valuable epoxy FA in genetically engineered common oilseed crops, we studied the substrate specificities of DGAT, the enzyme involved in the final synthesis step of TAG, of two natural high accumulators of vernolic acid, *V. galamensis* and *S. laevis*, as compared with soybean, a target crop for genetic engineering for epoxy FA accumulation. Developing seed microsomes were fed with either [^{14}C]18:1-CoA or [^{14}C]Va-CoA in combinations with no exogenous DAG or with DAG. Because vernolic acid is more polar than common FA, the resulting labeled TAG species that have no, one, two, or three vernolic moieties can be cleanly separated on TLC (Fig. 1). Among MAG and DAG species with no, one, or two vernolic acid residues, dioleoylglycerol runs farthest in this separation system but is still significantly behind and easily separated from trivernolin, the slowest-moving TAG species in the present study (data not shown).

For the quantification of microsomes, we determined both microsomal PC and protein concentrations. The ratio between microsomal protein and microsomal PC increased as the seeds developed over time for both *V. galamensis* and *S. laevis* (data not shown). The microsomes used in our studies have microsomal PC levels of 0.28, 0.24, and 0.44 nmol/μL and microsomal protein levels of 2.9, 2.3, and 6.3 μg/μL for *V. galamensis*, *S. laevis*, and soybean, respectively. Microsomal PC quantification was chosen over microsomal protein quantification because DGAT is a membrane-bound enzyme

and might be more correlated with microsomal PC levels. We also verified that the amounts of microsomes and substrates used for the study were within a linear range up to the incubation time of 30 min even for the substrate combinations that had the highest reaction rates. The substrates used contain no, one, or two vernolic residues. The DAG substrates also included stereoisomers of *sn*-1,2-DAG and racemic 1,2(2,3)-DAG, because we found dramatic differences between the two types of DAG in our preliminary DGAT assays. In order to determine whether phospholipid:diacylglycerol acyltransferase was interfering with our microsomal DGAT assays, *Vernonia* microsomes were fed with 5 μM of palmitoyl-[^{14}C]linoleoyl-PC or palmitoyl-[^{14}C]vernoloyl-PC synthesized as described previously instead of [^{14}C]acyl-CoA with no DAG, 100 μM *sn*-DODAG, or 100 μM *sn*-DVDAG using otherwise the same DGAT assay as described previously. The results showed no detectable TAG formed (data not shown).

The microsomal DGAT assay results for *V. galamensis* are presented in Figure 2. When [^{14}C]acyl-CoA and *sn*-1,2-DAG were fed individually to developing seed microsomes, the most preferred substrate combination for *V. galamensis* DGAT was Va-CoA with *sn*-DVDAG, followed by Va-CoA with *sn*-MVDAG, whereas the lowest DGAT activities were found with the substrate combination of Va-CoA with *sn*-DODAG, followed by 18:1-CoA with *sn*-DODAG (Fig. 2A). With either *sn*-MVDAG or *sn*-DVDAG, Va-CoA was preferred over 18:1-CoA. With either 18:1-CoA or Va-CoA, *sn*-DVDAG was preferred over *sn*-MVDAG. When the three *sn*-1,2-DAG were fed simultaneously with either [^{14}C]18:1-CoA or [^{14}C]Va-CoA for competitive DGAT assays, the results were similar to those when DAG were fed individually except that the higher DGAT activities toward the substrate combination of Va-CoA with *sn*-DVDAG were more dramatic (Fig. 2B). This is understandable because the substrate combination of Va-CoA with *sn*-DVDAG was dominant in the competition for the labeled Va-CoA. When Va-CoA but no exogenous DAG were fed to the samples, the DGAT activities using endogenous common FA DAG, MVDAG, and DVDAG also increased in this order although the overall DGAT activities were much lower, probably due to lower amounts of the endogenous microsomal DAG available compared with the samples fed *sn*-1,2-DAG (Fig. 2C). When 18:1-CoA but no exogenous DAG were fed, the DGAT activities using endogenous common FA DAG were higher than

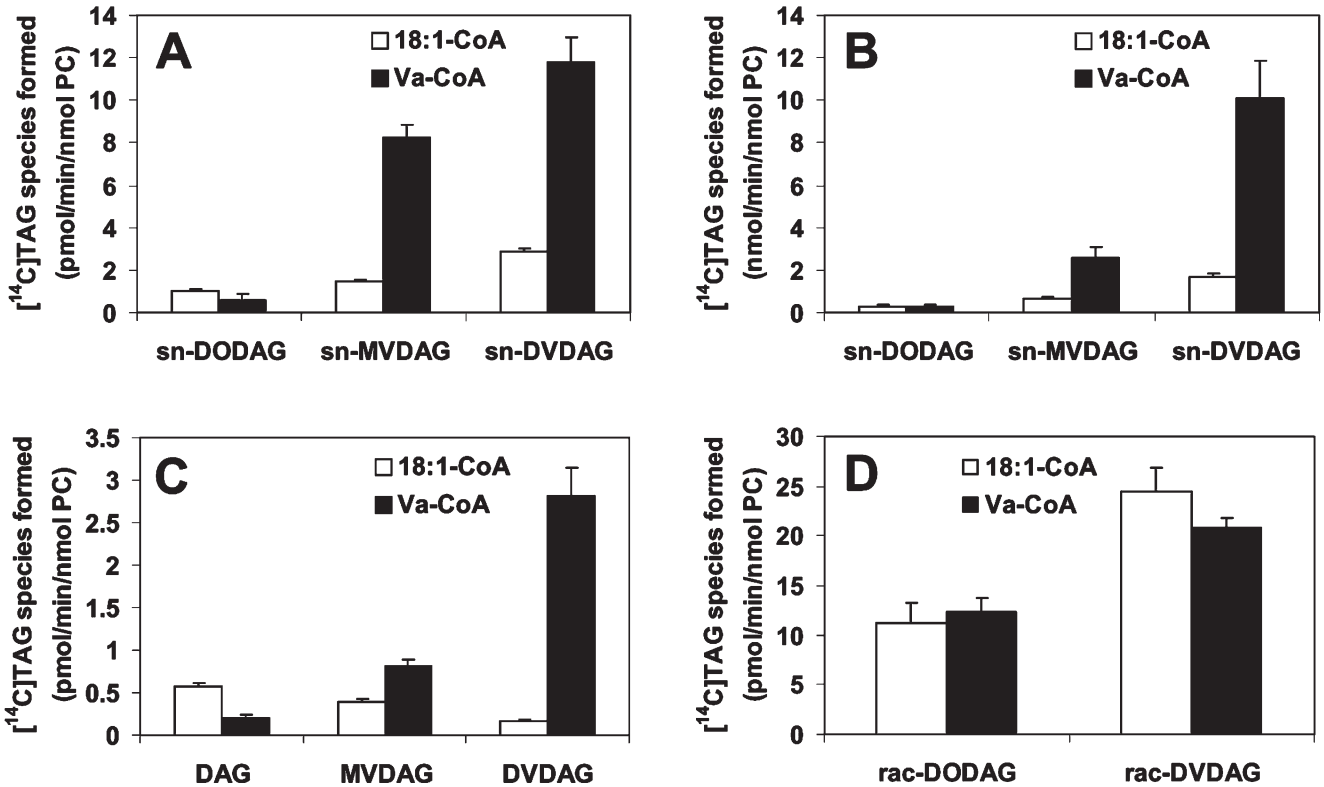

FIG 2. TAG formed from *V. galamensis* microsomal DGAT assays. The V. galamensis microsomes (eq. of 0.5 nmol microsomal PC) from developing seeds were fed with either [^{14}C]oleoyl-CoA (18:1-CoA) or [^{14}C]vernoloyl-CoA (Va-CoA) in combinations with or without exogenous DAG at 100 mM. The DAG treatments include exogenous 1,2-dioleoyl-*sn*-glycerol (*sn*-DODAG), 1-palmitoyl-2-vernoloyl-*sn*-glycerol (*sn*-MVDAG), or 1,2-divernoloyl-*sn*-glycerol (*sn*-DVDAG) added separately (A) or together (B); no exogenous DAG added (C); and exogenous 1,2-dioleoyl-*rac*-glycerol (*rac*-DODAG) or 1,2-divernoloyl-*rac*-glycerol (*rac*-DVDAG) added separately (D). The reaction mixture (200 μL) also included 1 mM $MgCl_2$, 0.5 mM CoASH, and 0.5 mM ATP and was incubated for 30 min at 30°C with shaking at 100 rpm. Values are mean ± SD (n = 6) of three experiments each with two replications.

those using MVDAG, which were in turn higher than those using DVDAG. These results were probably because the microsomal common FA DAG, MVDAG, and DVDAG were presumably in a steep decreasing order. When *rac*-1,2-DAG were fed individually with either [^{14}C]18:1-CoA or [^{14}C]Va-CoA, DGAT activities were much higher than with corresponding *sn*-1,2-DAG (Fig. 2D). With 18:1-CoA and Va-CoA, respectively, *rac*-DODAG was incorporated into TAG at about 10- and 20-fold higher levels relative to *sn*-DODAG, whereas *rac*-DVDAG was favored by about 8- and 2-fold more than *sn*-DVDAG. With either 18:1-CoA or Va-CoA, *rac*-DVDAG was preferred over *rac*-DODAG (about 2-fold). With *rac*-DODAG, no preference was found between 18:1-CoA and Va-CoA. However, with *rac*-DVDAG, 18:1-CoA was slightly preferred over Va-CoA ($P < 0.05$). DGAT substrate preference for unusual FA in the forms of acyl-CoA and/or DAG has been reported by several studies (12,14,27), most notably for medium-chain FA in two *Cuphea* species and a hydroxy FA in castor. However, to the best of our knowledge the dramatic difference in DGAT activities for *sn*-1,2-DAG and *rac*-1,2-DAG have not been reported. The lack of differences among *sn*-1,2-DODAG, *sn*-2,3-DODAG, and *rac*-1,2-DODAG found by other researchers (14,28) might have been due to different plant species under investigation.

The microsomal DGAT assay results for *S. laevis* are presented in Figure 3. The overall substrate preference pattern was quite similar to the results from *V. galamensis*. The DGAT activities for *S. laevis* were generally lower than those for *V. galamensis*. When [^{14}C]acyl-CoAs and *sn*-1,2-DAG were fed individually, the most preferred substrate combination for *S. laevis* DGAT was also Va-CoA with *sn*-DVDAG followed by Va-CoA with *sn*-MVDAG, whereas the lowest DGAT activities were found with the substrate combination of Va-CoA with *sn*-DODAG (Fig. 3A). Similar to the results from *V. galamensis*, with either *sn*-MVDAG or *sn*-DVDAG, Va-CoA was preferred over 18:1-CoA, and with either 18:1-CoA or Va-CoA, *sn*-DVDAG was preferred over *sn*-MVDAG. However, with 18:1-CoA, no difference was found between *sn*-DODAG and *sn*-MVDAG. When the three *sn*-1,2-DAG were fed simultaneously with either [^{14}C]18:1-CoA or [^{14}C]Va-CoA, the results were similar to those fed individually (Fig. 3B). With 18:1-CoA, *sn*-MVDAG was slightly preferred over *sn*-DODAG, and this is different from the results when the DAG were fed individually. This small difference might be due to the direct substrate competition involved when the DAG were fed simultaneously. When Va-CoA but no exogenous DAG were fed to the samples, the DGAT activities using endogenous common FA DAG, MVDAG, and

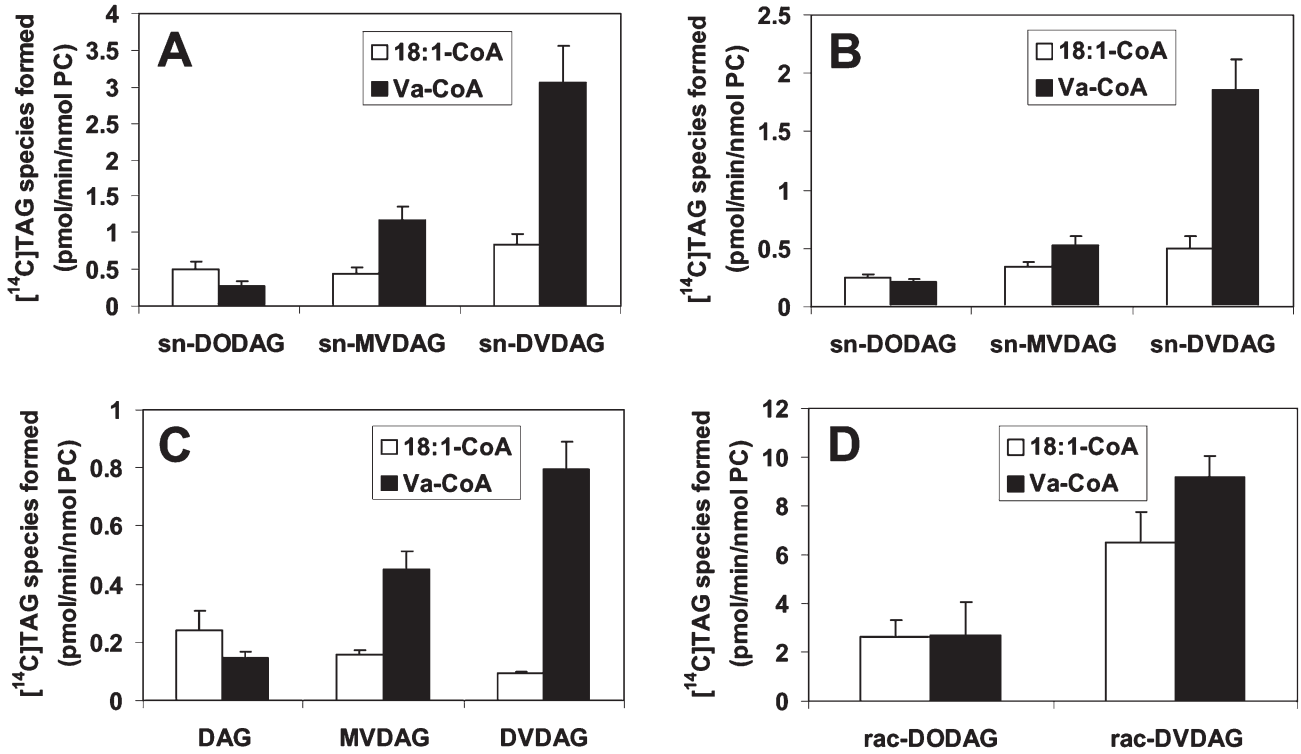

FIG 3. TAG formed from *S. laevis* microsomal DGAT assays. The *S. laevis* microsomes (eq. of 0.5 nmol microsomal PC) from developing seeds were fed with either [^{14}C]oleoyl-CoA (18:1-CoA) or [^{14}C]vernoloyl-CoA (Va-CoA) in combinations with or without exogenous DAG at 100 mM. The DAG treatments include exogenous 1,2-dioleoyl-*sn*-glycerol (*sn*-DODAG), 1-palmitoyl-2-vernoloyl-*sn*-glycerol (*sn*-MVDAG), or 1,2-divernoloyl-*sn*-glycerol (*sn*-DVDAG) added separately (A) or together (B); no exogenous DAG added (C); and exogenous 1,2-dioleoyl-*rac*-glycerol (*rac*-DODAG) or 1,2-divernoloyl-*rac*-glycerol (*rac*-DVDAG) added separately (D). The reaction mixture (200 µL) also included 1 mM $MgCl_2$, 0.5 mM CoASH, and 0.5 mM ATP and was incubated for 30 min at 30°C with shaking at 100 rpm. Values are mean ± SD (n = 6) of three experiments each with two replications.

DVDAG were of the same pattern as described for *V. galamensis* but with lower overall activities (Fig. 3C). When *rac*-1,2-DAG were fed individually with [^{14}C]acyl-CoAs, DGAT activities were much higher than with corresponding *sn*-1,2-DAG (Fig. 3D). With 18:1-CoA and Va-CoA respectively, *rac*-DODAG was about 5- and 10-fold more incorporated into TAG than *sn*-DODAG, whereas *rac*-DVDAG was about 8- and 3-fold higher than *sn*-DVDAG. With either 18:1-CoA or Va-CoA, *rac*-DVDAG was preferred over *rac*-DODAG (about 2.5-fold). With *rac*-DODAG, no preference was found between 18:1-CoA and Va-CoA. However, with *rac*-DVDAG, Va-CoA was slightly preferred over 18:1-CoA ($P < 0.05$), which is different from the results from *V. galamensis*.

The microsomal DGAT assay results for soybean are presented in Figure 4. When [^{14}C]acyl-CoA and *sn*-1,2-DAG were fed individually, DGAT activities with 18:1-CoA were 4- to 5-fold higher than with Va-CoA (Fig. 4A). With 18:1-CoA, *sn*-DODAG was slightly preferred over *sn*-MVDAG, which in turn was preferred over *sn*-DVDAG. However, with Va-CoA, no difference in DGAT activity was found for the three *sn*-1,2-DAG. When the three *sn*-1,2-DAG were fed simultaneously with either [^{14}C]18:1-CoA or [^{14}C]Va-CoA for competitive DGAT assays, the results were quite similar to those fed individually in DGAT substrate preferences but lower in overall DGAT activities (Fig. 4B). DGAT activities with 18:1-CoA were 3- to 4-fold higher than those with Va-CoA. With 18:1-CoA, *sn*-DODAG was slightly preferred over *sn*-MVDAG and *sn*-DVDAG, which had no difference between them. With Va-CoA, no difference in DGAT activity was found for the *sn*-DODAG and *sn*-DVDAG both of which were slightly higher than *sn*-MVDAG. When Va-CoA but no exogenous DAG were fed to the samples, the DGAT activities with 18:1-CoA was about 5-fold higher than those with Va-CoA, and no TAG formed from endogenous MVDAG and DVDAG (which are not present) was found (Fig. 4C). When *rac*-1,2-DAG were fed individually with [^{14}C]acyl-CoAs, DGAT activities were much higher than with corresponding *sn*-1,2-DAG (Fig. 4D). With 18:1-CoA and Va-CoA, respectively, *rac*-DODAG was about 4- and 5-fold more incorporated into TAG than *sn*-DODAG, whereas *rac*-DVDAG was about 6- and 10-fold higher than *sn*-DVDAG. With either *rac*-DODAG or *rac*-DVDAG, DGAT activities with 18:1-CoA were 2- to 3-fold higher than those with Va-CoA. With 18:1-CoA, no preference was found between *rac*-DODAG and *rac*-DVDAG. However, with Va-CoA, *rac*-DVDAG was slightly preferred over *rac*-DODAG ($P < 0.05$).

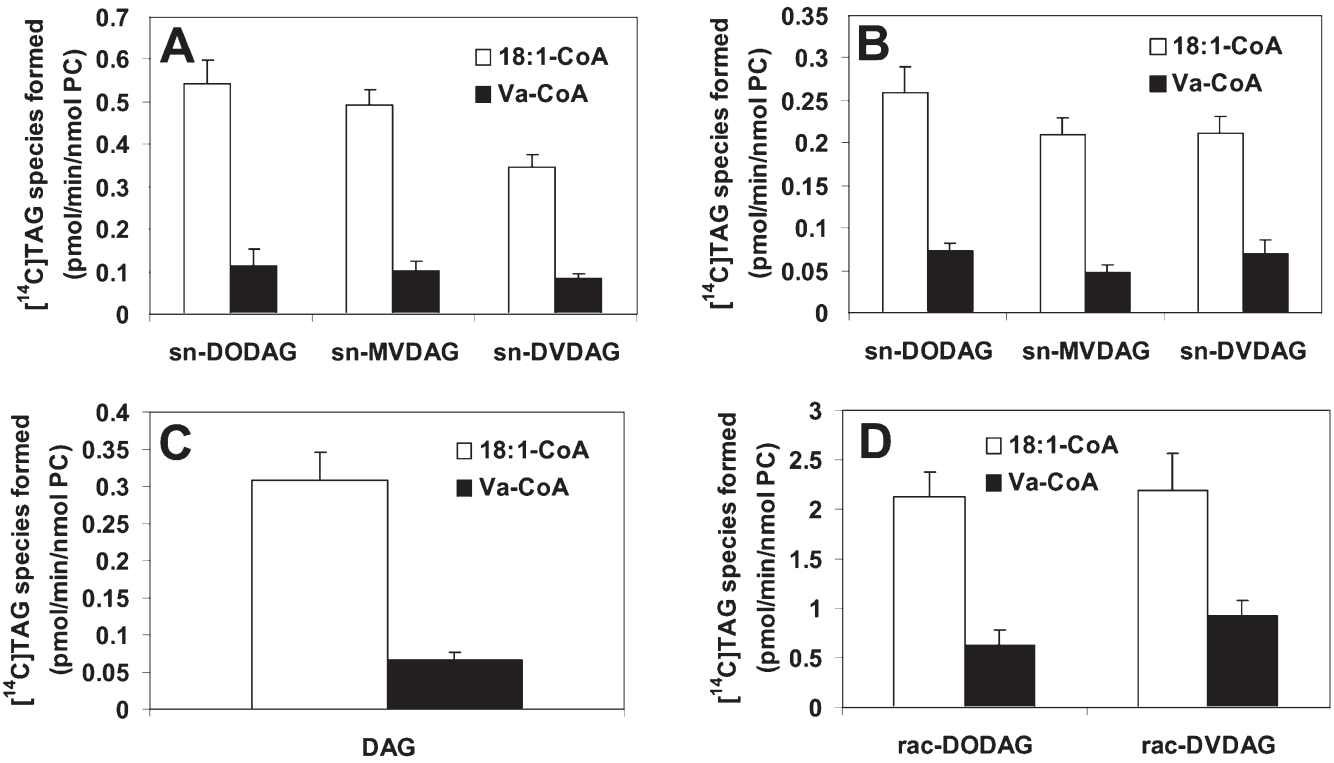

FIG 4. TAG formed from soybean microsomal DGAT assays. The soybean microsomes (eq. of 0.5 nmol microsomal PC) from developing seeds were fed with either [^{14}C]oleoyl-CoA (18:1-CoA) or [^{14}C]vernoloyl-CoA (Va-CoA) in combinations with or without exogenous DAG at 100 mM. The DAG treatments include exogenous 1,2-dioleoyl-*sn*-glycerol (*sn*-DODAG), 1-palmitoyl-2-vernoloyl-*sn*-glycerol (*sn*-MVDAG), or 1,2-divernoloyl-*sn*-glycerol (*sn*-DVDAG) added separately (A) or together (B); no exogenous DAG added (C); and exogenous 1,2-dioleoyl-*rac*-glycerol (*rac*-DODAG) or 1,2-divernoloyl-*rac*-glycerol (*rac*-DVDAG) added separately (D). The reaction mixture (200 µL) also included 1 mM $MgCl_2$, 0.5 mM CoASH, and 0.5 mM ATP and was incubated for 30 min at 30°C with shaking at 100 rpm. Values are mean ± SD (n = 6) of three experiments each with two replications.

DISCUSSION

The identification of epoxygenases from high vernolic acid accumulators has opened up an opportunity for genetically engineering oilseed crops such as soybean to produce vernolic acid (6,7), an important industrial feedstock for a variety of applications. However, genetically transformed arabidopsis and soybeans with epoxygenase alone can only result in a low accumulation of vernolic acid (7,9,10,29). In the present study, we found that the enzymes involved in the final step of synthesis of TAG, DGAT in both natural high accumulators of vernolic acid, *V. galamensis* and *S. laevis*, are highly selective for substrates with vernolic moieties in a manner consistent with their accumulation in their seed oils, with the most favorable substrate combination being Va-CoA and *sn*-DVDAG. The DGAT of the common oilseed crop soybean shows relatively lower activity for substrates with vernolic moieties. Instead, soybean DGAT has higher activity with 18:1-CoA than Va-CoA, and slightly higher activity with *sn*-DODAG compared with *sn*-1,2-DAG with vernolic moieties when 18:1-CoA was the cosubstrate. Lin *et al.* (30,31) investigated the incorporation of oleate and ricinoleate into microsomes from soybean and castor, a high accumulator of a hydroxy FA. Similar to our results, they found that castor selectively incorporated ricinoleate into TAG. However, they reported that soybean did not distinguish between ricinoleic acid and oleate. The lack of selectivity in soybeans might be due to the different unusual FA under investigation, or due to the significantly different experimental conditions employed in their study. They also suggested that the removal of ricinoleate and oleate from PC was different because of differing specificities of phospholipase A_2 that might affect the incorporation of the FA into TAG.

Surprisingly, the *rac*-1,2-DAG tested were all much better substrates than their corresponding *sn*-1,2-DAG for the DGAT of all three species, *V. galamensis*, *S. laevis*, and soybean. When *rac*-1,2-DAG were used in the studies, the strong selectivity of *V. galamensis* and *S. laevis* DGAT for substrates with vernolic moieties as described above was diminished. These results might be due to dramatically higher DGAT activities with *sn*-2,3-DAG possibly because of the lack of regulation by the DGAT from the plant species for *sn*-2,3-DAG, which do not occur to any extent in seeds. Such results might also be due to significant synergetic effects between *sn*-1,2-DAG and *sn*-2,3-DAG for DGAT activity. DGAT use both acyl-CoA and DAG as substrates; the important point might not be so much the relative activities between *sn*-1,2-DAG and *sn*-2,3-DAG but the change in selectivity toward acyl-CoA. Further investigations, such as the direct comparison of DGAT activities using *sn*-1,2-DAG and *sn*-2,3-DAG, would be useful to determine the basis for this. Previous studies comparing *sn*-1,2-DODAG, *sn*-2,3-DODAG, and *rac*-1,2-DODAG in safflower (*Carthamus tinctorius*) (28) and comparing *sn*-1,2-DODAG with *rac*-1,2-DODAG in *Cuphea procumbens*, sunflower (*Helianthus annuus*), and castor (14) showed no differences in terms of DGAT activities. This is very different from our results, in which all three plant species tested for DGAT activities with both pairs of DAG, *sn*-DODAG/*rac*-DODAG and *sn*-DVDAG/*rac*-DVDAG showed dramatically different activities. The differences between our results and the prior studies might be due to the different species under investigation. Further, previous researchers tested only dioleins with those species. Our results suggest that it may be worthwhile to use *sn*-1,2-DAG for DGAT assays even though it may be more difficult to prepare *sn*-1,2-DAG with unusual FA moieties.

Several studies have shown that the DGAT of unusual FA accumulators have substrate preferences for the unusual FA CoAs and/or unusual FA DAG, most notably in castor and several *Cuphea* species (12–14,27). In *C. carthagenensis*, the DGAT preference of lauroyl CoA over 18:1-CoA with *sn*-DODAG was not high, and the selectivity might be partly due to the higher solubility of lauroyl CoA than 18:1-CoA because the selectivity seemed to be correlated with the microsomal assay temperatures (27). In *C. lanceolata*, with 18:1-CoA, the DGAT preference for 1,2-dicaproyl-*sn*-glycerol over *sn*-DODAG was about 3-fold (12). In *C. procumbens*, the DGAT preference for caproyl CoA over 18:1-CoA with both 1,2-dicaproyl-*rac*-glycerol and *rac*-DODAG was about 2- to 3-fold (14). However, the DGAT preference for 1,2-dicaproyl-*rac*-glycerol over *rac*-DODAG was over 10-fold. They also studied castor DGAT and found that the DGAT was 2- to 4-fold more active with ricinoleoyl-CoA than with 18:1-CoA either with *rac*-DODAG or 1,2-diricinoleoyl-*rac*-glycerol (14). With either acyl-CoA, 1,2-diricinoleoyl-*rac*-glycerol was about 2-fold more incorporated into TAG than *rac*-DODAG by castor DGAT. Another study with castor using 18:1-CoA and *sn*-1,2-DAG showed that 1,2-diricinoloyl-*sn*-glycerol was incorporated into TAG by DGAT about 3-fold higher than *sn*-DODAG (12). Interestingly, monoricinoleoyl DAG was reported to have significantly lower incorporation into TAG than diricinoleoyl DAG. In a more recently study by He *et al.* (13), a castor DGAT was expressed in yeast and its substrate specificities examined. With 18:1-CoA, the castor DGAT expressed in yeast was about 2-fold more active with 1,2-diricinoleoyl-*rac*-glycerol than with diolein and dipalmitolein, although it was not reported whether the common FA DAG were racemic or of certain stereospecificity. Castor DGAT might be expected to be similar to *V. galamensis* and *S. laevis* DGAT because they are all natural high accumulators of oxygenated FA synthesized by FAD2-like enzymes from PC and may use similar mechanisms for the high accumulation of the unusual FA (6,9,32,33). In comparison, our results have more clearly demonstrated the high selectivity of *V. galamensis* and *S. laevis* DGAT for vernolic acid incorporation into TAG due to the discovery of the dramatic difference in activities of the tested DGAT with *rac*-1,2-DAG and *sn*-1,2-DAG. *V. galamensis* DGAT also showed slightly higher substrate selectivity for substrates with vernolic moieties than *S. laevis* DGAT.

Vernolic acid is known to be synthesized from linoleic acid at the *sn*-2 position of PC by an epoxygenase (5). The mechanisms for the channeling or other means of selective accumu-

lation of epoxy FA such as vernolic acid into TAG are largely unknown. Phospholipid:diacylglycerol acyltransferase and phospholipase have been shown to play major roles in removing vernolic acid from phospholipids in *Crepis palaestina* and *Euphorbia lagascae* (34). They did not show the absolute rates of the reactions, so it is difficult to compare the phospholipid:diacylglycerol acyltransferases with DGAT in terms of their relative importance for TAG synthesis. In the present study, we could not detect any phospholipid:diacylglycerol acyltransferase activities in *V. galamensis* microsomes by replacing [^{14}C]acyl-CoA with [^{14}C]PC under otherwise identical conditions for our DGAT assays with or without exogenous *sn*-1,2-DAG. This may be due to suboptimal assay conditions for phospholipid:diacylglycerol acyltransferase or due to intrinsically very low activities for the enzyme. Although it is not certain how relevant the microsomal DGAT activity is to accumulation of TAG *in vivo*, our results indicate that DGAT might play an important role in the selective accumulation of vernolic acid in *V. galamensis* and *S. laevis*. Verification by cloning and functional analyses of the genes encoding these enzymes will be very helpful to gain further insights and might yield a *V. galamensis* DGAT gene that would be useful, along with epoxygenases, for the high-level production of vernolic acid in genetically engineered common oil crops.

In summary, we have found that *V. galamensis* and *S. laevis* DGAT can preferentially incorporate substrates with vernolic moieties into TAG, whereas soybean DGAT does not have such specificities. In combination with acyl-CoA, *rac*-1,2-DAG are much better substrates than their corresponding *sn*-1,2-DAG for *V. galamensis*, *S. laevis*, and soybean DGAT. These studies suggest that DGAT might be an important enzyme for selective incorporation of vernolic acid into TAG in *V. galamensis* and *S. laevis*.

ACKOWLEDGMENTS

This research has been supported by the United Soybean Board, Ashland Inc., the Kentucky Science & Engineering Foundation, the Consortium for Plant Biotechnology Research, and the Kentucky Soybean Promotion Board. We gratefully acknowledge Dr. Thomas R. Hamilton-Kemp for his critical review and Dr. Hirotada Fukushige for his helpful discussions and synthesis of diazomethane.

ABSTRACT: Arachidonic acid (20:4n-6, ArA) and its eicosanoid metabolites have been demonstrated to be implicated in immune functions of vertebrates, fish, and insects. Thus, the aim of this study was to assess the impact of ArA supplementation on the FA composition and hemocyte parameters of oysters *Crassostrea gigas*. Oyster dietary conditioning consisted of direct addition of ArA solutions at a dose of 0, 0.25, or 0.41 μg ArA per mL of seawater into tanks in the presence or absence of T-*Iso* algae. Results showed significant incorporation of ArA into gill polar lipids when administered with algae (up to 19.7%) or without algae (up to 12.1%). ArA supplementation led to an increase in hemocyte numbers, phagocytosis, and production of reactive oxygen species by hemocytes from ArA-supplemented oysters. Moreover, the inhibitory effect of *Vibrio aestuarianus* extracellular products on the adhesive proprieties of hemocytes was lessened in oysters fed ArA-supplemented T-*Iso*. All changes in oyster hemocyte parameters reported in the present study suggest that ArA and/or eicosanoid metabolites affect oyster hemocyte functions.

Paper no. L9955 in *Lipids 41*, 567–576 (June 2006).

The dietary impact of long-chain n-3 and n-6 essential PUFA has been extensively studied in human medical research, including the modulation of the human immune system. Thus, long-chain n-3 PUFA have been shown to have anti-inflammatory and immunomodulatory properties for a number of immune functions including phagocytosis, reactive oxygen species production, and lymphocyte proliferation (1,2). The impact of dietary long-chain n-6 PUFA on immunity however has been less well investigated and is still controversial, with both proinflammatory and immunosuppressive properties having been associated with these molecules (2). *In vitro* studies have focused on the mechanisms by which n-6 PUFA, especially arachidonic acid (20:4n-6, ArA) and its eicosanoid metabolites, can affect immune functions (3–8). These studies demonstrated that ArA, generally found in high amounts in membranes of higher vertebrates (human, rat), can influence phagocytosis, NADPH oxidase activation, actin polymerization, and Ca^{2+} release, likely via its eicosanoid metabolites.

Similar studies on fish nutrition have evaluated the impact of n-3 and n-6 dietary PUFA on immune functions (9–15). Thus, Lin and Shiau (13) demonstrated that lipid-supplemented diets resulted in increased numbers of white blood cells, enhanced phagocytosis, and the generation of reactive oxygen species in grouper *Epinephelus malabarius* when compared with fish fed lipid-poor diets. Wu *et al.* (15) investigated more specifically the effect of long-chain n-3 PUFA (20:5n-3 [EPA] and 22:6n-3 [DHA]) on the immune functions of the grouper *E. malabarius*. The authors reported that DHA enhanced phagocytic function and T-cell proliferation and was superior to EPA in influencing the cellular defense responses of the grouper. Moreover, eicosanoid metabolites derived from ArA PUFA are also significant in fish immunity. Tafalla *et al.* (16) demonstrated that LTB_4 in leukocyte-derived supernatants have an antiviral activity against viral hemorrhagic septicemia virus in the turbot *Scophthalmus maximus*. However, the authors did not exclude the involvement of other factors such as PGE_2.

In bivalves, for more than two decades, studies have focused on the determination of the nutritional values of various algal species to support and improve larval development, growth, and metamorphosis under hatchery conditions (17–23). Fewer studies have investigated the impact of nutrition on immune responses of bivalves (24–26). Recently, Delaporte *et al.* (26) have demonstrated that feeding Pacific oysters *Crassostrea gigas* and Manila clams *Ruditapes philippinarum* with cultures of the microalga *Chaetoceros calcitrans* (a diatom) led to increases in hemocyte numbers, phagocytosis, and reactive oxygen species production. These authors suggested that the FA composition of *Chaetoceros calcitrans*, characterized by high proportions of EPA (17.8%) and ArA (2.0%), may be responsible for the changes observed in immune responses of both species, as demonstrated for vertebrates and fishes fed on different oils. Similarly, Hégaret *et*

Abbreviations: AASH, anti-aggregant solution for hemocytes; ArA, arachidonic acid; AU, arbitrary units; DCFH-DA, 2′7′-dichlorofluorescein diacetate; DPI, diphenylene iodonium chloride; DW, dry weight; ECP, extracellular products; FSSW, filtered sterile seawater; ROS, reactive oxygen species; WW, wet weight.

al. (24) showed that immune parameters of the Eastern oyster *Crassostrea virginica* were modulated by the quality of the algal diet. Nonetheless, no specific PUFA could be clearly identified as responsible for those changes. Lastly, dietary conditioning using lipid emulsion was used to assess the impact of EPA on hemocyte parameters of the oyster *C. gigas* (25). In this study, a decrease of phagocytosis and reactive oxygen species production was temporarily observed for oysters fed the highest dose of EPA. These results suggest that this PUFA may have an impact on hemocyte function, but unfortunately without excluding a concomitant impact of ArA because the lipid emulsion also contained a significant amount of ArA.

The aim of this current study was to specifically determine the impact of dietary ArA on hemocyte parameters of *C. gigas*. To do this, a new supplementation method developed by Séguineau *et al.* (27) based on the direct addition of individual PUFA along with T-*Iso* algae (deficient in ArA) was used.

EXPERIMENTAL PROCEDURES

Oyster dietary treatments. One-year-old oysters, *C. gigas* (Thunberg 1793), produced in 2003 at the IFREMER hatchery in La Tremblade (Charente, France), were conditioned in May 2004 at the IFREMER shellfish laboratory in Argenton (Finistère, France) in 50-L tanks. Oysters were acclimated to the experimental temperature of 17°C for 2 wk prior to the dietary experiment. After the acclimation period, oysters were divided randomly and distributed into 9 tanks (70 oysters per tanks, 3 replicates per treatment) filled with 45 L of 20-µm-filtered seawater, mixed and aerated using an immersed pump. Thereafter, oysters were fed *Isochrysis* sp., clone T-*Iso*, supplemented with ArA solution for 4 wk. T-*Iso* was chosen for this experiment because of its low (0.1%) concentration of ArA (26). The daily algal ration was established at 4% algal dry weight per oyster dry weight. A peristaltic pump was adjusted to distribute the algae ration over an 18-h period per day. ArA (Sigma A-9376) was dissolved in ethanol at the concentration of 10 mg mL^{-1} according to the procedure of Séguineau *et al.* (27). This ArA solution was further diluted in ethanol to allow addition of an equal volume of ethanol per tank and to obtain the following final concentrations: 0 µg (control ethanol solution), 0.25 µg, or 0.41 µg of ArA per mL of sea water. ArA solutions were added twice a day (half dose in the morning and half dose in the evening in order to avoid ArA oxidation). Tanks and oysters were cleaned daily. Every 2 wk, 15 oysters were sampled for biochemical analyses and 20 oysters for immune analyses. After the first sampling, volume of seawater per tank was adjusted in order to maintain a stable effective volume per oyster during the experiment. No mortalities were recorded over the whole experiment.

One month later, a separate control experiment was conducted for a period of 2 wk with the same experimental protocol to assess the assimilation of dissolved ArA without algal supply in oysters from the same origin.

Condition index and biochemical composition. At each sampling date, whole oyster, shell, and wet flesh weights were measured on 15 oysters. The condition index of oysters was calculated, as described by Walne and Mann (28), following the formula (dry flesh weight)/(dry shell weight) × 1,000. Thereafter, three pools constituted by the wet flesh tissues of five animals were generated. Pools were frozen in liquid nitrogen (–196°C) and treated as described in Delaporte *et al.* (29). Total lipid content was estimated according to Bligh and Dyer (30), and carbohydrate and protein contents were measured colorimetrically following the procedures of Dubois *et al.* (31) and Lowry *et al.* (32), respectively. Results are expressed as mg of carbohydrate, lipid, or protein per mg of oyster dry flesh weight.

FA analysis of oyster gills: Sampling and extraction. Gills were dissected from the same animals utilized for the hemocyte-parameter analyses. Three pools of gills from five animals were constituted and frozen in liquid nitrogen at –196°C. Pooled gill samples were ground with a Dangoumeau homogenizer, and 300 mg of the ground tissue were transferred to a tube containing 6 mL of chloroform-methanol mixture (2:1, vol/vol). After centrifugation, the lipid extract was transferred to a clean tube, sealed under nitrogen, and stored at –20°C.

Separation of polar and neutral lipids. Neutral and polar lipids of gill lipid extracts were purified on a silica gel microcolumn according to Marty *et al.* (33) and analyzed as described in Delaporte *et al.* (29). Briefly, an aliquot of the lipid extract in chloroform/methanol was evaporated to dryness. Then, lipids were redissolved in a chloroform-methanol mixture (98:2, vol/vol) and placed on a silica gel microcolumn (30 × 5 mm i.d. Kieselgel, 70-230 mesh [Merck] previously heated to 450°C and deactivated with 5 wt % water). Neutral lipids were eluted with a chloroform-methanol mixture (98:2, vol/vol), and the polar lipids were eluted separately with methanol. After transesterification of the neutral and polar lipid extracts from gills by 10% wt/wt boron trifluoride/methanol (34), FAME were analyzed in a gas chromatograph equipped with an on-column injector, a DB-Wax (30 m × 0.25 mm, 0.25 µm film thickness) capillary column, and a flame ionization detector. Hydrogen was used as the carrier gas. The FA were identified by comparing their retention times with those of standards and confirmed by GC–MS.

FA composition of gills was expressed as weight percentage of the total FA of each lipid fraction. Total FA content (neutral + polar lipids) per gill sample was expressed as µg of FA per mg of gill wet weight.

As polar lipids generally provide a good approximation of cell membrane lipids and are the dominant lipids in hemocyte and gill tissues (26,29,35), only FA composition values of the polar lipid fraction of gill lipid extracts were presented in this study to simplify the presentation of FA data.

Measurements of immunological parameters by flow cytometry. Measurements of hemocyte types, numbers, and functions were performed on a FACScalibur flow cytometer (B-D Biosciences, San Jose, CA) equipped with a 488-nm

argon laser. Hemolymph sampling and hemocyte parameter measurements are described next. For each assay, samples were filtered through an 80-μm mesh prior to flow cytometer analysis in order to eliminate large debris (>80 μm).

Hemolymph sampling. Hemolymph was withdrawn from individual oysters using a 1-mL plastic syringe fitted with a 25-gauge needle via a notch adjacent to the adductor muscle created just prior to the bleeding. All hemolymph samples were examined microscopically for contamination (e.g., oocytes, sperm, algae) and stored individually in microtubes at 0°C. Three pools of five individual samples were used for the following immunological assays.

Hemocyte viability, total hemocyte, and subpopulation concentrations. An aliquot of 100 μL of pooled hemolymph was transferred into a tube containing a mixture of 200 μL anti-aggregant solution for hemocytes (AASH) and 100 μL filtered sterile seawater (FSSW). AASH was prepared according to Auffret and Oubella (36). Hemocyte DNA was stained with two fluorescent DNA/RNA specific dyes, SYBR Green I (final concentration 10×) and propidium iodide (PI, final concentration 20 μg mL^{-1}), in darkness at room temperature for 60 min before flow-cytometric analysis. SYBR Green I permeates both dead and live cells, whereas PI permeates only through membranes of dead cells. SYBR Green fluorescence was measured at 500–530 nm (green) by flow cytometry whereas PI fluorescence was detected at 550–600 nm (red). Thus, by counting the cells stained by PI and cells stained by SYBR Green, it was possible to estimate the percentage of viable cells in each sample.

All SYBR Green I stained cells were plotted on a Forward Scatter (FSC, size) and Side Scatter (SSC, granularity) cytogram allowing identification of hemocyte subpopulations. Three subpopulations were distinguished according to their size and granularity and termed granulocytes (high FSC and high SSC), hyalinocytes (high FSC and low SSC) and small agranulocytes (low FSC and low SSC). Total and differential hemocyte concentrations are expressed as number of cells per mL.

Phagocytosis assay. An aliquot of 100 μL pooled hemolymph, diluted with 100 μL of FSSW, was mixed with 30 μL of YG 2.0 μm fluoresbrite microspheres, diluted to 2% in FSSW (Polysciences, Eppelheim, Germany). After 120 min of incubation at 18°C, hemocytes were fixed with 230 μL of a 6% formalin solution and analyzed at 500–530 nm by flow cytometry to detect cells containing fluorescent beads. The percentage of phagocytic cells was estimated by the percentage of hemocytes that had engulfed three beads and more according to Delaporte *et al.* (26).

Adhesion capacity. The adhesive capacity of *C. gigas* hemocytes was assessed by modifying the procedure of Choquet *et al.* (37). In the present study, live pathogenic bacteria were replaced by the extracellular products (ECP) of the *Vibrio aestuarianus*, previously demonstrated to inhibit adhesive capacity of *C. gigas* hemocytes (38). Two subsamples of each hemolymph pool were distributed (100 μL per well) in 24-well microplates. An aliquot of 100 μL FSSW was added to the first subsample as a control, and 100 μL ECP suspension was added to the second (30 μg protein mL^{-1} final concentration). After 3 h of incubation, the supernatant containing cells not adhering was transferred into a flow cytometer tube and fixed by addition of 200 μL of a 6% formalin solution. After 30 min of incubation with SYBR Green I, cell concentration was then evaluated as described above. Since the hemocyte adhesive capacity was measured with or without addition of ECP of *Vibrio aestuarianus*, results are expressed as the percentage of adhering hemocytes relatively to the initial total hemocyte concentration of the tested pool prior to incubation with or without ECP.

Reactive oxygen species (ROS) production. Measurement of the ROS production of hemocytes was assayed by modifying the procedure of Lambert *et al.* (39) using 2′7′-dichlorofluorescein diacetate (DCFH-DA). For this assay, two aliquots of 100 μL of hemolymph were diluted with 300 μL of FSSW in two flow cytometer tubes. In one of the tubes, 4 μL of diphenylene iodonium chloride (DPI, 5 μM final concentration), an NADPH-oxidase and NO-synthase inhibitor, was added. Subsequently, DCFH-DA (final concentration of 0.01 mM) was added to each tube previously maintained on ice, and tubes were incubated at 18°C for 120 min. After the incubation period, DCF fluorescence, quantitatively related to intracellular ROS production by hemocytes, was measured at 500–530 nm by flow cytometry. Results are expressed as the mean fluorescence in arbitrary units (A.U.) detected in hemocyte subpopulations maintained in FSSW (basal ROS production) and after addition of DPI (inhibited ROS production).

Statistical analysis. One- or two-way ANOVA was performed for each biochemical and hemocyte parameter using STATGRAPHICS Plus 5.1 statistical software (Manugistics, Inc., Rockville, MD), to test the ArA dose effect and the time effect after 2 and 4 wk of conditioning. Percentage data were transformed (arcsin of the square root) before ANOVA or MANOVA, but are presented in figures and tables as untransformed percentage values.

RESULTS

Condition index and biochemical composition. No significant differences between dietary treatments were observed for oyster condition index, oyster tissue dry weight (DW), or carbohydrate, protein, or lipid contents over the whole experiment (Table 1, 2-way ANOVA, $P > 0.05$). However it can be noted that oyster tissue DW and carbohydrate content were lower at the end of the experiment than initially. Meanwhile, total lipid contents of oysters increased from 0.087 mg/mg DW initially to an average of 0.110 mg/mg DW at the end of the experiment (2-way ANOVA, $P < 0.001$). Protein content of oysters was stable during the whole experiment.

FA composition of gill polar lipids: Impact of the dietary conditioning with ArA-supplemented T-Iso. Feeding oysters with T-*Iso* alone (without ArA supplementation) resulted in an enrichment of gill polar lipids with 18:1n-7, 18:1n-9, 18:2n-6, 18:3n-3, 18:4n-3, and 22:6n-3, and a decrease in

TABLE 1
Condition Index, Oyster Tissue Dry Weight, and Carbohydrate, Lipid, and Protein Contents of Oysters Fed T-*Iso* Supplemented with 0, 0.25, and 0.41 µg mL^{-1} of ArA[a]

	After 4 wk Conditioning			
	Initial	0 µg ArA mL^{-1}	0.25 µg ArA mL^{-1}	0.41 µg ArA mL^{-1}
Condition index	4.3 ± 0.9	3.6 ± 0.7	3.9 ± 0.5	3.5 ± 0.6

[a]All results are expressed as mean ± SD. For condition index and oyster tissue dry weight, $n = 15$. Carbohydrate, lipid, and protein contents are expressed in mg per mg oyster dry weight ($n = 3$ pools of 5 oysters). Asterisks indicate significant difference with initial composition (T-test, $P < 0.05$).

20:5n-3 (Table 2). Similar changes were observed in gill polar lipids of oysters fed ArA-supplemented T-*Iso* (Table 2), but ArA supplementation greatly increased the 20:4n-6 percentage of gill polar lipids as early as 2 wk into the dietary conditioning period (Table 2, Fig. 1). At the end of the experiment, percentages of 20:4n-6 reached 15.3% and 19.7% in gill polar lipid of oysters fed, respectively, T-*Iso* supplemented with 0.25 and 0.41 µg mL^{-1} of ArA solution, whereas it stayed at

[a]All results are expressed as mean ± SD. FA composition of the gill polar lipids is expressed as weight percentage of total FA in the fraction. Total FA is expressed as µg of FA per mg of gill wet weight. Different lowercase letters indicate significant differences between dietary treatments (1-way ANOVA, $P < 0.05$). Asterisks indicate significant difference with initial composition (T-test, $P < 0.05$). NMI = non–methylene interrupted FA; 20:2i = 20:2Δ5,11; 22:2i = 22:2Δ7,13; 20:2i = 20:2Δ5,13; 22:2j = 22:2Δ7,15; WW, wet weight.

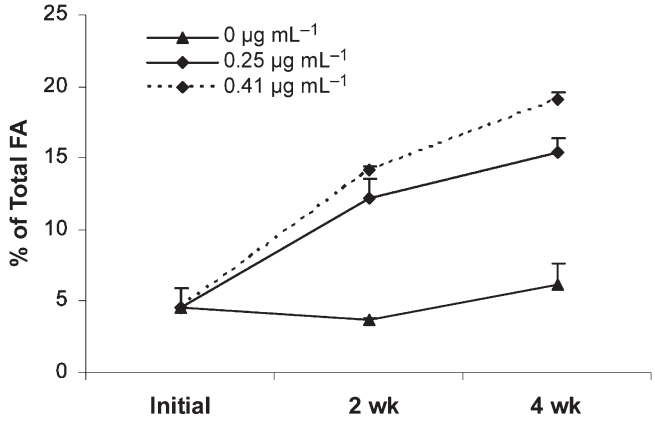

FIG. 1. ArA weight percentage of *C. gigas* gill polar lipids during the dietary conditioning (T-*Iso* supplemented with 0, 0.25, and 0.41 µg mL^{-1} ArA).

6.2% in those fed T-*Iso* alone. This high increase in 20:4n-6 also led to a significant decrease in 20:5n-3 and 22:6n-3, a significant increase in total n-6 FA contents in gill polar lipids, and consequently a decrease in the n-3/n-6 ratio and 20:5n-3/20:4n-6 ratio. However, the proportions of the different FA classes (SFA, MUFA, PUFA) were not affected by the dietary conditioning.

Impact of conditioning with ArA solution and without algae (control experiment). The FA composition of gill polar lipids was also greatly affected by 2 wk of ArA dietary conditioning with 0.25 and 0.41 µg mL^{-1} of ArA without algae supplementation (Table 3). The percentage of 20:4n-6 of gill polar lipids increased twofold after 2 wk with ArA supplementation and reached 11.3 and 12.1% in oysters fed 0.25 and 0.41 µg mL^{-1}, respectively. However, no dose effect was recorded. Similarly but to a lesser extent than in the experiment with algae, feeding oysters with 0.25 and 0.41 µg mL^{-1} also resulted in a significant decrease of 22:6n-3, a significant increase of total n-6 FA (from 9.8 to 14.5 and 15.5%, respectively) in gill polar lipids, and a significant decrease in n-3/n-6 ratio (from 4.0 to 2.2 and 2.4, respectively) and 20:5n-3/20:4n-6 ratio (from 1.7 to 0.9 and 1.0).

Hemocyte viability and concentrations. Hemocyte viability was high and similar for oysters fed T-*Iso* supplemented with 0.0, 0.25, and 0.41 ArA µg mL^{-1} (Table 4).

During the experiment, the total hemocyte (including granulocytes, hyalinocytes, and agranulocytes) tended to increase in oysters fed T-*Iso* supplemented with ArA solutions (1-way ANOVA, $P > 0.05$). When hemocyte subpopulations were evaluated, it was apparent that granulocyte and hyalinocyte concentrations of oysters fed T-*Iso* supplemented with 0.25 and 0.41 µg mL^{-1} of ArA solutions tended to be higher than those of oysters fed T-*Iso* alone (Table 4).

Percentage of phagocytic hemocytes. After 2 wk of experimental feeding, the percentage of phagocytic hemocytes from oysters fed T-*Iso* supplemented with ArA solutions was significantly higher than for oysters fed T-*Iso* alone (Figure 2, 1-way ANOVA, $P < 0.05$); however, it was not different anymore from control animals after 4 wk of dietary conditioning (1-way ANOVA, $P > 0.05$).

Adhesive capacity. After 2 and 4 wk of dietary conditioning, no change in adhesive capacity of hemocytes incubated with FSSW could be seen among the three treatment groups (average of 93% of adhering cells during the whole experiment, data not shown). However, hemocytes of oysters fed T-*Iso* alone showed a greater reduction in adhesion in response to ECP than did oysters fed T-*Iso* supplemented with ArA solutions, but this was not statistically significant (Figure 3).

Reactive oxygen species (ROS) production. ROS production by granulocytes and hyalinocytes is presented in Figure 4. A significant dietary effect was observed for the basal ROS

production of each hemocyte subpopulation after 4 wk of dietary conditioning (1-way ANOVA, $P < 0.05$). Granulocytes and hyalinocytes of oysters fed T-*Iso* supplemented with ArA at 0.25 and 0.41 µg mL^{-1} generated the highest basal ROS production (average of 360 A.U.). An increase of 160 A.U. for granulocytes and hyalinocytes was observed, when compared with the values obtained for oysters fed T-*Iso* alone (average of 198 A.U.). Moreover, the basal ROS production increased continuously between the initial sampling and the end of the experiment for hemocytes of oysters fed T-*Iso* supplemented with ArA solutions, whereas those of oysters fed T-*Iso* alone remained quite stable.

Regarding ROS production after DPI incubation, an inhibition of ROS production was observed for both hemocyte subpopulations, with an average of 64.5 and 56 A.U. of DCF fluorescence measured during the whole experiment in granulocytes and hyalinocytes, respectively. No dietary treatment

effect was detected for each hemocyte subpopulation when incubated with DPI (2-way ANOVA, $P > 0.05$).

DISCUSSION

Impact of the dietary conditioning on gill FA composition. Changes measured in the FA composition of hemocyte membranes were shown to be closely related to those in gill membranes in dietary experiments (25); therefore, in the present study FA analyses were performed on gills rather than on hemocyte samples, which are more difficult to collect in significant amounts.

The observed changes in FA composition of gill polar lipids are in agreement with other studies using T-*Iso* as a mono-specific diet (26,40–47). More noteworthy was the increased incorporation of ArA in gill polar lipids from 4.5% to 19.7% for oysters fed 4 wk T-*Iso* supplemented with ArA solutions. Such ArA enrichment of polar lipids was also reported by Séguineau *et al.* (27) using the same technique of supplementation in *C. gigas* oyster spat for 5 wk. High concentrations of ArA in bivalve phospholipids observed in the present report and in the study of Séguineau *et al.* (27) have not been previously reported in the literature, whatever the tissue, the development stages, and species considered. The highest percentage of ArA in polar lipids found in the other literature reached 7.5% in juveniles of *C. gigas* and 10% in *Ruditapes philippinarum* (26). Also, our results confirmed that this supplementation technique greatly increased the membrane contents of polyunsaturated FA, such as ArA. Interestingly, direct ArA supplementation without algae performed in this study showed that algal feeding was not necessary to obtain good incorporation of ArA supplied in solution directly into the tanks. Indeed, increases of 40% and 44% in the ArA content in gill polar lipids were observed after 2 wk of conditioning (from 6.8% to 11.3% and 12.2%). Thus, we can suggest, as proposed by Bunde and Fried (48), that the ArA may be directly incorporated through mantle and gill membranes without passing through the digestive system. However, it must be stressed that ArA solutions were twofold more efficiently incorporated when combined with the microalgae than when provided alone. The free ArA added to the rearing tank could be coated to or be incorporated by the algae favoring thus its high incorporation and assimilation in the oyster lipids.

Concomitant with ArA incorporation, a decrease in n-3 PUFA, especially EPA content in gills, was reported during the dietary experiment, resulting in a decrease in the n-3/n-6 and EPA/ArA ratios. Although the effect of ArA supplementation on oyster immune parameters may primarily reflect the ArA content increase, the decrease of EPA content and n-3/n-6 ratio may also affect these parameters. Indeed, in vertebrates, changes in n-3 and n-6 composition and their ratio are well known to affect immune parameters. For example, EPA, by competing with ArA for the eicosanoid production, can modulate immune functions (1,2).

Impact of the ArA supplementation on immune parameters. The immune system of bivalves relies on innate defense mechanisms for its response to pathogens. The cellular component of this innate immunity is mediated by hemocytes, which are responsible for recognition, phagocytosis, and elimination of non-self particles (49–51). For this purpose, they generate a variety of microbicidal products including ROS.

In the present study, total and subpopulation hemocyte concentrations tended to be higher for oysters fed T-*Iso* supplemented with ArA. This is in agreement with increased hemocyte concentration observed in the study of Delaporte *et al.* (26) in oysters and clams fed *Chaetoceros calcitrans*, which carried the highest amounts of ArA compared with two other algae, T-*Iso* and *Tetraselmis suecica*. However, in bivalves, it is not clear whether the increase in hemocyte concentration results from production of new cells due to an ArA-enriched diet effect or migration of cells from deeper tissue into the circulating system. Moreover, comparison of our results with vertebrate immune cell proliferation must be done with caution because in vertebrates this process occurs through the binding of a mitogen to a receptor (adaptive response), which leads to a complex cascade of biochemical events. However, Peres *et al.* (52) demonstrated that ArA can modulate lymphocyte proliferation of rats according to the concentration of ArA used for loading macrophages and the percentage of macrophage in the co-culture of cells. Concomitantly, in a review, Peters-Golden *et al.* (53) underlined that leukotrienes influence innate immune response by direct effect on leukocyte accumulation, microbial phagocytosis and killing, and indirect effects mediated by elaboration of other inflammatory molecules. Consequently, although scarce references concerning eicosanoid production in bivalves exist (54–56), we propose that changes in FA composition, especially in ArA, may have affected eicosanoid metabolite production, which may be implicated in the increased hemocyte concentration observed in the present study in oysters.

With regard to hemocyte functional activities, phagocytosis by hemocytes was significantly affected by the dietary treatments after 2 wk of conditioning. At this time, the percentage of phagocytic cells of oysters fed T-*Iso* supplemented with 0.25 and 0.41 μg mL^{-1} of ArA was higher than that of oysters fed T-*Iso* alone. The highest percentage of phagocytic hemocytes was associated with the highest ArA content of gill polar lipids. The relationship between ArA and phagocytosis observed in this study may also be related to ArA-derived eicosanoid metabolites. Indeed, Canesi *et al.* (57) demonstrated that bacterial killing of hemocytes of mussel *Mytilus edulis* was reduced by inhibitors of PLA_2 and cycloxygenase activities, indicating that eicosanoid production is involved in mediating the response to bacterial challenge. Moreover, ArA metabolites (i.e., prostaglandins) were demonstrated to be involved in the nodulation process of insect hemocytes, which is the predominant response to large bacterial infections and results in the formation of an over-

lapping sheath of hemocytes around an infection target (58–63). Several *in vitro* studies in vertebrates also demonstrated a modulating effect of ArA in the phagocytosis process (3–8). Meanwhile, Brock *et al.* (64) demonstrated that LTB_4 and PGE_2 are successively expressed in macrophages during a time exposition to LPS affecting the subsequent bacterial activity of macrophage when challenged with *Klebsiella pneumoniae.* Therefore, changes in the percentage of phagocytic hemocytes observed over the ArA dietary experiment may be related to subtle changes in the ratio of ArA derived eicosanoids (i.e., LTB4 / PGE2) produced by hemocytes.

Concomitant with the increase of phagocytosis, an increase of adhesive capacity of ECP challenged hemocytes from oysters fed T-*Iso* supplemented with 0.25 and 0.41 μg mL^{-1} of ArA was observed. This result is similar to the study of Mandato *et al.* (58) and Miller *et al.* (65), who demonstrated that ArA metabolites are involved in the hemocyte spreading process (similar to the process involved in our adhesive assay) in insects and suggests that eicosanoid products may also be implicated in the adhesive capacity of oyster hemocytes. Interestingly, although the inhibitory effect of ECP on hemocyte adhesive capacity demonstrated by Labreuche *et al.* (37) was confirmed in this study, ArA supplementation appeared to counteract its effect.

An increase of the basal ROS production by hemocytes was observed at the end of the experiment for oysters fed T-*Iso* supplemented with ArA solutions. It is important to note that addition of diphenylene iodonium chloride (DPI), an inhibitor of the NADPH-oxidase and the NO-synthase pathways, strongly decreased the basal ROS production from hemocytes. This allowed us to confirm that the basal ROS production was associated with NADPH-oxidase and/or NO-synthase-like activities. Also, the highest incorporation of ArA content in gill polar lipids of those oysters seemed to be associated with basal ROS production, as previously observed with *C. calcitrans* dietary conditioning (26). In an *in vitro* study, Mazière *et al.* (66) demonstrated that human fibroblasts incubated with ArA presented higher ROS production without stimulation than control fibroblasts, but also reported a higher content of lipid peroxidation products. Also, in a review, Calder (1) noted that LTB_4 (produced from ArA) enhanced ROS production of vertebrate leukocytes. Thus, in our study, the enormous change in ArA content in gill polar lipids may have lead to an overproduction of ROS by NADPH-oxidase (with or without the production of LTB_4) and/or an increase of lipid peroxide products as in vertebrates.

CONCLUSION

In conclusion, this study demonstrated that supplementation with ArA appeared to enhance hemocyte concentration, phagocytosis activity, and basal ROS production, and to reduce susceptibility of hemocyte adhesive capacity to *Vibrio aestuarianus*. Based on established knowledge on the role of ArA and its metabolites on immune functions in vertebrates and insects, we propose that ArA and/or its metabolites may also be important in immune responses of oysters. However, additional studies are needed, and the use of inhibitors of eicosanoid synthesis should help to establish the involvement of these ArA metabolites in oyster immune parameters. Finally, as the level of ArA reported in gill polar lipids at the end of the dietary conditioning attained the highest level ever reported in literature, we wonder whether such a level of ArA is not above physiologically normal levels in oysters. New experiments with lower doses of ArA should be done, perhaps in combination with a supply of antioxidants such as vitamins E and C.

ACKNOWLEDGMENTS

We are grateful to all coworkers from the Argenton hatchery for taking care of the oysters during the experimental conditioning. The authors would like to thank Dr. Gary H. Wikfors, NOAA Fisheries, Northeast Fisheries Center (Milford, Connecticut) and Dr. Fred Markham, Department of Pathology and Microbiology, University of Prince Edward Island (Prince Edward Island, Canada) for their critical review and helpful advice to improve the final manuscript. This research was a part of the MOREST project supported by a grant from IFREMER, the Région Bretagne, Région Normandie, Région Pays de Loire, Région Poitou-Charente, and the Conseil Général du Calvados. Contribution n°1009 of the IUEM European Institute for Marine Studies (Brest, France).

ABSTRACT: Human gallbladder bile dissolved in dimethylsulfoxide provides sharp and resolved signals for major bile components in ^{1}H NMR spectra. Characteristic well-resolved marker signals that invariably appear in ^{1}H NMR spectra of bile were identified for cholesterol (H18 methyl signal at 0.643 ppm), lipids (glycerol CH signal at 5.064 ppm), total bile acids (H18 signals in the range 0.520–0.626 ppm), total glycine conjugated bile acids (NH signal at 6.958 ppm), total taurine conjugated bile acids (NH signal at 7.646 ppm), and urea (NH_2 signal near 5.48 ppm), which enabled their rapid and accurate analysis. Excellent linearity and precision of quantitative analysis was observed for all the identified bile components ($R^2 >$ 0.99 for all). The method was demonstrated on gallbladder bile from 19 patients with gallbladder diseases. Urea in bile was identified by NMR for the first time and its quantitative analysis, along with several other bile components, is presented. The majority of the bile components could be analyzed in a single step. Accurate and rapid quantification of several bile components noninvasively by using the method presented herein may have far-reaching implications in the study of bile acid metabolism and pathophysiology of various hepatobiliary and gastrointestinal diseases.

Paper no. L9947 in *Lipids 41*, 577–589 (June 2006).

Major components of human bile are cholesterol, glycerophospholipids, and bile acids. Altered levels of bile components are associated with various hepatobiliary and gastrointestinal diseases (1). Abnormal bile composition causes dietary fat malabsorption and gallstone formation (2,3). Hence finding bile composition is an important component for studying pathophysiology and diagnosis of diseases associated with abnormal bile composition. Several analytical methods exist for estimation of these components, but they are not straightforward and involve tedious steps such as extraction, hydrolysis, derivatization, and/or purification before analysis (4–9). Further, separate procedures need to be adapted for the analysis of individual bile components. Nuclear magnetic resonance (NMR) spectroscopy offers immense potential as a tool for investigating hepatobiliary diseases (10). The greatest advantage of this method is that several components can be monitored noninvasively, both qualitatively and quantitatively. It is the simplicity of monitoring several intact components that makes NMR a potentially useful tool in understanding disease processes and furthering the knowledge on the metabolism of bile components. Although efforts have been made to quantitatively estimate major bile components by using ^{1}H NMR spectroscopy (11,12), until today, it has not been possible to accurately analyze all of them in intact bile in a single step due to the complexity of bile spectra arising from the overlap of signals from several bile components. The analysis problem gets further compounded due to the broadening of ^{1}H NMR signals since the bile components exist as aggregates under natural conditions (13,14). In this study, we have devised a simple NMR method to analyze major bile components such as cholesterol, glycerophospholipids, total conjugated and unconjugated bile acids, and urea. This has been achieved by the study of bile in a polar organic solvent such as dimethylsulfoxide, which provides resolved NMR signals. Detailed assignments of the spectra by using 1D and 2D techniques provide means for rapid one-step analysis of several major bile components.

Abbreviations: CDCA, chenodeoxycholic acid; DCA, deoxycholic acid; DMSO, dimethylsulfoxide-d_6; DQF-COSY, double quantum filtered correlated spectroscopy; FID, free induction decay; GCA, glycocholic acid; GCDCA, glycochenodeoxycholic acid; GDCA, glycodeoxycholic acid; HMBC, heteronuclear multiple bond correlation; HSQC, heteronuclear single quantum correlation; TCA, taurocholic acid; TCDCA, taurochenodeoxycholic acid; TDCA, taurodeoxycholic acid; TOCSY, total correlated spectroscopy; TSP, sodium salt of trimethylsilylpropionic acid-d_4.

EXPERIMENTAL PROCEDURES

Chemicals and human bile. Sodium salts of deoxycholic acid (DCA), chenodeoxycholic acid (CDCA), glycocholic acid (GCA), glycodeoxycholic acid (GDCA), glycochenodeoxycholic acid (GCDCA), taurocholic acid (TCA), taurodeoxycholic acid (TDCA), taurochenodeoxycholic acid (TCDCA), and cholesterol were purchased from Sigma-Aldrich (St. Louis, MO). Phosphatidylcholine was obtained from Life Care Remedies and urea from Ranbaxy (New Delhi, India). Deuterated acetonitrile, deuterated acetone, deuterated dimethylsulfoxide (DMSO), deuterium oxide (D_2O), and sodium salt of trimethylsilylpropionic acid-d_4 (TSP) were purchased from Sigma-Aldrich (Milwaukee, WI). Human gallbladder bile specimens obtained from patients undergoing cholecystectomy (laparoscopic or open) for symptomatic gallstone disease were used for the experiments.

NMR experiments. All NMR experiments were performed on a Bruker Biospin Avance 400- or 700-MHz NMR spectrometer using 5-mm broadband and broadband inverse probe

heads (400 MHz) or a cryo-probe head (700 MHz) (Bruker BioSpin AG, Fällanden, Switzerland). All the probe heads were equipped with shielded *z*-gradient.

One-dimensional ^1H NMR experiments. One-dimensional ^1H spectra of bile (20 μL) dissolved in polar deuterated organic solvents (500 μL) such as DMSO, acetonitrile, and acetone were obtained by using one-pulse sequence with the suppression of the residual water signal by presaturation during the relaxation delay. In each case, bile solution was taken in a 5-mm NMR tube and the ^1H spectrum was recorded in the presence of a reusable coaxial capillary tube containing 35 μL of 0.375% TSP in D_2O.

One-dimensional ^1H spectra of individual standard chemicals, that are supposedly found in bile, such as cholesterol (51.65 μg), phosphatidylcholine (289.13 μg), urea (30 μg), a mixture of glycine-conjugated bile acids (GCA, 0.6 mg; GDCA, 0.4 mg; and GCDCA, 0.2 mg), a mixture of taurine-conjugated bile acids (TCA, 0.4 mg; TDCA, 0.2 mg; and TCDCA, 0.2 mg), and a mixture of both glycine- and taurine-conjugated bile acids (GCA, 0.6 mg; GDCA, 0.4 mg; GCDCA, 0.2 mg; TCA, 0.4 mg; TDCA, 0.2 mg; and TCDCA, 0.2 mg), were obtained in DMSO-d_6 solvent (500 μL) by using the one-pulse sequence.

Typical parameters used for all one-dimensional experiments were as follows: spectral width: 4,800 (at 400 MHz) or 9,000 Hz (at 700 MHz); time domain data points: 32 K; flip angle: 45°; relaxation delay: 6 s; spectrum size: 32 K points; and line broadening for exponential window function: 0.3 Hz.

To estimate the T_1 relaxation times of characteristic signals of individual bile component compounds, inversion recovery experiments were performed at 400 MHz on standard chemicals (cholesterol: H18; phosphatidylcholine: 2-CH; urea: NH_2; glycine conjugated bile acids: NH; taurine-conjugated bile acids: NH; and total bile acids: H18). Parameters used were as follows: spectral width: 4,800 Hz; time domain points: 32 K; relaxation delay: 15 s; number of scans: 32; inversion recovery delay: varied between 10 ms and 10 s in 10 to 13 steps; spectrum size: 32 K and line broadening: 0.3 Hz. T_1 relaxation times were calculated by using the intensities of the recovered signals with respect to the recovery delays using Bruker Xwinnmr software version 3.1.

Two-dimensional experiments. ^1H-^1H two-dimensional double quantum filtered correlated spectroscopy (DQF-COSY) and ^1H-^1H two-dimensional total correlated spectroscopy (TOCSY) experiments were performed on human bile dissolved in DMSO at both 400 and 700 MHz. Suppression of the residual water signal was done by presaturation. Parameters used were as follows: spectral width, 4,800 (at 400 MHz) or 9,000 Hz (at 700 MHz) in both dimensions; time domain data points, 2,048; number of free induction decays (FID) with t_1 increments, 512; relaxation delay, 2.5 s; and number of transients, 24. Spin lock time of 80 ms was used for TOCSY experiments. Phase-sensitive data were obtained by a time-proportional phase increment (TPPI) method. The resulting data were zero-filled to 1,024 points in the t_1 dimension and Fourier transformed along both dimensions after multiplying the data by a squared sine-bell window function shifted by π/2.

Sensitivity enhanced (by preservation of equivalent pathways using gradients) and multiplicity edited ^1H-^{13}C heteronuclear single quantum correlation (edited HSQC) and gradient enhanced ^1H-^{13}C heteronuclear multiple bond correlation (HMBC) experiments were performed at 400 and 700 MHz for bile dissolved in DMSO. Spectral widths of 4,800 (at 400 MHz) or 9,000 Hz (at 700 MHz) in ^1H dimension and 24,000 (at 400 MHz) or 44,000 Hz (at 700 MHz) in ^{13}C dimension were used; 512 FID were collected with t_1 increments each of 2,048 data points, 32 transients, and 2-s recycle delay. Phase-sensitive data for edited HSQC experiment were obtained by using echo-antiecho mode, whereas magnitude mode data were obtained for HMBC. Resulting 2D data were zero-filled to 1,024 points in the t_1 dimension and double Fourier transformed after multiplying by a squared sine-bell window function shifted by π/2 along both dimensions.

NMR experiments with titration of DMSO solution of bile with water. Bile specimens from five patients were used to test the variation of signal intensity of the bile components as a function of water content in DMSO solutions. Ten solutions were prepared from each bile specimen in DMSO in 5-mm NMR tubes varying water concentration from 1% to 10% (vol/vol) in steps of 1%, keeping the total volume of each solution fixed (500 μL). The volumes of water and DMSO in ten 500-μL solutions, from each bile, were 5, 495; 10, 490; 15, 485; 20, 480; 25, 475; 30, 470; 35, 465; 40, 460; 45, 455; or 50, 450 μL, respectively. ^1H spectra for all the solutions were recorded at 400 MHz under identical conditions by using a single-pulse sequence by suppressing water signal by presaturation. At each water-DMSO composition, amounts of cholesterol, lipids, total bile acids, glycine conjugated, and taurine conjugated bile acids were determined through the integrals of their marker signals in the spectra with reference to TSP signal (taken in a reusable coaxial capillary). Considering the maximum signal integral with reference to TSP signal as 100%, plots of integral areas of individual bile components vs. the water content were made and the variations in the NMR signal integrals were compared.

Recovery experiments for total bile acids and glycine- and taurine-conjugated bile acids. Bile from five patients (60 μL each), having different quantities of bile acids, was used for the recovery experiments. Each bile sample was divided into three parts of 20 μL each. To one part taken in a 5-mm NMR tube, 65 μL of water and 550 μL of DMSO were added, which served as a control. To the remaining two parts, a mixture of a known quantities of bile acids (DCA, 151.1 μg; CDCA, 161.3 μg; GDCA, 337.8 μg; and TDCA, 199.8 μg) were added, separately, using the bile acids stock solution, such that total volume, and composition of water and DMSO, was the same as in the control solutions. ^1H spectra were recorded for all the solutions under identical conditions by using a one-pulse sequence by suppressing the residual water signal by presaturation. Integrals of the H18 methyl signals of total conjugated and unconjugated bile acids (0.520–0.626 ppm) as well as amide signals

of total glycine (6.958 ppm) and total taurine (7.646 ppm) conjugated bile acids were determined relative to TSP reference (taken in a reusable co-axial capillary). Using these integrals, the quantities of total bile acids, glycine-conjugated bile acids, and taurine-conjugated bile acids were calculated individually from all the control spectra and those obtained after the addition of standard bile acids stock solution. The accuracy and the reproducibility of the quantities were compared by integrating each signal five times, independent of one another.

Recovery experiments for cholesterol and phosphatidylcholine. Bile from five patients (60 μL each), having different quantities of cholesterol/phosphatidylcholine as observed by the intensity of the signals, was used for the recovery experiments. Each bile sample was divided into three parts of 20 μL each. One part was taken in a 5-mm NMR tube and dissolved in 500 μL of DMSO, which served as a control. The remaining two parts were taken in separate tubes; 20 μL of stock solution containing 51.65 μg of standard cholesterol (6.68 mM) was added to each tube, and the volume was made up to 520 μL with DMSO so as to keep the total volume the same as in the control. ^{1}H spectra were recorded for all the solutions under identical conditions by using a one-pulse sequence by suppressing residual water signal by presaturation. In each case, the quantity of cholesterol was determined by using the integral of H18 methyl protons (0.643 ppm) relative to the TSP signal (taken in a reusable coaxial capillary). Similarly, following the procedure described above, recovery experiments for phosphatidylcholine were performed by adding 289.13 μg (18.92 mM) of standard phosphatidylcholine in five different bile samples (each in duplicate). In each case, the quantity of phosphatidylcholine was determined by using the integral of the glyceryl 2-CH proton (5.064 ppm) relative to the TSP reference. The accuracy and the reproducibility of the quantities were compared by integrating each signal five times, independent of one another.

Urea in bile. Urea in bile was identified through the signal at the characteristic chemical shift (near 5.43 ppm) and its variation as a function of water concentration in DMSO solution. To confirm its assignment, one-dimensional ^{1}H spectra of bile in DMSO were recorded at 400 MHz before and after the addition of standard urea (2.0, 4.0, and 6.0 μg). One-dimensional ^{13}C spectra of bile were recorded on a 700-MHz spectrometer (3,000 μL bile concentrated to 500 μL by lyophilization) with proton decoupling, before and after the addition of 0.5 mg of standard urea to further verify the assignment. The parameters used were as follows: spectral width: 44,000 Hz; time domain points: 32 K; recycle delay: 2 s; flip angle: 30°; number of transients: 7,000 (for concentrated bile) and 5,000 (for concentrated bile + 0.5 mg urea); spectrum size: 32 K; line broadening: 3 Hz;

From the titration experiments described earlier (bile solution in DMSO with water), the integral of the urea signal in the spectra of bile dissolved in DMSO containing varying amounts of water (1–10% vol/vol) was determined, to determine the solvent composition range at which the urea signal shows maximum intensity that can be used reliably for quantitative estimation. Subsequently, using the bile solution containing 8% water (vol/vol) at which the urea signal showed maximum intensity, recovery experiments were performed to determine the accuracy and precision of urea estimation. For this, six bile solutions were prepared in duplicate, each solution containing 40 μL of bile and 460 μL of DMSO. One set served as a control; to the remaining five sets, varying quantity of standard urea was added (6.96, 13.92, 20.88, 27.84, and 34.8 μg). One-dimensional ^{1}H spectra were recorded for all the samples by using a one-pulse sequence with water suppression by presaturation. The integrals of the urea signal were determined with reference to the internal reference (TSP) taken in a reusable sealed capillary. The quantities of urea recovered were calculated by using the urea signal integral after subtracting the integral from the control spectra. The accuracy and the reproducibility were tested by following the procedure as mentioned previously for other bile components.

Analyses of components in gallbladder bile. Cholesterol, lipids, total bile acids, and taurine-conjugated bile acids were determined from human gallbladder bile of 19 patients by using a simple one-dimensional ^{1}H NMR spectra obtained at 400 MHz. In each case, 20 μL of bile dissolved in 500 μL of DMSO was taken in a 5-mm NMR tube and a reusable coaxial capillary containing the quantitative reference, TSP was inserted into the NMR tube and ^{1}H spectra were obtained. A 45° radiofrequency excitation pulse and a recycle delay of 6 s were used to ensure complete recovery of magnetization of all the marker signals of bile components as well as the TSP signal. Integrals of the marker signals relative to TSP were determined and amounts of cholesterol, glycerophospholipids, taurine-conjugated bile acids, and total bile acids (conjugated and unconjugated) were calculated by using a computer program. Subsequently, 35 μL of water was added to each sample to ensure recovery of full intensity for glycine (NH) and urea signals, ^{1}H NMR spectra were recorded again, and the total glycine-conjugated bile acids and urea were determined by using the integrals of their characteristic signals with reference to TSP signal. The reproducibility of the quantities of the bile components was determined by integrating each signal five times, independent of one another.

RESULTS

Spectral assignments. The structures of major bile components that could be analyzed by NMR in this study are shown in Figure 1. Among the polar organic solvents (acetone, acetonitrile, and DMSO) used to determine appropriate conditions for obtaining resolved signals for major biochemical constituents in bile, DMSO was found to be the most suitable since it provided spectra with fairly well-resolved signals for major bile components. In acetone and acetonitrile, all the components except cholesterol were either missing or weak in intensity due to their poor solubility. ^{1}H and ^{13}C NMR signals in the DMSO solvent were identified individually based on the analysis of ^{1}H-^{1}H and ^{1}H-^{13}C two-dimensional spectra

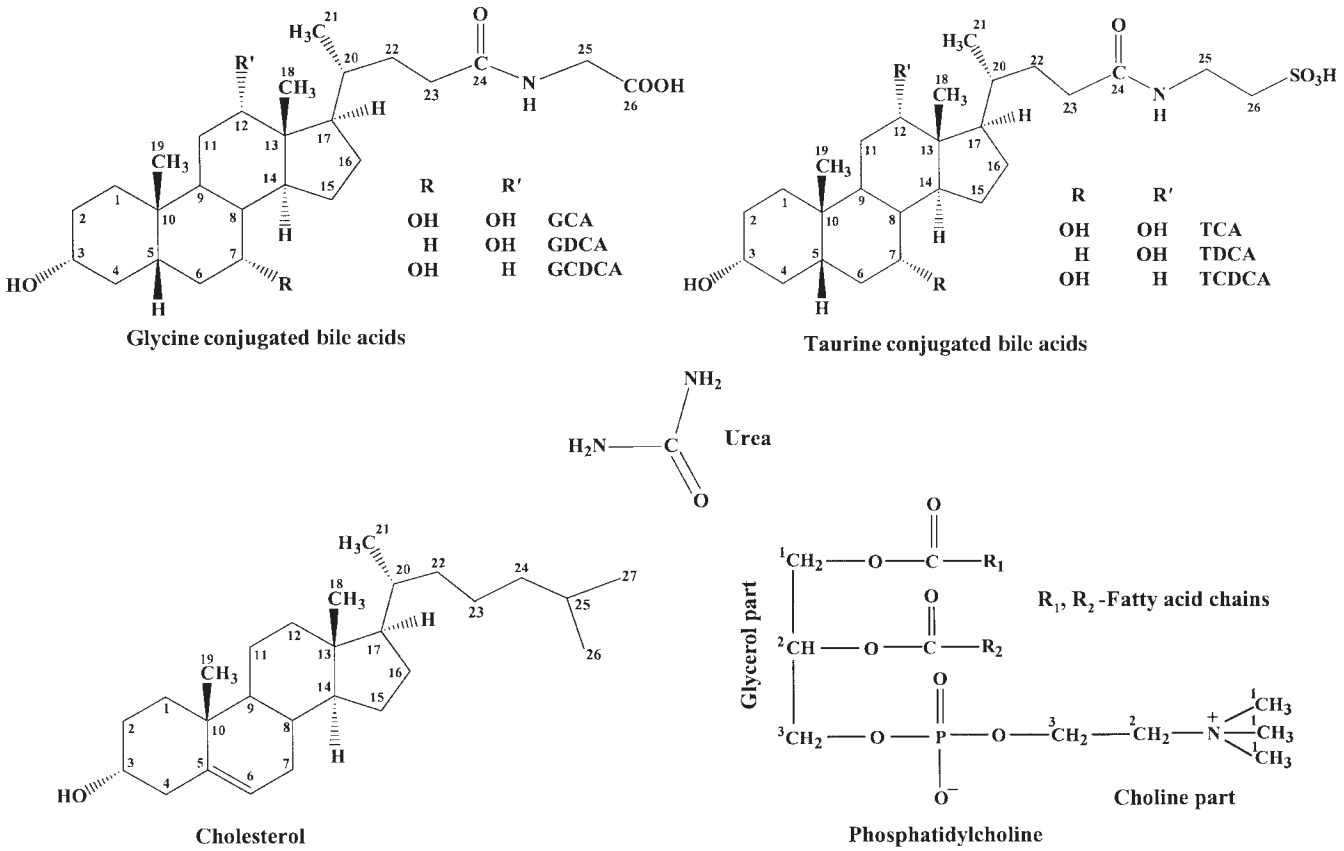

FIG. 1. Structures and numbering of protons and carbons of bile components dealt with in this study. The numbering of the proton(s) is the same as that of the corresponding directly attached carbon. The orientation of some substitutions in cholesterol and bile acids is marked with respect to the plane of the ring (crosshatched wedge, α substitution; bold wedge, β substitution).

obtained at 400 and 700 MHz and using the library of chemical shifts recently established for several conjugated and unconjugated bile acids (15). Parts of TOCSY, HSQC, and HMBC spectra along with the assignments of major signals are shown in Figures 2, 3, and 4, respectively. Although, ^{1}H NMR signals were relatively sharp in DMSO, many of the signals were still overlapping, obviously due to the presence of several components (Fig. 5). However, the methyl signal of cholesterol (H18, 0.643 ppm), the methyl signals of total bile acids (H18, 0.520–0.626 ppm), the glyceryl 2-CH signal of phosphatidylcholine (5.064 ppm), and the amide signals of glycine-conjugated (6.958 ppm) and taurine-conjugated (7.646 ppm) bile acids were invariably distinctly isolated from each other and from the rest of the signals in the ^{1}H NMR spectra. One-dimensional ^{1}H spectrum of a typical bile sample dissolved in DMSO (with assignments) is shown in Figure 6 along with the spectrum of neat bile diluted with water for comparison.

Bile signals intensity vs. water content in DMSO solution. In the spectrum of bile dissolved in DMSO, the intensities of signals from cholesterol, lipids, and amide signals of bile acids vary with the composition of water. Both cholesterol and lipids show maximum signal intensity in DMSO up to a water composition of about 4% (vol/vol). However, beyond 4% (vol/vol), the signals gradually broaden and eventually become undetectable (Fig. 7). Methyl signals of total bile acids and amide signals of taurine-conjugated bile acids show maximum intensity throughout the range of water-DMSO composition studied. Amide signals from glycine-conjugated bile acids show maximum intensity in DMSO containing ≥ 6% water (vol/vol). Consistent results obtained for bile specimens from five different patients are depicted for all the bile components in Figure 7.

Urea in bile. Urea in bile was initially tentatively assigned from the characteristic ^{1}H signal at 5.48 ppm (in DMSO solution containing 10% water). The urea signal overlaps with the unsaturated part of lipids signal (~5.31 ppm) in the ^{1}H NMR spectrum of bile in DMSO containing around 1% (vol/vol) water. However, as the water content in DMSO is increased, the signal gradually shifts to downfield. When the water content was increased to more than 3% (vol/vol), the signal separates out of the overlapping region. Parts of a few spectra showing the variation of urea chemical shift with reference to water content are shown in Figure 8. One-dimensional ^{1}H and ^{13}C NMR spectra recorded before and after the addition of standard urea into the bile solution clearly showed, after addition of urea, increase in signal intensities of both ^{1}H and ^{13}C signals of urea (Fig. 9), thus confirming the assignment of bile urea made for the first time in bile NMR spectrum.

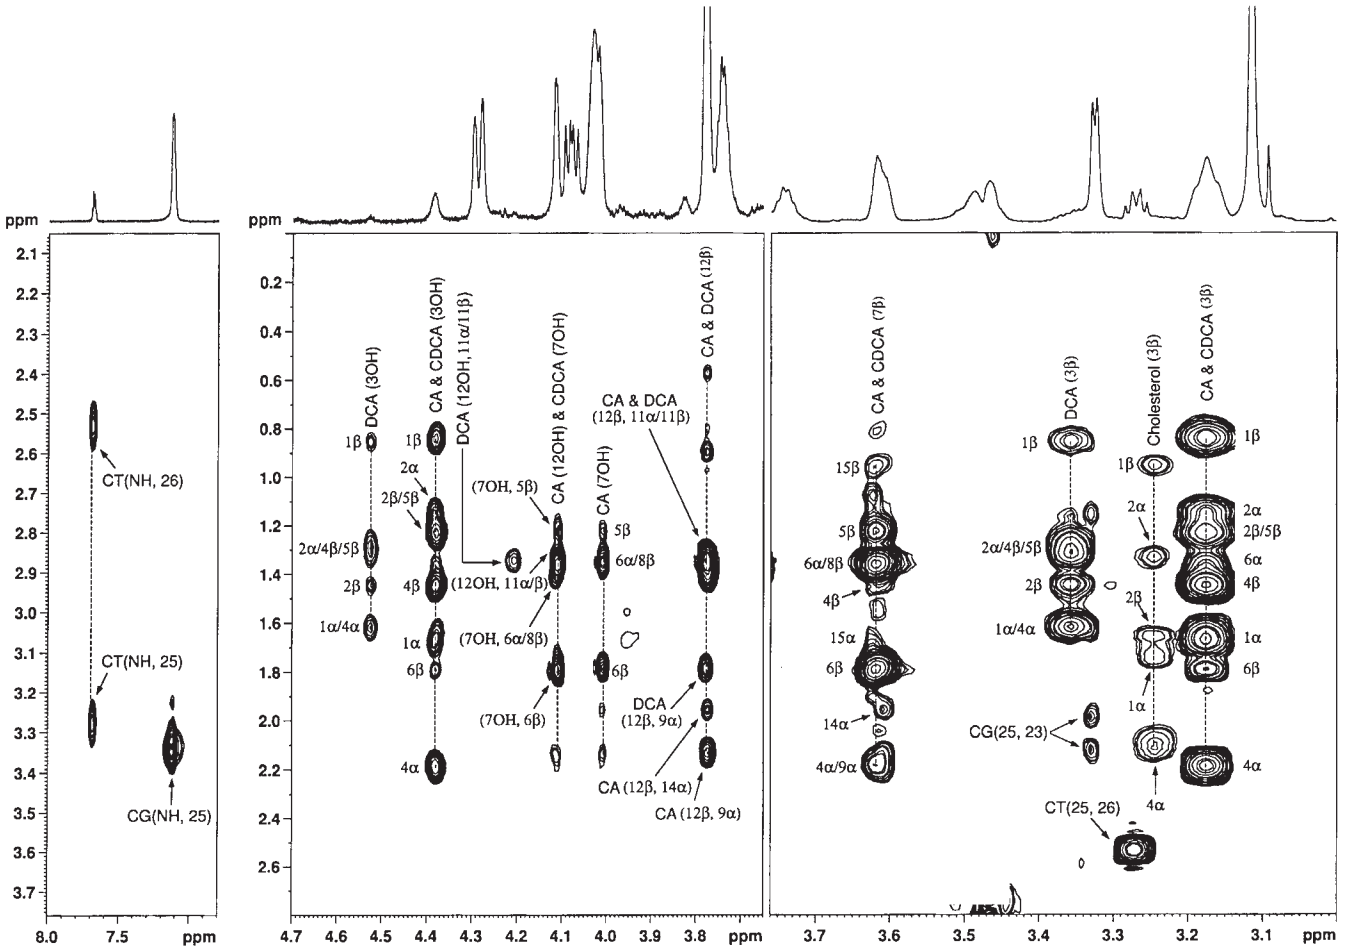

FIG. 2. Part of TOCSY spectrum of typical bile (20 µL) dissolved in 500 µL of DMSO with assignments of the signals. The spectrum was obtained on a Bruker Biospin AVANCE 700-MHz spectrometer (Bruker BioSpin AG, Fällanden, Switzerland). CT, conjugated taurine; CG, conjugated glycine; CA, glycine/taurine-conjugated cholic acid; DCA, glycine/taurine-conjugated deoxycholic acid; CDCA, glycine/taurine-conjugated chenodeoxy cholic acid. The numbering of protons is as shown in Figure 1. A trace of the 1D ^{1}H spectrum is shown on the 2D spectrum. The residual signals (T_1 noise) arising from the water peak at 3.5 ppm and phosphatidylcholine peak at 3.1 ppm are whited out for the sake of convenient labeling of the cross peaks (rightmost part of the spectrum).

A one-dimensional experiment on bile dissolved in DMSO with water varying from 1% to 10% (vol/vol) showed that, at a lower concentration of water, the urea signal intensity is lesser and it gradually increases as the concentration of water is increased, and the intensity was maximum (100%) at greater than a 7% (vol/vol) water concentration. Plots of urea signal integral vs. water composition for five different bile specimens dissolved in DMSO are included in Figure 7.

Accuracy and precision tests. The accuracy and precision of analysis of cholesterol, lipids, total bile acids, conjugated bile acids, and urea were determined from NMR of bile in DMSO by using recovery experiments. Comparison of the quantities of biochemical constituents recovered, in duplicate experiments, from intact bile in DMSO with the quantities added showed excellent correlation ($R^2 > 0.99$) for all the bile components.

Rapid analysis of human gallbladder bile. It is clear from Figure 7 that ^{1}H NMR spectra of bile in DMSO containing 4% or less (vol/vol) water show isolated signals with maximum intensity for cholesterol, lipids, total bile acids, and taurine-conjugated bile acids. This establishes that the signal intensities in DMSO containing 4% or less (vol/vol) water for cholesterol, lipids, total bile acids, and taurine-conjugated bile acids represent their true concentrations. Under these conditions (20 µL of bile dissolved in 500 µL of DMSO), cholesterol, lipids, total bile acids, and taurine-conjugated bile acids were estimated simultaneously in bile from 19 patients with gallbladder disease. Subsequently, glycine-conjugated bile acids and urea were estimated from the spectra obtained after the addition of 35 µL of water. In all the bile specimens, bile components appear consistently in the ^{1}H NMR spectra; however, the quantities as well as the relative composition of the components varied significantly. Table 1 shows the absolute quantities of various components thus determined from ^{1}H NMR for gallbladder bile of 19 patients. Parts of ^{1}H NMR spectra for bile from four representative patients are shown in Figure 10, highlighting variation of total and relative amounts of various components. The diagnosis

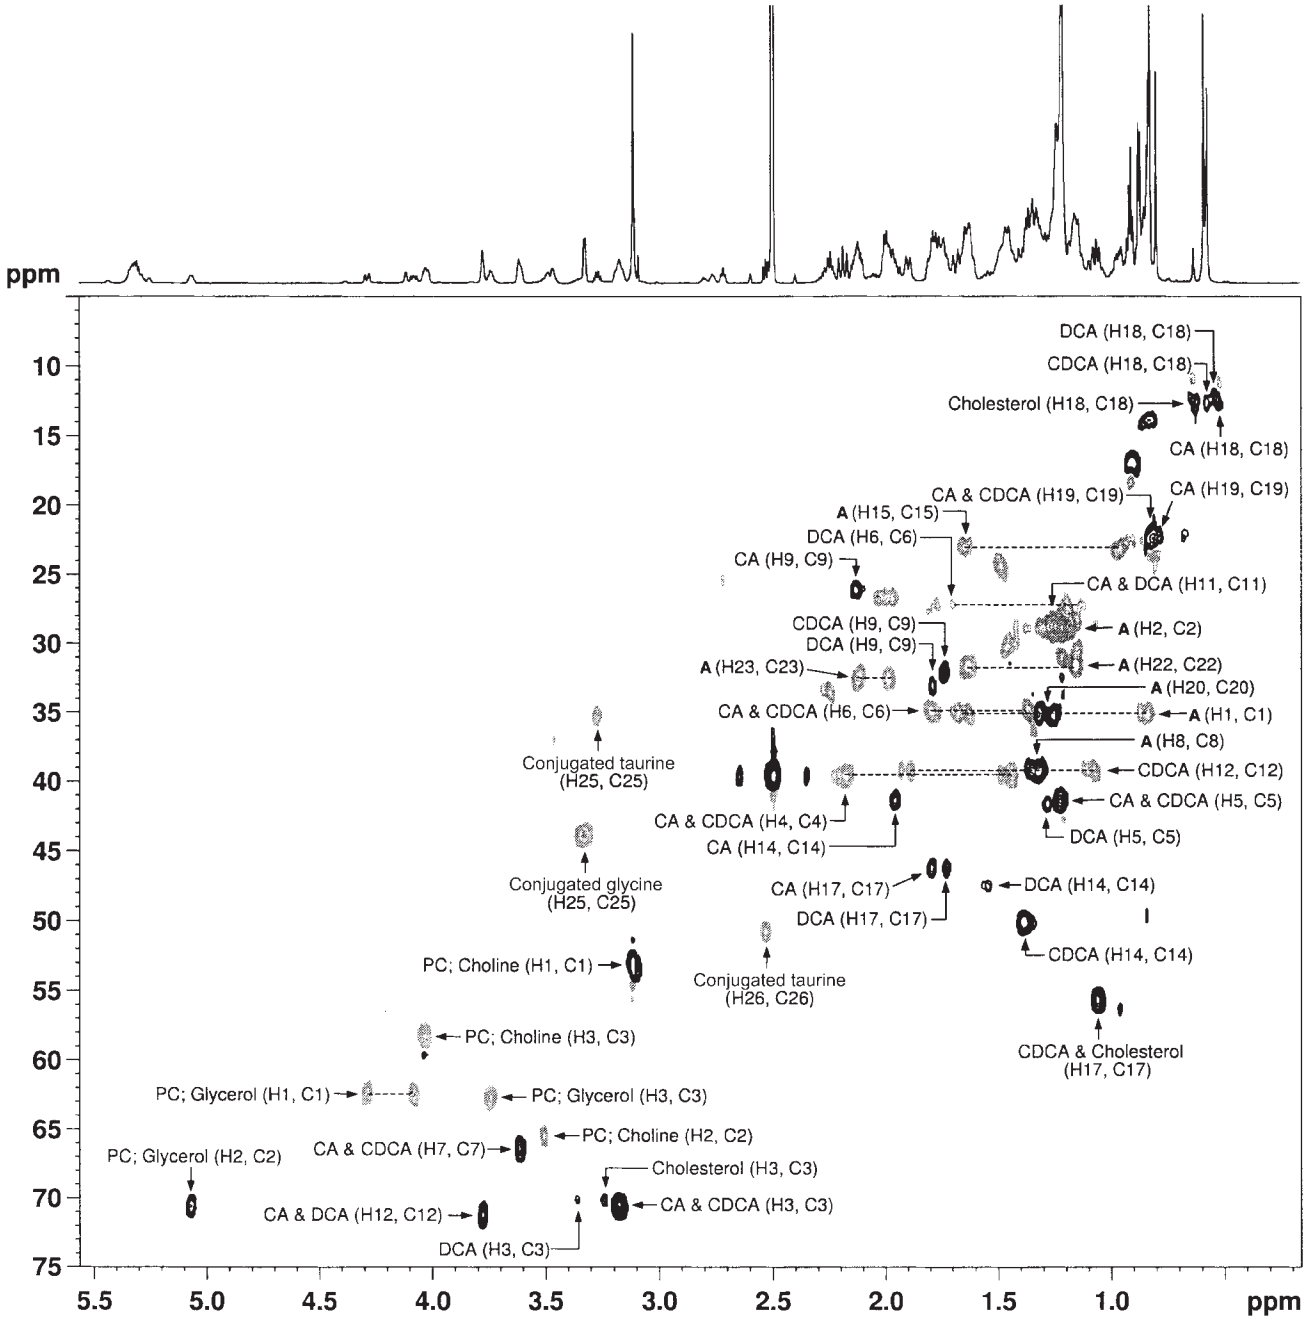

FIG. 3. Sensitivity-enhanced multiplicity edited ^{1}H-^{13}C HSQC spectrum of 20 µL of bile dissolved in 500 µL of DMSO obtained on a Bruker Biospin Avance 700-MHz spectrometer, along with the assignments of the cross peaks of protons and the attached carbons. For clarity, CH and CH_3 cross peaks are shown as dark continuous contours, whereas CH_2 cross peaks are shown in light discontinuous contours. Wherever the two protons of CH_2 are chemically different (nondegenerate), two distinct cross peaks were observed corresponding to H_α and H_β protons (each pair of cross peaks is joined by dashed lines). A trace of the 1D ^{1}H spectrum is shown on the 2D spectrum. PC, phosphatidylcholine; CA, glycine/taurine conjugated cholic acid; DCA, glycine/taurine-conjugated deoxycholic acid; CDCA, glycine/taurine-conjugated chenodeoxycholic acid. A: All glycine/taurine-conjugated bile acids. The numbering of the protons/carbons is as shown for the structures in Figure 1.

of the gallstone disease for each patient is also included in the Table.

DISCUSSION

Biochemical composition of bile reflects a multitude of cellular functions and hence it is important that a convenient method exists to monitor the dynamic variation of several of the bile components simultaneously. NMR spectroscopy happens to be a potentially useful tool for such a purpose. In an effort to quantify total glycine- and taurine-conjugated bile acids in bile, we have recently proposed a simple pulse NMR method (16). In this study, using polar organic solvents such as deuterated acetone, acetonitrile, and DMSO, we have attempted to simplify

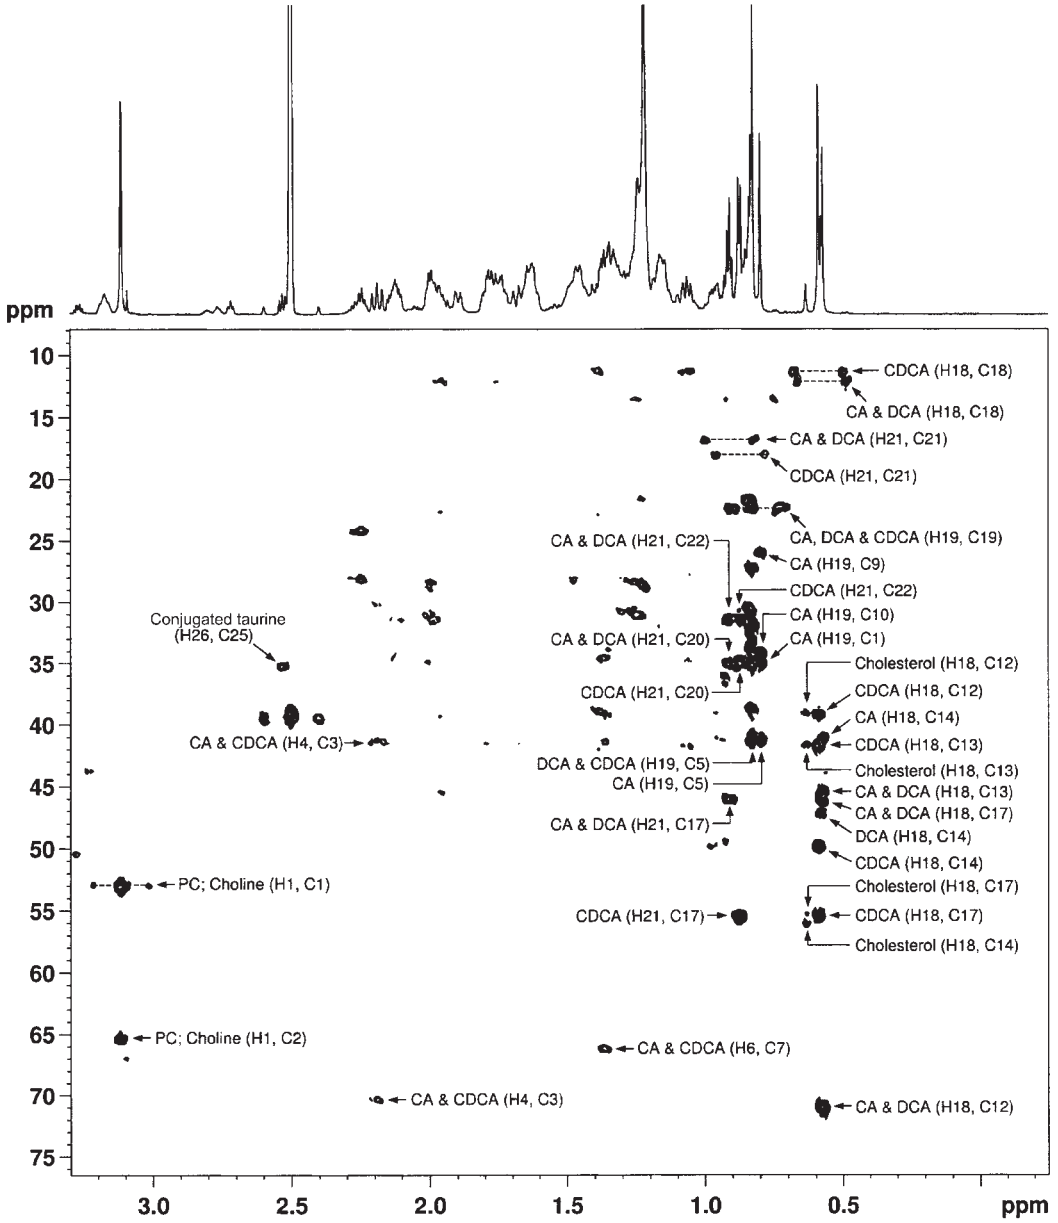

FIG. 4. ^{1}H-^{13}C HMBC spectrum of 20 µL of bile dissolved in 500 µL of DMSO obtained on a 700-MHz Bruker Biospin AVANCE spectrometer, along with the assignments of the cross peaks arising from one-, two-, or three-bond ^{1}H and ^{13}C couplings. Cross peaks due to one-bond proton-carbon coupling are joined by horizontal dashed lines. A trace of the 1D ^{1}H spectrum is shown on the 2D spectrum. PC, phosphatidylcholine; CA, glycine/taurine-conjugated cholic acid; DCA, glycine/taurine-conjugated deoxycholic acid; CDCA, glycine/taurine-conjugated chenodeoxy cholic acid. The numbering of the protons/carbons is as shown for the structures in Figure 1.

the complex human bile spectra to analyze several bile components, simultaneously, without resorting to any complex procedure. The signals from all bile components were not clearly observed in the spectra of bile in acetone or acetonitrile due to the poor solubility of especially urea and bile acids. However, the spectra of bile dissolved in a highly polar solvent, such as DMSO, provided signals with the characteristic marker signals for major bile components such as cholesterol, glycerophospholipids, total bile acids (conjugated and unconjugated), total glycine-conjugated bile acids, and total taurine-conjugated bile acids well separated from each other, which enabled their accurate quantitative analysis (Figs. 6 and 10). It may be noted that 95% of the phospholipids in the bile arise from phosphatidylcholine (17), and hence the contributions from other lipids are minor. Further, the 2-CH signal (at 5.064 ppm) couples with 1-CH_2 and 3-CH_2 of glycerol moiety, all have chemical shifts typical for phosphatidylcholine as observed in 2D DQF-COSY, TOCSY, and HSQC spectra (Figs. 1 and 3), and hence the 2-CH signal used as a marker for glycerophospholipids, in this study, arises purely from phosphatidylcholine. Identification of the bile components marker signals was, first, based on the assignment of ^{1}H and ^{13}C signals using one- and

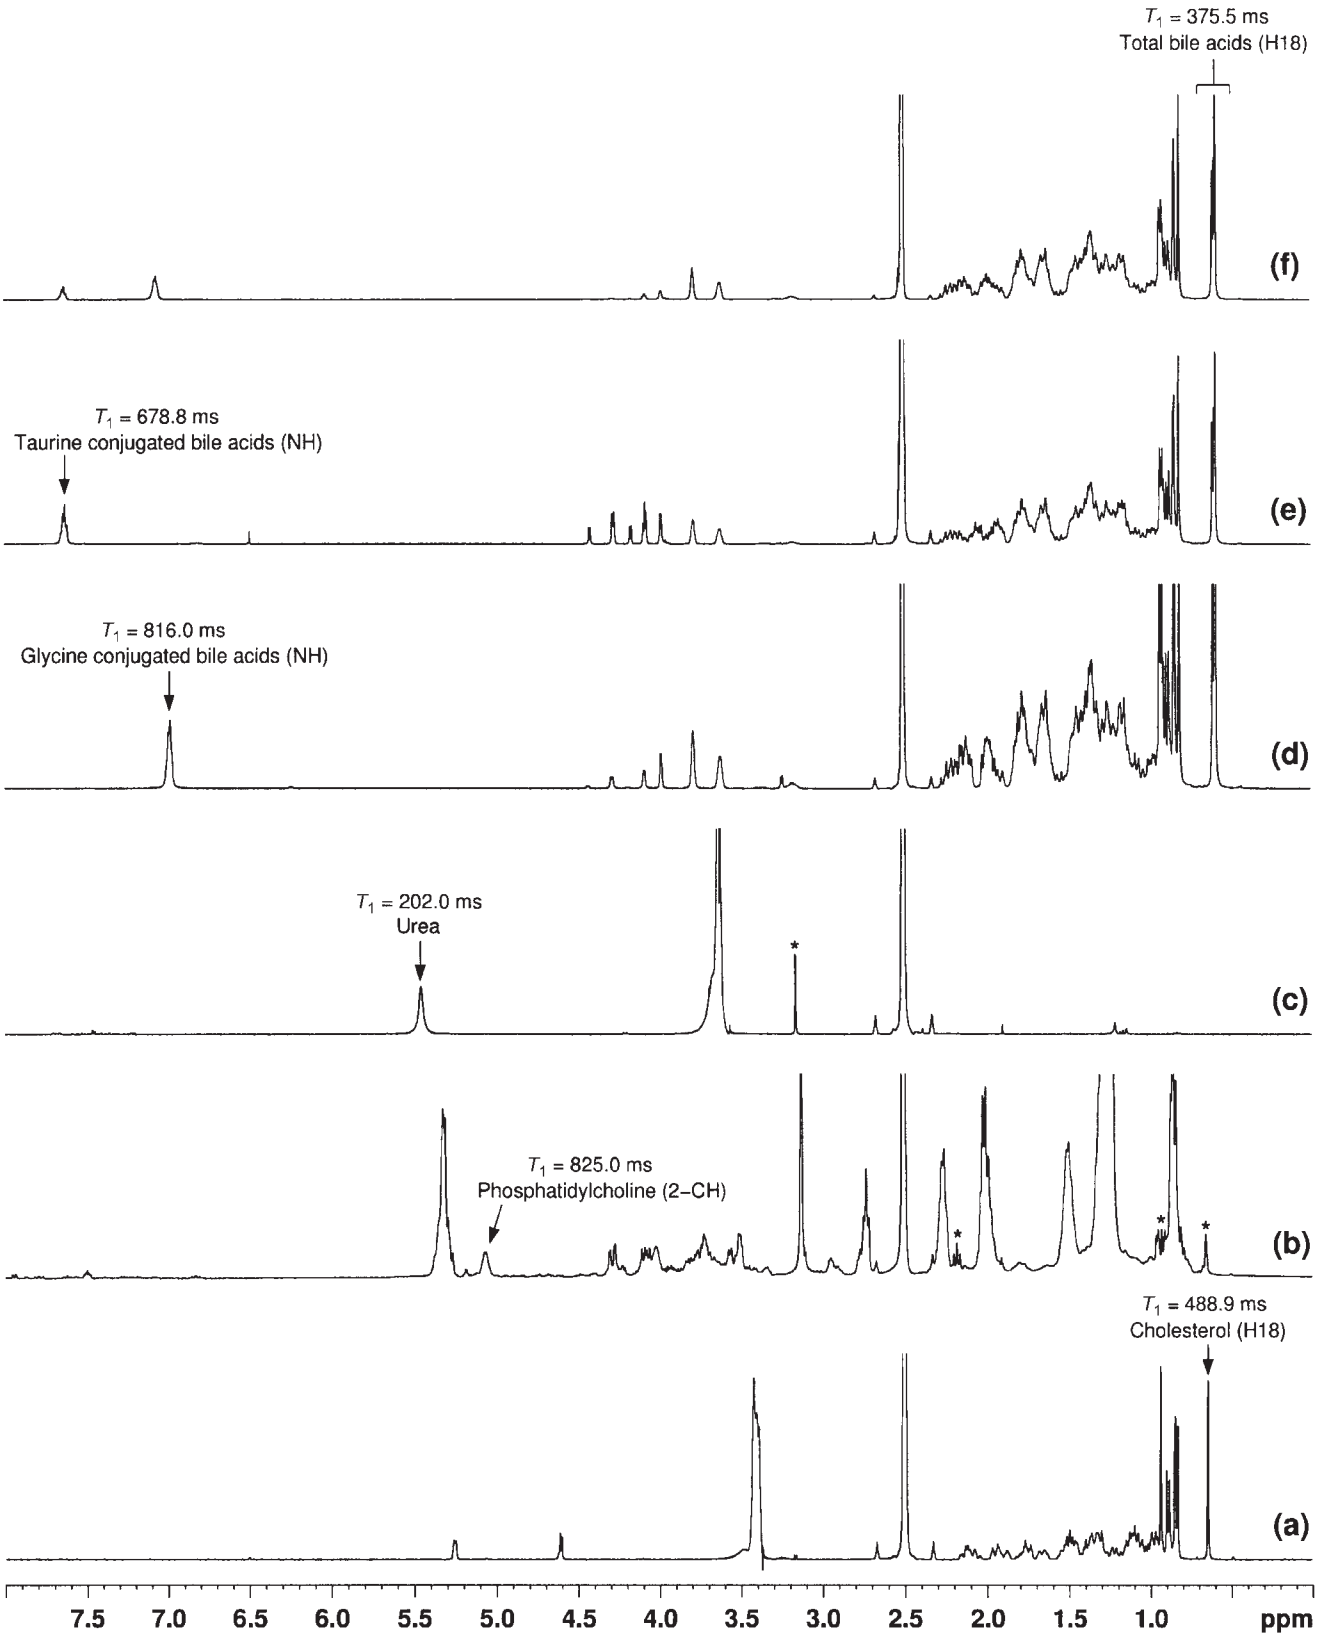

FIG. 5. One-dimensional ^{1}H spectra of individual bile component compounds obtained on a 400-MHz Bruker Biospin AVANCE spectrometer in DMSO solvent (500 µL): (a) cholesterol (51.65 µg); (b) phosphatidylcholine (289.13 µg); (c) urea (30 µg); (d) mixture of glycine-conjugated bile acids (GCA: 0.6 mg; GDCA: 0.4 mg; and GCDCA: 0.2 mg); (e) mixture of taurine-conjugated bile acids (TCA: 0.4 mg; TDCA: 0.2 mg; and TCDCA: 0.2 mg); (f) mixture of taurine- and glycine-conjugated bile acids (GCA: 0.6 mg; GDCA: 0.4 mg; GCDCA: 0.2 mg; TCA: 0.4 mg; TDCA: 0.2 mg; and TCDCA: 0.2 mg). The characteristic marker signal(s) and their T_1 values are marked. * = impurity signals.

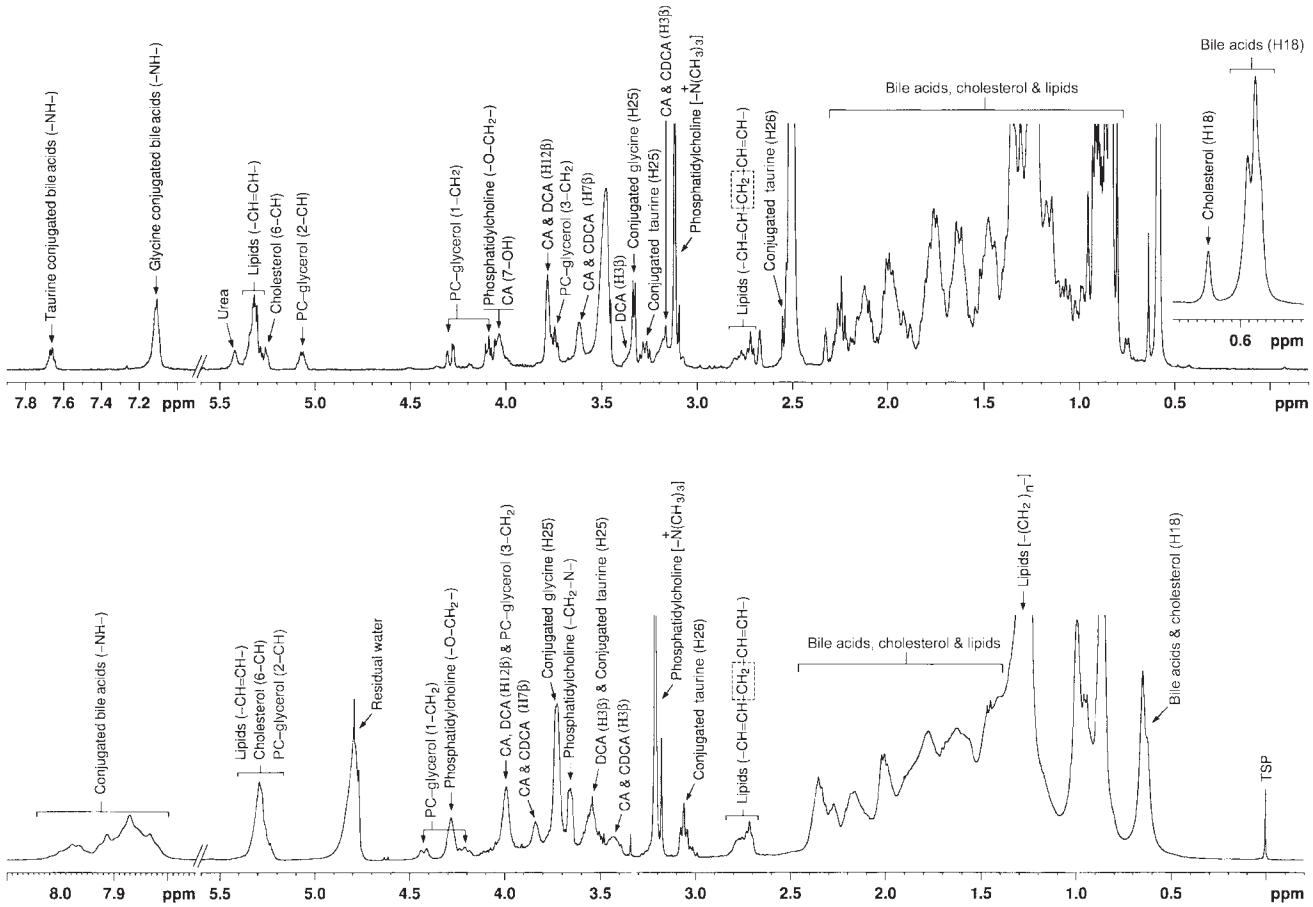

FIG. 6. One-dimensional ^{1}H spectra obtained on a 400-MHz Bruker Biospin AVANCE spectrometer. (Top) Spectrum of 20 µL of bile dissolved in 500 µL of DMSO with the assignments of the majority of the signals. Characteristic marker signals for cholesterol, lipids, total bile acids, glycine-conjugated bile acids, taurine-conjugated bile acids, and urea are distinctly observed. (Bottom) Bile spectrum in aqueous medium (100 µL of bile in 400 µL of water); note that the marker signals for individual classes of bile components are overlapping, thus making it difficult (or impossible) for analysis of bile components in the spectra from aqueous medium. PC, phosphatidylcholine; CA, glycine/taurine conjugated cholic acid; DCA, glycine/taurine-conjugated deoxycholic acid; CDCA, glycine/taurine-conjugated chenodeoxy cholic acid. The numbering of protons is as shown for the structures in Figure 1.

two-dimensional experiments (Figs. 2–4). Initially, partial assignments were made by using the NMR experiments at 400 MHz and the library of chemical shifts of several bile acids (15). Subsequent assignments using the spectra at 700 MHz greatly facilitated unambiguous assignment of the majority of ^{1}H and ^{13}C signals.

Quantitative estimation from ^{1}H NMR spectroscopy requires that at least one of the proton signals is separated from the crowded regions of the spectra. Even from the regions of the spectra with signals overlapping from several components, it is still possible to quantify them accurately provided the number of protons of each constituent in the overlapping signals is known and it is same for all the components. In the spectra of bile dissolved in DMSO, H18 methyl signals of total bile acids (conjugated and unconjugated) at 0.520–0.626 ppm, the H18 methyl signal of cholesterol at 0.643 ppm, glyceryl 2-CH of lipids at 5.064 ppm, urea amide signals near 5.48 ppm (in the presence of nearly 8% water), amide signals of total glycine-conjugated bile acids at 6.958 ppm, and amide signals of total taurine-conjugated bile acids at 7.646 ppm are the distinct markers of the individual class of components, which enabled their accurate analyses (Figs. 6 and 10). To choose an appropriate recycle delay for accurate quantitative measurement of all the components in a single measurement, we have estimated T_1 relaxation times for the key resonances by using an inversion recovery method and the values thus obtained are marked in Figure 5. It may be noted that the relaxation times of all the key resonance lie well within 1 s and hence favor quick acquisition of the NMR data. However, care should be taken while analyzing bile components in a single step since water content in DMSO greatly alters the intensities of several bile components signals. This is particularly important since bile itself is an aqueous medium, and, depending on the volume of bile dissolved in DMSO, the amount of water will automatically vary, which directly influences the outcome of the results. After a careful study of bile dissolved in DMSO with different amounts of water arising from the dissolution of different volumes of bile, we have

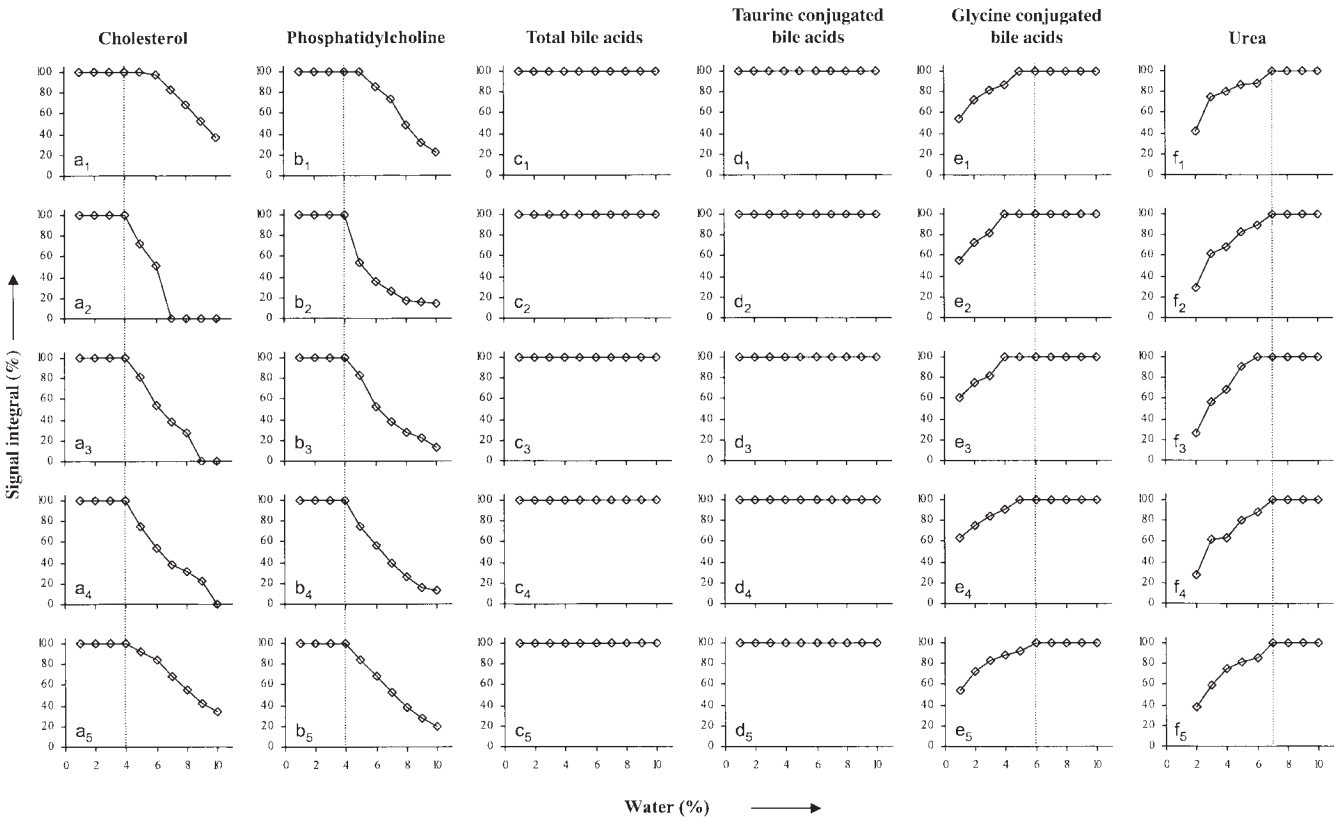

FIG. 7. Plots of intensity of signals vs. percentage of water in DMSO solution of bile studied for five patients' bile; 100% refers to the true integral corresponding to the actual quantity of the biochemical present in the solution. Clearly, maximum signal intensity is obtained for cholesterol (a_1 to a_5) and lipids (b_1 to b_5) when water is 4% (vol/vol) or less; for total bile acids (c_1 to c_5) and taurine conjugated bile acids (d_1 to d_5), the signal is maximum throughout; for glycine conjugated bile acids (e_1 to e_5) and urea (f_1 to f_5), the signal integral becomes maximum beyond nearly 6% and 7% (vol/vol), respectively.

shown that to analyze cholesterol and lipids along with total bile acids and taurine-conjugated bile acids, in a single step, the water content in DMSO must be limited to 4% (vol/vol) or less (Fig. 7). This condition is stringent for cholesterol and lipids analyses since their signal intensities drastically decrease at higher than 4% (vol/vol) water. This reduction in intensity presumably arises from the aggregation of the predominantly nonpolar lipid/cholesterol molecules. Thus, dissolution of about 20 µL or less of bile in about 500 µL of DMSO would satisfy the condition (water: 4% [vol/vol] or less) for rapid analysis of the components. As shown from this study, about 20 µL of bile is sufficient to obtain spectra with a good signal-to-noise ratio within a few minutes even with lower field NMR spectrometry (400 MHz).

Attenuation of the amide signal intensity of glycine-conjugated bile acids in DMSO containing less than 6% (vol/vol) water (Fig. 7) may arise from the interaction of the amide protons with the DMSO solvent. Upon increasing water concentration to greater than 6% (vol/vol), an attenuated glycine amide signal gains its full intensity, which appears to be due to the competing interaction of water with DMSO. Hence, for accurate analysis of total glycine-conjugated bile acids, an additional ^{1}H NMR experiment is required after increasing the amount of water to 6% (vol/vol) or more. However, it may be noted that bile acids constitute mainly glycine- and taurine-conjugated bile acids (4). In addition, our study on a large number of bile specimens from different patients showed the ratio of the sum of glycine and taurine amide signal integrals to the total bile acids H18 methyl signal integral to be 1:3, as expected for bile acids constituted by only glycine and taurine conjugates. It can also be seen from Table 1 that the total bile acids determined by using H18 methyl signals are nearly equal to the respective sum of glycine- and taurine-conjugated bile acids determined from the amide signal integrals. Under such conditions, an additional NMR experiment is not required for analyzing glycine-conjugated bile acids and it can be determined along with other bile components by subtracting total taurine-conjugated bile acids from the total bile acids (Table 1). On the other hand, after determining glycine-conjugated bile acids accurately from an additional experiment, unconjugated bile acids present in the bile, if any, may also be determined accurately by simply subtracting the sum of the glycine- and taurine-conjugated bile acids from the total bile acids. However, care should be used while interpreting such results since, similar to unconjugated bile acids, sulfonated or glucuronated (18,19) bile acids, if present in significant quantity, would also result in the increase of total bile acids marker signals.

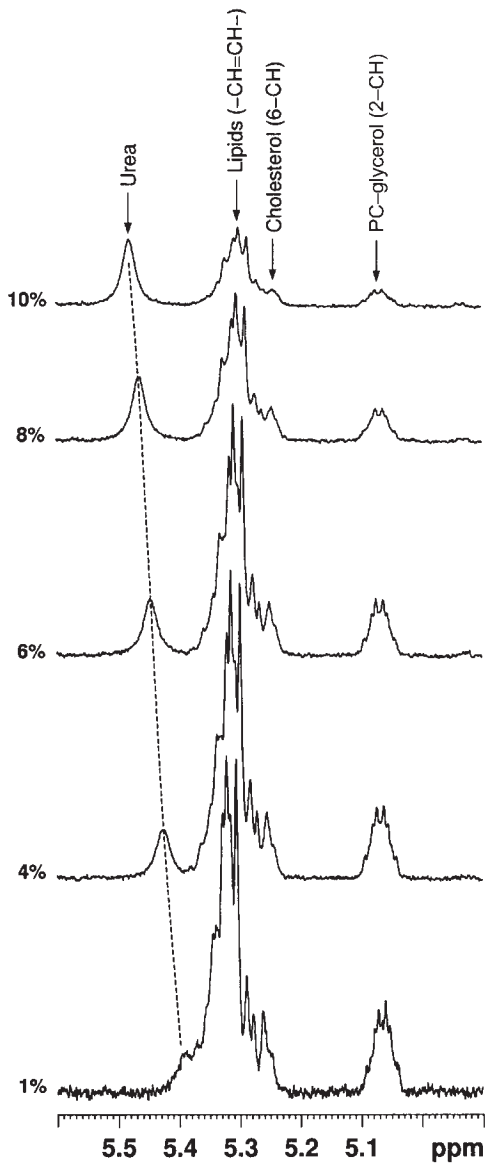

FIG. 8. Parts of ^{1}H NMR spectra of bile dissolved in DMSO, obtained on a 400-MHz spectrometer, highlighting the urea signal in bile and its variation (shifting toward higher chemical shift) of position as the water in the DMSO solution is increased from 1% to 10% (vol/vol). Note that the intensity of the urea signal also increases at higher percentages of water.

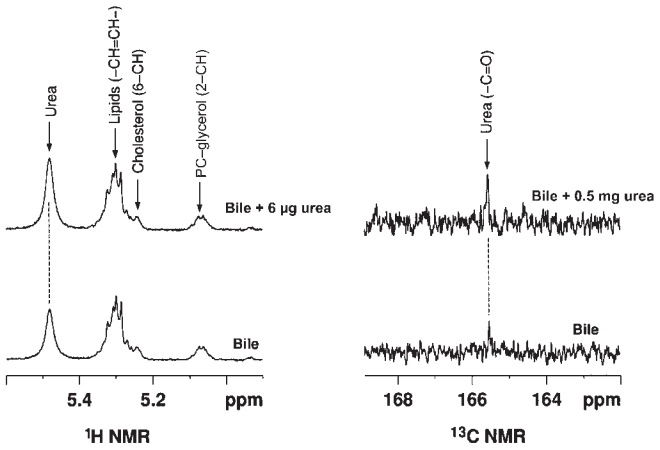

FIG. 9. (Left) Parts of 400-MHz ^{1}H NMR spectra of 20 µL of human bile dissolved in 500 µL of DMSO (containing 8% water) obtained under identical conditions before (bottom spectrum) and after (top spectrum) the addition of 6 µg of urea. (Right) Parts of 700-MHz ^{13}C NMR spectra of 3,000 µL of human bile concentrated to 500 µL obtained before (bottom spectrum) and after (top spectrum) the addition of 0.5 mg of urea. Note that the urea signal in both ^{1}H and ^{13}C NMR spectra increases after the addition of urea, thus confirming its identification, for the first time, in bile by NMR. More noise in the ^{13}C spectrum (top right spectrum) arises due to a fewer number of transients (5,000 transients) when compared with the number of transients for the control spectrum (7,000 transients; bottom right spectrum). The vertical scales for all the spectra are normalized with reference to the internal invariant bile acids signals.

The accuracy and precision of analysis of cholesterol, lipids, total bile acids (conjugated and unconjugated), and glycine-conjugated and taurine-conjugated bile acids were determined from the intact bile dissolved in DMSO before and after the addition of known quantities of standard compounds and showed good correlation ($R^2 > 0.99$). This accuracy of the analysis for bile components using ^{1}H NMR essentially stems from the fact that the characteristic marker signals for bile components in DMSO are well resolved, which enables measurement of the integrals of the characteristic signals precisely.

In this study, we also report the identification and quantitative estimation of urea in bile for the first time by using NMR. In DMSO with less than about 2% (vol/vol) water, the urea signal overlaps with the unsaturated part of lipids signals. However, with increasing water content, the urea signal gradually separates out from the overlapping region with a concomitant increase of the intensity. Reduced intensity at a lower concentration of water, similar to the amide signal of glycine-conjugated bile acids, may arise from the interaction with the DMSO solvent. This interaction of urea with DMSO appears to gradually diminish with increasing water content, apparently due to the competitive interaction of water with DMSO. The quantity of urea in bile analyzed before and after the addition of varying quantities of standard urea at a water-DMSO composition at which the signal intensity was maximal provides excellent precision and linearity.

The water signal in the DMSO solution of bile appears at about 3.5 ppm. Care should be used during the suppression of this signal because high water suppression power would attenuate nearby signals. The suppression power might even spread to the characteristic lipid and urea marker signals (near 5 ppm, Figs. 6 and 10), depending on the strength of the radiofrequency power used, and cause underestimation of lipids and urea. However, the suppression power of about 10 Hz or less is safe and sufficient to suppress the residual water signal without causing attenuation of required component signals.

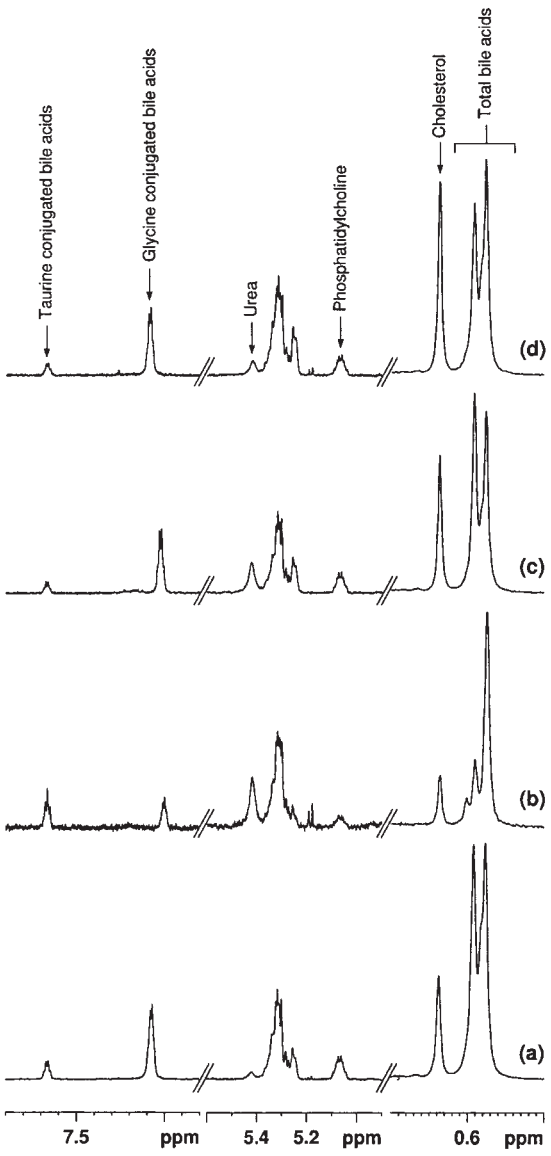

FIG. 10. Parts of 400-MHz ^{1}H NMR spectra of gallbladder bile (20 µL) dissolved in 500 µL of DMSO from four typical patients with gallbladder disease highlighting the isolated characteristic marker signals of several major bile components that can be accurately and rapidly analyzed. Variation of the relative intensities of the bile components within as well as between the bile specimens is clearly noticeable (see also Table 1). All the spectra were acquired and plotted under identical conditions for direct comparison of the relative quantities of various bile components. The regions 4.9 to 5.6 ppm and 6.8 to 7.9 ppm are plotted with increased vertical scale by a factor of 2 with respect to the region 0.5 to 0.7 ppm. (a) Normal (no diagnosed gallstone disease); (b) xanthogranulomatous cholecystitis (XGC); (c) gallbladder cancer (GBC); and (d) chronic cholecystitis (CC).

We have demonstrated simultaneous analysis of several bile components from gallbladder bile from 19 patients. As seen in Figure 10 and Table 1, significant differences in the absolute as well as the relative quantities of the bile components for these patients indicate the potential application of the method for better understanding of bile biochemistry. Further, in all the bile specimens, the amount of total bile acids determined from H18 methyl signals was nearly equal to the sum of total glycine- and taurine-conjugated bile acids (Table 1). This is in line with the fact that glycine and taurine conjugates are the predominant bile acids in bile (18). Although variation in the quantities of the individual bile components, as shown in Table 1, does not seem to show any direct correlation with the diagnosis, detailed and systematic studies are required to relate these variations to the underlying pathophysiology of hepatobiliary diseases.

In summary, we present here a simple method to analyze several major bile components such as cholesterol, lipids, total bile acids (conjugated and unconjugated), total glycine-conjugated bile acids, and total taurine-conjugated bile acids. This method allows analyses of major bile components such as cholesterol, lipids, and total bile acids, including taurine-conjugated bile acids, in a single step. An additional measurement with a few microliters of water will enable the analyses of glycine-conjugated bile acids and urea. Urea in bile was identified for the first time by using NMR. The whole process is so rapid that within a few minutes, all the components can be analyzed. This rapid and noninvasive method enables quick monitoring of dynamic variations of the bile components, providing greatly simplified access for better understanding of hepatic cell functions, bile synthesis, and the associated biliary diseases.

ABSTRACT: ^{1}H and ^{13}C NMR spectra of intact human bile were assigned using one-dimensional (^{1}H and ^{13}C) and two-dimensional (^{1}H-^{1}H and ^{1}H-^{13}C) experiments. Individual conjugated bile acids—glycocholic acid, glycodeoxycholic acid, glycochenodeoxycholic acid, taurocholic acid, taurodeoxycholic acid, and taurochenodeoxycholic acid—were identified. The bile acids were quantified accurately and individually in a single step by using distinct and characteristic amide signals. Making use of ^{13}C NMR, the study also suggests a way to analyze unconjugated bile acids separately, if present. Chemical shift assignments and rapid single-step analysis of individual conjugated bile acids from intact bile presented herein may have immense utility in the study of bile acid metabolism and deeper understanding of hepatobiliary diseases.

Paper no. L9954 in *Lipids 41*, 591–603 (June 2006).

Bile acids have been implicated in the digestion and absorption of fats and in several other important physiological functions, including cholesterol homeostasis and bile flow, help in the excretion or recirculation of drugs, vitamins, and endogenous and exogenous toxins (1,2). Recently, new biological properties of bile acids as signaling molecules and as regulators of their own synthesis have also been reported (3). Abnormal composition of the conjugated bile salts in bile may lead to various hepatobiliary and gastrointestinal diseases (4–6). Dietary fat malabsorption and gallstone formation are the common causes of abnormal bile composition in the bile (4,6). Conditions that prevent the synthesis of bile acids or their excretion cause cholestasis or impaired bile flow. Several human diseases arising from altered levels of bile acids underscore the essential role of bile acids in metabolism (7). Bile acids are considered to be involved in the development of biliary tract carcinoma, although the underlying mechanisms are yet to be established (8). They have long been implicated in the etiology of colorectal cancer, but epidemiologic evidence remains elusive (9). Deoxycholic acid is reported to cause higher risk for pressure ulcers in elderly bedridden patients (10). It has been suggested that the bile acids in the feces act as promoters of colon cancer, and among the bile acids, deoxycholic acid is said to have strong influence. The ratio of deoxycholic acid to cholic acid in feces is reported to have a diagnostic significance in colon cancer (11). Several reports indicate that bile acids cause DNA damage and act as carcinogens (12). Aggravation of taurochenodeoxycholic acid induced liver damage, and hepatocyte apoptosis is reported due to the inhibition of phosphatidylinositol 3-kinase (13). From the experiments with immortalized mouse cholangiocytes using several bile acids, carcinogenic potential of glycochenodeoxycholic acid in biliary tract has been demonstrated (8). Bile acid synthetic defects that are uncommon genetic disorders were reported to be responsible for approximately 2% of persistent cholestasis in infants. These defects lead to liver diseases that may be life threatening but are treatable by replacement of deficient primary bile acids (14).

In view of the multitude of useful as well as deleterious roles played by the bile acids, measurement of their conjugation pattern is necessary for understanding the pathophysiology of these diseases. Several methods for bile acids analysis have been proposed (15–25). Of these, liquid chromatography–mass spectrometry (22–25) and liquid chromatography–electrospray tandem mass spectrometry (2) methods are reported to be useful for routine qualitative/quantitative analysis. These methods are not straightforward since they involve tedious steps such as extraction, hydrolysis, derivatization, and/or purification before analyses. A simple and convenient method for determining identity and quantity of the individual bile acids has not been reported. Nuclear magnetic resonance (NMR) spectroscopy offers immense potential in this direction. However, major difficulties of NMR for such applications arise from severe overlap of signals of a large number of bile components. As a part of our efforts to unravel the signals from complex bile spectra for single-step analysis of several bile components, we reported ^{1}H and ^{13}C chemical shifts, under physiological conditions, for several conjugated and unconjugated bile acids that are supposedly found in bile/gastrointestinal fluids (26) and, subsequently, identified conjugated bile acid marker signals in human bile (27). In continuation, we present here assignments, identification, and

Abbreviations: DQF-COSY, double quantum filtered correlated spectroscopy; GCA, glycocholic acid; GCDCA, glycochenodeoxycholic acid; GDCA, glycodeoxycholic acid; HMBC, heteronuclear multiple bond correlation; HSQC, heteronuclear single quantum correlation; NOE, nuclear Overhauser enhancement; TCA, taurocholic acid; TCDCA, taurochenodeoxycholic acid; TDCA, taurodeoxycholic acid; TOCSY, total correlated spectroscopy; TSP, sodium salt of trimethylsilylpropionic acid-d_4.

single-step analysis of all major conjugated bile acids in human bile individually using simple ^{1}H NMR experiments.

EXPERIMENTAL PROCEDURE

Chemicals and human bile specimens. Sodium salts of glycocholic acid (GCA), glycodeoxycholic acid (GDCA), glycochenodeoxycholic acid (GCDCA), taurocholic acid (TCA), taurodeoxycholic acid (TDCA), taurochenodeoxycholic acid (TCDCA), deuterium oxide (D_2O), and sodium salt of trimethylsilylpropionic acid-d_4 (TSP) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Discarded specimens of human gallbladder bile from patients undergoing cholecystectomy (laparoscopic or open) for symptomatic gallstone disease were used for the study.

NMR experiments. All ^{1}H and ^{13}C NMR experiments of bile specimens were performed on Bruker Biospin Avance 400-, 700-, and/or 800-MHz NMR spectrometers using a 5-mm broadband or broadband inverse probe head (400 MHz) or cryoprobe heads (700 and 800 MHz), all equipped with shielded *z*-gradient accessories. Unless otherwise mentioned, all bile samples were prepared by diluting gallbladder bile by a factor of 10 using distilled water and NMR experiments were performed by using similar parameters as mentioned in our previous article in this issue.

One-dimensional (1D) ^{1}H NMR experiments. The 1D ^{1}H NMR experiments were performed with and/or without homonuclear decoupling (of glycine and taurine CH_2 protons of conjugated bile acids) by using a single-pulse sequence with suppression of water signal by presaturation during relaxation delay of 6 s. For homonuclear decoupled spectra, Gausssian multiplication window function was used with line and Gaussian broadening of –1.0 and 0.1 Hz, respectively.

1D ^{13}C NMR experiments. The 1D ^{13}C spectra were obtained by using one-pulse sequence, spin echo Fourier transform (SEFT), and quaternary carbon detection (QCD) (28) sequences with proton decoupling using WALTZ-16 composite pulse sequence. Typical parameters used were as follows: spectral width: 24,000, 42,000, and 48,000 Hz (at 400-, 700-, and 800-MHz spectrometers, respectively); data points: 32 K; acquisition time: 0.68, 0.39, and 0.34 s (at 400, 700, and 800 MHz, respectively); recycle delay: 3 s; number of transients: 2,000; spectrum size: 32 K points; and line broadening for exponential data multiplication: 3 Hz.

Assignment of ^{1}H and ^{13}C NMR spectra. Assignments of ^{1}H and ^{13}C signals of bile spectra were made by using the combination of 1D and 2D spectra. The signals in the 2D spectra were broad and weak due to the short transverse relaxation times of the signals arising from the aggregation of major bile components. The library of ^{1}H and ^{13}C chemical shifts (26), partial assignments on bile in aqueous media (27), and the assignments of bile dispersed in a polar organic solvent aided identification of signals in the complex spectra and distinguishing bile acids signals from lipids and cholesterol

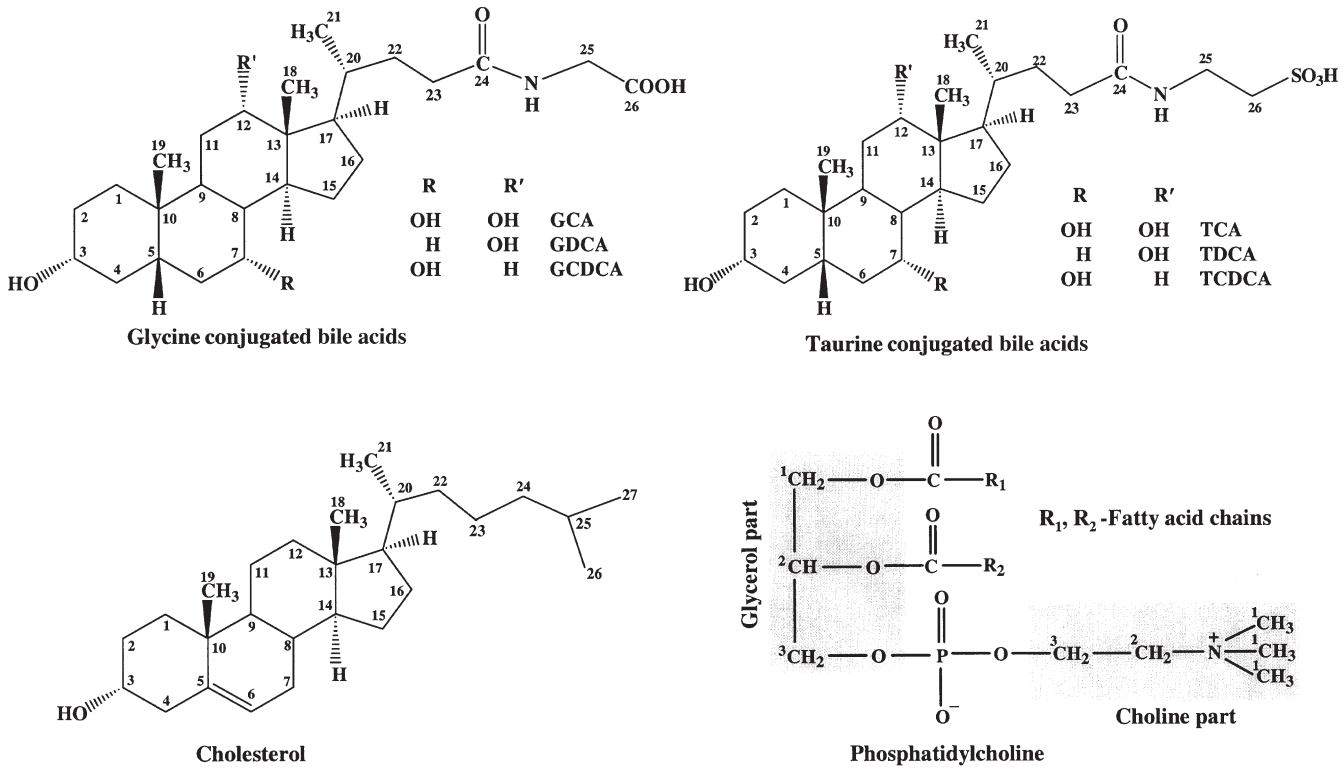

FIG. 1. Structures and numbering of protons and carbons of bile components identified in bile. The numbering of the proton(s) is the same as that of the corresponding directly attached carbons. The orientations of some substitutions in cholesterol and bile acids are marked with respect to the plane of the ring (cross-hatched) wedge: α substitution; bold wedge: β substitution).

signals (L9947 i.e. 29). Assignment from the combination of double quantum filtered correlated spectroscopy (DQF-COSY), total correlated spectroscopy (TOCSY), and multiplicity edited heteronuclear single quantum correlation; (HSQC) and heteronuclear multiple bond correlation (HMBC) spectra at 700 and 800 MHz confirmed assignments made at 400 MHz.

Identification of individual conjugated bile acids. In one-dimensional ^{1}H spectra, broad amide signals from conjugated bile acids, which invariably appear in the isolated region

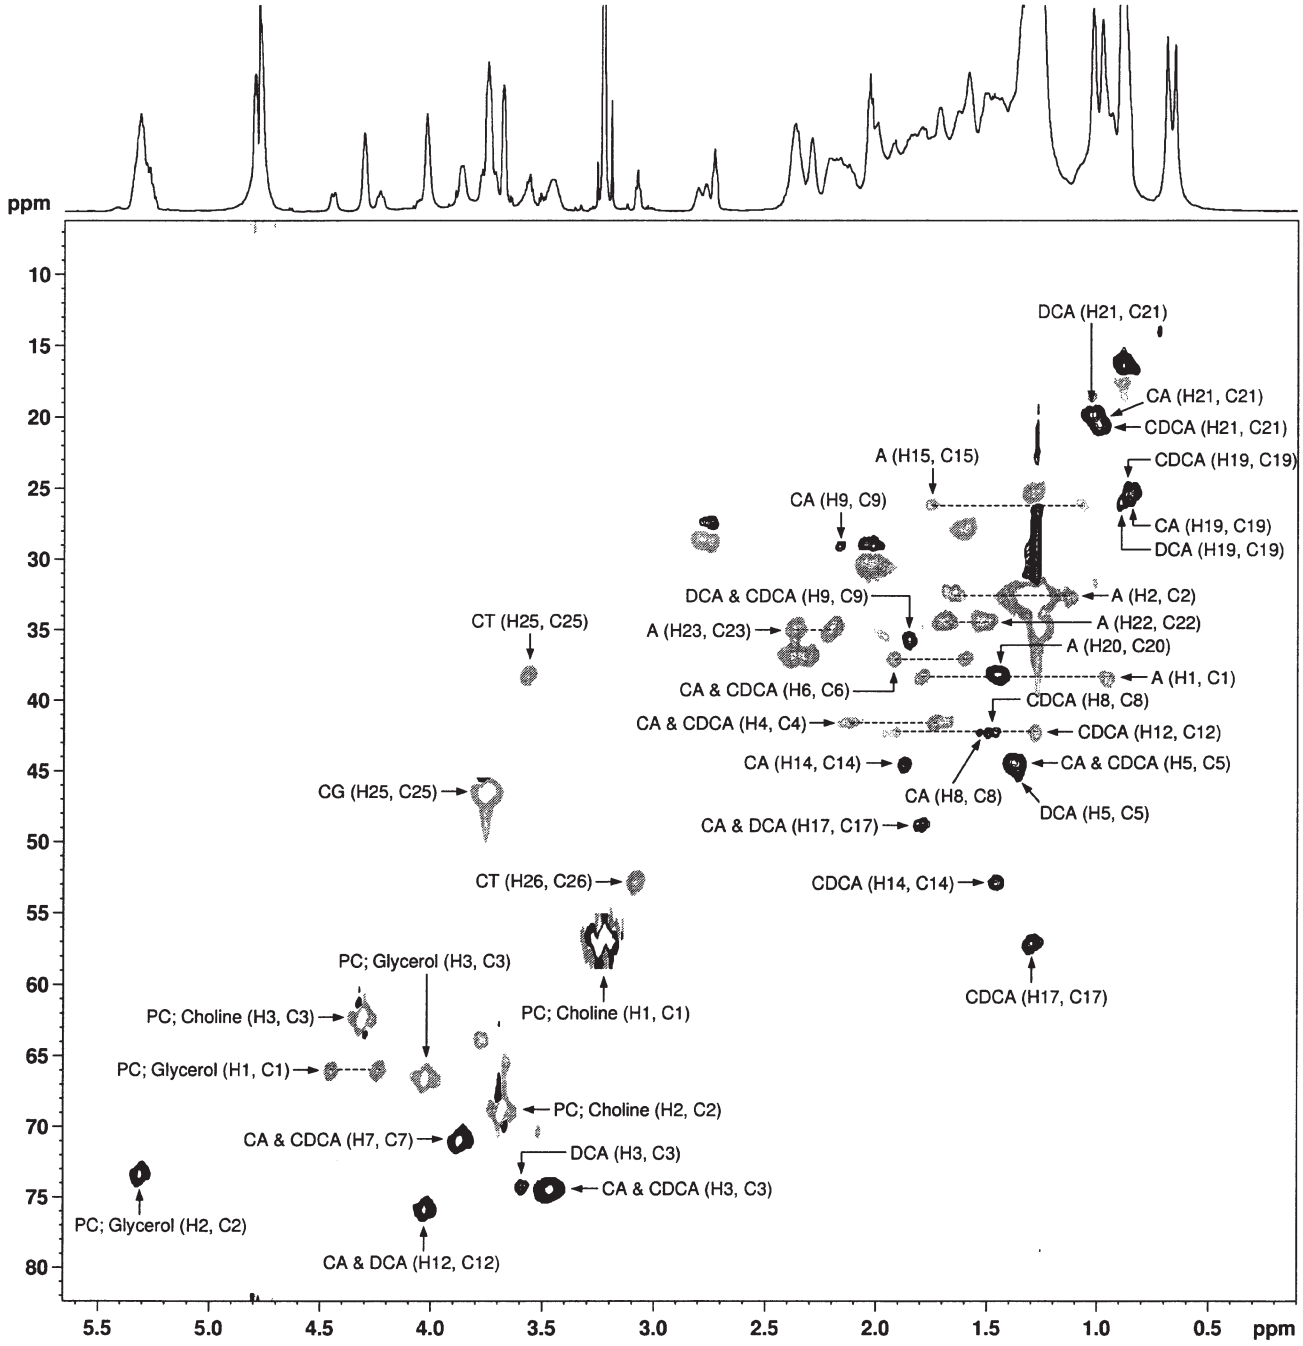

FIG. 2. Sensitivity-enhanced multiplicity edited ^{1}H-^{13}C HSQC spectrum of typical bile (50 µL diluted to 500 µL with water) obtained on a Bruker Biospin Avance 700-MHz spectrometer, along with the assignments of the cross peaks of protons and the attached carbons. For clarity, CH and CH_3 cross peaks are shown as dark continuous contours whereas CH_2 cross peaks are shown in light discontinuous contours. Wherever the chemical shifts of methylene protons (CH_2) are different (nondegenerate), two distinct cross peaks were observed corresponding to H_α and H_β protons (each pair of cross peaks is joined by dashed lines). PC, phosphatidylcholine; CT, conjugated taurine; CG, conjugated glycine; CA, glycine/taurine-conjugated cholic acid; DCA, glycine/taurine-conjugated deoxycholic acid; CDCA, glycine/taurine-conjugated chenodeoxycholic acid. A: All glycine/taurine conjugated bile acids. The numbering of protons/carbons is as shown for the structures in Figure 1. A trace of 1D ^{1}H spectrum is shown on the 2D spectrum.

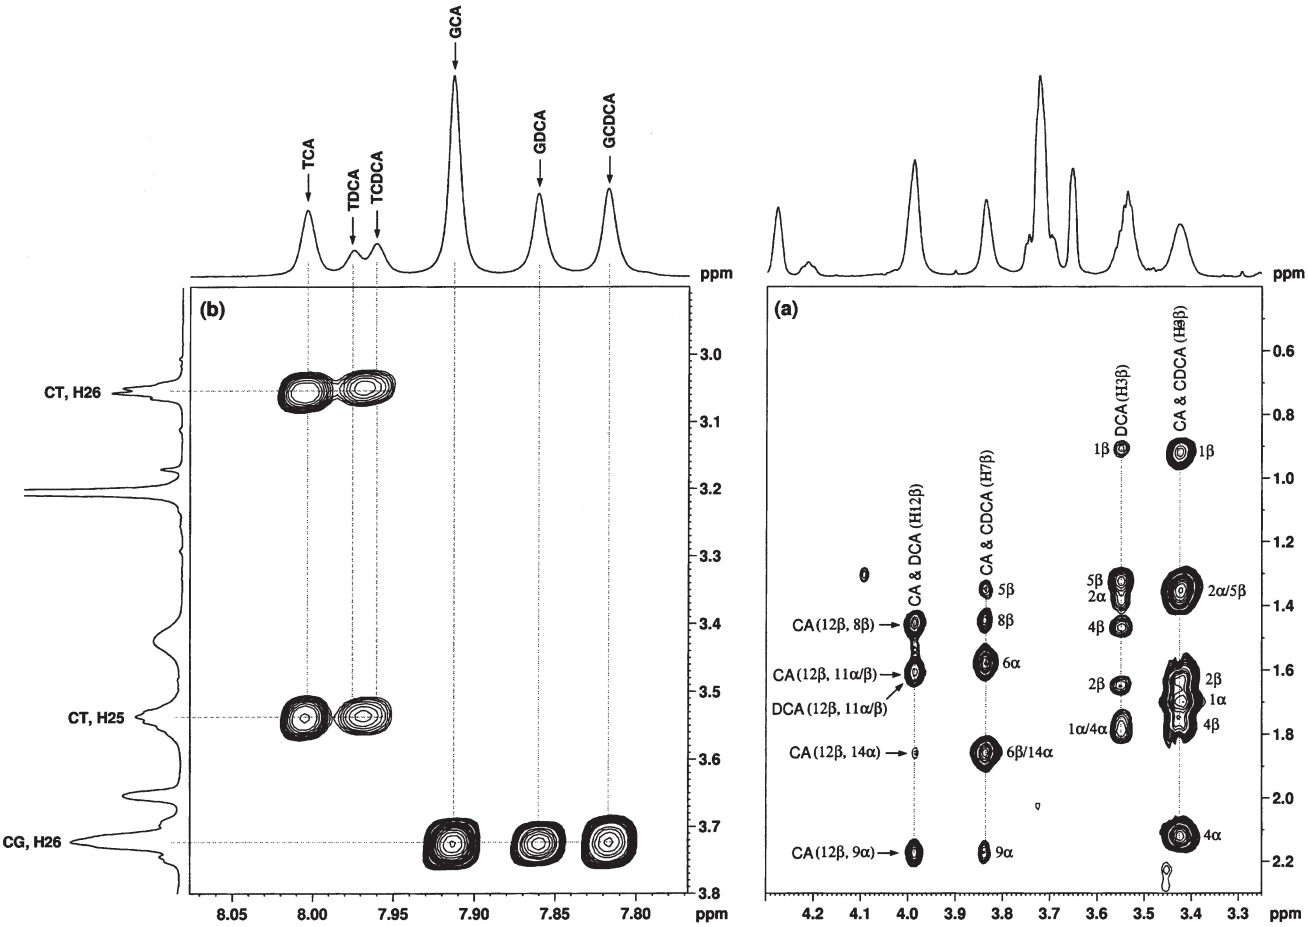

FIG. 3. Parts of TOCSY spectrum of typical bile (50 µL diluted to 500 µL with water) obtained on a Bruker Biospin AVANCE 800-MHz spectrometer. CT, conjugated taurine; CG, conjugated glycine; GCA, glycocholic acid; GDCA, glycodeoxycholic acid; GCDCA, glycochenodeoxycholic acid; TCA, taurocholic acid; TDCA, taurodeoxycholic acid; TCDCA, taurochenodeoxycholic acid; CA, glycine/taurine-conjugated cholic acid; DCA, glycine/taurine-conjugated deoxycholic acid; CDCA, glycine/taurine-conjugated chenodeoxy cholic acid. The numbering of protons is as shown in Figure 1. A trace of 1D ^{1}H spectrum is shown on the 2D spectrum.

(7.77 to 8.03 ppm) of the bile spectra, were nearly overlapping with each other. Experiments were performed to improve the resolution so as to identify the individual conjugated bile acids. The one-dimensional ^{1}H experiments were performed by using homonuclear decoupling sequence with decoupler offset set at 3.59 ppm, which is in between the chemical shifts of methylene protons (25-CH_2) of conjugated glycine (3.75 ppm) and conjugated taurine (3.56 ppm). From the analysis of the combination of spectra from 1D decoupled DQF-COSY and TOCSY experiments, two groups of amide signals were identified. Each group had three signals, one group corresponded to glycine-conjugated bile acids, and the other corresponded to taurine-conjugated bile acids. By comparison of these resolved amide and other ^{1}H and ^{13}C signals of bile acids with the library of chemical shifts of standard conjugated bile acids (26), the three amide signals of glycine were assigned to GCDCA (7.84 ppm), GDCA (7.88 ppm), and GCA (7.93 ppm) and the three amide signals of taurine-conjugated bile acids were assigned to TCDCA (7.98 ppm), TDCA (8.00 ppm), and TCA (8.02 ppm). To further confirm the assignments of the amide signals, ^{1}H spectra of bile were recorded separately at 800 MHz with simultaneously decoupling both 25-CH_2 signals of conjugated glycine and taurine, before and after the addition of each standard conjugated bile acid.

Bile acids recovery test. After identifying the six bile acids individually (GCA, GDCA, GCDCA, TCA, TDCA, and TCDCA) through their characteristic amide marker signals, NMR experiments were performed to test the accuracy and precision of quantitative analysis for each bile acid. The pH of a bile sample (4.0 mL diluted to 9.0 mL) was brought down (27) in the range 6 ± 0.5 using 6 N HCl, and, using this solution, six duplicate set of solutions (each 500 µL) were prepared in 5-mm NMR tubes. A reusable coaxial capillary containing quantitative reference, TSP (dissolved in 35 µL of D_2O), was inserted into the tube and ^{1}H spectra were recorded at 800 MHz by decoupling 25-CH_2 protons of conjugated glycine and taurine. The quantity of TSP in the capillary was

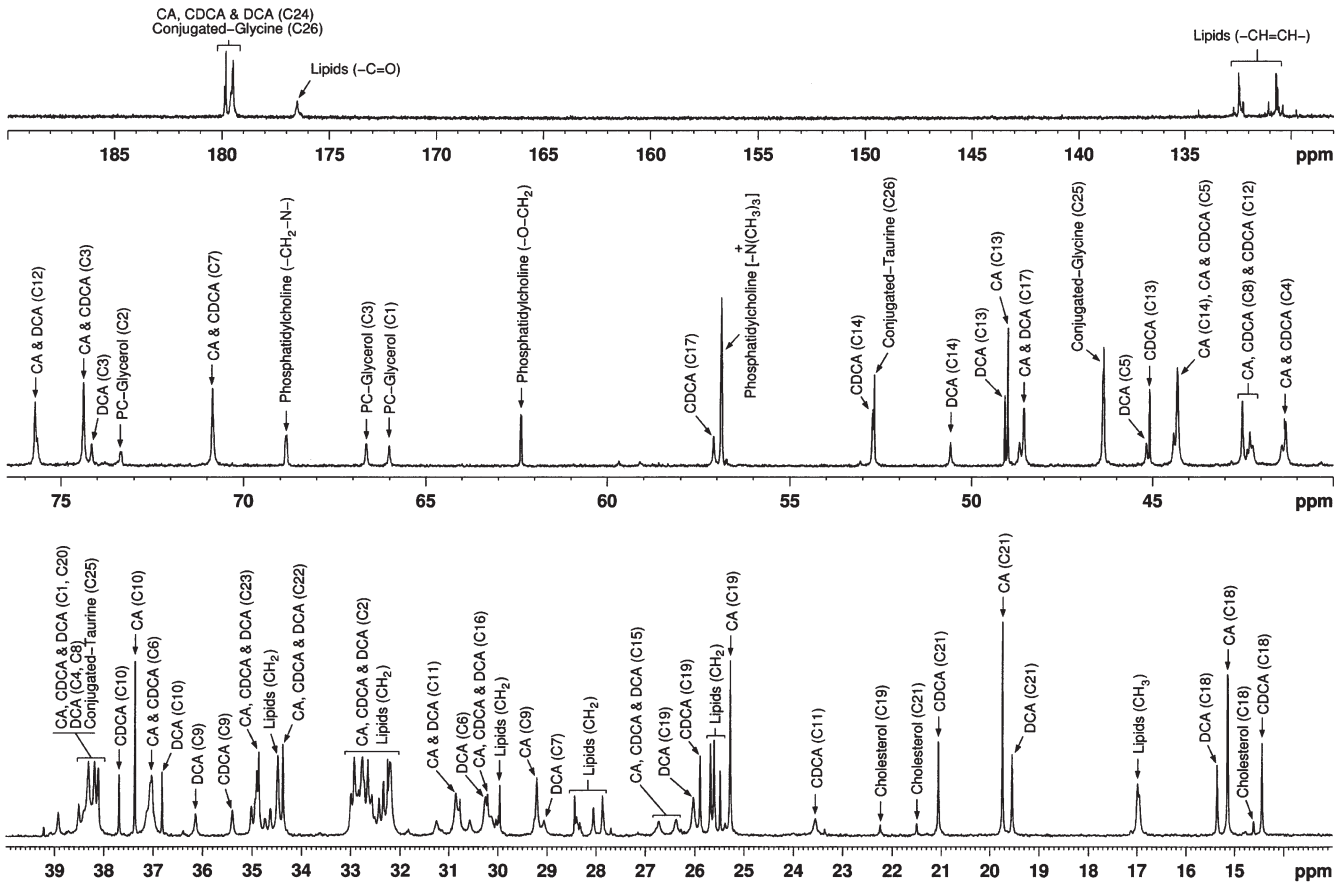

FIG. 4. Parts of ^{13}C spectrum of typical bile obtained on a Bruker Biospin Avance 800-MHz spectrometer with the assignments of most of the signals. PC, phosphatidylcholine; CA, glycine/taurine-conjugated cholic acid; DCA, glycine/taurine-conjugated deoxycholic acid; CDCA, glycine/taurine-conjugated chenodeoxycholic acid. The numbering of protons/carbons is as shown for the structures in Figure 1.

precalibrated by ^1H NMR experiment against a signal from a known concentration of a standard sample (30). Integral areas of the amide signals of all the six conjugated bile acids were determined relative to TSP by deconvolution of the signals using Xwinnmr software version 3.5 (Bruker Biospin Fällanden, Switzerland). Subsequently, known quantities of standard bile acids, GCA (1.04 mg), GDCA (0.84 mg), GCDCA (0.87 mg), TCA (0.87 mg), TDCA (0.84 mg), or TCDCA (0.75 mg), were added to the diluted bile solutions taken in separate sets of NMR tubes. ^1H NMR spectra were recorded again, under identical conditions, and the integrals of the amide signals were determined from the resultant spectra relative to the TSP signal. The quantity of each standard conjugated bile acid recovered through NMR was calculated from the corresponding amide integral (difference of amide integral before and after the addition of bile acid) and compared with the actual quantity of the added bile acid. In each case, deconvolution of the amide signals was repeated five times independently and the mean quantity of recovered bile acid along with the standard deviation was determined.

Quantitative estimation of bile acids. To demonstrate single-step analysis of individual conjugated bile acids, NMR experiments were performed on gallbladder bile specimens from 16 patients. The pH of each bile specimen was brought down in the range 6 ± 0.5 by addition of 1–2 μL of 6 N HCl. A reusable coaxial capillary tube containing TSP in D_2O was inserted into the NMR tube before recording the spectra. ^1H spectra at 800 MHz were obtained with decoupling 25-CH_2 protons of conjugated glycine and taurine. Integral areas of all the six amide signals were determined relative to TSP by deconvolution. Subsequently, quantities of all the six bile acids were determined, individually, using a computer program that takes into account integral area and molecular weight of each conjugated bile acid and the reference (TSP). In each case, deconvolution of the amide signals was repeated five times independently and the mean quantities along with the standard deviation were determined for each bile acid.

To determine whether decoupling of glycine and taurine methylene protons (25-CH_2) would alter the intensities of amide protons due to nuclear Overhauser enhancement (NOE) (if any), one-dimensional ^1H NMR experiments were performed on one of the bile specimens by suppressing the water signal using presaturation with 2-s acquisition time (during which homonuclear decoupling was also performed) and 45° excitation pulse. Spectra were recorded with and without decoupling of methylene protons by varying the re-

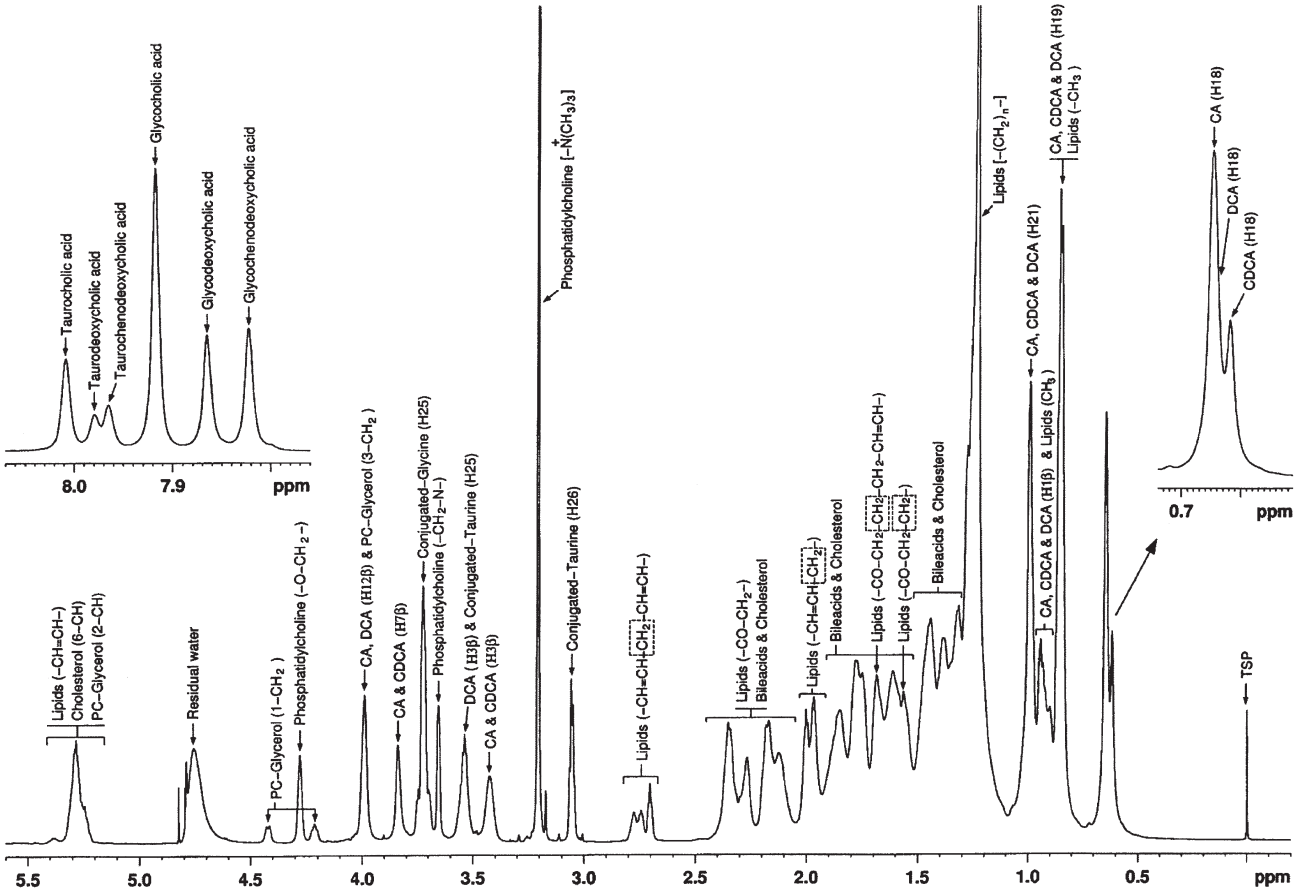

FIG. 5. Parts of ^{1}H spectrum of typical bile obtained on a Bruker Biospin Avance 800-MHz spectrometer with the assignments of most of the signals. PC, phosphatidylcholine; CA, glycine/taurine-conjugated cholic acid; DCA, glycine/taurine-conjugated deoxycholic acid; CDCA, glycine/taurine-conjugated chenodeoxycholic acid. The numbering of protons/carbons is as shown for the structures in Figure 1. Inset shows six amide signals, each corresponding to conjugated bile acid as indicated, obtained after decoupling 25-CH_2 protons of conjugated glycine and taurine.

cycle delay from 1 to 10 s in steps of 1 s. The integrals of all the amide signals at different recycle delay were obtained and compared.

RESULTS

Figure 1 shows the structures of bile components that are identified in intact gallbladder bile. Bile specimens from different patients were qualitatively consistent in terms of the signal pattern, but greatly varied in intensities of the signals from individual bile components. The cross peaks, particularly in heteronuclear 2D spectra, were weak in intensity due to short transverse relaxation times of the signals arising from aggregation of the bile components under natural conditions. Signals from cholesterol, lipids, and bile acids were identified from the analysis of two-dimensional spectra from DQF-COSY, TOCSY, multiplicity edited HSQC and HMBC experiments at 400, 700, and 800 MHz. Due to the structural similarity of various conjugated bile acids, most of the ^{1}H and ^{13}C signals of bile acids overlap, as shown in the typical edited HSQC and TOCSY spectra in Figures 2 and 3, respectively. Distinct chemical shifts of carbons C9, C10, C13, C18, C19, C21 of CA; C3, C5, C9, C10, C13, C14, C18, C19, C21 of DCA; and C9, C10, C11, C13, C17, C18, C19, C21 of CDCA, as shown in Figure 4, arising from the substitution effect (26) at position 7 and/or 12 (Fig. 1) enabled clear identification of CA, DCA, and CDCA moieties of the conjugated bile acids. Influence of glycine or taurine conjugation on almost all $^{1}H/^{13}C$ chemical shifts of bile acid moieties was minimal except in the vicinity of conjugation (Figs. 4 and 5). However, amide signals were distinctly observed for each conjugated bile acid. These amide signals appear very close to each other (7.77–8.03 ppm) at low magnetic fields (400 MHz) (Fig. 6a). However, at higher magnetic fields (700/800 MHz), four of six signals were resolved (Fig. 6d). Each amide signal is a triplet arising from indirect spin-spin coupling between amide (NH) and 25-CH_2 protons of conjugated glycine or taurine (Fig. 1). Upon removal of indirect spin-spin couplings by simultaneously decoupling the methylene protons of conjugated glycine (3.75 ppm) and conjugated taurine (3.56 ppm), amide signals further get resolved and all six bile acids signals were separated at 700 and 800 MHz (Fig. 6e). At 400 MHz, amide signals of TCDCA and TDCA were still overlapping (Fig. 6b).

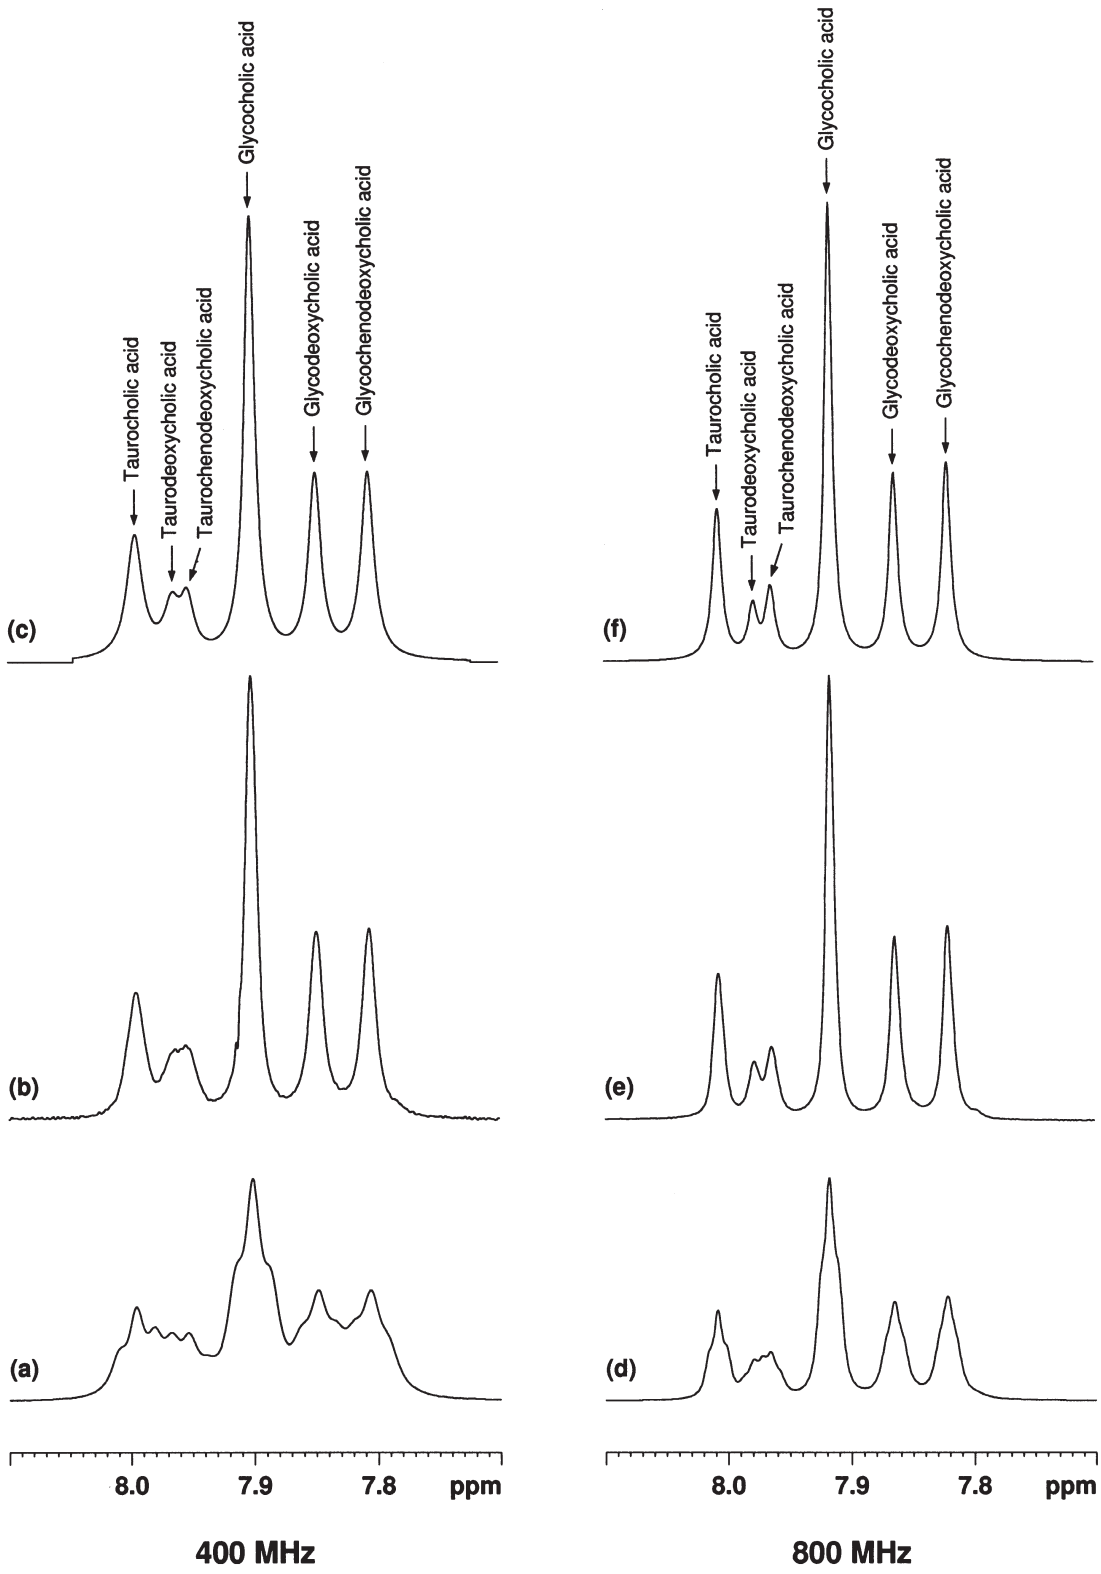

FIG. 6. Amide regions of bile spectra showing characteristic signals of glycochenodeoxycholic acid (GCDCA), glycodeoxycholic acid (GDCA), glycocholic acid (GCA), taurochenodeoxycholic acid (TCDCA), taurodeoxycholic acid (TDCA), and taurocholic acid (TCA). The spectra were obtained at 400 and 800 MHz without (a and d) and with (b and e) decoupling of 25-CH_2 protons of conjugated glycine and taurine. At 400 MHz, two of the amide signals (taurochenodeoxycholic acid and taurodeoxycholic acid) are still overlapping (b). All six amide signals are distinctly visible in the spectrum recorded at 800 MHz (d). The regions shown in c and f are the deconvoluted (Lorentzian) decoupled spectra b and e, respectively.

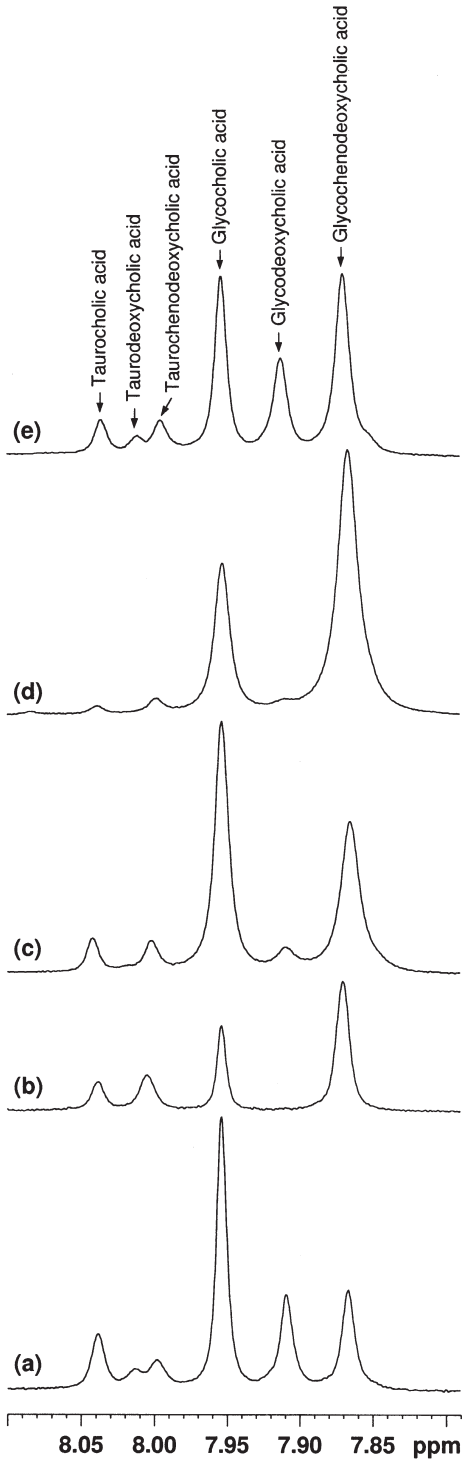

FIG. 7. Parts of 800-MHz ^{1}H NMR spectra of gallbladder bile (50 µL diluted to 500 µL with water) from five typical patients with gallbladder disease highlighting the variation of the relative intensities of the bile acids within as well as between the bile specimens (see also Table 4). All the spectra were plotted under identical conditions for direct comparison of the relative quantities of various bile acids. The bile samples were from patients (a) with chronic cholecystitis (CC); (b) with xanthogranulomatous cholecystitis (XGC); (c) normal (with no diagnosed gallstone disease); (d) with xanthogranulomatous cholecystitis (XGC); and (e) with chronic cholecystitis (CC).

Experiments performed before and after the addition of authentic conjugated bile acids confirmed the assignment of individual conjugated bile acids in bile. The ^{1}H and ^{13}C chemical shifts for the glycine- and taurine-conjugated bile acids in bile measured using 1D and 2D spectra are shown in Tables 1 and 2.

A typical best fit spectrum obtained after deconvolution of the decoupled amide region of a bile spectrum (Fig. 6e) is shown in Figure 6f. Integrals of individual amide signals in the best fit spectra were used for determining absolute quantities of individual conjugated bile acids. As shown in Table 3, the bile acids thus determined showed excellent agreement between the quantity of bile acid added and that recovered using ^{1}H NMR. Rapid and single-step analyses of individual conjugated bile acids were demonstrated on 16 human gallbladder bile specimens and the quantities of six bile acids thus determined are shown in Table 4. Significant differences in the quantities of bile acids within the bile and among various bile specimens were observed. Typical spectra for five gallbladder bile specimens, highlighting the variation in the absolute and relative quantities of individual bile acids in each bile specimen, are shown in Figure 7. Experiments performed to determine if there is any NOE buildup on the amide protons showed no change in integral of the amide protons in any of the spectra obtained with or without decoupling of the methylene protons of conjugated glycine and taurine.

DISCUSSION

Although NMR spectroscopy has tremendous advantages over conventional analytical methods, until today, its applications to human bile has been limited due to the complexity of the spectra arising from aggregation of major bile components such as cholesterol, phospholipids, and bile acids, which lead to broad signals. Several bile acids that are reported to be a part of major components of bile have very close structural resemblance, resulting in the severe overlap of most of the bile acid signals with each other, thus making the spectra further complicated to analyze. In the present study, assignment of ^{1}H and ^{13}C spectra of intact bile was greatly aided by the following sequential studies, which were aimed at devising a simple single-step method for simultaneously analyzing a large number of bile components that are detected by NMR: (a) establishment of the library of ^{1}H and ^{13}C chemical shifts by using various 1D and 2D experiments for several conjugated and unconjugated bile acids which are thought to be the components of human bile (26); (b) identification of bile acids and their distinct marker signals in human bile by using 1D and 2D experiments with the knowledge of the accurate chemical shifts of standard bile acids; in this study, amide signals were identified in human bile as conjugated bile acids markers (27); (c) assignment of ^{1}H and ^{13}C spectra of intact bile by using NMR experiments at 400 and 700 MHz after dispersing the bile in a polar organic solvent, which drastically reduced the signal line width due to increased transverse relaxation times and improved the spectral resolution (29).

[a]The chemical shift values of the standard bile acids (26) are given in parentheses. Numbering for carbons/protons is as given in Figure 1.

All amide signals do not get resolved even at higher magnetic fields (Fig. 6d). This necessitated performing experiments with decoupling of methylene protons (25-CH_2) of glycine and taurine to obtain resolved signals. At lower magnetic fields (400 MHz), TDCA and TCDCA signals still overlap even after decoupling (Fig. 6b), whereas at higher mag-

[a]The chemical shift values of the standard bile acids (26) are given in parentheses. Numbering for carbons/protons is as given in Figure 1.

netic fields, all the signals get resolved (Fig. 6e). We have shown that decoupling of methylene protons of conjugated glycine and taurine does not cause any change in intensity of the amide protons and thus it rules out interference from the NOE buildup on the amide protons during decoupling of the adjacent methylene protons. In fact, with a 45° excitation

pulse, all the amides proton magnetization reaches equilibrium even at a recycle delay of 3 s (including acquisition time). Thus the relaxation times of the amide protons are favorable for rapid analysis of individual bile acids. The longer recycle delay of 6 s used in this study was, however, necessitated due to longer relaxation time of the reference signal (TSP) used for quantitative analysis.

It is clear from Tables 1 and 2 that most bile acid signals severely overlap with each other except amide proton signals. In our previous study, we identified an unresolved bunch of amide signals to be markers of total glycine- and taurine-conjugated bile acids in bile (27). In this study, from the rigorous analysis of bile spectra under natural conditions, we have unraveled them into six individual conjugated bile acids. In the whole bile ^{1}H NMR spectrum, amide signals are the only ones that are distinct signatures of individual conjugated bile acids. Under physiological conditions of bile (pH = 7.0 to 7.7), amide signal intensities are attenuated due to the chemical exchange and hence they do not represent true concentration of the bile acids. Earlier we have made a detailed study under variable pH conditions for human bile as well as for several standard conjugated bile acids and shown that the attenuation of amide signals arising from chemical exchange can be suppressed by reducing the pH to slightly lower than the physiological value (6.0 ± 0.5) (27). Therefore, quantitative analysis of individual bile acids was performed after the addition of 1–2 μL of hydrochloric acid to bile solutions so as to bring down the pH in the range of 6.0 ± 0.5 and, as expected, the quantities thus determined show good agreement with the known amounts in the standard addition experiments (Table 3). Alternatively, bile solution pH may be adjusted by the addition of aqueous buffer (pH = 6.0) instead of diluting the bile using distilled water. This may allow better control of the pH and hence the pH-dependent signal intensity variations, if any.

TABLE 3
Quantity of Bile Acids Recovered from Gallbladder Bile Through Increase in Amide Signal Integral in 1H NMR Versus the Quantity Added (Each Experiment Was Performed in Duplicate)[a]

Bile acid	Quantity added to bile (mg)	Quantity recovered by NMR (mg) (mean ± SD)	Error (%) Mean ± SD
Glycocholic acid	1.04	0.99 ± 0.003	4.77 ± 0.28
		1.00 ± 0.003	3.61 ± 0.28
Glycochenodeoxycholic acid	0.87	0.81± 0.01	3.95 ± 1.20
		0.81 ± 0.01	3.92 ± 1.04
Glycodeoxycholic acid	0.84	0.82 ± 0.002	1.73 ± 0.20
		0.82 ± 0.001	2.82 ± 0.14
Taurocholic acid	0.87	0.85 ± 0.001	2.01 ± 0.11
		0.86 ± 0.011	0.49 ± 1.27
Taurochenodeoxycholic acid	0.75	0.74 ± 0.007	0.78 ± 0.94
		0.77 ± 0.005	2.21 ± 0.66
Taurodeoxycholic acid	0.84	0.83 ± 0.003	1.75 ± 0.32
		0.87 ± 0..005	3.49 ± 0.54

[a]Mean and standard deviation for each recovered quantity of the bile acid were obtained from deconvolution of the amide signal five times, independently.

[a]Mean and standard deviation for each bile acid were obtained from deconvolution of the amide signal five times independently. ND = Not detected; CC = chronic cholecystitis (gallstone disease); Normal = no diagnosed gallstone disease.

As seen in Table 4, in all 16 bile specimens analyzed, three each of glycine- and taurine-conjugated bile acids (GCA, GDCA, GCDCA, TCA, TDCA, and TCDCA) were observed, except in three bile specimens where GDCA and/or TDCA were not detected (Table 4 serial Nos. 1, 4, and 11). Further, although there was a large variation between the relative and absolute quantities of bile acids, the ratio of median values of taurine- to glycine-conjugated bile acids was 1:4 for primary bile acids (CA and CDCA) whereas the ratio was 1:5.7 for the secondary bile acid (DCA). These results show the potential of NMR for determining the individual conjugated bile acids rapidly in a single step. Furthermore, it is even possible to analyze unconjugated bile acids, if present. This can be achieved from the presence or absence of carbonyl carbon signal(s) near 187 ppm (26). The chemical shift region of the carboxylic carbons for unconjugated bile acids, which normally does not contain any other bile component signals, serves as a marker. In the ^{13}C spectrum of typical bile shown in Figure 4, the absence of such signals (near 187 ppm) clearly indicates the absence of any unconjugated bile acids (under the detection limits of present experimental conditions). Although variations in the bile acids, as shown in Table 4, does not seem to show any direct correlation with the diagnosis, detailed and systematic studies are required to relate these variations to the underlying pathophysiology of the hepatobiliary diseases.

In summary, we present here ^{1}H and ^{13}C NMR chemical shift assignment of intact bile under natural conditions and identified six major conjugated bile acids. Accurate and rapid analysis of all the conjugated bile acids in a single step presented herein is significantly advantageous over other methods. Moreover, the method is simple and does not need any sample processing. This may have significant impact on the studies of bile acid synthesis, metabolism, and associated hepatobiliary and gastrointestinal diseases. Studies using the method presented herein are currently in progress on bile specimens from a large number of patients with gallbladder disease, to have better understating of the diseases of biliary origin.

ACKNOWLEDGMENTS

Financial support from Department of Science and Technology, Government of India; and the use of the 700 MHz NMR facility at NMR Research Centre, Indian Institute of Science, Bangalore, and the 800 MHz NMR facility at Tata Institute of Fundamental Research, Mumbai, are gratefully acknowledged.

Accelerated Solvent Extraction for Quantitative Measurement of Fatty Acids in Plasma and Erythrocytes

Kiyonori Kuriki[a,*], Kazuo Tajima[a], and Shinkan Tokudome[b]

[a]Division of Epidemiology and Prevention, Aichi Cancer Center Research Institute, and [b]Department of Health Promotion and Preventive Medicine, Nagoya City University Graduate School of Medical Sciences, Nagoya, Aichi, Japan

ABSTRACT: Consumption of fish rich in n-3 highly unsaturated FAs (i.e., EPA and DHA) has been suggested to decrease the risk of lifestyle-related diseases such as coronary heart disease, cancer, diabetes, and dementia. Blood levels of those FA are known appropriate biomarkers of both the corresponding dietary FA intakes and fish consumption. In place of traditional handwork methods for extracting FA, we performed an accelerated solvent extraction (ASE) for at least 13 selected FA in plasma and erythrocytes to measure them by GLC. The FA levels (concentrations and compositions) in 35–50 μL of plasma or erythrocytes were extracted by ASE and measured by GLC. Intra- and interassay coefficients of variation were ≤6.0% for both blood materials, except with a minor group of FA (≤1.0% of total FA). When ASE was compared with two traditional handwork methods, FA levels in plasma from 18 healthy subjects were all coincident with very high Pearson's correlation coefficients for the three sets of the same 18 samples ($r \geq 0.85$ to 0.95, $P < 0.0001$), except for 18:0 ($r = 0.59$, $P < 0.01$). Using ASE and GLC, we have developed a new method for determination the levels of FA in plasma and erythrocytes as biomarkers for dietary intake of fish, fat, and FA. This new method makes it feasible to measure small volumes of samples, automatically, quantitatively, routinely, easily, rapidly and cheaply, with acceptable precision and accuracy.

Paper no. L9956 in *Lipids 41*, 605–614 (June 2006).

A high-fat diet, especially one rich in animal fat or saturated FA, is suggested to increase the likelihood of obesity and the development of so-called lifestyle-related diseases, such as hyperlipidemia, coronary heart disease, cancers in several sites (colorectum, breast, and prostate), diabetes, dementia, and allergies (1–7). Furthermore, n-6 PUFA such as 20:4n-6 (arachidonic acid) are converted into leukotrienes, prostaglandins, and thromboxanes, and those eicosanoids are suggested to cause arthritis, asthma, cell proliferation, thrombosis, vasospasm, and inflammatory disorders (7–9). On the other hand, consumption of fish and n-3 highly unsaturated FA (HUFA = 20:5n-3 [EPA] + 22:5n-3 + 22:6n-3 [DHA]) exhibits inverse relationships with such diseases (10–19). In contrast to findings based on only dietary assessment, we have demonstrated that increased and decreased risks of colorectal cancer are linked to high compositions of palmitic acid and DHA, respectively, in erythrocyte membranes (20). For accurate assessment of impact on risk, therefore, we think it essential to measure FA in biomaterials (2,19,21–23).

Blood levels (concentrations [mg/dL or mmol/L] and compositions [wt% or mol%]) of EPA, DHA, and n-3 HUFA are known as appropriate biomarkers of dietary intake of FA from fish (24–31). Traditional handwork methods (THM) for measuring FA in biomaterials have gradually been improved (32–38), but require the following common multiple steps (Fig. 1): (1) pretreatment of biomaterial samples; (2) extraction of lipids (triglycerides, cholesterol esters, and phospholipids) and free FA (32–34); (3) conversion from lipids to FA, and then to methyl esters (trans-methylation) (35,36); (4) extraction of methyl esters; and (5) measurement by GLC (37,38). In the first step, lipids and free FA can be separated by silica gel TLC (33,34). The precision for measuring FA is determined primarily by the second and fourth steps, and a total of three extractions with each organic solvent at each of the steps is required to maximize recovery. It takes several hours to perform the extraction procedure by hand with considerable physical effort. Hitherto, two different automatic extraction methods for FA from small numbers of samples of plasma and foodstuffs such as meat have been reported

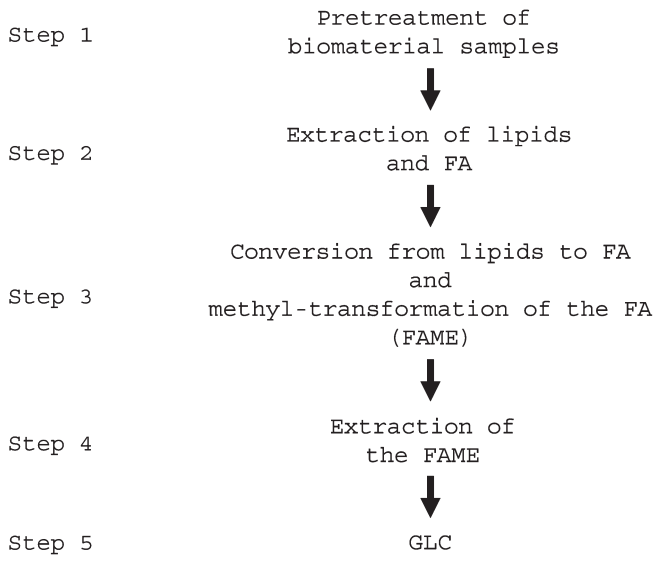

FIG. 1. Procedure for a representative traditional handwork method for measuring FA.

Abbreviations: ASE, accelerated solvent extraction; HUFA, highly unsaturated FA; THM, traditional handwork method.

(39,40), but we do not have enough information about such methods for biomaterials such as plasma and erythrocytes for clinical use or epidemiological investigations.

To improve the methodology for measuring FA in biomaterials, especially at the second and the fourth steps (Fig. 1), we have established an automatic extraction method featuring accelerated solvent extraction (ASE). Compared with two THM, we here demonstrate high precision and accuracy for quantitative measurement of FA levels (concentrations and compositions) in small volumes of plasma and erythrocytes by using this method.

MATERIALS AND METHODS

Samples and standards were systematically protected from contamination with both natural existing FA and detergents and from auto-oxidation by direct light and oxygen in air during sample processing. Most manipulations and storage were performed in glass tubes or bottles and handling was with glass pipettes (Pasteur pipettes) for organic solvents, to avoid the influence of plasticizers. A 10.0 μL quantity of an internal standard was pipetted with a micro glass syringe (SGE, Victoria, Australia), and the variation in accuracy (CV, %) for a series of 10 samples was ≤5%.

Reagents. We used the following reagents: petroleum ether (containing 20–30% of *n*-hexane), decane (Wako, Osaka, Japan), chloroform, methanol (Kanto Kagaku, Tokyo, Japan), sodium carbonate, disodium hydrogenphosphate dodecahydrate, and sodium dihydrogenphosphate dehydrate (Sigma, Tokyo, Japan). As standard chemicals, the following FA were obtained from Sigma: 14:0 (myristic acid), 16:0 (palmitic acid), 16:1n-7 (palmitoleic acid), 18:0 (stearic acid), 18:1n-9 (oleic acid), 18:2n-6 (linoleic acid), 18:3n-6 (γ-linolenic acid), 18:3n-3 (α-linolenic acid), 20:3n-6 (dihomo-γ-linolenic acid), 20:4n-6, EPA, 22:5n-3 (docosapentaenoic acid), and DHA. 17:0 (*n*-Heptadecanoic acid), BHT, and hydrogen chloride methanol reagent 10 (10–20% hydrochloride) were used as an internal standard, an antioxidant reagent, and a methyltransformation reagent (Tokyo Kasei Kogyo, Tokyo, Japan), respectively. Stock amounts of the internal standard and other standard chemicals were weighed on an analytical balance (with 0.01 mg precision), dissolved in decane containing BHT, then stored in Teflon-lined, screw-capped test tubes at 4°C. Stock solutions of BHT and decane were also made and stored at 4°C.

Blood materials. The Ethics Committee of each relevant institute approved the following three studies. First, in the framework of the Dietary Intervention to Polypectomized Patients (DIPP) study (41) and the Japanese Dietitians' Epidemiologic (JADE) study (29,30,42,43), we collected and stocked pooled plasma as a control, as described elsewhere (44). Plasma from anonymous patients with nonspecific medical conditions in Nagoya City University Hospital was gathered in one glass beaker on ice, mixed, and then poured into 1.5- to 5-mL stock tubes and stored at –80°C. We here used the pooled plasma for establishing measurement conditions for FA levels (mmol/L and mol%) in plasma according to the ASE.

Second, in the framework of the Hospital-based Epidemiologic Research Program at Aichi Cancer Center (HERPACC) (45), we routinely collect blood materials from patients in Aichi Cancer Center Hospital (20). Blood was collected using EDTA-2Na tubes and centrifuged at 2,000 *g* for 15 minutes at 4°C. Plasma and erythrocytes were prepared and stored at –80°C until analysis of individual FA by GLC. They were provided with an explanatory document and all gave their written informed consent for participation in the study. We here used erythrocytes from three noncancer controls for establishing the measurement conditions for FA composition (mol%) of erythrocytes according to ASE.

Third, in the framework of the Japanese Dietitians' Epidemiologic (JADE) study (29,30,42,43), we collected overnight fasting blood from 106 middle-aged Japanese dietitians (21 men and 85 women). Likewise, plasma and erythrocytes were simultaneously prepared in tubes including EDTA-2Na and stored at –80 °C until analysis of FA by GLC. We collected informed consent for participation in this study from all subjects. We here used plasma from nine male and nine female dietitians for comparison with two THM for measuring FA levels (mmol/L and mol%) in plasma as described herein. The 18 subjects were randomly selected and had no bias, and the samples were of sufficient volume to accomplish our objectives.

Instrumentation. For our ASE system, we used an Accelerated Solvent Extractor (ASE®) 200 (Nippon Dionex, Osaka, Japan), approved for use by the U.S. Environmental Protection Agency SW-846 Method 3545A for Pressurized Fluid Extraction, and accepted under the Contract Laboratory Program, Statement of Work OLMO 4.2. The system is computerized and comprises a cell oven, a cell tray for applying samples, a vial tray for recovering extracted solutions, a solvent sending pump, connected by a bound flexible line to solvent reserved bottles, and a nitrogen gas cylinder. To reduce solvent consumption, the line was changed from the standard 1.0 mm i.d. to 0.5 mm i.d. As optional equipment, an ASE® Solvent Controller allows for automatic mixing and delivery of different solvents. A small-size reciprocal air compressor, Toscon SLP5D-2SV (Toshiba, Tokyo, Japan), was included as part of the driving power to achieve safety for highly inflammable volatile solvents. The ASE 200 also features a series of cells (1 mL, 5 mL, and so on) that are stainless steel vessels for extracting target compounds from samples. A cylindrical cell body and two caps for the upper and bottom ends comprise one cell.

The system is usually employed with the following manipulations for each sample: (1) placement of a filter paper (Nippon Dionex, Osaka, Japan) in the bottom of a cell; (2) introduction of the sample into the cell; (3) movement of the cell to a cell oven; (4) introduction of the extracting solvent into the cell; (5) maintenance of an elevated temperature and pressure; (6) transfer of extracted solution to a glass vial and purging the residue from the cell with nitrogen gas when the extraction is completed. The filtered extracts are then taken

away from the extracted solution. This equipment automatically extracts, one by one, a maximum of 26 samples in minutes, by using conventional solvents at elevated temperatures and pressures, and reduces solvent consumption compared with general THM.

The equipment for the GLC system was as follows: a Shimadzu GC-2010 with a flame ionization detector (FID-2010), an auto-injector AOC-20i, and an auto-sampler AOC-20s and a hydrogen generator OPGU-2100S (Shimadzu, Kyoto, Japan). Shimadzu GC workstation software, GC solution version 2 (Shimadzu, Kyoto, Japan), provides multisystem PC control and advanced sample tracking. An air line bypasses from the line of the extraction system. A silica capillary column (30 m × 0.25 mm i.d.; DB-225 coating thickness 0.25 μm) (J&W Scientific, Folsom, CA) was employed (29,37).

GLC analysis. The GLC analysis has been detailed elsewhere (29,37), but was slightly modified according to the version of our GLC system. In brief, the oven temperature was programmed from 140°C to 180°C at a rate of 20°C/min and then from 180°C to 240°C at 3°C/min, with holding of the final temperature for 23.5 min. Total run time for one sample was 45.5 min. At about 42.5 min, the fraction of cholesterol esters and its derivatives were eluted. The nitrogen carrier flow rate was 10.2 mL/min (pressure, 200.0 kPa as a control mode) and for the nitrogen makeup gas was 28.0 mL/min. The column flow rate was 2.41 mL/min (line speed, 53.0 cm/s; purge flow rate, 3.0 mL/min). For the flame ionization detector, flow rates of hydrogen and air were 40.0 and 400.0 mL/min, respectively. The temperatures of the injection port and detector were 250°C and 260°C, respectively. The auto-injector was programmed to rinse a 10-μL syringe, once for each sample, pump three times to remove air bubbles, and then inject 3.0 μL of sample with a split-less method (sampling time, 1.0 min). The syringe was then rinsed five times with solvent. Integration and calculation of peak areas were performed with GC solution version 2 software, and the chromatographs and data were electronically stored.

Evaluation of FA levels in biomaterials. The identity of individual FA peaks was ascertained by comparison of the peak retention times with those of authentic standards. A single-point calibration was performed with an aliquot of an internal standard stock solution and the linearity of the method was checked by additional calibrators with a series of an internal standard concentration and appropriate dilutions of the stock solution. With integration of areas under the individual peaks adjusted for that of an internal standard, each FA was quantified as an absolute concentration (mmol/L) in plasma and compositions (molar weight percentage [mol%]) of total FA in plasma and erythrocytes. The following 13 FA were referenced to previous reports (29,30,43,46), which were investigated for associations between dietary intake of fish, fat, and FA, serum levels of triglycerides, total and HDL cholesterols, and the blood levels of FA: 14:0, 16:0, 16:1n-7, 18:0, 18:1n-9, 18:2n-6, 18:3n-6, 18:3n-3, 20:3n-6, 20:4n-6, EPA, 22:5n-3, and DHA.

Compared with THM-A as described herein, recovery rates (%) for the same 13 standard chemicals (a series of 10 samples) were calculated after step 2, step 4, and all procedures of the new method featuring ASE (Fig. 1). Intra-assay CV were based on the analysis of a series of 10 samples, derived from one sample/subject of pooled plasma or erythrocytes, and then all extracted and analyzed within a day. Interassay CV were based on replicate analyses of pooled plasma over a period of 10 d, and a total of 100 samples (10 samples/d × 10 d) were measured. Interassay reproducibility (CV), moreover, was checked according to two replicate measurements of the same pooled plasma per day for 20 d (total 40 samples = 2 samples/d × 20 d). With erythrocytes, samples from three subjects were used as each control, because a large volume of erythrocytes could not be collected from a single subject.

Comparison of methodologies. The new method featuring ASE was compared with two different THM for measuring FA levels (mmol/L and mol%) using 18 plasma samples from one part of the Japanese Dietitians' Epidemiologic (JADE) study (42) as described here previously. The three methods are distinctly different regarding extraction, trans-methylation, and GLC analyses of FA, respectively. Using the following THM-A (29), we have demonstrated relationships between dietary intakes of fish, fat, and FA and the corresponding FA levels in plasma in the study (29,30,43). The same samples were also measured by the following THM-B (47) at a clinical laboratory testing service (SRL Inc., Tokyo, Japan). We have no conflict of interest or collaborative agreement with the service company. The samples, therefore, were independently measured for us.

As THM-A (29), measurement was with the same reagents and procedures, except for the following: (1) the required sample volume was 100.0 μL; (2) the proportion of chloroform in the extracting solvent differed at the second step (Fig. 1); (3) each organic layer at the second and fourth steps was extracted from water-mixed phases by centrifugation. In brief, after 100.0 μL of plasma was transferred into a glass tube with a Teflon-lined screw-cap, 10.0 μL of an internal standard and 10 μL of BHT were added. Then 700 μL of 0.9 wt/vol% potassium chloride aqueous solution and 3 mL of Folch's solvent (chloroform/methanol, 2:1, vol/vol) (32) were added followed by vigorous mixing. After standing for 10 min at room temperature, 1 mL of water and 1 mL of chloroform were added with vigorous mixing, and then the lipids and free FA were extracted by centrifugation (2,000 *g*, 20°C, 5 min). The bottom chloroform layer was collected by using a glass pipette, and then the extraction was repeated a total of three times to maximize recovery with 2 mL of chloroform. The extracted solutions were pooled and evaporated to dryness under nitrogen gas, and then converted to FAME by 1 mL of hydrogen chloride methanol reagent 10 (10–20% hydrochloride), at 100°C for 60 min (29). At the fourth step, likewise, a total of three extractions with 2 mL of petroleum ether were performed. The GLC equipment was a Shimadzu GC-17A with a hydrogen gas cylinder and a Chromatopac Integrator C-R7A (Shimadzu, Kyoto, Japan). Measurement condition of GLC has been reported elsewhere (29,37). Re-

garding precision of the FA measurements in plasma, intra- and interassay CV were distributed from 1.8% to 4.8% and from 2.5% to 7.2%, respectively (29).

For THM-B (47), the measurement principles and the steps (Fig. 1) were basically the same as THM-A (29). The equipment was also the same as THM-A, except for a hydrogen generator, HGE-1A (Shimsadzu, Kyoto, Japan). However, the lipids and free FA were first extracted with Folch's solvent (32), and FA were then treated with 100% chloroform after acid hydrolysis by 0.5 M hydrochloride and acetonitrile/water (9:1, vol/vol). Then, 0.4 N potassium methoxide (Kanto Kagaku, Tokyo, Japan) and 14.0 wt% of boron trifluoride–methanol (GL Sciences, Tokyo, Japan) were used for transmethylation of FA at the third step (30,35). The FAME were extracted with Wako-gel C-200, *n*-hexane (Wako, Osaka, Japan), and water at the fourth step. The conditions of centrifugation were 2,000 *g* at 20 °C for 5 min. A fused silica capillary column (30 m × 0.25 mm i.d.; Omegawax 250 coating thickness 0.25 μm) (Supelco, Bellefonte, PA) was employed. For FA measurements in plasma, intra- and interassay CV were distributed from 2.1% to 8.1% and from 5.5% to 8.7%, respectively.

Statistics. Statistical analyses were performed with PC-SAS version 9.1 (SAS Institute Inc., Cary, NC). The data are given as mean ± SD. Pearson's correlation coefficients between the values (mmol/L and mol%) for plasma FA were calculated. All tests were two-sided and a P value of 0.05 or less was taken as significant.

RESULTS

Sample preparation for ASE. When plasma samples were directly introduced into a 1-mL cell for extraction with organic solvent on ASE 200, the extraction at the second step (Fig. 1) needed to be discontinued because very small particles of aggregated soluble proteins in plasma clogged the small exit of the cell bottom cap. As the first step, therefore, a membrane filter (OMMIPORE™, 0.2 μm, JG) (Millipore, Cork, Ireland) was firmly fixed between a cell body and the cell bottom cap to prevent clogging, and then two paper filters were laid on the membrane filter. This manipulation is not described in the manual for using ASE 200 and was our original idea. To prevent elution or contamination with FA, moreover, we washed the paper filters in the extracting solvent before use. The procedure for applying one plasma sample was as follows: (1) 10.0 μL of the internal standard (3.5 mmol/L) and 10 μL of BHT (0.45 mmol/L) were added into the cell; (2) 35.0 μL of plasma and 150 μL of extracting solvent (chloroform/methanol, 1:2, vol/vol) were vigorously mixed in a 1.5-mL micro tube, and then the solution was transferred into the cell; (3) 50 μL of extracting solvent was rinsed in the micro tube and then the residue was also added to the cell. Although we examined the range 25–50 μL of plasma sample for measurement, the optimal volume was 35.0 μL (data not shown). As described above, the extraction step from more than 50 μL of plasma may abort because of being clogged in the ASE 200 line due to aggregated soluble proteins. Two pieces of paper filter were used to absorb the internal standard and BHT, and the pretreated plasma sample, in that order.

To remove hemoglobin and prevent oxidative degradation of lipids and FA caused by iron of hemoglobin, erythrocytes were prepared to erythrocyte membranes (white ghosts) with 5 mM sodium phosphate buffer (pH 7.4) (48). The white ghosts from one sample were directly applied into a 1-mL cell put on one paper filter to extract. In this case, a membrane filter was not needed. As with plasma samples, 10.0 μL of the internal standard (1.0 mmol/L), 10 μL of BHT (0.45 mmol/L), and the white ghosts were added into the cell, in that order. The optimal volume of erythrocytes sample for measuring was 50.0 μL (data not shown). Less than 25 μL of erythrocytes could not be stably measured under our current conditions, while more than 100 μL required much increased rinsing time with sodium phosphate buffer to make white ghosts. It should be noted that FA contents in whole blood are not equivalent to those in erythrocyte membranes.

ASE for lipids, FA, and FAME extraction. After systematic changing in the conditions for ASE 200 at the second step (Fig. 1), the optimized conditions for extracting lipids and FA from blood materials were achieved as summarized in Table 1. There were the same for plasma and erythrocytes. Chloroform/methanol, 1:2 vol/vol, was used for the extraction. We extracted all 13 selected FA in blood materials at one time because the residual material was limited, as determined by repeated extraction tests. For one sample, the volume of the extracted solution

TABLE 1
Optimized Conditions for Extracting Lipids and FA at the Second Step and FAME at the Fourth Step with an Accelerated Solvent Extractor (ASE® 200)

	Lipids and FA (at the second step)	FAME (at the fourth step)
Extraction cell (mL)	1	5
Heating time (min)	0	0
Static time (min)	5	0
Temperature (°C)	75	50
Pressure (psi)	1,500	1,500
Extracting solvent	Chloroform/methanol (1:2, vol/vol)	Petroleum ether
Flash (%)	10% of extracting solvent	10% of extracting solvent
Purge (s)	30	30

and the extracting time were about 5.5–6 mL and 8.5 min, respectively. The time included rinsing of the line for ASE 200. The extracted solution was evaporated under a stream of nitrogen gas at 37°C.

All samples at step 3 (Fig. 1) were transferred into glass tubes with Teflon-lined screw-caps and then treated with 1 mL of hydrochloride-methanol reagent for FA conversion from lipids and subsequent methyl-transformation. The glass tubes were tightly capped and placed in a block heater (100°C), and then withdrawn and cooled after 60 minutes of heating. To prevent erosion of the stainless steel cells by the potent hydrochloric acid, 0.8–2 mL of 0.4 M sodium carbonate aqueous was added into the tubes and the solution was prepared to pH 7. The volume of aqueous sodium carbonate corresponded to 5–15% concentrations (depending on lot numbers of the products) of hydrochloride. In GLC analyses, alkaline hydrolysis of FAME caused by the addition of sodium carbonate aqueous was not observed (data not shown).

At the fourth step (Fig. 1), petroleum ether was used as an organic solvent for extracting FAME from the water-methanol layer on ASE 200, but the layer was not directly applied into a 5-mL cell because of leakage through the exit of the bottom cap. To prevent this, therefore, a membrane filter was firmly fixed between the cell body and the cell bottom cap. This manipulation is not described in the manual for using ASE 200 and was our original idea. Paper filters were not used here. First, the entire water-methanol layer was transferred into the cell. Second, the glass tube was rinsed with 500 μL of petroleum ether and then the residue was also added to the cell. After systematic changes, the optimized conditions for extracting methyl esters by ASE 200 are summarized in Table 1. In this step, we also extracted all 13 selected FAME at one time because residues were limited according to repeated extraction tests. For one sample, the volume of extracted solution and the extracting time (including rinsing time) were about 7.5–8 mL and 3.5 min, respectively.

GLC separation of individual FA. The extracted solution at the fourth step (Fig. 1) was evaporated under a stream of nitrogen gas at 37°C for complete removal of the solvent, and then the residue was redissolved in 400.0 μL of petroleum ether for application to GLC. Representative GLC profiles for individual FA in plasma and erythrocytes are shown in Figure 2. We could clearly demonstrate separation of individual FA.

Precision and accuracy. According to the analysis of a series of 10 samples, recovery rates of the internal standard were 86.4% after step 2, 97.6% after step 4, and 81.6% after all procedures with the new method featuring accelerated solvent extraction. For the 13 selected standard chemicals, however, the ranges of recovery rates (%) adjusted for an internal standard were distributed from 95.6% (for 18:3n-6) to 107.9% (18:0), 95.1% (18:0) to 102.1% (18:3n-6), and 94.5% (18:3n-6) to 109.1% (18:2n-6), in that order. Table 2 shows FA levels (mol/L and/or mol%) in blood materials and the intra- and interassay CV according to the new method. For

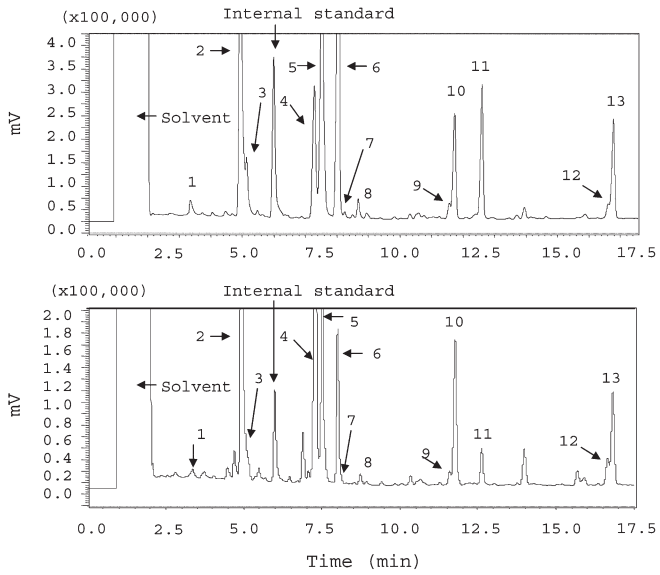

FIG. 2. Representative chromatograms after gas-liquid chromatography for the 13 selected FA in plasma (top) and erythrocytes (bottom). Peaks: internal standard (n-neptadecanoic acid, 17:0); 1, myristic acid (14:0); 2, palmitic acid (16:0); 3, palmitoleic acid (16:1n-7); 4, stearic acid (18:0); 5, oleic acid (18:1n-9); 6, linoleic acid (18:2n-6); 7, γ-linolenic acid (18:3n-6); 8, α-linolenic acid (18:3n-3); 9, dihomo-γ-linolenic acid (20:3n-6); 10, arachidonic acid (20:4n-6); 11, eicosapentaenoic acid (20:5n-3); 12, docosapentaenoic acid (22:5n-3); 13, docosahexaenoic acid (22:6n-3).

plasma, the intra-assay CV were ≤6.0%, except for the concentration and the composition of 14:0 (9.7% and 8.0%, respectively). The interassay CV for mean concentrations and compositions of the total 100 samples (10 samples × 10 d) were <6.0% for all 13 selected FA, and the distribution of the CV over a period of 10 d was <6.0%, except with the concentrations of 14:0, 16:1n-7, 18:3n-6, and 18:3n-3 (8.4, 6.8, 7.0, and 6.8%, respectively) and the composition of 14:0 (6.9%). For the compositions in erythrocytes, the intra-assay CV were also <4.0%, except a minor group of 14:0, 18:3n-6, and 18:3n-3 (≤0.5% of total FA for each). The interassay CV (total 100 samples) were also <4.0%, except for a minor group of 14:0, 18:3n-6, and 18:3n-3. We could not demonstrate CV for mean compositions because we could not collect sufficiently large volumes of erythrocytes from a single subject. Moreover, interassay reproducibility over a period of 20 d (the CV for a total 40 samples [2 samples × 20 d]) was almost the same distribution (data not shown).

Although we lack a gold standard method, the mean levels (mmol/L and mol%) and the SD for each FA were coincident and differences in values among the three different methods were not major (Table 3). For example, plasma concentrations of EPA, which are closely associated with dietary intake, were 0.20, 0.27, and 0.23 for the means and 0.12, 0.16, and 0.14 for the SD, in that order. The compositions were 1.7, 2.0, and 1.9, and 1.0, 1.1, and 1.0, respectively. We demonstrated, furthermore, that most of the Pearson's correlation coefficients between them were ≥0.95 ($P < 0.0001$) and all of them were

at least ≥0.85 ($P < 0.0001$), except for the composition of 18:0 (Table 4). The reason for the relatively low coefficients in this case was unclear, but the level with the new method featuring ASE significantly correlated with that with THM-A ($r = 0.72$, $P < 0.001$).

DISCUSSION

Some PUFA are particularly useful in assessing the corresponding intakes in the short term in plasma and serum, in the medium term for phospholipids in erythrocytes and platelets, and in the long term for adipose tissue (24,25), because they are not biosynthesized in humans. Especially the levels of EPA, DHA, and n-3 HUFA are appropriate biomarkers of the relative dietary intakes (26–31), but they have not routinely been used due to laborious handwork for measurement, which also means expense in the commercial setting. Using ASE, however, here we could develop a new method featuring ASE for measuring FA in plasma and erythrocytes that demonstrated acceptable precision and accuracy, with many practical advantages.

For footnotes, see Table 3.

ASE 200 is capable of concentrating small amounts of object chemicals and compounds rapidly, such as herbicides, pesticides, polychlorinated biphenyls (PCB), and dioxins, diluted in environmental media (soil and foods), according to the ASE kinetics made possible by increased temperature while keeping the solvent below its boiling point under pressure. We here demonstrated quantitative extraction of FA from ≤50 μL of blood materials, with acceptable values for accuracy and precision, intra- and interassay CV ≤6.0%, except for a minor group of FA, where most were <10.0%. According to our new method, the mean values of 20:3n-6, 22:5n-3, and DHA in plasma samples were about 20% lower than those with THM-A and B. As well as other 10 FA, however, the recovery rates for the three corresponding standard chemicals were adequately high and were 102.0, 97.9, and 97.1%, in that order. Therefore, we did not clarify the reason. Recovery experiments with repeated extraction also indicated that a single step does not result in large residues. Therefore, we just select the extraction program at the second and the fourth steps (Fig. 1) and push the start button after applying samples to cells of the ASE 200 for extraction of FA and FAME.

Even with our new method there are some limitations to routine measurement of FA in biomaterials. The series of necessary steps cannot be completely automated, and blood materials cannot be applied directly to the ASE system. It takes about 7 h for an extraction as a "day run" and 10 h for analysis as a "night run" to measure 12 samples of biomaterials. However, the method is applicable to homogenates of tissues and silica gel lipid fractions (triglycerides, cholesterol esters, phospholipids, and free FA) separated by TLC. Advantages, similarities, and disadvantages between the new method featuring ASE, THM-A, and B are summarized in Table 5. Compared with THM-A and B, our new method is performed easily without major physical effort, according to the automatic extraction of FA with ASE 200. Although total run time for 12 samples does not differ among the three different methods, our new method has an excellent time performance. However, the speed for extracting lipids or methyl esters, one by one, is a limitation with ASE 200. In the future, therefore, we still hope to make further improvements. The cost for a series of ASE 200 instruments is large, but there are no differences in the running costs for disposables and reagents

TABLE 5
Summary of the Differences for Measuring FA in Plasma and Erythrocytes According to a New Method Featuring Accelerated Solvent Extraction, THM-A, and THM-B

	New method	THM-A[a]	THM-B[a,d]
Instruments			
GLC for analyzing FA	Use	Use	Use
ASE 200 for extracting FA	Use	No use	No use

[a]THM-A and THM-B are described in detail in text.
[b]The figures for measuring FA of 12 samples are shown.
[c]Advantages (2 categories), similarities, and disadvantages between a new method, THM-A, and THM-B are here defined as ++ and +, ±, and –, in that order.
[d]When FA in plasma and erythrocytes were measured by THM-B in our laboratory, but not a clinical laboratory company (see the text), the estimated time is shown in parentheses.
[e]Run time is not included for some procedures, such as administration of an internal standard, an antioxidant chemical, and blood samples, and evaporation of the extracted solvents after the two extraction steps.

among the three methods. The commercial laboratory fee is very expensive.

In conclusion, using ASE and GLC, we have developed a new method for determining both the concentrations and the compositions of FA in plasma and erythrocytes as biomarkers for dietary intake of fish, fat, and FA. The advantages of our new method featuring ASE are that it is feasible to measure small volumes of multiple samples, automatically, quantitatively, routinely, easily, rapidly, and cheaply, with acceptable precision and accuracy. As a part of the Hospital-based Epidemiologic Research Program at Aichi Cancer Center (HERPACC) research, it will be a useful aid for the large numbers of blood samples available for Aichi Fatty Acid (AiFat) Research (20) necessitating routine measurement to clarify associations with cancers in different sites.

ACKNOWLEDGMENTS

We are in debt to T. Morii, N. Yamada, and M. Inoue from Nippon Dionex K.K. (Osaka, Japan) for technical support with ASE 200. The authors are grateful to M.A. Moore for checking the English usage and to R. Yoshio, S. Inui, M. Watanabe, H. Achiwa, T. Sato, and T. Saito for assistance with the FA measurements. The study

was supported in part by a Grant-in-Aid for Scientific Research on Cancer Epidemiology in a Special Priority Area (c) (Grant No. 12670383) from the Ministry of Education, Science, Sports, Culture and Technology of Japan, and a Grant-in-Aid for a Research Fellow of the Japan Society for the Promotion of Science (JSPS). K. Kuriki was supported by a Research Fellowship of JSPS for Young Scientists during the performance of the study. As a footnote, a patent for this method to quantitatively measure FA in biomaterials has been applied for (Japanese patent applied No. 2005-080461).

HPLC Method for Quantification and Characterization of Cholesterol and Its Oxidation Products in Eggs

Mônica R. Mazalli[a], Alexandra C.H.F. Sawaya[b], Marcos N. Eberlin[b], and Neura Bragagnolo[a,*]

[a]Department of Food Science, Faculty of Food Engineering, State University of Campinas, 13083-862, Campinas, SP, Brazil, and [b]Thomson Mass Spectrometry Laboratory, Institute of Chemistry, State University of Campinas, 13083-970, Campinas, SP, Brazil

ABSTRACT: A new method was developed for the simultaneous determination of cholesterol and its oxidation products in eggs, using HPLC with UV and refractive index (RI) detectors, and HPLC interfaced with atmospheric pressure chemical ionization coupled to MS (HPLC-APCI-MS). The best conditions for direct saponification of the sample and extraction of the nonsaponifiable material were defined using complete factorial designs with central points. The method showed accuracy and precision with a detection limit between 0.002 and 0.079 μg/g. The oxides cholest-5-ene-3β,20α-diol and cholest-5-ene-3β,25-diol identified by HPLC-UV-RI were not confirmed by HPLC-APCI-MS.

Paper no. L9961 in *Lipids 41*, 615–622 (June 2006).

Cholesterol takes part in essential functions of the human organism, but it is unstable, especially in the presence of light, heat, oxygen, moisture, radiation, low pH, or metals, producing oxides that may have adverse effects on human health. Cholesterol oxides are considered to be atherogenic and are related to inflammatory processes, rheumatoid arthritis, cytotoxicity, carcinogenesis, alterations in cell membrane properties (1), diabetes, and degenerative diseases such as Parkinson's and Alzheimer's (2,3). In food, cholesterol oxides are formed by a non-enzymatic oxidation process or autoxidation, which occurs by way of complex chain reactions based on the formation of free radicals with triplet and singlet oxygen (4). The consumption of these oxides and their possibly damaging effects have led to the need to develop methodology to identify and quantify these compounds in foods.

The cholesterol oxide contents found in the literature vary widely, due mainly to the analytical methodology used. HPLC and GC are frequently used to analyze the oxides. However, for analysis by GC, the samples need to be derivatized, which increases the time of analysis; heat destruction of cholesterol and hydroperoxides can also occur, with the formation of artifacts (5). Thus HPLC has been used more frequently, as it is carried out in a shorter time, and at relatively low temperatures. In particular, HPLC interfaced with atmospheric pressure chemical ionization coupled to MS (HPLC-APCI-MS) is capable of detecting samples that exist in trace amounts (6–8).

The simultaneous determination of cholesterol and its oxides is complex, especially as the oxides are present in food in minute amounts and show very similar structures (9). Some cholesterol oxides of biological importance, such as 5,6α-epoxy-5α-cholestan-3β-ol (5,6α-epoxy), 5,6β-epoxy-5β-cholestan-3β-ol (5,6β-epoxy), and 5α-cholestane-3β,5,6β-triol (triol), do not possess adequate characteristics for UV absorption (10,11). Although the refractive index (RI) detector is less sensitive than the UV and GC, it is useful for the detection of these oxides. Due to the instability of cholesterol, a mild analytical methodology is required to avoid the formation of artifacts, as the presence of air, light, solvents containing peroxides, or heat treatment can promote the formation of such compounds (12).

The majority of the methods used to analyze cholesterol oxides in foods involve an initial extraction of the fat followed by saponification (13,14). Using the values for standard deviation, the coefficient of variation, the formation of artifacts, and linearity, Dionisi *et al.* (15) showed that direct saponification of the samples was more efficient than the methods in which the fat was extracted first.

In the present study, a new method was developed for the simultaneous determination of cholesterol and its oxides using HPLC with UV and RI detectors and confirmed by HPLC-APCI-MS. The pre-chromatographic steps were evaluated by response surface methodology. In addition, after validating the method, it was applied to eggs.

MATERIALS AND METHODS

Solvents and chemicals. The HPLC-grade solvents used came from Mscience (Darmstadt, Germany), and the analytical-grade solvents were obtained from Merck (Darmstadt, Germany). The HPLC-grade solvents were vacuum filtered through 0.22-μm Millipore membranes (Bedford, MA) before use. The cholesterol, cholest-5-ene-3β,19-diol (19-OH), cholest-5-ene-3β,20α-diol (20α-OH), [22*R*]-cholest-5-ene-3β,22-diol (22(*R*)-OH), [22*S*]-cholest-5-ene-3β,22-diol

Abbreviations: RSD, relative standard deviation; DL, detection limits; QL, quantification limits; HPLC-APCI-MS, HPLC interfaced with atmospheric pressure chemical ionization coupled to MS; RI, refractive index; 19-OH, cholest-5-ene-3β,19-diol; 20α-OH, cholest-5-ene-3β,20α-diol; 22(*R*)-OH, [22*R*]-cholest-5-ene-3β,22-diol; 24(*S*)-OH, [24*S*]-cholest-5-ene-3β,24-diol; 22(*S*)-OH, [22*S*]-cholest-5-ene-3β,22-diol; 25-OH, cholest-5-ene-3β,25-diol; 7-keto, 3β-hydroxycholest-5-ene-7-one; 7β-OH, cholest-5-ene-3β,7β-diol; 7α-OH, cholest-5-ene-3β,7α-diol; 5,6α-epoxy, 5,6α-epoxy-5α-cholestan-3β-ol; 5,6β-epoxy, 5,6β-epoxy-5β-cholestan-3β-ol; triol, 5α-cholestane-3β,5,6β-triol.

(22(*S*)-OH), cholest-5-ene-3β,25-diol (25-OH), 3β-hydroxy-cholest-5-ene-7-one (7-keto), cholest-5-ene-3β,7β-diol (7β-OH), 5,6α-epoxy, 5,6β-epoxy, and triol standards were purchased from Sigma (St. Louis, MO). [24*S*]-cholest-5-ene-3β,24-diol (24(*S*)-OH) and cholest-5-ene-3β,7α-diol (7α-OH) were obtained from Steraloids (Newport, RI) and the standard reference material (SRM 1845, whole egg powder) from NIST (Gaithersburg, MD).

Samples. Commercial spray-dried whole egg powder, stored in the dark at a temperature of 25 ± 2°C, was used to optimize the methodology for the simultaneous determination of cholesterol and its oxides. After optimization and validation, the method was applied to fresh eggs, eggs enriched with n-3 PUFA, and recently prepared commercial spray-dried whole egg powder. The fresh eggs and eggs enriched with n-3 PUFA were purchased directly from a local egg-processing plant and the commercial spray-dried whole egg powder from the factory (Mizumotu Alimentos Ltda, Guapirama, Paraná, Brazil).

Determination of the moisture content. Moisture content was determined using the AOAC (16) methodology.

Optimization of the saponification and extraction procedure. The simultaneous determination of cholesterol and its oxides was based on the direct saponification of samples (15), using experimental complete factorial designs with central points to verify the best conditions for saponification (concentration of KOH in ethyl alcohol and saponification time) and extraction of the nonsaponifiable matter (type of solvent and number of extractions). Subsequently a complete factorial design was developed with the significant factors (concentration of KOH in ethyl alcohol and number of extractions), to optimize the methodology.

HPLC equipment and conditions. The HPLC system used was a Shimadzu (Kyoto, Japan) composed of a ternary pump (LAD10), a vacuum solvent delivery degasser, a thermostatted column compartment with cooling, and UV (SPD-10AV$_{vp}$) and RI (RID-10A) detectors. The analytical column used was a Nova Pack CN HP, 300 mm × 3.9 mm × 4 µm (Waters, Milford, MA) column, and the oven temperature was set at 32°C. A mobile phase of *n*-hexane:isopropyl alcohol (96:4, vol/vol) with an isocratic flow rate of 1 mL/min and a 20-min analysis time, was used to separate cholesterol from the following oxides: 19-OH, 20α-OH, 22(*R*)-OH, 24(*S*)-OH, 22(*S*)-OH, 25-OH, 7-keto, 7β-OH, 7α-OH, 5,6α-epoxy, and 5,6β-epoxy. To separate triol, *n*-hexane:isopropyl alcohol (90:10, vol/vol) was used with a flow rate of 1 mL/min and analysis time of 15 min. Triol, 5,6α-epoxy, and 5,6β-epoxy were determined by the RI detector, whereas the UV detector was used to determine cholesterol and the other oxides, with the absorbance measured at 210 nm. Identification of the cholesterol and cholesterol oxide peaks was done by comparison of the retention times of the sample peaks with those of the standards and by co-chromatography. Quantification was done by external standardization, the standard curves being constructed with 6 points using solutions of the standards, with concentrations varying from 1 to 100 µg/mL for the oxides, and from 2 to 2.5 mg/mL for cholesterol.

Mass spectrometry. HPLC-APCI-MS was used to confirm the identity of cholesterol and its oxides in the egg samples. HPLC was carried out using a Waters Alliance 2695 pump (Milford, MA) and the same chromatographic conditions as described in the previous section. The mass spectrometer used was a Qtrap (Applied Biosystems, Concord, Ontario, Canada) with a QqQ (linear ion trap) configuration. Injections of cholesterol and cholesterol oxide standards were used to optimize the conditions. The optimum conditions were: positive mode APCI; scan range *m/z* 250–500; 375°C; nitrogen as carrier gas (70 L/min), sheath gas (60 L/min), and curtain gas (30 L/min); nebulizer current set at 3,000 V; declustering potential at 30 V; and entrance potential at 9 V. Chromatograms were obtained in the selective ion monitoring (SIM) mode for the ions *m/z* 367, 369, 385, 401, and 403. To verify the accuracy of results found by HPLC-UV-RI, a comparison with the results obtained by HPLC-APCI-MS was carried out. For this purpose, 10 commercial spray-dried whole egg powder samples were prepared and injected for both HPLC-UV-RI and HPLC-APCI-MS.

Method validation. The analytical method was validated for recovery and repeatability; detection limits (DL) and quantification limits (QL) were carried out according to Long and Winefordner (17). Standard reference material (SRM 1845, NIST) was also used to validate cholesterol, as no certified reference material exists for the cholesterol oxides.

Statistical analysis. The experimental designs were analyzed by response surface methodology using the software Statistic 5.5 (Statsoft 2000, Santa Clara, CA). ANOVA was used for the HPLC results, also using the Statistic 5.5 software, and the means were compared by Tukey's test, significance being based on a 0.05 probability level.

RESULTS AND DISCUSSION

Optimization of the conditions for saponification and extraction. The conditions for saponification and extraction of the nonsaponifiable matter were optimized using a complete 2^2 factorial design with central points; the variables and levels studied were concentration of the KOH in ethanol (15, 20, and 25%) and number of extractions (2, 3, and 4).

An analysis of the results of this design showed that all the factors evaluated were significant ($P < 0.05$), with significant interaction ($P < 0.05$) between the concentration of KOH and the number of extractions for the oxides 7α-OH and 5,6β-epoxy.

A concentration of 15% KOH and four extractions showed a positive effect on the response for 5,6β-epoxy, but the interaction between the factors was shown to be negative. For 7α-OH, concentration of KOH of 15% also influenced positively the response for oxide, but the greatest number of extractions showed the opposite effect. The interaction between the factors showed a positive effect for 7α-OH. There was a significant effect ($P < 0.05$) for the number of extractions with the cholesterol results, that is, a positive response was obtained with the greatest number of extractions. However, the KOH

concentration (%) did not influence the cholesterol results and there was no interaction between the factors evaluated.

For 5,6β-epoxy, the best results were obtained by reducing the KOH concentration and increasing the number of extractions. The sensitivity of epoxides to alkaline pH has been already reported (18). In the present work loss of 7-keto was not observed, although alkaline hydrolysis, even when carried out at room temperature and in the dark, can result in severe losses (19,20). A reduction in the number of extractions would negatively affect 5,6β-epoxy and cholesterol.

Thus a complete 2^2 factorial design with central points using standard reference material for cholesterol was developed with the significant factors to optimize the methodology and evaluating the greatest possible number of extractions. Optimum saponification conditions were obtained with 15% KOH and five extractions of the nonsaponifiable matter, corresponding to the central points of the design. Only the results for the central points were similar to the value specified on the certificate (19 ± 0.2 mg cholesterol/g whole egg powder).

Thus the optimum methodology was established as follows: 1.0 g of sample plus 10 mL 15% KOH in absolute ethanol was shaken at 118 rpm on a shaker in the dark for 18 h. The solution was transferred to a 100-mL screw-topped test tube, 40 mL distilled water and 10 mL ethyl ether were added, and the solution was mixed on a vortex mixer for 1 min. After phase separation, the upper layer was transferred to a 125-mL separating funnel, and the extraction with ethyl ether was repeated four more times. A volume of 15 mL KOH (0.5 mol/L) was added to the combined ethereal phases in a separating funnel, and the ethereal solutions washed with 15-mL aliquots of aqueous sodium sulfate (0.47 mol/L). The upper phase was filtered through common filter paper containing anhydrous sodium sulfate and transferred to a 70-mL screw-topped tube, and the ether was evaporated off with a stream of N_2. The dry extract was dissolved in 1 mL of the mobile phase used for HPLC, filtered through 0.45-μm Millipore membranes, and immediately injected into the HPLC.

Simultaneous determination of cholesterol and cholesterol oxides by HPLC-UV-RI. Under the chromatographic conditions used by Baggio *et al.* (21), it was possible to separate cholesterol from the following oxides: 19-OH, 20α-OH, 22(*R*)-OH, 24(*S*)-OH, 22(*S*)-OH, 25-OH, 7-keto, 7α-OH, 7β-OH, 5,6α-epoxy, and 5,6β-epoxy. A more polar mobile phase, *n*-hexane/isopropyl alcohol (90:10, vol/vol), had to be used to separate triol. The oxides 5,6α-epoxy, 5,6β-epoxy, and triol were determined by RI because they contain no π electrons in their structures and therefore do not absorb in the UV region. Both the UV and RI detectors can be used to determine cholesterol and the other oxidation products, but UV was used because it is more sensitive and selective. Figures 1 and 2 show the chromatograms of the standards and of the powdered egg samples, using the UV and RI detectors, respectively. Figures 1B and 2B show that only 5 of the 12 oxides studied were found in the samples of commercial spray-dried whole egg powder. The retention times of the peaks obtained by HPLC-UV of the samples coincided with the retention times of 20α-OH and 25-OH, and were spiked by the respective standards solutions. However, in the HPLC-APCI-MS

chromatograms of the same samples, the fragmentation patterns of the peaks observed with the same retention time as 20α-OH and 25-OH did not correspond to the patterns of these oxides.

The same five oxides were also found by Fontana *et al.* (22). In their study, when the powdered egg samples were heated at 90°C for 24 h, the formation of triol and 25-OH was observed, plus a product with a retention time similar to the 20α-OH, which was not confirmed by high-resolution NMR (22). In other studies the oxides trio, 25-OH and 20α-OH were not detected (23,24) or were not mentioned (25,26).

Characterization, quantification, and confirmation of cholesterol and cholesterol oxides by HPLC-APCI-MS. Table 1 presents the main molecular and fragment ions of cholesterol and its oxides produced in APCI(+)MS. Cholesterol, 19-OH, 25-OH, and 7-keto showed distinctive ion distributions, but 20α-OH, 22(*R*)-OH, 24(*S*)-OH, and 22(*S*)-OH are structurally very similar isomers, resulting in small differences in their ion distributions. Nevertheless, these differences, coupled with their characteristic retention times (the chromatographic peaks of these compounds were clearly resolved), were sufficient to confirm the identity of these oxides.

The 5,6α-epoxy and 5,6β-epoxy as well as 7α-OH and 7β-OH oxides also displayed similar fragmentation patterns, but these also have well-resolved chromatographic peaks, and could therefore be distinguished by their retention times. The triol oxide, which displayed similar fragmentation patterns to those of 5,6α-epoxy and 5,6β-epoxy, could be clearly distinguished from these oxides as it eluted at the end of the chromatographic run.

When analyzing the egg samples, the high cholesterol concentration made the recognition of the oxides difficult. This problem was avoided by removing the *m/z* 369 ion from the SIM run. Thus cholesterol could still be identified from its

The numbered peaks correspond to (1) 19-OH, (2) cholesterol, (3) 20α-OH, (4) 22(*R*)-OH, (5) 24(*S*)-OH, (6) 22(*S*)-OH, (7) 25-OH, (8) 5,6α-epoxy, (9) 5,6β-epoxy, (10) 7-keto, (11) 7β-OH, and (12) 7α-OH.

less intense fragment ions of *m/z* 367 and 385, and the peaks of the oxides could also be observed. Figure 3B shows the confirmation of the presence of cholesterol, 7-keto, 7β-OH, 7α-OH, 5,6α-epoxy, and 5,6β-epoxy and Figure 4B shows the absence of triol in the commercial spray-dried whole egg powder.

In addition to the identification of the cholesterol oxides, a comparison between the results obtained by HPLC-APCI-MS and HPLC-UV-RI was carried out. As can be seen in Table 2, the results obtained by different detectors showed no significant difference ($P > 0.05$), demonstrating that all these detector systems can be used to quantify cholesterol and the oxides found in this study. The methodology was validated using the HPLC-UV-RI system and was applied to determine the cholesterol oxides in egg samples.

Method validation. Recovery was carried out at two levels of addition; 50 and 100 μg for the oxides found in the samples, and 100 and 200 μg for cholesterol. Each level of addition was carried out in duplicate. Table 3 shows the mean values for the recovery of cholesterol and cholesterol oxides in commercial spray-dried whole egg powder. The method showed good results for recovery, from 89 to 103% for the oxides and from 93 to 96% for cholesterol. Studies using the direct saponification method gave a higher recovery value for cholesterol (27), a lower value for 7-keto, and similar values for the oxides 7β-OH and 7α-OH (15).

The low values found for DL and QL (Table 4) demonstrate the adequate sensitivity of the method used in the analyses of cholesterol and its oxides. Repeatability, verified from the relative standard deviations (RSD) values (Table 5), varied from

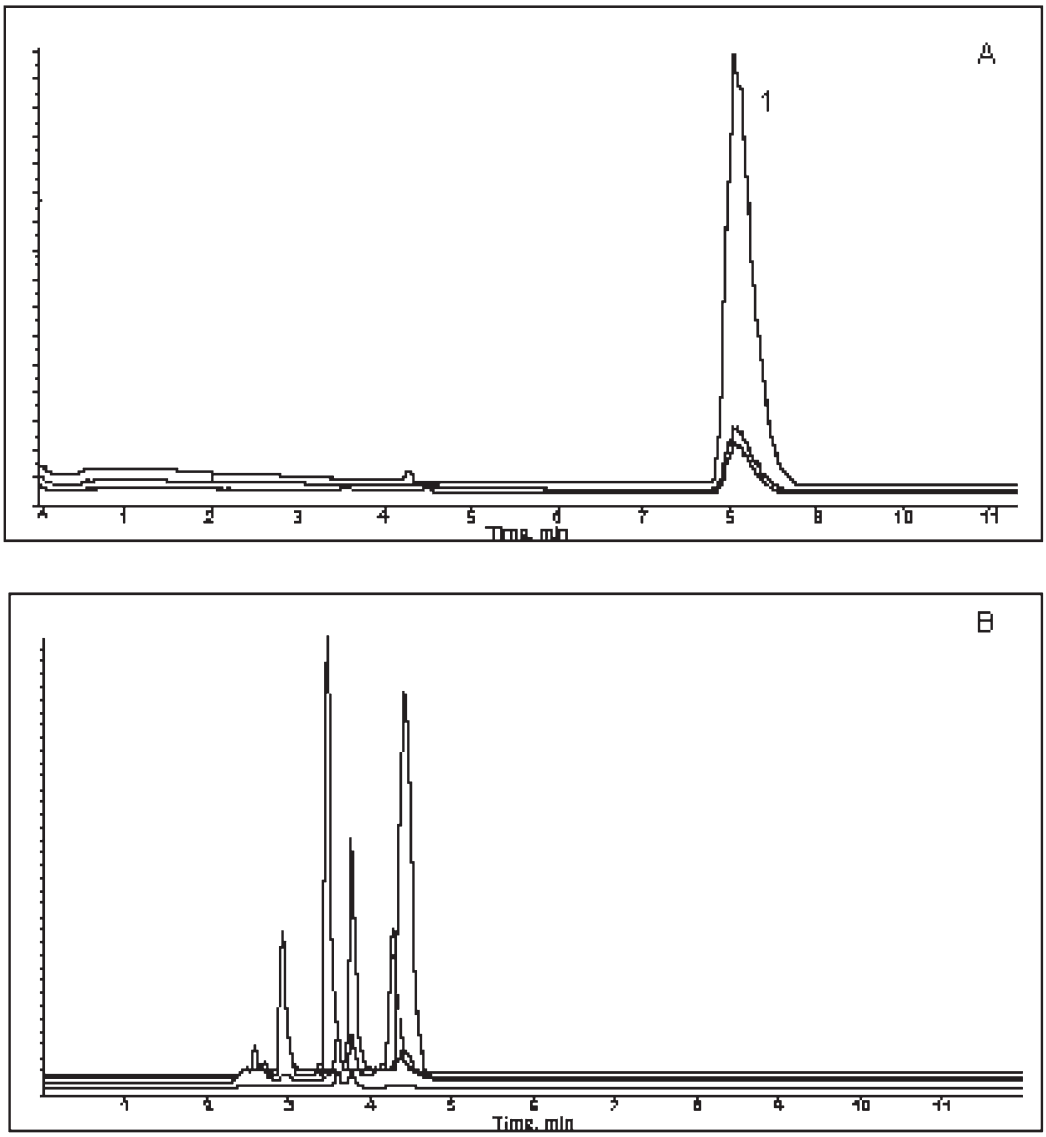

FIG. 4. Chromatograms of triol standard (A) and the commercial spray-dried whole egg powder (B), determined using HPLC-APCI-MS. The numbered peak corresponds to (1) triol.

4.3 to 15.2% for the oxides and from 2.5 to 3.7% for cholesterol. These values are considered acceptable for analytical repetitions (28), although Morgan and Armstrong (25) reported lower RSD values (3.1–8.0%) for the oxides.

The cholesterol content determined in the standard reference material (SRM 1845, NIST) was 19.0 ± 0.2 mg/g in

whole egg powder, identical to the value declared on the certificate of analysis.

Application of methodology on eggs samples. Of the 12 oxides studied, the following 5 oxides were identified, quantified, and confirmed in commercial spray-dried whole egg powder: 7-keto, 7α-OH, 7β-OH, 5,6α-epoxy, and 5,6β-epoxy. The following three oxides were found in fresh eggs: 7-keto, 7α-OH, and 7β-OH. Only 7α-OH and 7β-OH were found in fresh eggs enriched with n-3 PUFA (Table 5). A great variety of values for the amounts of cholesterol oxides determined in spray-dried whole egg powder can be found in the literature, varying from not detected to 37 mg/g for 7-keto, from not detected to 65 mg/g for 7b-OH, from not detected to 35 mg/g for 7a-OH, from 12 to 111 mg/g for 5,6a-epoxy, and from 5 to 46 mg/g for 5,6b-epoxy (29,30). In the present study the valves obtained for all oxides were lower than the maximum described in literature. The discrepancies found in the amounts of the oxides are probably due to differences in the spray-drying processes used and in part due to the different methodologies used to determine the oxides.

Similar values were found by Van de Bovenkamp *et al.* (20) for 7-keto in fresh egg yolk. Nourooz-Zadeh (31) quantified 7-keto (2.2 mg/g of lipid) and 7a-OH (2.7 mg/g of lipid) in fresh eggs. On the other hand, none of the eight cholesterol oxides commonly found in foods were detected in fresh eggs (32).

The formation of high amounts of cholesterol oxides in eggs enriched with n-3 PUFA would be expected; however, in this case, the eggs enriched with n-3 PUFA presented only two oxides, and in smaller amounts than those found in fresh eggs. Probably, those results are due to the addition of antioxidants such as vitamin E to birds' diets rich in n-3 PUFA (33).

The mean values found for cholesterol were higher for samples of both egg and egg enriched with n-3 PUFA, and similar for whole egg powder, than those reported by the USDA (34).

In summary, the factors studied in the extraction design influenced the cholesterol and cholesterol oxide contents. It was possible to establish the best conditions for saponification and extraction of non-saponifiable matter using response surface methodology. The proposed method was shown to have high sensitivity, precision, and recovery and to be easy to apply in the separation of cholesterol and cholesterol oxides in eggs. Confirmation of the oxides 20α-OH and 25-OH is required, as the presence of these oxides was not confirmed by HPLC-APCI-MS.

COMMUNICATION

Identification and Production of n-8 Odd-Numbered Polyunsaturated Fatty Acids by a Δ12 Desaturation-Defective Mutant of *Mortierella alpina* 1S-4

Shuo Zhang, Eiji Sakuradani, and Sakayu Shimizu*

Division of Applied Life Sciences, Graduate School of Agriculture, Kyoto University, Kyoto 606-8502, Japan

ABSTRACT: A mutant of *Mortierella alpina*, JT-180, which is defective in its Δ12 desaturase activity but exhibits enhanced activities of Δ5 and Δ6 desaturases, produced a high proportion (up to 80%) of odd-chain FA when grown on 3% *n*-heptadecane. Following growth of the mutant on *n*-heptadecane, three unusual odd-chain fatty acyl residues were identified as 6,9-heptadecadienoic acid (17:2), 8,11-nonadecadienoic acid (19:2), and 5,8,11-nonadecatrienoic acid (19:3) by means of GC-MS, MS-MS, and NMR analyses. The mycelial contents of these FA reached 20.3, 3.6, and 5.8 mg/g dry mycelia, respectively, when it was cultivated in medium comprising 4% (vol/vol) *n*-heptadecane and 1% (wt/vol) yeast extract, pH 6.0, at 28°C for 7 d. The biosynthetic route (n-8 route) to 19:3 was presumed to mimic the n-9 route to Mead acid (20:3n-9) in mammals: 17:0 → 9-17:1 → 6,9-17:2 → 8,11-19:2 → 5,8,11-19:3.

Paper no. L9938 in *Lipids 41*, 623–626 (June 2006).

The occurrence of odd-numbered, straight-chained PUFA has been reported in ruminants, fish, and several other animal lipids, in which they can account for a small percentage of the total FA. Moreover, such PUFA can undergo further desaturation reactions; for example, 9,12-heptadecadienoic acid and 6,9,12-heptadecatrienoic acid prepared from mullet oil are converted to odd-chain PUFA such as 8,11,14-nonadecatrienoic acid and 5,8,11,14-nonadecatetraenoic acid (19:4) in rat liver (1). In microorganisms, odd-chain-length FA may be produced when yeasts, bacteria, and fungi are grown on odd-chain-length alkanes (2–4). Additionally, several *Mortierella* species (5) can accumulate C_{19} PUFA derived from methyl pentadecanoate or *n*-pentadecane added to the medium. In particular, on cultivation of the arachidonic acid–producing *Mortierella alpina* 1S-4 with 5% *n*-heptadecane as the growth substrate, the amount of 19:4 reached 44.4 mg/g dry mycelia (0.7 mg/mL of culture broth). Here we report that a mutant of this fungus, JT-180, which is defective in its Δ12 desaturase activity but exhibits enhanced activities of Δ5 and Δ6 desaturases, can accumulate large amounts of unusual C_{17} and C_{19} PUFA in its mycelial lipids when grown with odd-chain *n*-alkanes. Normally when this mutant is grown on glucose or similar substrates, it produces Mead acid (20:3n-9) as its major PUFA (6).

MATERIALS AND METHODS

Chemicals. Odd-chain *n*-alkanes were purchased from Wako Pure Chemicals (Osaka, Japan). All reagents were of analytical grade.

Microorganism and cultivation. Strain JT-180, which is a mutant derived from *M. alpina* 1S-4 by chemical mutagenesis (7), was inoculated as a spore suspension into 20-mL Erlenmeyer flasks containing 4 mL of medium containing 3% (vol/vol) *n*-alkane and 1% (wt/vol) yeast extract (pH 6.0). It was grown at 28°C with reciprocal shaking (120 strokes/min) unless stated otherwise.

FA analysis. The cultivated mycelia were harvested by vacuum filtration, washed rapidly with *n*-hexane to remove residual *n*-alkanes from the cell surface, dried at 120°C for 3 h, and then transmethylated with methylene chloride/10% methanolic HCl (vol/vol) at 50°C for 3 h. The resultant FAME were extracted with *n*-hexane and then analyzed by GC, as described previously (8).

Identification. The FAME derived from JT-180 cultivated in a medium containing 2% (wt/vol) glucose, 1% (wt/vol) yeast extract, and 1% (vol/vol) *n*-heptadecane, pH 6.0, at 28°C for 10 d were first separated by HPLC using a Cosmosil column (5C18-AR, 20 × 250 mm, Nacalai Tesque, Kyoto, Japan). Acetonitrile/H_2O (8:2, vol/vol) was used as the mobile phase at 4 mL/min, and the effluent was monitored at 205 nm. The semipurified FAME were completely separated by HPLC on a different column (Cosmosil column 5C18-AR, 4.6 × 250 mm). The isocratic mobile phase was acetonitrile/H_2O (9:1, vol/vol) at 3 mL/min. The chemical structures of these FAME were determined by MS-MS and ^1H NMR. The MS-MS analyses were performed with a JEOL-HX110A/HX110A tandem mass spectrometer. The ionization method was FABMS, and the acceleration voltage was 3 kV. Glycerol was used as the matrix. The NMR experiment was performed with a Bruker Biospin DMX-750 (750 MHz for ^1H), and chemical shifts were assigned relative to the solvent signal. FAME were dissolved in $CDCl_3$ and analyzed by the two-dimensional NMR technique of ^1H-^1H chemical shift COSY.

GC-MS analysis of pyrrolidide derivatives. The purified FAME were converted to pyrrolidide derivatives as described previously (9). The pyrrolidide derivatives were identified by GC-MS using a Shimadzu GCMS-QP5050 operating at an ionization voltage of 70 eV.

RESULTS

Identification of the unknown odd-chain FA. When the mutant, JT-180, was cultivated in the medium containing 1% *n*-heptadecane, it accumulated three unknown FA (UK1, UK2, and UK3). The mass spectrum of the pyrrolidide derivatives of UK1, UK2, and UK3 showed molecular weights of *m/z* 319, 345, and 347, respectively. These results suggested that UK1, UK2, and UK3 were, respectively, a C_{17} FA with two double bonds, a C_{19} FA with three double bonds, and a C_{19} FA with two double bonds. The FABMS data for the free FA of UK1 indicated a molecular weight of 266 (Li-complex, *m/z* 287 $[M + Li]^+$). The material (*m/z* 287) was fragmented again by MS-MS, yielding *m/z* (FABMS$^-$, 8.00 kV) peaks at 271 (1.2), 257 (1.2), 243 (3.1), 215 (10.5), 201 (6.8), 187 (1.5), 175 (13.2), 161 (17.6), 147 (5.4), 135 (1.0), 121 (2.3), 107 (10.1), 94 (17.9), 93 (38.7), 80 (100), 79 (9.4), and 51 (8.7). The *m/z* 121, 147, 161, and 187 fragments were derived from cleavage between single bands 6-7 and 9-10, numbered from the carboxyl group. ^{1}H NMR analysis also revealed that UK1 was a 17:2 isomer, with NMR δ_H ($CDCl_3$) at 5.38 (4H, *m*, CH_2-C<u>H</u>=C<u>H</u>-CH_2), 3.67 (3H, *s*, O-C<u>H</u>$_3$), 2.77 (2H, *dd*, *J* = 6.14 Hz, =CH-C<u>H</u>$_2$-CH=), 2.21 (2H, *t*, *J* = 7.54 Hz, O=C-C<u>H</u>$_2$), 2.06 (4H, *dt*, *J* = 6.80, 2.60 Hz, CH_2-C<u>H</u>$_2$-CH=), 1.62 (2H, *tt*, *J* = 7.77, 7.58 Hz, CH_2-C<u>H</u>$_2$-CH_2), 1.39 (2H, *tt*, *J* = 7.71, 7.75 Hz, CH_2-C<u>H</u>$_2$-CH_2), 1.36 (10H, *m*, CH_2-C<u>H</u>$_2$-CH_2), 0.97 (3H, *t*, CH_2-C<u>H</u>$_3$). The sequence of the protons was determined on the basis of the signal pattern of the interactions between adjacent protons observed on COSY (data not shown). On the basis of these results, UK1 was identified as 6,9-heptadecadienoic acid (17:2n-8).

The FABMS data for the free FA of UK2 indicated a molecular weight of 292 (Li-complex, *m/z* 313 $[M+Li]^+$). The material (*m/z* 313) was fragmented again by MS-MS, yielding *m/z* (FABMS$^-$, 8.00 kV) peaks at 297 (1.2), 283 (5.7), 269 (4.6), 255 (4.0), 241 (17.5), 227 (22.9), 213 (3.6), 201(11.4), 187 (54.2), 174 (4.3), 161(9.0), 147 (22.3), 134 (2.23), 133(6.7), 121 (1.1), 103(12.0), 94 (100.0), 93 (75.6), 80 (86.3), and 50 (30.1). The *m/z* 121, 147, 161, 187, 201, and 227 fragments were derived from cleavage between single bands 5-6, 8-9, and 11-12, numbered from the carboxyl group. ^{1}H NMR analysis also revealed that UK2 was a 19:3 isomer, with NMR δ_H ($CDCl_3$) at 5.38 (6H, *m*, CH_2-C<u>H</u>=C<u>H</u>=C<u>H</u>-CH_2), 4.22 (3H, *s*, O-C<u>H</u>$_3$), 2.80 (4H, *dd*, *J* = 7.02 Hz, =CH-C<u>H</u>$_2$-CH=), 2.33 (2H, *t*, *J* = 7.54 Hz O=C-C<u>H</u>$_2$), 2.12 (2H, *dt*, *J* = 7.25 Hz, =CH-C<u>H</u>$_2$-CH_2), 2.05 (2H, *dt*, *J* = 7.16, 7.35 Hz, =CH-C<u>H</u>$_2$-CH_2), 1.71 (2H, *tt*, *J* = 6.55, 5.78 Hz, CH_2-C<u>H</u>$_2$-CH_2), 1.36 (10H, *m*, CH_2-C<u>H</u>$_2$-CH_2), 0.93 (3H, *t*, *J* = 7.51 Hz, CH_2-C<u>H</u>$_3$). The sequence of the protons was determined on the basis of the signal pattern of the interactions between adjacent protons observed on COSY (data not shown). On the basis of these results, UK2 was identified as 5,8,11-nonadecatrienoic acid (19:3n-8).

The pyrrolidide derivative of UK3 was fragmented by GC-MS, yielding peaks at *m/z* 347 (7.1), 318 (0.4), 304 (0.5), 290 (0.4), 276 (2.1), 262 (0.8), 248 (0.9), 222 (2.5), 208 (6.2), 194 (2.1), 182 (2.9), 168 (7.5), 154 (3.3), 140 (5.8), 126 (53.2), and 113 (100.0). The spectra included significant *m/z* 113 and 126 peaks typical of FA pyrrolidide derivatives. The differences of 26 atom mass units between *m/z* 248 and 222 and *m/z* 208 and 182 each indicated a double bond. As a result, UK3 was identified as 8,11-nonadecadienoic acid (19:2n-8).

Conversion of odd-chain alkanes to odd-chain FA by JT-180. The mycelia of JT-180 grown in the medium containing 3% (vol/vol) *n*-alkane and 1% (wt/vol) yeast extract accumulated considerable amounts of unusual odd-chain FA, as shown in Tables 1 and 2. Among these FA, three major components showed the same retention times as authentic 15:0, 17:0, and 19:0 FAME on GC and HPLC analyses. The structures of the other unknown FA were determined by the analytical methods described in the previous section. When JT-180 was cultivated in a medium containing 2% (wt/vol) glucose, 1% (wt/vol) yeast extract, and 1% (vol/vol) *n*-alkane, the added *n*-alkanes did not inhibit fungal growth and, indeed, its dry mass was higher than that without *n*-alkane (data not shown). Both the C_{15} and C_{17} alkanes were efficiently converted to C_{17} and C_{19} PUFA. In particular, with *n*-heptadecane, the total odd-chain FA accounted for almost 80% of the total FA (see Table 1).

Furthermore, the mycelial mass and the sum of 17:2, 19:2, and 19:3 yields were highest, 21.3 mg/mL and 28.8 (15.8, 5.1,

[a]JT-180 was grown in medium containing 1% (wt/vol) yeast extract and 3% (vol/vol) *n*-alkane, pH 6.0, at 28°C, for 7 d. Values are means ± SD, *n* = 3. C_{11}, *n*-undecane; C_{13}, *n*-tridecane; C_{15}, *n*-pentadecane; C_{17}, *n*-heptadecane; C_{19}, *n*-nonadecane; 15:0, petadecanoic acid; 17:0, heptadecanoic acid; 17:1, 9-heptadecenoic acid; 17:2, 6,9-heptadecadienoic acid; 19:0, n-nonadecanoic acid; 19:1,11-nonadecenoic acid; 19:2, 8,11-nonadecadienoic acid; 19:3, 5,8,11-nonadecatrienoic acid; 16:0, palmitic acid,; 18:1, oleic acid; 18:2, 6,9-octadecadienoic acid; 20:3, Mead acid.
[b]Others include 16:1 (palmitoleic acid), 18:0 (stearic acid), 20:0 (eicosanoic acid), 20:1 (11-eicosaenoic acid), 20:2 (8,11-eicosadienoic acid), 22:0 (docosanoic acid), and 24:0 (tetracosanoic acid).

and 7.9) mg/g dry mycelia, respectively, with *n*-heptadecane (see Table 2). On the other hand, the use of C_{13} alkane brought about the highest yield (8.4%) and mycelial content (12.8 mg/g dry mycelia) of 19:3, whereas the mycelial mass was not higher than those in the use of C_{15} or C_{17} alkanes. Shorter and longer carbon chain alkanes (*i.e.,* C_{11} and C_{19}) were not efficiently converted. When JT-180 was grown with C_{15}, C_{17}, and C_{19} saturated FAME, the C_{17} and C_{19} PUFA were not accumulated with the same efficiency as with the corresponding *n*-alkanes (data not shown).

Effects of n-heptadecane concentration and cultivation temperature on production of odd-chain PUFA. JT-180 was cultivated in medium containing 1% (wt/vol) yeast extract and 3, 4, or 5% (vol/vol) *n*-heptadecane at 12, 20, or 28°C, and the mycelial FA contents were analyzed as shown in Table 3. The mycelial contents of 17:2 and 19:2 were highest at the cultivation temperature of 28°C independent of the *n*-heptadecane concentration, whereas that of 19:3 was highest only at 20°C. On the other hand, the culture condition with 4% (vol/vol) *n*-heptadecane at 28°C led to highest mycelial mass of 21.6 mg/mL, and the mycelial contents of 17:2, 19:2, and 19:3 reached 20.3, 3.6, and 5.8 mg/g dry mycelia, respectively. The sum of the mycelial contents of these FA represented the maximal value at 28°C. The conversion rates ([produced 19:3/added *n*-heptadecane] × 100) were 0.41, 0.31, and 0.22 with 3, 4, and 5% (vol/vol) of *n*-heptadecane, respectively. As a result, the conversion rate was higher at the lower concentration of *n*-heptadecane.

DISCUSSION

Shimizu *et al.* reported that some *Mortierella* species, such as *M. alpina*, *M. elongata*, *M. verticillata*, and *M. kuhlmanii*, which normally produce C_{20} PUFA, could accumulate some C_{17} and C_{19} FA when grown with odd-chain *n*-alkanes (5). In particular, an arachidonic acid–producing fungus, *M. alpina* 1S-4, accumulated a large amount (44.4 mg/g dry mycelia) of 19:4 corresponding to arachidonic acid minus one carbon unit at the ω-terminal end (5). One of the predominant C_{19} PUFA produced by Mead acid–producing JT-180 (defective in Δ12 desaturase activity but with enhanced activities of Δ5 and Δ6 desaturases) was identified as 19:3 corresponding to Mead acid minus one carbon unit at the w-terminal end. The other odd-chain PUFA formed by JT-180 were identified as 17:2 and 19:2. These data suggest that these odd-chain PUFA were biosynthesized through the proposed pathway in Figure 1, which mimics the biosynthetic pathway for the n-9 series, in which the following are the successive reactions involved: oxidation of *n*-heptadecane to 17:0, desaturation to 6,9-17:2 via 9-17:1, elongation of 17:2 to 8,11-19:2, and further desaturation of 19:2 to 5,8,11-19:3. These odd-chain PUFA correspond to the equivalent even-chain PUFA minus one carbon unit at the ω-terminal end. The wild strain, *M. alpina* 1S-4, could not produce detectable amounts of n-8 series odd-chain PUFA such as 17:2, 19:2, and 19:3 because of its own Δ12 desaturation. On the other hand, in mammalian cells lacking Δ12-desaturation activity, n-8 series odd-chain PUFA may be inefficiently derived from exogenous or endogenous odd-chain FA.

TABLE 2
Production of Odd-Chain PUFA by JT-180 Grown with *n*-Alkanes[a]

[a]JT-180 was grown in medium containing 1% (wt/vol) yeast extract and 3, 4, or 5% (vol/vol) *n*-heptadecane, pH 6.0, at 28°C for 2 d and then at 12, 20, or 28°C for 5 d. Values are means ± SD, $n = 3$.

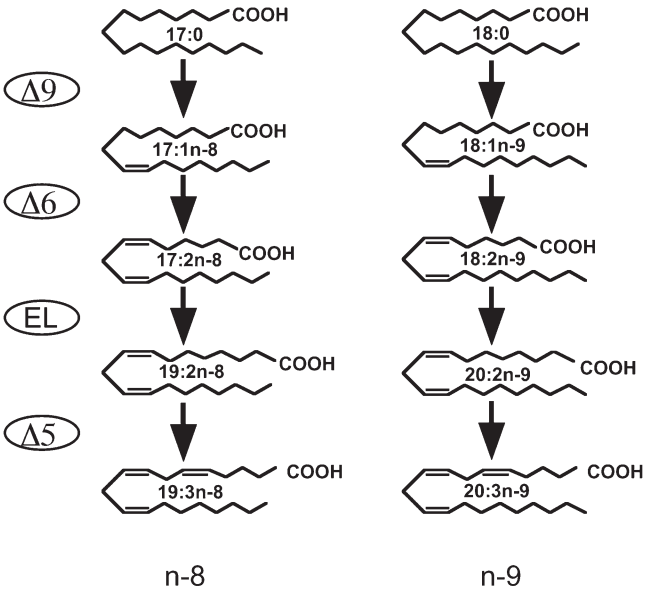

FIG. 1. Putative biosynthetic pathway for n-8 series odd-chain PUFA in JT-180. ΔX, ΔX FA desaturation; EL, FA elongation.

The 15:0 and 17:0 FAME were not effectively converted to 19:3, compared with *n*-alkanes as substrates (data not shown). The C_{11} or C_{19} alkanes were also not effectively converted to 19:3. The uptake efficiencies of fatty substrates into mycelia, oxidation of *n*-alkanes into FA, and elongation of shorter-chain FA into C_{19} FA may influence the rate of conversion to 19:3. *n*-Heptadecane as a sole carbon source led to the highest mycelial growth and total odd-chain FA yield. This indicates that JT-180 efficiently uptakes *n*-heptadecane and converts it to FA. In contrast, although C_{13} alkane led to the highest rate and mycelial content of 19:3, the mycelial mass and FA yield were not higher. This suggests that uptake efficiency of C_{13} alkane into mycelia is very low; however, the C_{13} alkane is easily converted to 19:3 once incorporated. Regardless of *n*-heptadecane concentration, the mycelial content of 19:3 showed the maximal value of 8.9–10.1 mg/g dry mycelia at the cultivation temperature of 20°C as shown in Table 3. It is assumed that FA elongation (17:2 → 19:2) and Δ5 desaturation (19:2 → 19:3) were activated at 20°C, resulting in more accumulation of 19:3 within mycelia. Previously, the highest accumulation of Mead acid was observed for JT-180 at the same cultivation temperature (6). This may be one reason why Δ5 and Δ6 desaturases show high activities at the lower cultivation temperature of 20°C. The low FA yield as shown in Table 3 may be due to the solid state of *n*-heptadecane at 12°C, which prevents incorporation of *n*-heptadecane into mycelia. Just considering the conversion rate of 19:3, 3% (vol/vol) of *n*-heptadecane may be comparable to the optimal concentration. Excess added *n*-heptadecane is thought to remain in the medium or adhere to the cell surface.

FAME containing mainly n-5 series odd-chain PUFA, such as 9,12-heptadecadienoic acid and 6,9,12-heptadecatrienoic acid, have been shown to cure the external symptoms of fat-deficient rats through conversion to 19:4 in the rat liver (1). However, other physiological functions of odd-chain PUFA have not been fully elucidated yet. When JT-180 was cultivated with 4% (vol/vol) *n*-heptadecane in 28°C for 7 d, the total amounts of 17:2, 19:2, and 19:3 reached 29.7 mg/g dry mycelia (see Table 3). n-8 Series odd-chain PUFA are unusual in natural sources, and this study suggests a new source of three odd-chain PUFA. We expect that n-8 series odd-chain PUFA should be useful as chemical reagents or help to clarify their own physiological functions in mammals.

Acyl Moieties Modulate the Effects of Phospholipids on β-Carotene Uptake by Caco-2 Cells

Lina Yonekura, Wakako Tsuzuki, and Akihiko Nagao*

National Food Research Institute, Tsukuba, Ibaraki 305-8642, Japan

ABSTRACT: The intestinal absorption of carotenoids is thought to be mediated by the carotenoid assembly in mixed micelles, followed by its transfer into the enterocytes and subsequent secretion to the lymph as chylomicron particles. In the present study we investigated the effects of phospholipids and lysophospholipids with diverse fatty acyl moieties on the uptake of β-carotene solubilized in mixed micelles by Caco-2 cells. Compared with phospholipid-free mixed micelles (NoPL), those containing long-chain PC inhibited β-carotene uptake (16:0,18:1-PC ≅ 16:0,18:2-PC < 14:0,14:0-PC ≅ 16:0,14:0-PC < 16:0,16:0-PC < NoPL). However, mixed micelles containing medium-chain PC enhanced β-carotene uptake (NoPL < 8:0,8:0-PC < 12:0,12:0-PC < 10:0,10:0-PC), and short-chain PC did not affect the uptake. Among the lysophosphatidylcholine (LysoPC) class, a marked increase of β-carotene uptake by medium-to-long-chain LysoPC was observed (NoPL < 12:0-LysoPC < 14:0-LysoPC < 18:1-LysoPC < 16:0-LysoPC), although short-to-medium-chain LysoPC (6:0-LysoPC to 10:0-LysoPC) did not affect β-carotene uptake. The long-chain 16:0,18:1-PC increased the β-carotene efflux from cells and drastically changed the β-carotene UV-visible absorbance spectrum, compared with those of NoPL micelles. The acyl moieties of long-chain PC may interact with the carotenoid in the micelle interior, shifting the β-carotene partition toward the micellar phase. Medium-chain PC and long-chain LysoPC, which have nearly equivalent hydrophobicities, may enhance β-carotene uptake through their interaction with the cell membrane.

Paper no. L10020 in *Lipids 41*, 629–636 (July 2006).

The intestinal absorption of dietary carotenoids comprises several steps, including the release of carotenoids from the food matrix, dispersion as lipid emulsion particles and assembly into mixed micelles in the digestive tract, uptake by intestinal epithelial cells, and secretion to lymph as chylomicrons (1,2). The uptake of carotenoids by the intestinal cells has been thought to occur through simple diffusion (3,4), similar to many other dietary lipids. However, recent observations indicate the existence of carotenoid transport mediated by the scavenger receptor class B type I (SR-BI) and possibly other receptors (5–7). The SR-BI–mediated transport seems to occur without energy expenditure, which implies the necessity of a concentration gradient between micelles and cells (8). Thus, an efficient solubilization of carotenoids into mixed micelles and release to cells would favor carotenoid uptake, whether it is mediated by simple diffusion or by facilitated transport.

Dietary and biliary lipids, together with their lipolytic products, are essential for the emulsification and micellar solubilization of carotenoids. Phospholipids, especially PC, are present in the diet either as a natural component of the food matrix or as an emulsifier/stabilizer in processed foods (9,10). Additionally, the bile constitutes a large physiological pool of phospholipids (mainly PC), which are introduced into the duodenum during the digestive process (11). In both foodstuff and bile, PC functions as an emulsifier and prevents the precipitation of lipophilic compounds. However, in contrast with the general idea that lipid absorption is proportional to its micellar solubilization, there has been some evidence indicating that PC suppresses the absorption of carotenoids and other lipophilic compounds despite promoting their emulsification and/or solubilization (12–17).

Our previous studies showed that PC inhibits the absorption of carotenoids by human intestinal Caco-2 cells (17) and mice (12). However, the replacement of PC by lysophosphatidylcholine (LysoPC) in micelles or the PC hydrolysis by phospholipase A_2 greatly improves β-carotene and lutein absorption by Caco-2 cells and experimental animals (12,17,18). Previous studies suggested that the acyl moieties of phospholipids interact with the lipophilic compounds in the micelle core, inhibiting their release for the uptake by enterocytes (13–16). The elimination of one acyl chain from PC, producing LysoPC, suggests a reduced hydrophobicity and a weaker association between the phospholipid and carotenoids in micelles, which is in accordance with the increase of carotenoid absorption observed by Sugawara *et al.* (17). However, the mechanisms underlying the effects of phospholipids on the intestinal uptake of carotenoids have not been fully elucidated, although the amphiphilic properties of phospholipids might affect the solubilization of carotenoids and cell membrane permeability. Because the acyl chain length of phospholipids is one of the critical factors determining their amphiphilic properties, it is worth evaluating the effects of phospholipids with a variety of fatty acyl moieties on carotenoid uptake by Caco-2 cells, in order to elucidate the mechanism of action of phospholipids on the intestinal absorption of carotenoids.

In the present study, we investigated the interactions between phospholipids and β-carotene in mixed micelles, using phospholipids and lysophospholipids with a wide range of acyl chains, and focusing on their resulting effects on β-carotene uptake by Caco-2 human intestinal cells.

EXPERIMENTAL PROCEDURES

Materials. Unless otherwise stated, all reagents for the preparation of micelles were purchased from Sigma-Aldrich Co. (St. Louis, MO). The effects of phospholipids and lysophospholipids on β-carotene uptake were assessed by using compounds with a wide range of acyl chain lengths. The effects of the acyl chain length and unsaturation of PC were evaluated by using 1,2-diacyl-*sn*-glycero-3-phosphocholine with the following fatty acyl groups: 1,2-dibutyryl (4:0,4:0-PC), 1,2-dihexanoyl (6:0,6:0-PC), 1,2-dioctanoyl (8:0,8:0-PC, Avanti Polar Lipids, Alabaster, AL), 1,2-didecanoyl (10:0, 10:0-PC), 1,2-didodecanoyl (12:0,12:0-PC), 1,2-dimyristoyl (14:0,14:0-PC), 1-palmitoyl-2-myristoyl (16:0,14:0-PC), 1,2-dipalmitoyl (16:0,16:0-PC), 1-palmitoyl-2-oleoyl (16:0,18:1-PC), and 1-palmitoyl-2-linoleoyl (16:0,18:2-PC). LysoPC acyl chain length and unsaturation effects were assessed by using 1-acyl-2-hydroxy-*sn*-glycero-3-phosphocholine with various acyl groups: hexanoyl (6:0-LysoPC), octanoyl (8:0-LysoPC, Avanti Polar Lipids), decanoyl (10:0-LysoPC, Avanti Polar Lipids), dodecanoyl (12:0-LysoPC), myristoyl (14:0-LysoPC), palmitoyl (16:0-LysoPC), and oleoyl (18:1-LysoPC). β-carotene (Type II, synthetic, ≥ 95% HPLC, crystalline) was dissolved in hexane and passed through a small column packed with 1.5 g of neutral alumina (grade III, ICN Biomedicals, Eschweger, Germany) in order to remove polar oxidation products. The eluate was stored at −80°C until use. All procedures involving β-carotene were performed under dim yellow light in order to minimize its degradation.

Cell culture. Caco-2 cells (American Type Culture Collection, Rockville, MD) were routinely maintained in 10-cm dishes, as previously reported (17). For the uptake and efflux experiments, the Caco-2 cells were seeded into 24-well plates at 10^5 cells/well in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% FBS (JRH Biosciences, Lenexa, KS), 4 mmol/L L-glutamine, 40,000 units/L penicillin, 40 mg/L streptomycin, and 0.1 mmol/L nonessential amino acids. The cells were cultured for 20–22 d at 37°C in a humidified atmosphere of 95% air and 5% CO_2, with the culture medium replaced every 2–3 d. For transport experiments, cells were seeded in polycarbonate Transwell® 6-well plates (Corning Inc., Corning, NY) at 7.5×10^5 cells/well, and cultured for 25–30 d under the same conditions described for uptake and efflux experiments. Transepithelial electrical resistance (TEER) was measured at the end of the culture period using a voltohmmeter equipped with a chopstick-type electrode (EVOMX and STX2 electrode, World Precision Instruments, Sarasota, FL); values of approximately 250 Ω were obtained, indicating the formation of tight monolayers.

Preparation of mixed micelles containing β-carotene. Mixed micelles were prepared as previously published (17). In brief, all components were previously dissolved in an adequate solvent, and appropriate volumes of each solution were transferred to glass test tubes. The solvent was evaporated under a stream of argon, and the samples were further submitted to vacuum centrifugation. The dry matter was vortexed with serum-free DMEM and filtered through a 0.20-μm PTFE membrane (DISMIC-25cs, Advantec Co., Tokyo, Japan). Each micellar component was added in the amount needed to reach the following concentrations: 2 mmol/L sodium taurocholate, 33.3 μmol/L oleic acid, 100 μmol/L monoolein, 1.0 μmol/L β-carotene, and 0 or 50 μmol/L of the phospholipid to be tested. The β-carotene concentration in the mixed micelles was set to 1.0 μmol/L in order to enable comparisons with our previous studies (17,19). This value is also comparable to the estimated β-carotene concentration in the micellar phase of the duodenal contents after the ingestion of a physiological dose of β-carotene from vegetables (20). The β-carotene concentration in the micelle preparations was determined by HPLC after a 9-fold dilution with dichloromethane/methanol (1:4, vol/vol), and this value was considered the initial micellar β-carotene concentration. Micelles were freshly prepared for each experiment and used within the same day.

β-carotene uptake, efflux, and transport assays. β-carotene uptake by Caco-2 cells was assayed according to a previous publication (17), with slight modifications. After two washings with 0.5 mL serum-free DMEM at 37°C, the Caco-2 monolayers in the 24-well plates were incubated for 2 h with 0.5 mL β-carotene mixed micelle preparations in serum-free DMEM. At the end of the incubation period, the plates were kept on ice while the apical medium was collected, and the monolayers were washed twice with 0.5 mL of 10 mmol/L sodium taurocholate in PBS and once more with PBS. The cells were homogenized with 1 mL PBS and 0.02 mL of 0.2 mmol/L α-tocopherol in methanol (as an antioxidant), by using a probe-type sonicator at moderate intensity. A 0.8-mL aliquot of the cell homogenate was collected, and 0.2 mL of ethanolic 0.4 mmol/L ethyl-β-apo-8′-carotenoate (internal standard) was added. Subsequently, 0.6 mL ethanol, 0.8 mL ethyl acetate, and 0.8 mL hexane were added and the mixture was vortexed after each addition. The upper phase was collected into centrifuge tubes and submitted to vacuum centrifugation. The dry residue containing β-carotene and the internal standard was then redissolved in 0.1 mL dichloromethane/methanol (1:4, vol/vol) and analyzed by HPLC. An aliquot of the apical medium was filtered through 0.2-μm PTFE membranes (Millipore, Bedford, MA). Samples of the unfiltered medium and the filtrates were subjected to β-carotene analyses by HPLC (as described above for the mixed micelles), in order to calculate the micellar (soluble) and extramicellar (aggregated, retained by the 0.2-μm membrane) β-carotene recoveries at the end of the incubation with Caco-2 cells.

For the efflux experiments, Caco-2 cells were washed twice with serum-free DMEM and incubated for 2 h with β-carotene micelles containing 50μmol/L 16:0-LysoPC and approximately 1.5μmol/L β-carotene, under the same conditions described above. After the uptake phase, the cells were washed twice with 0.5 mL serum-free DMEM, and were incubated for another 2 h (efflux period) with β-carotene-free micelles of varied phospholipid compositions. At the end of the efflux period, the media were collected and cell debris removed by centrifugation (400 × *g*, 3 min). β-carotene was extracted from a 0.3-mL aliquot of apical medium, and analyses were performed by the same procedures described above for the cell homogenates.

The uptake and transport of β-carotene across a Caco-2 monolayer was measured as previously published (19). β-carotene micelles in serum-free DMEM (1.5 mL) were added to the apical side, and 10% FBS-DMEM (2.5 mL) was added to the basolateral side. The cells were incubated for 16 h at 37°C in a humidified atmosphere of 95% air and 5% CO_2. The β-carotene extraction and analyses in the cells and basolateral medium were performed as described above, adjusting the internal standard concentration and sample dilution factors as required.

HPLC analyses. The β-carotene concentration in the medium and cells was determined by HPLC (LC-10AD pump, SPD-M10A photodiode array detector, CTO-10AS column oven, Shimadzu, Kyoto, Japan). Separations were done in an ODS column (Inertsil ODS-3, 2.1 mm i.d. × 100 mm, GL Science, Tokyo, Japan), and the mobile phase consisted of methanol/ethyl acetate (60:40, vol/vol), containing 0.1% ammonium acetate, flowing at 0.2 mL/min. The β-carotene concentration was calculated from the peak area at 450 nm against a β-carotene standard curve dissolved in dichloromethane/methanol (1:4, vol/vol).

Physical characteristics of micelles. Mixed micelles were prepared as described above, but using PBS as the dissolving medium. The UV-visible spectra (250–600 nm) of β-carotene in mixed micelles were taken in a spectrophotometer (Model U-3310, Hitachi, Japan) equipped with a water-thermostatic cell holder connected to a water bath at 37°C. The spectral bandwidths were measured at the height equivalent to one-half of the absorbance at the absorption maximum (λ_{max}) of each spectrum (full width at half maximum, FWHM). For measurement of the micelle size, β-carotene-free micelles were prepared in PBS with the same lipid composition as the original micelles. Micelle size was measured with a dynamic light scattering spectrophotometer (Otsuka Electronics, Osaka, Japan) at room temperature, using a He-Ne laser source.

Statistical analyses. Data from the uptake, transport, and efflux experiments are the means ± SD of a minimum of four wells per treatment within a single experiment, which were selected from at least three independent experiments with similar results. Statistical treatments of data consisted of one-way ANOVA, followed by *post hoc* comparisons by the Tukey-Krammer method at a 95% confidence interval.

RESULTS

In order to assess the involvement of LysoPC and PC acyl moieties on β-carotene uptake, we compared the β-carotene uptake by Caco-2 cells incubated for 2 h with micelles containing 50 μmol/L of LysoPC or PC with a wide range of acyl chain lengths. Phospholipid-free (NoPL) micelles were used as controls in each experiment. Although the initial micellar β-carotene concentration was kept between 0.9 and 1.1μmol/L, the uptake varied between experiments, depending on the Caco-2 cell passage number and other factors beyond our knowledge. Therefore, statistical comparisons were always made within one experiment, with simultaneously plated cells, from the same passage number.

The present study showed that short-chain PC, namely 4:0,4:0-PC and 6:0,6:0-PC, did not reduce β-carotene uptake by Caco-2 cells (Fig. 1A). Medium-chain PC with 8:0,8:0- to 12:0,12:0- acyl chains increased β-carotene uptake, with the highest uptake rates from micelles containing 10:0,10:0-PC, followed by those containing 12:0,12:0-PC and 8:0,8:0-PC (Fig.1A). Long-chain PC inhibited β-carotene uptake by Caco-2 cells, and the lowest uptake rates were from micelles containing 16:0,18:1-PC and 16:0,18:2-PC (Fig. 1B).

Among the LysoPC class, 6:0-LysoPC, 8:0-LysoPC (data not shown), and 10:0-LysoPC (Fig. 2) did not affect β-carotene uptake from micelles, as compared with the uptake from phospholipid-free (NoPL) control micelles. With the increase of the LysoPC acyl chain length from 12:0 to 16:0, we observed a marked increase in β-carotene uptake. The β-carotene uptake from micelles containing 18:1-LysoPC, the only LysoPC within this study having an unsaturated acyl chain, was slightly lower than that from 16:0-LysoPC micelles; however, it was still significantly higher than the β-carotene uptake from NoPL micelles (Fig. 2).

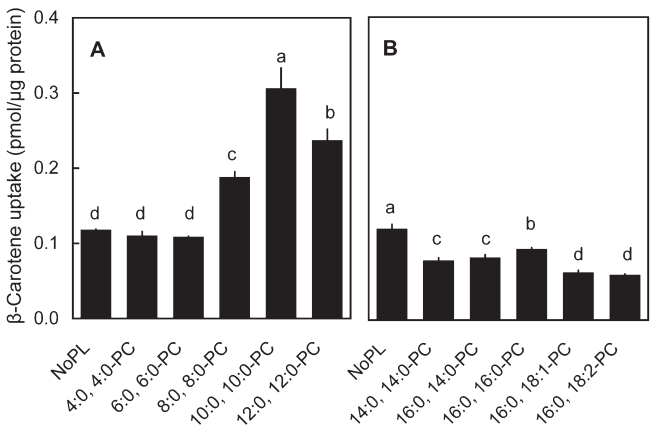

FIG. 1. Effects of short-to-medium-chain PC (A) or long-chain PC (B) on β-carotene uptake by Caco-2 cells. β-carotene (*ca.* 1 μmol/L) mixed micelles, prepared in serum-free DMEM, contained no phospholipid (NoPL) or 50 μmol/L of the corresponding phospholipid, and were incubated for 2 h at 37°C with Caco-2 cells (20–22 d post-seeding) on conventional 24-well plates. Bars represent the means ± SD of ≥ 4 wells, from a single experiment, selected from three independent experiments with similar results. Values within one graph not sharing a common letter are significantly different by the Tukey-Krammer test ($P < 0.05$).

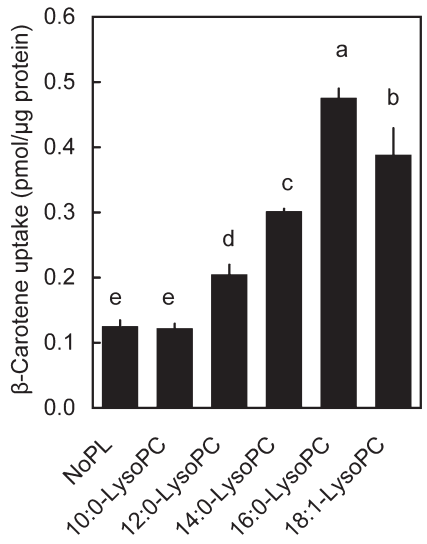

FIG. 2. Effects of medium-to-long-chain LysoPC on β-carotene uptake by Caco-2 cells. β-carotene (*ca.* 1 μmol/L) mixed micelles, prepared in serum-free DMEM, contained no phospholipid (NoPL) or 50 μmol/L of the corresponding phospholipid, and were incubated for 2 h at 37°C with Caco-2 cells (20–22 d post-seeding) on conventional 24-well plates. Bars represent the means ± SD of ≥ 4 wells, from a single experiment, selected from three independent experiments with similar results. Values not sharing a common letter are significantly different by the Tukey-Krammer test ($P < 0.05$).

TABLE 1
Effect of Phosphatidylcholine and Lysophosphatidylcholine with Various Acyl Moieties on the Micellar and Extramicellar β-Carotene Recovery in the Medium after Incubation with the Caco-2 Cells

Phospholipid type	Micellar β-carotene	Extramicellar β-carotene
Medium-to-long-chain LysoPC		
NoPL	16.0 ± 1.6^{e}	49.6 ± 1.6^{e}
10:0-lysoPC	16.4 ± 1.9^{e}	47.3 ± 1.9^{e}
12:0-lysoPC	25.8 ± 1.6^{d}	49.4 ± 1.6^{d}
14:0-lysoPC	41.8 ± 1.5^{c}	19.9 ± 1.5^{c}
16:0-lysoPC	48.4 ± 0.9^{b}	1.6 ± 0.9^{b}
18:1-lysoPC	56.2 ± 3.4^{a}	2.5 ± 3.4^{a}
Short-to-medium-chain PC		
NoPL	15.4 ± 3.1^{c}	51.0 ± 3.1^{c}
4:0,4:0-PC	17.8 ± 1.2^{c}	7.6 ± 1.2^{c}
6:0,6:0-PC	17.5 ± 1.9^{c}	9.0 ± 1.9^{c}
8:0,8:0-PC	50.9 ± 1.4^{b}	21.6 ± 1.4^{b}
10:0,10:0-PC	60.0 ± 0.9^{a}	6.1 ± 0.9^{a}
12:0,12:0-PC	63.5 ± 1.9^{a}	4.4 ± 1.9^{a}
Medium-to-long-chain PC		
NoPL	16.7 ± 2.0^{d}	52.7 ± 2.0^{d}
14:0,14:0-PC	76.2 ± 1.2^{bc}	50.7 ± 1.2^{bc}
16:0,14:0-PC	73.6 ± 1.2^{c}	39.3 ± 1.2^{c}
16:0,16:0-PC	60.3 ± 1.9^{c}	26.0 ± 1.9^{c}
16:0,18:1-PC	79.6 ± 1.0^{b}	2.2 ± 1.0^{b}
16:0,18:2-PC	84.0 ± 3.0^{a}	0.9 ± 3.0^{a}

Values are percent of the initial micellar β-carotene, reported as means ± SD of ≥ 4 wells from a single experiment, selected from three independent experiments with similar results. Values within one experiment not sharing a superscript letter are significantly different according to the Tukey-Krammer test ($P < 0.05$).

The micellar and extramicellar β-carotene recoveries in the medium at the end of the incubation with Caco-2 cells were largely influenced by the phospholipids. The 12:0- to 18:1-LysoPC significantly improved micellar β-carotene and reduced extramicellar β-carotene recoveries, in comparison with those of the NoPL micelles (Table 1). The micellar recoveries increased with the lengthening of the LysoPC acyl chains (Table 1). Short-chain PC (namely 4:0,4:0-PC and 6:0,6:0-PC) did not change micellar β-carotene recoveries, whereas medium- and long-chain PC drastically increased these values, as shown by lower extramicellar β-carotene recoveries in the medium, in comparison with the values for the NoPL micelles (Table 1). When incubated in the absence of cells, more than 95% of the initial β-carotene was retained in the micellar phase, regardless of the micelle phospholipid composition (data not shown).

The NoPL micelles had a diameter of 61.6 ± 8.9 nm, and the 16:0-LysoPC micelles were of a similar size (diameter 63.4 ± 17.7 nm) regardless of their marked improvement of β-carotene uptake. The micelles containing 10:0,10:0-PC (diameter 38.3 ± 4.9 nm) were smaller than the NoPL micelles and had higher β-carotene uptake ratios compared with those from NoPL micelles. However, the 16:0,18:1-PC micelles had the smallest diameter (15.4 ± 5.2 nm), despite the low β-carotene uptake rates from these micelles. Thus, micelle size was not associated with β-carotene uptake.

The UV-visible absorbance spectrum of β-carotene is known to change according to its interaction with the solvent or the microenvironment in which it is dissolved (21,22). Therefore, we obtained the UV-visible absorbance spectra of β-carotene in solvents and mixed micelles prepared in PBS. Compared with the typical β-carotene spectrum in hexane with λ_{max} = 449.4 nm (Fig. 3), the absorbance spectrum of β-carotene in oleic acid showed a bathochromic shift to λ_{max} = 460.0 nm. The absorption maxima of β-carotene in all micelles were similar to that observed in oleic acid. However, a broadening was observed in the spectra of the NoPL, 16:0-LysoPC, and 10:0,10:0-PC micelles, whose bandwidths (FWHM) were 94.0, 92.5, and 93.3 nm, compared with 80.0 nm of the β-carotene spectrum in oleic acid. Micelles containing 16:0,18:1-PC had a further broadened spectrum, with FWHM = 104.0 nm (Fig. 3). In addition to the increase of spectral bandwidth, 16:0,18:1-PC caused a 21.2% hypochromic effect (relative to the absorbance in oleic acid). The NoPL, 16:0-LPC, and 10:0,10:0-PC micelles exhibited 6.3–7.7% hypochromic effects.

Considering that the β-carotene uptake would result from a net positive flux into cells, a large efflux from β-carotene-loaded cells would denote a higher partitioning ratio or affinity of β-carotene toward the micelles and away from the cell membrane. The affinity between β-carotene and the micelles containing no phospholipid, 16:0-LysoPC, or 16:0,18:1-PC was evaluated by measuring the β-carotene efflux from Caco-2 cells to the micelles in the apical medium. Little efflux occurred from Caco-2 cells to the NoPL micelles (Fig. 4), whereas the 16:0-LysoPC micelles caused a larger β-carotene

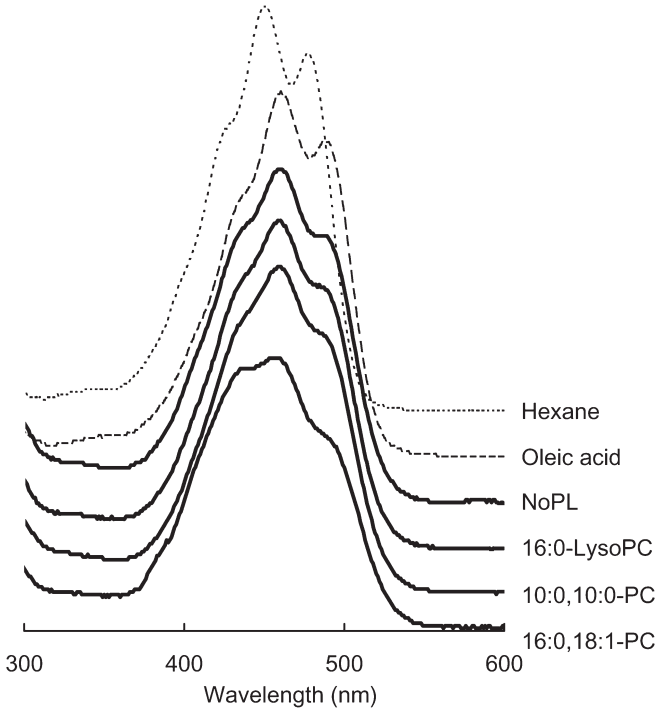

FIG. 3. UV-visible spectra of β-carotene at 37°C in hexane (dotted line; λ_{max} = 449.4 nm), oleic acid (dashed line; λ_{max} = 460.0 nm), or mixed micelles (solid lines), which were either phospholipid-free (NoPL; λ_{max} =459.5 nm) or contained 16:0-LysoPC (λ_{max} = 458.5 nm), 10:0,10:0-PC (λ_{max} = 457.3 nm), or 16:0,18:1-PC (λ_{max} = 458.7 nm). The micelles were prepared in PBS, with a lipid composition identical to that used for the uptake experiments (see Experimental Procedures). The β-carotene concentrations of all preparations were within 1.07–1.12 μmol/L.

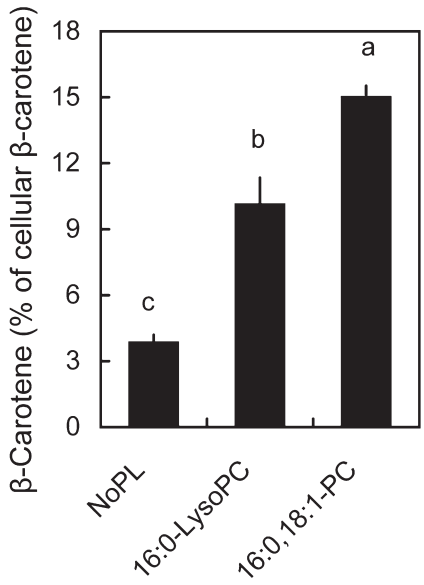

FIG. 4. β-carotene efflux from Caco-2 cells to micelles in medium containing 16:0-LysoPC, 16:0,18:1-PC, or no phospholipid (NoPL). Caco-2 cells (20–22 d post-seeding) in conventional 24-well plates were incubated for 2 h at 37°C with mixed micelles containing 1.5 μmol/L β-carotene and 50 μmol/L 16:0-LysoPC, in serum-free DMEM. After the uptake period, the cells were washed with serum-free DMEM and received β-carotene-free micelles containing none or 50 μmol/L of the corresponding phospholipid, and were incubated for 2 h at 37ºC. The β-carotene effluxed to the medium in each well was calculated as a percentage of the initial level of β-carotene accumulated in the Caco-2 cells. Bars represent the means ± SD of 4 wells, from a single experiment, selected from three independent experiments with similar results. Values not sharing a common letter are significantly different by the Tukey-Krammer test ($P < 0.05$).

efflux. The largest β-carotene efflux was observed for the 16:0,18:1-PC micelles (Fig. 4), indicating a great affinity between β-carotene and the micelles containing PC.

The β-carotene uptake during the 16-h incubation with Caco-2 cells grown in permeable supports (Transwell) showed a similar trend to that observed for Caco-2 monolayers in conventional 24-well plates (2-h incubation): 16:0,18:1-PC inhibited β-carotene uptake (although not significantly in this experiment), whereas 10:0,10:0-PC and 16:0-LysoPC enhanced it (Fig. 5). The amount of β-carotene secreted to the basolateral side was the lowest for cells incubated with NoPL micelles. The presence of 10:0,10:0-PC, 16:0,18:0-PC, or 16:0-LysoPC in the apical side significantly enhanced β-carotene secretion to the basolateral medium, with the highest values observed for cells incubated with micelles containing 16:0-LysoPC (Fig. 5). However, the amount of β-carotene secreted to the basolateral side was not proportional to its cellular uptake. The basolateral/cellular β-carotene ratio was the lowest for NoPL micelles (0.078 ± 0.012), increased significantly when 16:0-LysoPC (0.144 ± 0.010) or 10:0,10:0-PC (0.130 ± 0.020) was added to the mixed micelles, and reached the highest values when the micelles contained 16:0,18:1-PC (0.313 ± 0.026, Fig. 5), despite the low β-carotene uptake from these micelles. After the incubation with the micelles, the TEER values and the amount of triglycerides in the basolateral medium were similar in all treatments (data not shown).

DISCUSSION

Phospholipids are known to modulate the absorption of lipophilic compounds, including carotenoids. Previous studies showed that PC caused a marked inhibition of carotenoid absorption by Caco-2 cells, rats, and mice, whereas LysoPC enhanced it (12,17,18). However, the mechanisms underlying this phenomenon remain largely unknown. We hypothesized that once carotenoids are solubilized in mixed micelles, their interactions with the hydrophobic parts of micelle lipids as well as the interaction of micellar components with cell membranes may modulate the intestinal uptake of carotenoids. Therefore, we investigated the effects of micellar phospholipids and lysophospholipids with various fatty acyl moieties on β-carotene uptake by Caco-2 cells, relating the β-carotene availability to its surrounding microenvironment inside the micelles.

Despite the general knowledge that egg PC, soy PC, and pure dipalmitoyl- or palmitoyl-oleoyl-PC inhibit carotenoid uptake (13,16,23,24), and that LysoPC enhances it (12,17,18),

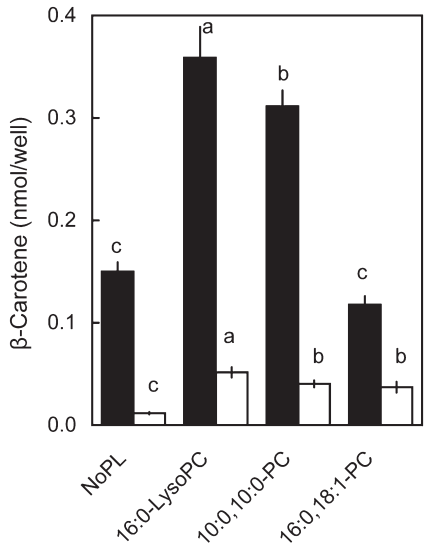

FIG. 5. Effects of 16:0-LysoPC, 10:0,10:0-PC, and 16:0,18:1-PC on β-carotene uptake and secretion to the basolateral side of Caco-2 monolayers. The mixed micelles in serum-free DMEM (1.5 mL) containing *ca.* 1 μmol/L β-carotene without phospholipid (NoPL) or with 50 μmol/L of the corresponding phospholipid were placed in the apical side of Caco-2 monolayers in 6-well Transwell plates. The basolateral side received 2.5 mL of 10% FBS-DMEM, and the cells were incubated for 16 h at 37°C. The solid bars represent the amount of β-carotene in the cells, and the open bars represent the β-carotene secreted to the basolateral medium (nmol/well). Values are means ± SD of 3–4 wells, from a single experiment, selected from three independent experiments with similar results. Values represented by the same symbols that do not share a common letter are significantly different by the Tukey-Krammer test ($P < 0.05$).

almost no information is available on the role of phospholipids' acyl groups in this event. Our results showed that in fact only medium-to-long-chain LysoPC (12:0- to 18:1-LysoPC) enhanced β-carotene uptake. Likewise, the effect of PC on β-carotene uptake was related to their acyl chain lengths. Long-chain PC (with 14:0 or longer fatty acyl chains) inhibited β-carotene uptake, whereas medium-chain PC (with 8:0 to 12:0 fatty acyl chains) enhanced β-carotene uptake by Caco-2 cells. The acyl moieties of naturally occurring PC are mostly long-chain; therefore, our results are in agreement with previous reports on the reduced uptake of lipophilic compounds by egg yolk or soy PC (23,24) However, the enhancement of β-carotene uptake by 8:0,8:0-, 10:0,10:0-, and 12:0,12:0-PC has not been previously reported. The 10:0,10:0-PC enhanced β-carotene uptake in comparable efficiency to 16:0-LysoPC. In accordance with our findings, 10:0;10:0-PC and 16:0-LysoPC were found to be equivalent enhancers of propanolol permeation across porcine buccal mucosa *ex vivo* (25) and had similar CMC, which were 5 ± 2 μmol/L for 10:0,10:0-PC (26) and 4.00 ± 0.35 μmol/L for 16:0-LysoPC (27). The CMC values decrease exponentially with the increase of methylene groups in the acyl moieties of PC and LysoPC (27), confirming that the hydrophobicity of 10:0,10:0-PC was nearly equivalent to that of 16:0-LysoPC, and providing evidence that the enhancement of the β-carotene uptake by long-chain LysoPC and medium-chain PC is related to their amphiphilic properties. Nevertheless, we cannot disregard the possibility that LysoPC may enhance β-carotene uptake by stimulating the intracellular processing of lipids, facilitating the formation and secretion of chylomicrons (16).

Medium-chain PC and long-chain LysoPC may facilitate the permeation of β-carotene by altering cell membrane properties. Short- and medium-chain PC have been reported to be very effective biosurfactants (28,29), like the long-chain LysoPC (30). 10:0,10:0-PC enhances drug absorption by the nasal epithelium (31,32), probably by altering the permeability of the cell membrane. At concentrations in the millimolar range (10^3-fold the concentrations used in our experiments), 7:0,7:0-PC solubilizes cell membranes, forming micellar aggregates (28,29), promoting cell lysis mainly by interaction with the membrane lipids. At lower concentrations, when 7:0,7:0-PC penetrates into the outer leaflet of the cell membrane, it generates a wedge-like effect due to its large polar head and short acyl chains (29). In a similar way, long-chain LysoPC would disturb membrane bilayer packing due to their cone-like shape (30). Therefore, the similar increases of β-carotene uptake by 8:0,8:0- to 12:0,12:0-PC and 14:0- to 18:1-LysoPC in our study is in agreement with the similar effects of short-to-medium-chain PC and long-chain LysoPC on membrane permeability.

Changes in the microenvironment surrounding the β-carotene molecule within the micelle structure may modulate carotenoid desorption and, therefore, cellular uptake. The UV-visible absorbance spectra of carotenoids are known to change according to the interactions between the carotenoid and its surrounding environment such as solvents (21), the interior of lipoprotein particles (33), and aggregated carotenoid molecules(34,35). The λ_{max} is proportional to solvent polarizability, and thus to its refractive index (21). The λ_{max} in the UV-visible spectra of β-carotene solubilized in mixed micelles was shifted to approximately 460 nm. A similar λ_{max} was observed when β-carotene was dissolved in oleic acid. Therefore, in our experiments β-carotene was most likely to be solubilized in a microenvironment with similar polarizability to that of oleic acid. Such environment corresponds to the micelle core, where the β-carotene molecule is surrounded by the hydrophobic moieties of oleic acid and monoolein. Further comparisons between the β-carotene UV-visible spectra in mixed micelles and those in oleic acid indicated slight higher FWHM values for the spectra of NoPL, 16:0-LPC, and 10:0,10:0-PC micelles. An additional spectral broadening and a partial loss of the vibrational fine structure were detected in the spectrum of 16:0,18:1-PC. Hashimoto *et al.* (34) reported increases in the spectral bandwidth along with increases of β-carotene aggregation levels. Therefore, in the present study, part of the β-carotene molecules may have aggregated in the micelle interior, particularly when it contained 16:0,18:1-PC, delaying β-carotene desorption from these micelles. The strong hypochromic effect caused by 16:0,18:1-PC also indicates a very distinct microenvironment surrounding the β-

carotene molecules in micelles containing this phospholipid (33).

Considering that β-carotene uptake would depend on a concentration gradient between the micellar phase in the medium and the cells, we cannot rule out the possibility that an increased micellar β-carotene recovery at the end of the incubation would favor higher uptake rates. However, the incorporation of long-chain PC (14:0,14:0-, 16:0,14:0-, 16:0,16:0-, 16:0,18;1-, and 16:0,18:12-PC) markedly enhanced micellar β-carotene recovery, without proportional increases in β-carotene uptake. This indicates that the β-carotene level in the micellar phase was not the major factor modulating the uptake. Instead, the micelle's capacity to hold or retain the carotenoid molecule and to delay its desorption to the intermicellar phase may modulate carotenoid uptake.

Smaller micelles are believed to travel faster through the unstirred water layer in the small intestine and reach the epithelial cells. Nevertheless, our data indicate that micelle size was not correlated with the β-carotene uptake by Caco-2 cells. Using segments of rabbit small intestine, Rampone and Machida (13) also found no relation between micelle size and the uptake of cholesterol.

Given that micelle size and micellar β-carotene recovery could not fully explain the effects of phospholipids on β-carotene uptake, we evaluated the affinity between β-carotene and mixed micelles by measuring β-carotene efflux from β-carotene-enriched cells back to carotene-free micelles in the apical medium. In comparison with the β-carotene efflux to NoPL and l6:0-LysoPC micelles, the larger β-carotene efflux to micelles containing 16:0,18:1-PC indicated a strong affinity between β-carotene and these micelles, shifting the partition of β-carotene from the cells toward the micelles, and supporting the hypothesis of a restricted desorption of β-carotene from mixed micelles containing long-chain PC. In agreement with these results, Hamada *et al.* (24) reported that the presence of egg yolk PC in the micelle reduced cholesterol transfer to triolein *in vitro*, and inhibited cholesterol absorption by rats and by Caco-2 cells.

Considering the lipophilic nature of carotenoids, their intracellular transport may resemble that of other lipids. However, most of the mechanisms regarding the intracellular transport of carotenoids, as well as the factors regulating its efficiency, remain unknown. We compared the effects of selected PC and LysoPC on the apical uptake and basolateral secretion of β-carotene by using Caco-2 cells grown in porous membranes (Transwell). The results for uptake resembled those from Caco-2 in conventional wells. However, compared with the NoPL control, 16:0,18:0-PC stimulated β-carotene secretion to the basolateral side, despite its low uptake. Mathur *et al.* (36) reported an increased secretion of triacylglycerol-rich lipoproteins when Caco-2 cells were incubated with di18:1-PC or egg-PC. An increase of triacylglycerol and apolipoprotein B synthesis in cells and their subsequent secretion to the basolateral side would explain the relative increase of β-carotene secretion by 16:0,18:0-PC observed in our experiment. However, we did not detect any change of triacylglycerol secretion (data not shown), and we did not assess the apolipoprotein B secretion to the basolateral medium. In our experiments, the concentration of phospholipids in the apical medium was one-fifth of that used in the study by Mathur *et al.* (36), which could explain the discrepancy with our results. Therefore, the explanation for such increase of β-carotene secretion by phospholipids awaits further investigation.

The absorption of carotenoids and other lipophilic compounds involves their solubilization in mixed micelles prior to uptake by the enterocytes. In the present study, we showed that the β-carotene uptake was largely affected by the fatty acyl moieties of phosphatidylcholines and lysophosphatidylcholines in mixed micelles. Although the entire mechanism involved in the modulation of β-carotene absorption by these phospholipids remains to be clarified, this study showed that the long acyl chains of PC molecules interact with β-carotene in the micelle interior, shifting the partition toward the micellar phase and inhibiting carotenoid uptake by enterocytes. Medium-chain PC and long-chain LysoPC have similar amphiphilic properties and may enhance β-carotene uptake by increasing cell membrane permeability.

ACKNOWLEDGMENTS

We are grateful to Prof. Sosaku Ichikawa (Tsukuba University) for his kind advice on the measurement of micelle size. This work was supported in part by a postdoctoral fellowship from the Japan Society for the Promotion of Science to L.Y. and by the MAFF Nanotechnology Project.

Fatty Acid Composition of Habitual Omnivore and Vegetarian Diets

Neil Mann*, Yvonne Pirotta, Stella O'Connell, Duo Li, Fiona Kelly, and Andy Sinclair

Lipid Research Group, School of Applied Science, RMIT University, Melbourne 3001, Australia

ABSTRACT: High-fat diets are implicated in the onset of cardiovascular disease (CVD), cancer, and obesity. Large intakes of saturated and *trans* FA, together with low levels of PUFA, particularly long-chain (LC) omega-3 (n-3) PUFA, appear to have the greatest impact on the development of CVD. A high n-6:n-3 PUFA ratio is also considered a marker of elevated risk of CVD, though little accurate data on dietary intake is available. A new Australian food composition database that reports FA in foods to two decimal places was used to assess intakes of FA in four habitual dietary groups. Analysis using the database found correlations between the dietary intakes of LC n-3 PUFA and the plasma phospholipid LC n-3 PUFA concentrations of omnivore and vegetarian subjects. High meat-eaters (HME), who consumed large amounts of food generally, had significantly higher LC n-3 PUFA intakes (0.29 g/d) than moderate meat-eaters (MME) (0.14 g/d), whose intakes in turn were significantly higher than those of ovolacto-vegetarians or vegans (both 0.01 g/d). The saturated FA intake of MME subjects (typical of adult male Australians) was not different from ovolacto-vegetarian intakes, whereas n-6:n-3 intake ratios in vegetarians were significantly higher than in omnivores. Thus, accurate dietary and plasma FA analyses suggest that regular moderate consumption of meat and fish maintains a plasma FA profile possibly more conducive to good health.

Paper no. L9979 in *Lipids 41*, 637–646 (July 2006).

The high dietary fat intake of Western societies has been implicated as a major cause of chronic diet-related diseases such as cardiovascular disease (CVD), which is one of the leading causes of premature death in these societies. However, the absolute intake of dietary fat may be less important than the type of fat ingested (1). Blood cholesterol levels, which are linked with risk of heart disease, are strongly related to the percentage of total dietary energy intake provided by saturated fats (2). A diet high in saturated FA (SFA) and low in PUFA is an important contributor in the onset of atherosclerosis and CVD (3). Only one SFA, stearic acid (18:0), is an exception to this, as it has no effect or actually helps to lower LDL cholesterol levels, echoing the effects of monounsaturated FA (MUFA) and PUFA (4).

Abbreviations: AA, arachidonic acid; BMI, body mass index; BP, blood pressure; CVD, cardiovascular disease; DPA, docosapentanoic acid; HME, high meat-eater; LA, linoleic acid; LNA, alpha-linolenic acid; LC, long-chain; MME, moderate meat-eater; MUFA, monounsaturated FA; ovolacto, ovolacto-vegetarian; SFA, saturated FA.

Dietary PUFA contain two biologically important and non-interchangeable groups, the omega-3 (n-3) and omega-6 (n-6) PUFA. Numerous studies have indicated the positive effects on health of PUFA from both n-3 and n-6 families. However, the long-chain (LC) forms of n-6 PUFA (those with >18 carbon atoms) give rise to several eicosanoids with deleterious effects, whereas LC n-3 PUFA produce eicosanoids with beneficial cardiovascular effects (5). Because n-3 and n-6 FA compete for the same enzymes for conversion to the different vasoactive eicosanoids, the balance of intake of these FA will largely determine the type and amounts of eicosanoids that are present in the human body (6).

The most abundant dietary n-3 PUFA is α-linolenic acid (LNA, 18:3n-3), found mainly in plant foliage and some plant oils such as flaxseed, soybean, and canola (7). It is a metabolic precursor for LC n-3 PUFA such as EPA (20:5n-3) and DHA (22:6n-3), both of which have numerous and beneficial roles in eicosanoid formation and cell membrane function. These roles of EPA and DHA have been reviewed elsewhere (8). However the conversion of LNA to EPA and DHA in humans is notoriously poor; in males for example the conversion of dietary LNA to EPA has been shown to be of the order of 3–8%, with only minute amounts proceeding through to DHA (9). Due to the competition between linoleic acid (LA, 18:2n6) and LNA for the same elongase and desaturase enzymes, the usual high LA intakes observed in Western diets further suppresses the conversion of the relatively small dietary intake of LNA to EPA and DHA (10), although there can be substantial elongation and desaturation of LNA to EPA in diets very low in LA (11). Consumption of the foods and supplements rich in the preformed LC n-3 PUFA (EPA, DHA) lead to more significant and rapid increases in tissue levels of these LC PUFA (9). These foods include oily fish, fish oils rich in EPA and DHA, and lean meats rich in EPA and docosapentanoic acid (DPA, 22:5n-3) and seal oils rich in EPA, DPA, and DHA (12).

The importance of dietary n-3 PUFA was first highlighted by studies on Greenland Eskimos, whose consumption of large amounts of marine animals contributed to a high n-3 PUFA intake that appeared to be responsible for their low occurrence of CVD despite a high-fat diet (13). Several clinical and epidemiological studies have supported the role of n-3 PUFA in preventing CVD (14). Two of particular significance were the DART (Diet and Reinfarcation Trial), which showed a 62% reduction in CVD-related deaths in subjects consuming 450 mg/d of EPA and DHA (15) and the GISSI prevention trial, which

showed that post–myocardial infarct patients taking 850 mg/d of n-3 PUFA had a 30% reduction in coronary death over 3.5 y (16). In more recent times, LC n-3 PUFA have been shown to have some benefits in the area of psychiatric disorders (17,18).

Clinical trials have also indicated a reduction of plasma triglycerides in subjects who consumed n-3 PUFA (19), whereas consumption of LC n-3 PUFA also prolongs bleeding time by decreasing platelet activity (20) and also shows improvements in insulin sensitivity (21). However, because plants cannot convert LNA to LC n-3 PUFA, humans on plant-based diets must rely on endogenous synthesis to obtain these valuable LC n-3 PUFA (22).

The intake as well as type of n-3 PUFA recommended in different countries varies greatly, depending on the scientific rationale on which it was based (i.e., whether an intake level was selected to avoid deficiency, affect biomarkers, or prevent disease) (23). The recommended daily British intake for LC n-3 PUFA is 1,430 mg of EPA and DHA combined for men and 1,145 mg for women (23,24). An expert committee in the Netherlands recommends a daily intake of 200 mg LC n-3 PUFA (25). However, an expert committee from the International Society for the Study of Fatty Acids and Lipids (ISSFAL) promotes a minimum intake of double this amount, 500 mg/d combined EPA and DHA (26). A recent French survey found a mean intake of LC n-3 PUFA of 497 mg/d in men and 400 mg/d in women (27). These intakes essentially matched the French recommendations for LC n-3 PUFA consumption: 500 mg/d, including DHA intake of 120 mg/d, for men; and 400 mg/d, with 100 mg/d DHA intake, for women (27). The American Heart Association recommends that all adults without CHD consume approximately 1,000 mg/d of EPA and DHA combined (28). The intake for Americans is apparently below these levels, with an average total consumption of 1,600 mg/d total n-3 PUFA, mainly from LNA, with an estimate of 200 mg/d from EPA and DHA (29). Many organizations now present recommendations in terms of ratios between LA and LNA, as the major sources of n-6 and n-3 PUFA, or as a percentage of total energy intake, such as a recommendation for n-3 PUFA intake of 1–2% of daily energy for the general adult population by the World Health Organisation (30).

In Australia, the majority of n-3 PUFA in the diet is also LNA from plant matter (31). There is evidence that consumption of Australian red meat increases LC n-3 PUFA levels in plasma phospholipids (32), but there has been an overall drop in the consumption of meat as well as poultry and fish, previously the major sources of LC PUFA**,** in the Australian diet (33). The increased intake of sugar, alcohol, dairy products, and grain-based products (rich in LA), which now provide over 60% of energy in the average western diet (34), is a trend that may have negative consequences for health by reducing n-3 PUFA intake and overemphasising n-6 PUFA intake, leading to a systemic imbalance in these two FA families.

Since the 1960s, the introduction of new foods containing PUFA, such as polyunsaturated margarines and cooking oils, initially led to changes in the types of fats eaten by consumers in Australia without changing their total fat intake (35). However, a survey of dietary habits in Australia in 1993 found that fat consumption was now decreasing in the average diet, mainly because of a reduced consumption of PUFA (36). This conclusion was supported by the large National Nutrition Survey of 1995 (NNS 1995), which indicated that the total intake of PUFA in the Australian diet had decreased to 5% of total energy intake in both men and women (37), but little is known about LC PUFA intake.

The modest levels of LC PUFA present in foods have previously been difficult to measure to more than a tenth of a gram per 100 g, with lesser amounts than this recorded as zero in food composition tables and therefore discounted entirely in dietary analyses. In NUTTAB 95, a comprehensive food composition database widely used for dietary analyses in Australia (38), the previous FA supplement was limited, if not inaccurate, due to old laboratory techniques (packed-column GC) and because it related to foods present in the food supply prior to 1992 rather than current foods (39). Development of new technology now enables more accurate FA measurement and hence recording of trace LC PUFA amounts in foods. In the wake of this, the FA database recently developed at RMIT University Melbourne reports FA values in foods to two decimal places, enabling far greater accuracy in the calculation of dietary intakes of LC PUFA in individual subjects (40).

The aim of this study was to determine the amount, type, and source of FA, particularly LC PUFA, in four habitual diets consumed by healthy male Australian subjects, and to compare the dietary intakes for each individual with their plasma FA levels of corresponding FA.

EXPERIMENTAL PROCEDURES

Background. This study formed part of a larger study examining health aspects of four habitual diet groups (41). The study was approved by the Human Ethics Committee of RMIT University, and all subjects consented in writing to participation.

Subjects. Data was collected from 147 healthy male nonsmokers aged 20–55 y and originally recruited through university advertisements and local Melbourne newspapers. Selection criteria involved exclusion of volunteers if they showed evidence of CVD or had a family history of CVD, hypertension, renal disease, hyperlipemia, hematological disorders, diabetes, or excessive alcohol intake, or if they took medications or nutrient supplements (41). Eight recruited subjects were subsequently eliminated (prior to data analysis or diet group identification) due to abnormally high blood pressure and/or lipoprotein lipids or the use of medications. A final cohort of 139 healthy male subjects was investigated.

Data collection and grouping of subjects. Anthropometric data such as age, weight, height, and body mass index (BMI) were recorded for each subject and a semiquantitative food frequency questionnaire completed with assistance from trained nutritionists and a dietician. The dietary information obtained was first analyzed (41) using Diet 1 version 4 software (Xyris, Brisbane) combined with the NUTTAB 95 database, which is based on the published Composition of Foods, Australia (42).

Data was obtained for the intake of nutritional factors including total energy, total fat, and the three fat subgroups: saturated fats, monounsaturated fats, and polyunsaturated fats.

Subjects were divided into groups on the basis of their habitual food intake during the 6 mon prior to the study. When the daily meat intake of the meat-eaters was plotted in a scatter diagram, it was found that subjects divided naturally into two distinct groups: those who consumed less than 260 g/d meat (which included lean meat cuts and the meat portion of meat products, dishes, and takeaway foods) and those who consumed 285 g or more meat per day (163.2 ± 48.4 g vs. 387.2 ± 122.0 g, mean ± SD, $P < 0.001$). The two groups were therefore known as the MME and HME, although these descriptions did not take into account the relative quantities of other foods consumed. In general, the HME consumed considerably more total food by weight and energy intake on a daily basis than the MME (16.4 ± 3.3 MJ vs. 11.3 ± 2.5 MJ, $P < 0.001$). The non-meat-eaters were divided into the ovolacto-vegetarian (ovolacto) group, where subjects ate meat no more than six times per year but consumed eggs and dairy products, and the vegan group, who consumed no meat or eggs, and dairy products no more than six times per year (41). Hence, the four subject groups consisted of HME (n = 18), MME (n = 60), ovolacto (n = 43), and vegans (n = 18). However, 13 of these subjects were excluded from the dietary analysis part of the study because of incomplete or questionable dietary data (underreporting, energy intake < 95% of BMR; overreporting > 160% BMR). Hence reliable dietary intake data was collected for 126 subjects from the four subject groups, consisting of HME (n = 16), MME (n = 53), ovolacto (n = 40), and vegans (n = 17).

FA analysis. The dietary data was analyzed using the FA database developed by the RMIT University Lipid Research Group (40) (which is included in the Food Works software package, Xyris, Brisbane). The database includes sections of the NUTTAB 95 FA supplement (39) and covers 11 SFA, 7 MUFA, 10 PUFA (6 n-6 and 4 n-3), and 3 *trans* FA. FA data (g/100 g food) is presented to two decimal places for 1,044 Australian foods (concentrating on common foods, lipid-rich foods, and any foods in the Australian diet containing LC PUFA), enabling meaningful data to be obtained for the dietary LC PUFA intake of subjects. To ensure consistency of data, the total fat content generated by the FA database was compared with the NUTTAB 95 database values for individual fat content of foods. Also the total fat consumption derived from analysis of each subjects food frequency questionnaire using the new FA database was validated against the NUTTAB 95 dietary analysis for total fat intake.

Where study subjects had consumed foods that were not listed in the FA database, these were replaced during analysis (following standard dietary analysis procedures) by a related food with a similar FA profile (e.g., Weetbix entered as "wheat breakfast biscuit"; milkshake entered as "milk, flavored, chocolate, fluid"). Replacement was not always possible, as many complex foods consumed by subjects were not present in the FA database. In that case, "recipes" were created using ingredients already present in the FA database to produce replacement food items containing similar overall total fat contents and FA profiles. The new food items were then added to the database. However, these food items were all low-fat with minimal LC PUFA content; thus, any inaccuracy involved in this process had minimal impact on the accumulated LC PUFA content of the habitual diets. The dietary intake data for all the subjects, and subsequently their FA profiles, were grouped according to their habitual diet. The mean total fat intake and intake of each FA was then calculated for each dietary group.

Plasma phospholipid FA determination. Plasma was obtained from citrated (overnight fasted) whole blood by centrifugation at 3,000 rpm for 15 min at 4°C. Plasma phospholipid (PL) fractions were separated by TLC. The FAME of the plasma phospholipids were prepared by saponification using potassium hydroxide (0.68 mol/L methanol) and transesterification with 20% boron trifluoride in methanol. The FA compositions of plasma phospholipids were determined by gas-liquid chromatography as previously described (41).

Statistical analysis. One-way ANOVA was carried out (SPSS v. 12, SPSS Inc, Chicago, IL) to compare the variability in scores for each FA intake between the four habitual diet groups. The Levene test for homogeneity of variance determined that all the FA intakes had a significantly different variance ($P < 0.05$) when a Bonferroni correction was applied, except for LNA ($P = 0.481$). The Tamhane and Dunnett T3 post-hoc tests were applied (using a significance level of $P < 0.05$) to the FA with non-equal variance. The equal-variance Tukey's HSD and Scheffe post-hoc tests were applied to the LNA data (significant at $P < 0.05$).

Regression analysis was carried out (SPSS v. 12) to determine whether there was a significant correlation between the subjects' mean intake levels (g/d) and their plasma phospholipid concentrations (mg/100 mL) of specific FA. Preliminary analyses were performed to ensure no violation of the assumption of normality, linearity, and homoscedasticity in the data. This involved generating a scatter plot for each correlation and inspecting the distribution of the data points to check for outliers, determining the direction of the relationship between the variables, confirming linearity, and ensuring that there were no unpaired data for the two variables.

RESULTS

The age, anthropometric, and blood pressure characteristics of each group (Table 1), have been published in detail previously (41). Both vegetarian groups had significantly lower BMI than the omnivore groups but there were no differences between the groups in systolic blood pressure, although diastolic pressures were lower in the ovolacto group than in the omnivore groups.

As explained in the Methods section, HME consumed significantly more meat, both white and red meat, than the MME group (Table 2). Vegans did not consume any meat, whereas the ovolacto group did not consume red meat but some individuals had occasional small intakes of white meat or fish. The HME group had a significantly higher energy intake than each

TABLE 1
Age, Anthropometric, and Blood Pressure Characteristics of Subjects in the Four Dietary Groups

Characteristic	High-meat group (HME) (n = 18)	Moderate-meat group (MME) (n = 60)	Ovolacto group (n = 43)	Vegan group (n = 18)
Age (years)	34.2 ± 9.4[a]	38.3 ± 7.3[b]	34.9 ± 9.0[a]	33.0 ± 7.7[a]
BMI	27.0 ± 3.4[a]	26.4 ± 3.4[b]	23.6 ± 2.8[c]	23.3 ± 3.5[c]
Waist/hip ratio	0.88 ± 0.06[a]	0.88 ± 0.05[a]	0.86 ± 0.04[b]	0.85 ± 0.05[b]
Systolic BP	129.8 ± 14.6	125.7 ± 10.5	124.4 ± 13.4	122.1 ± 9.7
Diastolic BP	83.4 ± 8.0[a]	81.7 ± 7.9[a]	77.7 ± 10.4[b]	77.7 ± 7.8[b]

Values are mean ± SD. Values in the same row that have different superscripts are significantly different from each other ($P < 0.01$).

of the other three dietary groups, and HME subjects consumed, as a percentage of energy intake, significantly more protein and fat and less carbohydrate than the other groups. Nonetheless, in all groups, the largest percentage of energy intake was supplied by carbohydrates, followed by fats and then proteins. The high energy intake and total fat intake of the HME was derived from their substantial consumption of all kinds of food, not just their meat intake (43).

Daily FA intakes. Table 3 displays the daily dietary intakes of specific FA for each of the four dietary groups. There was a significant difference ($P < 0.05$) between the dietary group values for myristic acid (14:0), palmitic acid (16:0), stearic acid (18:0), and total SFA. Compared with the other groups, the HME group consumed significantly more of each SFA and had the largest total intake of saturated fats (77.17 ± 33.81 g/d). The vegan group consumed significantly less of each SFA than the other groups and had the lowest total intake (16.71 ± 6.16 g/d). There was no significant difference between the individual and total SFA consumptions of the MME group (35.24 ± 15.81 g/d) and the ovolacto group (32.40 ± 14.51 g/d). The predominant SFA consumed by each dietary group was palmitic acid (16:0).

There was a significantly higher intake ($P < 0.05$) of both oleic acid (18:1) and total MUFA in the HME group compared with the other three groups (Table 3).

The intake of LA was lowest in the MME group (10.90 ± 5.69 g/d) by a significant margin ($P < 0.05$), whereas the other three groups had similar intakes (Table 3).

The HME group consumed significantly more LNA (1.96 ± 0.66 g/d) than any other group (Table 3), which appeared to be derived both from their higher intake of foods generally, including plentiful meats and some fish, and from a larger consumption of canola-based margarine and oils (43).

The intake of AA was significantly different for each of the four dietary groups, the only FA where this was the case. As AA is found only in animal tissue (44), it was not surprising that HME subjects consumed the largest amounts (0.24 ± 0.11 g/d), followed by the MME group (0.10 ± 0.04 g/d), ovolacto group (0.03 ± 0.03 g/d), and vegan group (0.00 ± 0.00 g/d) (Table 3).

Similarly, EPA and DPA, which are both present mainly in marine vertebrates (particularly deep-sea fish) and to a lesser extent terrestrial animals, were not consumed in measurable quantities by the ovolacto or vegan groups (Table 3). HME subjects consumed significantly more EPA (0.07 ± 0.02 g/d) and DPA (0.09 ± 0.05 g/d) than the MME group (0.04 ± 0.03 g/d and 0.03 ± 0.02 g/d, respectively) (Table 3).

There was no significant difference between the two omnivore groups in their intake of DHA, which is found mainly in foods of marine origin and eggs. The daily intakes of 0.12 ± 0.10 g for HME and 0.07 ± 0.10 g for MME subjects were significantly greater than that of the ovolacto subjects (0.01 ± 0.01 g), who most likely consumed DHA in the form of eggs, which contain approximately 238 mg DHA/100 g (12). Vegan subjects consumed no DHA at all (Table 3).

The total n-3 intake was significantly higher for the HME group (2.25 ± 0.74 g/d) compared with the three other groups,

TABLE 2
Selected Daily Dietary Factors of the Four Habitual Diet Groups

Dietary Factors	High-meat group (HME) (n =18)	Moderate-meat group (MME) (n = 60)	Ovolacto group (n = 43)	Vegan group (n = 18)
White meat (g)	109.6 ± 51.6[a]	53.7 ± 27.1[b]	0.2 ± 0.7[c]	0.0 ± 0.0[c]
Red meat (g)	270.4 ± 118.0[a]	108.9 ± 41.1[b]	0.0 ± 0.0[c]	0.0 ± 0.0[c]
White and red meat (g)	387.2 ± 122.0[a]	163.2 ± 48.4[b]	0.2 ± 0.7[c]	0.0 ± 0.0[c]
Fish (g)	27.7 ± 23.9[a]	26.1 ± 18.3[a]	1.4 ± 3.4[b]	0.7 ± 1.8[b]
Energy (MJ)	1.64 ± 3.31[a]	1.13 ± 2.48[b]	1.15 ± 2.46[b]	1.18 ± 2.44[b]
Protein (% of energy)	19.4 ± 1.3[a]	17.9 ± 2.2[b]	14.7 ± 2.2[c]	14.1 ± 2.4[c]
Carbohydrate (% of energy)	40.3 ± 4.4[a]	45.7 ± 6.8[b]	50.9 ± 6.4[c]	57.4 ± 5.4[d]
Total fat (% of energy)	37.8 ± 4.2[a]	32.8 ± 6.1[b]	32.7 ± 6.2[b]	28.2 ± 4.3[c]

Values are mean ± SD. Values in the same row that have different superscripts are significantly different from each other ($P < 0.01$).

TABLE 3
The Daily Dietary Consumption of Selected FA for the Four Dietary Groups

FA	High-meat group (HME) (n = 16)	Moderate-meat group (MME) (n = 53)	Ovolacto group (n = 40)	Vegan group (n = 17)
14:0	8.33 ± 4.89[a]	3.70 ± 1.98[b]	3.21 ± 1.97[b]	0.95 ± 0.70[c]
16:0	39.57 ± 16.29[a]	18.32 ± 8.41[b]	17.34 ± 7.39[b]	10.19 ± 4.20[c]
18:0	20.22 ± 8.11[a]	9.05 ± 3.93[b]	7.21 ± 3.29[b]	3.19 ± 1.75[c]
Total SFA	77.17 ± 33.81[a]	35.24 ± 15.81[b]	32.40 ± 14.51[b]	16.71 ± 6.16[c]
18:1	58.55 ± 20.84[a]	30.63 ± 11.63[b]	34.23 ± 12.65[b]	29.17 ± 9.16[b]
Total MUFA	63.72 ± 22.47[a]	32.98 ± 12.40[b]	36.64 ± 13.33[b]	31.22 ± 10.12[b]
18:2n-6 (LA)	20.29 ± 10.39[a]	10.90 ± 5.69[b]	18.43 ± 8.61[a]	21.60 ± 9.59[a]
18:3n-3 (LN)	1.96 ± 0.66[a]	1.27 ± 0.56[b]	1.42 ± 0.70[b]	1.15 ± 0.75[b]
20:4n-6 (AA)	0.24 ± 0.11[a]	0.10 ± 0.04[b]	0.03 ± 0.03[c]	0.00 ± 0.00[d]
20:5n-3 (EPA)	0.07 ± 0.02[a]	0.04 ± 0.03[b]	0.00 ± 0.00[c]	0.00 ± 0.00[c]
22:5n-3 (DPA)	0.09 ± 0.05[a]	0.03 ± 0.02[b]	0.00 ± 0.01[c]	0.00 ± 0.00[c]
22:6n-3 (DHA)	0.12 ± 0.10[a]	0.07 ± 0.10[a]	0.01 ± 0.01[b]	0.00 ± 0.00[c]
Total PUFA	23.00 ± 11.13[a]	12.48 ± 5.96[b]	19.90 ± 8.88[a]	22.75 ± 10.08[a]
Total n-3 PUFA	2.25 ± 0.74[a]	1.14 ± 0.61[b]	1.43 ± 0.70[b]	1.22 ± 0.75[b]
Total n-6 PUFA	20.75 ± 10.49[a]	11.07 ± 5.71[b]	18.46 ± 8.61[a]	22.87 ± 9.59[a]
Total LC n-3 PUFA	0.29 ± 0.15[a]	0.14 ± 0.14[b]	0.01 ± 0.01[c]	0.01 ± 0.00[c]
n6:n3	9.2: 1	9.7: 1	12.9: 1	18.7: 1

Values are g/d, mean ± SD. Values in the same row that have different superscripts are significantly different from each other ($P < 0.01$).

whose intakes were not significantly different (MME: 1.14 ± 0.61 g/d; ovolacto: 1.43 ± 0.70 g/d; and vegan:1.22 ± 0.75 g/d). In each group, the total n-3 intakes were mainly in the form of LNA.

Total n-6 intakes, however, were similar in the HME, ovolacto, and vegan groups (20.75 ± 10.49, 18.46 ± 8.61, and 22.87 ± 9.59 g/d, respectively). All three groups consumed significantly more n-6 FA than the MME group (11.07 ± 5.71 g/d), primarily due to the higher intake of LA in these three groups.

All groups consumed some LC n-3 PUFA. The modest intake in the ovolacto (0.01 ± 0.01 g/d) and vegan subjects (0.01 ± 0.00 g/d) was most likely due to the occasional consumption of small amounts of fish by some vegans and the contribution of DHA from eggs consumed by the ovolacto group. The daily LC n-3 PUFA intake in the HME group (0.29 ± 0.15 g/d) was greater than in the MME group (0.14 ± 0.14 g/d), although foods containing these FA, including red meat and oily fish, were consumed by both groups. The HME group simply consumed greater quantities.

Importantly, the dietary intake ratio of n-6:n-3 FA became larger as the meat intake of the groups decreased. Hence, the ratios were 9.2:1 in HME subjects, 9.7:1 in MME subjects, 12.9:1 in ovolacto subjects, and 18.7:1 in vegan subjects (Table 3).

Plasma phospholipid concentrations of selected FA. The plasma phospholipid (PL) levels of each of the FA were determined for all subjects in the study. These results have been previously reported by Li *et al.* (41), and an abbreviated version is shown in Table 4.

Plasma PL total SFA levels were slightly but significantly lower in the vegan group (40.0 ± 1.9 mg/100 mL) than in the other groups, whereas total PUFA was highest in the vegan group (44.8 ± 1.3 mg/100mL). Total MUFA levels showed no significant difference between groups.

There were higher arachidonic acid PL levels in the HME subjects (10.6 ± 1.6 mg/100 mL) and MME subjects (10.5 ± 1.7 mg/100 mL) than in the ovolacto group (9.5 ± 1.9 mg/100 mL), but not the vegan group (10.6 ± 1.5 mg/100 mL) (Table 4).

EPA PL levels for the HME group (1.1 ± 0.5 mg/100 mL) and MME group (1.0 ± 0.3 mg/100 mL) were significantly greater ($P < 0.001$) than for the ovolacto or vegan groups (0.7 ± 0.3 and 0.6 ± 0.3 mg/100 mL, respectively) (Table 4). This was also the case for DHA (HME, 3.4 ± 1.0 mg/100 mL; MME, 3.3 ± 0.8 mg/100 mL; ovolacto, 2.2 ± 0.07 mg/100 mL; vegan, 2.0 ± 0.4 mg/100 mL; $P < 0.001$ for the omnivore vs. vegetarian groups). The same pattern was observed for DPA (HME, 1.3 ± 0.2 mg/100 mL; MME, 1.2 ± 0.2 mg/100 mL; ovolacto, 1.1 ± 0.2 mg/100 mL; vegan, 1.0 ± 0.3 mg/100 mL; $P < 0.01$ for the omnivore vs. vegetarian groups). Total n-6 PUFA plasma PL levels were significantly higher in the vegetarian groups, and total n-3 PUFA levels significantly higher in the omnivore groups.

Comparison of FA intake and plasma phospholipid concentrations. The dietary intake ratios (Table 3) of n-6:n-3 PUFA increased across the groups as the quantity of animal foods in the diets decreased (HME 9.2:1, MME 9.7:1, ovolacto 12.9:1, vegan 18.7:1). This pattern was also observed in the plasma PL levels (HME 5.9:1, MME 6.4:1, ovolacto 9.4:1, vegan 10.2:1). The mathematical relationship between the FA consumed and the plasma PL concentrations of these same FA in individual subjects was assessed using regression analysis (Table 5). Several significant positive correlations were found when data from all the subjects (both the omnivore and the vegetarian dietary groups) were combined.

There were no significant correlations between FA intake and plasma PL FA level for myristic acid (14:0), palmitic acid (16:0), LA, or LNA. Although stearic acid (18:0) was the only SFA that

TABLE 4
Plasma Phospholipid FA Concentrations of the Four Dietary Groups

FA	High-meat group (n = 18)	Moderate-meat group (n = 60)	Ovolacto group (n = 43)	Vegan group (n = 18)
14:0	0.3 ± 0.01	0.3 ± 0.1	0.3 ± 0.1	0.3 ± 0.1

This data was adapted, with permission from Dr. Duo Li, from previously reported data (Li *et al.*, 1999). Values are mg/100 mL, mean ± SD Values in the same row that have different superscripts are significantly different from each other ($P < 0.01$).

showed a significant correlation for the combined groups (r = 0.312, $P < 0.01$), the intake values for total SFA were also significantly correlated with plasma PL levels (r = 0.194, $P < 0.05$) (Fig. 1). A significant association was shown between the dietary intake and plasma PL levels of oleic acid (18:1), AA, EPA, DPA, and DHA ($P < 0.01$) (Table 5). Total LC n-3 PUFA intake was also significantly correlated with plasma PL levels for the combined group (r = 0.474, $P < 0.01$) (Fig. 2).

DISCUSSION

A low intake of LC n-3 PUFA and a high n-6:n-3 intake ratio have been indicated to be markers of elevated risk of CVD (3,45). Conversely, results from experimental, epidemiological, and cross-cultural studies suggest that consumption of foods rich in PUFA, particularly the LC n-3 PUFA, has a positive effect on health and assists in the prevention of chronic disease (14,46). The aim of this study was to investigate the FA composition of habitual diets of healthy male subjects, particularly their average intakes of LC n-3 PUFA, compare the intake level with selected international dietary n-3 PUFA recommendations, and correlate intake levels with plasma PL levels.

The HME food and energy intakes were much greater than those of most Australians (16.4 MJ/d compared to an average of 11.0 MJ/d for Australian males aged 19 y and over) (37), and therefore this groups' dietary FA intakes would not be typical of Australian intakes. Of the four dietary groups investigated,

TABLE 5
Correlations Between the Dietary Intakes and Plasma Phospholipid Concentrations of Selected FA in Combined Dietary Groups

FA	All subjects (n = 126)
16:0	NS
18:0	$r = 0.312^b$
Total SFA	$r = 0.194^a$
18:1	$r = 0.188^a$
Total MUFA	NS
20:4n-6 (AA)	$r = 0.275^b$
20:5n-3 (EPA)	$r = 0.394^b$
22:5n-3 (DPA)	$r = 0.344^b$
22:6n-3 (DHA)	$r = 0.409^b$
Total PUFA	NS
Total LC n-3 PUFA	$r = 0.474^b$

The degree of significance is indicated by the following: $^aP < 0.05$, $^bP < 0.01$. NS, not significant.

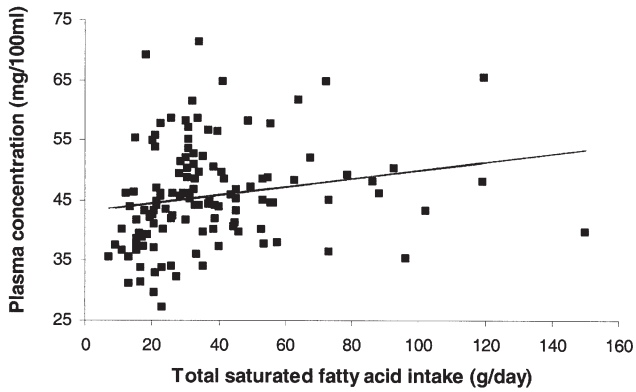

FIG. 1. Comparison of the dietary intake and plasma phospholipid concentrations of total SFA for omnivore (n = 69) and vegetarian (n = 54) subjects combined (n = 123; r = 0.194; P < 0.05).

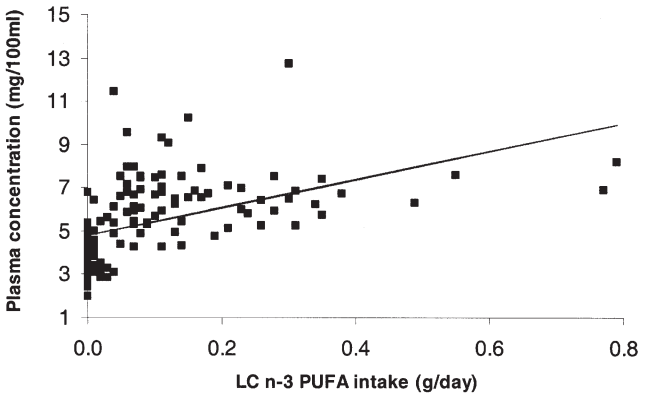

FIG. 2. Comparison of the dietary intake and plasma phospholipid concentrations of total LC n-3 PUFA for omnivore ($n = 69$) and vegetarian ($n = 54$) subjects combined ($n = 123$; $r = 0.474$; $P < 0.01$).

the food intake of the MME group (11.3 MJ/d) most closely resembled that of adult male Australians, as presented in the NNS 1995 survey (37). The mean MME group consumption of fat, 96.2 g/d and 32.8% of energy intake, was almost identical to the Australian NNS 1995 figures of 98.5 g/d fat intake and 32.4% of energy intake for adult men (aged 19 y and older) (37).

The MME group consumed significantly less LA, than the other three groups. This is explained by LA being the most abundant dietary n-6 PUFA, found largely in plant matter such as grains and seeds (47). Subjects who ate more food overall (the HME group) or more plant matter (the ovolacto and vegan groups) than the MME subjects, would indeed consume larger amounts of this FA. LNA, which is found in a variety of cereal- and vegetable-based foods as well as meats (47), was consumed in significantly higher amounts by the HME group than the other three dietary groups, due to their overall larger food intake. However, LNA was the only n-3 FA contributing substantial amounts (g/d) to the total n-3 FA intake of the two vegetarian groups, as the LC n-3 PUFA (EPA, DPA, and DHA), are found in foods of animal origin and thus were not included to any significant extent in their diet.

The AA intake was significantly different in all four groups and corresponded to the amount of meat consumed: HME subjects had the highest AA consumption whereas vegans had a zero intake (Table 3). These findings support the suggestion that diets rich in meat contribute to the high-AA tissue content of people in Westernized societies (5,12,48). Findings by Meyer *et al.* (47) indicated that Australian adults consume 52 mg of AA per day, but the two omnivore groups in this study consumed approximately two to four times this amount: 100 mg/d for MME and 240 mg/d for HME. The MME values, however, are similar to previous Australian studies, which found that adult males consumed approximately 130 mg/d of AA (12) up to 153mg/d (49).

The total n-3 PUFA (1.14 g/d) and LC n-3 PUFA (140 mg/d) intakes of the MME subjects (who would most closely resemble that of the average Australian adult) were both significantly greater than those of the vegetarian groups, although significantly less than the mean HME intakes (2.25 g/d and 290 mg/d, respectively). Two evaluations of the dietary intake data from NNS 1995 using this new Australian FA database indicated that the average Australian male was consuming 1.17 g/d of LNA and 189 mg/d of LC n-3 PUFA (47), or more recently 1.07 g/d of LNA and 246 mg/d LC n-3 PUFA (49), figures similar to those obtained in this present smaller study. These results also closely resemble figures estimated by Kris-Etherton *et al.* for intakes in the United States, of 1.6g/d of total n-3 PUFA, of which 0.1–0.2 g/d were EPA and DHA (29).

The MME total n-3 PUFA intake was equal to the lower dietary levels recommended for Canada (1.1–1.6 g/d) (50) and slightly less than the recommendation in Japan (1.6 g/d) (51). The daily LC n-3 PUFA intake of MME subjects fell below the various recommended intake levels, such as the European Academy of Nutrition recommendation of 210 mg/d (DPA, EPA plus DHA) (23), the British Nutrition Foundation level of 1–2 g EPA + DHA (24), the 500 mg/d (combined DHA and EPA) recommended by ISSFAL (26), and the 750–1,000mg/d suggested by Hibbeln for lowering the risk of psychiatric disorders (52). The recently released Nutrient Reference Values for Australia and New Zealand recommend adult male intakes of 1.3 g/d LNA and 160 mg/d LC n-3 PUFA (53). The HME group, being representative of individuals in society who consume high-energy diets, including substantial amounts of red meat, were able to meet some but not all of these recommendations for both total n-3 PUFA and LC n-3 PUFA intake. However this dietary approach is certainly not recommended by the authors. Neither vegetarian group consumed LC n-3 PUFA in amounts close to those suggested by these various authorities.

This study, even though small in size, was able to show that dietary intake of LC FA has a direct effect on systemic levels, as indicated by fasting plasma PL levels of these FA (Table 5, Fig. 2). The fact that the study consisted of differing habitual diets with very different LC PUFA intakes highlighted the impact that these intake levels can have on tissue levels of these FA. A recent study has similarly demonstrated positive correlations for LC n-3 PUFA (total LC n-3 PUFA, EPA, and DHA) but no correlations between LA or LNA intake and plasma concentrations in Japanese subjects (54).

One limitation of this study was that although subjects consumed a wide variety of different foods, only a limited number of foods (1,044 items) were available in the FA database. As a result, some items had to be substituted with another similar food, or new recipes created to resemble as closely as possible, but not necessarily duplicate, the FA profile of new foods. This may have limited the identification of true total intakes of the various FA by subjects. Secondly, this study involved an unequal number of participants in the various dietary groups (16 HME, 53 MME, 40 ovolacto, and 17 vegan subjects). Despite the limiting factors in this study, the use of the new Australian FA database, accurate to 10 mg/100 g food item (40) and a dietary data tool (FFQ) specifically designed to isolate information on lipid amount and type in the diet, means that the data reported here, particularly for LC n-3 PUFA is of a high degree of accuracy.

It was perhaps surprising to find that the total dietary intake of SFA was not significantly different in the omnivore MME

group and the ovolacto group. This was also true of the MUFA. The intake values for the individual LC PUFA, as well as total LC n-3 PUFA, were higher in the MME group than in the two vegetarian groups, as were the plasma PL levels of LC n-3 PUFA. Roshanai and Sanders (1984) also were able to show a zero intake of all LC PUFA in British vegans and intakes of LA (26.0 g/d) and LNA (1.5 g/d) similar to this more recent Australian study (21.6 g/d and 1.2 g/d, respectively). They also reported a LC n-3 PUFA intake of 510 mg/d in omnivore subjects, however it should be noted that only 10 subjects were assessed, and a small number of these consumed considerable levels of fish, thus limiting the representative nature of the population group (55). A more recent British study also reported lower proportions of plasma EPA and DHA in vegetarians and vegans compared to omnivores (56). Although the total n-3 PUFA intakes were similar in the MME group and both vegetarian groups (due to LNA levels), total n-6 PUFA intakes were significantly higher in the vegan and ovolacto groups because of their larger intakes of LA. These total values resulted in n-6:n-3 intake ratios of 9.7:1 in the MME subjects, 12.9:1 in the ovolacto subjects, and 18.7:1 in the vegan group. Because a high n-6:n-3 FA ratio is considered to be a risk factor for CVD (48), the results suggest that the consumption of red meats, which provide useful amounts of LC n-3 FA such as EPA and DPA (12), can contribute to a healthier balance of FA without necessarily supplying elevated levels of saturated fats. This may be particularly true in Australia, where beef cattle and sheep are raised predominantly on pasture and their meat contains some EPA and DPA (47) as well as very little marbling with the visible fat that provides high levels of SFA (57,58). Meat from beef raised on grain contains lower levels of n-3 FA (12). However, even small amounts of n-3 PUFA appear to be very effective in promoting an improved n-6:n-3 ratio and preventing CHD (59). The MME subjects' intake of 140 mg/d (likely to be typical for an adult Australian male), did not reach the levels recommended by many nutrition authorities. However, omnivores had significantly higher LC n3 PUFA intake than those of the ovolacto and vegan groups who consume minimal preformed LC n3 PUFA.

In conclusion, use of a new FA database of Australian foods allowed the investigation of the FA intake of subjects consuming four different habitual diets. The diet of subjects had a significant effect on their FA intake profiles and in many cases the plasma PL concentrations of those FA. Omnivore subjects consuming moderate amounts of meat (and other foods) had similar intakes of saturated and MUFA to vegetarian subjects but significantly higher intakes of total LC n-3 PUFA and a reduced n-6:n-3 intake ratio. Despite a continuing perception, even among health professionals, that consumption of red meat is deleterious to health (60), our findings do not support this argument. Rather, the data suggest that inclusion of lean red meat in the diet may actually increase the dietary intake and plasma PL ratio of n3:n6 PUFA. Consumption of lean red meat will also contribute significantly to daily intakes of protein, vitamin B12, niacin, iron, and zinc (57). Further, when consumed as part of a diet low in saturated fat, lean red meat does not increase plasma cholesterol levels or thrombotic risk factors (8). Public health messages to consume more lean meats and fish in combination with other nutritious foods could thus result in improved health outcomes in the community.

ABSTRACT: The hypertriglyceridemic waist (HTGW) phenotype (hypertriglyceridemia and increased waist circumference) has been proposed as an inexpensive tool to monitor individuals with the atherogenic metabolic triad, hyperinsulinemia, hyperapobetalipoproteinemia, and increased levels of small, dense LDL (sdLDL) particles. We assessed the association of the HTGW phenotype with the metabolic syndrome (MetSyn) and the atherogenic metabolic triad in inhabitants (n = 260) of northwestern Greece attending the Outpatient Lipid Clinic of the University Hospital of Ioannina. The LDL subfractions were assessed using the Lipoprint LDL System. HTGW (+) individuals had a more adverse lipid and lipoprotein profile compared with HTGW (–) individuals. Moreover, HTGW (+) subjects had elevated levels of sdLDL-C, as well as decreased mean and peak LDL particle size compared with HTGW (–) subjects. To our knowledge, this is the first report documenting the sdLDL-C abnormality in HTGW (+) subjects. Among men (n = 105), 52.3% of the MetSyn (+) individuals and 66.7% of the HTGW (+) individuals had the metabolic triad. Among women (n = 155), the corresponding percentages were 42.3% and 50.0%. Only 22.2% and 10.6% of the MetSyn (–) subjects (men and women, respectively) and 19.6% and 15.2% of the HTGW (–) subjects (men and women, respectively) had the atherogenic metabolic triad. In conclusion, the HTGW (+) phenotype is associated with a hostile lipid profile that includes higher levels of sdLDL-C and decreased LDL particle size. The HTGW phenotype, compared with the MetSyn criteria, can provide an easy and inexpensive tool to monitor patients characterized by an adverse lipid and lipoprotein profile.

Paper no. L9968 in *Lipids 41*, 647–654 (July 3006).

The hypertriglyceridemic waist (HTGW) phenotype has been proposed as an inexpensive tool to monitor individuals characterized by the atherogenic metabolic triad, hyperinsulinemia, elevated apolipoprotein B levels, and increased concentrations of small, dense LDL (sdLDL) particles, in men (1). Similarly, the HTGW phenotype was associated with the atherogenic metabolic triad as well as with coronary heart disease (CHD) risk factors in apparently healthy women (2). Furthermore, the results of the Hoorn study indicated that men and women with the HTGW phenotype were at increased risk for cardiovascular disease (CVD), even if they had normal glucose metabolism (3). Tanko *et al.* also reported that postmenopausal women with enlarged waist and elevated triglycerides (TG) were at increased risk for fatal CVD events; this risk was even higher than that observed in women with the metabolic syndrome (MetSyn) (4).

MetSyn represents a constellation of lipid and nonlipid CVD risk factors, and it has been recognized by the National Cholesterol Education Program (NCEP) Adult Treatment Panel (ATP) III as a secondary target for hypolipidemic therapy (5,6). Furthermore, MetSyn is associated with an increased risk for CVD and acute ischemic/nonembolic stroke in elderly patients (7–9).

Men with the metabolic triad are at increased risk for CVD; their odds ratio (OR) is 5.9, compared with that of men with normal levels for two of the three components of the triad (10). Additionally, the results of the Quebec cardiovascular study indicated that men with an elevated proportion of cholesterol carried in LDL particles with diameters smaller than 25.5 nm are at increased risk for CVD (11–13). Furthermore, MetSyn patients commonly have increased levels of the atherogenic sdLDL particles, increased sdLDL cholesterol (sdLDL-C) concentrations, and decreased mean and peak LDL particle size compared with non-MetSyn individuals (14–16).

The aim of the present study was to investigate the presence of the HTGW phenotype in men and women with or without the MetSyn, as well as the association of the HTGW phenotype with the atherogenic metabolic triad, including sdLDL-C levels and mean and peak LDL particle size.

MATERIALS AND METHODS

Study population. Patients (n = 260) attending the Outpatient Lipid Clinic of the University Hospital of Ioannina participated in the present study. The diagnosis of the MetSyn was based on the NCEP ATP III criteria (5). Blood pressure was measured in the sitting position after a 5-min rest. Two consecutive measurements were carried out with an interim of 3 min, and the

Abbreviations: BMI, body mass index; CHD, coronary heart disease; CVD, cardiovascular disease; HTGW, hypertriglyceridemic waist; MetSyn, metabolic syndrome; sdLDL-C: small, dense LDL cholesterol; NCEP ATP III, National Cholesterol Education Program Adult Treatment Panel III; PPD, peak particle diameter; TC, total cholesterol.

mean value was used. Waist circumference was measured midway between the iliac crest and the lowest rib.

Exclusion criteria were: prior atherosclerotic disease (myocardial infarction, unstable angina, ischemic stroke, peripheral arterial disease, percutaneous transluminal coronary angioplasty, or coronary artery bypass graft), known diabetes mellitus (fasting glucose ≥ 126 mg/dL), liver disease (serum aminotranferase activity greater than threefold, i.e., > 120 IU/L for normal range 5–40 IU/L), impaired renal function (serum creatinine levels greater than 1.5 mg/dL, normal range 0.6–1.2 mg/dL), or hypothyroidism (TSH greater than 5 μIU/mL, normal range 0.5–4.8 μIU/mL). Moreover, patients receiving drugs that could affect lipid metabolism as well as renal or hepatic function were excluded.

The HTGW phenotype was defined differently in men and women: waist circumference ≥ 90 cm and TG levels ≥ 180 mg/dL (1) for men, and waist circumference ≥ 88 cm and TG levels ≥ 150 mg/dL for women (2). The cutoff points for apolipoprotein (apo) B and insulin for the definition of the metabolic triad were derived from the median values of these parameters in non-obese, defined as body mass index (BMI) < 25 kg/m^2, men (n = 50) and women (n = 50) who did not fulfill any of the MetSyn criteria or the criteria of the HTGW phenotype, as described above. A mean LDL particle size cutoff point (26.8 nm) was used for both men and women, according to the Lipoprint LDL System instructions (see LDL subclass analysis section) (17). Because of the different reference range for apo B and insulin in men and women, the metabolic triad was defined separately: apo B > 96 mg/dL, insulin > 8 mU/L, and mean LDL particle size ≥ 26.8 nm for men; and apo B > 85 mg/dL, insulin > 6.85 mU/L, and mean LDL particle size ≥ 26.8 nm for women. The Ethics Committee of the University Hospital of Ioannina approved the study and every participant gave his/her written consent.

Biochemical parameters. All biochemical determinations were carried out after an overnight fast (approximately 12 h). Serum total cholesterol (TC), HDL cholesterol (HDL-C), and TG were determined enzymatically with an Olympus AU600 automated analyzer (Olympus Diagnostica, Hamburg, Germany). Serum LDL-cholesterol (LDL-C) levels were calculated using the Friedewald formula (provided that TG levels were lower than 400 mg/dL). In patients with TG levels greater than 400 mg/dL (n = 11) the LDL-C concentration was not recorded. Serum apo A-I and B were measured with a Behring Holding Gmbh analyzer (Liederbach, Germany). Serum insulin levels were measured by microparticle enzyme immunoassay on an AxSYM analyzer (Abbott Diagnostics). The homeostasis model assessment (HOMA) index was calculated as follows: fasting insulin (mU/L) × fasting glucose (mg/dL)/405.

LDL subclass analysis. Electrophoresis was performed using high-resolution 3% polyacrylamide tube gel and Lipoprint LDL System (Quantimetrix, Redondo Beach, CA) according to the manufacturer's instructions (17,18). Briefly, 25 μL of sample was mixed with 200 μL of Lipoprint Loading Gel and placed on the upper part of the 3% polyacrylamide gel. After 30 min of photopolymerisation at room temperature, electrophoresis was performed for 60 min with 3 mA for each gel tube. Each electrophoresis chamber involved two quality controls (sample provided by the manufacturer). For quantification, scanning was performed with a ScanMaker 8700 digital scanner (Mikrotek Co.) and iMac personal computer (Apple Computer Inc.). After scanning, electrophoretic mobility (Rf) and the area under the curve (AUC) were calculated qualitatively and quantitatively with the Lipoprint LDL system Template and the Lipoware software (Quantimetrix Co., Redondo Beach, CA), respectively. The LDL subfraction was calculated using the Rf between the VLDL fraction (Rf 0.0) and the HDL fraction (Rf 1.0). LDL is distributed from Rf 0.32 to Rf 0.64 as seven bands, whose Rf values are 0.32, 0.38, 0.45, 0.51, 0.56, 0.6, and 0.64 (LDL1 to LDL7, respectively). LDL1 and LDL2 are defined as large, buoyant LDL, and LDL3 to LDL7 are defined as sdLDL. The cholesterol concentration (in mg/dL) of each LDL subfraction is determined by multiplying the relative area (AUC) of each subfraction by the TC concentration of the sample (the TC concentration of the sample is measured independently). The proportion of sdLDL-C (sdLDL%) was defined as the percentage of the LDL-C carried in sdLDL (i.e., bands 3 to 7). LDL peak particle diameter (LDL-PPD) (nm) was determined using the Rf of the highest peak of the LDL bands according to the following equation proposed: LDL-PPD = (1.429-Rf) × 25 (19). Moreover, the Lipoprint LDL System provides a mean LDL particle size (nm) and uses a size of 26.8 nm as a cutoff point to classify individuals into phenotypes A (absence of sdLDL particles) and non-A (presence of sdLDL particles).

Statistical analysis. Preliminary analysis was performed to ensure no violation of the assumptions of normality and linearity. The Shapiro-Wilk test was used to evaluate whether each variable followed a Gaussian distribution. Data are expressed as mean ± SD, except for parameters not following a Gaussian distribution, which are expressed as median (range). The relationships between study parameters were assessed using the Pearson product-moment correlation coefficient (r) or Spearman's rank order correlation (rho) as appropriate. Independent samples t-test (or Mann-Whitney U test when appropriate) was used to assess differences between HTGW (+) and HTGW (−) individuals. One-way ANOVA or the Kruskal-Wallis test was used to explore differences between Gaussian and non-Gaussian results, respectively, according to waist circumference and TG levels. The Chi-square test (with Yates's correction) was used to assess the differences in the proportion of subjects characterized by the metabolic triad.

The sensitivity of HTGW phenotype to identify individuals with increased levels of sdLDL-C or decreased mean LDL particle size was calculated using the following equation:

[True positives/(true positives + false negatives)]*100

where true positives is the number of patients with sdLDL-C levels equal to or greater than 6 mg/dL or mean LDL particle size less than 26.8 nm correctly classified by the HTGW phenotype and false negatives is the number of patients with

sdLDL-C levels equal or greater than 6 mg/dL or mean LDL particle size less than 26.8 nm misclassified by HTGW phenotype. The specificity of the previously mentioned phenotype was calculated using the following equation:

[True negatives/(true negatives + false positives)]*100

where true negatives is the number of patients with sdLDL-C levels less than 6 mg/dL or mean LDL particle size greater than or equal to 26.8 nm correctly classified by HTGW phenotype and false positives is the number of patients with sdLDL-C levels less than 6 mg/dL or mean LDL particle size greater than or equal to 26.8 nm misclassified by phenotype. The positive and negative predictive values were calculated as [true positives/(true positives + false positives)]*100 and [true negatives/(true negatives + false negatives)]*100, respectively. A P value of less than 0.05 was considered to be significant. All analyses were carried out with the SPSS 13.0 softpack.

RESULTS

Of the total cohort, 133 individuals (53 men and 80 women) fulfilled the NCEP ATP III criteria for the diagnosis of the MetSyn, and 127 (52 men and 75 women) did not. Of the MetSyn subjects, 66.2% presented with the HTGW phenotype (n = 88), whereas the corresponding proportion in the non-MetSyn group was 5.5% (n = 7).

Table 1 shows the clinical and biochemical characteristics of the total cohort as well as of the men and women separately. In the overall cohort, HTGW (+) subjects were older than HTGW (–) individuals, and this was due to the difference in age in women. By definition, HTGW (+) subjects across all study groups had greater waist circumference compared with HTGW (–) individuals. Moreover, HTGW (+) subjects had higher systolic and diastolic blood pressure in the overall cohort and in women compared with HTGW (–) subjects, but blood pressure did not differ between HTGW (+) and HTGW (–) men. Finally, HTGW (+) individuals had a more adverse glycemic profile with elevated fasting glucose and insulin levels, as well as increased HOMA index compared with HTGW (–) subjects; this finding was consistent across all study groups.

Table 2 shows the lipid and lipoprotein profile of the study participants. In the overall cohort, HTGW (+) subjects had increased levels of TC, TG, non-HDL cholesterol, apo B, and the atherogenic index apo B/apo A-I ($P < 0.001$ for all comparisons), as well as decreased concentrations of HDL-C and apo A-I ($P < 0.001$ for both) compared with HTGW (–) individuals. LDL-C levels did not differ between the two groups. In men, the same pattern was observed with the exception of TC levels, which were similar in HTGW (+) and HTGW (–) individuals. In women, LDL-C levels were higher in the HTGW (+) group compared with the HTGW (–) group ($P < 0.05$).

The HTGW (+) group had higher concentrations of VLDL-C, sdLDL-C, and sdLDL% compared with HTGW (–) subjects ($P < 0.001$ for all comparisons) (Table 2). Moreover, HTGW (+) patients had significantly lower mean LDL particle size and LDL-PPD ($P < 0.001$ for all comparisons) compared with HTGW (–) individuals, and this finding was present in the overall cohort, as well as in the male and female subpopulations (Table 2).

Because menopause is associated with a body fat redistribution (20), we analyzed pre- and postmenopausal women separately to establish whether the differences in LDL subfractions were maintained. Indeed, the waist circumference in the HTGW (–) women was significantly greater in the postmenopausal group (100 vs. 89 cm, $P = 0.001$). However, a similar difference in the HTGW (+) women was not significant (111 vs. 104 cm), possibly reflecting the small number of HTGW (+) premenopausal women (n = 11). The differences in LDL characteristics between HTGW (+) and HTGW (–) were similar in pre- and postmenopausal women. Thus, in premenopausal women, comparing HTGW (–) (n = 63) with HTGW (+) (n = 11) groups: sdLDL-C, 3 (0–42) vs. 11 (0–51) mg/dL, $P = 0.02$; sdLDL%, 2.9 (0–41.2) vs. 9.9 (0–37.2), $P = 0.02$; LDL-PPD, 28.0 (25.0–29.0) vs. 26.7 (25.7–28.7) nm, $P = 0.03$; mean LDL particle size, 27.0 (24.9–27.5) vs. 26.4 (25.2–27.4) nm, $P = 0.008$. In postmenopausal women, comparing HTGW (–) (n = 38) with HTGW (+) (n = 43) groups: sdLDL-C, 5 (0–40) vs. 21.5 (1–79) mg/dL, $P < 0.001$; sdLDL%, 4.0 (0–22.1) vs. 15.8 (0.8–51.4), $P < 0.001$; LDL-PPD, 28.0 (26.0–28.7) vs. 26.6

[a]Statistics are as follows: [a]$P < 0.001$ and [b]$P < 0.05$ compared with the corresponding HTGW (+) group.
[b]HTGW, hypertriglyceridemic waist; TC, total cholesterol; HDL-C, HDL-cholesterol; LDL-C, LDL-cholesterol; Apo, apolipoprotein; Lp(a), lipoprotein (a); VLDL-C, VLDL-cholesterol; sdLDL, small, dense LDL.

(23.7–29.0) nm, $P < 0.001$; mean LDL particle size, 26.8 (25.9–27.4) vs. 26.2 (24.4–27.3) nm, $P < 0.001$.

Among all study participants, waist circumference correlated with HDL-C ($r = -0.23$, $P < 0.001$), nonHDL-C ($r = 0.32$, $P < 0.001$), TG (rho = 0.52, $P < 0.001$), apo B ($r = 0.24$, $P < 0.001$), apo B/apo A-I (rho = 0.35, $P < 0.001$), glucose ($r = 0.34$, $P < 0.001$), insulin (rho = 0.42, $P < 0.001$), and the HOMA index (rho = 0.46, $P < 0.001$). Moreover, waist circumference correlated with sdLDL-C and sdLDL% (rho = 0.32, $P < 0.001$ for both) as well as with mean LDL particle size and LDL-PPD (rho = –0.35 and rho = –0.3 respectively, $P < 0.001$ for both). TG levels were negatively correlated with HDL-C (rho = –0.36, $P < 0.001$), and positively correlated with non-HDL-C (rho = 0.56, $P < 0.001$), apo B (rho = 0.44, $P < 0.001$), apo B/apo A-I ratio (rho = 0.52, $P < 0.001$), glucose (rho = 0.3, $P < 0.01$), as well as with insulin levels and the HOMA index (rho = 0.43, $P < 0.001$ for both). As expected, TG levels were positively correlated with sdLDL-C and sdLDL% (rho = 0.61 and rho = 0.6, respectively, $P < 0.001$ for both) and were negatively correlated with mean LDL particle size and LDL-PPD (rho = –0.63 and rho = –0.6 respectively, $P < 0.001$ for both).

We divided the participants into three groups according to their waist circumference and into four groups according to their TG concentrations, separately for men and women (see Fig. 1 caption). Figures 1A and 1B show the distribution of sdLDL% and LDL-PPD across waist circumference and TG groups in men and women, respectively. In both men and women, sdLDL% increased and LDL-PPD decreased as waist circumference and TG levels increased ($P < 0.01$ and $P < 0.001$, respectively). sdLDL-C levels increased in both sexes with increasing waist circumference ($P < 0.01$) and TG concentrations ($P < 0.001$) (data not shown).

Table 3 shows the mean levels of apo B and median values of insulin and mean LDL particle size across groups by waist circumference and TG concentrations in men and women. In men, mean LDL particle size decreased ($P < 0.01$) and insulin and apo B levels increased ($P < 0.001$ and $P < 0.05$, respectively) as waist circumference increased. These relationships were not linear for insulin and for apo B in men. Mean LDL particle size decreased ($P < 0.001$) and insulin and apo B levels increased ($P < 0.05$ and $P < 0.001$, respectively) as TG levels increased. The pattern was the same for women (Table 4).

We evaluated the proportion of subjects with the MetSyn and/or the HTGW phenotype who also had the metabolic triad (Fig. 2). Among men, 52.3% of the MetSyn (+) individuals and 66.7% of the HTGW (+) individuals had the metabolic triad. Among women the corresponding percentages were 42.3% and 50.0%. Only 22.2% and 10.6% of the MetSyn (–) subjects (men and women, respectively) and 19.6% and 15.2% of the HTGW (–) subjects (men and women, respectively) presented with the atherogenic metabolic triad (Fig. 2). When we evaluated the proportion of patients with the metabolic triad who had both the MetSyn and HTGW criteria, the proportion was not significantly different from the comparison when only one of these criteria was used.

We estimated the sensitivity, specificity, and positive and negative predictive values of the HTGW phenotype to identify individuals with increased sdLDL-C levels or decreased mean LDL particle size. The sensitivity and the specificity of the HTGW phenotype to identify subjects with elevated sdLDL-C levels were 53.9% and 87.3%, respectively, whereas the corresponding values for the identification of patients with decreased mean LDL particle size were 58.5% and 88.5%, respectively. Moreover, the positive and negative predictive values of the HTGW phenotype to identify subjects with elevated sdLDL-C levels were 85.4% and 57.8%, respectively, and the corresponding values for the identification of patients with decreased mean LDL particle size were 85.4% and 64.9%, respectively.

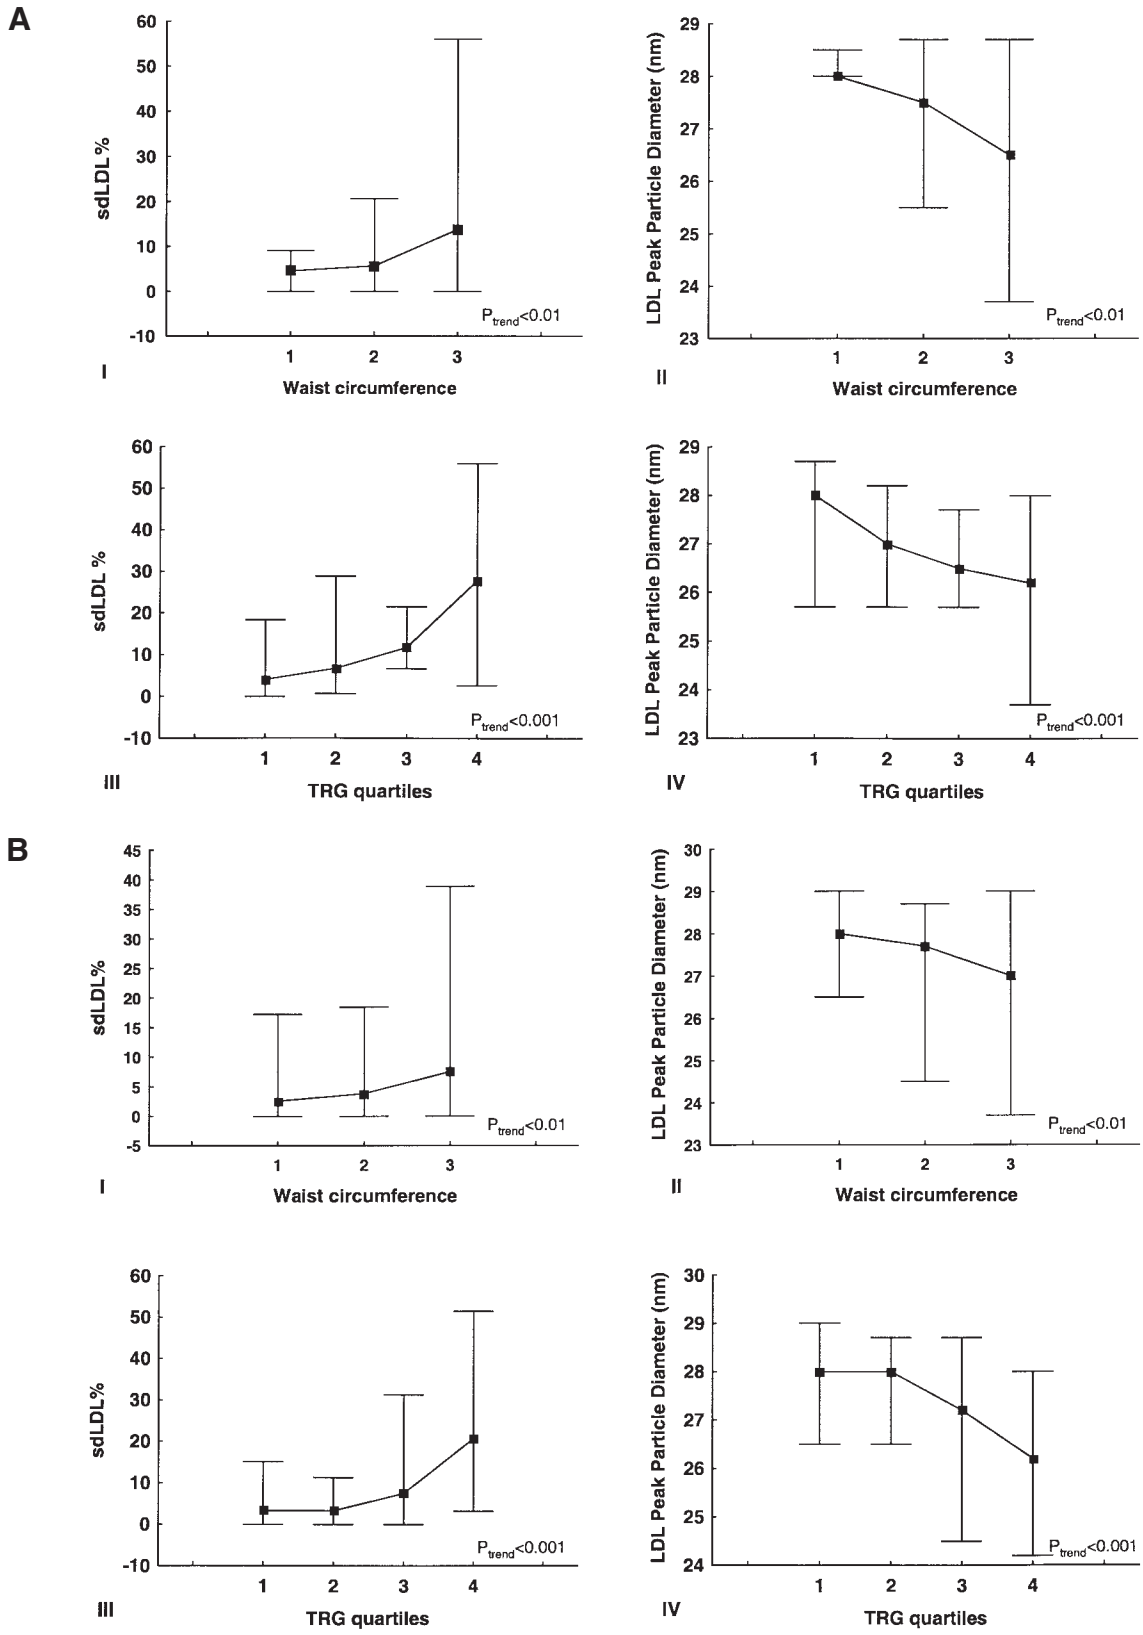

FIG. 1. (A) Small, dense LDL proportion and LDL peak particle diameter according to waist circumference and triglyceride levels in men. Waist circumference: Group 1, <90 cm; Group 2, 90–101 cm; Group 3, ≥102 cm. Triglyceride levels: Group 1: ≤149 mg/dL; Group 2, 150–179 mg/dL; Group 3, 180–200 mg/dL; Group 4, ≥201 mg/dL. (B) Small, dense LDL proportion and LDL peak particle diameter according to waist circumference and triglyceride levels in women. Waist circumference: Group 1, <88 cm; Group 2, 88–99 cm; Group 3, ≥100 cm. Triglyceride levels: Group 1, ≤130 mg/dL; Group 2, 131–149 mg/dL; Group 3, 150–200 mg/dL; Group 4, ≥201 mg/dL.

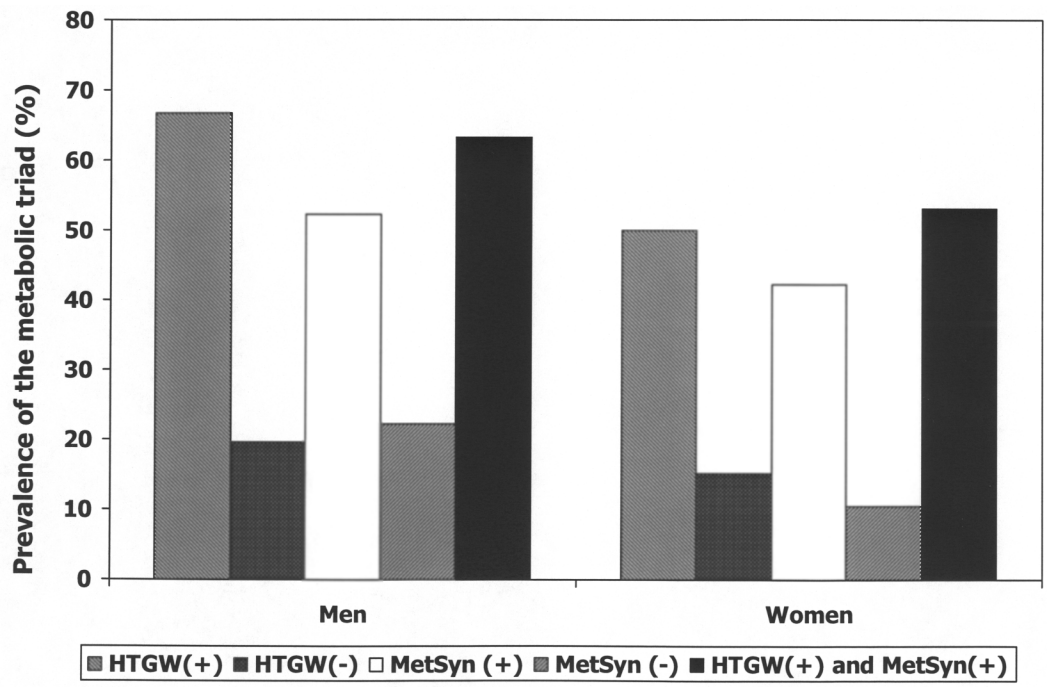

FIG. 2. Proportion of study participants with the metabolic triad. The metabolic triad was defined as mean LDL particle size < 26.8 nm, insulin > 8 mU/L for men and > 6.8 for women, and apolipoprotein B > 96 mg/dL for men and > 85 mg/dL for women.

DISCUSSION

The present study is to our knowledge the first to evaluate associations of HTGW (+) and MetSyn (+) with the amount of cholesterol carried in sdLDL particles and mean and peak LDL particle size.

Lemieux *et al.* in 2000 (1) were the first to propose that the HTGW phenotype is an inexpensive and sensitive marker of the atherogenic metabolic triad (characterized by hyperinsulinemia, hyperapolipoprotein B, and the presence of sdLDL particles). According to their results, about 80% of 185 apparently healthy men with a waist circumference ≥ 90 cm and TG levels ≥ 2 mmol/L (about 180 mg/dL) had the metabolic triad (1). According to our results, the corresponding proportion is similar at about 70%. However, we did not use as a cutoff point the median values of LDL-PPD as proposed by Lemieux *et al.* (1). Instead we used a cutoff point of mean LDL particle diameter less than or greater than 26.8 nm, as proposed by the manufacturer of the Lipoprint LDL system to identify individuals with phenotype A (mostly large, buoyant LDL particles) or non-A (presence of sdLDL particles) (17). Another study (2) showed that about 66% of HTGW (+) women had the metabolic triad. Our results show that among HTGW (+) women only 50% had the metabolic triad. A possible explanation for this discrepancy may be that in the other study (2) the LDL particle size was not recorded; it was substituted by LDL-C levels. In our study LDL-C levels in the female population showed only a weak correlation with mean LDL particle size (rho = −0.16, $P = 0.05$); thus, the metabolic triad in the study by La Monte *et al.* (2) might have been incorrectly estimated. Furthermore, in our study only 20% of HTGW (−) men and 15% of HTGW (−) women were characterized by the metabolic triad; the corresponding proportions in the studies by *Lemieux* (1) and LaMonte (2) were 10% in men and 22% in women.

The CVD risk factor profile tended to be worse in both HTGW (+) men and women compared with HTGW (−) individuals (Tables 1 and 2). This finding is in accordance with previous studies in both sexes (1,2,4,21). In the present study we evaluated more thoroughly the profile of the apo B-containing lipoproteins in HTGW (+) compared with previous studies. We found that HTGW (+) subjects were characterized by elevated concentrations of VLDL-C and sdLDL-C compared with HTGW (−) individuals (Table 2). Moreover, HTGW (+) patients had a decreased mean and peak LDL particle size compared with HTGW (−) individuals (Table 2). sdLDL% and sdLDL-C concentration increased and mean and peak LDL particle size decreased with increasing waist circumference and TG levels. The results of the Quebec Cardiovascular Study indicated that the amount of cholesterol carried in sdLDL particles predicts CVD risk even better than mean and peak LDL particle size (12). This finding gives more relevance to the present study which evaluated sdLDL-C levels in HTGW (+) individuals.

In our study menopause was associated with an increased waist circumference, and the effect was significant in the HTGW (−) group. Nevertheless, the difference in sdLDL-C, sdLDL%, as well as in mean and peak LDL particle size followed a similar pattern when comparing pre- and postmenopausal women with or without the HTGW phenotype.

The prevalence of the atherogenic metabolic triad was higher in HTGW (+) compared with MetSyn (+) subjects (66.7% vs. 52.3% in men, 50% vs. 42.3% in women, although these differences were not significant). The HTGW phenotype provides some degree of sensitivity and specificity for the identification of individuals with elevated sdLDL-C levels and decreased mean LDL particle size values.

In conclusion, HTGW (+) patients had an adverse metabolic profile characterized not only by altered concentrations of the classic lipid factors but also by disturbed apo B-containing lipoprotein profile. The HTGW phenotype provides an estimate of the presence of the atherogenic metabolic triad in adults of both sexes. Furthermore, the HTGW phenotype has the ability to recognize more subjects characterized by the metabolic triad than the presence of the MetSyn. This finding in addition to the fact that the diagnosis of the MetSyn requires more laboratory data than the diagnosis of the HTGW phenotype makes this a useful tool for the identification of individuals at increased risk for CVD.

Soy Protein Containing Isoflavones Favorably Influences Macrophage Lipoprotein Metabolism but Not the Development of Atherosclerosis in CETP Transgenic Mice

ABSTRACT: The possibility that soy protein containing isoflavones influences the development of experimental atherosclerosis has been investigated in ovariectomized mice heterozygous for the human CETP transgene and for the LDL-receptor null allele ($LDLr^{+/-}$ $CETP^{+/-}$). After ovariectomy at 8 wk of age they were fed a fat/cholesterol-rich diet for 19 wk and divided into three experimental groups: dietary unmodified soy protein containing isoflavones (mg/g of diet), either at low-dose (Iso Low, 0.272, $n = 25$), or at high-dose (Iso High, 0.535, $n = 28$); and the atherogenic diet containing an isoflavone-depleted alcohol-washed soy protein as a control group ($n = 28$). Aortic root lipid-stained lesion area (mean $\mu m^2 \times 10^3 \pm$ SD) did not differ among Iso Low (12.3 ± 9.9), Iso High (7.4 ± 6.4), and controls (10.7 ± 12.8). Autoantibody titers against plasma oxidized LDL did not differ among the experimental groups. Using the control mice as the reference value (100%), *in vitro* mouse peritoneal macrophage uptake of labeled acetylated LDL-cholesterol was lower in the Iso High (68%) than in the Iso Low (85%) group. The *in vitro* percent removal by exogenous HDL of labeled unesterified cholesterol from macrophages previously enriched with human [4-^{14}C]-cholesteryl oleate acetylated LDL was enhanced in the Iso High group (50%). In spite of these *in vitro* potentially antiatherogenic actions, soy protein containing isoflavones did not modify the average size of lipid-stained area in the aortic root.

Paper no. L9983 in *Lipids 41,* 655–662 (July 2006).

Although most retrospective epidemiological studies have indicated that hormonal replacement therapy effectively reduces coronary artery disease outcomes in postmenopausal women, recent large intervention trials have failed to demonstrate these beneficial effects (1–3). Due to the controversies surrounding conventional estrogen replacement therapy, soy-based food has been proposed as a dietary alternative to lower the plasma lipid concentration (4), in addition to improving the menopause-related symptoms (5,6) and osteoporosis (7). However, in spite of a suggestion that the intake of phytoestrogens has diminished the incidence of coronary heart disease in Japan (8) a definite proof of this benefit in Western societies is lacking (9–12). In addition, in humans, soy isoflavones have been shown to lower plasma lipids according to two meta-analyses (4,13), but not in two recent studies (14,15). Nonetheless, in several animal species, protection against the development of experimental atherosclerosis has been ascribed to phytoestrogens (16), soy isoflavones (17–20), a specific soy protein (21), and a soy-rich diet (22–24). However, on reviewing these studies, we noticed that in four (17,18,21,22), but not in four others (19,20,23,24), reductions of atherosclerosis and of plasma cholesterol occurred simultaneously. On the other hand, rabbits fed phytoestrogens have shown significantly reduced aortic cholesterol, an effect that the authors deem comparable to that of the estrogen replacement therapy (25). In addition to the fact that dietary soy cannot be strictly compared to isoflavone administration, it is worth noting that with the exception of some experiments involving moderate degrees of hypercholesterolemia (17,18,23), in all other experiments hypercholesterolemia attained by the experimental animals was remarkable or even extremely severe (16,18–22,24). Degrees of hypercholesterolemia attained are not ideal models for the effects of isoflavones in the human population, where plasma cholesterol concentrations are far more modest. Furthermore, these mentioned studies cannot strictly be compared because diets differed according to several components, such as soy, soy isolates, phytoestrogens, and pure isoflavones, making it difficult to interpret them in regard to their usefulness in humans. In spite of these considerations, several potentially beneficial actions of isoflavones concerning protection against premature atherosclerosis have been proposed, such as a reduction of LDL susceptibility to oxidation, improvement in vascular reactivity, and inhibition of pro-inflammatory cytokines, cell adhesion, and platelet aggregation (26,27).

We measured the effects of treatments with low and high doses of soy protein containing isoflavones on the development of aortic root lipid-laden lesions, and, considering the possible antiatherogenic mechanisms involved, we measured the formation of serum antibodies against oxidized LDL and the cholesterol uptake and efflux by mouse peritoneal macrophages *in vitro*. We utilized ovariectomized mice partially deficient in LDL receptor ($LDLr^{+/-}$), expressing a human CETP minigene ($CETP^{+/-}$), as previously reported

*To whom correspondence should be addressed at Av. Dr. Arnaldo, 455, sala 3317, CEP 01246-000, São Paulo, SP, Brazil. E-mail: lipideq@usp.br

(28,29). This model was chosen because the total cholesterol concentration was mild, well within the range of a normal human population, and human CETP was expressed.

EXPERIMENTAL PROCEDURES

Animals. The animal protocols were approved by the University of São Paulo Medical School Ethics Committee (protocol number 191/01). Female $LDLr^{+/-}$ $hCETP^{+/-}$ mice (n = 110) on a C57BL/6 background were obtained from the crossbreeding of female LDLr-knockout (from the Jackson Laboratory, Bar Harbor, ME) with male CETP-transgenic (a kind gift from Dr. H.C.F. Oliveira, Unicamp, Campinas, São Paulo, Brazil). Mice were weaned at 4 wk of age, and thereafter fed an *ad libitum* commercially available diet for 5 wk (Nuvital Nutrientes Ltda., Curitiba, PR, Brazil), housed 5 mice per cage and kept in a 12-h light-dark cycle in a conventional room. At 8 wk of age, they were ovariectomized, and 3 wk afterward their vaginal smears were collected to evaluate ovariectomy effectiveness. Only those animals that presented atrophic vaginal epithelium during a 5-d consecutive follow-up period were included. Animals were separated into three groups: those fed soy protein containing isoflavones at low dose (Iso Low, n = 25), those fed soy protein containing isoflavones at high dose (Iso High, n = 28), and controls fed isoflavone-depleted alcohol-washed soy protein (C, n = 28).

Diets and feeding procedures. Experimental diets were made utilizing the TD 88137 (21% milk saturated fat; 0.2% cholesterol by weight) supplied by Harlan Teklad (Madison, WI). All the experimental diets and the soy protein isolates (Clinical 670 Blend and FXP-H-0140) were a kind gift from Dr. Susan M. Potter (Solae Company, St. Louis, MO). The Clinical 670 Blend contained (mg/g product): genistein, 1.10; daidzein, 0.84; and glicytein, 0.20. The FXP-H-0140 component presented 0.04 mg/g of the product total aglycone. Although the FXP-H-0140 is an isoflavone-free ethanol-extracted product (AWISP), a diet totally devoid of isoflavones is not feasible; hence, insignificant amounts of isoflavones may be detected. The diet made with soy protein containing isoflavones at high dose (Iso High) was prepared using 250 g of Clinical 670 Blend, and the diet made with soy protein containing isoflavones at low dose (Iso Low) was prepared using 125 g of FXP-H-140 and 125 g of Clinical 670 Blend as the source of protein. The diet of the control mice was prepared with 250 g of FXP-H-140. In order to correct for the differences in protein content between FXP-H-140 and Clinical 670 Blend, small amounts (1.1% and 0.57%, respectively) of casein were added to Iso High and Iso Low diets. These diets did not differ regarding the proportions of calories that were represented as protein (19.4%), fat (42.0%), and carbohydrates (38.6%); diets are summarized in Table 1.

During the 19-wk study period, animals were fed the following amounts of isoflavones/100 g diet: 1 mg (C), 27 mg (Iso Low), and 53 mg (Iso High).

Lipid analysis. Plasma total cholesterol (TC) and triacylglycerol (TAG) concentrations were determined by enzymatic assays with commercially available kits (Boehringer Mannheim, Darmstadt, Germany, and Merck KgaA, Buenos Aires, respectively).

[a]Iso High: Clinical 670 Blend; Iso Low: 50% Clinical 670 Blend plus 50% FXP-H-0140; C: FXP-H-0140.

Histological analysis of atherosclerotic lesions. Mice were anesthetized with ketamine (100 mg/kg, ip, Ketalar, Parke-Davis, São Paulo, Brazil) and xylazine (32 mg/kg, ip, Rompum, Bayer S.A., São Paulo, Brazil) and their hearts perfused *in situ* with phosphate-buffered saline (PBS) followed by 10% PBS-buffered formaldehyde, after which they were excised and fixed in 10% formaldehyde for at least 2 d. The hearts were then embedded sequentially in 5%, 10%, and 25% gelatin. Processing and staining were carried out according to Paigen *et al.* (30). Briefly, the heart was sectioned directly under and parallel to the axis of the atrial leaflets; the upper section was embedded in tissue-freezing medium (TBS, Triangle Biomedical Sciences, Durham, NC) and frozen. Because several other studies revealed a preference for the development of lesions in the aortic root, the segment chosen for analysis extended from beyond the aortic sinus up to the point where the aorta first becomes rounded and was expressed as the sum of the lesions in six 10-µm sections, 80 µm distant from each other in a total aortic length of 480 µm. The slides were stained with oil red O and counterstained with Harris's hematoxylin and with light green. The lipid-stained lesions were quantified as described by Rubin *et al.* (31) using the Image Pro Plus software (version 3.0) for image analysis (Media Cybernetics, Silver Spring, MD). The slides were read by an investigator blinded to the experimental groups.

Detection of antibodies to oxidized LDL. Antibodies against holo-oxidized LDL (oxLDL) or antibodies anti-apoB epitope derived from oxLDL (ApoB-D) were measured in mouse plasma by ELISA (28,32). ApoB-D is a 22-amino acid peptide from a region of ApoB-100 not accessible to trypsin. Polystyrene microtiter plates (Costar, Cambridge, MA) were coated with 50 µL of human oxLDL (7.5 µg/mL, 20 mM Cu^{2+}, for 24 h) or 50 µL/well of ApoB-D (1 µg/mL) and kept overnight at 4°C. The plates were blocked with gelatin 1% (Invitrogen Co., Carlsbad, CA, USA) at room temperature for 2 h. Plates were washed twice with PBS (100 µL). Plasma

samples (50 μL, 1:100) were added, and the plates were incubated for 2 h at 4°C, followed by washing with 1% Tween 20 in PBS. A peroxidase-conjugated goat anti-mouse IgG (Pharmigen, San Diego, CA, USA) (50 μL, 1:5.000 in PBS) was added, and after 1 h at room temperature, the plates were washed. Finally, 75 μL of substrate solution (250 mg of tetramethylbenzidine in 50 mL of DMSO, 10 μL of 30% H_2O_2, 12 mL of citrate buffer, pH 5.5) were added, and, after incubation at room temperature for 15 min, the reaction was stopped by adding 25 μL of 2.0 M sulfuric acid. The optical density (OD) was then measured in a microplate reader (Titertek Multiskan MCC/340P, model 2.20, Labsystems, Finland) at 450 nm.

Cell culture studies. Freshly resident mice peritoneal macrophages were harvested in PBS (0.8% NaCl, 0.06% Na_2HPO_4, 0.02% KCl, and 0.04% KH_2PO_4), pH 7.4. Pelleted cells obtained after centrifugation at 500 *g*, 4°C for 3 min were resuspended at a final concentration of 3×10^6 cells/mL in RPMI 1640 medium containing 20% (vol/vol) fetal calf serum (FCS), penicillin (100 U/mL), and streptomycin (0.1 mg/mL), (L-glutamine-penicillin-streptomycin, Sigma Chemical, St. Louis, MO, USA). An aliquot (0.5 mL) was transferred into 24-well tissue culture plates and incubated in a humidifier incubator (5% CO_2 atmosphere at 37°C). To remove non-adherent cells after a 2-h incubation period, each plate was washed twice with RPMI 1640 medium without FCS and used for subsequent experiments.

HDL-mediated cellular cholesterol efflux. Adhered mouse peritoneal macrophages were loaded with CE according to the method described by Brown and Goldstein (33). Briefly, macrophages were incubated in RPMI 1640 medium containing 2 mg/mL FA-free BSA in the presence of [^{14}C]cholesteryl oleate-labeled acetylated LDL ([^{14}C]CE-acLDL, 50 μg of protein/mL) for 24 h, at 37°C and washed once with DMEM (Dulbelcco's Minimum Essential Medium) containing antibiotics. [^{14}C]CE-acLDL–loaded macrophages were incubated for 6 h with DMEM containing 2 mg/mL BSA in the presence of human HDL (100 μg protein/mL) as cellular cholesterol acceptor, and the medium was drawn for radioactivity analysis (Ultima Gold) in the LS6000 Beckman Beta Counter. Cells were washed with PBS and dissolved in 0.2 N NaOH for the measurements of cell-associated radioactivity and protein. Efflux rate was defined as the amount of [^{14}C] unesterified cholesterol in the medium expressed as a percentage of total [^{14}C] in the medium plus cells. Blank values were obtained by the incubation of labeled cells in medium containing only 2 mg/mL BSA and no acceptor lipoprotein.

Acetylated LDL cholesteryl ether uptake by cells. Adhered macrophages were incubated in RPMI 1640 medium containing 10% (vol/vol) lipoprotein deficient human serum (3.5 mg protein/mL of medium) in the presence of acetylated LDL (34) labeled with [^{3}H]cholesteryl oleoyl ether ([^{3}H]COE LDL), 50 μg of protein/mL, for 6 h at 37°C in a humidified incubator (5% CO_2 atmosphere). At the end of the incubation, cells were washed with PBS and solubilized in 0.2 N NaOH for the measurement of the cell-associated radioactivity and protein content. Cellular [^{3}H]COE uptake was defined as the amount of ^{3}H in the cells expressed as a percentage of that offered to the cells per mg of cellular protein.

Cholesteryl ester transfer protein activity assay (CETP). Plasma CETP activity was measured by an exogenous method. Briefly, a mixture of human VLDL and LDL (200 μL, 200 mg cholesterol/dL) was incubated with pooled donor human HDL particles (50 μL, 40 mg cholesterol/dL) labeled with [4-^{14}C]-CE and mouse plasma (10 μL), as the source of CETP and 10 μL of Tris buffer, in a final volume of 300 μL. Blanks were prepared with Tris/saline/EDTA buffer (10 mM/140 mM/1 mM), pH 7.4, and control plasma from chow diet–fed C57BL/6 mice that do not express CETP. Incubations were carried out at 37° C for 2 h. The apoB containing lipoproteins were then precipitated with a 1.6% dextran sulfate/1 M $MgCl_2$ solution (1:1) and radioactivity measured in the remaining supernatant in a scintillation solution Ultima Gold (Eastman Kodak Co., Rochester, NY) in the LS6000 Beckman Beta Counter (Beckman Instruments, Palo Alto, CA). The percentage of 4-^{14}C CE transferred from [^{14}C]-CE-HDL to VLDL + LDL was calculated as: [1 – (sample radioactivity/control radioactivity)] × 100.

Hepatic CETP mRNA measurement: extraction of total RNA. The total mouse liver RNA was isolated using Trizol reagent (Invitrogen Co., Carlsbad, CA, USA) according to the manufacturer's instructions. The integrity of all RNA samples was evaluated on borate agarose gel electrophoresis after ethidium bromide staining. The reverse transcription was performed with Superscript II pre-amplification system (Invitrogen) from 1 μg of total RNA in a final volume of 20 μL.

Determination of hepatic CETP mRNA level. The hepatic mRNA expression of CETP was determined by RT-PCR using the mouse glyceraldeyde-3-phosphate dehydrogenase (GAPDH) mRNA as an internal control. The sequences of each primer pair (sense and antisense) used in the RT-PCR reaction were the following: human CETP (225 bp, GenBank accession no. NM_000078, 5′-CCA AGG TGA TCC AGA CCG-3′ and 5′-TGG TGT AGC CAT ACT TCA GGG-3′); and GAPDH (394 bp, GenBank accession no. M32599, 5'-CTG CAT CCA CTG GTG CTG-3′ and 5′- AGG GTT TCT TAC TCC TTG GAG G-3′). The RT-PCR reaction was performed in a DNA thermal cycler PTC-200 (MJ Research Inc., Watertown, MA, USA) using the reverse transcription product co-amplified in the presence of sense and antisense primers of GAPDH (7.5 pmol) and CETP genes (15 pmol) in PCR buffer (50 mM KCl, 1.5 mM $MgCl_2$, 20 mM Tris-HCl, pH 8.3), 200 mM of each dNTP, 5% DMSO, 2 U Taq DNA polymerase (Amersham Biosciences, Little Chalfont, Buckinghamshire, UK), in a final volume of 50 μL. The PCR conditions were 94°C for 4 min, and subsequently 28 cycles at 94°C for 1 min, 54°C for 90 s, 72°C for 2 min, and finally at 72°C for 10 min. The PCR products were then submitted to electrophoresis in 2% agarose gel, stained with ethidium bromide, and the band densities were analyzed by the software from Alpha Imager TM 1220 (Alpha Innotec Co., SanLeandro, CA, USA). The relative density of each sample was nor-

malized to the signal of GAPDH and was expressed as the sample/GAPDH ratio.

Lecithin cholesterol acyltransferase assay (LCAT). The LCAT-mediated cholesterol esterification reaction was measured using endogenous substrates (35). Briefly, mice plasma (20 μL) was incubated with [4-^{14}C]-free cholesterol at 37°C for 24 h, and the free cholesterol (4-^{14}C-FC) and cholesterol ester (4-^{14}C-CE) were separated by TLC for radioactivity measurement in the scintillation solution Ultima Gold in a LS6000 Beckman Beta Counter.

Statistical analysis. All comparisons were analyzed by statistical tests using the GraphPad Prism, version 3.0 for Windows (GraphPad Software Inc., San Diego, CA). Differences were considered significant when $P < 0.05$.

RESULTS

The amount of diet consumed did not differ among all groups throughout the study (3.0 ± 0.7 g/d). Iso Low, Iso High, and control groups gained weight from the basal to the final periods (Table 2). At the end of the study, Iso High animals were the heaviest of the three groups.

Plasma lipid and lipoprotein concentrations. Plasma lipid and lipoprotein concentrations were determined 2 wk after ovariectomy (basal values), and again at the end of the study (19th wk). At the basal period, there were no differences among the groups, and at the end of the study, plasma triglycerides levels of Iso Low group were higher than the other groups (Table 3).

The average areas of atherosclerotic lesion did not differ among Iso Low, Iso High, and control groups (Table 4). Because of this lack of difference, we investigated the percent distribution of the lesions according to their size in reference to the control group median size (8.1×10^3 μm^2) so as to define small lesions (below median) and large lesions (above median). We found that the number of mice with small and large lesions were roughly evenly distributed in the Iso Low group, but in the Iso High group, there was a distribution trend favoring the prevalence of smaller lesions: 70% of all mice in this group presented small-type lesions ($P = 0.085$ by κ^2 test).

Antibody titers against oxidized LDL or against an epitope of oxidized apolipoprotein B (ApoB-D) did not differ among the three experimental groups (Table 5).

When compared with the Iso Low and control groups, Iso High mice presented lower mouse peritoneal macrophage up-

TABLE 2
Basal and Final Body Weights[a]

Body weight (g)	Iso Low	Iso High	Control
Basal	18.8 ± 2.9 (25)	20.0 ± 3.2 (27)	19.8 ± 4.1 (27)
Final	27.4 ± 3.9[b] (25)	33.5 ± 7.7[b,c] (28)	29.5 ± 4.8[b] (28)

[a]Mean ± SD. Values in parenthesis represent the number of animals in each group. Statistical comparisons: ANOVA followed by Newman-Keuls multiple comparison test.
[b]Basal vs final, $P < 0.05$.
[c]Final weight of Iso High is greater than the other groups.

[a]Paired student's t test: $P < 0.001$, basal vs final in the experimental groups. mRNA values were normalized to GAPDH mRNA content and expressed as relative values.
[b]ANOVA followed by Newman-Keuls multiple comparison test: Iso Low and Iso High lower than control group at $P < 0.05$.

take of [^{3}H]COE acetyl-LDL (68%), and higher ^{14}C-cholesterol efflux rate (50%) from macrophages preloaded with [^{14}C]CE acetyl-LDL (Fig. 1).

Although the hepatic CETP mRNA expression was lower in Iso Low and Iso High than in the control group, plasma CETP activity was not influenced by the isoflavone treatment (Table 6).

Lecithin cholesterol acyl transferase (LCAT), hepatic (HL), and peripheral lipoprotein lipase (LPL) activities did not differ among all the groups (data not shown).

DISCUSSION

Considering that in addition to plasma cholesterol and lipoprotein concentrations, several other factors play roles in the pathogenesis of atherosclerosis, in this work we investigated the effects of soy protein containing isoflavones on the cholesterol uptake and efflux by mouse peritoneal macrophages, levels of antibodies against oxidized LDL, and average size distribution of the lipid-laden area in the aortic root.

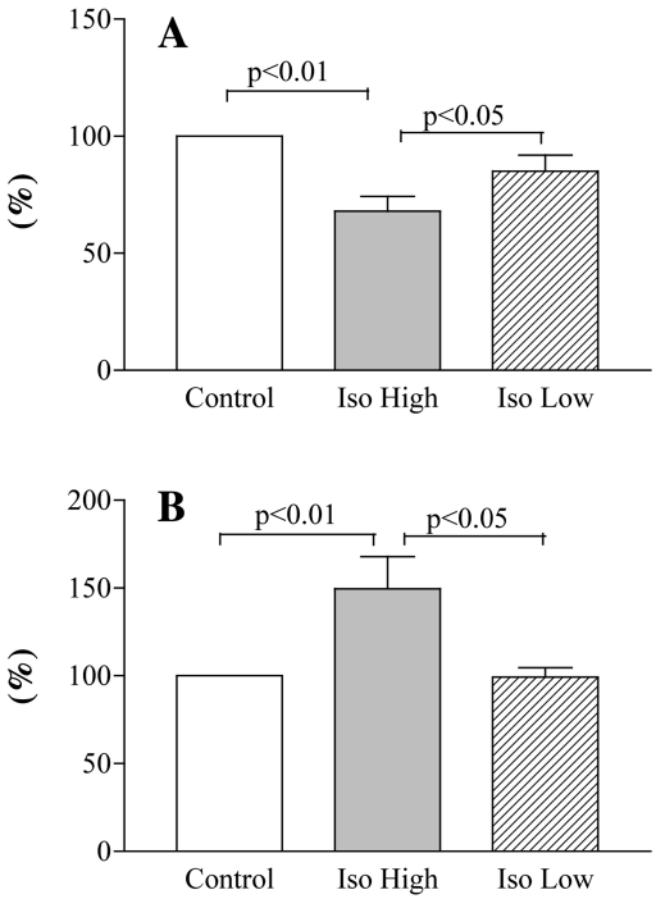

FIG. 1. Mouse peritoneal macrophage uptake of [^{3}H]COE acetyl-LDL (A) and HDL-mediated efflux of cellular unesterified ^{14}C-cholesterol (^{14}C present in the medium) in macrophages that had previously been loaded with [^{14}C]CE acetyl-LDL (B). Data are relative to the control group. Eight replicates of cell pools of from six to eight mice in each experimental condition are shown. Statistical comparison: ANOVA followed by Newman-Keuls multiple comparison test displayed in the figures.

Macrophages drawn from the Iso High group took up significantly less cholesterol and delivered into the culture medium significantly more of the internalized cholesterol than the Iso Low and control groups (Fig. 1). However, these results did not significantly modify the average size of lipid-stained area in the aortic root of isoflavone-treated mice (Fig. 2).

It is known that antibodies against ox-LDL are positively associated with the ox-LDL content in the atherosclerotic lesions in LDL receptor knockout mice (36), as well as with the severity of coronary arterial disease in humans (37). Nonetheless, the results remain controversial in humans; Heikkinen *et al.* (38) did not find differences in ox-LDL antibodies titers in postmenopausal women after one year on hormonal replacement, whereas Uint *et al.* (39) described increased anti-ox-LDL titers after 90 d on this treatment. In this regard, Wen *et al.* (40) and Santanam *et al.* (41) showed that, except for plasma concentrations over 7343 pmol/L, estrogens at physiological concentrations (499 to 4,993 pg/mL) do not protect LDL particles against oxidation. On the other hand, Damasceno *et al.* (32) found that rabbits fed soy protein containing isoflavones have lower autoantibodies against ox-LDL compared with casein-fed rabbits. However, in our study, antibodies against ox-LDL and against apoB-D did not differ among the experimental groups. Regarding the antioxidant action of isoflavones on LDL, although Samman *et al.* (42) did not find differences in the oxidation susceptibility of human LDL after isoflavones or placebo treatment, Meng *et al.* (27) described an increased lag time during the oxidation process, indicating resistance to oxidation likely due to the incorporation of esterified isoflavones into the LDL particles.

Measuring CETP activity in plasma was necessary in our study because plasma CETP inhibition has potentially antiatherogenic effects in humans and in experimental animals (43), but CETP activity was not influenced by the added isoflavones.

In general, estrogen treatment protects against aortic fat accumulation in rabbits, monkeys, and mice, as reviewed by Hodgin and Maeda (44). Nonetheless, in the majority of these investigations, including in our own, in transgenic mice expressing the human CETP (28,29), this protection seems to be related to the lowering of plasma total cholesterol in the non-HDL-C fraction, namely, in apoB-containing lipoproteins.

The present investigation showed that soy protein containing isoflavones resulted in (1) a trend for the formation of smaller lipid-laden aortic lesions, (2) impairment of the macrophage cholesterol loading, and (3) stimulation of HDL-mediated cellular cholesterol efflux, conferring a potentially antiatherogenic effect. Nonetheless, a cautionary note regarding our study concerns the fact that soy protein containing isoflavones and other alcohol isolated soy protein lower but do not eliminate the ability of soy protein to reduce atherosclerosis and thus as suggested by others may have influenced our results because alcohol-extracted soy protein was utilized in our investigation (45).

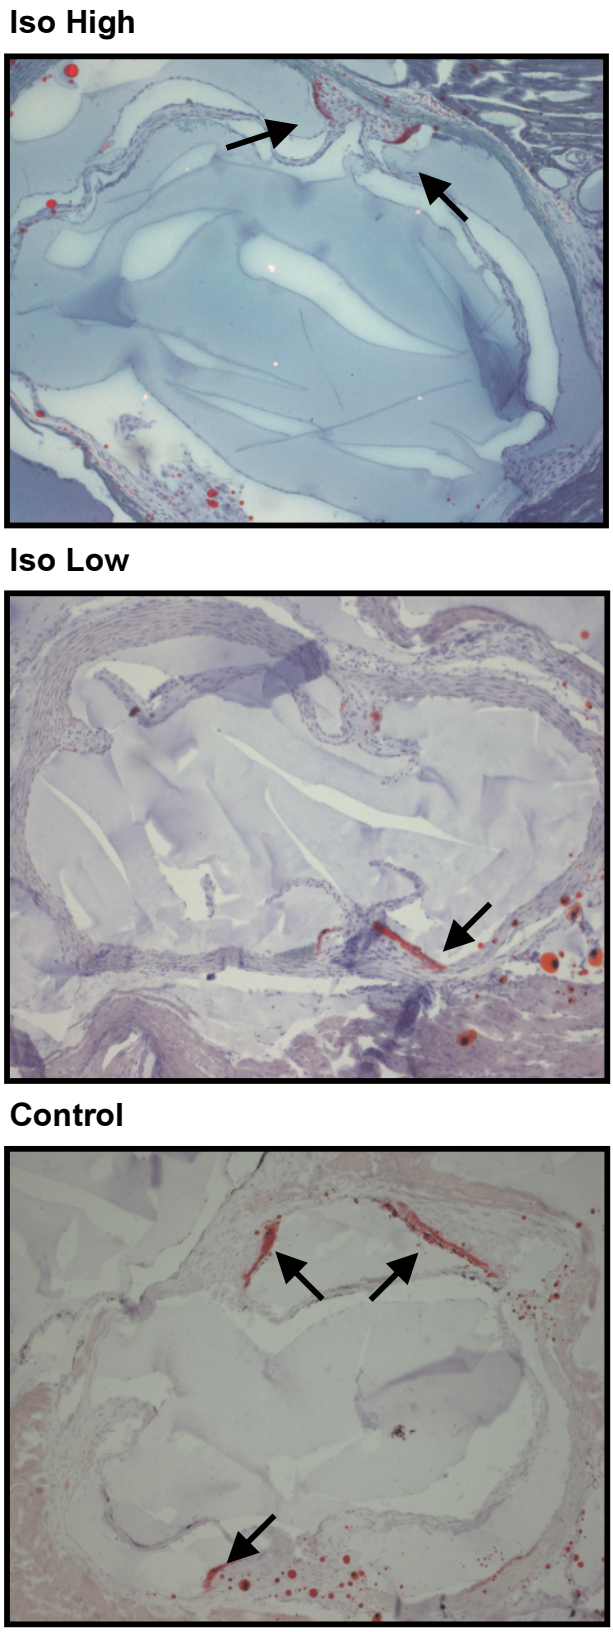

FIG. 2. Histological typical lesions stained with Oil red O and counterstained with Harris hematoxylin and with light green are indicated by arrows. Size increased 10 times.

Our study on the effects of soy protein containing isoflavones on atherosclerosis differs from other investigations in that we chose an experimental model where severe hypercholesterolemia was avoided. We then observed that soy protein containing isoflavones did not reduce the plasma cholesterol concentration or the degree of experimental atherosclerosis, a finding that agrees with another experimental study (23). On the other hand, in a few animal experiments where the degree of hypercholesterolemia was mild, soy isoflavone reduction or prevention of the development of the experimental atherosclerosis seemed consequent to the reduction of plasma cholesterol (17,18). However, in few studies where severe hypercholesterolemia was induced soy isoflavones protected against atherosclerosis without modifying the concentration of plasma cholesterol (19,20). Nonetheless, our study sheds light on the beneficial effects of soy protein containing isoflavones on the macrophage cholesterol metabolism that could have been more efficacious to protect against experimental atherosclerosis in the presence of severe hypercholesterolemia.

These effects need to be taken into account for the human use of this supplemental nutrient, considering that in humans the effects of isoflavones on plasma lipid concentration are controversial and that no trials have been published on the effects of isoflavones on cardiovascular disease (46,47).

ACKNOWLEDGMENTS

This study was supported by a grant (01/00994-9) from Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP). We are grateful to Solae Company for their contribution of the soy products and the diets and to Mr. Pedro A.F. Neto for caring for the animals.

ABSTRACT: Dyslipoproteinemia of the Nagase analbuminemic rat (NAR) is characterized by elevated concentrations of VLDL and LDL attributed to increased rates of liver lipoprotein synthesis. Increased lysophosphatidylcholine (LPC) in NAR HDL has been attributed to high plasma LCAT activity. We show here that, as compared with Sprague-Dawley rats (SDR), NAR plasma triacylglycerol (TAG), total cholesterol (TC), HDL TAG, protein, total phospholipids (PL), LPC, and PS are increased. These alterations rendered the NAR HDL particle more susceptible to the activity of the enzyme hepatic lipoprotein lipase (HL), which otherwise was unaltered in our study. Fractional catabolic rates in blood of the autologous ^{125}I-apoHDL (median and lower quartile values), were, respectively, 0.231 and 1.645 (n = 10) in NAR as compared with 0.140 and 0.109 (n = 10) in SDR (P = 0.012), corresponding to synthesis rates of HDL protein of 89.8 ± 33.7 mg/d in NAR and 17.4 ± 6.5 mg/d in SDR (P = 0.0122). Furthermore, Swiss mouse macrophage free-cholesterol (FC) efflux rates, measured as the percent [^{14}C]-cholesterol efflux/6 h, were 8.2 ± 2.3 (n = 9) in NAR HDL and 11.2 ± 3.2 (n = 10) in SDR HDL (P = 0.03). Therefore, in NAR the modification of the HDL composition slows down the cell FC efflux rate, and together with the increased rate of plasma HDL metabolism influences the reverse cholesterol transport system.

Paper no. L9941 in *Lipids 41*, 663–668 (July 2006).

Hypoalbuminemia, proteinuria, hypercoagulability, edema, and dyslipoproteinemia that includes alterations of HDL composition and metabolism are common features of nephrotic syndrome (NS) (1). Understanding the mechanisms involved in this hyperlipidemia is critical to explain the increased cardiovascular risk in NS (2,3). Nephrotic syndrome animal models and the Nagase analbuminemic rat (NAR) share several alterations in the metabolism of lipoproteins (4).

From a stock of Sprague-Dawley rats (SDR), Nagase *et al.* (5) produced a strain of hyperlipidemic rats, NAR, completely deficient in serum albumin. The serum albumin deficiency is inherited as an autosomal recessive trait. Similar to NS, NAR hyperlipidemia has been characterized by increased total cholesterol (TC), TAG, free FA (FFA), and phospholipid (PL) plasma concentrations. Plasma apolipoproteins (apo) A-I, B, and E, as well as HDL lysophosphatidylcholine (LPC) are also significantly increased in NAR (6,7).

NAR total serum protein concentration is normal (5) but the plasma oncotic pressure is reduced (8). Although the relationship between low oncotic pressure and hyperlipidemia is not completely understood, previous studies have shown increased plasma TAG and VLDL synthesis rates in NAR that explain the pathogenesis of hyperlipidemia in NS (9,10).

In analbuminemia, substantial amounts of FFA and LPC (6,7) are bound to lipoprotein (LP) fractions, whereas in normal animals albumin is the main carrier of these components (11,12). Higher LPC concentration in NAR erythrocytes is normalized after albumin addition to blood (13), and monolayer cell permeability of human coronary artery endothelial cells is increased in a time- and dose dependent manner with LPC treatments (14). Furthermore, albumin protects endothelium-dependent relaxation against the inhibitory effect of LPC (15) and reduces LPC uptake by cultured endothelial cells (16). Thus, the role of albumin as a reservoir for LPC may be important to maintain the integrity of the monolayer endothelial cell. Injury or dysfunction of the monolayer endothelial cell is considered one of the critical events in the development of atherosclerosis (14).

Although rats are not suitable models for studies of atherosclerosis (17), NAR and human analbuminemia (5) are useful tools for understanding whether alterations in the metabolism of HDL play a role in the regulation of the body cholesterol homeostasis that may explain the mechanisms of premature atherosclerosis in humans. Thus, the current study aims at investigating whether the anti-atherogenic role of HDL is impaired by modifications of the HDL composition due to alterations of HDL metabolism in NAR.

EXPERIMENTAL PROCEDURES

Animals. Breeding NAR and SDR colonies were kindly supplied by Professors Roberto Zatz and Clarice K Fujihara (Renal Division of University of São Paulo Medical School). Animals were raised and fed *ad libitum* a pelleted commercial chow (Nuvilab-Nuvital, São Paulo, Brazil) in conventional housing at 22 ± 2°C with a light-dark cycle of 12 h. Animal experiments were performed in accordance with protocols approved by the Institutional Animal Care and Research Advisory Committee (nos. 582/01 and 029/02). In order to avoid the interference of chylomicron TAG on plasma total measurements, all experiments were carried out in the morning after a 12-h overnight fasting period. Under ketamine (60 mg/kg body weight, i.p.) and xylazine (10 mg/kg body weight, i.p.) anesthesia, the right carotid and abdominal aorta arteries of 3-mon-old male NAR and SDR were cannulated with indwelling polyethylene catheters PE-50 and PE-100 (Intramedic, Clay Adams, Parsippany, NJ), respectively, previously rinsed with liquid silicon (Silicone Prontosil, Rio de Janeiro, Brazil). The right carotid artery isolation was carried out by a small incision in the ventral median line of the neck, and the abdominal aorta artery was cannulated after a median abdominal laparotomy. All experiments started after the animals had completely recovered from surgery. At the end of metabolic studies rats were sacrificed in a CO_2 chamber.

Isolation and labeling of HDL. Blood was drawn over heparin (20 IU, 5μL) by exsanguination from the rat abdominal aorta (NAR, $n = 12$; SDR, $n = 9$). HDL ($d = 1.063$–1.21 g/mL) was separated from plasma by sequential ultracentrifugation (L-80 ultracentrifuge, Beckman Instruments, Palo Alto, CA) in a 50Ti rotor after spinning at $d > 1.21$ g/mL, 200 000 × g, for 40 h at 4°C as previously described (18). HDL purification was performed by discontinuous gradient ultracentrifugation (19) utilizing an SW 41 rotor spinning at 200 000 × g for 24 h at 4°C. LP was dialyzed against EDTA-PBS. The protein content was determined according to Lowry *et al.* (20). HDL LPC, sphingomyelin (SM), PC, PS, and PE fractions were separated by TLC (21) and measured by the modified micro-procedure of Bartlett (22). TC and TAG were determined using commercially available kits (Roche Diagnostics, Mannheim, Germany). Fresh NAR ($n = 12$) or SDR ($n = 9$) HDL (500 μL) was incubated with 17 μl of L-dipalmitoyl [choline-methyl-^{14}C] PC (^{14}C-PC) (Dupont-New England Nuclear, Boston, MA) and their respective infranatants (3 mL; $d > 1.21$ g/mL) in a shaking water bath for 18 h at 37°C (23). The purity of the isotope was checked by silica gel TLC and shown to be higher than 98%. NAR and SDR ^{14}C-PC-HDL were then re-isolated by sequential ultracentrifugation as described above.

Hepatic post-heparin plasma lipolytic activity. Four minutes after intra-carotid heparin injection (100 IU/kg body weight), NAR ($n = 3$) and SDR ($n = 3$) post-heparin plasma lipases were obtained from the abdominal aorta. This time was selected based upon the time-course of appearance of lipolytic activities (24), and the hepatic lipase (HL) activity was determined after inhibition of the peripheral lipoprotein lipase activity as previously described (25). Nonetheless, the measurement of HL at a single time point does not reflect the HDL TAG hydrolysis rate over time. Briefly, NAR and SDR HDL were incubated with Tris-HCl (2 M NaCl, pH 8.0; Sigma Chemical Co., St Louis, MO) using autologous and heterologous post-heparin plasma in a shaking bath for 1 h at 37°C. Folch (3 mL chloroform/methanol, 2:1, vol/vol; E. Merck, Darmstadt, Germany) was added to the samples at the end of incubation. Following an overnight period at 4°C, the infranatant was then evaporated under N_2 flow. After separation by TLC, radioactivity counts in PC and LPC bands were determined in a beta scintillation counter (LS 6000-TA8, Beckman Instruments). HL activity was estimated as the percentage conversion of PC to LPC.

Iodination and kinetics of HDL. After dialysis, NAR HDL (3.69 mg/dL) and SDR HDL (1.61 mg/dL) protein pools were iodinated with iodine monochloride (Sigma Chemical Co.) and sodium iodide I-125 (Na-^{125}I) (MDS Nordion, Kanata, Ontario, Canada) (26). Radioactive HDL (^{125}I-apoHDL) pools were exhaustively dialyzed against PBS (pH 7.4), and an aliquot precipitated by TCA (E. Merck). More than 95% of ^{125}I-apoHDL was precipitated by TCA.

Four days before as well as during the ^{125}I-apoHDL kinetic study, animals had free access to drinking water containing potassium iodide and iodine (1.5 mg in each 500 mL) to avoid ^{125}I uptake by the thyroid. Before and after the experiment, blood samples (70 μL) were drawn for hematocrit, TAG, and TC measurements. Blood samples (100 μL) were sequentially drawn from the tail vein over a period of 48 h (at 3 min, 10 min, 6 h, 10 h, 24 h, 32 h, and 48 h) after an intra-carotid autologous infusion of NAR or of SDR ^{125}I-apoHDL. For this purpose rats were lightly restrained but not anesthetized. Radioactivity was measured in 40-μL plasma aliquots in a gamma counter (Cobra Model, Packard Instruments, Meriden, CT). Rats were normally fed 3 h after the ^{125}I-apoHDL infusion. Plasma ^{125}I-apoHDL clearance curves were analyzed as the fractional catabolic rate (FCR), according to a compartmental analysis of the plasma protein radioactivity vs. time. The system is based on a two-pool model that assumes the existence of an intravascular pool in dynamic equilibrium with an extravascular pool and that new input or exit of radiolabeled HDL occurs from the intravascular pool only (27). FCR values were derived directly from the kinetic model as the clearance rate from the intravascular pool. Biexponential ^{125}I-apoHDL decay curves for rats were individually modeled using a modified SAAM (simulation, analysis, and modeling) program, Compartmental Analysis Program (Institute of Nuclear Research IPEN, São Paulo, Brazil) (28) as summarized in Figure 1.

Cellular cholesterol efflux. Swiss mouse macrophages were harvested from peritoneal cavity in sterile PBS (0.8% NaCl, 0.006% Na_2HPO_4, 0.02% KCl, and 0.04% KH_2PO_4), with added penicillin (100 U/mL), streptomycin (100 U/mL), and fungizone (2.5 μg/mL) (Gibco BRL, Life Technologies, Rockville, MD). Pelleted cells after centrifugation at 90 × g for 2 min, at 4°C were suspended in the tissue culture medium (RPMI 1640; Gibco BRL, Life Technologies) including 10% FBS (Gibco BRL, Life Technologies), attaining final concentration of

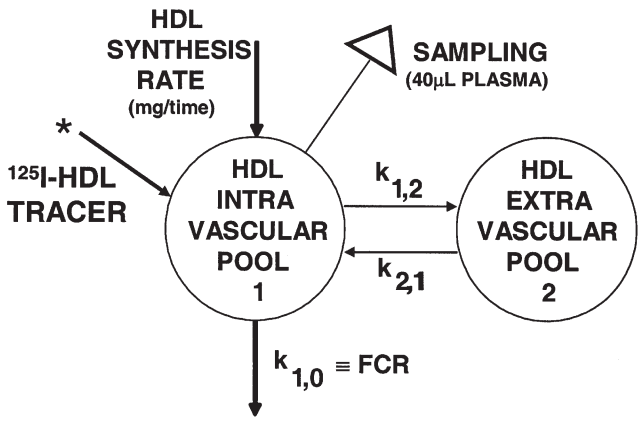

FIG. 1. Schematic model of the HDL kinetics. The model consists of two compartments, or pools, the intravascular and the extravascular compartments. It is assumed that the compartments are in dynamic equilibrium. The $k_{i,j}$ (min^{-1}) values represent the transfer rate of HDL among the compartments. The constants $k_{i,j}$ are associated with the half-life time (min) according to $t_{1/2} = 0.693/k_{i,j}$. In addition, the same quantity of synthesized HDL (mg/time) that is introduced in compartment 1 is removed from the system; thus, synthesis rate of HDL can be estimated using the following formula: HDL synthesis (mg/d) = plasma HDL (mg/mL) × plasma volume (mL) x FCR (h^{-1}) × 24 h/d. This model also assumes that ^{125}I-HDL is injected instantaneously in the intravascular compartment (arrow with asterisk). From compartment 1 a fraction $k_{1,2}$ of HDL is transferred to compartment 2 at each time unit. On the other hand, a fraction $k_{2,1}$ of HDL contained in the extravascular compartment returns to the intravascular compartment in each time unit. The tracer sampling was made in compartment 1 (line with a triangle).

1.5×10^6 cells/well. Cell solution were dispersed into 24-well plastic dishes and kept in a humidified incubator with a 5% CO_2 atmosphere at 37°C, for 24 h. Adherent cells were washed twice in PBS containing antibiotics and 0.1% FA-free albumin (FAFA; Sigma Chemical Co.). Macrophage cholesterol loading was carried out on 24-h incubation in Dulbecco's modified Eagle`s medium (DMEM; Gibco BRL, Life Technologies) containing 0.1% FAFA, 0.5 μCi/mL [4-^{14}C]-free cholesterol ([4-^{14}C]-FC; Dupont-New England Nuclear), and acetylated LDL (50 μg of protein/mL). The purity of the isotope was checked by silica gel TLC and shown to be higher than 98%. Cellular cholesterol pools were equilibrated for 24 h in DMEM/FAFA prior to the incubation with HDL. Cholesterol-enriched cells were next washed twice in PBS-FAFA, and thereafter incubated with NAR and SDR HDL (100 μg of HDL protein/mL) for 6 h. Control incubations were done with DMEM/FAFA only. The medium was drawn into tubes and centrifuged at $125 \times g$ for 10 min to remove cell debris, and the radioactivity was measured in a beta scintillation counter. Cells were rinsed twice with cold PBS/FAFA and twice with cold PBS and extracted with hexane/isopropanol (3:2, vol/vol) (E. Merck). Solvent was evaporated and radioactivity measured. The percentage of ^{14}C-FC efflux was calculated as (^{14}C-FC in the medium/^{14}C-FC in cells plus medium) × 100. The difference between the efflux elicited by HDL plus albumin and that by the albumin-enriched media expresses the HDL-mediated efflux. Protein measurement was done after cell lysis in 0.2 N NaOH (29,30).

Statistical analyses. Data were expressed as mean ± SD. The student's t-test was used for statistical comparison of the data, except in the study of ^{125}I-apoHDL kinetics, where the Mann-Whitney rank sum test was used and data expressed as median and lower quartile. Data evaluation was calculated using GraphPad Prism version 2.01 (GraphPad Software Inc., San Diego, CA). Results of the statistical tests were considered significant at the 95% confidence level ($P < 0.05$).

RESULTS

Similarity of body weight was attained in both experimental groups; however, plasma TAG and TC (Table 1) as well as HDL TAG, TC, PL, and protein concentrations were higher in NAR than in SDR. HDL LPC and PS concentrations were also higher in NAR, but HDL SM, PC, and PE concentrations did not differ between the two groups (Table 2).

We have investigated whether the differences in the HDL composition could be ascribed to differences in post-heparin lipase activity. SDR and NAR HDL particles labeled with L-dipalmitoyl [choline-methyl-^{14}C] were incubated with plasma containing HL according to several combinations possible. In autologous as well as in heterologous incubations HDL-PL hydrolysis *in vitro* was significantly higher when NAR HDL was used as substrate (Table 3). The higher PL hydrolysis of NAR HDL was solely attributed to alteration of the HDL composition and not to differences in intrinsic HL activities between NAR and SDR.

Autologous ^{125}I-apoHDL was infused intra-arterially to further explore whether altered NAR HDL composition brings on modifications in the kinetics of HDL. Total plasma HDL from pools of donor NAR and SDR were labeled with ^{125}I and pulse-infused into the carotid of NAR and SDR rats. Thereafter, radioactivity was measured over the course of 48 h and expressed per mL of plasma. Data derived from the FCR curves expressed as median and lower quartile were, respectively, 0.231 and 1.645 ($n = 10$) in NAR, as compared with 0.140 and 0.109 ($n = 10$) in SDR ($P = 0.012$), indicating a faster rate of HDL metabolism in NAR that can only be explained by a higher HDL synthesis rate in this animal (Fig. 2).

As HDL is the main LP fraction involved in the reverse cholesterol transport system, that is, in the FC removal mechanism from extra-hepatic tissues and its transport to the liver, it was then investigated whether the HDL-mediated cell cholesterol efflux of [^{14}C]-cholesterol enriched macrophages from donor mice was altered in the presence of HDL drawn from NAR. Indeed,

TABLE 1
Characteristics of NAR and SDR Used in This Study

L-Dipalmitoyl [choline-methyl-^{14}C] HDL particles were incubated with hepatic lipase (HL). HDL particles and HL were drawn from SDR and from NAR, and experiments were designed in a crossover fashion.
Data are expressed as mean ± SD. Values express percent hydrolysis of the radioactive phospholipids; figures in parentheses represent n for the measurement.
[a]Statistical comparison by student's t test

the percent [^{14}C]-cholesterol macrophage efflux was 8.2 ± 2.3 (n = 9) utilizing NAR HDL and 11.2 ± 3.2 (n = 10) utilizing SDR HDL, a difference significant at $P = 0.03$.

DISCUSSION

Albumin plays an important role on the transport of FFA, bilirubin, ions, heavy metals, drugs, hormones, enzymes, and bile acids (31–33). NAR are characterized by analbuminemia, hypercholesterolemia, hypertriacylglycerolemia, and high plasma PL levels (5). These are also characteristics of human analbuminemia (1,2). In addition, several of these features are present in the hypoalbuminemia of NS. The absence of albumin presents potential problems regarding plasma FFA and LPC transport. For instance, LPC and FFA are mainly bound to LP and not to albumin in NAR plasma (7).

The two- to threefold elevated LPC concentration in NAR HDL can be explained by synergistic processes. A faster rate of HDL catabolism in NAR reflects an increased production of HDL, and, consequently, a greater HDL particle number exposure to the action of the HL, which otherwise is normal in these animals. Although Kaysen *et al.* (34) had reported a reduced

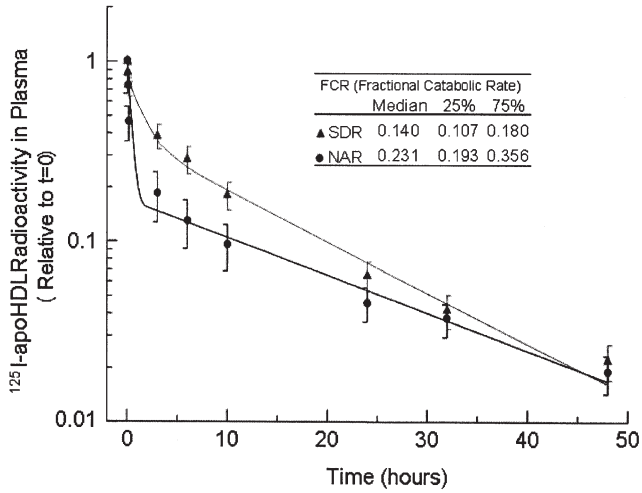

FIG. 2. Plasma radioactivity curves (in 40 µL aliquots) from tail vein blood sequentially drawn over a period of 48 h (3 min, 10 min, 6 h, 10 h, 24 h, 32 h, and 48 h) after an intracarotid autologous infusion of NAR (circles) or of SDR ^{125}I-apoHDL (triangles). Each experimental point represents the mean ± SEM (n = 10) relative to t = 0. Median FCR values (h^{-1}) were derived directly from the kinetic model as the clearance rate from the intravascular pool. NAR FCR 0.231 *vs* SDR FCR 0.140, difference significant at $P = 0.012$. FCR and the HDL-protein concentration in plasma allowed for the calculation of the absolute HDL-protein synthesis rates as mg/d ± SEM, which were 89.8 ± 33.7 mg/d in NAR and 17.4 ± 6.5 mg/d in SDR (difference significant at $P = 0.0122$).

apo-AI fractional catabolic rate in NAR, their apo-AI kinetics had been carried out utilizing apo-AI HDL drawn from normal SDR, and not from NAR. The enhanced conversion of PC to LPC (35) should be accounted for by the HL-induced modification of the LP. In this regard, the HL activity provides the major (~55%) route for PC removal from plasma, which is consistent with the elevated plasma PC concentration observed in humans with HL deficiency (36). The faster plasma clearance of ^{125}I-apoHDL in NAR compared with SDR reflects an increased synthesis rate and plasma HDL concentration simultaneous with an elevated concentration of NAR HDL TAG, PL, and apo-AI. The latter is likely the outcome of the metabolism of TAG-rich particles; a previous study from our laboratory has shown faster plasma TAG and VLDL synthesis rates in NAR than in SDR (10). Our data are compatible with an increased rate of hepatic cholesterol synthesis in NAR as reported by others (37,38).

Hepatic scavenger receptor B type I (SR-BI) protein is not altered in NAR (38). SR-BI internalizes HDL cholesteryl ester but little HDL protein. Thus, the faster turnover rate of HDL protein means that specific receptors, such as kidney cubilin and megalin, must be involved in HDL protein metabolism in NAR (39).

The higher rate of LCAT activity in NAR (7) prevents the concentration of HDL PC from further rising. In other words, an elevated concentration of PC must have occurred early on due to the increased HDL production rate. On the other hand, the higher HDL PS concentration in NAR may have rendered the HDL particle more susceptible to the action of HL, as previously reported

(40). Furthermore, greater plasma apoE and apo-AI concentrations in NAR, attributed mostly to the apoE-loaded HDL (7), may also activate the HDL PC hydrolysis by HL (7,35,41–45). Finally, LPC is known to modulate the metabolism of lipoproteins upon modifying their clearance *in vivo* and *in vitro* (46,47).

Considering that HDL is a critical protecting factor against premature atherosclerosis (48,49), we investigated the role of this particle on the removal of unesterified cholesterol from mouse peritoneal macrophages. This is the first step in the reverse cholesterol transport system (RCT) that ultimately delivers peripheral cholesterol to the liver (43,50). As compared with SDR the NAR HDL capacity for FC efflux from the lipid-loaded macrophages is significantly impaired. In this regard, it is known that the PL content and composition are important factors determining the HDL capacity for FC efflux from peripheral cell plasma membranes (51–53). For instance, HDL PC hydrolysis by phospholipase A2 slows down the rate of the SR-BI-mediated cholesterol efflux (53). Thus, the increased LPC content in NAR HDL may have contributed simultaneously to the impaired cell FC efflux rate and to the faster hepatic HDL uptake. Increased formation of HDL LPC and decreased HDL-dependent FC efflux from lipid-loaded mouse macrophages have also been reported in the human HDL pretreated with human secretory phospholipase (54). However, an impaired adenosine triphosphate-binding cassette transporter A1 receptor expression in NAR could not be ruled out and needs further investigation.

In summary, this study indicates that in NAR, plasma concentrations of TAG, PL, and TC are elevated largely due to the HDL fraction reflecting higher rate of HDL protein synthesis. The increased HDL lipid content renders the particle more susceptible to the otherwise unaltered intrinsic HL activity. Moreover, the efficiency of the NAR HDL to remove cell cholesterol is impaired. Therefore, alterations in the HDL metabolic profile described in NAR help explain disturbances of the RCT.

ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions of Glaucia R. Antunes, Clarice M.F. Ferreira, Romildo D. Lima, and Luciano Lopes for the animal care. We are also grateful to the Biotechnology Department of the Institute of Nuclear Research (IPEN) for kindly providing Na-^{125}I and to the Department of Rheumatology (LIM-17) for the availability of their animal housing unit. This work was made possible by the generous support from Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP) and Medical Laboratory Investigation of Hospital das Clínicas (LIM).

ABSTRACT: CLA intake in exclusively breast-fed infants is close to levels found to have physiological effects in animals. However, in the majority of studies mixtures of CLA isomers have been used and the independent effects of the major CLA isomer in human milk, *cis*-9,*trans*-11 CLA, at the intake level in exclusively breast-fed infants have hardly been studied. We therefore studied the effects of *cis*-9,*trans*-11 CLA on plasma lipids and glucose, immune function, and bone metabolism in growing rats. Thirty male Sprague-Dawley rats (n = 10/group) were fed either 20 mg/kg/d *cis*-9,*trans*-11 CLA and 20 mg/kg/d sunflower oil (CLA20), 40 mg/kg/d *cis*-9,*trans*-11 CLA (CLA40), or 40 mg/kg/d sunflower oil (placebo) for 8 wk. No significant differences between groups were found in plasma lipids, glucose, insulin, C-reactive protein, or lipid peroxidation. Liver fat content was lowest in the CLA20 group. *In vitro* interleukin 2 (IL-2) production increased, and tumor necrosis factor alpha, IL-1ß, prostaglandin E_2, and leukotriene B_4 production decreased in the CLA20 group. No differences between groups were detected in IL-4, IL-6, or interferon gamma production, plasma osteocalcin, insulin-like growth factor, or urinary deoxypyridinoline crosslinks. Plasma tartrate-resistant acid phosphatase 5b activity was significantly increased in the CLA40 group. The results indicate anti-inflammatory effects and enhanced T-cell function for the CLA20 group. No adverse effects were seen in the CLA20 group, whereas indications of increased bone resorption rate were observed in the CLA40 group.

Paper no. L9951 in *Lipids 41*, 669–677 (July 2006).

CLA, a group of positional and geometric isomers of linoleic acid (*cis*-9,*cis*-12 18:2), has been shown to possess a multitude of beneficial physiological effects, including anticarcinogenic, antiatherogenic, and antidiabetic properties as well as effects on body composition (1,2). Evidence also suggests that it may enhance selective immune functions, while ameliorating negative effects of abnormal immunological responses, possibly via altered cytokine and immunoglobulin production (3). Effects of CLA on bone metabolism have been reported in few studies, with both increased (4) and decreased (5) bone formation rates being reported.

However, adverse effects in both animals and humans have also been reported. Increased liver (6,7) and spleen weight (6) and/or increase in liver lipids (up to 5-fold) (7,8) have been found in mice fed a CLA mixture or *trans*-10,*cis*-12 CLA. Indications of increased insulin resistance were observed in mice fed a CLA mixture (6) and in overweight subjects fed *trans*-10,*cis*-12 CLA (9). Serum C-reactive protein (CRP), an acute-phase reactant, was doubled in subjects receiving *trans*-10,*cis*-12 CLA (10). Two studies have shown a several-fold increase in lipid peroxidation, measured as urinary 8-iso-prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) in subjects fed a CLA mixture or *trans*-10,*cis*-12 CLA (10,11). Evidence from studies using pure isomers thus suggests that the isomer responsible for the adverse effects may be *trans*-10,*cis*-12 CLA. However, in a recent study *cis*-9,*trans*-11 CLA decreased insulin sensitivity by 15% and increased lipid peroxidation by 50% in abdominally obese men (12).

CLA intake relative to body weight is significantly higher in exclusively breast-fed infants than in adults, and is close to levels reported to have beneficial physiological effects in animals (~23 mg/kg body wt/d) (13,14). Human milk CLA concentrations have been reported to range from 2.23 to 5.43 mg/g fat (15). Milkfat-based infant formulas also contain CLA, whereas it is generally not detected in vegetable oil–based formulas (15). Data from both animal and human studies suggests that CLA intake during critical phases of development may have effects later in life (16–18). Most earlier studies have used CLA isomer mixtures containing equal amounts of the *cis*-9,*trans*-11 and *trans*-10,*cis*-12 isomers. The independent effects of the major CLA isomer in human milk, *cis*-9,*trans*-11 CLA, at intake levels corresponding to those in exclusively breast-fed infants have not been studied. We therefore studied the physiological effects of *cis*-9,*trans*-11 CLA in a developing animal model.

EXPERIMENTAL PROCEDURES

The study was conducted at the Laboratory Animal Centre of the University of Helsinki, Finland. The protocol was approved by the Laboratory Animal Ethics Committee of the University of Helsinki. Three-week-old male Sprague-Dawley rats (n = 30)

*To whom correspondence should be addressed at University of Helsinki, Department of Applied Chemistry and Microbiology (Nutrition), PO Box 66, 00014 University of Helsinki, Finland. E-mail:anu.turpeinen@helsinki.fi

Abbreviations: Con A, concavalin A; CRP, C-reactive protein; DPD, deoxypyridinoline; IFN-γ, interferon gamma; IGF-1, insulin-like growth factor; IL, interleukin; LPS, lipopolysaccharide; LT, leukotriene; PG, prostaglandin; TNF-α, tumor necrosis alpha; TRACP, tartrate-resistant acid phosphatase.

were purchased from Harlan (Horst, the Netherlands). The animals were housed in plastic cages, two rats per cage, in a temperature- and humidity-controlled animal facility, with 12-h light/dark cycle. After a 4-d adaptation period, they had free access to standard rodent laboratory chow (Teklad Global 18% Protein Rodent Diet, Harlan, Horst, the Netherlands) for the 8-wk feeding period. The chow contained 5.7 g fat/100 g, of which 17.1% was saturated FA (SFA), 22.6% monounsaturated FA (MUFA), and 60.2% PUFA. Commercial soy-based infant formula (SoijaTutteli, Valio, Helsinki, Finland) was provided as drinking fluid. Infant formula was used to simulate the diet of infants, with the formula being the main source of energy and nutrients. The infant formula contained 1.9 g protein, 7.0 g carbohydrates, and 3.5 g fat per 100 mL formula. Of the fat, 32.8% was SFA, 50.7% MUFA, 13.4% n-6 PUFA, and 2.7% n-3 PUFA. Traces of CLA were detected.

The animals were randomly assigned to three groups, and received 40 mg/kg/d sunflower oil (placebo), 20 mg/kg/d *cis*-9,*trans*-11 CLA and 20 mg/kg/d sunflower oil (CLA20), or 40 mg/kg/d *cis*-9,*trans*-11 CLA (CLA40). CLA intake in the CLA20 group was formulated to simulate intake in exclusively breast-fed infants (15). *cis*-9,*trans*-11 CLA as TAG was purchased from Natural Inc. (Hovdebygda, Norway) and contained 91.1% *cis*-9,*trans*-11 CLA, 4.8% oleic acid, 2.4% *trans*-10, *cis*-12 CLA, and 1.3% other conjugated 18:2 isomers. The concentration of other FA was <0.1%. Both CLA and a placebo were orally administered daily by the same person throughout the study. Body weight was recorded weekly, and doses of CLA and placebo were adjusted according to weight gain. The initial daily dose was 2 mg and was increased according to weight gain up to 6 mg/d in the CLA20 group and 12 mg/d in the CLA40 group during the last week to provide daily doses of 20 and 40 mg/kg.

Sampling. Mid-study (4 wk), nonfasting blood samples were obtained from the lateral tail vein, centrifuged, and stored at –70°C. A metabolic cage was used to collect urine samples prior to sacrifice. Urine was aliquoted and stored at –70°C. The animals were without food for 16 h, and were killed by CO_2 asphyxiation. After sacrifice selected organs (liver, spleen, pancreas, heart, brain) were removed and weighed, and blood was drawn from the caudal vena cava into sodium heparin tubes. Blood for lymphocyte stimulations was stored at 4°C. The rest of the blood was aliquoted, snap frozen in liquid nitrogen, and stored at –70°C.

Samples of liver and heart were taken from all rats ($n = 30$) for the analysis of FA composition, snap frozen in liquid nitrogen, and stored at –70°C. Samples of liver, heart, and pancreas for histological evaluation were placed in 10% buffered formalin for fixation and storage.

Glucose and lipid metabolism analyses. Plasma glucose, TG, total cholesterol, HDL, and LDL were analyzed with an automated blood analyzer (Konelab, Thermo Clinical Instruments, Vantaa, Finland). Plasma insulin and CRP were determined using EIA kits from SPI-BIO (Massy Cedex, France) and Alpha Diagnostic International (San Antonio, TX), respectively.

Plasma and tissue FA analyses. Fat was extracted from 200 μL plasma with dichloromethane-methanol (2:1) (19) and from 50–100 mg liver or heart tissue with hexane-isopropanol (3:2) (20). Total FA were methylated with acidic methanol (5% H_2SO_4) (21). Liver FAME concentration was determined by adding internal standard (19:0 methyl ester) to the extraction solution, and the result was expressed as μg per mg weighed liver tissue from duplicate tissue samples. Half of the ventricular part of the heart was taken for homogenization and extraction. The percentage composition of plasma and tissue methylated total FA from 14:0 to 22:6n-3 was determined by a HP 6890 GC (Hewlett Packard, Palo Alto, CA) and Chemstation (version A.06.03) with a 25-m NB-351 column (i.d. 0.32 mm, phase layer 0.20 mm, HNU-Nordion Ltd Oy, Helsinki, Finland), split injection, with hydrogen as carrier gas. A temperature program from 160°C to 230°C was used. The percentage composition of FAME was normalized to 100%.

Lipid peroxidation. Urine samples collected prior to sacrifice were analyzed for 8-iso-$PGF_{2\alpha}$, an indicator of nonenzymatic lipid peroxidation. Nonextracted urine was analyzed using highly specific and sensitive radioimmunoassay as previously described (22). Concentrations of 8-iso-$PGF_{2\alpha}$ were adjusted for creatinine values measured with a commercial kit (IL test, Monarch Instrument, Amherst, NH).

Histological analyses. Formalin-fixed samples were dehydrated and embedded in paraffin wax using standard histological techniques. The tissues were sectioned to the thickness of 5 μm, and the slices were mounted on glass slides and stained with hematoxylin and eosin. The slides were examined using a light microscope by a pathologist (J.L.) blinded to grouping, with emphasis on vacuolation (fat accumulation) and inflammation. The tissues for histological examination and pathological endpoints were selected based on findings in previous studies (6,23). Inflammatory changes in the liver and hepatocellular vacuolation were graded from 1 to 5, with 1 depicting incidental or minimal changes and 5 depicting severe or extensive changes. Besides grading, the nature of the alterations, including main inflammatory cell types and type of vacuolation, as well as their extent (focal to diffuse) were recorded.

Blood lymphocyte stimulation. Lymphocytes were isolated from 2 mL heparin blood by Ficoll-Paque centrifugation (24). Blood was diluted with 10% FCS/RPMI culture media (1:1). Cells were counted in a Neubauer Improved counting chamber and diluted in the culture media to achieve a concentration of 2×10^6/mL. Cells were then frozen at –70°C.

Lymphocytes were stimulated using concavalin A (Con A; Amersham Pharmacia Biotech, Uppsala, Sweden), a T-cell mitogen, and lipopolysaccharide (LPS; Sigma Chemicals, St. Louis, MO), a B-cell mitogen. Mitogens were diluted using 10% FCS/RPMI media. Final concentrations of Con A and LPS were 5 mg/L and 10 mg/L, respectively. Mitogen concentrations and incubation times were selected based on earlier studies.

Diluted mitogens were pipeted into 96-well microplates and cell suspensions (2×10^6/mL) were added to each well containing mitogen or blank (10% FCS/RPMI). Each sample was ana-

lyzed in triplicate. The plates were incubated at 37°C, 5% CO_2 for 4 and 24 h. Samples were centrifuged, and supernatants were collected. Supernatants of replicate wells were pooled and stored at –70°C until analyzed. Two time points were used in order to detect early events and possible differences in cytokine profiles and responses at different time points.

In vitro production of cytokines. All cytokines were analyzed using ELISA kits from R&D Systems (Minneapolis, MN) according to the manufacturer's instructions. TNF-α, IL-6, IL-1β, and PGE_2 were measured in the supernatant of LPS-stimulated cells. IL-2, IL-4, IFN-γ, and LTB_4 were analyzed in supernatants of Con A–stimulated cells. All samples were analyzed in duplicate. Control samples included in each kit were analyzed with each batch of samples.

Markers of bone metabolism. Plasma insulin-like growth factor (IGF-1) and osteocalcin were analyzed as markers of bone formation. Urinary deoxypyridinoline (DPD) crosslinks and plasma tartrate-resistant acid phosphatase (TRACP) 5b, derived from osteoclasts, were analyzed as markers of bone resorption. ELISA/EIA kits were used to analyze plasma IGF-1 (IDS Ltd, Boldon, UK), plasma osteocalcin (BTI Inc, Stoughton, MA), and urinary DPD (Metra Total DPD, Quidel Corp, San Diego, CA). DPD concentrations were adjusted for creatinine, analyzed with a commercial kit (IL test; Monarch Instrument, Amherst, NH). A solid-phase immunofixed-enzyme activity assay (SBA Sciences, Turku, Finland) was used to measure TRACP 5b in plasma. This assay is specific for active TRACP 5b molecules freshly liberated into the circulation from osteoclasts. Control samples included in each kit were analyzed with each batch of samples.

Statistical analyses. Values are means ± SD. Statistical analyses were performed by using SPSS (version 10.0, SPSS Inc, Chicago, IL). One-way ANOVA was used to detect differences between groups. Results for graded histological analysis for microvesicular hepatocellular vacuolation were analyzed using the Kruskall Wallis test. Spearman correlation coefficient was determined from pairwise correlations. A $P < 0.05$ was considered significant.

RESULTS

Growth. Growth was similar in the three groups (data not shown). Initial average weights were 84 ± 13 g, 87 ± 13 g, and 89 ± 14 g, and final average weights were 318 ± 26 g, 332 ± 18 g, and 329 ± 34 g in the CLA20, CLA40, and control groups, respectively. Infant formula was the main source of energy and provided on average 70% of total energy intake (as measured by milk and chow consumption).

No differences between groups were observed in the weights of the heart (1.2 ± 0.1 g, 1.2 ± 0.1 g, and 1.2 ± 0.1 g in the CLA20, CLA40, and control groups, respectively), liver (9.8 ± 1.3 g, 9.8 ± 0.9 g, and 10.3 ± 1.4 g in the CLA20, CLA40, and control groups, respectively), spleen (0.7 ± 0.1 g, 0.7 ± 0.1 g, and 0.7 ± 0.1 g in the CLA20, CLA40, and control groups, respectively), pancreas (1.2 ± 0.3 g, 1.4 ± 0.3g, and 1.4 ± 0.2 g in the CLA20, CLA40, and control groups, respectively), or brain (1.8 ± 0.1g, 1.9 ± 0.0g, and 1.8 ± 0.1g in the CLA20, CLA40, and control groups, respectively). However, liver fat content in the CLA20 group was significantly lower (1.62%) than in the control (1.81%) or CLA40 groups (1.88%) ($P = 0.02$).

Plasma and tissue FA. *cis*-9,*trans*-11 CLA in plasma and liver showed a dose-response increase in the three groups (Table 1), but not in heart tissue (data not shown). Its proportion in heart tissue (0.02%, 0.05%, and 0.05% in the control, CLA20, and CLA40 groups, respectively) was 2- to 3-fold lower than in plasma and liver. No other differences between groups were observed in heart FA compositions. In the liver, stearic acid (18:0) was significantly lower in the CLA40 group than in the CLA20 group, as a percentage of total FA ($P = 0.04$). Linoleic acid (18:2n-6; LA) was significantly lower in the CLA20 group than in the CLA40 group both in the liver (as % total FA) ($P = 0.02$) and plasma ($P = 0.02$), but did not differ from controls. The proportion of DHA (22:6n-3) in plasma was higher in both CLA groups than in controls ($P = 0.03$), whereas in the liver, DHA (as % total FA) was lowest in the CLA40 group ($P = 0.004$). Δ5 (20:4n-6/20:3n-6), Δ6 [(18:3n-6 + 20:3n-6)/18:2n-6], and Δ9 (18:1/18:0) desaturation indices did not differ between groups in plasma or in the liver.

Lipid and glucose metabolism. Plasma total cholesterol, LDL cholesterol, HDL cholesterol, and triglyceride concentrations were similar in all three groups (Table 2).

Nonfasting plasma glucose at 4 wk and fasting plasma glucose at 8 wk tended to increase with increasing CLA concentrations, whereas plasma insulin and CRP tended to decrease, but the differences between groups were not significant (Table 2).

After adjusting for creatinine, no differences between groups in 8-iso-$PGF_{2\alpha}$ were observed (Table 2). 8-iso-$PGF_{2\alpha}$ concentrations were not correlated with CRP, glucose, or insulin.

Histological analyses. Histological analyses of the heart, liver, and pancreas revealed incidental focal inflammatory changes in the liver of three rats (one in the control group, two in the CLA40 group). The foci consisted mostly of macrophages, lymphocytes, and plasma cells, but cellular debris and a few other leucocytes were sometimes present. There was no predisposition toward any of the acinar zones, and the foci were no more than 5–10 hepatocytes in diameter. These types of changes are commonly detected in various strains of normal rats; their etiology is uncertain but they are of no functional significance. Patchy or diffuse hepatocellular microvesicular vacuolation was observed in all groups (data not shown). Marked (grade 4) hepatocellular vacuolation was observed in four rats, all from the CLA40 group. The difference in graded changes between groups (2.4, 2.5, and 3.1 for the control, CLA20, and CLA40 groups, respectively) was, however, not significant.

Cytokines. No differences between groups were seen in IL-2 at 4 h, whereas at 24 h concentrations in the CLA20 group were significantly higher compared to controls (207.8 pg/mL vs. 93.9 pg/mL, $P < 0.01$) (Table 3). The CLA40 group did not differ from controls. Concentrations increased 4-fold between 4 h and 24 h in the CLA20 group, but only doubled in the two other groups.

[a]Values are mean ± SD, $n = 10$. Control diet, 40 mg/kg/d sunflower oil; CLA20, 20 mg/kg/d *cis*-9,*trans*-11 CLA; CLA40, 40 mg/kg/d *cis*-9,*trans*-11 CLA. Values in a row not sharing a common superscript differ from each other ($P < 0.05$, ANOVA).

The concentrations of IL-4, IL-6, and IFN-γ did not differ between groups at 4 h or 24 h (Table 3). IL-4 concentrations decreased from 4 h to 24 h, but were low at both time points in all groups. Concentrations of IL-6 increased 1.4- to 3.2–fold, and those of IFN-γ doubled between 4 h and 24 h in all groups (Table 3).

TNF-α concentrations were significantly lower at 4 h in the CLA20 group (56.0 pg/mL) than in the control or CLA40 group (138.2 and 137.8 pg/mL, respectively; $P < 0.001$). The same difference was seen also at 24 h (42.7 pg/mL, 130.6 pg/mL, and 112.8 pg/mL for the CLA20, CLA40, and control groups, respectively; $P < 0.01$). The control and CLA40 groups did not differ at either time point (Table 3).

IL-1β was significantly lower in the CLA20 group at 24 h than in the two other groups ($P = 0.01$). A similar tendency was seen also at 4 h, but the differences were not significant. Concentrations increased 3-fold from 4 h to 24 h in all groups.

PGE_2 and LTB_4 concentrations were significantly lower in the CLA20 group than in the two other groups at 4 h ($P < 0.05$), but not at 24 h (Table 3). PGE_2 concentrations increased 8- to

[a]Values are mean ± SD, $n = 10$. Control diet, 40 mg/kg/d sunflower oil; CLA20, 20 mg/kg/d cis-9,*trans*-11 CLA and 20 mg/kg/d sunflower oil; CLA40, 40 mg/kg/d *cis*-9,*trans*-11 CLA.
[b]Nonfasting plasma glucose concentrations.
[c]Fasting plasma glucose concentrations.

16-fold from 4 h to 24 h, while those of LTB_4 remained unchanged in the control and CLA40 groups, but increased 2.5-fold in the CLA20 group.

TNF-α was significantly correlated with IL-1β ($r = 0.695$, $P = 0.006$), IL-6 ($r = 0.698$, $P = 0.005$), PGE_2 ($r = 0.611$, $P = 0.016$), and LTB_4 ($r = 0.776$, $P = 0.003$), and negatively correlated with IL-2 ($r = -0.577$, $P = 0.024$). Significant correlations were also seen between IL-1β and IL-6 ($r = 0.630$, $P = 0.016$), and between PGE_2 and LTB_4 ($r = 0.841$, $P = 0.001$).

Bone metabolism. Plasma IGF-1 showed a tendency to increase with increasing CLA intake, but the differences between groups were not significant (Table 2). Plasma osteocalcin concentrations were also similar in all groups (Table 2). In the CLA40 group, plasma TRACP 5b activity was 40% higher than in the control and CLA20 groups ($P < 0.05$; Fig. 1). However, no differences between groups were seen in the other marker of bone resorption, urinary DPD (Table 2). TRACP 5b activity was correlated with plasma PGE_2 concentrations ($r = 0.602$, $P = 0.018$)

DISCUSSION

The effects of 20 and 40 mg/kg/d *cis*-9,*trans*-11 CLA in growing rats were studied. Minor differences between groups in plasma and liver FA were observed, but we did not find indications of altered LA or linolenic acid metabolism. A recent human study reported an increase in plasma LA and a decrease in Δ6-desaturation by both 3 g/d *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA (25), whereas, in line with our study, another study found no effects with 0.59–2.38 g/d of the same isomers (26).

Microvesicular steatosis of the liver was found in all groups in the present study. This was probably due to all diets containing more fat than the general rodent diet. Liver fat content in the CLA20 group was significantly lower than in the two other groups. The inflammatory changes seen in the liver of three rats were considered unrelated to the treatments, because they were present both in the control and CLA40 groups and are commonly detected in various strains of normal rats. Increased liver weight (6,12) and hepatocellular hypertrophy (6,23) have been

TABLE 3

[a]Values are mean ± SD, all values are in pg/mL, $n = 10$. Control diet, 40 mg/kg/d sunflower oil; CLA20, 20 mg/kg/d *cis*-9,*trans*-11 CLA and 20 mg/kg/d sunflower oil; CLA40, 40 mg/kg/d *cis*-9,*trans*-11 CLA. Values in a row not sharing a common superscript differ from each other ($P < 0.05$, ANOVA).

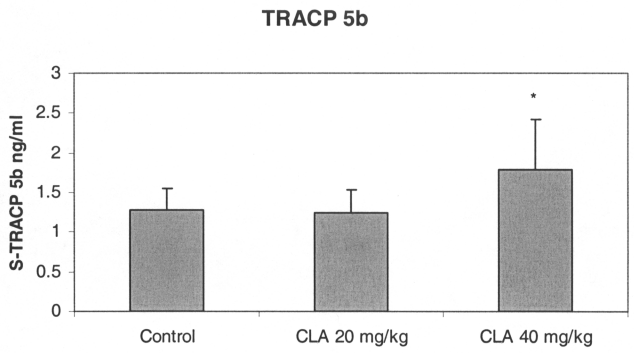

FIG. 1. Plasma tartrate-resistant acid phosphatase (TRACP) 5b concentrations in rats fed control diet, 20 mg/kg/d CLA, or 40 mg/kg/d CLA. An asterisk (*) indicates that the result is significantly different from the two other groups ($P = 0.015$, ANOVA).

reported following CLA feeding in rats and mice. Liver fat content increased in mice fed diets containing 0.5–1.5% (wt/wt) CLA mixture (8) or 0.5% *trans*-10,*cis*-12 CLA (7), but not when the diet contained 0.5% *cis*-9,*trans*-11 CLA (7). In an oral toxicity study, hepatocellular vacuolation was observed in both controls and rats fed 1, 5, or 15 wt% CLA mixture containing equal amounts of the *cis*-9,*trans*-11 and *trans*-10,*cis*-12 isomers, but there was no evidence of fat accumulation in the liver (23). Also our results do not suggest fat accumulation at the intake levels used in the present study.

Most previous animal and human studies do not suggest a significant effect for *cis*-9,*trans*-11 CLA on plasma lipids or glucose (27–32), thereby supporting our results. Increased insulin concentrations have been observed in several studies in mice after 1 wt% CLA supplementation (6,33,34), whereas in Zucker prediabetic fatty rats 1.5% CLA mixture (*cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA 50:50) improved insulin action and hyperinsulinemia (35,36). In type 2 diabetic subjects, CLA supplementation (3 g/d *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA, 1:1) increased fasting plasma glucose and reduced insulin sensitivity (37), whereas no effect of isomer on plasma insulin was detected in healthy males fed different doses (0.59–2.38 g/d) of *cis*-9,*trans*-11 CLA or *trans*-10,*cis*-12 CLA (38).

A proinflammatory and pro-oxidative effect for CLA has been suggested by human studies showing increased CRP and lipid peroxidation in subjects fed 3 g/d *trans*-10,*cis*-12 CLA (10), 3 g/d *cis*-9,*trans*-11 CLA (12) or 4.2 g/d CLA mixture (11,39) and by studies showing increased IL-6 secretion in mice fed pure 0.5 wt% *cis*-9,*trans*-11 (40,41) or *trans*-10,*cis*-12 CLA (40). Two recent studies did not, however, find any effects on CRP in patients with type 2 diabetes fed 3 g/d CLA mixture (37) or in healthy males fed *cis*-9,*trans*-11 or *trans*-10,*cis*-12 CLA 0.59–2.38 g/d (42). In addition, decreased antigen-induced IL-6 production in rats (43) and pigs (44) has also been reported. We also found no evidence of increased CRP or IL-6 with 20 or 40 mg/kg *cis*-9,*trans*-11 CLA. No differences between groups in urinary isoprostanes were detected after adjusting for creatinine, although the higher CLA dose in the present study, 40 mg/kg/d, is comparable to the dose used by Riserus *et al.* (12). Thus, our results do not suggest proinflammatory or pro-oxidative effects for *cis*-9,*trans*-11 CLA at 20 or 40 mg/kg daily doses.

Anti-inflammatory effects, on the other hand, were observed in the present study as production of the proinflammatory cytokines TNF-α and IL-1β decreased in the CLA20 group. Why the effect was observed only in the CLA20 but not the CLA40 group is not obvious. TNF-α and IL-1β decreased also in healthy subjects fed 3 g/d CLA mixture (45) and basal TNF-α secretion of peritoneal macrophages decreased in rats fed 1 wt% CLA (43). A recent study in weaned pigs showed an overall anti-inflammatory effect: 2 wt% CLA prevented an increase in mRNA expression and production of TNF-α and IL-6 in spleen and thymus, whereas the expression of anti-inflammatory IL-10 was enhanced (44). This and most other studies (41,46,47) have found no effects on IFN-γ.

IL-2 plays a central role in cell-mediated immune response. Consistent with our results, several previous studies have reported increased IL-2 concentrations in response to CLA, suggesting an improvement of the proliferative abilities of lymphocytes. Studies in rats and mice using CLA mixture 0.3–1 wt% of diet have shown increased *in vitro* IL-2 production (48,49,50). The only other study using purified isomers found, however, no effects for 0.5 wt% *cis*-9,*trans*-11 CLA or *trans*-10,*cis*-12 CLA on splenocyte IL-2 production in mice (40). In pigs infected with type-2 porcine circovirus, IL-2 mRNA expression was upregulated in the group fed CLA and was associated with less severe clinical manifestation of the disease (51). Based on the functions of IL-2, this data implies an important role for CLA in immune development.

IL-4 and PGE_2 play a role in IgE-mediated hypersensitivity reactions. Two studies in mice fed CLA mixture (52) or purified *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA isomers (40) reported decreased IL-4 secretion in stimulated lymphocytes. In our study, IL-4 concentrations were low at both time points in all groups, including the control group, and no effect for CLA was observed. Reduced plasma PGE_2 levels were associated with decreases in splenic and exudate cell LTB_4 production in rats (48), which was seen as an indication of the potential of CLA to attenuate allergic reactions. Also in the present study, *in vitro* production of both PGE_2 and LTB_4 decreased and a highly significant correlation between the two was observed. In a guinea pig model of hypersensitivity, ovalbumin-induced release of LTB_4 in lungs, trachea, and bladder was not affected by CLA feeding, but the production of LTC_4, LTD_4, and LTE_4 significantly decreased in lungs (53). In the same guinea pig model, CLA significantly reduced PGE_2 secretion by sensitized tracheae (54). 1% CLA had no effect on splenocyte PGE_2 production in young or old mice (55). Turek *et al.* (43) suggest that the effect of CLA on PGE_2 production is dependent on the FA composition of the background diet, with the effect of CLA increasing as the ratio of n-6:n-3 PUFA increases. The only study using pure *cis*-9,*trans*-11 and *trans*-10,*cis*-12 isomers detected no differences in splenocyte PGE_2 production between isomers or compared with controls in mice fed 0.5 wt% CLA (40).

Thus far, data on the effects of CLA on bone metabolism are available from few studies, all of which have used a mixture of isomers. Reduced mineral apposition rate, indicating reduced bone formation following CLA feeding, was reported by Li *et al.* (5). Watkins *et al.* (4), on the other hand, reported increased bone formation (increased IGF-1) in growing chicks fed butterfat (a rich natural source of *cis*-9,*trans*-11 CLA), whereas no effects on bone formation were seen in another study with rats fed 1 wt% CLA (56). We also found no effect for CLA on IGF-1 or another marker of bone formation, plasma osteocalcin. All published studies thus far show no effect for CLA on plasma osteocalcin. Osteocalcin was not affected in rats and chicks fed 1 wt% CLA in the diet (4,5,56) or in a recent human study in healthy males fed 3 g/d *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA (1:1) (57). It has been suggested that the effects of CLA on bone formation may be dependent on the amount of n-6 and n-3 FA in the diet (4).

A bone resorption marker, urinary DPD excretion, was unaffected by CLA in rats fed 1 wt% CLA (53) and in healthy males supplemented with 3 g/d CLA (57). The C-terminal telopeptide α-1 chain of type 1 collagen was used as a marker of resorption in two other studies and was also not affected by CLA (5,57). Our results using a novel resorption marker, TRACP 5b, on the other hand, suggest increased bone resorption at the higher CLA dose (40 mg/kg/d). TRACP 5b activity was correlated with plasma PGE_2 concentrations. PGE_2 is a potent stimulator of bone resorption and the primary prostaglandin affecting bone metabolism (58). These findings should be confirmed in other studies. The effects of diet or CLA on plasma TRACP have not been reported earlier.

In conclusion, no adverse effects were seen with 20 mg/kg/d CLA in growing rats. The novel bone resorption marker used (TRACP 5b) showed increased bone resorption rate on the higher CLA intake level (40 mg/kg/d). Our results show anti-inflammatory effects and enhanced T cell function at *cis*-9,*trans*-11 CLA doses comparable to intakes in exclusively breast-fed infants. If applicable to humans, CLA-induced anti-inflammatory effects could decrease the risk to allergies and atopic diseases, which are increasingly prevalent in infants and young children. *cis*-9,*trans*-11 CLA intake in exclusively breast-fed infants may thus be sufficient to provide beneficial immunological effects. Because it has been proposed that CLA intake during certain periods of growth and development may have long-term benefits and reduce the risk of certain diseases, further studies should be conducted to determine whether vegetable oil–based infant formulas should be supplemented with *cis*-9,*trans*-11 CLA.

1-*O*-Alkyl-2-(ω-oxo)acyl-*sn*-glycerols from Shark Oil and Human Milk Fat Are Potential Precursors of PAF Mimics and GHB

Karsten Hartvigsen[a,b] Amir Ravandi[b], Richard Harkewicz[c], Hiroshi Kamido[d], Klaus Bukhave[a], Gunhild Hølmer[a], and Arnis Kuksis[b,*]

[a]Biocentrum-DTU, Biochemistry and Nutrition, Centre for Advanced Food Studies, Technical University of Denmark, DK-2800 Lyngby, Denmark, [b]Banting and Best Department of Medical Research, University of Toronto, Toronto, ON M5G 1L6, Canada, [c]Department of Chemistry and Biochemistry, University of California, La Jolla, California 92093-0601, and [d]Department of Medicine, Kurume University, Kurume, Fukuoka, Japan

ABSTRACT: This study examines the feasibility that peroxidation and lipolysis of 1-*O*-alkyl-2,3-diacyl-*sn*-glycerols (DAGE) found in shark liver oil and human milk fat constitutes a potential source of dietary precursors of platelet activating factor (PAF) mimics and of gamma-hydroxybutyrate (GHB). Purified DAGE were converted into 1-*O*-alkyl-2-acyl-*sn*-glycerols by pancreatic lipase, without isomerization, and transformed into 1-*O*-alkyl-2-oxoacyl-*sn*-glycerols by mild autooxidation. The various core aldehydes without derivatization, as well as the corresponding dinitrophenylhydrazones, were characterized by chromatographic retention time and diagnostic ions by online electrospray mass spectrometry. Core aldehydes of oxidized shark liver oil yielded 23 molecular species of 1-*O*-alkyl-*sn*-glycerols with short-chain *sn*-2 oxoacyl groups, ranging from 4 to 13 carbons, some unsaturated. Autooxidation of human milk fat yielded 1-*O*-octadecyl-2-(9-oxo)nonanoyl-*sn*-glycerol, as the major core aldehyde. Because diradylglycerols with short fatty chains are absorbed in the intestine and react with cytidine diphosphate-choline in the enterocytes, it is concluded that formation of such PAF mimics as 1-*O*-alkyl-2-(ω-oxo)acyl-*sn*-glycerophosphocholine from unsaturated dietary DAGE is a realistic possibility. Likewise, a C_4 core alcohol produced by aldol-keto reduction of a C_4 core aldehyde constitutes a dietary precursor of the neuromodulator and recreational drug GHB, which has not been previously pointed out.

Paper no. L9953 in *Lipids 41*, 679–693 (July 2006).

Platelet-activating factor (PAF), 1-*O*-alkyl-2-acetyl-*sn*-glycerophosphocholine (GroPCho), is a biologically active phospholipid with diverse physiological and pathological effects in a variety of cells and tissues (1). Gamma-hydroxybutyric acid (GHB) is a simple four-carbon FA with an extraordinary range of physiological and pharmacological effects (2). PAF is known to be enzymatically synthesized by either the remodeling or the *de novo* pathways. PAF mimics, however, are generated by secondary peroxidation of unsaturated 1,2-diacyl-*sn*-GroPCho in cell membranes, which retain a short-chain residue esterified at the *sn*-2 position (3). This short-chain residue may contain either a ω-methyl, ω-aldehyde, ω-alcohol, or ω-carboxyl group for PAF-like activity. Investigations of the biological activities by multiple assays have shown that PAF-like lipids containing an *sn*-1 alkyl ether linkage are more effective than the corresponding *sn*-1 acyl derivatives, and that, in general, the shorter the *sn*-2 chain residue the more active the PAF mimic (4,5). Although it has been suggested (2) that GHB may also arise via lipid peroxidation, the exact mechanism has not been established.

In the present report, we demonstrate the feasibility of metabolic transformation of 1-*O*-alkyl-2,3-diacyl-*sn*-glycerols (DAGE) from shark liver oil and human milk into the corresponding core aldehydes, 1-*O*-alkyl-2-(ω-oxo)acyl-*sn*-glycerols, by mild autooxidation and lipolysis. We have previously shown that short-chain 1,2-diradyl-*sn*-glycerols are absorbed intact in the intestine (6,7) and that exogenous 1,2-diradyl-*sn*-glycerols are incorporated intact into the phosphatidylcholines (PtdCho) (8). We have shown elsewhere (9) that such PAF mimics prepared synthetically induce platelet aggregation and inhibit endothelium-dependent arterial relaxation. We postulate that the C_4 core aldehydes, either as glycerolipids or glycerophospholipids, are reduced to the corresponding C_4 core alcohols by endogenous aldol-keto reductases (10) before release into circulation as GHB. There has been no previous work on the core aldehydes arising from oxidation of alkyldiacylglycerols, although the nonvolatile oxidation products of triacylglycerols have been previously discussed (11–16).

EXPERIMENTAL PROCEDURES

Materials. Crude deep-sea shark liver oil was a gift from Baldur Hjaltason, LYSI Ltd., Reykjavik, Iceland. The lyophilized

human milk sample was a gift from Dr. J. Cerbulis of the Eastern Regional Research Center, USDA, Philadelphia, PA. It was one of six milk samples obtained from nursing mothers in the Philadelphia area and used in a collaborative investigation of chloropropanediol diesters in human milk samples (17). The alkyldiacylglycerol composition of these samples ranged from 0.5 to 5 mol%. Linoleic acid, 4-dimethylaminopyridine, and *N*,*N*′-dicyclohexylcarbodiimide were obtained from Sigma-Aldrich (St. Louis, MO). 1-*O*-Octadecyl-*sn*-glycerol was obtained from Fluka (Ronkonkoma, NY). All solvents used were of analytical or HPLC grade.

Preparative TLC. Several preparative TLC systems were employed to purify the various transformation products. All TLC plates were prepared in the laboratory (200 × 200 × 0.25 mm) and activated for 2 h at 110°C before use. System A consisted of silica gel H, developed in hexane/diethyl ether (90:10, vol/vol). System B consisted of silica gel G containing 5% boric acid, developed in hexane/isopropyl ether/acetic acid (50:50:4, by vol). System C consisted of silica gel H, developed in hexane/diethyl ether/acetic acid (80:20:2, by vol). Lipids were visualized under UV light after spraying with 0.2% 2,7-dichlorofluorescein in ethanol (18), whereas the core aldehydes were visualized as purple areas after spraying with the Schiff base reagent (19). Migration of a component is given as the relative retention factor (R_f). Lipids and core aldehydes were recovered from the TLC plates by scraping off the gel, extracting it with chloroform/methanol (2:1, vol/vol), washing with water, drying over anhydrous sodium sulfate, evaporating under nitrogen, and dissolving in chloroform/methanol (2:1, vol/vol). The 2,7-dichlorofluorescein was removed with 1% ammonium hydroxide.

GLC. Injections were made at 100°C, and after 30 s the oven temperature was programmed at 20°C/min to either 130°C (FAME) or 180°C (diacetyl-derivatized 1-*O*-alkyl-*sn*-glycerols (GE)), and then to 240°C at 5°C/min (18). The GLC system consisted of a polar capillary column (SP 2380, 15 m × 0.32 mm i.d., Supelco, Mississauga, ON) installed in a Hewlett-Packard (Palo Alto, CA) Model 5880 gas chromatograph equipped with a flame ionization detector. Hydrogen was used as carrier gas at 3 psi. FAME and diacetyl-GE were identified on the basis of retention times (RT) compared with commercially available external reference compounds.

HPLC. Reversed-phase HPLC was performed with a Hewlett-Packard Model 1090 liquid chromatograph (Palo Alto, CA) using an HP ODS Hypersil C_{18} column (5 μm; 200 × 2.1 mm i.d.; Hewlett-Packard, Palo Alto, CA) and eluted isocratically with 100% Solvent A (methanol/water/30% ammonium hydroxide, 88:12:0.5, by vol) for 3 min, followed by a linear gradient to 100% Solvent B (methanol/hexane/30% ammonium hydroxide, 88:12:0.5, by vol) in 25 min, which was kept for another 6 min (20). Kim *et al.* (20) washed the HPLC column with 0.1 M ammonium acetate at 0.5 mL/min for 5 min at the end of each run and did not observe any ill effects on the performance of column or the quality of the mass spectra. When 2,4-dinitrophenylhydrazine (DNPH) derivatives were analyzed, the effluent was led through a UV detector (358 nm) installed before the mass spectrometer. The flow was 0.4 mL/min.

Electrospray ionization MS (ESI-MS). Reversed-phase HPLC with online electrospray ionization MS (LC/ESI-MS) was performed by admitting the entire HPLC column effluent into a Hewlett-Packard Model 5988B quadrupole mass spectrometer (Palo Alto, CA) equipped with a nebulizer-assisted electrospray interface (Hewlett-Packard Model 59987A, Palo Alto, CA) as previously described (19). Nitrogen was used as both nebulizing (60 psi) and drying gas (60 psi, 270°C). Capillary voltage was set at 4 kV, the endplate voltage was 3.5 kV, and the cylinder voltage was 5 kV in the positive mode of ionization. In the negative mode, the values were −3.5 kV, −3 kV, and −3.5 kV, respectively. Both negative and positive ESI spectra were taken in the mass range 300–1100 amu. The capillary exit (CapEx) was set at 120 and −120 V in the positive and negative ion mode, respectively.

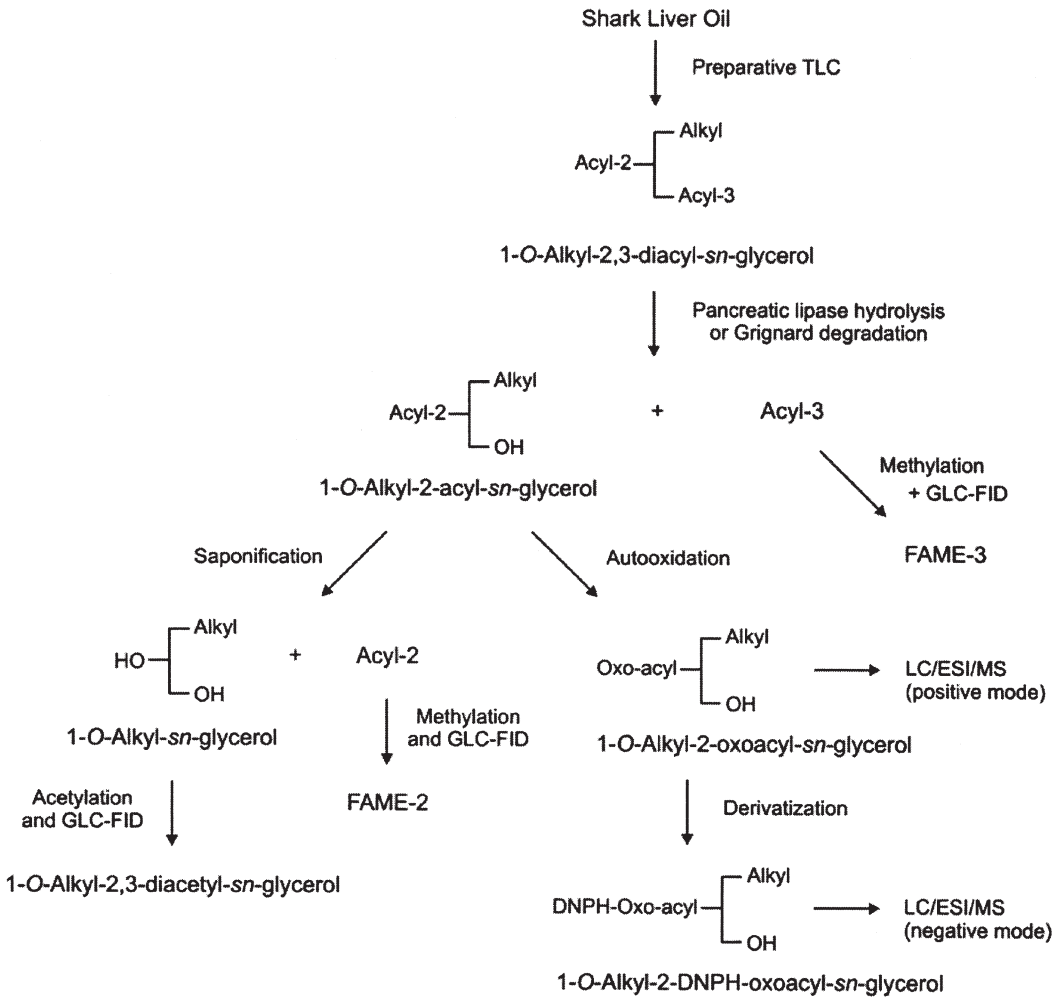
Preparation of DAGE from shark liver oil and human milk. A total lipid extract of freeze-dried human milk was prepared as previously described (21). DAGE was recovered from the human milk lipid extract and the shark liver oil by preparative double one-dimensional TLC (system A). The purified DAGE was subjected to regiospecific analysis to reveal the *sn*-1-*O*-alkyl-, *sn*-2 acyl-, and *sn*-3 acyl-chain composition and distribution. The complete procedure is outlined in Scheme 1.

Hydrolysis with pancreatic lipase and Grignard degradation. Purified DAGE of shark liver oil and human milk were hydrolyzed by digestion with diethyl ether pre-extracted pancreatic lipase (22). The digestion was performed in the presence of gum arabic for 30 min, and the digestion products were extracted with diethyl ether. Alternatively, the purified DAGE were deacylated by Grignard degradation (23) in order to verify the results obtained from pancreatic lipase digestion. The degradation products were resolved and recovered by TLC (system B).

Preparation of FAME and diacetyl-GE. Purified fractions of DAGE, 2-MAGE, and 3-MAGE originating from shark liver oil were treated with 6% H_2SO_4 in methanol for 2 h at 80°C to produce FAME and GE. After the reaction, the lipids were extracted twice with chloroform. GE and FAME were resolved and recovered by preparative TLC (system C). Purified GE was derivatized to diacetyl-GE for 30 min at 80°C with acetic anhydride/pyridine (1:1, vol/vol; 75 μL). The profiles of FAME and diacetyl-GE were determined by GLC.

Autooxidation of 2-MAGE. Mild peroxidation was performed by flushing the purified 2-MAGE from either shark liver oil or human milk in a tube with oxygen, capping, and heating at 80°C for 3 h. The peroxidized 2-MAGE was analyzed by reversed-phase LC/ESI-MS.

Preparation of DNPH derivatives. Aldehyde preparations of oxidized 2-MAGE were derivatized by reaction with DNPH in the dark (0.5 mg in 1 mL 1 N HCl) for 2 h at room temperature and 1 h at 4°C (24). The DNPH derivatives were extracted with chloroform/methanol (2:1, vol/vol), dried over anhydrous sodium sulfate, evaporated under a stream of nitrogen, dissolved in chloroform/methanol (2:1, vol/vol), and analyzed by



SCHEME 1. Flow sheet for the regiospecific analysis of DAGE from shark liver oil and the procedure for isolation and characterization of core aldehydes from oxidized and digested DAGE.

reversed-phase LC/ESI-MS. Derivatization with DNPH, therefore, increased the detection limit for the core aldehydes by MS, and further provided additional ions for characterization of the alkyl ether core aldehydes, as well as an opportunity to monitor the components by UV detection at 358 nm.

Preparation of reference 1-O-octadecyl-2-(9-oxo)-nonanoyl-sn-glycerol. The esterfication of 1-*O*-octadecyl-*sn*-glycerol with linoleic acid was performed by the carbodiimide-mediated process (25). Linoleic acid (75 μmol), 1-*O*-octadecyl-*sn*-glycerol (100 μmol), and 4-dimethyl-aminopyridine (10 μmol) were dissolved in dry n-hexane. This solution was added to a suspension of *N*,*N*′-dicyclohexylcarbodiimide (100 μmol) in dry n-hexane and shaken vigorously for 17 h at room temperature. After filtration, solvent was evaporated under nitrogen, and the residue was purified by preparative TLC (system B). We have previously reported the LC/ESI-MS analysis of this and other related synthetic neutral ether lipids (26).

The synthesized and purified 1-*O*-octadecyl-2-octadecadienoyl-*sn*-glycerol was subjected to triphenylphosphine reductive ozonization as previously described (19). The resulting reference core aldehyde, 1-*O*-octadecyl-2-(9-oxo)nonanoyl-*sn*-glycerol (R_f = 0.11), was purified by preparative TLC (system B) and analyzed by reversed-phase LC/ESI-MS, and its identity was established on basis of RT, averaged mass spectrum, and fragmentation pattern.

RESULTS

Isolation of DAGE. Preparative TLC resolved the crude shark liver oil into six bands, which corresponded to monoacyl (monoradyl) glycerols (R_f = 0.01), free cholesterol (R_f = 0.13), triacylglycerol (R_f =0.37), DAGE (R_f = 0.55), cholesteryl esters (R_f = 0.93), and squalene (R_f = 0.97). The TLC bands were scraped off the plate and analyzed by high-temperature GLC, which indicated that the DAGE made up 55% of the shark liver oil. Reversed-phase LC/ESI-MS indicated that DAGE was composed of at least 50 species eluting between 10 and 37 min (chromatogram not shown). Similarly, the DAGE content of human milk was estimated to be approximately 1% of total fat and was made up of numerous species, of which only a few were abundant.

Regiospecific analysis of DAGE (26). The purified DAGE were subjected to a regiospecific analysis to reveal the *sn*-1-*O*-

alkyl, *sn*-2-acyl, and *sn*-3-acyl chain composition and distribution, which were determined by TLC (system B) and GLC, following pancreatic lipase hydrolysis and Grignard degradation.

Pancreatic lipase hydrolysis of the DAGE yielded 1-*O*-alkyl-2-acyl-*sn*-glycerols (2-MAGE, R_f = 0.32) as the major product (97%) and 1-*O*-alkyl-3-acyl-*sn*-glycerol (3-MAGE, R_f = 0.41) as the minor product (3%), along with GE (R_f = 0.05), free FA (R_f = 0.66), and original DAGE (R_f = 0.90).

The high recovery of 2-MAGE compared with 3-MAGE is consistent with the resistance of the *sn*-1 ether linkage to the action of most enzymes, and furthermore indicates a very low rate of isomerization and a low affinity of the pancreatic lipase for the *sn*-2-position of DAGE. The non-selective Grignard degradation yielded the 2-MAGE and 3-MAGE in equal amounts together with GE and the free FA as the tertiary alcohols (Grignard reaction products). The DAGE, 2-MAGE, and 3-MAGE fractions recovered from the pancreatic lipase digestion and Grignard degradation were treated with sulfuric acid/methanol to produce FAME and glyceryl ethers (GE), which were resolved by preparative TLC (system C). The purified GE were converted into the diacetyl GE by reaction with acetic anhydride and pyridine, and the FAME and the GE acetates were identified and quantified by GLC. Reversed-phase LC/ESI-MS analysis of 2-MAGE isolated from the shark liver oil following pancreatic lipolysis of DAGE showed a total of 49 species, of which 20 species were abundant, eluting between 10 and 26 min (chromatogram not shown).

Table 1 gives the regiospecific distribution of the fatty chains of shark liver oil DAGE as determined by GLC analysis of products of pancreatic lipolysis and Grignard degradation. The predominant *sn*-1-*O*-alkyl fatty chains were the monounsaturated alcohols (18:1n-9, 54.9%, and 16:1n-7, 12.2%) and saturated alcohols (16:0, 11.2%), with much smaller amounts of a diunsaturated alcohol (18:2n-6, 1%). Small amounts of odd-carbon saturated and monounsaturated fatty alcohols were also detected. Pancreatic lipase digestion and Grignard degradation gave similar FA profiles and selectivity for the *sn*-2- and *sn*-3-positions. The most abundant *sn*-2-FA were 16:0, 16:1n-7, 18:1n-9, 20:1n-9, 22:1n-11/13, 22:5n-3, and 22:6n-3, with 18:1n-9 accounting for more than 50% of the total. The most abundant *sn*-3-FA were 16:0, 16:1n-7, 18:0, 18:1n-9, 20:1n-9, 22:1n-11/13, and 22:4n-3. The FA 18:1n-9, 22:5n-3, and 22:6n-3 were preferentially associated with the *sn*-2-position, whereas 18:0, 20:1n-9, 22:1n-11/13, and 22:4n-3 were mostly in the *sn*-3-position.

LC/ESI-MS characterization of reference core aldehydes. The identities of all synthetic neutral ether lipids were established by combined TLC and LC/ESI-MS analysis. The 1-*O*-octadecyl-2-(9-oxo)nonanoyl-*sn*-glycerol was produced in high yield and purity by reductive ozonization of 1-*O*-octadecyl-2-(9-*cis*,12-*cis*)-octadecadienoyl-*sn*-glycerol. Figure 1A shows the total LC/ESI-MS positive ion current profile (CapEx +120 V) of synthetic 1-*O*-octadecyl-2-(9-oxo)nonanoyl-*sn*-glycerol (RT = 14.8 min). Figure 1B shows the full mass spectrum averaged over the entire peak with eight major ions being observed. The assignments for the observed ions, their corre-

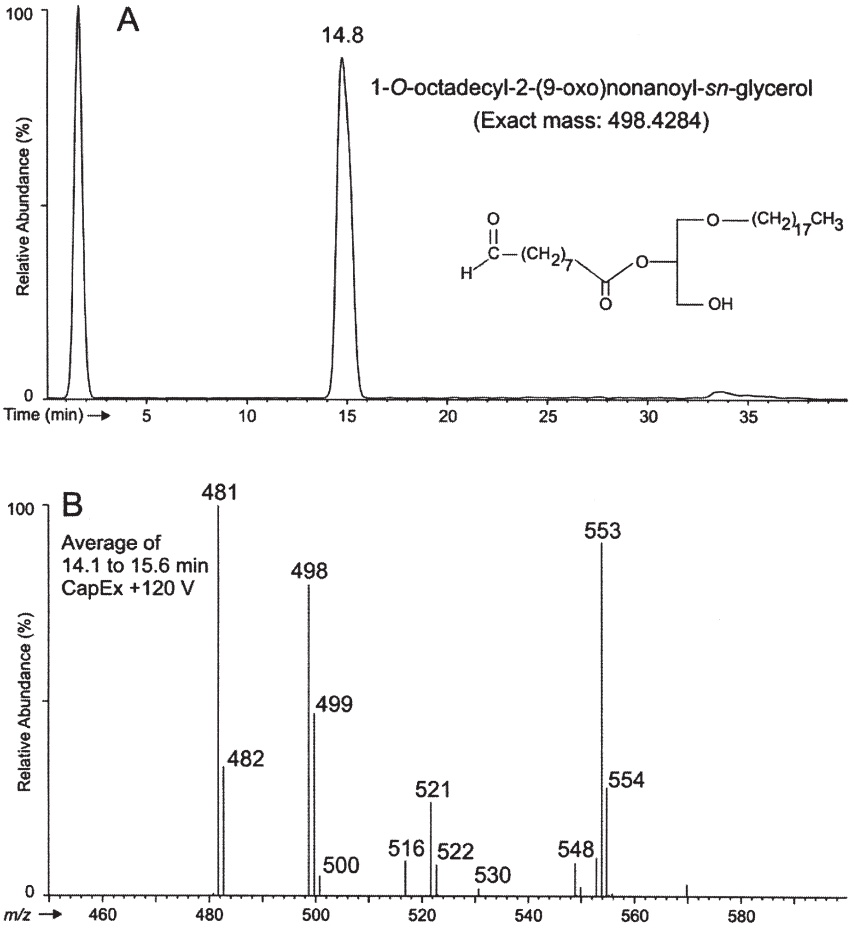

FIG. 1. Reversed-phase LC/ESI-MS analysis of synthetic 1-*O*-octadecyl-2-(9-oxo)nonanoyl-*sn*-glycerol. (A) Total positive ion current profile. (B) Full mass spectrum averaged over the entire peak, zoomed to *m/z* 450–600, in (A). All of the ions detected in the spectrum were assigned to the original reference compound. Note the high abundance for the *m/z* 499 ion relative to *m/z* 498, suggesting that the *m/z* 499 ion is not entirely composed of the ^{13}C isotopic ion of *m/z* 498. The LC/ESI-MS analysis showed that the optimal diagnostic ion of the 1-*O*-alkyl-2-(ω-oxo)acyl-*sn*-glycerols is the $[M - 17]^+$ ion, which in (B) corresponds to *m/z* 481. Additional details are given in Table 2, Scheme 2, and the text.

sponding ^{13}C isotopic components, and their relative abundances are presented in Table 2. The proposed molecular structures for these assigned ions are shown in Scheme 2. Sodium and ammonium adducts are common features of ESI, and it is also known that aldehydes in methanol solutions, as encountered in the mobile phase, are converted to the corresponding neutral hemi-acetal form (a methanol adduct).

The presence of an ion at *m/z* 498.70 corresponding to the $[M]^+$ ion was unexpected and only observed in the samples with the underivatized monoalkylglycerols containing a free aldehyde ester group. We confirmed this observation with the corresponding 3-isomer reference compound, 1-*O*-octadecyl-3-(9-oxo)nonanoyl-*sn*-glycerol (data not shown). It would be expected that the observed ion would have *m/z* 499.75 corresponding to the protonated molecular ion $[M + H]^+$. As indicated in Table 2 and Scheme 2, we propose that the $[M]^+$ ion at *m/z* 498.70 arises from a dehydrated ammonium adduct, $[M + NH_4 - H_2O]^+$, and not directly from the ionization as a radical cation, $[M]^{+\cdot}$. Another unexpected observation was the relatively high abundance (59%) of the *m/z* 499.75 ion compared with the *m/z* 498.70 ion, which is much higher than the calculated contribution of the ^{13}C isotope (32%) for this compound. The other ions have the ^{13}C contribution showing the expected ~32% relative abundance (Table 2). This suggests that the peak at *m/z* 499.75 is actually composed of two different species, $[(M + {}^{13}C_1) + NH_4 - H_2O]^+$ and the protonated molecular ion, $[M + H]^+$. As indicated in Table 2 and Scheme 2, we propose that the $[M + H]^+$ ion can also arise indirectly from the neutral loss of ammonia from the molecular ammonium adduct, $[M + NH_4 - NH_3]^+$.

Due to the lengthy and complicated ion assignment and the multiple possible pathways of ion formation, we have decided to describe the ions as mass difference from the exact mass of the 1-*O*-alkyl-2-(ω-oxo)-*sn*-glycerol, that is, $[M \pm X]^+$.

TABLE 2
Mass Spectrometric Analysis of Synthetic 1-*O*-Octadecyl-2-(9-Oxo)Nonanoyl-*sn*-Glycerol: Assignment of Detected Ions Including Corresponding ^{13}C Isotopic Ions and Their Relative Abundance[a]

Ion ID	Ion (m/z) (Rel. Ab.)[b]	^{13}C Ion (m/z)	(Rel. Ab.)	Ion assignment

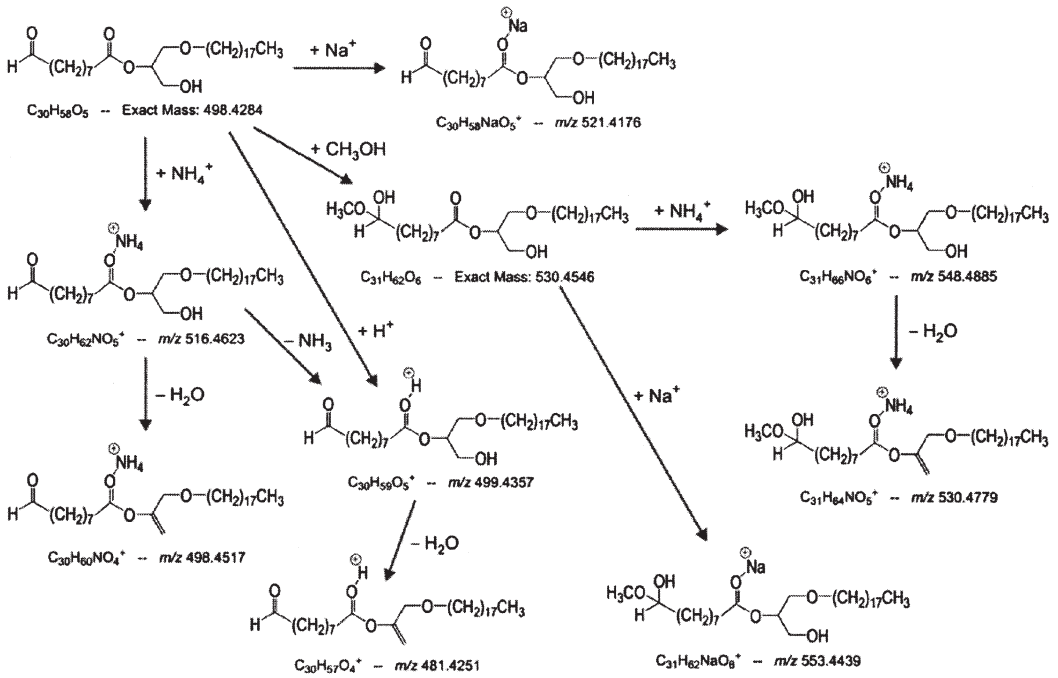

SCHEME 2. Proposed ionization and formation of various ions in the spectrum of synthetic 1-*O*-octadecyl-2-(9-oxo)nonanoyl-*sn*-glycerol. Additional details are given in Figure 1, Table 2, and the text.

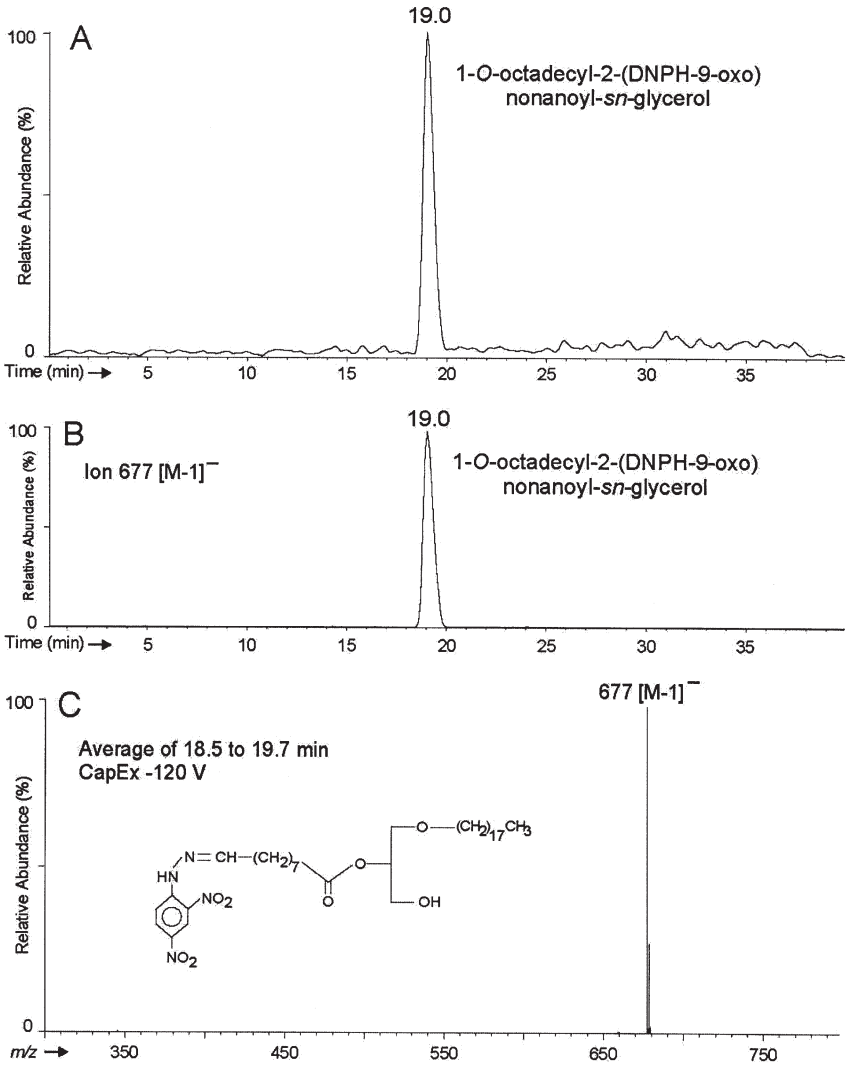

FIG. 2. Reversed-phase LC/ESI-MS analysis of synthetic and DNPH derivatized 1-*O*-octadecyl-2-(9-oxo)nonanoyl-*sn*-glycerol. (A) Total negative ion current profile. (B) Reconstructed single-ion chromatogram of the *m/z* 677 $[M - 1]^-$ ion. (C) Full mass spectrum averaged over the entire peak, zoomed to *m/z* 300–800, in (A). The diagnostic ion of 1-*O*-alkyl-2-(DNPH-oxo)acyl-*sn*-glycerols is thus the $[M - 1]^-$ ion.

The best diagnostic ion of 1-*O*-alkyl-2-oxoacyl-*sn*-glycerols under our experimental LC/ESI-MS conditions was the $[M - 17]^+$ ion at *m/z* 481.65, which we propose arises from the dehydration of the *m/z* 498.70 $[M + 1]^+$ ion (Fig. 1B, Table 2, and Scheme 2).

Further identification of 1-*O*-octadecyl-2-(9-oxo)nonanoyl-*sn*-glycerol was performed by derivatization with DNPH. Figure 2 shows the total LC/ESI-MS negative ion current profile with CapEx at −120 V of the DNPH-derivatized 1-*O*-octadecyl-2-(9-oxo)nonanoyl-*sn*-glycerol (RT 19.0 min, Fig. 2A) along with the reconstructed single-ion chromatogram (Fig. 2B) for the $[M - 1]^-$ ion, and the full mass spectrum (Fig. 2C) averaged over the entire peak. As demonstrated in Figure 2C, 1-*O*-octadecyl-2-(DNPH-9-oxo)nonanoyl-*sn*-glycerol was characterized by the deprotonated molecular ion, $[M - 1]^-$ at *m/z* 677, which was used as the diagnostic ion.

Characterization of 2-MAGE core aldehydes in autooxidized shark liver oil. Figure 3 shows the total positive ion current profile of the 1-*O*-alkyl-2-acyl-*sn*-glycerols before autooxidation (Fig. 3A) and after 3 h autooxidation (Fig. 3B) of shark liver oil 2-MAGE. The resulting ether core aldehydes (i.e., 1-*O*-alkyl-2-(ω-oxo)acyl-*sn*-glycerols) eluted with retention times ranging from 9 to 15 min, the hydroperoxides (i.e., 1-*O*-alkyl-2-(hydroperoxy)acyl-*sn*-glycerols) and other oxidation products with retention times ranging from 5 to 25 min, and the non-oxidized 1-*O*-alkyl-2-acyl-*sn*-glycerols with retention times from 25 to 35 min. The core aldehydes made up about 5%, and the other oxidation products about 40%, of the total peak area (Fig. 3B). Figure 3 also shows the reconstructed single-ion chromatograms for the $[M - 17]^+$ ion of 1-*O*-octadecenyl-2-(4-oxo)butyroyl-*sn*-glycerol (Fig. 3C) and 1-*O*-octadecenyl-2-(9-oxo)nonanoyl-*sn*-glycerol (Fig. 3D). Several 1-*O*-

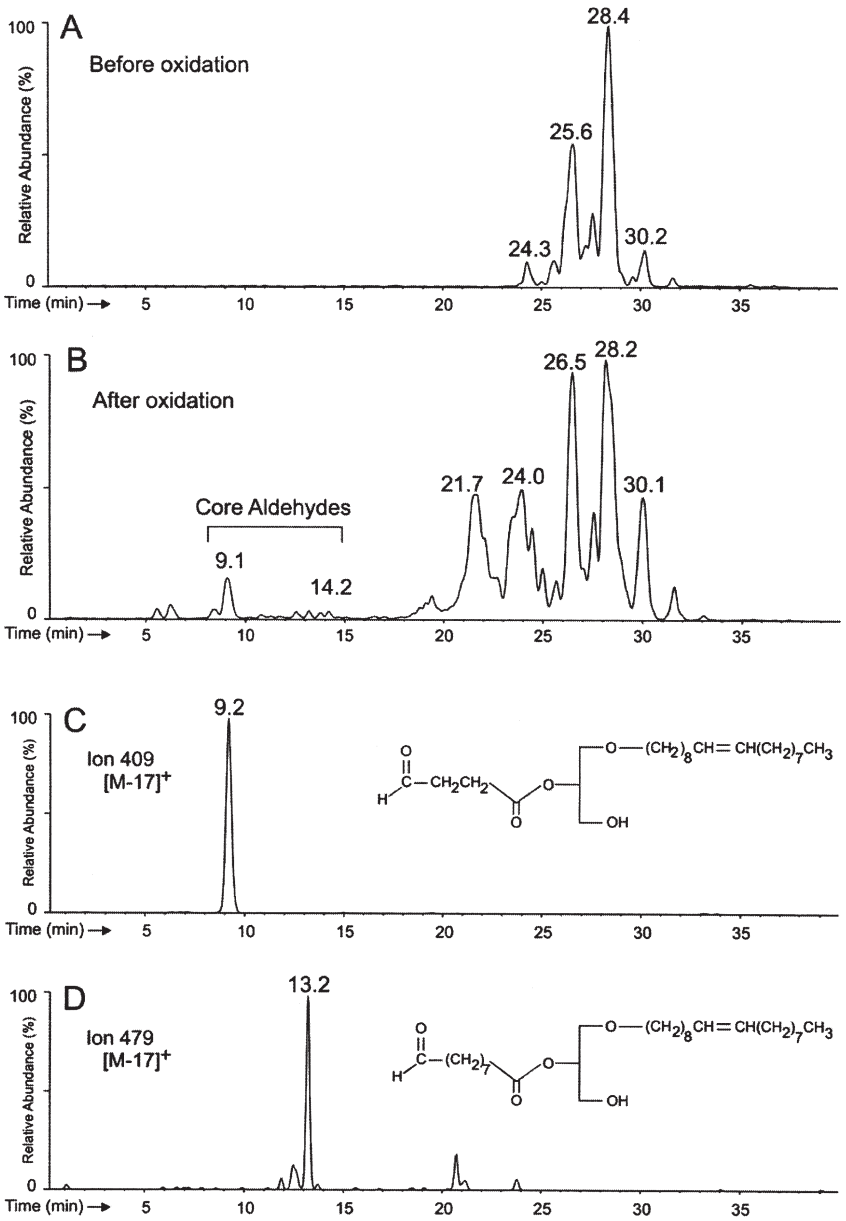

FIG. 3. Reversed-phase LC/ESI-MS analysis of 1-*O*-alkyl-2-acyl-*sn*-glycerols isolated from shark liver oil before and following oxidation. (A) and (B) Total positive ion current profiles of non-oxidized and autooxidized (80°C for 3 h in oxygen atmosphere) 1-*O*-alkyl-2-acyl-*sn*-glycerols, respectively. (C) and (D) reconstructed single-ion chromatograms of the *m/z* 409 and 479 $[M - 17]^+$ diagnostic ion of 1-*O*-octadecenyl-2-(4-oxo)butyroyl-*sn*-glycerol and 1-*O*-octadecenyl-2-(9-oxo)nonanoyl-*sn*-glycerol, respectively.

alkyl-2-oxoacyl-*sn*-glycerols were identified on the basis of the $[M - 17]^+$ and $[M]^+$ ions (Table 3). The major ether core aldehydes corresponded to 18:1-4:0Ald (20%), 16:1-9:0Ald (18:1-7:0Ald) (10%), 16:0-9:0Ald (2%), 16:0-10:1 (17:1-9:0Ald) (2%), 18:1-9:0Ald (20%), and 18:1-10:1Ald (7%).

Figure 4 shows the total LC/ESI-MS negative ion current profile (Fig. 4A) of DNPH-derivatized and purified 1-*O*-alkyl-2-oxoacyl-*sn*-glycerol, derived from shark liver oil DAGE, along with selected, reconstructed single-ion mass chromatograms for the $[M - 1]^-$ ion of 1-*O*-hexadecenyl-2-(DNPH-4-oxo)butyroyl-*sn*-glycerol (Fig. 4B), 1-*O*-hexadecyl-2-(DNPH-4-oxo)butyroyl-*sn*-glycerol (Fig. 4C), 1-*O*-octadecenyl-2-(DNPH-4-oxo)butyroyl-*sn*-glycerol (Fig. 4D), 1-*O*-octadecenyl-2-(DNPH-7-oxo)heptanoyl-*sn*-glycerol (Fig. 4E), 1-*O*-octadecenyl-2-(DNPH-9-oxo)nonanoyl-*sn*-glycerol (Fig. 4F), and 1-*O*-octadecyl-2-(DNPH-9-oxo)nonanoyl-*sn*-glycerol (Fig. 4G), which all were eluted over the time period of 10 to 20 min.

Table 4 lists the identified molecular species along with the uncorrected peak areas attributed to them. The $[M - 1]^-$ ion provides only the molecular weight of the compound. Further

TABLE 3
Identification of Molecular Species of 1-*O*-Alkyl-2-Oxoacyl-*sn*-Glycerols, Produced by Autooxidation of Pancreatic Lipase Treated Shark Liver Oil DAGE and Estimated by LC/ESI-MS[a]

[a]Two analyses. RT, retention time; Ald, aldehyde; nd, not detected.

confirmation of the structure was obtained from the linear correlation ($R = 0.982$) obtained between retention time and molecular mass among the 1-*O*-alkyl-2-DNPH-oxoacyl-*sn*-glycerols, when the latter was calculated as the total carbon number minus one carbon per double bond (Table 4). This elution factor makes it possible to calculate the relative retention times of unknowns with considerable accuracy, which helped to choose among likely structures represented by the same molecular mass within the reversed-phase LC/ESI-MS profile. Further characterization of the molecular species was obtained from knowledge of the possible formation of esterified aldehyde residues and the ratios of the corresponding *sn*-1 and *sn*-2 fatty chain moieties (Tables 1 and 4). For example, the masses at *m/z* 577 and 579 ($[M - 1]^-$ ions) can only represent the 1-*O*-hexadecenyl- and 1-*O*-hexadecyl-2-(DNPH-4-oxo)butyroyl-*sn*-glycerols (Figs. 4B and 4C), respectively. The ion at *m/z* 605 $[M - 1]^-$, however, could represent both the 1-*O*-octadecenyl-2-(DNPH-4-oxo)butyroyl-*sn*-glycerol and the 1-*O*-pentadecyl-2-(DNPH-7-oxo)heptanoyl-*sn*-glycerols (Table 4 and Fig. 4D), but on the basis of the much higher abundance of *sn*-1 alkyl 18:1n-9 in comparison with 15:0 (Table 1), it is obvious that the peak area mainly represents the 1-*O*-octadecenyl-2-(DNPH-4-oxo)butyroyl-*sn*-glycerol. The alternative identities of the species are written in parentheses in Table 4.

Characterization of 2-MAGE core aldehydes in autooxidized human milk. The small DAGE fraction isolated from human milk fat yielded a 1-*O*-hexadecylglycerol and oleic acid from the *sn*-2- and *sn*-3-positions as the major fatty chains. Figure 5 shows the total LC/ESI-MS negative ion current profile (Fig. 5A) of DNPH-derivatized 1-*O*-alkyl-2-oxoacyl-*sn*-glycerols, derived from human milk DAGE, along with the reconstructed single-ion mass chromatogram (Fig. 5B) for the $[M - 1]^-$ ion of 1-*O*-octadecyl-2-(DNPH-9-oxo)nonanoyl-*sn*-glycerol (RT = 18.8 min), and the full mass spectrum (Fig. 5C) averaged over the entire peak. This was the only ether core aldehyde characterized from human milk.

DISCUSSION

The major source of PAF-like lipids (or mimics/analogues) is the unregulated oxidative modification of cellular and plasma phospholipids. There have been numerous reports on isolation of the PAF-like lipids containing a long-chain fatty ester in the *sn*-1-position and a short-chain (ω-oxo)acyl group in the *sn*-2-position of PtdCho (27). The immediate precursors of these mimics are the 1,2-diacyl- and 1-*O*-alkyl-2-acyl-*sn*-GroPCho with saturated acyl and alkyl chains in the *sn*-1-position. Among these, the most frequently reported are 1-hexadecanoyl- and 1-octadecanoyl-2-(5-oxo)pentanoyl-*sn*-GroPCho, which are generated from the corresponding arachidonates (27). The corresponding *sn*-1 alkyl ether derivative, which is structurally more closely related to PAF, has been studied less frequently due to the more limited supply of potential precursors, although it was the first PAF analogue identified (27) and both DAGE and 1-*O*-alkyl-2-acyl-*sn*-glycerophospholipids are present in significant amounts of tissue lipids (28). The present study demonstrates the feasibility of generating PAF analogue precursors in the intestine by lipolysis and peroxidation of the DAGE, which constitute a significant proportion of dietary fats such as shark liver oil and milk fat. In addition, this study has recognized certain unusual features of 1-*O*-alkyl-2-(ω-oxo)acyl-*sn*-glycerols as precursors of PAF analogues. The 1,2-diradyl-*sn*-glycerol moieties generated from DAGE of shark liver oil were characterized by the presence of sites of unsaturation in both fatty chains. The peroxidation would, therefore, be expected largely to affect the 18:2n-6, 18:3n-3, and especially the 22:5n-3 and 22:6n-3, which would be anticipated to yield C_4 to C_9 core aldehydes in combination with both saturated and monounsaturated alkyl chains in the *sn*-1-position. The present results confirm that peroxidation of the monounsaturated 1-*O*-alkyl chains was limited during the mild conditions as previously described (29).

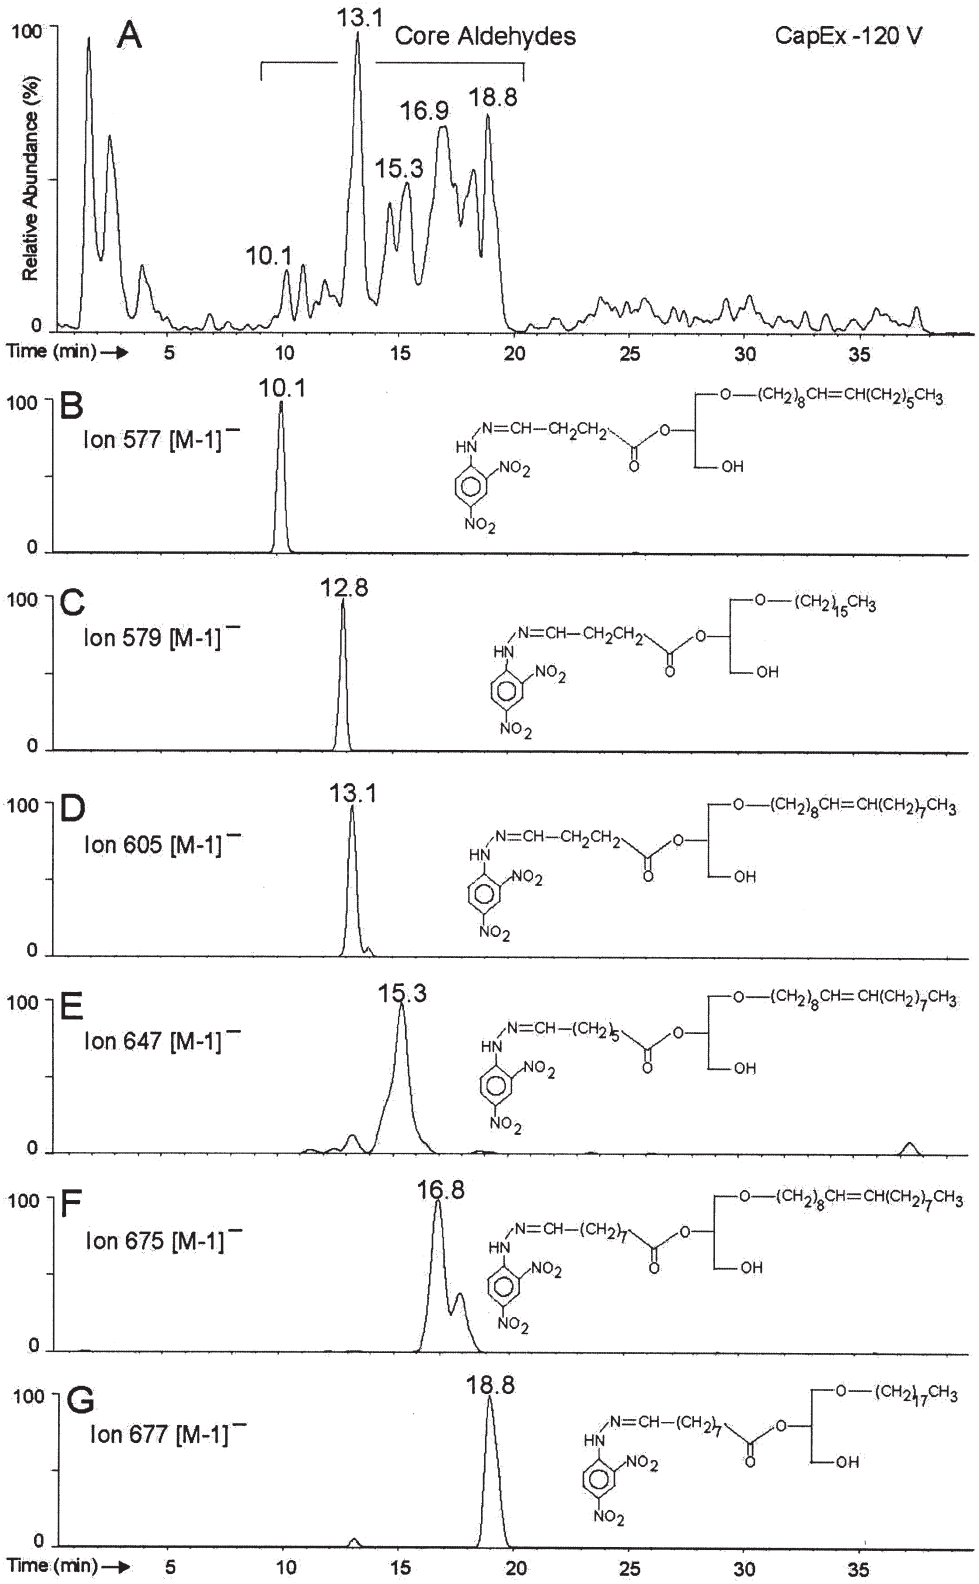

FIG. 4. Reversed-phase LC/ESI-MS analysis of autooxidized and DNPH derivatized 1-*O*-alkyl-2-oxoacyl-*sn*-glycerols from shark liver oil. (A) Total negative ion current profile of 1-*O*-alkyl-2-(DNPH-oxo)acyl-*sn*-glycerols. (B–G) reconstructed single-ion mass chromatograms of *m/z* 577, 579, 605, 647, 675, and 677 $[M - 1]^-$ diagnostic ions of 1-*O*-hexadecenyl-2-(DNPH-4-oxo)butyroyl-*sn*-glycerol, 1-*O*-hexadecyl-2-(DNPH-4-oxo)butyroyl-*sn*-glycerol, 1-*O*-octadecenyl-2-(DNPH-4-oxo)butyroyl-*sn*-glycerol, 1-*O*-octadecenyl-2-(DNPH-7-oxo)heptanoyl-*sn*-glycerol, 1-*O*-octadecenyl-2-(DNPH-9-oxo)nonanoyl-*sn*-glycerol, and 1-*O*-octadecyl-2-(DNPH-9-oxo)nonanoyl-*sn*-glycerol, respectively.

[a]Average of two determinations. ECN, equivalent carbon number; RT, retention time; Peak area, percent of cumulative peak area of recovered $[M-1]^-$ ions; Ald, aldehyde.

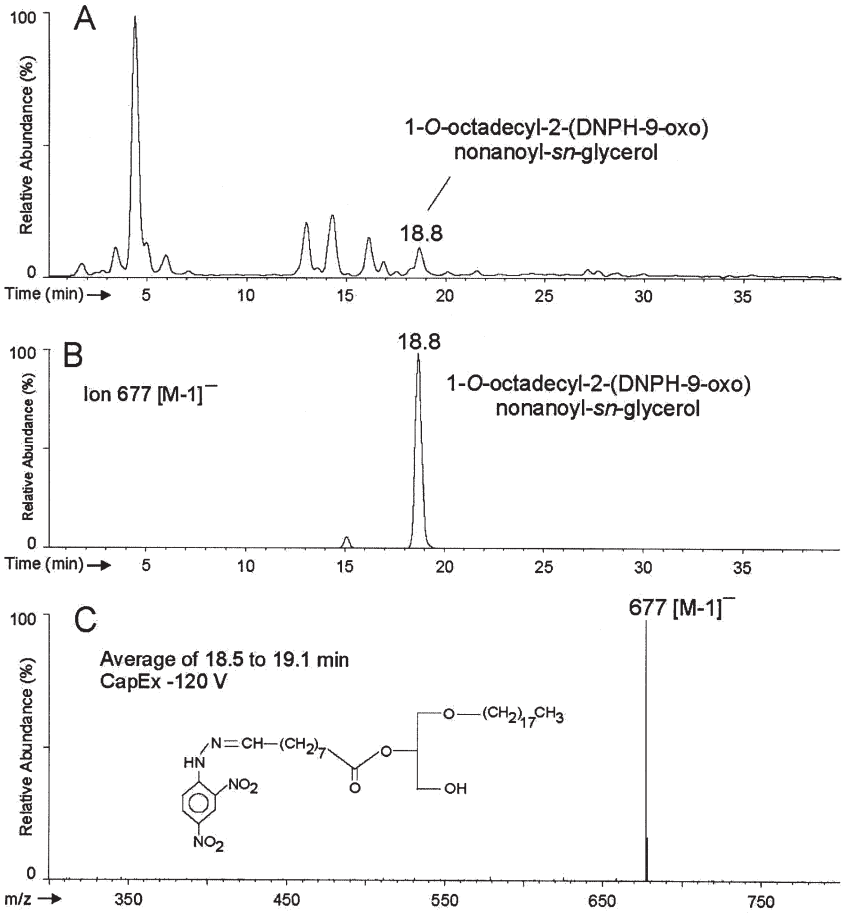

FIG. 5. Reversed-phase LC/ESI-MS analysis of autooxidized and DNPH derivatized 1-*O*-alkyl-2-acyl-*sn*-glycerols from human milk. (A) Total negative ion current profile. (B) Reconstructed single-ion chromatogram of the *m/z* 677 $[M - 1]^-$ diagnostic ion of 1-*O*-octadecyl-2-(DNPH-9-oxo)nonanoyl-*sn*-glycerol. (C) Full mass spectra averaged over the entire peak of 1-*O*-octadecyl-2-(DNPH-9-oxo)nonanoyl-*sn*-glycerol (zoomed to *m/z* 300–800) in (A).

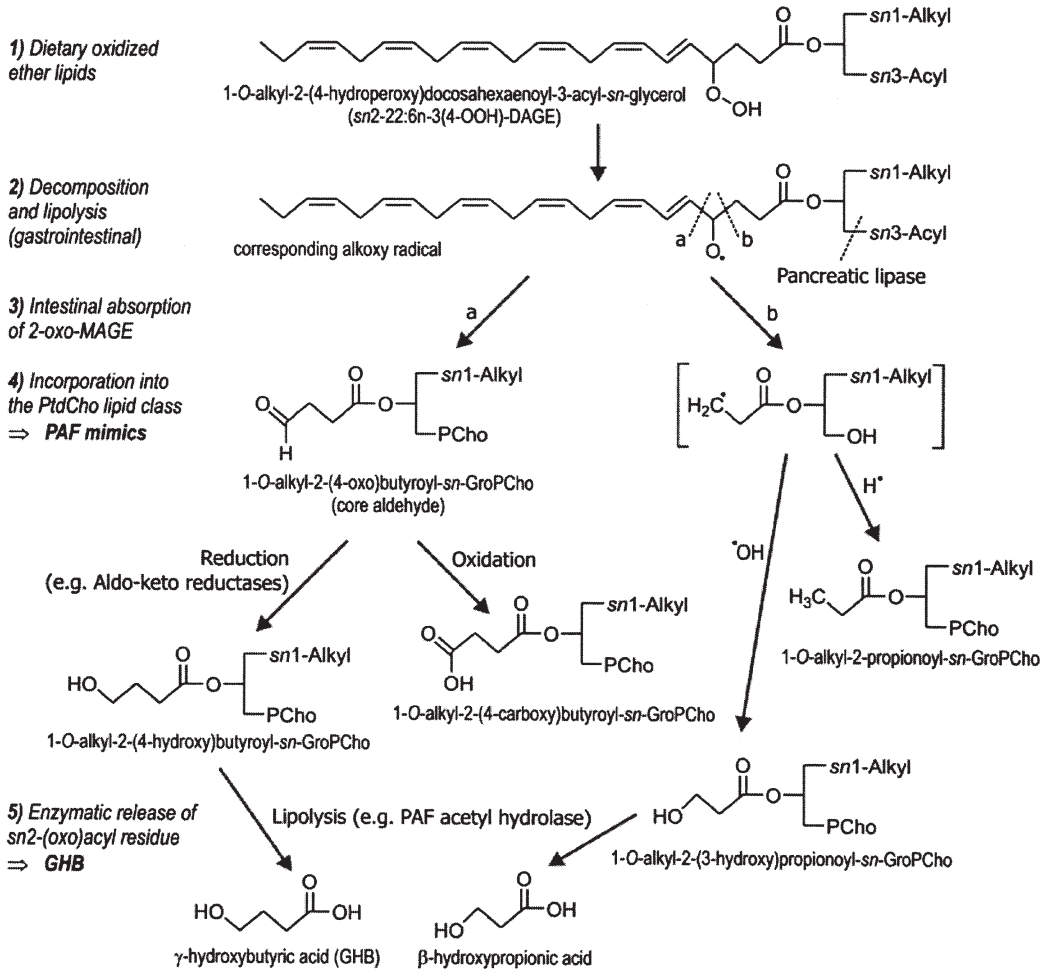
Core aldehyde–containing triacylglycerols have been isolated from autoxidized vegetable oils (13,14) and from pig plasma lipoproteins following feeding of peroxidized fats and oils (15). Others have recovered core aldehyde–containing cholesteryl esters from autoxidized synthetic and natural (30) PUFA esters of cholesterol and from atheroma tissue (31). The present study describes the isolation and characterization of $C_{4:0}$ and $C_{5:0}$ core aldehydes from polyunsaturated diacylglycerol ethers from shark liver oil, and $C_{9:0}$ core aldehydes from human milk fat, which had not been previously reported.

Of special interest is the identification of the $C_{4:0}$ aldehyde (originating from 22:6n-3) ester in combination with the abundant 18:1n-9 alkyl moiety (50%), that is, 1-*O*-octadecenyl-2-(4-oxo)butyroyl-*sn*-glycerol, which, because of the shorter *sn*-2 chain length, could provide a higher affinity for the PAF receptor than the corresponding $C_{5:0}$ derivative, originating from 20:4n-6 esters. The 22:6n-3 (4.1% of *sn*-2 position) is highly susceptible to oxidation, and may, when esterified, yield a wide spectrum of short-chain core aldehydes with several double bonds by β-cleavage (32), such as $C_{4:0}$, $C_{7:1}$, $C_{8:2}$, and $C_{10:2}$. Another FA, highly susceptible to oxidation, is 22:5n-3 (1.6% of *sn*-2-position). This FA can yield the $C_{7:0}$ core aldehyde along with other core aldehydes with one or more double bonds. Oxidation of the remaining *sn*-2 FA would yield the $C_{9:0}$, $C_{11:0}$, $C_{12:1}$, and $C_{13:2}$ core aldehydes. We were able to characterize the *sn*-2 $C_{4:0}$, $C_{7:0}$, $C_{9:0}$, and $C_{10:1}$ short-chain aldehydes in combination with *sn*-1 18:1n-9-alkyl moiety as "free" core aldehydes.

Potential precursors of PAF mimics were also anticipated in human milk. However, we were able to identify only the 1-*O*-alkyl-2-(9-oxo)nonanoyl-*sn*-glycerol. The fatty alcohol and FA profiles of human milk preparation had previously been analyzed in our laboratory (17). The total composition was 16:0 (24%), 17:0 (2%), 18:0 (43%), and 18:1n-9 (31%) for the fatty alcohols and 16:1n-7 (3%), 18:1n-9 (36%), 18:2n-6 (5%), and 20:1n-9 (1%) for the unsaturated FA. Mild autooxidation would mainly affect the 18:2n-6 (29), and yield $C_{9:0}$ core aldehydes with minor quantities of $C_{12:1}$. Besides, oxidation of monounsaturates would yield the $C_{9:0}$ core aldehydes as well, with the exception of 20:1n-9 (1%). In other words, mild autooxida-



SCHEME 3. Proposed mechanism/pathway for formation of PAF mimics and GHB from DAGE containing docosahexaenoic acid.

tion of human milk would probably yield mainly the 1-*O*-octadecyl-2-(9-oxo)nonanoyl-*sn*-glycerol.

The isolation of the short-chain core aldehydes from the 1-*O*-alkyl-2-acyl-*sn*-glycerols is of special interest because it could lead to formation of mimics of PAF following intestinal absorption and entry into the CDP-choline pathway of PtdCho formation, bypassing the *de novo* step of diradylglycerol formation. A possible mechanism/pathway leading from a common DAGE to a PAF mimic is outlined in Scheme 3. Short-chain diacyl and diradylglycerols have been shown to be converted into short-chain PtdCho during incubation with appropriate enzymes and substrates (8). Because 1-*O*-alkylglycerols (28), and long-chain 2-*O*-alkylglycerols (28) are incorporated into glycerophospholipids following prior conversion into 1,2-diradyl-*sn*-glycerols in the intestinal microsomes, it is likely that the core aldehyde–containing 1,2-diradyl-*sn*-glycerols would also be incorporated into intestinal PtdCho to yield PAF mimics. According to Paltauf (28), the dietary 1-*O*-alkyl-*sn*-glycerols are preferentially incorporated into the glycerophosphoethanolamine *in vivo*, which, however, could be N-methylated to yield the corresponding GroPCho. Tanaka *et al.* (4) have discussed the PAF-like phospholipids formed during peroxidation of diacylglycerophosphocholines from different foodstuffs. A short-chain FA terminating in an aldehyde, hydroxyl, or carboxyl group located in the *sn*-2-position of 1-alkyl or 1-acyl glycerophosphocholine can mimic the action of natural PAF.

The short-chain core aldehydes of the *sn*-1-*O*-alkylglycerol would be expected to be readily absorbed by the intestinal mucosa because of their lower molecular weight, greater polarity, and overall similarity to monoacylglycerols. There is evidence for the intestinal uptake of intact short-chain diacylglycerols (6,7,33) as well as of oxygenated FA and acylglycerols (34–36). The presence of an alkyl group in the *sn*-1-position and a short-chain core aldehyde in the *sn*-2-position would render the molecule resistant to the endogenous lipases in the absence of isomerization, as already shown for pancreatic lipase.

The alkylglycerol core aldehydes would be expected to exhibit many of the metabolic properties of the core aldehydes of acylglycerols. Thus, these aldehydes would be expected to form Schiff bases, as demonstrated with the core aldehydes of 2-monoacylglycerols (16), and the core aldehydes of PtdCho (37) and cholesteryl esters (38). In fact, the adducts of the alkyl ether core aldehydes would be anticipated to be more resistant

to a detachment from the polypeptide and protein molecules because of the presence of the alkyl ether group. We have shown elsewhere (9) that the core aldehydes of alkyl glycerophosphocholines in atheroma induce platelet aggregation and inhibit endothelium-dependent arterial relaxation.

Furthermore, it is possible that the C_4 core aldehydes of alkylglycerols as well as of acylglycerols might be reduced by aldol-keto reductases to the corresponding C_4 core alcohols, which upon lipolysis would be released as GHB. The reduction of C_4 core aldehydes of glycerophosphocholine has already been demonstrated by Srivastava *et al.* (10), and the hydrolysis of C_4 core alcohol containing glycerophosphocholines to GHB has also been shown (4). Scheme 2 outlines a plausible mechanism/pathway for the formation of GHB from a DAGE containing a docosahexaenoic acid. Although the reduction of triacylglycerol core aldehydes to the corresponding core alcohols has not been specifically shown, such a reduction has been demonstrated for the neutral cholesteryl ester core aldehydes (Bhatnagar, 2006, personal communication). The broad substrate specificity of the aldol-keto reductases (39) promises that such reductions would take place also with triradylglycerol core aldehydes. The C_4 core alcohol groups associated with the primary positions of the triradylglycerol or triacylglycerol molecule would be anticipated to be readily released by the lingual and gastric lipases, which preferentially attack the short-chain FA (40). Any C_4 core alcohol groups associated with the secondary position of the glycerol molecule would have to undergo isomerization to a primary position before enzymatic release, as the *sn*-2-position is not known to be attacked directly.

In the brain, GHB is known to be formed from gamma-aminobutyric acid (GABA) (41) as well as from succinic semialdehyde (SSA) derived from GABA via a specific SSA reductase. The endogenous brain levels of GHB (2–5 nmol/g) are believed to be too low to stimulate $GABA_B$ receptors (K_i between 80 and 120 μM), although the synaptic cleft concentration is not known (42). Cortical GHB concentrations approaching 250 nmol/g, which are sufficient to stimulate $GABA_B$ receptors have been obtained by administration of 100–400 mg/kg of exogenous GHB (43). In any event, exogenously administered GHB causes a wide range of physiological and pharmacological properties, including addiction, tolerance, withdrawal, and intoxication, which are probably mediated via the $GABA_B$ receptor (44). This review shows that dietary sources are likely to contribute readily metabolizable precursors of GHB, the supply of which would increase with the increased consumption of omega-3 FA that is currently being actively promoted.

ACKNOWLEDGMENTS

Insulin-Status-Dependent Modulation of FoF_1-ATPase Activity in Rat Liver Mitochondria

Samir P. Patel* and Surendra S. Katyare

Department of Biochemistry, Faculty of Science, The Maharaja Sayajirao University of Baroda, Vadodara, Gujarat 390 002, India

ABSTRACT: Early and late effects of alloxan diabetes and insulin treatment on mitochondrial membrane structure and function were evaluated by studying the kinetic properties of mitochondrial membrane marker enzyme FoF_1-ATPase and its modulation by membrane lipid/phospholipid composition and membrane fluidity. Under all experimental conditions the enzyme displayed three kinetically distinguishable components. In 1wk-old diabetic animals the enzyme activity was unchanged; however, K_m and V_{max} of component I increased and K_m of component II decreased. Insulin treatment resulted in lowering of K_m and V_{max} of components II and III. One-mon diabetic state resulted in decreased enzyme activity, whereas insulin treatment caused hyperstimulation. K_m of components I and II decreased together with decreased V_{max} of all the components. Insulin treatment restored the K_m and V_{max} values. In late-stage diabetes the catalytic efficiency of components I and II increased; insulin treatment had drastic adverse effect. Binding pattern of ATP was unchanged under all experimental conditions. Diabetic state resulted in progressive decrease in energy of activation in the low temperature range (E_L). Insulin treatment lowered the energy of activation in the high temperature range (E_H) without correcting the E_L values. The phase transition temperatures increased in diabetic state and were not corrected by insulin treatment. Long-term diabetes lowered the total phospholipid content and elevated the cholesterol content; insulin treatment had partial restorative effect. The membrane fluidity decreased in general in diabetic condition and was not corrected by insulin treatment at late stage. Regression analysis studies suggest that specific phospholipid classes and/or their ratios may play a role in modulation of the enzyme activity.

Paper no. L9905 in *Lipids 41,* 695–703 (July 2006).

Diabetes mellitus is the condition characterized by defective glucose metabolism with absolute or relative deficiencies in insulin secretion and/or in insulin action (1–4). It is also recognized that insulin, besides regulating glucose metabolism, also regulates practically all anabolic processes. These include transport of monosaccharides and amino acids, lipid synthesis, protein synthesis, turnover of RNA, and phosphorylation of several metabolic intermediates (2). It has been reported that the plasma phospholipids profile changes in Type 1 and Type 2 diabetic patients and in rat model of diabetes (5–7). It has also been reported that in human diabetics the plasma phospholipid transport protein (PLTP) decreased significantly (6–8). Changes in phospholipid composition and cholesterol content of reticulocytes and erythrocytes in human diabetics have been reported (9–11). These changes are believed to be responsible for acceleration of maturation process and/or decreased lifespan of red blood cells (11). Likewise, it has been shown that in experimental diabetes the phospholipid and FA composition of liver as well as heart microsomes changes significantly (12,13). Specifically, the activities of 18:3 and 22:6 desaturases decrease, resulting in a decrease in unsaturation index (12,14). The changes in lipid metabolism have been correlated with Na^+,K^+-ATPase activity in nerve, human placenta, and sarcolemmal membrane from rat hearts (12,14,15). A few studies have also been carried out to examine the effects of diabetes-induced disturbances in mitochondrial function and lipid metabolism (16–18).

The FoF_1-ATPase (Complex V) of mitochondria is localized in the inner membrane and requires specific phospholipids—diphosphatidyl glycerol (DPG), PC, and PE for its activity (19–21). The enzyme *in situ* utilizes transmembrane proton gradient and membrane potential $\Delta\Psi$, generated during substrate oxidation to synthesize ATP. The enzyme is a reversible proton-translocating ATPase and can generate a transmembrane proton gradient and $\Delta\Psi$, by hydrolyzing ATP (20,21). Thus, the enzyme is crucial for energy transduction functions in mitochondria (20,21). Because of its location in the inner membrane and specific requirement for phospholipids (19–21), the enzyme becomes an ideal candidate to evaluate the modulatory effects of diabetes-induced changes in mitochondrial lipid/phospholipid composition.

In view of these facts, we examined the effects of alloxan-induced diabetes at early and late stages on the kinetic properties of rat liver mitochondrial FoF_1-ATPase. Effects of insulin treatment were also evaluated. These findings are summarized in the present communication.

EXPERIMENTAL PROCEDURES

Chemicals. BSA fraction V, 1,6-diphenyl-1,3,5-hexatriene, and sodium salt of EDTA were purchased from Sigma Chemical Co. (St. Louis, MO). Sodium salt of ATP was obtained from SRL (Mumbai). Silica gel G was from E. Merck (Darmstadt, Germany), and NPH insulin (40 U/mL) was obtained

Abbreviations: CHL, cholesterol; DPG, diphosphatidyl glycerol; Lyso, lysophospholipid; PI, phosphatidylinositol; PLTP, plasma phospholipid transport protein; PS, phosphatidylserine; s.c., subcutaneously; SPM, sphingomylein; TPL, total phospholipid.

from Lilli (Fegersheim, France). All other chemicals were of AR grade and were purchased locally.

Animals. Adult male albino rats of Charles-Foster strain (weighing between 200 and 250 g) were used. The animals were fasted overnight, and the diabetic state was induced by injecting 12 mg alloxan/100 g bogy weight subcutaneously (s.c.) (22,23). Alloxan solutions were prepared freshly in saline. The control rats received an equivalent volume of the vehicle.

Experiments were carried out at the end of 1 wk or 1 mon of induction of diabetic state to ascertain the early onset and long-term effects, respectively (16,24). Diabetic state was confirmed in terms of hyperglycemia, polyuria, and glucosuria as detailed previously (16). For 1-wk studies the diabetic animals received insulin from the fifth day of induction of diabetes for three consecutive days, and for 1-mon studies diabetic animals received insulin starting from the fourth week of induction of diabetes for seven consecutive days at a dose of 0.8 units of NPH insulin/100 g body weight twice daily (around 7:00 AM and 6:00 PM) by s.c. route (22,23).

Isolation of mitochondria. Isolation of liver mitochondria was carried out by the procedure described earlier using the isolation medium comprising 0.25 M sucrose, 10 mM Tris-HCl buffer, pH 7.4, and 1 mM EDTA; 250 µg BSA/mL of isolation medium was included (25).

Estimation of protein was by the method of Lowry *et al.* (26) using BSA as the standard.

Analytical methods. The extraction of mitochondrial lipids/phospholipids, estimation of cholesterol, and determinations of phospholipid profile by TLC and membrane fluidity were according to the procedures described previously (27–30).

ATPase assay. Measurements of ATPase activity were carried out in the assay medium (total volume 0.1 mL) containing 50 mM Tris-HCl buffer, pH 7.4, 75 mM KCl, 0.4 mM EDTA, 6 mM $MgCl_2$, and 100 µM 2,4-dinitrophenol. After preincubating the mitochondrial protein (30–50 µg) in the assay medium at 37ºC for 1 min, the reaction was initiated by the addition of ATP at a final concentration of 5 mM (31). The reaction was terminated after 10 min by the addition of 0.1 mL of 5% (wt/vol) SDS solution, and the amount of librated inorganic phosphorus was estimated by the method of Katewa and Katyare (32). For the substrate kinetics studies, concentration of ATP was varied in the range from 0.1 mM to 10 mM. For temperature kinetics studies, experiments were carried out with fixed ATP concentration (5 mM), and the temperature was varied from 5 to 53ºC with an increment of 4ºC at each step and, depending on the temperature, the reaction was carried out for 5–10 min. Reaction velocity, v, is expressed as µmol of P_i liberated/10 min/mg protein.

Kinetics data analysis. The data for substrate kinetics were computer analyzed by three methods: the Lineweaver-Burk, Eadie-Hofstee, and Eisenthal and Cornish-Bowden plots for the determination of K_m and V_{max} using Sigma Plot version 6.1 (23,33). The values of K_m and V_{max} obtained by the three methods were in close agreement and were averaged. The K_{cat} or turnover number, which represents the number of substrate molecules transformed s^{-1}, was derived from corresponding V_{max} values (in mol) by using the equation (34):

$$K_{cat} = V_{max} \times N/(3{,}600 \times 5.60 \times 10^5) \quad [1]$$

where N is Avogadro's number and 5.60×10^5 is the molecular weight of FoF_1-ATPase (35). The ratio K_{cat}/K_m [M] is taken as the index of the catalytic efficiency of the enzyme (34). However, it is not possible to know the number of enzyme molecules/mg of mitochondrial protein, Hence we normalized the K_{cat}/K_m values to ${}^{App}K_{cat}/K_m$ by dividing the K_{cat}/K_m values by corresponding values of v at 37ºC. The ${}^{App}K_{cat}/K_m$ values thus calculated refer to unit mitochondrial protein. The data on temperature kinetics were analyzed for determination of energies of activation in the high and low temperature ranges (E_H and E_L, respectively) and phase transition temperature (T_t) according to the method described previously (23).

The regression analysis across the groups and statistical evaluation of the data by ANOVA was carried out using Jandel Sigmastat Statistical Software, version 2.0.

RESULTS

Effects of alloxan-induced diabetes and subsequent treatment with insulin on body and liver weights conformed to our previously reported observations (data not shown) (16).

As expected, the blood sugar levels increased by 3.6- and 4.6–fold, respectively, in the two diabetic groups. Insulin treatments had partial restorative effect, and the serum glucose levels were always higher compared with those in the corresponding control groups (Table 1). Other diabetes parameters such as polyuria and glucosuria were in conformity with our earlier published values (16).

In preliminary studies, we determined the effect of alloxan-induced diabetes on FoF_1- ATPase activity in the liver mitochondria at 25 and 37ºC; the data are given in Table 2. The enzyme activity was not affected in 1-wk diabetic animals. Although insulin treatment marginally increased the activity at 25ºC, the activity ratio decreased. By contrast, in 1-mon diabetic animals the activity decreased by 58%. Insulin treatment resulted in hyperstimulation (64% and 41% increase, respec-

TABLE 1
Effects of Alloxan-Induced Diabetes and Subsequent Treatment with Insulin on Blood Glucose Level

Group	Treatment	Serum glucose (mM)
One week	Control	4.21 ± 0.35
	Diabetic	15.02 ± 0.65[a]
	Diabetic + insulin	6.01 ± 0.35[a,b]
One month	Control	4.31 ± 0.33

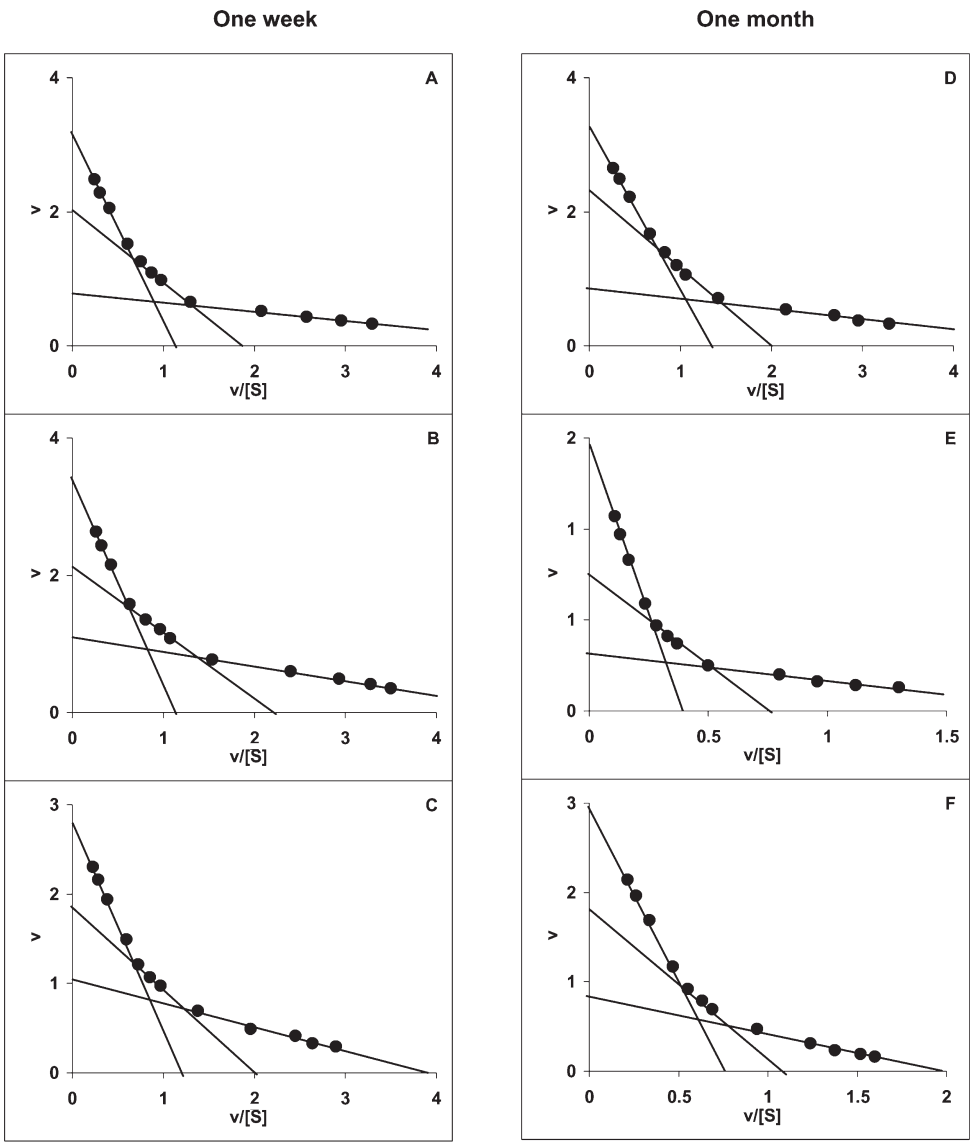

FIG. 1. Typical Eadie-Hofstee plots for FoF_1-ATPase from liver mitochondria. The enzyme activity *v* is plotted vs. *v*/[S], where *v* is the enzyme activity at the given ATP concentration [S] for (A) 1-wk control, (B) 1-wk diabetic, (C) 1-wk insulin-treated diabetic, (D) 1-mon control, (E) 1-mon diabetic, and (F) 1-mon insulin-treated diabetic. The plots are typical of 6–8 independent experiments in each group.

tively, at the two temperatures), ultimately leading to a significant and greater decrease in the activity ratio (Table 2).

In view of these differential effects of insulin treatment (Table 2), further experiments were carried out to examine the kinetics behavior of the enzyme as a response to change in the substrate, that is, ATP concentration. Analysis by three methods cited above (23,33) revealed that in the control as well as all the experimental groups the enzyme activity resolved in three kinetically distinguishable components. It has been shown earlier by us and other researchers that the rat liver mitochondrial FoF_1-ATPase activity resolves in three kinetically distinguishable components (36,37). It has been suggested earlier that the kinetic components represent the potential and the response of the enzyme to increasing concentrations of the substrate (32). Typical Eadie-Hofstee plots for all groups are shown in Figure 1A–F. K_m and V_{max} values of the three components as affected by insulin status are given in Table 3. Thus, in the 1-wk diabetic group, both K_m and V_{max} of component I increased, whereas K_m of component II decreased. Insulin treatment restored the K_m and V_{max} of component I. For component II both K_m and V_{max} decreased. Long-term diabetic state had a general V_{max} lowering effect, and the K_m of component I and II decreased. Treatment with insulin restored V_{max} values in general near normality, whereas K_m of component I increased by 2-fold and that of component II was restored.

In view of the observed changes in the K_m and V_{max} values under the different experimental conditions, we computed the catalytic efficiency $^{App}Kcat / K_m$ of the three components. The data are given in Table 4. As is evident, 1-wk diabetic state did not affect the catalytic efficiency of any of the kinetic components. Treatment with insulin reduced the catalytic efficiency of component III. One-mon diabetic state increased the catalytic efficiency of components I and II. Insulin treatment, in general, reduced the catalytic efficiency of all the kinetic components; the effect being most pronounced on component I (Table 4).

Analysis of substrate kinetics data by Hill plots indicated that up to 1.15 mM ATP concentration one ATP molecule was bound; beyond this concentration of substrate two molecules of ATP were bound under all experimental conditions (data not shown).

In the next set of experiments, we evaluated the effect of alloxan-induced diabetes and subsequent treatment with insulin on the temperature-dependent change in the enzyme activity. The typical activity-vs.-temperature plots and corresponding Arrhenius plots for 1-wk and 1-mon groups are shown in Figures 2 and 3, respectively. The plots of activity vs. temperature and the corresponding Arrhenius plots for diabetic and insulin-treated diabetic animals (early as well as late stage) differed considerably from the controls. The optimum temperature in the control group (49°C) increased by 4°C to 53°C in both the diabetic groups. At the early stage treatment with insulin was ineffective in normalizing the optimum temperature, whereas at late stage the optimum temperature was restored to normality after insulin treatment (Figs. 2 and 3). The differences were also reflected in terms of the energies of activation in high and low temperature ranges (E_H and E_L, respectively) and phase transition temperature (T_t) (Table 5). Thus, in 1-wk diabetic animals the value of E_L decreased; insulin treatment lowered the value of E_H (Table 5). In the 1-mon diabetic group the pattern was repeated and the decrease in E_L was more pronounced. Insulin treatment, besides lowering the E_H, caused further decrease in E_L. The generalized feature in both the groups was increase in T_t in diabetes, which could not be corrected by insulin treatment in the 1-mon group (Table 5).

The observed changes in the substrate and temperature kinetics properties prompted us to examine the effects of insulin status on lipid/phospholipid profiles of the mitochondria. These results are given in Tables 6 and 7. In the 1-wk diabetic group the content of total phospholipid (TPL) and cholesterol (CHL) did not change significantly, and insulin treatment had no effect. Nevertheless the membrane fluidity decreased significantly, which was corrected by insulin treatment. By contrast, in the 1-mon diabetic group the TPL content decreased by 32%, and CHL content increased by 51%. This was reflected in terms of decreased molar ratio of the two entities (data not shown) and lowering of membrane fluidity. Insulin treatment restored CHL content but had marginal effect on

The values of $^{App}K_{cat}/K_m$ were computed as described in the text. The results are given as mean ± SEM of 6–8 independent experiments in each group.
[a]$P < 0.05$ compared with the corresponding control.
[b]$P < 0.05$ compared with the corresponding diabetic.

TPL content; the membrane fluidity was not restored to normality (Table 6).

Analysis of phospholipid profile (Table 7) revealed that diabetic state had a generalized effect of increasing lysophospholipid (Lyso), sphingomylein (SPM), phosphatidylinositol (PI), and phosphatidylserine (PS), and a tendency to decrease PC and PE. Insulin treatment could correct the Lyso component and partially correct the PC and PE composition (Table 7). The computed contents of the individual phospholipid classes were generally consistent with the observed changes (data not shown but can be easily derived by multiplying the values of TPL with percent composition of individual phospholipid class).

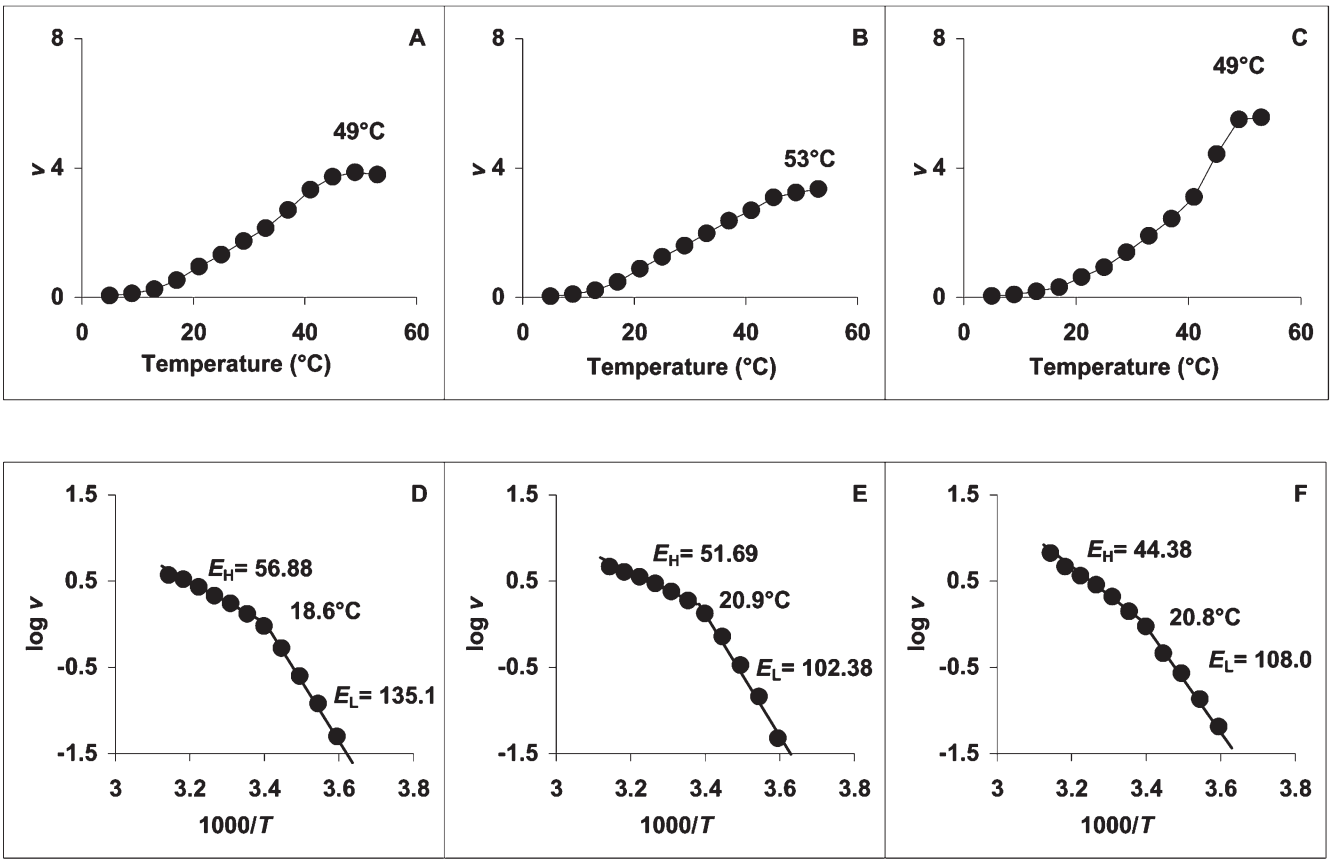

FIG. 2. Typical plots depicting dependence of enzyme activity on the temperature, and corresponding Arrhenius plots for 1-wk groups. In temperature curves, enzyme activity *v* is plotted vs. temperature (°C) for (A) Control, (B) diabetic, and (C) insulin-treated diabetic groups. In Arrhenius plots log *v* is plotted against 1,000/*T*, where *v* represents the activity at corresponding absolute temperature *T*, for (D) control, (E) diabetic, and (F) insulin-treated diabetic groups. Values of energies of activation in high and low temperature ranges (E_H and E_L) are in KJ/mole. Phase transition temperature T_t is in °C. The plots are typical of 6–8 independent experiments in each group.

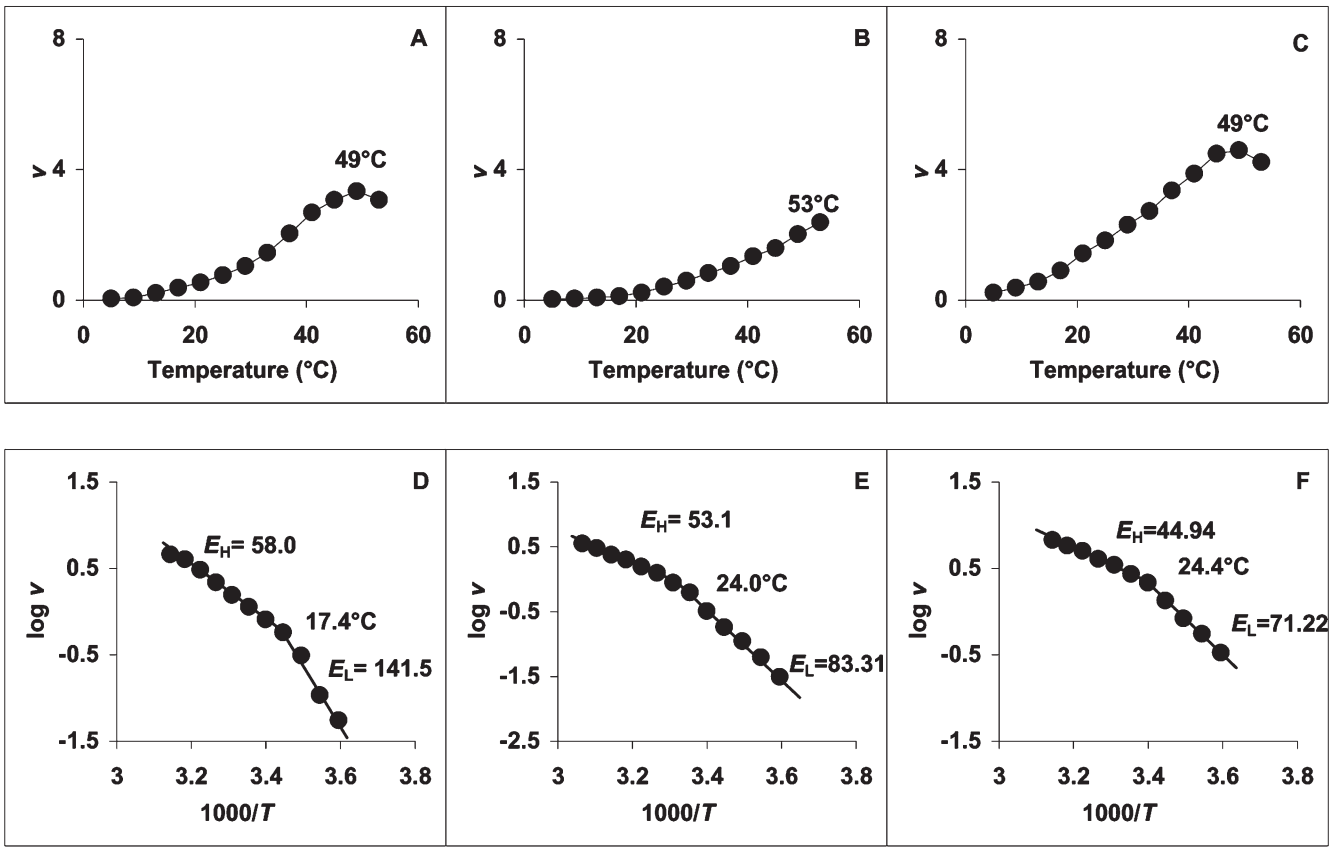

FIG. 3. Typical plots depicting dependence of enzyme activity on the temperature, and corresponding Arrhenius plots, for 1-mon groups. In temperature curves, enzyme activity *v* is plotted vs. temperature (ºC) for (A) control, (B) diabetic, and (C) insulin-treated diabetic groups. In Arrhenius plots log *v* is plotted against 1,000/*T* for (D) control, (E) diabetic, and (F) insulin-treated diabetic groups. Values of energies of activation in high and low temperature ranges (E_H and E_L) are in KJ/mole. Phase transition temperature T_t is in °C. The plots are typical of 6–8 independent experiments in each group.

DISCUSSION

As these results show, FoF_1-ATPase activity did not change in the early stage of alloxan-induced diabetes, or with subsequent treatment with insulin, whereas at the late stage the enzyme activity decreased to a great extent and insulin treatment caused hyperstimulation (Table 2). These results are consistent with our earlier findings on the oxidative phosphorylation in the liver mitochondria, which was not affected by early diabetic stage but at later stage the energy coupling efficiency decreased to a significant extent and insulin treatment more or less normalized the oxidative phosphorylation parameters (16).

The important observations of the present studies were altered substrate and temperature kinetics properties. The observation that the diabetic state resulted in lowering of K_m of component II in both the groups suggests that this is an adaptive mechanism. However, this adaptive mechanism seems to have the opposite effect on the K_m of component I. A similar situation of opposite effects was obtained even with respect

[b]$P < 0.05$ compared with the corresponding diabetic.

to insulin treatment. Thus, in the 1-wk diabetic group insulin treatment resulted in generalized decrease in K_m, whereas in the 1-mon diabetic group insulin treatment significantly elevated the K_m values of components I and II. Interestingly, long-term diabetes seemed to improve the catalytic efficiency of the enzyme (Table 4); insulin treatment of these animals drastically curtailed the catalytic efficiency (Table 4). Decrease in the values of E_L in diabetic state is another interesting feature, and may represent a modulatory response to improve catalytic efficiency (Table 5).

The above-mentioned observations suggest that the changes in lipid/phospholipid profile of mitochondria may be responsible for these modulatory effects. Indeed significant changes occurred in the mitochondrial TPL and CHL contents, membrane fluidity, and phospholipid composition and content. Because FoF_1-ATPase has known requirements of phospholipids, especially DPG, PC, and PE (19–21), it was of interest to find out whether the observed changes in kinetic properties across the groups could be correlated with lipid classes or their molar ratios. This possibility was evaluated by carrying out regression analysis across the groups, and the data are summarized in Table 8. As Table 8 shows, PE and total basic phospholipids (BPL), but not PC or SPM, are positive modulators of V_{max2} and V_{max3}. By contrast, the acidic phospholipids PI, PS, and DPG are negative modulators (Table 8). The molar ratio of TPL:CHL correlated positively with V_{max} values of all three kinetic components. V_{max} values of components II and III correlated positively with molar ratio of TPL:PI, TPL:PS, and TPL:PI + PS. A negative correlation of PC/PE, PI/BPL, PS/BPL, and DPG/BPL with V_{max2} and V_{max3} was another interesting feature. E_L correlated positively with PE, TPL/PI, TPL/PS, and TPL/PS + PI, whereas negative correlations were obtained with SPM, PI, PS, SPM/PC, PI/BPL, and PS/BPL (Table 8). Based on these observations, it may be suggested that besides changes in the phospholipid composition, the charge distribution across the membrane and especially in the lipid microdomains in which FoF_1-ATPase is embedded and changes in membrane fluidity may play a significant modulatory role.

It has been recognized that the 18:3 and 22:6 desaturase activities decrease in diabetes thus lowering the unsaturation index (12,14), The increase in T_t that we note here (Table 5) is consistent with these observations.

Mutations in mitochondrial DNA leading to dysfunction of FoF_1-ATPase complex has been proposed to be an underlying cause of mitochondrial diabetes. However dysfunction of Pyruvate dehydrogenase complex can also lead to a diabetic state (38–40). It is not clear at this stage whether a similar situation would prevail following exposure to alloxan. However, from the data presented it is apparent that changes

in membrane lipid/phospholipid domains may play a regulatory role.

Our results also show that the aberrations introduced by alloxan-induced diabetes could not be fully corrected by treatment with insulin. This is consistent with the well-acknowledged fact that insulin does not correct all the maladies of diabetes (1,41,42). One therefore wonders whether complete restoration to normality could be achieved by combined treatment with insulin and c-peptide (41,42). This interesting possibility is worth exploring further.

ABSTRACT: Flax's recent popularity in human and animal foods is mostly due to its desirable FA composition. Flax is an excellent source of omega-3 FA, which have been shown to have many health benefits. To date, little is known about the genetic and environmental factors that control the FA composition of flax seeds. To elucidate some of the important genetic components, reverse transcriptase (RT)–PCR and real-time PCR were used to determine the expression profiles of two key FA biosynthetic genes during seed development. Plants of flax cultivar AC McDuff were grown under field conditions, and RNA was extracted from ovaries and developing bolls collected from 2 d after anthesis (DAA) to maturity. Desaturation enzymes stearoyl-ACP desaturase (SAD) and Δ12 FA desaturase 2 (FAD2) were both expressed in ovaries, and their expression was differentially modulated throughout seed development. SAD was most highly expressed in ovaries. Its expression quickly decreased until 4 DAA; this was followed by a slight peak at 8 DAA, only to return to relatively low levels of expression in maturing bolls, ranging from 2.1% to 4.5% relative to the level observed in ovaries. FAD2 expression displayed a different temporal pattern. While expression of FAD2 did decrease in the early stages of seed development, expression increased starting at 8 DAA, peaking at 16 DAA, when it was 158% relative to the level observed in ovaries. FAD2, which desaturates oleic acid (18:1*cis*Δ9) into linoleic acid (18:2*cis*Δ9,12), is therefore controlled at the transcription level. To relate enzyme expression with FA profile, GC was performed on the same subsamples used for RT-PCR and real-time PCR, and proportions of palmitic, stearic, oleic, linoleic, and linolenic acids were determined for the same developmental stages. Although FAD2 expression increased from 8 to 16 DAA, relative changes in linoleic acid (18:2*cis* Δ9,12) were not observed. However, linolenic acid (ALA; α-18:3; 18:3*cis*Δ9,12,15) levels increased steadily, meaning that linoleic acid (18:2*cis*Δ9,12) is a transient substrate converted by FAD3 as quickly as it is produced by FAD2. Phenotypes are the result of genotypes, environment, and the interaction of the two. To evaluate the environmental impact on the production of FA in flax, FA profiles were assessed in a total of four environments (two locations, two years). Warm and dry environmental conditions resulted in lower levels of PUFA 18:2*cis*Δ9,12 and 18:3*cis*Δ9,12,15, and higher levels of 18:1*cis*Δ9. FAD2 expression and/or activity may therefore be affected by the environment.

Paper no. L9958 in *Lipids 41*, 705–712 (July 2006).

Omega-6 FA such as linoleic acid (18:2*cis*Δ9,12) and omega-3 FA such as linolenic acid (18:3*cis*Δ9,12,15) are EFA. They are components of cell membranes and play many important metabolic roles. They are precursors to long-chain FA critical to normal development (1). Adequate intake and proper balance of EFA are necessary to ensure proper physiological functions of the human body.

Numerous health benefits have been associated with functional FA, particularly omega-3 (2). Their role in reducing the risk of sudden cardiac death and coronary heart disease, cancer, and other human health risk factors has been scientifically demonstrated (3,4). Flax seed is an excellent source of α-linolenic acid (ALA), and the effects of dietary flax seed in reducing serum cholesterol and cardiovascular incidence have recently been demonstrated in model organisms such as rats and rabbits (5,6).

Omega-3 FA are found in fish, algae, and plants such as flax, walnuts, soybean, and canola. Flax seeds and flax oil are the richest sources of ALA in the North American diet. Traditional linseed varieties have approximately 45–50% ALA, whereas high-linolenic lines may comprise more than 70% ALA. Flax is therefore an oilseed of choice when it comes to designer oil because of the intrinsic quality of its oil and its genetic variability for oil composition with a potential for very high content of ALA. Solin varieties such as Agricore United Linola™ varieties have been developed for very specific markets and have less than 5% ALA.

From a plant perspective, FA are essential for cell biology not only as cell membrane structural components but also as storage lipids (7). FA biosynthesis in oilseeds is catalyzed by a set of condensing and desaturation enzymes located in plastids and endoplasmic reticulum (ER), and the series of reactions necessary for *de novo* synthesis of FA up to 18 carbons in length have been described (8,9). Of the plastid *de novo*–synthesized acyl-ACP (16:0, 18:0, and 18:1*cis*Δ9) pools in *Arabidopsis* mesophyl cells, 38% remain in chloroplasts, and 62% are cleaved from ACP by acyl-ACP thioesterases (10). The free FA are then converted to acyl-CoA by an outer-envelope long-

Abbreviations: DAA, days after anthesis; FAD2, Δ12 FA desaturase 2; RT, reverse transcriptase; SAD, stearoyl-ACP desaturase.

chain acyl CoA synthetase (LACS) isoform, exported to ER, and used in several metabolic pathways including those of storage lipid synthesis in developing seeds, those of cutin and suberin production, and those of cuticular wax layer components synthesis, depending on tissue type and developmental stage (10–12). Desaturation of 18:0 FA into 18:1*cis*Δ9, 18:2*cis*Δ9,12 and 18:3*cis*Δ9,12,15 is performed by SAD, FAD2, and FAD3 enzymes, for which some gene members have recently been cloned in flax (13–15). Little is known about the genetic control of these enzymes, particularly whether their activity is controlled at the transcription, translation, or post-translation level.

FA composition in the seeds of oilseed crops is influenced by the environment. The phenotypic plasticity and the diversity of metabolites are the abilities of a genotype to produce multiple phenotypes and/or metabolite profiles in response to different environments. Understanding the molecular basis of this plasticity is important for breeding programs (16–18). To date, several studies have examined the role of temperature on FA biosynthetic gene expression (19,20). In soybean (*Glycine max* L.), the vital role of temperature, location, and year in FA biosynthesis has been reported (21). Soybean plants exposed to high daily temperatures were shown to produce reduced linoleic and linolenic acid and increased oleic acid content (22,23). It has also been reported that lines with reduced linolenic acid were less sensitive to wide temperature changes (24). The effect of temperature on oil composition during seed maturation has been investigated in low-linolenic flax genotypes, where high temperatures considerably decreased the relative proportions of linoleic and linolenic acids (25). In short, genotype (G), environment (E), and genotype–environment interaction (G–E) have all been demonstrated to influence plant oil production and the oil composition in mature seeds.

The objectives of the present research were threefold: to quantify the FA composition of flax during seed development; to quantify the expression levels of the genes encoding two desaturases (SAD and FAD2) in order to establish the role of transcriptional control in FA composition; and to estimate the environmental effect on FA composition.

EXPERIMENTAL PROCEDURES

Plant materials. Flax plants (*Linum usitatissimum* L. cv AC McDuff) were grown at Winnipeg (49°54' N, 97°14' W) and Morden (49°12' N, 98°61' W), Manitoba, Canada, under rainfed conditions over the growing seasons 2002 and 2003. AC McDuff is late-maturing oilseed flax with high oil content (47%), of which 50% is linolenic acid (26). At anthesis, referred to as 0 d after anthesis (DAA), individual flowers were tagged sequentially, and developing bolls were harvested at 0, 2, 4, 8, 12, 16, 20, 24, 28, and 32 DAA and at maturity. The 0 DAA samples consisted of ovaries free of other flower tissues. Sampling took place in late July and August. Developing bolls were immediately frozen in liquid nitrogen and then stored at –80°C. Subsamples were used for RNA extraction and FA profiling.

RNA isolation. Total RNA was isolated from 0 to 32 DAA samples of developing bolls and mature bolls collected in Winnipeg in summer 2002 using a Trizol procedure adapted for seed material (http://plantsciences.montana.edu/wheat-transformation/molecular.htm#totalrnamini). Briefly, 0.5 mL of extraction buffer (50 mM Tris pH 9.0, 200 mM NaCl, 1% Sarkosyl, 20 mM EDTA pH 8.0 and 5 mM DTT) was added to 50–100 mg of tissue ground in liquid nitrogen and homogenized by vortexing. Extraction was performed with 0.5 mL phenol/chloroform/isoamyl alcohol (49:49:2). After centrifugation at 18,300*g* for 5 min at 4°C, 1 mL of Trizol reagent (Invitrogen, Burlington, Ontario, Canada) was added to 0.5 mL upper aqueous phase in a fresh 2-mL tube and vortexed. Then, 0.2 mL chloroform was added, and samples were vortexed and then centrifuged at 18,300*g* for 5 min at 4°C. A total of 0.5 mL chloroform was added to 0.75 mL upper aqueous phase in a new 2-mL tube, vortexed, and centrifuged again. Approximately 0.6 mL of supernatant was precipitated by adding 1.2 mL of 100% ethanol and 90 μL of 2 M sodium acetate. The samples were then vortexed and incubated at –80°C for 1 h. Samples were centrifuged at 18,300*g* for 20 min at 4°C. The pellets were washed with 70% ethanol, air dried for about 10 min, and subsequently resuspended in RNAse-free water. RNA was quantified by spectrophotometry, and quality was verified by formaldehyde-agarose gel eletrophoresis.

First-strand synthesis, RT-PCR, and real-time PCR of SAD and FAD2. Total RNA (2 μg) from bolls collected at different developmental stages was first treated with RNase-free DNAse I (Invitrogen) and used as template in first-strand synthesis following the manufacturer's recommendations. Samples were subsequently treated with RNAse H (Invitrogen). For PCR reactions, cDNA samples were diluted 10-fold, and 1 μL was used as template. For real-time PCR reactions, first-strand cDNA samples were quantified by spectrophotometry and diluted to 200 ng/μL. Primers used in this study were designed based on FA biosynthetic gene sequences (CD760586 for linSAD and CD760583 for linFAD2, reported in Fofana *et al.* (14)) to amplify fragments of approximately 80–100 bp (Table 1). Preliminary RT-PCR reactions were performed to determine the optimized annealing temperature of each primer pair. Amplification reactions contained 1 μL of 10-fold-diluted first-strand cDNA reaction, 1X reaction buffer, 1.5 mM $MgCl_2$, 0.4 mM dNTPs, 0.4 μM of each primer, 5U Taq DNA polymerase, and were completed to 50 μL with sterile RNAse-free, DNase-free water. Samples were first denatured at 94°C for 2 min, and then followed 35 cycles consisting of 94°C for 30 s; 48°C (linSAD) or 55°C (linFAD2) for 30 s, depending on primer annealing temperature; and then 72°C for 60 s. Final extension was conducted at 72°C for 10 min. RT-PCR was performed using RNA from 0-DAA to 32-DAA developing bolls and mature bolls. Aliquots of 10 μL of the PCR products were separated on 1% (wt/vol) agarose gels stained with ethidium bromide.

Real-time PCR reactions were performed in triplicate using the ABI SYBR Green PCR Master Mix (Applied Biosystems, Foster City, California) and analyzed using an iCycler iQ real-time detection system (BioRad, Mississauga, Ontario, Canada),

TABLE 1
Primer Sequences Used for SAD and FAD2 Gene Expression Analyses by RT-PCR and Quantitative Real-Time PCR

Gene ID (GenBank) Accession number)	Forward Primer Sequence	Reverse Primer Sequence	Annealing temperature (°C) RT-PCR	Annealing temperature (°C) Real-Time PCR
linSAD (CD760586)	CGGTGACCTTCTCAACAA	AGAGCCGATGAGGTACTGA	48	48
linFAD2 (CD760583)	CATTCGTCCCTCCTTGTT	CTCATCACGATCAAGCGA	55	59

according to the manufacturer's instructions. Amplification reactions consisted of 1X SYBR Green Master Mix, 12.5 pmoles of each primer, 200 ng of first-strand synthesis cDNA obtained from developing bolls (0 to 28 DAA) as described earlier, and completed to 25 μL with sterile H_2O. Real-time PCR reactions were performed as follows: a denaturation step at 95°C for 10 min followed by 40 cycles consisting of 95°C for 30 s, 48°C (linSAD) or 59°C (linFAD2) for 30 s, and 72°C for 30 s. Following the final amplification cycle, a melting dissociation curve was generated to ensure specificity of the primers and to confirm that only a single product was present. The reactions were held for 10 s at the primer's respective annealing temperature and then ramped up by 0.5°C every 10 s for 85 steps. Three independent reactions, each with a different cDNA sample, were carried out. Means of triplicate reactions were expressed as relative gene expression at different time points compared with the expression detected at 0 DAA.

FA profiling. FAME were extracted from five bolls per replicate (three replicates in total) for each time point and for each location according to the procedure described by Fofana *et al.* (14). FA composition of developing bolls was performed using GC analysis. The weight percentage of FA was calculated according to the procedure outlined in AOAC method 996.06. ANOVA was performed using the SAS program (SAS Insttitute Inc., Cary, NC, release 8.2, 1996). The mean squares for the ANOVA were calculated by PROC GLM, and the estimates of the variance components were calculated using PROC MIXED. The mean percentages of FA content obtained from six measurements (three samples in duplicate) for each developmental stage, location, and year were presented with their standard error. FA profiles were interpreted in close relationship with weather data obtained from meteorological services for each growing season.

RESULTS

FA biosynthetic gene expression. Expression of two FA biosynthetic genes, namely SAD and FAD2, was estimated by RT-PCR and real-time PCR in flax ovaries and developing bolls from early stages to maturity. RT-PCR is considered a semiquantitative evaluation of transcript accumulation, whereas real-time PCR is a sensitive and robust tool for monitoring gene expression and providing quantitative evaluation of transcript copies (27). The accuracy of real-time PCR depends on the development of primers highly specific to the target gene. Tight single-peak melting point dissociation curves indicative of the uniqueness of the target sequence were observed for both SAD and FAD2 real-time PCR reactions. The linear relationship between threshold cycle (Ct) and cDNA templates was established. High correlation coefficient and high PCR efficiency were observed for each gene, permitting accurate quantification of transcript copy number.

Expression of linSAD and linFAD2 was measured as relative transcript abundance compared with the levels measured in ovaries (0 DAA) (28). LinSAD and linFAD2 transcripts were both highly accumulated at 0 DAA (Fig. 1A, 2A). LinSAD mRNA accumulation declined gradually between 0 and 4 DAA. A slight peak at 8 DAA was followed for the later seed developmental stages by levels of mRNA transcripts representing less than 5% of the level in ovaries (Fig. 1A). LinFAD2 transcripts were undetectable at 2 DAA. Its expression was relatively low at 4 and 8 DAA, and steadily increased to peak at 16 DAA (Fig. 2A), when the expression was nearly 1.6 times the level observed in ovaries. A slow decline was observed from 16 to 28 DAA, when expression levels were similar to that observed at 4 DAA.

RT-PCR was performed on the same RNA samples used for real-time PCR. Amplification of both genes under study using RT-PCR revealed single bands (Fig. 1B, 2B), confirming primer specificity as shown in real-time PCR. The semiquantitative RT-PCR amplification results, specifically amplicon relative intensity, closely matched the real-time PCR results for both SAD (Fig. 1A, 1B) and FAD2 (Fig. 2A, 2B) genes. RT-PCR was performed on 32-DAA and mature boll samples and showed low level of expression for SAD. No transcripts were amplified for FAD2 at these late developmental stages.

FA accumulation during seed development. Determination of FA profiles by GC analysis revealed a significant difference ($P < 0.0001$) in FA contents according to boll developmental stages. Palmitate (16:0), linoleate (18:2*cis*Δ9,12), and linolenate (18:3*cis*Δ9,12,15) were the most abundant FA at early stages, that is, 0–4 DAA (Fig. 3). The relative proportion of palmitate decreased during later seed development from 4 to 32 DAA. Meanwhile, unsaturated FA (oleate, linoleate, and linolenate) represented an increasingly large proportion of the total FA content. Omega-3 ALA (18:3*cis*Δ9,12,15) was the

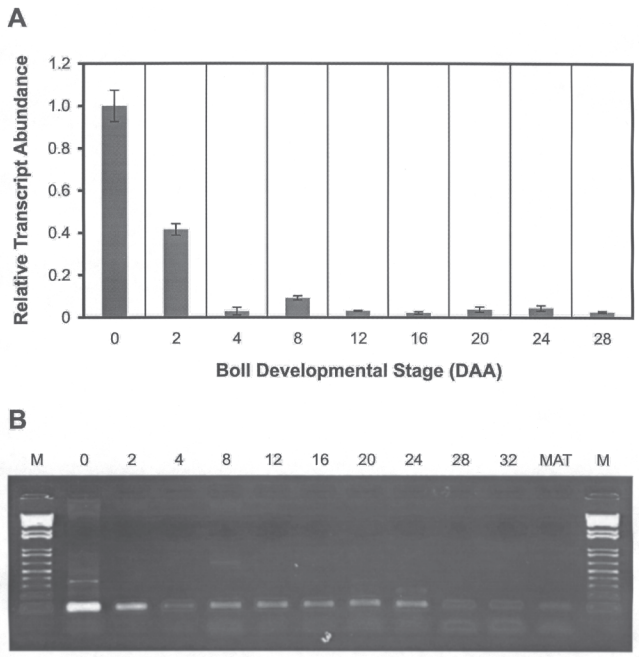

FIG. 1. Relative expression of linSAD at different developmental stages including ovaries (0 DAA) and stages of boll development ranging from 2 DAA to maturity (MAT). (A) Real-time PCR determination of the relative expression calibrated against the expression measured in ovaries (0 DAA) for developing bolls from 2 to 28 DAA. Time point expressions were obtained from triplicate independent reactions and standard errors of the ratios of the means are represented; (B) RT-PCR displayed a unique fragment whose intensity varied according to the developmental stages tested (ovaries to mature bolls) and that correlated with the quantitative real-time PCR measurements in (A). Marker (M) is 0.24–9.5 Kb RNA ladder (InVitrogen).

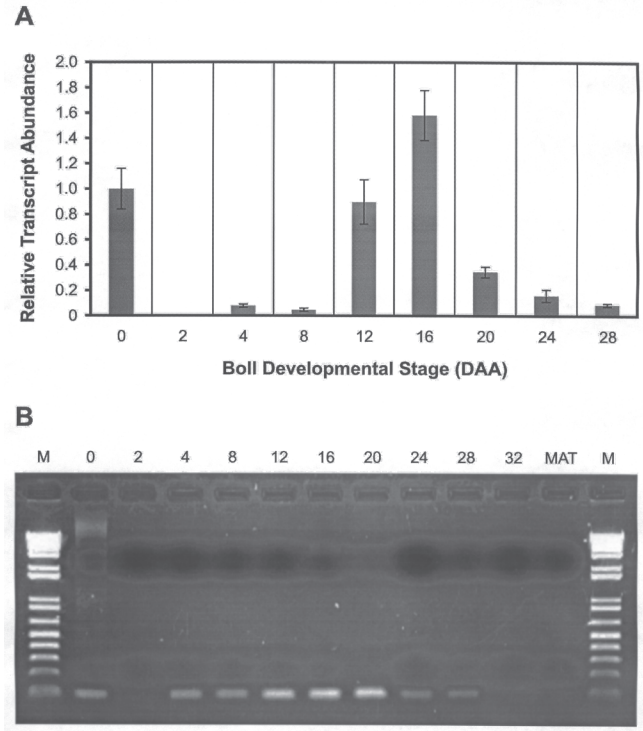

FIG. 2. Relative expression of linFAD2 at different developmental stages including ovaries (0 DAA) and stages of boll development ranging from 2 DAA to maturity (MAT). (A) Real-time PCR determination of the relative expression calibrated against the expression measured in ovaries (0 DAA) for developing bolls from 2 to 28 DAA. Time point expressions were obtained from triplicate independent reactions and standard errors of the ratios of the means are represented; Peak expression is observed at 16 DAA, when the level was nearly 1.6-fold the level observed in ovaries. (B) RT-PCR displayed a unique fragment whose intensity varied according to the developmental stages tested and that correlated with the quantitative real-time PCR measurements in (A). Marker (M) is 0.24–9.5 Kb RNA ladder (InVitrogen).

most abundant FA found from 8 to 32 DAA, exceeding 50% of the FA composition at maturity.

Environmental effect on FA accumulation. Environmental conditions are crucial during seed development. On the Canadian Prairies, flax plants bloom and the bolls mature in late July and August. Mid to late July 2002 was slightly warmer on average (22.1°C) than mid to late July 2003 (21.2°C), and the first half of August 2002 was definitely cooler (18°C) than August 2003 (23.1°C). The rainfall recorded from mid-July to mid-August was higher in 2002 (84 mm) than in 2003 (42 mm). The rainfall recorded in 2002 was similar in both locations (203 mm in Winnipeg and 205 mm in Morden). However, 2003 was drier than 2002, and Morden received only half of the rainfall recorded in Winnipeg (64 mm vs. 130 mm).

FA profiles for the same growing season were comparable at both locations (Figures 3A-C and B-D). A significant difference ($P < 0.0001$) was observed between years in each location for oleic (18:1*cis*Δ9) and linoleic (18:2*cis*Δ9,12) acids. In 2002, no difference could be observed between oleic (18:1*cis*Δ9) and linoleic acids (18:2*cis*Δ9,12) from 8 DAA to maturity within or between locations (Fig. 3A, C). In 2003 (warmer August), however, the level of 18:1*cis*Δ9 was higher than that of 18:2*cis*Δ9,12 at both locations (Fig. 3B, D). The proportion of linolenic acid (18:3*cis*Δ9,12,15) increased markedly between 8 and 20 DAA at Morden, and this trend continued up to 24 DAA at Winnipeg. The linolenic acid content accounted for the highest proportion of PUFA in both locations. Moreover, the overall 18:3*cis*Δ9,12,15 content was approximately 3–5% higher in 2002 (cool) as compared with 2003 (warm) in both locations from 12 DAA to maturity.

DISCUSSION

FA metabolism is an important biological function for living organisms, and plant oil metabolic engineering has become an attractive research target (9,29,30). In this study, we examined the expression of two FA biosynthetic genes in developing bolls of flax cv AC McDuff using semiquantitative RT-PCR and quantitative real-time PCR. FA profiles of this oilseed crop were also studied during two growing seasons, at two locations, and for a number of development stages ranging from 0 to maturity. Real-time PCR is a sensitive and robust tool for monitoring gene expression (27). Using this technique, our results

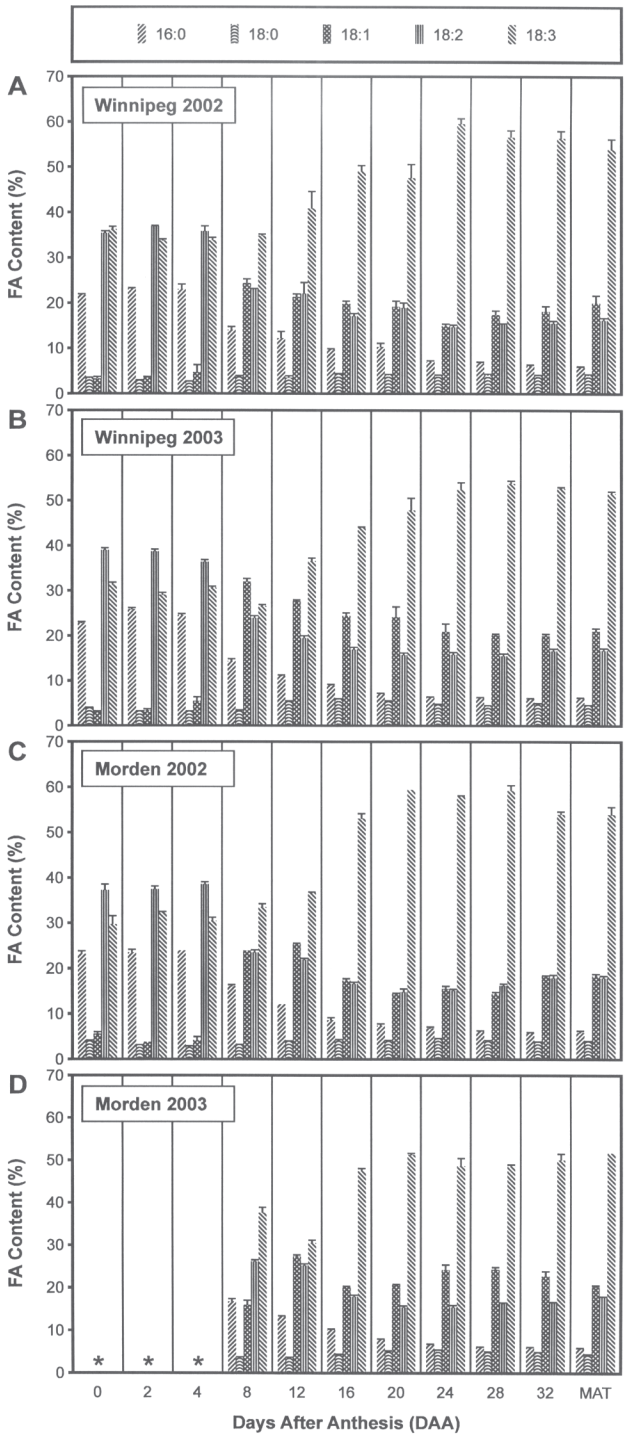

FIG. 3. FA profile obtained by GC analysis and expressed as the partitioning (%) in palmitic, stearic, oleic, linoleic, and linolenic acid measured in ovaries (0 DAA) and several stages of developing bolls ranging from 2 to 32 DAA and at maturity. The samples were obtained from two locations and during two growing seasons, namely (A) Winnipeg 2002, (B) Winnipeg 2003, (C) Morden 2002, and (D) Morden 2003. Vertical bars represent standard error of the mean obtained from six independant measurements using five bolls per replicate and run in duplicate. Missing data (*) and mature boll stage (MAT) are indicated on the *x*-axis.

showed that desaturases, also expressed early, appeared to be regulated and coordinated during boll development.

SAD expression decreased gradually from anthesis to 4 DAA, spiked at 8 DAA, and remained relatively constant in later stages of development. In flax, previous studies based on Southern hybridization have reported a single copy for SAD (13,14), although cross hybridization between closely related isoforms cannot be ruled out. Indeed, two SAD, SAD1 and SAD2, have been reported (31). However, because gene-specific primers were designed from the most seed-specific SAD gene (SAD1, AJ006957), and a single fragment was amplified, as confirmed by RT-PCR and melting curve, one might reasonably assume that the seed-specific SAD1 isoform was the one investigated in this study. The temporal regulation of this enzyme was also shown in *Brassica napus,* and the seed tissue specificity of the *Brassica* SAD was demonstrated in transgenic tobacco (32,33). To our knowledge, there are no previous reports on the expression profiling of SAD in developing flax bolls. SAD1 and SAD2 gene expressions were not studied at very early stages by Jain *et al.* (31). SAD expression does not seem to be limited to the developing seeds. Expression in ovaries (14) and in tapetum and pollen grains (33) was reported in flax and rapeseed, respectively.

The FAD2 gene encodes the enzyme that catalyzes the desaturation of oleate to linoleate (34). Two closely related FAD2 copies, as determined by Southern and cDNA sequence analyses, were found in flax cv AC Mcduff (14). FAD2 orthologs have also been cloned and characterized in a number of plant species such as rapeseed, soybean, cotton, flax, olive, maize, peanut, *Arabidopsis*, and *Lesquerella* (14,34–40), Of particular interest, two seed-specific microsomal FAD2 isoforms have been cloned (37,39,40), only one (FAD2-1) was strongly expressed in seed, whereas FAD2-2 was constitutively expressed (40). The FAD2 expression data reported in this study is consistent with that of the seed-specific FAD2-1 previously reported (40) and suggest that FAD2-1 was the isoform investigated in this study, although submembers (FAD2-1A and FAD2-1B) for this gene have been recently reported (40). However, our data could not assign which of the FAD2-1 submembers (FAD2-1A or FAD2-1B) was measured in this study. Nevertheless, this does not affect the conclusion drawn from the FAD2 expression profile reported herein. In soybean, post-transcription modification such as phosphorylation was proposed as an important mechanism for FAD2-1 activity in seed (40). This result was not contrasted with potential regulation at the transcription level. In flax, the present study demonstrated the transcriptional control of FAD2 expression during seed development. FAD2 transcript expression differed significantly from the SAD expression pattern. FAD2 expression increased sharply up to 16 DAA to a level surpassing that at anthesis and slowly decreased as the bolls matured, corroborating findings in *Arabidopsis* by Ruuska *et al.* (41), in which a bell-shaped pattern was also observed. These results, based on the whole seed-specific FAD2 gene expression, were supported by phenotypic data showing a high desaturation ratio of stearate (18:0)

across all development stages, and thereafter of oleate (18:1*cis*Δ9) and linoleate (18:2*cis*Δ9,12). Although bolls from 0 to 32 DAA were used as starting materials, our expression data from 4 DAA to maturity was well correlated with FAD2 tissue specificity as previously reported (41). Phenotypic data indicated high desaturation activities from 8 to 24 DAA followed by a plateau in accumulation of oleic, linoleic, and linolenic acids (Fig. 3) correlating with the expression of FAD2 (Fig. 2A), whose transcript level was undetectable at 32 DAA and at maturity (Fig. 2B). Sorensen *et al.* (42) observed the same trends up to 20 DAA in cultivars AC Emerson and Vimy. However, the level of ALA did not surpass 50% in these two cultivars at any stage of development, whereas AC McDuff consistently reaches levels of ALA between 50% and 60% regardless of the environmental conditions.

The genetic stability of genotypes is a key determinant of crop performance in the field. The phenotypic characterization of flax cv AC McDuff's developing bolls' FA content was assessed at two locations over two years. Environmental variations between years altered the FA profiles. From 8 DAA to maturity, the level of 18:1*cis*Δ9 was higher than that of 18:2*cis*Δ9,12 in 2003, compared with 2002, in which no difference could be observed between these two FA. The overall 18:3*cis*Δ9,12,15 content was slightly lower in 2003 compared with 2002, suggesting low desaturation efficiency of 18:2*cis*Δ9,12 into 18:3*cis*Δ9,12,15 in 2003. Delta-12 FA desaturase FAD2, which is known to be responsible for the desaturation of 18:1*cis*Δ9 into 18:2*cis*Δ9,12 (42), was shown to be transcriptionally regulated. Real-time PCR data revealed increased FAD2 overall transcript accumulation from 8 to 16 DAA, but 18:2*cis*Δ9,12 levels did not increase. However, 18:3*cis*Δ9,12,15 levels increased steadily, indicating that 18:2*cis*Δ9,12 is transient under normal weather conditions (2002), and FAD3, encoded also by two genes (15), converts 18:2*cis*Δ9,12 into 18:3*cis*Δ9,12,15 as quickly as FAD2 converts 18:1*cis*Δ9 into 18:2*cis*Δ9,12. This observation was further confirmed by FA profiles obtained under the warmer and dryer weather conditions of 2003. It seems that the high temperatures recorded in summer 2003 might have affected FAD2 activity. Consequently, a reduced oleic desaturation ratio (ODR) may have led to low substrate (18:2*cis*Δ9,12) availability for Δ-15 FA desaturase 3 (FAD3) enzymes involved in the desaturation of 18:2*cis*Δ9,12 to 18:3*cis*Δ9,12,15 (15). Green (25) reported that high temperatures considerably decreased the ODR and the relative proportions of linoleic and linolenic acids in controlled environments. Further studies will be needed to elucidate the role of temperature and environmental conditions on transcription, translation and post-translation control of FAD enzyme activity.

This study is the first, under field conditions, to examine flax FA profiles at different developmental stages and their correlation, within a single environment, with FA desaturase expression. The study suggested that FAD2, because of its key role in converting 18:1*cis*Δ9 into 18:2*cis*Δ9,12, is the most sensitive of the FA biosynthetic genes examined to environmental variations in the alteration of FA profiles under the field conditions investigated. SAD and FAD2 enzymes are also actively transcribed and translated at anthesis, suggesting that the desaturases may be involved in flower development, possibly by providing precursors of plant hormones such as jasmonic acid and oxylipins involved in the regulation of anthesis (44-46), or epicuticular wax biosynthesis which is required for inflorescence development and pollen fertility (47-50). Manipulation of these genes to produce designer flax with optimized FA content should take into consideration the roles played by these enzymes in other tissues (such as ovaries) as they may affect other essential biosynthetic pathways. Overall, this study provided evidence that SAD and FAD2 enzymes are highly expressed in ovaries and that 12–16 DAA constitutes a critical expression time for FA desaturase FAD2 in flax. This gene expression pattern was supported by phenotypic FA profiles that showed, independent of growing season, an increased accumulation of 18:3*cis*Δ9,12,15 by 12 DAA as a result of high activity of FA desaturases.

ACKNOWLEDGMENTS

This research was supported by a bioeconomic grant under the NorthStar Initiative. B. Fofana received a Visiting Fellowship from the Natural Sciences and Engineering Research Council (NSERC). This publication is Agriculture and Agri-Food Canada Contribution No. 1900. Statistical support was provided by Dr Sheila Woods (CRC, Winnipeg). Docosahexaenoic Acid Levels in the Lipids of Spotted Mackerel *Scomber australasicus*

Kazufumi Osako*, Hiroaki Saito, Mohammed Anwar Hossain, Koichi Kuwahara, and Akira Okamoto

Food Science and Technology Section, Nagasaki Prefectural Institute of Fisheries, Nagasaki-shi 851-2213, Japan

ABSTRACT: The lipid and FA compositions of various organs and of the stomach contents of *Scomber australasicus* were analyzed. DHA was characteristically the major FA of all the major lipid classes of all organs except for liver TAG. The mean DHA contents of the various organs accounted for more than 17% of the total FA (TFA), whereas those in the stomach contents, originating from the prey, fluctuated and were generally low. In particular, the DHA levels in the TAG from all organs of *S. australasicus* accounted for up to 17% of TFA, even though it is a neutral depot lipid. *S. australasicus* contained markedly high levels of DHA, even though it is a small-sized Scombridae species, and its high levels of DHA were close to those in large-sized highly migratory tuna species. Furthermore, DHA levels in its muscle TAG were consistently high, compared with those in the visceral TAG, which might be directly influenced by the prey lipids. These phenomena suggest that long-distance migration has a close relationship with high accumulation of DHA in fish tissues, since *S. australasicus* is reported to migrate in offshore water, similar to highly migratory tuna species. Additionally, the physiological selective accumulation of DHA in the muscle during migration is caused by *in vivo* metabolism of FA in the vascular system, suggesting that DHA is poorly used as a source of migration energy, though it is provided abundantly through the prey lipids.

Paper no. L9911 in *Lipids 41*, 713–720 (July 2006).

Occurrences of markedly high DHA contents in tissue lipids (more than 20% of crude total lipids [TL]) of large-sized tuna species belonging to the Scombridae family, such as *Thunnus thynnus* (1), *T. alalunga* (2,3), *T. albacares* (4), *Euthynnus pelamis* (1,5,6), *E. affinis* (7), *Auxis rochei*, and *A. thazard* (1,8), have been reported. Such fish actively and widely migrate in the offshore zones and exhibit different movement behavior from demersal, pelagic, coastal migratory, or reef fish. It has been hypothesized that these high levels are the result of accumulation of DHA during long-distance migration (7) because DHA is the most important essential FA in marine fishes (9,10) and is less effective than other FA as an energy source (11–13). On the other hand, DHA levels in the tissue lipids of nonmigratory fish, such as *Solea solea* (14), *Pagrus major* (15), *Lateolabrax japonicus* (15), *Seriola dumerili* (15), *Paralichthys olivaceus* (15), and *Caranx delicatissimus* (15), were reported to be relatively low (less than 20% of TL).

It is well known that DHA levels in the tissue phospholipids of all fish species are generally high, in comparison with the relatively low levels of n-3 PUFA in the neutral depot lipid TAG. In many cases, the FA composition of neutral lipids varies with environmental conditions, such as the stage of fish maturation, seawater temperature, and the lipid content of food sources (16,17). Moreover, in marine fishes, the DHA content in neutral lipids is generally less than 20% of the total FA (TFA), whereas saturated FA (SFA) and monounsaturated FA (MUFA), such as 16:0, 18:0, and 18:1n-9, have been found as major components.

On the other hand, tuna species characteristically contain high levels of DHA in the neutral lipids of orbital fats and head oils (see, for *T. obesus* and *E. pelamis*, (18); for *Thunnus* spp. and *E. pelamis*, (19)). There are no reports of high DHA content in neutral lipids except for the lipids of these tuna species, except for the report on muscle neutral lipids by Saito *et al.* (20). Recently, Saito *et al.* reported on the lipid of *Thunnus tonggol,* demonstrating that neutral lipids in muscle contained high levels of DHA compared with other organs (20). They suggested that comparatively high levels of DHA in muscle neutral lipids of the fish were caused by bioaccumulation of DHA during migration. Moreover, they also suggested that highly migratory fishes contain high levels of DHA in their muscle neutral lipids. In the case of tuna species, there are some reports on high levels of DHA in muscle TL compared with those in visceral TL, but there is no information on which lipid class of muscle TL contains most of the DHA, except for the report by Saito *et al*. We presumed that high levels of muscle DHA compared with visceral DHA may be due to high levels of DHA in muscle neutral lipids, as suggested by Saito *et al*. (20). It has been assumed that one of the reasons for the bioaccumulation of DHA observed in tuna species is that n-3 PUFA, including DHA, is poorly metabolized as an energy source compared with SFA or MUFA (21), and that DHA is left unused in the organs during the active metabolism associated with migration.

From those previous findings, it seems likely that highly migratory fishes, even if they are not tuna species, contain high levels of DHA in their muscle neutral lipids.

Scomber australasicus, belonging to family Scombridae, is one of the most common fishes in Japan (together with *Scomber japonicus*), and has huge biomass in temperate to subtropical waters of the East China Sea. Although the body shape of the fish is similar to that of *S. japonicus*, the ecology of the two fish species differs. *S. australasicus* migrates widely throughout the tropical and temperate waters of the East China Sea (22–24), whereas the migration of *S. japonicus* is limited to coastal waters (22,24–26).

High DHA levels in the muscles of *S. australasicus* might be expected if the high level of DHA was caused by the active migration, even though the mean size of this species is not as large (24).

To determine the DHA levels in the various lipid classes of this species, and to estimate the relationship between its lipid physiology and ecology, the lipid classes and FA composition of its muscles, other internal organs, and stomach contents were analyzed in the present study.

MATERIALS AND METHODS

Materials. Sampling locations and body dimensions of *Scomber australasicus* examined in the present study are listed in Table 1. The specimens were caught in the east China Sea (34°09′N, 127°39′E and 34°55′N, 132°10′E) by using set-net in October 2002 (sample no. 1) and in December 2004 (sample no. 2). Both the samples were brought to our laboratory under ice-storage condition on the following day of catch. The biological data of the sample 1 specimens (fork length: 277 ± 7 mm, body weight: 272 ± 27 g, $n = 5$) and sample 2 specimens (fork length: 335 ± 9 mm, body weight: 567 ± 54 g, $n = 6$) were measured. The fish were immediately frozen and kept at −80°C for 2 wk to 1 mon prior to lipid extraction.

Lipid extraction and the analysis of lipid classes. Frozen fish were partially thawed, and their dorsal ordinary muscles (white muscle), liver, and other viscera (without stomach contents and gill) were cut out using a scalpel after wiping. The stomach contents were then removed and used as samples. Each sample was homogenized in a mixture of chloroform and methanol (2:1, vol/vol), and a portion of each homogenized sample was extracted according to the Folch *et al.* procedure (27). The crude TL (50–100 mg) were separated into classes on silicic acid columns (Kieselgel 60, 70–230 mesh, Merck and Co. Ltd., Darmstadt, Germany), and a quantitative analysis of the lipid constituents was performed using gravimetric analysis of fractions collected from column chromatography. The first eluate (dichloromethane/*n*-hexane, 2:3, vol/vol) was collected as the steryl ester (SE), which contained a small amount of wax ester (WE). This was followed with: dichloromethane eluting the TAG; dichloromethane/ether (35:1, vol/vol) eluting the sterols (ST); dichloromethane/ether (9:1, vol/vol) eluting the DG; dichloromethane/methanol (9:1, vol/vol) eluting the FFA; dichloromethane/methanol (1:1, vol/vol), eluting the PE; dichloromethane/methanol (1:5, vol/vol), eluting the other minor phospholipids; and dichloromethane/methanol (1:20, vol/vol) to elute the PC (28). Individual lipids from each lipid class were identified with authentic samples by comparison of *Rf* values using TLC (Merck & Co. Ltd., Kieselgel 60, thickness of 0.25 mm for analysis) (29). All sample lipids were dried under nitrogen at room temperature and stored at −80°C.

Preparation of methyl esters and GLC of the esters. The TAG, PE, and PC fractions were directly trans-esterified with boiling methanol containing 1% of concentrated hydrochloric acid under reflux for 1.5 h as previously reported to produce the FAME (30). These methyl esters were purified using silica gel column chromatography by elution with dichloromethane.

Analyses of FAME were performed on a gas chromatograph (GC–17A, Shimadzu Seisakusho Co., LTD, Kyoto, Japan) equipped with a capillary column (Omegawax–250, 30m × 0.25 mm i.d., 0.25 μm film thickness; split ratio, 20:1; Supelco Japan Co., Ltd, Tokyo, Japan). The temperatures of the injector, column, and detector were maintained at 250°C, 205°C, and 250°C, respectively. Helium was used as carrier gas at a constant inlet rate of 0.8 mL/min. Linear velocity of the carrier gas was 26.2 cm/s.

Quantitation of individual components was performed by means of Shimadzu Model C-R7A (Shimadzu Seisakusho Co. Ltd., Kyoto, Japan) electronic integrators. The weight percentages of individual components in the lipids were expressed as relative percentage of peak area to total peak area.

Analysis of FAME by GC–MS. Analysis of the FAME was performed on GC–MS QP 2010 (Shimadzu Seisakusho Co., LTD, Kyoto, Japan) GC–MS equipped with the same capillary. The temperatures of the injector and the column were held at 240°C and 210°C, respectively. The split ratio was 1:76, and the ionization voltage was 70 eV. Helium was used as the carrier gas at a constant inlet rate of 0.7 mL/min.

FAME were identified using, (i) marine lipid methyl esters as standards (Supelco 37 Component FAME Mix, Supelco Japan Ltd., Tokyo, Japan) and (ii) by comparison of mass spectral data obtained by GC–MS.

Statistical analyses. Significant differences in the data of the total SFA, total MUFA, total n-6 PUFA, and total n-3 PUFA of the classes (TAG, PE, and PC) of samples 1 and 2 were determined using one-way ANOVA at a significance level of $P < 0.05$.

RESULTS AND DISCUSSION

Lipid content with biological data. The biological data of the specimens examined and their TL contents are given in Tables 1 and 2. The body sizes of each specimen from sample 1 were smaller than those of sample 2. In each organ, the TL contents of sample 1 (muscle, 1.3%; pyloric cecum, 8.2%; other viscera, 8.1%) were significantly lower than those of sample 2 (muscle, 5.3%; pyloric cecum, 13.8%; other viscera, 28.3%), except for that in liver lipids (sample 1, 9.4 ± 1.5%; sample 2, 11.8 ± 3.1%).

In both samples, the TL contents of muscle (1.3–5.3%) were much lower than those of other tissues (liver, 9.4–11.8%;

TABLE 1
Locality of Capture and Biological Data of *S. australasicus* Examined[a]

Scientific name	Sampling no.	Date	Locality	Replicate animals (*n*)	Fork length (mm)	Body weight (g)
Scomber australasicus	1	October 7, 2002	34°09'N 127°39'E	5	276.6 ± 7.7	271.9 ± 26.7
	2	December 13, 2004	34°55'N 132°10'E	6	334.5 ± 9.3	567.4 ± 53.8

[a]Results are expressed as mean ± SD (n = 5 or 6).

pyloric cecum, 8.2–13.8%; other viscera, 8.1–28.3%). In comparison with other migratory fishes belonging to family Scombridae, the content of muscle TL of *S. australasicus* was higher than those of tuna species reported in the literature: *Thunnus obesus,* 0.8 ± 0.3% (1); *T. albacares,* 0.6 ± 0.0% (1) and 0.5 ± 0.3% (4); and *T. thynnus,* 1.0 ± 0.5% (1) and 1.4 ± 0.6% (31). However, the content of *S. australasicus* muscle TL was lower than those of *S. japonicus* (32) caught during autumn to winter (2.8–18.9%). These findings may suggest that *S. australasicus* and *S. japonicus* can use their muscles for lipid storage, as other small-sized pelagic fishes do (33,34).

Lipid classes of the respective organs of S. australasicus. In all the organs, the lipids mainly contained TAG, sterols (ST), and FFA in the neutral depot lipids, and PE and PC in the polar tissue lipids, with small levels of SE, WE, and DAG (Table 2).

The total lipids of all the specimens consistently contained high levels of the glycerol derivatives, such as TAG, PE, and PC. The total amounts of the three major classes (TAG, PE, and PC) were more than 50% (71.9–93.5% for the muscles, 55.4–92.0% for the viscera) of TL in all of the organs. These high levels of glycerol derivatives might be a typical characteristic of marine fish species, similar to those in other fish species. The TAG levels of each organ from sample 1 (36.5–55.2%) were statistically lower than those contained in each organ of sample 2 (69.0–90.4%). This suggests that the TL contents in the tissues vary due to TAG composition, whereas polar lipid contents, such as PE or PC, do not vary.

Moderate levels of FFA (2.6–24.5%) were found in the internal organs; in particular, the digestive organs (pyloric cecum and liver). This may be a result of the degradation of glycerol derivatives, such as TAG and phospholipids, by enzymatic metabolism; the high FFA levels were mainly found in digestive viscera that may have active enzymes for digestion. Similar tendencies were reported for *T. tonggol* internal organs by Saito *et al*. (20). Sterols were found at moderate levels (2.4–8.8%) in all samples.

FA composition in TL and TAG. The FA compositions of the three major components (TAG, PE, and PC) with TL in each class, separated from the various organs of *S. australasicus*, are shown in Tables 3–6. At least 50 FA components were detected and identified, of which around 40 compounds occurred at a level of 0.1% or more of TFA. In the FA of TL, only five components were found as major FA of all the organs: two SFA, 16:0 (20.3–24.4%) and 18:0 (5.3–11.1%); one MUFA, 18:1 n-9 (10.2–29.4%); and two n-3 PUFA, 20:5 n-3 (EPA, 3.2–8.2%) and DHA (9.1–27.5%), as shown in Table 3. These main FA were detected at levels of about 5% or more in almost all of the organs. Noticeable amounts (>mean 2%) of several other FA for both of two replicate samples 1 and 2, 14:0 (0.9–4.7%), 16:1n-7 (1.8–5.2%), 18:1n-7 (2.1–4.7%), and 20:1n-9 (1.0–3.7%), were found. There was only one exception; the DHA levels in the liver of the sample 2 were extremely low (9.1 ± 2.5%). In the stomach contents, FA compositions fluctuated between the samples, and the DHA levels of sample 1

[a]Results are expressed as weight percent of total FA. Data are mean ± SD for several samples (n = 5–6)

were lower than those of the organs, whereas the levels of sample 2 were almost the same as those of the organs.

The remarkably high DHA levels (18.6–27.5%) observed in muscle TL of *S. australasicus* were comparable to those of highly migratory tuna species, such as *Thunnus thynnus* (32.1%) (1), *T. alalunga* (24.3–25.9%) (2,3), *T. albacares* (27.3–36.0%) (4), *E. pelamis* (33.3%) (1,5,6), *E. affinis* (21.3%) (7), *Auxis rochei* (19.8%), and *A. thazard* (29.1%) (1,8). Moreover, the DHA levels were much higher than those of *S. japonicus* (10.5–18.1%) (32) or *Scomberomorus commerson* (8.4–8.6%) (35), although their body shape is very similar to that of *S. australasicus* (22–26).

It is known that marine fishes are unable to synthesize DHA (36–43). The characteristically high levels of DHA observed in highly migratory tuna species have been explained by their highest trophic position in the marine grazing food chain, as well as their high migration with active consumption of MUFA and SFA and accumulation of n-3 PUFA.

In the FA of TAG, only five components were found as major FA of all the organs, similar to those observed in the FA of TL: two SFA, 16:0 (17.9–25.2%) and 18:0 (4.7–8.0%); one MUFA, 18:1n-9 (11.4–33.5%); and two n-3 PUFA, EPA (2.4–8.2%) and DHA (5.4–17.4%), as shown in Table 4. Noticeable amounts of several other FA were found in both of two replicate samples 1 and 2: 14:0 (1.1–5.0%), 16:1n-7 (2.1–5.1%), 18:1n-7 (2.2–5.4%), and 20:1n-9 (1.1–4.1%). There was only one exception; the DHA levels in the liver of sample 2 were extremely low (5.4 ± 2.0%), whereas the MUFA levels of the sample were higher than those in the other organs' TAG.

The DHA levels in the TAG of the muscles were significantly high (17.0–17.4%) compared with the liver TAG (5.4–12.9%), and did not fluctuate between samples, whereas those in liver TAG fluctuated between samples. Although there were no significant differences in DHA levels among muscle, pyloric cecum, and other viscera, mean DHA levels in muscle TAG were highest, and the levels in pyloric cecum and other viscera fluctuated between the samples. The consistently high DHA levels of muscle TAG may be characteristic of highly migratory fishes belonging to Scombridae, and it may suggest that in these species DHA was selectively accumulated through the internal organs. The MUFA levels in the liver from both samples were higher than those of prey lipids, as well as liver of fatty sample 2 contained higher levels of MUFA than those contained in the liver of lean sample 1. Such phenomena observed in the liver TAG may suggest that the liver plays a role

[a]Results are expressed as weight percent of total FA. Data are mean ± SD for several samples (n = 5–6).

as an energy storage site, and that MUFA, which is easily oxidized as an energy source, rather than DHA, which is hardly oxidized, is accumulated. The fluctuation of the DHA levels in TAG from pyloric cecum and other viscera between the samples may be influenced by variations in the FA composition of their prey lipids.

FA composition in tissue phospholipids. Similar to the FA composition of its tissue TAG, high levels of n-3 PUFA (20.3–49.0% for PE and 26.4–44.1% for PC) were found in the tissue phospholipids of both samples 1 and 2 (Tables 5 and 6). Four major FA were also found in the PE of all specimens at levels of about 5% or more of the TFA: two SFA, 16:0 (7.1–17.5%) and 18:0 (12.0–16.7%); one MUFA, 18:1n-9 (4.6–8.9%); and one n-3 PUFA, DHA (15.7–43.0%). Similar FA were also the major components in the PC: two SFA, 16:0 (25.2–34.6%) and 18:0 (2.1–6.1%); one MUFA, 18:1n-9 (5.1–10.4%); and two n-3 PUFA, EPA (6.9–12.4%) and DHA (17.4–34.9%). Noticeable amounts (>2%) of other FA were also found in these phospholipids: the MUFA 18:1n-7 (2.1–3.4% for PE and 1.0–2.7% for PC); the n-6 PUFA 20:4n-6 (4.8–8.8% for PE and 4.0–7.1% for PC); and the n-3 PUFA EPA (2.4–5.6% for PE). Although the major components of PE were similar to those of PC, slightly high n-3 PUFA levels in PC were found in all organs compared with those of PE. In particular, EPA was considered to be a major component of PC only.

It is well known that high levels of n-3 PUFA are generally found in the tissue PL of all marine fish species (1,44,45) because polar tissue PL work as cell membrane lipids and are generally rich in n-3 PUFA for membrane fluidity. Almost all DHA levels in the PL (PE and PC) in the *S. australasicus* lipids exceeded 20% of TFA, similar to other fish species including tuna species (1,44,45).

The major components in the PE were similar to those in the PC, and n-3 PUFA levels in PC were higher than those in PE; this is general tendency of all marine fish species. EPA was a major component of the PC, along with high levels of DHA.

Characteristically high levels of DHA in S. australasicus *muscle lipids.* Generally, it has been believed that only large-sized tuna species contain high levels of DHA in their tissues, whereas those in scomber species are comparatively low. Actually, *S. japonicus* and *S. commerson* contained comparatively low levels of DHA in their muscle TL, though body size, feeding habitat, and position in the marine grazing food chain of these fishes would be very similar to those of *S. australasicus*. One of the large differences in ecology is their migration; both *S. japonicus* and *S. commerson* migrate in coastal water, whereas *S. australasicus* migrates in offshore current, as tuna species do (22–26,35).

The occurrence of high levels of DHA in the organs of highly migratory tuna species is believed to be due to DHA

accumulation during long-distance migration (7,20), because MUFA and SFA are easily metabolized as energy sources prior to PUFA such as DHA (21). It is probably due to the requirement of higher energy usage of the fish during active migration in offshore current than coastal one need. Such offshore migration associated with FA metabolism might cause selective consumption of MUFA and SFA prior to PUFA, and that result in high levels of DHA in active migratory *S. australasicus* or in tuna species.

These previous findings (7,20,21) and our study may suggest that DHA is accumulated in neutral lipids of active fishes, as well as in neutral lipids of metabolically active organs. Actually, in the case of *Trachurus japonicus*, PUFAs were decreased prior to SFA and MUFA in the muscle TAG when the fish was non-active (30).

Based on the findings of the present study, it was inferred that high levels of DHA particularly in muscle TAG of *S. australasicus* may be caused by their offshore migration, similar to the situation in large-sized tuna species.

ACKNOWLEDGMENT

We thank Mr. Tetsuro Kawajiri and Mr. Koji Goto for their skilled analyzing technique and assistance in our study.

Lipid Class and Fatty Acid Composition of the Boreal Soft Coral *Gersemia rubiformis*

Andrey B. Imbs[a,*], Olga A. Demina[b], and Darja A. Demidkova[b]

[a]Institute of Marine Biology, Far Eastern Branch of the Russian Academy of Sciences, 690041 Vladivostok, Russian Federation, and [b]Far Eastern National University, 690950 Vladivostok, Russian Federation

ABSTRACT: Total lipid, phospholipid, and FA composition and distribution of FA between polar lipids (PL) and neutral lipids (NL) were investigated in the boreal soft coral *Gersemia rubiformis* from the Bering Sea. The total lipids were mostly hydrocarbons and waxes (33.7%) and PL (33.1%). The content of monoalkyldiacylglycerols (9.7%) exceeded the content of TAG (6.7%). PC and PE constituted 31.4% and 25.6% of total phospholipids, respectively. Principal FA were 16:0, 16:1n-7, 18:0, 18:1n-9, 18:1n-7, 20:1n-7, 20:4n-6, 20:4n-3, 20:5n-3, 22:5n-3, 22:6n-3, 24:5n-6, and 24:6n-3. Most n-6 PUFA (52% of total FA) were associated with the PL fraction; this was especially true for arachidonic and tetracosapentaenoic acids. The NL were enriched with mono-, di-, trienoic, and n-3 PUFA. The variation in EPA levels in both NL and PL suggests an origin of this acid from lipids of diatoms consumed by the corals.

Paper no. L9932 in *Lipids 41*, 721–725 (July 2006).

A number of recently published articles testify to an increased interest of biochemists in lipids and FA of corals. Total lipid concentrations of 10–40% of dry biomass have been reported for a number of corals from tropical seas (1–3). Except for structural functions in cell membranes, the main role of coral lipids is to serve as a long-term energy reserve (4). In particular, it has been shown that some species of reef-building corals contain enough lipids to support their normal caloric demand for up to 114 d when no photosynthetically fixed carbon is transported from symbiotic algae to the coral host under conditions of insufficient sunlight (5). Global coral bleaching events in tropical oceans that resulted in a large-scale coral mortality and degradation of coral reef communities are accompanied by significant variations in total lipid content and proportions of the main lipid classes in coral colonies (6). Also, corals experience a natural variation in lipid concentrations during an annual cycle (7). Corals are rich in PUFA that are converted to biologically highly active oxylipins (including prostaglandins, oxypolyunsaturated acids, and clavulones) in the tissues of several coral species (8). Many coral families are characterized by the presence of unusual FA, for example, tetracosapolyenoic acids, and it has been suggested that the FA composition may be useful for the biochemical classification of these coelenterates (9).

The overwhelming majority of investigations of lipid and FA compositions have been carried out for reef-building stony coral species from the warm Caribbean, Red Sea, Sea of Japan, and Hawaii (3,6,7,10,11). Noticeably fewer articles have been dedicated to the lipid composition of algal symbionts of hermatypic corals (12) and tropical soft corals (13–15). Only a few works on lipids of soft corals from cold-water seas have been published. Oxylipins derived from arachidonic acid have been studied in the soft coral *Gersemia fruticosa* from the White Sea (16), and the FA compositions of some Octacorallia species from the Sea of Okhotsk have been investigated (17). Earlier, we made an attempt to determine the oxylipin composition and seasonal variations in the main FA for the soft coral *Gersemia rubiformis* (18). This paper examines total lipid, lipid class, phospholipid, and FA compositions, as well as the distribution of FA between polar lipids (PL) and neutral lipids (NL) in the soft coral *G. rubiformis* from the Bering Sea.

EXPERIMENTAL PROCEDURES

Colonies of the soft coral *G. rubiformis* (class Octocorallia, order Alcyonaria, family Alcyoniidae) were collected by SCUBA divers in the Avachinskaya Guba Inlet (52°46’38’’N, 158°36’55’’E, Starichkov Island, the Bering Sea) in August 2004 at 12 m depth. The colonies were washed in seawater and carefully cleaned of all noncoral debris. For a lipid analysis, at least three different colonies were used.

Extraction of total lipids was conducted according to Bligh and Dyer (19). The total lipid content was determined by gravimetry after lipid extract evaporation under reduced pressure. Lipid classes were separated by one-dimensional silica gel TLC. The precoated Merck (Darmstadt, Germany) Kieselgel 60 G plates (10 cm × 10 cm) were first developed to their full length with $C_6H_6/Et_2O/CH_3COOH$ (70:30:1, by vol), and finally to 25%-length with $CHCl_3/CH_3OH/C_6H_6/28\%$ NH_4OH (65:30:10:6, by vol). After drying in a stream of air, plates were sprayed with 10% H_2SO_4/MeOH and heated at 180°C for 10 min. The chromatograms were scanned by an image scanner Epson Perfection 2400 PHOTO (Nagano, Japan) in a grayscale mode. The software used for scanning was Adobe Photoshop (Adobe Systems, San Jose, CA). Percentages of lipid contents were determined based on band intensity with the use of the

Abbreviations: CAEP, ceramide aminoethylphosphonate; MADAG, monoalkyldiacylglycerol; NL, neutral lipids; PL, polar lipids.

image analysis program Sorbfil TLC Videodensitometer DV (Krasnodar, Russia). The units were calibrated using known standards for each lipid class.

The total lipids were separated into NL and PL fractions by column chromatography on silica gel according to Rouser *et al*. (20). Polar lipids were separated by two-dimensional silica gel TLC with $CHCl_3/CH_3OH/C_6H_6/28\%$ NH_4OH (65:30:10:6, by vol) in the first direction and $CHCl_3/CH_3OH/CH_3COOH/CH_3COCH_3/C_6H_6/H_2O$ (70:30:4:5:10:1, by vol) in the second direction. To identify lipids on TLC plates the same specific spray reagents used earlier were employed (21). The phospholipid content was determined spectrophotometrically after digestion with perchloric acid (22). FAME were obtained by a sequential treatment of the lipids with 1% MeONa/MeOH and 5% HCl/MeOH according to Carreau and Dubacq (23) and purified by preparative TLC development in benzene. *N*-Acylpyrrolidide derivatives of FA were prepared by direct treatment of the FAME with pyrrolidine/acetic acid (10:1, by vol) in a capped vial (24 h, 25°C) followed by ethereal extraction from the acidified solution and purification by preparative TLC developed in ethyl acetate.

GC analysis of FAME was carried out on a Shimadzu GC-17A chromatograph (Kyoto, Japan) with a flame ionization detector on a SUPELCOWAX 10 (Supelco, Bellefonte, PA) capillary column (25 m × 0.25 mm i.d.) at 210°C. Helium was used as the carrier gas. FAME were identified by a comparison with authentic standards and using a table of ECL (24). The structures of FA were confirmed by GC–MS of their methyl esters and *N*-acylpyrrolidide derivatives. GC–MS of FAME was performed with a Shimadzu GCMS-QP5050A instrument (Kyoto, Japan). A Supelco MDN-5S (Bellefonte, PA) capillary column (30 m × 0.25 mm i.d.) was used at 160°C with a 2°C/min ramp to 240°C, which was held for 20 min. Injector and detector temperatures were 250°C. GC–MS of *N*-acylpyrrolidides was performed on the same instrument; injector and detector temperatures were 300°C, and column temperature was 210°C with a 3°C/min ramp to 270°C, which was held for 40 min.

The data were assessed statistically by a one-way ANOVA and Tukey HSD-test for *a posteriori* comparisons. Differences with $P < 0.05$ were taken as significant. All tests were performed using Statistica 6.0 statistical software.

RESULTS AND DISCUSSION

Total lipids constituted 2.2% of the wet weight in *G. rubiformis*. The percentages of individual lipid classes and phospholipids are shown in Tables 1 and 2, respectively. Similar to many species of Coelenterates (2,3,25), the total lipids of *G. rubiformis* contained a considerable proportion of NL, in particular hydrocarbons and wax esters (Table 1). Intriguing was the presence of a remarkable amount (up to 12% of the total lipids) of a less common monoalkyldiacylglycerol (MADAG). The content of TAG was lower than that of MADAG (Table 1). The presence of MADAG (up to 17% of total lipids) was previously shown for some species of scleractinian, soft, and hydroid corals from Okinawan, Caribbean, and Red Sea regions (2,3,25). In the NL fraction of *G. rubiformis*, sterols, FFA, and DAG constituted 30%. The content of the sterols detected in the total lipids of *G. rubiformis* did not appreciably exceed an average amount of the sterol fraction (about 7%) reported earlier for several species of hermatypic (6) and soft corals (3). In our opinion, the noticeable level of FFA detected in *G. rubiformis* (Table 1), as well as the extremely high level (up to 22% of total lipids) of FFA described by Grottoli *et al*. (6) for some reef-building coral species, may be a result of high phospholipase activity in these organisms, but this supposition needs further investigation. Until now, the content of DAG in corals was not clearly documented. Our data on the DAG content in *G. rubiformis* (2.9%) noticeably differed, for example, from similar analyses reported for *Porites compressa* and *Montipora verrucosa* in which the percentages of DAG were below the detection limit and amounted to 30%, correspondingly (6). Similarity of the total NL profile of *G. rubiformis* to those of other coral species makes it possible to postulate that the DAG content depends mainly on environmental conditions and cannot serve as a taxonomic characteristic of an individual coral species.

In *G. rubiformis*, PL concentrations were 31% of total lipids (Table 1). Most of the PL (more than 80%) was composed of phospholipids. The main phospholipids identified were PC, PE, and PS (Table 2). Along with the widespread phospholipids (PC, PE, and PS), two types of less common phosphonolipids, ceramide aminoethylphosphonate (CAEP) and ceramide methylaminoethylphosphonate, constituting 29% of phosphorus-containing lipids, were identified (Table 2). Noticeable was a distinct lack of phospholipid lyso-forms in *G. rubiformis*. In 1979, PC, PE, PS, and CAEP were reviewed by Joseph (25) as the principal phospholipids for several Anthozoa species. A similar phospholipid distribution was observed later in 3 species of tropical gorgonians (*Psam-*

Ceramide methylaminoethylphosphonate	13.3 ± 3.0

[a]Data presented as mean ± SD, $n = 5$.

mogorgia nodosa, *Bebryce indica*, and *Mopsella aurantia*) (26) and in 22 species of tropical alcyonarians, belonging to the genera *Sinularia*, *Lobophytum*, and *Sarcophyton* (15). PC, PE, PS, and CAEP amounted to up to 40.4, 30.4, 19.8, and 23.1%, correspondingly, of the total phospholipid fraction of the soft coral mentioned above (15,26). The main phospholipids from 11 species of tropical gorgonians, belonging to the genera *Gorgonia*, *Pseudopterogorgia*, and *Eunicea*, were characterized as PE, PC, and PS by Carballeira (13), but either the percentages of phospholipids or the presence of CAEP were not recorded.

In tropical soft corals, about three-fourths of PE and one-quarter of PC and PS molecules have been shown to be present in plasmalogenic forms (15); the same phenomenon was observed for the main phospholipid classes in the boreal soft coral *G. rubiformis* (data not shown). Both plasmalogens and phosphonolipids appeared to be common in soft corals, and have chemical bonds stable against hydrolytic enzymes such as phospholipases and phosphatases. Hydrolysis of MADAG by lipases is also hindered. We agree with Joseph (25) that the unusual plasmalogens, phosphonolipids, and MADAG may stabilize coral membranes that are exposed to highly active hydrolytic enzymes.

Within the total lipids of *G. rubiformis*, the principal FA were 16:0, 18:1n-9, 20:1n-7, 20:4n-6, 20:5n-3, 24:5n-6, and 24:6n-3, as shown in Table 3. In comparison with 23 FA described previously (18), we defined the FA composition of *G. rubiformis* more exactly (46 FA) and have redefined the earlier assumed tetracosateraenoic acid 24:4 as tetracosapentaenoic acid 24:5n-6. The mass spectra of methyl ester of this acid gave a molecular ion peak at *m*/*z* 372 (M^+), confirming the presence of five double bonds and a C_{24} chain in the original FA, and a strong peak at *m*/*z* 108, which is characteristic of the mass spectra of methyl esters of methylene-interrupted PUFA of the n-3 family. In contrast, in the n-6 family, a strong peak at *m*/*z* 150 is particularly abundant (27). The mass spectra of the *N*-acylpyrrolidide derivative of 24:5n-6 gave molecular ion peaks at *m*/*z* 411 (M^+) and five pairs of fragments at *m*/*z* 154 and *m*/*z* 166, *m*/*z* 194 and *m*/*z* 206, *m*/*z* 234 and *m*/*z* 246, *m*/*z* 274 and *m*/*z* 286, and *m*/*z* 314 and *m*/*z* 326, indicating that the double bonds were localized at the 6, 9, 12, 15, and 18 carbon atoms of the original FA (17,28).

PUFA with 24 carbon atoms and 5 to 6 methylene-interrupted *cis*-double bonds are typical constituents of representatives of all orders of subclass Octacorallia (Anthozoa): Alcyonaria, Gorgonaria, Helioporida, and Pennatularia (9,13). A non-food origin of tetracosapolyenoic acids in Octacorallia is strongly supposed (9). Thus, the large amount of the tetracosapolyenoic acids (10.4% of total FA) defined in the boreal soft coral *G. rubiformis* confirms chemotaxonomic significance of these acids for the octacorals.

Saturated, monoenoic, and polyunsaturated FA accounted, correspondingly, for 10.6, 25.0, and 61.8%, of the total FA composition of *G. rubiformis* collected in August (Table 3) at the highest (8–10°C) water temperature in the Avachinskaya Guba Inlet. We cannot assert that a noticeable amount of unsaturated FA is a sign of boreal octacorals inhabiting perennial cold waters, because no remarkable variation was noted for the concentrations of unsaturated FA in *G. rubiformis* dur-

[a]Values are reported as percent of total FA, mean value ± SD. In PL and NL fractions, FA marked by * and ** have significantly different contents at $P < 0.05$ and $P < 0.01$, correspondingly.

ing the annual cycle (18), and a high concentration of unsaturated FA has been documented for some tropical octacoral species (e.g., 74.7% for *Mopsella aurantia* (14)).

The FA composition of NL and PL fractions in *G. rubiformis* was investigated (Table 3). The concentration of mono-, di-, and trienoic acids in NL was significantly higher ($P < 0.05$) than that for PL. No significant difference between the NL and PL fractions was noted for the concentrations of saturated, penta-, and hexaenoic acids ($P > 0.05$). The NL contained much lower concentrations of the tetraenoic acids, were enriched with EPA (20:5n-3), and were deficient in arachidonic (20:4n-6), docosatetraenoic (22:4n-6), and tetracosapentaenoic (24:5n-6) acids. Accordingly, the fraction of n-3 FA was concentrated in the NL, and the fraction of n-6 FA significantly dominated (n-6/n-3 = 2.6) in the PL ($P < 0.01$). A similar predomination of the n-6 PUFA in phospholipid fractions from 11 species of tropical gorgonian octacorals was reported by Carballeira (13), whereas in the hermatypic hexacoral *Stylopora pistillata*, the ratio n-6/n-3 in PL FA was about 1.0 (11).

Based on the biosynthesis of n-6 FA from linoleic acid (18:2n-6) and n-3 FA from linolenic acid (18:3n-3), it is suggested that 24:5n-6 and 24:6n-3 acids may originate through elongation-desaturation of arachidonic acid (20:4n-6) and EPA (20:5n-3), respectively (17). PL and NL are often called structural and storage (reserve) lipids according to their main functions in living cells; furthermore, an excess of lipids and FA obtained from food is accumulated by animals mainly in storage NL. The predominance of the n-6 C_{20}–C_{24} PUFA in structural lipids of *G. rubiformis* indicates that these n-6 FA are basically synthesized by octacoral host tissues, whereas the predominance of EPA (20:5n-3) in the storage lipids of *G. rubiformis* and a relatively high variation in the 20:5n-3 content between individual coral colonies (Table 3) is most likely caused by the variability in the incoming main part of 20:5n-3 from food sources.

Similar to all heterotrophic soft corals, one of the important food sources for *G. rubiformis* is phytoplankton. In the Avachinskaya Guba Inlet, where the coral originated, the phytoplankton consists of two main groups of microalgae, diatoms, and phytoflagellates (mainly, dinoflagellates) (29). Diatoms are characterized by the presence of high level of 20:5n-3, and two other FA, 18:4n-3 and 22:6 n-3, are considered to be the biomarkers of dinoflagellates (30). It is well known that some distinctive FA from foods may accumulate in the lipids of consumers as biomarker FA. We compared our data on seasonal changes of FA composition in *G. rubiformis* obtained earlier (18) with the seasonal dynamics of phytoplankton population density in the Avachinskaya Guba Inlet (29). In *G. rubiformis*, the maximum content of 18:3n-3 and 18:4n-3 (up to 17% of total FA) was observed in April and November; the maximum content of 20:5n-3 and the lowest of 18:4n-3 were detected in June (18). According to Konovalova (30), two abundant blooms of the dinoflagellates constituting more than 90% of phytoplankton biomass appeared in late April and October. In June and August, the proportion of the dinoflagellates in phytoplankton decreased up to 55% owing to an increase on the part of the diatoms. Thus, we observe a simultaneous increase in the biomass of a certain phytoplankton group and in the concentration of coral FA that are the recognized biomarkers of the phytoplankton group. It can be assumed that a high level of 18:3n-3, 18:4n-3 (in sum, up to 28% of total FA), and 22:6 n-3 (about 7% of total FA) found in phospholipids of some tropical gorgonians (13) is caused by feeding of the corals on certain phytoplankton (e.g., dinoflagellates) containing high amounts of these FA.

ACKNOWLEDGMENTS

We are grateful to Dr. A.G. Bazhin (Kamchatka Fisheries and Oceanography Research Institute) and Dr. N.P. Sanamjan (Kamchatka Branch of the Pacific Institute of Geography FEB RAS) for collecting the corals for our study.

METHOD

The Analysis of Lipids *via* HPLC with a Charged Aerosol Detector

Robert A. Moreau*

U.S. Department of Agriculture, Agricultural Research Service, Eastern Regional Research Center, Wyndmoor, Pennsylvania

ABSTRACT: Because most lipid extracts are a mixture of saturated and unsaturated molecules, the most successful strategies for the quantitative analysis of lipids have involved the use of so-called "mass" or universal detectors such as flame ionization detectors and evaporative light scattering detectors. Recently a new type of HPLC "mass" detector, a charged aerosol detector (CAD), was developed and is now commercially available. This detection method involves nebulizing the HPLC column effluent, evaporating the solvents, charging the aerosol particles, and measuring the current from the charged aerosol flux. In the present study, the CAD was evaluated with several normal phase and reverse phase HPLC methods commonly used for the quantitative analysis of lipid classes and lipid molecular species. The CAD detected common lipids such as triacylglycerols, diacylglycerols, glycolipids, phospholipids, and sterols. Lower molecular weight lipids such as free FA had smaller peak areas (50–80% lower). FAME were not detected by the CAD, probably because they were completely evaporated and did not form aerosol particles. The minimum limits of detection of the CAD with lipids varied with different mobile phase solvents. Using solvent systems that were predominantly hexane, the minimum limits of detection of triacylglycerols, cholesterol esters, and free sterols were about 1 ng per injection and the mass-to-peak area ratio was nearly linear from the range of about 1 ng to about 20 mg per injection. Three other solvents commonly used for HPLC lipid analysis (methanol, isopropanol, and acetonitrile) caused higher levels of background noise and higher minimum limits of detection. These experiments indicate that the CAD has the potential to become a valuable tool for the quantitative HPLC analysis of lipids. Long-term studies are needed to evaluate full instrument performance.

Paper no. L9959 in *Lipids 41*, 727–734 (July 2006).

Several reviews have described in detail the numerous HPLC methods that have been developed for the quantitative analysis of plant, animal, and microbial lipids (1–4). The most common and least expensive detection method for HPLC is the UV-visible detector (1). UV-visible detectors have proven to be useful for those lipids that have chromophores, but they have been of limited use for the analysis of lipid extracts that contain a mixture of saturated and unsaturated molecules. Beginning in the mid-1980s, the first HPLC methods were developed for the quantitative analysis of lipids using "mass" detectors such as FID and ELSD, which could detect both saturated and unsaturated lipids. The first method that employed an ELSD for the analysis of lipid classes was published by W.W. Christie in 1985 (5). In 1990, our group published a similar HPLC method for the analysis of lipid classes using an FID (6) and demonstrated that FID and ELSD technologies were comparable. Although FIDs were successfully used for HPLC analysis for several years, FID technology was quickly surpassed by ELSD technology, and the manufacturing of FID ceased in the mid-1990s. In the last 15 years the sensitivity of ELSD has improved greatly and numerous methods have been developed for the analysis of lipids by HPLC-ELSD (1,3). Whereas the minimum limits of detection with early ELSD were about 10–20 μg per peak, the minimum limits of detection of lipids with modern ELSD has improved to about 50 to 100 ng (1).

Besides the FID and ELSD, a third type of aerosol-based detector was reported with examples of applications for lipid analysis (7). When used with a microbore column, this condensation nucleation light scattering detector (not commercially available) was reported to have minimum limits of detection of less than 1 ng.

Recently a new type of HPLC "mass" detector, a charged aerosol detector (CAD), was developed and is now commercially available (8,9). This detection method involves nebulizing the HPLC column effluent, evaporating the solvents, charging the aerosol particles, and measuring the current from the charged aerosol flux. In the present study, the CAD was evaluated with several normal phase and reverse phase HPLC systems commonly used for the quantitative analysis of lipid classes and lipid molecular species.

EXPERIMENTAL PROCEDURES

Materials. All organic solvents were freshly opened bottles of Baker Analyzed® HPLC grade solvents, obtained from Mallinckrodt Baker Inc. (Phillipsburg, NJ). Chromatographic standards of lipids [Non-polar Lipid Mix A (cat# 1129), Non-polar Lipid Mix B (cat# 1130), and Polar Lipid Mix (cat# 1127), all for TLC] were obtained from Matreya (Pleasant Gap, PA). Lecithin granules (97% soy phosphatides) were obtained from the Vitamin Shoppe (North Bergen, NJ). Barley lipid extract was obtained by extracting ground barley kernels (the cultivar was Doyce) with hexane, as previously described (10).

Abbreviations: CAD, charged aerosol detector; T, tocopherol; T3, tocotrienol.

HPLC system. The HPLC was an Agilent Model 1100 with autosampler. For experiments that involved injecting various masses of lipids, solutions were prepared at concentrations of 0.001, 0.01, 0.1, and 1.0 mg/mL, and triplicate injections of 1, 2, 5, and 10 μL of each concentration were made. Detection was by two methods, in series. An Agilent Model 1100 Fluorescence Detector (Agilent Technologies, Avondale, PA), with excitation at 294 nm and emission at 326 nm (flow cell volume, 8 μL) was used upstream of an ESA Corona™ Charged Aerosol Detector (ESA Biosciences, Chelmsford, MA) operated with nitrogen as a nebulizing gas and at a range of 500 pA. All other CAD parameters were preset by the manufacturer. The volume of solvent in the 50 cm of 0.010-in. i.d. PEEK tubing between the fluorescence detector and CAD was approximately 25 μL.

Normal phase nonpolar lipid HPLC analyses. This method was originally developed for use with an evaporative light scattering detector (11). A LiChrosorb 7 μm diol column (3 × 100 mm, packed by Chrompack, Raritan, NJ) was used. The binary gradient had a constant flow rate of 0.5 mL/min, with Solvent A = 99.9 % hexane/0.1% acetic acid (all solvent compositions are vol/vol), Solvent B = 99% hexane/1% isopropanol. Gradient timetable: at 0 min, 100/0 (%A/%B); at 8 min, 100:0; at 10 min, 75:25; at 40 min, 75:25; at 41 min, 100:0; and at 60 min, 100:0. These nonpolar lipid components were identified by comparison to the retention times of commercial standards.

Normal phase polar lipid HPLC analyses. Polar lipids (including acylated steryl glucosides, steryl glucosides, and phospholipids) were quantitatively analyzed by a similar method developed for use with an ELSD (12). The polar lipid components were identified by comparison to the retention times of commercial standards. The diol column and flow rates were the same as above. For isocratic analyses the mobile phase consisted of 45.9% hexane/50% isopropanol/4% water/0.1% acetic acid. For gradient analyses, the ternary gradient consisted of: Solvent A = 99.9% hexane/0.1% acetic acid, Solvent B = 100% isopropanol, and Solvent C = 100% water. Gradient timetable: at 0 min, 90:10/0 (%A/%B/%C); at 30 min, 58:40:2; at 40 min, 45:50:5; at 50 min, 45:50:5; at 51 min, 50:50:0; at 52 min, 90:10:0; and at 60 min, 90:10:0.

Normal phase tocopherol and tocotrienol HPLC analyses. Tocopherols and tocotrienols were quantified by using a modified version of the previously published method (13). The diol column and flow rates were the same as above. The binary gradient consisted of: Solvent A = 98% hexane/2% methyl *t*-butyl ether and Solvent B = 100% isopropanol. Gradient timetable: at 0 min, 100:0 (%A/%B); at 40 min, 100:0; at 45 min, 95:5; A/B, at 50 min, 95:5; at 51 min, 100:0; and at 60 min, 100:0. The MS was used to aid in peak identification. Gelcap supplements of tocopherols (Bio E Gamma Plex, Soloray Inc., Park City, UT) and tocotrienols (Tocopherol Complex, Solgar, Leonia, NJ) were purchased at a local vitamin store and the following peaks were confirmed by LC-MS, performed with an Agilent 1100 MSD equipped with an Atmospheric Pressure Chemical Ionization interface operated in the positive mode (drying gas at 6.0 L/min, nebulizer pressure at 60 psi, drying gas temperature at 350ºC, vaporizer gas temperature at 325ºC, capillary voltage at 4,000 V, and corona current at 4.0 μA, and fragmentor at 80 V): αT (M + 1 = *m/z* 431.4), αT3 (M + 1 = *m/z* 425.3), βT and γT (M + 1 = *m/z* 416.3), δT3 and γT3 (M + 1 = *m/z* 411.2), δT (M + 1 = *m/z* 402.3), and δT3 (M + 1 = *m/z* 397.1), where T = tocopherol and T3 = tocotrienol.

Reverse phase lipid molecular species HPLC analyses. This new method was recently developed to separate molecular species of triacylglycerols and other nonpolar lipids. The column was a Prevail RP18 3 μm (150 × 2.1 mm), packed by Alltech Associates, Deerfield, IL). The binary gradient had a constant flow rate of 0.5 mL/min, with Solvent A = 49.8% methanol/47% acetonitrile/3% dichloromethane/0.2% acetic acid, Solvent B = 100% isopropanol. Gradient timetable: at 0 min, 100:0 (%A/%B); at 20 min, 95:5; at 40 min, 50:50; at 50 min, 50:50; at 51 min, 100:0; and at 60 min, 100:0. These nonpolar lipid components were identified by comparison to the retention times of commercial standards.

RESULTS AND DISCUSSION

The first HPLC method to be evaluated with the CAD was a normal phase gradient elution method developed to quantitatively analyze the major nonpolar lipid class components (phytosterol esters, triacylglycerols, free FA, and free phytosterols) in vegetable oils and hexane extracts (11). The baseline was relatively smooth with this system (Fig. 1A). A commercial mixture that contained equal masses of five nonpolar lipid classes (cholesterol:oleate, triolein, oleic acid, methyl:oleate, and cholesterol) was injected in this system (Fig. 1B and C). Detector response (peak areas) for cholesterol:oleate and triolein were similar whereas that of cholesterol and oleic acid were approximately 10% and 80% lower, respectively. Methyl:oleate was not detected by the CAD, presumably because this lower MW component was completely evaporated and did not form aerosol particles. Similar results were previously reported for the ELSD—methyl esters were partially evaporated at a detector temperature of 40°C and completely evaporated at higher temperatures (1). Similarly (with the ELSD), free FA were partially evaporated at detector temperatures of 40°C and 60°C and completely evaporated at higher temperatures (1). Unlike most ELSDs, the nebulizer temperature of the CAD is preset and not variable. With this HPLC method, the minimum limits of detection with the CAD were about 1 ng, and the mass-to-peak area ratio was nearly linear from the range of about 1 ng to 20 ng per injection (Fig. 1D). In other experiments the standard curve was extended up to 20 μg and the mass-to-peak area ratio continued to remain nearly linear (data not shown).

The second HPLC method to be evaluated with the CAD was a normal phase method developed to quantitatively analyze the major polar lipid class components (mainly glycolipids and phospholipids) in extracts of plant material extracted with polar solvents (12). This system was evaluated with both isocratic elution (Fig. 2) and gradient elution (Fig. 3). In our

experience, the isocratic method is adequate to separate simple standard mixtures, but the gradient method is required to separate most plant lipid extracts. In the isocratic polar lipid system the baseline was relatively smooth (Fig. 2A). A commercial mixture that contained equal masses of four polar lipid classes (cholesterol, phosphatidylethanolamine [PE], phosphatidylcholine [PC], and lyso-phosphatidylcholine [lyso PC]) was injected in this system (Fig. 2B), and the components were well separated. With this HPLC system, the minimum limits of detection were about 25 ng, and the mass-to-peak area relationship was evaluated in the range from about 25 ng to about 10 µg per injection (Fig. 2C). Because it would have made the mass-to-peak area graph (Fig. 2C) difficult to read, the same data, with standard deviations are also reported in Table 1.

In using the normal phase polar lipid class gradient method, the baseline was relatively smooth until about 35 min, but it increased and "plateaued" from about 40 to 55 min, and then dropped back down to the original level for the remainder of the chromatogram (Fig. 3A). The four polar lipid classes in the standard were also well resolved in the gradient system (Fig. 3B). A sample of soy lecithin was then injected (Fig. 3C) and the CAD detected the same major glycolipids (acylated steryl glycoside and steryl glucoside) and phospholipids (PE, PC, lyso PC, and PI) that we previously observed by using an evaporative light scattering detector (14).

The next HPLC method evaluated was a normal phase method developed to separate the eight natural isomers of tocopherols and tocotrienols (13). Because tocopherols and to-

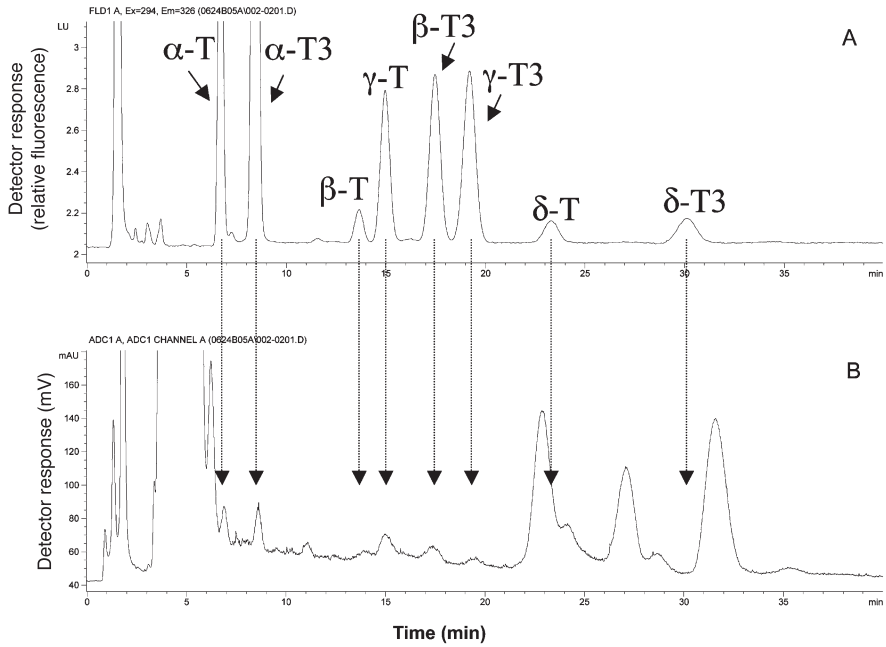

FIG. 4. Normal phase tocopherol/tocotrienol HPLC system showing the peaks of tocopherols and tocotrienols in unrefined oil obtained by extracting ground Doyce hulless barley kernels with hexane. (A) Detection was with a fluorescence detector (294 nm excitation and 326 nm emission). Abbreviations: T, tocopherol; T3, tocotrienol. (B) Detection with CAD.

cotrienols fluoresce, fluorescence detection (294 nm excitation and 326 nm emission) is a very selective detection method that has been used to accurately quantify these compounds, with minimum limits of detection of about 1 ng (15). Because the CAD also potentially has minimum limits of detection at about 1 ng, we prepared an extract of barley and compared the detection with the fluorescence detector (Fig. 4A) and the CAD (Fig. 4B). Interestingly, the CAD revealed several large peaks with retention times similar to tocopherols and tocotrienols (but since the components in these peaks did not fluoresce, they were not tocopherols or tocotrienols). Although it appears that the CAD could potentially be used to quantify some tocopherols and tocotrienols, the presence of other unknown peaks with similar retention times complicates the chromatogram. Under these conditions, it appears the fluorescence detection is still the HPLC detection method of choice for the quantitative analysis of tocopherols and tocotrienols.

The final HPLC method studied was a reverse phase method recently developed to separate the molecular species of triacylglycerols (e.g., triolein and trilinolein) and other nonpolar lipids. The baseline was noisier with this reverse phase system than with the normal phase systems (Fig. 5A). The reason for this increased noise was not examined. The nonpolar lipids in two commercial standard kits were separated with this system, at component concentrations of 25 ng (Fig. 5B) and 200 ng (Fig. 5C). Because the system was quite noisy, the minimum limits of detection with this system appear to be about 25 ng.

While conducting the previous experiments it was observed that the CAD baseline was relatively smooth with some solvents and noisy with others. The next experiment was designed to measure the effect of various common HPLC solvents on the CAD baseline (Fig. 6) at a constant flow rate of 0.5 mL/min, without a column and without injecting any lipid samples. The HPLC pump was programmed to deliver hexane for 10 min and then perform a 1-min gradient to transition to 100% isopropanol for the next 9 min, and similarly transition to methanol, water, isopropanol, and finally return to hexane. Among the four solvents evaluated in the first experiment, methanol produced the highest CAD background (Fig. 6A). Among the four solvents evaluated in the second experiment, acetonitrile produced the highest CAD background (Fig. 6B). Methanol and acetonitrile are the most common HPLC solvents for reverse phase HPLC. Clearly, more studies are needed to fully investigate the effects of these solvents on the noise and performance of the CAD.

These preliminary results indicate that the CAD has the potential to become a valuable tool for the quantitative HPLC analysis of lipids. The major advantages of the CAD are its low minimum limits of detection and its nearly linear mass-to-peak area relationship for many types of lipids. Long-term studies are needed to confirm that the results are reproducible and that the instrument is durable and reliable.

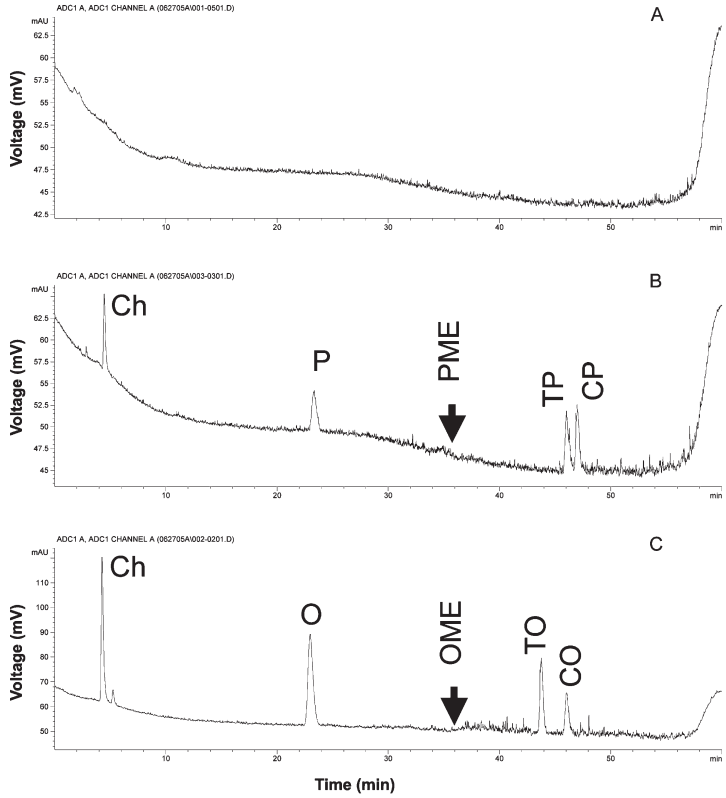

FIG. 5. Reverse phase nonpolar lipid HPLC system evaluated with Matreya nonpolar mix A and B. (A) Gradient blank, no lipid injected. (B) Matreya nonpolar lipid mix A with an injection comprised of 25 ng of each component. (C) Matreya nonpolar lipid mix B with an injection comprised of 200 ng of each component. ABSTRACT: *Schizochytrium* sp. is a marine microalga that has been developed as a commercial source for docosahexaenoic acid (DHA, C22:6 ω-3), enriched biomass, and oil. Previous work suggested that the DHA, as well as docosapentaenoic acid (DPA, C22:5 ω-6), that accumulate in *Schizochytrium* are products of a multi-subunit polyunsaturated fatty acid (PUFA) synthase (1). Here we show data to support this view and also provide information on other aspects of fatty acid synthesis in this organism. Three genes encoding subunits of the PUFA synthase were isolated from genomic DNA and expressed in *E. coli* along with an essential accessory gene encoding a phosphopantetheinyl transferase (PPTase). The resulting transformants accumulated both DHA and DPA. The ratio of DHA to DPA was approximately the same as that observed in *Schizochytrium*. Treatment of *Schizochytrium* cells with certain levels of cerulenin resulted in inhibition of ^{14}C acetate incorporation into short chain fatty acids without affecting labeling of PUFAs, indicating distinct biosynthetic pathways. A single large gene encoding the presumed short chain fatty acid synthase (FAS) was cloned and sequenced. Based on sequence homology and domain organization, the *Schizochytrium* FAS resembles a fusion of fungal FAS β and α subunits.

Paper no. L10047 in *Lipids 41*, 739–747 (August 2006)

DHA, along with other long chain (LC-, those fatty acids with carbon chain lengths greater than 18) PUFAs, have been identified as important dietary compounds for humans. The ω-3 LC-PUFAs, such as DHA and eicosapentaenoic acid (EPA, C20:5), are implicated in early neural and retinal development, the prevention of arteriosclerosis and coronary heart disease, alleviation of inflammation, and retarding the growth of tumor cells (2). The effects are seen as a result of the ω-3 fatty acids acting as competitive inhibitors of ω-6 fatty acids and from the beneficial effects of the ω-3 compounds in their own right (*3*).

A major dietary source of ω-3 LC-PUFAs is from marine fish or fish oil supplements. However, due to emerging concerns with sustainability of marine resources and with the levels of environmental contaminants (PCBs, dioxins, and mercury) in fish (4), major efforts have been made to identify or create alternative sources. One area that has received considerable attention is the creation of crop plants whose seed oils are enriched in LC-PUFA via the use of genetic engineering techniques (5, 6). The oils of these plants do not normally contain LC-PUFA but can contain significant amounts of the C18 PUFAs: linoleic (C18:2 ω-6) and α-linolenic (C18:3 ω-3) fatty acids. Most of the engineering strategies are based on modification of the plant's endogenously produced PUFA through introduction of foreign genes, encoding a variety of enzymes that can either elongate the fatty acid chain or insert additional *cis*-double bonds (i.e., elongases and desaturases, respectively). These efforts have achieved significant progress. Genes have been isolated that encode the entire suite of enzymes needed to convert linoleic and/or α-linolenic fatty acid precursors into a range of LC-PUFA up to and including DHA, and initial results of LC-PUFA production in plants have been published (6,7). A major challenge associated with this approach is the channeling of the products of these individual enzymes to the next desired reaction (8).

The cultivation of microbial organisms has provided an alternative commercial source of oils enriched in LC-PUFA. The fungus *Mortierella alpina* and a dinoflagellate, *Crypthecodinium cohnii*, are both currently grown via fermentation as sources of oils enriched in LC-PUFA [arachidonic acid, ARA (C20:4 ω-6), and DHA, respectively] that are added to infant formulas (9, 10). The microalga *Schizochytrium* sp., as well as other strains of Thraustochytrids, can produce large amounts of oil—up to 55% of the cell weight—in which DHA can comprise as much as 35% of the total fatty acids (11). *Schizochytrium* sp. is grown on a commercial scale via fermentation for both biomass (for animal feed) and for its oil (11).

Until recently, it was assumed that all LC-PUFA were produced by variations of the same basic pathway mentioned above. That is, an FAS system produces short chain saturated fatty acids, and these products are subsequently modified by the actions of distinct elongase and desaturase enzymes. Indi-

Abbreviations: ACP, acyl carrier protein; ARA, arachidonic acid (C20:4 ω-6); bp, nucleotide base pair; DHA, docosahexaenoic acid (C22:6 ω-3); DPA, docosapentaenoic acid (C22:5, this study refers exclusively to DPA ω-6); EPA, eicosapentaenoic acid (C20:5 ω-3); IPTG, isopropyl-1-thio-β-D-galactopyranoside; KAS, β-ketoacyl-ACP synthase; LC-PUFA, those PUFA with carbon chain lengths greater than 18; Orf; open reading frame; Orf B*, *Schizochytrium* PUFA synthase Orf B modified for expression in *E. coli*; PKS, polyketide synthase; PPTase, phosphopantetheinyl transferase; RBS, ribosome binding site.

[1]Current address: United States Dept. of Agriculture, Agricultural Research Service, Washington State University, Pullman, WA

cations of the existence of an alternative pathway for LC-PUFA synthesis initially came from studies of certain marine bacteria. In 1986, DeLong and Yayanos (12) reported the detection of LC-PUFA (either EPA or DHA) in several strains of psychrophilic marine bacteria. Subsequently, Yazawa (13) identified a segment of genomic DNA from an EPA-producing bacterium (*Shewanella* strain SCRC-2738) that when transformed into *E. coli* resulted in EPA accumulation in those cells. It was then determined that proteins encoded by five open reading frames (Orfs) were necessary and sufficient for this activity (14). A number of observations led to the conclusion that four of those proteins represented subunits of an enzyme complex capable of *de novo* synthesis of EPA (1). This PUFA synthase enzyme possessed multiple domains, some of which showed homology to those found in FAS systems while others were similar to those of polyketide synthase (PKS) systems. The fifth essential gene required for EPA synthesis in *E. coli* encoded a phosphopantetheinyl transferase (15) that activated the acyl carrier protein (ACP) domains present on the enzyme by attachment of a cofactor (16). Genes with homology similar to the *Shewanella* EPA gene cluster have been identified in other marine bacteria, including one which accumulates DHA (16-18). It is possible that most, or all, of the marine bacteria that synthesize LC-PUFA will be found to utilize this system.

A set of three genes encoding a PUFA synthase homologous to those found in marine bacteria was also discovered in *Schizochytrium*. A number of biochemical and physiological observations, in addition to the molecular data, indicated that the abundant LC-PUFAs that accumulate in this organism are the products of a PUFA synthase, or synthases (1, 11). Here we confirm that the three genes identified in *Schizochytrium* do indeed encode subunits of a PUFA synthase and that this synthase accounts for production of both DHA and DPA. Additionally, we provide evidence that the other abundant fatty acids present in *Schizochytrium* oil (C14:0 and C16:0) are the products of a separate FAS. With regard to both sequence homology and domain organization, the *Schizochytrium* FAS resembles those found in fungi. However, in contrast to the two subunits of the fungal FAS, all of the domains of the *Schizochytrium* FAS are found on a single large protein.

EXPERIMENTAL PROCEDURES

Strains. *Schizochytrium* sp. is available from the American Type Culture Collection (ATCC 20888) as are *Nostoc* sp. PCC7120 (ATCC 27893, deposited as *Anabaena* sp.) and *Bacillus subtilus* (ATCC 21332). The *E. coli* strain BL21 [BL21(DE3)] was obtained from Novagen.

General preparation of E. coli transformants. DNA containing Orfs encoding the *Schizochytrium* PUFA synthase subunits A, B, and C were cloned separately and together into *E. coli* expression vectors derived from pET21c (Novagen). The constructs were transformed into BL21 cells and expressed using the T7 system with IPTG (isopropyl-1-thio-β-D-galactopyranoside) induction (Novagen). Initial assembly of the Orfs, each containing modifications to facilitate cloning, was done in the pBluescript II SK(+) plasmid (Stratagene, Inc.). The fragments used to assemble the PUFA synthase subunits, as well as the *Schizochytrium* FAS, were cloned from a lambda library of genomic DNA. Standard methods were used to produce that library as well as polymerase chain reaction (PCR)-derived probes (based on sequences obtained from cDNA clones) for isolation of the respective DNA fragments. Sequences for the Orfs encoding PUFA synthase subunits are available from GenBank (accession numbers: AF378327, AF378328, AF378329 for subunits A, B, and C, respectively). The GenBank sequences provide the reference base pair (bp) positions and restriction site locations described in the cloning steps listed below. The Orf encoding the FAS gene was sequenced using a combination of subcloning and primer walking. The accession number for the *Schizochytrium* FAS Orf is EF015632.

Orf A was cloned as three pieces. Part 1 included the beginning of the Orf and extended to a unique PstI site 18 bp from the start codon. This fragment was generated using two complimentary oligonucleotides that were designed to add EcoRI and PacI restriction enzyme sites and a bacterial ribosome binding site (RBS) upstream of the start codon. Additionally, they incorporated an NdeI site at the start codon. Part 2 was a 1.2-kb fragment extending from the PstI site to a unique XmaI site at 1243 bp. Part 3 was a 7.5-kb fragment extending from the XmaI site to a SpeI site 6 bp downstream of the stop codon. Parts 2 and 3 were assembled into pBluescript II cut with PstI and SpeI. Part 1 was added to this construct as an EcoRI-PstI fragment generating the modified Orf A clone.

Orf B was cloned in four parts. Part 1 was generated by PCR and included the beginning of the Orf, and extended to a BsiWI site 237 bp from the start of the Orf. The 5′ primer included an EcoRI site followed by an RBS and an NdeI site at the start codon. The 3′ primer included a SacII site to facilitate further cloning. The PCR product was digested with EcoRI and SacII and cloned into pBluescript II digested with the same restriction enzymes. Part 2 was a 4.36-kb restriction fragment extending from the BsiWI site to a SacII site 4605 bp into the Orf. Part 3 was a gel-purified 1.54-kb restriction fragment extending from the SacII site at 4605 bp to a ClaI site 6147 bp into the Orf. Part 4 extended from the ClaI site at 6147 bp to the end of the Orf. This short (68 bp) fragment was generated using two overlapping oligonucleotides that included EcoRI and SacII sites upstream of the ClaI site and a BamHI site just downstream of the stop codon to facilitate further cloning. The modified Orf B was assembled in the following sequence. The cloned part 1 was digested with BsiWI and SacII and ligated together with the gel-purified part 2 fragment. The new clone was digested with EcoRI and SacII, and the 4.6-kb fragment gel purified. The part 4 clone was digested with SacII and ClaI, and ligated together with the gel-purified part 3 fragment. This plasmid was opened up by digestion with EcoRI and SacII and ligated together with the 4.6-kb gel-purified fragment containing parts 1 and 2.

Orf C was cloned in four parts. Part 1 contained the start codon and extended to a NarI site 255 bp into the Orf. This fragment was generated by PCR. The 5′ primer included an

EcoRI site followed by an RBC and an NdeI site at the start codon. The primer for the 3′ end contained a BamHI site just beyond the NarI site to facilitate further cloning. The PCR product was digested with EcoRI and BamHI and ligated into pBluescript II digested with the same restriction enzymes. Part 2 was a 0.7-kb restriction fragment extending from the NarI site to a BamHI site 971 bp into the Orf. Part 3 was a 3.3-kb restriction fragment extending from the BamHI site to a PflMI site at 4248 bp. Part 4 extended from the PflMI site to the end of the Orf. This fragment was generated by PCR using primers that added BamHI and EcoRI sites upstream of the PflMI site and NheI, HindIII, and XbaI sites downstream of the stop codon to facilitate further cloning. The PCR product was digested with BamHI and XbaI and ligated into pBluescript digested with the same enzymes. The modified Orf C was assembled using the following steps. The plasmid containing part 1 was digested with NarI and BamHI and ligated together with the gel-purified part 2 fragment. This plasmid was digested with EcoRI and BamHI, and the 1-kb fragment containing parts 1 and 2 was gel purified. The plasmid containing part 4 was digested with PflMI and BamHI and ligated together with the part 3 fragment. The plasmid containing parts 3 and 4 was opened up by digestion with EcoRI and BamHI and ligated together with the fragment containing parts 1 and 2.

Cloning of modified Orfs A, B, and C individually into a modified pET21c and testing for protein expression in E. coli. To facilitate cloning into pET21c, restriction sites for NheI, PacI, PmeI, and SpeI were added, in that order, to the multiple cloning region between the XhoI and BlpI sites using two adapter oligonucleotides. The modified vector (pMET21) was used for the cloning of the individual, as well as multiple, PUFA synthase Orfs. The modified PUFA synthase Orf A was cut out of pBluescript II with NdeI and SpeI. The resulting 8.7-kb fragment was gel purified and ligated into pMET21 cut with the same enzymes. The modified Orf B was cut out of pBluescript II with NdeI and BamHI. The resulting 6.2-kb fragment was gel purified and ligated into pMET21 cut with NdeI and BamHI. The modified Orf C was cut out of pBluescript II with NdeI and HindIII. The resulting 4.5-kb fragment was gel purified and ligated into pMET21 cut with NdeI and HindIII.

BL21 cells carrying the various pMET21 constructs were grown in Luria Broth plus ampicillin (100 μg/mL) at 32°C with shaking to an A_{600} of 0.5. IPTG was added to a final concentration of 1 mM, the cells grown for an additional four hours, and then harvested by centrifugation. The cell pellets were heated in an SDS sample buffer and the extracted proteins analyzed by SDS-PAGE (sample buffer, 4-20% polyacrylamide Tris-glycine gels, and Simple Blue stain, all from Novex).

Resynthesis of a serine codon TCT repeat region in Orf B and testing for protein expression. Orf B contains a stretch of 15 consecutive, identical serine codons (TCT), located at 4510 to 4554 bp. An approximately 200-bp segment, containing the region from a BspHI site at 4416 bp to the SacII site at 4605 bp, was resynthesized by use of PCR and a series of partially overlapping oligonucleotides, using the two-stage amplification protocol outlined in reference 19 as a guide. The final PCR product was cloned and sequenced and the BspH-SacII fragment gel purified for subsequent cloning. This fragment replaced the native region of Orf B (forming Orf B*) using the steps outlined for the general preparation of the Orf B clone described above. The pBluescript clone containing part 1 was cut with BsiWI and SacII. Into this was ligated a 4.2-kb BsiWI-BspHI fragment derived from the clone containing parts 1 and 2, plus the resynthesized BspHI-SacII fragment. Digestion of this clone with EcoRI and SacII yielded a 4.6-kb fragment which was gel purified and ligated into the clone of parts 3 and 4 digested with the same enzymes. This clone contained the complete, modified Orf B*, which was then transferred to pMET21, using the same cloning strategy as described above, and tested for protein expression.

Cloning of Orfs A, B, and C into pMET21, and construction of pMET21-Orf B/Orf C/Orf A.* Starting with the pMET21-Orf B clone, Orfs C and A were sequentially added downstream of the previously inserted genes. This created a polycistronic construct with the expression of all three genes driven by the single T7 promoter in pMET21. Orf B utilized the vector-encoded RBS, while a new RBS was supplied with Orfs C and A. A 4.5-kb EcoRI-NheI fragment isolated from pMet21-Orf C (containing Orf C plus an upstream RBS), was ligated into pMET21-Orf B cut with the same enzymes. The resulting pMET21-OrfB/Orf C was digested with PacI and SpeI. Into this was ligated an 8.7-kb PacI/SpeI fragment containing Orf A plus an upstream RBS, isolated from pMet21-Orf A. The resulting plasmid, pMET21-Orf B/Orf C/Orf A was used as the source of a 13.2-kb EcoRI-SpeI Orf C/Orf A fragment used to construct pMET21-Orf B*/Orf C/Orf A. This construct was generated by digesting pMET21-Orf B* with EcoRI and SpeI and ligating in the gel-purified fragment.

Cloning of sfp and HetI into pACYC184. Two PPTases were tested in the *E. coli* PUFA synthase expression system: sfp, from *Bacillus subtilis* (20), and HetI, from the cyanobacterium *Nostoc* strain 7120 (21). An expression vector for sfp was built by cloning the coding region along with defined upstream- and downstream-flanking DNA into pACYC184 (New England Biolabs, Inc.). The oligonucleotides: CGGGGTACCCGGGAGCCGCCTTGGCTTTGT (forward); and AAACTGCAGCCCGGGTCCAGCTGGCAGGCACCCTG (reverse), were used to amplify this region from genomic *B. subtilus* DNA. Restriction enzyme sites were included in the oligonucleotides to facilitate cloning into the EcoRV site of pACYC184. This pACYC184-sfp clone was used to create a HetI expression cassette. The sfp coding region (along with three nucleotides immediately upstream of the ATG) was replaced with a section of DNA containing NdeI and XhoI restriction sites. The ATG sequence embedded in the NdeI site was utilized as the initiation methionine codon for the introduced HetI Orf. There are no methionines present in the Orf, but there are several potential alternative start codons (TTG and ATT) near the 5′ end (see reference 21, Figs. 2 and 3). PCR was used to amplify the Orf with primers designed to replace the furthest 5′ TTG codon with an ATG codon as part of the above-mentioned NdeI site. PCR was also used to introduce an XhoI site just beyond the stop codon. The modified HetI

coding sequence was then inserted into the NdeI and XhoI sites of the pACYC184 vector construct containing the sfp regulatory elements. Upon introduction into BL21 cells, transformants were selected based on chloramphenicol (35 μg/mL) resistance.

Fatty acid content of E. coli cells expressing Schizochytrium PUFA synthase subunits A, B, and C plus sfp or HetI. BL21 cells containing pMET-OrfB*/OrfC/OrfA and either pACYC184-sfp or pACYC184-HetI were grown in various media supplemented with ampicillin (100 μg/mL) and chloramphenicol (35 μg/mL) to A_{600} = 0.5. IPTG was then added to a final concentration of 0.5 mM. Incubation was continued for 24 hours and the cells were harvested by centrifugation, washed in 50 mM Tris pH 7.5, and processed for FAME analysis. The following media were tested: Luria Broth, Luria Broth supplemented with 5- or 10% glycerol and 765 medium (recipe available from the ATCC) supplemented with 10% (wt/vol) glycerol. Cells were grown at 20°C or 32°C with shaking. Cells transformed with pMET-OrfC/OrfA served as the negative control.

Fatty acids present in the culture were converted to FAMEs and identified by comparison of retention times of standards using GC-FID. FAMEs were prepared by adding 2 mL of 1.5 N anhydrous HCl in methanol and 1 mL toluene to aliquots of the wet pellets and heating at 100°C for two hours with frequent mixing. After cooling to room temperature, 1 mL of NaCl-saturated water was added, the samples mixed, and the organic layer removed for analysis. Determination of carbon-carbon double bond positions was made by interpretation of MS data of dimethyloxazoline (DMOX) derivatives of the FAME samples (22). 100 μL of the FAME solution was transferred to screw top test tubes and the solvent removed with nitrogen gas. One mL of 2-amino-2-methyl propanol was added, the tubes flushed with nitrogen, capped, and heated at 150°C for 18 hours. The residue was dissolved in 5 mL of dichloromethane, 5 mL of water was added, and the aqueous layers were removed after thorough mixing. The wash step was carried out five times. The dichloromethane solution was dried over anhydrous sodium sulfate, filtered, and concentrated using nitrogen gas to 1 mL final volume. Identification of fatty acids in the DMOX derivatives was based on comparison with published data when available, and with the interpretation of MS of individual sample peaks.

Effects of cerulenin on ^{14}C acetate labeling of fatty acids in Schizochytrium cells. Schizochytrium cells were grown in a medium designed to promote oil accumulation (23), with shaking at 27ºC, until the start of logarithmic growth (A_{600} of ~3.0). Cerulenin (Sigma) dissolved in EtOH was added to glass tubes and the solvent evaporated prior to adding 1 mL aliquots of the culture. The amount of cerulenin in the tubes represented final concentrations of 0, 0.5, 1.0, 5.0, 10, 25, 50,100, or 200 μM in the cell culture. The cells were incubated for 10 minutes prior to the addition of ^{14}C acetate (39 mCi/mmol: Sigma) to a final concentration of 20 μM. Incubations were continued until >90% of the label had been removed from the medium (~45 minutes). Cells were collected by centrifugation, and FAMES were prepared essentially as described above. The solvent was removed with nitrogen gas and the residue dissolved in hexane and applied to silica gel G TLC plates (J.B. Baker) that had been treated with a 10% silver nitrate solution. Plates were developed with hexane/diethyl ether/acetic acid (70:20:2). Radioactive areas on the plates were detected using a phosphorimaging system (BioRad, FX Pro Plus). The intensities of photon emissions from the storage phosphor screens were used to measure the relative amounts of radioactive material present and are expressed as "counts" in rectangles of equivalent areas. Identities of the FAMEs on the plates were established by comparison to unlabeled FAME standards (C14:0, C16:0, DPA, and DHA: NuCheck Prep). The C14:0 and C16:0 standards co-migrated on the plates near the solvent front, while DPA and DHA ran as separate bands near the origin.

RESULTS

Expression of Schizochytrium PUFA synthase subunits A, B, and C in E. coli. We sought to confirm that the *Schizochytrium* Orfs A, B, and C encode a PUFA synthase and to verify its fatty acid products by expressing that system in *E. coli*. The PUFA synthase genes previously expressed in *E. coli* or in a cyanobacterium are from marine bacteria, and the Orfs encoding the subunits of those PUFA synthases are organized in apparent operons. Expression of those systems in *E. coli* utilized the promoter, initiation, and translation elements of the source DNA (13, 14, 16). The eukaryotic nature of the *Schizochytrium* genes precluded this approach. We utilized the Novagen pET vectors to express the genes encoding subunits A, B, and C individually and together as a synthetic operon. SDS-PAGE analyses of extracts from *E. coli* in which the individual genes were induced revealed that the genes encoding subunits A and C produced proteins of the expected sizes. In contrast, extracts from cells expressing the subunit B gene accumulated a novel protein with an apparent mass of 165 kDa instead of the 224 kDa protein predicted by translation of the coding sequence (data not shown). Examination of the Orf B nucleotide sequence revealed a region containing 15 sequential identical serine codons (TCT) at a position in the Orf that could account for generation of the truncated protein.

A 200-bp fragment of Orf B containing the serine repeat region was resynthesized so that a random mix of the three serine codons commonly used by *E. coli* replaced the TCT repeat. Some other potentially problematic codons in this fragment were also changed while maintaining the original deduced amino acid sequence (Fig. 1). The native fragment of Orf B was replaced with the modified one (creating Orf B*) and expressed in *E. coli*. In this case an apparently full-length subunit B protein was detected. Analysis of cells expressing the construct containing all three Orfs (A, B*, and C) revealed the presence of three new proteins of the expected sizes. Analysis of the fatty acids in these cells did not reveal any LC-PUFA.

Selection and cloning of a PPTase-HetI. Subunit A of the *Schizochytrium* PUFA synthase contains nine adjacent, highly homologous, ACP domains. ACPs require conversion from an inactive apo-form to a functional holo-form by attachment of a

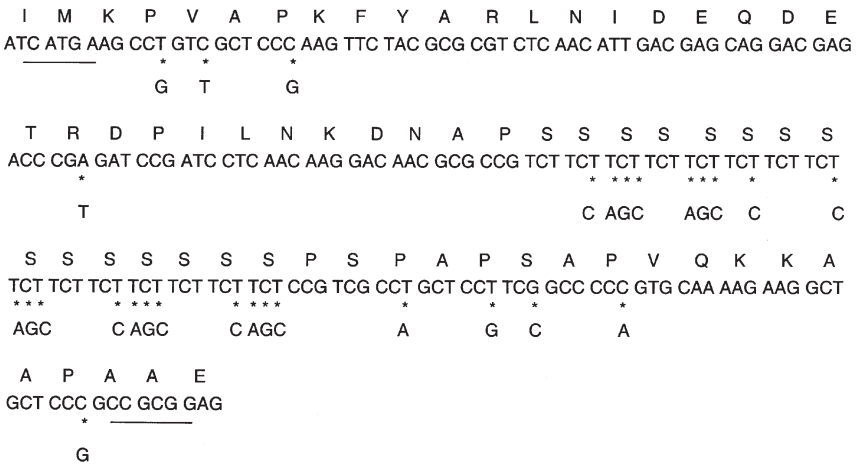

FIG. 1. Modification of the *Schizochytrium* PUFA synthase Orf B nucleotide sequence for expression in *E. coli*. The sequence of codons associated with a BspHI-SacII fragment (restriction enzyme recognition sites are underlined) is shown, along with the encoded amino acids. Nucleotides changed in the resynthesized fragment are indicated by *, with the altered nucleotide shown below. The first and last nucleotides shown correspond to positions 4414 and 4608, respectively, of the complete *Schizochytrium* Orf B sequence (Accession number, A378328).

phosphopantetheine prosthetic group. Enzymes of the PPTase superfamily catalyze this post-translational modification (15). Previous work suggested that *E. coli's* endogenous PPTases would be incapable of activation of the ACPs of PUFA synthases (16). A PPTase that was likely to meet our requirements was identified by searching for ones that may activate ACP domains with significant homology to those of the PUFA synthases. The *hetI* gene is presumed to encode a PPTase (HetI) and is found in a cluster of genes in *Nostoc* sp. responsible for the synthesis of long-chain hydroxy-fatty acids (21, 24). It is likely that HetI activates the two ACP domains of the protein encoded by the *hglE* gene present in that same cluster. The ACP domains of HglE have a high degree of sequence homology to each other and to the ACP domains found in *Schizochytrium* Orf A as well as those of other PUFA synthases (Fig. 2). The amino acids in the region immediately surrounding the phosphopantetheine attachment site are identical in these ACP domains, and there is significant homology in the extended sequence. In contrast, the *E. coli* ACP has relatively few residues that are identical to those in this alignment. To our knowledge, HetI has not been tested previously in a heterologous system, and the endogenous start codon of HetI has not been identified. There are no ATG codons in the potential coding region, but there are several alternative bacterial start codons (TTG and ATT) near the 5′ end of the Orf (21). A HetI expression construct was made by replacing the farthest 5′ alternative start codon (TTG) of the Orf with a methionine codon. Regulatory elements obtained from the upstream region of the *sfp* gene of *B. subtilus* were used to drive expression of the gene. SDS-PAGE analysis of extracts from *E. coli* transformed with this plasmid revealed the appearance of a new protein of the appropriate size (not shown). The gene-encoding sfp has been used extensively for activation of ACP domains of PKS systems as well as the peptidyl carrier protein domains of non-ribosomal peptide synthase systems during heterologous expression (15). We also tested the effect of expression of sfp with the *Schizochytrium* PUFA synthase genes in *E. coli*.

Accumulation of DHA and DPA in E. coli expressing the Schizochytrium Subunits A, B, and C plus HetI or sfp. E. coli cells were transformed with various plasmids containing some or all of the putative *Schizochytrium* PUFA synthase genes and with a second plasmid containing a PPTase gene. Transcription of the genes dependent on the T7 polymerase was induced by addition of IPTG, the cultures incubated overnight, and the fatty acids analyzed. A typical GC profile of FAMEs derived from control cells (lacking at least one component of the PUFA synthase system) is shown in Fig. 3A. The major peaks on the chromatogram were identified as 16:0, 16:1, 18:0, and 18:1 (*cis*-vaccenic acid), as well as two cylcopropane fatty acids (17:0 and 19:0). No peaks corresponding to DHA or DPA, or any other PUFA, were detected in these samples. In contrast,

FIG. 2. Alignment of the highly conserved central regions of the first ACP domains from a heterocyst glycolipid synthase of *Nostoc* sp. PCC7120 (HglE), the PUFA synthase from *Shewanella* SCRC3728 (Orf 5), and the PUFA synthase of *Schizochytrium* (Orf A). Identical amino-acid residues are indicated by the grey background. Underlined amino acids indicate residues of the *E. coli* ACP that are identical to those in this alignment. An * marks the conserved serine pantetheinylation site. The accession numbers and the range of amino acid sequences used are the following: HglE, BAB77050, 1320–1353; Orf 5, AAB81123, 1269–1302; Orf A, AAK72879, 1135–1168; *E. coli*, AAC74178, 15–48.

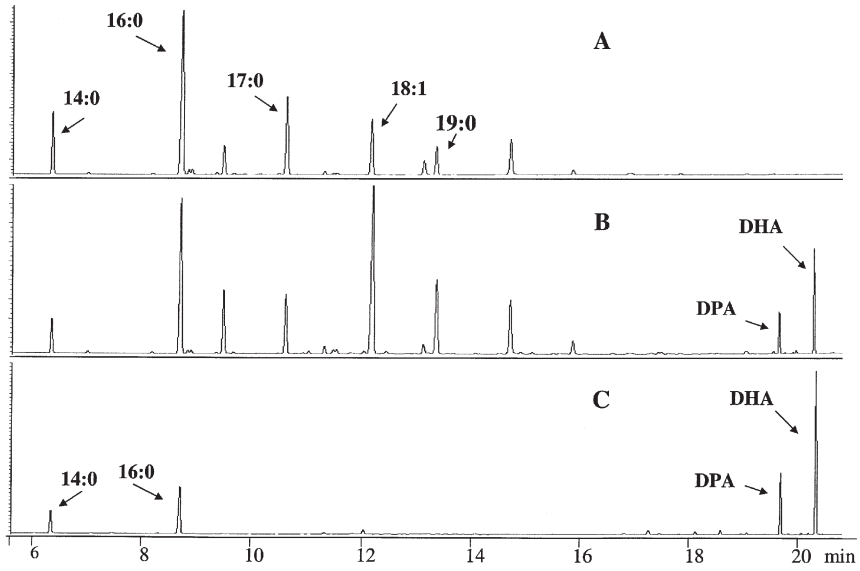

FIG. 3. GC profiles of FAMEs prepared from the following: A) control *E. coli*; B) *E. coli* expressing Orfs A, B, and C of the *Schizochytrium* PUFA synthase plus HetI; and C) oil extracted from *Schizochytrium*. The horizontal axis represents retention time on the column, and the vertical axis the relative response signal of the detector. Identities of the labeled FAME peaks have been confirmed by GC-MS. The 18:1 peak is *cis*-vaccenic acid. The *Schizochytrium* oil FAME profile is shown for comparison to the novel fatty acids produced in the *E. coli* expressing the *Schizochytrium* PUFA synthase system.

expression of *Schizochytrium's* Orfs A, B, and C, along with either HetI or sfp—under several conditions—resulted in the accumulation of DHA and DPA in those cells. The highest level of PUFA (DHA plus DPA), often representing greater than 10% by weight of the total FAME, was found in cells with HetI grown at 32°C in 765 medium supplemented with 10% (wt/vol) glycerol (Fig. 3B). In all of the experiments in which the two PPTases, sfp and HetI, were compared, significantly more DHA and DPA accumulated in the cells containing HetI than in cells containing sfp. SDS-PAGE analysis suggested approximately equivalent amounts of the proteins were being produced, but we did not attempt further analysis of the relative enzyme activities. Fig. 3C shows a typical GC separation of FAMEs prepared from purified *Schizochytrium* oil. There are four prominent peaks in the chromatogram, representing C14:0, C16:0, DPA, and DHA. The ratio of DHA to DPA observed in *E. coli* expressing this PUFA synthase system is about 2.3 to 1. This approximates that of the endogenous DHA and DPA production observed in *Schizochytrium* itself.

Cerulenin differentially affects fatty acid synthesis in Schizochytrium. Rapidly growing cells were treated with various amounts of the β-ketoacyl-ACP synthase inhibitor, cerulenin, for ten minutes prior to the addition of and incubation with ^{14}C-labeled acetate. Radiolabeled fatty acids present in those cells were converted to FAMEs, separated by TLC, and quantitated using a phosphorimaging system. Three major bands, identified as DHA, DPA, and short-chain-saturated (C16:0 and C14:0) FAMEs, were evident in the image, and all were affected by the cerulenin at some concentration. The inhibitor affected incorporation of labeled acetate into DHA and DPA equally and required high concentrations (>5 μM), while labeling of the short-chain-saturated fatty acids was blocked at lower concentrations (Fig. 4). In some cases, for example, at 5, 10, 25, and 50 μM, there is significant labeling of the PUFAs, while labeling of the short-chain saturates has been severely inhibited. The results indicate a separate pathway for synthesis

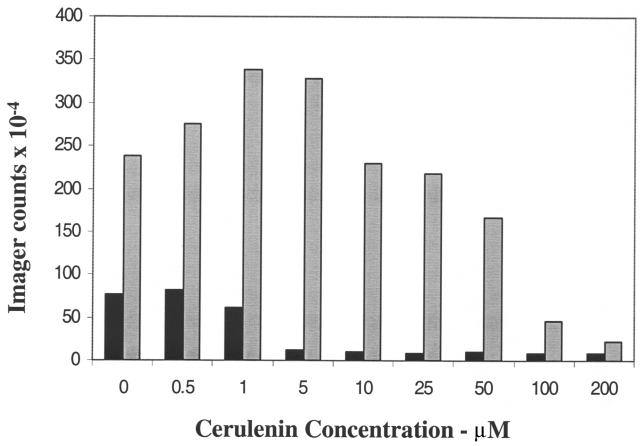

FIG. 4. Relative incorporation of radioactivity into PUFAs (DHA plus DPA - grey bars) or short-chain saturated fatty acids (C14:0 plus C16:0 - black bars) from ^{14}C acetate by *Schizochytrium* cells preincubated with various concentrations of the FAS inhibitor, cerulenin. Imager counts are values in equal-sized areas of the phosphorimager data collected from a scan of a TLC plate on which FAMEs derived from the cells were separated.

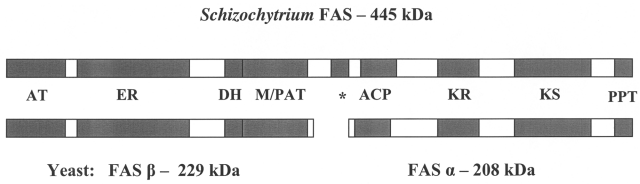

FIG. 5. The apparent domain organization of the *Schizochytrium* FAS (all on a single protein) with that of *Saccharomyces cerevisiae* FAS (domains distributed on the β and α subunits). Relative sizes of the domains reflect the results of Pfam profiling. Domain indicators refer to both *Schizochytrium* and yeast FAS proteins. The * indicates the location in the *Schizochytrium* FAS of a putative ACP domain not present in the yeast FAS. The following are abbreviations used: AT, acetyltransacylase; ER enoyl-reductase; DH, dehydratase; M/PAT, malonyl/palmitoyl transacylase; ACP, acyl carrier protein; KR, β-ketoacyl reductase; KS, β-ketoacyl synthase; PPT, phosphopantetheinyl transferase.

of the two major types of fatty acids that accumulate in *Schizochytrium*.

Cloning of the gene encoding the Schizochytrium FAS. Homologs of bacterial PUFA synthase genes were initially detected in *Schizochytrium* by analysis of sequences obtained from randomly picked cDNA library clones (1). Further analysis of the cDNA library identified many sequences (43 out of approximately 8,500) that showed homology to proteins of FAS systems. The best matches were, in most cases, to the FAS subunits of fungal organisms. Using the sequence tags as a guide, we cloned the corresponding regions of genomic DNA encoding those cDNA-derived sequences. A single large Orf was found in the genome that contained all of the EST sequences. The *Schizochytrium* FAS Orf contains 12,408 bp and encodes a protein with a deduced molecular mass of 444,884 Daltons. No evidence for introns could be found, either by analysis of the genomic sequence itself or by comparison to available cDNA sequences. Blast and Pfam results plus motif analyses were used to establish a preliminary structure and functional identification of the domains of this Type I protein. Both in terms of amino acid sequence and in the sequential organization, the *Schizochytrium* FAS resembles a fusion of the head (N-terminus) of the fungal FAS α subunit to the tail (C-terminus) of the β subunit (Fig. 5, the well-characterized *Saccharomyces cerevisiae* FAS shown for comparison). This similarity includes regions corresponding to an acetyltransferase initiation domain, a malonyl/palmitoyl acyltransferase domain, and a terminal PPTase domain. One other difference is the presence of what may be a second ACP domain at the fusion junction.

DISCUSSION

Schizochytrium sp. is a member of the Thraustochytrids, a group of marine microorganisms taxonomically related to the heterokont algae (25). Organisms of this group have attracted attention recently due to their ability to produce large amounts of oil enriched in DHA (11). Additionally, several genes encoding key enzymes of the standard pathway of PUFA synthesis, including a Δ-4 desaturase, have been cloned from the Thraustochytrid species closely related to *Schizochytrium* (26). It was somewhat surprising, therefore, that homologs of PUFA synthase genes, previously identified only in marine bacteria were found in *Schizochytrium*. Although there are some differences between the bacterial systems and the one found in *Schizochytrium*, all of the domains known to be required for PUFA synthesis in bacteria have been identified (1). One scenario that could account for the appearance of these genes in this eukaryote is a lateral gene transfer from the bacteria. Thraustochytrids are known to be phagocytotic; bacteria can be used as a food source, and this may have facilitated such a process. The isolation of genes encoding enzymes involved in the synthesis of LC-PUFA from shorter-chain, less unsaturated fatty acid precursors suggests that Thraustochytrids are, or were, capable of DHA synthesis via that pathway. When cultures of *Schizochytrium* sp. were supplied with radiolabeled 16:0, 18:1, or 18:3 fatty acids, none of the label appeared in LC-PUFA (1), indicating that at least some elements of the standard pathway have been lost in this particular organism. As more Thraustochytrids are studied, research may reveal a range of expression of these distinct LC-PUFA synthesis pathways.

The PUFA synthases characterized in marine bacteria appear to produce predominantly a single product: either EPA or DHA. In contrast, the *Schizochytrium* fatty acid profile contains significant amounts of two LC-PUFA: DHA and DPA (Fig. 3C). Based on the lack of evidence for more than one set of PUFA synthase genes, we predicted that both fatty acids would be the product of one enzyme system. This prediction was confirmed by the accumulation of both DHA and DPA in *E. coli* expressing the *Schizochytrium* genes (Fig. 3B).

The PPTases present in *E. coli* are apparently unable to modify the apo-ACP domains of the PUFA synthases. It is now recognized that the detection by Yazawa of EPA in *E. coli* transformed with a genomic fragment of *Shewanella* SCR2738 DNA was made possible because the gene encoding that PUFA-synthase-specific PPTase was also present on the fragment (15, 16). We have not identified a gene in *Schizochytrium* that encodes a PUFA-synthase-specific PPTase. While the *Shewanella* PPTase has been shown to activate other PUFA synthase enzymes (16), the psychrophilic nature of that organism suggested it might not be appropriate for our purposes. The nitrogen-fixing cyanobacterium, *Nostoc* PCC7120 (formerly called *Anabaena*), grows well at relatively high temperatures (e.g., 30ºC) and contains a cluster of genes associated with the synthesis of a long-chain hydroxyl-fatty acid that forms part of an oxygen-excluding glycolipid layer of the heterocysts (21). Many of the domains present in the proteins encoded by these genes, including 2 ACP domains, are highly homologous to those of PUFA synthases. The *hetI* gene, encoding a presumed PPTase, is adjacent to this fatty acid synthesis cluster. As in the case of the *Shewanella* PPTase, it is not clear from the nucleotide sequence what the endogenous start codon is for *hetI*. We found that an active enzyme could be produced by replacing the first potential alternative (bacterial) start codon in the HetI Orf with an ATG in an expression construct. HetI, like sfp, may have utility in activating ACP domains of a variety of PKS

systems in addition to those of the PUFA synthases when they are expressed in heterologous hosts.

While it is clear that the LC-PUFAs in *Schizochytrium* are the products of a PUFA synthase, little is known about the source of the short-chain saturated fatty acids (C16:0 and C14:0) that are also prominent components of the TAG fraction. To our knowledge, no characterization of FAS systems in Thraustochytrids has been published by others. Cerulenin is a fungal antibiotic that irreversibly inhibits β-ketoacyl-ACP synthases (KAS) of FAS systems (27). The sensitivity of specific KAS enzymes to this antibiotic varies widely. Cerulenin has been used to enhance PUFA accumulation in marine bacteria that contain PUFA synthase systems (28), presumably by selectively inhibiting the Type II FAS in those bacteria. The differential effect of cerulenin on incorporation of ^{14}C-acetate into short-chain fatty acids versus PUFA in whole cells of *Schizochytrium* (Fig. 4) confirmed our expectation that these fatty acids are products of separate pathways. EST data suggested the presence of a Type I FAS in *Schizochytrium*. In all cases, the best matches to the EST sequences were to FAS proteins found in fungi. In these organisms the Type I FAS is composed of two subunits (α and β), each carrying a distinct set of enzymatic domains (29). In contrast, we found that the *Schizochytrium* FAS contains all of these domains on one large protein. Animal FASs contain all of their catalytic domains on one large protein, but the domain arrangement and both the loading and termination mechanisms differ from that found in the fungal FAS (29). As was the case for the PUFA synthase, the EST data indicate that there is a single copy of the FAS gene in *Schizochytrium* and that messages derived from that gene are highly expressed in oil-producing cells.

In summary, our data confirm that the DHA and DPA present in the oil of *Schizochytrium* are the products of a single PUFA synthase enzyme. It is likely, though yet to be confirmed by detailed molecular analyses, that the genes encoding this enzyme were acquired at some time in the past from an LC–PUFA-producing marine bacterium. The data suggest that the two short-chain saturated fatty acids (C14:0 and C16:0) that are the other major components of the *Schizochytrium* oil, are the products of an FAS enzyme encoded by the gene we have cloned and characterized. The FAS encoded by this gene shows strong resemblance to many other fungal FAS proteins, but has the unique feature of having all of its domains present on one large protein.

Different Kinetic in Incorporation and Depletion of n-3 Fatty Acids in Erythrocytes and Leukocytes of Mice

H. Mu*, R.L. Thøgersen, K. Maaetoft-Udsen, E.M. Straarup, H. Frøkiær

BioCentrum-DTU, Technical University of Denmark, 2800 Lyngby, Denmark

ABSTRACT: n-3 PUFA are well known for their anti-inflammatory effects. However, there has been only limited study on the kinetics of incorporation and depletion of n-3 PUFA in immune cells. In the present study we investigated the incorporation and depletion of n-3 PUFA in erythrocytes and leukocytes in mice during a 6-wk feeding period. Over the first 3-wk period (the incorporation period) the mice were fed a special diet with a high n-3/n-6 PUFA ratio. In the following 3-wk period (the depletion period) the mice were fed a standard chow diet. A linear increase of the concentration of EPA and DHA in erythrocyte membranes was observed during the incorporation period, whereas a stagnation was observed after the second week for leukocytes. The level of EPA did not fall to the background level after the depletion period, and the level of DHA was kept almost constant during the depletion period in the erythrocyte membranes. In leukocytes the concentration of both EPA and DHA decreased during the depletion period, but did not reach the background level after the 3-wk depletion. In conclusion, the kinetics of EPA and DHA in the different cells are different. The rate of incorporation is faster than that of depletion for n-3 PUFA. More n-3 PUFA can be incorporated into leukocytes in comparison with erythrocytes. The ratio of n-3/n-6 PUFA is more important than the amount of n-3 FA in changing the FA compositions of membrane lipids.

Paper no. L10026 in *Lipids 41*, 749–752 (August 2006).

Fatty fish contain high concentrations of long-chain n-3 PUFA such as EPA (20:5n-3) and DHA (22:6n-3). A high intake of these FA has been correlated with beneficial healthy effects such as reduced risk of coronary heart disease (1,2) and decreased inflammation in rheumatoid arthritis (3). The concentration of both n-3 PUFA (DHA and EPA) and the n-6 PUFA arachidonic acid (AA, 20:4n-6) and linoleic acid (LA,18:2n-6) of erythrocyte phospholipids have been suggested to be the best markers of n-3 PUFA intake (4).

Animal feeding experiments have been widely used in biochemical and nutritional studies of n-3 PUFA. Even though there are many reports about tissue FA changes in response to dietary enrichment with n-3 PUFA (2,5,6), only limited information about the kinetics of incorporation and depletion of n-3 PUFA in immune cells existed in the literature (7,8). In the present study, we investigated the kinetics for incorporation and depletion of n-3 PUFA in both erythrocytes and leukocytes in mice. The results of this study contribute to a better understanding of lipid metabolism, and may also have potential implications for clinical nutrition.

Abbreviations: AA, arachidonic acid; LA, linoleic acid.

MATERIALS AND METHODS

Animals, diets and experimental design. The experiment was approved by The Danish National Committee for Animal Experiments and conducted with 8-wk-old BALB/c female mice (Taconic M&B, Lyngby, Denmark). The mice were housed in polyethylene cages in a temperature (21 ± 3ºC) and humidity (50 ± 15%) controlled room with a 12-h day-night rhythm at arrival. Thirty-six mice were randomly assigned into nine experimental groups with four mice in each group: three control groups on standard chow (Altromin 1324, Chr. Petersen A/S, Ringsted, Denmark), and six groups on special diet. The overall composition of the special diet was as follows (wt%): 56% maize-starch (Bestfoods Nordic A/S, Skovlunde, Denmark), 4% fat, 20% casein (Miprodan milkproteins, MD Foods, Viby, Denmark), 10% sucrose (Danisco Sugar, Copenhagen, Denmark), 5% salt mixture (including trace elements), 4% cellulose powder (MN 100, Frisenette ApS, Ebeltoft, Denmark), 0.5% choline chloride (Merck, Darmstadt, Germany), and 0.5% vitamin mixture (Aaes-Jørgensen and Hølmer). The control diet was Altromin (1324, Chr. Petersen, Ringsted, Denmark), which also contained 4% fat. The FA composition of each of the diets is listed in Table 1. The ratio of n-3/n-6 PUFA was 2.4 for the special feed, in which EPA and DHA constituted 2.2% and 3.5% of total FA, respectively, whereas the ratio was 0.2 for chow, in which EPA and DHA constituted 1.0% and 2.2% of total FA, respectively. During the first 3 wk the mice were fed on the two different diets (chow or n-3 diet); afterward they all ate the standard chow. Each week a group was sacrificed to study the incorporation or depletion of n-3 PUFA. The three control groups were sacrificed in the first week (week 0) and at week 3 and week 6. At the end of the experimental period the mice were killed, and blood was collected by cardiac puncture with a syringe containing EDTA. The spleen and mesenteric lymph nodes were dissected.

Analysis of membrane lipids from erythrocytes. The EDTA-blood was centrifuged, and the erythrocytes were separated and washed with physiological saline after hemolysis in redistilled water (9). The membrane phospholipids were extracted and methylated as described previously (10). FAME were separated and quantified by GC (Hewlett-Packard Inc., Waldbronn, Germany) using the reported program (10). FAME were identified by comparing their retention times with those of standards (NU-Check-Prep Inc., Elysian, MN).

Analysis of phospholipids of leukocytes from the spleen and mesenteric lymph nodes. The spleen and mesenteric lymph nodes were removed aseptically and transferred to separate petri dishes containing sterile PBS. The spleen was mashed to free the cells from the tissue with the temple of a 1-mL syringe. The cell suspension was transferred to a 50-mL centrifugation glass. The same procedure was followed for the lymph nodes. The suspensions were centrifuged, and the supernatant was removed from the cells. The cells were incubated on ice for 5 min after adding 10 mL of 0.83% NH_4Cl. Then 30 mL of PBS was added, the supernatant was removed after centrifugation, and 2.5 mL of PBS was added to the cells. After transferring the solution to glass tubes and centrifuging, lipids were extracted from the pellet using the method mentioned above after adding the internal standard PC 15:0. The lipid extracts were separated by TLC, and phospholipids were scraped off and extracted. After methylation, the FAME were analyzed by GC.

Statistical analysis. Results are presented as means ± SD. Statistical analysis was performed using GraphPad PRISM version 3.02 (GraphPad software, San Diego, CA). Data were analyzed by one-way and two-way ANOVA. Differences were considered significant at $P < 0.05$.

RESULTS

Incorporation and depletion of PUFA in erythrocyte membranes. The composition of selected FA in erythrocyte membranes during the incorporation and depletion periods is shown in Table 2. The concentrations of EPA, DHA, and total n-3 FA

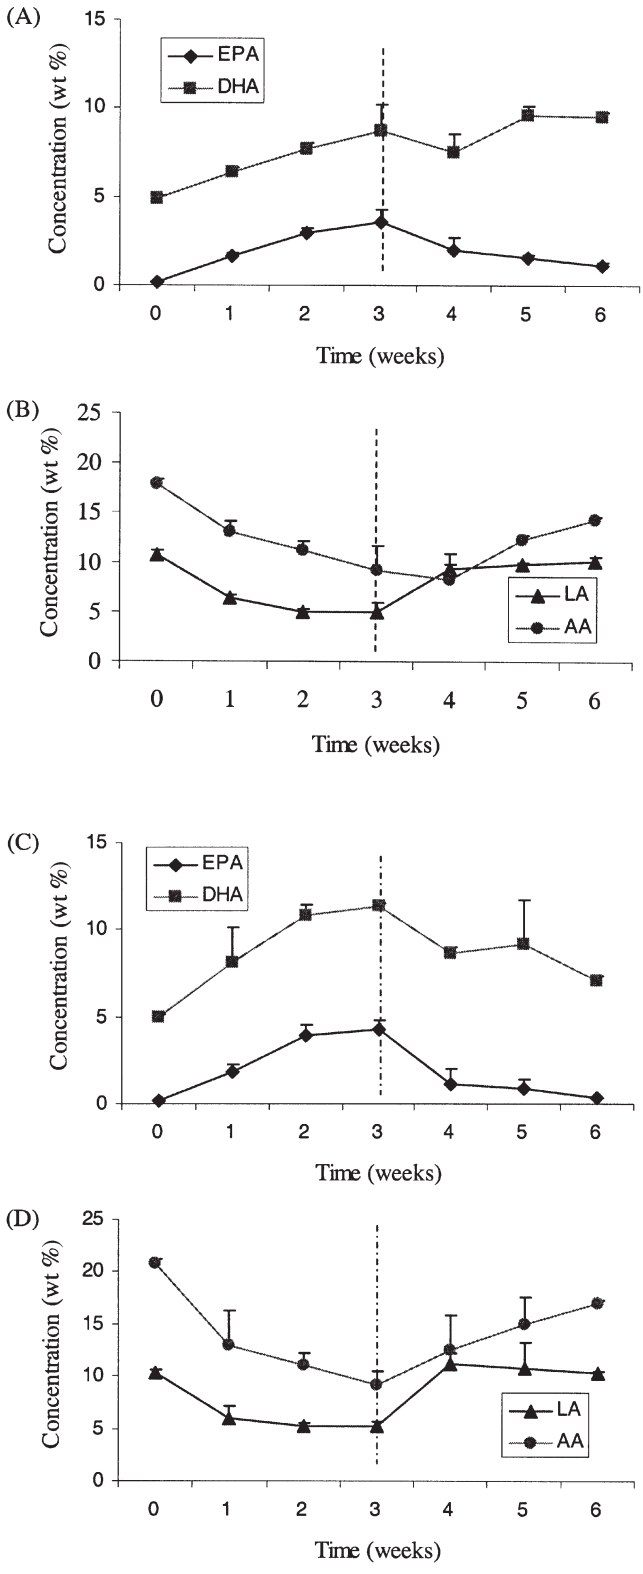

FIG. 1. The concentrations of (A) EPA and DHA in erythrocyte membrane lipids, (B) LA and AA in erythrocyte membrane lipids, (C) EPA and DHA in spleen leukocyte phospholipids, and (D) LA and AA in spleen leukocyte phospholipids, as a function of time. Values are shown for experimental groups fed special diet for the first 3 wk, then standard chow for the last 3 wk. Values are means + SD, $n = 4$.

[a]Values are means ± SD, $n = 4$. Values in the same row with no superscript letter in common are significantly different ($P < 0.05$).

increased linearly during the incorporation period (Fig. 1a). During the 3-wk depletion period, however, the concentration of DHA remained almost constant. The concentration of EPA decreased significantly during the first week of depletion, followed by slow but continued reduction during the next 2 wk. The level of EPA was still significantly higher than the background level after 3 wk of depletion.

The concentrations of AA and LA declined throughout the incorporation period, and the level of LA changed very fast with changes of dietary lipids (Fig. 1b). In both cases, there was no significant difference between week 2 and week 3. During the depletion period, the concentration of n-6 PUFA increased; LA increased during the first week and already reached the background level after 1 wk, whereas AA increased after the first week and did not reach the background level after 3 wk.

Incorporation and depletion of PUFA in phospholipids of spleen and lymph leukocyte. We studied the FA of phospholipids from both spleen leukocytes and mesenteric lymph leukocytes during the whole feeding period. The composition of selected FA of phospholipids from spleen leukocytes during the whole feeding period is listed in Table 3. Both EPA and DHA of phospholipids from spleen leukocytes increased as a function of feeding time during the first 3 wk (Fig. 1c). Similar results were obtained for lymph node leukocytes (data not shown). Dissimilar to the erythrocyte phospholipids, the concentration of both EPA and DHA decreased during the depletion period, with the most significant decrease during the first week, but they did not reach the level measured at the beginning of the feeding period.

The concentration of both AA and LA declined during the first 3 wk, and increased again after changing back to the normal chow diet (Fig. 1d).

DISCUSSION

The ratio of n-3/n-6 PUFA in both erythrocyte and leukocyte was similar to that in the chow when the feeding experiment was started. Even though the concentrations of EPA and DHA of the special feed were only 2 and 1.5 times, respectively, higher than that in the chow, the ratio of n-3/n-6 PUFA in the special feed was 10 times higher than that in the chow because of the high concentration of LA in the chow. Therefore the significant increase of EPA and DHA in both erythrocytes and leukocytes indicates that the ratio of n-3/n-6 PUFA is more important than the absolute amount of n-3 FA.

The ratio of n-3/n-6 PUFA in both erythrocyte and leukocyte increased when mice got the special feed. However, the incorporation of EPA and DHA in erythrocytes was different from that in leukocytes. Because of the linear increase in the incorporation of EPA and DHA into erythrocytes (Fig. 1), one may expect that more EPA and DHA will be incorporated into erythrocytes if the mice get the special diet for a longer period, corresponding to the relative long lifespan of erythrocytes (3 mon). The concentrations of AA and LA in erythrocytes changed in the opposite ways

in the erythrocytes, reflecting the metabolic competition between both PUFA families.

Yaqoob *et al.* (11) studied plasma phospholipids and blood mononuclear cell FA composition of people taking fish oil capsules for 12 wk, and they found that the concentration of EPA and DHA in both plasma phospholipids and mononuclear cell lipids reached the highest level at week 4, and there was no significant differences during the following 8 wk. There was no information about how the FA composition changed during the first 4 wk in their study. In the present study we found that the concentration of EPA and DHA in leukocyte phospholipids also increased linearly in the first 2 wk; thereafter a slower incorporation was observed in mice. This could be due to the fast turnover time of leukocytes in comparison with erythrocytes. These results may have important implications for clinical nutrition, in addition to contributing to a better understanding of lipid metabolism.

In conclusion, the present study shows that dietary lipids strongly influence the FA composition of erythrocyte membranes and leukocyte phospholipids in mice, but the incorporation rate of n-3 FA in erythrocytes and leukocytes are different. The rate of incorporation is faster than that of depletion for n-3 PUFA. More n-3 PUFA can be incorporated into leukocytes in comparison with erythrocytes. The ratio of n-3/n-6 PUFA is more important than the amount of n-3 FA in changing the FA compositions of membrane lipids, but more study is required to support this conclusion.

ABSTRACT: During adult life athymic (nude) male mice display not only a severe T-cell–related immunodeficiency but also endocrine imbalances and a moderate hyperglycemia. We studied the impact of congenital athymia on hepatic lipid composition and also assessed the ability of neonatal thymulin gene therapy to prevent the effects of athymia. We constructed a recombinant adenoviral vector, RAd-metFTS, expressing a synthetic DNA sequence encoding met-FTS, an analog of the thymic peptide facteur thymique sérique (FTS), whose Zn-bound biologically active form is known as thymulin. On postnatal day 1–2 homozygous (nu/nu) nude and heterozygous (nu/+) mice were injected with 10^8 pfu of RAd-metFTS or RAd-βgal (control vector) intramuscularly. The animals were processed at 52 d of age. Serum thymulin, glycemia, hepatic phospholipid FA composition and free and esterified cholesterol were determined. Adult homozygous male nudes were significantly ($P < 0.01$) hyperglycemic when compared with their heterozygous counterparts (2.04 vs. 1.40 g/L, respectively). The relative percentage of 16:0, 18:1n-9, and 18:1n-7 FA was lower, whereas that of 18:0, 20:4n-6, and 22:6n-3 FA was higher, in hepatic phospholipid (PL) of nu/nu animals as compared with their nu/+ counterparts. Some of these alterations, such as that in the relative content of 22:6n-3 in liver PL and the unsaturation index, were completely or partially prevented by neonatal thymulin gene therapy. We conclude that the thymus influences lipid metabolism and that thymulin is involved in this modulatory activity.

Paper no. L10045 in *Lipids 41*, 753–757 (August 2006).

During adult life, congenitally athymic (nude) mice display, in addition to a severe immunodeficiency, multiple endocrine alterations (1–4) that are reflected by deficits in some hormone-dependent functions such as reproduction (5,6). There is evidence that these hormone-dependent functional alterations may also include glucose homeostasis. Thus, it has been reported that after 1 mon of age, nude BALB/c mice develop spontaneous hyperglycemia and impaired glucose tolerance (7,8). Furthermore, these animals show peripheral insulin insensitivity with normal pancreatic β-cell reserve and normal lean body mass (9). Assessment of pancreatic islet cell populations in hyperglycemic nudes revealed an increase in the D-cell (somatostatin-producing) population. Also, somatostatin content in pancreatic tissue was higher in the athymic nudes as compared with heterozygous sex- and age-matched counterparts (10). Adult thymectomy in Wistar rats was reported to increase circulating insulin levels without significant changes in blood glucose (11).

Although we are unaware of documented studies characterizing lipid metabolism in athymic nude mice as compared with heterozygous counterparts, there are studies pointing to a modulatory activity of thymic factors on lipid metabolism. A thymic protein factor was reported to reduce serum cholesterol levels in rats, increase LDL catabolism, and inhibit the activity of hepatic HMG-CoA reductase, the rate-limiting enzyme in cholesterol synthesis (12–14).

In the present study we document that adult athymic nude mice display a number of differences in hepatic lipid composition relative to heterozygous counterparts. We also report that implementation of neonatal gene therapy with a synthetic gene for the thymic metallopeptide thymulin prevents the emergence of some of these differences in adult athymic nudes.

MATERIALS AND METHODS

Adenoviral vector RAd-metFTS. We constructed a DNA sequence, 5'-ATGCAAGCCAAATCTCAAGGTGG-ATCCAA-CTAGTAG-3', coding for the peptide met-QAKSQGGSN (met-FTS), an analog of the thymic peptide facteur thymique sérique (FTS), whose biologically active form is called thymulin. Here, this DNA sequence is referred to as synthetic gene for thymulin. Subsequently, a recombinant adenoviral (RAd) vector harboring the synthetic gene for thymulin was constructed by a variant of the two-plasmid method (15) employing the AdMax® plasmid kit (Microbix, Hamilton, Canada) as previously described (16). The newly generated vector, termed RAd-metFTS, had the met-FTS synthetic gene under the control of the mouse cytomegalovirus promoter (Fig. 1). The virus was rescued from HEK293 cell lysates and it was plaque purified. The virus was further purified by ultracentrifugation in CsCl gradient. Final virus stocks were titrated by a serial dilution plaque assay.

Abbreviations: FTS, facteur thymique sérique; GH, growth hormone; LH, luteinizing hormone; pfu, plaque-forming units; PL, phospholipid; PRL, prolactin; RAd, recombinant adenovirus; TSH, thyrotropin; Tx, thymectomized;

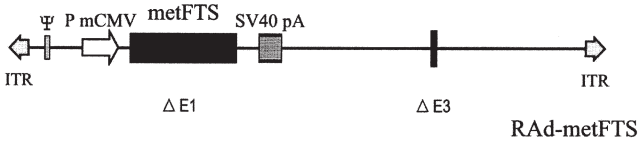

FIG. 1. Diagrammatic representation of the RAd-metFTS vector. PmCMV, mouse cytomegalovirus promoter; metFTS, synthetic gene for met-FTS; frt, recognition element for the yeast FLP recombinase; ITR, inverted terminal repeat; ΔE1 and ΔE3, deletions in the Ad5 genome; SV40, simian virus 40 polyadenylation signal; Ψ, packaging signal.

RAd-βgal (control vector). This RAd was kindly provided by Dr. Michel Perricaudet, Institut Gustave Roussy, CNRS, Villejuif, France. In this vector, the E1 genomic region has been replaced by an expression cassette containing the *E. coli* lac Z reporter gene under the control of the Rous sarcoma virus long terminal repeat. The vector was expanded in HEK 293 cells and purified and titrated as indicated for RAd-FTS.

Animals and in vivo procedures. The male offspring from NIH homozygous (nu/nu) nude male and heterozygous (nu/+) female mice were used in the present study. All mice were maintained on a γ-irradiated chow diet and sterilized water. Animals had free access to food and water and were kept at 22ºC with a light/dark cycle of 12/12 h. All experiments on animals were done in conformity with the Guidelines on Handling and Training of Laboratory Animals published by the Universities Federation for Animal Welfare (17).

At postnatal day 1 or 2, each pup received a single bilateral intramuscular (hindlegs) injection of 10^8 plaque-forming units (pfu) RAd-metFTS or RAd-βgal in 10 µL PBS (5 µL per side). At 5–6 d of age heterozygous and homozygous pups could be easily identified by the presence of absence of hair, respectively. Pups of both phenotypes were kept together in each litter. On postnatal day 51–52 mice were bled from the retroorbital plexus and immediately sacrificed by cervical dislocation. Livers were removed and processed as indicated below.

Lipid extraction and analysis. Plasma glucose concentration was determined by the glucose oxidase method. Hepatic lipids were extracted with chloroform/methanol (2:1 vol/vol) (18). An aliquot was used to separate and quantitate free and esterified cholesterol by TLC as described elsewhere (19). The PL fraction was separated from the rest of the organic phase by a microcolumn chromatography method described by Hannahan *et al.* (20). Lipid phosphorous (21) was determined. FAME from PL were prepared by methylation with BF_3/methanol according to the method of Morrison and Smith (22). The analyses were performed using a Shimadzu 9A gas chromatograph (Tokyo, Japan) fitted with a Omegawax 250 fused-silica column, 30 m × 0.25 mm, with 0.25 µm phase (Supelco, Bellafonte, PA). After 1 min initial hold, the oven temperature was programmed to increase from 185 to 220°C at 3°C/min. Peaks were identified by comparing the retention times with those from a mixture of methyl ester standards (Sigma Chemical Co., St. Louis, MO).

Thymulin bioassay. Biologically active thymulin was measured in serum by a rosette bioassay described in detail elsewhere (23). This method is based on the ability of thymulin to restore the inhibitory effect of azathioprine on rosette formation in spleen cells from thymectomized (Tx) mice. The inhibitory activity of samples was compared with that of a standard curve using synthetic thymulin (a kind gift of Dr. Peter Heinklein, Humboldt University, Berlin, Germany). Serum values were expressed as fg/mL bioactive thymulin.

Statistical analysis. Statistical analyses were performed by means of ANOVA using GB-STAT Professional Statistics and Graphics Version 4.0 (Dynamic Microsystems Inc., Silver Springs, MD). The Tukey t-test was used for comparisons between means. Statistical significance was assigned to $P < 0.05$.

RESULTS

Effects of congenital athymia on plasma levels of glucose. As expected, 3-mon-old congenitally athymic nude mice showed a significant ($P < 0.01$) hyperglycemia. Thus, nu/+ and nu/nu mice (10 animals per group) had a glycemia of 1.40 ± 0.18 and 2.04 ± 0.63 (g/L; mean ± SD), respectively.

Restorative effect of thymulin gene therapy on serum thymulin in nude mice. Neonatal intramuscular injection of RAd-metFTS, but not RAd-βgal, increased the circulating levels of biologically active thymulin in both heterozygous and homozygous nude mice tested at 51–52 d of age (Table 1). At 13 d of age the RAd-metFTS-treated mice already had increased serum thymulin levels (Table 1). In adult mice, thymectomized (Tx) after puberty, and which have undetectable levels of serum thymulin, intramuscular injection of RAd-βgal failed to induce detectable serum thymulin levels, whereas Tx animals injected with RAd-metFTS showed a progressive increase in serum thymulin (data not shown). However, lipid changes were not studied in Tx because Tx

TABLE 1
Effect of Neonatal RAd-metFTS Intramuscular Injection on Serum Levels of Thymulin in Heterozygous and Homozygous Nude Mice[a]

performed in adult rodents has no immune or endocrine consequences, and therefore changes in liver lipid profiles are unlikely. On the other hand neonatal Tx in mice is associated with a high mortality.

Effect of thymulin gene therapy on hepatic lipid composition in nude mice. FA composition of PL from nu/nu and nu/+ livers are shown in Table 2. Significant differences were observed in palmitoleic (16:1n-7), oleic (18:1n-9), vaccenic (18:1n-7), stearic (18:0), arachidonic (20:4n-6), and docosahexaenoic (22:6n-3) acids.

The relative percentage of 16:0, 18:1n-9, and 18:1n-7 was lower, whereas that of 18:0, 20:4n-6, and 22:6n-3 was higher, in hepatic phospholipid of nu/nu animals as compared with nu/+ counterparts. The higher percentage of arachidonic and docosahexaenoic acid accounted for the higher unsaturation index (UI) found in nu/nu mice relative to heterozygous animals (Table 2).

The content of monounsaturated and saturated FA was unaffected by thymulin gene therapy, but the treatment prevented the increase of 20:4 and 22:6 observed in the control nudes relative to control heterozygous counterparts. The changes induced by athymia in the UI were also prevented by neonatal thymulin gene therapy. Other less abundant (<0.6%) FA were detected in our study, but none of them was significantly affected by athymia or thymulin gene therapy (data not shown). Although neither congenital athymia nor thymulin gene therapy significantly affected free, esterified, and total liver cholesterol or PL:cholesterol ratio, near significant differences were observed in some cases (Fig. 2).

DISCUSSION

The present results confirm previous studies reporting that adult nude mice develop a moderate hyperglycemia (7,8). Our data additionally document, for the first time to our knowledge,

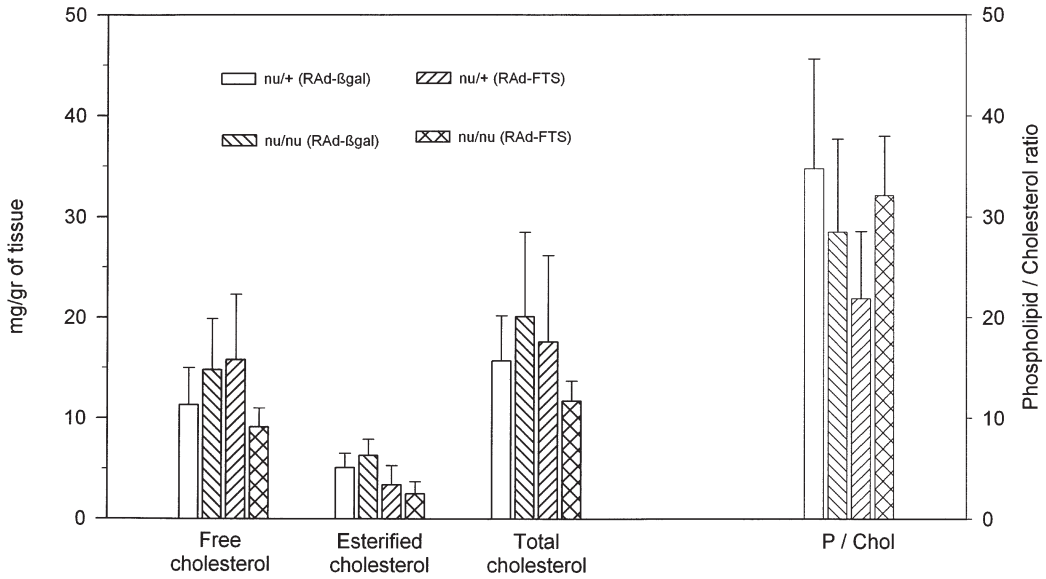

FIG. 2. Effect of thymulin gene therapy on hepatic cholesterol composition in nude mice. Male 51–52-d-old mice were used. Data are expressed as mean ± SD. Although no significant differences were found among groups, trends toward a difference were detected for some of the parameters studied.

that adult male nudes have a number of alterations in their hepatic FA composition profiles. Because the biosynthesis of polyenoic acids is largely modified by a wide variety of hormonal conditions (24,25) and congenital athymia is associated with alterations in the balance of several hormones (6,26), our finding of altered FA composition of PL in the liver of nude mice was not unexpected. On the other hand, liver cholesterol metabolism does not seem to be affected by athymia, although this might not be completely so in view of the trend toward a change observed for athymic mice for some of the cholesterol variables measured.

The ability of neonatal thymulin gene therapy to prevent some of the changes induced by athymia in hepatic FA composition of PL may be explained by a possible restorative activity of thymulin on the endocrine balance. This hypothesis is supported by the evidence showing that athymia and thymulin administration have opposite effects. Thus, congenital athymia is associated with reduced levels of circulating and pituitary gonadotropins in female nude mice (6), whereas in male nudes thyrotropin (TSH), prolactin (PRL), growth hormone (GH), and gonadotropin responses to immobilization and cold stress are reduced, as are serum basal levels of the same hormones (2–4). Conversely, thymulin has been shown to stimulate luteinizing hormone (LH) release from perifused rat pituitaries (27) and corticotropin release from incubated rat pituitary fragments (28). Thymulin also stimulates gonadotropin, PRL, TSH, and GH release in dispersed rat pituitary cells at doses ranging from 10^{-8} to 10^{-5} M, an effect that declines with the age of the pituitary donors (29–31).

Although a direct effect of thymulin at hepatic level cannot be ruled out, in pilot studies (unpublished) in which A549 cell cultures were exposed to different doses of synthetic thymulin, we could not detect significant changes of FA composition in total PL. It should be also mentioned that although there are no documented studies on the effect of thymulin on lymphocyte lipid composition, it is not unlikely that thymulin may modulate, by a direct action, lipid metabolism in thymulin-responsive T-lymphocytes.

Considering that liver desaturases are sensitive to endocrine factors (25), the possibility exists that thymulin may have a modulatory action (direct or indirect) on the activity and/or expression of these enzymes.

Our results also indicate that although some of the changes induced by athymia in hepatic FA composition are prevented by thymulin gene therapy, others are not. The former case corresponds to the relative content of 22:6n-3 in liver PL and UI, whereas the latter case corresponds to the relative content of 16:1 and 18:0. In general, treatment of heterozygous nudes with RAd-metFTS did not affect hepatic FA composition despite the fact that the viral vector significantly increased serum thymulin levels in both homozygous and heterozygous nudes. This observation suggests that thymulin may act as a permissive molecule that allows an optimal performance of primary effectors on lipid metabolism and/or the endocrine balance.

The present results point to the thymus as an organ that, acting during early life, influences lipid metabolism in adult life, and also to thymulin as a mediator of part of this modulatory activity.

Intrasample Variability of Intramyocellular Triacylglycerol

Lianzhen Zhou and ZengKui Guo*

Endocrine Research Unit, Mayo Foundation, Rochester, Minnesota 55905

ABSTRACT: Intrasample variability of intramyocellular triacylglycerol (imcTG) in the skeletal muscle of rats has been examined. Aliquoting after homogenization of muscle samples reduced imcTG variability considerably compared with aliquoting before homogenization. The results suggested that skeletal muscle samples be homogenized before aliquoting in order to reduce imcTG variability.

Paper no. L10044 in *Lipids 41*, 759–761 (August 2006).

Intramyocellular triacylglycerol (imcTG) is an indispensable energy source for muscle work (1). Measuring imcTG has been used as a means to quantify the utilization of imcTG, but there is a high degree of difficulty in detecting changes in imcTG pool size. Thus, imcTG utilization remains controversial (2). The difficulty is mainly contributed by the inherently high variability of imcTG content itself (3–6). Although not preferred (7), the method has the advantage of simplicity. It is still widely used in research.

It is a common practice to take an aliquot from a muscle sample for imcTG determination. However, if intrasample variability (IV) is high, the result may not represent the entire sample and thus introduces errors. Therefore, it is necessary to examine IV of imcTG measurement, which so far has not been studied adequately. To date, the majority of imcTG variability studies are focused on intersample or interindividual variability. Recently, Wendling *et al.* (4) evaluated the variability between two aliquots of pulverized powder from same muscle samples, an approach potentially useful for reducing imcTG variability. Unfortunately, the study did not investigate this issue in more detail.

In the present studies, we compared two different approaches to processing muscle samples for the measurement of imcTG, namely, muscle samples are homogenized either before or after being aliquoted for imcTG analysis. Variability of non-esterified FA was also determined and compared to that of imcTG.

MATERIALS AND METHODS

Animals and protocol. Sprague-Dawley male rats (n = 10, 450–500 g body wt) were purchased from Harlan Sprague Dawley (Indianapolis, IN). The animals were kept in a room with 12 h/12 h light/dark cycles and stable temperature and humidity. They were studied after an overnight fast, awake. The study protocols were approved by Mayo Institutional Animal Care and Use Committee.

In order to monitor potential lipid contamination by extracellular lipids and imcTG stability during sample storage and processing, the imcTG pool was first labeled by intravenous infusion of ^{14}C-glycerol at 0.1 μCi/kg/min via a tail vein for 120 min while rats rested calmly in a metabolic cage (8). At the end, the animals were anesthetized by pentobarbital injection (50 mg/kg) and euthanized by open heart bleeding in order to reduce blood in tissues. Red gastrocnemius and tibialis anterior muscles were swiftly excised and divided into two approximately equal portions (~200 mg each). Each portion was cut into small pieces (~20 mg, so that they are chilled into the core instantaneously), labeled, and saved in liquid nitrogen. Visible fat and connective tissues were removed rapidly but no detailed dissection was performed until sample processing and lipid extraction.

Prior to lipid extraction, the frozen small muscle pieces from each portion were individually thawed on ice and dissected under a stereo microscope (10X-40X, Motic Microscopes) on ice to remove fat cells (this would have been impossible if cold tongs were used to clamp-freeze the samples as it crushes the fat cells, (9)). Upon completion, each piece was set on dry ice. When all pieces from one portion (set A) were completed, they were randomly divided into two aliquots of similar size (~100 mg each) (pair A) and homogenized separately in chloroform-methanol (2:1), kept on ice (aliquoting before homogenization, ABH). All the pieces from the other portion (set B) were homogenized together before being divided into two aliquots of similar size (~100 mg each, pair B) (aliquoting after homogenization, AAH). All of the homogenates were extracted according to Folch (10), and imcTG and NEFA were purified by TLC in a solvent system of hexane:ether:acetic acid (70:30:1). The purified imcTG and NEFA were quantified enzymatically (11). One aliquot of the imcTG-glycerol from pair A was also used to count for ^{14}C activity in order to determine specific activity.

IV of imcTG and NEFA using the ABH approach was determined from pair A and expressed as the absolute difference in imcTG or NEFA content ($|\Delta|$) between the two aliquots divided by their average imcTG or NEFA content (M):

$$\text{IV} = |\Delta|/M \times 100\% \quad [1]$$

IV of imcTG specific activity was calculated in a similar way. Processing variability (PV) for imcTG using the AAH approach was determined from pair B using an equation analogous to Equation 1.

Abbreviations: AAH, aliquoting after homogenization; ABH, aliquoting before homogenization; imcTG, intramyocellular triacylglycerol; IV, intrasample variability; PV, processing variability.

Statistics. Comparisons of imcTG contents within pairs, of variability between pairs, and between IV of imcTG and NEFA were made using paired Student's t-test.

RESULTS AND DISCUSSION

imcTG variability. Table 1 shows that imcTG contents for the two aliquots from gastrocnemius and tibialis anterior using the ABH approach were similar ($P > 0.2$). The IV were high: 22.4 ± 7.0% for gastrocnemius and 22.7 ± 6.1% for tibialis anterior. By comparison, the PV were 4 times lower ($P < 0.01$) than the IV: 5.9 ± 0.9% for gastrocnemius and 6.5 ± 1.4% for tibialis anterior. This indicated that the sample processing and analysis were reproducible. Thus, most (>75%) of the IV was due to muscle heterogeneity. The observed IV was similar to the intersample (4) and interindividual variability (12–14) reported in some studies, but lower than those reported in other studies (5,15,16).

IV at this level can cause significant errors in imcTG determination. For example, if aliquot 1 or aliquot 2 were used to measure imcTG content of the entire sample, the magnitude of potential errors is ~22%. This suggested that the lower detection limit for changes in imcTG is 22% (15,16). In order to detect a difference equal to the variability, a sample size of 17 is required at $\alpha = 0.05$ level with a statistical power of 0.80 (18). Many studies do not use samples of this size, and this could have contributed to the failures of detecting imcTG utilization. To detect imcTG changes of 1.5 times or twice the variability, the sample size is reduced to $n = 9$ or $n = 6$, respectively, the size more commonly used in research. However, in such cases, the lower detection limits increase to 37.5% or 50%, respectively. Such magnitudes of changes in imcTG content are relatively rare. Thus, high imcTG variability appears to be the main reason why many studies failed to detect changes in imcTG (2,5,17).

It is important to note that the observed high variability of imcTG using the ABH approach was not caused by lipid contamination, as demonstrated by the consistent imcTG ^{14}C-specific activity between the two aliquots. This would have been impossible if the samples were contaminated by extracellular lipids (adipocytes), which dramatically change the specific activity of imcTG due to their distinct metabolism. But, the variability (IV) of imcTG ^{14}C-specific activity obtained using ABH was also high, and comparable ($P > 0.05$) to that of imcTG content (Table 1). As expected, the variability (PV) of imcTG ^{14}C-specific activity obtained using the AAH approach was reduced significantly ($P < 0.05$, values not shown). The high IV when using the ABH approach was not due to imcTG autolipolysis either during sample processing, because NEFA content for these samples had low variability, which is less likely if uncontrolled autolipolysis was present.

imcTG variability was reduced to approximately 6% by using the AAH approach. Pulverization of freeze-dried samples appeared to have a similar degree of the same effect (4). Together, these observations suggested that, for the purpose of imcTG measurement, the AAH approach helps reduce the variability significantly by mixing the entire sample, thereby eliminating intrasample heterogeneity. Thus, the result should be more representative of the sample. Apparently, however, this approach does not apply in some cases, such as if fiber type–specific information is sought (19). Lipid contamination, if present, may render the approach less useful because it will spread the contaminants to the entire sample. Nonetheless, using the ABH approach does not solve this issue either. Therefore, removing lipid contaminants is a prerequisite in all cases.

NEFA variability. By comparison, even using the ABH approach, IV for NEFA was significantly lower than that for imcTG ($P < 0.05$) for both gastrocnemius (12.2 ± 2.1%) and tibialis anterior (11.8 ± 3.4%). However, by using the AAH approach, the variability was not significantly reduced (not shown). Intersample variability of NEFA is also lower than that for imcTG. For gastrocnemius, the average coefficient of variation (a measure of intersample variability) for the two aliquots was 9% and 45% for NEFA and imcTG, respectively. The corresponding values for tibialis anterior were 14% and 27%. These data suggest that muscle heterogeneity mainly affects imcTG with smaller effect on NEFA. Because imcTG variability is mainly caused by nonhomogeneous fiber type distribu-

tion (19,20), the observation indicated that non-esterified FA exist more evenly among different fiber types than imcTG, which is more concentrated in oxidative fiber types (I > IIa > IIb).

CONCLUSION

For imcTG analysis, homogenization before aliquoting can help reduce IV significantly. The relatively low variability for non-esterified FA suggest that the metabolite is more homogeneously distributed than triacylglycerol among different muscle types.

Desaturation Indices in Liver, Muscle, and Bone of Growing Male and Female Mice Fed *trans*-10,*cis*-12 Conjugated Linoleic Acid

Srikant Viswanadha, Michael L. McGilliard, and Joseph H. Herbein*

Department of Dairy Science, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061

ABSTRACT: *trans*-10,*cis*-12-CLA (*t*10,*c*12-CLA) inhibits lipid deposition in adipose tissue of many species, but it also enhances lipid deposition in liver. We evaluated effects of dietary *t*10,*c*12-CLA content and gender on carcass composition, FA profile of selected tissues, and expression of FA synthase (FAS) and stearoyl-CoA desaturase-1 (SCD) mRNA in adipose tissue. Male and female (63 of each) CD-1 mice were assigned a diet containing 0.0, 0.15, or 0.30% *t*10,*c*12-CLA at 4 wk of age. Seven mice per dietary group within gender were sacrificed after 2, 4, or 6 wk. The CLA isomer caused dose-dependent reductions in dry carcass weight and fat content, without altering protein content, but carcass fat and epididymal fat pad weights of males were reduced to a greater extent than carcass fat and inguinal fat pad weights of females. FAS and SCD mRNA in adipose tissue was more abundant in females than males, but expression in both genders decreased as the *t*10,*c*12-CLA content of the diet increased. Although the weight of gastrocnemius muscle was not influenced by diet, total FA content of the muscle of both genders decreased in response to dietary *t*10,*c*12-CLA content. Femur weight of male mice increased as the *t*10,*c*12-CLA content of the diet increased, but the weight increase was associated with a reduction in total FA content. The Δ9 desaturation indices for muscle and femur suggested a linear reduction in SCD activity, whereas Δ9 indices for liver indicated linear enhancement of SCD activity. Overall, results suggested that growing male mice were more susceptible than females to *t*10,*c*12-CLA inhibition of lipid deposition.

Paper no. L9970 in *Lipids 41*, 763–770 (August 2006).

Alterations in lipid metabolism attributed to *trans*-10,*cis*-12-CLA (*t*10,*c*12-CLA) include reduced deposition of lipid in body fat depots, increased deposition of lipid in liver, and reduced monounsaturated FA content of tissues, blood plasma, milk, and eggs due to inhibition of stearoyl-CoA desaturase-1 (SCD) activity or mRNA expression in tissues (1–7). FA concentrations in plasma lipid fractions of humans were used to calculate Δ5, Δ6, and Δ9 desaturase indices in response to a diet containing a mixture of equal amounts of *cis*-9,*trans*-11-CLA (*c*9,*t*11-CLA) and *t*10,*c*12-CLA (8) or diets containing purified *c*9,*t*11-CLA or *t*10,*c*12-CLA (9). Both reports suggested a reduction in overall capacity for Δ6 and Δ9 desaturation and an increase in Δ5 desaturation capacity due to the CLA mixture or the individual isomers in the diet. Desaturation indices derived from FA concentrations in blood lipid fractions, however, probably were confounded by differential effects of CLA isomers on liver, muscle, adipose tissue, bone, and other tissues. Other confounding factors may include gender (3), metabolic status (1), genetic potential for body fat accretion (1,4), dietary CLA content (6,10), or overall fat content and FA profile of the diet (11,12).

Excess hepatic lipid deposition in response to *t*10,*c*12-CLA may be a consequence of the pronounced inhibition of lipid accumulation and cell development in adipose tissue. In adipocytes, *t*10,*c*12-CLA alters expression of several transcription factors that target genes, including SCD and FA synthase (FAS), required for lipid synthesis and accumulation during cell differentiation and maturation (13). Quantification of cell number and diameter indicated reduced adipocyte cell volume accounted for reduced epididymal fat pad weight of lean rats fed a CLA mixture for 35 d (4). Although subcutaneous adipocyte cell number and diameter in male pigs fed a CLA mixture for 35 d were not altered, the Δ9 desaturation index and SCD activity were reduced (14). Reduced SCD expression in adipose tissue may be linked to enhanced lipid oxidation, as well as reduced triacylglycerol synthesis and storage (15).

An initial evaluation of hepatic SCD response to a dietary CLA mixture or the purified *c*9,*t*11-CLA isomer indirectly indicated that reduced hepatic SCD mRNA expression and reduced hepatic Δ9 desaturation index (ratio of oleic acid to stearic acid) in growing male mice (16) was most likely due to the *t*10,*c*12-CLA in the CLA mixture. A subsequent study with HepG2 cells indicated reduced SCD activity and Δ9 desaturation index (ratio of oleic to stearic) due to *t*10,*c*12-CLA, but SCD mRNA expression was not altered (17). In agreement with the *in vitro* study, hepatic SCD activity, but not SCD mRNA expression, in lactating mice (18) was reduced by *t*10,*c*12-CLA (1% of the diet). In contrast, dietary *t*10,*c*12-CLA (0.5% of the diet) increased the ratio of oleic acid to stearic acid in liver lipids of nonlactating mice, indicating an increase in hepatic SCD activity (19).

Due to these inconsistencies, the present study evaluated carcass composition, FA profiles and total FA in selected tissues, and SCD expression in liver and adipose tissue of growing male

Abbreviations: CP, crude protein; EE, ether extract; FAS, FA synthase; SCD, stearoyl-CoA-desaturase; *c*9,*t*11-CLA, *cis*-9,*trans*-11-CLA; *t*10,*c*12-CLA, *trans*-10,*cis*-12-CLA.

and female mice fed diets containing 0.0, 0.15, or 0.30% purified *t*10,*c*12-CLA for 6 wk. FA profiles for muscle and bone were used to calculate Δ9 and Δ5 plus Δ6 desaturation indices, which served as estimates of CLA-induced alterations in FA metabolism in lean body mass, for comparison with alterations in desaturation indices in liver. Because a dietary concentration of *t*10,*c*12-CLA as low as 0.1% may be adequate to obtain some of the desirable metabolic responses to this CLA isomer, such as inhibition of tumor metastasis (11), the 0.15% level was included in this study. The 0.30% level approximated the amount of *t*10,*c*12-CLA in a diet containing 0.5–1.0% CLA mixture.

EXPERIMENTAL PROCEDURES

Animals, diets, and sampling. All procedures involving animals were approved by the Virginia Polytechnic Institute and State University Animal Care Committee. Sixty-three male and 63 female, 3- to 4-wk-old CD-1 mice (Harlan, Madison, WI) were housed individually with access to food and water at all times. A 12-h light/12-h dark cycle was maintained throughout the study. For 7 d before the start of the study, all mice were fed Harlan Teklad (Harlan, Madison, WI) Global Rodent Diet (2018) (18% protein, 5% fat) with 3% (wt/wt) high-oleic sunflower oil added. On day 1 of the study, male and female mice were randomly assigned to receive diets containing 3.0% high-oleic sunflower (control), 2.85% high-oleic sunflower oil + 0.15% *t*10,*c*12-CLA, or 2.70% high-oleic sunflower oil + 0.30% *t*10,*c*12-CLA. The free FA form of *t*10,*c*12-CLA (>95% purity) was obtained from Natural Lipids (Hovdebygda, Norway). Mice were fed daily at 1600 h, and food refusals were weighed to estimate intake during the previous 24 h. Samples of each diet were obtained each week and stored at 4°C prior to FA analysis (Table 1).

Body weights were determined twice weekly and the day of sacrifice. At the end of weeks 2, 4, and 6, seven mice per dietary treatment within gender were anesthetized with Metofane® (Pitman-Moore, Inc, Washington Crossing, NJ) prior to cervical dislocation. The liver was removed, rinsed with diethyl pyrocarbonate (Sigma, St. Louis, MO) in distilled water (1:1000, vol/vol), and weighed. A portion of liver was frozen in liquid nitrogen and stored at –80°C prior to mRNA analysis. The remainder of the liver was stored at –20°C prior to FA analysis. Adipose tissue from the inguinal region of females or the epididymal region of males was excised, weighed, frozen in liquid nitrogen, and stored at –80°C prior to mRNA analysis. After evisceration, the head, skin, feet, and tail were removed. Gastrocnemius muscle and femur in the left hind leg of the carcass were excised and stored at –20°C prior to FA analysis. The remainder of the carcass was stored at –20°C prior to drying at 55°C, grinding, and analyses (20) for crude protein (CP) and ether extract (EE) content.

Lipids in diets, liver, femur, and muscle were extracted using the Folch procedure (21). Undecenoic acid (Nu-Check Prep, Inc., Elysian, MN), added to extracted lipids prior to formation of FAME (22), served as an internal standard. Using an Agilent 6890N gas chromatograph equipped with a flame ionization detector (Agilent Technologies, Palo Alto, CA), FAME were separated by a 100 m × 0.25 mm i.d. (0.2 μm film thickness) CP-Sil 88 column (Varian, Lake Forest, CA) protected by a 2.5 m × 0.25 mm i.d. fused silica retention gap. Ultrapure hydrogen at constant pressure was the carrier gas. Pure methyl ester standards (Nu-Check Prep, Inc.) were used for identification and quantification of sample FA (23). Quantities of substrate and product FA (μg/mg of tissue) for selected FA desaturation reactions were used to calculate desaturation indices for liver, muscle, and femur, where desaturation index = substrate/(substrate + product).

Northern blotting. A pkk160 plasmid containing the mouse SCD fragment was donated by Dr. James Ntambi (Department of Biochemistry, University of Wisconsin—Madison), and a pmFAS/CR11 plasmid containing the mouse FAS fragment was obtained from Dr. Hitoshi Shimano (Department of Internal Medicine, University of Tsukuba, Japan). The pDrive cloning vector containing rat β-actin was obtained from Dr. William Huckle (Department of Biomedical Sciences and Pathobiology, Virginia Tech). Plasmids were used to prepare cDNA probes as previously described (18). Total adipose tissue and liver RNA were extracted using TRI REAGENT® (MRC, Cincinnati, OH), separated by electrophoresis on 1% agarose gel containing 0.66 M formaldehyde, and transferred to a Magna Charge nylon membrane (MSI, Westborough, MA) by downward capillary blotting and UV crosslinking. Specific mRNA bands on the membrane were detected using the DIG High Prime DNA Labeling and Detection Starter Kit 2 (Roche Diagnostics Corporation, Indianapolis, IN). Intensity of bands was determined by GelWorks® 1D Intermediate software, version 4.01 (UVP, Inc., Upland, CA). The β-actin band was used for normalization of SCD and FAS mRNA abundance.

Statistical analysis. Data were analyzed as a completely randomized design with a factorial arrangement of treatments using the MIXED procedure of SAS® (Windows version 9.1, Cary, NC). Interactions in the initial model were dietary treat-

ment × gender, treatment × week, gender × week, and treatment × gender × week. Because gender had a significant ($P < 0.05$) effect on most variables in the initial model, data for each gender were analyzed separately. The separate analyses for males and females included a treatment × week interaction. Least-square means ± SEM (combined observations for weeks 2, 4, and 6) for variables within gender are presented in tables and figures. Within each gender, contrasts were performed to test the linear (dose-dependent) effects of the amount of dietary *t*10,*c*12-CLA on each variable.

RESULTS

Table 2 lists overall (mean of weeks 2, 4, and 6) effects of dietary *t*10,*c*12-CLA content on body weight, carcass composition, tissue weights, and total FA in tissues in male and female mice. Dietary *t*10,*c*12-CLA did not alter body weight or food intake (data not shown) during the 6-wk study, regardless of gender, when compared with the control groups. Dry carcass weight, however, was reduced by *t*10,*c*12-CLA. In the initial statistical analysis, which included both genders, a gender by

[a]Values are an overall least-square mean for 21 observations, where seven mice within each gender were sacrificed after consuming their assigned diet for 2, 4, or 6 wk.
[b]Probability of a linear effect due to dietary *t*10,*c*12-CLA content.

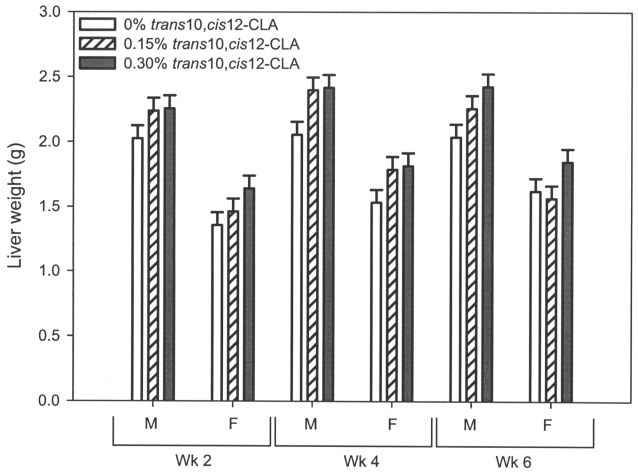

FIG. 1. Biweekly changes in liver weight for male (M) and female (F) mice fed 0.15% or 0.30% *t*10,*c*12-CLA, where $n = 7$. The overall (combined data for weeks 2, 4, and 6) increase in liver weight due to dietary CLA content was linear ($P < 0.01$) for male and female mice, as indicated in Table 2.

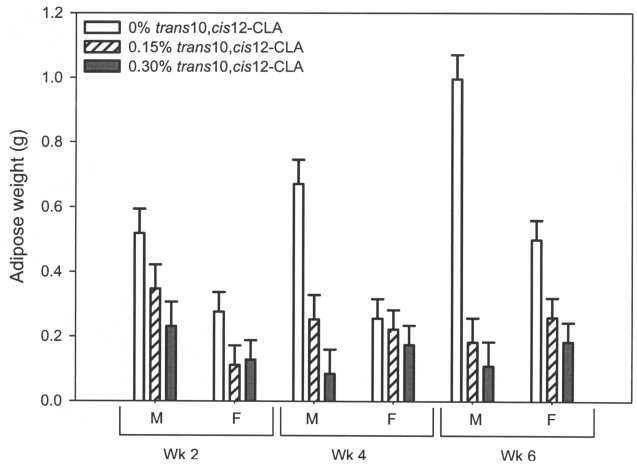

FIG. 2. Biweekly changes in epididymal (M) or inguinal (F) fat pad weight of mice fed 0.15% or 0.30% *t*10,*c*12-CLA, where $n = 7$. The overall (combined data for weeks 2, 4, and 6) reduction in fat pad weight due to dietary CLA content was linear ($P < 0.01$) for male and female mice, as indicated in Table 2.

treatment interaction ($P < 0.05$) resulted due to females responding to the dietary treatments to a lesser extent than males. At 6 wk, carcass weight was 30% lower for males fed 0.15% or 0.30% *t*10,*c*12-CLA, compared with the control, but female dry carcass weight was reduced by only 13%. The reduced carcass weight of males and females was due primarily to a dose-dependent reduction in the amount (g) of EE, whereas amount of carcass CP was similar for all dietary treatments. Thus, CP became a greater percentage of carcass weight as dietary *t*10,*c*12-CLA content increased.

Overall, liver weight of male and female mice increased in response to dietary *t*10,*c*12-CLA in a dose-dependent manner, and the increase was accompanied by an increase in total FA content (Table 2). With the exception of females at 6 wk, liver weight was consistently greater for mice fed *t*10,*c*12-CLA at 2, 4, and 6 wk (Fig. 1). There were overall reductions in inguinal (female) and epididymal (male) fat pad weights in response to increasing dietary *t*10,*c*12-CLA content. The CLA-induced reductions in epididymal adipose tissue weight in males were greater than the reductions in inguinal adipose tissue weight in females due primarily to a biweekly increase in epididymal adipose tissue weight for control-fed male mice compared with a decline in weight for those fed 0.15% or 0.30% *t*10,*c*12-CLA (Fig. 2). Gastrocnemius muscle weight was not altered by dietary treatments, but total FA content of muscle of male and female mice decreased in a dose-dependent manner in response to dietary *t*10,*c*12-CLA. Although femur weight was numerically greater for male and female mice fed 0.15% or 0.30% *t*10,*c*12-CLA, compared with the control groups, the response was significant ($P < 0.01$) only for males. Likewise, the reduction in femur total FA content in response to increasing dietary *t*10,*c*12-CLA content was significant ($P < 0.01$) only for males.

When expressed as a percentage of total FA (data not shown), concentration of *t*10,*c*12-CLA was highest in muscle (0.36% and 0.59% for mice fed 0.15% and 0.30% *t*10,*c*12- CLA, respectively), intermediate in femur (0.20% and 0.39%), lowest in liver (0.15% and 0.31%), and not detectable in these tissues of mice fed the control diet. Palmitic acid (19–24% of total FA), stearic acid (6–10%), oleic acid (29–36%), and linoleic acid (15–21%) were the primary FA in muscle and femur. Palmitic acid (22–23% of total FA) and linoleic acid (17–21%) concentrations in liver were similar to those in muscle and femur. However, stearic acid (17–23%) was greater and oleic acid (20–23%) was lower in liver compared with muscle or femur.

Desaturation indices for liver, gastrocnemius muscle, and femur are listed in Table 3. Potential substrates for the Δ9 desaturation reaction include palmitic acid, stearic acid, and vaccenic acid (*trans*-11-18:1). Desaturation of vaccenic acid was included in Table 3 because it accounted for a small portion of total FA in all diets (Table 1). The desaturation indices for 18:0 and *trans*-11-18:1 in liver of males and females were reduced by dietary *t*10,*c*12-CLA. In contrast, the desaturation indices for 16:0 and 18:0 in muscle (males and females) and femur (males only) were elevated by *t*10,*c*12-CLA. The desaturation index for 18:2n-6, which includes Δ5 and Δ6 desaturases, in liver was not influenced by dietary *t*10,*c*12-CLA content, but it was reduced in muscle (males and females) and femur (males only) of mice fed *t*10,*c*12-CLA. The 18:3n-3 desaturation index in liver of male mice was elevated in response to dietary *t*10,*c*12- CLA, but was not altered in muscle or femur of either gender.

FA analysis of adipose tissue was not possible, because all available tissue was needed for RNA isolation. Evaluation of adipose tissue RNA revealed linear reductions in SCD (Fig. 3) and FAS (Fig. 4) mRNA, regardless of gender, due to increasing dietary *t*10,*c*12-CLA content. In addition, SCD and FAS expression in adipose tissue of females was greater ($P < 0.05$) than in males. Unlike adipose tissue, overall hepatic SCD mRNA expression was not affected by dietary *t*10,*c*12-CLA content or gender (data not shown).

[a]Desaturation index = substrate/(substrate + product). Values are an overall least-square mean for 21 observations, where seven mice within each gender were sacrificed after consuming their assigned diet for 2, 4, or 6 wk.
[b]Probability of a linear effect due to dietary *t*10,*c*12-CLA content.

DISCUSSION

Despite reductions in weight of the dry carcass and carcass fat content in this study, total body weight and food intake were not influenced by 0.15% or 0.30% dietary *t*10,*c*12-CLA. Previous dose-response studies using male mice indicated diets containing 0.5% or more CLA mixture were needed for reductions of body weight or energy intake (10,24), and these reductions eventually were attributed to dietary *t*10,*c*12-CLA rather than *c*9,*t*11-CLA (25).

A dry carcass without head, skin, feet, and tail was used in the present study to obtain estimates of changes in lipid and protein content of structural body components in response to dietary *t*10,*c*12-CLA. Carcass weight, carcass lipid content,

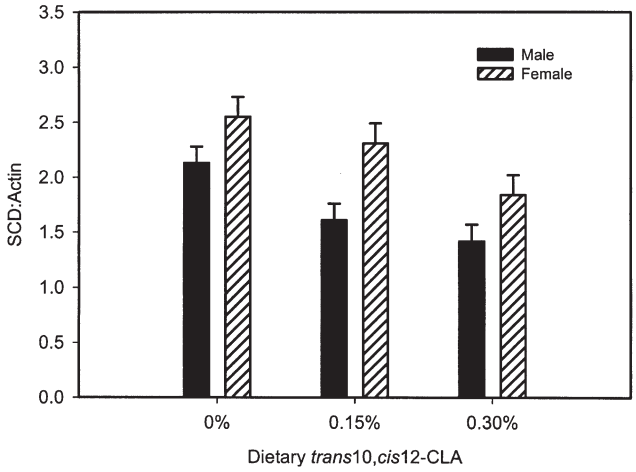

FIG. 3. SCD mRNA in epididymal adipose tissue of male mice and inguinal adipose tissue of female mice fed 0.15% or 0.30% *t*10,*c*12-CLA. Each bar represents the mean for 21 mice, where seven mice were sacrificed at 2, 4, or 6 wk within the 6-wk study. The decline in SCD mRNA due to dietary *t*10,*c*12-CLA content was linear ($P < 0.05$) for male and female mice, and SCD mRNA abundance was greater ($P < 0.05$) for females compared with males.

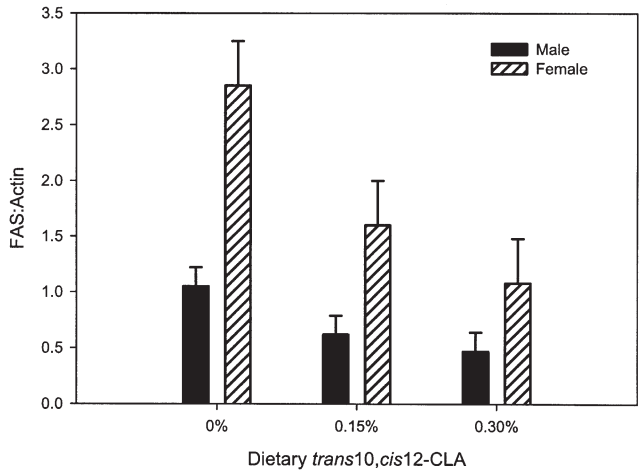

FIG. 4. FAS mRNA in adipose tissue of male and female mice fed *t*10,*c*12-CLA. Each bar represents the mean for 21 mice, where seven mice were sacrificed at 2, 4, or 6 wk within the 6-wk study. The decline in FAS mRNA due to dietary *t*10,*c*12-CLA content was linear ($P < 0.05$) for male and female mice, and FAS mRNA abundance was greater ($P < 0.05$) for females compared with males.

and weight of the epididymal or inguinal fat pad were reduced in a dose-dependent manner. Reduction in carcass fat content accounted for a majority of the reduction in dry carcass weight, because protein content of the carcass was not altered. Although there was a dose-dependent decrease in total FA in muscle of both genders, femur FA content was reduced to a greater extent in males (45%) than in females (21%). In association with reduced deposition of lipids in peripheral tissues, however, was a 15–18% increase in weight of the liver. Liver enlargement was reported for male mice fed a diet containing 1.0% CLA mixture (40% *t*10,*c*12-CLA) (24), male mice fed 1.5% CLA mixture (48% *t*10,*c*12-CLA) (26), female mice fed 1% CLA mixture (36% *t*10,*c*12-CLA) (27), female mice fed 0.4% purified *t*10,*c*12-CLA (28), and male and female mice fed 1.0% purified *t*10,*c*12-CLA (29). Hepatic enlargement was associated with a 3- to 7-fold increase in triacylglycerol content (26,28). The dose-dependent increase in liver weight and total FA content noted in this study suggested the lower threshold for these hepatic responses may be 0.15% *t*10,*c*12-CLA or less in a diet.

Gastrocnemius muscle weight of male and female mice was not affected by dietary treatments. However, femur weight increased due to 0.15% and 0.30% dietary *t*10,*c*12-CLA. Increased bone weight may be due to a decrease in 20:4n-6 concentration in bone (30), which also was observed in the current study (data not shown). Inadequate 20:4n-6 may reduce production of eicosanoids, including prostaglandin E2 (1), essential for bone resorption and osteoclastic activity (31). In response to reduced osteoclastic activity, net bone turnover may be low and lead to increased bone forming rate.

Previous studies evaluated potential causes of reduced body fat deposition, including adipocyte apoptosis and insulin resistance, due to CLA mixtures or purified *t*10,*c*12-CLA (13,27,28,29). Female mice fed a diet with 1.0% CLA mixture for 5 mon had reduced FAS mRNA expression in white adipose tissue (27). In contrast, SCD mRNA expression was reduced in mouse 3T3-L1 pre-adipocytes in response to *t*10,*c*12-CLA (13). In the current study, there was a linear decrease in expression of FAS and SCD mRNA in response to dietary *t*10,*c*12-CLA in male and female mice. Males, however, had lower FAS and SCD mRNA in adipose tissue than females. Lower expression of FAS and SCD in males suggested that their adipose tissue depots may be more susceptible to the inhibitory effects of *t*10,*c*12-CLA, which appeared to be confirmed by the greater dose-dependent reduction in epididymal fat pad weight of males compared with inguinal fat pad weight reduction of females at 4 and 6 wk (Fig. 2).

FA desaturation indices as indicators of Δ9, Δ5, and Δ6 desaturation in this study were based on the concentration (μg/mg) of a selected FA in a tissue and calculated as a ratio of substrate to (substrate plus product). In the liver and most other tissues, SCD catalyzes the conversion of 16:0 to *cis*-9-16:1 and 18:0 to *cis*-9-18:1 by insertion of a double bond at the Δ9 position (32). Likewise, SCD desaturates *trans*-11-18:1 to *c*9,*t*11-18:2 (33). Highly unsaturated FA, such as 20:4n-6 and 20:5n-3, are formed from 18:2n-6 or 18:3n-3 by Δ5 and Δ6 desaturation. Thus, an increase in a desaturation index (Table 3) suggested a reduction in activity of a corresponding desaturase enzyme. Increases in 16:0 and 18:0 desaturation indices for muscle (male and female) and femur (males only) were observed for mice fed *t*10,*c*12-CLA, indicating a corresponding reduction in SCD activity as previously reported for mouse mammary tissue (18) and pre-adipocytes (13). In contrast, reductions in 18:0 and *trans*-11-18:1 desaturation indices for liver of male and female mice were observed in the present study, and suggested enhanced hepatic SCD activity. Expression of SCD mRNA in the liver of male and female mice in the present study, however, was not altered by dietary *t*10,*c*12-

CLA. Hepatic SCD mRNA in lactating mice also was not altered by dietary *t*10,*c*12-CLA, but SCD activity was reduced (18). The *t*10,*c*12 CLA isomer most likely altered hepatic SCD activity by post-translational mechanisms rather than gene transcription (17).

The hepatic 18:2n-6 desaturation index was not altered by dietary treatments in this study, but the index was reduced in muscle (males and females) and femur (males only). The proportion of 20:4n-6, the product of 18:2n-6 desaturation and elongation, in bone and muscle of male and female mice was increased (data not shown). An increase in activity of Δ5 or Δ6 desaturase in muscle and femur may be a metabolic response to compensate for the apparent decrease in Δ9 desaturase activity noted above. In contrast, dietary *t*10,*c*12-CLA caused an increase in the hepatic 18:3n-3 desaturation index of male mice, suggesting inhibition of Δ5 or Δ6 desaturation. There was a reduction in Δ6 desaturation in Hep2G cells in response to *t*10,*c*12-CLA when the ratio 20:3n-6 to18:2n-6 was used as an index (34). Likewise, the ratio of (18:3n-6 + 20:3n-6) to 18:2n-6 in plasma phospholipids suggested potential inhibition of Δ6 desaturation in response to daily consumption of purified *t*10,*c*12-CLA by overweight men and women (9). In addition, hepatic Δ6 desaturase activity was reduced by *c*9,*t*11-CLA and *t*10,*c*12-CLA added to microsomal incubations (35). Thus, alterations in 18:2n-6 or 18:3n-3 desaturation indices in this study may have resulted primarily from changes in activity of Δ6 desaturases.

Our results indicated gender accounted for minor differences in the capacity of adipose tissue, via FAS and SCD, to respond to the inhibitory actions of dietary *t*10,*c*12-CLA on lipid synthesis and storage. However, results also indicated that evaluations of lower concentrations of dietary *t*10,*c*12-CLA are needed to establish the appropriate amount of this CLA isomer required for acceptable long-term reductions in body fat content with minimal negative effects on liver lipid content and essential FA desaturation in muscle, bone, and other tissues. For example, conjugated EPA (36) apparently has fewer of the undesirable side effects associated with *t*10,*c*12-CLA. Thus, both conjugated isomers could be compared at similar dietary concentrations in future studies to determine their desirable and undesirable dose-dependent characteristics in male and female animals.

ACKNOWLEDGMENTS

This work was supported by a fellowship and research funds from the John Lee Pratt Animal Nutrition Program. We thank Dr. Hitoshi Shimano (Department of Internal Medicine, University of Tsukuba, Japan), Dr. James Ntambi (Department of Biochemistry, University of Wisconsin—Madison), and Dr. William Huckle (Department of Biomedical Sciences and Pathobiology, Virginia Tech) for the plasmids containing FAS, SCD, and actin cDNA respectively.

ABSTRACT: CLA refers to a group of geometrical and positional isomers of linoleic acid (LA) with conjugated double bonds. CLA has been reported to have diverse health benefits and biological properties. Traditional organic synthesis is highly capital-intensive and results in an isomeric mixture of CLA isomers. Biotechnology presents new alternatives to traditional lipid manufacturing methods. The objective of this study was to examine the effect of protein isolation procedures on linoleate isomerase (LAI) recovery from microbial cells and biocatalysis of LA to CLA. Protein isolation experiments were carried out using *Lactobacillus acidophilus* L1 and two strains of *Lactobacillus reuteri* (ATCC 23272 and ATCC 55739). Under the same assay conditions, ATCC 55739 had the highest LAI activity among the microbial cultures examined in this study. Efficiency of cell lysis methods, which included various combinations of lysozyme and mutanolysin treatments in combination with sonication and osmotic rupture of cells with liquid nitrogen, was very low. Although treatment of cell material with a detergent (octylthioglucoyranoside) freed a significant amount of LAI activity into the solution, it was not sufficient to recover all the LAI activity from the residual cells. Crude LAI preparations produced mainly the *cis*-9,*trans*-11 CLA isomer. Time and substrate/protein ratio had a significant effect on biocatalysis of LA to CLA. It appears that the mechanism and kinetics of enzymatic conversion of LA to CLA are quite complex and requires further research using pure LAI preparations.

Paper no. L10059 in *Lipids 41*, 771–776 (August 2006).

CLA refers to a group of geometrical and positional isomers of linoleic acid (LA) with conjugated double bonds. Although a total of 54 CLA isomers are possible (1), only about 20 CLA have been identified, including *cis*,*cis*; *trans*,*trans*; *cis*,*trans*; and *trans*,*cis* isomers of 7,9; 8,10; 9,11; 10,12; and 11,13 C18 diene acids (2). It is believed that the *cis*-9,*trans*-11 and *trans*-10,*cis*-12 isomers are the most bioactive CLA forms (3). CLA has been reported to have diverse health benefits and biological properties including being anticarcinogenic (4,5), antiatherogenic (6,7), antidiabetic (8), antiobesity (9), antioxidative (10), immunomodulative (11), antibacterial (2), cholesterol lowering, and growth promoting (12). It also has been reported that dietary intake of CLA helps to build lean muscle, reduce deposition of fat, and mitigate some undesirable aspects of the immune response such as anorexia and protein breakdown (13,14). Most of these effects have been demonstrated only in animal studies.

CLA can be produced through organic synthesis, microbial fermentation, enzymatic isomerization, or genetic engineering/bioengineering (15). Traditional organic synthesis is highly capital-intensive and results in an isomeric mixture of CLA. There have been several reports that microorganisms containing the enzyme linoleic acid isomerase (LAI) are capable of converting LA to CLA (14,16–19). Hence, CLA production by fermentation and utilization of microorganisms containing LAI may be a viable alternative to organic synthesis. It is also possible that pure enzymes containing isomerase activity can be used to manufacture CLA. A great advantage of biocatalysis by whole microorganisms or purified enzymes is that there is high specificity for the isomers that are produced.

A rumen bacterium, *Butyrivibrio fibrisolven*, was the first identified to convert LA to CLA (20). Since then there have been numerous reports that a large number of benign bacteria, which are naturally present in the environment and intestinal tract of ruminant animals, can convert LA to CLA (14,17–19). Fairbank *et al.* (21) were the first to detect CLA in *Lactobacillus* cultures. Later Pariza and Yang (14) developed a method for production of *cis*-9,*trans*-11 CLA utilizing *Lactobacillus* sp. Their patent covers the conversion of LA to CLA by using whole bacterial cells of *L. reuteri* PYR8. Jiang *et al.* (19) screened 19 different strains of lactobacilli, lactococci, streptococci, and propionibacteria for their ability to produce CLA. Two strains of *Propionibacterium freudenreichii* ssp. *freudenreichii* and one strain of *P. freudenreichii* ssp. *sheramnii* were able to convert free LA to CLA, and *cis*-9,*trans*-11 was the dominant isomer. Alonso *et al.* (18) tested four different cultures, two strains each of *L. acidophilus* and *L. casei* for their ability to produce CLA from free LA. All the cultures were able to produce free CLA in MRS broth supplemented with LA.

Although conversion of LA to CLA by microorganisms has been reported extensively, literature on the utilization of enzyme extracts and purified enzyme preparations for LA isomerization is limited (22). A cell-free protein preparation catalyzing the isomerization of LA and linolenic acids was obtained from *B. fibrisolvens* (23). It was reported that occasionally cultures of intact cells of *B. fibrisolvens* tended to settle rapidly and failed to isomerize LA readily when incubated with the substrate. This phenomenon was explained by the production of a capsular material, which altered the permeability of the cell to LA. However, isomerase isolated from these cells had the

Published with approval of the Director, Oklahoma Agricultural Experiment Station.

Abbreviations: LA, linoleic acid; LAI, linoleate isomerase; PAI, polyenoic FA isomerase.

ability to rapidly convert LA to CLA. Park *et al.* (24) isolated LAI from *B. fibrisolvens* A-38 cultured anaerobically. They also determined the molecular weight and partial amino acid sequence of the enzyme. The isomerase was a single polypeptide with a molecular weight of 19 kDa. Yang (25) isolated and characterized a LAI enzyme from *L. reuteri*. The linoleic acid isomerase of *L. reuteri* MRS8 was membrane-bound, and had a molecular weight of more than 100 kDa. Optimal activity of the enzyme was in the pH range of 4.7 to 5.4. Recently, Lin *et al.* (26) prepared enzyme extracts from *L. acidophilus* and *P. freudenreichii* ssp. *shermanii.* These extracts were used for isomerization of LA, and *trans*-10,*cis*-12; *cis*-11,*tran*-13; and *cis*-9,*trans*-11 were the three major CLA isomers produced. Liavonchanka *et al.* (22) reported overproduction of a polyenoic FA isomerase (PAI) in *Escherichia coli* and its purification as a yellow-colored protein. PAI catalyzes the double-bond isomerization of LA to CLA. A world patent also describes determination of linoleate isomerase enzyme nucleic acid and amino acid sequences and genetic modification of the naturally occurring enzyme (27).

Although limited data is available on the conversion of LA to CLA using microbial enzymes, the efficiency of enzyme recovery from whole bacterial cells during protein isolation has not been reported. Hence, the objective of this study was to examine the effect of protein isolation procedures on efficiency of enzyme recovery from whole microbial cells. This study also examines the effect of substrate/protein ratio and time on CLA isomer formation using solubilized crude protein solutions.

MATERIALS AND METHODS

Culture growth. Culture growth experiments (1, 2, and 4 L) were carried out using *L. acidophilus* L1 (obtained from the stock culture collection of the Food Microbiology Laboratory at the Food and Agricultural Products Research and Technology Center, Oklahoma State University), and two strains of *L. reuteri* (ATCC 23272 and ATCC 55739) (commercial cultures). All the cultures studied in this project were subcultured three times (1% inoculum into 10 mL MRS broth, incubated 18 h at 37°C) just prior to use. Then a 1% inoculum was added into the final volume (1, 2, and 4 L) of MRS broth (Difco Laboratories, Detroit, MI) and incubated at 37°C for 18 h.

Protein isolation. Several enzyme isolation protocols were tested for highest activity in the crude preparations. A typical crude enzyme preparation protocol included the following steps. (1) Cells were harvested from the growth medium by centrifugation at 10,000*g* for 10 min at 4°C and washing the pellet with 0.85% NaCl (30 mL) and buffer (either phosphate buffer pH 7 or tris-maleate buffer pH 5.4). (2) Cell disruption: Three different methods were tested. The first involved lysozyme treatment (7 mg/mL, Sigma, St. Louis, MO) (20°C for 10 min) and sonication for 10 min (Model 450 Sonifier, Branson Ultrasonics Corporation, Danbury, CT) in an ice-bath. The second was lysozyme treatment (1 hr at 37°C) then addition of 4 M NaCl and sonication for 10 min in an ice-bath. Sonication was carried out in 2-min intervals to avoid overheating of the solution. The third was treatment with an enzyme mixture containing 1 mM EDTA, 24% sucrose, 2% lysozyme, and 50 U/mL mutanolysin (Sigma, St. Louis, MO) at 37°C for 90 min and osmotic rupture of the cells (cells were frozen in liquid nitrogen and thawed in warm water; this procedure was repeated twice). The degree of cell lysis was examined with a stain microscope after each treatment. (3) After the cell lysis, the solution (lysate) was centrifuged at 10,000*g*, 4°C for 60 min, to separate solid and liquid fractions. All the protein fractions obtained at each step of the isolation process were tested for enzyme activity using free LA as a substrate. (4) The solid fraction that had the enzyme activity was treated with a detergent, octylthioglucoyranoside (OSGP) (Sigma, St. Louis, MO), at 4°C for 2 h to solubilize LAI from the membrane fraction. The detergent solution and a solid fraction suspension in buffer were mixed at 1:1 to obtain the final detergent concentrations of 0.1, 0.3, 0.5, 1, and 2%. (5) Detergent solubilized protein mixture was ultrafiltered through 500, 300, and 100 kDa pore size membranes.

Protein assay. Protein amount in the samples was determined by the Bradford method (28) using a standard curve of BSA (Sigma, St. Louis, MO) in 6–200 μg protein range. Coomassie Brillant Blue G-250 (Sigma, St. Louis, MO) at 0.033 g/L concentration was used for protein-dye binding. The absorbance of the solutions was determined at 595 nm by using a UV spectrophotometer (Model Beckman DU640, Beckman Coulter, Inc., Fullerton, CA). Coomassie brillant blue without protein solution was used as blank.

Enzyme assay. Enzyme activity tests were carried out with 100 μL of 50 mg LA/mL methanol, and extracts containing 100–600 μg of protein. The volume of the substrate protein mixture was adjusted to 3 mL by adding tris maleate (pH = 5.4) or phosphate buffer (pH 7). Then the mixture was incubated at 37°C for 3 h in a mechanical shaker (1024 Tecator, at speed setting 5, Foss North America, Eden Prairie, MN).

Extraction and methylation procedure. After internal standard addition (0.25 mg/mL heptadecanoic acid in methanol), lipids in enzyme assay solution were extracted three times with 5 mL of hexane (total 15 mL). The hexane extract was dried first over anhydrous sodium sulfate (ACS grade, EMD Chemicals Inc., Gibbstown, NJ) followed by nitrogen drying using a Reacti-Vap evaporation unit (Model 18780, Pierce, Rockford, IL) set at 40°C. Then 100 μL of 1.0 N NaOH in methanol and 1 mL of BF_3-methanol solutions (10–15% solution, Sigma, St. Louis, MO) were added to the dried lipid sample. Methylation was carried out at room temperature for 30 min. Three milliliters of saturated aqueous NaCl and 2 mL of hexane were added to the methylation solution, which was mixed well. The hexane layer was recovered and dried with Na_2SO_4. Before injection into the GC, the hexane phase was concentrated to 1 mL.

Methyl esters of CLA were quantified by using a HP 6890 Series GC system equipped with a flame ionization detector (Agilent Technologies, Palo Alto, CA). A fused silica capillary column SP-2560 (100 m × 0.25 mm × 0.2 μm film thickness) from Supelco (Bellefonte, CA) was used for the analysis. The oven temperature was programmed as follows: temperature was maintained at 135°C for 1 min, increased from 135°C to 165°C with 1°C/min heating rate, maintained at 165°C for 1

min, increased from 165°C to 167°C with 0.5°C/min rate, maintained at 167°C for 1 min, increased from 167°C to 240°C at 1.75°C/min, and maintained at 240°C for 5 min. Helium was used as carrier gas at a flow rate of 1.0 mL/min. The inlet temperature was 250°C. The split ratio was 1:50. One microliter of sample was injected into the GC by an autosampler (HP 7683, HP Company, Wilmington, DE). Isomers of CLA in the samples were identified by comparing retention times of standard CLA isomers (*cis*-9,*trans*-11; *trans*-10,*cis*-12; *cis*-9,*cis*-11; and *trans*-9,*trans*-11) and the mass spectra with those of the authentic compounds. MS (5973 Network Mass Selective Detector, Agilent Technologies, Palo Alto, CA) parameters were as follows: MS transfer line 280°C, ion source 230°C, and MS quadrupole temperature 150°C. The ionization energy was 70 eV. The scan range and rate were 100–600 amu and 2 scans/s, respectively. The peaks were also confirmed with NIST/EPA/NIH Mass Spectral Library (Version 2.0).

RESULTS AND DISCUSSION

A number of large-scale (1, 2, and 4 L) culture growth experiments were carried out using *L. acidophilus* L1 and two strains of *L. reuteri* (ATCC 23272 and ATCC 55739). Microbial cells were harvested when the culture reached the stationary growth phase. Wet cell yield was about 3–4 g/L growth medium. All the microbial cultures examined in this study produced similar cell yields. Several cell lysis protocols were tested for their efficiency to release enzyme activity from cell material. Figure 1 shows the effect of lysozyme and lysozyme + sonication treatment on cell integrity. A significant portion of the cells were still intact even after treatment of whole cells with lysozyme (20°C for 10 min) followed by 10 min sonication. The same trend was observed for all of the cultures examined in this study, indicating that cell disruption would be a major challenge for large and/or commercial isolation of LAI from these strains. Enzyme activity assay and the GC method used in this study do not cause isomerization of LA in the absence of LAI (Fig. 2). Base-catalyzed BF_3 methylation at room temperature appears to be an effective method for methylation with no isomerization of conjugated dienes (29).

Preliminary enzyme assays carried out using protein solutions (100 μg protein for all assays) obtained from lysozyme treatment (20°C for 10 min) and sonication (10 min) of microbial cells indicated differences in enzyme activity in the crude protein solutions (Fig. 3). *Lactobacillus reuteri* ATCC 55739 gave the highest LAI activity in crude enzyme preparations resulting in 10% (w/w) LA conversion to CLA in 3 h. Protein solutions obtained from two other cultures examined in this study had lower enzyme activity than ATCC 55739 (<1% LA conversion to CLA) under the same conditions. Main CLA isomers formed by ATCC 55739 were *cis*-9,*trans*-11 and *trans*-10,*cis*-12, which are believed to be the most biologically active CLA isomers. Higher LAI activity in ATCC 55739 was also confirmed by comparing enzyme assays performed with three whole cell cultures tested in this study. Hence, further protein purification experiments were carried out using ATCC 55739. An increase in lysozyme concentration, treatment temperature, and time did not improve LA1 activity in crude enzyme preparations.

A series of protein isolation experiments were performed to examine the effect of isolation procedures on LAI activity and conversion of LA to CLA (Fig. 4). Treatment of whole ATCC 55739 cells (S1) with CelLytic (Sigma, St. Louis, MO), which is proprietary blend of a detergent and enzymes optimized for in-culture bacterial cell lysis did not release detectable amount of LAI activity into solution. Nonetheless, solubilization and removal of some of the proteins that do not posses LAI activity from the cell material during CelLytic treatment caused concentration of LAI activity (mg CLA/mg cell) in the residual cell material (Fig. 4, S2). Further treatment of residual cell material with a lysozyme/mutanolysin mixture in tris maleate buffer at pH 5.4 followed by osmotic cell rupture resulted in release of some LAI activity into solution (L3) and reduction in enzyme activity in

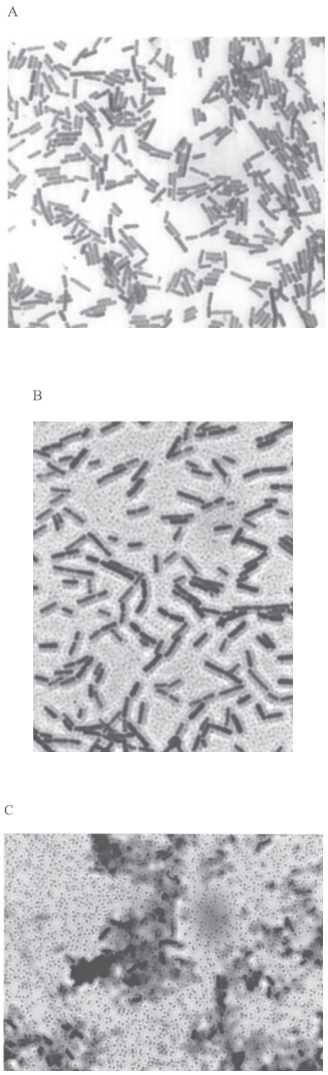

FIG. 1. Effect of lysozyme treatment and sonication on *Lactobacillus reuteri* (ATCC 55739) cell integrity. A: Intact cells before treatment; B: Lysozyme treatment at 20°C for 10 min—majority of the cells are still intact; C: Lysozyme treatment at 20°C for 10 min + 10 min sonication—although there is some cell disruption, significant number of cells are still intact.

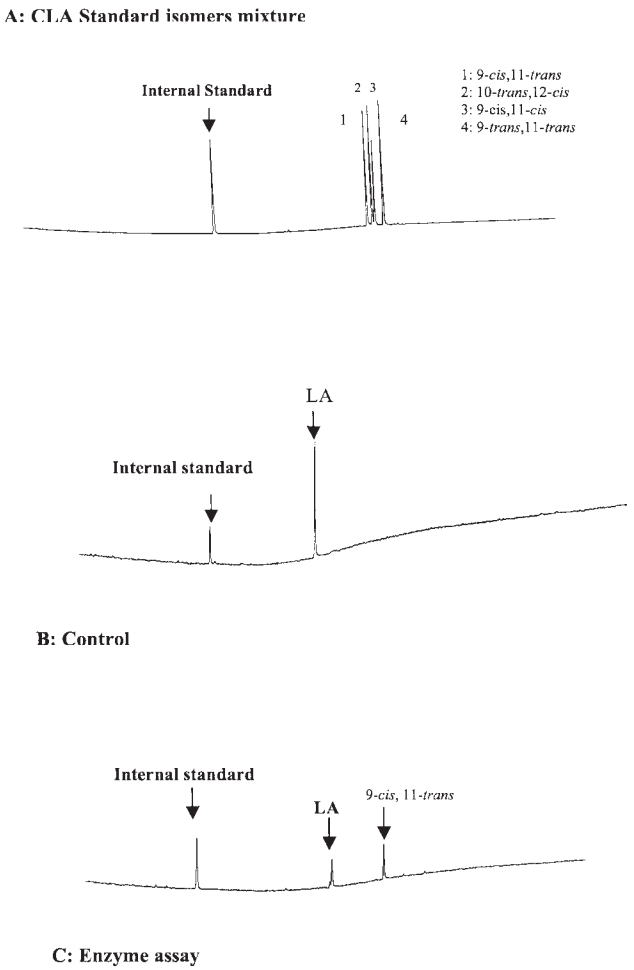

FIG. 2. Effect of fatty acid methylation method and enzyme assay on isomerization of LA.

the residual cell material (S3) (Fig. 4). However, a significant amount of LAI activity still remained in the residual cell material (S3), indicating that LAI may be cell-bound. Although treatment of residual cells with a detergent solution (octylthioglucopyranoside) released some more enzyme activity into the solution (L4), it was not possible to recover all the LAI activity from cell material (S4). Even after a second detergent treatment, a significant amount of LAI activity was detected both in solution (L5) and in the cell residue (S5). Increasing the detergent amount and incubation time for one treatment was not as effective as two sequential detergent treatments in LAI recovery from the cell residue. Ultrafiltration of combined protein solutions (L3 + L4 + L5) through a 100-kDa membrane facilitated concentration of LAI activity in the retentate (L6). These results indicate that expression of LAI in a microorganism that would secrete this enzyme into a growth medium is essential for economical feasibility of large-scale LAI isolation/production.

Effects of time and substrate/protein ratio on CLA isomer formation were also examined. Minor revisions to protein isolation protocols described in the Material and Methods section were made to maximize enzyme recovery and obtain enough protein solution to run these tests. The revised protein isolation protocol was as follows.

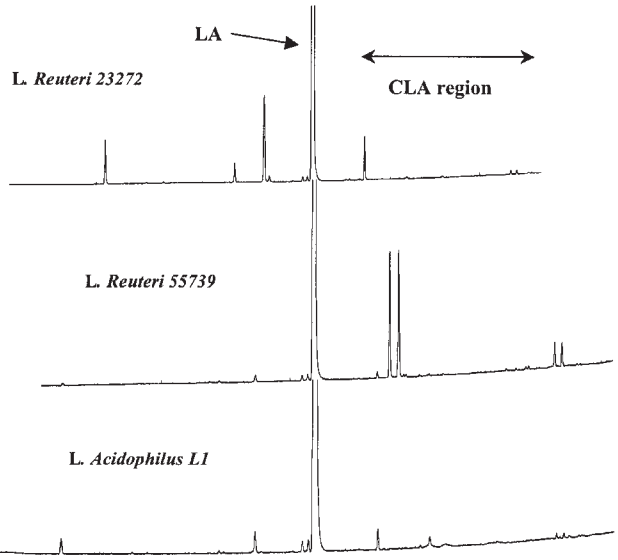

FIG. 3. Effect of microbial culture type on enzymatic conversion of LA to CLA. Enzyme assays were carried out using substrate/protein ratio of 0.2 (w/w) for 3 h. Linoleic acid in free form and protein solutions obtained after lysozyme treatment (20°C, 10 min) + sonication were used for the assay.

(1) Whole cells were treated with an enzyme mixture (phosphate buffer pH 7) followed by centrifugation at 8,000*g* for 20 min to separate solid (SA) and liquid phases (LiqA). (2) Osmotic

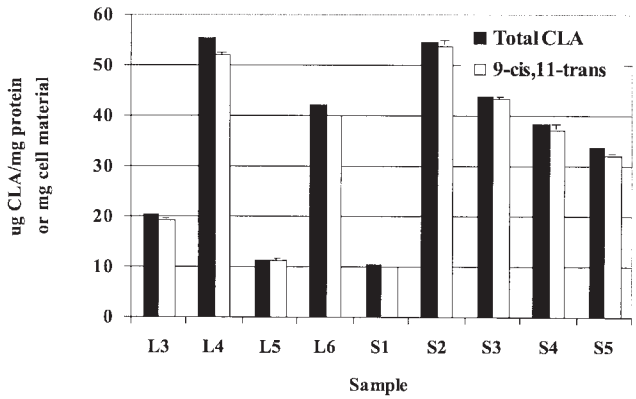

FIG. 4. Effect of protein isolation procedures on LAI recovery and CLA formation. ATCC 55739 culture was used for these experiments. **S1**: Whole ATCC 55739 cells; **S2**: Residual cell material after treatment of S1 with 10 mL CelLytic B cell lysis reagent (Sigma St. Louis, MO) at 20°C for 15 min; **S3**: Residual cell material after treatment of S2 with a lysozyme + mutanolysin mixture (Materials and Methods, Protein Isolation Section, 2-c); **S4**: Residual cell material after treatment of S3 with a detergent solution (Materials and Methods, Protein Isolation Section, 4 at 0.3% detergent concentration in the final solution); **S5**: Residual cell material after treatment of S4 with a detergent solution (Materials and Methods, Protein Isolation Section, 4 at 0.3% detergent concentration in the final solution); **L3**: Protein solution obtained after treatment of S2 with a lysozyme + mutanolysin mixture (Materials and Methods, Protein Isolation Section, 2-c); **L4**: Protein solution obtained after treatment of S3 with a detergent solution (Materials and Methods, Protein Isolation Section, 4 at 0.3% detergent concentration in the final solution); **L5**: Protein solution obtained after treatment of S4 with a detergent solution (Materials and Methods, Protein Isolation Section, 4 at 0.3% detergent concentration in the final solution); **L6**: Retentate obtained after ultrafiltration of combined L3 + L4 + L5 solution through a 100 kDa membrane. Protein content of the final solution was 0.96 mg/mL.

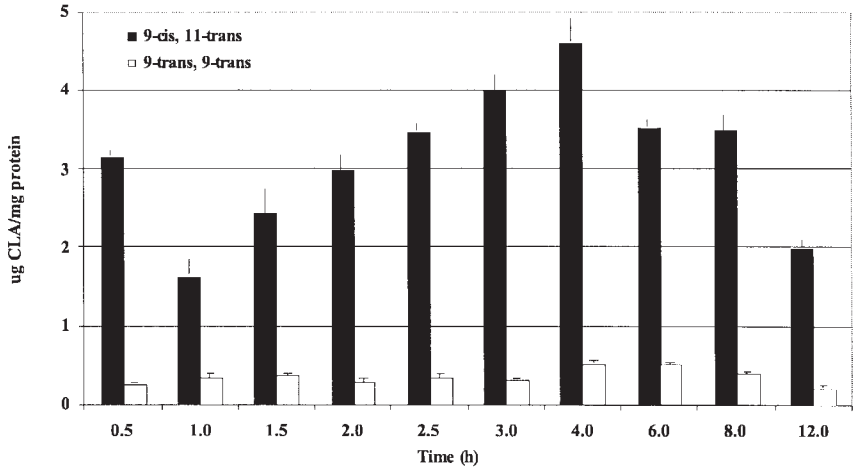

FIG. 5. Effect of time on enzymatic conversion of LA to *trans*-9,*trans*-11 CLA isomer. Crude enzyme preparations were obtained from ATCC 55739 cultures as explained in the text.

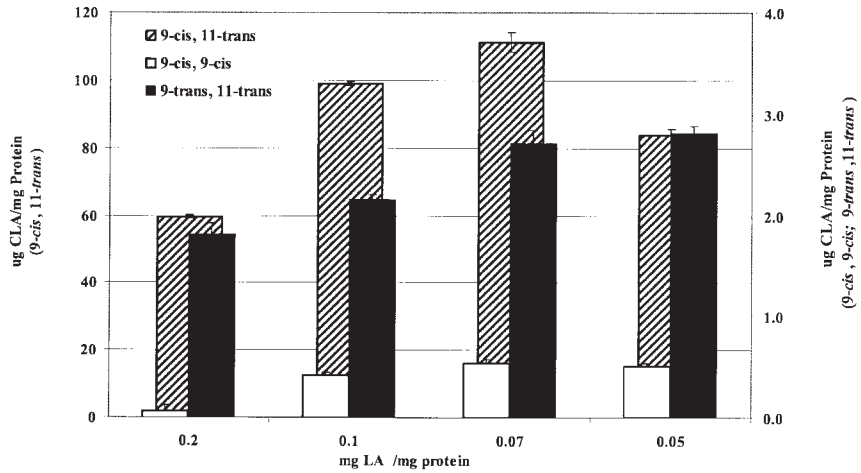

FIG. 6. Effect of substrate/protein ratio on enzymatic conversion of LA to *trans*-9,*trans*-11 CLA isomer. Crude enzyme preparations were obtained from ATCC 55739 cultures as explained in the text.

rupture of the SA was followed by centrifugation at 8,000*g* for 20 min to separate solid (SB) and liquid phases (LiqB). (3) Treatment of SB with a detergent solution (0.12 g/50 mL membrane fraction + 50 mL detergent solution) was followed by centrifugation at 8,000*g* for 20 min at 4ºC to separate solid (SC) and liquid phases (LiqC).

The detergent treatment was repeated twice. Then protein solutions containing LAI activity (LiqA + LiqB + LiqC) were combined and ultrafiltered through a 300-kDa membrane. Retentate fraction from the ultrafiltration was used for the evaluation. Although there was some enzyme activity in the permeate fraction, the majority of the LAI activity was retained in the retentate fraction which had a concentration of 0.96 mg protein/mL solution.

Effect of time on CLA isomer production is shown in Figure 5. Maximum LA conversion to CLA was observed at 4 h (Table 1). Both *cis*-9,*trans*-11 and *trans*-9,*trans*-11 isomer formations were maximum at this time. Incubation of LA with protein solution longer than 4 h did not improve *cis*-9,*trans*-11 and *trans*-9,*trans*-9 isomer accumulation in the assay solution. Rather, a decrease in LA conversion to CLA was observed after 4 h (Fig. 5). These results were in agreement with the LA tests carried out in the assay solutions, which showed a slight increase in LA concentration at 4 h and after.

TABLE 1
Conversion of LA to CLA as a Function of Time[a]

Time (h)	0.5	1	1.5	2	2.5	3	4	6	8	12
LA converted (%, w/w)	3.4	2.0	2.8	3.3	3.8	4.3	5.1	4.0	3.9	2.2

[a]See Figure 6 for experimental conditions.

Substrate/enzyme ratio is an important parameter for understanding the mechanism of biocatalysis of LA to CLA. Effect of substrate/enzyme ratio on CLA formation was examined using the solutions obtained from the same protein isolation procedure described above. Decreasing LA/protein ratio (wt/wt) from 0.2 to 0.07 improved LA to CLA conversion (Fig. 6). The same trend was observed for all three CLA isomers detected in the assay solutions, *cis*-9,*trans*-11; *cis*-9,*cis*-9, and *trans*-9,*trans*-11. However, a further decrease in LA/protein ratio from 0.07 to 0.05 caused a significant decrease in biocatalysis of LA to CLA.

This study clearly showed that incomplete cell lysis is a major impediment for efficient isolation of LAI from microbial cells. Evaluation of effect of time and substrate/enzyme ratio on CLA formation indicates that the mechanism and kinetics of biocatalysis of LA to CLA are quite complex. Utilization of crude LAI preparations further complicates the evaluation. A better understanding of the mechanism of enzymatic CLA production requires further research using higher purity LAI preparations. Expression of LAI activity in microbial cells which would secrete the enzyme into a growth medium would be the key for the success of future research and development work in the field.

ABSTRACT: Three approaches for the synthesis of octadecadienoic acids with conjugated double bond systems are presented: synthesis of (10*Z*,12*Z*)-octadecadienoic acid *via* an enyne-substructure; the use of an educt with a conjugated double bond system for the synthesis of (10*E*,12*E*)-octadecadienoic acid; and the Suzuki cross coupling for the synthesis of (7*E*,9*Z*)-octadecadienoic acid.

Paper no. L9625 in *Lipids 41*, 777–788 (August 2006).

There are a number of positional and geometrical isomers of octadecadienoic acids, showing conjugated double bonds, that are referred to as conjugated linoleic acid (CLA). They are found predominantly in milk and meat, with 9*Z*,11*E*-CLA as the main isomer. In ruminants, CLA are formed by *Butyrivibrio fibrisolvens* in the rumen and also in adipose tissue during dehydrogenation of monounsaturated FA. Since their discovery, their potential benefits to human health have become evident. In various animal bioassays, CLA showed anticarcinogenic, antiatherogenic, and antidiabetogenic properties and proved to be a modulator for body composition. These studies were mostly conducted using CLA mixtures prepared by base-catalyzed isomerization of linoleic acid or with pure 9*Z*,11*E*-CLA or 10*E*,12*Z*-CLA, the only isomers that are commercially available. There is evidence that the 10*E*,12*Z*-isomer reduces the uptake of lipids by the adipocytes, whereas the 9*Z*,11*E*-isomer is active in inhibiting carcinogenesis in animal models, and both have been suggested to inhibit atheriosclerosis (1,2). Because of these differences in activities it is important to use pure stereoisomers in further investigations dealing with the biological significance of these compounds.

Several syntheses of pure isomers have been reported. Methyl 9*Z*,11*E*-CLA was prepared from methyl ricinoleate in 83% purity (3). Higher purities could be obtained by alkali isomerization of methyl linoleate with low-temperature crystallization (4). Pure 9*Z*,11*E*- and 9*Z*, 11*Z*-isomers were also synthesized by zinc reduction of methyl santalbate (5). A mixture of the 9*Z*,11*E*-isomer and the 9*E*,11*E*-isomer, labeled with deuterium, was prepared and separated by a combination of reversed-phase and silver silica chromatography in purities of >97–99% (6). Lipase-induced esterification of a mixture of stereoisomeric acids yielded butyl(9*Z*,11*E*)-octadecadienoate in purities of 90% (7). A mixture of 9*Z*,11*E*- and 10*E*,12*Z*-CLA was prepared in technical grade by selective isomerization of linoleic acid with metal catalysts (8). Pure 9*Z*,11*E*-, 10*E*,12*Z*-, and 10*Z*,12*Z*-CLA were synthesized by using stereochemically defined 1,2-dichloroethene as a building block (9). All these approaches yielded single isomers on purification of mixtures of two or more isomers. Purification, either by crystallization or chemoenzymatic methods, always resulted in laborious multistep procedures causing significant loss of material. Here we report new and easy stereoselective methods for the synthesis of (10*E*,12*E*)-octadecadienoic acid using an educt with a conjugated double bond system, (10*Z*,12*Z*)-octadecadienoic acid *via* an enyne-substructure, and the Suzuki cross coupling for the synthesis of (7*E*,9*Z*)-octadecadienoic acid.

MATERIALS AND METHODS

Mass spectra were obtained with the instruments GC 8000 Series/MD800 (Fisons instruments) using a fused-silica capillary column (CP 8944, VF-5ms factor four WCOT; 30 m × 0.25 mm i.d., 0.25 μm film thickness; Varian, Darmstadt, Germany). GC-FTIR data were obtained with the instruments Finnigan Trace GC Ultra GC (Thermo Electron, Dreieich, Germany) with a Vertex 70 spectrometer (Bruker, Rheinstetten, Germany) using a fused-silica capillary column (CP-Sil 88, 100 m × 0.25 mm i.d., 0.2 μm film thickness). NMR spectra were recorded in $CDCl_3$ with a Bruker 400 MHz spectrometer. Liquid chromatography was performed with 60 Å silica gel from MP Biomedicals (Illkirch, France).

All reactions of air- and water-sensitive materials were performed in dried glassware under an argon atmosphere. Most chemicals were purchased from Aldrich; 1-heptyne, dry THF, and dry pyridine were purchased from Fluka (Buchs, Switzerland), while $PdCl_2[PhCN]_2$ was obtained from Merck (Darmstadt, Germany). Dichloromethane was dried over calcium hydride and distilled.

*Preparation of 8-bromo-1-octanol (**2**).* 1,8-Octanediol (**1**) (9.4 g, 64 mmol), 50 mL aqueous hydrobromic acid (48%), and toluene were placed in a liquid-liquid extractor. The extractor was kept at 80°C for 40 h, and the toluene in the flask was heated under reflux. Owing to the circulation of the solvent, the 8-bromo-1-octanol formed during the reaction was transferred to the flask. The toluene containing the reaction product from the flask was washed once with water, twice with saturated

sodium hydrogen carbonate solution, and then with brine. The organic layer was dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was used directly for the next step of the synthesis. Yield: 12.6 g (94%).

*Preparation of 1-(2′-tetrahydropyranyloxy)-8-bromooctane (**3**).* Crude 8-bromo-1-octanol **(2)** (12.6 g) and 1.5 g (7.8 mmol) PPTS in 120 mL of dry dichloromethane were added dropwise at 0°C to a solution of 6 mL (55 g, 66 mmol) of 3,4-dihydropyran in 30 mL of dry dichloromethane. The mixture was stirred overnight at 4°C and poured into ice water. The phases were separated, and the aqueous phase was extracted three times with diethyl ether. The combined organic layers were washed with diluted sodium hydrogen carbonate solution and with brine, then dried over anhydrous magnesium sulfate; then the solvent was removed *in vacuo*. The crude product was purified by flash chromatography over silica using 10:1 hexane/ethyl acetate. Yield: 14.8 g (79 %). MS [*m/z* (%)]: 111 (8), 101 (9), 85 (100), 69 (4), 67 (12), 55 (43), 43 (33), 41 (30), 39 (23). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 1.29–1.48 (*m*, 8H, 3-H to 6-H), 1.49–1.64 (*m*, 6H)/1.67–1.76 (*m*, 1H)/1.79–1.90 (*m*, 3H) (3′-H to 5′-H, 2-H and 7-H), 3.37–3.44 (*m*, 3H, 1-H_a and 8-H), 3.48–3.55 (*m*, 1H, 6′-H_a), 3.69–3.77 (*m*, 1H, 1-H_b), 3.84–3.91 (*m*, 1H, 6′-H_b), 4.56–4.60 (*m*, 1H, 2′-H).

*Preparation of (2E,4E)-decadienol (**5**).* Freshly distilled *(2E,4E)*-decadienal **(4)** (16 g, 10 mmol), dissolved in 65 mL dry dichloromethane, was added to 21 mL (21 mmol) diisobutylaluminum hydride (1 M in dichloromethane) at –78°C over a period of 15 min. The mixture was stirred for an additional 4.5 h at –78°C, and 0.65 mL methanol as well as 20 mL saturated Seignette salt (potassium sodium tartrate) solution was added. After warming to room temperature, the mixture was stirred for an additional 40 min and extracted twice with diethyl ether. The combined organic layers were washed with brine, dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. Yield of the crude product: 1.6 g (79%). MS [*m/z* (%)]: 154 (M^+, 10), 136 (8), 110 (9), 97 (12), 84 (42), 83 (74), 79 (46), 70 (32), 67 (59), 67 (59), 57 (19), 55 (80), 43 (28), 41 (100), 39 (34). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 0.88 (*t*, 3H, *J* = 6.8 Hz, 10-H), 1.22–1.42 (*m*, 6H, 7-H to 9-H), 2.03–2.11 (*m*, 2H, 6-H), 4.11 (*d*, 2H, *J* = 6.1 Hz, 1-H), 5.65–5.73 (*m*, 2H, 2-H and 5-H), 5.99–6.08 (*m*, 1H)/6.15–6.24 (*m*, 1H) (3-H and 4-H).

*Preparation of (2E,4E)-decadienylacetate (**6**).* Catalytic amounts of dimethylaminopyridine and 1.6 g of the crude *(2E,4E)*-decadienol **(5)** were dissolved in 60 mL dry pyridine. To this mixture was added dropwise 1 mL (11 mmol) acetic anhydride, and stirring was continued overnight. After pouring it into 50 mL of ice water, the mixture was extracted three times with hexane. The combined organic layers were washed with brine, dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was purified by flash chromatography over silica using 10:1 hexane/ethyl acetate. Yield: 1.8 g (67%). MS [*m/z* (%)]: 196 (M^+, 6), 153 (2), 136 (2), 110 (4), 97 (2), 80 (16), 79 (26), 70 (3), 67 (15), 55 (10), 53 (4), 43 (100), 41 (20), 39 (9). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 0.79 (*t*, 3H, *J* = 6.8 Hz, 10-H), 1.14–1.34 (*m*, 6H, 7-H to 9-H), 1.95–2.00 (*m*, 5H, 6-H and 2′-H), 4.47 (*d*, 2H, *J* = 6,6 Hz, 1-H), 5.53 (*dt*, 1H, *J* = 15.3 Hz/6.6 Hz)/5.65 (*dt*, 1H, *J* = 15.3 Hz/7.1 Hz)/(2-H and 5-H), 5.88–5.98 (*m*, 1H)/6.16 (*dd*, 1H, *J* = 15.3 Hz/4.8 Hz) (3-H and 4-H).

*Preparation of (10E,12E)-1-(2′-tetrahydropyranyloxy)-octadecadiene (**7**).* In a flask, 0.170 g (7 mmol) magnesium turnings were covered with dry THF, and 2 drops of 1,2-dibromoethane were added. Subsequently, a solution of 1.35 g (4.6 mmol) 1-(2′-tetrahydropyranyloxy)-8-bromooctane **(3)** in 10 mL dry THF was added in such a manner that the solution remained gently boiling. After complete addition, the mixture was heated under reflux for an additional 30 min.

At room temperature, 0.40 g (2 mmol) (2*E*,4*E*)-decadienylacetate **(6)** and 0.8 mL lithium tetrachlorocuprate (0.1 M in THF) in 15 mL dry THF were stirred for 15 min. At –20°C, the solution of 1-(2′-tetrahydropyranyloxy)-8-octylmagnesiumbromide was added, and the mixture was stirred at 0°C for 4 h. After warming to room temperature, the mixture was stirred for an additional hour and poured into an ammonium chloride/hexane mixture at 0°C, which was then extracted three times with hexane. The combined organic layers were washed with brine, dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was purified by flash chromatography over silica using 30:1 hexane/ethyl acetate. Yield: 0.41 g (60%). MS [*m/z* (%)]: 350 (M^+, 0.2), 266 (1), 149 (1), 137 (1), 135 (2), 121 (3), 109 (3), 101 (7), 95 (11), 85 (100), 79 (17), 69 (7), 67 (32), 57 (12), 55 (27), 43 (22), 41 (70), 39 (11). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 0.85 (*t*, 3H, *J* = 6.9 Hz, 18-C), 1.17–1.37 (*m*, 16H, 2-H to 7-H and 16-H to 17-H), 1.45–1.60 (*m*, 8H)/1.65–1.73 (*m*, 1H)/1.75–1.85 (*m*, 1H) (3′-H to 5′-H and 8-H and 15-H), 1.96–2.07 (*m*, 4H, 9-H, and 14-H), 3.36 (*dt*, 1H, *J* = 9.4 Hz/6.7 Hz, 1-H_a), 3.43–3.51 (*m*, 1H, 6′′-H_a), 3.7 (*dt*, 1H, *J* = 9.7 Hz/7.1 Hz 1-H_b), 3.81–3.88 (*m*, 1H, 6′-H_b), 4.53–4.57 (*m*, 1H, 2′H), 5.46–5.58 (*m*, 2H, 10-H, and 13-H), 5.90–6.01 (*m*, 2H, 11-H, and 13-H),

*Preparation of (10E,12E)-octadecadienol (**8**).* Catalytic amounts of 4-toluenesulfonic acid and 0.41 g (1,2 mmol) (10*E*,12*E*)-1-(2′-tetrahydropyranyloxy)-octadecadiene **(7)** were dissolved in 10 mL methanol. After stirring for 30 min at 60°C, solid sodium hydrogen carbonate was added, and the suspension was stirred for an additional 15 min. *In vacuo* the mixture was reduced to *ca*. 30% of the original volume. After the addition of water, the mixture was extracted three times with diethyl ether. The combined organic layers were dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. Yield of the crude product: 0.37 g (*ca*. 100%). MS [*m/z* (%)]: 266 (M^+, 4), 150 (1), 135 (3), 110 (5), 95 (23), 81 (33), 79 (37), 69 (11), 67 (56), 55 (42), 43 (27), 41 (100), 39 (21). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 0.88 (*t*, 3H, *J* = 6.8 Hz, 18-H), 1.24–1.41 (*m*, 16H, 4-H to 8-H and 15-H to 17-H), 1.51–1.60 (*m*, 2H, 2-H), 2.00–2.08 (*m*, 4H, 9-H, and 14-H), 3.63 (*t*, 2H, *J* = 6,6 Hz, 2-H), 5.51–5.60 (*m*, 2H, 10-H, and 13-H), 5.94–6.04 (*m*, 2H, 11-H and 12-H).

*Preparation of (10E,12E)-octadecadienoic acid (**A**).* Crude (10*E*,12*E*)-octadecadienol **(8)** (0.37 g) was dissolved in 5 mL acetone, and Jones reagent [acidic solution of Cr(VI)] was

added dropwise at 0°C, until the reddish-brown color did not switch to green. After addition of one drop of 2-propanol, the suspension was filtered, and the mixture was reduced *in vacuo* to *ca*. 25% of the original volume. After addition of 10 mL water and 10 mL diethyl ether, the aqueous layer was extracted four times with diethyl ether. The combined organic layers were extracted four times with a 1 N solution of sodium hydroxide. Subsequently, the alkaline soapy solution was acidified with 2 N hydrochloric acid to pH 4 and was extracted four times with diethyl ether. The combined organic layers were dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was recrystallized from methanol to give 10 mg (3%) of the desired product. For NMR data see Table 1.

*Preparation of (Z)-1-bromo-1-heptene (**11**).* 1-Heptyne **(9)** (1.7 g, 17.7 mmol) and 2.1 g 1,3,2-benzodioxaborole (17.7 mmol) were placed in a dry 25-mL flask. The mixture was heated for 2 h at 70°C and cooled to room temperature. After addition of 5 mL dry dichloromethane, the solution was cooled to –20°C; and 2 mL bromine, dissolved in 8 mL dry dichloromethane, were added dropwise. After the addition was completed, 20 mL 2 N sodium hydroxide solution was added carefully at –80°C, and the solution was stirred for 1 h at room temperature. The solution was then extracted three times with dichloromethane; the combined organic layers were washed with brine and dried over anhydrous magnesium sulfate. The solvent was removed *in vacuo,* and the product was purified by kugelrohr distillation to give 2.3 g (72%) of (*Z*)-1-bromo-1-heptene. MS [*m/z* (%)]: 178 (M^+, 8), 176 (M^+, 8), 136 (1), 134 (1), 121 (7), 119 (7), 97 (19), 70 (31), 55 (100), 41 (62). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 0.89 (*t*, 3H, *J* = 6.9 Hz, 7-H), 1.24–1.46 (*m*, 6H, 4-H to 6-H), 2.16–2.22 (*m*, 2H, 3-H), 6.05–6.15 (*m*, 2H, 1-H, and 2-H).

*Preparation of 1-(2′-tetrahydropyranyloxy-)-10-undecyne (**13**).* At 0°C a solution of 2.8 g (3 mL, 33 mmol) 2,3-dihydropyrane in 15 mL dry dichloromethane was added dropwise to a solution of 5.0 g 10-undecyn-1-ol **(12)** (30 mmol) and 0.75 g pyridinium-4-toluene sulfonate (3 mmol) in 60 mL dry dichloromethane. The mixture was stirred overnight at 4°C, poured into ice water, and extracted three times with diethyl ether. The combined organic layers were washed with diluted sodium hydrogen carbonate and brine and dried over anhydrous magnesium sulfate. The solvent was removed *in vacuo,* and the crude product was purified by flash chromatography on silica using 8:1 hexane/ethyl acetate. Yield: 5.6 g (74%). MS [*m/z* (%)]: 251 (M^+, 1), 101 (17), 95 (11), 85 (100), 67 (23), 55 (25), 41 (26). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 1.23–1.43 (*m*, 12H, 2-H to 7-H), 1.47–1.63 (*m*, 6H)/1.66–1.75 (*m*, 1H)/1.77–1.87 (*m*, 1H) (3′-H to 5′-H and 4-H), 1.93 (*t*, 1H, *J* = 2.6 Hz, 1-H), 2.17 (*dt*, 2H, *J* = 2.5/7.1 Hz, 3-H), 3.38 (*dt*, 1H, *J* = 9.4/6.7 Hz, 6′-Ha), 3.46–3.53 (*m*, 1H, 1-Ha), 3.72 (*dt*, 1H, *J* = 9.4/6.7 Hz, 6′-Hb), 3.83–3.90 (*m*, 1H, 1-Hb)

*Preparation of (Z)-1-(2′-tetrahydropyranyloxy)-octadec-10-yn-12-ene (**14**).* (*Z*)-1-Bromo-1-heptene **(11)** (0.71 g, 4 mmol), 76 mg copper(I) iodide (0.4 mmol), 76 mg bis(benzonitrile)-dichloropalladium(II) ($PdCl_2[PhCN]_2$, 0.2 mmol), and 12 mL piperidine were placed in a 25-mL dry flask. To this suspension 2.0 g (8 mmol) 1-(2′-tetrahydropyranyloxy-)-10-undecyne (**13**) was added at room temperature. After stirring for 2 h, saturated aqueous ammonium chloride solution was added to the suspension, which was extracted three times with diethyl ether. The combined organic layers were washed with 0.2 N hydrochloric acid, saturated sodium hydrogen carbonate solution, and twice with water. The organic layer was dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo.* The crude product was purified by flash chromatography over silica using 50:1 hexane/ethyl acetate. Yield: 1.2 g (86%). MS [*m/z* (%)]: 348 (M^+, 2), 264 (1), 219 (2), 205 (1), 177 (1), 163 (1), 121 (4), 101 (5), 85 (100), 79 (21), 55 (32), 41 (60). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 0.89 (*t*, 3H, *J* = 6.9 Hz, 18-H), 1.26–1.45 (*m*, 16H, 2-H to 7-H and 16-H to 17-H), 1.50–1.62 (*m*, 8H)/1.67–1.75 (*m*, 1H)/1.79–1.88 (*m*, 1H) (3′-H to 5′-H and 8-H and 15-H), 2.24–2.35 (*m*, 4H, 9-H and 14-H), 3.38 (*dt*, 1H, *J* = 9.7 Hz/6.6 Hz, 1-H_a), 3.47–3.53 (*m*, 1H, 6′-H_a), 3.73 (*dt*, 1H, *J* = 9.66 Hz/6.9 Hz, 1-H_b), 3.83–3.90 (*m*, 1H, 6′-H_b), 4.53–4.59 (*m*, 1H, 2′-H), 5.40–5.45 (*m*, 1H, 12-H), 5.80 (*dt*, 1H, *J* = 10.7 Hz/7.4 Hz, 13-H).

*Preparation of (10Z,12Z)-1-(2′-tetrahydropyranyloxy)-octadecadiene (**15**).* Dropwise and at 0°C, 0.43 mL (9 mmol) borane dimethyl sulfide complex was added to a solution of 0.90

mL (9 mmol) cyclohexene in 21 mL dry hexane. The mixture was stirred until a white precipitate had formed (*ca*. 10 min).

At 0°C, 3.6 mL of the freshly prepared dicyclohexylborane solution was added to 0.35 g (*Z*)-1-(2′-tetrahydropyranyloxy-)-octadec-10-yn-12-ene **(14)** (1 mmol), dissolved in 20 mL dry hexane. The mixture was stirred for 2 h at room temperature and diluted with 8 mL dry THF. After the addition of 0.50 mL acetic acid, the mixture was heated to 50°C for 3 h. The solution was cooled to room temperature and hydrolyzed with 2 mL sodium hydroxide solution (5 M) and 0.44 mL of 30% aqueous hydrogen peroxide solution. The mixture was stirred for an additional 30 min, poured into ice water, and extracted three times with hexane. The combined organic layers were washed with brine, dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was purified by flash chromatography over silica using 100:1 hexane/ethyl acetate. Yield: 216 mg (62%). MS [*m/z* (%)]: 350 (M^+, 0.1), 266 (1), 101 (12), 95 (10), 85 (100), 81 (13), 67 (25), 55 (16), 41 (24). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 0.89 (*t*, 3H, *J* = 6.9 Hz, 18-C), 1.25–1.40 (*m*, 16H, 2-H to 7-H and 16-H to 17-H), 1.48–1.61 (*m*, 8H)/1.67–1.75 (*m*, 1H)/ 1.80–1.86 (*m*, 1H) (3′-H to 5′-H and 8-H and 15-H), 2.13–2.20 (*m*, 4H, 9-H and 14-H), 3.38 (*dt*, 1H, *J* = 9.7 Hz/6.6 Hz, 1-H_a), 3.46–3.53 (*m*, 1H, 6′-H_a), 3.73 (*dt*, 1H, *J* = 9.7 Hz/6.9 Hz, 1-H_b), 3.84–3.91 (*m*, 1H, 6′-H_b), 4.56–4.59 (*m*, 1H, 2′H), 5.40–5.48 (*m*, 2H, 10-H and 13-H), 6.20–6.30 (*m*, 2H, 11-H and 12-H).

*Preparation of (10Z,12Z)-octadecadienol (**16**).* (10*Z*,12*Z*)-1-(2′-Tetrahydropyranyloxy)-octadecadiene **(15)** (0.216 g, 0.62 mmol) was dissolved in 10 mL methanol, and catalytic amounts of *p*-toluenesulfonic acid were added. After the mixture had been stirred overnight at room temperature, solid sodium hydrogen carbonate was added, and the suspension was stirred for an additional 15 min. *In vacuo* the mixture was reduced to *ca*. 25% of the original volume, water was added, and the solution was extracted three times with diethyl ether. The combined organic layers were dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was purified by flash chromatography over silica using 5:1 hexane/ethyl acetate. Yield: 0.188 g (*ca*. 100%). MS [*m/z* (%)]: 266 (M^+, 4), 248 (1), 149 (2), 135 (7), 121 (11), 109 (14), 95(40), 81 (65), 67 (100), 55 (47), 41 (73). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 0.89 (*t*, 3H, *J* = 6.9 Hz, 18-C), 1.25–1.40 (*m*, 20H, 2-H to 8-H and 15-H to 17-H), 1.51–1.60 (*m*, 4H, 9-H and 14-H), 3.63 (*t*, 2H, *J* = 6,6 Hz, 1-H), 5.40–5.49 (*m*, 2H, 10-H and 13-H), 6.20–6.28 (*m*, 2H, 11-H and 12-H).

*Preparation of (10Z,12Z)-octadecadienoic acid (**B**).* (10*Z*,12*Z*)-Octadecadienol (**16**) (97 mg, 0.4 mmol), dissolved in 5 mL acetone, was added dropwise to Jones reagent at 0°C until the reddish-brown color did not switch to green. After addition of one drop of 2-propanol, the suspension was filtered. Subsequently, the mixture was concentrated *in vacuo* to *ca*. 25% of the original volume. Then, after addition of 10 mL water and 10 mL diethyl ether, the aqueous layer was extracted four times with diethyl ether. The combined organic layers were dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was purified by flash chromatography over silica using 2:3 hexane/ethyl acetate. Yield: 56 mg (50%). For NMR data see Table 1.

*Preparation of (Z)-1-bromo-1-decene (**19**).* In a dry flask 4.2 g (40 mmol) 1-decyne **(17)** and 4.8 g (40 mmol) 1,3,2-benzodioxaborole were heated for 2 h at 70°C. The mixture was cooled to room temperature and dissolved in 25 mL dry dichloromethane. At –20°C, 4.1 mL bromine dissolved in 18 mL dry dichloromethane was added, and the solution was brought to –80°C. Sodium hydroxide solution, 41 mL, 2 N, was added slowly so that the temperature inside the flask did not rise above –20°C. After stirring for 1 h at room temperature, the mixture was extracted three times with dichloromethane, washed with brine, dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was used in the next step without further purification.

*Preparation of 7-octyne-1-ol (**21**).* Dry 1,3-diaminopropane (110 mL) and 15 g (214 mmol) lithium were stirred until all lithium had been dissolved (30 min). The obtained blue solution was kept at 70°C until a white suspension formed, and the blue color disappeared (overnight). The mixture was cooled to room temperature, and 16 g (142 mmol) potassium *tert*-butanolate was added. The resulting yellow solution was stirred for an additional 20 min. The mixture was cooled in a water bath, and 4.5 g (36 mmol) 2-octyne-1-ol (**20**) was slowly added so that the temperature remained below 30°C. After stirring for 30 min at room temperature, the solution was poured into ice water and extracted four times with hexane. The combined organic layers were washed with water, 10% hydrochloric acid, brine, dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was purified by flash chromatography over silica using 2:1 hexane/ethyl acetate. Yield: 2.5 g (55%). MS [*m/z* (%)]: 107 (2), 95 (13), 93 (30), 79 (60), 67 (64), 55 (36), 41 (100). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 1.30–1.44 (*m*, 4H, 3-H and 4-H), 1.46–1.58 (*m*, 4H, 2-H and 5-H), 1.91 (*t*, 1H, *J* = 2.7 Hz, 8-H), 2.15 (*dt*, 2H, *J* = 2.5 Hz/7.0 Hz, 6-H), 3.59 (*t*, 2H, *J* = 6.6 Hz, 1-H).

*Preparation of (E)-1-octenylboronic acid (**22**).* 1,3,2-Benzodioxaborole (21 mL, 19 mmol) was slowly added to 1.2 g (9.5 mmol) 7-octyn-1-ol (**21**) dissolved in 5 mL dry THF. After the formation of hydrogen had ceased, the mixture was refluxed for 5 h. After cooling to room temperature, 10 mL water was added, and stirring was continued for 2 h. The generated white precipitate was put in the refrigerator overnight and was isolated upon filtration at 0°C the next day. The precipitate was washed with ice-cold water to remove excess catechol. The crystals were dried over P_2O_5. The crude product was used in the next step without further purification. Yield: 0.81 g (35%).

*Preparation of (7E,9Z)-octadecadien-1-ol (**23**).* A mixture of 0.72 g (3 mmol) (*E*)-1-octenylboronic acid (**22**), 0.41 g (6 mmol) sodium ethanolate in 3 mL ethanol (2 M), and catalytic amounts of 2(3)-*tert*-butyl-4-methoxyphenol (BHA) were dissolved in 3 mL toluene. The mixture was added dropwise at room temperature to a mixture of 0.46 g (2 mmol) (*Z*)-1-bromo-1-decene (**19**) and 0.10 g (0.1 mmol) $Pd(PPh_3)_4$, dissolved in 6 mL toluene. The solution was heated for 2 h at

65°C. After cooling to room temperature, 6 mL 30% aqueous hydrogen peroxide and 6 mL 2 N sodium hydroxide solution were added slowly to destroy the excess borane. The reaction mixture was extracted three times with diethyl ether, and the combined organic layers were washed with water, brine, dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was purified by flash chromatography over silica using 5:1 hexane/ethyl acetate. Yield: 0.34 g (61%). MS [*m/z* (%)]: 266 (M^+, 11), 248 (2), 149 (3), 135 (7), 121 (11), 109 (11), 95 (25), 79 (70), 67 (100), 55 (36), 41 (83). ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 0.88 (*t*, 3H, *J* = 6.9 Hz, 18-H), 1.24–1.44 (*m*, 18H, 3-H to 5-H and 12-H to 17-H), 1.54–1.61 (*m*, 2H, 2-H), 2.07–2.17 (*m*, 4H, 6-H and 11-H), 3.64 (*t*, 2H, *J* = 6.6 Hz, 1-H), 5.31 (*dt*, 1H, *J* = 10.7 Hz/7.4 Hz, 10-H), 5.64 (*dt*, 1H, *J* = 15.0 Hz/7.1 Hz, 7-H), 5.93 (*dd*, 1H, *J* = 10.9 Hz/10.9 Hz, 9-H), 6.30 (*ddd*, 1H, *J* = 10.9 Hz/15.0 Hz/1.28 Hz, 8-H).

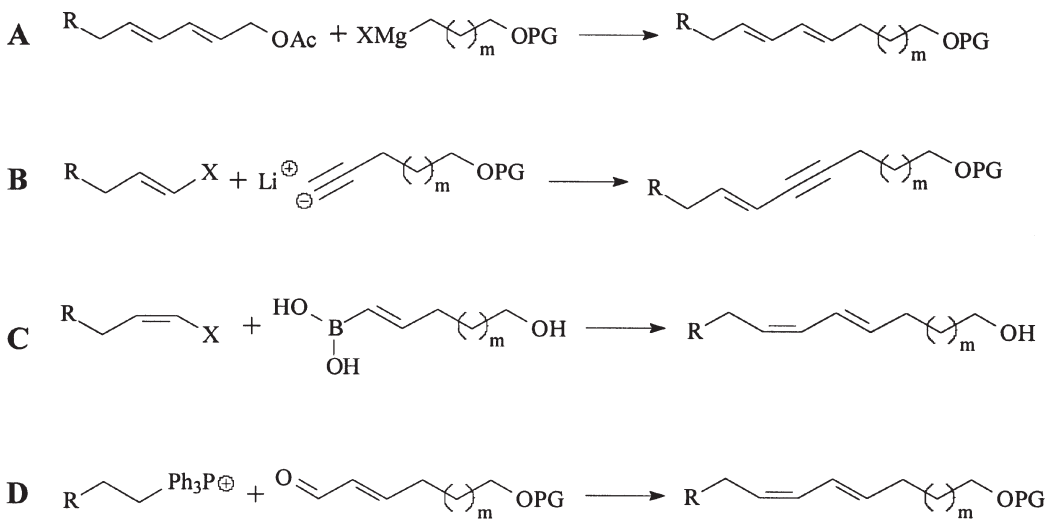
*Preparation of (7E,9Z)-octadeca-7,9-dienoic acid (**C**).* At room temperature and for 2.5 h 0.34 g (1.3 mmol) (7*E*,9*Z*)-octadecadien-1-ol (**23**), 1.95 g (5.2 mmol) pyridinium dichromate, and 7.8 mL dimethylformamide (DMF) were stirred. The mixture was poured into water, which was acidified with hydrochloric acid and then extracted three times with diethyl ether. The combined organic layers were washed with brine, dried over anhydrous magnesium sulfate, and the solvent was removed *in vacuo*. The crude product was purified by flash chromatography over silica using 5:1:0.05 hexane/ethyl acetate/formic acid. Yield: 163 mg (45%). For NMR data see Table 1.

RESULTS AND DISCUSSION

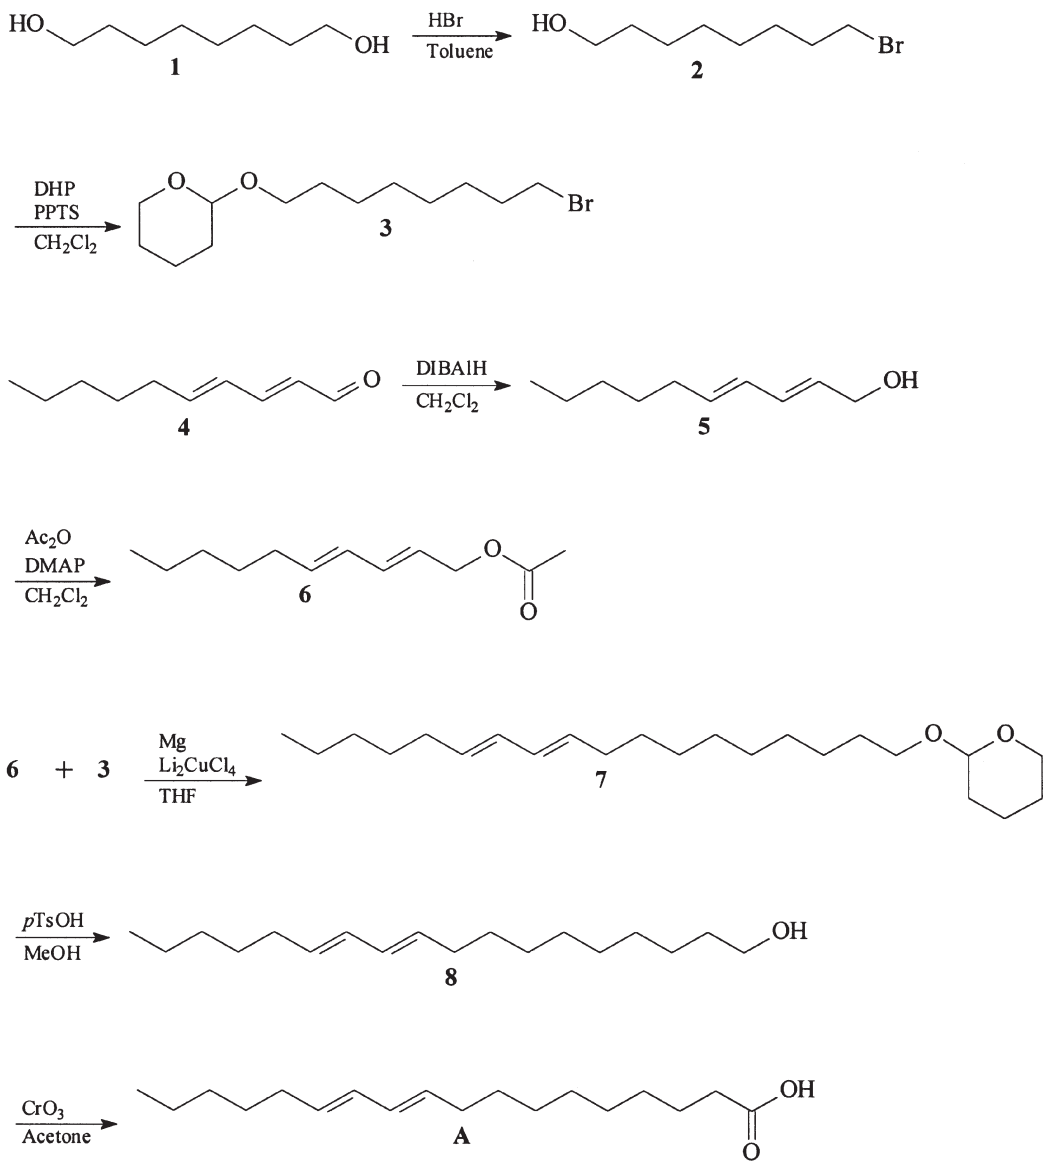
Because of the difficulties in the isolation of single isomers from more or less complex mixtures, stereoselective syntheses of octadecadienoic acids with conjugated double bonds, also called CLA, are advantageous as they do not entail further purification procedures. Several strategies are used in the preparation of stereochemically pure CLA. The approach of choice depends largely on the availability of the corresponding starting material and yields, as well as on demands concerning absolute amounts and (stereochemical) purity of the product. In this paper we describe four different syntheses, three of which we followed in detail to evaluate the reactions with respect to the above-mentioned criteria.

A simple method (Scheme 1A) involves chain elongation of an appropriate dienic compound with a Grignard reagent using Schlosser–Fouquet conditions (10). If the Grignard reagent is prepared from a protected ω-halogen alcohol, the resulting protected dienol needs to be converted to the corresponding dienoic acid. Yields of the reaction are good, and the stereochemical purity of the product is the same as that of the educt.

A second sequence (Scheme 1B) involves the construction of an enyne system followed by stereoselective hydrogenation of the triple bond. The enyne may be formed upon Sonogashira reaction of an (*E*)- or (*Z*)-configured vinyl halide with the anion of a terminal alkyne (11). Whereas the triple bond cannot be successfully transformed to an (*E*)-double bond, hydrogenation by using a copper-activated zinc catalyst (12) or a borane (13) generates a double bond with high (*Z*)-selectivity. Other methods, for example the reduction of alkynes by metallic sodium or lithium dissolved in liquid ammonia, also yield *trans*-alkenes, but the purity of the products would be insufficient for the synthesis of pure isomers. As a result, depending on the configuration of the vinyl halogenide and on the location of the additional terminal oxygen-containing functional group (either in the vinyl halide or in the alkyne), conjugated (*Z*,*Z*)-, (*Z*,*E*)-, and (*E*,*Z*)-systems may be produced. Yields of the reactions are good to excellent, but the stereochemical purity of the products is not constantly high. The coupling reaction is somewhat tricky with respect to stereoselectivity, and conditions must be carefully optimized and controlled. It should be mentioned that the (*Z*,*Z*)-configured dienes are always a bit unstable and prone to rearrangements.



SCHEME 1



SCHEME 2

An alternative approach, also resulting in the formation of an enyne, would be a stereoselective Wittig reaction involving a propargylic aldehyde. A simpler reaction of a readily available (*E*)-2-alkenal with an appropriate Wittig reagent would directly yield a conjugated system (Scheme 1C). In our hands, yields of reactions were always good; however, the stereoselectivity was frequently found to be insufficient.

An elegant and versatile method for the generation of a conjugated double bond system is the Pd(0)-catalyzed coupling of a vinyl halide with a corresponding partner (Scheme 1D). The Suzuki reaction provides access to all four stereoisomers, as an (*E*)-or (*Z*)-1-alkenylboronic acid may be linked to an (*E*)- or (*Z*)-configured vinyl halide (14). While we could not constantly obtain very high yields, the stereoselectivity of the reaction was always excellent.

The first approach, a simple method for the synthesis of (10*E*,12*E*)-octadecadienoic acid **(A)** (Scheme 2), uses 1,8-octanediol (**1**) and commercially available (2*E*,4*E*)-decadienal (**4**). 1,8-Octanediol was converted to 8-bromo-1-octanol (**2**) using a liquid-liquid extractor to avoid bromination of both hydroxy groups. The free hydroxy group was then protected with 3,4-dihydropyran, yielding 8-(2′-tetrahydropyranyloxy)-1-bromooctane (**3**) as the first building block. The second building

TABLE 2
Yields and Purities of Synthesized Octadecadienols

Compound	Overall yield (%)	Stereochemical purity (%)	Method
10*E*,12*E* **(A)**	40	93[a]	Diene elongation

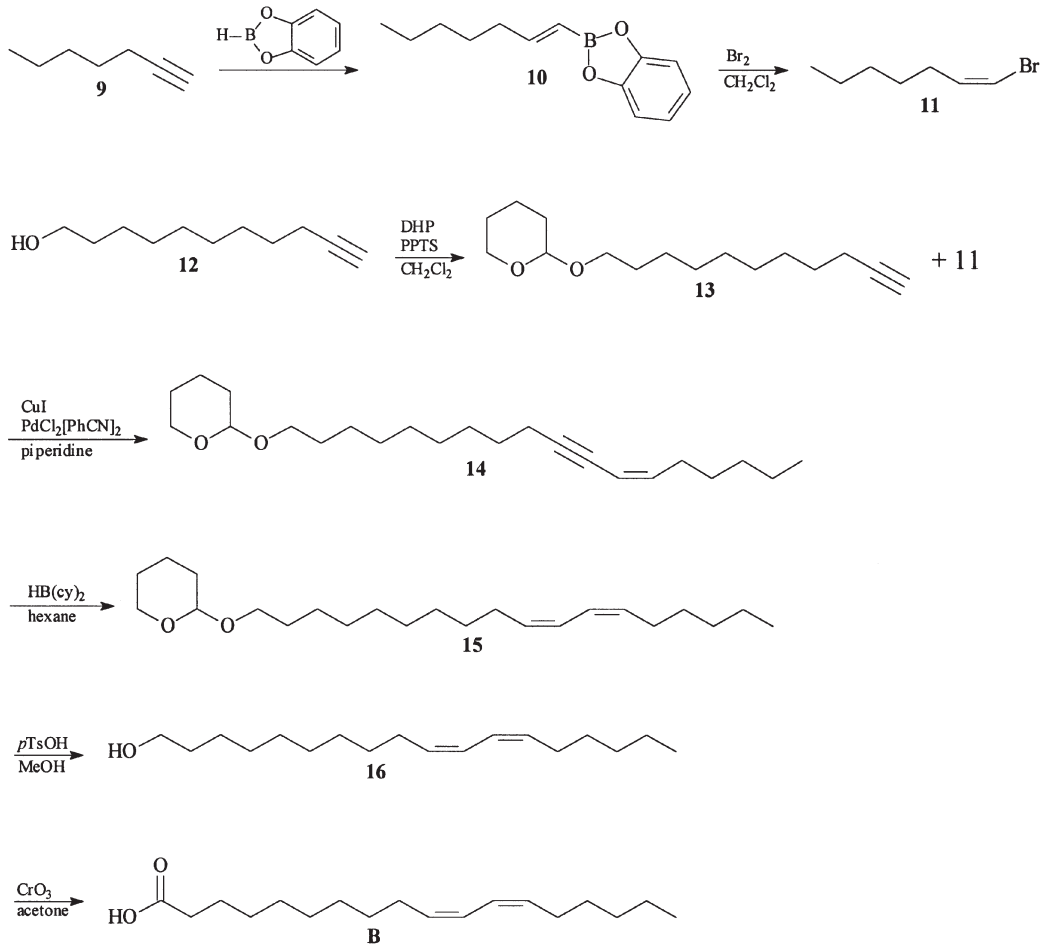
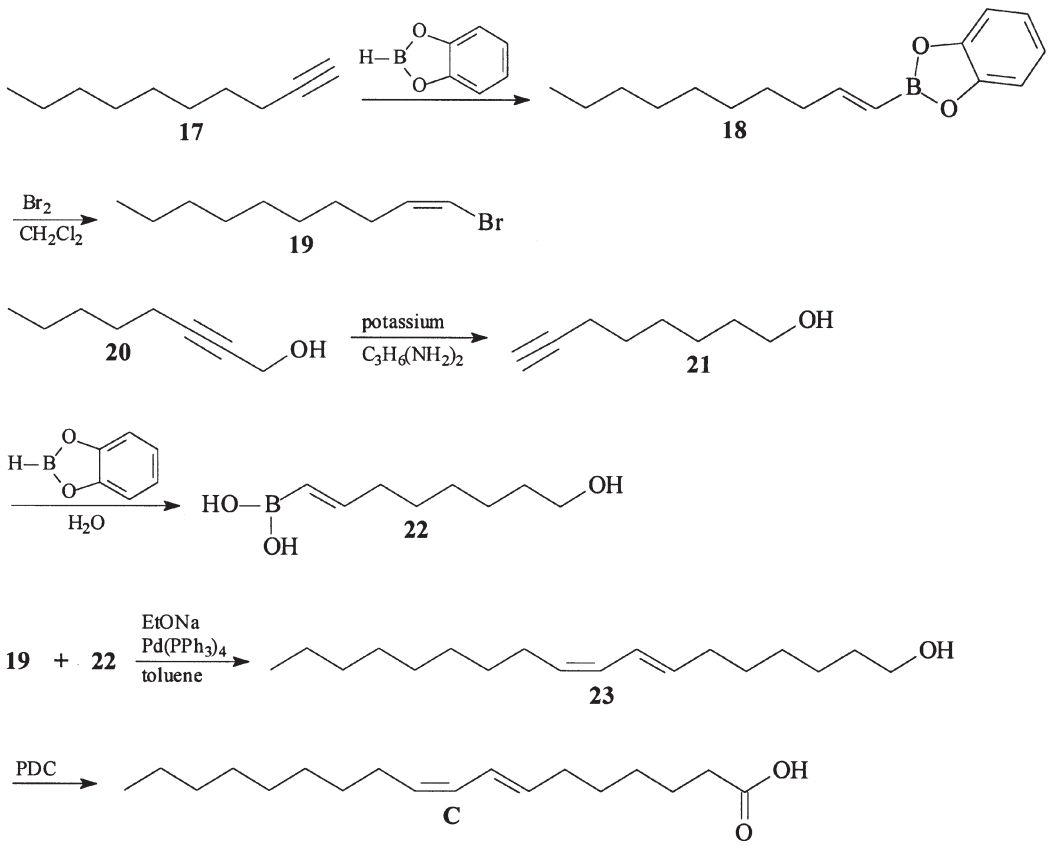


SCHEME 3

block was generated from (2*E*,4*E*)-decadienal, which was reduced to (2*E*,4*E*)-decadienol using diisobutylaluminum hydride. The hydroxy group was acetylated with acetic anhydride yielding (2*E*,4*E*)-decadienylacetate (**6**). For the coupling of these two building blocks, 8-(2′-tetrahydropyranyloxy)-1-bromoctane (**3**) was converted to the Grignard reagent, which was then added to a solution of (2*E*,4*E*)-decadienylacetate (**6**) and lithiumtetrachlorocuprate (10). The obtained protected alcohol (**7**) showing a conjugated (*E*,*E*)-configured double bond system was deprotected to yield (10*E*,12*E*)-octadecadienol (**8**), which was oxidized to (10*E*,12*E*)-octadecadienoic acid **A** with Jones reagent (15). Owing to dehydrobromination of the protected alkenyl bromide, 1-(2′-tetrahydropyranyloxy)-7-octene may be formed as a by-product during the coupling reaction with lithium tetrachlorocuprate. This impurity can be easily removed by liquid chromatography or by recrystallization of the acid from methanol. This method furnished (10*E*,12*E*)-octadecadienoic acid in a stereochemical purity of 93% (capillary GC, CP 8944, VF-5ms factor four WCOT; see Table 2).

The second approach, the synthesis of (10*Z*,12*Z*)-octadecadienoic acid **(B)**, proceeding *via* an enyne substructure (Scheme 3), requires (*Z*)-1-bromo-1-heptene (**11**) and 1-(2′-tetrahydropyranyloxy)-undec-10-yne (**13**) as the building blocks. (*Z*)-1-Bromo-1-heptene (**11**) was prepared by reaction of 1,3,2-benzodioxaborole with 1-heptyne (**9**), yielding the (*E*)-1-alkenylboronic acid ester **10**. The *trans*-configured double bond was reacted with bromine, which proceeded with *trans*-addition. The following elimination of the borone moiety and bromide produced the desired (*Z*)-1-bromo-1-heptene (16). Coupling this intermediate to protected 10-undecyn-1-ol yielded (*Z*)-1-(2′-tetrahydropyranyloxy)-octadec-10-yn-12-ene (**14**). The subsequent coupling was catalyzed by copper iodide and bis(benzonitrile)dichloropalladium(II), furnishing good yields with piperidine as the ideal solvent (11). The (*Z*,*Z*)-configured conjugated diene system was generated by hydrogenation of the triple bond using dicyclohexylborane (15). Stereoselective *syn*-addition of dicyclohexylborane followed by deprotection yielded (10*Z*,12*Z*)-octadecadienol (**16**). The latter was oxidized with Jones reagent to yield (10*Z*,12*Z*)-octadecadienoic acid **B**. This approach is suitable for isomers with at least one *Z*-configured double bond, because selective hydrogenation of the triple bond to the *E*-configured double bond is not possible. For the synthesis of (10*Z*,12*Z*)-octadecadienoic acid an overall yield of 20% with a stereochemical purity of 80% was achieved (capillary



SCHEME 4

GC, CP 8944, VF-5ms factor four WCOT, see Table 2). The major impurity was (10*Z*,12*E*)-octadecadienoic acid.

The third approach, a Suzuki coupling to (7*E*,9*Z*)-octadecadienoic acid (**C**) (Scheme 4), started with 1-decyne (**17**) and 7-octyn-1-ol (**21**), prepared from 2-octyne-1-ol (**20**) through Zipper reaction (17). To obtain the boronic acid (**22**), 7-octyne-1-ol was reacted with 1,3,2-benzodioxaborole using THF as the solvent. Hydrolysis to **22** was achieved by adding water and stirring for 2 h at room temperature (14). The second building block was prepared from 1-decyne (**17**), which was reacted with 1,3,2-benzodioxaborole to yield the (*E*)-1-alkenylboronic acid ester **18**. The *trans*-configured double bond was reacted with bromine, which proceeded with *trans*-addition. The following elimination of the borone moiety and bromide produced the desired (*Z*)-1-bromo-1-decene (**19**) (16). Coupling of the two building blocks was achieved with tetrakis triphenylphosphine palladium(0) using sodium ethanolate as base (14). The obtained (7*E*,9*Z*)-octadecadien-1-ol (**23**) was oxidized with pyridinium dichromate in DMF (18) yielding (7*E*,9*Z*)-octadecadienoic acid (**C**) in good yields. By following this method, all four geometrical isomers of

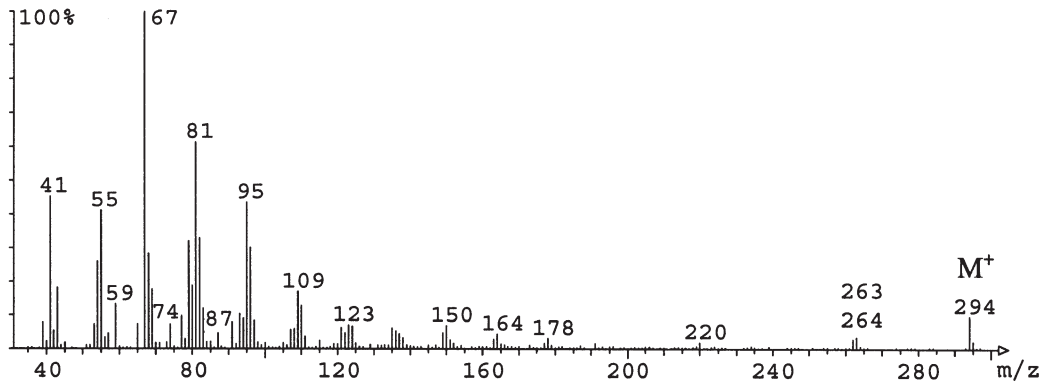


FIG. 1. Mass spectrum of methyl (10*E*,12*E*)-octadecadienoate.

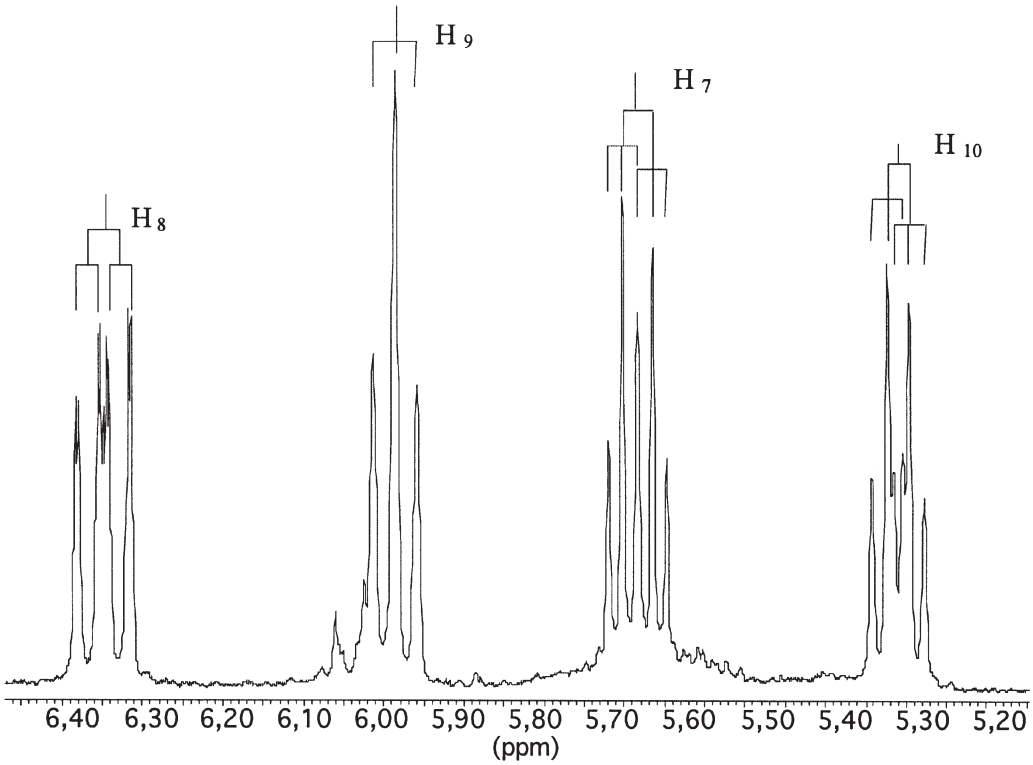

FIG. 2. ^{1}H NMR of olefinic protons of 7*E*,9*Z*-CLA.

octadecadienoic acid are accessible (14). For the synthesis of (7*E*,9*Z*)-octadecadienoic acid, an overall yield of 10% and a stereochemical purity of 98% was achieved (capillary GC, CP 8944, VF-5ms factor four WCOT, see Table 2).

In the context of our investigations, two different approaches for the oxidation of octadecadienols were followed: oxidation with Jones reagent (15) or with pyridinium dichromate (18). Oxidation with Jones reagent furnished low yields (<20%). Relatively large amounts of by-products were formed on decomposition of the chain. Several recrystallization steps were necessary for purification. Oxidation with pyridinium dichromate yielded the desired products in yields up to 45%, and lower amounts of by-products were formed. A third method proved to be even superior to PDC: During a two-step procedure, the alcohol is first oxidized to the aldehyde [e.g., Swern oxidation (19) or Dess–Martin oxidation (20)], which is then further oxidized with sodium chlorite (21). Although the synthesis of CLA involves an additional step, yields were higher and purification of the crude products was easier.

For the characterization of synthesized compounds, several methods were used. Mass spectra of methyl esters of dienoic acids may confirm the presence of a conjugated double bond system; however, they do not provide reliable information about the position or configuration of double bonds. As an example, the mass spectrum of methyl (10*E*,12*E*)-octadecadienoate is shown in Figure1. Mass spectra of methyl esters of stereoisomers look the same; the fragmentation pattern of positional isomers is also very similar.

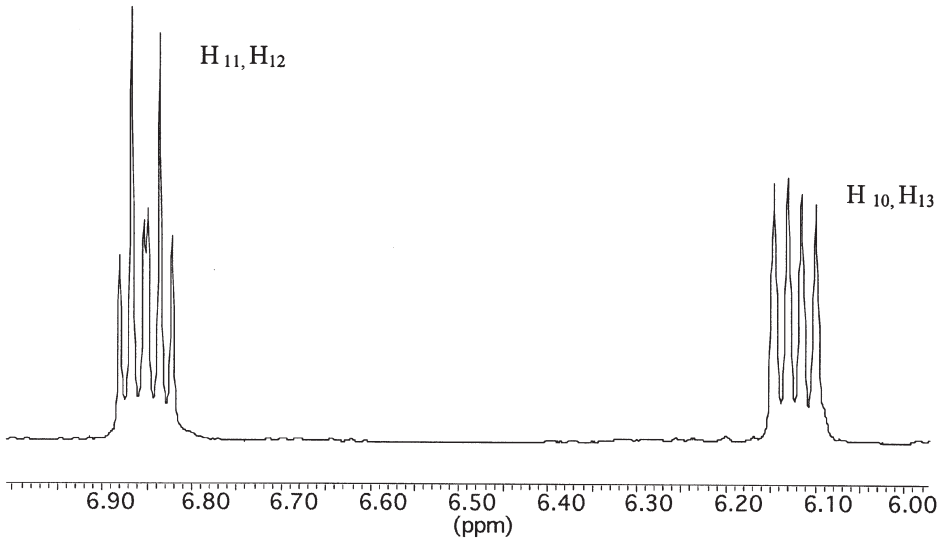

FIG. 3. ^{1}H NMR of olefinic protons of 10*Z*,12*Z*-CLA.

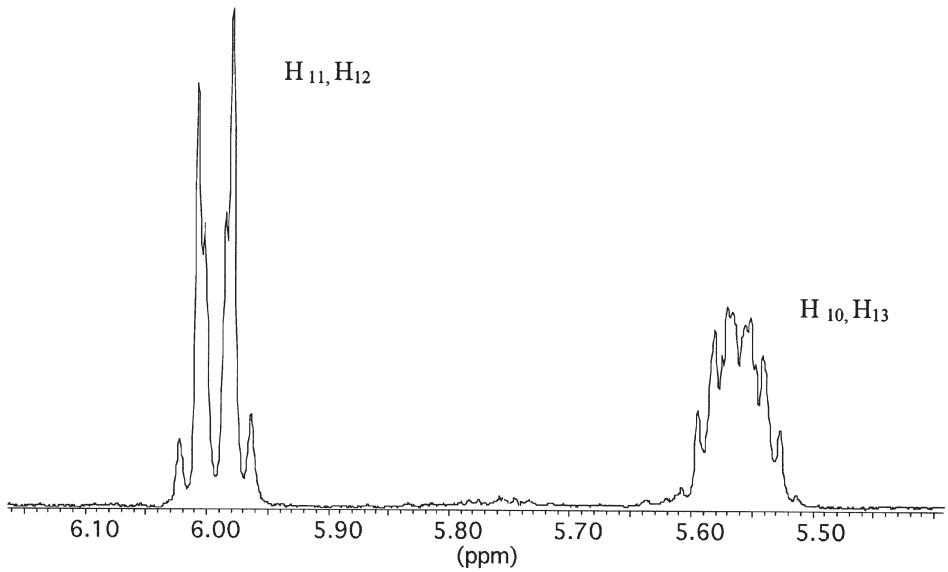

FIG. 4. ^{1}H NMR of olefinic protons of 10*E*,12*E*-CLA.

Information on the configuration of double bonds can be obtained from ^{1}H NMR spectra. Figure 2 shows the olefinic protons of 7*E*,9*Z*-CLA. Owing to the appearance of distinct signals for every olefinic proton, the conformation can be determined by investigation of the coupling constants (see Table 3). as *EE*- or *ZZ*-configured dienes represent symmetrical systems, attribution of configuration *via* coupling constants is very difficult or even impossible (Figs. 3, 4). In contrast, IR spectra provide valuable information to distinguish between these two stereoisomers (Fig. 5). For *EE*-configured isomers, a sharp absorption just below 1000 cm^{-1} can be seen. In contrast, *ZE*- or *EZ*-configured isomers show two smaller absorptions in the same region, whereas *ZZ*-configured isomers do not show a pronounced absorption between 900 and 1000 cm^{-1} (22).

ABSTRACT: The object of this study was to investigate the characteristics of lipid metabolism in obese subjects, with particular emphasis on the alteration of HDL subclass contents and distributions. A population of 581 Chinese individuals was divided into four groups (25 underweight subjects, 288 of desirable weight, 187 overweight, and 45 obese) according to body mass index (BMI). Apoprotein A-I (apoA-I) contents of plasma HDL subclasses were determined by 2-D gel electrophoresis associated with an immunodetection method. The concentrations of TG and the apoA-I content of pre-β_1-HDL were significantly higher ($P < 0.01$ and $P < 0.01$, respectively), but the levels of HDL cholesterol, and the apoA-I contents of HDL_{2a} and HDL_{2b} were significantly lower ($P < 0.01$, $P < 0.05$, and $P < 0.01$, respectively) in obese subjects than in subjects having a desirable weight. Moreover, with the elevation of BMI, small-sized pre-β_1-HDL increased gradually and significantly, whereas large-sized HDL_{2b} decreased gradually and significantly. Meanwhile, the variations in HDL subclass distribution were more obvious with the elevation of TG levels in obese as well as overweight subjects. In addition, Pearson correlation analysis revealed that BMI and TG levels were positively correlated with pre-β_1-HDL but negatively correlated with HDL_{2b}. Multiple regression analysis also showed that TG concentrations were associated independently and positively with high pre-β_1-HDL and independently and negatively with low HDL_{2b} in obese and overweight subjects. The HDL particle size was smaller in obese and overweight subjects. The shift to smaller size was more obvious with the elevation of BMI and TG, especially TG levels. These observations, in turn, indicated that HDL maturation might be abnormal, and reverse cholesterol transport might be impaired.

Paper no. L9976 in *Lipids 41*, 789–796 (August 2006).

Epidemiologic data have firmly established that HDL evaluated by its cholesterol (C) content is inversely correlated with the incidence and prevalence of atherosclerosis (1,2). Low HDL-C level has been a significant independent risk factor for atherosclerosis in many prospective human population studies. (3,4). This antiatherogenic action of HDL is probably related to reverse cholesterol transport (RCT), by which excess peripheral cholesterol is returned to the liver (5). In recent years, changes in HDL subclass distribution have been considered as more closely correlated with atherosclerosis than low plasma HDL-C levels (6). Many investigators believe that measuring HDL subclasses provides additional information about atherosclerotic risk as well as about the underlying physiological mechanism(s) responsible for that risk. Atger *et al.* (7) considered that the alteration of plasma HDL subclasses might be an important marker for susceptibility to the development of coronary heart disease (CHD).

Differences in the quantitative and qualitative content of lipids, apolipoproteins (apo), enzymes, and lipid transfer proteins result in the various HDL subclasses, which are characterized by shape, density, size, charge, and antigenicity (8). Subclasses of HDL can be separated by zonal (9) or single-spin vertical ultracentrifugation (10), heparin-magnesium precipitation (11), NMR spectroscopy (12), or 1- and 2-D PAGE. Using 2-D gel electrophoresis (13,14) and subsequent immunoblotting, HDL can be subdivided into large- (HDL_{2a} and HDL_{2b}) and small-sized subclasses (pre-β_1-HDL, HDL_{3c}, HDL_{3b}, and HDL_{3a}) and pre-β_2-HDL (15). The smallest pre-β_1-HDL picks up free cholesterol efficiently from endothelial cell membranes, then is transformed by the activity of LCAT, which catalyzes cholesterol ester formation from free cholesterol and lecithin-derived FA on the surface of HDL particles. With the further participation of LCAT and other specific plasma factors, such as hepatic lipase (HL), CETP, and the phospholipids transfer protein (PLTP), cholesterol ester is concentrated into the center of the lipoprotein molecule; HDL particles are transformed from nascent lipid-poor pre-β_1-HDL to mature spherical HDL_2. It has been postulated that RCT indeed is the metabolic process by which nascent pre-β_1-HDL converts to mature HDL_2, following the route of pre-β_1-HDL $\rightarrow$ pre-β_2-HDL $\rightarrow$ pre-β_3-HDL $\rightarrow$ HDL_3 $\rightarrow$ HDL_2. Owing to the important role of RCT in maintaining cholesterol homeostasis and in antiatherosclerosis, the HDL maturation process and distributions of HDL subclasses may directly influence the atherogenic progress (7,16,17).

Obesity is a major risk factor for CHD (18) and is also associated with an atherogenic lipoprotein profile. Low levels of

Abbreviations: ApoA-I, apoprotein A-I; BMI, body mass index; CE, cholesteryl ester; CHD, coronary heart disease; CM, chylomicrons; HDL-C, HDL cholesterol; HL, hepatic lipase; LDL-C, LDL cholesterol; LPL, lipoprotein lipase; PLTP, phospholipids transfer protein; RCT, reverse cholesterol transport; SRC, standardized regression coefficient; TC, total cholesterol.

plasma HDL-C and high levels of plasma TG are commonly found in obese subjects (19). The relationship of a low HDL-C concentration to an increased risk of CHD has become a widely accepted concept. Data from the Québec Cardiovascular Disease Study (20) have shown that low HDL-C and high TG concentrations were associated with a substantial increase in the risk of CHD in obese subjects. Likewise, epidemiological studies provide increasing evidence that plasma TG level is an important independent risk indicator of CHD (21,22). On this basis, the aim of the present study was to investigate lipid metabolism in obese subjects, especially examining differences in HDL subclass distributions and content, which may help us understand the pathogenesis of atherosclerosis in obese subjects.

MATERIALS AND METHODS

Subjects. Five hundred eighty-one Chinese subjects aged 33–78 yr (431 were from West China University of Medical Science, Sichuan University, and Sichuan Normal University, in Chengdu, Sichuan Province, PR China; 150 were from Nan Hua University in Hengyang, Hunan Province, PR China) were recruited to participate in a study examining plasma lipid and apo concentrations. The study protocol was approved by an ethics committee, and all subjects gave informed consent. Exclusion criteria included the presence of (i) nephritis, diabetes mellitus, hypothyroidism, hepatic impairment; (ii) major cardiovascular event (myocardial infarction, severe or unstable angina pectoris, surgery), stroke; (iii) consumption of lipid-altering medications in the previous month; (iv) presence of chylomicrons (CM) in the refrigerator test; (v) history of smoking, drug, or alcohol abuse.

Body mass index (BMI) was calculated as the ratio of weight (kg) to the square of height (m^2). Finally, according to the recommended criterion (23) for BMI of the Working Group on Obesity in China (WGOC) under the support of International Life Sciences focal point in China (23), the subjects were divided into four groups: underweight, of desirable weight, overweight, and obese.

Twenty-five subjects with BMI < 18.5 kg/m^2 were assigned to the underweight group, 288 with BMI 18.5–24 kg/m^2 were assigned to the group having a desirable weight, 187 with 24 < BMI ≤ 28 kg/m^2 were considered overweight, and 45 with BMI > 28 kg/m^2 were defined as obese.

To investigate the impact of TG levels on the distributions of HDL subclasses, we divided obese and overweight subjects into four groups according to plasma TG levels, that is, normal (<1.69 mmol/L), borderline-high (1.69–2.25 m mol/L), high (2.26–5.64 m mol/L), and very high (≥5.65 m mol/L), and observed alterations of the HDL subclasses.

The TG levels selected for classification generally conform to the Adult Treatment Panel III guidelines (24).

Specimens. Blood specimens were drawn after a 12-h overnight fast into EDTA-containing tubes. Plasma was separated at room temperature within 1–2 h. Plasma was stored at 4°C and used within 24 h for lipid and apo analyses. An aliquot of plasma was stored at –70°C for the determination of HDL subclasses.

Plasma lipid and apo analyses. Plasma TG, total cholesterol (TC), and HDL-C were measured by standard techniques. TG and TC were determined with enzymatic kits (Beijing Zhongshen Biotechnological Corporation, Beijing, P.R. China). HDL-C was determined after precipitation of apoB-containing lipoproteins by phosphotungstate/magnesium chloride. When TG was less than 4.52 m mol/L, LDL-cholesterol (LDL-C) was calculated using the Friedwald formula. When TG exceeded 4.52 m mol/L, LDL-C was determined with enzymatic kits (Beijing Zhongshen). Plasma apoA-I, B100, C-II, C-III, and E were determined by radial immunodiffusion methods using kits developed at the Apolipoprotein Research Laboratory, West China Medical Center, Sichuan University.

HDL subclass analyses. HDL subclass distribution was determined with 2-D gel electrophoresis associated with an immunodetection method as described previously (14). In brief, 10 μL of plasma was applied to 0.7% agarose gel in the first dimension. After electrophoretic separation of lipoproteins in agarose gel, they were further separated by electrophoresis in 2–30% nondenaturing polyacrylamide gradient gel in the second dimension. To determine HDL subclasses, western blotting was performed after electrophoresis, using horseradish peroxidase-labeled goat anti-human apoA-I–IgG. The relative concentration of each HDL subclass was calculated as the percentage of plasma apoA-I according to the density of each spot. HDL particle sizes were calibrated using a standard curve that included BSA, ferritin, and thyroglobulin (Pharmacia, Hong Kong, P.R. China). Then the relative percent concentration of each HDL subclass was multiplied by the apoA-I concentrations in each individual, respectively, to provide the relative concentration of each HDL subclass of apoA-I (mg/L, apoA-I in the subclasses). The interassay CV of relative concentration of pre-β_1-HDL, pre-β_2-HDL, HDL_{3c}, HDL_{3b}, HDL_{3a}, HDL_{2a}, and HDL_{2b} in plasma samples were 9.4, 9.8, 4.9, 6.2, 7.3 11.1, and 7.9%, respectively ($n = 5$).

Statistical analysis. Numerical data are expressed as mean ± SD. Plasma TG was logarithmically transformed owing to its skewed distribution. Grouped data were compared by ANOVA. Differences were considered statistically significant at $P < 0.05$. Linear correlation (Pearson) and multiple regression analysis were used to test correlations between BMI, lipid, and HDL subclasses. All statistical analysis was performed using the statistical package SPSS 13.0 (SPSS Inc., Chicago, IL).

RESULTS

Concentrations of plasma lipids and apo. As shown in Table 1, when comparing subjects having a desirable weight with those who were obese, values for BMI; concentrations of TG, $apoB_{100}$, apoC-II, apoC-III; and the ratios of TG/HDL-C and TC/HDL-C were significantly higher whereas the levels of HDL-C and apoA-I were significantly lower. Underweight subjects showed the opposite trend in the parameters just mentioned.

ApoA-I contents of HDL subclasses. Figure 1 shows the distributions of HDL subclasses for representative subjects from the group having desirable weights (normolipidemia) (A) and

from the obese (B) group. In the obese subjects, spots for the small-sized subclasses (pre-β_1-HDL, HDL_{3a}, HDL_{3b}, and HDL_{3c}) were larger, whereas large-sized HDL_2 (HDL_{2a} and HDL_{2b}) had spots that were smaller in comparison with the normolipidemic subjects. Moreover, quantification of the HDL subclasses confirmed this observation. Data in Table 2 indicate that the concentrations of small-sized pre-β_1-HDL were significantly higher, whereas the concentrations of large-sized HDL_{2b} were significantly lower in both overweight and obese subjects, and HDL_{2a} were significantly lower only in obese

[a]Values are expressed as mean ± SD. Abbreviations: Pre-β_1-HDL, pre-β_2-HDL, HDL_{3c}, HDL_{3b}, HDL_{3a},HDL_{2a}, HDL_{2b}: HDL subfractions; for other abbreviations see Table 1.
[b]$P < 0.05$.
[c]$P < 0.01$, vs. group having desirable weights.

subjects vs. subjects having a desirable weight. However, compared with those having desirable weights, the concentrations of large-sized HDL_{2a} and HDL_{2b} were significantly higher in underweight subjects.

Frequency distributions of pre-β_1-HDL and HDL_{2b} in subjects having desirable weights and in obese subjects. The general profile of frequency distributions of pre-β_1-HDL (Fig. 2) and HDL_{2b} (Fig. 3) levels of obese subjects shifted to the right and left, respectively, compared with those of subjects having desirable weights, which indicated that plasma HDL particles tend to be smaller in obese subjects.

ApoA-I contents of HDL subclasses at different plasma TG levels in obese and overweight subjects. Table 3 showed that, with the elevation of TG levels, apoA-I contents of small-sized particles (especially pre-β_1-HDL and HDL_{3a}) gradually and significantly increased, whereas large-sized HDL_{2a} and HDL_{2b} gradually and significantly decreased.

Correlation coefficients between apoA-I contents of HDL subclasses, plasma lipids, and BMI in overweight and obese subjects. Correlation analysis revealed (Table 4) that BMI and plasma levels of TG were significantly and positively correlated with small-sized pre-β_1-HDL and negatively correlated with large-sized HDL_{2b}; conversely, levels of HDL-C showed a negative correlation with pre-β_1-HDL and a positive correlation with HDL_{2b} in obese and overweight subjects. Of note, TC showed a positive correlation only with pre-β_1-HDL.

Multiple regression analysis between apoA-I contents of HDL subclasses, plasma lipids, and BMI in overweight and obese subjects. To obtain a better understanding of the determinants of HDL subclass distribution in obese subjects, we performed stepwise multivariate regression analyses using apoA-I contents of pre-β_1-HDL and apoA-I contents of HDL_{2b} as dependent variables (Table 5). The pre-β_1-HDL was significantly and independently predicted by TG [standardized regression coefficient (SRC) 0.620, $P < 0.001$. The adjusted r^2 for this model, 0.304, explained about 30% of the variation in pre-β_1-HDL. In

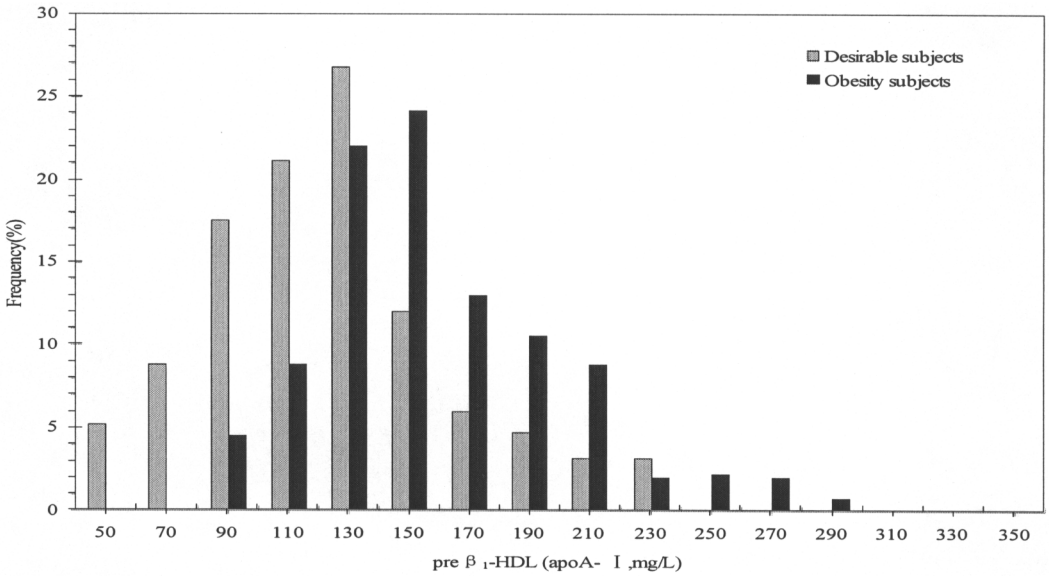

FIG. 2. Frequency distribution of pre-β_1-HDL levels in subjects having desirable weights and in obese subjects.

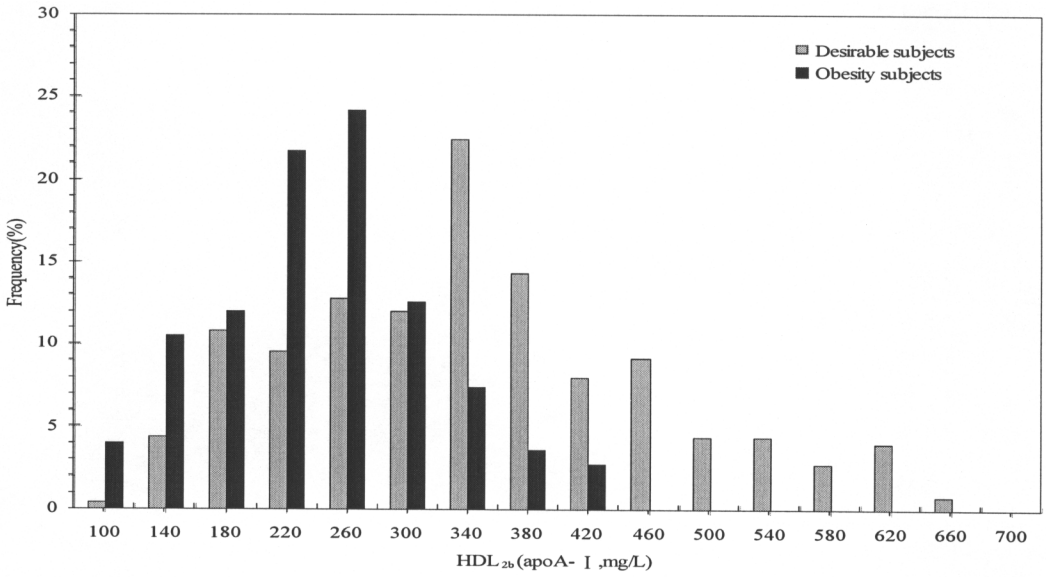

FIG. 3. Frequency distribution of HDL_{2b} levels in subjects having desirable weights and in obese subjects.

similar analyses with HDL_{2b} as the dependent variable, TG (SRC = –0.515, $P < 0.001$). The adjusted r^2 for this model was 0.307; however, BMI was not related to pre-β_1-HDL or HDL_{2b} and was removed from the final model.

DISCUSSION

The obese state accentuates the known risk factors for atherosclerotic disease. The prevalence of individuals who are overweight or obese is increasing rapidly in the Chinese population. The causes of obesity are complex. The consensus is that people become obese as result of a lifestyle consisting of low levels of physical activity and that consumption of excess calories plays a dominant role in the development of obesity. It is well known that obesity, especially central obesity (when the main deposits of fat are localized around the abdomen and upper body), is associated with dyslipidemia characterized by increased TG and decreased HDL-C (25–28). Several studies demonstrated the influence of obesity on lipoproteins and apo, but few investigations to date focused on relationship between obesity and HDL subclass distribution. Our laboratory had investigated the apoA-I contents of HDL subclass distribution in a Chinese population that was hyperlipidemic and experiencing endogenous hypertriglyceridemia by 2-D gel electrophoresis in association with an immunodetection method (15,29–32). Although there were some minor differences of HDL subclass distribution in hyperlipidemic subjects having different phenotypes, the common tendency was of increased small-sized HDL and decreased large-sized HDL particles. In the present study, we mainly investigated the characteristic of lipid metabolism, especially the distribution profile of HDL subclasses in obese subjects.

We observed that the concentration of TG and the contents of apoA-I of small-sized pre-β_1-HDL were significantly higher, but the concentration of HDL-C and the contents of apoA-I of large-sized HDL_{2a} and HDL_{2b} were significantly lower in obese subjects compared with subjects having a desirable weight. The results indicate that maturation metabolism of HDL might be ab-

TABLE 3
The apoA-I Contents[a] of HDL Subclasses at Different TG Levels in Subjects with BMI > 24 kg/m^2

	Normal TG (<1.69 mmol/L) (n = 65)	Borderline-high TG (1.69–2.25 mmol/L) (n = 33)	High TG (2.26–5.64 mmol/L) (n = 119)	Very high TG (≥5.65 mmol/L) (n = 15)
Pre-β_1-HDL	71.3 ± 21.1	88.6 ± 37.4[b]	126.1 ± 44.3[d]	171.5 ± 46.9[d]
Pre-β_2-HDL	54.0 ± 19.1	48.1 ± 16.8	59.9 ± 20.1	62.8 ± 18.4
HDL_{3c}	70.2 ± 30.6	70.6 ± 30.4	70.9 ± 27.9	71.7 ± 28.2
HDL_{3b}	129.1 ± 42.5	142.9 ± 46.2	145.6 ± 50.3	179.5 ± 36.2[d]
HDL_{3a}	238.5 ± 43.8	287.8 ± 76.2[c]	289.9 ± 82.0[c]	332.4 ± 80.1[d]
HDL_{2a}	290.9 ± 70.4	241.2 ± 85.1[c]	226.4 ± 66.2[d]	191.7 ± 45.6[d]
HDL_{2b}	365.8 ± 87.8	335.3 ± 76.7[c]	259.4 ± 97.3[c]	178.3 ± 50.3[d]

normal in obese subjects. The mechanism for the alteration of HDL subclass distribution in the obese subjects may be related to the several lipoprotein-modifying plasma enzymes: lipoprotein lipase (LPL), HL, LCAT, CETP, and others. Many researchers have demonstrated that impaired LCAT and LPL activities are associated with high plasma TG levels (33,34). LPL plays an important role in hydrolyzing TG transported in CM and VLDL particles (34). When catabolized by LPL, CM and VLDL release TG, TC, phospholipids, apoA-I, and apo C. Subsequent binding of these products to HDL_3 results in formation of HDL_2 particles. LCAT may convert unesterified cholesterol to cholesterol ester and promote the conversion of pre-β_1-HDL and HDL_3 to HDL_2 (33). Thus, reduced plasma LPL and LCAT activity leads to the reduction of HDL_2. Likewise, increased HL and CETP activity are associated with higher plasma TG levels (35–37). HL promotes the conversion of HDL_2 to HDL_3 *via* hydrolysis of its TG and phospholipids (35). CETP mediates exchange of TG and cholesteryl ester (CE) between VLDL-TG, LDL-TG, and HDL-CE, resulting in TG enrichment of HDL (36,37). The subsequent hydrolysis of transferred TG in HDL_2 levels leads to the formation of small HDL particles. Consequently, enhanced HL and CETP activities promote the conversion of HDL_2 to HDL_3, hydrolyze excess surface phospholipids, and lead to the dissociation of apoA-I from HDL_2; the latter may generate much of the small-sized pre-β_1-HDL. Most studies have demonstrated increased CETP activity increased and decreased PLTP activity in subjects with low HDL-C levels. PLTP can transfer phospholipids (surface remnants) from TG-enriched lipoproteins onto HDL (38); hence, it favors the formation of larger-sized HDL particles. Therefore, reduction of HDL-C and elevation of TG resulted in the marked increase in small-sized HDL subclasses and decrease in large-sized HDL subclasses.

To investigate the influence of plasma TG levels on the distributions of HDL subclasses, subjects with BMI > 24 kg/m^2 were separated into four subgroups according to the plasma TG levels identified in this study. We observed that with increased plasma TG levels, apoA-I contents of small-sized HDL particles (especially pre-β_1-HDL and HDL_{3a}) increased too, but those of large-sized HDL particles decreased, which suggested that the particle size of HDL tended to shift to smaller size, with the trend being more obvious with the increase of plasma TG levels in obese and overweight subjects. Meanwhile, compared with subjects with normal TG levels, an increase (24, 77, 140%) in pre-β_1-HDL and a decrease (8.9, 29, 52%) in HDL_{2b} were found in those with borderline high, high, and very high TG levels in the obese and overweight groups. These findings suggest that plasma TG levels have a significant effect on the distribution of HDL subclasses, which is in accordance with our previous finds on endogenous hypertriglyceridemic subjects (29). The Pearson correlation analysis confirmed that TG concentration was positively correlated with small-size pre-β_1-HDL and negatively correlated with large-size HDL_{2a} and HDL_{2b}. Multiple regression analyses also revealed that TG concentrations were associated independently and positively with high pre-β_1-HDL, but independently and negatively with low HDL_{2b} in obese and overweight subjects. Thus, an abnormal HDL subclass distribution seems to be one of the adverse metabolic consequences of hypertriglyceridemia, as discussed by Grundy and Vega (39). Of note, the change in HDL size and distribution is already apparent at only moderately elevated TG levels.

In conclusion, our data showed the general shift toward smaller HDL particle size in obese as well as in overweight subjects. The shift was more obvious with the elevation of BMI, and especially with increased TG levels. This suggests

HDL maturation might be abnormal and RCT might be weakened in obesity.

ABSTRACT: Our *ex vivo* study revealed that BRE had significantly stronger ability to inhibit LDL oxidation than white rice extract (WRE). The purpose of this study was to investigate whether black rice extract (BRE) supplementation might ameliorate oxidative stress and enhance antioxidant enzyme activities in HepG2 cells and in C57BL/6 mice. In the cellular study, superoxide anions ($O2^{\bullet-}$) and reactive oxygen species (ROS) in the BRE group were significantly suppressed. The BRE group also showed significant increases in superoxide dismutase (SOD) and catalase (CAT) activities by 161.6% and 73.4%, respectively. The major components responsible for the free–radical-scavenging and antioxidative properties might be cyanidin-3-O-glucoside chloride and peonidin-3-O-glucuside chloride. In the animal study, male C57BL/6 mice were divided into three groups (control, BRE, and WRE). Plasma HDL-cholesterol was significantly higher, and thiobarbituric, acid-reactive substances were significantly lower in the BRE group, whereas plasma levels of total cholesterol and triglyceride were not affected by BRE supplementation. Increased hepatic SOD and CAT activities were observed in BRE-treated mice as compared to the control mice. However, no changes were detected for the protein expression of antioxidant enzymes by Western blot analysis. Our data suggest that antioxidative effects exerted by BRE are mediated through decreases in free-radical generation as well as increases in SOD and CAT activities both *in vitro* and *in vivo*.

Paper no. L9992 in *Lipids 41*, 797–803 (August 2006).

Rice is a widely consumed food source for over half of the world's population (1). There are many different kinds of rice, including white rice and a variety of colored rice. Rice with colored hulls has long been considered to be a health food. Black and red rice are planted mainly in South Asian countries and other places such as the United States, Italy, and Greece. Europeans eat more black rice than South Asians (2). Recent reports have shown that supplementation of diets with black rice pigments markedly reduced atherosclerotic lesions in hypercholesterolemic rabbits and apolipoprotein–E-deficient mice (3,4). Black rice pigments are mainly located in the aleurone layer, which is characterized as dark purple to black in color and probably represents a mixture of anthocyanins. Most dietary intake of anthocyanins comes from fruits and vegetables (5). There are about 17 anthocyanins found in nature (6), whereas only six of them (cyanidin, delphinidin, malvidin, pelargonidin, peonidin, and petunidin) are ubiquitously distributed (7). The water-soluble fraction of black rice might serve as an extra source of dietary anthocyanins (8). Most people consumed a diet of rice by boiling the natural grain in water, but there are no studies concerning the effects of water extract of rice on oxidative stress. This raises the question of whether supplementation with water extract of black rice may be of importance in controlling oxidative stress.

Oxidative damage usually accompanies the development of many age-related diseases (9). Accumulating evidence suggests that oxidative modification of low-density lipoprotein (ox-LDL) may play a critical role in the development of atherosclerosis (10,11). Oxidative stress is one of the main risk factors for LDL oxidation. Reduction of LDL oxidation is an essential target that is used to evaluate dietary factors with antioxidant activity. Conjugated diene (CD) is one of the intermediate products formed during the peroxidation of polyunsaturated fatty acids in LDL lipids (12). Furthermore, thiobarbituric acid-reactive substances (TBARS) are measured as a means of indicating aldehydic breakdown products of oxidized LDL (13). In this study, we assess the effect of BRE on LDL oxidation using assays that measure CD formation *ex vivo* and TBARS levels *in vivo*.

Reactive oxygen species (ROS) are free radicals produced during metabolism and the aging process. ROS include superoxide anion ($O_2^{\bullet-}$), hydrogen peroxide (H_2O_2), and hydroxyl radicals (•OH). ROS can cause DNA strand breaks, base modification, lipid peroxidation, and protein modification, resulting in oxidative stress. Emerging evidence indicates that ROS are important risk factors in the pathogenesis of many diseases if the antioxidant system is impaired. The measurement of changes in endogenous antioxidant enzyme activity is considered a fairly sensitive biomarker of the response to oxidative stress. Superoxide dismutase (SOD), catalase (CAT), and glutathione peroxidase (GPx) are primary antioxidant enzymes that protect cells from damage caused by ROS. The protective mechanisms against oxidative stress by black rice extract in he-

patic cells and in the animal model remain largely unknown. In this study, we investigate effects of water extracts from black and white rice on free radical generation and antioxidant enzyme activities in HepG2 cells, as well as in C57BL/6 mice. The results cast light on the physiological significance and the mechanism by which black rice suppress oxidative stress and decrease lipid peroxidation.

MATERIALS AND METHODS

Materials. The raw materials of white and black rice came from an Agricultural Research Center for the Taiwan Region, and the whole rice was washed, dried, and ground to powder. One hundred grams of rice powder was refluxed with 700 mL of double distilled water for 5 h at 80°C, cooled, and vacuum filtered through Whatman filter paper. This was repeated three times, and all extracts were pooled after lyophilization. The residue was re-dissolved in water and diluted with the reaction mixture for the subsequent assay.

Anthocyanins (cyanidin-3-O-glucoside chloride, delphinidin chloride, malvidin chloride, pelargonide chloride, peonidin-3-O-glucoside chloride, and petunidin chloride) were purchased from Extrasynthese (Genay, France) and were HPLC grade. Anti-Mn-SOD and anti-Cu,Zn-SOD antibodies were obtained from Upstate (Charlottesville, VA). Anti-catalase and anti-β-actin antibodies were obtained from Calbiochem (San Diego, CA) and Sigma Chemical Co. (St. Louis, MO), respectively.

Human LDL oxidation. Determination of CD formation was conducted in accordance with our previously reported method (14). Briefly, blood from healthy subjects was collected in the presence of 1 mM EDTA in order to prevent oxidation during lipoprotein separation. Plasma was isolated by centrifugation at 1500 × g for 15 min, and LDL was isolated by sequential density gradient ultracentrifugation (15). The isolated LDL was dialyzed against PBS (10 mM, pH 7.4) overnight and stored at 4°C before being used. Oxidation of LDL (50 μg of protein/mL) was initiated at 37°C by 5 μM $CuSO_4$ for at least 6 h. The extent of CD formation in the absence or presence of 10 μg/mL or 50 μg/mL of BRE or WRE was measured by monitoring the increase in absorbance at 234 nm as previously described (16). The protein content of the LDL fraction was determined using the Bradford assay (Bio-Rad, Hercules, CA) with BSA as the standard.

Identification of anthocyanin content in black and white rice extracts. To obtain a more comprehensive knowledge of the composition of BRE and WRE, we determined the content of anthocyanin components in BRE and WRE by HPLC and LC-MS (8). The anthocyanins were extracted using methanol/water/acetic acid (0.5:15:0.5, vol/vol/vol) according to the method described by Wu et al. (17). The extracted solutions were then diluted with acidic methanol and filtered using a 0.22-μm filter before HPLC analysis equipped with an autosampler/injector and diode array detector. An analytical SB-C_{18} column (4.6 × 250 mm, 5 μm, Agilent Technologies, Rising Sun, MD) was used for separation. The mobile phase was prepared from water/formic acid/acetonitrile (87:10:3, vol/vol/vol), eluent A, and water/formic acid/acetonitrile (40:10:50, vol/vol/vol), eluent B. The gradient program was: 5% B (5 min), 5% B to 20% B (15 min), 20% B to 40% B (15 min), 40% B to 100% B (7 min), 100% B to 5% B (3 min), 5% B (5 min). The flow-rate was 0.4 mL min^{-1}. Monitoring was performed at 520 nm, and the diode-array detector was set at an acquisition range from 200 nm to 600 nm at a spectral acquisition rate of 1.25 scan s^{-1}. To construct calibration plots, volumes of standard stock solution (1000 μM) of cyanidin-3-O-glucoside chloride, delphinidin chloride, malvidin chloride, pelargonide chloride, peonidin-3-O-glucoside chloride, and petunidin chloride were diluted with eluent A, and six concentration levels (1, 5, 20, 100, 200, 500 μM) were analyzed. For quantification, peak areas were correlated with concentrations in accordance with the calibration plot. Final concentrations were expressed as mg per 100 g of dry weight of BRE or WRE. The LC-MS was controlled by Masslynx 3.5 software (Micromass). Positive ion mode was performed with capillary voltage, 3.0 kV; cone voltage, 40V; source temperature, 120°C; desolvation temperature, 250°C; cone gas flow, 50 L/h; and desolvation gas flow, 250 L/h. Anthocyanin components were identified by both retention time and mass profile in comparison to authentic standards.

Cell culture and ROS assays. HepG2 cells were cultured in DMEM containing 100 units of penicillin/streptomycin and 10% fetal bovine serum and seeded at a density of 2×10^5 cells/well into 24-well plates. After 24-h growth at 37°C under 5% CO_2, cells were treated with BRE or WRE at a final concentration of 5 mg/mL for another 24 h. To avoid interferences due to cytotoxicity, we used a 3-(4,5-dimethyl-thiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay to evaluate the cytotoxic effect of BRE or WRE in HepG2 cells (18). Briefly, cultured cells were treated with BRE or WRE at a final concentration of 5 mg/mL for 24 h, and MTT solution (0.5 mg/mL) was added into the cell medium. Cells were incubated at 37°C and 5% CO_2 for an additional 4 h. DMSO and a glycine buffer (0.1 M glycine, 0.1 M NaCl, pH 10.5) were added to each well, and the dissolved solutions were detected at 570 nm by a microplate ELISA reader (Dynex technologies, Chantilly, VA). The absorbance of untreated cells was considered as 100%. Treatment of cells with 5 μg/mL of cyanidin-3-O-glucoside chloride or peonidin-3-O-glucoside chloride was performed as the positive control group. Cultured cells were harvested in triplicate to assess the generation of $O_2^{\bullet-}$ and ROS. The ROS levels in HepG2 cells were measured using the dye 2′,7′-dichlorodihydrofluorescein diacetate (DCFH-DA) (19). This reduced dye was added to cells (1×10^6 cells/mL) at a final concentration of 10 μM. The fluorescence of the oxidized dichlorofluorescein was monitored by Flow Cytometry with an excitation wavelength of 488 nm and an emission wavelength of 525 nm. Similar measurements were made with 10-μM hydroethidine (HE), which has been reported to be more specifically oxidized by $O_2^{\bullet-}$ (20). In this case, the fluorescence was monitored by Flow Cytometry with excitation at 495 nm and emission at 637 nm. The results were expressed as the relative fluorescence intensity. $O_2^{\bullet-}$ and ROS levels in HepG2 cells

without rice extract treatment were used as the negative control.

Assessment of antioxidant enzyme activities. Assays of antioxidant enzyme activities were carried out as previously described (21). Briefly, SOD activity in the extract of HepG2 or the liver homogenates of C57BL/6 mice was assayed using the hydroxylamine-reduction method (22). In this method, the reduction of hydroxylamine by $O_2^{\bullet -}$ is monitored at 550 nm, utilizing the hypoxanthine/xanthine oxidase system as the source for $O_2^{\bullet -}$. One unit (U) of SOD activity is defined as the amount of enzyme necessary to decrease the reduction of hydroxylamine by 50%. CAT activity in the extract of HepG2 or the liver homogenates of C57BL/6 mice was assayed using the method of Aebi (23). In this method, the decomposition of H_2O_2 due to CAT activity was assayed by monitoring the decrease in the absorbance of H_2O_2 at 240 nm. One U of CAT activity is defined as the amount of enzyme required to catalyze 1 μmol of H_2O_2 per min at 25°C. GPx activity in the extract of HepG2 or the liver homogenates of C57BL/6 mice was quantified by a coupled-enzyme (GPx and glutathione reductase) procedure (24). This method measures the decrease in absorbance at 340 nm as NADPH is converted to NADP. One U of GPx activity is defined as the amount of enzyme required to oxidize 1 μmol of NADPH per min. Specific activities of SOD and CAT were expressed in U/mg of protein, but GPx activity was expressed in mU/mg of protein with the protein content determined as stated above.

Animals. At eight weeks of age, 33 male C57BL/6J mice were randomly assigned to one of the three groups. Three or four animals were housed in each cage and maintained at 25°C in an animal room with a 12-h light/dark cycle. The investigation conformed with the *Guide for the Care and Use of Laboratory Animals* published by the US National Institutes of Health (NIH Publication No. 85-23, revised 1996). Mice were allowed free access to food and tap water for 10 weeks during the experiment. The composition of the experimental diet is shown in Table 1. The mineral and vitamin mixtures were obtained from ICN Biochemicals (Costa Mesa, CA). To exclude that ROS generation and lipid peroxidation were affected by differences in energy utilization or hyperlipidemia, we compared body weight and plasma lipid levels of animals of the control, BRE, and WRE groups. After a 12-h overnight fast, the mice were anesthetized with CO_2, and blood samples were taken for biochemical analyses. Plasma was isolated by centrifugation at 1500 × g for 15 min and was stored at –35°C for subsequent lipid and TBARS analyses. The liver tissues were rapidly removed, blotted dry, weighed, frozen in liquid nitrogen, and then stored at –80°C for antioxidant enzyme activity analyses. Before analyses, the liver tissue was homogenized in 10 volumes of a 50-mM phosphate buffer (pH 7.4) on ice for 30 s using a polytron homogenizer. The homogenate was transferred into centrifuge tubes and centrifuged at 9000 × g at 4°C for 20 min. The supernatant was used for the measurement of protein concentration and antioxidant enzyme activities. Twenty micrograms protein was separated on SDS-PAGE, transferred to a nitrocellulose membrane and immunoblotted with rabbit anti-human Mn-SOD, Cu,Zn-SOD, and catalase antibodies (dilution as recommended) using the standard Western-blot analysis. Immune complexes were visualized with horseradish peroxidase-conjugated immunoglobins and detected using enhanced chemiluminescence (Amersham Biosciences).

L-Cystine	0.3	0.3	0.3

[a]BRE, black rice extract; WRE, white rice extract.

Plasma lipids and TBARS analyses. The concentrations of total cholesterol (TC) and triglyceride (TG) were assayed enzymatically using commercial reagents (Merck). The levels of HDL-cholesterol (HDL-C) and LDL-cholesterol (LDL-C) were determined by precipitation with phosphotungstic acid/magnesium chloride and heparin/sodium citrate, respectively, using reagents supplied by Merck. The products of lipid peroxidation were measured as TBARS at 532 nm (25) using a standard curve of thiobarbituric acid (TBA) adduct formation with freshly diluted 1,1,3,3-tetraethoxypropane as the standard.

Statistical analyses. Data are given as the mean ± SD. Results were analyzed by one-way analysis of variance (ANOVA) using the SAS program (version 6.12, SAS Institute, Cary, NC). Differences between mean values were evaluated by the post-hoc test and were considered significant if $P < 0.05$.

RESULTS

Inhibition of LDL oxidation by BRE. Conjugated diene formation on exposure of copper-catalyzed LDL to 10 or 50 μg/mL rice extract is shown in Fig. 1. The initial amount of CD formed did not differ among groups. Addition of 10 and 50 μg/mL BRE significantly decreased the oxidation rates and maximal amounts of diene formation, whereas WRE had little or no effect. The lag-phase duration, which represents the resistance of LDL to lipid peroxidation, was prolonged from 72 min to 198 min when the BRE treatment was increased from 10 to 50 μg/mL. The presence of WRE at increased concentrations had no significant effect on the lag time, LDL oxidation rate, or maximal amounts of diene formation.

Quantitative analyses of anthocyanin components in rice extract. HPLC analysis was performed to estimate the content of anthocyanin components in brown and white rice extract. As shown in Table 2, cyanidin-3-O-glucoside chloride and peonidin-3-O-glucoside chloride were identified as the two major

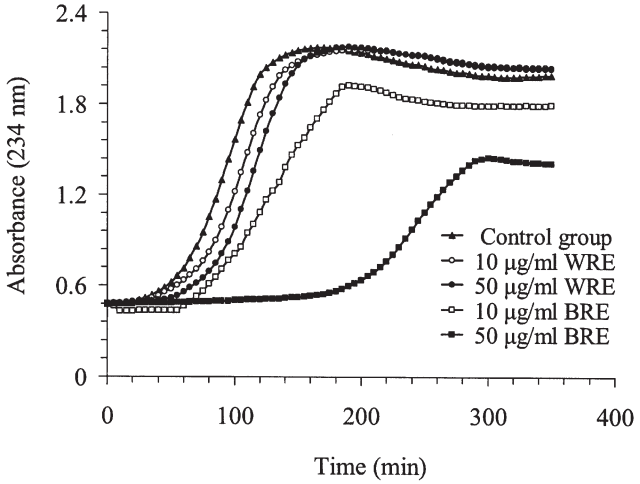

FIG. 1. Effects of white (WRE) and black (BRE) rice extracts on the generation of conjugated dienes (CD) in LDL. The oxidation of LDL (50 μg protein/mL) was initiated by the addition of 5 μM copper. White and black rice extracts were added to LDL at final concentrations as shown. CD generation was monitored by measuring the increase in absorbance at 234 nm. Values shown are from a representative experiment.

TABLE 2
Anthocyanin Content (mg/100 g dry weight) of Black Rice Extract (BRE) and White Rice Extract (WRE)

Compound	BRE	WRE
Cyanidin-3-O-glucoside chloride	26.8	14.2
Delphinidin chloride	4.3	n.d.a
Malvidin chloride	2.4	n.d.
Pelargonidin chloride	n.d.	n.d.

contents of BRE by comparison of the retention time and the photodiode array spectrum with those of authentic anthocyanins. We thus used cyanidin-3-O-glucoside chloride and peonidin-3-O-glucoside chloride as the positive control to compare their effects on free-radical scavenging capacities and antioxidant enzyme activities in HepG2 cells.

Effects of rice extracts and anthocyanins on ROS levels and antioxidant enzyme activities in HepG2 cells. Cell toxicity was evaluated by MTT assay. The result from the cell viability assay showed that BRE and WRE had no obvious toxicity (94.7 ± 10.3% and 92.3 ± 6.5% of control, respectively) to HepG2 cells at the concentration of 5 mg/mL. The oxidative status was reflected from the levels of $O_2^{\bullet -}$ and ROS in HepG2 cells (Fig. 2). BRE (5mg/mL) supplementation significantly suppressed $O_2^{\bullet -}$ and ROS levels by 34.0% and 39.3%, respectively, as compared to the control group. Significant suppression of ROS generation was also obtained by cyanidin-3-O-glucoside chloride and peonidin-3-O-glucoside chloride by 63.0% and 44.3%, respectively, at a final concentration of 5 μg/mL. However, HepG2 cells treated with a WRE (5 mg/mL) diet showed no significant difference in levels of $O_2^{\bullet -}$ and ROS compared to the control cells.

Effects of BRE, WRE, and anthocyanins on activities of antioxidant enzymes in HepG2 cells are shown in Fig. 3. SOD and CAT activities were significantly higher in the BRE group than in the control group, whereas GPx activity was not altered. However, cells treated with WRE and anthocyanins did not cause significant changes in antioxidant enzyme activities compared to the control group.

Body weight and plasma lipid levels in the C57BL/6J mice. The body weight of mice in each group before study entry (eight weeks of age) was 21.2 ± 2.6 g, and at the end of the study (18 weeks of age) was 27.5 ± 4.4 g, 25.6 ± 2.7 g, and 26.8 ± 3.3 g in the control, BRE, and WRE groups, respectively. The differences in body weight across the three groups were not significant.

No significant differences were found for the plasma levels of triglyceride, total cholesterol, and LDL-cholesterol among the BRE, WRE, and control groups. However, plasma HDL-cholesterol was significantly higher, and TBARS showed a significant decrease, in mice fed with the BRE diet, whereas no change was found in the WRE group (Table 3).

Effects of rice extracts on antioxidant enzyme activities and protein expression in livers of C57BL/6J mice. The levels of the hepatic antioxidant enzyme activities are shown in Table 4. The BRE-treated animals exhibited markedly increased hepatic SOD and CAT activities. In contrast, there was no increase in GPx activity in livers of BRE-treated animals. Hepatic SOD activity of the BRE group also displayed a greater increase than the WRE group, whereas CAT and GPx activities did not differ between the BRE and WRE groups. By using Western-blot analysis, the relatively small differences in the expression of Mn-SOD, Cu,Zn-SOD, and catalase were statistically non-significant among the BRE, WRE, and control groups (Fig. 4).

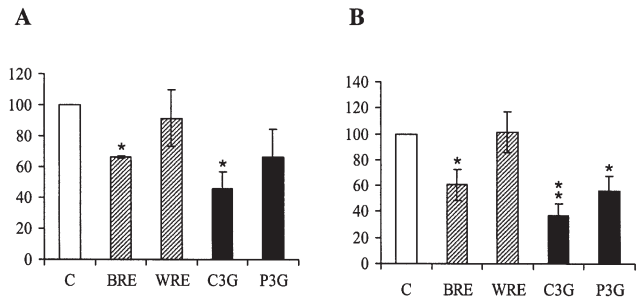

FIG. 2. Effects of rice extracts and anthocyanin components on the levels of $O_2^{\bullet -}$ (A) and ROS (B) in HepG2 cells. Cells were incubated with 5 mg/mL of rice extracts (black rice extract, BRE, and white rice extract, WRE) or 5 μg/mL of anthocyanin components (cyanidin-3-O-glucoside chloride, C3G, and peonidin-3-O-glucoside chloride, P3G) for 24 h at 37∞C. $O_2^{\bullet -}$ and ROS were determined as described in Methods. The results are representative of three different assays. All of the corresponding control values (arbitrary unit) were converted as 100%. The data represent the mean ± SD. Statistical analyses: $^*P < 0.05$ and $^{**}P < 0.01$ versus the control.

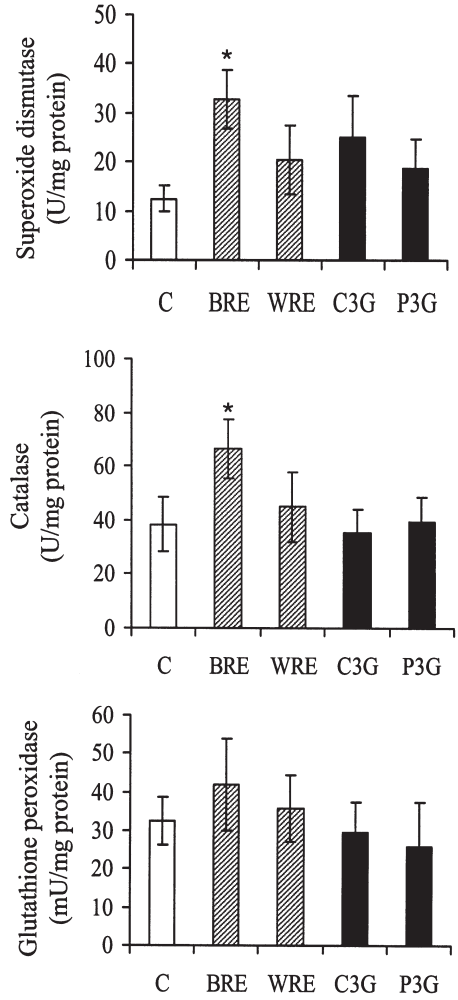

FIG. 3. Effects of rice extracts and anthocyanin components on the levels of antioxidant enzyme activities in HepG2 cells. Antioxidant enzyme activities were analyzed as described in Methods. The results are representative of three different assays. The data represent the mean ± SD. Statistical analyses: *$P < 0.05$ versus the control.

DISCUSSION

The results of this study show that black rice contains anthocyanin components with notable antioxidative properties for potential use in nutraceutical benefit in preventing human diseases pathologically related to oxidative stress (9). Cupric ion-induced LDL oxidation is a common marker for evaluating antioxidant activity relative to the prevention of lipid and protein (apolipoprotein B) oxidation (14). We have clarified for the first time that BRE evoked a remarkably greater inhibition of CD formation than that in WRE. This prompted us to investigate the antioxidant effects of BRE in cellular and animal models.

HepG2, a well–differentiated, transformed cell line, is a reliable model and widely used for biochemical and nutritional studies. In this study, we investigated the ROS scavenger effect by rice extract and anthocyanins (cyanidin-3-O-glucoside chloride and peonidin-3-O-glucoside chloride) in HepG2 cells to assist in elucidating the mechanism of reduction in oxidative

TABLE 3
Plasma Lipid Profiles and TBARS Levels[a] in C57BL/6J Mice Fed a Control Diet with and without Black Rice Extract (BRE) or White Rice Extract (WRE

stress by BRE. Anthocyanins are the largest group of water-soluble pigments in the plant kingdom. They are widely distributed in the human diet through crops, beans, fruits, and vegetables and seem to possess strong antioxidant, anti-inflammatory, and anticarcinogenic properties (26). However, little is known about the anthocyanin profile of whole black rice. We thus quantitatively characterized the anthocyanin contents in black rice—specifically, a black rice pigmented fraction extract (BRE)—in the present study. The molecular mechanisms of the ROS-scavenging effect by BRE and anthocyanins were also determined.

The mechanism for the antioxidative effect of BRE was unclear at the start of this study. We hypothesized that BRE might exert its antioxidant effects through suppression of ROS and induction of antioxidant enzyme activities. To test this hypothesis, we determined free-radical generation and activities of SOD, CAT, and GPx in HepG2 cells treated with BRE or WRE, as well as cyanidin-3-O-glucoside chloride or peonidin-3-O-glucoside chloride. It is of note that BRE exerted its antioxidative effect via the induction of SOD and CAT activities in hepatoma cells. By contrast, enzyme activities of SOD and CAT were not affected by the addition of cyanidin-3-O-glucoside chloride and peonidin-3-O-glucoside chloride to the culture medium. Recent studies have suggested that cyanidin-3-O-glucoside chloride is thought to play an antioxidant role through the suppression of peroxynitrite-induced oxidation (8,27). Our results indicate that cyanidin-3-O-glucoside chloride and peonidin-3-O-glucoside

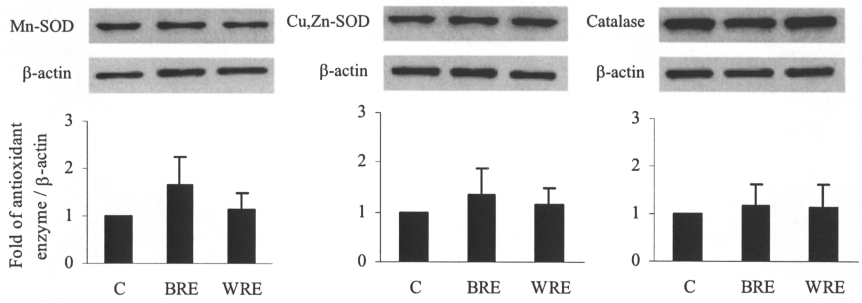

FIG. 4. Effects of black (BRE) and white (WRE) rice extracts on protein expression of Mn-superoxide dismutase (Mn-SOD), Cu,Zn-SOD, and catalase in livers of C57BL/6 mice (n = 6). Representative blots of protein expression are depicted and antioxidant enzyme expression was normalized to β-actin level as the internal control. Histograms show densitometric analyses of protein expression levels. The results are shown as fold increases above the untreated controls. Data are the mean ± SD from at least six independent experiments.

chloride may scavenge ROS through other biological pathways independent of the induction of antioxidant enzyme activities.

Antioxidant enzymes, such as SOD, CAT, and GPx, are endogenous factors that protect cells from oxidative damage caused by ROS. SOD catalyzes the dismutation of the $O2^{\bullet-}$ to molecular oxygen and H_2O_2, which in turn is metabolized to harmless water and oxygen by CAT and GPx. The activities of SOD and CAT were higher in livers of C57BL/6 mice treated with the BRE diet. These results suggest that BRE supplementation may attenuate oxidative stress by reducing ROS and increasing antioxidant enzyme activities both in vitro and in vivo. However, the increased enzyme activities observed in the BRE group may not be the result of increased gene expression via the evaluation of the protein expression of Mn-SOD, Cu,Zn-SOD, and CAT by Western-blot analysis. The lack of an exact relationship between the changes in the antioxidant enzyme activities and those in the protein levels indicates that antioxidant enzyme activities are possibly post-translationally regulated.

Previous studies have revealed that lipids are susceptible to oxidative damage. Lipid peroxidation is usually quantified by using a TBARS assay (28). Our data from plasma TBARS analyses are in accordance with the results obtained from the *ex vivo* study. Among all the major lipoproteins, HDL is considered to be an endogenous protective factor against atherosclerosis (29). Our previous studies have suggested that HDL has the potential to limit the oxidative modification of LDL (14). The results from this study suggest that BRE may also exert its antioxidative effects through the induction of plasma HDL in C57BL/6 mice.

In summary, our data shed new light on the molecular basis that BRE contributes to marked increases in SOD and CAT activities that may cause a decrease in free-radical generation and oxidative stress. This observation points to a new direction when trying to understand the physiological function of black rice as a benefit to human health.

ACKNOWLEDGMENT

We thank Fu-Rue Shieh for excellent technical assistance in HepG2 cell culture. This study was supported by Research Grant No. DOH95-TD-F-113-019 from the Department of Health, Taiwan and Grant No. MMHYM 94-019 from Mackay Memorial Hospital, Taipei, Taiwan.

Phospholipid Molecular Profiles in the Seed Kernel from Different Sunflower (*Helianthus annuus*) Mutants

Joaquín J. Salas*, Enrique Martínez-Force, and Rafael Garcés

Instituto de la Grasa (CSIC), Av. Padre García Tejero 4, Sevilla 41012, Spain

ABSTRACT: Phospholipids are essential components of plant cell membranes whose acyl composition appears to be influenced by oil composition in the sunflower. In the current study, we have determined the diacylglycerol profile of the main phospholipids using phospholipase C degradation and separation of the diacylglycerols by HPLC and GLC. The main polar lipid molecular species were defined in different classes of sunflower kernel: PC, PE, and PI. The proportions of each were determined at different stages of development in order to define the point at which the mutations carried by each sunflower line affected the phospholipid composition of the seeds. The results indicated that modifications to intraplastidial *de novo* FA synthesis affected the seed phospholipid profile during the whole period of the seed formation, including accumulation and maturation, whereas the influence of mutations in the endoplasmic reticulum desaturases were more readily detected at later stages of development. These results are discussed in terms of the pathways involved in glycerolipid synthesis and phospholipid conversion in sunflower seeds.

Paper no. L9982 in *Lipids 41*, 805–811 (August 2006).

Phospholipids are the main components of cell membranes and therefore they are not only ubiquitous among living organisms but they are also fundamental for life (1). The galactolipids monogalactosyl diacylglycerol (MGDG) and digalactosyl diacylglycerol (DGDG) are the most abundant glycerolipids in chloroplasts and plant tissues (2). However, cytosolic, mitochondrial and vacuolar membranes are composed of phospholipids, among which PC, PE, and PI are the most prominent species (3). The primary function of those phospholipids is to maintain the integrity of the cell membrane under different environmental conditions. It is also remarkable that when associated with oleosin proteins, these compounds are essential for the construction of the oil bodies present in oilseeds such as sunflower (4). These organelles accumulate the TAG synthesized in the endoplasmic reticulum, preventing their coalescence, and they anchor the lipases during the germination process. In addition to their structural function, plant phospholipids are important metabolic intermediates and indeed, PC is a substrate for the oleate desaturase (ODS) enzymes (5). The control of these metabolic pathways is tightly regulated by a series of mechanisms that depend on both the temperature and oxygen availability, and that determine the oleate/linoleate ratio of the oil accumulated in the seeds (6). On the other hand, PI and its phosphorylated derivatives are well-known intermediates in signal transduction pathways (7).

The synthesis of phospholipids in oilseeds is closely associated with TAG assembly (Fig. 1). Hence, zwitterionic phospholipids such as PE and PC are synthesized from DAG produced by the Kennedy pathway in reactions that involve the transfer of choline or ethanolamine phosphate groups. In contrast, the intermediate in PI and PG synthesis is PA, to which inositol or glycerol phosphate is added. Furthermore, phospholipids of a specific type can be converted into those of another type through different mechanisms, including the conversion of phospholipids to their DAG or PA precursors mediated by the action of C- or D-type phospholipases, or the methylation of the head residues with amine groups *via* S-adenosyl methionine (8).

Previous studies on sunflower seed kernels indicated that the most abundant phosphoglyceride species present are PC, followed by PE and PI (9). Trace amounts of the phospholipids PG and PA were also found, as well as the galactolipids MGDG and DGDG. In this regard, studies of sunflower lines carrying mutations that affect the FA composition of the oil indicate that

Abbreviations: DGDG, digalactosyl diacylglycerol; MGDG, galactolipids monogalactosyl diacylglycerol; ODS, oleate desaturase; dilinoleoyl PC, PC-LL, PC-OL, oleoyl-linoleoyl PC-OO, dioleoyl-PC; PC; PDAT, phospholipid-DAG acyltransferase enzyme; PC-PL, .palmityl-linoleoyl PC; PC-PO, palmityl-oleoyl PC; PC-SL, stearoyl-linoleoyl PC.

although the absolute ratios of the seed lipid classes were not significantly altered, the FA composition of the corresponding phospholipids was also affected (9,10). As far as we can tell, these mutations do not affect the FA compositions of the leaf lipids. In other studies (11) there were no significant differences in the FA compositions of MGDG, DGDG, and PG in controls vs. those mutants analyzed. The changes in the seed acyl composition of phosphoglycerides in such lines could provide interesting information about the plant responses to the mutations responsible for their different traits. Moreover, because the 1- and 2-acyl positions within phospholipids are not equivalent, it is necessary to define the exact changes in the different molecular species of the most important sunflower seed phospholipids to obtain more complete information.

In the present study, we have defined the molecular species of the polar lipids PC, PE, and PI from different sunflower mutants at distinct stages of development. As well as the common sunflower CAS-6 line, we have studied lines that contain mutations in different genes involved in FA synthesis. The mutants suffered alterations in enzymes such as oleate desaturase, stearoyl-ACP desaturase, and β-ketoacyl-ACP synthase II that affected the acyl composition of both TAG and polar lipids. These mutations gave rise to the high-oleate CAS-9 line, the high-stearate high-linoleate CAS-3 line, and the high-palmitate high-oleate CAS-12 line (12–14). The study of the polar lipids provided information about the impact of these mutations on functional membrane lipids, as well as on the ability of the plant to compensate for their excess of saturated FA. Finally, we discus the mechanisms of phospholipid synthesis and conversion in sunflower seeds in relation to the results obtained.

EXPERIMENTAL PROCEDURES

Plant material. Sunflower seeds were germinated in wet perlite at 25°C and transferred to a germination chamber for 2 wk for full seedling development. Subsequently, they were moved to growth chambers equipped with fertigation lines and maintained at 25°/15°C (day/night), with a 16-h photoperiod and a photon flux density of 300 $\mu mole \cdot m^{-2} \cdot s^{-1}$ until harvested.

Lipid extraction. Total lipids were extracted following the method described by Hara and Radin (15). Freshly harvested sunflower kernel endosperm weighing from 0.05 to 0.5 g was ground in 5 mL of hexane/2-propanol 3:2 in a screw-capped tube using a glass bar and sea sand until the tissue was reduced to a fine powder. The resulting suspension was heated at 80°C for 10 min before adding 2.5 mL of sodium sulfate 6.7% and vigorously shaking the tubes. The hexane-enriched supernatant was separated by centrifugation at 5,000 × *g* for 5 min. in a benchtop centrifuge and transferred to a clean tube. The aqueous residue was again extracted with 3.75 mL of hexane/2-propanol 7:2, and the resulting organic phases were combined with those previously obtained. The total lipid extract was then submitted to fractionation.

Lipid fractionation. Crude lipid extracts obtained in the preceding step were evaporated under nitrogen and the residues dissolved in 5 mL of chloroform. The resulting solutions were fractionated following the protocol described by Nash and Frankel (16) in Lichrolut 0.5 g silica gel cartridges (Merck, Darmstadt, Germany) that were set in a vacuum manifold and equilibrated with 2 mL of chloroform. Total lipid extracts were loaded and washed with another 15 mL of chloroform to elute the neutral lipids from the column, and with 10 mL of methanol to quantitatively recover polar lipids. This fraction was evaporated to dryness under nitrogen, dissolved in 0.15 mL of chloroform/methanol (2:1) and the lipid classes were separated by TLC.

TLC fractionation. Purified lipid fractions were loaded onto TLC plates (Si60, 5 μm, Merck, Darmstadt, Germany) and developed with chloroform/methanol/acetic acid/water (85:15:5:2.5). Bands were visualized by spraying the plates with a solution of 2,3-dichlorofluoresceine in methanol, and they were identified by comparing their Rfs with those of the corresponding standards. Bands corresponding to PC, PE, and PI were scrapped from the plate and the lipids were eluted from the silica gel with 10 volumes of chloroform/methanol (2:1).

Derivation of phospholipids by phospholipolysis. The polar lipids purified by TLC were subjected to phospholipase C hydrolysis to form their corresponding DAG (17). Phospholipid solutions containing approx. 1 mg of the corresponding lipid were evaporated to dryness under nitrogen and resuspended in 1 mL of 50 mM potassium phosphate pH 7.2, 2 mM $CaCl_2$. The suspension was fully dispersed by applying several pulses of sonication with a probe sonicator. For PC, a volume of enzyme stock corresponding to 5 U of phospholipase C from *Chlostridium perfringes* was added and the reaction mixture was incubated at 30°C for 1 h. In contrast, phospholipase C from *Bacillus cereus* was used for PE and PI, the former requiring 5 U of the enzyme in each assay while 10 units were added for PI. The reaction mixtures were incubated at 30°C for 1 and 3 h, respectively, to complete hydrolysis. Reactions were stopped by the addition of 0.1 mL 6 M HCl and 1 mL sodium sulfate 6.7%. The DAG were extracted three times with 2 mL hexane, whereafter the organic phases were pooled, evaporated under nitrogen, dissolved in acetonitrile/acetone (70:30), and subjected to HPLC and GLC analysis.

HPLC analysis. DAG molecular species obtained from hydrolysis of PC by phospholipase C were analyzed by reverse phase HPLC in a C18 column (Ultrasphere ODS 4.6 × 250, Beckman, Fullerton, CA). Samples were dissolved in equilibration solvent and injected into the column equilibrated with acetonitrile/acetone (70:30). The different molecular species were then eluted by increasing the acetone content to a final ratio of acetonitrile/acetone of 50:50 after 24 min. Then polarity was increased in one minute to 15:85 acetonitrile/acetone, and that composition was maintained for 4 min. Subsequently, the column was equilibrated with the initial solvent mixture in preparation for the next injection. The molecular species were identified by either comparing their retention times with those of available commercial standards. Some peaks were identified by determining their FA composition by GLC.

This HPLC method allowed the separation and quantification of all the molecular species present in sunflower seed phos-

pholipids in the form of DAG, except for the pair 1-palmitoyl-2-oleoyl glycerol/1-stearoyl-2-linoleoyl glycerol that had to be resolved by GLC. The PC isolated from the seed kernels was easily degraded by phospholipase C from *Clostridium perfringens*. However, because this enzyme was not active on PE or PI, these phospholipids were degraded with phospholipase C obtained from *Bacillus cereus*. Although the yield of the degradation was complete and quantitative for PC and PE, PI was only partially degraded (approx. 50%). Determinations were carried out using three different populations of seeds coming from different plants.

HPLC system. HPLC separation was carried out in a Waters 2695 Module (Milford, MA) equipped with a Waters 2420 ELS detector. The flow rate was 1 mL/min, and samples were dissolved in the same solvent in which the column was equilibrated at the time of injection. Data were processed using Empower software. Fraction collection was carried out with a Waters on-line fraction collector III. The evaporative light scattering detector was regularly calibrated using high purity commercial standards of each lipid.

Analysis of DAG by GLC. The GLC method used was a modification of that described by Perez-Camino *et al.* (18). DAG produced from the different phospholipid classes were evaporated to dryness under a flowing nitrogen. Then, 50 µL of a silanizing mixture (1 mL tetramethylsilane, 3 mL hexadecyl disilazane, 5 mL dry pyridine) per mg of sample were added, and the reaction was left to stand at room temperature for 15 min. The resulting TMS-DAG were dissolved in 0.2 mL heptane and analyzed in an Agilent 6890 gas chromatograph (Palo Alto, CA), using a DB-17HT column (25 m length, 0.25 mm internal diameter, 0.15 µm phase thickness; J&W Scientific, Folsom, CA) and hydrogen as the carrier gas. The injector and FID detector temperature was 340°C, whereas the column temperature was set at 240°C. Mass spectrometry of TMS-DAG species was performed with a Finnigan MAT95 high-resolution mass spectrometer (Finnigan, Bremen, Germany) interfaced with a Hewlett–Packard 5890 Series II gas chromatograph (Palo Alto, CA) using the aforementioned conditions for chromatography. Electron impact (EI) spectra were recorded at 70 eV and full spectra (50–1000 amu) with a scan speed of 2 s decay^{-1} over the entire elution profile. Data were analyzed using an ICIS II Data System from Finnigan MAT (Finnigan, Bremen, Germany).

Analysis of FAME. FAME were prepared by treating the lipid sample with 3 mL of methanol/toluene/sulfuric acid (88:10:2, by vol) for 1 h at 80°C (19). After cooling, FAME were extracted twice with 2 mL of heptane and analyzed by GLC using a Supelco (Bellefonte, PA) SP-2380 fused silica capillary column (30 m length, 0.25 mm i.d., 0.20 µm film thickness). Hydrogen was used as the carrier gas at 28 cm·s^{-1}, the detector and injector temperature was 200°C, and the oven temperature was 170°C. Different methyl esters were identified by comparison with known standards.

RESULTS AND DISCUSSION

Sunflower seeds accumulate carbon and energy in the form of TAG in order to feed the embryo during germination. Seed genesis and oil storage is a process that is carefully regulated, and it typically lasts from 40 to 45 d in commercial *Helianthus*. As reported for other oil crops (20), three different phases can be distinguished within this period. The first of these involves cell division and little accumulation of reserves, and it extends from 0 to 10–15 d after flowering (daf). A rapid deposition of oil then takes place in a second phase that embraces from 15 to 30 daf, this being the period in which *de novo* FA and TAG synthesis is most active. Finally, the last stage of seed development involves desiccation and the shutting down of the metabolic pathways involved in oil synthesis. Therefore, we studied the molecular species of the most prominent membrane lipid classes present in sunflower at each of these three phases, denominated stage 1 (15 daf), stage 2 (25 daf), and stage 3 (40 daf). Sunflower mutants with modified seed FA composition provide us with a good model to study how these changes in FA affect membrane phospholipids during seed development and desiccation. The FA compositions of the mutant seeds used in this work are shown in Table 1.

PC molecular species. The most abundant phospholipid class in the sunflower was PC (9). This phospholipid has both important structural and metabolic roles in plant physiology. Not only is it the main nonphotosynthetic membrane component, but it is also the substrate for oleate desaturation in the endoplasmic reticulum by the action of the ODS isoenzymes (5). Thus, the linoleate present in oilseeds is produced by desaturating the oleate present in the *sn*-2 position of PC. Hence, if we take into account the high proportion of TAG when compared to the PC content in oil seeds (approx 90:1), we can conclude that there is a considerable exchange of acyl moieties between these two lipid classes via DAG, lysophosphatidate intermediates (21), or through the direct action of the phospholipid-DAG

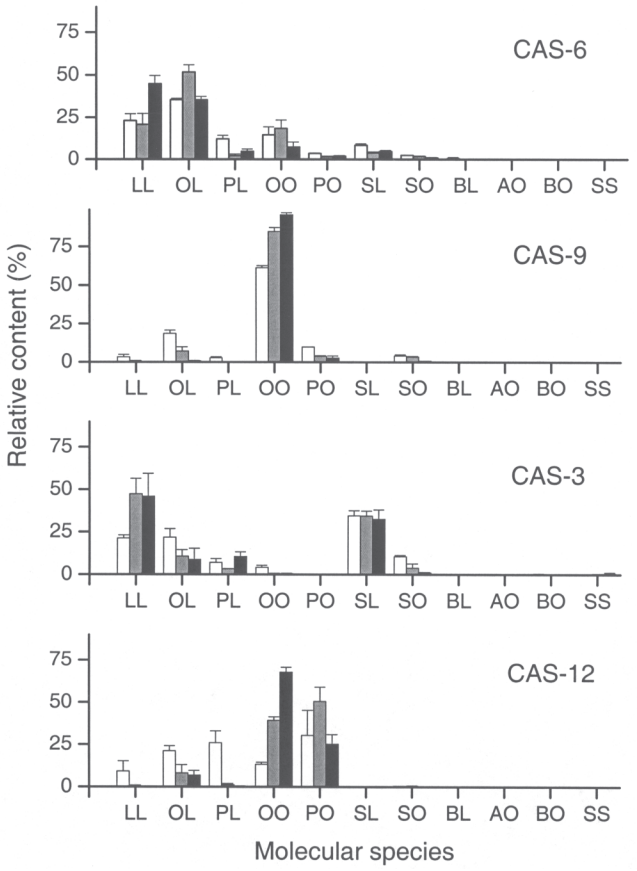

FIG. 2. Molecular species corresponding to PC isolated from common sunflower (CAS-6), high-oleic (CAS-9), high-stearic high-linoleic (CAS-3), and high-palmitic high-oleic (CAS-12). Data are the averages of three independent determinations ± SD. Lipids were isolated from sunflower kernels at 15 (stage 1, □), 25 (stage 2, ▒), and 40 (stage 3, ■) days after flowering. The molecular species were coded with two letters representing the FA. Palmitic acid (P), stearic acid (S), oleic acid (O), linoleic acid (L), arachidic acid (A), and behenic acid (B) were present in the molecular species quantified.

acyltransferase enzyme (PDAT; 22). The close relationship between TAG and PC metabolism was reflected in the different profiles of the accumulation of PC species between sunflower mutants (Fig. 2).

In the case of common sunflower lines, stages 1 and 2 were characterized by a higher content of species containing oleate and linoleate, mainly oleoyl-linoleoyl PC (PC-OL), dilinoleoyl PC (PC-LL), and some dioleoyl-PC (PC-OO). These species increased at stage 3 when the main species found were PC-LL and PC-OL. This molecular profile of PC species indicated that the synthesis of oleate predominates at the beginning of oil accumulation but the action of endoplamic reticulum ODS later shifts the emphasis toward linoleate accumulation, in agreement with previous studies on TAG accumulation (23). The activation of ODS takes place during stage 2 of development, and it stays active until the seed is fully developed and it enters the drying period. This is reflected by the increases in the PC linoleate containing species from stage 2 to stage 3. Furthermore, species such as palmityl-linoleoyl PC (PC-PL), palmityl-oleoyl PC (PC-PO) and stearoyl-linoleoyl PC (PC-SL) were relatively more abundant in stage 1 than stage 2, when they diminished before increasing again in stage 3. This may be caused by the high rates of oleate synthesis characteristic of the exponential phases of oil accumulation. Indeed, this is when the plastidial condensation enzymes, the stearoyl-ACP desaturase, and acyl-ACP thioesterase A enzymes display the highest levels of activity (24).

The profile of PC species found in the high-oleate CAS-9 mutant was, on the other hand, very different from that in the common sunflower. This line is characterized by a mutation that silences the endoplamic reticulum ODS during seed development (25). For this reason the PC-OO species was always the most abundant at each of the three stages studied. Indeed, the relative abundance of this species did alter during development, accounting for 60% of the total PC during stage 1 and increasing to 90 and 96.5% during stages 2 and 3, respectively. However, the presence of PC species containing relatively high proportions of linoleate PC-LL and PC-OL during stage 1 indicated that there was probably an ODS that was active in this period that was later turned off, in agreement with earlier results (10). Moreover, the considerable accumulation of oleate in the PC species was remarkable in this mutant. Thus, PC-OO represented more than 95% of the total PC fraction, representing the highest oleate content of the lipid species found in this plant. This could be due to the accumulation of an oleate acyl moiety at the *sn*-2 position of PC where it would normally be desaturated by ODS. Because the rate of desaturation diminished in high-oleate mutants, this FA remained in PC during the period of seed kernel development.

A different profile of PC species appeared in the high-stearate line CAS-3 in which the high-stearate trait was maximally expressed in PC during the first stage of development. During this period, the PC-SL species accounted for more than 30% of the total PC, and this was maintained throughout stages 2 and 3. The early accumulation of stearate was probably due to the early intraplastidial modification of lipid synthesis that occurs in this mutant. Thus, CAS-3 is a SAD-deficient mutant (13) that expressed its high-stearate phenotype throughout the whole period of seed development (23), altering both *de novo* FA synthesis and glycerolipid synthesis. In this mutant, the accumulation of stearate in PC was coupled to an increase in the accumulation of linoleate-containing species such as PC-LL and PC-OL in the seeds, the former to a similar level as that in the common CAS-6 line. This was in agreement with earlier observations of high linoleate content in the oil of highly saturated sunflower lines. Indeed, this accumulation of linoleate indicates that the excess of stearate in the membranes is compensated for by a mechanism that activates ODS enzymes, increasing the content of PUFA to maintain membrane fluidity.

PC species isolated from the high-palmitate high-oleate mutant CAS-12 accumulated early, like the saturated FA in membrane lipids. Thus, PC-PL and PC-PO were the most abundant species at 15 daf, with a relatively high proportion of species containing oleate and linoleate. Again, mutation of a gene encoding for an intraplastidial enzyme such as β-ketoacyl-ACP

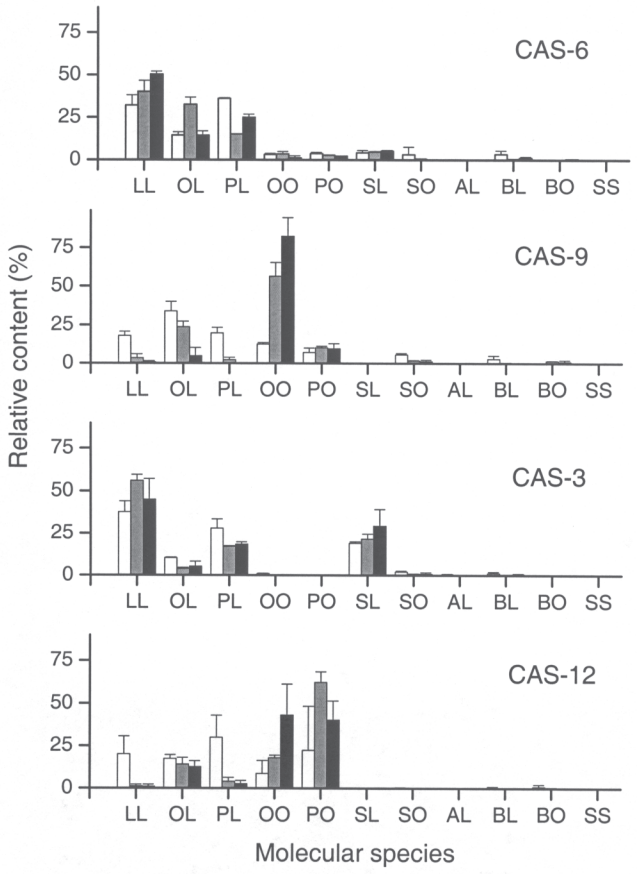

FIG. 3. Molecular species corresponding to PE isolated from common sunflower (CAS-6), high-oleic (CAS-9), high-stearic high-linoleic (CAS-3), and high-palmitic high-oleic (CAS-12). Data are the average of three independent determinations ± SD. Lipids were isolated from sunflower kernel at 15 (stage 1, □), 25 (stage 2, ■), and 40 (stage 3, ■) days after flowering. The molecular species were coded with two letters representing the fatty acids. Palmitic acid (P), stearic acid (S), oleic acid (O), linoleic acid (L), arachidic acid (A), and behenic acid (B) were present in the molecular species quantified.

synthase II induced the early expression of the trait (23). This was associated with a concomitant increase of the ODS enzymes in stage 1, probably to compensate for the excess of palmitate in the membranes. Subsequently, in stages 2 and 3 oleate accumulated in PC due to the lack of endoplasmic reticulum ODS expression. Hence, the main species in the PC fraction of the CAS-12 mutant were PC-OO and PC-PO. An unexpectedly high content of PC-OO was again found in this mutant, indicating that this is a common occurrence in high-oleate sunflower mutants.

PE molecular species. Like PC, PE was also modified by mutations that altered the FA composition of the oil in the different sunflower mutants. The variation observed in the PE species in the common sunflower line CAS-6 was similar to that found for PC. Hence, there was an accumulation of dilinoleoyl PE (PE-LL) at all three stages, whereas the accumulation of oleoyl-linoleoyl PE (PE-OL) reached a maximum at stage 2. This PE species later decreased, leading to an increase the content of PE-LL in mature seeds probably due to the action of endoplamic reticulum ODS (Fig. 3). It was also remarkable that more PE species containing saturated FA were detected than for PC. These phospholipids containing saturated FA accounted for 33% of the total PE content in the fully developed kernels, more than double the 15% of PC species with saturated FA. Indeed, palmitate was more abundant in PE at stages 1 and 3 of development, which is probably related to the synthesis of cell membranes and those of the oil bodies. The high-oleate line CAS-9 also displayed an enrichment of oleate in the PE species. Unlike PC, this trait was not evident in seeds harvested 15 daf, when the predominant species were PE-OL and palmitoyl-linoleoyl PE. Rather, the high-oleate trait was evident in stages 2 and 3, when dioleoyl PE (PE-OO) was the most abundant molecular species, followed by PE-OL and palmitoyl-oleoyl PE (PE-PO). The relative abundance of PE-OO in mature seeds was lower than that in PC at the same stage, which probably reflected a lower accumulation of the oleate acyl moieties in PE. The phenotype of the high-stearate CAS-3 mutant was again expressed at early stages of development, with a predominance of PE-LL and stearoyl-linoleoyl PE at the three stages studied. Again, PE species were enriched in palmitate when compared with those found in PC phospholipids, as seen in the control and high-oleate lines. Finally, the high-palmitate high-oleate CAS-12 line displayed the mutant phenotype in PE at an earlier stage, with a higher relative abundance of PE-PO, again reflecting the preference of PE to accumulate palmitate. The proportion of both PE-PO and PE-OO species increased at stages 2 and 3, at the expenses of species containing linoleate.

PI molecular species. The third lipid class studied here was PI, present in sunflower kernels at similar levels as PE. However, PI fulfills different functions and these phospholipids are synthesized through different pathways. Thus, they displayed a very different composition, with a higher proportion of saturated FA, as reported previously (10). Although PI is synthesized from phosphatidate and does not therefore serve as a direct TAG precursor (Fig. 1), the acyl composition of the oil has an important impact on the molecular PI species. These changes were most apparent at stages 2 and 3, when oil was accumulating more actively. At stage 1, all mutants displayed similar PI profiles, in which palmitoyl-linoleoyl PI (PI-PL) was most abundant (Fig. 4). Nevertheless, the early accumulation of stearate and linoleate in CAS-3 made stearoyl-linoleoyl PI (PI-SL) almost as abundant as the PI-PL species at the beginning of seed development. Furthermore, the CAS-6 common sunflower line accumulated PI-PL and PI-SL as the main species at later stages of development. The predominant species found at stages 2 and 3 in CAS-3 and CAS-12 were PI-SL and palmitoyl-oleoyl PI respectively, whereas concomitantly a high-dioleoyl PI content was displayed by the CAS-9 line. This saturated FA-rich composition indicated that enzymes involved in PI synthesis are more specific for glycerolipids carrying these acyl moieties. Hence, the enzyme PI synthase (26) seemed to be the number one candidate to select these species. Indeed, it has been indicated that PI synthase from the organs of different plants shows a high selectivity for

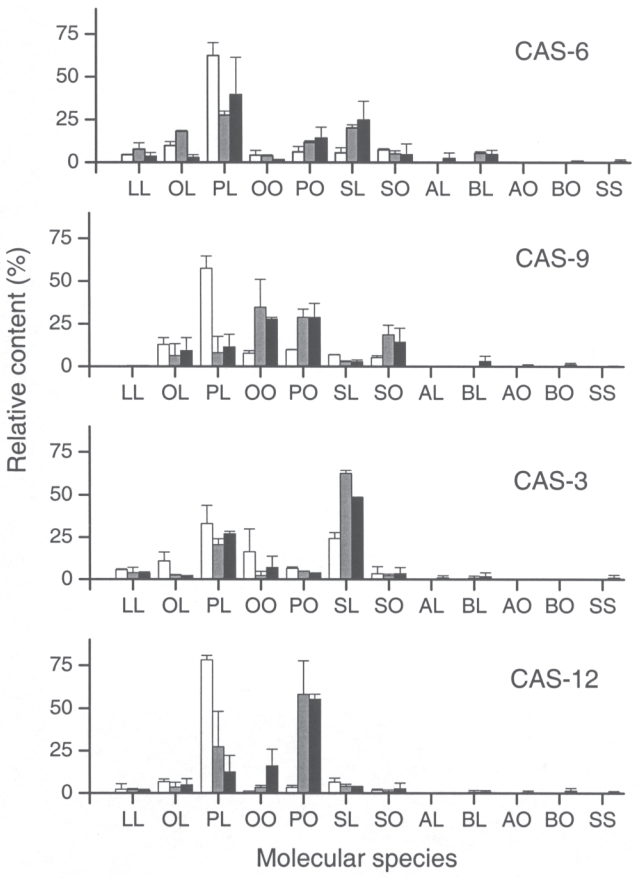

FIG. 4. Molecular species corresponding to PI isolated from common sunflower (CAS-6), high-oleic (CAS-9), high-stearic high-linoleic (CAS-3), and high-palmitic high-oleic (CAS-12). Data are the average of three independent determinations ± SD. Lipids were isolated from sunflower kernel at 15 (stage 1, □), 25 (stage 2, ■), and 40 (stage 3, ■) days after flowering. The molecular species were coded with two letters representing the FA. Palmitic acid (P), stearic acid (S), oleic acid (O), linoleic acid (L), arachidic acid (A), and behenic acid (B) were present in the molecular species quantified.

the synthesis of saturated-unsaturated PI species (27). Moreover, similar results were observed in maize coleoptile microsomes (28) and in *E. coli* expressing an exogenous PI synthase from Arabidopsis (29). The importance and function of this enrichment in saturated FA of PI has not been yet determined.

The results obtained here indicated that mutations affecting the FA composition of sunflower oil have a direct impact on the accumulation of different molecular species of membrane phospholipids. Furthermore, the acyl composition of phospholipids appears to be dependent on the stage of seed development. These changes were mainly related to the activity of the enzyme ODS and the intraplastidal *de novo* FA biosynthetic pathway. The relatively early accumulation of PC-LL and PE-LL species in the high-stearate CAS-3 mutant indicated that there are mechanisms that activate ODS when saturated FA increase in cell membranes. However, it is not clear how the plant might detect this situation or how this might produce such a response. It was also remarkable that PC contained an unexpectedly high proportion of diolein moieties in the high-oleate mutants CAS-9 and CAS-12. This probably reflects the high accumulation of oleate in the *sn*-2 position of PC as well as the high proportion of oleate in the acyl-CoA pool that would thus be easily incorporated in the *sn*-1 and *sn*-2 positions by the endoplasmic reticulum glycerol-3-phosphate acyl-CoA acyltransferase and lysophosphatidate acyl-CoA acyltransferase, respectively. Nevertheless, the molecular species of PE and PC were very similar in all the sunflower lines studied indicating that they share an important part of their biosynthetic pathways. In contrast, the acyl composition of PI was different displaying higher saturated FA content, stearate or palmitate depending on the mutant. This also revealed the selectivity of the enzymatic machinery involved in the synthesis of this phospholipid.

The results regarding PC species gave interesting information about how TAG are assembled in the sunflower, indicating that PC and TAG share DAG as their direct precursor. Furthermore, the different molecular species provide data about the specificity of some of the enzymes in the Kennedy pathway, which have been shown to be an important constraint at the time of isolating sunflower mutants with a higher saturated fatty acid content. This aspect of TAG biosynthesis could be examined by comparing the composition of the PC and TAG species in each mutant. Thus, in the CAS-6 common sunflower the predominant species among the TAG were dioleoyl-linoleoyl glycerol, oleoyl-dilinoleoyl glycerol, and trilinoleoyl glycerol. This indicates that TAG were mostly assembled from the most abundant PC (or DAG) species containing oleoyl-linoleoyl and dilinoleoyl acyl moieties (Fig. 2), and the oleoyl and linoleoyl-CoA substrates. On the other hand, the TAG in the high oleic lines were comprised of approximately 70% trioleoyl glycerol, followed by 12% of stearoyl-dioleoyl glycerol (30). This proportion contrasted with the compositions of more than 95% PC-OO and less than 1% of stearoyl-oleoyl PC, indicating that most stearic acid was transferred to glycerolipids via acyl-CoA-diacylglycerol acyltransferase or PDAT in the last step of the pathway. This hypothesis was supported by the TAG and PC composition of the high stearic line CAS-3, in which the predominant TAG were distearoyl-linoleoyl glycerol, stearoyl-oleoyl-linoleoyl, and stearoyl-dilinoleoyl glycerols, produced by esterification of stearoyl-CoA on dilinoleoyl, stearoyl-linoleoyl, or oleoyl-linoleoyl DAG or PC precursors. Thus, by considering the molecular species of PC in sunflower, it appears that the first enzyme of the Kennedy pathway, GPAT has low specificity for stearoyl-CoA and a preferance for linoleate, oleate or palmitate derivatives. The following condensing enzyme, LPAAT was very specific for oleoyl-CoA which was quickly desaturated to linoleate in the *sn*-2 position of PC, whereas stearate is preferentially introduced at the *sn*-3 position by the DAGAT or PDAT enzymes. These aspects of sunflower lipid biosynthesis have been confirmed by biochemical studies and studies of the FA distribution in the TAG molecules of sunflower. These studies indicated that stearic acid was asymmetrically distributed in sunflower TAG (31), an important constraint at the time of producing sunflower oils with very high content of this FA.

Summarizing, this work shows that modifications in storage

TAG from sunflower seeds have a direct effect on membrane lipids, provided they share biosynthetic pathways. This means that modifications in the FA biosynthesis introduced in new lines of sunflower or other oil crops are limited by the impact of these modifications on the functionality of the seed membranes. Furthermore, the study of the composition of molecular species of phospholipids revealed interesting aspects of TAG biosynthesis in sunflower, like the sequential action of the enzyme ODS and the specificity of the acyltransferases of the Kennedy pathway.

ABSTRACT: The oil content, FA, and lipid class composition of the mature seeds of six *Cordia* species were analyzed. Mature seeds of each species were collected in their natural habitat from 2002 to 2004. The total lipid content varied from 1.9% to 13.2%, there being significant differences between the results found in different years for each species and between the species analyzed. The contents of FFA varied from 2.0% to 7.9% of total lipids. Neutral lipids (NL) were the largest class, making up between 89.6% and 96.4% of the total lipids; the phospholipids (PL) were the second largest class (3.0% to 8.9% of the total lipids), and the glycolipids (GL) were the smallest class (0.6 to 3.4%). The presence of GLA was determined in each class of lipids; it is predominant in the NL. Levels of GLA ranged from 1.2% to 6.8% of total seed FA. This is, to our knowledge the first study of lipid composition in seeds of species of *Cordia* from Brazil.

Paper no. L9942 in *Lipids 41*, 813–817 (August 2006).

GLA, a FA belonging to the omega-6 (ω-6) family, has received considerable attention in recent years due to its beneficial effects on the treatment and control of: cardiovascular disease (1), diabetes (2), atopic dermatitis (3), alcoholism (4), premenstrual syndrome (5), hypertension (6,7), and tumors (8). Studies have also shown that it reduces VLDL, LDL, and cholesterol levels (9,10).

Heath products containing GLA mainly consist of lipid extracts from *Oenothera biennis* L., *Borago officinalis* L. and *Ribes nigrum* L. (11). But other species belonging to the Boraginaceae, Aceraceae, and Ranunculaceae families can also be potential sources of GLA. A study of 36 species, belonging to 20 genera of the Boraginaceae family showed that all the accessions analyzed contained GLA and that GLA was a potential chemotaxonomic marker for this family (12). Although no species of *Cordia* (Boraginaceae) were included in that study, the results suggested that other Boraginaceae species might also contain GLA. Although previous studies reported the FA composition of the seed oil of several wild and cultivated *Cordia* species (13–18), they did not included Brazilian *Cordia* species. In a study of three Brazilian *Cordia* species (*C. ecalyculata, C. myxa,* and *C. selowiana)*, the analysis of the FA composition of seed oil revealed the presence of GLA (11). For this reason, we found it interesting to further evaluate Brazilian *Cordia species* for GLA content.

The objective of this study was to analyze the composition of lipids in mature seeds of six different native Brazilian species of *Cordia,* with emphasis on determining the presence of GLA, and to see whether this acid is found in the reserve lipids.

EXPERIMENTAL PROCEDURES

Sample collection and preparation. Seeds from mature plants of *Cordia* species were collected in different regions of Brazil (Table 1). The species used were *Cordia ecalyculata, C. glabrata, C. sellowiana, C. superba, C. trichotoma,* and *C. goeldiana.* The seeds were peeled, and only the nut and mesocarp were ground and homogenized in a food processor. The obtained powder was immediately analyzed. Three samples were taken from each plant at each location and time of collection, and these replicates were processed individually.

Extraction and quantification of total lipids. Twenty grams of the homogenized powder obtained from the procedure just described were extracted according to the method of Bligh and Dyer (19). Samples were first extracted with 50 mL of chloroform/methanol/water (1:2:0.8, by vol), and then with 50 mL of the same solvent system but with a different proportion (2:2:1.8). The extract was filtered and dried using sodium anhydride, and 10 mL of this extract was transferred to a previously weighed beaker and kept in an oven at a temperature of 105°C until constant weight. Total oil content was measured gravimetrically and expressed as a percentage of dry seed weight.

Separation of different classes of lipids by column chromatography. Lipids were separated following the procedure described by Christie (20). Total lipids were partitioned into classes by column chromatography. A glass column (20 cm long by 1.25 cm i.d.) containing 20 g of silica gel 60 (70–230 mesh, Merck) was used as stationary phase, and chloroform, acetone, and methanol were sequentially applied to the column

[a]Results are expressed as means ± SD of three measurements. Means within a column that do not share a superscript letter are significantly different ($P \leq 0.05$).
[b](1) São Paulo state (city of Rio Claro); (2) Mato Grosso state (Xingu Indian Reservation); (3) Pará state (city of Boa Vista); (4) São Paulo state (city of Vargem); (5) Minas Gerais state (city of Bueno Brandão).

to elute neutral lipids (NL), glycolipids (GL), and phospholipids (PL), respectively. The lipid fractions were reduced in volume at 40°C using a rotary evaporator. Then 100–300 mg of each fraction were transferred to preweighed flasks; the residual solvent was evaporated under nitrogen, and the samples were placed in a desiccator until constant weight. The content of each lipid class was calculated by weight, and expressed as a percentage of the total lipid dry weight.

FFA content. The FFA content of the lipid fractions was determined colorimetrically according to Kwon and Rhee (21). The total content of FFA in the samples was expressed as oleic acid equivalents using a standard curve.

GLC of FAME. Total lipids were converted into methyl esters of FA using BF_3 methanol as esterifying agent, according to the method suggested by the American Oil Chemist's Society (22). The methyl esters were diluted in hexane and analyzed by GC using a Chrompak chromatograph (model CP 9001) with a flame ionization detector and a CP-Sil 88 capillary column (Chrompak, WCOT Fused Silica 59 m × 0.25 mm). Detector temperature was 270°C, and temperature of the injector was 250°C. Initial temperature was 80°C for 7 min, programmed to increase 10°C per min up to 180°C, hold for 3 min, and then increase 3°C/min up to a maximum temperature of 210°C. Carrier gas used was hydrogen at a flow rate of 2 mL/min. The identification of the FA was done by comparison of the retention times of the sample components with authentic standards of FAME injected under the same conditions. Coelution (spiking) of samples was also used. FA composition, as percentage of total FA weight, was calculated using area counts of the chromatogram.

GC–MS. The FA composition was confirmed by using a Hewlett Packard 5890 GC–MS. FAME were separated using an Ultra-2 (Hewlett Packard) apolar column (25 m length × 0.22 mm internal diameter × 0.33 μm film thickness). The following temperature program used: 1 min at 60°C, then a linear increase from 60°C to 300°C at 10°C/min, and held at 300°C for 5 min. Helium was used as carrier gas. The mass spectrometer used electron ionization (EI) with filament potential of 70 eV and temperature of 100°C, and a quadrupole mass analyzer in rf/DC mode. Components of the sample were identified by comparison with data from mass spectrometry libraries.

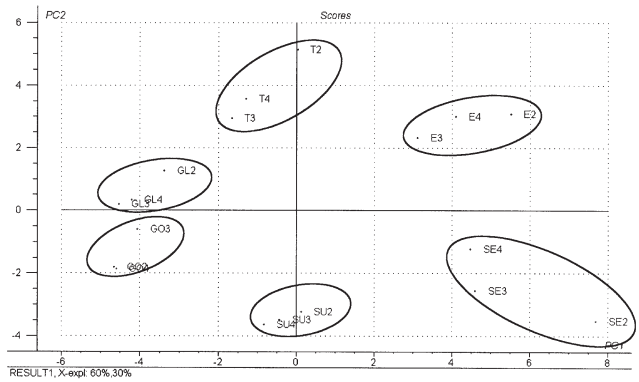

FIG. 1. PCA of the data in Table 1. Data for three samples of each species are shown. T2, T3, and T4: *C. trichotoma* Vell.; E2, E3, and E4: *C. ecalyculata* Vell.; SE2, SE3, and SE4: *C. sellowiana* Cham.; SU2, SU3, and SU4: *C. superba* Cham.; GO2, GO3, and GO4: *C. goeldiana* Huber; GL2, GL3, and GL4: *C. glabrata* DC. Variables analyzed: place of collection, total lipid content (%), FFA content (%), and major lipid classes (% of total).

Statistical analysis. One-way ANOVA and Tukey's studentized range test were used to determine the differences in mean values for each sample based on data collected from three replications of each sample. Significance was established at $P \leq 0.05$.

Principal component analysis (PCA) of the data in Table 1 was performed using the 2.60 version of Pirouette software from Infometrix (Woodinville, WA), in order to group the samples. The data was preprocessed using autoscale and the PCA method was run.

RESULTS AND DISCUSSION

The total lipid contents, FA contents, and contents of the main classes of lipids detected in the mature seeds of six *Cordia* species are shown in Table 1. The total lipid content varied between 1.9% and 13.2%, there being significant differences between the results found in different years for each species and between the species analyzed. Based on these results, the samples can be divided into three groups: those with total lipid content of up to 2.5% total seed weight (*C. glabrata* and *C. goeldiana*); those with total lipid content between 3% and 6% (*C. superba* and *C. trichotoma*), and those with total lipid contents over 7% (*C. ecalyculata* and *C. sellowiana*).

Of these, *C. ecalyculata* and *C. sellowiana* seeds collected in 2002 had significantly higher total lipid content than the seeds collected in the following years (2003 and 2004). For *C. superba, C. glabrata,* and *C. trichotoma,* the same trend was observed, but not for *C. goeldiana.* The differences, however, were not statistically significant in relation to both of the following years. It is known that different climatic conditions, such as rainfall, temperature, soil, and stage of germination of the seeds, can cause significant variations in the lipid contents and composition of seeds of the *Boraginaceae* family (23,24,25). According to meteorological bulletins reported by the governmental agency INPE (National Space Research Institute of the Brazilian Science and Technology Ministry), the year 2002 was the hottest since 1860, and rains were below average in most of Brazil the same year. On the other hand, the years 2003 and 2004 presented higher rainfall than usual for the state of São Paulo (26). Apparently a hotter and drier climate resulted in higher lipid content, although other factors may also be involved in this result.

PCA of the data in Table 1 was run using the following as variables: the place of collection, total lipid content (%), FFA content (%), and the percentages of each lipid class (PL, GL, and NL) for each sample analyzed. The samples were grouped according to their species, indicating that the differences between species were greater than variations between years within each species due to differences in meteorological conditions. PC1 explains 60% of the variability, and PC2 explains 30%.

In relation to total lipid content, the results obtained for *C. superba* (4.4–6.0%) and *C. trichotoma* (3.1–4.3%) seeds are similar to those found by Kleinman *et al.* (16) for seeds of *C. obliqua* Wild (4.0%) and by Mukarram *et al*. (17) for *C. myxa* (3.0%) seeds. Other authors reported higher lipid contents: Daulatabalad *et al.* (15) found 18.0% for *C. rothii.* Mayworm *et al*. (18) reported 19.6% lipid content for seeds of *C. glabrata* A. DC. from the semi-arid region of the Brazilian northeast. A recent study (11) reported 25.8% lipid content in fresh *C. sellowiana* seeds collected in the same region at the same time of the year as Mayworm *et al.* (18). Some plants of the Boraginaceae family are known for their high lipid contents, especially *Myosotis discolor* Pers. (34.1%) and *M. sylvatico* Hoffm. (31.8%) (12). Guil-Guerrero *et al.* (27) analyzed 20 species collected in Spain belonging to the Boraginaceae family and reported lipid contents of 6.6% for *Echium humille* and 30.7% for *Borago officinalis*, but no samples of *Cordia* were analyzed.

The contents of FFA varied between 2.0% and 7.9% of total lipids. NL were the largest class, making up between 89.6–96.4% of the total lipids, the PL were the second largest class with 3.0–8.9% of the total lipids, and the GL the smallest class (0.6– 3.4%). The presence of GLA vas determined in each class of lipids; it is predominant in the NL, making up 95–98% of the FA content of this class of lipids (data not shown). To our knowledge no previous studies have reported the classes of lipids found in seeds of *Cordia.* These results are comparable to those obtained by Senanayake and Shahidi (25) for *Borago officinalis* L. seeds, another member of the same family (Boraginaceae), with an average of 84.1% of NL, 8.6% of PL, and 7.3% of GL in relation to total lipids. The results of Hamrouni *et al.* (24) differ, as they did not report the presence of glycolipids for *Borago officinalis* L seeds.

Table 2 presents the relative composition of the FA found in the six species of *Cordia*. In all species, oleic acid is the predominant FA, ranging from 37% to 48%, followed by linoleic acid (17–25%) and palmitic acid (15–20%). Alpha-linolenic (18:3n-3) and stearidonic (18:4n-3) acids were present in all analyzed *Cordia* species. GLA contents ranged from 1.2% in *C. sellowiana* to 6.8% in *C. ecalyculata*, and was not found in *C. trichotoma*. The variations in GLA content between seeds of the same species collected in different years were not significant at $P = 0.05$.

The predominance of oleic acid was also reported by Mayworm *et al.* (18) for seeds of *C. glabrata* A. DC. (40.8% of total FA), a species from the northeast of Brazil. Other authors have reported very different FA compositions in other species of *Cordia*. In the seed oil of *C. rothii*, linoleic acid was the main FA (40%), followed by palmitic (32.8%), ricinoleic acid (10.8%), and oleic acid (7.8%) (15). Alpha-linolenic acid (24.1%), eicosenoic acid (17.5%), and arachidic acid (8.7%) were found to be predominant in the FA composition of *C. myxa* seeds by Mukarram *et al.* (17), who did not report the presence of GLA in these seeds. Presence of GLA was also not reported in seeds of *C. rothii* (syn. *C.angustifolia)* (15) collected in India, nor in *C. salicifolia* (syn. *C. ecalyculata*) and *C. verbenacea* collected in Beltsville, Maryland (16), nor in seeds of *C.glabrata* A. DC. from the northeast of Brazil (18). Only low concentrations of GLA were found for seeds of *C. obliqua* Wild (0.1%) collected in Beltsville, Maryland, by Kleinman *et al.* (16). However, in a previous study carried out

by our group, GLA was found in seeds of *C. ecalyculata*, *C. myxa,* and *C. sellowiana* collected in Brazil in 2001, ranging from 0.6% to 2.5% of total FA (11). These results suggest that differences in place and time of collection might significantly influence the FA composition of the seeds, although not as much as genetic differences. More detailed studies as to the conditions that result in higher contents of specific FA should be carried out if these seeds are used commercially for the extraction of GLA or other FA.

The concentrations of linoleic, alpha-linolenic, and stearidonic acids and GLA have been indicated as having special taxonomic importance within the Boraginaceae family (12,13,27). Nine species of Boraginaceae from Mongolia (Central Asia) analyzed by Tsevegüren and Aitzetmüller (28) contained GLA (ranging from 6.6% to 13.0%) and stearidonic acid (ranging from 2.4% to 21.4%). *Borago officinalis* L. was found to contain 18.5–24.5% of GLA, but only 0.2– 0.3% of stearidonic acid (12). Another species of Boraginaceae worthy of mention is the plant known in Brazil as confrey (*Symphytum officinale*), as it contains 26–27% of GLA (16,29).

As a previous study indicated, Brazilian *Cordia* species are sources of GLA, a biologically important FA, and five of the six species tested contained GLA in different proportions. The presence of GLA was determined in each class of lipids, and it was found to be predominant in the NL. This is, to our knowledge, the first study on the classes of lipids found in mature seeds of species of *Cordia* found in Brazil.

ACKNOWLEDGMENTS

We thank CPTEC/INPE for the meteorological data and Dr. Fernando de Oliveira for the identification of the Cordia species. This work was supported by PROPEP/ USF and CNPq.

Insulin Status-Dependent Alterations in Lipid/Phospholipid Composition of Rat Kidney Microsomes and Mitochondria

Samir P. Patel and Surendra S. Katyare*

Department of Biochemistry, Faculty of Science, The Maharaja Sayajirao University of Baroda, Vadodara, Gujarat 390 002, India.

ABSTRACT: Early and late effects of alloxan-diabetes on lipid/phospholipid composition in rat kidney microsomes and mitochondria were examined. In microsomes, early diabetic state resulted in an increase in contents of total phospholipids (TPL), cholesterol (CHL), with an increase in the lysophospholipids (Lyso), phosphatidylcholine (PC), and phosphatidylinositol (PI) components. The sphingomyelin (SPM), phosphatidylethanolamine (PE), phosphatidylserine (PS), and phosphatidic acid (PA) content decreased. Treatment with insulin had no effect on PC but PE increased and the other components decreased. In the 1-month diabetic group PI, PS, PE, and PA components decreased, whereas Lyso and PC increased. Treatment with insulin had restorative effects on PE, PI, and PS; Lyso was further elevated whereas PA decreased. In mitochondria, at an early stage of diabetes marginally increased CHL content was restored by insulin treatment. Long-term diabetes lowered the TPL and elevated the CHL content. Treatment with insulin partially restored the TPL and CHL content. A diabetic state decreased the proportion of PE and diphosphatidylglycerol (DPG) components but increased the Lyso, SPM, PC, PI, and PS components in the mitochondria. Treatment with insulin had a partial restorative effect. The membrane fluidity of both microsomes and mitochondria decreased in general in the diabetic condition and was not corrected by insulin treatment at a late stage. However, at an early stage, treatment with insulin fluidized both membranes.

Paper no. L9897 in *Lipids 41*, 819–825 (September 2006).

Diabetic nephropathy is a major cause of diabetes-related morbidity and mortality (1,2). Diabetic nephropathy affects about 15–25% of all type 1 diabetic patients and 20–40% of all patients with type 2 diabetes (3,4).

In our earlier studies we have observed that streptozotocin-diabetes and subsequent treatment with insulin significantly altered the oxidative energy metabolism in kidney mitochondria (5). We have also observed that alloxan-diabetes and subsequent treatment with insulin resulted in significant changes in the kinetic properties of kidney mitochondrial FoF_1-ATPase and succinate oxidase (6,7). Simultaneous studies on kidney microsomes revealed that the kinetic properties of Na^+,K^+-ATPase and of glucose-6-phosphatase were altered in alloxan-diabetes and by subsequent treatment with insulin (Patel, S.P., and Katyare, S.S., unpublished data). The aforementioned mitochondrial and microsomal membrane-bound enzymes are known to have a requirement for specific phospholipids (9–13).

It was therefore of interest to find out the effect of insulin status on the lipid/phospholipid makeup of kidney microsomes and mitochondria. To this end, we have examined the early and late effects of alloxan-diabetes and subsequent treatment with insulin on the lipid/phospholipid profile of rat kidney microsomes and mitochondria. These results are summarized here.

EXPERIMENTAL PROCEDURES

Chemicals. Sodium salt of ethylenediaminetetraacetic acid (EDTA), 1,6 diphenyl-1,3,5-hexatriene (DPH), and bovine serum albumin fraction V (BSA) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Silica gel G was purchased from E. Merck (Darmstadt, Germany) and NPH insulin (40 U/mL) was obtained from Eli Lilly (Fegersheim, France). All other chemicals were of analytical-reagent grade and were purchased locally.

Animals. Adult male albino rats of Charles-Foster strain weighing between 200 and 250 g were used. The animals were fasted overnight and the diabetic state was induced by injecting 12 mg of alloxan/100 g of body weight subcutaneously (s.c.) (14–16). Alloxan solutions were prepared freshly in saline. The control rats received an equivalent volume of the vehicle. The early and late effects were examined at the end of 1 week and 1 month of induction of a diabetic state to ascertain the early-onset and long-term effects (5,17). A diabetic state was confirmed in terms of hyperglycemia, polyuria, and glucosuria as detailed previously (5,14–16). For 1-week studies the diabetic animals received insulin from the fifth day of induction of diabetes for three consecutive days, and for 1-month studies diabetic animals received insulin starting from the fourth week of induction of diabetes for seven consecutive days at a dose of 0.8 units of NPH insulin/100 g of body weight twice daily (around 7:00 AM and 6:00 PM) by s.c. route (14–16).

Abbreviations: CHL, cholesterol; DPG, diphosphatidylglycerol; DPH, 1,6 diphenyl-1,3,5-hexatriene; Lyso, lysophospholipids; PC, phosphatidylcholine; PI, phosphatidylinositol; PE, phosphatidylethanolamine; PS, phosphatidylserine; PA, phosphatidic acid; s.c., subcutaneously; SPM, sphingomyelin; TPL, total phospholipids.

Isolation of mitochondria and microsomes. Isolation of kidney mitochondria was essentially according to the procedures described earlier with some modifications employing the isolation medium comprising 0.25 M sucrose, 10 mM Tris-HCl buffer pH 7.4, and 1 mM EDTA; 250 μg of BSA/mL isolation medium was included (19–21). The postmitochondrial supernatant was subjected to further centrifugation at 12,000 × *g* for 10 min for sedimenting the light mitochondrial fraction. The resulting supernatant was then centrifuged at 100,000 × *g* for 1 h for sedimenting the microsomal fraction. The pellet was washed once by resuspending and resedimenting (22).

The purity of mitochondrial fraction was ascertained by measuring the glucose-6-phosphatase (G6Pase) (a microsomal marker enzyme) activity (Patel, S.P., and Katyare, S.S., unpublished data) and microsomal contamination was found to be less than 2%. The succinate-DCIP-reductase (SDR) activity was not detectable in the microsomal fraction, indicating that there was no mitochondrial contamination. Lactate dehydrogenase (LDH) activity in both microsomal as well as mitochondrial fractions was undetectable, thereby ruling out cytosolic contamination.

Analytical methods. (i) Lipid extraction. Extraction of lipids from the kidney microsomes and mitochondria was carried out essentially according to the method of Folch *et al.* with some modifications as described previously (23,24). Thus briefly, aliquots of microsomal or mitochondrial suspensions containing 4–6 mg of proteins were extracted with 4.0 mL of freshly prepared chloroform/methanol mixture (2:1 vol/vol). The tubes were vortex mixed vigorously, allowed to stand, and after centrifugation at 2,000 rpm for 10 min the organic phase was removed. The samples were then reextracted with 2.0 mL of chloroform/methanol mixture and the organic phase was removed after centrifugation. To the pooled extract 0.2 vol of 0.017% (wt/vol) $MgCl_2$ solution was added and the tubes were vortex mixed. Phase separation was achieved by centrifugation at 3,000 rpm for 10 min and the lower organic phase was carefully removed using a broad gauge needle attached to a syringe, taking care to avoid protein and proteolipid interphase. The organic phase was completely evaporated under a stream of nitrogen and the lipids were redissolved in a known volume of chloroform/methanol mixture (2:1 vol/vol). Suitable aliquots were taken for the determination of total phospholipid (TPL) (25), cholesterol (CHL) (26), and for separation of individual phospholipids by TLC (24,27).

(ii) Separation of phospholipids by TLC. Separation of phospholipid classes was carried out by one-dimensional TLC (24,27). The conditions for preparation of TLC plates, chamber saturation, and so forth were according to the procedure described earlier by Stahl (28). The solvent system used was chloroform/methanol/acetic acid/water (25:15:4:2, by vol) (27). After the run was completed the plates were left at room temperature to remove the solvents. The spots of individual phospholipids were visualized after brief exposure to iodine vapor and marked.

(iii) Estimation of phospholipid phosphorus. After scraping the individual phospholipid spots, the samples were digested with 0.5 mL of 10 N sulfuric acid by heating in a sand bath for 2.5 h. The tubes were allowed to cool and a drop of 70% perchloric acid was added. The tubes were then heated in the sand bath for 25 h to ensure that optically clear samples are obtained and that simultaneously the traces of perchloric acid are removed. The samples taken for estimation of total phospholipid content were also treated in the similar manner. The estimation of phospholipid phosphorus was according to the method described by Bartlett (25).

Membrane fluidity measurements were carried out at 25°C spectrofluorophotometerically using DPH as the probe (24).

Estimation of protein was by the method of Lowry *et al.* using BSA as the standard (29).

Regression analysis was carried out using Jandel Sigmastat Statistical Software, version 2.0.

Statistical evaluation of the data was by Student's *t* test.

RESULTS

Alloxan-diabetes resulted in 15% and 38% reduction in the body weight, respectively, at the end of 1 week and 1 month (Table 1). Treatment with insulin had a marginal restorative effect in the 1-week group while in the 1-month group insulin treatment almost completely restored the body weight (Table 1). At the end of 1 week and 1 month the kidney weight of the

The results are given as mean ± SEM of the number of independent observations indicated in parentheses.
$^{a}P < 0.05$; $^{b}P < 0.02$ and $^{c}P < 0.001$ compared to the corresponding control.
$^{\S}P < 0.05$ and $^{\Psi}P < 0.001$ compared with corresponding diabetic values.

diabetic rats increased by 15% and 35%, respectively. Treatment with insulin had a partial restorative effect only in the 1-month diabetic group. The relative kidney weight increased significantly in the diabetic condition and the increase was more pronounced in the 1-month diabetic animals; insulin treatment had partial restorative effects (data not given). These results are consistent with our previously reported observations (5,14).

Compared to the corresponding controls, the levels of glucose in the serum increased by 3.3- and 4.1-fold in the two diabetic groups. Although insulin treatment lowered the serum glucose levels, the values were always somewhat higher (6.21 and 5.62 mM, respectively) compared to those in the corresponding controls (Table 1). Polyuria in the diabetic state was reflected in terms of 21- and 27-fold increases in the urine volume respectively in two diabetic groups (data not shown). Insulin treatments restored the urine volume to normality (2.2–2.7 mL/24 h). The urinary sugar excretion amounted to about 1.2–1.3 g/24 h in the two diabetic groups; insulin treatment completely abolished the urinary sugar excretion (data not shown). The results agree well with our previously reported observation (5,6,18,30).

The data in Table 2 show that an early diabetic state resulted in increased TPL and CHL contents (28% and 47% increase, respectively) in the microsomal membranes. Insulin treatment was ineffective in restoring the TPL content while CHL content increased further. The TPL content was unaltered in the late diabetic stage, but the CHL content increased by 59%. Insulin treatment had a marginal restorative effect only on CHL content. The TPL/CHL (mol:mol) ratios decreased in the diabetic groups and remained low after insulin treatment. The membrane fluidity decreased in diabetic animals and treatment with insulin significantly fluidized the membrane in the 1-week diabetic animals, whereas the opposite effect was seen in the 1-month diabetic animals (Table 2).

In the mitochondrial membranes the TPL content did not change in the 1-week diabetic animals, whereas the CHL content increased by 16%. Insulin treatment had no effect on TPL content but restored the CHL content. In the 1-month diabetic group the TPL content decreased by 52% and the CHL content increased by 63%. Insulin treatment partially restored the TPL and CHL contents. The TPL/CHL (mol:mol) ratios decreased in the diabetic groups and insulin treatment was effective in normalizing it only in the early stage. The membrane fluidity decreased in diabetic animals and insulin treatment fluidized the membrane in 1-week diabetic animals (Table 3).

The data on phospholipid composition of microsomal membranes are given in Table 3. An early diabetic state resulted in a

significant increase in lysophospholipids (Lyso), phosphatidylcholine (PC), and phosphatidylinositol (PI) components, whereas sphingomyelin (SPM), phosphatidylethanolamine (PE), phosphatidylserine (PS), and phosphatidic acid (PA) components decreased. Insulin treatment had no effect on the PC component, which remained elevated. PE increased beyond the control level after insulin treatment, and there was a further lowering of the other phospholipid classes.

The 1-month diabetic group was characterized by the lowering of PI, PS, PE, and PA components, whereas Lyso increased and PC was somewhat elevated. Insulin treatment completely restored PE and PI with partial restoration of PS; Lyso was further elevated while the opposite effect was noted for the PA component (Table 4).

Analysis of the phospholipid profile of mitochondria revealed that the diabetic state had a general effect of increasing Lyso, SPM, PC, PI, and PS and a tendency to decrease PE and diphosphatidylglycerol (DPG) components. Insulin treatment partially corrected the Lyso and PS composition in both the diabetic groups. Insulin treatment could not correct the PI and PE components in the 1-week group and elevated the latter component in the 1-month group (Table 5).

DISCUSSION

The foregoing results emphasized that the early and late effects of the diabetic state on the microsomal membranes differed considerably and the effects of insulin treatment were also differential. As against this, in the mitochondria, a more or less comparable effect was evident at an early as well as late stage of the diabetic state. However, the effects of insulin treatment differed. In any event, the TPL, the CHL contents, the membrane fluidity, or the phospholipid composition did not reach normality after insulin treatment. However, the failure to fully restore membrane lipid composition and membrane fluidity to baseline (or normality) with insulin treatment may reflect the inability to completely model endogenous insulin secretion with exogenous insulin treatment. The results provide evidence that insulin treatment can control the blood sugar levels and induce specific changes in renal subcellular lipid composition that may mediate certain changes in renal cellular activity. Regression analysis revealed that the kidney weight showed progressive positive correlation with microsomal CHL content, with the values of *r* being +0.544 and +0.976, respectively, for the 1-week and 1-month groups; the combined value of *r* for

both the groups was +0.899. The kidney weight also showed progressive negative correlation with mitochondrial TPL content (r = –0.574 and r = –0.943, respectively, for the 1-week and 1-month groups) and a strong positive correlation with mitochondrial CHL content in the 1-month group (r = +0.789). Whether these lipid changes correlate with renal growth and functional renalopathies associated with diabetes *in vivo* remains to be determined. Insulin has been reported to not always successfully correct certain maladies/pathologies associated with diabetes (31–33), and resistance may be reflected in subcellular responses to the hormone as observed in the present study.

A majority of the phospholipid classes except SPM and DPG are synthesized in the microsomes and transferred to other membrane systems. The latter two are synthesized in the plasma membranes and mitochondria, respectively (34–36). Since the diabetic state affected the contents and composition of lipids/phospholipids in the two membrane systems we examined, it was of interest to find out if a correlation existed between the contents of the TPL, CHL, PC, PI, PS, and PE components in the microsomal and mitochondrial membranes. Regression analysis across the control, diabetic, and insulin-treated diabetic animals revealed that in the 1-week group PI and PE components correlated positively (r = +0.632 and r = +0.811, respectively). On the other hand, in the 1-month group, CHL showed a strong positive correlation (r = +0.800); PS and PE showed weak negative and positive correlation, respectively (r = –0.558 and r = +0.577). The results thus imply that the transfer of these lipid components from microsomes to mitochondria is differentially affected by insulin status at an early and late stage of the disease. Decreased plasma phospholipid transfer protein in diabetes has been reported (37–39). Our results suggest that a similar situation may prevail even within the cell (35).

It is interesting to note that the diabetic state significantly lowered the DPG component in the mitochondria and that insulin treatment was ineffective in restoring these values (Table 5). The role of thyroid hormones in DPG synthesis has been demonstrated (40). It has also been shown that the thyroid hormone levels decreased in diabetes [41–46]. Hence the observed effects may be indirectly due to decreased thyroid hormones level (41–46).

It is true that the changes in the phospholipid composition (Tables 4 and 5) appear to be of small magnitude at times. However, if the content of the individual phospholipid class is computed (by multiplying TPL content with % of the individual phospholipid) the differences get amplified. Thus the changes in the content of individual phospholipids will significantly affect the individual phospholipid/protein ratio in the membrane and will also affect the charge distribution and can have bearing on the function of membrane-bound enzymes since membrane-bound enzymes have a requirement of specific phospholipids for their activity (9–13). That this is the case is exemplified by our observations on mitochondrial energy transduction functions, and changes in the kinetic properties of microsomal Na^+,K^+-ATPase and glucose-6-phosphatase and mitochondrial FoF_1-ATPase referred to previously (6,7,47; Patel, S.P., and Katyare, S.P., unpublished data).

Insulin status–dependent alterations in the lipid/phospholipid composition of reticulocytes, red blood cells, liver and heart microsomes, and in the fatty acid desaturase levels have been reported (12,13,48–51). Likewise, thyroid status–dependent changes in the lipid/phospholipid composition of subcelluar membranes have also been reported (52–55). However, as far as we are aware, insulin status–dependent alterations in lipid/phospholipid composition of subcellular components of kidney have not been reported thus far.

Lymphatic Recovery of Exogenous Oleic Acid in Rats on Long Chain or Specific Structured Triacylglycerol Diets

Bodil Vistisen*, Huiling Mu, and Carl-Erik Høy

BioCentrum-DTU, Section of Biochemistry & Nutrition, The Technical University of Denmark, 2800 Lyngby, Denmark

ABSTRACT: Specific structured triacylglycerols, MLM (M = medium-chain fatty acid, L = long-chain fatty acid), rapidly deliver energy and long-chain fatty acids to the body and are used for longer periods in human enteral feeding. In the present study rats were fed diets of 10 wt% MLM or LLL (L = oleic acid [18:1n-9], M = caprylic acid [8:0]) for 2 wk. Then lymph was collected 24 h following administration of a single bolus of ^{13}C-labeled MLM or LLL. The total lymphatic recovery of exogenous 18:1n-9 24 h after administration of a single bolus of MLM or LLL was similar in rats on the LLL diet (43% and 45%, respectively). However, the recovery of exogenous 18:1n-9 was higher after a single bolus of MLM compared with a bolus of LLL in rats on the MLM diet (40% and 24%, respectively, $P = 0.009$). The recovery of lymphatic 18:1n-9 of the LLL bolus tended to depend on the diet triacylglycerol structure and composition ($P = 0.07$). This study demonstrated that with a diet containing specific structured triacylglycerol, the lymphatic recovery of 18:1n-9 after a single bolus of fat was dependent on the triacylglycerol structure of the bolus. This indicates that the lymphatic recovery of long-chain fatty acids from a single meal depends on the overall long-chain fatty acid composition of the habitual diet. This could have implications for enteral feeding for longer periods.

Paper no. L9975 in *Lipids 41*, 827–834 (September 2006).

The specific structured triacylglycerol MLM is composed of medium-chain fatty acids (M) in the *sn*-1,3 positions and a long-chain fatty acid (L) in the *sn*-2 position. The medium-chain fatty acids deliver fast energy due to rapid hydrolysis and portal absorption followed by oxidation in the liver (1–5). The long-chain fatty acids are absorbed as *sn*-2 monoacylglycerols in the enterocytes, reacylated, incorporated into chylomicrons, and become available for oxidation or deposition in organs and tissues (6).

When structured triacylglycerols (a mixture of medium- and long-chain fatty acids on the same glycerol backbone) instead of a physical mixture of medium-chain triacylglycerols and long-chain triacylglycerols are incorporated in the parenteral nutrition for patients after surgery, an improved nitrogen balance and faster plasma triacylglycerols and free fatty acid clearance have been observed (7). Similar results were found in several other studies of patients on parenteral feeding with administration of either long-chain triacylglycerols or structured triacylglycerols for a shorter period (5–10 days) and up to 2 months (8–10).

Herzberg *et al.* (11) revealed that the lymphatic transport of fatty acids increased in rats fed a 10 wt% fat diet of fish oil compared with corn oil. Likewise, Jensen *et al.* (12) observed a higher mesenteric lymphatic transport of linoleic acid (18:2n-6) after administration of MLM compared with a randomized oil (the same fatty acid composition as MLM, but no specific structure at the glycerol backbone) in rats fed 20 wt% fish oil compared with rats fed 20 wt% vegetable oil. Furthermore, the fecal excretion of fat was lower in rats fed structured triacylglycerol MLM compared with a randomized oil for 3 wk (13). These studies indicate that alterations in fat absorption could be caused by variation in the dietary fatty acid composition for several days or weeks. However, only limited information is available regarding the influence of a diet containing specific structured triacylglycerol or long-chain triacylglycerols on the absorption of dietary fatty acids.

Several studies have shown a higher lymphatic transport of long-chain fatty acids after administration of specific structured triacylglycerols compared with randomized oils or long-chain triacylglycerols in rats (14–16). However, the recovery of exogenous fatty acids was not determined in these studies, because an unknown amount of endogenous fatty acids contributes to the lymphatic output (17). The lymphatic recovery of the exogenous fatty acids can be determined by isotope labeling. In support of the above-mentioned lymphatic transport studies we recently found a faster lymphatic recovery of ^{13}C-labeled 18:2n-6, when incorporated in MLM (M = caprylic acid [8:0], L = 18:2n-6) compared with long-chain triacylglycerols (18). In contrast, the lymphatic recovery of long-chain fatty acids after continuous infusion of ^{14}C-labeled LLL was significantly higher than after infusion of two ^{14}C-labeled structured triacylglycerols, MLM and MML (L = 18:2n-6, M = 8:0) (19). A study of oleic acid (18:1n-9) from our laboratory supports the results of Tso *et al.* (19). We found a higher lymphatic recovery of ^{13}C-labeled 18:1n-9 after LLL compared with MLM (M = 8:0, L = 18:1n-9) administration in rats (20). The discrepancy between the studies, where isotope-labeled triacylglycerols were used, remains unclear, but could be due to different experimental designs and fatty acid species.

No studies have determined the lymphatic recovery of ^{13}C-labeled long-chain fatty acids of a single bolus of specific structured triacylglycerol or long-chain triacylglycerols in rats fed lipids with different triacylglycerol structures for several weeks.

Abbreviations: APs, atom percent of a sample; L = long-chain fatty acid; M = medium-chain fatty acid.

Therefore, in the present study rats were fed a diet with 10 wt% LLL (L = 18:1n-9) or MLM (M = 8:0) for 2 wk. Then the rats received a single bolus of ^{13}C-labeled MLM or LLL and the lymphatic recovery of the exogenous fatty acids was determined. The purpose was to evaluate differences in the lymphatic recovery of exogenous fatty acids due to adaptations to the triacylglycerol structure of the dietary fats and to the acute fat intake (the fat bolus), respectively. We expected to find a faster lymphatic uptake of the long-chain fatty acids incorporated in the MLM bolus and that feeding a diet with MLM would further increase the uptake of long-chain fatty acids due to adaptation to the triacylglycerol structure.

EXPERIMENTAL PROCEDURES

Feeding and housing of rats. Male rats (130 g, Wistar; Møllegården Breeding and Research Centre, Lille Skensved, Denmark) were kept at 21 ± 1°C, a humidity of 50 ± 5%, and a light period from 6:00 h until 18:00 h. They had free access to tap water. After acclimatization rats received the experimental diets containing 10% LLL (high oleic sunflower oil; Aarhus Olie A/S, Aarhus, Denmark) or 10% MLM (see following), 40% corn starch, 20% casein, 14% cellulose, 10% sucrose, 5% mineral mixture, 0.5% vitamin mixture, and 0.5% choline chloride (wt%) for 2 wk. The rats were randomized by weight into the two diet groups and their weight development during the 2 wk of feeding was in the same range (LLL diet: 228 ± 6 g and MLM diet: 228 ± 4 g, NS, *t* test). The subgroups of rats, which received the MLM bolus or LLL bolus in the 2 diet groups, had similar weights at the time of surgery.

Production of specific structured triacylglycerols. The specific structured triacylglycerols were produced by enzyme-catalyzed interesterification as described previously (21). The ^{13}C-labeled specific structured triacylglycerols were produced by batch interesterification of 8:0 (Sigma Aldrich, Steinheim, Germany) and ^{13}C-labeled LLL (Cambridge Isotope Laboratories, [Andover, MA, USA). The 2 components were mixed at a substrate ratio of 8:1 (mol:mol), added immobilized *sn*-1,3 specific lipase (10 wt% of the solution, Lipozyme IM; Novozymes A/S, Denmark), and incubated at 50°C for 5 h with constant stirring. After incubation the solution was filtered to remove the lipase. The ^{13}C-labeled MLM was purified by preparative HPLC (22).

Preparation of the fat bolus. At the beginning of the experiment (see following) rats received an isocaloric bolus of either 0.3 mL of MLM or LLL and 0.3 mL of taurocholate solution (20 mM taurocholate and 10 mg/mL choline). The solution was mixed 2 times for 10 s with a Whirly mixer and sonicated 10 s (M.S.E. 150 watt Ultrasonic Disintegrator; M.S.E. Inc., Crawley, England; settings: power = medium and amplitude = 3). The LLL bolus was added as 5 µL of ^{13}C-labeled LLL and the MLM was added as 5 µL of ^{13}C-labeled MLM. There were 4 experimental groups; rats fed the LLL diet or the MLM diet received a bolus of LLL or MLM.

Analysis of oils. LLL and MLM oils were transmethylated by KOH in methanol (23) for determination of the triacylglycerol fatty acid composition. The triacylglycerol structure illustrated by the fatty acid composition of the *sn*-2 position was determined by Grignard degradation (24) followed by the separation on TLC (Silica gel 60; Merck, Darmstadt, Germany), recovery of the *sn*-2 monoacylglycerol, and KOH methylation.

The fatty acid methyl esters were analyzed by a Hewlett-Packard 6890 gas chromatograph (Hewlett-Packard GmbH, Walbronn, Germany) on a fused silica capillary column (SP-2380, 60 m, i.d. 0.25 mm, 0.20 µm film; Supelco Inc., Bellefonte, PA). The injector was 260°C and it was used in the split mode with a split ratio of 1:20. The fatty acids were separated by an initial temperature of 70°C, which was kept for 0.5 min, then raised to 160°C at 15°C/min, at 1.5°C/min to 200°C, which was held for 15 min, and finally raised at 30°C/min to 225°C. This temperature was maintained for 10 min. The temperature of the detector (flame ionization) was 300°C. The fatty acid compositions of the triacylglycerols and of the *sn*-2 position are listed in Table 1. The relatively low mol% of 8:0 indicates that the specific structured oil consisted of MLM and MLL/LLM triacylglycerol species, but the oil will be referred to as MLM.

Animal experiment. The experiment was approved by the Danish Committee for Animal Experiments. At the day of surgery, rats were anaesthetized with 0.055 mL/100 g of body weight Zoletil mixture (consisting of zolazepam [125 mg/10.5 mL], tiletamine [125 mg/10.5 mL], Narcoxyl vet [10 mL of 20 mg/mL], Veterinaria AG, Schweiz and Torbugesic [0.5 mL of 10 mg/mL], Fort Dodge Laboratories, Fort Dodge, IA). A clear vinyl tube (o.d. 0.8 mm, i.d. 0.5 mm; Critchley Electrical Products Pty. Ltd, NSW, Australia) was inserted into the mesenteric lymph vessel (25). The tube was subcutaneously led to the abdomen of the rat, through the skin, and fastened with tape (26). The lymph was collected in a 5-mL plastic bottle taped to the trunk of the rat. To prevent the rats from eating the catheter a plastic collar was placed around the neck of the rat. After surgery, rats were administered 0.05 mL of antidote (Antisedan, Farmos, Finland) intramuscularly and 5 mL of saline water (9 g/L NaCl) subcutaneously to prevent dehydration. Rats were placed in individual plastic cages with free access to tap water and a glucose solution (55 g/L glucose; Sigma Aldrich, Steinheim, Germany). Two to 4 h after surgery, rats

received 0.2 mL of Torbugesic (diluted 1:10 with sterile water).

The next day, a 5-mL bottle with 0.1 mL of EDTA (10 % [wt/vo]) Na_2-EDTA-$2H_2O$; Merck, Darmstedt, Germany) was fastened to the abdomen of the rat and lymph was collected for an hour ("0-sample"). Afterward rats were fed by gavage a bolus of LLL or MLM. Lymph was collected in 1-h fractions for the next 8 h, a night fraction of 15 h, and a 1-h fraction the next morning beginning at 23:00 h. After 24 h of lymph collection, rats were killed by an overdose of sodium pentobarbital. Until analysis lymph samples were kept at –20°C.

Comparisons of this nonrestrained lymph collection model with the conventional restrained model of lymph collection (27) revealed that the data obtained from the 2 models were comparable (data not shown).

Lymph analysis. The lymph samples were extracted by chloroform and methanol (28) after adding an internal triacylglycerol standard (TG-15:0; Sigma Aldrich). The extract was methylated with the KOH-catalyzed method and analyzed by GC-C-IRMS (gas chromatograph-combustion-isotope ratio mass spectrometry; Delta^{PLUS}; Thermo-Finnigan, Bremen, Germany). The samples were injected at 250°C with a split ratio of 1:15 and separated on a fused silica capillary column (same as previously) with the following temperature program: The initial temperature (70°C) was maintained for 3 min and then raised to 150°C at 15°C/min, to 169°C at 1.5°C/min, to 173°C at 0.5°C/min, to 188°C at 3°C/min, and finally raised to 200°C at 20°C/min and maintained for 14 min. The $^{13}C/^{12}C$ ratio of the fatty acid carbon atoms was quantified. The stability of the mass spectrometer was checked every day by a standard on-off test (18 injections of CO_2) and B-scan (control of all mass values, especially water, nitrogen, and argon) and with CO_2 injections in the beginning and end of each run. Correct determinations of sample $^{13}C/^{12}C$ ratios were checked by standard samples with known values. The individual fatty acids were identified by comparing their retention times with retention times of authentic standards (Nu-Chek Prep Inc., Elysian, MN).

Calculations. The atom percent is used for quantitative description of the ^{13}C enrichment of a sample. The atom percent of a sample (AP_S) is calculated from the ratio of $^{13}C/^{12}C$ of the sample (δ_S) and a reference δ of a specific limestone, Pee Dee Belemnite ($\delta = 0.0112372$) (29, 30):

$$AP_s = \frac{100 * 0.0112372 * (0.001 * \delta_s + 1)}{1 + 0.0112372 * (0.001 * \delta_s + 1)} \quad [1]$$

The lymphatic transport of ^{13}C-labeled 18:1n-9 is calculated by multiplying AP_S with the total lymphatic transport of 18:1n-9 in the sample. The recovery of 18:1n-9 is then found by dividing this result with the amount of administered ^{13}C-labeled 18:1n-9 at the beginning of the experiment.

Statistics. Amounts and ratios are stated as average ± SE values. Average lymph flow in the experimental groups was compared with one-way ANOVA. The accumulated lymphatic recovery of ^{13}C-labeled 18:1n-9 after LLL and MLM administration in rats on the LLL or MLM diet was compared with a Student's *t* test. Likewise, the accumulated lymphatic transport of fatty acids was compared with a Student's *t* test. All statistics were performed with SigmaStat (version 2.03; Jandel Corporation, Erkrath, Germany). The level of significance was $P < 0.05$.

RESULTS

Lymph flow. The lymph flow in the 4 experimental groups did not differ [$P = 0.33$, 1W AN (one-way ANOVA)]. It was 0.39 ± 0.05 mL/h and 0.48 ± 0.04 mL/h in rats fed LLL and administered a single bolus of LLL and MLM, respectively. Likewise, the lymph flow was 0.42 ± 0.03 mL/h and 0.51 ± 0.07 mL/h in rats on the MLM diet and administered a single bolus of LLL or MLM, respectively.

AP of the test bolus and the lymph. The AP of the LLL and MLM fat bolus was 1.18 and 1.17, respectively. The baseline AP (just before administration of the fat bolus) was 1.08 ± 0.00 in all groups. In rats fed the LLL diet the AP of the lymph was 1.17 ± 0.02 and 1.16 ± 0.01 three hours after administration of the LLL and MLM fat bolus, respectively. Likewise, in rats fed the MLM diet, the AP was 1.17 ± 0.01 and 1.15 ± 0.00 three hours after administration of the LLL and MLM fat bolus, respectively. Twenty four hours after fat administration the AP was 1.11 ± 0.01 in all groups.

Recovery of ^{13}C-enriched lymphatic 18:1n-9. The maximum rate of lymphatic recovery of ^{13}C-labeled 18:1n-9 was obtained 2–3 h after administration of the lipid bolus. A similar accumulated lymphatic recovery of ^{13}C-labeled 18:1n-9 was observed in rats on the LLL diet 24 h after administration of an LLL or an MLM lipid bolus (Fig. 1A). In contrast, a higher accumulated lymphatic recovery of exogenous 18:1n-9 was found after 24 h in rats on an MLM diet and administered a bolus of MLM compared with a bolus of LLL (Fig. 1B; $P = 0.009$, *t* test).

There was no difference between the accumulated recovery of ^{13}C-labeled 18:1n-9 after consumption of the MLM bolus in rats on the LLL compared with the MLM diet ($P = 0.64$, *t* test). However, a tendency to reduced recovery of lymphatic ^{13}C-labeled 18:1n-9 was observed in rats fed the MLM diet compared with the LLL diet after administration of an LLL lipid bolus ($P = 0.07$, *t* test).

The ^{13}C-labeled 18:1n-9 was the only enriched fatty acid detected in the lymph samples indicating neither elongation nor chain shortening of the administered fatty acid.

Lymphatic transport of medium-chain fatty acids. 8:0 was detected during the first 8 h of lymph collection in rats, which had received the MLM bolus (Fig. 2). The lymphatic transport of 8:0 peaked 2 h after oil administration in both diet groups with a maximum transport of approximately 1.5 mg/h and no significant differences between groups ($P = 0.10$, *t* test). The accumulated transport of 8:0 eight hours after MLM administration constituted approximately 3% of the administered dose (2.6% in rats on the MLM diet and 4.3% in the rats on the LLL diet).

Lymphatic transport of fatty acids. There were no differences in the accumulated lymphatic transport of both exogenous and endogenous 18:1n-9 in rats fed the LLL diet 24 h after

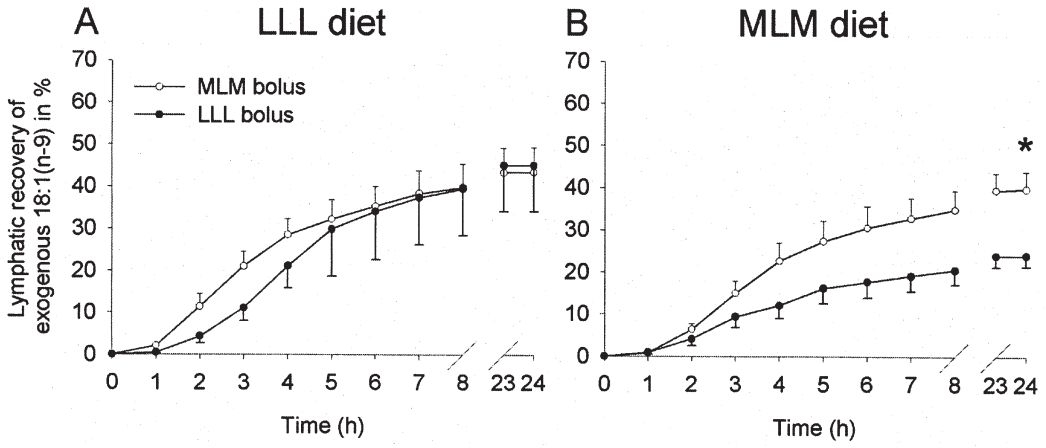

FIG. 1. Recovery of lymphatic 18:1n-9 after feeding bolus of LLL (filled circles) or MLM (empty circles) in rats on (A) LLL diet, $n = 6–9$, and (B) MLM diet, $n = 7–8$. Average ± SEM.

administration of an LLL or an MLM bolus (Fig. 3A; $P = 0.94$, *t* test). Likewise, no differences were observed in the accumulated lymphatic transport of palmitic acid (16:0), stearic acid (18:0), and 18:2n-6 after administration of an LLL or an MLM bolus in rats fed the LLL diet (Fig. 3B–D; $P = 0.15–0.94$, *t* test). However, the lymphatic transport of the endogenous fatty acid 20:4n-6 was higher 24 h after administration of MLM compared with LLL in the rats fed LLL (Fig. 3E; $P = 0.03$, *t* test).

The accumulated lymphatic transport of 18:1n-9 was similar 24 h after LLL and MLM administration in rats fed an MLM diet (Fig. 4A; $P = 0.48$, *t* test). Furthermore, the accumulated lymphatic transport of 16:0 and 18:0 was similar following administration of an LLL or an MLM bolus in rats fed the MLM diet (Fig. 4B–C; $P = 0.32$ and $P = 0.51$, respectively, *t* test). However, the lymphatic transport of 18:2n-6 was higher 24 h after administration of MLM compared with LLL in the rats on the MLM diet (Fig. 4D; $P = 0.03$, *t* test), whereas there was a tendency to a higher accumulated lymphatic transport of the endogenous fatty acid 20:4n-6 after intake of the MLM compared with the LLL bolus (Fig. 4E; $P = 0.06$, *t* test).

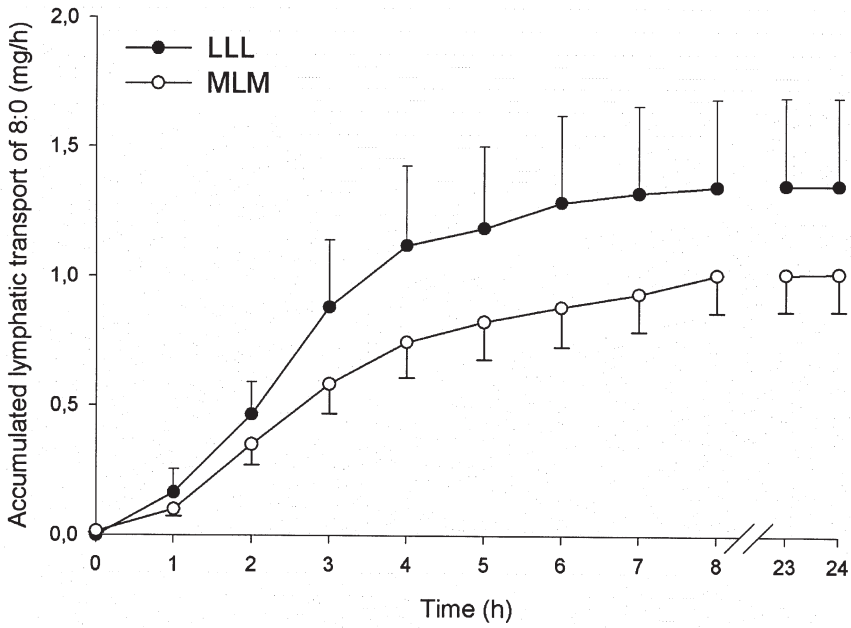

FIG. 2. Lymphatic transport of 8:0 (mg/h) after administration of a single bolus of MLM in rats on the LLL diet (filled circles), $n = 9$, and rats fed MLM (empty circles), $n = 8$. Average ± SEM.

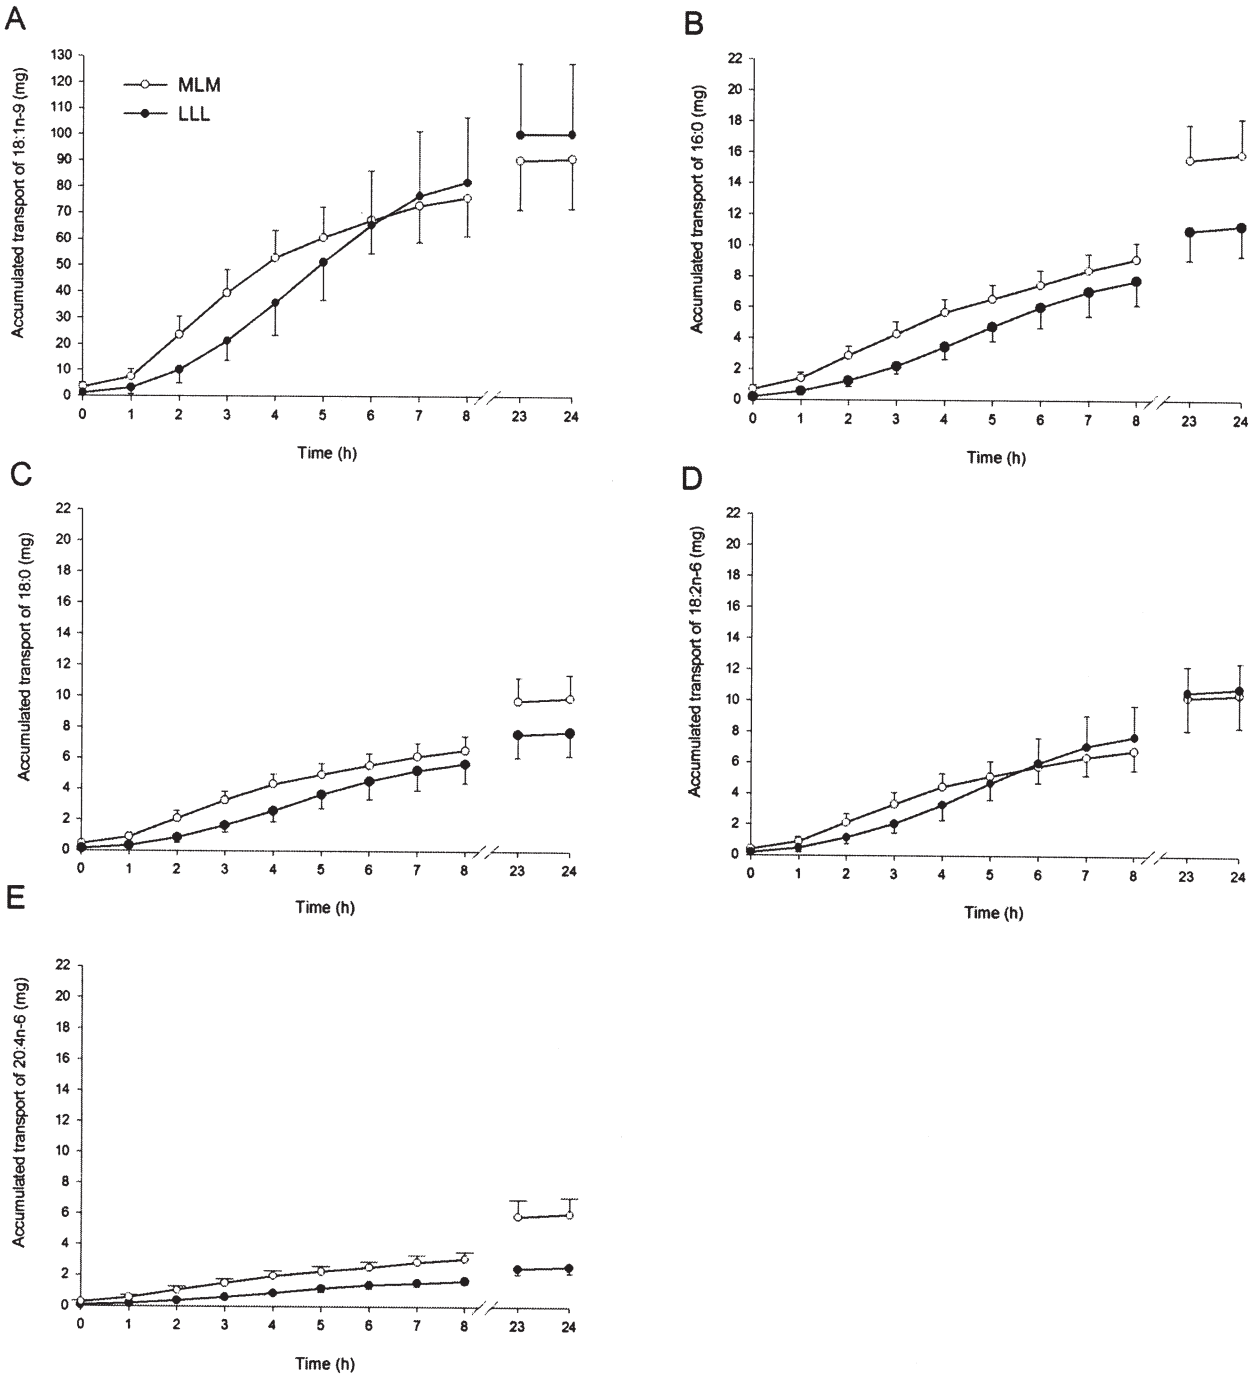

FIG. 3. Accumulated lymphatic transport (mg) of 18:1n-9 (A), 16:0 (B), 18:0 (C), 18:2n-6 (D), and 20:4n-6 (E) following a single bolus of LLL (filled circles) or MLM (empty circles) in rats on the LLL diet, n = 6–9. Average ± SEM.

DISCUSSION

The main finding of the study is that adaptation to a diet containing specific structured triacylglycerol (MLM, M = 8:0, L = 18:1n-9) for 14 days resulted in a higher lymphatic recovery of ^{13}C-labeled 18:1n-9 after administration of a single bolus of MLM compared with LLL. In contrast, rats fed a diet containing LLL had similar lymphatic recovery of exogenous 18:1n-9 after administration of a lipid bolus of MLM or LLL.

The lymphatic recovery of ^{13}C-labeled 18:1n-9 in rats fed the MLM or the LLL diet after administration of a single meal of MLM was at the same level, whereas administration of an LLL bolus in the 2 diet groups tended to reveal a higher lymphatic recovery of ^{13}C-labeled 18:1n-9 in the LLL diet group.

Structured triacylglycerols are used as the lipid component for parenteral feeding and have advantages compared with

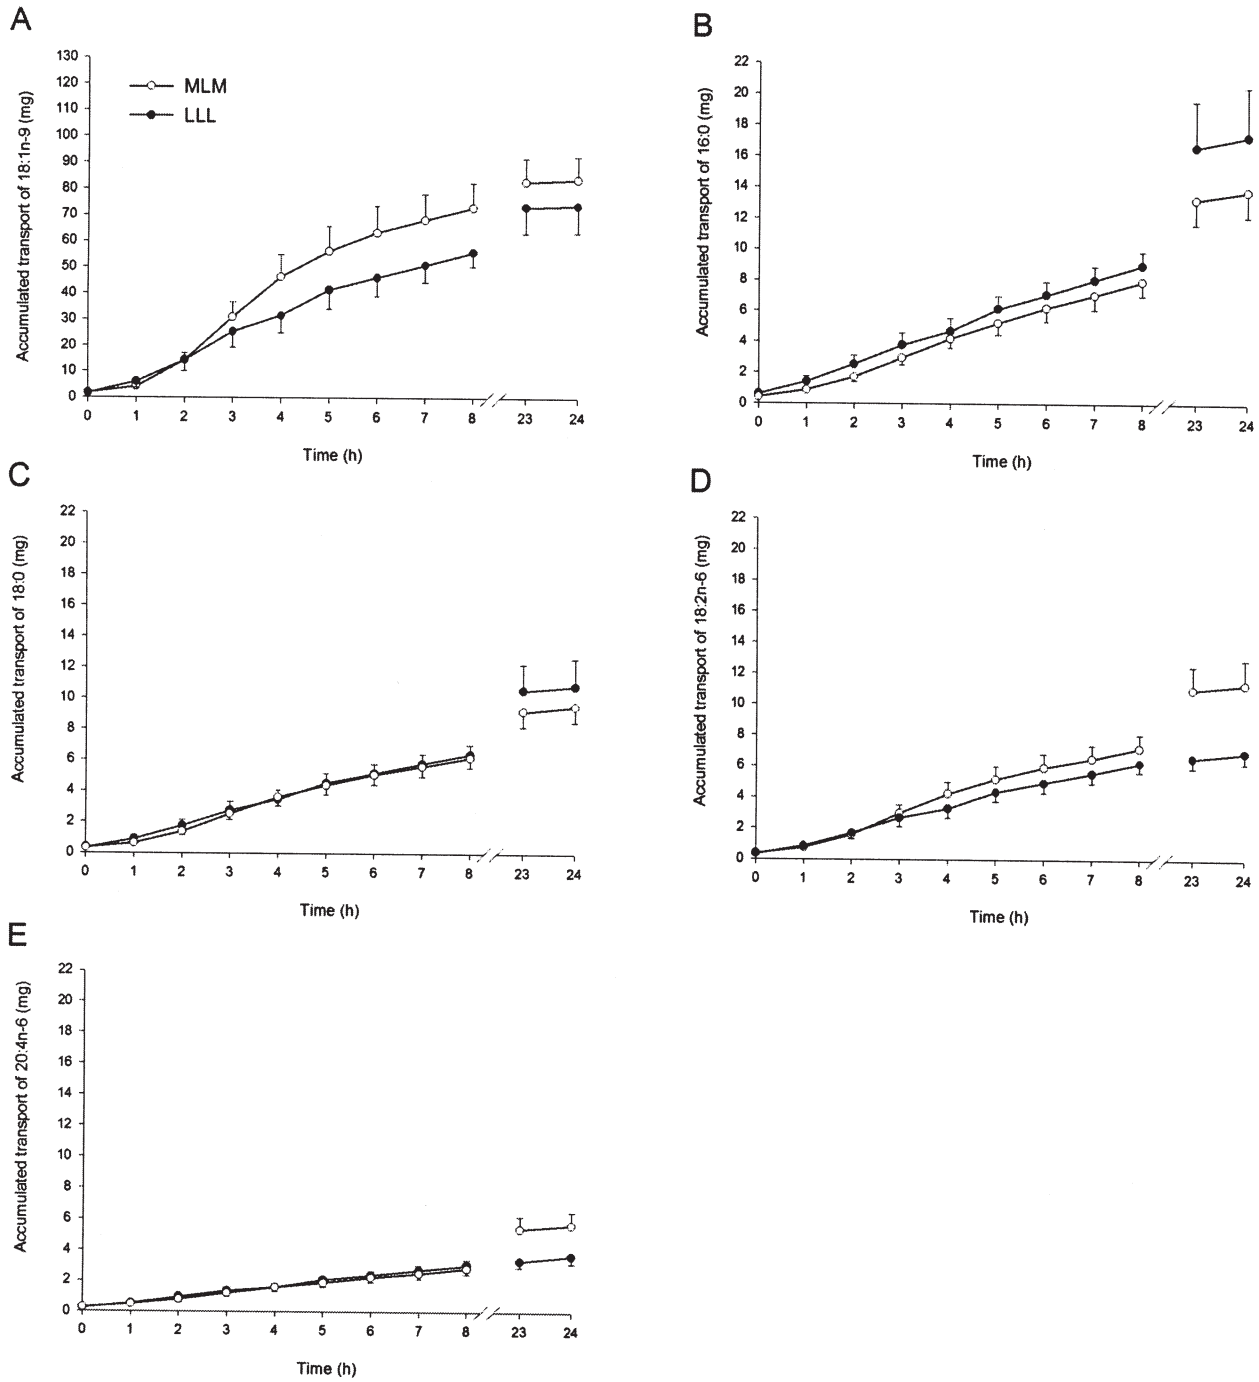

FIG. 4. Accumulated lymphatic transport (mg) of 18:1n-9 (A), 16:0 (B), 18:0 (C), 18:2n-6 (D), and 20:4n-6 (E) following a single bolus of LLL (filled circles) or MLM (empty circles) in rats on the MLM diet, $n = 7–8$. Average ± SEM.

long-chain triacylglycerols (8–10). However, long-term effects on the lipid absorption of a diet containing structured triacylglycerols have not been examined. Our results show that the MLM bolus provided a better absorption of 18:1n-9 compared with the LLL bolus in rats on the MLM diet. Studies without adaptation to specific structured triacylglycerols for a longer period have demonstrated higher (14–16,18) or lower (19,20) lymphatic transport of long-chain fatty acids after administration of MLM compared with LLL or randomized oils.

When MLM is ingested, hydrolyzed, and absorbed, there is a limited amount of exogenous fatty acid available for resynthesis of triacylglycerols in the enterocyte due to the low content of long-chain fatty acids and transport of the medium-chain fatty acids *via* the portal vein. Therefore, endogenous

long-chain fatty acids are mobilized from the intestine and bile and used for reacylation (17). In the present study, rats were allowed to adapt to the specific structured triacylglycerols with low exogenous amounts of long-chain fatty acids for 2 wk before lymph cannulation, which could have induced a higher level of endogenous long-chain fatty acids available for resynthesis of triacylglycerols in the enterocyte and thereby increase the lymphatic recovery of the ingested long-chain fatty acids of the MLM.

Rats, which received the LLL diet during 2 wk exhibited similar lymphatic recovery of ^{13}C-labeled 18:1n-9 after administration of the LLL and the MLM lipid bolus. Nevertheless, the recovery of ^{13}C-labeled 18:1n-9 during the first hours after administration of the lipid bolus (Fig. 1A) revealed a tendency to a faster recovery of 18:1n-9 after administration of the MLM bolus compared with the LLL bolus. This is in line with earlier results from our laboratory, where the lymphatic transport of docosahexaenoic acid (22:6n-3) and eicosapentaenoic acid (20:5n-3) was higher during the first hours after administration of an MLM bolus compared with randomized oil, but after 24 h, the accumulated lymphatic transport was similar without differences in regard to triacylglycerol structure (15). Likewise, a faster lymphatic recovery of ^{13}C-labeled 18:2n-6 was observed in rats after consumption of MLM compared with LLL, but the accumulated recovery after 24 h was the same in both groups (18).

The effect of the 2 diets on the lymphatic absorption of long-chain fatty acids after the single bolus of MLM did not differ. This indicates that the capacity for absorption of this specific structured triacylglycerol was not dependent on the type of diet before ingestion of the MLM bolus. Interestingly, it was observed in both diets that the accumulated lymphatic transport of the endogenous fatty acid 20:4n-6 was higher 24 h after feeding the MLM bolus compared with the LLL bolus (Figs. 3E and 4E) indicating a higher transport of endogenous fatty acids.

The absorption of the LLL bolus after 14 days on the MLM diet tended ($P = 0.07$) to be lower than the recovery of 18:1n-9 in the rats fed the LLL diet. In earlier studies it has been observed that the fat composition of the diet influences the uptake of the long-chain fatty acids of a single meal (11,12). However, in these studies the fatty acid species in the different diets varied considerably, whereas the long-chain fatty acid content of both diets in the present study was 18:1n-9. One could speculate that the lower recovery of 18:1n-9 after administration of the LLL bolus could be due to a higher availability of endogenous fatty acids in rats on the MLM diet as mentioned previously, which would then result in competition between the endogenous and exogenous long-chain fatty acids during absorption. Furthermore, the lower recovery could also be due to MLM diet-induced changes in the intestinal brush border membrane lipid composition or reduced enzyme activity in the hydrolysis and or resynthesis of triacylglycerols in the enterocyte.

The lymphatic recovery of exogenous 18:1n-9 did not exceed 40–45%. This result agreed with the transport of an entirely exogenous fatty acid in the study of Straarup and Høy (31) (20:5n-3: 41%). Likewise, in a study with constant infusion of ^{14}C-labeled LLL and MLM, the lymphatic recoveries of long-chain fatty acid were 62% and 48%, respectively (19). Furthermore, during the first hours of absorption of the fat bolus, the lymph mainly consisted of exogenous fatty acids as indicated by the high AP level of the lymph collected 3 h after fat administration (~1.15–1.17) compared with the AP level of the fat bolus itself (~1.17–1.18).

No other ^{13}C-labeled fatty acids were observed in the lymph, which demonstrated that 18:1n-9 was not elongated and/or desaturated in the enterocyte. The expected fate of the nonessential 18:1n-9 is mainly oxidation in organs and peripheral tissue, which was demonstrated by Watkins *et al.* (32), who observed a higher oxidation of ^{13}C-labeled trioleylglycerol (11%) compared with ^{13}C-labeled 16:0 as free fatty acid (7%) after simultaneous administration of the lipids.

The lymphatic transport of 8:0 was similar in both feeding groups. This revealed that the lymphatic distribution of 8:0 after digestion and absorption of MLM was independent of the diet type. Up to 4.3% of the administered 8:0 was found in the lymph, which is comparable to the findings of Ikeda *et al.* (16) and Mu and Høy (22). The majority of the ingested 8:0 was not esterified in the enterocyte, but transported directly through the cell as free fatty acids and via the portal vein to the liver (3,33).

The MLM oil consisted of different triacylglycerol species (MLM, MLL, and LLM) due to technical limitations during preparation. This implies that a faster and eventually higher recovery of the 18:1n-9 could be expected if it had been possible to produce an oil of pure MLM.

The present study indicates that the dietary fat structure and composition influence fat absorption not only after a single bolus of fat, but also as an adaptation following 14 days with diets composed of long-chain triacylglycerols or specific structured triacylglycerol. We found that a diet containing specific structured triacylglycerol (MLM) enhances the lymphatic recovery of exogenous 18:1n-9 after administration of a single bolus of MLM compared with a bolus of LLL. The implication of this finding for enteral feeding is that specific structured triacylglycerols can be used for longer periods without decreasing the absorption of the long-chain fatty acids of the diet.

ACKNOWLEDGMENTS

We thank Xuebing Xu for preparing the unlabeled structured triacylglycerols and Zahra Roudaki, Karen Jensen, Lillian Vile, and Egon Christensen for their technical assistance.

ABSTRACT: In humans and animals, intestinal flora is indispensable for bile acid transformation. The goal of our study was to establish gnotobiotic mice with intestinal bacteria of human origin in order to examine the role of intestinal bacteria in the transformation of bile acids *in vivo* using the technique of gnotobiology. Eight strains of bile acid–deconjugating bacteria were isolated from ex–germ-free mice inoculated with a human fecal dilution of 10^{-6}, and five strains of 7α-dehydroxylating bacteria were isolated from the intestine of limited human flora mice inoculated only with clostridia. The results of biochemical tests and 16S rDNA sequence analysis showed that seven out of eight bile acid–deconjugating strains belong to a bacteroides cluster (*Bacteroides vulgatus, B. distasonis,* and *B. uniformis*), and one strain had high similarity with *Bilophila wadsworthia*. All five strains that converted cholic acid to deoxycholic acid had greatest similarity with *Clostridium hylemonae*. A combination of 10 isolated strains converted taurocholic acid into deoxycholic acid both *in vitro* and in the mouse intestine. These results indicate that the predominant bacteria, mainly *Bacteroides*, in human feces comprise one of the main bacterial groups for the deconjugation of bile acids, and clostridia may play an important role in 7α-dehydroxylation of free-form primary bile acids in the intestine although these strains are not predominant. The gnotobiotic mouse with bacteria of human origin could be a useful model in studies of bile acid metabolism by human intestinal bacteria *in vivo*.

Paper no. L10005 in *Lipids 41*, 835–843 (September 2006).

Bile acids are transformed by the intestinal microflora. Bile acids in humans are synthesized from cholesterol in the liver, and conjugated to either glycine or taurine. Bile salts are secreted into the small intestine as a component of bile and play an important role in the absorption of lipids. More than 90% of bile acids are reabsorbed, mostly in the ileum and recycled via the enterohepatic circulation. The rest enter the large intestine, where all bile acids (primary and secondary) are deconjugated and primary bile acids such as cholic acid (CA) and chenodeoxycholic acid (CDCA) are further 7α-dehydroxylated to deoxycholic acid (DCA) and lithocholic acid (LCA), respectively. Levels of secondary bile acids including DCA and LCA appear to show a strong correlation with colorectal cancer *in vitro* (1,2) and in animal models (3–5). Epidemiological studies reported that the level of fecal 7α-dehydroxylase activity was significantly higher in colorectal cancer patients than in controls (6–8).

Bile salt hydrolase activity is found in many kinds of intestinal bacteria (9–12). 7α-Dehydroxylating activity has also been reported in certain groups of intestinal bacteria (13). However, in some species, results are contradictory. Some reports indicate that bacterial strains that belong to *Bifidobacterium* (14), *Bacteroides* (14), and *Lactobacillus* (15,16) showed 7α-dehydroxylating activity. By contrast, other groups showed the negative results for the activity in *Bifidobacterium* strains (17,18), *Bacteroides* strains (19,20), or *Lactobacillus* strains (18,21). Only certain strains belonging to *Eubacterium* and *Clostridium* have been examined specifically for their 7α-dehydroxylating activity (22–26). It is considered that the difficulty in isolating 7α-dehydroxylating bacteria from the intestine arises from the small populations of these bacteria in the intestine (27,28), although most of the primary bile acids in the intestine are deconjugated and further transformed into secondary bile acids. The precise mechanism by which the small numbers of bacteria responsible for 7α-dehydroxylation transform most of the bile acids in the intestine remains to be elucidated.

In our previous study, we inoculated human intestinal bacteria with the ability to transform bile acids *in vitro* into germ-free (GF) mice. However, only small amounts of secondary bile acids were observed in the cecal content, indicating that the ability of bacteria to transform bile acids *in vitro* does not necessarily reflect that *in vivo* (29,30). Then we produced various groups of limited-flora mice inoculated with intestinal bacteria of human origin. Approximately 90% of the cecal bile acids were deonjugated when GF mice were inoculated with human fecal dilutions of 10^{-2} or 10^{-6}, or anaerobic growth from a dilution of 10^{-6}. In those ex-GF mice, bacteroidaceae colonized in the intestine at the highest levels, followed by eubacteria and clostridia. In contrast, in the cecal contents of ex-GF mice inoculated only with clostridia, unconjugated bile acids accounted for less than 40% of all bile acids. However, the percentage of DCA in these mice was the same as that in the other groups. These results indicate that the dominant anaerobic bacterial combination is efficient for the deconjugation of primary bile acids, and that clostridia in human feces may play an important

role in the 7α-dehydroxylation of unconjugated primary bile acids in the intestine (31). However, the attempt to establish gnotobiotic (GB) mice whose intestinal bile acids consisted of a certain amount of secondary bile acid with predominant bacteria isolated from limited human flora mice was not successful, indicating that bile acid–transforming bacteria are not necessarily the predominant population in the intestine.

The objective of this study was to obtain combinations of human intestinal bacteria that are able to transform conjugated primary bile acids to secondary bile acids *in vivo*, and to produce GB mice with human intestinal bacteria as an *in vivo* model for the analysis of bile acid metabolism by intestinal bacteria.

MATERIALS AND METHODS

Animals. Female GF BALB/c mice (12–15 wk old) were bred in our laboratory under GF conditions in flexible vinyl isolators. Each group of female GF mice was transferred to an autoclavable stainless steel isolator (32) and given a pelleted commercial diet (CMF, Oriental Yeast Co., Tokyo, Japan) sterilized with γ-irradiation at 50 kGy and autoclaved water *ad libitum*. The study was approved by the Laboratory Animal Use and Care Committee of the Faculty of Agriculture, University of Tokyo.

Bacterial strains. Clostridium hiranonis TO-931^T (JCM 10541^T) and *Eubacterium lentum*–like c-25 were provided by Dr. F. Takamine (Laboratory of Microbiology, School of Health Science, Faculty of Medicine, University of Ryukyus, Okinawa, Japan), and by Dr. H. Oda (Department of Bacteriology, Faculty of Medicine, Kagoshima University, Kagoshima, Japan), respectively.

Production of ex-GF mice associated with limited human fecal flora. Ex-GF mice with the ability to convert bile acids in the intestine were produced previously (31). Briefly, 1 g of fresh feces from a healthy human male was immediately placed in 9 mL of an anaerobic diluent (33) under oxygen-free CO_2 gas. A portion was transferred into an anaerobic chamber and serially diluted with anaerobic trypticase soy (TS) broth supplemented with 0.084% Na_2CO_3, 0.05% agar, and 0.05% cysteine hydrochloride monohydrate. Next, 10^{-6} diluted fecal suspensions were prepared for inoculation into GF mice to produce ex-GF mice. Another portion of the 10^{-2} dilution of human feces was treated with chloroform according to the method of Itoh and Mitsuoka (34). A fecal suspension was added to a final concentration of 3% chloroform, was shaken vigorously for about 30 s, and was subsequently incubated with shaking for 1 h at 37°C. After the incubation, chloroform was eliminated from the suspension by percolating with O_2-free N_2 gas. Only bacterial spores survived after this treatment (34).

Each fecal dilution and bacterial suspension (0.5 mL) was orally inoculated into the stomach of GF mice with a stainless steel catheter.

Bile acids. CA, CDCA, ursodeoxycholic acid (UDCA), DCA, LCA, and glycine and taurine conjugates of each of these were obtained from Calbiochem (La Jolla, CA). The following bile acids were obtained from Steraloids (Wilton, NH): hyocholic acid (HCA), hyodeoxycholic acid (HDCA), α-muricholic acid (α-MCA), β-muricholic acid (β-MCA), ω-muricholic acid (ω-MCA), and 3α-12-Oxo (3α12=O). 7-Oxo-deoxycholic acid (7=O DCA) was purchased from GL Science, Inc. (Tokyo, Japan). The following glycine (G)- and taurine (T)-conjugated bile acids were synthesized according to the method of Tserng and Klein (35): G-HCA, T- HCA, G-HDCA, T-HDCA, G-α-MCA, T-α-MCA, G-β-MCA, T-β-MCA, G-ω-MCA, and T-ω-MCA.

In vitro screening of bile acid transforming activity. A modified peptone-yeast extract broth (MPYG) (18,27) was used for culture with some modifications. This medium (100 mL) contained 200 μM CA or TCA, 0.1 g of glucose, 1 g of proteose peptone no. 3, 1 g of trypticase peptone, 1 g of yeast extract, 0.05 g of cysteine hydrochloride, 4 mL of salt solution, 0.02 mL of vitamin K solution, and 1.0 mL of hemin solution dissolved in 0.1 M sodium phosphate buffer (pH 7.5). The medium was dispensed in 2.0-mL aliquots, and transferred to an anaerobic chamber after autoclaving. Bacterial strains isolated from ex-GF mice were pre-incubated in EGF broth (33), and 0.05 mL of each overnight culture was inoculated into the MPYG and incubated for 3–7 d at 37°C in an anaerobic chamber. For the isolation of 7α-dehydroxylating bacteria, a bacterial mixture from agar plate was directly inoculated into MPYG (Fig. 1). After centrifugation at 3,000 rpm for 10 min, 0.5 mL of the supernatant was extracted with 10 mL of absolute ethanol at 90°C for 60 min. After filtration and drying under reduced pressure, the pellet was dissolved in 2.0 mL of methanol/0.1 M dibasic ammonium phosphate (50/50) solution. After filtration through a 0.45-μm filter (Gelman Science, Tokyo, Japan), 10 μL of the solution was used for HPLC analysis.

Cecal bile acid determination. Three weeks after GF mice were orally inoculated with human fecal suspension or mixture of human fecal bacteria, the cecal contents of each mouse were collected, freeze- dried, and pulverized. A 50-mg portion of the dry cecal material was treated three times with 10 mL of absolute ethanol at 90°C for 1 h, and filtered. The extracts were mixed, dried, and suspended in 90% ethanol, subjected to piperidinohydroxypropyl Sephadex-LH-20 column chromatography (Shimadzu Co., Kyoto, Japan) to obtain free, glycine-conjugated, and taurine-conjugated fractions (36).

HPLC conditions. Each of the bile acids was separated using the LC module-1 HPLC system (Waters, MA) with a Symmetry C18 separation column (4.6 mm i.d. × 150 mm, Waters). Bile acids were then detected by the post-column fluorescent method with a 3α-HSD immobilized column (E-3α-HSD, 4.0 mm i.d. × 20 mm, Sekisui Chemical Co. Ltd., Osaka, Japan), β-NAD solution delivered by an A-60-S pump (Eldex Laboratories Inc., CA) and a 474-nm scanning fluorescence detector (Waters) at an excitation wavelength of 340 nm and an emission wavelength of 460 nm (36,37). Each bile acid was identified by its relative retention time compared with that of standard bile acids, and peak heights were calculated automatically on a Waters 805 data station.

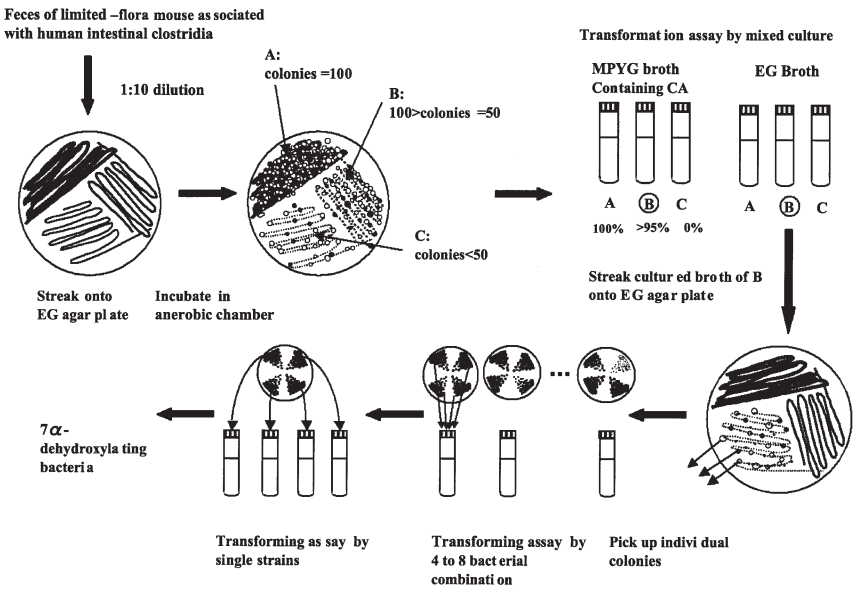

FIG. 1. Isolation of cholic acid 7α-dehydroxylating bacteria from fecal samples of ex-germ-free mice associated with human intestinal clostridia.

Enumeration of fecal bacteria in GB mice. Three weeks following gastric inoculation of a mixed human fecal flora, feces of mice were collected, immediately weighed, and transferred to an anaerobic chamber. They were homogenized with a 50-fold volume (vol/wt) of anaerobic TS broth, serially diluted, and inoculated on EG agar plates. Bacteria were counted and identified by Gram staining, cell morphology, and colony morphology. The numbers of bacteria were expressed as log 10 counts of viable bacteria per gram wet weight of feces.

Isolation of bile acid–transforming bacteria from limited human flora–associated mice. The intestinal microflora of ex-GF mice inoculated with a human fecal dilution of 10^{-6} showed a good ability to deconjugate taurine-conjugated bile acids (31). The feces from these ex-GF mice were diluted in an anaerobic diluent (33), inoculated onto NBGT selective agar plates [bacteroidaceae selective medium; (33)], and incubated for 48 h in an anaerobic steel wool jar filled with 100% CO_2. Twenty-four strains of bacteria grown on NBGT agar plates were isolated and screened for the ability to deconjugate TCA to CA *in vitro.*

Clostridial strains capable of bile acid 7α-dehydroxylation were isolated from ex-GF mice inoculated with human intestinal clostridia, according to the method of Takamine and Imamura (28) with minor modifications. Feces of ex-GF mice were immediately transferred into an anaerobic chamber, and one loopful of a 10-fold dilution in reduced TS broth was directly streaked onto EG agar plates and incubated at 37ºC for 3 d. The developed colonies were grouped in three areas, A (more than 100 colonies), B (between 50 and 100 colonies), and C (less than 50 colonies). The mixed organisms grown in each area of the EG agar plates were inoculated into MPYG broth containing CA for the screening of 7α-dehydroxylation *in vitro*. The remaining organisms were incubated in EG broth at 37ºC for 2 d in the anaerobic chamber and further kept at room temperature. One loopful of the cultured EG broth from an appropriate area was again inoculated onto an EG agar plate and incubated at 37ºC for 2 d in the anaerobic chamber. After incubation, each of the single colonies was isolated and reinoculated onto EG agar plates to obtain single cultures. Four to eight of the single strains were mixed and checked for bile acid 7α-dehydroxylation activity. From the mixed cultures that were positive for 7α-dehydroxylation each of the single strains was screened for 7α-dehydroxylating activity.

Identification and characterization of bacteria. Morphological and biochemical characteristics were determined as described by Kaneuchi *et al.* (38) and Holdmann and Moore (39). The growth in peptone-yeast extract broth containing 4% (vol/vol) Fildes' digest (PYF broth) (40) was used for the biochemical tests. Based on the results of the biochemical tests, each strain was identified using Bergey's *Manual of Systematic Bacteriology* (41) and copies of the *International Journal of Systematic and Evolutionary Microbiology.*

Analysis of 16S rDNA sequences. Approximately 1500 bp of the 16S rDNA gene of the isolated bacteria were sequenced according to methods published previously (42,43). One bacterial colony was scraped from the agar plate and suspended in 50 µl of TE buffer, then frozen at –20ºC and heated three times at 100ºC for 5 min each time (44). This raw DNA was used as a template for PCR. The PCR amplification was performed with a TAKARA PCR Thermal Cycler 480 (Takara, Japan). The PCR mixture contained 10× Ex Taq buffer (10 µL). A mixture of dNTP (2.5 mM) (8 µL), 4 µL of each of the primers (20 pM) (8F, 5'-AGA GTT TGA TCM TGG CTC AG; 15R, 5'-AAG GAG GTG ATC CAR CCG CA), 1 µL of raw template DNA and 3 U of Ex Taq (Takara). Distilled water was added to make the volume 100 µL, and 50 µL of mineral oil was then added. Initially, these mixtures were preheated for 3 min at 72ºC, then,

35 cycles of amplification in total were performed with denaturation of the template at 94ºC for 30 s, followed by annealing of the primers at 55ºC for 30 s, and extension of the primers at 72ºC for 2 min, and finally postheating for 2 min at 94ºC. The PCR products were separated by electrophoresis in agarose gels and stained with ethidium bromide (1 μL/mL). PCR products were purified using MicroSpin S-400HR columns (Amersham Biosciences) according to the manufacturer's instructions. The 16S rDNA gene sequence was determined by direct PCR sequencing using the method of Anzai *et al.* (45). The 16S rDNA gene sequences of other bacteria were available from GeneBank, EMBL, and DDBJ. Levels of sequence similarity were calculated and used to produce an unrooted phylogenetic tree with the neighbor-joining method (46). The alignment and stability of relationships were assessed by bootstrapping using CLUSTAL W (47).

Statistical analysis. A statistical analysis was performed with ANOVA followed by Bonferroni's *t*-test, and a *P* value less than 0.05 was considered to be significant.

RESULTS

Bile acid deconjugation in the cecal contents of GB mice inoculated with bacteria grown on NBGT agar plates. Feces from ex-GF mice inoculated with a human fecal dilution of 10^{-6}, in which most of the cecal bile acids were deconjugated, were collected. Serial dilutions of the feces were spread onto NBGT agar plates, and single colonies were isolated from the cultured plates. Among 24 bacterial strains isolated from the plates, eight strains, NB-1, NB-4, NB-6, NB-8, NB-11, NB-12, NB-13, and NB-14, were found to be capable of deconjugating TCA to CA by screening *in vitro*. Then, several mixtures of these bacterial cultures were introduced into GF mice. In the GB mice inoculated with strains NB-6, NB-8, NB-12, NB-13, and NB-14, which showed relatively high levels of deconjugating activity of TCA *in vitr*o, fecal bile acids were highly deconjugated. However, when we omitted NB-12 from this combination, the extent of deconjugation was significantly decreased (Fig. 2). Interestingly, when introduced by itself, strain NB-12 didn't colonize the GF intestine (data not shown). On the other hand, when three bacterial strains, NB-1, NB-4, and NB-11, were introduced into GF mice, the percentage of deconjugated bile acids in the intestine was low (Fig. 2). In all GB groups, inoculated bacteria were detected at concentrations of more than 10^{10}CFU/g feces.

Characterization of bile acid–deconjugating strains isolated from limited human flora associated mice. The five bacterial strains NB-6, NB-8, NB-12, NB-13, and NB-14 were characterized based on biochemical tests, and their phylogenetic positions were investigated based on the 16S rDNA sequence analysis

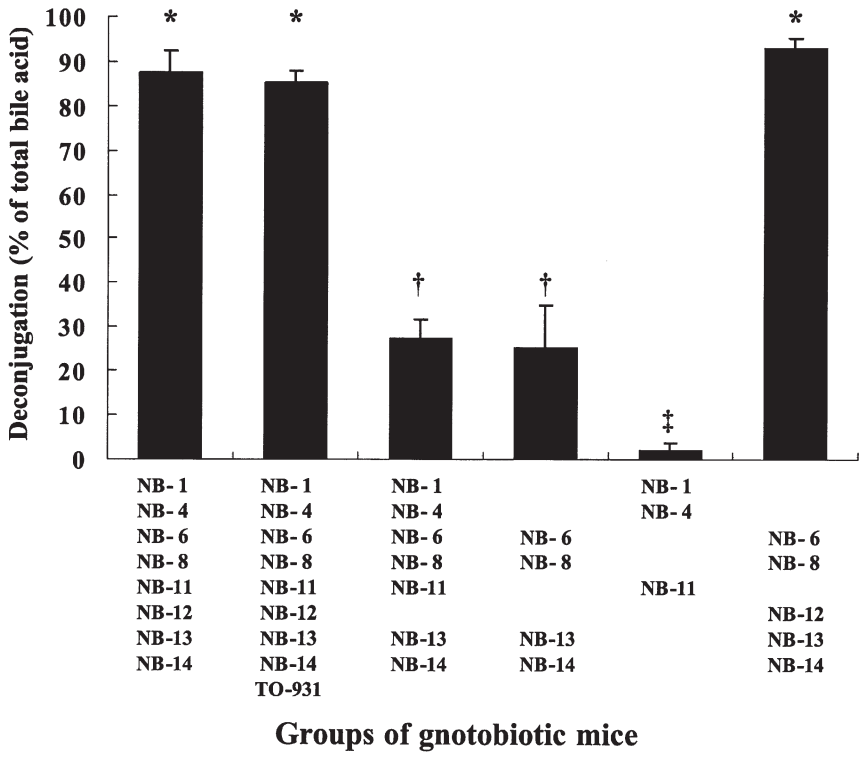

FIG. 2. Deconjugation ratio of bile acids in the cecal contents of various gnotobiotic mice associated with human intestinal bacteria. Various combinations of bacterial strains from eight bile acid–deconjugating bacteria (NB-1, NB-4, NB-6, NB-8, NB-11, NB-12, NB-13, and NB-14) and *Clostridium hiranonis* strain TO-931. NB-6. NB-8, NB-13, and NB-14 showed strong taurocholic acid-deconjugating activity and NB-1, NB-4, and NB-11 showed weak activity of deconjugation in vitro. Bars marked with different letters are significantly different ($P < 0.05$).

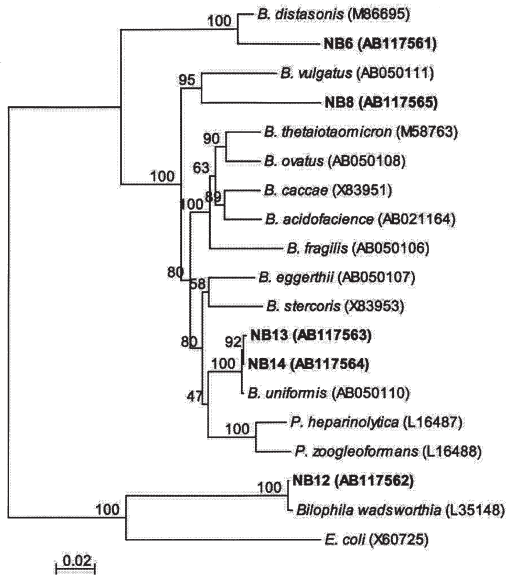

FIG. 3. Phylogenetic tree of NB strains isolated from ex–germ-free mice associated with a 10^{-6} dilution of human feces. NB strains based upon the alignment of the most similar 16S rDNA sequences with the neighbor-joining method. Bar indicates a genetic distance of 0.02.

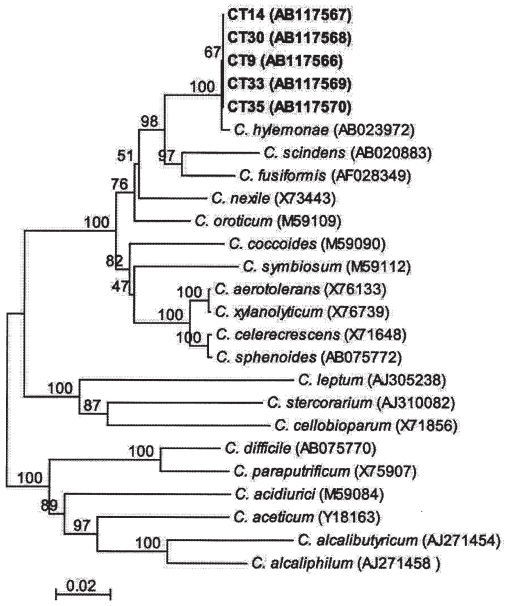

FIG. 4. Phylogenetic tree of CT strains in the *Clostridium* cluster and E. coli based upon the alignment of the most similar 16S rDNA sequences with the neighbor-joining method. Bar indicates a genetic distance of 0.02.

(Fig. 3A). NB-6 and NB-8 were identified as *Bacteroides distasonis* and *Bacteroides vulgatus*, respectively, a result confirmed by 16S rDNA sequence analysis. Strains NB-13 and NB-14 were identified as *Bacteroides uniformis*. NB-12 showed very weak responses to the regular biochemical tests using peptone-yeasts (PY) broth as a basic medium. In the sequence analysis of the 16SrDNA genes and alignment with the other sequences from the DDBJ, NB-12 showed the greatest sequence similarity with *Bilophila wadsworthia* (99.6%) (Fig. 3).

Isolation of and characterization of cholic acid 7α-dehydroxylating clostridia from limited human flora mice. The bacterial mixture from area A of each of five plates showed 100% conversion of CA to DCA. Three out of five bacterial mixtures from area B also showed 100% conversion, and the other two mixtures showing 95% and 90% conversion, respectively. On the other hand, the bacterial mixture from area C did not show any conversion of CA to DCA, suggesting that predominant clostridia in the intestine of limited flora mice inoculated with human clostridia were not capable of 7α-dehydroxylation.

We isolated 64 colonies from area B of the EG plates inoculated with the bacterial mixture from feces of limited flora mice harboring intestinal clostridia. These colonies were divided into nine groups, each containing four or eight strains. Among them, only three groups showed conversion of CA to DCA. The individual strains were screened for 7α-dehydroxylating activity *in vitro*, and finally we isolated five strains of 7α-dehydroxylating clostridia, CT-9, CT-14, CT-30, CT-33, and CT-35. All of the five strains were similar in colony morphology, being grayish and disc-shaped on EG agar plates. Cells grown on EG agar plates presented as small gram-variable, non-motile, straight to slightly curved thin rods. The sugar fermentation patterns of these bacteria were poor and variable. However, biochemical properties were identical with those described for the type strain of *C. hylemonae* strain TN-271^T, that is, H_2S and gas were produced, indole was not produced, nitrate was not reduced, and esculin and starch were not hydrolyzed. Although all of the five CT-strains belonged to *Clostridium* Cluster 14a (48) according to the 16S rDNA sequence analysis and had the highest level of similarity with *Clostridium hylemonae* (99.9%) (Fig. 4), these five strains were divided into two groups based on the production of organic acid from glucose as a source. Strains CT-30 and CT-33 produced lactate from EG broth, whereas the other strains did not.

Formation of DCA in the intestine of GB mice inoculated with a combination of isolated bacteria. DCA was detected in the feces of ex-GF mice associated with a human fecal dilution of 10^{-6}. However, we could not isolate 7α-dehydroxylating bacteria from the predominant population in the feces. The bile acid–deconjugating bacteria together with known 7α-dehydroxylating bacteria, specifically *Clostridium hiranonis* TO-931^T or *Eubacterium lentum*–like c-25, showed the formation of a small amount of DCA in the intestine of GB mice (Table 1). Further, combinations of five NB strains and five CT strains were inoculated into GF mice, and the composition of bile acid in the intestine was investigated. DCA was detected in the cecal contents of the GB mice with the five NB strains and five CT strains, equivalent to that in the cecal contents of GB mice with the five NB strains and strain TO-931^T (Table 1).

DISCUSSION

The transformation of conjugated primary bile acids into secondary bile acids by intestinal bacteria has been well investi-

TABLE 1
Composition of Cecal Bile Acid from Gnotobiotic Mice Associated with Human Intestinal Bacteria

	Groups of gnotobiotic mice

gated mostly *in vitro*. Although there are many reports of 7α-dehydroxylating bacteria, it has not been proven that such bacteria play an important part in bile acid transformation in the intestine. In rats, Uchida *et al.* reported that secondary bile acids are formed when GF rats are inoculated with clostridia of rat origin (49). However, in humans it is difficult to verify whether bacterial strains that have 7α-dehydroxylating activity *in vitro* also play an important role in bile acid formation in the colon. In this study, we isolated human fecal bacteria with the ability of transformation of bile acids in vitro and inoculated them into GF mice, and finally established GB mice with certain amount of DCA, 7α-dehydroxylated form of CA in their intestine. This result clearly indicates that the isolated bacteria from human feces could contribute secondary bile acid formation *in vivo*.

Batta *et al.* (50) reported that the deconjugation of bile acids is required for further bacterial 7α-dehydroxylation *in vitro*. We therefore attempted to use a combination of two kinds of bacterial groups, one group responsible for the deconjugation of conjugated bile acids, and the other for the 7α-dehydroxylation of primary bile acids. *Bacteroides* is known to be the predominant anaerobe in both human and mouse intestine. Notably, the "*fragilis*" group of *Bacteroides* showed growth stimulation in bile, and some selective media for *Bacteroides* contain high concentrations of sodium taurocholate (33). In the present study, GB mice inoculated with various combinations of bile acid-deconjugating strains had total bacterial counts in the feces of more than 10^{11} CFU/g feces. On the other hand, clostridial count in GB mice was 10^{10} CFU/g feces or less. These results suggest that *Bacteroides* (mainly the "*fragilis*" group) of human intestine are able to colonize in mouse intestine, and that clostridial strains in relatively low numbers are able to transform CA to DCA, if these primary bile acids are deconjugated by another bacterial group.

Strain NB-12 was identified as *Bilophila wadsworthia* based on the 16S rDNA sequence. *Bilophila wadsworthia* is reported to be isolated not only from gangrenous and perforated appendicitis, but also from normal fecal specimens (13). This strain is also bile-resistant. It is speculated that the resistance against bile or growth stimulation by bile might be related to the ability to deconjugate conjugated bile acids as reported in *Lactobacillus* or *Bifidobacterium* (10,51). Interestingly, strain NB-12 could not colonize the mouse intestine when inoculated alone. The rate of deconjugation in GB mice was lower than 30% without strain NB-12. It is suspected that a complex combination of intestinal bacteria or some metabolic or nutritional support from other bacteria is necessary to colonize the intestine.

Previously, we tried to isolate 7α-dehydroxylating bacteria from the predominant group of limited-flora mice with human intestinal clostridia. However, all the strains isolated from the predominant population, that is, bacteria grown from a 10^{-8} dilution of their feces, were negative for cholic acid 7α-dehydroxylation (31). In the present study, we used the method of Takamine and Imamura (28), which enabled us to isolate 7α-dehydroxylating bacteria in relatively small numbers in the fecal suspension.

Recently, several important strains with bile acid 7α-dehydroxylating activity were shown to belong to new phylogenetically proposed species. *Clostridium hiranonis* (52) includes strains HD-17 and TO-931^T, both of which have a high level of bile acid 7α-dehydroxylating activity (53,54). Another newly proposed species is *Clostridium hylemonae* (55), which has relatively low activity for 7α-dehydroxylation. Furthermore, the strain formerly known as *Eubacterium* sp. VPI 12708 (56) was recognized as a member of *Clostridium scindens* (55). This strain is known to be capable of 7α-dehydroxylation *in vitro,* and it is reported that a multistep biochemical pathway is needed for its transformation. The genes encoding several enzymes that either transport bile acids or catalyze various reactions in the 7α-dehydroxylation pathway of strain VPI 12708 were cloned (57). These studies strongly support the hypothesis that clostridial strains are responsible for secondary bile acid formation in the human intestine. It is reported that *Clostridium hiranonis* and *Clostridium scindens*, which have high bile acid 7α-dehydroxylation activity, could be detected by nested PCR in human fecal samples, indicating that populations of these strains are small in the intestine (58).

In this study, we isolated five strains of clostridia and found them to be most similar to *Clostridium hylemonae* based on 16SrDNA sequences. These bacteria showed 7α-dehydroxylation of CA to DCA in the GB mouse intestine when they were inoculated in combination with bile acid– deconjugating bacteria. It is strongly suggested that clostridia play an important role in transforming primary bile acids into secondary bile acids in the intestine, although the population of these bacteria in the gut is small.

Our results indicate that *Bacteroides* in human feces is one of the main bacterial groups for the deconjugation of bile acids, and clostridia play an important role in the 7α-dehydroxylation of free-form primary bile acids in the intestine. To our knowledge, this is the first report of a gnotobiotic animal model with human intestinal bacteria that can convert TCA to DCA.

Using gnotobiotic techniques, it is possible to simplify the complicated ecosystem of the intestine, and to understand the interaction between defined bacteria and the host animal. Although we should be aware that there is an obvious difference between humans and animal models, the gnotobiotic mice produced in this study could be used to study bile acid metabolism by human intestinal bacteria *in vivo,* and may provide information on regulating the metabolism by controlling these bacteria in the human intestine.

Biomarker Validation of a Long-Chain Omega-3 Polyunsaturated Fatty Acid Food Frequency Questionnaire

Bethany L. Sullivan, Peter G. Williams, and Barbara J. Meyer*

School of Health Sciences and Smart Foods Centre, University of Wollongong, Wollongong NSW 2522

ABSTRACT: Long-chain omega-3 PUFA (LC n-3 PUFA) are beneficial for health. To date there is no specific food frequency questionnaire (FFQ) to assess LC n-3 PUFA intakes. The objective of this study is to validate our newly developed FFQ by comparison with LC n-3 PUFA content of both red blood cells (RBC) and plasma, expressed as a percentage of total FA. Fifty-three healthy male and female subjects were recruited from Wollongong, Australia. Average LC n-3 PUFA intakes (mg/d) were estimated using the new FFQ. RBC and plasma FA were assessed using GC. Spearman correlation coefficients were used to assess the linear relationship between FFQ intakes and both RBC and plasma FA. The results show that there were significant Spearman's correlation coefficients between the FFQ intakes and RBC (and plasma) FA for total LC n-3 PUFA, EPA, and DHA (0.50 (0.54), 0.39 (0.54) and 0.40 (0.48), respectively) but not for docosapentaenoic acid. The FFQ was also an effective ranking tool. The FFQ is a valid method based on erythrocyte and plasma FA as biochemical markers. In conclusion, the new FFQ is a valid method that can be used to estimate the LC n-3 PUFA intake of adults.

Paper no. L9962 in *Lipids 41*, 845–850 (September 2006).

The various health benefits of consuming the long-chain n-3 PUFA (LC n-3 PUFA), particularly EPA and DHA, have been reported widely (1–6). The LC n-3 PUFA are obtained predominately from fish, seafood, meat, and eggs (7,8) and in recent years from enriched food products such as bread, milk, margarine, and eggs. Recommendations for dietary intakes of LC n-3 PUFA vary considerably from the consumption of two fish meals a week (9) to EPA plus DHA intakes of 500 mg/d (10); the Japanese recommend consumption of LC n-3 PUFA of 1.6 g/d (11).

Currently there is no tailor-made food frequency questionnaire (FFQ) to assess LC n-3 PUFA intakes. We have developed a new FFQ that estimates the dietary intakes of LC n-3 PUFA. The FFQ was found to be highly reproducible and valid compared with 3-d weighed food records in 53 healthy adults (12). However, as biochemical measurements of specific nutrients in the blood or other tissues can also provide useful assessments of nutrient intake (13), it is desirable to validate the FFQ further using biomarkers of LC n-3 PUFA intake.

Abbreviations: FFQ, food frequency questionnaire; FR, –food record; ISSFAL, International Society for the Study of Fatty Acids and Lipids; LC n-3 PUFA, long-chain n-3 PUFA; NNS, National Nutrition Survey; RBC, red blood cells.

There are several choices of a biomarker for the measurement of LC n-3 PUFA, including FA in adipose tissue (14), red blood cells (RBC), platelets, plasma, cholesterol esters, phospholipids (13), and potentially cheek cells (15). RBC may be a useful marker as they can provide an indication of the previous 120 d intake of LC n-3 PUFA, the approximate lifespan of a single RBC (16). RBC were found to be a good biomarker of LC n-3 PUFA intake as EPA and DHA were incorporated into RBC according to dose (17). Plasma has also been found to reflect LC n-3 PUFA intake in various studies (18,19).

The aims of this study were to (1) compare estimates of dietary LC n-3 PUFA intakes using the new FFQ with previously published results; (2) compare estimates of dietary LC n-3 PUFA intakes using the new FFQ with RBC FA; (3) compare estimates of dietary LC n-3 PUFA intakes with plasma FA; and (4) determine the efficacy of the FFQ to rank individuals into quintiles of intakes of LC n-3 PUFA by comparison with quintiles of RBC and plasma FA.

MATERIALS AND METHODS

Subject recruitment and clinic visits. Poster and e-mail advertisements were used to recruit staff and students from the University of Wollongong, Australia. There were no exclusion criteria, and the only requirement was that subjects had maintained a constant diet over the previous 3 mon. Vegetarians were encouraged to volunteer to ensure a wide range of dietary habits among the subjects. Based on RBC data from a previously unpublished study, it was determined that a minimum of 50 subjects should be sufficient to detect an effect size of 1 with more than 99% power at a significance level of 0.05, assuming that the correlation between methods is 0.6. The effect size is the difference between the means of the two methods, divided by the SD of either method.

Subjects attended a single clinic appointment and came in after an overnight fast to provide a fasted blood sample for RBC and plasma FA analysis. Digital scales and a wall-mounted stadiometer were used to measure weights and heights, respectively. Subjects then completed the FFQ. Approval to conduct the study was obtained from the University of Wollongong Human Research Ethics Committee, and subjects gave their written consent.

LC n-3 PUFA FFQ and determination of intakes. The 28-item semi-quantitative FFQ consists of a list of food items that are currently the only major contributors to LC n-3 PUFA intake. The foods included in the 28 questions are from the following

food groups: fish and seafood (6 questions), meats (12), cereals (4), fat spreads (2), dairy (2), and eggs (2), including LC n-3 PUFA–fortified products such as breads, milks, margarines, and eggs. Fish oil capsules are also included in the questionnaire. The FFQ also asks the subject to estimate usual meat serving size in terms of pictures of meat servings on a plate. The dietary validation of this FFQ has been published elsewhere (12). The FFQ was self-administered by subjects and took approximately 15 min to complete. The LC n-3 PUFA intakes of FFQ and the 3-d weighed Food Record (FR) were determined as described by Sullivan *et al.* (12).

Comparison with other published intakes. To determine whether the FFQ is measuring a plausible intake, another dietary intake comparator was necessary. Therefore, the intakes estimated using the FFQ were compared with those of a larger Australian sample using a 24-h recall method taken from the 1995 National Nutrition Survey (NNS) to estimate LC n-3 PUFA intake (20). The NNS collected data from 10,591 Australians aged 19 years and older, but at a time when omega-3 fortified foods were not on the market. The Wilcoxon signed rank test was used to compare the FFQ data (without the inclusion of fortified foods or fish oil capsules) to the 3-d weighed food record (FR) as previously described (12) with comparison with the NNS data (21).

Blood collection and preparation and analysis of RBC and plasma FA. Blood was collected into tubes containing EDTA and placed on ice. The samples were separated by centrifugation (10 min, 3,000 rpm, 4°C). The plasma was separated from the sample into labeled eppendorf tubes. The white buffy layer was removed and discarded, and the remaining RBC were transferred into labeled eppendorf tubes. RBC and plasma samples were stored at –80°C until analyzed.

RBC membranes were prepared for FA analysis as described by Ridges *et al.* (22). The total volume of the resuspended pellets was transferred into glass tubes for direct transesterification as described by Lepage and Roy (23). Briefly, 2 mL of methanol:toluene (4:1) was added to each sample. While vortexing, 200 μL of acetyl chloride was added dropwise to each sample using a positive displacement pipette. Samples were then heated for 60 min at 100°C in a heating block. After the tubes had been cooled in cold water, 3 mL of potassium chloride (10%) and 100 μL of toluene were added to each tube before centrifugation for 10 min (3,000 rpm, 4°C). The FAME, contained in the upper toluene phase, were removed and placed into GC vials. The FAME were analysed by flame-ionization GC (model GC-17A, Shimadzu) using a 30 m × 0.25 mm i.d. capillary column. Individual FA were identified upon comparison with known FA standards (Supelco FAME mix C4–C24 (plus added DPA), #18919-1AMP, Sigma-Aldrich, Castle Hill, Australia).

Total plasma FA were determined using the method of Lepage and Roy (23). Aliquots of 200 μL of plasma were transferred into glass tubes for direct transesterification (23) as briefly described above; however, instead of using 3 mL potassium chloride (10%), 5 mL potassium chloride (5%) was used, and instead of adding 100 μL toluene, no toluene was added. FAME were analyzed as described above.

Comparison of FFQ and LCn-3 PUFA content of RBC and plasma. Means (SD) were calculated for the total LCn-3 PUFA, EPA, docosapentaenoic acid (DPA), and DHA content (as a percentage of total FA) of the RBC and plasma. Spearman's correlation coefficients were determined for the relationship between FFQ estimated daily intakes and LCn-3 PUFA content of both RBC and plasma.

Quintile agreement. Subjects were ranked in ascending order of their daily total intake of LC n-3 PUFA estimated from the FFQ and both RBC and plasma FA. They were then separated into quintiles. Quintiles were determined by assessing the actual intakes from 53 subjects ranging from 0 to 1,100 mg/d and then dividing the subjects into 5 equal groups, where quintile 1 equals 0–98 mg/d, quintile 2 equals 99–188 mg/d, quintile 3 equals 189–304 mg/d, quintile 4 equals 305–449 mg/d, and quintile 5 equals 450–1,100 mg/d. The percentage agreement was determined between the quintile assignments using the FFQ and RBC FA, and separately for the FFQ and plasma FA.

Statistical analysis. Means (SD) were calculated for the total LCn-3 PUFA, EPA, DPA, and DHA content (as a percentage of total FA) of the RBC and plasma. The relationships between FFQ estimated daily intakes and LCn-3 PUFA content of both RBC and plasma were assessed by Spearman's correlation coefficients.

Quintile agreement was assessed by determining the percentage agreement between quintile assignments using the FFQ and RBC FA and for FFQ and plasma FA.

Statistical analysis was performed using JMP statistical analysis program (version 5.1, SAS Institute, Cary, NC). Statistical significance was set at $\alpha = 0.05$ for all analyses.

RESULTS

Fifty-three subjects (20 male and 33 female) were recruited for the validity study, including seven self-reported vegetarians. Two vegetarians were vegans, one ate extremely small amounts of fish, and two were lactoovovegetarians. The remaining two reported eating significant amounts of fish in the FFQ. The subject characteristics are presented in Table 1.

Comparison of our FFQ LC n-3 PUFA intakes with the NNS of Australia. Table 2 shows the LC n-3 PUFA intake data estimated from the FFQ (excluding fortified foods and fish oil capsules) in comparison with the analysis of the NNS of Australia conducted by Howe *et al.* (20). There were no significant differences between the estimates in this study using the FFQ and the NNS data.

Comparison of our LC n-3 PUFA FFQ with the FA content of RBC and plasma. Comparison of the LC n-3 PUFA intakes estimated from the FFQ with the percentage of the total FA content of RBC and plasma is shown in Table 3.

Bivariate plots of the FFQ estimation of LC n-3 PUFA intakes and percentage of total FA content of the RBC showed that there were good, significant relationships for total LC n-3 PUFA, EPA, and DHA (Figs. 1a, 1b, and 1d). There was no apparent relationship for DPA (Fig. 1c). Similar patterns were ob-

served for the relationship between the FFQ estimated intakes and LC n-3 PUFA content of plasma. As seen with the RBC, there was no relationship between FFQ estimation of DPA intakes and the content of plasma as indicated by the non-significant Spearman's correlation of 0.09.

The efficacy of the FFQ to rank individuals into quintiles of intakes of LC n-3 PUFA. Subjects were also assigned quintiles based on total LC n-3 PUFA content of the RBC (% of total FA) (Table 4). Forty percent of subjects were correctly assigned into the same quintiles, and 75% of subjects were assigned to either the same or adjacent quintile. The FFQ was most successful at identifying individuals with very low intakes. Similar results were obtained for agreement of quintile assignment between FFQ total LC n-3 PUFA intakes and total LC n-3 PUFA content of plasma (Table 4). Five out of the seven vegetarian subjects were found in the first quintile for both analyses.

(B) Bivariate plot of EPA intakes estimated by the FFQ vs. the EPA content of the RBC as a percentage of total FA with calculated Spearman correlation coefficient. (C) Bivariate plot of DPA intakes estimated by the FFQ vs. the DPA content of the RBC as a percentage of total FA with calculated Spearman correlation coefficient. (D) Bivariate plot of DHA intakes estimated by the FFQ vs. the DHA content of the RBC as a percentage of total F\A with calculated Spearman correlation coefficient.

DISCUSSION

Our new FFQ estimates the dietary intakes of LC n-3 PUFA very well as the results compare favorably with the results from the NNS of Australia (Table 2, and ref. 20). The NNS intakes of EPA and DPA were slightly higher and the NNS intakes of DHA were slightly lower than in our study, which could be explained by the fact that our study group contained seven vegetarians. With meat being a rich source of DPA (24), the inclusion of seven vegetarian subjects (who did not eat meat) in this study may account for the lower DPA intakes.

Other studies have used various biomarkers to validate newly developed or existing FFQ, although not many have been validated for LC n-3 PUFA intake, and those that do use biomarkers other than RBC. Woods *et al.* (25) validated an existing semiquantitative FFQ for measuring fish intake with plasma FA composition. That FFQ was assessing overall dietary intake over the preceding 12 mon and was originally developed for use by the Anti Cancer Council of Victoria. Significant Pearson correlation coefficients were obtained between percentage of plasma FA and grams of steamed, grilled, or baked fish and grams of total non-fried fish consumed ($r = 0.33$

2 ($n = 11$)	2	5	4	2	5	4
3 ($n = 11$)	5	5	1	3	6	2
4 ($n = 11$)	3	4	4	1	8	2
5 ($n = 10$)	3	4	3	2	5	3
Total no. (%)	21 (40)	19 (36)	13 (24)	15 (28)	26 (49)	12 (23)

for DHA and 0.34 for total LC n-3 PUFA). Significant Pearson correlation coefficients were also obtained between the percentage of total plasma n-3 PUFA and the same two variables (both 0.33). Our FFQ shows higher Spearman's correlation coefficients ($r = 0.50$ for total LC n-3 PUFA, $r = 0.39$ for EPA, and $r = 0.40$ for DHA), hence our newly developed FFQ is an improvement on previously validated FFQ to estimate LC n-3 PUFA intakes (25).

There are a few reasons why our new FFQ shows higher correlations. First, in Woods *et al.* (25), intakes of fish (steamed, baked, grilled, fried, and takeaway fish) and tinned fish were calculated without the inclusion of other types of seafood. There was no distinction between different fish species, which are known to have large variations in LC n-3 PUFA content (24). Second, other foods that contain LC n-3 PUFA, such as eggs and meat, were not included in the analysis (8), and these may account for nearly 50% of LC n-3 PUFA intakes (20). Finally, a major limitation was that at the time of the study there was no Australian database for the estimation of DHA and EPA intakes from the FFQ, which has now been rectified by Mann *et al.* (26).

Our correlation coefficients between RBC and dietary intakes of LC n-3 PUFA compare favorably with the study by Anderson *et al.* (18). Correlation coefficients between plasma phospholipid FA and dietary intakes of EPA and DHA were 0.51 and 0.49, respectively. Their correlation between fish intake and n-3 PUFA in plasma phospholipids was 0.37, whereas our correlation coefficient of total intake of LC n-3 PUFA and RBC LC n-3 PUFA was 0.5. Their lower correlation between fish intake and n-3 PUFA in plasma phospholipids further highlights the fact that foods other than fish and seafood contribute to LC n-3 PUFA intake (20).

The mean percentages of LC n-3 PUFA in RBC in our study were comparable to those determined in other studies (17,26). LC n-3 PUFA content of plasma was, however, lower than reported in other studies (25,27). RBC and plasma were found to be good biomarkers of total LC n-3 PUFA, EPA, and DHA intakes as highlighted by the significant Spearman's correlation coefficients, but RBC and plasma were not found to be good biomarkers of DPA intakes ($r = 0.05$). Significant correlations between dietary intakes and RBC FA were expected for EPA and DHA as both FA have been found to be incorporated into RBC by dose (17). However, DPA intakes estimated from the FFQ were found to be highly reproducible with a highly significant Spearman's correlation coefficient of 0.89 (12). This evidence strongly suggests that the lack of correlation is not due to the FFQ instrument itself and that it is more likely due to biological or metabolic factors and this warrants further investigation.

Quintile assignment proved that the FFQ was able to adequately identify individuals according to their RBC levels of LC n-3 PUFA. Five out of the seven vegetarians were correctly assigned to the first (lowest intake) quintile based on intakes measured by the FFQ and LC n-3 content of the RBC. Agren *et al.* (28) also found that Finnish vegans had significantly lower EPA, DPA, and DHA in their RBC than omnivorous subjects. The other two self-reported vegetarians, as expected, had higher LC n-3 PUFA content of RBC due to significant intakes of fish and seafood. Overall, the quintile assignment in this study was better than or consistent with other studies. The FFQ used by Erkkola *et al.* (29) classified 62% of individuals into the same or adjacent quintiles based on total n-3 PUFA intakes. The ability of this FFQ to classify more than 75% of individuals into identical or adjacent quintiles may be useful in clinical settings to identify individuals with low LC n-3 PUFA status.

In summary, the FFQ performed well against the RBC membrane and total plasma FA, apart from the lack of correlation between DPA intakes and DPA content of both RBC and plasma, suggesting that these may not be good biomarkers of DPA intake. The FFQ is therefore an adequate dietary assessment tool for the estimation of total LC n-3 intakes in healthy Australian adults and would be a useful screening tool for low intakes of LC n-3 PUFA. It is an appealing alternative to other dietary assessment methods due to its validity, low subject burden and low cost, and being very fast to complete. In conclusion, the FFQ is a valid dietary assessment tool for the estimation of dietary LC n-3 PUFA.

ACKNOWLEDGMENTS

The authors would like to acknowledge Sr Sheena McGhee, Liz Grigonis-Deane, and staff at the Exercise Science and Rehabilitation Centre for assistance in, and use of, the clinic facilities; Dr. Ken Russell for statistical advice; and the study volunteers for their involvement in the study.

If you are using this questionnaire to determine the long-chain omega-3 PUFA intakes in Australia, then contact Dr. Barbara Meyer (bmeyer@uow.edu.au or phone 02 4221 3459) to obtain further information regarding the automated electronic version of this questionnaire.

The Long-Chain Omega-3 Polyunsaturated Fatty Acid Questionnaire

INSTRUCTIONS:

This questionnaire consists of 28 questions about your **usual** eating habits **over the past 12 months**.

Before completing the questionnaire, please fill in the following information:

The date that you completed this questionnaire: _____

Your gender: ☐ male ☐ female

Your age: ☐ under 19 ☐ 19-24 ☐ 25-29 ☐ 30-34 ☐ 35-39 ☐ 40-44
☐ 45-49 ☐ 50-54 ☐ 55-59 ☐ 60-64 ☐ 65 and over

Human Milk Fatty Acid Composition from Nine Countries Varies Most in DHA

Rebecca Yuhas*, Kathryn Pramuk, and Eric L. Lien

Department of Nutrition Research, Wyeth Nutrition, 500 Arcola Road, Collegeville, Pennsylvania 19426

ABSTRACT: Many published studies of breast milk FA composition are limited to populations from one or two countries. We aimed to examine the degree to which FA compositions vary across a number of diverse populations. Because diet and maternal adipose stores influence breast milk FA composition, differences in FA composition between groups most likely reflect habitual dietary differences. Approximately 50 breast milk samples (full breast expression) were collected from women in Australia, Canada, Chile, China, Japan, Mexico, Philippines, the United Kingdom, and the United States. The proportion of saturated FA was relatively constant among countries, with the exception of the Philippines, where levels of lauric and myristic acids were elevated (means greater than two times the mean of most other countries). Monounsaturated FA also varied little, with the exception of low levels of oleic acid in the Philippines and high levels of erucic acid in China. Although arachidonic acid (C20:4n-6) levels were similar among all countries (means ranging from 0.36 wt % to 0.49 wt %), mean DHA (C22:6n-3) levels ranged from 0.17 to 0.99 wt %, with the highest levels in Japanese milk and the lowest levels in Canadian and U.S. samples. The results of this study demonstrate that the proportion of saturated and monounsaturated FA are relatively constant across a large number of countries, whereas the level of some of the PUFA, especially DHA, are highly variable.

Paper no. L9973 in *Lipids 41*, 851–858 (September 2006).

Breast feeding is the most appropriate means of providing nutrition to healthy term infants. Human milk is not a static, invariant fluid, but fluctuates in micro- and macronutrient composition over the course of a feeding, longitudinally from birth to weaning, and, at least for some components, as a consequence of maternal diet. For example, during the course of a single feed, total lipid concentration increases several fold from foremilk to hindmilk (1). Total nitrogen content for human milk falls precipitously during the first month of lactation, but does not change dramatically after that (2). Diet affects levels of fat-soluble components of human milk, such as fatty acids (FA), carotenoids, vitamin A, and vitamin E (3–5).

The lipids of human milk provide approximately half of the energy needs for the neonate, and also provide essential FA and fat-soluble vitamins. The levels of some FA in human milk, such as docosahexaenoic acid (DHA, 22:6n3), are clearly dependent on dietary intake. Women who consume fish and other foods containing high levels of n–3 long-chain PUFA (LCP) have relatively high milk DHA levels compared with milk from women who consume diets low in these components (6,7). Milk DHA levels increase in a dose-related manner in women receiving either fish oil supplements (8) or DHA supplements from an algal single cell oil (9). Linoleic acid (LA, C18:2n-6) in breast milk is also dependent on diet. The consumption of PUFA has increased in many countries over the past 40 years, with the result that the proportion of LA in human milk has doubled in countries such as the United States (10). Beyond specific dietary FA, total maternal dietary fat intake also alters the concentration of selected human milk FA. For example, levels of lauric acid (C12:0) are relatively low in the milk of women who consume moderate- to high-fat diets; however, in women consuming low-fat diets, mammary gland FA synthesis is elevated, which increases the level of milk lauric acid (11–13).

The present study was designed to evaluate the FA profiles of a large number of mature (postpartum day ≥ 30) human milk samples from each of nine countries. The collection countries were designed to be reflective of a global sample with collection sites in Asia (China, Japan, and the Philippines), Australia, Europe (the United Kingdom), North America (Canada, the United States, and Mexico), and South America (Chile).

MATERIALS AND METHODS

The study subjects were healthy, nonsmoking mothers (age 14 to 41 y), exclusively breastfeeding single-birth, full-term, healthy infants aged 1 to 12 mon. Mothers were under no rigorous dietary restrictions and their diets included at least three servings of fruits and vegetables per day. Mothers recorded their 24-h dietary intake records on the day prior to their milk donation, and all records were reviewed at study completion by one dietitian; the number of servings of fruits and vegetables for each diet record was calculated using the American Dietetic Association Exchange Lists. The pediatric clinics that participated in recruitment served middle socioeconomic populations, with the exceptions of Manila, Philippines, and Chengdu, China (lower socioeconomic class).

Milk samples represented a single full breast expression and were collected by electric pump (with the exception of Japan, where milk was collected by manual expression) between 1:00 and 5:00 PM, 2–4 h after the last feeding. Written informed

Abbreviations: AA, arachidonic acid; ALA, alpha-linolenic acid; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FA, fatty acid; LA, linoleic acid; long-chain PUFA (LCP); PUFA, polyunsaturated fatty acid.

consent was obtained from all subjects. Following expression, milk samples were immediately placed on dry ice or in a freezer at –20°C, then shipped within 10–14 d on dry ice to a central laboratory where the samples were stored at –70°C. Lipid was extracted from the milk using a modified Roese Gottlieb mixed ethers extraction (14). Samples were acidified prior to extraction to ensure recovery of any free FA generated by lipase activity. Total lipids were determined for each milk sample and reported in a previous publication (4). Fatty acid methyl esters (FAME) were prepared with BF_3/methanol (14% wt/vol) and extracted into hexane (15).

Analyses were performed with a Hewlett Packard 5890 gas chromatograph equipped with a flame ionization detector (Little Falls, DE). The carrier gas was hydrogen with a linear velocity of 45 cm/s and a 1:60 split ratio. The column was a 30-m capillary (0.32 mm i.d.) Omegawax™ (Supelco, Bellefonte, PA). Chromatographic conditions were isothermal, 200°C. The injector and detector temperatures were 220°C and 230°C, respectively. FA were identified by equivalent chain length as determined using retention times generated by reference mixes of FAME. Detector response factors were calculated using quantitative reference mixes of FAME (Nu Chek Prep, Elysian, MN).

Most of the FA were normally distributed, and normal distribution was assumed for the statistical analyses of the FA profiles. The weight percent of human milk FA for the nine countries were compared by the Student-Newman-Keuls test at the $P = 0.05$ level following a one-way ANOVA. Ratios of LA:alpha-linolenic acid (ALA, C18:3n-3), eicosapentaenoic acid (EPA, 20:5n-3):DHA, and AA:DHA were calculated for each sample, and then the mean ratios were determined for each country. Concentrations of LA, AA, ALA, and DHA were calculated from the FA profiles and the concentration of total lipid (reported in reference 4) for each sample. These values were not corrected for lipids other than triglycerides; triglycerides account for greater than 98% of lipids in human milk (11). The concentration data were not normally distributed and therefore a log transformation was conducted prior to statistical analysis (16).

RESULTS

Study population. The total number of samples was 440, and the mean age of mothers was 29.5 y. Mean parity was 1.2. The number of participants per country varied from 44 to 54. A more complete description of the mothers is provided in a previous publication (4).

Saturated FA. Lauric acid was only a modest component of milk FA, with means of 4.24–6.15 wt % in all countries, with the exception of the Philippines, where the mean was 13.82 wt % (Table 1). Myristic acid (C14:0) followed a similar pattern (a range of 3.61% to 6.80% for all countries except the Philippines, where the level was 12.12%). For these FA, the mean level in the Philippines was significantly higher than all other countries. Palmitic acid (C16:0) was the predominant saturated FA in all countries, with Philippine samples having the highest

level. In contrast to other saturated FA, Philippine samples had the lowest level of stearic acid (C18:0).

Monounsaturated FA. Oleic acid (C18:1n-9) was the predominant monounsaturated FA in breast milk samples from all countries (Table 2), and, with the exception of the Philippines, was also present at higher proportions than any saturated or PUFA. The oleic acid levels in most countries were above 30%, with the exception of Chile (26.19%) and the Philippines (21.85%). Erucic acid (C22:1n-9) levels were below 0.2% in all countries with the exception of China, where the mean level was 1.21%. Eicosenoic acid (C20:1n-9) followed a similar pattern to erucic acid, with the levels in China being greater than twice that of any other country (1.25% in China vs. a range of 0.28% to 0.55% in other countries).

PUFA. LA levels ranged from 7.90% in the Philippines to 17.75% in Chile (Table 3), with the mean level of all samples being 12.93%. The levels of AA were relatively constant across all countries (Table 3, Fig. 1), with the mean level of all samples being 0.41%. Other n-6 FA (18:3n-6, 20:3n-6) also fell within relatively narrow ranges. The ALA levels were constant among most countries at approximately 1% of FA (Table 4). However, the ALA levels in samples from China were significantly higher (2.02%), and levels in samples from the Philippines were significantly lower (0.43%) than all other countries. The mean ALA level of all samples was 1.14%. DHA levels were much more variable, with a range from 0.17% in the United States and Canada to 0.99% in Japan, with a global mean of 0.41% (Table 4, Fig. 2). Countries with the highest DHA levels also had the highest EPA (C20:5n-3) levels (Japan: 0.26%; the Philippines: 0.15%).

The LA:ALA ratio varied approximately twofold among countries, whereas the AA:DHA ratio varied more widely, from 0.51:1 in Japan to 3.16:1 in the United States (Table 4). The mean AA:DHA ratio for all samples was 1.63:1. The EPA:DHA ratio varied inversely with the DHA content: the EPA:DHA ratio was high in countries with low DHA (Australia, Canada, the United Kingdom, and the United States), and was low in countries with high DHA (Chile, China, Japan, and the Philippines).

The concentrations of the essential FA, LA and ALA, as well as the LCP AA and DHA, were calculated from the FA profiles and the fat concentration in each milk sample (Table 5). High total milk fat in the samples from China resulted in relatively high concentrations of all PUFA from that country.

DISCUSSION

The current study evaluated the FA profiles of approximately 50 mature human milk samples from each of nine countries, making this one of the largest analyses of its type to date. Many previous studies have reported values from one or two countries; however, methodological differences make comparisons among studies difficult. The present study employed the same collection and analysis conditions, which permit a comparison

among countries independent of methodological variations. Although the data are reported as samples coming from a specific country, it must be kept in mind that the samples from each country were taken from one specific geographical area, and are specific solely to that area, not to the country as a whole. Previous studies have demonstrated regional differences in several countries, such as France (17) and China (18).

Parallels can be seen between the levels of several milk FA and maternal diets. For example, our data demonstrated that milk LA levels were relatively high in countries typically consuming

a high-maize diet, such as Mexico (19) and Chile (20). The Philippines presented an unusual profile, with low LA levels and high levels of lauric and myristic acids, most likely indicating consumption of diets limited in both essential FA and total fat. Our observations support a relationship between dietary LA intake and milk LA composition, although the direct dietary control of milk FA content cannot be proven in the present study. Studies using stable isotope-labeled LA demonstrated that approximately 30% of LA appearing in milk is derived from the isotopic label (21,22). These data suggest that both diet and a pool of LA that turns over relatively slowly[AUQ2] (for example, adipose tissue) are responsible for a substantial portion of LA appearing in milk.

In contrast to LA levels, which varied more than twofold

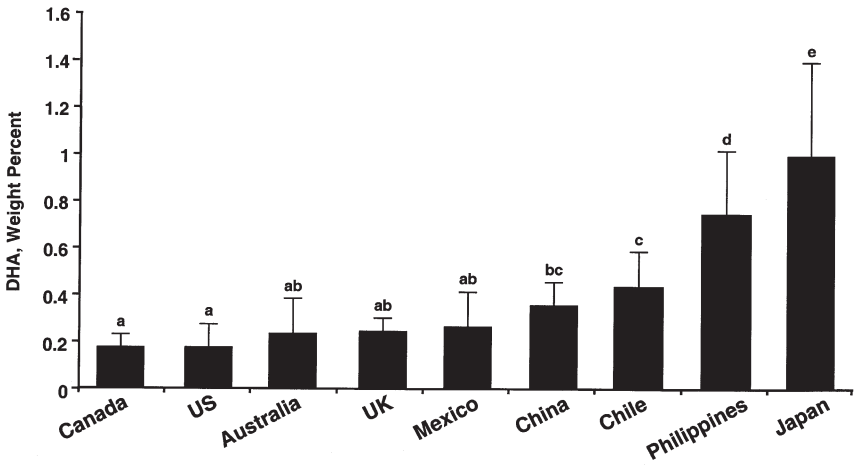

FIG. 2. DHA as weight percent of total FA in mature human milk of women from nine countries. Values are means ± SEM with 44 to 54 samples per group. Means with different superscripts are statistically different ($P < 0.05$).

among countries, the mean AA level was relatively constant among all countries. The conversion of dietary, isotopically labeled LA to AA is very inefficient. Demmelmair *et al.* (22) found that only approximately 0.02% of an isotopically labeled oral LA dose appeared as milk AA over a 5-d period. The authors conclude that AA may be derived from sources other than dietary LA; however, concerns about a large endogenous pool of AA prevent definite conclusions from being drawn. The ratio of LA to AA in our human milk samples also argues against a direct, unregulated conversion of dietary LA to human milk AA. The LA:AA ratio varied almost twofold between countries (paralleling the proportion of LA in milk), but high proportions of milk LA did not predict high AA levels.

In the present study, elevated levels of milk DHA occurred in areas with high dietary consumption of fish. For example, countries with coastal collection sites and high fish or fish product consumption, such as Japan (23), the Philippines, and Chile (20), had DHA levels above 0.4%. In contrast, both Canada and the United States, where the interior collection sites had low fish consumption[AUQ3] (Edmonton, Alberta, and Tucson, Arizona, respectively), had very low DHA levels (below 0.2%). Dietary influences on milk DHA content are quite clear. For example, supplementation studies with fish oil (8) or DHA from a single cell oil[AUQ4] (9) rapidly elevated milk DHA levels in a dose-related manner. The AA:DHA ratio varied substantially in the present study, from 0.51:1 in Japan to 3.16:1 in the United States, as a result of relatively constant AA levels and highly variable DHA levels. Such variability in both DHA levels and in AA:DHA ratios means that there is no single, generally recognized standard for the composition of human milk LCP. Controlled randomized clinical studies with LCP-supplemented infant formulas have demonstrated that these FA may mediate improvements in both visual and cognitive function in preterm, and possibly also in term, infants (24–26). Positive results have been found when formulas contain 0.20–0.35 wt % DHA and an AA:DHA ratio between 1.5:1 and 2:1. The human milk LCP levels and AA:DHA ratios identified in the current study are clearly broader than the ranges evaluated in infant formula studies. To date there have not been dose-response studies to determine optimal DHA supplementation levels. Further research is necessary to evaluate the potential benefits of alternate addition levels.

The levels of lauric and myristic acids were similar among all countries, with the exception of the Philippines. The samples from the Philippines were obtained from women of low economic status; high milk levels of lauric and myristic acids suggest that the diet of these women was relatively high in carbohydrate and low in fat. Insull *et al.* (27) compared milk composition of women receiving either a fat-free diet or an isocaloric diet containing 40% of calories as fat. The lauric and myristic acid levels of milk in the group consuming the fat-free diet were much higher than levels in women consuming the fat-containing diet. Studies of milk composition from women whose typical diet was low in fat agree with our finding that lauric and myristic acid levels are elevated (19,28,29).

Oleic acid constituted the primary monounsaturated FA in all samples. Samples from Canada and China had the highest oleic acid content, confirming that these countries had diets characterized by relatively high consumption of canola or rapeseed oils (30,31). Diets high in oleic acid have previously been demonstrated to result in elevated human milk oleic acid levels (32). China also had milk erucic acid levels eight times higher than any other country and eicosenoic acid levels more than two times greater than any other country. These data are consistent with the consumption of rapeseed oil in China.

We have calculated the concentration of LA, ALA, AA, and DHA in the samples on a mg/L basis in order to compare levels found in human milk with regulatory requirements for infant formula. In order to estimate total FA concentrations, we made the assumption that the breast milk collection was representative of human milk during an entire 24-h period. A number of studies have evaluated diurnal variation of total human milk fat (reviewed in 33). In general, in Western women, milk fat tends to rise during the day with the peak occurring early in the evening. In developing countries, the peak tends to be early in the morning. Our collection time, during the afternoon, would be a midpoint in the diurnal cycle for all study populations. In terms of specific FA, Lammi-Keefe *et al.* (34) reported no significant diurnal variation in LA concentrations. The regulatory requirements for essential FA in formulas (generally expressed

as mg/100 kcal) have been converted to mg/L, using 670 kcal/L as a conversion factor, in order to permit direct comparisons with the present study's data. The LA content of all samples was greater than the U.S. FDA minimum requirement (35) of 300 mg/100 kcal (or 2,010 mg/L) and met current European Union (EU) guidelines (36) of providing from 300–1,200 mg/100 kcal (2,010–8,040 mg/L). Although the United States does not specify a requirement for ALA, the current EU Directive requires a minimum of 50 mg/100 kcal (335 mg/L). The overall mean ALA concentration in our survey would meet this level; however, the individual means of several countries including Chile, the Philippines, and the United States are below this minimum. The EU also requires the LA:ALA ratio to fall within the range of 5:1 to 15:1. Our data indicate that the mean of this ratio is greater than 15:1 in four of the countries surveyed (Chile, Mexico, the Philippines, and the United States). Smit *et al.* (37) conducted an extensive evaluation of human milk FA concentrations compared with regulatory standards and found that the levels of specific FA (LA, ALA, AA, DHA, lauric acid, and myristic acid) from the milk of numerous mothers fell outside of the regulatory guidelines.

In conclusion, we have determined the FA profiles of 440 human milk samples from nine countries. Levels of AA demonstrated only modest variation between countries. This relative consistency is of interest considering the large variation in habitual diets among those countries. In contrast, DHA demonstrated greater than a fivefold variation in breast milk composition among countries. The mean AA level in our survey of 0.41% is similar to the recommendation of the Child Health Foundation that at least 0.35% AA be added to formula (38). The Child Health Foundation also recommended at least 0.2% DHA be added to formula. The substantial variability of DHA among countries in our study, ranging from 0.17% to 0.99%, suggests that a formula addition level of 0.2% is an acceptable addition level, but future research is required to determine an optimal DHA level.

ABSTRACT: Atherosclerosis is a multifactorial disorder. Recent studies indicate that the plasma level of sphingomyelin, which yields ceramide, correlates with the risk of coronary heart disease. Therefore, ceramide, a well-known lipid causing apoptosis in various cell types, may contribute to atherogenesis. We examined the relationship between ceramide concentration and risk factors of atherosclerosis in normal human plasma using electrospray tandem mass spectrometry (LC-MS/MS). Major ceramides in human plasma were C24:0 and C24:1. The ceramide concentration showed a significant positive correlation with total cholesterol (TC) and triglycerides (TG). In addition, plasma ceramide level increased drastically at a high level of LDL cholesterol (more than 170 mg/dL). Our previous studies demonstrated that the sum of fragmented and conjugated apolipoprotein B-100 proteins (B-ox), which were products of a radical reaction of LDL as well as plasma, was a reliable index of atherosclerosis. B-ox showed a significant positive correlation with the plasma ceramide level. Based on these results, we propose that the ceramide level in human plasma is a risk factor at the early stages of atherosclerosis.

Paper no. L10034 in *Lipids 41*, 859–863 (September 2006).

Ceramide has been implicated in regulating cell cycle arrest, apoptosis, and cell senescence (1–3) and is reported to serve as an intracellular second messenger (4). One of the major sources of ceramide is from sphingolipid biosynthesis (1). *De novo* synthesis starting from serine palmitoyl-CoA transferase (SPT) also plays an important role in the biosynthesis of ceramide (5). A recent study indicated a significant positive correlation between plasma levels of sphingomyelin (SM) and the severity of coronary heart disease (6). Plasma SM levels increased in human familial hyperlipidemias (7). Recent studies demonstrated correlations between sphingomyelin and atherogenic risk factors of plasma in humans and inhibitions of SM and SPT reduced atherosclerotic lesion in apolipoprotein E knockout mice (8–10). These studies indicate that plasma SM levels and sphingomyelinase (SMase) activity may be risk factors for atherosclerosis, suggesting a role of ceramide in atherogenesis. However, a correlation between ceramide species in human plasma and atherosclerosis has never been examined.

Atherosclerosis is closely associated with modifications in LDL (11,12). Aggregation of LDL has been proposed to represent an essential and central process in atherogenesis (11), and LDL extracted from atherosclerotic lesions is aggregated or is prone to aggregate. Aggregated LDL in atherosclerotic lesions is enriched with ceramide (13), and LDL treated with SMase induces foam cell formation *in vitro* (13,14). Oxidative modification of LDL is also an important factor in the development of atherosclerosis (15). Uptake of oxidized LDL (oxLDL) by macrophages and smooth muscle cells leads to foam cell formation, which accumulates as lipid drops (16,17). Based on these reports, a correlation between ceramide and oxLDL is suggested.

Although LDL is composed of lipids, protein, and sugar chains, studies on the oxidation of LDL have focused mainly on lipid peroxidation (18). The protein part of LDL, apolipoprotein B-100 (apoB), is also reactive to radical oxidation and it undergoes fragmentation and conjugation (18–22). Among plasma proteins, apoB is unusually reactive to radical reactions compared to albumin and transferrin (21), and its reactivity is even comparable to α-tocopherol (21). In normal human serum, both fragmented and cross-linked apoB proteins are present and these oxidation reaction products of LDL tend to increase with age (23). In addition, we reported that B-ox, namely the sum of fragmented and conjugated apoB proteins determined by an immunoblot assay, showed a significant positive correlation with intima-media thickness of the carotid artery (IMT) and LDL cholesterol, and a negative correlation with HDL cholesterol and plasma vitamin C, which was an outstanding antioxidant in plasma (23,24). These reports suggest that B-ox is a reliable mechanism-based indicator of atherosclerosis. In this study, we examined for the first time correlations of ceramide with associated indices with atherosclerosis, including B-ox.

Abbreviations: apoB, apolipoprotein B-100; IMT, intima-media thickness of the carotid artery; oxLDL, oxidized LDL; SM, sphingomyelin; SMase, sphingomyelinase; SPT, serine palmitoyl-CoA transferase; TC, total cholesterol; TG, triglyceride.

EXPERIMENTAL PROCEDURES

Materials. All solvents were purchased from Wako Pure Chemicals Co. (Osaka, Japan). All other reagents were obtained from Funakoshi Co. (Tokyo, Japan). Silica gel 60 TLC plates were purchased from Merck (Darmstadt, Germany). Vectastain ABC-PO (goat IgG) kit was purchased from Vector Lab. Inc. (Burlingame, CA, USA). Anti-human lipoprotein B goat IgG was purchased from Sigma Chemical Co. (St. Louis, MO, USA). Polyvinylidene difluoride (PVDF) membrane filters were purchased from Millipore (Tokyo, Japan). Electrophoresis reagents were purchased from Nacalai Tesque Inc. (Kyoto, Japan).

Subjects. We screened 100 Japanese inhabitants who participated in the annual local health-check program in Kisei Town (a rural area in Mie Prefecture, Japan). Table 1 gives the characteristics of the subjects. This study was approved by the Ethics Committee of International University of Health and Welfare and the study subjects gave informed consent to participate in the study.

Analytical method. Total cholesterol (TC), LDL cholesterol, HDL cholesterol, triglycerides (TG), phospholipid, and free fatty acid were measured using a commercially available diagnostic kit (Wako Pure Chemicals Co., Osaka, Japan).

Lipid extraction. The plasma (1 mL) was diluted with 1 mL of PBS, and 5 mL of a mixture of chloroform and methanol (2:1, vol/vol) was added. After vigorous shaking and centrifugation for 5 min at 3,400 *g*, the chloroform layer was collected. To the residue, 4 mL of chloroform was added and the extraction was performed again. The combined chloroform layer was evaporated with an evaporator and the resulting lipid was dissolved in 1 mL of chloroform. The recovery of exogenously added C16:0 ceramide to the plasma was satisfactorily in the range of 75–80% compared to 60–90% in a previous study (25).

Mass spectrometry. Quantitative measurement of ceramide species was made using a triple-quadrupole mass spectrometer (Finnigan MAT TSQ 7000). ESI-MS/MS was performed as previously described (25,26). HPLC was conducted with a μ-Bondasphere column (5 μC18 100A Waters). Elution was performed at a flow rate of 0.2 mL/min with a mixture of 5 mM ammonium formate, methanol, and tetrahydrofuran at a volume ratio of 1:2:7. The mobile phase stream was connected to the ionspray interface of an ESI-MS/MS system. Standards and cellular ceramide extracts were stored at –20°C. Mass analysis was performed in the positive mode in a heated capillary tube at 250°C with an electrospray potential of 4.5 kV, a sheath gas pressure of 70 psi, and a collision gas pressure of 1.6–2.0 mtorr. Under optimized conditions, monitoring ions were ceramide molecular species $(M+H)^+$ for the product ion at *m/z* 264 of the sphingoid base (25–28). Standards and samples were injected with 5 μL of 5 pmol/μL C8:0-ceramide as an internal standard for ESI-MS/MS. The quantity of each ceramide was calculated from each ceramide/C8:0-ceramide ratio, assuming that the calibration curve of ceramides bearing C16–24 acyl chains was similar to that of C16:0-ceramide. This assumption was verified previously (25). Each sample was analyzed in duplicate.

Electrophoresis, blotting, and immunoblot analysis. For electrophoresis, 15 μL of the sample was applied to SDS gel electrophoresis on a 4% polyacrylamide slab gel (1 mm thick) as described (22,29). Immunoblot analysis was performed as previously described previously (21–23). Proteins separated on the gel were eletrophoretically transferred to PVDF membrane filters and immunoblotting analyses of apoB were performed as previously described (23).

Statistical analysis. The data were expressed as mean ± SE. Results were analyzed by a Fisher test or using one-way ANOVA followed by Pearson's correlation test. Differences between group means were considered significant at $P < 0.05$.

RESULTS

Plasma ceramide concentration. Table 2 shows the distribution of ceramide species in human plasma. Major ceramides in plasma were C24:0 and 24:1. Other ceramides, C16:0, C18:0, C22:0, and C24:2, were also detected. These results were consistent with the report of Drobnik *et al.* (30), who reported that C24:0 was the main component, while C18:0 was minor, in the plasma.

Correlation of plasma ceramide level with clinical parameters of atherosclerosis. Total ceramide in the plasma showed a significant positive correlation with TC ($r = 0.651$, $P < 0.01$), TG ($r = 0.444$, $P < 0.01$), phospholipid ($r = 0.660$, $P < 0.01$), and free fatty acid ($r = 0.266$, $P < 0.01$) (Table 3). It did not correlate

TABLE 1
Characteristics of the Subjects[a]

Variable	
Age (years)	60.7 ± 1.2
Body mass index (kg/m^2)	23.5 ± 0.3
Total cholesterol (mg/dL)	219 ± 4
LDL cholesterol (mg/dL)	138 ± 3
HDL cholesterol (mg/dL)	61.5 ± 0.1
Triglyceride (mg/dL)	118 ± 6
Phospholipid (mg/dL)	241 ± 3
Free fatty acid (mg/dL)	0.65 ± 0.03
Blood glucose (mg/dL)	100 ± 4

TABLE 3
Correlation Coefficients of Plasma Ceramide Level with Other Parameters[a]

	Total ceramide	C24:0 ceramide
Total cholesterol	0.651[b] (100)	0.616[b] (100)
Triglyceride	0.444[b] (100)	0.390[b] (100)
Phospholipid	0.660[b] (100)	0.614[b] (100)
Free fatty acid	0.266[b] (100)	0.256[b] (100)
Systolic blood pressure	0.223[a] (100)	0.212[a] (100)
Diastolic blood pressure	0.157 (100)	0.159 (100)

[a]The numbers of subjects are shown in parentheses ([a]$P < 0.05$, [b]$P < 0.01$).

with HDL cholesterol. Total ceramide showed a significant positive correlation with systolic blood pressure ($r = 0.223$, $P < 0.05$), but not with diastolic blood pressure (Table 3). Moreover, positive correlations were observed between total ceramide and apoB, apoC, and apoE (data not shown). Ceramide of C24:0 showed a similar correlation (Table 3).

Relationship between LDL cholesterol and plasma ceramide. The subjects were divided into three groups according to LDL cholesterol level, because correlation of plasma ceramide level with TC was high and LDL cholesterol is the main carrier of cholesterol. The normal group had an LDL cholesterol level of less than 140 mg/dL ($n = 52$, LDL cholesterol average: 113.3 mg/dL), the moderate group had an LDL cholesterol level from 140 to 170 mg/dL ($n = 30$, LDL cholesterol average: 152.4 mg/dL), and the high group had an LDL cholesterol level of more than 170 mg/dL ($n = 20$, LDL cholesterol average: 184.4 mg/dL). The high group showed a significantly higher level of total ceramide than the normal and the moderate groups (Fig. 1).

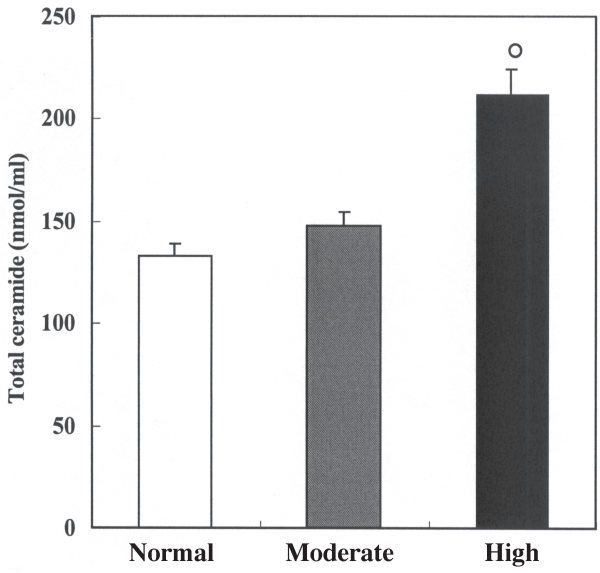

FIG. 1. The relationship between LDL cholesterol and total ceramide in plasma. The normal group had LDL cholesterol levels of less than 140 mg/dL. The moderate group had LDL cholesterol levels from 140 to 170 mg/dL. The high group had LDL cholesterol levels of more than 170 mg/dL. Values are expressed as means ± SE. ○P < 0.01 vs. normal group.

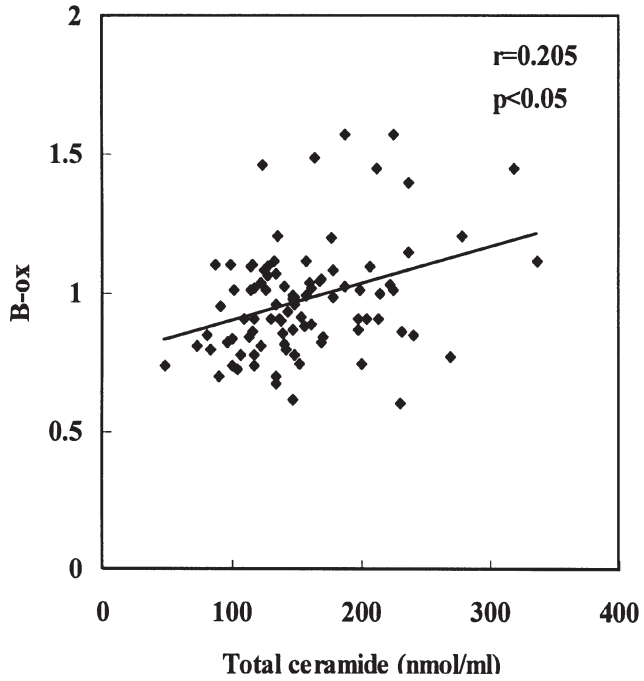

FIG. 2. Correlation coefficient of total ceramide with B-ox in plasma. We introduced an index "B-ox" to quantify the sum of fragmented and conjugated apolipoprotein B-100, products of radical reaction of LDL (23).

Correlation of plasma ceramide level with B-ox. Total ceramide showed a significant positive correlation with B-ox ($r = 0.205$, $P < 0.05$) (Fig. 2). Similar correlations ($r = 0.204$, $P < 0.05$) were observed when C24:0 was tested instead of total ceramide.

DISCUSSION

In this study, we measured the plasma levels of ceramides using ESI-MS/MS. Major ceramides of human plasma were C24:0 and C24:1. Plasma ceramide fatty acids of our study were different from that of Gorska *et al.* (31) and plasma SM fatty acids of Myher *et al.* (32,33). These differences may be due to the difference of analysis methods. Sphingolipids such as ceramide and sphingosine-1-phosphate are bioactive lipid mediators (34). The importance of sphingolipids as mediators in cardiovascular pathophysiology has recently been reported (35,36). In our results, ceramide showed significant positive correlations with TC and TG. These results suggested that an increase in plasma ceramide correlated directly with well-known lipid risk factors of atherosclerosis.

Since the correlation coefficient of cholesterol and total ceramide was high, we examined the relationship between LDL cholesterol and total ceramide in plasma. The subjects were divided into three groups according to LDL cholesterol level. As a result, the high group in LDL cholesterol showed dominantly high ceramide level. Ceramide can be generated by hydrolysis of sphingomyelin, catalyzed by SMase (1). It was reported that treatment of LDL with SMase induces aggregation and foam

cell formation (13,14,37). Therefore, there might be correlation between ceramide increases in plasma and high level of aggregated LDL. Thus, a ceramide increase in plasma may contribute to atherogenesis.

OxLDL is assumed to play a key role in the inflammatory process in atherosclerotic lesions (15). The protein part of LDL, apoB, undergoes fragmentation and cross-linking by radical oxidation (19,20,22,38–41). ApoB has an unusually high reactivity to radical reactions among plasma proteins and its reactivity is almost comparable to α-tocopherol (21), a typical antioxidant. The extremely high reactivity of apoB to radical reactions explains why fragmented and cross-linked apoB proteins exist in normal human plasma (22,23). These studies indicate that B-ox representing the fragmentation and cross-linkage pattern of apoB reflects the oxidative stress in individuals, and that it may be a mechanism-based index for atherosclerosis (23). Ceramide concentrations in plasma showed a significantly positive correlation with B-ox. It is possible that oxidation of LDL stimulates ceramide production and *vice versa*.

OxLDL has been shown to promote macrophage recruitment and apoptosis of endothelial cells, as well as to activate the SMase-ceramide pathway in vascular smooth muscle cells (42–44). Therefore, it is suggested that ceramide, which is increased in oxLDL, induces apoptosis in endothelial cells and is related to atherogenesis. However, oxLDL-induced activation of the SMase-ceramide pathway has not yet been fully studied (45). The relationship between ceramide and oxLDL, especially B-ox, should be further examined.

The results of our study show for the first time that ceramide concentrations in human plasma had a significantly positive correlation with products of a radical reaction of LDL, and lipid markers that associated with atherogenesis. Ceramides have been shown to cause apoptosis in a variety of cells and apoptosis of endothelial cells is widely implicated in the early stage of atherosclerosis. Therefore, an increase in plasma ceramide may be a risk factor at the early stages of atherosclerosis. It is necessary to examine the underlying mechanism by biochemical studies.

ACKNOWLEDGMENT

This work was supported by the Ministry of Education, Culture, Sports, Science, and Technology of Japan and a Research Grant for Cardiovascular Diseases (14C-6) from the Ministry of Health, Labour and Welfare.

ABSTRACT: Regiospecific and traditional analysis, of both storage and membrane lipids, was performed on gill, white muscle, and red muscle samples taken from Atlantic salmon (*Salmo salar*) to gauge the effect of elevated water temperature. The fish, fed a commercial diet, were held at an elevated water temperature of 19°C. Total n-3 PUFA, total PUFA, and n-3/n-6 and unsaturated/saturated fatty acid (UFA/SFA) ratios in the FA profile of the total lipid extract in the white muscle were fairly low compared with fish grown at 15°C. Adaptation of structural and storage lipids at elevated temperatures was shown by a significant ($P < 0.01$) reduction in PUFA especially in the percentage of EPA (6–8%). Further adaptation was indicated by the percentages of SFA, which were significantly ($P < 0.05$) higher in gill (56%) and white muscle (58%) polar lipid fractions and coincided with lower percentages of n-3, n-6, and total PUFA. The regiospecific profiles indicated a high affinity of DHA to the *sn*-2 position in both the TAG (61–68%) and polar lipid (35–60%) fractions. The combination of detailed regiospecific and lipid analyses demonstrated adaptation of cell membrane structure in Atlantic salmon grown at an elevated water temperature.

Paper no. L9837 in *Lipids 41*, 865–876 (September 2006).

Examination of the regiospecificity profile of the lipid classes of Atlantic salmon (*Salmo salar* L.) at an elevated temperature of 19°C has yet to be fully investigated. Regiospecificity is the position of individual FA on the glycerol backbone of both storage and membrane lipids. These lipids are present and act in the body as complex molecules and therefore should be studied as whole molecules. Traditional lipid class and FA profiling provides important compositional information; however, it does not reveal the regiospecific details of the molecule, which can play a key role in their function including bioactivity in humans and other animals (1–3).

The FA composition of lipids is important, but so too are the particular combinations of FA within individual phospholipid classes (4). Up to 70 different polar lipid (PL) molecular species have been identified for a range of different fish species (5–8), and their diversity and abundances can depend on species, tissue sampled, dietary and environmental factors (9). The composition of these molecular species and their role in the cell membrane can be influenced by many factors, but little is known about how they function in fish.

With advances in analytical and computing facilities, new techniques and methods can be used to examine intact lipids and focus on the regiospecific distribution of specific FA. Electrospray ionization reversed-phase liquid chromatography-MS (ESI RP-LCMS) provides a rapid and accurate method to measure molecular species. This method provides regiospecific information on how membranes adapt to different factors such as temperature, hormonal states, and photoperiod. This method has had only limited application to Atlantic salmon (10) and it has yet to be used to explore a range of tissues.

The regiospecific distribution of the TAG fraction of salmon has been examined by ^{13}C NMR (11). The regiospecific distribution of the TAG fraction may affect its physical characteristics and potentially have a profound influence on function and resultant bioactivity to consumers (1,2). It was first shown in infant nutrition that the regiospecific distribution of FA in the diet affects their absorption (3). Therefore, absorption of the long-chain PUFA (LC-PUFA) by human consumers of salmon may be affected by position on the TAG molecule.

Regiospecific analysis has been performed for other fish species *via* destructive and/or time-consuming methods, such as using lipases (12,13) and TLC combined with HPLC (5,7,8,14). These two techniques allow a rapid and detailed examination of intact membrane and storage lipids. In studying intact molecules it is possible to determine the regiospecificity of the FA and whether the molecular structure plays a role in their function, storage, and absorption, in particular in regard to n-3 LC-PUFA.

The physical properties of cell membranes and their lipid content can be affected by temperature (13,15–18). Fish may exploit the structural diversity of lipids within their membranes to adapt to physical properties, such as change in ambient temperature. The tailoring of membrane lipid composition is probably the most ubiquitous and continuously graded cellular response to temperature change (13). Most studies have investigated Atlantic salmon lipids within a temperature range of

2–12°C (19–22), but none have measured salmon at higher temperatures such as 19°C, a temperature that is now commonly encountered by farmed salmon in Tasmanian waters and that approaches their upper threshold for survival (23).

This is the first detailed examination, including regiospecific profiling, of the membrane and storage lipids of salmon from a feeding experiment performed at an elevated temperature of 19°C. This study aims to combine and apply these two regiospecific analyses for both storage and structural lipids from a range of different tissues. With global waters increasing in temperature, this study will indicate possible adaptive changes in salmon lipid makeup at elevated temperature.
