REVIEW

Astonishing Diversity of Natural Surfactants: 7. Biologically Active Hemi- and Monoterpenoid Glycosides

Valery M. Dembitsky*

Department of Organic Chemistry and School of Pharmacy, Hebrew University, Jerusalem, Israel

ABSTRACT: This review article presents 90 hemi- and 188 monoterpenoid glycosides, isolated and identified from plants and microorganisms, that demonstrate different biological activities. These natural bioactive glycosides are good prospects for future chemical preparations from these compounds as antioxidants and as anticancer, antimicrobial, and antibacterial agents. These glycosidic compounds have been subdivided into several groups, including hemiterpenoids; acyclic, monocyclic, and bicyclic monoterpenoids; and iridoid monoterpenoids.

Paper no. L9886 in *Lipids 41*, 1–27 (January 2006).

Terpenes (terpenoids) are the second-largest group of secondary metabolites (nearly 23,000 are known). They are incredibly diverse in structure and activity, even though they all originally derive from a simple molecule called isoprene. Many terpenes are hydrocarbons, but oxygen-containing compounds such as alcohols, aldehydes, or ketones (terpenoids) are also isolated from natural sources. Their building block is the hydrocarbon isoprene CH_2=C(CH_3)–CH=CH_2. The German chemist Otto Wallach was the first to propose that monoterpenoids were constructed of a linkage of isoprene units (in head-to-tail form) (2). Wallach (born March 27, 1847, in Königsberg, died February 26, 1931, in Göttingen) was awarded a Nobel Prize in Chemistry in 1910. His interest began with the analysis of fragrant essential oils—oils removed from plants by steam distillation, with industrial uses; he then started researching their molecular structure. Wallach succeeded in determining the structure of several terpenes, including limonene, in 1895 (3,4). He showed that terpenes were derived from isoprene, C_5H_8—his "isoprene rule"—and therefore had the general formula $(C_5H_8)_n$.

Such compounds were classified by molecular size in a way that was systematic, but not consistent with the idea of isoprene as the structural unit. Later, Leopold (Lavoslav) Ruzicka (pronounced closely following the French transcription, "Rougitchka"; born on September 3, 1887, in Vukovar, Croatia; died on September 26, 1976, in Zürich, Switzerland) (5,6) formulated a classification system in which he defined monoterpenes as having carbon skeletons with two 5-carbon isoprene units, sesquiterpenes with three isoprenes, and so on. In 1953 his "biogenetic isoprene rule," which was pioneered by Wallach, became the crowning achievement of his lifetime. Ruzicka's main work, started in 1921, involved macrocyclic compounds, higher terpenes, and steroids. He shared the Nobel Prize with Adolf Friedrich Johann Butenandt (1903–1995) in 1939.

The hemiterpene isoprene, which contains five carbons (one isoprene unit, C_5), is a gas emitted into the atmosphere by many plant species. A monoterpene (monoterpenoid) contains 10 carbons (two isoprene units, C_{10}); a sesquiterpene, 15 carbons (three isoprene units, C_{15}); and a diterpene, 20 carbons (four isoprene units, C_{20}). Sesterpenes (five isoprene units, C_{25}) were isolated from insect protective waxes and from fungal sources. Triterpenes (six isoprene units, C_{30}) are important structural components of plant cell membranes. Many plant pigments, including the yellow and red carotenoids, are tetraterpenes (eight isoprene units, C_{40}). Natural rubber is a polyterpene containing more than 40 isoprene units (7,8).

Terpenes are largely found in essential oils, and they were known and used in ancient Egypt for various religious aims. The terpene camphor, obtained from the camphor tree (*Cinnamomum camphora* syn. *Laurus camphora*, Lauraceae) was used to reduce fevers, soothe gums, and treat epilepsy. Camphor trees are native to China and Japan and are cultivated for their wood for the extraction of camphor oil. Marco Polo was the first to note that the Chinese used camphor oil as a medicine, scent, and embalming fluid. Camphor crystals have strong antiseptic, stimulant, and antispasmodic properties and are applied externally as unguents or balms as a counterirritant and analgesic liniment to relieve arthritic and rheumatic pains, neuralgia, and back pain. It may also be applied for skin problems such as cold sores and chilblains, and used as a chest rub for bronchitis and other chest infections. Camphor was introduced in Europe from the East by the Arabs around the 11th century. The process of obtaining plant essential oils by fat extraction was known by the early Middle Ages. These compounds have important uses as flavorings and perfumes, as well as intermediates in the production of other commercial products such as solvents and adhesives. Many terpenes play roles as plant hormones and in the chemical defenses of plants against microbial diseases and insect herbivores; many others have important medicinal properties. Many terpenoids and isoprenoids are toxic to insects, and a few are also repellents and toxicants to subterranean termites, although the mechanism of toxicity is not well known.

Iridoids, a widely distributed class of natural monoterpenoids, have shown encouraging biological activities including hepatoprotective, anticancer, immunostimulant, and antileishmanial activities (9,10).

Abbreviations: IPP, isopentenyl diphosphate; MEP, methylerythritol phosphate.

Hemi- and monoterpenoid glycosides are representatives of a water-soluble group isolated from terrestrial and marine plants and organisms. They can be subdivided into several known groups including hemiterpenoids, monoterpenoids (acyclic, monocyclic, and bicyclic), and iridoid monoterpenoids and are presented in this review article.

HEMITERPENOID GLYCOSIDES AND RELATED COMPOUNDS

A small group of terpenes named hemiterpenes are made up of one 5-carbon unit (or from C5 to C9), and are the simplest of all terpenes. Isoprene is emitted from the leaves of many plants, and experimental data have been partly reviewed in some articles (11–15). Hemiterpenes accumulate in plant tissues and can be found in association with other compounds such as alkaloids, coumarins, phenols, and/or flavonoids (16,17).

Plants have been shown to use the mevalonate pathway for the biosynthesis of sterols and triterpenes in the cytoplasm and to use the recently discovered deoxyxylulose phosphate pathway for the biosynthesis of a variety of hemiterpenes, monoterpenes, and diterpenes, as well as for the biosynthesis of carotenoids and the phytol side chain of chlorophyll in plastids (18). In higher plants, the five-carbon building blocks of all terpenoids, isopentenyl diphosphate (IPP), and dimethylallyl diphosphate are derived from two independent pathways localized in different cellular compartments (19). The methylerythritol phosphate (MEP, or nonmevalonate) pathway, localized in the plastids, is thought to provide IPP and dimethylallyl diphosphate for hemiterpene, monoterpene, and diterpene biosynthesis, whereas the cytosol-localized mevalonate pathway provides C_5 units for sesquiterpene biosynthesis. It has been shown that only one of the two pathways, the plastid-localized MEP pathway, is active in the formation of volatile terpenes. The MEP pathway provides IPP precursors for both plastidial monoterpene and cytosolic sesquiterpene biosynthesis in the epidermis of snapdragon petals. The trafficking of IPP occurs unidirectionally from the plastids to the cytosol. The MEP pathway operates in a rhythmic manner controlled by the circadian clock, which determines the rhythmicity of terpenoid emission (19). Different Salicaceae species contain from 2 to 8% hemiterpenes of the total volatile oil (20).

Foeniculum vulgare, the common fennel, is a biennial or perennial plant with a whitish, tap-shaped root, the whole herb being smooth and of a deep glaucous green. It inhabits the southern parts of Europe and is naturalized in Japan, Kurdistan, Malaysia, Mexico, Spain, Turkey, and Venezuela. For the medicinal use of its fruit (commonly called seeds), fennel is largely cultivated in the south of France, Saxony, Galicia, and Russia, as well as in India and Persia. Fennel was well known to the ancients and was cultivated by the ancient Romans for its aromatic fruit and succulent, edible shoots.

The *F. vulgare* fruit extract exhibited anti-inflammatory, analgesic, and antioxidant activities (21) and showed acaricidal activities against *Dermatophagoides farinae* and *D. pteronyssinus* (22) as well as antimicrobial activity against some phytopathogenic bacterial species (*Pseudomonas syringae, P. cichorii, P. viridiflava, P. corrugate, P. tolaasii, P. reactans, P. agarici, Erwinia carotovora* subsp. *carotovora, Agrobacterium tumefaciens, Burkholderia gladioli* pv. *agaricicola,* and *Xanthomonas campestris*) (23). Some hemiterpenoid glycosides (**1–9)** were obtained from the water-soluble fraction of the methanol extract of the fennel fruit (*F. vulgare*, Umbelliferae) (24).

A new hemiterpene glucoside, (2*E*)-4-hydroxy-2-methyl-2-butenyl β-D-glucopyranoside **10**, was isolated from Italian populations of *Ornithogalum montanum* (Liliaceae) (25). Four new nonbasic hemiterpenoid glucosides, woorenosides VI **12**, VII **13**, VIII **11**, and IX **14**; the nonglycosidic woorenosides X and XI; and a new acetylated flavone glycoside, woorenoside XII, were isolated from the fresh rhizomes of *Coptis japonica* var. *dissecta* (26). (*S*)-2-Methylbutan-1-yl-β-D-glucopyranoside **15** was isolated in a yield of 0.01% from the leaves of *Bystropogon plumosus* (Lamiaceae) endemic to the Canaries (27). The essential oil of some species of the genus *Bystropogon—B. plumosus*, *B. origanifolius* var. *palmensis*, *B. wildpretii*, *B. maderensis*, and *B. canariensis* var. *smithianus*—showed antimicrobial and antifungal activities (28). A new hemiterpenoic acid glycoside named securiterpenoside **16** was isolated from the Chinese medicinal plant *Securidaca inappendiculata* (Polygalaceae), whose bark is used for bathing and shampooing the hair (29).

Two new hemiterpene glycosides were isolated from wine of the grape *Vitis vinifera* cv. Gewurztraminer and were identified by MS and NMR spectroscopy as *O*-β-D-apiofuranosyl-(1→6)-*O*-β-D-glucopyranosides of 3-methyl-3-butenol **17** and of 3-methyl-2-butenol **18** (30). Two hemiterpene glycosides, (2*Z*)-3-hydroxy-1-methyl-1-propenyl-β-D-glucopyranoside **19** and (2*Z*)-3-hydroxy-2-methyl-1-propenyl-β-D-glucopyranoside **20**, were identified in a water-soluble extract obtained from Riesling grapevine leaves and purified by HPLC (31).

Ilex (holly) is a genus of about 400 species of flowering plants in the family Aquifoliaceae. *Ilex* is the old Latin name for holly (*Ilex aquifolium*) or the aohada holly (*Ilex macropoda*) now being used in medicine (32). Extracts from species of the genus *Ilex* showed proteasome inhibitor activity (33) and were capable of inhibiting advanced glycation end products (34). Phytochemical studies of *I. macropoda* led to the isolation of four new hemiterpene glycosides—(2*E*)-4-hydroxy-2-(hydroxymethyl)-2-butenyl β-D-glucopyranoside **21**, aohadaglycoside A **22**, aohadaglycoside B **23**, and aohadaglycoside C **24**—identified from a bark extract (35).

The hemiterpenoid glucoside 1,1-dimethylallyl β-glucoside **25** was isolated from flower buds of *Musa paradisiacal* (36), and furocoumarin **26**, having a similar structure, was isolated from a methanolic extract of the root and rhizoma of *Glehnia littoralis* (Umbelliferae; Hamabofu in Japanese) (37). A methanolic extract of the roots of *Streptocaulon juventas* showed strong antiproliferative activity against the highly metastatic human HT-1080 fibrosarcoma cell line; two new hemiterpenoids, (4*R*)-4-hydroxy-3-isopropylpentyl β-rutinoside **27** and (*R*)-2-ethyl-3-methylbutyl β-rutinoside **28**, were isolated from this extract (38). Two new hemiterpene glucosides named pubescenosides A **29** and B **30** were isolated from the root of *Ilex pubescens* (39). A pharmacological investigation of pubescenosides A and B indicated that both possessed potent antiplatelet aggregation activities.

Acylated hemiterpenoid glycosides called hymenosides A **31**, B **32**, C **33**, D **34**, E **35**, and F **36**, where HPA = 4-hydroxyphenylacetate, were isolated from a methanolic extract of the Japanese fern *Hymenophyllum barbatum* belonging to the family Hymenophyllaceae (40). Hymenosides K **37**, Q **38**, R **39**, S **40**, L **48**, M **43**, N **45**, O **46**, P **47**, W **44**, and U **49** and the methyl ester of 3-(β-D-glucopyranosyloxy)-5-hydroxy-hexanoic acid, **50**, were identified from the same species (41). The structures of those aglycons were divided into four types: 2-methyl-but-2-ene-1,4-diol, 2-hydroxymethyl-but-2-ene-1,4-diol, 2-methylene-butane-1,3,4-triol, and 3-hydroxy-5-hexanolide. The sugar moieties, which were acylated by phenylacetic acid derivatives, were also established by chemical and spectroscopic methods. Eight glucosides of the isolated compounds had a bitter or weakly pungent taste. It is clear that a phenylacetyl group attached to a glucose or allose as an ester is responsible for the bitter taste. In addition to the hymenosides discovered, **31**–**50**, three new acylated hymenosides—hymenosides G **51**, H **52**, and I **53**—were identified from a methanolic extract of

H. barbatum (42). Hemialboside **54**, (*S*)-1-hydroxy-3-methyl-but-3-en-2-yl-β-D-glucopyranoside, was isolated from *Lamium album* (43).

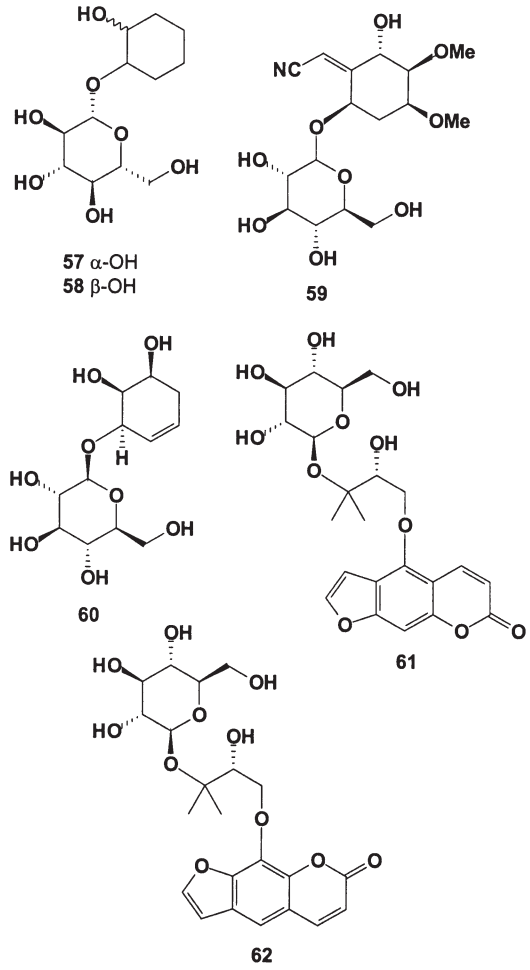
Streptocaulon juventas, a plant in the Asclepiadaceae family, is native to Indochina. This plant is called Ha thu o trang in Vietnam, and its roots are used as a tonic for anemia, chronic malaria, rheumatism, menstrual disorders, neurasthenia, and dyspepsia as an equivalent of Ha thu o do (the roots of *Polygonum multiflorum*, Polygonaceae). A methanolic extract of the roots of *S. juventas* strongly and selectively inhibited proliferation of the human HT-1080 fibrosarcoma cell line (IC_{50} value, 1.2 μ/mL) (44–47). Two hemiterpenoids, **55** and **56**, were isolated from the roots of *S. juventas* (48).

Two rare hemiterpene cyclohexyl glucosides, **57** and **58**, were isolated from the water-soluble portion of rhizome methanolic extracts of *Atractylodes lancea* and *A. japonica* (49). Simmondsin **59** is an unusual 2(cyanomethylene)cyclohexyl glucoside from *Simmondsia californica* (50). A 70% ethanolic extract of the root bark of *Alangium platanifolium* showed binding activities to nine receptors in the central nervous system and contained (1*S*,5*R*,6*R*)-5,6-dihydroxy-2-cyclohexen-1-yl-β-D-glucopyranoside **60** (51). An ethyl acetate extract of the stems and roots from *Prangos pabularia* (Umbelliferae) afforded two complex hemiterpeneoid glucosides, named oxypeucedanin **61** and *tert-O*-β-glucosylheraclenol **62**

(52). The leaves and blossoms of this plant, which grows wild in central Asia, are usually used as fodder for cattle.



Some γ-pyrone derivatives, such as pyrocomenic acid, kojic acid, comenic acid, 3-(acetoyloxy)-4(*H*)-pyran-4-one, maltol, ethylmaltol, and hydroxymaltol, are effective in preventing UV-induced suntans or sunburns in humans. These compounds are also effective in bleaching black goldfish and in preventing UV-induced color changes in lotus roots (53). The kojic acid derivatives showed antifungal, antineoplastic, and antileukemic activities (54,55). The 2-pyrones demonstrated potent inhibitory activity against *Bacillus subtilis, Escherichia coli, Staphylococcus aureus, Schizosaccharomyces pombe*, and *Botrytis cinerea*, as well as growth-inhibitory activities in A2780 human ovarian carcinoma and K562 human chronic myelogenous leukemia cell lines using an *in vitro* cell culture system [3-(4,5-dimethylthiazol-2-yl)2,5-diphenyl tetrazolium bromide assay] (56,57).

A glucoside of pyrocomenic acid, 3-(β-D-glucopyranosyloxy)-4H-pyran-4-one **63**, named erigeroside, was isolated for the first time from Dengzhanhua (*Erigeron breviscapus*) (58). Erigeroside had Extra Strength Pain-Off protective effects (2–10 mg/kg) on cerebral ischemia-reperfusion injury in the rat and showed antioxidant and free radical-scavenging abilities *in vitro* (59). More recently, erigeroside **63** was isolated from the flowers of *Stenactis annua* (60) and *E. breviscapus* (61). Glucoside **63** and a 2-methyl derivative named dianthoside (maltol 3-*O*-glucoside) **64** were identified from ethanolic extracts of *E. ramosus* and from *Dianthus* sp., respectively (62). The occurrence of dianthoside **64** in 17 species of Pinaceae (*Abies, Pseudo tsuga, Tsuga,* and *Larix*) was reported (63). Dianthoside **64** was isolated from the needles of *Abies veitchii* and erigeroside **63** in three *Erigeron* species. 3′-*O*-Caffeylerigeroside **65** was obtained from the leaves of *E. annuus* as a new pyromeconic acid derivative (64), together with the γ-pyrone of pyrocomenic acid and its γ-glucoside (erigeroside **63**). Another erigeroside isomer, 6′-*O*-caffeylerigeroside (erigeside I **66**), was obtained from *E. multiradiatus* (65). *Erigeron multiradiatus* is a perennial herb distributed abundantly in the mountainous area of southwestern China; it is used in folk medicine for treating the common cold, a panting cough, rheumatic fever, enteritis, and toothaches. Two new glycosides, erigeside D **67**, together with erigeside I **66**, were isolated from *E. breviscapus* (66). Pyromeconic acid and its β-D-glycoside, **63**, also were extracted from *E. acris* leaves (67).

2*H*-Pyrane and its glucoside, **68**, were isolated from the leaves of *Erigeron annuus* and showed properties as a glycosidase inhibitor (68). The cut leaves of *E. canadensis* stored in an aqueous solution of **68** (1 mg/10 mL) showed neither discoloration nor growth of filamentous fungi as compared with the fragmentation and fungal growth in control leaves. Also, compound **68** completely inhibited the hydrolysis of soluble starch by α-amylase in a potassium phosphate buffer (68). An aqueous ethanolic extract from fresh stems of the cactus *Opuntia dillenii* showed potent radical-scavenging activity (69). This extract contained a new compound, opuntioside I **69**. Kojic acid glucoside **70**, isolated from plant sources, showed a good antiperspirant effect (70). A methanolic extract of the aerial parts of *Adenocaulon himalaicum* (Asteraceae) yielded a new compound, parasorboside **71** (71).

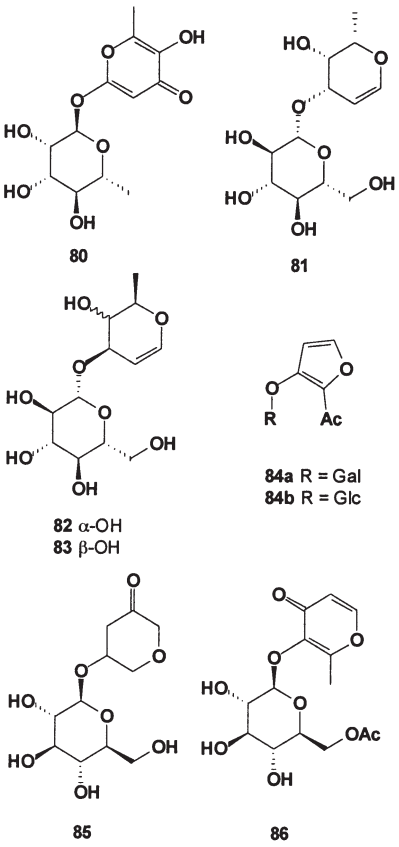
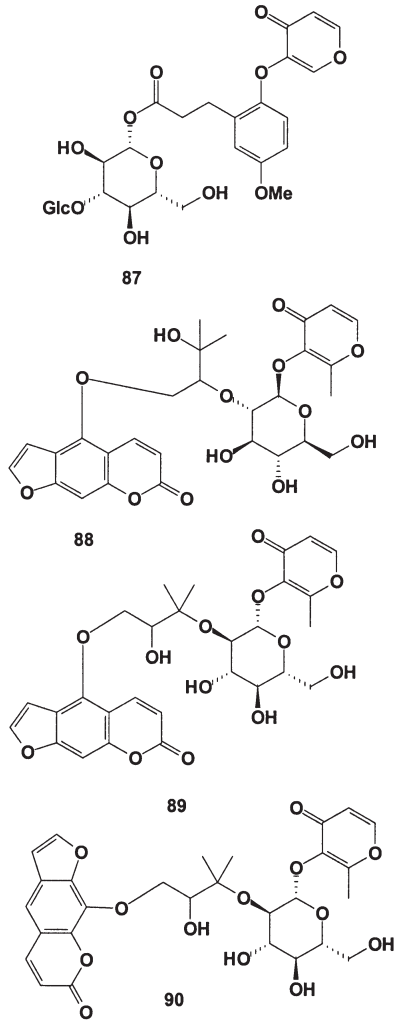
An acylated 4-pyrone glycoside, 2-[6′-*O*-*trans*-cinnamoyl)-β-D-glucopyranosyloxy]-3-methyl-4*H*-pyran-4-one **72**, was isolated from a chloroform–methanol extract of the shoots of *Silene vulgaris* (Caryophyllaceae) (72). Three pyrone glucosidic derivatives, **67**, **73**, and **74**, together with the known pyrocomenic acid glucoside **63**, were obtained from the aerial parts of *Conyza albida* (73). A new acylated γ-pyrone glucoside, **75**, was isolated from the leaf extract of *Gordonia axillaris* (Theaceae) (74). Hydroxymaltol 3-*O*-β-D-glucoside **76**; two maltol glucosides, bockiosides A **77** and B **78**; and isoinnovanoside **79** were isolated from the tuber *Smilax bockii* (Liliaceae) (75).

The new glycosides (2*S*)-eriodictyol-7-*O*-Me ether-3′-*O*-β-D-glucopyranoside **80** and maltol-3-*O*-β-D-glucopyranoside **64** were isolated from the fronds of *Pseudocyclosorus subochthodes* and *Pseudocyclosorus esquirolii* (76). Sapopyroside **81** was isolated from *Saponaria officinalis*, and a new glycoside, barbapyroside **82**, isomeric with the former but

having a different configuration, was isolated from *Dianthus barbatus* and *D. deltoids* (77). Compound **81** was also isolated from *D. superbus* var. *longicalycinus* (78), and **83**, an isomer of barbapyroside **82**, was found in an extract of the aerial parts of the Vietnamese *Helichrysum zeyheri* (Asteraceae) (79). Isomaltal β-D-galactoside **84a** and isomaltol α-D-glucoside **84b** were extracted from milk spiked with this glucosyl β-pyranone **85**, while avoiding the use of any deproteinizing agent, and were detected by a sensitive and interference-free HPLC method (80). Maltol-(6-*O*-acetyl)-β-D-glucopyranoside **86** was isolated from *Prangos pabularia* (52).

A few complex 4*H*-pyrone glycosides with biological activities containing multiple structural units, including pyrocomenic acid, kojic acid, comenic acid, maltol, ethylmaltol, and/or hydroxymaltol, that are not linked with a sugar and/or that contain more than three structural units have been discovered in plant species. A new complex 2-methyl-3-*O*-{2′-[β-D-glucoside-(1‴→3″)-β-D-glucoside]-propionyloxy-4′-methoxyphenyl}-4-pyrone, **87**, was isolated for the first time from whole parts of *Scleranthus uncinatus* (81). Pabularin A **88**, B **89**, and C **90**, three glucosides of γ-pyrone with antibacterial activity and inhibition of cytokine release, were identified from an extract of the roots of *P. pabularia* (52).



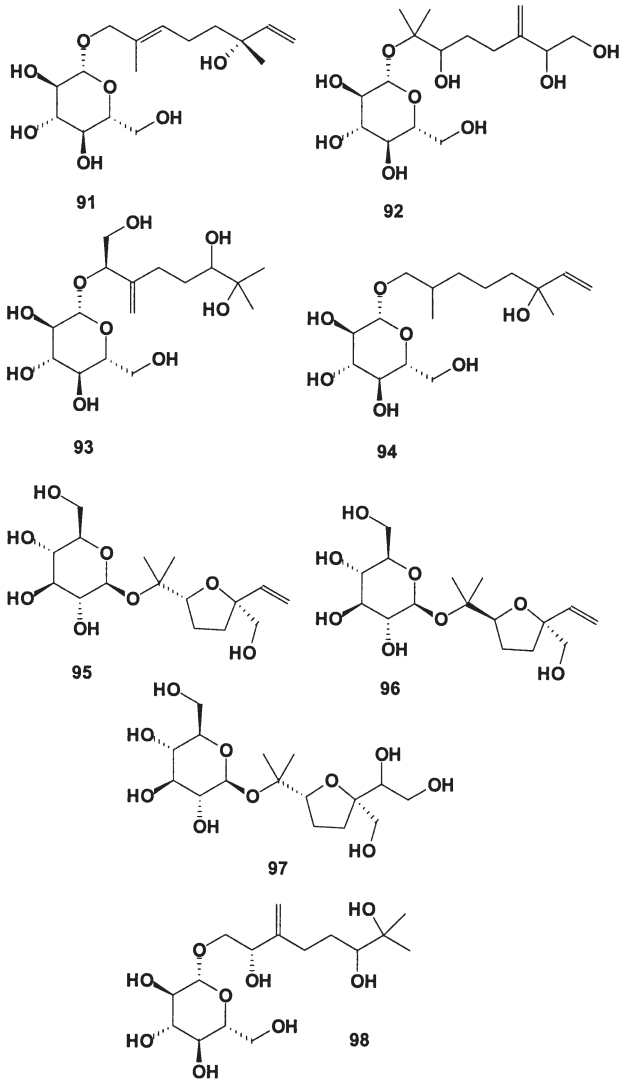


MONOTERPENOID GLYCOSIDES

Monoterpenoids have a head-to-tail formation of their 10-carbon precursor, geranyl pyrophosphate (14,15). Some of their oxygenated derivatives, such as alcohols, ketones, and carboxylic acids, are present in plant volatile oils, and were also identified from microorganisms and some marine sources (82). Monoterpenoids often have a strong smell. They are the source of such scents as spearmint (carvone), bergamot and lavender (both of which contain linalyl acetate), and sweet rose (nerol) (83,84). Acyclic monoterpenoids occur in insect pheromones as well (85,86). Acyclic, monocyclic, and bicyclic monoterpenoids vary in pharmacological use as expectorants, anticholesteremics, anthelmintics, antiseptics, and insecticides (82,84,87). Iridoids are also monoterpenoids based on a cyclopentan-[*C*]-pyran skeleton, which may consist of 10, 9, or (rarely) 8 carbon atoms, in which C_{11} is more frequently missing than C_{10}. This class of monoterpenoids can be subdivided into five groups according to their chemical structures: acyclic (or linear), monocyclic, monocyclic iridoids, bicyclic, and bicyclic iridoids. Glycosidic compounds belonging to all five groups are represented below.

Acyclic Monoterpenoid Glycosides

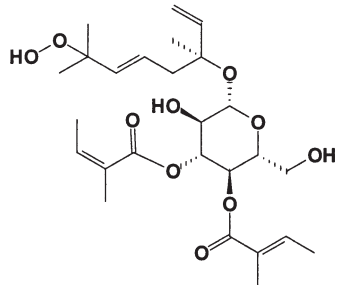
From the water-soluble fraction of a methanolic extract of the herbal medicine fennel (*Foeniculum vulgare*), betulalbuside A **91** and five new acyclic monoterpenoid glycosides, **92–97**, were identified, three of which (**95–97)** contain an oxide linkage (88). Ajowan (*Carum ajowan*, also spelled ajwain, the Hindi name for tiny), which belongs to the family Umbelliferae, is cultivated mainly in southern India and is known as a popular aromatic herb and spice. Its fruit has been used as much for medicine as in cooking, and is primarily used to control flatulence and indigestion. Ajowan contains thymol, which is a germicide and antiseptic, and is prescribed for diarrhea, colic, and other bowel problems to help expel wind and mucus. Sometimes used in the treatment of asthma, the seeds are smoked in a pipe to relieve shortness of breath (89). A methanolic extract of the fruit of *C. ajowan* (ajowan) was found to contain a new acyclic monoterpenoid and its glycoside, **98** (90).



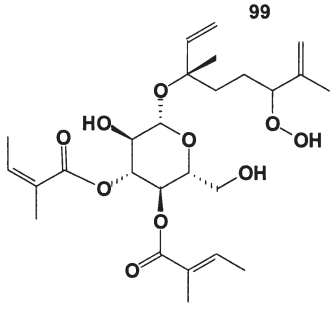
Aster scaber (Asteraceae) has been used in traditional Korean and Chinese medicine to treat bruises, snakebites, headaches, and dizziness. The aerial part of *A. scaber* yielded two new monoterpene peroxide glycosides, (3*S*)-3-*O*-(3′,4′-diangeloyl-β-D-glucopyranosyloxy)-7-hydroperoxy-3,7-dimethylocta-1,5-

diene **99** and (3*S*)-3-*O*-(3′,4′-diangeloyl-β-D-glucopyranosyloxy)-6-hydroperoxy-3,7-dimethylocta-1,7-diene **100** (91).

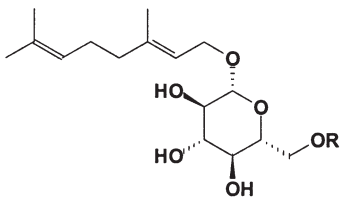
Prunioside A **102**, a unique, highly oxidized monoterpene glycoside, was isolated from a methanolic extract of the roots of *Spiraea prunifolia* var. *simpliciflora* (92). The ester derivatives of prunioside A **102** showed suppressive effects on the generation of nitric oxide in murine macrophage-like RAW 264.7 cells stimulated by lipopolysaccharide and γ-interferon.



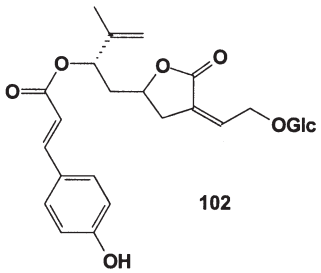
99



100

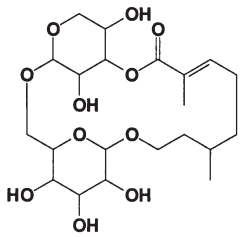


101 R = Rha

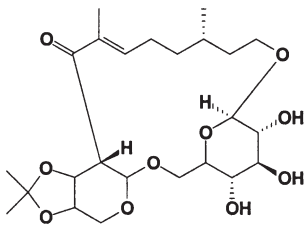


102

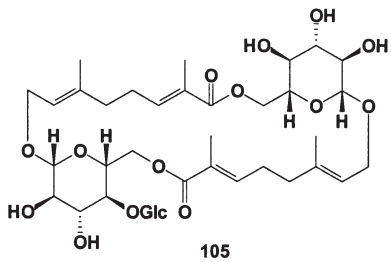
Unusual monoterpenoid glycosides were isolated from extracts of the stem bark of *Winchia calophylla* (93). The new compounds included two cyclodiglycosides, named wincaloside A **103** and wincaloside B **104**. A similar novel monoterpene glycoside, mileenside **105**, was isolated from *Swertia mileensis* (94). *Linaria capraria* (Scrophulariaceae), a species endemic to the Tuscany archipelago (Italy), was found to contain acyclic glucoside **106** (95) and glycoside **107**, and the known betulalbuside A **91** was found in the Turkish trees *Phlomis samia* and *P. carica* (96).



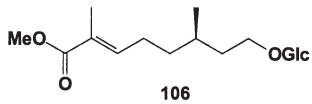
103



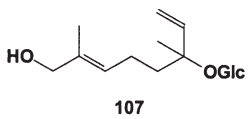
104



105



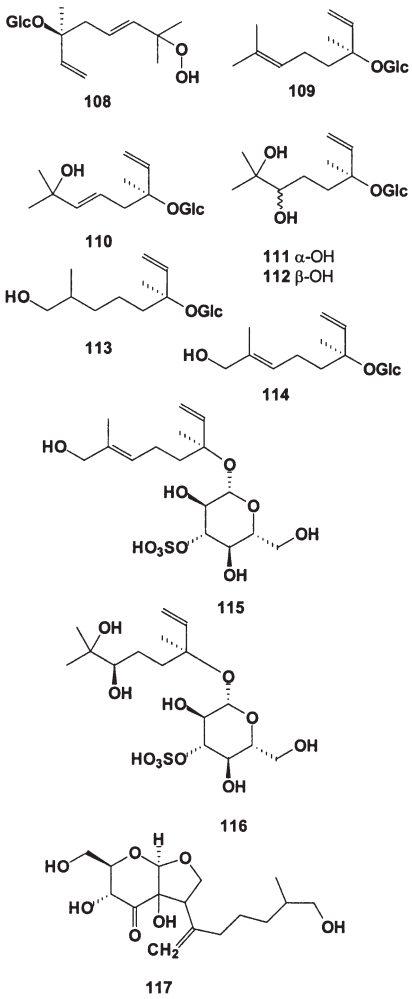
106



107

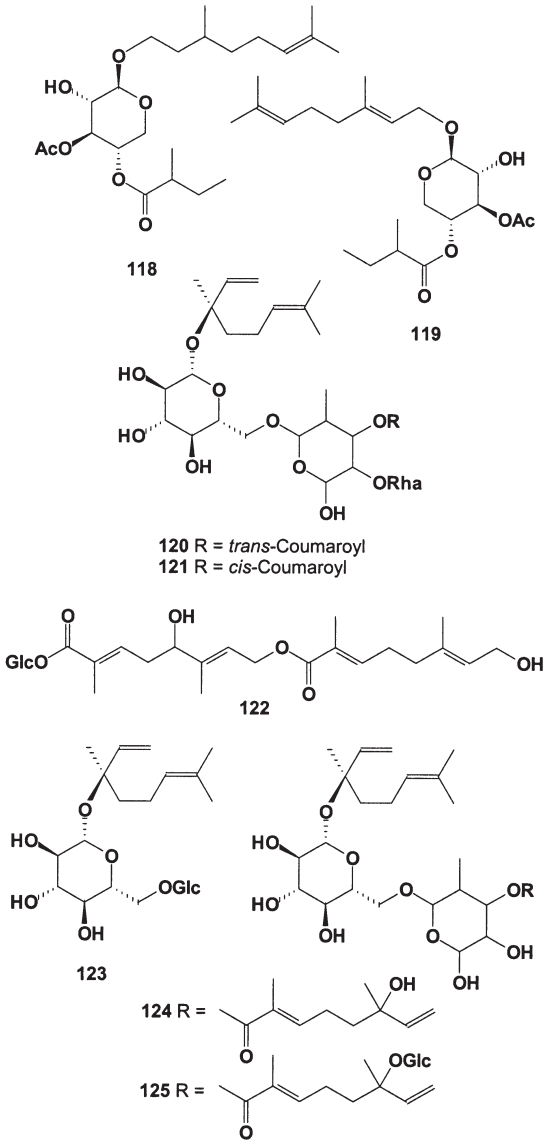
Three monoterpene glucosides, **108**–**110**, including one new hydroperoxide, **108**, were isolated from a methanolic extract of the Korean *Portulaca oleracea* (family Portulacaceae) (97). *Portulaca oleracea*, commonly known as purslane in the United States, is an herbaceous weed. It can be found growing wild and/or cultivated in much of the world. It existed in the New World before the arrival of Columbus and was found in Europe by the late 16th century. Purslane (also called wild portulaca, or pigweed) can be found growing in cold-climate areas (Canada) as well as warm areas (the Caribbean). It has been used in salads and as a medicinal plant for hundreds of years. Both aqueous and ethanolic extracts of *P. oleracea* showed gastroprotective action, validating its use in folk medicine for gastrointestinal diseases; both extracts showed a dose-dependent reduction in the severity of ulcers (98). From the water-soluble fraction of a methanolic extract of coriander (the fruit of *Coriandrum sativum*), which has been used as a spice and medicine since antiquity, four new monoterpenoid glycosides,

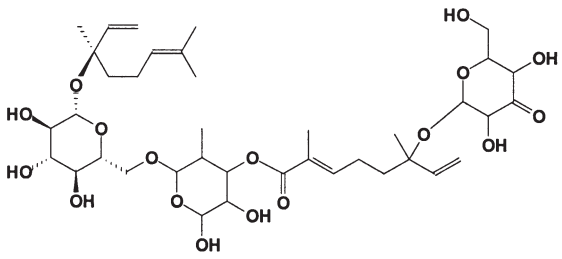
111–**114**, a hemiterpenoid, **6**, and two rare new monoterpenoid glucoside sulfates, **115** and **116**, were identified (99). An unusual monoterpene glycoside named dissectol A **117** was isolated from the ethanolic extract of *Incarvillea dissectifoliola* (100,101). Antimicrobial bioassays showed that **117** had modest inhibitory activity against *Mycobacterium tuberculosis* when compared with rifampicin in an agar diffusion assay.



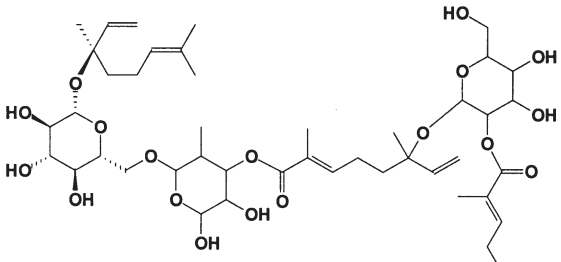
Polemonium viscosum (blue whirl) yielded several new diterpenes with labdane and pimarane skeletons and two new monoterpene glycosides, **118** and **119** (102). Two monoterpene glycosides, (3*S*)-*O*-α-L-rhamnopyranosyl-(1→3)-[4-*O*-(*E*)-coumaroyl]-α-L-rhamnopyranosyl-(1→6)-β-D-glucopyranosyl-linalool **120** and (3*S*)-*O*-α-L-rhamnopyranosyl-(1→3)-[4-*O*-(*Z*)-coumaroyl]-α-L-rhamnopyranosyl-(1→6)-β-D-glucopyranosyl-linalool **121**, were isolated from a methanolic extract of the leaves of *Eriobotrya deflexa* (103). Digipenstroside **122**, a novel dimeric open-chain monoterpene glucoside, was isolated from the leaves of *Penstemon digitalis* (104).

Five new acyclic monoterpene glycosides were isolated from the leaves of *Viburnum orientale* (Caprifoliaceae) (105): monoterpene diglycoside anatolioside **123**, and four derivatives of **123** containing additional monoterpene and sugar units connected by ester and glycoside bonds, i.e., anatoliosides A **124**, B **125**, C **126**, and D **127**. A new open-chain monoterpene glycoside, anatolioside E **128**, was isolated from the leaves of *V. orientale* in addition to the known acyclic monoterpene glycosides betulalbuside A **91**, betulalbuside B **129**, and glucoside **114** (106). The two stereoisomeric monoterpenoid glycosides, betulalbusides A **91** and B **129**, were also isolated from the leaves of *Betula alba* (Betulaceae) and from the fruits of *Chaenomeles japonica* (Rosaceae) (107).

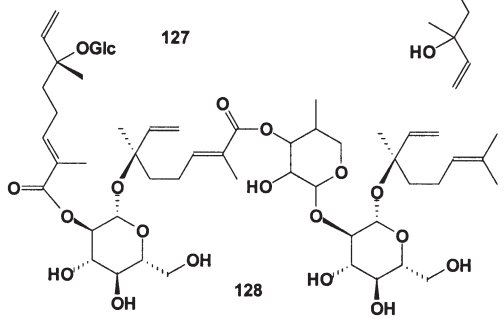




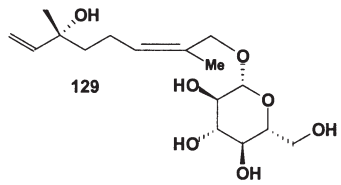
126



127

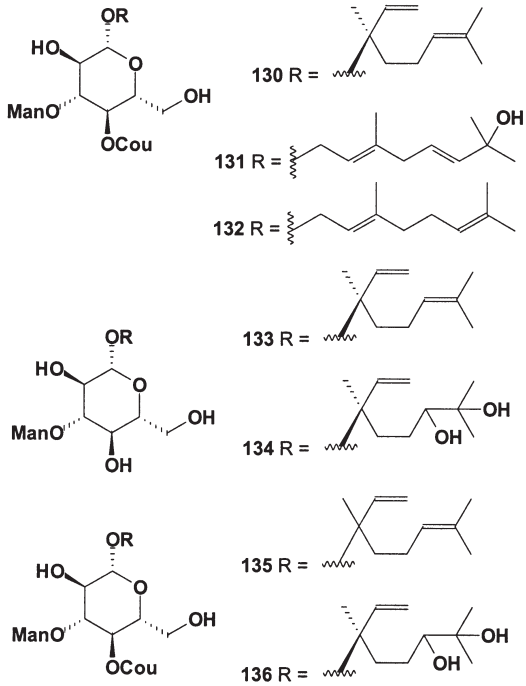


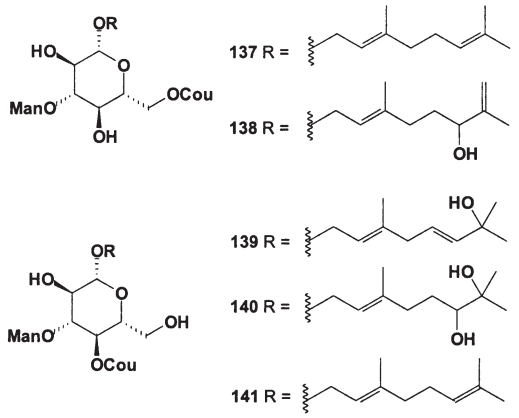
128



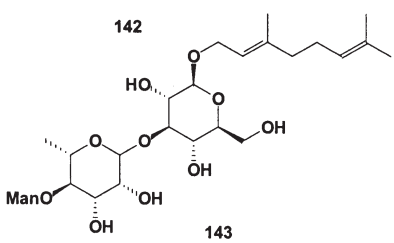
129

Lipedoside B III **130** (also known as lipedoside B IIIb) and two new monoterpene glycosides, kudingosides A **131** (also known as ligurobustoside C) and B **132** (also known as ligurobustoside I), were isolated from the bitter tea Ku-Ding-Cha (*Ligustrum pedunculare*) (108). Kudingosides A and B inhibited acyl-CoA:cholesterol acyltransferase, with IC_{50} values of 2.70×10^{-3} M and 2.88×10^{-3} M, respectively. Five monoterpene glycosides, lipedosides B-I **133**, B-II **135**, B-III **130**, B-VI **134**, and B-V **136**, were isolated together with three known constituents, anatolioside **123** (the diglycoside of linalool), linalool (not the glycoside), and osmanthuside B (the phenylethanoid glycoside), from *L. pedunculare* (109). The monoterpene glycosides **123**, **130**, and **133**–**136** were also present in the bitter tea (*L. pedunculare*) (110). The crude glycoside fraction was found to strongly protect human LDL from oxidation. The results obtained demonstrated that the bitter tea as a beverage contained effective antioxidants that may have benefits similar to those of green tea in terms of antioxidant activity. The monoterpenoid glycosides named ligurobustosides A **142**, B **141**, C **131**, E **137**, F **138**, I **139**, J **143**, and K **140**, as well as compound **132**, were isolated from the leaves of *Ligustrum robustum* (111).





142



143

A new monoterpene glycoside, 2,6-dimethyl-2*E*,6*E*-octadienoic acid 1,6′-lactone 8-β-D-glucopyranoside **144**, was isolated from *Swertia punicea* (112). A dimeric monoterpenoid glycoside having a structure similar to mileenside **105**, named diclirip ariside A **145**, was isolated from an aqueous ethanolic extract of the whole plant *Dicliptera riparia* (113).

Acidic fractions obtained from the roots of *Paeonia peregrina* and *Paeonia tenuifolia* inhibited the growth of *Staphylococcus aureus*, *Escherichia coli*, and *Candida albicans* (114). The roots of *P. peregrina* afforded two new acylated "cage-like" monoterpene glucosides, named paeonidaninols A **146** and B **147** (115). Paeoniae Radix (*Paeonia lactiflora*), a Chinese herbal extract, inhibited hepatoma cell growth by inducing apoptosis in a p53-independent pathway (116). A similarly active monoterpene glycoside, 6-*O*-β-D-glucopyranosyl-lactinolide **148**, was isolated from the Japanese Paeoniae Radix (*P. filciflora*); **148** was found to inhibit the release of histamine from rat peritoneal exudate cells induced by an antigen–antibody reaction (117).

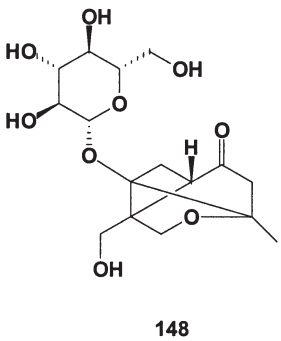
146 α-OH
147 β-OH



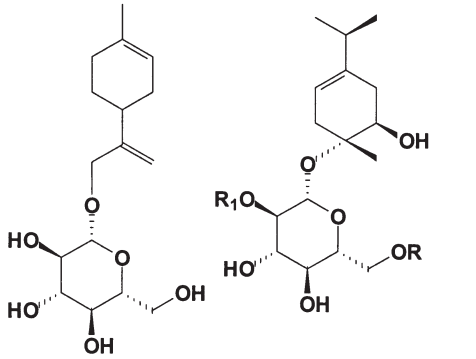
148

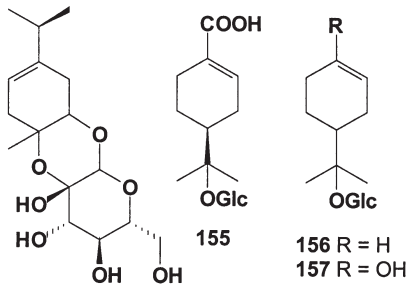
Monocyclic Monoterpenoid Glycosides

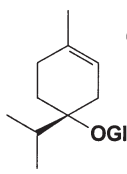
Dracocephalum kotschyi is a wild-growing flowering plant belonging to the family Labiatae found abundantly in southwestern Asia. *Dracocephalum kotschyi* has been used for several years as a medicinal herb in Iranian folk medicine for its antispasmodic and analgesic properties. Antihyperlipidemic and immunomodulatory effects have also been reported for *D. kotschyi* (118,119), and the essential oil from Iranian *D. kotschyi* has shown antivisceral pain effects in mice (120). From the whole plant of *D. kotschyi*, two new monoterpene glycosides were isolated, **149** and **150** (121). Their structures were detected as limonen-10-ol 10-*O*-β-D-glucopyranoside and limonen-10-ol 10-*O*-β-D-glucopyranosyl-(1→2)-β-D-glucopyranoside, respectively. The isolated compounds **149** (3.1 μM) and **150** (3.1 μM) were effective against epimastigotes of *Trypanosoma cruzi*.

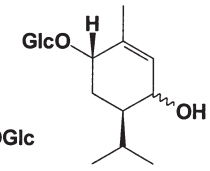
Thyme, the humble plant from the western Mediterranean (*Thymus vulgaris*, Labiatae), is among those plants having many different common names, such as broadleaf English, Greek gray, and narrow-leaved French. The leaves can be used fresh at any time, but for drying, it is best to cut the fresh growth after the bloom cycle. From a water-soluble extract of thyme (*T. vulgaris*) leaves, which has been used as an important stomachic, a carminative, a component in a prepared cough tea, and herb, the monoterpenoid glycosides **151**–**153** and thymuside A **154** were isolated (122). A new monoterpene glucoside, **155**, was isolated from the twigs and leaves of *Juniperus communis* var. *depressa* (Cupressaceae) collected in Oregon (United States) (123). This isolated compound demonstrated antibacterial activity against the spiral-shaped bacterium *Helicobacter pylori*. The bacterium *H. pylori* can lead to digestive illnesses, including gastritis (the irritation and inflammation of the lining of the stomach), peptic ulcer disease (characterized by sores that form in the stomach or the upper part of the small intestine, called the duodenum), and even stomach cancer later in life.

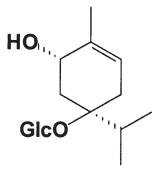
The monoterpenoid profiles of three white grape varieties (Alvarinho, Loureiro, and Avesso) and two red varieties (Amaral and Vinhao) from the Vinhos Verdes region of Portugal were studied for their presence in either free or glycosidically bound fractions (124). Seventeen compounds in the free form and 12 in the glycosidically bound form (**156**–**167**) were identified and quantified. The profiles of the terpene compounds varied to a significant degree for the grape varieties studied and, as was already known empirically, the white varieties were richer than the red varieties, especially for Loureiro.

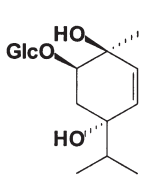


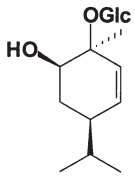


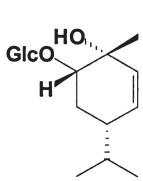






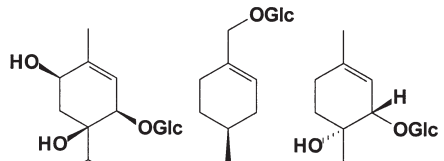


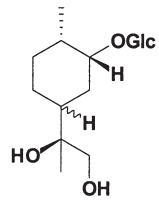


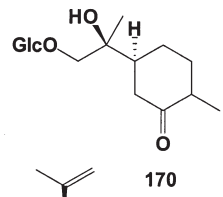


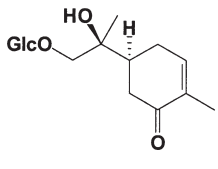
Dill (*Anethum graveolens*, Apiaceae, Umbelliferae) is a very important herb and is grown commercially in India, Pakistan, Egypt, Fiji, Mexico, The Netherlands, the United States, England, Hungary, and Germany. Dill has been used as a medicinal and culinary herb for thousands of years and was cultivated in ancient Egypt, Palestine, Greece, and Rome. An essential oil (0.8–1.6% fresh weight) can be produced from dill that contains carvone, limonene, anethofuran, phellandrene, and other terpenoids. The essential oil of Bulgarian dill seeds that were stored for a long time was analyzed and found to contain the aroma-impact compounds D-carvone (50.1%) and D-limonene (44.1%). The essential oil of *A. graveolens* showed high activity against the mold *Aspergillus niger* and the yeasts *Saccharomyces cerevisiae* and *Candida albicans* (125). From the water-soluble fraction of a methanolic extract of dill (the fruit of *A. graveolens*), 33 compounds were isolated, including six new monoterpenoid glycosides, **168**–**173** (126).

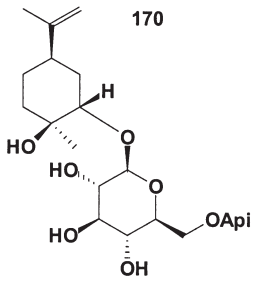
A new monoterpenoid glucoside isolated from Indian *Illicium griffithii* (Magnoliaceae) fruit has been characterized as *p*-menth-1(7),4(8)-diene-3-*O*-β-D-glucoside **174** (127). *Illicium griffithii* is exploited in the industry for its medicinal properties and as a spice (128), and both the seeds and oil of the fruit (star anise) possess the stimulant, diuretic, carminative, and slightly anodyne properties of anise. Monoterpenoid glucoside **175** was found in the water-soluble fraction of the caraway (the fruit of *Carum carvi*) (129). The hypoglycemic effect of aqueous extracts of the fruits of *C. carvi* in STZ rats was reported (130), as were the antioxidant activities of aqueous extracts of five umbelliferous fruits, i.e., caraway (*C. carvi*), coriander (*Coriandrum sativum*), cumin (*Cuminum cyminum*), dill (*A. graveolens*), and fennel (*Foeniculum vulgare*) (131). Monoterpenoid epoxy glucoside **176** was found in the fruit of *Carum ajowan* (ajowan) (90).

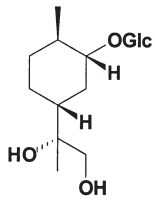


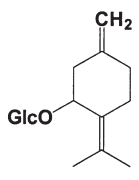


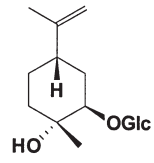


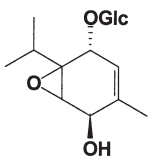










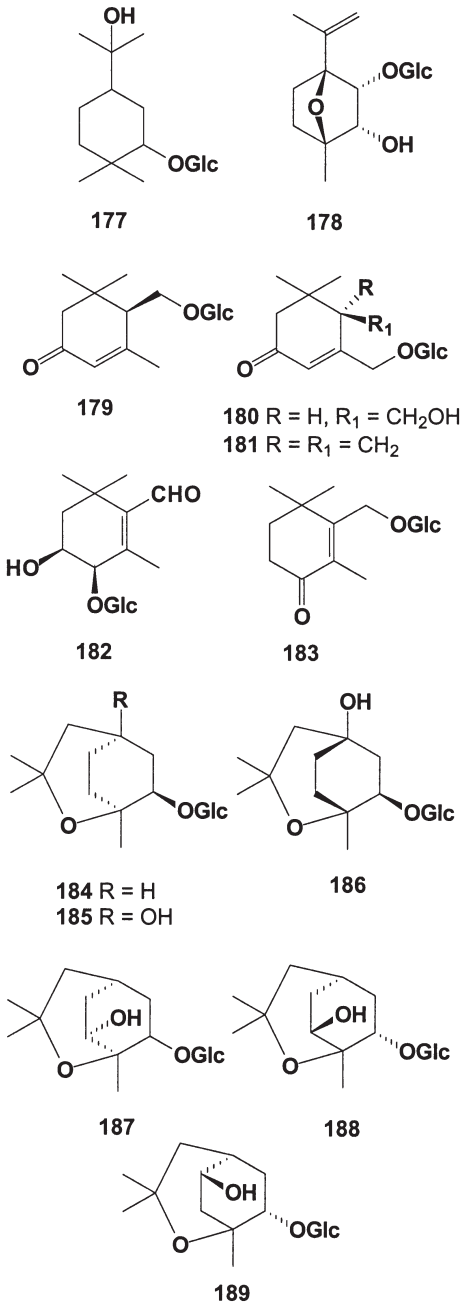


A novel cyclohexanoid monoterpene glucoside named melacoside A **177** was isolated from an aqueous ethanolic extract of the leaves of *Melaleuca quinquenervia* grown in Egypt (132). Melacoside A can possibly play a role in the biogenesis, transport, and accumulation of components of the essential oil of the plant. This compound had not been previously reported in nature. A new monoterpene glucoside called petroside **178** that was isolated from the aerial parts of *Petroselinum crispum* (parsley) showed potent estrogenic activity (133).

The Chinese herb *Gardeniae fructus* (called Huanglin-Jie-Du-Tang in Chinese) could play an important role in the treatment of acute pancreatitis, a common critical emergency illness with a high mortality rate. An extract of *G. fructus* (called Hwangryun-Hae-Dok-Tang in Korean) and its constituents also reduced ischemia-reperfusion brain injury and neutrophil infiltration in rats (134). New monoterpenoids named jasminosides A **179**, B **180**, C **181**, and D **183** and the known **182** have been isolated from *G. fructus* (135).

The genus *Salvia* belongs to the family Lamiaceae (Labiateae), and in Pakistan *Salvia* has been used as a traditional medicine for the cure of different diseases (136). A new monoterpene glycoside (2-exo-β-D-glucopyranosyl-1,8-cineol) named bucharioside **184** was isolated from the methanolic fraction of *Salvia bucharica* (137).

A series of new monoterpene glycosides, foeniculosides V **185**, VI **186**, VII **187**, VIII **188**, and IX **189**, were isolated from the fruit of *F. vulgare* (138).

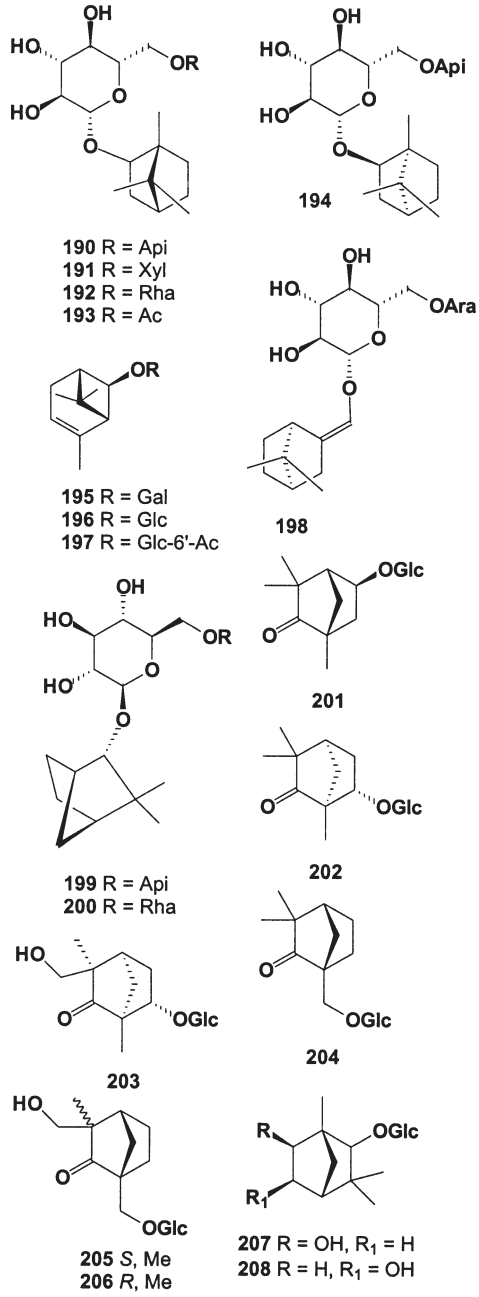


BICYCLIC MONOTERPENOID GLYCOSIDES

Borneol is a simple bicyclic monoterpene, and its structural analog camphor is used for analgesia and anesthesia in traditional Chinese and Japanese medicine. It is found in the essential oils of medicinal herbs such as valerian (*Valeriana officinalis*), chamomile (*Matricaria chamomilla*), and lavender (*Lavandula officinalis*) (139). Extracts of these plants are used traditionally to relieve anxiety, restlessness, and insomnia (140–143). Valerian extracts and essential oils demonstrate significant sedative activity in animal and human studies, providing sedation equivalent to conventional sedative and hypnotic agents while also increasing sleep depth (144,145). (+)-Borneol was found to have a highly efficacious positive modulating action at $GABA_A$ receptors, as did its enantiomer (−)-borneol (146). Borneol, which is derived from pine oil, is used as a disinfectant and deodorant, and camphor is used as a counterirritant, anesthetic, expectorant, and antipruritic, among many other uses.

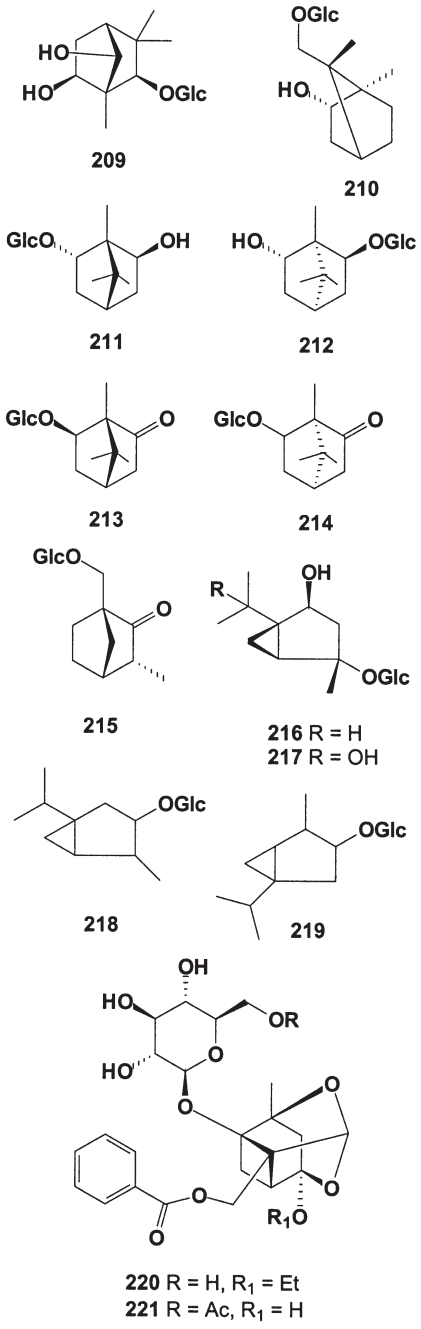
A series of disaccharides of borneol-β-D-glucosides were isolated from different plant sources: **190**, in which Api = apiose, was isolated from Radix Ophiopogonis (147), **191** was isolated from the flower buds of *Gardenia jasminoides* (148), and **192** was isolated from *Ophiopogon japonicus* (Liliaceae) roots (149). Furthermore, a monoacetylated borneol-β-D-glucoside, **193**, was present in the North American Compositae species *Psilostrophe villosa* (150). Glucosides **190** and **194** were found in an ethyl acetate extract of the Vietnamese medicinal plant *O. japonicus* (151,152).

Alcoholic and aqueous extracts of *Picris echoides* are usually used for the treatment of indigestion and against intestinal nematodes and other parasites. A new monoterpenoid glycoside named (−)-*cis*-chrysanthenol-β-D-galactopyranoside **195** was isolated from the aerial parts of *P. echoides* (Asteraceae, tribe Lactuceae) (153). An extract from the same plant contained the (−)-*cis*-chrysanthenol-β-D-glucopyranoside **196** and its 6′-acetate **197** (154). Glucoside **196** was also isolated from the aerial parts of *Artemisia sieberi* (155). A monoterpene glycoside, (*Z*)-(1*S*,5*R*)-β-pinen-10-yl β-vicianoside **198**, was isolated from the roots of *Paeonia lactiflora* (156). Two new monoterpene glycosides named shionosides A **199** and B **200** were obtained from the root of *Aster tataricus* (Compositae) (157). Nine fenchane-type monoterpenoid glycosides, **201**–**209**, were isolated from the water-soluble portion of the methanolic extract of fennel, the fruit of *Foeniculum. vulgare* (Umbelliferae) (158).

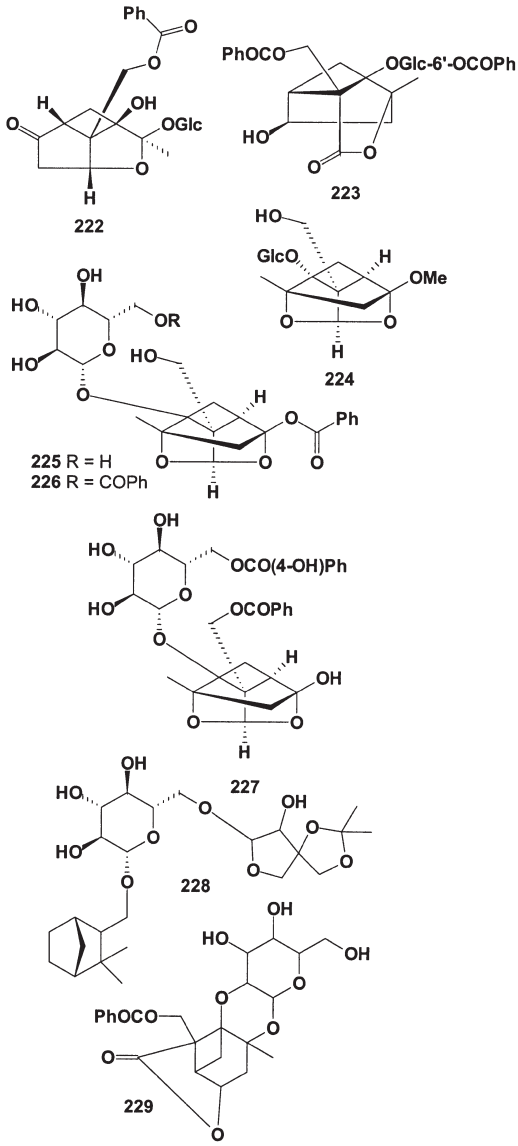


The monoterpenoid glucosides **207** and **210**–**214** were isolated from a methanolic extract of the amomum seed (seed of *Amomum xanthioides*), which has been used as a medicine for

stomachic and digestive disorders (159). Compounds **214** and **215**, and two new thujane-type monoterpenoids, **216** and **217**, were found in fennel extract (160). An extract from the petals of *Tanacetum vulgare* (Compositae, Asteraceae) contained 0.06% of monoterpene β-D-glucosides: isothujol **218** and neoisothujol **219** (161). *Tanacetum vulgare* (commonly known as tansy, golden buttons, or garden tansy) is a perennial herb in the sunflower family. This species, native to Europe, has a long history of medicinal use. It was first introduced to North America for use in folk remedies and as an ornamental plant. The unusual monoterpene glycoside 4-*O*-ethylpaeoniflorin **220** was isolated from the root cortex of *Paeonia delavayi* (162), and acetoxypaeoniflorin **221** was isolated from the root cortex of *Paeonia veitchii* (163).



A series of bicyclic monoterpenoid glycosides have been identified from these plants. A monoterpene glucoside named albiflorin R1 **222** was isolated from the roots of *Paeonia lactiflora* (164). In the structure of albiflorin R1, the aglycon was connected with a glucose at its 2-OH, while the hemiacetal hydroxy in the glucose moiety was free. A monoterpene glycoside named paeonivayin **223** was isolated with seven other known compounds from the roots of *P. delavayi* (165). Debenzoyl paeoniflorin methyl ether **224** was isolated from the roots of *Scrophularia buergeriana* and *Paeonia albiflora* by a soil bacterial hydrolysis method (166). The monoterpene glycosides wurdin **225** and benzoylwurdin **226**, along with the known compounds paeoniflorin, lactiflorin, and oxypaeoniflorin, were isolated from *Paeonia emodi* (167), and mudanpioside C **227** was found in the Japanese Paeoniae Radix (117). An interesting monoterpenoid glucoside named shionoside C **228** was obtained from *Aster tataricus* (168). The roots of *P. lactiflora*, used in traditional Chinese medicine, afforded a monoterpene glycoside named lactiflorin **229** (169).

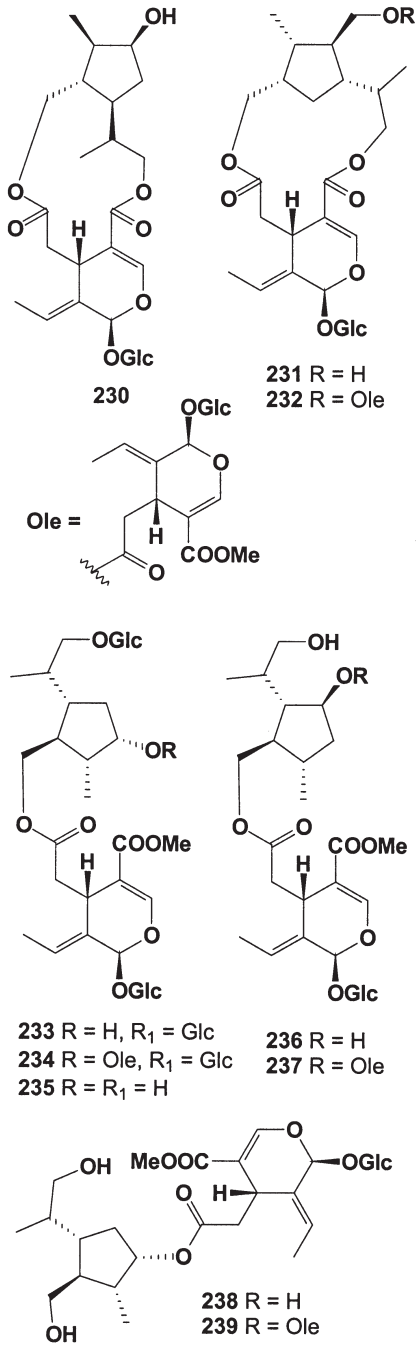


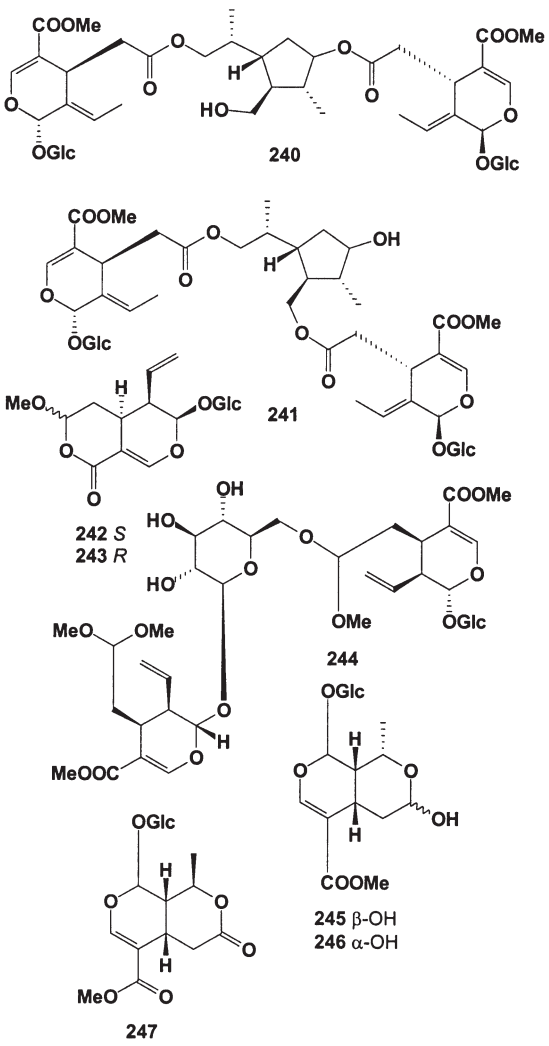
IRIDOID MONOTERPENOID GLYCOSIDES

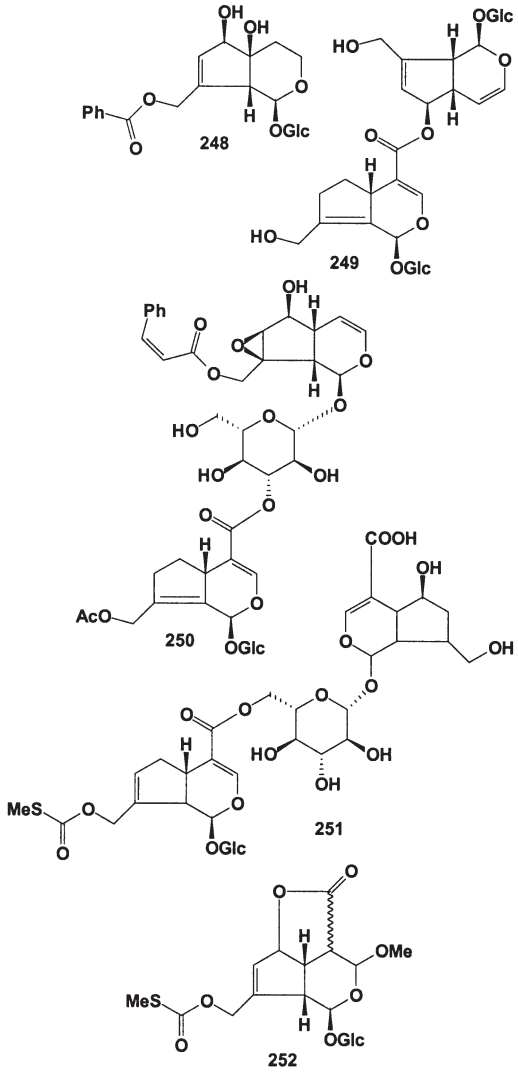
Cyclic metabolites having the iridane skeleton (1-isopropyl-2,3-dimethylcyclopentane) belonging to monoterpenoids have been isolated from plant species. Only a limited number of plant taxa possess the enzymes that give rise to the cyclopentane ring that is characteristic of the carbocyclic iridoids. In plants, iridoids are usually found as glucosides; thus, they are basically water soluble. Approximately 1400 different iridoids and secoiridoids (not counting the complex indole alkaloids) are known so far. Different aspects of biology, biochemistry, and chemistry of iridoids and their glycosides have been reviewed (169–177).

The leaves of *Jasminum nudiflorum* contain a number of secoiridoid glucosides: jasnudiflosides F-L F **235**, G **238**, H **239**, J **231**, I **230**, K **233**, L **234**; nudifloside D **236**; and others, **232**, **234**, and **237** (178). Jasnudiflosides D **240** and E **241** also were isolated from the same plant (179).

A new bis-iridoid glucoside, secologanin Me hemiacetal-yl-6-secologanin di-Me acetal, named chrysathain I **244**, was isolated from a methanolic extract of the leaves of the Chinese medicinal plant *Lonicera chrysantha* (Caprifoliaceae) along with the known iridoid glucosides 8-epi-kingiside **247**, 7α-morroniside **246**, 7β-morroniside **245**, vogeloside **242**, and 7-epi-vogeloside **243** (180). The isolated compounds showed moderate *in vitro* antitumor activity against human promyelocytic leukemia (HL-60) cells. Species of the genus *Lonicera* are a common homeopathic remedy used for asthma, breathing difficulties, and syphilis.







In the flora of Turkey, the genus *Globularia* (Globulariaceae) is represented by nine species, some of which are traditionally used as diuretics, laxatives, carminatives, and tonics and for the treatment of hemorrhoids (181). From a methanolic extract of the underground parts of *G. cordifolia* (Globulariaceae), a new iridoid glycoside, 5-hydroxydavisioside **248**, and a new bis-iridoid glycoside, globuloside C **249**, were isolated (182). Another species of the genus *Globularia*, *G. trichosantha*, contained a new bis-iridoid glycoside named globuloside A **250**, which was obtained from the aerial parts (183).

Two new sulfur-containing bis-iridoid glucosides, saprosmosides A **251** and B **252**, were isolated from the leaves of *Saprosma scortechinii* (Rubiaceae) (184). *Saprosma scortechinii*, a rubiaceous plant endemic to the Malay Peninsula, is also known as *sekentut*, a local name associated with the fetid odor emitted by bruised plant tissues. In the traditional medicinal system of Malaysia, the roots are used by the native communities in decoctions to treat fever, while the young leaves are eaten as a vegetable (185).

A new bis-iridoid glucoside, korolkoside **253**, was isolated from *Lonicera korolkovii* (Caprifoliaceae) (186). Korolkoside consists of two secologanin moieties connected by an acetal linkage. The secoiridoid glucoside named GI 5 **254**, a dimeric secoiridoid glycoside through a 4-hydroxyphenylethyl alcohol spacer, was isolated from a methanolic extract of the leaves of *Fraxinus excelsior* (Oleaceae). This is the first report of the occurrence of the dimeric secoiridoid glucoside GI 5 in *F. excelsior* (187). A new secoiridoid glycoside, 6′-*O*-β-apiofuranosylsweroside **255**, was identified from the leaves of *Lonicera angustifolia* (188). The novel secoiridoid glycoside 6′-*O*-β-apiofuranosylsweroside **256**, together with the known sweroside **257**, were isolated from the leaves of *L. angustifolia* (189). From Scottish plants, two secoiridoid glycosides, sweroside **257** and swertiamarin **258**, were isolated from the aerial parts of *Centaurium erythraea* (family, Gentianaceae) (190) and the antibacterial, free radical-scavenging activities, and general toxicity of these glycosides were assessed. Both compounds inhibited the growth

of *Bacillus cereus, B. subtilis, Citrobacter freundii*, and *Escherichia coli*. Swertiamarin was also active against *Proteus mirabilis* and *Serratia marcescens*, and sweroside inhibited the growth of *Staphylococcus epidermidis*. Swertiamarin and sweroside exhibited significant general toxicity in a brine shrimp lethality bioassay: The LD_{50} values (dose of a chemical that kills 50% of a sample population) were 8.0 and 34 μg/mL, respectively, whereas that of the positive control podophyllotoxin, a well-known cytotoxic lignan, was 2.79 μg/mL. The chemotaxonomic implications of these compounds in the family Gentianaceae have also been discussed briefly. Gentiopicroside **259**, a secoiridoid glycoside isolated from the aerial parts of *Centaurium erythraea*, was assessed for antibacterial and free radical-scavenging activities (191). The general toxicity of **259** was also detected by a brine shrimp lethality bioassay. Gentiopicroside **259** showed antibacterial activity against *B. cereus*, *B. subtilis*, *Centaurium umbellatum*, *C. freundii*, *Enterococcus faecalis*, *E. coli*, *Klebsiella pneumoniae*, *Lactobacillus plantarum*, *Micrococcus luteus*, *P. mirabilis*, and *Pseudomonas aeruginosa*, and radical-scavenging activity against *Salmonella goldcoast*, *S. marcescens*, *Staphylococcus aureus*, *S. epidermidis*, and *S. hominis*.

A methanolic extract of *Swertia chirata*, which was found to inhibit the catalytic activity of topoisomerase I of *Leishmania donovani*, was subjected to fractionation to yield three secoiridoid glycosides: amarogentin **260**, amaroswerin **261**, and sweroside **257**. Amarogentin **260** was a potent inhibitor of type I DNA topoisomerase from *Leishmania* and exerted its effect by interaction with the enzyme, preventing the formation of binary complexes (192).

Fraxuhdoside **262** (193) and insularoside **263** (194) were obtained from extracts of *Fraxinus uhdei* and *F. insularis*, respectively. *Fraxinus uhdei* is native to western and southern Mexico, Guatemala, and Honduras and has been planted as an ornamental tree in other countries, including Costa Rica, Puerto Rico, and Hawaii. Its wood is used for baseball bats, paddles, and tool handles. Three new secoiridoid glucosides, jasamplexosides A **264**, B **265**, and C **266**, were isolated from the crude drug Niu Du Teng, the leaves and stems of *Jasminum amplexicaule* (195). In Pakistan, some species belonging to the genus *Jasminum* are usually used as a diuretic, emmenagogue, and

anthelmintic; for the skin, headaches, weak eyes, and scorpion stings; to cure ringworm; for ulcerations or eruptions in the mouth; and for the ears in otorrhea (196). The flowers are used to prepare perfumes. Several *Jasminum* species have been used in cancer treatment. Jasmine flower oil is important in high-grade perfumes and cosmetics, such as creams, oils, soaps, and shampoos. Jasmine is beneficial for the skin, reducing problems such as dry, greasy, irritated, or sensitive skin (it is good for dry, sensitive skin, especially when there is redness or itching). Its flowers are used in jasmine tea and other herbal black and green teas. The roots and leaves of some jasmine species have been used in folk medicine as an anthelmintic that is active against ringworm and tapeworm, and it is also used to treat muscle spasms, sprains, catarrh, coughs, hoarseness, laryngitis, uterine disorders, labor pains, frigidity, depression, and nervous exhaustion. The *Jasminum* spp. have traditionally been considered an aphrodisiac and a calmative. In the Orient the root is used to treat headaches, insomnia, and pain caused by dislocated joints and broken bones (197).

An acylated secoiridoid glucoside of the foliamenthin type, named exaltoside **267**, has been isolated from the aerial parts of the water plant *Villarsia exaltata* (Menyanthaceae) (198). Watt and Breyer-Brandwijk (199) recorded that when prepared as an ointment, the plant has been used in traditional medicine as a remedy for hemorrhoids. Eustomoside **268**, angustioside **269**, gentomoside **270**, eustomorusside **271**, and one chlorine-containing secoiridoid glucoside named eustoside **272** were isolated from species of the Gentianaceae (gentian) family (170). Eustomoside **268** and angustioside **269** were isolated from *Swertia angustifolia* (200), gentomoside **270** was isolated from the seeds of *Styrax perkinsiae* (201), and eustomorusside **271** and eustoside **272** were found in the lisianthus *Eustoma russellianum* (202). Linarioside, a chlorine-containing iridoid glucoside, **273**, was isolated from *Linaria japonica* (Scrophlariaceae) (203,204) and more recently was found in the snapdragon, *Antirrhinum majus* (205). The snapdragon (*A. majus*) has bitter and stimulant properties, and the leaves of this and several allied species have been used on the continental part of Europe in cataplasms for tumors and ulcers. The snapdragon is closely allied to the toadflaxes. Like the toadflax, it was valued in olden times as a preservative against witchcraft. The bitter leaves and flowers are used as antiphlogistics, resolvents, and stimulants. It is effective in the treatment of all kinds of inflammation and is also used on hemorrhoids (206).

Thunbergioside **274**, which has a structure similar to linarioside **273**, was isolated from four species of *Thunbergia* (207), from *Retzia capensis* (208), and from *T. alata* (209) and is also present in plants of the Thunbergioideae, Mendoncioideae, and Nelsonioideae subfamilies (all belonging to Acanthaceae) (210).

Treatment of the iridoid glucoside antirrhinoside **275** with pyridinium chloride in dimethylformamide yielded two possible *trans*-halohydrins, linarioside **273** and isolinarioside **277**. Pyridinium bromide yielded two analogous bromohydrins, **276** and **278** (211). The iridoid glucosides 8-*epi*-muralioside from *Linaria arcusangeli* and 7,8-*epi*-antirrhinoside from *Linaria dalmatica* were both shown to be identical to isolinarioside **277**.

SUMMARY

Medicinal plants are widely used nowadays for the preparation of various pharmaceutical formulations or as food additives. Plants produce secondary metabolites, which, among other functions, protect them against microbial and herbivorous attack or UV irradiation. Secondary metabolites also have direct uses for human beings. Hemi- and monoterpenoids, for example, have health-promoting activities as food ingredients, and many iridoid glycosides have pharmacological activities. The chemical features of medicinal plants serve as an integral determinant of their species specificity and pharmacological properties, and enable their wide use in medical practice. The use of and search for drugs and dietary supplements derived from plants have accelerated in recent years. Pharmacologists and natural-products chemists are combing the earth for phytochemicals and "leads" that could be developed for the treatment of infectious diseases. Traditional healers have long used plants to prevent or cure infectious conditions, and Western medicine is trying to duplicate their successes. Plants are rich in a wide variety of secondary metabolites; hemiterpenoids; acyclic, monocyclic, and bicyclic monoterpenoids; and iridoid glycosides, which have been found to have antimicrobial, anticancer, and other properties.

Intravenous Application of Omega-3 Fatty Acids in Patients with Active Rheumatoid Arthritis. The ORA-1 Trial. An Open Pilot Study

Burkhard F. Leeb*, Judith Sautner, Ingrid Andel, and Bernhard Rintelen
Second Department of Medicine, Lower Austrian Center for Rheumatology, Humanisklinikum Lower Austria, Stockerau, Austria

ABSTRACT: The objective of this work was to assess the therapeutic efficacy and tolerability of intravenously applied n-3-PUFA in patients with active rheumatoid arthritis (RA). Thirty-four patients with active RA [identified as having a DAS28 (disease activity score including a 28 joint count) > 4.0] were enrolled into this 5-wk open pilot study (one group design). From the time of screening (visit 0, or V0), background therapy had to remain unchanged. Patients received 2 mL/kg (= 0.1–0.2 g fish oil/kg) fish oil emulsion intravenously on 7 consecutive days (Visit 1–Visit 2, or V1–V2) in addition to their background therapy. A decrease of the DAS28 > 0.6 at day 8 (Visit 2) was the primary efficacy measure. Moreover, the DAS28 at day 35 (Visit 3, or V3), the modified Health Assessment Questionnaire, the American College of Rheumatology (ACR) response criteria (V2, V3) and the Short Form-36 (V3) were assessed. Thirty-three patients completed the trial. The mean DAS28 at V1 was 5.45;at V2, 4.51 ($P < .001$ V1–V2) and at V3, 4.73 ($P < .001$ V1–V3; V2–V3, not significantly different). Of the 34 patients, 56% achieved a reduction of the DAS28 > 0.6 at V2 (mean 1.52); 27% > 1.2. At V3, 41% of the patients showed a DAS28 reduction > 0.6 (mean 1.06), and 36% > 1.2. ACR 20 and 50% responses at V2 were seen in 29 and 12% of patients, respectively; at V3, the comparable values were 18 and 9%, respectively. Overall tolerability was excellent. Intravenous application of n-3-PUFA (as an add-on therapy) was considerably well tolerated and led to improvement of the disease activity status in a reasonable number of RA patients. Future trials are warranted to answer whether the intravenous application of n-3-PUFA constitutes a therapeutic option in RA patients.

The habitual lifelong intake of fish and vegetables and dietary measures including the use of olive oil are supposed to exert independent protective effects on the development or severity of rheumatoid arthritis (RA) (1–3). These hypotheses are supported by epidemiological observations from selected geographical regions (4,5).

The n-3 PUFA, EPA and DHA, are highly concentrated in oily fish and fish oils. These n-3 PUFA are structurally and functionally different from n-6 PUFA. In typical cases of human inflammation, the cells involved contain far higher concentrations of the n-6 PUFA arachidonic acid than of n-3 PUFA. Arachidonic acid is the precursor of prostaglandins and leukotrienes, which are known to be highly active mediators of inflammation. Consumption of fish oil causes partial replacement of arachidonic acid in inflammatory cell membranes by EPA (6).

This exchange leads to a decrease of arachidonic acid-derived mediators, resulting in a potentially beneficial anti-inflammatory effect of n-3 PUFA. Moreover, a number of other effects may result from altered eicosanoid production or may be independent of this activity. For example, several animal and human studies demonstrated that the application of fish oil suppresses the synthesis of proinflammatory cytokines and is capable of reducing adhesion molecule expression (6).

In clinical studies, oral supplementation with fish oil reduces signs and symptoms of RA in patients despite ongoing therapy with disease-modifying antirheumatic drug(s) (DMARD) (7). Also, fish oils have protective clinical effects in occlusive cardiovascular disease, for which patients with RA are at increased risk (8,9).

Implementation of the clinical use of anti-inflammatory fish oil doses has been poor, in view of the sometimes only modest beneficial effect of oral supplementation or diets, however evident, and some problems concerning patients' compliance. Secondly, the onset of dietary fish oil supplement efficacy is delayed up to 3–4 mon. To initiate a treatment with such a delayed effect requires belief in the efficacy of the prescriber and often difficult and time-consuming articulation to the patient (10).

Therefore, we intended to assess the efficacy and tolerability of an intravenously administered fish oil emulsion in patients with active RA despite ongoing therapy with disease-modifying agents and corticosteroids in hopes of achieving a rapid onset of efficacy. To our knowledge, this is the first investigation dealing with the intravenous application of highly

unsaturated FA in active RA patients. As this trial constituted the very first attempt, whether this treatment modality was worthwhile for further investigations the one group-design seemed to be one of the appropriate choices to be made in deciding .

Here we report the results of this pilot study.

PATIENTS AND METHODS

All patients gave their written informed consent according to the Declaration of Helsinki. The design of the study has been approved by the local ethics committee.

To be included, patients had to have active RA, according to the American Rheumatism Association criteria (11), defined as a DAS28 (disease activity score including a 28-joint count) (12) higher than 4.0 at the screening visit (visit 0, or V0) despite ongoing treatment, consisting of disease-modifying drugs, corticosteroids up to 10 mg prednisolone/d, and NSAID [nonsteroidal anti-inflammatory drug(s)] on demand. The intake of n-3- and n-6 PUFA and the average joule intake/d in the last week before inclusion were assessed. All patients were told not to change their usual diet until the end of the study (V3), to which they agreed. From V0, no change of the background therapy was allowed during the observation period.

Exclusion criteria were changes in the DMARD regimen, relevant changes (exceeding ±2.5 mg prednisolone equiv/d) in the corticosteroid dosage, oral supplementation of unsaturated FA, and physiotherapy within the last 3 mon. After the screening visit (V0), patients were assessed before the first infusion (V1), after the last infusion at day 8 (V2), and 28 d thereafter (V3).

Patients received 2 mL/kg (= 0.1–0.2 g fish oil/kg) fish oil emulsion (Omegaven®; Fresenius-Kabi, Graz, Austria) intravenously over 4 h on 7 consecutive days in addition to their background therapy. One hundred milliliters of this preparation contains 6.56 g of n-3 PUFA, comprising 2.82 g EPA (20:5n-3), 3.09 g DHA (22:6n-3), 0.20 g a-linolenic acid (18:3n-3), and 0.45 g docosapentaenoic acid (22:5n-3). The change in the DAS28 at V2 constituted the primary efficacy criterion. A reduction of the DAS28 > 0.6 was regarded as a primary response (13). Secondary efficacy criteria comprised the DAS28 change at V3; the American College of Rheumatology (ACR) response rates (14), including the modified Health Assessment Questionnaire (M-HAQ) (15) at V2 and V3; the Medical Outcomes Study Short Form 36 (SF-36) (16) at V3; and the consumption of NSAID at V2 and V3.

Tolerability was assessed by clinical examination; laboratory tests, comprising liver function tests, kidney function tests, complete blood cell count, neutral fat, total cholesterol, HDL- and LDL-cholesterol, fasting blood glucose, and coagulation analysis (Quick-Test, aPTT) and additionally by the reporting of side effects at V2 and V3. The body mass index (BMI) was calculated for each patient at every study phase.

Statistical evaluation. The sample size estimation was based on the pilot data of 16 patients (ΔDAS28 V0→V1: mean = 0.37, SD = 1.0) and on the assumption that ΔDAS28 V1→V3 will be 0.6 lower than ΔDAS28 V0→V1. With a type I error of 5% (two-tailed) and a power of 90%, a sample size of 30 (valid cases for efficacy) was calculated.

Analyses were carried out by applying the McNemar test and Student's *t*-test for dependent variables. For analyzing variables that were not normally distributed, the Wilcoxon-rank test was applied. Data evaluation was purely descriptive without adjustments of the *P*-values. Consequently, significances at $P < .05$ reflect the probability of differences, which can at best be used for generating hypotheses but not for proving them.

RESULTS

Thirty-four patients (27–81 yr; 29 female, 5 male; 25 IgM-rheumatoid factor-positive) were enrolled into this open pilot study [intent-to-treat (ITT) population]. Personal data at baseline are given in Table 1. Thirty-three patients completed the trial; one patient dropped out between V2 and V3 (see Fig. 1). Three more patients were excluded from the per protocol efficacy analysis due to a DAS28 < 4.0 at V1, resulting in a per protocol population of 30 patients.

Two-thirds of the patients were treated as in-patients during the 7-d treatment period, mostly for the distance between the hospital and their residence. No differences could be found between the in-patients and the group of outpatients.

TABLE 1
Personal and Baseline Data of the Patient Population Investigated[a]

	PP-population (n = 30)	ITT-population (V1–V2: n = 34) (V1–V3: n = 33)
Age (yr; median ± 95% CI)	60 [± 4.6]	61 [± 4.2]
Gender (M/F; %)	17/83	15/85
Body weight (kg; median ± 95% CI)	74.5 [± 5.5]	74[± 5.3]
BMI (kg/m^2) (median ± 95% CI)	28.1 [± 4.73]	28.4 [± 4.64]
Disease duration (mon; median ± 95% CI)	105 [± 44.0]	90 [± 45.6]
DAS28 (V0; median ± 95% CI)	5.52 [± 0.27]	5.47 [± 0.26]
M-HAQ (V1; median ± 95% CI)	1.4 [± 0.24]	1.4 [± 0.22]
Morning stiffness (min; median ± 95% CI)	25 [± 26.5]	30 [± 25.3]
Clinically active joint regions (*n*/patient; median ± 95% CI)	2 [± 0.4]	2 [± 0.4]
Arthritis of the hand and finger joints (%)	100	97
Symmetrical arthritis (%)	80	79
Nodules (%)	13	15
RF positivity (%)	76	76
Erosions (%)	76	76

[a]All metric variables are expressed as medians [95% CI in brackets]. PP, per protocol analysis; ITT, intent-to-treat analysis; CI, confidence interval; BMI, body mass index; DAS28, disease activity score including a 28-joint count; M-HAQ, modified health assessment questionnaire; RF, IgM-rheumatoid factor (determined by immunoturbidimetry); V0, screening visit; V1, study entry visit.

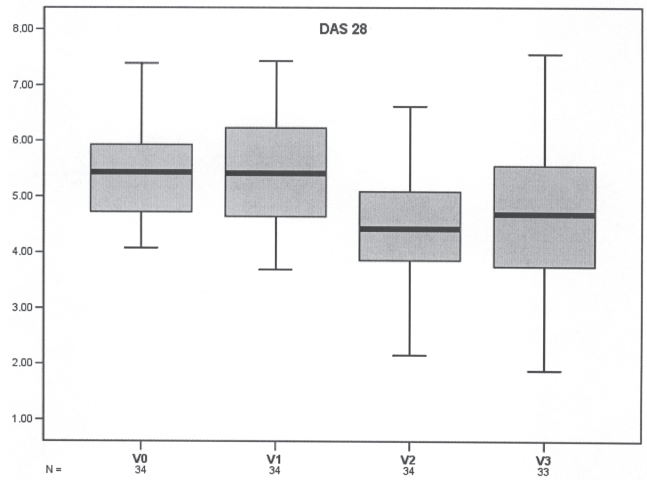

FIG. 1. Box-plots of the DAS28 in the ITT patient population (V1–V2: $n = 34$, V1–V3: $n = 33$; $P < .001$ V1–V2; $P < .001$ V1–V3; not significantly different V2–V3). DAS28, disease activity score including a 28-joint count; ITT, intent-to-treat analysis; VI, study entry visit; V2, second visit, 7 d after V1; V3, third visit, 35 d after V1.

The mean values for the DAS28 in the ITT-population at the screening visit V0 (5.1, 4.08–7.39) and at V1 (5.45; 3.69–7.43) were not significantly different. At V2, immediately after the intervention, the mean DAS28 was 4.51 (2.16–6.62); at V3, 28 d after the intervention, a reincrease to a mean of 4.71 (1.89–7.56) was evident. A highly significant decrease in the DAS28 mean of 0.94 from V1 to V2 ($P < .001$) was apparent that could be maintained to V3 (DAS28 reduction to V1 0.72; $P < .001$), although a tendency to a reincrease [0.20; NS (difference not statistically significant) V2 to V3] indicated a relatively short treatment effect (see Fig. 1).

In fact, 56% of the patients met the limit of a reduction of the DAS28 > 0.6 at V2, whereas at V3 in 41% of the patients this threshold could still be achieved. The 19 patients (17 female) achieving a reduction of the DAS28 > 0.6 at V2 were therefore regarded as primary responders; in 9 patients the DAS28 reduction was >1.2 (27%). At V3, 14 patients showed a DAS28 reduction >0.6, 12 patients >1.2 (36%). The mean DAS28 reduction in the responders amounted to 1.53 between V1 and V2 ($P < .001$) and to 1.06 between V1 and V3, respectively ($P < .001$).

Even in the nonresponders a positive trend toward decreasing disease activity was noted. Indeed, only four patients experienced an increase of the DAS28 (mean 0.19; 0.11–0.35) at V2, whereas at V3 eight patients faced such an increase (mean 0.46; 0.04–0.97) compared with V2. Subgroup analysis of responders and nonresponders failed to demonstrate significant differences between the two groups or reveal predisposing factors for response.

Changes of the single parameters of the DAS28 in the ITT population were as follows. The tender joint count (TJC) mean at V1 was 10 (1–25), decreased to 6 (0–25) at V2 ($P = .015$) and was 7 (0–26) at V3 (NS V1–V3; NS V2–V3).

The mean value for the swollen joint count (SJC) was 7 (0–17) at V1, 5 (0–17) at V2 ($P = .014$), and 5 (0–14) at V3 ($P = .043$ V1–V3; NS V2–V3) see Table 2.

The courses of C-reactive protein (CRP)-levels and the erythrocyte sedimentation rate (ESR) are shown also in Table 2**.** CRP values failed to demonstrate significant differences, whereas ESR showed a significant decrease ($P = .007$ V1–V2, $P = .015$ V1–V3). The patients' global assessment (VAS-GH; visual analog scale of patient's general health) averaged 46 (16–82) at V1, decreased to25 (0–80) at V2 ($P < .001$) and rose to 39 (0–82) at V3 (NS V1–V3; $P < .001$ V2–V3). Physician's global assessment (VAS-ph) and patient's pain assessment (VAS pain) also were found to decrease significantly after the therapeutic intervention (VAS-ph: $P < .001$ V1–V2; $P = .006$ V1–V3; patient's pain: $P < .001$ V1–V2; $P = .019$ V1–V3), see also Table 2**.** Analysis of the per protocol population gave congruent results.

The ACR response rates are given in Table 3. Whereas the M-HAQ did not change significantly throughout the observation period after the administration of the fish oil preparation (Table 2), general health as assessed by the SF-36 improved significantly from V1 to V3 ($P = .015$).

NSAID consumption remained unchanged in 85% of the patients during the observation period; in 9% a reduction and in 6% an increase of the NSAID consumption were evident.

Tolerability. Patients did not report spontaneously any of the unpleasant side effects usually associated with the oral intake

TABLE 2
Disease Activity Parameters and DAS28 at V1, V2, and V3[a]

	V1 mean (± SD)	V2 mean (± SD)	*P*-value V1–V2	V3 mean (± SD)	*P*-value V1–V3
TJC	9.94 (7.19)	6.09 (5.82)	.015	7.33 (7.63)	.303 (NS)
SJC	6.94 (4.22)	4.62 (3.58)	.014	4.82 (3.54)	.043
ESR (1st hour)	40.59 (19.82)	35.00 (18.00)	.007	32.85 (19.12)	.015
CRP (mg/dL)	2.47 (2.32)	2.12 (2.50)	.216 (NS)	2.18 (2.41)	.683 (NS)
VAS GH (0–100)	45.59 (17.72)	25.18 (21.53)	<.001	39.39 (23.23)	.094 (NS)
VAS ph (0–100)	46.35 (22.38)	23.24 (19.89)	<.001	34.03 (23.11)	.006
VAS pain (0–100)	49.24 (20.08)	29.74 (24.19)	<.001	39.27 (22.38)	.019
M-HAQ (0–3)	1.36 (0.68)	1.24 (0.76)	.09 (NS)	1.30 (0.71)	.531 (NS)
DAS28	5.45 (1.05)	4.51 (1.05)	<.001	4.71 (1.33)	<.001

[a]Values are expressed as means ± SD. TJC, tender joint count out of a 28-joint count; SJC, swollen joint count out of a 28-joint count; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; VAS-GH, visual analog scale of patient's general health; VAS ph, visual analog scale of physician's global assessment; VAS pain, visual analog scale of patient's pain; NS, not significantly different; for other abbreviations see Table 1.

TABLE 3
ACR Response Rates in the Entire Patient Cohort[a]

	PP-population (n = 30)	ITT-population (V1–V2: n = 34, V1–V3: n = 33)
ACR 20 (V1–V2) (%)	30	29
ACR 50 (V1–V2) (%)	10	12
ACR 70 (V1–V2) (%)	7	6
ACR 20 (V1–V3) (%)	17	18
ACR 50 (V1–V3) (%)	7	9
ACR 70 (V1–V3) (%)	3	3

[a]ACR, American College of Rheumatology; for other abbreviations see Table 1.

of unsaturated FA such as fishy halitosis or fishy body odor (17). Among the measured blood parameters, no significant differences between V1 and V3 could be observed. Only LDL-cholesterol changed significantly; an initial increase was followed by a final decrease at V3, matching well the experimental experience of the antihypercholesterolemic action of omega-6 FA (18). The BMI did not change significantly throughout the trial.

Overall tolerability, including local reactions at the infusion site, was excellent. One patient dropped out because of a severe flare-up of the disease, another severe adverse event was caused by an acute lumbar disc herniation. Three upper respiratory tract infections and one case of local phlebitis were also observed. No adverse effect was assessed as being putatively drug-related.

DISCUSSION

To our knowledge, this pilot trial constitutes the first investigation dealing with the intravenous administration of n-3 PUFA, namely, a fish-oil emulsion containing high amounts of EPA and DHA, in patients with active RA. The preparation, Omegaven, is licensed for parenteral nutrition therapy. In contrast to the published trials applying capsules or diets (19,20), no problems with patients' compliance, factors possibly influencing the absorption of the compounds, or gastrointestinal intolerance were to be expected in case of intravenous administration. Moreover, the doses applied during this trial were apparently higher than those that were used during preceding investigations. A major difference between oral and intravenous therapy is cost, with Omegaven treatment likely to be far more expensive on the basis of the actual price for the preparation. However, a formal cost-effectiveness calculation needs to be performed on the assumption of reduced costs for Omegaven, if it is to be routinely administered in a larger patient population.

As a first result we found a mean reduction of the DAS28 at V2 and V3 in the entire patient population exceeding 0.6, which represents the threshold of the European League Against Rheumatism response criteria (EULARC) (13) for a moderate therapeutic response in patients at medium disease activity. Moreover, a primary response in about 60% of the patients with a mean DAS28 reduction of about 1.5, which is considerably higher than a moderate response according to the EULARC (13), was observed.

This response rate, as measured by the DAS28, which strongly reflects patient's satisfaction (21) and was just recently proposed for use in clinical trials (22), gives evidence for a mixed effect (drug + placebo) rather than for a simple placebo effect. Response as expressed by the ACR criteria was considerably lower, with an ACR 20% response in about 30% of the patients; although relatively low in this short-term observation, this response exceeds the placebo response rates in blinded RA trials (23,24).

Interestingly, parameters such as the TJC, the SJC, the VAS pain, and the VAS-GH declined significantly, whereas the acute phase reactants, particularly CRP levels, did not change appreciably (Table 2). One explanation could be that the relatively short-term application of n-3 PUFA resulted in insufficient substitution of arachidonic acid within the cell membranes. This hypothesis is supported by a common feature of the patients' nutrition, the consumption of a relatively high concentration of n-6 PUFA, prior to the investigation (25).

The other explanation could be a placebo effect, which is inherent in open, noncontrolled trials. Considering the nature of the intervention, namely, intravenous infusion, the placebo effect could be higher than usually seen with oral interventions. Thus, the results of the study, while encouraging, have to be interpreted cautiously with regard to the placebo effect. However, a time-dependent reincrease of the disease activity parameters between V2 and V3 constituted a greater effect than is generally found with a placebo.

Compared with a recently published trial dealing with the therapeutic efficacy of Mediterranean diet vs. ordinary Western diet, the mean DAS28 reduction in all patients in our investigation was almost twice as high and significant according to the EULARC (0.94 vs. 0.56) when compared with the DAS28 reduction in the Mediterranean diet group (20). Moreover, the decrease was achieved far more rapidly, namely, after 1 wk, whereas in the aforementioned trial the DAS28 decreased even after week 6. In both trials a significant amelioration of the patients' general health, as expressed by the SF-36, was seen, whereas in our investigation the M-HAQ did not change significantly. It is doubtful, however, that the M-HAQ constitutes a tool for monitoring disease activity of RA (26).

Two previous blinded trials compared the efficacy of oral fish-oil supplementation at dosages of 40 mg/kg/d for 15 wk and 130 mg/kg/d for 30 wk (27,28). As the DAS28 was not included in those trials a comparison can only be drawn on the basis of the single activity parameters. In both investigations the TJC and patient's global assessment decreased significantly throughout the observation period, yet much slower as in the case of intravenous administration.

Thus, the primary question—whether intravenous administration of n-3 PUFA leads to a significantly earlier treatment effect—could be answered positively. As in preceding trials with oral preparations or diets, a positive treatment effect could be achieved, but it was far more pronounced as measured by the EULARC and occurred far earlier (20,27,28). Moreover, even in the nonresponders a positive trend to a decrease of RA activity was observed. Regardless of the consequences on RA

activity, an additional advantage of n-3 PUFA substitution (10) for RA patients is that it reduces the risk of cardiovascular disease (29), to which they are more susceptible. Given the excellent tolerability of the intravenously administered fish oil emulsion, as shown here, it seems worthwhile to investigate further the therapeutic potential of such preparations in RA patients. As the treatment effect of the intravenous application was relatively short, but occurred rapidly, the administration of repeated treatment cycles should be carefully investigated including blinded study designs. Another possibility to be evaluated would be an initial intravenously applied loading dose of n-3 PUFA followed by sustained long-term oral administration. However, the efficacy of all dietary or orally administrable therapeutic interventions depends far more on the patient's compliance and nutritional habits than intravenously applicable therapeutic regimes.

In summary this pilot trial of intravenous administration of n-3 PUFA revealed moderate short-term efficacy with rapid onset and excellent tolerability. Besides the great progress in the treatment of RA during the last decade (30,31), the therapeutic administration of n-3 PUFA may constitute another possibly effective and presumably safe option for treating RA, for treating other inflammatory rheumatic diseases, and perhaps for reducing patients' cardiovascular risk (17,32).

COMPETING INTERESTS

Study medication was supplied and statistical evaluation was financially supported by Fresenius-Kabi, Austria.

ACKNOWLEDGMENTS

The authors wish to thank Fresenius-Kabi, Austria, for the supply of the study medication and financial support regarding the statistical evaluation, as well as Christian Celedin, M.D., for his logistical and scientific support. Additionally, the authors extend their warm thanks to Wolfgang Schimetta, Ph.D., and the Institute of Systems Research and Statistics (University of Linz, Austria) for monitoring and statistically evaluating the study. Their competence and support in conducting the trial were very much appreciated.

ABSTRACT: In this study, we determined the phospholipid FA composition in the mammary gland of the transgenic Fat-1 mouse. This is the first animal model developed that can endogenously synthesize n-3 PUFA. The synthesis of n-3 PUFA is achieved through the expression of the *fat-1* transgene encoding for an n-3 desaturase from *Caenorhabditis elegans*, which utilizes n-6 PUFA as substrate. Wild-type and Fat-1 female mice were terminated at 7 wk of age and the fifth mammary gland was removed. Lipids were extracted and phospholipids were separated by TLC and converted to FAME for analysis by GC. There was no significant change in total saturated, monounsaturated, and PUFA composition. However, there was a significant increase in total n-3 PUFA and a corresponding decrease in n-6 PUFA. The major n-3 PUFA that were enriched included 20:5n-3 and 22:6n-3. The n-6 PUFA that were reduced included 20:4n-6, 22:4n-6, and 22:5n-6. Overall, these findings demonstrate that female Fat-1 mice have elevated levels of n-3 PUFA in the mammary gland. Moreover, the n-3 desaturase products are the same n-3 PUFA found in fish oil, which have been shown to have chemoprotective properties against breast cancer. Therefore, this newly developed mouse model may be highly useful for investigating molecular and cellular mechanisms by which n-3 PUFA prevents and inhibits breast cancer growth.

Paper no. L9859 in *Lipids 41*, 35–39 (January 2006).

Studies have shown that n-3 PUFA may prevent or inhibit the growth of breast cancer cells. Results from epidemiological studies have been equivocal (1–4). However, there is stronger evidence from animal and cell culture studies demonstrating that n-3 PUFA can delay the onset of tumor development, reduce the tumor burden, and induce tumor cell death (5–10). Currently, our understanding of mechanisms of action is poorly understood. Many mechanisms have been proposed, including the modulation of eicosanoid synthesis, cell cycle regulatory proteins, gene expression, and alterations in membrane structure and function (11–16). However, relevant transgenic animal models have been lacking that may have important utility for gaining insight into mechanisms of action.

Kang *et al.* (17) recently described the development of the transgenic Fat-1 mouse. This mouse contains the *fat-1* gene from *Caenorhabditis elegans*, which encodes for an n-3 desaturase that can synthesize n-3 PUFA from 18–22 carbon n-6 PUFA. Levels of n-3 PUFA are reportedly increased in many major tissues, including the muscle, liver, heart, erthyrocytes, brain, kidney, and spleen (17). However, the FA composition of the female mammary gland was not reported. In this study we report the detailed FA composition of the major phospholipid fractions in the mammary gland of female Fat-1 transgenic mice.

MATERIALS AND METHODS

Animals and diet. All mice were housed in a temperature- and humidity-controlled animal facility with a 12-h light/dark cycle. Male Fat-1 mice were obtained from Dr. Jing Kang (Harvard Medical School). Male Fat-1 mice were mated with C57Bl/6 female mice (Charles River Laboratories, Wilmington, MA). Fat-1 mice convert n-6 PUFA to longer-chain n-3 PUFA; thus, these mice may potentially become n-6 PUFA deficient. To prevent deficiency, all mice were fed a modified AIN-93G diet containing 10% safflower oil high in 18:2n-6 (Product #D04092701; Research Diets, New Brunswick, NJ). At 7 wk of age, female wild-type ($n = 3$) and Fat-1 ($n = 3$) mice were terminated by CO_2 asphixiation and the fifth mammary gland was removed for FA analysis. All procedures were done in accordance with the animal experimentation guidelines of the University of Toronto.

Analysis of phospholipid FA. Total lipids were extracted from the mammary gland by the method of Folch *et al.* (18). TLC plates (Cat. #10011; Analtech, Newark, DE) were activated by heating at 100°C for 1 h. Phospholipid fractions were separated by developing with chloroform/MeOH/2-propanol/KCl (0.25% wt/vol)/triethylamine (30:9:25:6:18, by vol) (19). Bands corresponding to PC, PS, PI, and PE were visualized under UV light after lightly spraying with 8-anilino-1-naphthalene sulfonic acid (0.1% wt/vol). Bands were scraped and converted to FAME with 14% boron trifluoride/methanol at 100°C for 1 h. FAME were quantified on an Agilent 6890N gas chromatograph equipped with an FID and separated on an Agilent J&W fused-silica capillary column (DB-23; 30 m, 0.25 μm film thickness, 0.25 mm i.d.; Agilent, Palo Alto, CA). Samples were injected in splitless mode. The injector and detector ports were set at 250°C. FAME were eluted using a temperature program set initially at 50°C and held for 2 min, increased at 20°C/min and held at 170°C for 1 min, increased at 3°C/min, and held at 212°C for 10 min to complete the run. The carrier gas was helium, set to a 0.7 mL/min constant flow rate.

Statistical analyses. Differences in the level of FA between wild-type and Fat-1 mice were compared using Student's *t*-test. Results are expressed as means ± SD. $P < 0.05$ was considered significant.

RESULTS

Animal and tissue weights. There was no significant difference in animal body weights between Fat-1 and wild-type mice (data not shown). However, there was a significant ($P < 0.01$) 28% reduction in the weight of Fat-1 mammary glands relative to those of wild-type mice.

Composition of phospholipid FA in the mammary gland. Levels of total saturated, monounsaturated, and polyunsaturated FA were not different between Fat-1 and wild-type mice. However, there were marked differences in the level of specific n-3 and n-6 PUFA. In particular, levels of EPA (20:5n-3) and DHA (22:6n-3) in Fat-1 mice were significantly increased in all phospholipid fractions relative to those of wild-type mice (Tables 1–4). Concomitantly, there was a significant decrease in total n-6 PUFA in PE, and no significant difference was observed in PC, PS, and PE in Fat-1 mice relative to wild-type mice. Reductions were mainly observed in 20:4n-6, 22:4n-6, and 22:5n-6. Consequently, the n-6 to n-3 ratio was markedly reduced in all phospholipid fractions in Fat-1 mice (Tables 1–4).

DISCUSSION

Two previous *in vitro* studies have demonstrated that adenoviral transfer of the *fat-1* gene into breast cancer and mouse mammary cells can increase n-3 PUFA content (20,21). Although these cell lines have utility for studying mechanisms, an animal model would be of greater utility for integrative studies. We have demonstrated that transgenic Fat-1 mice, which contain a heritable n-3 desaturase from *C. elegans*, have higher levels of n-3 PUFA in phospholipids of the mammary gland relative to those of wild-type mice. The Fat-1 mouse represents a

significant advance in the development of a more sophisticated research model to investigate mechanisms of action in an intact animal system.

The consumption of fish rich in n-3 PUFA is recommended for its health benefits to protect against heart disease, diabetes, and potentially cancer (22). The major n-3 PUFA enriched in phospholipids were EPA and DHA. These are also the major n-3 PUFA found in fish oil, and they have been shown to be incorporated into human breast tissue and rodent mammary glands (23–25) and to experimentally inhibit breast cancer cell growth (5–10). Most important, levels of total n-3 PUFA in Fat-1 mice, which ranged between ~2 and 9%, were similar in magnitude to levels found in total lipid extracts of human breast adipose tissue, which comprise 1% of total lipids (23). The levels of EPA and DHA reported herein for PC, PE, and PI are remarkably similar to levels found in the same phospholipid classes from R3230AC mammary tumor cells that were implanted in rats fed a fish oil diet (2.5% w/w of diet) for 2–3 wk (25). Collectively, these observations suggest that the Fat-1 mouse has utility as a model to study the role of n-3 PUFA in breast cancer because (i) EPA and DHA, the relevant FA in the human diet that confer protection, are enriched in Fat-1 mammary phospholipids, and (ii) the level of incorporation is comparable to levels found in humans and in conventional feeding studies.

In contrast to n-3 PUFA, there is experimental evidence suggesting that n-6 PUFA promotes the development of mammary carcinogenesis, tumor growth, and metastasis (10,26,27). Therefore, another consideration is the apparently opposing effects of n-3 and n-6 PUFA, which suggests that the relative ratio between n-6 and n-3 PUFA is an important determinant in the overall health benefits of consuming n-3 PUFA (4,28). The n-6 to n-3 ratio consumed in the present Western diet is between 10:1 and 20:1; however, our ancestors had a diet closer to 1:1 (29). These observations suggest that a lower n-6 to n-3 ratio may be optimal for one's health. Analyses of breast adipose tissue from breast cancer patients and controls have shown that a high n-6 to n-3 ratio was correlated with increased risk, whereas a lower ratio reduced the relative risk of breast cancer (23,24). We observed a marked reduction in the n-6 to n-3 ratio, ranging between 111 and 29 and between 19 and 4 in wild-type and Fat-1 mice, respectively. The importance of the n-6 to n-3 ratio is another characteristic that can be studied in this animal model.

The significant ($P < 0.05$) 28% reduction in the weight of the Fat-1 mammary gland suggests that increased levels of n-3 PUFA had a profound impact on the growth and development of the mammary gland. Currently, the implications of this observation are unknown, and ongoing investigations are focused on understanding the effect of n-3 PUFA on mammary gland development.

Modification of membrane FA composition is one of the mechanisms by which n-3 PUFA may protect or inhibit tumor cell growth. Consequently, this influences the synthesis of eicosanoids from arachidonic acid (20:4n-6), which may enhance tumor growth and metastasis (8,27). Changes in eicosanoid synthesis are likely, given that there was a trend toward higher levels of linoleic acid and reduced levels of arachidonic acid in Fat-1 mice, suggesting that elongation and desaturation were inhibited by the presence of n-3 PUFA. This pattern was also present in bone and muscle tissue (data not shown). Although yet to be investigated in breast cancer, changes in membrane FA composition may also potentially influence caveolae-mediated signaling (15,16) and Akt signaling mediated by DHA incorporation into PS (30). These novel mechanisms may be investigated using cell culture systems or rodent feeding studies. However, the transgenic Fat-1 mouse model has unique properties that may be considered advantageous over conventional rodent model systems.

Cell culture systems are certainly powerful systems for studying mechanisms but may not be physiologically relevant, e.g., for a given dose of treatment. Therefore, it is also necessary to conduct parallel dietary feeding studies using intact animal model systems. However, dietary fat studies are confounded by the need to formulate isocaloric diets with respect to fat content. For example, to create a control diet without n-3 PUFA and an experimental diet with high n-3 PUFA, the addition of n-3 PUFA would require a compensatory reduction in another type of fat, such as n-6 PUFA. Thus, it could be argued that any change observed is due to either an increase in n-3 PUFA or a reduction in n-6 PUFA. In addition, to formulate diets with different n-6 to n-3 ratios requires the blending of several oil sources; thus, the fat composition between control and experimental diets is difficult to control. The Fat-1 mouse model is not subject to these potential confounders, given that Fat-1 mice can endogenously synthesize n-3 PUFA; thus, only one diet need be provided to both wild-type and Fat-1 mice. These considerations make the Fat-1 mouse an attractive model system that can provide more conclusive evidence demonstrating the beneficial effects of n-3 PUFA.

Overall, this study demonstrated that the Fat-1 mouse has high levels of n-3 PUFA in mammary gland phospholipids and a low n-6 to n-3 ratio relative to that of wild-type mice. In addition, the strengths of this mouse model suggest that it will have great utility in future investigations for studying molecular and cellular mechanisms by which n-3 PUFA protects against breast cancer.

ABSTRACT: The aim of the present study was to characterize plasma lipids and lipoprotein cholesterol and glucose concentrations in hamsters fed either *cis*-9,*trans*-11 CLA (9*c*,11*t* CLA); *trans*-10,*cis*-12 CLA (10*t*,12*c* CLA); or linoleic acid (LA) on the accumulation of aortic cholesterol in hypercholesterolemic hamsters. One hundred male F_1B strain Syrian Golden Hamsters (*Mesocricetus auratus*) (BioBreeders Inc., Watertown, MA) approximately 9 wk of age were housed in individual stainless steel hanging cages at room temperature with a 12-h light/dark cycle. Hamsters were given food and water *ad libitum*. Following a 1-wk period of acclimation, the hamsters were fed a chow-based (nonpurified) hypercholesterolemic diet (HCD) containing 10% coconut oil (92% saturated fat) and 0.1% cholesterol for 2 wk. After an overnight fast, the hamsters were bled and plasma cholesterol concentrations were measured. The hamsters were then divided into 4 groups of 25 based on similar mean plasma VLDL and LDL cholesterol (nonHDL-C) concentrations. Group 1 remained on the HCD (control). Group 2 was fed the HCD plus 0.5% 9*c*,11*t* CLA isomer. Group 3 was fed the HCD plus 0.5% 10*t*,12*c* CLA isomer. Group 4 was fed the HCD plus 0.5% LA. Compared with the control, both CLA isomers and LA had significantly lower plasma total cholesterol and HDL cholesterol concentrations ($P < 0.001$) after 12 but not 8 wk of treatment and were not significantly different from each other. Also, both CLA isomers had significantly lower plasma nonHDL-C concentrations ($P < 0.01$) compared with the control after 12 but not 8 wk of treatment and were not significantly different from each other or the LA-fed hamsters. Plasma TG concentrations were significantly higher ($P < 0.004$) with the 10*t*,12*c* CLA isomer compared with the other treatments at 8 but not at 12 wk of treatment. Plasma TG concentrations were also significantly lower ($P < 0.03$) with the 9*c*,11*t* CLA isomer compared with the control at 12 wk of treatment. Also, the 10*t*,12*c* CLA isomer and LA had significantly higher plasma glucose concentrations compared with the control and 9*c*,11*t* CLA isomer ($P < 0.008$) at 12 wk of treatment, whereas at 8 wk, only the LA treatment had significantly higher plasma glucose concentrations ($P < 0.001$) compared with the 9*c*,11*t* CLA isomer. Although liver weights were significantly higher in 10*t*,12*c* CLA isomer-fed hamsters, liver total cholesterol, free cholesterol, cholesterol ester, and TG concentrations were significantly lower in these hamsters compared with hamsters fed the control, 9*c*,11*t* CLA isomer, and LA diets ($P < 0.05$). The 9*c*,11*t* CLA isomer and LA diets tended to reduce cholesterol accumulation in the aortic arch, whereas the 10*t*,12*c* CLA isomer diet tended to raise cholesterol accumulation compared with the control diet; however, neither was significant. In summary, no differences were observed between the CLA isomers for changes in plasma lipids or lipoprotein cholesterol concentrations. However, the 9*c*,11*t* CLA isomer did appear to lower plasma TG and glucose concentrations compared with the 10*t*,12*c* CLA isomer. Such differences may increase the risk of insulin resistance and type 2 diabetes in humans when the 10*t*,12*c* CLA isomer is fed separately.

Paper no. L9699 in *Lipids 41*, 41–48 (January 2006).

Animal studies in our laboratory as well as in others have shown that feeding a predominantly linoleic acid (LA)-containing diet such as corn oil or safflower oil results in dramatic decreases in blood LDL cholesterol (LDL-C) concentrations, which are associated with reductions in atherosclerosis (1,2). However, in these experiments blood LDL-C is reduced so dramatically that the nature of the LDL is unimportant. In contrast, in human studies, the magnitude of the blood LDL-C reduction with LA-rich diets is usually on the order of 5–10%; thus, these LDL particles enriched in LA are more susceptible to oxidation (3) and are presumably more atherogenic (4). Support for the atherogenicity of LA-enriched LDL comes from studies recently completed in our laboratory in which hypercholesterolemic animals fed a diet enriched in sunflower oil (LA-containing) and cholesterol had dramatically more aortic atherosclerosis than animals fed TriSun® oil (oleic-containing; SVO Enterprises, Eastlake, OH) plus cholesterol despite similar, albeit elevated, LDL-C levels (5). Moreover, the increase in aortic atherosclerosis with sunflower oil feeding was highly associated with greater LDL oxidative susceptibility and accumulation of aortic oxidized LDL (5).

These observations beg the question of whether CLA would be more effective than LA in terms of reducing the progression of the aortic lesion. Although several studies have confirmed the anticancer properties of CLA, only a few published reports support its antiatherosclerotic effects, and only one has shown the influence of the purified 9-*cis*,11-*trans* (9*c*,11*t*) CLA iso-

Abbreviations: 9*c*,11*t* CLA, *cis*-9,*trans*-11 CLA; 10*t*,12*c* CLA, *trans*-10,*cis*-12 CLA; HDL-C, HDL cholesterol; LA, linoleic acid; LDL-C, LDL cholesterol; nonHDL-C, VLDL and LDL cholesterol.

mer. Preliminary evidence from a non-dose–response study from our laboratory would suggest that animals fed mixed CLA isomers had less atherosclerosis than those fed LA (6). However, for reasons mentioned hereafter, these preliminary studies must be interpreted with caution. Also, a recent study (7) showed that CLA feeding promoted fatty streak formation in the C57BL/6 mouse atherosclerosis model. However, this finding may be specific to this animal model and not to others. A study by Lee *et al.* (8) in rabbits showed that at the only concentration studied, 0.5% (w/w), CLA as the FFA reduced aortic atherosclerosis. Recently, a study published by Gavino *et al.* (9) showed that feeding a diet containing an isomeric mixture of CLA significantly reduced plasma TG and total cholesterol levels in hamsters compared with LA and the 9*c*,11*t* CLA isomer. However, their study did not investigate the development of atherosclerosis.

Our recent study in hamsters fed a chow-based diet containing 0.05, 0.1, and 1.0 en% mixed CLA isomers as the FFA also showed an antiatherogenic effect that was associated with increased plasma vitamin E levels (10). Our preliminary study (6) suggested that the FFA was more effective than TG as an antiatherogenic compound. In our earlier mixed-CLA isomer study (10), hamsters were extremely hypercholesterolemic (plasma cholesterol levels >700 mg/dL), raising the question of the efficacy of CLA during more moderate hypercholesterolemia. Also, in that study (10), the hamsters were housed grouped, which may be the reason for the very high levels of blood cholesterol in those animals; in another study in our laboratory, group housing of hamsters was shown to be associated with adverse effects on plasma lipids (11). Data have also indicated that mixed and individual isomers of CLA are effective inhibitors of atherogenesis and also cause regression of established atherosclerosis in rabbits (12–14).

Much of the previous work that has been performed in animals fed CLA has been done using the mixed-isomer formulation of commercially available CLA. The current study examines the purified form of either 9*c*,11*t* or *trans*-10,*cis*-12 (10*t*,12*c*) CLA in the hypercholesterolemic hamster model to determine whether they have similar hypocholesterolemic, glucose hemostatic, and antiatherogenic properties.

EXPERIMENTAL PROCEDURES

Experimental design and diets. One hundred male F_1B strain Syrian Golden Hamsters (*Mesocricetus auratus*) (BioBreeders Inc., Watertown, MA) approximately 9 wk of age were housed in individual stainless steel hanging cages at room temperature with a 12-h light/dark cycle. Hamsters were given food and water *ad libitum*. Animals were fed Purina chow 5001 (Ralston Purina, St. Louis, MO) for a period of 1 wk prior to the start of the study to become acclimated to the facility. All 100 hamsters were fed a chow-based (nonpurified) hypercholesterolemic diet (HCD) containing 10% coconut oil (92% saturated fat) and 0.1% cholesterol for 2 wk. A nonpurified diet, rather than a semipurified diet, was used because published data from our laboratory (15) and those from another laboratory (16) indicated that hamsters on a nonpurified diet were more responsive to various cholesterolemic interventions and a resultant lipoprotein profile [VLDL and LDL cholesterol (nonHDL-C) > HDL cholesterol (HDL-C)] which was similar to that of humans. After an overnight fast, the hamsters were bled and plasma cholesterol concentrations were measured. The hamsters were then divided into 4 groups of 25 based on similar mean plasma nonHDL-C concentrations. Group 1 remained on the HCD (control). Group 2 was fed the HCD plus 0.5% 9*c*,11*t* CLA. Group 3 was fed the HCD plus 0.5% 10*t*,12*c* CLA. Group 4 was fed the HCD plus 0.5% LA. Dietary CLA isomers in pure form and LA were added to the diets as the FFA form and were obtained from Matreya, Inc. (Pleasant Gap, PA). The two CLA isomers and LA were >98% pure by GC. The FA composition of the treatment diets is provided in Table 1. Dietary treatments were fed for 12 wk. Plasma lipids were measured at 0, 8, and 12 wk of dietary treatment. At the end of dietary treatment, the hamsters were sacrificed and aortas were collected. Food disappearance and body weights were measured on a daily basis throughout the study. The animals were maintained in accordance with the guidelines of the Committee on Animal Care of the University of Massachusetts Lowell Research Foundation, as well as the guidelines prepared by the Committee on Care and Use of Laboratory Animals of the Institute of Laboratory Resources, National Research Council (DHEW publication no. 85–23, revised 1985), following approval by the Institutional Animal Care and Use Committee.

Plasma lipoprotein cholesterol, TG, and glucose measurements. Blood samples were collected after an overnight fast (16 h). Blood from fasted hamsters, anesthetized with ultrapure 50:50 CO_2/O_2 (Northeast Airgas, Salem, NH), was collected *via* the retro-orbital sinus into heparinized tubes, and plasma was harvested after low-speed centrifugation at 2500 × *g* for 15 min at room temperature. Plasma was frozen at −80°C until analyzed for plasma total cholesterol, HDL-C, nonHDL-C, TG, and glucose concentrations. Plasma cholesterol (17) and TG (18) were measured enzymatically, and after the apoB-containing lipoproteins VLDL and LDL were precipitated with phosphotungstate reagent (19), the supernatant was assayed for HDL-C (Sigma, St. Louis, MO). Plasma nonHDL-C was calculated from the difference between total cholesterol and HDL-C. Plasma lipid determinations are standardized by participa-

tion in the Center for Disease Control–National Heart, Lung, and Blood Institute Standardization Program. Plasma glucose concentrations were also measured enzymatically using Kit #17–100 (Sigma).

Liver lipid measurements. Liver lipid concentrations were measured by a previously described method (20). A 100-mg (wet wt) portion of liver was homogenized with 50 mg of sodium sulfate. Four milliliters of methanol was then added and the tissue was homogenized a second time, followed by addition of 8 mL of chloroform. After mixing, 3 mL of a solution containing 1.25% KCl and 0.05% H_2SO_4 was added and centrifuged at 400 × *g* at room temperature for 10 min. The bottom layer was transferred, and the supernatant was re-extracted with 3 mL of chloroform/methanol (2:1) and centrifuged at 400 × *g* at room temperature for 10 min. The bottom layer was transferred and pooled with the previous supernatant. The solution was placed in a 37°C water bath under N_2. When approximately half of the solution was evaporated, 1 mL of chloroform containing 1% Triton-100 was added, mixed, and evaporated to dryness at 37°C under N_2. Five hundred microliters of distilled water was added to the samples, which were mixed and placed in a shaking water bath at 37°C for 20 min to solubilize the lipid. After incubation, liver total and free cholesterol and phospholipid concentrations were determined enzymatically using Wako total and free cholesterol C and phospholipid kits (Wako Chemicals, Richmond, VA). The hepatic cholesterol ester concentration was determined as the difference between the total and free cholesterol concentrations. Liver TG concentrations were as stated above for plasma TG measurements.

Collection of aortas. At the time of sacrifice (week 12), hamsters were anesthetized with an ip injection of sodium pentobarbital (62.5 mg/mL at a dosage of 0.2–0.25 mL/200 g body weight) (Henry Schein, Port Washington, NY), and aortic tissue was obtained for aortic cholesterol analysis (21). The heart and thoracic aorta were removed and stored in vials containing PBS at 4°C for subsequent analysis. To measure the extent of the aortic cholesterol accumulation in the aortic arch, a piece of thoracic aortic tissue extending from as close to the heart as possible to the branch of the left subclavian artery was used.

Aortic cholesterol measurement. The tissue was weighed and placed in a 25-mL screw-capped test tube (21). Four milliliters of methanol and 8 mL of chloroform were added. After mixing, the solution was allowed to stand at room temperature for 48 h for extraction of cholesterol from the blood vessel wall. After extraction, the aortic tissue was removed and the solution was placed in a 37°C water bath under N_2. When approximately half of the solution was evaporated, 1 mL of chloroform containing 1% Triton-100 was added, mixed, and evaporated to dryness at 37°C under N_2. Two hundred microliters of distilled water was added to the samples, which were mixed and placed in a shaking water bath at 37°C for 20 min to solubilize the lipids. After incubation, aortic total and free cholesterol concentrations were determined enzymatically using Wako total and free cholesterol C kits (Wako Chemicals). The aortic cholesteryl ester concentration was determined as the difference between the total and free cholesterol concentrations. A pilot study was conducted to evaluate the extent to which this procedure removed tissue cholesterol. Aortic cholesterol concentrations were determined after tissue was placed in solvent (4 mL of methanol and 10 mL of chloroform) overnight with frequent vigorous mixing, and were compared with the concentrations obtained following tissue mincing or homogenization as reported previously (22). No significant differences in aortic cholesterol content were observed between the different cholesterol extraction procedures.

Statistical methods. SigmaStat software was used for all statistical evaluations (Jandel Scientific, San Rafael, CA) (23). Differences between time points were determined by using repeated-measures one-way ANOVA followed by Student–Neuman–Keuls *post hoc* test. Differences between the dietary treatments were determined using one-way ANOVA followed by Student–Neuman–Keuls *post hoc* test. All values are expressed as mean ± SD, and significance was set at $P < 0.05$.

RESULTS

All the animals survived the treatment period. As seen in Table 2, there were no differences between any of the animals for initial or final body weights and between food consumption over the course of the study. Also, all the animals in each group gained body weight over the course of the study. Liver weights were significantly greater in the animals fed the 10*t*,12*c* CLA isomer compared with the control (18%), 9*c*,11*t* CLA isomer (14%), and LA (16%) animals ($P < 0.03$) (Table 2).

No significant differences were observed for plasma lipids within dietary treatments between the week 8 and week 12 data. However, statistical differences between groups for plasma lipid measurements were different at 8 and 12 wk; thus, the data have been shown separately. No differences between any of the dietary treatments were observed for plasma total cholesterol, nonHDL-C, and HDL-C concentrations after 8 wk

[a]Values are mean ± SD; $n = 25$. Values in a column not sharing a roman superscript are significantly different at $P < 0.05$. For abbreviations see Tables 1 and 3.

of dietary treatment (Table 3). Plasma TG, however, were significantly higher in the hamsters fed the 10*t*,12*c* CLA isomer compared with hamsters fed the control (40%), 9*c*,11*t* CLA isomer (29%), and LA (39%) diets after 8 wk of treatment ($P < 0.004$). Also, hamsters fed the LA diet had significantly higher plasma glucose concentrations compared with hamsters fed the 9*c*,11*t* CLA isomer (15%) after 8 wk of treatment ($P < 0.001$).

After 12 wk of dietary treatment, plasma total cholesterol and HDL-C concentrations were significantly lower in the hamsters fed the 9*c*,11*t* CLA isomer (−35 and −17%, respectively), 10*t*,12*c* CLA isomer (−35 and −24%, respectively), and LA (−28 and −26%, respectively) diets compared hamsters fed the control diet ($P < 0.001$) (Table 4). Plasma nonHDL-C concentrations were significantly lower in hamsters fed the 9*c*,11*t* CLA isomer (−44%) and the 10*t*,12*c* CLA isomer (−40%) diets but not in those fed the LA diet, compared with hamsters fed the control diet after 12 wk of treatment ($P < 0.001$). Plasma TG concentrations were significantly lower in the hamsters fed the 9*c*,11*t* CLA isomer compared with those fed the control (−52%) diet after 12 wk of treatment ($P < 0.03$). Also, hamsters fed the 10*t*,12*c* CLA isomer and the LA diets had significantly higher plasma glucose concentrations compared with those fed the control (25 and 11%, respectively) and 9*c*,11*t* CLA isomer (35 and 23%, respectively) diets after 12 wk of treatment ($P < 0.008$).

Although liver weights were significantly higher in hamsters fed the 10*t*,12*c* CLA isomer diet, liver total cholesterol, free cholesterol, cholesterol ester, and TG concentrations were significantly lower in these hamsters than in those fed the control (−51, −28, −59, and −45%, respectively), 9*c*,11*t* CLA isomer (−53, −33, −60, and −46%, respectively), and LA (−47, −30, −53, and −40%, respectively) diets ($P < 0.05$) (Table 5). None of the other treatment groups were significantly different from each other for these same variables. Also, no treatment groups were significantly different from each other for liver phospholipid concentrations (Table 5).

Table 6 shows the data for aortic cholesterol accumulation measurements after 12 wk of dietary treatment. Although there were no statistically significant differences between any of the dietary treatments for aortic cholesterol accumulation, a small trend was observed. The 9*c*,11*t* CLA isomer tended to reduce total cholesterol and cholesteryl ester accumulation in the aortic arch compared with the 10*t*,12*c* CLA isomer (−18 and −13%, respectively, $P = 0.11$), but not significantly.

DISCUSSION

Our results indicate that supplementing the diets of hypercholesterolemic hamsters with individual CLA isomers reduces plasma cholesterol concentrations when compared with controls, without any changes in body weight and aortic cholesterol accumulation. The effects of CLA on body weight and composition have been controversial in both animal and human studies. In the current study, no differences in final body

weights were observed between hamsters fed the control diet or diets supplemented with CLA isomers or LA. Previous work in young rats fed diets supplemented with 0.5% CLA showed, in animals fed the CLA, an increase in body weight without changes in food consumption compared with controls (24). In contrast to this study, Park *et al.* (25) reported in mice that the effects of CLA on body composition changes appeared to be due in part to reduced fat deposition and increased lipolysis in adipocytes. Animal studies in general have suggested that the 10*t*,12*c* isomer, and not the 9*c*,11*t* isomer, has the most potent body fat-reducing properties (9,25). In the current study, no differences were observed for perirenal adipose tissue weight. However, the 10*t*,12*c* CLA isomer did reduce it slightly compared with the control. One possible explanation for the nonsignificant effect of either CLA isomer on the reduction of fat tissue is that the effects of CLA on the perirenal depot are more sensitive when diets are low in fat (4%), but not when diets are high in fat (10%) (26), as in the current study. In humans, the majority of studies have shown no effect on body weight or composition when individual or mixed isomers of CLA were fed (27–31). However, one recent long-term trial (1 yr) showed that CLA feeding decreased body fat mass without any adverse effects (32). Other differences between earlier studies that showed positive effects and this study on body weight changes may be due to feeding the mixed CLA isomer in the earlier studies compared with feeding the individual isomers in the current study, or to species differences. Since previous work in hamsters fed a mixed-isomer diet showed significantly less weight gain than did either the 9*c*,11*t* isomer- or LA-supplemented groups (9) and showed that the mixed-isomer diet decreased fat depot weights compared with the 9*c*,11*t* isomer diet in other studies (25,33), there may be synergistic effects on body weight or composition when both the 9*c*,11*t* and 10*t*,12*c* CLA isomers are supplemented simultaneously. Overall, however, there is no conclusive evidence to suggest that consumption either of mixtures of CLA isomers or of highly enriched preparations of individual isomers results in a significant reduction in body composition in animals, including humans.

Some studies have shown that feeding only the 10*t*,12*c* CLA isomer is associated with greater liver weights in hamsters and with a significant decrease or no change in the amount of TG accumulation in the liver (33–35). However, other studies in mice have shown the same hepatomegoly with mixed CLA isomer feeding, and this was associated with greater TG accumulation (36–39). In the current study, larger livers were also found in hamsters fed the 10*t*,12*c* CLA isomer but not in hamsters fed the 9*c*,11*t* CLA isomer or LA. Similar to previous work in hamsters (35), this increase in liver weights in hamsters fed the 10*t*,12*c* CLA isomer was not due to increased lipid accumulation. In fact, levels of liver TG, cholesterol esters, and free cholesterol were significantly decreased in these hamsters compared with the effects of other dietary treatments. Differences between the current study and those by others in which an increase in lipid accumulation was observed (36–39) may be due to the feeding of individual isomers vs. mixed CLA or due to different species (mice vs. hamsters) being studied. However, it is still unknown what may have led to the increase in liver weights in hamsters fed the 10*t*,12*c* CLA isomer in the current study, but it could be due to an increase in the total number of hepatocytes with the 10*t*,12*c* CLA isomer, as previously observed (35).

Previous studies from our laboratory (6,10) and from others (8,9) have shown reductions in plasma cholesterol concentrations in mixed CLA-fed animals compared with controls. The results of the current study with the individual CLA isomer formulations compared with controls are consistent with these previous studies (40) for plasma cholesterol lowering. However, in the current study we observed no significant differences between feeding the individual CLA isomers and LA for plasma cholesterol lowering, whereas an earlier study from our laboratory did show that mixed CLA feeding produced significantly lower plasma cholesterol levels compared with LA (10), but another did not (6). Presently, there is no explanation for this discrepancy, although the difference may be due to the different diets that were used in these studies. In the present study, we fed the different isomers individually in the diets, compared with feeding a mixed CLA isomer formulation in the earlier study (10). Previous work (9) showed that the 9*c*,11*t* CLA isomer had no effect on plasma cholesterol concentrations compared with control hamsters. However, in that study (9) only 0.2% of the 9*c*,11*t* CLA isomer was fed to hamsters, whereas in the current study 0.5% was fed to hamsters. Another study (40) also showed a reduction in plasma cholesterol concentrations with both the 9*c*,11*t* and 10*t*,12*c* CLA isomers and with LA when compared with control hamsters. Similar contradictory results have been observed in human studies. Tricon *et al.* (27) showed a significant effect of isomer supplementation on blood cholesterol concentrations in humans. Their data suggest a trend toward a decrease in plasma cholesterol and LDL-C concentrations after supplementation with the 9*c*,11*t* CLA isomer, but not the 10*t*,12*c* CLA isomer (27). Other studies have also shown a cholesterol-lowering effect of CLA in humans

(30,41). However, more studies appear to have shown no effect on blood cholesterol levels in humans when fed CLA (31,42,43). The observation in the present study that individual or mixed CLA isomer feeding reduced plasma HDL-C is similar to some previous studies in animals (31,36) and humans (44), but not to others (6,9,10,27,42,43).

We also observed an increase in plasma TG when feeding the 10*t*,12*c* CLA isomer compared with the other treatments after 8 wk of supplementation, but not after 12 wk. By 12 wk of treatment, the 9*c*,11*t* CLA isomer had significantly lowered plasma TG compared with hamsters fed the control. These results are similar to our previous study (6), which showed that feeding mixed-isomer CLA increased plasma TG more than did LA. In contrast, previous studies in hamsters (9,10) and humans (29) have shown that feeding the mixed CLA either reduced or had no effect on plasma TG concentrations. The differences between those studies and the current study may be due to the different concentrations of purified isomers used in these studies or to the use of mixed CLA isomers vs. individual isomers. However, one study (27) in healthy humans showed that plasma TG concentrations were higher during supplementation with the 10*t*,12*c* CLA isomer than during supplementation with the 9*c*,11*t* CLA isomer. The TG-raising potential of mixed CLA may be predominantly due to the 10*t*,12*c* isomer, as shown in the current study and in others (27). Along with the slight changes in plasma TG concentrations with the different CLA isomers, we also observed changes in plasma glucose concentrations. In the current study, the 9*c*,11*t* CLA isomer resulted in significantly lower plasma glucose concentrations compared with the 10*t*,12*c* CLA isomer and LA diets, similar to previous studies in humans (27,44). Risérus *et al.* (44) also showed that feeding the 9*c*,11*t* CLA isomer decreased insulin resistance whereas feeding the 10*t*,12*c* CLA isomer increased insulin resistance in obese men. Also, a study by Moloney *et al.* (45) showed that supplementation with mixed CLA significantly increased fasting glucose concentrations. In contrast, CLA feeding was shown to improve glucose concentrations in type 2 diabetics (46) and in rats (47). The difference between these studies (46,47) and the current one may again be due to the use of mixed CLA vs. individual isomers, or to species differences.

The present study also showed that feeding CLA as individual isomers did not produce a significant change in early aortic atherosclerosis, as measured by aortic cholesterol accumulation, compared with both LA and the control diet, a result that is inconsistent with previous work (9,10). However, this observation in the former study (10) was not significant until the data for the three different doses of CLA feeding were combined and then compared with the HCD-fed animals; also, the CLA used for the earlier studies was mixed CLA. Additionally, in our earlier study (10), the hamsters that were fed CLA had a significantly greater plasma tocopherol/total cholesterol ratio than did hamsters fed a control diet or LA-containing diet. These results suggest that CLA may be tocopherol sparing and thus act directly or indirectly as an antioxidant *in vivo*, which may contribute to its antiatherogenic properties. Another possible explanation for the discrepancy is that earlier studies have either used fatty streak area (10) or visual staining procedures (15), measures of early atherosclerosis that may not be as appropriate as the biochemical measurement of aortic cholesterol accumulation used in the current study. Recently, Mitchell *et al.* (40) showed a similar result when feeding the individual isomers compared with LA, in that there were no significant differences in aortic fatty streak lesions but that a slight decrease was observed with the CLA isomers.

Although, in the current study, feeding LA to hamsters produced a significant decrease in plasma total cholesterol and HDL-C concentrations, similar to CLA feeding, it did not produce a significant reduction in nonHDL-C concentrations, as did the CLA isomers after 12 wk of dietary treatment or in early atherosclerosis. This nonsignificant reduction in aortic atherosclerosis with LA feeding in the present study may be due to an increase in LDL oxidative susceptibility that is associated with LA feeding, which was not measured. Previous studies have shown that LDL particles enriched with LA are more susceptible to oxidation and presumably more atherogenic than are oleate-rich diets (3,4).

In summary, both CLA isomers produced significant lowering in plasma total cholesterol and nonHDL-C concentrations; however, the majority of human studies have shown no effect. Also, no significant differences were observed between the CLA isomers (9*c*,11*t* vs. 10*t*,12*c*) for changes in plasma lipids or lipoprotein cholesterol concentrations; however, the 10*t*,12*c* CLA isomer did raise plasma glucose concentrations compared with the 9*c*,11*t* CLA isomer, and only the 9*c*,11*t* CLA isomer reduced plasma TG compared with the control. The lower plasma glucose concentrations, along with the lower plasma TG concentrations, may decrease the risk of insulin resistance and type 2 diabetes in humans when the 9*c*,11*t* CLA isomer is fed alone.

ACKNOWLEDGMENTS

This project was funded by beef and veal producers and importers through their $1-per-head checkoff and was produced for the Cattlemen's Beef Board and state councils by the National Cattlemen's Beef Association and Kraft General Foods (T.A.W.). The authors would like to thank Benjamin Woolfrey, Catherine Jones, Wendy DeSimone, and Subbiah Yoganathan for their technical support and Maureen Faul for her administrative support.

ABSTRACT: The present study investigated the dietary effect of conjugated linolenic acid (CLnA) on lipid profiles and lipid peroxidations in alloxan-induced diabetes mellitus in rats. Diabetic rats were fed with 20% sunflower oil (diabetic control), sunflower oil supplemented with 0.5% CLnA, sunflower oil supplemented with 0.15% α-tocopherol, and sunflower oil containing 0.25% CLnA + 0.15% α-tocopherol. The results demonstrated that 0.5% CLnA, 0.15% α-tocopherol, and 0.25% CLnA + 0.15% α-tocopherol each on supplementation significantly lowered total cholesterol and non-HDL-cholesterol in comparison with the diabetic control group. The TAG level was significantly lowered in both the 0.15% α-tocopherol and 0.25% CLnA + 0.15% α-tocopherol groups. LDL-lipid peroxidation and erythrocyte membrane lipid peroxidation were reduced significantly in each of the experimental groups vs. the control group. The CLnA + α-tocopherol diet induced a greater reduction in membrane lipid and liver lipid peroxidation than the α-tocopherol diet alone. In conclusion, dietary CLnA exerts antioxidant activity as evidenced by reduced lipid peroxidation in chemically induced diabetes mellitus.

Paper no. L9700 in *Lipids 41*, 49–54 (January 2006).

Oxidant free radicals have been implicated in the pathogenesis of type I diabetes mellitus (DM) (1,2). In addition, diabetic patients have significant defects of antioxidant protection (3,4). Glucose auto oxidation, polyol pathway, and protein glycation are biochemical pathways associated with hyperglycemia and toxic superoxide intermediates (4). DM is also associated with the peroxidation of lipids and plasma lipoproteins (5). Oxidized lipoproteins lead to the development of atherosclerosis and diabetic vascular complications.

Antioxidants scavenge free radicals and reduce the deleterious consequences within the lipid. Conjugated linoleic acid (CLA) has been proved to prevent noninsulin-dependent DM (6). Garlic oil (7), fenugreek (8), and ferulic acid (9) each act as an antioxidant and reduce pathological conditions of DM in rats.

Conjugated linolenic acid (CLnA) (α-eleostearic acid: 9*c*,11*t*,13*t*-18:3), commonly found in karela seed (*Momordica charantia*), was evaluated nutritionally in a previous study (10). When CLnA was fed as dietary FA to rats at 0.5, 2, and 10% levels with sunflower oil, CLnA significantly lowered plasma lipid peroxidation, erythrocyte membrane (EM) lipid peroxidation, and liver tissue lipid peroxidation in comparison with the sunflower oil group at a 0.5% level (11). The antioxidant property decreased with the increase of CLnA level in the diet. Koba *et al.* (12) reported significant effects of dietary CLnA on body fat, serum lipid, and liver lipid levels in rats. A cancer chemoprotective activity in the early phase of colon tumorigenesis has also been reported (13).

The aim of the present study was to examine the antioxidant activity of CLnA, in the absence and presence of α-tocopherol as a protective agent against atherosclerosis and DM.

EXPERIMENTAL PROCEDURES

Dietary fat sources. Oil was extracted from authentic karela (bitter gourd) seed, obtained from the local market in Calcutta, India, in a Soxhlet apparatus with food-grade *n*-hexane (40–60°C boiling range). The FFA present in the oil were then removed by the miscella refining process (14). The extracted oil containing hexane, known as miscella (hexane/oil 2:1, vol/wt) was mixed with 10% NaOH solution (20% excess of the theoretical amount required) to neutralize the FFA at 40°C for 30 min. The soap formed was removed by centrifugation, and the organic phase was washed with water. Deacidified oil was recovered after removing the solvent under vacuum distillation and drying under vacuum. The refined oil was bleached with Tonsil earth (1% w/w) obtained from P.T. Sud-Chemical (Jakarta, Indonesia) and activated carbon (2% w/w), supplied

Abbreviations: CLA, conjugated linoleic acid; CLnA, conjugated linolenic acid; DC, diabetic control group (group of rats feeding on sunflower oil under diabetic conditions); D-CLnA, diabetic conjugated linolenic acid group (group of rats feeding on sunflower oil containing 0.5% CLnA under diabetic conditions); DM, diabetes mellitus; D-Toc, diabetic tocopherol group (group of rats feeding on sunflower oil containing 0.15% α-tocopherol under diabetic conditions); D-Toc-CLnA, diabetic tocopherol and conjugated linolenic acid group (group of rats feeding on sunflower oil containing 0.15% α-tocopherol + 0.25% CLnA under diabetic conditions); EM, erythrocyte membrane; LA, linoleic acid; LOS, lipoprotein oxidation susceptibility; MDA, malondialdehyde; NDC, nondiabetic control group (group of rats feeding on sunflower oil under normal conditions); RBC, red blood cell; TBA, thiobarbituric acid.

TABLE 1
FA Composition of Dietary Oils and Oil Mixtures

	FA composition (area%)				
Dietary fats	16:0	18:0	18:1	18:2	18:3 (CLnA, 9*c*,11*t*,13*t*-18:3)
Sunflower oil	6.2	3.4	32.8	57.6	—
Karela seed oil	1.4	31.5	6.2	3.2	57.7
Sunflower oil + karela seed oil (99:1, w/w)	6.1	3.9	32.4	57.1	0.5
Sunflower oil + karela seed oil (99.5:0.5, w/w)	6.1	3.9	32.55	57.2	0.25

by E. Merck India Pvt. Ltd. (Bombay, India) at 60°C under vacuum for 20 min. After the bleaching operation, the oil was recovered by vacuum filtration and stored at –40°C under nitrogen.

Dietary fat blends. Sunflower oil was obtained from I.T.C. Limited (Hyderabad, India). Sunflower oil was mixed with karela seed oil, α-tocopherol, and a mixture of karela seed oil and α-tocopherol to give final oil mixtures containing 0.5% by weight of CLnA, 0.15% α-tocopherol, and 0.15% α-tocopherol + 0.25% CLnA; see Table 1 for FA composition of dietary oil mixtures.

Analysis of fat products. GC (Hewlett-Packard 5890A) was used to determine FA composition (11). The chromatographic conditions were: detector, FID; carrier gas, nitrogen; flow rate, 30 mL/min; column, 10% diethylene glycol succinate, $6' \times 1/8''$ (1800×3 mm) i.d. The oven, injection port, and detector block temperatures were 190, 230, and 240°C, respectively. The sample of methyl ester (0.1–1 μg) was injected with a Hamilton syringe and the chromatogram was obtained. The identifications of FA were made by comparison with the retention times of GLC-grade standard methyl esters of varying chain lengths and unsaturations. The percent compositions of the component FA were determined by measuring the areas of the peaks with the help of the integrator (Hewlett-Packard model 3390A).

Preparation of methyl ester. About 50 mg of oil was dissolved in 0.5 mL of diethyl ether, and 1.0 mL of 0.5 N methanolic KOH solution was added. The reaction mixture was shaken for 10 min at room temperature and after the addition of 1.0 mL of 1 N HCl was then shaken vigorously. Methyl esters were extracted with 3×1 mL portions of petroleum ether. The extracts were combined in a screw-capped test tube, and the solvent was removed by a flow of nitrogen.

Conjugation of α-eleostearic acid present in karela seed oil was determined by UV spectrometric analysis at 262, 268, and 274 nm (15).

Feeding experiment. Male albino rats of Charles Foster strain (selected for the authenticity of the strain) were housed in individual cages. The work was done under the supervision of the Animal Ethical Committee of the Department of Chemical Technology (University of Calcutta). The animals were divided into five groups (average body weight 70–80 g), each consisting of eight animals. Diabetes mellitus was induced in control and experimental groups of rats (after attaining their average body weight 100 g) by a single intraperitoneal injection of 200 mg alloxan/kg body weight, freshly prepared in sterilized water (7). The rats with blood sugar levels >230 mg/dL, indicating glycemia, were considered diabetic. The first group was the nondiabetic control group (NDC) without any treatment. The second group received sunflower oil and served as the diabetic control group (DC). The third, fourth, and fifth groups received sunflower oil along with karela seed oil (D-CLnA), α-tocopherol (D-Toc), and α-tocopherol + karela seed oil (D-Toc-CLnA), respectively.

The rats were fed experimental diets having the following composition: fat-free casein, 18%; fat, 20%; starch, 55%; salt mixture 4% [composition of salt mixture No. 12 (in g): NaCl, 292.5; KH_2PO_4, 816.6; $MgSO_4$, 120.3; $CaCO_3$, 800.8; $FeSO_4 \cdot 7H_2O$, 56.6; KCl, 1.66; $MnSO_4 \cdot 2H_2O$, 9.35; $ZnCl_2$, 0.5452; $CuSO_4 \cdot 5H_2O$, 0.9988; $CoCl_2 \cdot 6H_2O$, 0.0476 (16)]; cellulose, 3%; and one multivitamin capsule (vitamin A I.P. 10,000 units, thiamine mononitrate I.P. 5 mg, vitamin B I.P. 5 mg, calcium pantothenate USP 5 mg, niacinamide I.P. 50 mg, ascorbic acid I.P. 400 units, cholecalciferol USP 15 units, menadione I.P. 9.1 mg, folic acid I.P. 1 mg, and vitamin E USP 0.1 mg) per kg of diet. The diets were adequate in all nutrients.

Rats were maintained on the above diets *ad libitum* for 6 wk. The amount of daily diet consumed by each rat and weekly body weight gain were recorded. Rats were fasted overnight for 12 h and then sacrificed under anesthesia; blood was collected, and liver and heart were immediately excised, blotted, and stored frozen (–40°C) for analysis.

Lipid analysis. According to the standard methods, the lipid components such as total cholesterol (17), and HDL-cholesterol (18) of plasma were analyzed using enzyme kits supplied by Ranbaxy Diagnostics Ltd. (New Delhi, India).

Plasma lipid peroxidation was measured by the assay of TBARS according to the standard method (19). The amount of malondialdehyde (MDA) formed was calculated by taking the extinction coefficient of MDA to be $1.56 \times 10^5\ M^{-1}\ cm^{-1}$.

Lipoprotein oxidation susceptibility (LOS) test. A 500-μL plasma sample was treated with 50 μL of a solution containing 0.2 mM dextran sulfate (M.W. 50,000; Genzyme, Cambridge, MA) and 0.5 M $MgCl_2 \cdot 6H_2O$ to precipitate the apolipoprotein B-containing lipoproteins (LDL and VLDL) according to Bachorik and Albers (20). After centrifugation at $3000 \times g$ at 20°C for 10 min, the supernatant was removed, and 1 mL of 6% BSA and another 50 μL of the dextran sulfate solution was added. The solution was briefly vortexed and recentrifuged as above

to wash away any HDL or residual serum proteins (except, of course, albumin). The supernatant was removed, and washed precipitate (containing LDL and VLDL) was dissolved in 2.5 µL of 4% NaCl. A volume of redissolved precipitate containing 100 µg of non-HDL-cholesterol was combined with sufficient 4% NaCl to give a total volume of 500 µL (approximately a 1:5 dilution). Fifty microliters of a 0.5 mM $CuCl_2 \cdot 2H_2O$ solution was added (final copper concentration was 46 µM), and then the samples were incubated at 37°C in a shaking water bath for 3 h. Next TBARS was measured by adding 2 mL of the TBARS reagent to each tube. The mixture was heated at 100°C in a water bath for 15 min. After removing and cooling the tubes, 2.5 mL *n*-butanol was added, the tubes were vortexed and then centrifuged for 15 min at 3000 × *g* at room temperature. The pink upper layer was removed and the O.D. was determined in a spectrophotometer at 532 nm according to the method described by Phelps and Harris (21).

Preparation and oxidative sensitivity of EM ghost (22). After plasma separation, the red blood cells (RBC) were washed three times by centrifugation at 3000 × *g* for 10 min with 3 vol of a cooled isotonic solution containing 0.15 M NaCl and 10^{-5} M EDTA. RBC were hemolyzed using hypotonic solution and centrifuged at 20,000 × *g* for 40 min at 4°C. The supernatant was removed carefully with a Pasteur pipette. The process was repeated two more times. After the last wash step, the supernatant was removed as much as possible and the loosely packed milky-looking membrane pellet was resuspended at the bottom of the tube using 0.89% NaCl solution. The concentrated membrane solution was taken into a 2 mL screw-capped vial and stored at –40°C.

A modification of the 2-thiobarbituric acid (TBA) test (23) was used to measure the lipid peroxides. A 0.5 mL aliquot of the red blood cell membrane suspension was mixed with 1.0 mL of 10% TCA and 2.0 mL of 0.67% 2-TBA. The mixture was heated at 95°C for 15 min, cooled, and centrifuged. The absorbance of the supernatant was measured at 534 nm in a spectrophotometer (Shimadzu, Tokyo, Japan), and the relative amounts of lipid peroxides were expressed in absorbance units, A_{534} nm (24).

Liver tissue lipid extraction and peroxidation. For lipid peroxide measurement, approximately 1 g of liver tissue was placed into a glass centrifuge tube (70 mL) for 2 min in a solvent mixture consisting of 10 mL of chloroform and 20 mL of methanol, and homogenized on ice. Then, 10 mL of chloroform was added and homogenization continued for another 30 s. Finally, 10 mL of redistilled water was added and the mixture was homogenized for 30 s. The tubes were then centrifuged for 20 min at 4000 × *g*, and the chloroform layer was separated in a separatory funnel. A TBA test in chloroform phase from a Bligh and Dyer extraction (25) was performed according to the method described by Schmedes and Hølmer (26). Chloroform (2.5 mL) from the Bligh and Dyer extraction was pipetted into a 30-mL autoclavable glass culture tube (Kimax; Kimble/Kontes, Vineland, NJ) having a Teflon-lined screw cap; 4 mL of the TBA reagent was added and the tube was capped tightly. Safety-shielded tubes were heated for 30 min in a boiling water bath and cooled in tap water. After cooling, 3.5 mL TCA (5%) was added to each tube, mixed thoroughly, and the tubes were then centrifuged at 3000 × *g*.

Statistical analysis. The data were expressed as mean ± SD. A one-way ANOVA was also used for statistical analysis between groups. The *F* ratio of one-way ANOVA is significant when the *P* value < 0.05. Tukey's multiple range method (27) was used for comparison. The statistical program was Minitab release 13.31 (Minitab, State College, PA).

RESULTS

The FA composition of the dietary oils and oil blends is given in Table 1. Oleic (18:1) and linoleic (18:2) acid contents are generally similar in content for the control and experimental dietary fats.

The plasma total cholesterol, HDL-cholesterol, non-HDL-cholesterol, TAG, and blood sugar level of the rats (NDC and DC groups), raised on sunflower oil and sunflower oil containing 0.5% CLnA (D-CLnA group), 0.15% α-tocopherol (D-Toc group), and 0.15% α-tocopherol + 0.25% CLnA (D-CLnA-Toc group) diets, were quantified (Table 2). Diabetes induced by alloxan increased total cholesterol, HDL-cholesterol, non-HDL-cholesterol, TAG, and blood sugar levels significantly in comparison with the corresponding values of the control nondiabetic rats. Plasma total cholesterol in each of the experimental

TABLE 2
Plasma Lipid Profile and Blood Sugar Level of Rats in Different Groups[a,b]

Groups	Total cholesterol (mg/dL)	HDL-cholesterol (mg/dL)	Non-HDL cholesterol (mg/dL)	TAG (mg/dL)	Blood sugar (mg/dL)
Control (nondiabetic, NDC)	63.75 ± 3.25	34.51 ± 2.99	22.368 ± 0.53	55.08 ± 5.89	81.13 ± 4.69

TABLE 3
Plasma Lipid Peroxidation and Lipoprotein Peroxidation of Rats of Different Groups[a,b]

Groups	Plasma peroxidation (nmol of MDA/mL of plasma)	LDL peroxidation (nmol of MDA/mg of non-HDL-cholesterol)
Control (NDC)	2.89 ± 0.62	0.239 ± 0.011
Diabetic control (DC)	14.00 ± 1.11[a]	0.567 ± 0.353[a]
0.5% CLnA (D-CLnA)	12.07 ± 1.55	0.18 ± 0.05
0.15% Tocopherol (D-Toc)	11.09 ± 1.43	0.16 ± 0.04
0.15% Tocopherol + 0.25% CLnA (D-Toc-CLnA)	13.39 ± 1.93	0.061 ± 0.174

[a]MDA, malondialdehyde; for other abbreviations see Table 2.
[b]All values are means of 8 rats/diet. [a]NDC vs. DC. Significant *F* ratios for plasma peroxidation (*P* value: 0.0001). No significant *F* ratio for LDL peroxidation, *F* < critical *F*.

groups was significantly lower than that of the diabetic control (DC) sunflower oil group. There was also a significant lowering of the plasma non-HDL-cholesterol levels in all three experimental groups compared with the DC group. The TAG level was significantly lowered in the D-Toc and D-Toc-CLnA groups.

Plasma lipid peroxidation and LOS induced by copper were measured in the five dietary groups (Table 3). Plasma lipid peroxidation and LDL peroxidation both increased significantly in the DC group compared with the NDC group. No significant differences were noted between the experimental groups and the DC group in the *in vitro* plasma lipid peroxidation. There was significant lowering of LOS in the three experimental diabetic groups of rats when compared with that of the DC group.

The lipid profiles and the extent of lipid peroxidation in EM ghost of the five dietary groups of rats were analyzed (Table 4). Phospholipid and cholesterol contents in the DC group did not increase significantly compared with the NDC group. However, EM lipid peroxidation increased significantly in the DC group. The cholesterol and phospholipid contents showed no significant difference in the experimental dietary groups of rats and the DC group. But TBARS production in EM ghosts of D-CLnA, D-Toc, and D-Toc-CLnA groups was significantly lower than the control DC group without CLnA.

In the case of liver lipids (Table 5), no significant difference was noted in the content of total lipid, total cholesterol, and phospholipid between the NDC group and the DC group. But TAG content and liver lipid peroxidation increased significantly in the DC group compared with the NDC group. The production of TBARS *in vitro* in liver lipid of the D-Toc-CLnA group decreased significantly compared with the DC group. CLnA + α-tocopherol diet decreased liver lipid peroxidation significantly more than α-tocopherol alone.

DISCUSSION

Antioxidative defense systems against oxidative stress, which is related to various degenerative diseases such as DM, cardiovascular disease, arthritis, and aging, are well documented (28). In alloxan-induced DM, high levels of free radicals are generated (29) and cause oxidative damage. Endogenous antioxidants become important in the defense against oxidative damage. We previously reported that CLnA present in karela seed oil has scavenging action against lipid peroxidation (11) and that 0.5% CLnA in the dietary lipid was the optimal dose for the antioxidative effect, as was used also in the current study. Individually, α-tocopherol and CLnA evoked similar antioxidative responses at 0.5 and 0.15% dosage levels, respectively. In the present study, the effect of lipid profiles and lipid peroxidations was examined by reducing the amount of dietary CLnA from 0.5 to 0.25% without changing the dose of α-tocopherol.

Besides changing the blood sugar level, diabetes induced by alloxan changed lipid profiles dramatically. Unlike dietary CLA that significantly increased fasting glucose as demonstrated by Moloney *et al.* (30), dietary CLnA did not increase

TABLE 5
Liver Lipid Profile and Lipid Peroxidation of Rats[a,b]

Groups	Total lipid (g/g of tissue)	Total cholesterol (mg/g of tissue)	Phospholipid (mg/g of tissue)	TAG (mg/g of tissue)	Liver lipid peroxidation (nmol of MDA/mg of tissue lipid)
Control (nondiabetic, NDC)	0.08 ± 0.01	2.08 ± 0.36	16.01 ± 0.68	6.74 ± 0.57	0.85 ± 0.06
Diabetic control (DC)	0.06 ± 0.02	2.49 ± 0.14	15.78 ± 1.18	12.31 ± 1.61[a]	1.49 ± 0.25[a]
0.5% CLnA (D-CLnA)	0.08 ± 0.02	2.06 ± 0.26	16.27 ± 1.53	6.94 ± 0.78[b]	1.24 ± 0.30
0.15% Tocopherol (D-Toc)	0.07 ± 0.02	3.07 ± 0.38	14.46 ± 1.57	7.7 ± 0.51[c]	1.2 ± 0.17
0.15% Tocopherol + 0.25% CLnA (D-Toc-CLnA)	0.07 ± 0.02	2.30 ± 0.37	16.19 ± 1.25	12.22 ± 1.45	0.54 ± 0.06[d,e]

[a]For abbreviations see Tables 2 and 4.
[b]All values are means of 8 rats/diet. [a]NDC vs. DC; [b]DC vs. D-CLnA; [c]DC vs. D-Toc; [d]DC vs. D-Toc-CLnA;, [e]D-Toc vs. D-Toc-CLnA. Significant *F* ratios for liver lipid peroxidation (*P* value: 0.029), liver TAG (*P* value: 0.001). *F* < critical *F* for liver total lipid, phospholipids, and cholesterol.

blood sugar levels in diabetic rats. The total HDL-cholesterol concentration did not change with dietary CLnA, but CLnA significantly reduced non-HDL-cholesterol such that the HDL/non-HDL cholesterol ratio increased. The presence of 0.15% α-tocopherol, or 0.5% CLnA, or the combination of 0.25% CLnA + 0.15% α-tocopherol in the diet, lowered total cholesterol and non-HDL-cholesterol levels in diabetic rats to similar extents. The combination of CLnA and α-tocopherol did not evoke responses that were significantly different from those evoked by α-tocopherol alone. Koba *et al.* (12) reported a significant lowering of serum cholesterol concentration in rats fed CLnA compared with those fed linoleic acid (LA). It was previously reported that α-tocopherol has cholesterol- and TAG-lowering effects (31). CLnA at a 0.5% level failed to reduce TAG levels significantly in the lipids of diabetic rats, as reported previously for nondiabetic rats (11). α-Tocopherol significantly lowered TAG levels in plasma of diabetic rats to levels found in nondiabetic control animals. The combination of CLnA (0.25%) with α-tocopherol also significantly reduced TAG levels, but these levels were not significantly different from α-tocopherol alone.

The effects of different synthetic and natural antioxidants as inhibitors of LDL peroxidation and their possible therapeutic effects to counteract atherogenesis are well documented (32,33). LDL-lipid peroxidation and its inhibition by antioxidants are important in the molecular mechanism of atherosclerosis. Superoxides generated in response to hyperglycemia lead to the peroxidation of lipids of plasma, lipoprotein, and EM (33). Oxidized lipoproteins lead to the development of atherosclerosis and diabetic vascular complications. In the present study, the CLnA-fed diabetic rats showed a significant decrease in EM LOS, which was equivalent to the α-tocopherol group. The plasma peroxidation showed no significant difference. The peroxidation level in DM was so high that neither 0.5% CLnA nor α-tocopherol, nor a combination of these agents, decreased peroxide production, although in normal rats the peroxidation level decreased with 0.5% CLnA intake (11).

It is interesting that CLnA, α-tocopherol, and their combination significantly decreased the EM lipid peroxidation level without changing the phospholipid and cholesterol content and their ratios. These data corroborate previous observations (11) that CLnA lowered EM lipid peroxidation in normal rats. It suggests that CLnA at a 0.5% level is effective in both normal and diabetic conditions as an antioxidant. However, the combination of 0.25% CLnA and α-tocopherol did not induce significantly different EM lipid peroxidation changes compared with animals fed α-tocopherol alone.

The liver total lipid, cholesterol, and phospholipid profiles showed no significant differences between the control and diabetic groups of rats irrespective of their dietary intake of CLnA and α-tocopherol or their combination. However, whereas CLnA alone and α-tocopherol alone failed to lower liver lipid peroxidation levels significantly in diabetic animals, liver lipid peroxidation was significantly reduced by about 50% in the group fed α-tocopherol together with a lower dose of CLnA.

A comparison of antioxidant activity between dietary CLnA and CLA has both importance and relevance in the context of claims made in favor of CLA. Kim *et al.* (34) reported that dietary CLA reduced lipid peroxidation by increasing oxidative stability in rats, increasing the proportions of higher saturated and monounsaturated FA in both plasma and hepatic membrane, while lowering levels of oxidatively susceptible PUFA such as linoleic, linolenic, and arachidonic acids. A similar reasoning may explain the relations of dietary CLnA and α-tocopherol in the lowering effect of lipid peroxidation.

A conservative explanation for the antioxidant activity of CLnA can be drawn based on the bioconversion reactions of CLnA. Under *in vivo* conditions, CLnA can undergo isomerization, hydrogenation, and oxidation reactions to form PUFA of both nonconjugated acids (LA and LnA) and conjugated CLA. It is known that CLA reduces superoxide dismutase activity while having no catalase-enhancing activity. This response may have enhanced the antioxidant activity of CLnA when used even at a reduced dose with the fixed dose of α-tocopherol.

The present report provides scope to investigate the effects of orally administered CLnA in diabetes (rats or human beings). The results of the present study demonstrate the beneficial effect of CLnA ameliorating the adverse free radical-generating influence of alloxan-induced DM. This is the first report demonstrating the synergistic effect of CLnA with α-tocopherol as *in vivo* antioxidative agents on lipid peroxidation in diabetic rats.

ABSTRACT: In this study, we examined whether the increased availability of lipids in blood resulting from two types of diet manipulation regulated metabolic gene expression in the skeletal muscle of rats. Feeding for 4 wk on an isocaloric-sucrose or a hypercaloric-fat diet increased plasma TAG in the fed condition by increments of 70 and 40%, respectively, and increased fasting insulinemia (approximately 3-fold) compared with a starch diet. The fat diet impaired glucose tolerance and caused obesity, whereas sucrose-fed rats maintained their normal weight. We analyzed the expression of genes that regulate the exogenous FA supply (LPL, FAT/CD36, FATP1), synthesis (ACC1), glucose (GLUT4, GLUT1, HK2, GFAT1, glycogen phosphorylase) or glycerol (glycerol kinase) provision, or substrate choice for oxidation (PDK4) in gastrocnemius and soleus muscles at the end of the glucose tolerance test. LPL, FAT/CD36, FATP1, PDK4, and GLUT4 mRNA as well as glycogen phosphorylase and glycerol kinase activity levels in both muscles were unchanged by the diets. Increased mRNA levels of GLUT1 (1.6- and 2.6-fold, respectively) and GFAT1 (about 1.7-fold) in gastrocnemius, and of ACC1 (about 1.5-fold) in soleus, were found in both the sucrose and fat groups. In the fat group, HK2 mRNA was also higher (1.8-fold) in the gastrocnemius. Both sucrose and saturated-fat diets prompted hyperinsulinemia and hyperlipemia in rats. These metabolic disturbances did not alter the expression of LPL, FAT/CD36, FATP1, PDK4, and GLUT4 genes or glycogen phosphorylase and glycerol kinase activity levels in either analyzed muscle. Instead, they were linked to the coordinated upregulation in gastrocnemius of genes that govern glucose uptake and the hexosamine pathway, namely, GLUT1 and GFAT1, which might contribute to insulin resistance.

Paper no. L9793 in *Lipids 41*, 55–62 (January 2006).

In rats, hyperlipemia appears after a few weeks on diets that include sucrose (1) or fat (2) as the main nutrient. Nevertheless, sucrose (3–5) and fat (6–8) diets promote quite distinct metabolic phenotypes in rats. Isocaloric replacement of dietary starch by sucrose does not increase body weight (9–11), whereas the elevation of blood insulin is controversial, since normal (4,5) and high levels of insulin (12,13) have been reported. Hypercaloric fat diets, in turn, trigger obesity and insulin resistance (14). The mechanisms by which each type of diet raises blood lipids are distinct. In sucrose-fed rats, metabolic changes are mainly mediated by fructose, which induces hepatic lipogenesis (15). High-fat diets raise lipemia owing to the increased supply of FA (16).

Skeletal muscle is a key contributor to metabolite clearance. The competitive use of FA and glucose by the muscle tissue is considered a basic mechanism of normal metabolic homeostasis. However, there is scarce information (17,18) about the regulation, in hyperlipemic conditions, of genes that control the FA and glucose supply to skeletal muscle, which may contribute to this imbalance. A previous study analyzed the expression of FA transport and β-oxidation genes in the skeletal muscle of humans during a short-term (days) isocaloric fat diet (19). Key genes in muscle FA metabolism are: lipoprotein lipase (LPL), which hydrolyzes plasma lipoprotein TAG (20); FA translocase (FAT/CD36) (21,22) and the FABP FATP1 (23), which promote FA uptake; and the acetyl-CoA carboxylase ACC1 isoform, which is primarily involved in FA synthesis (24). Glycerol kinase may also be a relevant gene in FA metabolism, since it may limit FA esterification (25). Crucial genes involved in the regulation of muscle cell glucose disposal are the glucose transporters GLUT4 and GLUT1 (26); hexokinase, the predominant muscle isoform HK2, which catalyzes subsequent glucose phosphorylation (27); and glycogen phosphorylase, which controls the endogenous glucose supply from glycogen (28). Pyruvate dehydrogenase kinase, PDK4, which is primarily expressed in muscle, is a putative regulatory gene of glucose and FA selectivity for oxidation (29). PDK4 inactivates pyruvate dehydrogenase activity, the enzyme that limits the formation of acetyl-CoA from glucose, thereby negatively regulating glucose oxidation. Finally, the ubiquitous isoform of glutamine:fructose-6-phosphate amidotransferase, GFAT1, is the rate-limiting enzyme for hexosamine biosynthesis, which is a nutrient-sensing pathway that signals insulin resistance (30).

Abbreviations: ACC1, acetyl-Co carboxylase 1; CT, threshold cycle; FAT/CD36, fatty acid translocase; FATP1, fatty acid transport protein 1; GFAT1, glutamine:fructose-6-phosphate amidotransferase 1; GLUT1 and GLUT4, glucose transporters; HK2, hexokinase 2; II_{30}, insulinogenic index after 30 min; LPL, lipoprotein lipase; PDK4, pyruvate dehydrogenase kinase, isoenzyme 4; QUICKI, quantitative insulin sensitivity check index; RPLP0, ribosomal protein large, P0; UDP-GlcNAc, uridine diphosphate-*N*-acetylglucosamine.

Thus, the aim of this study was to compare the effects of a sucrose-based diet vs. a starch-based diet on whole body insulin sensitivity and the expression of metabolic genes in skeletal muscle. An earlier study had compared the effects of a high-sucrose or high-fat diet on FA metabolic genes in the liver (31) exclusively. Here, mRNA levels of FA uptake- and deposition-regulating genes, such as LPL, FAT/CD36, FATP1, ACC1 or the glucose transporters GLUT1 and GLUT4; the glucose-metabolism-regulating genes GFAT1, HK2, and PDK4; and the enzyme activities of glycogen phosphorylase and glycerol kinase were assessed in soleus and gastrocnemius muscles.

EXPERIMENTAL PROCEDURES

Animals, diets, and food intake control. Male Wistar rats were purchased from Interfauna (Harlan Ibérica, Barcelona, Spain) and had an average weight of 200–225 g. They were placed in standard cages (two rats per cage) fitted with special powder feeders and kept at a constant temperature of 23°C with a 12-h light/dark cycle. Rats had free access to water and diet. During the first week of acclimation, they were fed a standard high-starch-based diet (control) (A04; Panlab, Barcelona, Spain). The composition was: 17.5% protein, 2.9% sucrose, 63.3% starch, 3.3% lard, 5.5% fiber, 1.0% vitamin mixture, 6.0% mineral mix, 0.3% DL-methionine, and 0.2% choline bitartrate (364 kcal/100 g). Thereafter, groups of 6 rats were fed the control diet or a sucrose- or lard-based diet for 4 wk. Sucrose and lard diets were prepared at the Nestlé Research Center (Lausanne, Switzerland). The composition of the two diets were: (i) sucrose [20% protein, 50% sucrose, 13.3% starch, 5% lard, 5% fiber, 1.5% vitamin mixture, 4.7% mineral mix, 0.3% DL-methionine, and 0.2% choline bitartrate (378 kcal/100 g)], and (ii) lard [25.4% protein, 8.5% sucrose, 16.9% starch, 33.9% lard, 8.4% fiber, 1.5% vitamin mixture, 4.7% mineral mix, 0.4% DL-methionine, and 0.3% choline bitartrate (508 kcal/100 g)]. Rats and food were weighed every 2 d to calculate weight gain and food intake, respectively. Animal treatment protocols were approved by the Comitè Etic d'Experimentació Animal of the University of Barcelona (Barcelona, Spain).

Glucose tolerance test and tissue sampling. Four weeks after dietary treatment, animals were fasted for 18 h and then anesthetized with pentobarbital (70 mg/kg of body weight), and an isotonic solution of glucose (2 g/kg of body weight) was administered by ip injection. Rats were always bled *via* the tail before and 10, 20, 30, 60, 90, and 120 min after glucose administration. At the end of the test (2 h after glucose injection), gastrocnemius and soleus muscles were excised and immediately frozen in liquid N_2 and stored at −80°C. The abdominal cavity was then opened and the epididymal fat pads were removed and weighed before being frozen in liquid N_2.

Measurement of metabolite and insulin. Plasma insulin levels were assayed by ELISA (Crystal Chem Inc., Chicago, IL). TAG and FFA were measured in plasma samples using kits from Sigma Chemical Co. (St. Louis, MO) and Roche (Basel, Switzerland). Lactate was measured enzymatically in plasma. Blood glucose was analyzed with a reflectometer (GlucoTouch®; Lifescan Johnson & Johnson, Milpitas, CA). QUICKI, a quantitative insulin sensitivity check index (32), was calculated as QUICKI = 1/[log(Gb) + log(Ib)], where Gb is fasting plasma glucose (mg/dL), and Ib is the fasting plasma insulin (μU/mL). The insulinogenic index at 30 min (II_{30}) (33) was calculated as the ratio of increase at 30 min of plasma insulin, $\Delta I_{30} = Ins_{30min}$ (mU/L) − Ins_{0min} (mU/L), vs. that of glucose, $\Delta Glu_{30} = glucose_{30min}$(mmol/L) − $glucose_{0min}$(mmol/L), $II_{30} = \Delta I_{30}/\Delta Glu_{30}$, during the glucose tolerance test.

Enzyme activity assays. Muscle samples were homogenized with a Polytron (Kynematica Polytron, Westbury, NY) in a buffer containing 50 mM Hepes (pH 7.8), 40 mM KCl, 11 mM $MgCl_2$, 1 mM EDTA, and 1 mM DTT to measure glycerol kinase, or in a buffer containing 10 mM Tris-HCl (pH 7.0), 150 mM KF, 15 mM EDTA, 600 mM sucrose, 15 mM 2-mercaptoethanol, 10 μg/mL leupeptin, 1 mM benzamidine, and 1 mM phenylmethylsulfonyl fluoride to measure glycogen phosphorylase. Homogenates were centrifuged at 10,500 × *g* for 15 min at 4°C, and the resulting supernatants were used. To quantify glycerol kinase activity, 5 μL of muscle supernatant (approximately 20–30 μg of protein) was mixed with 25 μL of reaction buffer containing 100 mM Tris (pH 7.4), 6 mM ATP, 13.3 mM $MgSO_4$, 100 mM KCl, 20 mM 2-mercaptoethanol, and 21 μM [U-^{14}C]glycerol (specific activity 5.25 GBq/mmol). Reactions were performed for 40 min at 37°C (progress curves were linear for more than 1 h in these conditions) and then terminated by addition of 50 μL of ice-cold 98% ethanol. A 30-μL quantity of reaction mixture was spotted onto DEAE-cellulose discs and then allowed to dry for 1 h at room temperature. The discs were placed on a filter holder attached to a vacuum tube and washed twice with 5 mL and once with 50 mL of water. After drying, the papers were dropped in vials with 4 mL of scintillation liquid and counted in a Wallac scintillation counter to quantify the [^{14}C]glycerol-3-phosphate retained. Glycogen phosphorylase activity was detected following the incorporation of [U-^{14}C]glucose 1-phosphate into glycogen in the absence or presence of the allosteric activator AMP (5 mM) (34). Protein concentration was measured (Bio-Rad, Hercules, CA).

RNA extraction, reverse transcription, and real-time PCR. Total RNA was extracted from muscle samples following the instructions of the RNeasy minikit (Qiagen, Valencia, CA). Extracts were homogenized with a Polytron (Kynematica Polytron). The integrity of isolated RNA was verified by electrophoresis and ethidium bromide staining. A 0.5-μg quantity of total RNA was retrotranscribed with TaqMan reverse transcription reagents from Applied Biosystems (Branchburg, NJ) using random hexamers. Real-time PCR was performed in the ABI PRISM 7700 sequence detection system with the TaqMan universal PCR master mix and probes for LPL, ACC1, GLUT1, GLUT4, FAT, FATP1, GFAT1, HK2, and PDK4 from Applied Biosystems. β2-microglobulin and ribosomal protein P0 (RPLP0) were used as endogenous controls to normalize the threshold cycle (CT) for each probe assay as stated. Real-time PCR was performed in duplicate. Relative gene expression was estimated as $2^{-\Delta CT}$ and gene fold change was estimated as $2^{-\Delta\Delta CT}$ (35).

TABLE 1
Body Weight Gain and Plasma Metabolites After Dietary Treatments in Fasted and Fed Animals[a]

	Control	Lard	Sucrose
Caloric intake (kcal/d)	51.1 ± 1.69	81.0 ± 16.2**	62.0 ± 4.4**
Body weight gain (g)	74.6 ± 6.8	104 ± 16.4*	68.2 ± 5.6
Epididymal WAT weight (g)	3.4 ± 0.4	8.1 ± 2.4**	5.3 ± 1.2*
Fed plasma TAG (mg/dL)	107 ± 9.17	150 ± 20.4**	186 ± 13***
Fasting plasma TAG (mg/dL)	87.5 ± 28.8	62.2 ± 28.6	57.5 ± 11.6
Fed plasma FFA (μM)	410 ± 40	728 ± 93***	507 ± 115
Fasting plasma FFA (μM)	830 ± 99	885 ± 126	870 ± 52
Fed plasma lactate (mg/dL)	42.2 ± 3.7	50.4 ± 4.7*	39.4 ± 1.1
Fasting plasma lactate (mg/dL)	19.3 ± 7.8	15.9 ± 8.4	16.0 ± 2.6

[a]Values are means ± SD of 6 subjects. The significance of the differences vs. controls was: *$P < 0.05$, **$P < 0.01$, and ***$P < 0.001$. WAT, white adipose tissue.

Statistical analysis. All data are presented as means ± SD and the significance of the difference was analyzed by Student's *t*-test, except real-time PCR data, which were examined using the Relative Expression Software Tool (36). Where significant differences were found, the *P* values have been stated in the figure legend. Values were considered significant at $P < 0.05$.

RESULTS

Body weight and plasma metabolites under diet treatments. Rats were fed a control, isocaloric sucrose-based, or hypercaloric lard-based diet *ad libitum* for 4 wk. Daily caloric intake was higher in animals fed on lard (60%) and sucrose (20%) than in controls (Table 1). At the end of the treatment, average body weight in the lard group was 40% higher than in controls, whereas no significant difference from controls was detected in the sucrose group. In contrast, the weight of epididymal adipose tissue was higher in the sucrose (1.5-fold) and lard (2.3-fold) groups than in controls.

Plasma TAG levels did not differ significantly between the three diet groups in 18 h-fasted animals (Table 1). Neither plasma FFA nor lactate were altered in this nutritional condition. In contrast, in the fed condition, TAG, FFA, and lactate were higher in the lard group by 40, 77, and 19%, respectively, than in controls. In the sucrose group, only the 70% rise in TAG was significant.

Plasma fasting glucose was the same in controls as in the sucrose group, whereas the lard group showed 15% higher levels (Table 2). Remarkably, clear-cut increments in fasting insulinemia were observed in the lard (3-fold) and sucrose (3.7-fold) groups compared with controls, suggesting insulin resistance. We used QUICKI as an index of insulin sensitivity in the fasting condition. This index highly correlates with the insulin response, as assessed by euglycemic hyperinsulinemic clamps (32). QUICKI was lower in the sucrose and lard groups compared with controls, indicating that the former two diets triggered insulin resistance. We then evaluated glucose tolerance. Two hours after intraperitoneal administration of a bolus of glucose, glycemia was 20% higher in the lard group only (Table 2). Glucose and insulin concentrations were measured 30 min after the glucose load and the insulinogenic index (II_{30}) was assessed. This index estimates the first phase of insulin response (33) and is based on the increase in insulinemia over 30 min (ΔI_{30}) relative to the increase in glucose concentration (ΔGlu_{30}). The ΔI_{30} was similar in controls and the sucrose group (mean values 143 and 149, respectively) but lower in the animals fed on lard (103). ΔGlu_{30} was comparably lower in animals fed a diet of lard or sucrose (mean values 4.6 and 4.5, respectively) than in controls (6.4). Therefore, the II_{30} (Table 2) was similar for the control and lard groups, whereas the sucrose group showed a 42% increase over controls.

mRNA levels of metabolic genes in soleus and gastrocnemius muscles. The relative mRNA levels of LPL, FAT/CD36,

TABLE 2
Glucose Tolerance and Insulin Sensitivity[a]

	Control	Lard	Sucrose
Plasma glucose, 0 min (mM)	4.26 ± 0.47	4.94 ± 0.48*	4.51 ± 0.41
Plasma glucose, 30 min (mM)	10.7 ± 3.50	9.55 ± 1.14	9.0 ± 1.36
Plasma glucose, 120 min (mM)	5.6 ± 0.52	7.2 ± 0.74**	6.9 ± 1.96
Plasma insulin, 0 min (mU/L)	16.4 ± 4.4	51.1 ± 28.4*	60.3 ± 28.1*
Plasma insulin, 30 min (mU/L)	160 ± 27.5	154 ± 40.0	210 ± 42.7
QUICKI	0.55 ± 0.04	0.43 ± 0.05**	0.41 ± 0.05**
Insulinogenic index (II_{30})	26.4 ± 11.0	25.3 ± 6.0	37.6 ± 10.9

[a]Blood glucose and plasma insulin were measured before (0 min), 30 min after, and 120 min after administration of glucose. Values are means ± SD of 6 subjects. The significance of the differences vs. time-matched controls was: *$P < 0.05$, **$P < 0.01$. QUICKI, a quantitative insulin sensitivity check index.

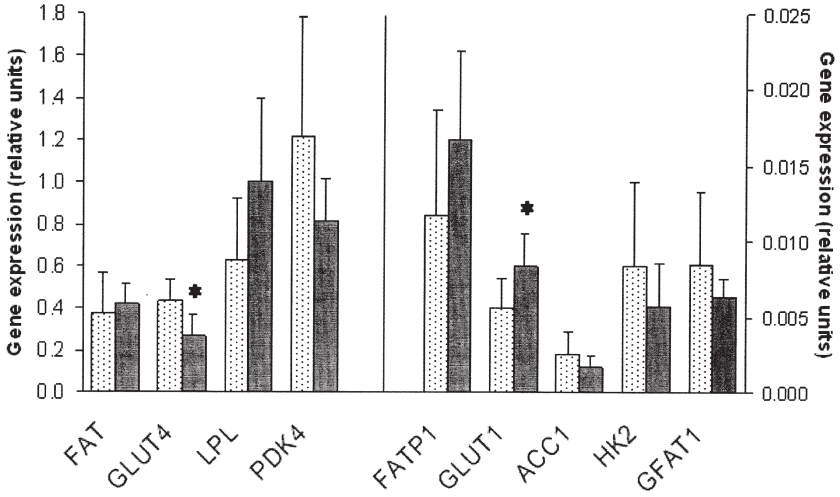

FIG. 1. Relative muscle gene expression. Animals were administered a control diet for 4 wk, fasted overnight, and subsequently subjected to a glucose tolerance test. Expression of LPL, GLUT1, GLUT4, FATP1, FAT, ACC1, GFAT1, HK2, and PDK4 was assessed by real-time PCR in soleus (dark bars) and gastrocnemius (dotted bars) muscles harvested at the end of the test. The threshold cycle (CT) values for the reference probe beta2-microglobulin were subtracted from FAT, FATP1, GLUT1, GLUT4, and LPL probes CT (ΔCT), whereas ACC1, GFAT1, HK2, and PDK4 were compared with RPLP0. Data are expressed as $2^{-\Delta CT}$. Values are means ± SD from 6 muscles of each type. The significance of the differences of gastrocnemius vs. soleus muscle was: $^*P < 0.05$.

FATP1, ACC1, GLUT4, GLUT1, GFAT1, HK2, and PDK4 were assessed in slow- twitch (soleus) and fast-twitch (gastrocnemius) muscles (37) by real-time PCR, using beta2-microglobulin and RPLP0 as endogenous controls. Expression of each control gene was the same in both muscles and all diet groups (data not shown). Significant differences were observed for (i) GLUT1, which was approximately 48% more abundant in soleus (Fig. 1), and for (ii) GLUT4, which was predominant in gastrocnemius (60% higher relative expression). In the sucrose and lard groups, the expression of the FABP FAT and FATP1 showed a tendency to decrease in gastrocnemius, but no clear trend was detected in soleus. However, these decreases were not significant (Table 3). ACC1 expression increased in the sucrose and lard groups in the soleus only (Table 3). In contrast, GFAT1 and HK2 showed a tendency to upregulate in the gastrocnemius only, although differences were not significant for HK2 in the sucrose diet (Table 3). No major effects were observed on LPL or PDK4 expression. Regarding the glucose transporters, GLUT4 expression was not significantly modified by diet treatments, whereas GLUT1 mRNA was upregulated exclusively in gastrocnemius in the sucrose and lard groups (Table 3).

TABLE 3
Fold Change in Muscle Gene Expression After Dietary Treatments[a]

	Soleus		Gastrocnemius	
	Sucrose	Lard	Sucrose	Lard
FAT	−1.25	−1.15	−1.30	−1.35
FATP1	−1.13	−1.05	−1.22	−1.32
GLUT1	−1.11	+1.03	+1.62*	+2.68**
GLUT4	−1.27	−1.23	−1.08	+1.00
LPL	−1.09	−1.11	+1.02	−1.40
ACC1	+1.52	+1.46**	+1.28	+1.24
GFAT1	+1.10	+1.26	+1.71*	+1.89*
HK2	−1.05	+1.09	+1.65	+1.88*
PDK4	−1.03	+1.23	−1.03	−1.01

[a]Expression of GLUT1, GLUT4, FATP1, FAT, LPL, ACC1, GFAT1, HK2, and PDK4 was assessed in muscles from 6 controls, 6 sucrose-fed animals, and 6 lard-fed animals subjected to a glucose tolerance test. The threshold cycle (CT) values for the reference probe beta2-microglobulin were subtracted from each probe as in Figure 1. Data are expressed as $2^{-\Delta\Delta CT}$ for upregulated genes and $1/2^{-\Delta\Delta CT}$ for downregulated ones. The former are shown by + and the latter by −. The significance of the differences was: $^*P < 0.05$ and $^{**}P < 0.01$.

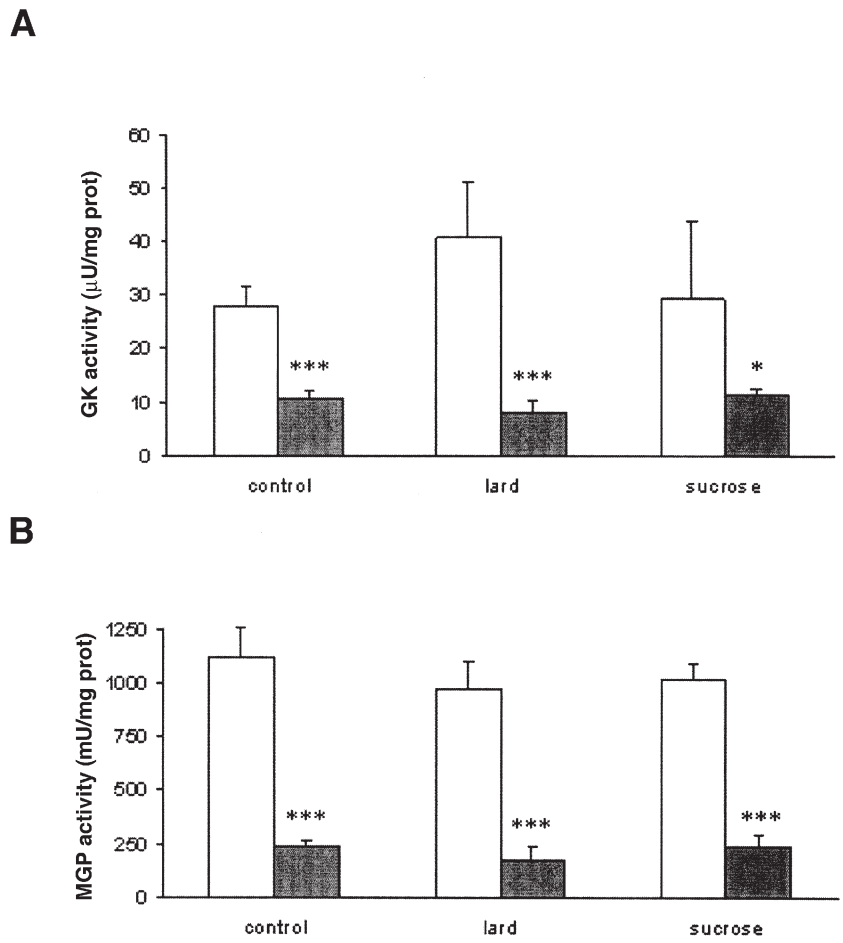

FIG. 2. Glycerol kinase and glycogen phosphorylase activities in muscle. Four weeks after dietary treatment, animals were fasted overnight and then subjected to a glucose tolerance test. At the end of the test, glycerol kinase (GK) (panel A) and glycogen phosphorylase (MGP) (panel B) activities were analyzed in extracts from soleus (dark bars) and gastrocnemius muscles (open bars). Values are means ± SD of 6 subjects. The significance of the differences of gastrocnemius vs. soleus was: $^{***}P < 0.001$ and $^{*}P < 0.05$.

Activity of glycerol kinase and glycogen phosphorylase in the muscle tissues. In controls, glycogen phosphorylase and glycerol kinase activities were higher in gastrocnemius than in soleus, by 4.6- and 2.7-fold, respectively. The administration of the two experimental diets did not alter these enzyme activity levels in either muscle type (Fig. 2).

DISCUSSION

This study shows that the sucrose-based diet, like the lard diet, impaired insulin sensitivity, as assessed by the increase in fasting plasma insulin and the reduction in the insulin sensitivity index, the QUICKI value. This is a reliable, easily applicable index used to estimate insulin effectiveness in humans (32) and is suitable for rats (6) and mice (38) as well, based on the increase in fasting insulin and glucose concentrations. Previous data on fasting insulin levels after sucrose nurturing are inconsistent. Certain authors have reported no increase 4–5 wk after administration of sucrose to rats, although the euglycemic–hyperinsulinemic clamp technique revealed insulin resistance (4,5), whereas others have described slight (12) or even marked fasting hyperinsulinemia (13). On the other hand, fat diets have consistently been shown to induce hyperinsulinemia (6,14) and to lower insulin sensitivity index (QUICKI) values (6).

The lard diet significantly impaired glucose tolerance, as assessed by the higher 120-min glycemia after administration of a glucose bolus, whereas the sucrose diet did not. Nevertheless, glucose clearance in hyperglycemic–hyperinsulinemic conditions, during the first 30 min after the glucose bolus, was enhanced by both diets, as deduced from the lower 30-min glucose increase (ΔGlu_{30}). On the other hand, the 30-min insulin increase (ΔI_{30}), which is a measure of insulin secretion (39), was steady in the sucrose group but lower in the lard group. Thus, the insulinogenic index (II_{30}), which correlates well with early-phase insulin response to the intravenous glucose tolerance test in humans (39), was higher in the sucrose group but remained unchanged in the lard group.

Both sucrose and fat diets increased postprandial plasma TAG and FA. Since little is known about potential alterations in gene expression in skeletal muscle, which may contribute to this metabolic disturbance, we performed a comparative analysis in soleus and gastrocnemius muscles at the end of the glucose tolerance test in rats fed starch-, sucrose-, and saturated fat-based diets. The uptake of FA in muscle may have been restricted by the activity of LPL, which hydrolyzes plasma lipoprotein TAG, and by the cell content of FABP, such as FAT/CD36 and FATP1, which respectively facilitate the transport and import of these molecules (21–23). However, we found that the mRNA of LPL, FAT, and FATP1 in rats fed on sucrose or lard did not differ significantly from those of controls. Of note, the FATP1 protein content was lower in the gastrocnemius of animals fed lard than in those fed starch (6). We also examined the expression of acetyl-CoA carboxylase ACC1, a cytosolic protein that catalyzes the formation of malonyl-CoA for the *de novo* synthesis of FA (24). ACC1 mRNA levels increased significantly in soleus muscle. The conditions that increased the expression of ACC1 in liver (40,41) were associated with the marked enhancement of lipid output and thus hyperlipemia (40), but there is no information on the regulation of ACC1 expression or the consequences of its higher expression in muscle.

Next, we tested whether the genes related to glucose clearance were altered. Glucose uptake was restricted by the glucose transporters, mainly GLUT4 and GLUT1 (26). Thus, we examined whether the expression of these genes was affected. The expression of the GLUT4 isoform was not altered by either experimental diet. However, the translocation of this transporter may have been impaired since the response of fast- and slow-twitch skeletal muscle glucose transport to stimulation by insulin or contraction decreased in rats fed a sucrose (3,5) or fat diet (17,18). In contrast, GLUT1 gene expression in gastrocnemius muscle was slightly increased by the sucrose diet and was more than doubled by lard. To our knowledge, there is only one report of GLUT1 upregulation associated with insulin desensitization, performed in patients with acanthosis nigricans, in which GLUT4 expression was also normal (42). High expression of GLUT1 in the muscle of transgenic mice enhances glucose uptake at high glucose concentrations but impairs the response to insulin (43). Thus, the increase in GLUT1 in the muscle of animals fed on sucrose or lard may be related to the two conditions observed: improved glucose clearance in hyperglycemic conditions and insulin resistance. Glucose uptake is also limited by hexokinase activity. We found that the lard diet increased the expression of the main muscle isoform, HK2, exclusively in gastrocnemius. The sucrose diet showed the same tendency, although differences did not reach significance. Our data are consistent with a previous finding that the HK2 gene is stimulated by insulin in either the cultured muscle cell line L6 (44) or in rat muscle *in vivo* after use of a hyperinsulinemic clamp method (27). Finally, we found that expression of the ubiquitous isoform of GFAT1 in muscle was increased by both sucrose and lard diets, again exclusively in gastrocnemius. This enzyme limits the hexosamine synthethic pathway, whose terminal metabolite is uridine diphosphate-*N*-acetylglucosamine (UDP-GlcNAc) (30), a donor substrate for the addition of GlcNAc to the hydroxyl groups of serine or threonine residues of proteins (45). Augmentation of this pathway enhanced O-GlcNAc modification of cell proteins (45) and generated insulin resistance, as shown by overexpression of the gene in muscle and adipose tissues (30). These findings therefore suggest that increases in GFAT1 expression in the muscle of hyperlipemic animals fed sucrose and lard diets may contribute to insulin resistance.

We also tested whether glycogen phosphorylase, which limits glycogen hydrolysis, was regulated through the diet. Animals fed a lard- or sucrose-based diet showed no significant alteration compared with controls. Glycerol kinase levels were also assessed, since glycerol 3-phosphate, which may limit FA esterification and disposal, may be generated by direct uptake of glycerol and subsequent phosphorylation by this enzyme (46). Glycerol kinase activity was not affected by either experimental diet. Finally, we tested whether the expression of PDK4 was affected. PDK4 expression in muscle has been shown to be upregulated by starvation and streptozotocin-induced diabetes in rats (47). However, we found no changes resulting from either diet, providing further evidence that, under diet-induced hyperinsulinemic conditions, gene expression is not suppressed.

In conclusion, we showed that the sucrose diet caused hyperinsulinemia and hyperlipemia in rats, as did the saturated-fat diet. Neither of these diets altered the expression in muscle of a number of genes involved in FA or glucose uptake, namely, LPL, the FABP FAT/CD36 or FATP1 and GLUT4, or of the enzymes responsible for the endogenous supply of glucose or glycerol, such as glycogen phosphorylase and glycerol kinase, or of PDK4, the regulator of glucose oxidation. In contrast, both diets regulated the mRNA levels of a number of metabolic genes in muscle in a similar fashion, although the effects of the sucrose diet were less pronounced. mRNA levels may be regulated by stability changes as well as transcriptional activity in response to the changes in diet. On the other hand, although changes were noted in certain gene mRNA levels, they may not directly correlate with translated protein levels or by enzyme activities that were not determined in these tissues. Genes involved in glucose uptake, GLUT1 and HK2, as well as diversion toward hexosamine synthesis, GFAT1, were upregulated in gastrocnemius muscle, whereas the FA synthetic gene ACC1 was induced in soleus muscle. Nevertheless, overexpression of both GLUT1 and GFAT1 has been associated with impaired insulin response, which suggests that this coordinated upregulation may contribute to sucrose- and high-fat diet-induced insulin resistance.

[a]Division of Healthcare Science, Research Laboratory, Nisshin Oillio Group, Yokosuka, Kanagawa 239-0832, Japan, and [b]Kyushu University and Prefectural University of Kumamoto, Fukuoka 813-0043, Japan

ABSTRACT: Lymphatic transport of a mixture of medium-chain TAG (MCT) and long-chain TAG (LCT) was studied in lymph-cannulated rats. Animals were administered a test emulsion containing either triolein, tricaprylin, or a 1:1 mixture of triolein and tricaprylin, and the lymph was collected for 24 h. The lymphatic recovery rate of medium-chain FA (MCFA) was significantly higher in rats given the TAG mixture than in those given MCT alone. The lymphatic recovery rate of long-chain FA (LCFA) also was significantly higher in rats given the TAG mixture than in those given LCT alone. No TAG containing three MCFA (i.e., MCT) was detected, and 37.7% of TAG containing one or two MCFA was detected in the lymph TAG when rats were given the TAG mixture. These results indicate that lymphatic transport of MCFA and LCFA can be modified by the combination of MCT and LCT.

Paper no. L9844 in *Lipids 41*, 63–66 (January 2006).

Medium-chain TAG (MCT) has been used as the fat source for enteral nutrition because of its absorption characteristics (1). When an enteral nutrient is compounded of MCT, long-chain TAG (LCT) is also added to supply EFA (2). However, dietary MCT is metabolized differently from LCT. Ingested LCT is degraded to FA and 2-MAG by pancreatic lipase in the upper intestine. In intestinal mucosal cells, the 2-MAG is reesterified with FA of exogenous or endogenous origin (3). Resynthesized TAG in the intestinal mucosa forms chylomicrons and flows into the venous system *via* lymphatic vessels. In contrast, ingested MCT is more easily and completely degraded to FA and glycerol than is LCT (4). Long-chain FA (LCFA) are activated to their CoA derivatives through the action of fatty acyl-CoA ligase and are resynthesized to TAG together with 2-MAG by acyltransferase. The ligase has low activity toward medium-chain FA (MCFA) (5). Therefore, most MCFA absorbed by the small intestinal mucosa are bound to albumin without the resynthesis of TAG and are transferred to the liver *via* the portal vein (6). Ikeda *et al*. (7) reported that the lymphatic absorption rate of caprylic acid was only 4% in rats given tricaprylin, whereas the rate of linoleic acid was 77% in those given trilinolein.

The lymphatic absorption rate of MCFA is affected by giving TAG simultaneously. Lee *et al.* (8) reported that when MCT was given with LCT, there was at most a threefold increase in the quantity of MCFA transported as TAG in the lymph. However, no information is available about the type of TAG in the lymph. Reesterification of MCFA may be promoted by the simultaneous intake of LCT. To determine the mechanism responsible for the enhanced MCFA transport by LCT, we analyzed the composition and regiospecificity of the lymph TAG in lymph-cannulated rats given a physical mixture of MCT and LCT.

MATERIALS AND METHODS

This study was carried out under the approval of the Laboratory Animal Care Committee of the Research Laboratory, Nisshin Oillio Group. Male Sprague-Dawley rats (Japan SLC, Hamamatsu, Japan) weighing 250–280 g were used. The surgery and lymph collection were completed according to the method of Ikeda *et al.* (9). Briefly, under Nembutal anesthesia, animals were subjected to cannulation of the left thoracic lymphatic channel, and an indwelling catheter was placed in the stomach. The next morning, after the collection of lymph for 2 h (blank lymph), each animal was administered 3 mL of a test emulsion through the gastric tube and the lymph was collected for 24 h. The test emulsion contained 200 mg of sodium taurocholate, 50 mg of FA-free albumin, and 200 mg of either LCT (triolein), MCT (tricaprylin), or a 1:1 mixture of MCT and LCT. Triolein (purity 99%) and tricaprylin (purity 99%) were obtained from Wako Pure Chemical Industries (Osaka, Japan).

Lipids of the lymph collected for 0–24 h after administration of the test emulsion were extracted according to the method of Folch *et al.* (10). The FA composition of the lymph total lipids was determined by GLC as described earlier (11), using heptadecanoic acid (Sigma-Aldrich, St. Louis, MO) as an internal standard. The FA recovery rate was calculated by subtracting the amount of FA in the blank lymph from that in the lymph collected after administration of the test emulsion. After trimethylsilylation, the TAG composition in the lymph collected for 0–4 h after administration of the emulsion was analyzed by GLC with a capillary column (DB-1ht; Agilent, Palo Alto, CA). Trimethylsilylation was performed using a trimethylsilylating

Abbreviations: 1M2L, TAG containing one MCFA and two LCFA; 2M1L, TAG containing two MCFA and one LCFA; 3L, TAG containing three LCFA; MCFA, medium-chain FA; MCT, medium-chain TAG; LCFA, long-chain FA; LCT, long-chain TAG.

reagent (TMS-HT; TCI, Tokyo, Japan) according to the manufacturer's instructions. The reagent was a pyridine solution containing hexamethyldisilazane and chlorotrimethylsilane. Approximately 1 mg of TAG and 0.2 mL of the trimethylsilylating reagent were mixed, and the mixture was left at room temperature for 30 min. One milliliter of hexane and distilled water was added for phase separation. After centrifugation, the organic phase was subjected to GLC. Regiospecific analysis of the lymph TAG collected for 0–4 h after administration of the test emulsion was performed by silver-ion HPLC as described by Adlof (12). A Toso 8020 series HPLC system (Toso, Tokyo) with a column containing silver ions (ChromSpher 5 Lipids; Varian, Palo Alto, CA) was used. Lymph lipids (10 mg) were dissolved in 1 mL hexane and filtered through a polytetrafluoroethylene filter before injecting 3 μL of lipids into the HPLC instrument. HPLC-grade hexane with 0.5% acetonitrile was used in the mobile phase at a flow rate of 1.0 mL/min. Analyses of lymph TAG, FFA, phospholipids, and cholesterol were carried out on a model 7450 automated enzymatic system (Hitachi, Tokyo, Japan).

All statistical analyses were performed with SPSS for Windows, version 10.0 J (SPSS Japan, Inc., Tokyo, Japan). Data were expressed as the mean ± SEM. Data on the lymph flow and recovery of FA were analyzed by two-way ANOVA. Statistical differences in lipid levels in the lymph were determined by one-way ANOVA, and significance between the different groups was tested by the Tukey test. The result of the regiospecific analysis was determined by Student's unpaired *t*-test. All statistical tests were considered significant at $P < 0.05$.

RESULTS

The differences among TAG contained in the test emulsion did not affect the lymph flow rate (Fig. 1A). The lymphatic recovery rate of caprylic acid was significantly higher in the mixture group than in the MCT group (Fig. 1B). The lymphatic recovery rate of oleic acid was slightly but significantly higher in the mixture group than in the LCT group (Fig. 1C).

As shown in Table 1, there were no significant differences in the FFA and cholesterol concentrations of the lymph collected for 0–4 h. The concentration of lymph phospholipids was significantly lower in the MCT group than in the LCT and mixture groups. The TAG concentration in the lymph was highest in the LCT group and lowest in the MCT group, with the mixture group being in-between; the difference among groups was significant.

The TAG composition and concentration of lymph collected for 0–4 h are shown in Table 2. Only a negligible level (0.1 ± 0.1%) of MCT was detected in lymph TAG when rats were given MCT. No MCT was detected in the LCT group or in the mixture group. The proportions of TAG containing two MCFA and one LCFA (2M1L) were the same in rats given MCT and those given a mixture of MCT and LCT, whereas those of TAG containing one MCFA and two LCFA (1M2L) were significantly higher when the mixture was given than when MCT alone was given: 17.8 ± 1.5% and 31.0 ± 0.8%, respectively.

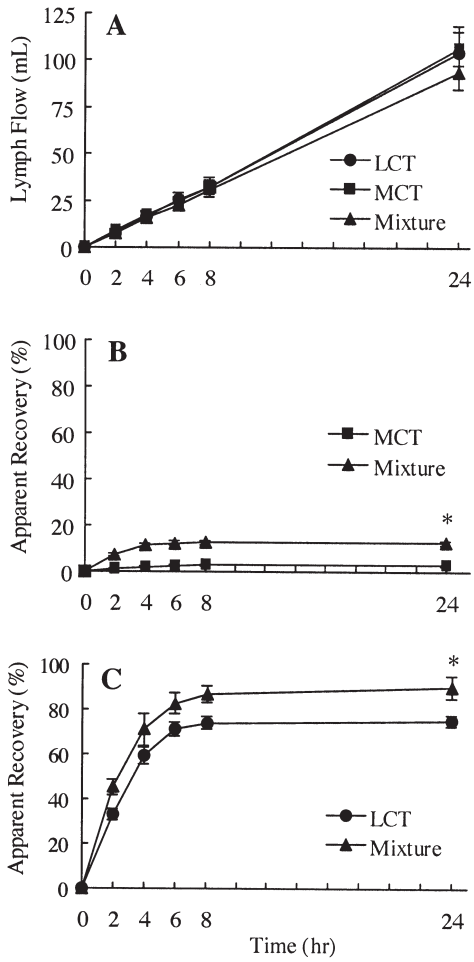

FIG. 1. Lymph flow (A) and recovery of caprylic acid (B) and oleic acid (C) in the thoracic duct lymph of rats after intragastricadministration of long-chain TAG (LCT), medium-chain TAG (MCT), or a mixture of MCT and LCT. Data are means ± SEM, $n = 4$ to 6. Asterisks indicate significant difference ($P < 0.05$).

Concentrations of 2M1L and 1M2L were significantly higher in the mixture group than in the MCT group, whereas those of TAG containing three LCFA (3L) were significantly higher in the LCT group than in the MCT and mixture groups. The 3L level of the LCT group was more than 10 times that of the MCT group, and was approximately twice that of the mixture group.

FA compositions of lymph collected for 0–4 h are shown in Table 3. The proportion of oleic acid was significantly higher when LCT alone was given than when the mixture was given: 80.4 ± 1.9% and 60.8 ± 1.8%, respectively. The proportion of caprylic acid in the MCT group was only 8.3 ± 1.2% when MCT alone was given. The proportions of palmitic and linoleic acids in the MCT group were 27.3 ± 2.0% and 24.7 ± 0.5%, respectively.

Results of the regiospecific analysis of the lymph TAG collected for 0–4 h in the mixture group are shown in Table 4. The proportion of symmetrical TAG was significantly lower, whereas that of asymmetrical TAG was significantly higher in the 2M1L-type TAG than in the 1M2L-type TAG.

[a]Data are means ± SEM, $n = 4$ to 6. Values with different roman superscripts are significantly different ($P < 0.05$).

DISCUSSION

We studied the effects of LCT on the transport of MCFA and the TAG composition in the lymph of rats using MCT, LCT, or a mixture of MCT and LCT. The lymphatic recovery rate of caprylic acid was four times higher in the mixture group than in the MCT group. We thus confirmed the observation of Lee *et al.* (8) that in rats, the lymphatic transport of MCFA is enhanced when it is administrated simultaneously with LCT. No MCT was detected in lymph TAG, even when rats were given MCT as the sole source of TAG, and most of the MCFA occurred as TAG containing both MCFA and LCFA. Nor was MCT detected in the lymph TAG of rats given the mixture, and a considerable proportion was detected as TAG of the MCFA–LCFA type. These results indicate that a portion of the MCFA in the MCT administered, after partial hydrolysis, could have been reesterified with endogenous or exogenous LCFA in the enterocytes. Christophe *et al.* (13) reported that after feeding LCT and MCT to patients with ascitic fluid accumulation, the ascitic fluid contained TAG consisting of both MCFA and LCFA, indicating that part of the MCFA was absorbed as TAG containing LCFA.

20:4	3.1 ± 0.4[a]	9.7 ± 0.6[c]	5.3 ± 0.4[b]

[a]Data are means ± SEM, $n = 4$ to 6. For abbreviations see Tables 1 and 2.

The lymphatic recovery rate of oleic acid was 15% higher in the mixture group than in the LCT group, indicating that MCT could promote lymphatic recovery of LCT when the two are given together. Christensen *et al.* (14) observed that lymphatic absorption of LCFA (linoleic and linolenic acid) was higher in rats given a mixture of MCT and soybean oil than in those given soybean oil alone. In contrast, Straarup and Høy (3) failed to find evidence of a promoting effect of MCT on lymphatic absorption of LCFA as rapeseed oil (oleic and linoleic acids). Christensen *et al.* (14) used MCT containing mainly caprylic acid, and Straarup and Høy (3) used MCT containing only capric acid. The type of MCFA may influence the LCFA absorption, as Ikeda *et al.* (7) reported the lymphatic absorption rate of caprylic acid to be lower than that of capric acid in rats.

In this study, we did not monitor the portal vein transport of MCFA and LCFA. Therefore, the total absorption rate (portal vein and lymph) of these FA was not clear. The lymphatic recovery rate of caprylic acid was significantly higher when rats were given the mixture of MCT and LCT than when they were given MCT alone. Most MCFA is absorbed *via* the portal vein. It is a reasonable inference that a portion of the MCFA principally absorbed *via* the portal vein was transported to the lymph. The lymphatic recovery rate of oleic acid was significantly higher when rats were given the mixture of MCT and LCT than when they were given the LCT alone. Because most LCFA is transported to the lymph vessels, the enhanced lymphatic recovery rate of oleic acid in the mixture group may indicate an increase in the total absorption of oleic acid.

During the intestinal absorption of the mixture of LCT and MCT, TAG with LCFA in the *sn*-2 position and MCFA in the *sn*-1,3 position (M-L-M) or TAG with LCFA in the *sn*-2 position and MCFA and LCFA in the *sn*-1,3 position (M-L-L or L-L-M) could be synthesized from long-chain 2-MAG and MCFA in the enterocytes. Also, TAG with MCFA in the *sn*-2 position and LCFA in the *sn*-1,3 position (L-M-L) or MCFA and LCFA in the *sn*-1,3 position (M-M-L or L-M-M) could be synthesized from LCFA and the partial hydrolysis products of MCT. All these types of TAG were detected in the lymph of rats given the TAG mixture. This result thus indicates that TAG

TABLE 4
Result of Regiospecific Analysis of Lymph TAG Collected for 0–4 h in Rats Given a Mixture of MCT and LCT[a]

	2M1L (% of total 2M1L TAG)	1M2L (% of total 1M2L TAG)
Symmetric	18.0 ± 2.3 (M-L-M)	33.8 ± 2.0* (L-M-L)
Asymmetric	82.0 ± 2.3 (M-M-L or L-M-M)	66.2 ± 2.0* (M-L-L or L-L-M)

[a]Data are means ± SEM, $n = 4$ to 6. Asterisks indicate significantly different from 2M1L ($P < 0.05$). For abbreviations see Tables 1 and 2.

containing MCFA and LCFA could be resynthesized from LCT and MCT backbones in the intestinal mucosa.

When rats were given only MCT, 27% of palmitic acid and 25% of linoleic acid were detected in the lymph FA. In contrast, only 8% of caprylic acid was detected. Only 0.1% of MCT was detected in lymph TAG after the administration of MCT alone. Most of the MCFA was recovered in the lymph as TAG composed of both MCFA and LCFA. These results indicate that MCFA is transported to the lymph after it is resynthesized with endogenous LCFA when rats are given MCT alone.

The TAG concentration of the lymph was correlated with the lymphatic recovery rate of caprylic and oleic acids, respectively. The concentration of lymph phospholipids in the MCT group was lower than those of the LCT and mixture groups. The secretion of phospholipids into the lymph increases during chylomicron secretion, because they are constituents of the chylomicrons. The lower concentration of lymph phospholipids may be related to a decrease in chylomicron secretion of the MCT group compared with the LCT and mixture groups.

In conclusion, the results of the present study indicate that the enhanced lymphatic transport of MCFA by a simultaneous administration of LCT is related to the synthesis of TAG containing MCFA and LCFA in the intestinal mucosa. This study also demonstrates that MCT enhances the transport of LCT. Thus, the lymphatic transport of MCFA and LCFA can be modified by the combination of MCT and LCT. This observation, together with the enhancement of LCT absorption by MCT, may contribute to the utilization not only of the physical mixture but also of the structural mixture (3,7,14,15) of MCT and LCT in various aspects of lipid nutrition.

ACKNOWLEDGMENTS

We thank Seiichi Shirasawa, Chiemi Satou, Akiko Sasaki, and Shin Arimoto for their technical assistance in FA and TAG analyses. The authors also thank Hiroaki Tsuji for his statistical analyses.

Monitoring Monohydroperoxides in Docosahexaenoic Acid Using High-Performance Liquid Chromatography

Ann-Marie Lyberg* and Patrick Adlercreutz

Department of Biotechnology, Center for Chemistry and Chemical Engineering, Lund University, SE-221 00 Lund, Sweden

ABSTRACT: The oxidation of free DHA has been investigated with respect to monohydroperoxides and polyhydroperoxides, which were analyzed with a novel HPLC method. The temperature and physical system, i.e., bulk and liposome, were varied. We have also studied the effects of antioxidants such as α-tocopherol, ascorbic acid, and juice from sea buckthorn on DHA. The HPLC method, which was performed isocratically, eluted eight peaks, each containing one or two isomers of monohydroperoxy-DHA. This method showed that the double bond farthest from the carboxyl group was easily oxidized, as shown by the rapid increase in the amount of C20-monohydroperoxy-DHA, which always provided the largest contribution to the total amount of monohydroperoxides. The monohydroperoxy-DHA containing the hydroperoxy group located on the double bond nearest the carboxyl group also was shown to increase considerably during an increase in the total amount of monohydroperoxides. This demonstrates that the double bonds located nearest and farthest from the carboxyl group were the most prone to hydroperoxide formation. DHA was more stable when stored in liposomes than as bulk. Addition of α-tocopherol to the DHA-containing liposomes reduced the oxidation of these double bonds. The antioxidant effect of α-tocopherol was prolonged when combined with ascorbic acid, since α-tocopherol was regenerated.

Paper no. L9857 in *Lipids 41*, 67–76 (January 2006).

Auto-oxidation of PUFA such as the n-3 FA DHA produces primary oxidation products, which may be further oxidized to secondary oxidation products. The oxidizability increases with the number of bis-allylic positions within a FA, and thus DHA with five bis-allylic positions is highly prone to oxidation (1). The oxidation of this PUFA is usually initiated by the loss of one hydrogen atom to another radical (1). The FA radical formed can react with oxygen and then take a hydrogen atom from another PUFA. The hydroperoxy FA produced is regarded as a primary oxidation product, which can be further oxidized by, for example, cyclization into hydroperoxy epidioxides and bicycloendoperoxides, which may be broken down into malonaldehyde. Another oxidation path of the hydroperoxy FA is linkage to another PUFA to form a dimeric compound. A third oxidation path is the cleavage of the FA containing the hydroperoxide.

Abbreviation: Q-TOF, quadrupole time-of-flight.

Addition of antioxidants is a common method of protecting PUFA. Some antioxidants are classified as chain-breaking or primary antioxidants, which react with the FA radical or peroxyl or alkoxyl radicals and can thus inhibit or reduce oxidation (2). Other antioxidants are classified as preventive or secondary antioxidants, which reduce the oxidation rate (2). Within this class, the metal inactivators are considered to be the most important because they deactivate metal ions, which induce both initiation and decomposition of hydroperoxides (1). Combining a chain-breaking (such as tocopherol) and preventive (such as citric acid) antioxidant usually leads to significant synergistic effects.

To evaluate strategies for protecting PUFA such as DHA, suitable methods are needed to analyze the oxidation products. The most suitable method depends on the oxidation conditions. Under mild and harsh oxidation conditions, primary and secondary oxidation products dominate, respectively. Two methods of determining the total amount of primary oxidation products are measurements of the peroxide value or the conjugated dienes (1). In some situations, however, it is necessary to obtain information on where the hydroperoxide groups are situated in the DHA molecule. In such cases, the isomers must be separated, either with GC or HPLC. The drawback of GC is the need for derivatization of hydroperoxy-DHA before analysis (3). Since the hydroperoxy-DHA can be analyzed as is with HPLC (4), this type of analysis is preferable.

The aim of this study was to develop a new HPLC method for investigating the stability of DHA when both temperature and the type of physical system were varied. This method was also used to monitor the oxidation of DHA liposomes containing antioxidants when incubated at 40°C. The method was used to quantify several isomer groups of monohydroperoxy-DHA and the total amount of polyhydroperoxides. The isomers eluted using HPLC were characterized with quadrupole time-of-flight (Q-TOF) tandem MS. The advantage of this HPLC method is that the isomers are eluted isocratically. This was achieved with a shorter analysis time than when using a previously described thermospray LC-MS method (4) using a gradient.

MATERIAL AND METHODS

Materials. DHA (95% purity) was purchased from Larodan Fine Chemicals AB (Malmö, Sweden). Acetonitrile (HPLC grade) and acetic acid (analytical grade) were bought from

Merck (Darmstadt, Germany). L-α-PC (L-α-lecithin consisting of about 40% L-α-PC), L-ascorbic acid (vitamin C), and α-tocopherol (vitamin E) were purchased from Sigma (St Louis, MO). $FeSO_4 \cdot 7H_2O$ was purchased from the Aldrich Chemical Company (Milwaukee, WI). Sea buckthorn berries (*Hippophae rhamnoides*) were donated by SLU (Balsgård, Sweden) and processed at 80°C by the Department of Food Technology at Lund University (Lund, Sweden). These berries are rich in vitamin C.

Analysis of mono- and polyhydroperoxy-DHA. HPLC analysis of different monohydroperoxides and the total amount of polyhydroperoxides in DHA was carried out on a LaChrom system (Hitachi High Technologies America, Schaumburg, IL) consisting of a D-7000 interface, an L-7100 pump, an L-7250 autosampler (20 µL injection loop) and an L-7400 UV detector (offset at 234 nm). The separation of different monohydroperoxides in DHA was performed on a Lichrospher® 100 RP-18 (5 µm) column (Merck, Darmstadt, Germany) with a 1 mL/min flow rate of mobile phase consisting of an acetonitrile/aqueous solution of acetic acid (1%) 55:45 (vol/vol) for 40 min. The monohydroperoxy-DHA eluted within 19–36 min, while the polyhydroperoxides eluted between 1 and 10 min. The total amount of polyhydroperoxides was obtained from the sum of the peaks between 1 and 10 min. To prevent DHA accumulating in the column, each analysis was terminated with an increase in the acetonitrile concentration to 90% for 1 min, after which the concentration was maintained for 9 min. The acetonitrile concentration was then decreased to 55% for 1 min to equilibrate the column before the next analysis. This concentration was maintained for 14 min.

To be able to quantify the different isomers, the HPLC equipment was calibrated against a spectrophotometer. The model substance was *p*-nitrophenol dissolved in a mobile phase consisting of 0.2 M sodium acetate buffer pH 4.5/methanol 50:50. Several concentrations of *p*-nitrophenol were analyzed on a UV-1650 PC spectrophotometer (Shimadzu Corporation, Kyoto, Japan) and on the HPLC equipment described above. Detection in both measurements was performed at a wavelength of 305 nm. By assuming that all monohydroperoxy-DHA isomers have an extinction coefficient (ε) of 23,300 $(M \cdot cm)^{-1}$ (5), it was possible to calculate the concentration with Equation 1. The extinction coefficient of *p*-nitrophenol, $\varepsilon_{p\text{-nitrophenol}}$, was obtained from the measurements on the spectrophotometer, whereas the calibration slope of *p*-nitrophenol ($HPLC_{p\text{-nitrophenol}}$) was obtained from the HPLC measurements.

$$\text{concentration} = \frac{\varepsilon_{p\text{-nitrophenol}}}{HPLC_{p\text{-nitrophenol}} \cdot \varepsilon_{\text{conjugated-diene}}} \cdot \text{area} = k \cdot \text{area} \quad [1]$$

The value of k was determined to be $4.029 \cdot 10^{-11}$ M/area unit.

Analysis of DHA content. To determine the DHA content, analysis was performed with a light-scattering detector added to the same HPLC system as that described above for the analysis of monohydroperoxy-DHA. The same column was also used, and a mobile phase consisting of acetonitrile/aqueous acetic acid (1%) 80:20 (vol/vol) with a flow rate of 1 mL/min allowed DHA to elute after 11 min. DHA was then quantified with a 500 ELSD (Alltech Associates, Deerfield, IL) with a nebulizer gas flow of 2.26 standard liters per minute and a drift tube temperature of 91°C.

LC-MS. The different isomers of monohydroperoxy-DHA were characterized with LC-MS. They were first separated on an HPLC from PerkinElmer (Boston, MA) according to the method described above. One-tenth of the flow from the column was then led into the QSTAR® Q-TOF hybrid tandem mass spectrometer (PE Sciex, Toronto, Canada) with a TurboIonSpray™ source set to negative ion mode. The TOF-MS mode and the product ion mode were set to ranges of *m/z* 70–700 and *m/z* 70–520, respectively.

Oxidation conditions. The stability of DHA with respect to the formation of monohydroperoxy-DHA and polyhydroperoxy-DHA and the reduction of DHA were monitored at 6, 25, and 40°C for a period of 7 d, in two different systems, i.e., bulk and liposomes. DHA bulk (0.12 g) was stored in an open 10-mL vial inside a sealed 500-mL bottle, whereas DHA in liposomes (7 mL) was stored in a sealed 50-mL bottle. Thus, an excess of oxygen was available in the air present in the bottles at the beginning of the stability test, although the bottles were sealed during incubation. Air was also let in during sampling. All samples were shielded from UV light. An additional liposome experiment with 0.1 mM $FeSO_4 \cdot 7H_2O$ incubated at 25°C was also performed.

DHA liposomes containing antioxidants incubated at 40°C were then investigated with respect to resistance to oxidation for a period of 7 d. The antioxidants tested were ascorbic acid (0.5 mM), α-tocopherol (0.5 mM), a combination of ascorbic acid (0.5 mM) and α-tocopherol (0.5 mM), and juice from sea buckthorn. The latter was centrifuged at $11{,}500 \times g$ for 4 min. Part of the oil phase and part of the water phase were withdrawn separately (the precipitate formed was not used). The liposome with sea buckthorn juice contained mainly three important antioxidants, i.e., ascorbic acid (1.6 µg/mL liposome), α-tocopherol (0.13 µg/mL liposome), and quercetin-glucosides (0.15 µg/mL liposome) (6,7). Even though ascorbic acid was the predominant antioxidant in sea buckthorn, the liposome with pure ascorbic acid contained over 50 times more of this antioxidant than the liposome containing sea buckthorn juice.

Each experiment was performed three times, and on each sampling occasion one sample was withdrawn for hydroperoxide measurement and one for DHA content determination. These samples were diluted with acetonitrile when necessary to obtain DHA concentrations of 1.67 mg DHA/mL (for analysis of hydroperoxides) and 0.84 mg DHA/mL (for analysis of DHA content).

Preparation of liposomes. Lecithin, DHA, and a lipophilic antioxidant (α-tocopherol or 23 mg oil phase of the sea buckthorn juice), if used, were dissolved in chloroform, which was then evaporated to obtain a homogeneous starting material for the preparation of liposomes. Water (40 mL) at a temperature of 50°C was added, and the system containing 1.67 mg DHA/mL and 16 mg lecithin/mL was stirred at 700 rpm in a round-bottomed flask in a 50°C water bath for 30 min. The solution was homogenized with a Yellowline DI25 basic disperser (IKA®

Werke GmbH & Co. KG, Staufen, Germany) at 8,000 rpm for 3×5 s. The solution was then stirred at 700 rpm for 65–75 min, while the temperature was maintained at 50°C. To reduce the range of vesicle sizes in the liposome system, the solution was passed 11 times through a 0.1 μm Nuclepore polycarbonate membrane (Whatman, Brentford, United Kingdom) (1 mL at a time) using a mini-extruder (Avanti Polar Lipids, Inc., Alabaster, AL) that was heated to approximately 40°C. To prevent oxidation during the preparation of liposomes, nitrogen gas was added several times. When hydrophilic antioxidants [ascorbic acid, the hydrophilic fraction of the sea buckthorn juice (19 μL/7 mL liposome preparation)] were used, they were added after the sample had been withdrawn at time zero.

Evaluation. The unit mol% hydroperoxides was used for both mono- and polyhydroperoxides, and mol% DHA was used for DHA. The former unit corresponds to mol hydroperoxide divided by the amount of pure DHA (mol) expected in an unoxidized sample, expressed as a percentage. The latter unit was defined as the measured DHA content (mol) divided by the measured initial DHA content (mol) obtained as an average of the starting values within an experimental series, expressed as a percentage.

An approximation of the maximum amount of DHA containing hydroperoxides was calculated according to Equation 2. This calculation will give the exact amount of DHA containing hydroperoxides if all polyhydroperoxides contain two hydroperoxy groups. When polyhydroperoxides with more than two hydroperoxide groups are present, the total fraction of DHA containing hydroperoxides will be overestimated.

$$\sum \mathrm{DHA}_{\mathrm{hydroperoxides}} = \sum \mathrm{monohydroperoxides} + \frac{\sum \mathrm{polyhydroperoxides}}{2} \quad [2]$$

Statistics. Three samples were analyzed under each set of experimental conditions. The average of these values without and with a 95% confidence limit was calculated at the starting point and other times in each experiment. The confidence limit is based on the pooled SD for all values after the starting value within an experimental series. When appropriate, whether the difference between two points within one or between two experimental series was significant was tested. The underlying data were tested with a two-sided *t*-test in Microsoft Excel™ (unless stated otherwise) assuming that the values tested had the same variance.

RESULTS

Identification of isomers of monohydroperoxy-DHA. The HPLC method developed provided eight peaks, each of which contained one or two isomers of monohydroperoxy-DHA (Fig. 1). The identification of the isomers is described in the paragraph below. The first peak, with the shortest retention time, corresponded to DHA with a hydroperoxide group on carbon 20 (C20-hydroperoxide). The second peak contained both C17- and C16-hydroperoxides (see Scheme 1; in this scheme each number corresponds to a peak in the chromatogram, and the position of the number indicates the location of the hydroperoxide group in DHA). C13- and C14-hydroperoxides were identified in the third peak. The fourth, fifth, sixth, and seventh peaks contained DHA with a hydroperoxide on carbons 10, 11, 7, and 8, respectively. The last peak corresponded to the C4-hydroperoxide together with a minor contribution from the C5-hydroperoxide. When a hydroperoxide is incorporated at a double bond of the DHA molecule, this bond will move one step in the carbon chain and a conjugated diene is usually formed. Our method, which was highly sensitive to conjugated dienes because a wavelength of 234 nm was used, thus shows a high response to all the hydroperoxides except those not containing a conjugated diene, i.e., hydroperoxides situated at carbons 3, 5, 19, or 21. Only the C5-hydroperoxide was found using LS-MS.

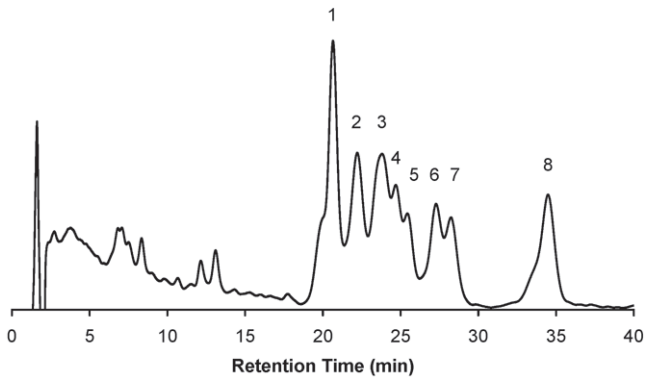

FIG. 1. Different isomers of monohydroperoxy-DHA can be seen in the chromatogram. The range in retention time for the peaks was 19–36 min, where Peak 1 has the shortest retention time. This sample was a bulk DHA incubated at 6°C for 3 d.

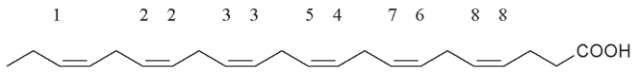
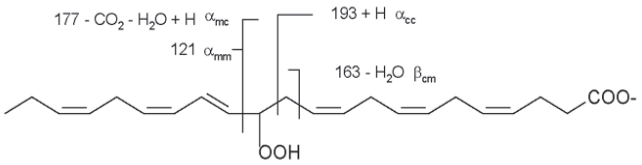
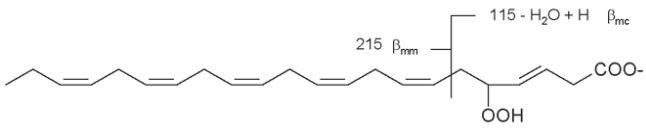
To identify the various monohydroperoxy-DHA isomers, fragments were created using Q-TOF tandem MS. Some fragments could be identified by the characteristic location of the hydroperoxide group; that is, the DHA molecule was cleaved adjacent to the hydroperoxide, and the characteristic fragment could then be identified as the part not containing the hydroperoxide (8). When the cleavage of the carbon chain was toward the carbonyl end (c) or the methyl end (m), the fragment will be defined below as an α_{cc}-fragment or α_{mm}-fragment, respectively (Scheme 2, fragments created from the C13-hydroperoxide). (The first letter in the subscript defines the cleavage position, whereas the second defines whether the fragment contains the carboxyl or methyl side of the monohydroperoxy-DHA isomer.) Other characteristic fragments are created when cleavage takes place one carbon atom away from the hydroperoxide carbon (8). The characteristic fragment containing the functional group will lose a water molecule and be transformed into a hy-



SCHEME 1



SCHEME 2



SCHEME 3

droxide, and a double bond is then formed between the cleavage carbon and the carbon of the functional group. When the cleavage within the carbon chain is toward the carbonyl end or the methyl end, the fragment is denoted below as β_{cm} or β_{mc}, respectively (see Schemes 2 and 3, the latter indicating fragments created from the C5-hydroperoxide). The characteristic fragments of the different isomers of monohydroperoxy-DHA in the eight peaks of the HPLC chromatogram are presented in Table 1. Besides α_{cc}-, α_{mm}-, β_{cm}-, and β_{mc}-fragments, α_{mc}- and β_{mm}-fragments also were found. Some fragments created were common to all of the isomers and thus did not give any further information on where the hydroperoxide was situated. Such fragments were $[M - H - H_2O]^-$ at *m/z* 341 and $[M - H - H_2O - CO_2]^-$ at *m/z* 297, which were created when water or both water and carbon dioxide were lost from the molecule, respectively.

Oxidation of bulk DHA at three temperatures. The total amount of monohydroperoxy-DHA in bulk DHA incubated at 6, 25, and 40°C during a period of 7 d is presented in Figure 2. Although the monohydroperoxy-DHA formation was slowest at 6°C, this temperature gave rise to the highest amount of monohydroperoxy-DHA over the 7 d (9 mol%, day 4). The samples maintained at 25 and 40°C exhibited nearly the same initial formation rate of monohydroperoxy-DHA. However, the 40°C sample reached a peak of 4 mol% at 12 h, while the monohydroperoxy-DHA of the 25°C sample continued to increase for another 12 h, reaching 7 mol%. After the highest amount of monohydroperoxy-DHA was reached at the three temperatures, the monohydroperoxides decreased. This indicates that the monohydroperoxy-DHA continued to be oxidized at a higher rate than the rate at which hydroperoxide was incorporated into pure DHA.

The contribution of the eight monohydroperoxy-DHA isomers, detected with our HPLC method, to the total amount of monohydroperoxides varied. During the increase in the total amount of monohydroperoxides at 6 and 25°C (Fig. 2), the C4-monohydroperoxide increased most: 7–8% relative to the other isomers (Fig. 3A). When the temperature was increased to

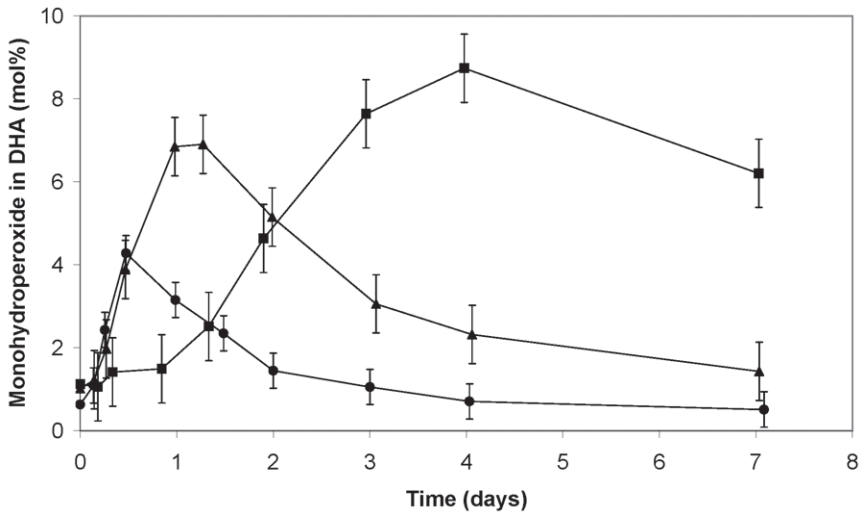

FIG. 2. Total amount of monohydroperoxides in bulk DHA at 6 (■), 25 (▲), and 40°C (●).

40°C, this isomer increased most only during the first 3 h (11% relative to the other 10 isomers, Fig. 3B). During the decrease in the total amount of monohydroperoxides, the C4-monohydroperoxide decreased most relative to the other isomers at all three temperatures, which was probably caused by further oxidation. However, the predominant isomer at all temperatures was the C20-monohydroperoxide. This isomer increased by 3, 17, and 18% at 6, 25, and 40°C, respectively, relative to the other isomers over the first 4 d. The increase continued at the two lower temperatures, while a decrease (6%) was observed at 40°C. Thus, the C20-monohydroperoxide decreased at the slowest rate during the decrease in the total amount of monohydroperoxides, according to Equation 3. (FI_x and CI_x are defined as "formation of isomer *x*" and "conversion of isomer *x* to another compound," respectively.) This isomer had either the highest formation rate (term 1) or the slowest conversion rate to another compound such as a polyhydroperoxide (term 2) during the decrease in the total amount of monohydroperoxides. A combination of both explanations is also possible.

$$\frac{\Delta \text{isomer}_x}{\Delta t} = \frac{\Delta FI_x}{\Delta t} - \frac{\Delta CI_x}{\Delta t} \quad [3]$$

The initial formation rate of polyhydroperoxides in DHA was lowest at 6°C and higher at 25 and 40°C (Fig. 4). The polyhydroperoxides in the 6°C sample increased during the 7 d and reached 10 mol%. The polyhydroperoxides in the 40°C sample increased for the first 24 h. The level reached was thereafter fairly constant. The polyhydroperoxide in the 25°C sample increased further and leveled out after 3 d. The levels of polyhydroperoxide in the 25 and 40°C samples after 7 d were 7 and 5 mol%, respectively, i.e., a significant difference ($P < 0.001$).

The DHA content decreased with time at all temperatures (Fig. 5). The 6°C sample exhibited the slowest reduction rate, which was maintained during the 7 d, with the DHA content finally reaching 15 mol%. The initial reduction rate increased with temperature, and the highest degradation occurred at

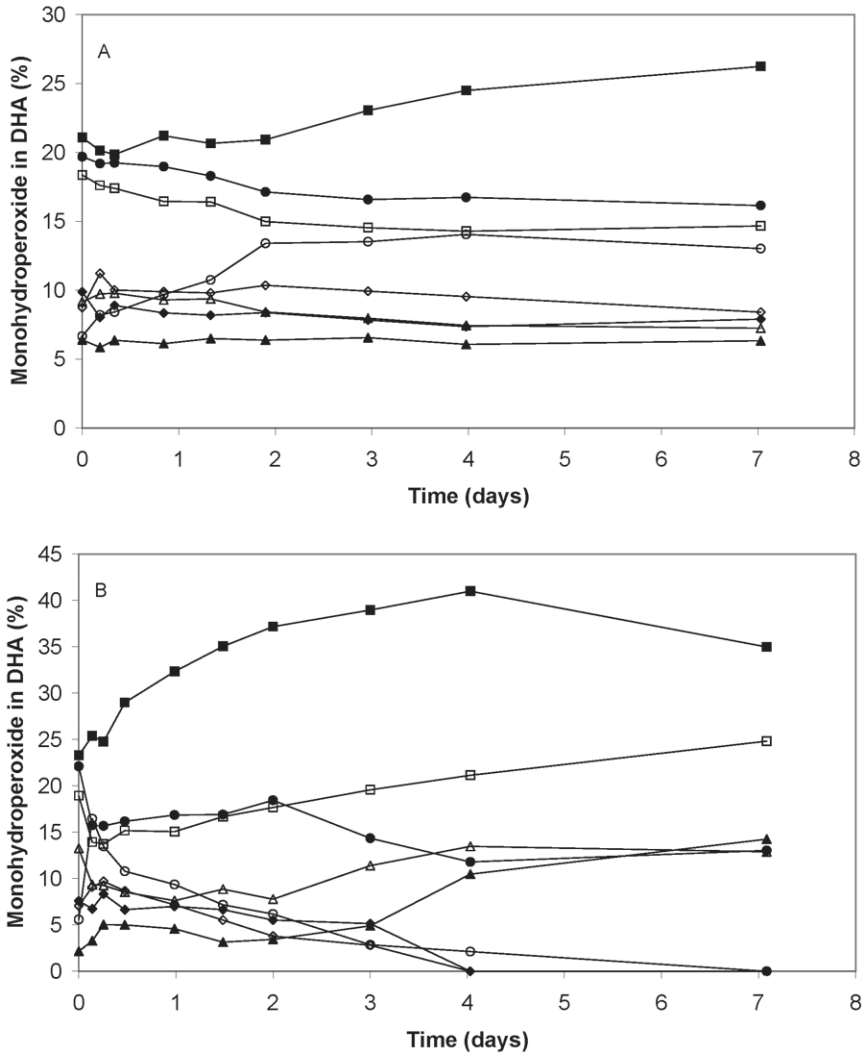

FIG. 3. The isomer profile of bulk DHA at 6 (A) and 40°C (B). C20 (■), C16 + C17 (□), C13 + C14 (●), C10 (△), C11 (▲), C7 (◇), C8 (◆), and C4 (○).

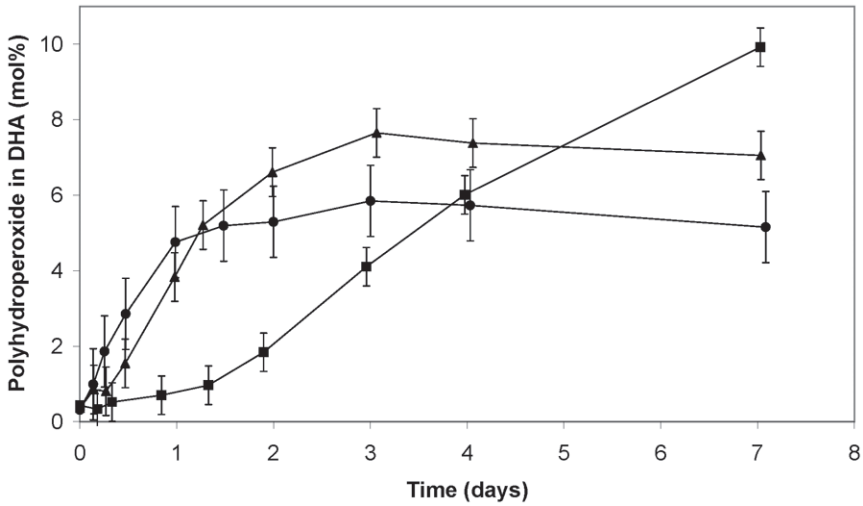

FIG. 4. Total amount of polyhydroperoxides [hydroperoxide groups (mol) in polyhydroperoxides/amount (mol) of DHA in an unoxidized sample] in bulk DHA at 6 (■), 25 (▲), and 40°C (●).

40°C. When approximately 30 mol% DHA was left in the samples incubated at 25 and 40°C, the degradation rate slowed, and after 7 d 14 and 4 mol% DHA was left, respectively. The fraction of DHA that was converted to mono- and polyhydroperoxides (according to Eq. 2) after 7 d was, at most, 11, 5, and 3 mol% at 6, 25, and 40°C, respectively. Thus, a larger proportion of DHA was converted to other oxidation products than hydroperoxides, measured with our HPLC method. Since the DHA became more viscous with time, it is probable that one of these oxidation products was polymerized DHA.

Oxidation of DHA in liposomes at three temperatures. Oxidation of DHA in liposomes was monitored with respect to both hydroperoxide formation and reduction in DHA content. The lecithin used to prepare the liposomes contained linoleic acid and a small amount linolenic acid according to the lecithin supplier. Thus, the hydroperoxides found in this study were generated not only from DHA but also from linoleic acid. Unfortunately, the monohydroperoxides of linoleic acid showed three peaks (two contained double peaks), which interfered with the measurement of the first five monohydroperoxy-DHA peaks eluted in the chromatogram. These peaks were therefore overestimated with respect to the monohydroperoxy-DHA isomers. The polyhydroperoxides arose from oxidation of both DHA and linoleic acid.

The total amount of monohydroperoxides in liposomes containing DHA incubated at 6, 25, and 40°C is presented in Figure 6. The sample at 6°C was quite resistant to oxidation with respect to monohydroperoxides, which increased only by 0.4 mol% (which was, however, a significant increase according to the one-sided *t*-test, $P < 0.0001$). When the temperature was

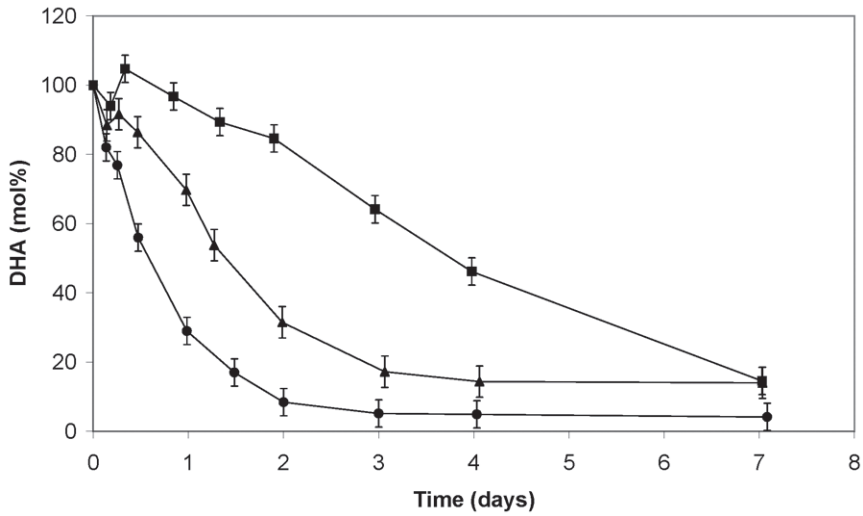

FIG. 5. The relative DHA concentration of bulk DHA at 6 (■), 25 (▲), and 40°C (●).

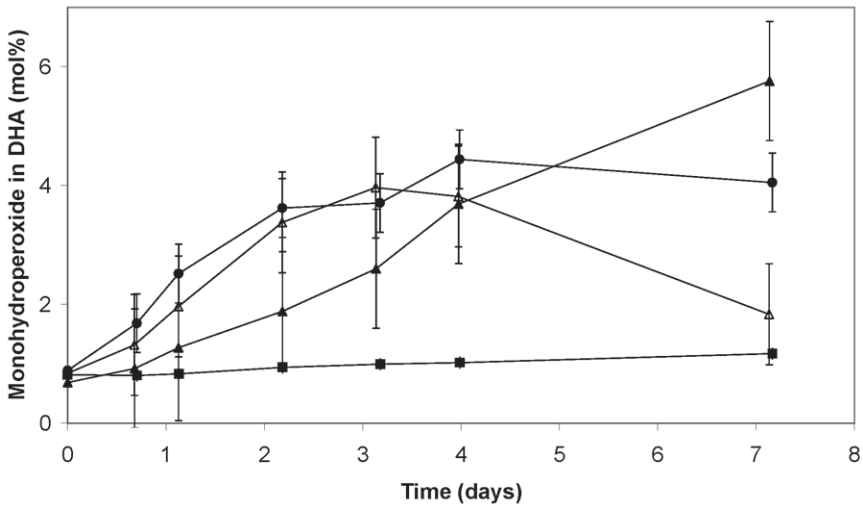

FIG. 6. Total amount of monohydroperoxides in liposomes without $FeSO_4$ at 6 (■), 25 (▲), and 40°C (●) and with $FeSO_4$ at 25°C (△).

increased to 25°C, the monohydroperoxides increased to 6 mol% after 7 d. At 40°C the initial oxidation rate was higher, and a peak (4 mol%) was exhibited after 4 d. When a liposome sample containing both DHA and 0.1 mM $FeSO_4$ was incubated at 25°C, the increase in monohydroperoxides was similar to that in the liposome incubated at 40°C during the first 3 d. Then the monohydroperoxides decreased more rapidly, and the monohydroperoxide level of the liposome containing iron and the liposome incubated at 40°C differed significantly ($P < 0.02$) at day 7.

Among the monohydroperoxy-DHA isomers the monohydroperoxide on C4 and on C20 exhibited the most distinct trends. Initially, the C4-monohydroperoxide increased most relative to the other isomers. At 6°C the C4 isomer increased relative to the other isomers over the 7 d, while a peak was reached after 2 d and 1 d at 25 and 40°C, respectively. The peak (data not shown) containing both the C20-monohydroperoxy-DHA isomer and a hydroperoxy isomer in linoleic acid exhibited the highest relative contribution to the total amount of monohydroperoxides. This peak increased with both time and temperature.

With respect to polyhydroperoxide formation, the liposome incubated at 6°C was fairly stable (data not shown), since the polyhydroperoxides only increased from 1.2 to 1.8 mol% after 7 d (this was, however, a significant difference, $P < 0.01$). The polyhydroperoxides increased with time and temperature. After 7 d at 25 and 40°C, 25 and 35 mol% polyhydroperoxides were observed, respectively. Addition of 0.1 mM $FeSO_4$ to a liposome solution incubated at 25°C led to a polyhydroperoxide formation profile similar to that of the liposomes stored at 40°C without any $FeSO_4$. A two-sided *t*-test at the 95% confidence level rejected a difference between the samples at all points in time.

The DHA content of the liposomes is shown in Figure 7. The liposome incubated at 6°C was stable, since the minor re-

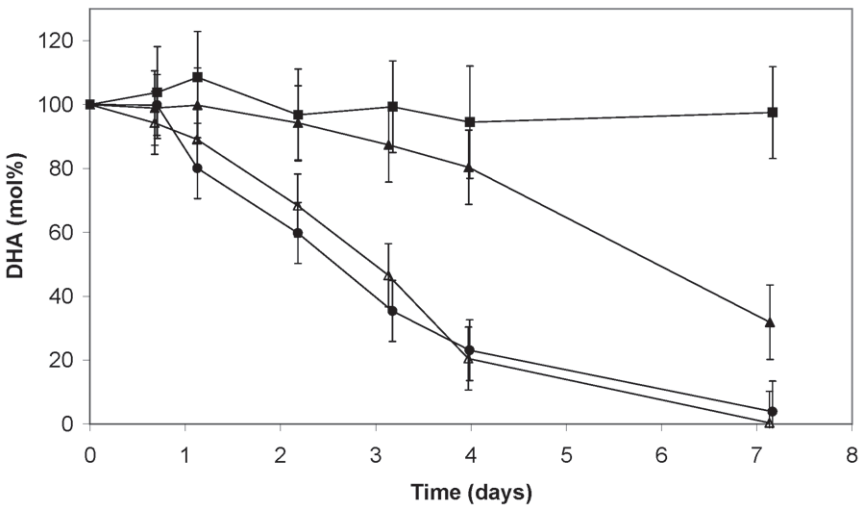

FIG. 7. The relative DHA concentration of DHA in liposomes without $FeSO_4$ at 6 (■), 25 (▲), and 40°C (●) and with $FeSO_4$ at 25°C (△).

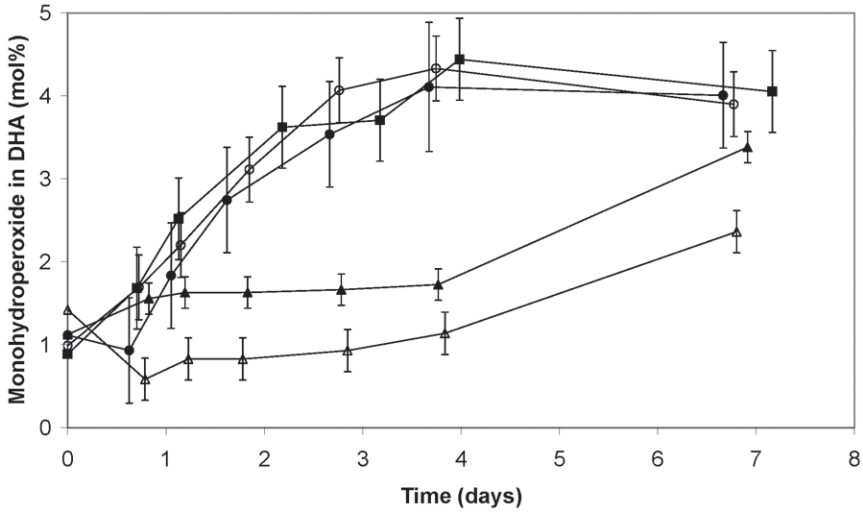

FIG. 8. Total amount of monohydroperoxides in liposomes without antioxidants (■) or with antioxidants: ascorbic acid (●), α-tocopherol (▲), α-tocopherol + ascorbic acid (△), and sea buckthorn juice (○).

duction of DHA was not significant. The DHA content decreased with time and temperature as shown in Figure 7. After 7 d of storage, 31 and 0.4 mol% DHA remained at 25 and 40°C, respectively. Addition of $FeSO_4$ to a liposome stored at 25°C led to a DHA content profile similar to that of the liposome at 40°C without any $FeSO_4$. A two-sided *t*-test at the 95% confidence level of the samples rejected a difference between all sampling times except the last. The maximal proportions of DHA converted to monohydroperoxides and polyhydroperoxides were only 18 and 21 mol% at 25 and 40°C, respectively, over 7 d. Thus, a large part of the DHA was converted to products other than the hydroperoxides as measured with our HPLC method at these two temperatures.

Oxidation of DHA in liposomes after addition of antioxidants. The amount of monohydroperoxides in samples containing antioxidants incubated at 40°C is presented in Figure 8. Addition of α-tocopherol (0.5 mM) reduced the oxidation to monohydroperoxides during the first 4 d. Then the monohydroperoxides increased, reaching 3.4 mol%. A two-sided *t*-test at the 95% confidence level showed that there was a significant difference between the reference and liposome containing α-tocopherol on day 4, while a difference on day 7 was rejected. Addition of both α-tocopherol and ascorbic acid reduced the oxidation to monohydroperoxides even more; the difference according to the *t*-test was significant at the 95% confidence level. It should be noted that the percentage of C4-monohydroperoxide was quite stable in both experiments over the 7 d (data not shown). Addition of only ascorbic acid or juice from sea buckthorn did not lead to any reduction in the monohydroperoxides, which was supported by a two-sided *t*-test at the 95% confidence level.

Addition of α-tocopherol reduced the formation of polyhydroperoxides considerably (data not shown). The combination of α-tocopherol and ascorbic acid showed a similar pattern, and a difference between the liposome containing only α-tocopherol and the combination of α-tocopherol and ascorbic acid was rejected, according to a two-sided *t*-test at a confidence level of 95%, during the first 4 d. However, on day 7, the liposome with the vitamin combination showed a lower amount of polyhydroperoxide (12 mol%) than the liposome with α-tocopherol alone (17 mol%) (this differences was significant). Addition of ascorbic acid or sea buckthorn juice provided no protection to DHA in liposomes with respect to the formation of polyhydroperoxides, and levels of 32 and 34 mol% were reached, respectively, after 7 d of incubation at 40°C.

The relative DHA content of the liposomes is shown in Figure 9. Addition of α-tocopherol almost completely prevented the degradation of DHA during the first 4 d. Then, on day 7 the DHA content was reduced to 58 mol%. When the combination of α-tocopherol and ascorbic acid was added, the DHA content was reduced slowly and reached 70 mol% after 7 d. A significant difference between the two samples based on a *t*-test at the 95% confidence level was observed after 2 d. The ascorbic acid seemed to protect the DHA during the two first days. The DHA content then decreased considerably and was as degraded as the reference. The DHA degradation was not reduced when juice from sea buckthorn was added. Since the level of hydroperoxide formed in liposomes when α-tocopherol was added corresponded to the reduction in DHA during the first 4 d, significant amounts of other oxidation products were not formed. DHA was then degraded further to other oxidation products as well. The liposomes containing other additives were degraded to other oxidation products earlier.

DISCUSSION

The analysis method developed allowed quantification of eight isomer groups of monohydroperoxy-DHA, and showed that these oxidation products initially increased faster in the bulk system than in the liposome system. The C20-monohydroper-

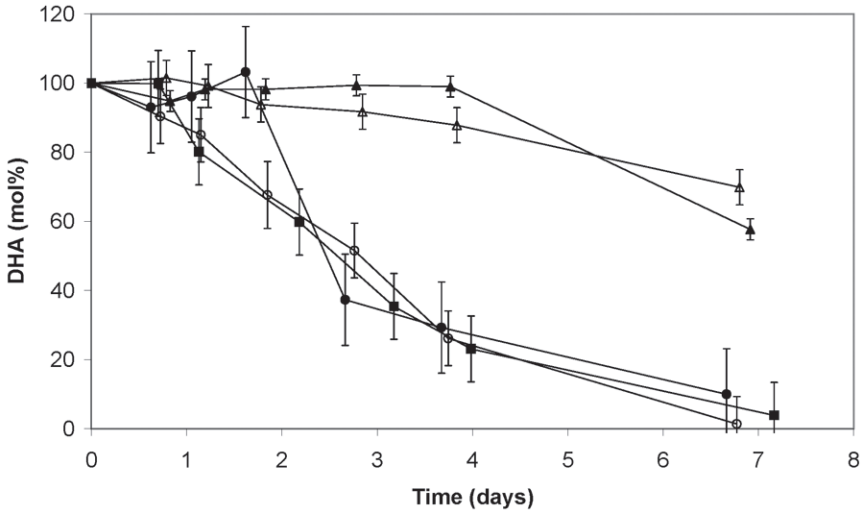

FIG. 9. The relative DHA concentration of liposomes without antioxidants (■) or with antioxidants: ascorbic acid (●), α-tocopherol (▲), α-tocopherol + ascorbic acid (△), and sea buckthorn juice (○).

oxy-DHA provided the largest contribution to the total amount of monohydroperoxides and showed a rapid increase, thus demonstrating that the double bond farthest from the carboxyl group was highly sensitive to oxidation. Although all isomers decreased after a peak in the total amount of monohydroperoxides was reached, this isomer continued to increase relative to the other isomers. This could be interpreted either as further degradation of this isomer at a slower rate than the other isomers, or a continued increase in this isomer at a higher rate than the other isomers, although the degradation rate was higher than the formation rate. Furthermore, the C4-monohydroperoxide, which is situated on the double bond nearest the carboxyl group, was sensitive to oxidation and showed behavior that deviated from that of the other isomers. The C4-monohydroperoxide increased considerably during the initial increase in the total amount of monohydroperoxides. However, when the maximum of the total amount of monohydroperoxides was reached, this isomer decreased faster than the other isomers, indicating that it was most sensitive to further oxidation. The other isomers, i.e., a hydroperoxide group on either carbon 17, 16, 14, 13, 11, 10, 8, or 7, increased to a lesser extent, indicating that the second to fifth double bonds within the DHA molecule were less sensitive to oxidation. However, the hydroperoxides at double bonds two to five are highly prone to further oxidation to hydroperoxy epidioxides and hydroperoxy bicycloendoperoxides (1). These oxidation products cannot be formed from the hydroperoxide groups situated on carbons 20 and 4, since they are located outside the group of double bounds. This may explain why the formation of C20 and C4 isomers was most extensive. Double bonds two to five were probably oxidized more than the detected monohydroperoxides, and the hydroperoxy epidioxides and hydroperoxy bicycloendoperoxides formed were instead detected as polyhydroperoxides. Our findings are supported by another study in which the DHA ethyl ester incubated in chloroform with a radical inducer at 37°C exhibited the highest hydroperoxide formation at carbon 20 and carbon 4 (9). However, when the DHA ethyl ester was incubated in an aqueous emulsion instead, the hydroperoxide formation at carbons 16, 4, 20, and 10 was highest. This result was explained by the epidioxide formation being slower at carbons 16 and 10 and/or that the oxygen attack was greater at these positions in the emulsion system.

Our method also revealed the profile of the total amount of monohydroperoxides with time, which increased most initially, and then decreased in the bulk system to the benefit of other oxidation products. At the lowest temperature investigated, i.e., 6°C, the amounts of monohydroperoxides and polyhydroperoxides found were quite low and stable in the liposome system, whereas these oxidation products increased much more in the bulk system at this temperature. In the liposome system the polyhydroperoxides increased considerably with temperature and time. In contrast, the polyhydroperoxides initially increased fast at 25 and 40°C in the bulk system. A peak was reached and then the polyhydroperoxides slowly decreased. This is probably caused by a considerable amount of polymerization, which was visually observed in the bulk system.

The measured DHA content confirmed that the liposome system containing DHA incubated at 6°C was stable, whereas only 15 mol% DHA was left in the bulk system after 7 d at the same temperature. The degradation increased with temperature and time for both the liposome and bulk systems. Thus, the liposome system provided better protection of DHA than the bulk system, although at a temperature of 25°C and above there was considerable degradation of DHA. Other studies also have shown that liposomes provide better protection against oxidation than a bulk system when the PUFA are incorporated into either PC or TG (10,11). When DHA was dissolved in acetonitrile at the same concentration as in the liposome system, the DHA was found to degrade at a slower rate (data not shown). Only 10% degradation of DHA was found after 4 d of incubation at 6, 25, or 40°C.

The addition of α-tocopherol to the DHA liposomes incubated at 40°C resulted in a considerable reduction in mono- and polyhydroperoxide formation together with slower degradation of unoxidized DHA. This vitamin is lipophilic and therefore probably evenly distributed among the DHA molecules in the liposome structure. The protection offered was greatest during the first 4 d. On day 7 the rate of oxidation was seen to increase, indicating that most of the α-tocopherol had been consumed. Addition of both α-tocopherol and ascorbic acid to the DHA liposome produced lower degradation on day 7, which has been explained by the α-tocopherol radical being regenerated by the ascorbic acid (1). Addition of only ascorbic acid provided no protection of the DHA liposome. Thus, ascorbic acid acted as neither an antioxidant nor a pro-oxidant. However, the latter effect may be induced by the addition of iron, since ascorbic acid can reduce Fe^{3+} to Fe^{2+}, which can decompose hydroperoxides (12). *In vivo*, iron is bound to metal proteins, and therefore the pro-oxidant effect of ascorbic acid may be eliminated (12). The fact that the sea buckthorn juice provided no protection of DHA in the liposome system may be explained by the low level of antioxidants. Even though sea buckthorn juice is rich in ascorbic acid, the liposome with sea buckthorn juice contained 50 times less ascorbic acid than the liposomes with pure ascorbic acid. The other antioxidants, α-tocopherol and quercetin-glucosides, provided an even lower concentration in the liposomes containing sea buckthorn juice.

Compared with currently available methods for analyzing primary oxidation products of PUFA, i.e., hydroperoxides, this method offers the advantage of differentiating between several monohydroperoxy-DHA isomers without requiring any derivatization step prior to analysis. For example, when GC was used to separate the isomers (3), the FA had to be derivatized prior to the analysis. Thus, this method may give misleading results due to either the derivatization step or the high temperature used during the measurements, both of which can affect the fragile hydroperoxide. In another study, thermospray LC-MS was used with a gradient of methanol and aqueous ammonium acetate to separate the isomers (4). Although the mobile phase and the column were not the same as those used in our method, the isomers were found to elute in the same order, but a longer analysis time was needed. A simplified HPLC method for analyzing the total amount of hydroperoxides and the reduction of unoxidized PUFA such as DHA also has been reported (13). The total amount of hydroperoxides can also be estimated by determining the peroxide value by titration or spectrophotometric measurements (1).

Our method thus provides a straightforward and accurate means of determining which part of DHA is most vulnerable to hydroperoxide formation. Double bonds 6 and 1 from the carboxyl group must be protected to reduce hydroperoxide formation. Since the other bonds probably form hydroperoxy epidioxides and hydroperoxy bicycloendoperoxides, these bonds should also be protected. One proposed strategy is to add antioxidants, such as the combination of α-tocopherol and ascorbic acid (investigated above), or squalene, which was discovered to have a protective effect on DHA (13). Another option might be to incorporate the DHA molecule into a lipid molecule such as a phospholipid (14). Hydroperoxide formation was completely prevented at carbons 4, 7, 8, and 11 when DHA was incorporated at one position of either PC or PE and incubated at 25°C. Furthermore, DHA should be stored in a suitable system, and liposomes were shown to be better than bulk in the current study.

Lipase-Catalyzed Esterification of 2-Monoricinolein for 1,2(2,3)-Diricinolein Synthesis

Charlotta Turner, Seiji Wani, Rosalind Wong, Jiann-Tsyh Lin, and Thomas McKeon*

Western Regional Research Center, U.S. Department of Agriculture, Albany, California 94710

ABSTRACT: The purpose of this investigation was to develop conditions for producing 2-monoricinoleoyl DAG. We used lipase-catalyzed hydrolysis of triricinolein to obtain 2-monoricinolein and thereafter synthesized 1,2(2,3)-diricinolein through esterification of 2-monoricinolein, using ricinoleic acid as the acyl donor. Five different 1,3-specific immobilized lipases were tested for the initial methanolysis reaction: *Candida antarctica* type B, *Rhizomucor miehei*, *Rhizopus oryzae* (ROL), *Thermomyces lanuginosus*, and *Aspergillus niger*. For the second esterification reaction, we investigated these five lipases plus *Pseudomonas cepacia*, *Penicillium roquefortii*, *Candida rugosa*, and *Pseudomonas fluorescence*. Toluene and diisopropyl ether (DIPE) were examined as reaction media at a water activity of 0.11. ROL in DIPE gave the highest yield of 2-monoricinolein from triricinolein, 78% after 3 h of reaction. The isolated 2-monoricinolein was esterified with ricinoleic acid for synthesis of 1,2(2,3)-diricinolein. ROL in DIPE gave the highest yield of 1,2(2,3)-diricinolein, 58% after 1 h of reaction, and NMR analysis showed that the purity was 97.2%. This methodology can be used for synthesizing radiolabeled 1,2(2,3)-diricinolein to study lipid biosynthesis in castor and other oilseeds.

Paper no. L9798 in *Lipids 41*, 77–83 (January 2006).

Castor (*Ricinus communis* L.) seeds contain a highly viscous oil rich in triricinolein, around 71 wt% of the total oil content (1). The ricinoleate content of castor oil is approximately 90 wt%. Ricinoleic acid is a hydroxy FA, which gives the oil its highly viscous properties. Castor oil is an industrially important oil, useful in lubricants and in the production of paints, cosmetics, coatings, and polymers (2). Unfortunately, castor seeds contain ricin, a toxic protein that inhibits protein synthesis in mammalian cells by attacking the ribosome (3). Therefore, work has been done in our laboratory exploring the possibility of producing triricinolein in a plant lacking toxins.

DAG acyltransferase (DGAT) is one of the key enzymes responsible for synthesizing triricinolein from 1,2-diricinolein in castor seeds. In our laboratory, the cDNA for DGAT in castor (RcDGAT) seeds was cloned and expressed in the yeast *Saccharomyces cerevisiae* (4) to produce an enzymatically active protein. To characterize the specific activity of the expressed DGAT enzyme, 1,2-diricinolein was needed as a substrate. In previous work, we described how to produce 1,2(2,3)-diricinolein from triricinolein by methanolysis using *Penicillium roquefortii* lipase (5). However, to further characterize the RcDGAT, it would be helpful to have a source of radiolabeled 1,2-diricinolein to broaden our understanding of the RcDGAT substrate specificity.

Only glycerol and ricinoleic acid are available for purchase as radiolabeled compounds; hence, only a few options exist for lipase-catalyzed synthesis of radiolabeled 1,2(2,3)-diricinolein. The approach is complicated by the need to esterify a hydroxy FA in a reaction for DAG synthesis. A key advantage of using an enzymatic approach instead of chemical radiolabeling is the elimination of side reactions, and there is no need for protecting groups with the choice of a suitable lipase and appropriate reaction conditions. The first option is to esterify radiolabeled glycerol with ricinoleic acid to form 1,2(2,3)-diricinolein directly. However, this is rather difficult to achieve, since no known lipase specifically catalyzes such a reaction. Generally, the products will be a mixture of 2-MAG, 1,3-DAG, and TAG (6), or if the water content is continuously removed, a high yield of TAG (7). The second option is esterification of radiolabeled glycerol with ricinoleic acid to make triricinolein, followed by hydrolysis/alcoholysis of triricinolein into 1,2(2,3)-diricinolein. This reaction was tried in our laboratory, but the first step of the reaction gave only low yields of triricinolein, even though water was removed using molecular sieves. A possible explanation is the inevitable polymerization reactions of hydroxy FA into estolides (8). A third option is hydrolysis/alcoholysis of triricinolein to 2-monoricinolein, followed by esterification of 2-monoricinolein with radiolabeled ricinoleic acid. The first step of the reaction can be optimized to give high yields using 1,3-specific lipases, and the second step can be controlled using a one-to-one molar fraction of ricinoleic acid to 2-monoricinolein. This is the approach that was determined to be the most suitable for our purposes. Hence, in this study we have developed a method for synthesizing 1,2(2,3)-diricinolein involving methanolysis of triricinolein to 2-monoricinolein followed by esterification of 2-monoricinolein with ricinoleic acid.

EXPERIMENTAL PROCEDURES

HPLC system. A Waters Millenium HPLC system consisting of a computer, a model 600 gradient pump, a model 717 autosampler, and a model 2487 UV-vis detector (Waters Associates, Milford, MA) was used. A Phenomenex Luna column, CN 5 μ, 250 × 4.6 mm (Phenomenex, Torrance, CA), was used for normal-phase HPLC analysis, a Phenomenex Luna column, C18(2) 100 Å, 5 μ, 250 × 15 mm, was used for preparative chromatography of castor oil, and a Phenomenex Luna column, CN 10 μ, 250 × 10 mm, was used for normal-phase preparative chromatography of monoricinolein.

Solvents. HPLC-grade 2-propanol, toluene, methanol, and hexane were obtained from Fisher Scientific (Fair Lawn, NJ), diisopropyl ether (DIPE) was purchased from Fluka Chemie (Buchs, Germany), and methyl *tert*-butyl ether (MTBE) was obtained from Aldrich (Milwaukee, WI).

Chemicals. Accurel MP1000 was obtained from Membrana (Obernburg, Germany). Molecular sieves (3 Å, 8–12 mesh), lithium chloride, and methyl ricinoleate were purchased from Sigma (St Louis, MO). Sodium sulfate and magnesium nitrate were obtained from J.T.Baker Inc. (Philipsburg, NJ). Potassium sulfate, sodium phosphate, and disodium phosphate were purchased from Spectrum Chemical MFG Corp. (Gardena, CA).

Enzymes. Crude lipases from *Pseudomonas cepacia* (PCL), *Rhizopus oryzae* (ROL), *Thermomyces lanuginosus* (TLL), *Aspergillus niger* (ANL), *Candida rugosa* (CRL), *Pseudomonas fluorescens* (PFL), and *P. roquefortii* (PRL) were kind gifts from Amano Enzymes Inc. (Nagoya, Japan). Novozyme 435 [immobilized *Candida antarctica* lipase type B (CALB), 10.000 propyl laurate units/g] and Lipozyme RM IM [immobilized *Rhizomucor miehei* lipase (RML), 6.1 batch acidolysis units Novo (BAUN)/g] were generous gifts from Novozymes North America (Franklinton, NC). The activity of Novozyme 435 is based on ester synthesis from 1-propanol and lauric acid at 60°C for 15 min. The ester formation is calculated based on the acid values of the reaction mixture measured by titration before and after reaction, and given as propyl laurate units/g. BAUN is based on acidolysis of high oleic acid sunflower oil and decanoic acid at 70°C for 60 min. The rate of the reaction is determined by measuring the amount of decanoic acid incorporated into the 1- and 3-positions of the TAG.

Preparation of triricinolein. Triricinolein is not commercially available, but was produced in our laboratory by preparative chromatography from castor oil, which is composed of 71% triricinolein plus diricinoleins (1). To obtain triricinolein, 0.5 mL of castor oil (0.5 g/mL in 2-propanol) was injected onto the preparative column. The mobile phase used was a gradient of methanol (A) and 2-propanol (B), and the flow rate was 7 mL/min, eluted with 100% A for 5 min, a linear gradient of A/B (80:20) over 10 min, and held for 5 min. The column was then reconditioned back to 100% A over 5 min and held for 5 min. Triricinolein was collected at a retention time of 10 min. The solvent was removed under nitrogen and mild heating, and the purity of the fractions was checked by analytical HPLC.

Immobilization of lipases. Crude lipases were immobilized on a polypropylene powder (Accurel MP1000, formerly called EP100) using adsorption, as described by Gitlesen *et al.* (9). Crude enzyme (5 g) was mixed with 100 mL of phosphate buffer (pH 6.0, 20 mM) and then added to 5 g of Accurel MP1000 that had been prewetted with 15 mL of ethanol. The mixture was incubated overnight at room temperature while stirring. The following day the mixture was filtered, and the filtrate was washed with 5 mL of phosphate buffer (pH 7.0, 200 mM). The immobilized enzyme was dried overnight under vacuum. The activity of the lipases was determined by mixing 40 mg of triolein with 2.5 mL of DIPE (a_w = 0.11) and 20 μL of methanol (a_w = 0.11) and 50 mg of immobilized lipase (a_w = 0.11). Several fractions were taken at 10–30 min intervals, up to 3 h total reaction time. The enzyme activity was expressed as milligrams triolein consumed per gram of enzyme per hour of reaction time. The hydrolytic activities for the enzymes tested in this work were: 3.1 (CRL), 10.1 (PRL), 18.5 (ANL), 22.6 (CALB), 34.8 (PCL), 54.4 (PFL), 250.9 (RML), 280.8 (TLL), and 320.3 (ROL).

Equilibration of the reaction system. Immobilized enzymes, reaction media (toluene, hexane, and DIPE), and methanol were allowed to equilibrate for at least 48 h in airtight desiccators to a water activity (a_w) of 0.11 over saturated LiCl solution (10).

HPLC analysis. The expected products of the lipase reactions, ricinoleic acid, methyl ricinoleate, 1,2(2,3)-diricinolein, 2-monoricinolein, and triricinolein, were analyzed by injection of 20 μL on a normal-phase HPLC column using a mobile phase of MTBE (A) and hexane (B). The gradient was as follows: held for 5 min at A/B (30:70), then a gradient to A/B (60:40) in 15 min, held for 5 min, then a gradient back to A/B (30:70) in 1 min, and held for 9 min. The total run time was 35 min. The flow rate was 1.0 mL/min, with detection at 205 nm.

Methanolysis reaction. Triricinolein (100 mg) was dissolved in 2.5 mL of reaction media and 50 μL of methanol. A 100-μL quantity was removed as a first fraction to determine the starting concentration of triricinolein (which was set to 100% yield on the axis of Figs. 3A, 3B). Thereafter, 50 mg of immobilized enzyme was added, and the reaction took place in glass tubes rotated at room temperature. Fractions (100 μL) were removed at time intervals, the solvent of each collected fraction was removed under nitrogen, and 0.5 mL of mobile phase solution [hexane/MTBE (7:3, vol/vol)] was added. The fractions were stored in a freezer at −20°C until HPLC analysis. The reactions were performed in duplicate.

Optimized methanolysis reaction. ROL, DIPE, and methanol were pre-equilibrated to a_w 0.11 for at least 48 h. Triricinolein (1 g) was dissolved in 10 mL of DIPE and 0.5 mL of methanol. ROL (0.5 g) was added, and the mixture was allowed to react for 30 min with stirring at room temperature. The enzyme was removed by filtration at the end of the reaction time. The solvent was removed by nitrogen, and 0.5 mL of hexane/MTBE (7:3) was added.

Fraction collection of monoricinolein. Portions (0.5-mL) of methanolyzed triricinolein were injected onto the normal-phase HPLC preparative column. A mobile phase consisting of hexane

(A) and MTBE (B) was used at a flow rate of 5.0 mL/min. The gradient elution was as follows: held for 5 min at A/B (30:70), then a gradient to A/B (60:40) in 15 min, then held for 5 min, and a gradient back to A/B (30:70) in 1 min, then held for 4 min. The total run time was 30 min. Fractions of 2.5 mL were collected, and those representing the monoricinolein peak eluting at 17 min were pooled. The solvent was removed by nitrogen under mild heating. The monoricinolein oil recovered was stored at –20°C.

Esterification reaction. 2-Monoricinolein (25 mg) and ricinoleic acid (20 mg) (1:1 molar proportion) were dissolved in 2 mL of reaction media (a_w = 0.11). A sample of 100 µL was taken out as a first fraction to determine the starting concentration of 2-monoricinolein (which was set to 100% yield on the axis of Fig. 5). Thereafter, 10 molecular sieve beads for drying and 50 mg of immobilized enzyme were added, and the reaction took place in glass tubes rotated at room temperature. Fractions of 100 µL were taken out at time intervals, the solvent of each collected fraction was removed by nitrogen, and 0.5 mL of mobile phase solution [hexane/MTBE (7:3, vol/vol)] was added. The fractions were stored in a freezer at –20°C until HPLC analysis. The reactions were performed in duplicate.

Optimized esterification reactions. ROL and DIPE were pre-equilibrated to a_w 0.11 for at least 48 h, 25 mg of 2-monoricinolein and 20 mg of ricinoleic acid (1:1 molar proportion) were dissolved in 2 mL of DIPE, 0.5 g of ROL and 10 molecular sieve beads were added, and the mixture was allowed to react for 1 h with stirring at room temperature. The enzyme was removed by filtration at the end of the reaction time. The solvent was removed by nitrogen, and 0.5 mL of hexane/MTBE (7:3, vol/vol) was added.

Fraction collection of 1,2(2,3)-diricinolein. The procedure was the same as for fraction collection of monoricinolein (see above). The 1,2(2,3)-diricinolein peak was collected at a retention time of 12 min. The solvent was removed by nitrogen under mild heating. The 1,2(2,3)-diricinolein oil recovered was stored at –20°C.

NMR spectroscopy. NMR spectra were obtained at 27°C from samples in $CDCl_3$ with TMS as an internal standard on a Bruker model ARX400 spectrometer (Bruker BioSpin Corp., Fremont, CA) at a frequency of 100.62 MHz for carbon and 400.13 MHz for proton. A 30° pulse at a 2.3-s repetition rate was used for carbon, and a 90° pulse at a 7- to 8-s repetition rate was used for protons. The number of attached protons for ^{13}C signals was determined from distortionless enhancement by polarization transfer (DEPT) 90 and DEPT135 assays.

RESULTS AND DISCUSSION

The purpose of this work was to synthesize 1,2(2,3)-diricinolein by incorporating ricinoleic acid into 2-monoricinolein. Since 2-monoricinolein is not commercially available, this compound was enzymatically synthesized from triricinolein. The reactions examined in this work are shown in Figure 1.

Figure 1A shows the lipase-catalyzed methanolysis reaction of triricinolein to produce 2-monoricinolein. To achieve a high

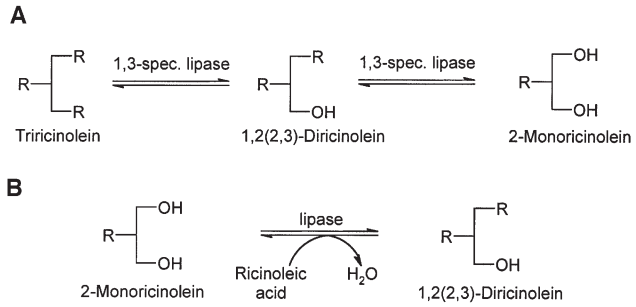

FIG. 1. (A) Reaction scheme for lipase-catalyzed hydrolysis/methanolysis of triricinolein to 2-monoricinolein. (B) Reaction scheme for lipase-catalyzed esterification of 2-monoricinolein and ricinoleic acid to 1,2(2,3)-diricinolein.

yield of 2-monoricinolein (and not complete methanolysis/hydrolysis of triricinolein to glycerol), it is important to use a 1,3-specific lipase. Some of the most highly 1,3-specific lipases are CALB, RML, ROL, TLL, and ANL (11). These were all examined in this study. Figure 1B illustrates the esterification reaction between 2-monoricinolein and ricinoleic acid to produce 1,2(2,3)-diricinolein. In this reaction, one molecule of water is formed for each molecule of diricinolein made by the enzyme. It is important to realize that the water content must be kept at a minimal level; otherwise, the reaction will be driven in the other direction toward hydrolysis. Therefore, molecular sieves were used in all the esterification reactions. Nine different lipases were tested for this reaction, CALB, RML, ROL, TLL, ANL, PCL, PRL, CRL, and PFL.

HPLC analysis. Figures 2A and 2B show examples of chromatography of fractions taken during the methanolysis and esterification reactions, respectively. Complete separation of methyl ricinoleate, ricinoleic acid, triricinolein, 1,2(2,3)-diricinolein, and 2-monoricinolein was accomplished within 30 min of chromatography. Furthermore, 1,2(2,3)-diricinolein was baseline separated from its positional isomer 1,3-diricinolein, although this compound was not formed in any significant amount in any of the reactions.

Optimization of the methanolysis reaction. The conversion of triricinolein to 2-monoricinolein was examined using five different 1,3-specific lipases, CALB, RML, ROL, TLL and ANL. The reactions were carried out in two different solvents, toluene and DIPE. A summary of the results for the methanolysis reaction is shown in Table 1. ROL is clearly the preferred enzyme for catalyzing the desired reaction, giving yields of 2-monoricinolein of approximately 75%. Previous research has shown ROL to be a highly 1,3-specific lipase (12,13).

Figures 3A and 3B show the time course for the ROL-catalyzed reaction in DIPE and toluene, respectively. The reaction was fast in both solvents, as shown by the rapid consumption of triricinolein. However, in DIPE the 2-monoricinolein formed was further converted to glycerol and methyl ricinoleate after its peak at 78% yield. In toluene, the 2-monoricinolein formed was relatively stable for at least 24 h.

The ROL-catalyzed reactions in both DIPE and toluene were scaled up using one gram of triricinolein as the starting

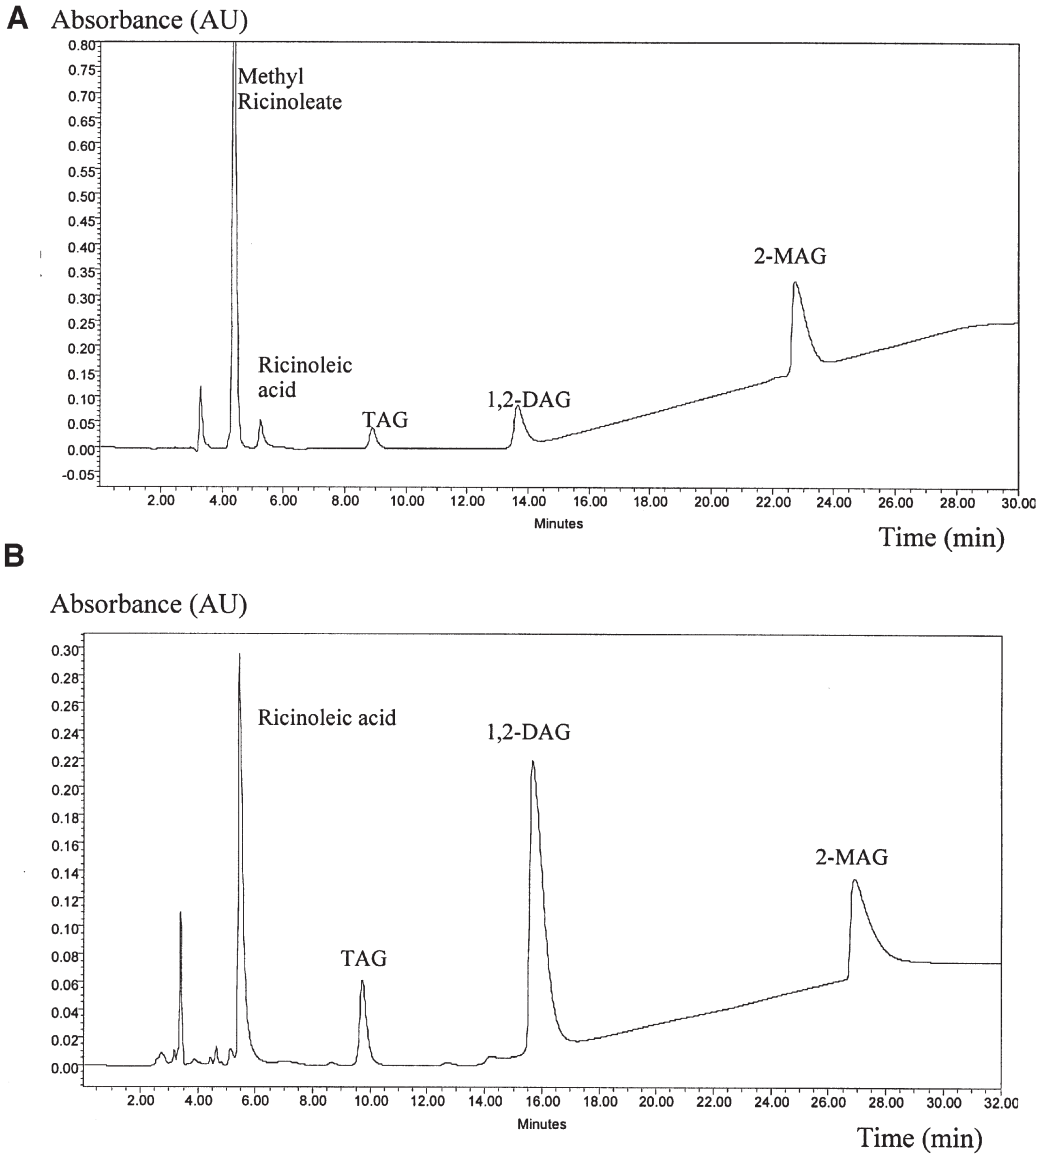

FIG. 2. (A) HPLC of a fraction taken after 1 h of methanolysis reaction of triricinolein using *Rhizomucor miehei* lipase (RML) in diisopropyl ether (DIPE). (B) HPLC of a fraction taken after 30 min of esterification reaction between 2-monoricinolein and ricinoleic acid using *Rhizopus oryzae* lipase (ROL) in DIPE. TAG, triricinolein; DAG, 1,2(2,3)-diricinolein; MAG, 2-monoricinolein.

material. Fractions were taken after certain time intervals. The reaction in toluene was rather slow compared with that in DIPE, requiring more than 24 h of reaction to give approximately 75% yield. The optimized methanolysis reaction was therefore performed in DIPE, giving 78% yield of 2-monoricinolein after only 30 min of reaction. The 2-monoricinolein fraction was collected using a preparative HPLC system (see the Experimental Procedures section). Figure 4 shows a chromatogram from a preparative run of the reaction products obtained using the optimized methanolysis conditions. The 2-monoricinolein was collected from fractions eluting between 16 and 20 min.

The 2-monoricinolein fraction was examined for purity

TABLE 1
Maximum Yields of 2-Monoricinolein (%) from Lipase-Catalyzed Methanolysis of Triricinolein[a]

Lipase	Solvent	
	DIPE	Toluene
CALB	6 (1 h)	1 (48 h)
RML	50 (3 h)	35 (3 h)
ROL	78 (3 h)	75 (3 h)
TLL	47 (1 h)	37 (1 h)
ANL	68 (24 h)	24 (1 h)

[a]Data represent the means of two experiments. The reaction times giving these maximum recoveries are shown within parentheses. ANL, *Aspergillus niger* lipase; DIPE, diisopropyl ether; CALB, *Candida antarctica* lipase type B; RML, *Rhizomucor miehei* lipase; ROL, *Rhizopus oryzae* lipase; TLL, *Thermomyces lanuginosus* lipase.

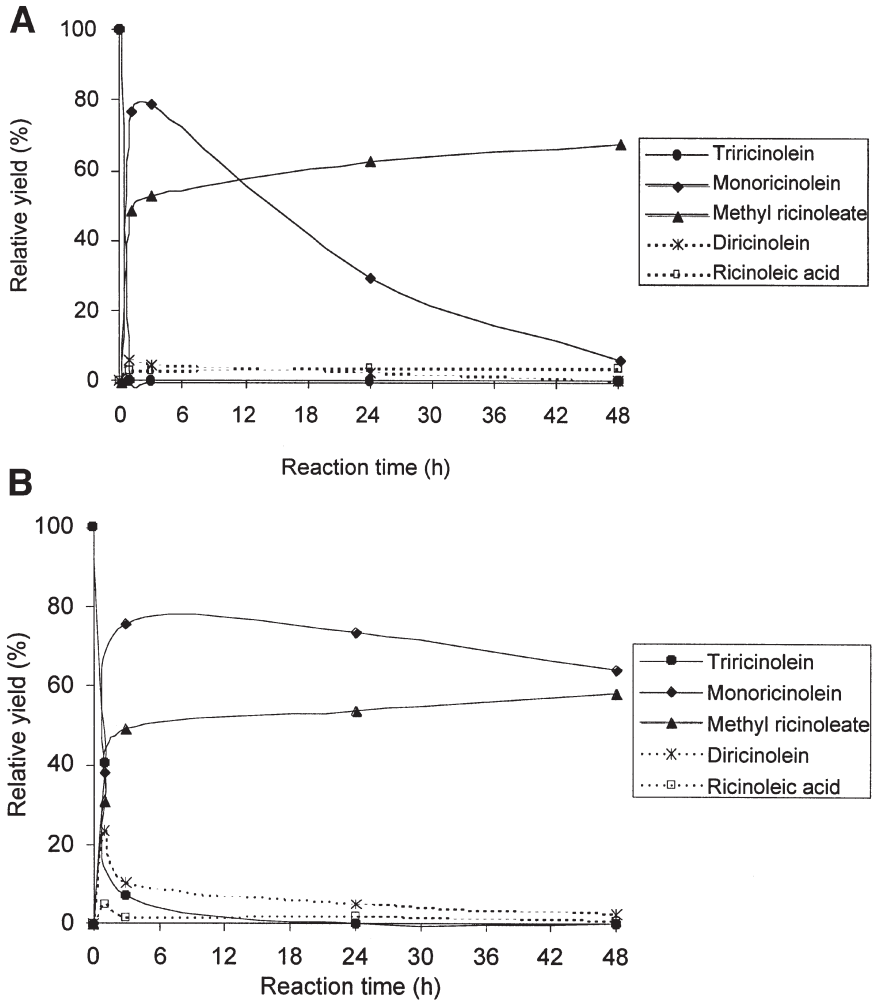

FIG. 3. Time course of the ROL-catalyzed methanolysis reaction of triricinolein in (A) DIPE and (B) toluene. Data points represent the means of two experiments. For abbreviations see Figure 2.

using ^{1}H and ^{13}C NMR. The results showed that the 2-monoricinolein produced approached 100% purity.

Optimization of the esterification reaction. The 2-monoricinolein was esterified with ricinoleic acid to form 1,2(2,3)-diricinolein. Nine different immobilized lipases were examined, CALB, RML, ROL, TLL, ANL, PRL, CRL, PCL and PFL. The reactions were again performed in toluene and DIPE. Table 2 shows the results from all the experiments for this reaction.

As shown in Table 2, RML and ROL in either solvent and TLL in toluene gave high recoveries of 1,2(2,3)-diricinolein, 54–59%. The reaction times giving maximum yields were relatively fast, 0.5–1.5 h. After studying the chromatograms, TLL was excluded as it showed several unknown peaks, which eluted near diricinolein and would thereby contaminate the final fraction of 1,2(2,3)-diricinolein or affect recovery of a pure fraction (data not shown). RML and ROL, on the other hand, showed clean chromatograms. For example, Figure 2B shows a fraction taken after 30 min of ROL-catalyzed reaction in DIPE. For simplicity, ROL-catalyzed esterification in DIPE was chosen as the preferred reaction system, since this was also used in the optimized methanolysis reaction. The time course for the ROL-catalyzed esterification of 2-monoricinolein with ricinoleic acid in DIPE is shown in Figure 5. As can be seen from the figure, the reaction is rapid, with a maximum yield of 58% 1,2(2,3)-diricinolein after one hour of reaction. Reactions longer than one hour gave decreased amounts of diricinolein in the reaction mixture.

Figure 6 shows an HPLC chromatogram of the collected 1,2(2,3)-diricinolein peak, indicating the purity of the final product. Furthermore, ^{1}H and ^{13}C NMR showed that the purity of 1,2(2,3)-diricinolein vs. possibly coeluting 1,3-diricinolein was 97.2%.

In conclusion, ROL was the optimal lipase for catalyzing both the conversion of triricinolein to 2-monoricinolein and the esterification reaction of 2-monoricinolein with ricinoleic acid. DIPE was chosen as the best reaction solvent at a_w of 0.11. Schmid *et al.* (14) also found ROL to be the most suitable for

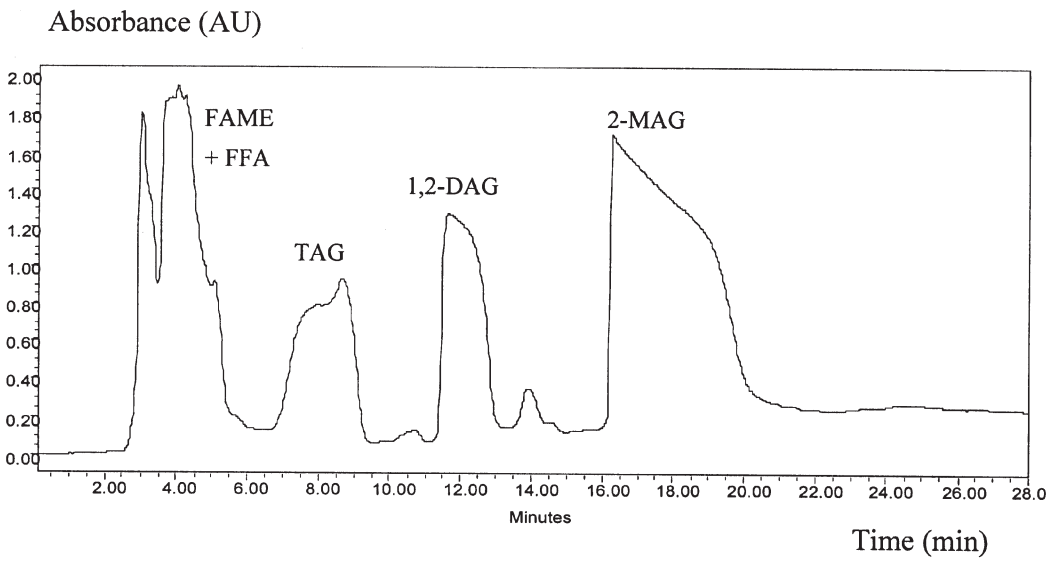

FIG. 4. Preparative HPLC of the reaction products after 30 min of ROL-catalyzed methanolysis reaction of triricinolein in DIPE. FAME, methyl ricinoleate; FFA, ricinoleic acid; for other abbreviations see Figure 2.

selective synthesis of 1,3-oleoyl-2 palmitoyl-glycerol. The optimal reaction time was only 30 min for the methanolysis reaction and one hour for the esterification reaction. For the methanolysis reaction, these conditions gave a 2-monoricinolein yield of 78% and a purity of nearly 100%. For the second esterification reaction, the optimized reaction gave a 1,2(2,3)-diricinolein yield of 58% and a purity of 97.2%. This reaction scheme can be used for the production of high-purity (>97%) radiolabeled 1,2(2,3)-diricinolein. Work is in progress in our laboratory to make this radiolabeled DAG and to test it in reactions with the DGAT enzyme expressed in yeast.

[a]Department of Food Science and Nutrition, Zhejiang University, Hangzhou, China, 310029, and
[b]School of Applied Science, RMIT University, Melbourne, Victoria, 3000, Australia

ABSTRACT: The aim of this study was to investigate the possibility of a relationship between plasma homocysteine (Hcy) and phospholipid FA (PUFA) in healthy Australian males. One hundred thirty six healthy male subjects aged 20–55 yr were recruited from the Melbourne metropolitan area. Each volunteer completed a semiquantitative food frequency questionnaire and gave a blood sample. Plasma Hcy concentrations were determined by an established HPLC method; the plasma phospholipid FA were determined by standard methods. Plasma Hcy concentration was significantly negatively correlated with plasma phospholipid concentration of the PUFA 20:5n-3 (r = –0.226, P = 0.009), 22:5n-3 (r = –0.182, P = 0.036), 22:6n-3 (r = –0.286, P = 0.001), total n-3 (r = –0.270, P = 0.002) and the ratio n-3/n-6 PUFA (r = –0.265, P = 0.002), and significantly positively correlated with 20:4n-6 (r = 0.180, P = 0.037). In the partial correlation analysis, after controlling for serum vitamin B_{12} and folate concentration, plasma Hcy was significantly negatively correlated with the plasma phospholipid concentration of 22:6n-3 (r = –0.205, P = 0.019), total n-3 (r = –0.182, P = 0.038) and the ratio n-3/n-6 PUFA (r = –0.174, P = 0.048). Evidence indicates that an increased concentration of n-3 PUFA in tissues has a beneficial effect on cardiovascular health. Our findings provide further evidence that increased consumption of dietary n-3 PUFA increases the concentration of n-3 PUFA in plasma phospholipid, which is associated with a protective effect on cardiovascular diseases and lower plasma Hcy levels. The mechanism that might explain the association between plasma 22:6n-3 and Hcy levels is not clear.

Paper no. L9771 in *Lipids 41*, 85–89 (January 2006).

Increased plasma homocysteine (Hcy) levels have been suggested to be an independent risk factor for cardiovascular diseases (1–3). Hcy is an intermediate metabolite in the metabolism of methionine to cysteine. The normal metabolism of Hcy involves two pathways: remethylation and transsulfuration. Remethylation of Hcy to methionine requires vitamin B_{12} (methylcobalamin form) as a coenzyme for Hcy methyltransferase (methionine synthetase) and N^5-methyl-tetrahydrofolate as a methyl donor. The transsulfuration pathway of Hcy to cysteine requires vitamin B_6 as a coenzyme for both cystathionine β-synthase (converts Hcy to cystathionine) and cystathionine lyase (converts cystathionine to cysteine). A lack of dietary vitamin B_{12} and/or folic acid or vitamin B_6 results in elevation of plasma Hcy (4). We previously reported that plasma Hcy concentration was significantly negatively correlated with serum vitamin B_{12} concentration in healthy Australian males, but there was no significant correlation with folate (5).

Increased dietary intake of n-3 PUFA will lead to an increased tissue level of these FA, which has a beneficial effect on cardiovascular morbidity and mortality (6,7) *via* reduction in blood pressure (8) and serum/plasma TAG levels (9,10), antithrombotic effect (11,12), anti-inflammatory effect (13), increase in heart rate variability (14), and secondary prevention of cardiovascular disease (15,16).

Grundt *et al.* (17) have reported a beneficial effect after 1 yr of a high-dose n-3 PUFA (2 gelatin capsules daily, each capsule containing 850–882 mg EPA and DHA ethylesters) treatment (n = 150) on lowering plasma Hcy levels in a prospective, randomized, double-blind study compared with corn oil (n = 150) in acute myocardial infarction (MI) patients (P = 0.022) (17). However, it is not clear what the mechanism for the finding is. We had an opportunity to study whether plasma phospholipid (PL) PUFA concentrations, as surrogate markers of dietary intake of PUFA, are correlated with Hcy, since we had collected semiquantitative food frequency questionnaires and blood samples from four groups of men with widely varying intakes of n-3 PUFA. The aim of this study was to investigate the relationship of plasma Hcy with PL FA concentrations (as biomarker) in healthy Australian male subjects with variable n-3 PUFA intake.

METHODS

Subjects. The present study formed a part of a larger project investigating the association between diet and cardiovascular risk factors in Australian men (18). The study protocol was approved by the Human Ethics Committee of the RMIT University (Melbourne, Australia), and all subjects were volunteers who gave their written consent prior to participation in the study. A total of 139 subjects (18 vegans; 43 ovolacto vegetarians; 60 omnivores; 18 high meat-eaters ≥ 280 g raw meat/d)

*To whom correspondence should be addressed at Dept. of Food Science and Nutrition, Zhejiang University, 268 Kaixuan Rd., Hangzhou, Zhejiang, China 310029. E-mail: duoli@zju.edu.cn

Abbreviations: Hcy, homocysteine; MI, myocardial infarction; PL, phospholipid

were recruited from the Melbourne metropolitan area; all were healthy nonsmoking males in the age range 22–55 yr, with no family history of cardiovascular disease, and not taking any vitamin-fortified supplements.

Blood collection and dietary analysis. All subjects attended the RMIT University Medical Clinic on one morning following a 12-h overnight fast. Blood collection and dietary analysis were as described previously (18).

Laboratory measurements. Total Hcy was quantified in plasma as the ammonium 7-fluorobenzo-2-oxa-1,3-diazole-4-sulfonate derivative (19), using a HPLC separation, fluorometric detection method as described by Dudman *et al.* (20). To determine plasma PL FA, the total lipid of plasma was extracted with solvents, the plasma PL fraction was separated by TLC, and the methyl esters of the FA of the plasma PL fraction were prepared and separated by GLC as described previously (18).

Statistics. The data analyses were performed using a SPSS version 12 (SPSS Inc., Chicago, IL) software program. The correlation between Hcy and plasma PL FA concentration was initially determined by bivariate analysis. Partial correlation analysis was further performed, controlled for serum concentrations of vitamin B_{12} and folate. The level of significance was $P < 0.05$.

RESULTS

The original data on fish intake, plasma PL concentrations of various n-3 PUFA, and arachidonic acid have been published previously (18). The mean intake of fish was 28, 26, 1.4, and 0.7 g/d in high meat-eaters, moderate meat-eaters, ovolacto vegetarians, and vegans, respectively. Plasma PL concentrations of mean total n-3 PUFA were 7.2, 6.9, 4.5, and 4.0 mg/100 mL, respectively. The plasma PL 22:6n-3 concentrations were 4.1, 4.0, 2.3, and 2.1, respectively, and the 20:5n-3 concentrations were 1.4, 1.2, 0.8, and 0.6, respectively. The plasma PL concentrations of 20:4n-6 were 12.8, 12.6, 10.0, and 10.6 mg/100 mL, respectively.

Plasma Hcy concentrations were greater than 20 μmol/L in 5.9% of the subjects, between 20 and 15 μmol/L in 16.2%, between 14.9 and 10 μmol/L in 52.9%, and less than 10 μmol/L in 25%. Table 1 shows the correlations between the concentrations of plasma Hcy and PL FA. Plasma Hcy concentration was significantly negatively correlated with plasma PL concentration (mg/100 mL) of 20:5n-3 ($r = –0.226$, $P = 0.009$), 22:5n-3 ($r = –0.182$, $P = 0.036$), 22:6n-3 ($r = –0.286$, $P = 0.001$), total n-3 ($r = –0.270$, $P = 0.002$) and the ratio n-3/n-6 PUFA ($r = –0.265$, $P = 0.002$), and significantly positively correlated with 20:4n-6 ($r = 0.180$, $P = 0.037$).

TABLE 1
Bivariate Correlations Between Plasma Concentrations of Homocysteine and Phospholipid FA[a]

FA	Std. coeff.	*P*-value
20:4n-6	0.18	0.037
20:5n-3	–0.226	0.009
22:5n-3	–0.182	0.036
22:6n-3	–0.286	0.001
Total n-3	–0.27	0.002
n-3/n-6	–0.265	0.002

[a]n = 136; Std. coeff. = standardized coefficients.

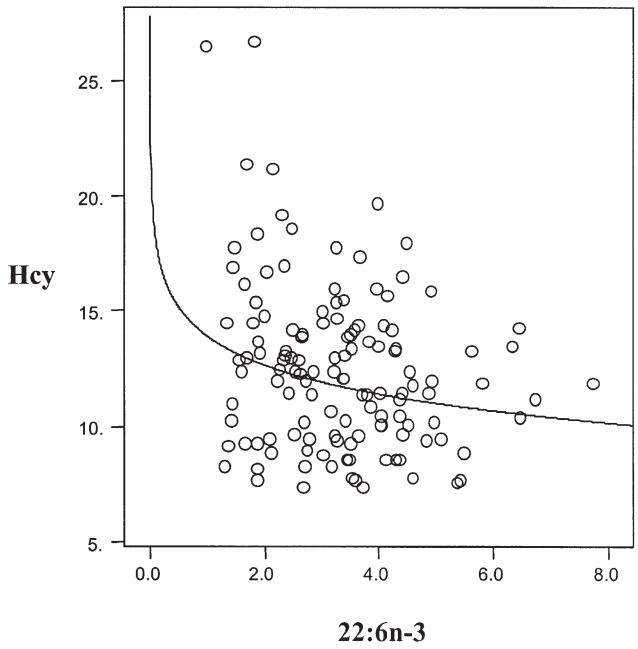

FIG. 1. Correlation of plasma concentrations of homocysteine (Hcy) with phospholipid DHA concentration.

In the partial correlation analysis, after controlling for dietary groups and serum concentrations of vitamin B_{12} (pg/mL) and folate (ng/mL), plasma Hcy was significantly negatively

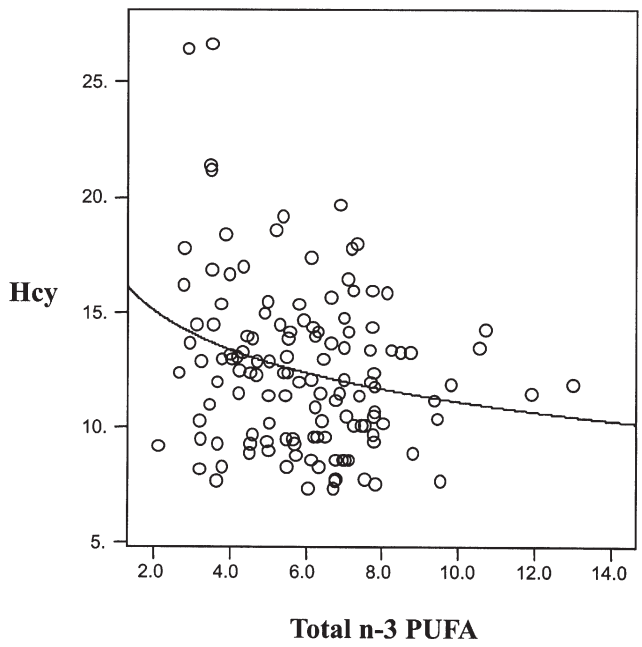

FIG. 2. Correlation of plasma concentrations of Hcy with phospholipid total n-3 PUFA concentration. For abbreviation see Figure 1.

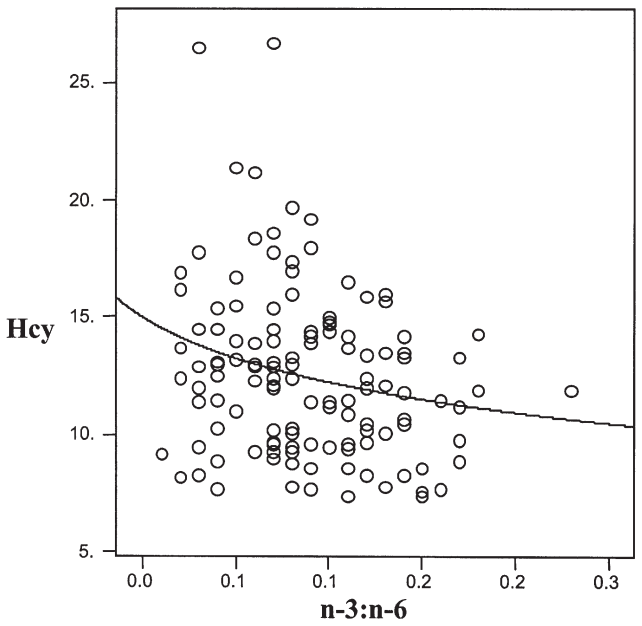

FIG. 3. Correlation of plasma Hcy concentration with phospholipids ratio of n-3 to n-6 PUFA. For abbreviation see Figure 1.

correlated with plasma PL concentration of 22:6n-3 (r = –0.205, P = 0.019), total n-3 (r = –0.182, P = 0.038), and the ratio n-3/n-6 PUFA (r = –0.174, P = 0.048) (Figs. 1–3, Table 2).

Table 3 shows that the plasma PL 20:4n-6, 20:5n-3, 22:5n-3, 22:6n-3, total n-3 PUFA, and n-3/n-6 ratio were significantly positively correlated with serum vitamin B_{12}, but not folate, in the present study.

DISCUSSION

Results from epidemiological, case-control, and cross-sectional studies have identified that elevated concentrations of plasma Hcy are an independent risk factor for cardiovascular disease. In a large prospective study from the United States (Physician's Health Study) (1), 14,916 male physicians, aged 40–84 yr, with no prior MI or stroke, provided plasma samples at baseline and were followed up for 5 yr. The results indicated that the 271 subjects who later had MI had significantly higher mean baseline levels of Hcy than subjects that were matched with paired controls who remained free of infarction. Subjects whose Hcy levels were in the highest 5% had about three times the risk of MI compared with those with lower levels (P = 0.005), even after adjustment for a variety of coronary risk factors. In a large-scale prospective nested case control study (Tromsø Study) (2), 21,826 subjects (10,963 males and 10,863 females), aged 12–61 yr, who were free from MI at the screening were studied. Three years later, 123 subjects developed coronary heart disease. Levels of serum Hcy were found to be higher in cases than in controls (P = 0.002), but with no threshold level. In a cross-sectional study (Framingham Heart Study) of 1,041 elderly subjects (418 men and 623 women; aged 67–96 yr) (21), the results showed a clearly graded increase in the prevalence of carotid artery stenosis with increasing plasma levels of Hcy. Individuals in the group having the highest levels of Hcy had twice the risk of severe stenosis when compared with the group with lowest Hcy levels. Similar findings were reported for the risk of carotid artery thickening (22), for angiographically defined coronary artery stenosis (23), for occlusive arterial disease (24), for MI (22,25), and for stroke (26). A study in 482 patients already at high risk of atherosclerosis from hyperlipidemia, assessed by logistic regression, indicated that high Hcy levels were an independent risk factor for atherosclerotic vascular disease. The relative risk for atherosclerotic events was almost three times higher (P = 0.0004) in patients in the top (≥11.4 μmol/L) compared with the bottom (<6.9 μmol/L) quintile of Hcy. There were significant Hcy/HDL (P = 0.012) and Hcy/TAG (P = 0.02) interaction terms. The highest risk of an atherosclerotic event was seen when Hcy was high and HDL and TAG were low (27). Reis *et al.* (28) investigated the correlation between the Hcy and early cerebrovascular disease in 33 (19 male, 14 female) patients under 55 yr old who suffered a stroke from 3 mon to 1 yr before the study. The patients were

[a]For footnote see Table 1.

matched with a group of normal subjects in terms of age and sex. They found that hyperhomocysteinemia was a risk factor for thrombotic cerebrovascular disease before the age of 55 (28). In a nested case-control study of 5,661 British men aged 40–59 yr during a12-yr followup, there were 141 incidents of stroke among men with no history of stroke at screening. Serum Hcy concentrations were significantly higher in 107 cases than 118 controls (who did not develop a stroke or MI during followup) ($P = 0.004$) (29).

Hcy is an intermediate metabolite of the metabolism of methionine to cysteine. Normal metabolism from Hcy to cysteine involves two pathways: remethylation and transsulfuration, which require vitamins B_{12}, B_6, and folate as coenzymes. Lack of vitamins B_{12} and/or folic acid or vitamin B_6 will results in elevation of plasma Hcy (4). Previously, we reported a significant negative correlation between plasma Hcy concentration and serum vitamin B_{12} concentration, and we also found no significant correlation with plasma folate in healthy male Australians (5). A similar finding has been reported from Chile (30).

In a double-blind intervention study, 57 healthy subjects were randomly divided to receive either a daily dose of 4 g of 85% 20:5n-3/22:6n-3 ($n = 28$) or corn oil ($n = 29$) for 12 wk. No significant changes in plasma Hcy levels appeared in either group after 12 wk of treatment compared with baseline (31). However, following 1 yr of n-3 PUFA treatment in the acute MI patients from the same research group with the same dose of n-3 PUFA, plasma Hcy levels were significantly lower in the n-3 PUFA group ($n = 150$) than in the corn oil group ($n = 150$) at follow-up ($P = 0.022$) (17). The authors attributed these contradictory results to the limited subject numbers in their first study (31). Bohles *et al.* (32) determined the plasma Hcy and erythrocyte PL FA in mothers ($n = 60$, age range 21–39 yr) and their newborn children. Maternal plasma Hcy concentration was significantly positively correlated with that of their newborns ($r = 0.71$, $P < 0.0001$). The maternal plasma Hcy levels were significantly negatively correlated with their offspring erythrocyte PL 22:6n-3 concentrations ($r = -0.51$, $P < 0.0003$) (32). However, there are no data in the literature on the influence of habitual n-3 PUFA intake on plasma Hcy levels.

Results from the present study showed that plasma Hcy concentration was significantly negatively correlated with the concentrations of plasma PL 20:5n-3, 22:5n-3, 22:6n-3, total n-3 PUFA, and ratio of n-3 to n-6 PUFA, and significantly positively correlated with 20:4n-6. It has been known that both n-3 PUFA and vitamin B_{12} only occur in animal- and marine-based food. In fact, plasma PL 20:4n-6, 20:5n-3, 22:5n-3, 22:6n-3, total n-3 PUFA, and n-3:n-6 ratio were significantly positively correlated with serum vitamin B_{12}, but not folate in the present study (Table 3). However, after controlling for serum vitamin B_{12} and folate, plasma Hcy concentration was still significantly negatively correlated with the concentrations of plasma PL 22:6n-3, total n-3 PUFA, and ratio of n-3 to n-6 PUFA. A possible mechanism for this relationship is that n-3 PUFA, especially 22:6n-3, may modulate gene expression of an enzyme(s) that are involved in formation and metabolism of plasma Hcy.

In conclusion, the present results provide further information that increased n-3 PUFA levels in plasma PL may have a protective effect on cardiovascular diseases in relation to lowering plasma Hcy levels. The mechanism that might explain the association between plasma DHA and Hcy levels is not clear.

The Real Radical Generator Other Than Main-Product Hydroperoxide in Lipid Autoxidation

Makio Morita[a] and Masako Tokita[b,*]

[a]Department of Health and Nutrition, Niigata University of Health and Welfare, 950-3198 Niigata City, Japan, and [b]Department of Food and Nutrition, Japan Women's University, Tokyo, Japan

ABSTRACT: The theory of initiation in lipid autoxidation, which deals with the supply of radicals to the chain reaction, has not been substantively advanced for several decades. Most researchers have long assumed a mechanism of initiation in which main-product hydroperoxide is centrally responsible for autocatalytic radical generation. However, this paper, in which we investigate autoxidizing methyl linoleate, presents decisive evidence against such an assumption: Autoxidation-accelerating activity under mild conditions was not found in the chromatographically separated main-product hydroperoxide fraction but was found in other fractions; and highly active substances with structures containing a peroxide-linked dimer with two hydroperoxy groups were actually obtained.

Paper no. L9845 in *Lipids 41*, 91–95 (January 2006).

A great deal of attention has been focused recently on the damage to biological systems by free radicals. An important source of free radicals is the autoxidation of lipids. Despite the large number of studies conducted in this field, the theory of initiation, which deals with the supply of radicals to the autoxidation chain reaction, has not been substantively advanced for several decades as can be seen in comparing reviews (1–3). The factors that govern the rate of oxidation and the level of radicals remain incompletely elucidated. The main product of autoxidation is a type of hydroperoxide. Since the 1940s, most researchers have assumed a mechanism of initiation in which this hydroperoxide is centrally responsible for autocatalytic radical generation, but we have entertained a minority opinion (4–6) that this role is not in fact played by the hydroperoxide. This paper, in which we investigate autoxidizing methyl linoleate (oxML), presents decisive evidence corroborating our opinion.

EXPERIMENTAL PROCEDURES

Linoleate materials. Methyl linoleate and pentyl linoleate were prepared as described (7). Methyl linoleate was also supplied from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan). In a preliminary experiment, the metal contents of prepared methyl linoleate were determined and found to be 0.17 ppm Fe and 0.053 ppm Cu before vacuum distillation and 0.011 ppm Fe and 0.0033 ppm Cu after six repetitions of vacuum distillation. The distilled methyl linoleate, however, did not exhibit a lower rate of autoxidation; once-distilled methyl linoleate and the purchased methyl linoleate showed oxidation tendencies that were not different from the material that had been redistilled six times. So, once-distilled methyl linoleate and the purchased material were used in these experiments. For the measurement of oxidation rate described herein, pentyl linoleate was purified by passage through a silica gel column using the purified solvents described later.

HPLC fractionation of oxML. A sample of oxML at 20°C, containing about 2 μmol main-product hydroperoxide, was subjected to HPLC on a 7.6 × 250 mm Nucleosil®100–5 column (Agilent, Palo Alto, CA) using hexane/diethyl ether (92:8, vol/vol) at a flow rate of 4 mL/min, monitored at 234 nm. Main-product hydroperoxide (MLOOH) was eluted from 11 to 20 min and the solvent was exchanged with methanol. Eluates before and after the elution of MLOOH were combined (oxML-MLOOH). Fractions obtained were concentrated under reduced pressure below 30°C.

Measurement of autoxidation-accelerating activity. Two microliters of pentyl linoleate, the oxidation substrate, was placed in a flat-bottomed vial of 9 mm i.d. The sample to be tested was added in acetone (0.2–0.4 mL), and the acetone was removed under a stream of nitrogen. The vial was allowed to stand in the dark at 20°C for 12 h, at 35°C for 3.5 h, or at 50°C for 1 h. The contents of the vial were then analyzed by HPLC for main-product hydroperoxide of pentyl linoleate, using a 4.6 × 150 mm Nucleosil 100–5 column with hexane/diethyl ether (88:12, vol/vol) at a flow rate of 1.5 mL/min, monitored at 234 nm (7). The oxidation rate was expressed using the rate of formation of main-product hydroperoxide. Each figure described and used for the subsequent calculation was the average obtained from 4–6 runs. The autoxidation-accelerating activity was calculated on the basis that the square of the oxidation rate increases in linear fashion with the concentration of oxidation-accelerating (radical-generating) material added, and was expressed as 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile) equivalent (Azo eq).

Purification of solvents. Distilled hexane, diethyl ether, and methanol were used for HPLC fractionation. A glass apparatus with a rectifying column was used. Methanol was distilled under reduced pressure. The solvents were tested for acceptability as follows: 60 mL of solvent obtained from distillation was placed in a flask and evaporated under reduced pressure.

*To whom correspondence should be addressed at Department of Food and Nutrition, Japan Women's University, 112-8681 Bunkyo-ku, Tokyo, Japan. E-mail: asano@fc.jwu.ac.jp

Abbreviations: Azo eq, 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile) equivalent; MLOOH, main-product hydroperoxide of methyl linoleate; oxML, autoxidizing methyl linoleate.

The flask was washed with 0.2–0.4 mL acetone, which was added to 2 μL pentyl linoleate, and the oxidation rate of the pentyl linoleate was measured. An unchanged rate showed that the solvent was acceptable for use.

Sephadex LH-20 column chromatography. A sample of less than 1 g was chromatographed on a 12.5 × 1100 mm Sephadex LH-20 column (Amersham Biosciences, Uppsala, Sweden) using methanol at a flow rate of about 0.5 mL/min. The eluates were examined by TLC.

Reduction with triphenylphosphine. An excess of 2% triphenylphosphine in hexane was added to the sample to be reduced. After 30 min, the mixture was separated in a 7.6 × 250 mm Nucleosil 100–5 column using a hexane/2-propanol solvent (97:3) at a flow rate of 4 mL/min, and the reduced material was recovered.

Reduction with $NaBH_4$. An excess of 2% $NaBH_4$ in methanol containing 0.05 M sodium methoxide was added to the sample to be reduced. After 30 min, a drop of acetic acid was added. The sample was diluted with water and added to a 7.6 × 250 mm Inertsil column (GL Science, Tokyo, Japan) monitored at 234 nm, and the reduced material was recovered with methanol at a flow rate of 2 mL/min. Methyl hydroxyoctadecadienoate was eluted separately from the unreacted materials.

GC–MS. After conversion to the trimethylsilyl derivative, the sample was analyzed by GC–MS (JEOL JMS600) with a DB-1 capillary column (length, 30 m; i.d., 0.25 mm; film thickness, 0.25 μm; J&W Scientific, Folsom, CA) at a flow rate of 1 mL/min from 150 to 300°C at a ramping rate of 8°C/min. Methyl trihydroxyoctadecenoate was identified by referring to previously reported data (8).

Determination of moderately reducible peroxide. A sample containing about 0.2 μmol of conjugated diene was refluxed in 1.2 mL of 2-propanol containing 0.12 mL acetic acid and 100 mg NaI for 20 min (9). The mixture was then titrated with 0.005 mol/L $Na_2S_2O_3$.

RESULTS

We estimated the autoxidation-accelerating activity of oxML and fractions separated from it (Table 1). In experiment 1, the activity of chromatographically separated main-product hy-

[a]See Experimental Procedures section for experimental details.
[b]The oxidation rate of pentyl linoleate was represented by the formation rate of its main-product hydroperoxide.
[c]Autoxidation-accelerating activity was calculated from the oxidation rate of pentyl linoleate and expressed by the equivalent concentration of 2,2′-azobis(4-methoxy-2,4-dimethylvaleronitrile).
[d]In Experiment 1, 2 μL of pentyl linoleate, the oxidation substrate, was placed in a vial with a sample to be tested for autoxidation-accelerating activity. Each sample contained 234 nm-absorbing material of 1.5 OD × mL, corresponding to about 5.5×10^{-8} mol hydroperoxide.
[e]Control: the oxidation substrate only.
[f]oxML1, oxML2, oxML3, oxML4: autoxidizing methyl linoleate; main-product hydroperoxide contents of oxML1, oxML2, oxML3, and oxML4 were about 30, 250, 500, and 600 μmol/mL, respectively.
[g]MLOOH: main-product hydroperoxide fraction chromatographically separated from autoxidizing methyl linoleate.
[h]Fraction X: a polar fraction from autoxidizing methyl linoleate as shown in Figure 1.
[i]In Experiment 2, 2 μL of pentyl linoleate was used in each vial; oxML4 of 1.5 OD × mL was placed in a vial; for MLOOH and oxML–MLOOH samples, the amount chromatographically fractionated from oxML4 to give 1.5 OD × mL was placed in a vial.
[j]oxML–MLOOH: combined sample of residual fractions, namely, chromatographically separated fractions other than MLOOH.

droperoxide was compared with that of unseparated oxML, with each sample containing materials which had the same 234-nm absorbing ability as represented by the same OD × mL value. The activity of the unseparated linoleate increased as autoxidation proceeded, but no activity was exhibited at 20°C by main-product hydroperoxide obtained at any stage. In experiment 2, a chromatographically separated main-product hydroperoxide fraction and a combined sample of residual fractions were examined at 20, 35, and 50°C. The hydroperoxide fraction was not active at 20 or 35°C, and the combined sample showed almost the same activity as the unseparated sample. At 50°C, some activity was observed in the main-product hydroperoxide fraction, although whether the activity was intrinsic to the hydroperoxide was uncertain.

Autoxidation-accelerating activity in oxML was distributed widely over fractions separated by normal and reversed-phase HPLC. A highly active fraction, X, separated by normal-phase HPLC, was found to be more polar than main-product hydroperoxide (Fig. 1) and to have a UV absorption maximum near 234 nm and an activity of 183×10^{-5} M Azo eq at 20°C, as shown in experiment 1 of Table 1. The concentration of X rapidly increased at a later stage of autoxidation. Its amount relative to that of main-product hydroperoxide on the absorption basis at 234 nm was 2.1% at a hydroperoxide level of 380 μmol/mL, and 5.6% at 700 μmol/mL. If we assume that X is present in oxML3 (a highly autoxidizing sample in Table 1) at roughly a 3% level on an absorption basis, one can estimate from the activity data in Table 1 that X is responsible for about one-fourth of the total activity of oxML3.

Although X was a mixture, the components were similar to each other in various behaviors. Using a Sephadex LH-20 column with methanol, the fraction was eluted from 100 to 110 mL while the main-product hydroperoxide eluted from 130 to 140 mL. In the 100–110 mL region, both DAG prepared from sunflower oil and a nonpolar dimer of methyl linoleate (10) were eluted, which suggested that X had a dimeric structure. X contained easily reducible peroxide, which was reduced with iodide at room temperature. Triphenylphosphine also could reduce it as follows:

$$\text{ROOH} \xrightarrow{\Phi_3P} \text{ROH}$$

The reduction product with triphenylphosphine, Y, was found in the dimer region of the Sephadex column eluates (100–110 mL). On a molar basis, the amount of triphenylphosphine consumed was twice the amount of conjugated diene found by measuring absorption at 234 nm, which suggests that the compounds of group X may be characterized as dimers with two hydroperoxy groups. On treatment with $NaBH_4$, Y gave methyl hydroxyoctadecadienoate and methyl trihydroxyoctadecenoate. The former is the same compound as the reduced derivative of main-product hydroperoxide. The latter gave four peaks at retention times of 15.50, 15.78, 15.92, and 15.98 min in GC–MS. Their mass spectra had fragment ions at *m/z* 545 (M − 15), 460 (M − 100), 387, 301, 259, 173, and 155, which are characteristic of methyl 9,10,13-trihydroxy-11- and 9,12,13-trihydroxy-10-octadecenoate. The intensity ratios of *m/z* 259 and 173 showed that the first and third peaks were methyl 9,10,13-trihydroxy-11-octadecenoate and the second and the fourth peaks were methyl 9,12,13-trihydroxy-10-octadecenoate (8). The cleaved bond was confirmed to be a moderately reducible peroxide since it was reduced with iodide by refluxing in 2-propanol. So, the above reduction with $NaBH_4$ can be written as:

$$\text{ROOR}' \xrightarrow{NaBH_4,\ H^+} \text{ROH} + \text{R'OH}$$

Although Y contained unreacted materials after treatment with $NaBH_4$, they were not found in the first part of the eluate from a 7.6 × 250 mm Nucleosil 100–5 column using a hexane/2-propanol solvent (97:3) at a flow rate of 4 mL/min, which was analyzed for peroxide. Its peroxide and conjugated diene contents were found to be roughly equal on a molar basis, indicating that Y contained a dimer in which two moieties (methyl octadecadienoate and methyl dihydroxyoctadecenoate) are linked with a peroxide bridge.

It was difficult to isolate such a fraction chromatographically from X, as $NaBH_4$ treatment of this fraction resulted in changed materials only. So, X was divided into fractions giving different yields of methyl hydroxyoctadecadienoate on a 7.6 × 250 mm Nucleosil®100–5 column using a hexane/2-propanol solvent (99:1) at a flow rate of 4 mL/min. With each sample containing 2.0 OD × mL of material, three fractions giving methyl hydroxyoctadecadienoate (at 19.1, 25.7, and 38.8% yields; from total 234 nm absorption) showed autoxidation-accelerating activities of 70.3, 92.2, and 141×10^{-5} M Azo eq, respectively, demonstrating a clear proportional relationship between methyl hydroxyoctadecadienoate yield and activity. The correlation coefficient of 0.997 indicated that the substances that generated methyl hydroxyoctadecadienoate were themselves autocatalysts.

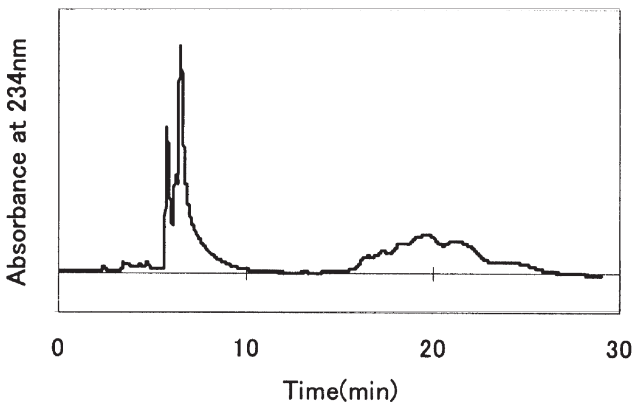

FIG. 1. Elution pattern of active fraction X on HPLC. On a 7.6 × 250 mm Nucleosil®100–5 column (Agilent, Palo Alto, CA) using hexane/2-propanol (99:1, vol/vol) at a flow rate of 4 mL/min, monitored at 234 nm, fraction X was eluted during the 16–26 min period and the main-product hydroperoxide was eluted in the 6–8 min period.

DISCUSSION

The results in Table 1 show that main-product hydroperoxide has little autocatalytic radical-generating activity at room or body temperature, and that autocatalytic roles are played by other substances. It seems extremely important that the mild conditions used in the present experiments cover a very wide area of lipid autoxidation in biological systems and food storage.

As ordinary hydroperoxide does not tend to generate radicals by homolytic cleavage, there has long been speculation that main-product hydroperoxide may generate radicals in the presence of trace transition metals (2). However, if main-product hydroperoxide acted as the main autocatalyst with trace metals that still remained in the samples of our experiments and the separated hydroperoxide became inactive by removal of the metals, it would seem impossible to explain why the combined sample of the residual parts retained almost all the activity of the unseparated sample.

It is worth asking why we had not previously been able to reach the conclusion obtained here. Our answer is that there was considerable difficulty in finding suitable methods for obtaining these results. For chromatographic separation, it was necessary to use solvents that had absolutely no effect on the subsequent oxidation experiment; also, to obtain an inactive main-product hydroperoxide fraction, the sample that was applied to HPLC had to be limited to a small size.

For the autocatalytic substances in fraction X, an isomeric mixture of dimer structures is likely, which has reported by Miyashita *et al.* (11) in oxidized products of the main-product hydroperoxide of methyl linoleate; the probable mechanism is the addition of a peroxy radical to the conjugated diene of main-product hydroperoxide followed by the usual propagation process, as shown in Scheme 1.

Such formation of a peroxy bridge is known to occur in the autoxidation of conjugated olefins, giving relatively unstable olefin-oxygen copolymers; and their instability is explained in terms of concerted decomposition of their repeated α,β-diperoxide structures as shown in Scheme 2 (12,13). The formation of aldehydes is thought to be energetically favorable for the reaction. The reaction is estimated using group additivity rules (14) to be exothermic at levels of about 18 kcal/mol for alkanal formation and 22 kcal/mol for conjugated alkenal formation. It is noted that radicals and aldehydes are simultaneously formed on decomposition.

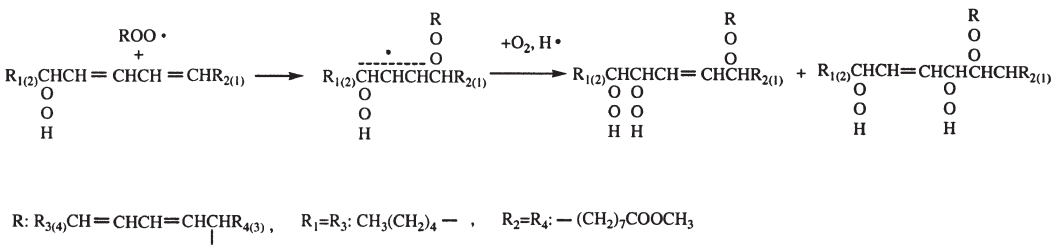
As the present substances have a minimum repetition structure of the polymer, they are expected to display considerable radical-generating activity.

Although present substances are only a kind of the autocatalysts in oxML and many other types may exist, it seems very important that a kind of potent autocatalysts was actually obtained here and we got a promising clue to the elucidation of the autocatalytic initiation.

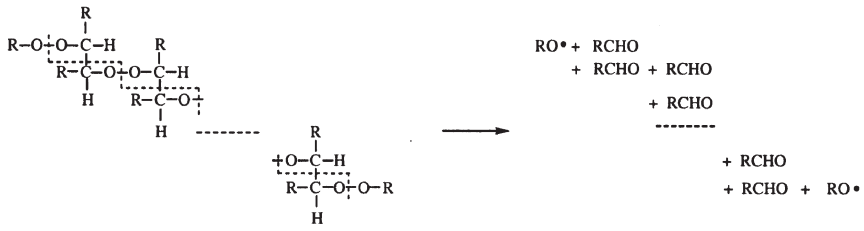
We propose a classification system for autocatalytic products. The first category is based on the mechanism of formation, which is divided into primary and secondary types. A primary-type mechanism means that the product is formed from species in the chain reaction without participation of the accumulated products, e.g., *via* a minor route of the chain reaction or the termination. A secondary-type mechanism means that the product is formed from an accumulated product. This type is further subdivided into two types: products formed with the participation of chain-reaction species, and those formed without such participation. The second category in our classification system is based on the stability of a substance, which can be deduced from its tendency to accumulate. A case in which almost all of the product is accumulated and only a small part participates in radical generation is found at the beginning of the scale on the stability of a substance; at the end is a product that decomposes to give radicals immediately after formation, resulting in almost no accumulation. There are many possible intermediate cases.

The substances obtained in this study are of the secondary type and have some tendency to accumulate. They may be responsible for a marked increase in rate at a late stage of autoxidation, as shown in Table 1 in the comparison between oxML2 (hydroperoxide level, 250 μmol/mL; autoxidation-accelerating activity, 7.44×10^{-5} Azo eq) and oxML3 (500 μmol/mL; 23.6×10^{-5} Azo eq); a remarkable increase in their accumulation was observed during this period.

A primary product with a tendency to accumulate is expected to be responsible for an increase in rate over all stages of autoxidation. If the working autocatalyst is of a type in which there is extensive accumulation, with only a small part participating in radical generation (i.e., close to the beginning of the scale in the second category of our classification system), the slope of the oxidation curve is expected to increase gradually from an initial value of 0; if it is at the other end of the scale (a tendency to immediate decomposition), the oxidation curve will be straight, as



SCHEME 1



SCHEME 2

the amount of the autocatalyst is not increased by accumulation, although it displays high activity. In our experiences involving the oxidation of the substrate pentyl linoleate in this study, carefully purified esters of linoleic acid resulted in straight-line oxidation courses, with positive slopes from the beginning.

What kind of compounds can exist as autocatalytic substances involving the latter type? Formation of the substances under discussion, a peroxide-linked dimer with two hydroperoxy groups, is thought to begin with the addition of a peroxy radical to a conjugated diene. In a similar mechanism, intramolecular addition of a linoleate peroxy radical to its conjugated diene can result in ring peroxidic compounds. In linolenate autoxidation, the intramolecular addition of peroxy radicals is known to occur (15,16). Another possibility is addition to minor conjugated polyene components of lipids such as conjugated polyene FA. These reactions may be important in the formation of autocatalytic substances; some of the substances formed may be unstable and thus appear near the end of our scale. The search for these substances is in progress.

Contrary to widely held opinion, the aldehydes hexanal, 2-heptenal, 2-octenal, and 2,4-decadienal were not formed from main-product hydroperoxide during linoleate autoxidation under mild conditions (7,17). The autocatalytic substances under discussion and those we expect to find share a structural feature that results in the joint formation of radicals and aldehydes during decomposition. Such decomposition may be an important route to aldehyde formation, and Miyashita *et al.* (18) reported that hydroxy aldehydic products were found in oxidation products of the dimer fraction described in Reference 11.

Novel Imine from *Hemsleya macrocarpa* var. *clavata*

Yu-ping Lin[a,c], Jian Yan[a,b], and Ming-hua Qiu[a,b,*]

[a]State Key Laboratory of Phytochemistry and Plant Resources in West China, Kunming Institute of Botany, Chinese Academy of the Sciences, Kunming 650204, [b]Graduate School of Chinese Academy of Sciences, Beijing 100039, and [c]Yunnan College of Traditional Chinese Medicine, Kunming 650200, People's Republic of China

ABSTRACT: The new substance hemsleyin imine A (**1**) was isolated along with with (2*S*,3*S*,4*R*,2′*R*)-2-(2′-hydroxytetracosanoylamino)-octadecan-1,3,4-triol (**2**), (2*S*,3*R*,4*E*,8*E*)-1-*O*-β-D-glucopyranosyl-3-hydroxy-2-(2′*R*-hydroxypalmitoylamino)-4,8-octadecadiene (**3**) from the rhizomes of *Hemsleya macrocarpa* var. *clavata*. Their chemical structures were established mainly by spectral analysis and chemical evidence. Compound **1** possesses the skeleton of an imine moiety, which is novel in natural products.

Paper no. L9818 in *Lipids 41*, 97–99 (January 2006).

Hemsleya macrocarpa var. *clavata* (Cucurbitaceae), a perennial plant found in northwestern China, is used as folk medicine to treat bronchitis, bacillary dysentery, and tuberculosis (1). Cucurbitacin and triterpenoid glycosides have been isolated from some species of *Hemsleya* (2,3). During our investigations on *Hemsleya* plants (4–6), a novel imine of sphingolipids, hemsleyin imine A (**1**), was isolated along with two known compounds, (2*S*,3*S*,4*R*,2′*R*)-2-(2′-hydroxytetracosanoylamino)-octadecan-1,3,4-triol (**2**) (7) and (2*S*,3*R*,4*E*,8*E*)-1-*O*-β-D-glucopyranosyl-3-hydroxy-2-(2′*R*-hydroxypalmitoylamino)-4,8-octadecadiene (**3**) (8) (see Fig. 1). Sphingolipids have been reported more often from higher fungi, such as the family Russulaceae (9,10), than from higher plants. In this work, compounds **1–3** were obtained for the first time from members of the Cucurbitaceae. This paper mainly describes the isolation and structural identification of the novel imine from the ethyl acetate fraction of the 90% ethanol extract of *H. macrocarpa* var. *clavata*.

EXPERIMENTAL PROCEDURES

Instrumentation. Melting points were obtained on an XRC-1 apparatus (Sichuan, People's Republic of China); IR spectra were obtained on a Bio-Rad FTS-135 spectrometer (Bio-Rad, Richmond, CA) with KBr disc; 1D- and 2D-NMR spectra were recorded on Bruker AV-400 and DBX-500 spectrometers (Karlsruhe, Germany), with trimethylsilane as internal standard. Chemical shifts (δ) are reported in ppm and coupling constants in hertz (Hz); mass spectra were determined on a VG-Auto Spec-3000 spectrometer.

Materials. Column chromatography (CC) was carried out on silica gel (200–300 mesh) and silica gel H (10–40 mesh). TLC was carried out on plates precoated with silica gel GF_{254} (Qingdao Haiyang Chemical Ltd., Qingdao, P.R. China).

Plant material. The aerial part of *H. macrocarpa* var. *clavata* was collected in Lincang County, Yunnan, China, in September 2001 and identified by Prof. Shukun Chen (Kunming Institute of Botany, Chinese Academy of the Sciences). A voucher specimen (K20010715) of this plant was deposited at the Kunming Institute of Botany, the Chinese Academy of Sciences.

Extraction and isolation. The dried and powdered plants (2.8 kg) were extracted with 90% ethanol at room temperature for 3 d. The filtrate was concentrated *in vacuo*, and the residue was partitioned between H_2O and ethyl acetate (AcOEt), then between H_2O and *n*-butanol. The AcOEt-soluble fraction (112 g) was subjected to CC (petroleum ether/acetone 50:1; 20:1; 10:1; 5:1, vol/vol) to afford several fractions. The fraction from petroleum ether/acetone 20:1 was further purified by CC (petroleum ether/AcOEt 10:1, vol/vol) to give compound **1** (30 mg). The fraction from petroleum ether/acetone 5:1 was separated by CC ($CHCl_3$/MeOH 8:1, vol/vol) to give the compound **2** (40 mg). The *n*-butanol fraction (90 g) was subjected to D101 column (Tianjin Chemical Factory, Tianjin, P.R. China) eluted with 20% EtOH, 40% EtOH, 60% EtOH, and 80% EtOH to give several fractions. The 80% EtOH fraction was purified by CC ($CHCl_3$/MeOH/H_2O 7:1:0.1, by vol) to afford compound **3** (23 mg).

*(2S,3R,4E,8E)-1-O-β-D-Glucopyranosyl-3-hydroxy-2-(2′R-hydroxypalmitoylamino)-4,8-octadecadiene (**3**).* White amorphous solid, m.p. 130–131°C, $[\alpha]_D$ = +1.03 (*c* = 0.97, CH_3Cl). IR (KBr) ν_{max} cm^{-1}: 3450–3315 (OH; NH), 2920, 2850, 2486, 2395, 1738 (C=O), 1656 (C=C), 1636, 1533 (–NH–), 1027, 720. FABMS *m/z* (%): 712 $[M - H]^+$ (70), 688 $[M - Me]^+$ (35), 688 $[M - 192]^+$ (70), 255 $[M - 457]^+$ (13), 227 $[M - 485]^+$ (5), 153 $[M - 559]^+$ (100). HR-FABMS *m/z*: 712.5448 $[M - H]^-$ ($C_{40}H_{74}NO_9$, calc. 712.5443). The NMR and IR spectra of **3** were identical with those reported in the literature (8).

*Alkaline reaction of **1**.* To a solution of compound **1** (0.88 mg) dissolved in MeOH (2 mL) was added MeONa (1 mg). The mixture was allowed to stand for 2 d at room temperature. The reaction mixture was extracted with *n*-hexane to give the *n*-hexane extract. The EI-MS spectrum of the mixture offered characteristic MS ion peaks for the methyl ester of stearic acid at *m/z* (%): 298 (M^+, 0.5), 267 ($[M - OCH_3]^+$, 4), 253 (5), 239 (6), 225 (6), 211 (8), 197 (8), 183 (11), 169 (14), 155 (15), 141 (20), 127 (24), 113 (34), 99 (40), 85 (100), 71 (94), 57 (93).

RESULTS AND DISCUSSION

Compound **1** was obtained as a white powder. The molecular formula $C_{39}H_{77}NO_3$ was provided by the ion peak at *m/z* 607.5653 in the HR-EI-MS spectrum, combined with the ^{13}C distortionless enhancement by polarization transfer (DEPT)-NMR spectrum. The IR spectrum indicated the presence of the hydroxyl group (3315 cm^{-1}), carbonyl group (1738 cm^{-1}),

[b]No signal detected.

imine (3013, 1656 cm^{-1}), and aliphatic chains (2923, 2857, 719 cm^{-1}). The ^{13}C NMR spectrum (DEPT) showed the signals of two quaternary carbons at δ_C 179.1 and 173.3 (carbonyl and imine), only one oxymethine at δ_C 68.9, methylenes (including an oxymethylene), and methyl group δ_C 14.1, which suggested the presence of long aliphatic chains. The ^1H NMR data of **1** revealed the presence of two terminal methyls at δ_H 0.80 (6H, *t, J* = 6.8 Hz), methylene protons at δ_H 1.18–1.36, 1.54, 2.25 (64H, *brs*), one oxymethylene with two protons at δ_H 4.07 (1H, *dd*, *J* = 11.8, 6.0 Hz, H-1) and 4.22 (1H, *dd*, *J* = 11.8, 4.0 Hz, H-1), and one oxymethine proton vicinal to the imine bond at δ_H 5.20 (1H, *m*), which strongly indicated that **1** had an imide skeleton with long chains (7,9). In the ^{13}C NMR spectrum, C-1′ resonated at a relative low field (δ 175.6), suggesting that the imine bond was at C-2. The imine C-atom at C-2 was further confirmed by the heteronuclear multiple bond coherence (HMBC) correlations of H-1 (δ_H 4.07, *dd*, *J* = 11.8, 4.0 Hz, H-1); 4.22 (*dd*, *J* = 11.8, 6.0 Hz) with C-2 (δ_C 173.3, *s*) and C-3 (δ_C 68.9, *d*) and H-1, H-3 (δ_H 5.20, *m*) and H-4 (δ_H 2.25, *m*) with C-2. Furthermore, correlations between δ_C 173.3 (*s*, C-2) and H-1 (δ_H 4.22 and 4.07, 2H), H-3 (δ_H 5.20, *m,* 1H), H-4 (δ_H 2.25, *m*, 2H) were observed, which further confirmed that the imine C-atom was C-2. The correlation between H-3 (δ_H 5.20, *m,* 1H) and C-1 (δ_C 62.1, *t*) in HMBC suggested that the hydroxyl group was at C-3. Compound **1** could be considered to possess normal side chains because the carbon atom signals due to terminal methyl groups were observed at δ_C 14.1 (normal form) (11). Comparing optical rotation data (**1**, $[\alpha]_D$ = −3.41) with those of the literature (7,9) and considering the possible biosynthetic pathway, it is difficult for us to confirm the absolute configuration at C-3 of **1**. On the basis of the above-mentioned evidence, the structure of **1** was 2-octadecanoylimino-heneicosan-1,3-diol. Compound **1** is particularly interesting in view of the rare imine moiety in natural products.

Compounds **2** and **3** were identified by comparing their spectral and physical data with those reported (7,8).

Regulation of the α-Tocopherol Transfer Protein in Mice: Lack of Response to Dietary Vitamin E or Oxidative Stress

Deborah L. Bella[a], Bettina C. Schock[b,c], Yunsook Lim[b], Scott W. Leonard[a], Crystal Berry[a], Carroll E. Cross[b], and Maret G. Traber[a,*]

[a]Linus Pauling Institute, Oregon State University, Corvallis, Oregon 97331, [b]Department of Internal Medicine, Center for Comparative Lung Biology & Medicine, School of Medicine, University of California, Davis, California 95616, and [c]Department of Medicine, Queen's University Belfast, Belfast, United Kingdom

ABSTRACT: The α-tocopherol transfer protein (TTP) plays an important role in the regulation of plasma α-tocopherol concentrations. We hypothesized that hepatic TTP levels would be modulated by dietary vitamin E supplementation and/or by oxidative stress. Mice were fed either a High E (1150 mg *RRR*-α-tocopheryl acetate/kg diet) or a Low E (11.5 mg/kg diet) diet for 2 wk. High E increased plasma and liver α-tocopherol concentrations approximately 8- and 40-fold, respectively, compared with Low E-fed mice, whereas hepatic TTP increased approximately 20%. Hepatic TTP concentrations were unaffected by fasting (24 h) in mice fed either diet. To induce oxidative stress, chow-fed mice were exposed for 3 d to environmental tobacco smoke (ETS) for 6 h/d (total suspended particulate, 57.4 ± 1.8 mg/m3). ETS exposure, while resulting in pulmonary and systemic oxidative stress, had no effect on hepatic α-tocopherol concentrations or hepatic TTP. Overall, changes in hepatic TTP concentrations were minimal in response to dietary vitamin E levels or ETS-related oxidative stress. Thus, hepatic TTP concentrations may be at sufficient levels such that they are unaffected by either modulations of dietary vitamin E or by the conditions of environmentally related oxidative stress used in the present studies.

Paper no. L9620 in *Lipids 41*, 105–112 (February 2006).

The α-tocopherol transfer protein (TTP) is a 33-kDa protein that is predominantly expressed in the mammalian liver (1) but which has also been detected in the rat brain, spleen, lung, and kidney (2); in the human brain (3); and in mouse liver, brain (4,5); and uteri (6). Based on sequence analysis, TTP is classified as a member of the SEC14-like protein family, with a characteristic CRAL_TRIO lipid-binding domain (7,8). In the closed TTP crystal structure, a mobile helical surface segment seals the hydrophobic binding pocket (9,10) and is responsible for the TTP selectivity for α-tocopherol (11).

Mutations in the TTP gene in humans [ataxia with vitamin E deficiency; (12)] are associated with extraordinarily low plasma E concentrations (13). In addition, in TTP-knockout and heterozygote mice, plasma α-tocopherol concentrations in plasma are 5 and 50% those of the wild-type mice, respectively (14,15). Clearly, TTP plays an important role in the regulation of plasma α-tocopherol concentrations. However, studies conducted on the regulation of TTP in response to dietary vitamin E intake have yielded conflicting results.

Kim *et al.* (16) showed that levels of rat hepatic TTP mRNA and protein were lower in response to high levels of dietary vitamin E (600 mg DL-α-tocopherol/kg diet) compared with rats fed the control diet (50 mg DL-α-tocopherol/kg diet). In rats that were fed vitamin E-deficient diets, TTP mRNA was higher, but protein levels were unchanged compared with controls. In contrast, Shaw and Huang (17) showed that in vitamin E-deficient rats, hepatic TTP was lower compared with rats fed control diets (50 mg all-*rac*-α-tocopheryl acetate/kg diet) but control and vitamin E-supplemented (5,000 mg all-*rac*-α-tocopheryl acetate/kg diet) rats had similar TTP concentrations. No changes in TTP mRNA were observed. Last, Fechner *et al.* (18) showed that rat hepatic TTP mRNA levels were unchanged by dietary vitamin E depletion and fasting (24 h). However, refeeding α-tocopherol to vitamin E-depleted rats followed by an additional 24-h fast increased the expression of TTP mRNA about sevenfold; however, TTP protein levels were not measured. Since α-tocopherol is secreted from the liver and associated with plasma VLDL (19), fasting, which is known to be associated with low levels of VLDL, might be expected to be accompanied by reduced liver cell release of α-tocopherol to plasma and modulations of TTP levels. Overall, no consistent changes in TTP protein in response to different dietary levels have been reported. However, oxidative stress has been suggested to increase hepatic TPP (20).

Environmental tobacco smoke (ETS) contains highly reactive components, many of which cause oxidative stress and activate host inflammatory-immune processes (21,22). Exposure of plasma to gas-phase cigarette smoke *in vitro* causes depletion of antioxidants such as vitamins C and E (23). Since smokers have a higher rate of vitamin E disappearance (24,25) despite maintaining normal or somewhat depleted plasma α-tocopherol concentrations (26–30), we hypothesized that the oxidative stress of cigarette smoke exposure might increase hepatic TTP concentrations. The purpose of the present study was to evaluate whether hepatic TTP in mice is regulated in response to variations in dietary vitamin E, fasting, or ETS exposure.

The first and second investigators contributed equally to this work.

EXPERIMENTAL PROCEDURES

TTP regulation by dietary vitamin E: Animals and dietary treatment. The protocols for the care and use of animals were approved by the Institutional Care and Use Committee at Oregon State University or at the University of California at Davis. For the dietary experiments, male C57BL/6 mice that weighed ~20–22 g (~7 wk of age) were purchased from Simonsen Laboratories, Inc. (Gilroy, CA). Mice were housed individually in stainless-steel mesh cages in a room maintained at 22°C and 40–60% humidity. Animals were weighed and then randomly assigned to the High E ($n = 6$) or Low E ($n = 7$) diet, respectively (diet study 1). Mice had free access to diet and water throughout the experiments. Animal weight and diet consumption was recorded twice per week. On day 15, mice were anesthetized by CO_2 inhalation. Blood was drawn from the heart into a 2-mL purple-topped vacutainer tube (1 mg/mL EDTA), mixed, separated by centrifugation, and the plasma was stored at −80°C. The liver was rinsed with ice-cold saline, blotted, weighed, immediately frozen in liquid nitrogen, and stored at −80°C. α-Tocopherol was extracted from the plasma and liver and analyzed as described by Podda *et al.* (31). The same protocol was followed for a second group of animals (High E: $n = 6$, and Low E: $n = 6$) except that half ($n = 3$) of the animals in each diet group were fasted for 24 h prior to sacrifice (diet study 2).

The diet composition for the two diet studies is given in Table 1. Diets were based on AIN 93M (32) and were prepared to contain *RRR*-α-tocopheryl acetate (ADM Nutraceuticals, Decatur, IL), either 11.5 mg *RRR*-α-tocopheryl acetate/kg diet (Low E) or 1150 mg *RRR*-α-tocopheryl acetate/kg diet (High E). The diet composition was analyzed in our laboratory to confirm the dietary vitamin E contents. The Low E diet contained half of the recommended vitamin E for mice [22 mg α-tocopheryl acetate per kg diet (33). The Low E diet provided the animals with approximately 2.3 mg of *RRR*-α-tocopheryl acetate/d. This diet was designed to provide the equivalent of approximately 100 mg *RRR*-α-tocopherol per day for a 70-kg human (based on an average mouse intake of 4 g diet per day and an average weight of 20 g).

TABLE 1
Composition of Low and High E Diets[a]

Ingredients	Experimental diets (g per kg diet)	
	Low E	High E
Vitamin-free casein	140	140
L-Cystine	1.8	1.8
Cornstarch	455.9	454.7
Maltodextrin	155	155
Sucrose	109.8	109.8
Cellulose	50	50
Tocopherol-stripped corn oil	40	40
RRR-α-tocopheryl acetate in tocopherol-stripped corn oil	0.012	1.2
Mineral mix (AIN-93M-MX)	35	35
Vitamin mix[b] (AIN-93M-VX)	10	10
Choline bitartrate	2.5	2.5

[a]Diets were prepared by Harlan Teklad (Madison, WI).
[b]Vitamin E was excluded from the vitamin mix and replaced with sucrose.

TABLE 2
Composition of Diet[a] Fed to Environmental Tobacco Exposed (ETS) Mice

Ingredients	g per kg diet
Protein	180
L-Cystine	25
Fat (ether extract)	60
Fibre (crude)	50
Mineral (Ash)	80
Vitamin E (IU/kg)	45

[a]Commercially available through Purina Lab Diet, diet #5K52 (www.labdiet.com)

TTP regulation by oxidative stress. (i) Animals and experimental treatment. C57BL6 mice (~12 wk of age) were exposed to ETS (ETS: $n = 8$; filtered air: $n = 8$, n indicated in the figure legends; insufficient sample was available for use in all assays) for 3 consecutive days. Mice exposed to ETS were purchased from Jackson Laboratory (Bar Harbor, ME). They were fed the vendor's diet (Purina 5K52; LabDiet, Richmond, IN) containing 45 IU/kg α-tocopherol (Table 2). At the end of the experimental treatment (day 3), animals were anesthetized with an intraperitoneal injection of 120 mg sodium pentobarbital/kg body weight. Sample collection, storage, and analysis were conducted as described for the diet studies.

(ii) Exposure of mice to cigarette smoke. Exposures of mice to ETS were conducted at the Institute of Toxicology and Environmental Health, University of California at Davis. The exposure system and methods used to generate ETS have been described elsewhere (34,35). Briefly, mice were exposed to a mixture of mainstream and sidestream cigarette smoke (aged and diluted) from 1R4F reference research cigarettes (1.2 mg nicotine/cigarette) obtained from the Tobacco and Health Research Institute of the University of Kentucky. An automatic cigarette-smoking machine generated cigarette smoke in a staggered manner at the rate of a 35-mL puff over a 2-s duration each min. During this period of "passive" smoking, mice were exposed to total suspended particulates (TSP, 57.4 ± 1.8 mg/m^3), carbon monoxide (262 ± 6 ppm), and nicotine (10.5 ± 1.0 mg/m^3) for 6 h/d × 3 d.

Western blot analysis for TTP and 4-hydroxy-2-nonenal (4-HNE). To obtain the soluble liver fraction for Western blot analysis, a portion of liver (frozen in liquid nitrogen on the day of sacrifice) from each animal was homogenized in PBS (0.1 M phosphate buffer, 0.0027 M KCl, and 0.137 M NaCl, pH 7.4) (20%, wt/vol). The homogenate was centrifuged at 20,000 × g for 30 min at 4°C and the resulting low-speed supernatant was centrifuged at 100,000 × g for 60 min at 4°C to obtain the high-speed supernatant. The high-speed supernatant was stored at −80°C until Western blot analyses were performed. The protein concentration in the liver supernatant samples was determined by a commercially available kit (Bio-Rad Protein Assay, Bio-Rad Laboratories, Hercules, CA).

Rabbit antirat TTP serum was a gift from Dr. Robert Farese (Gladstone Institute of Cardiovascular Disease and the

Cardiovascular Research Institute, Department of Medicine, University of California at San Francisco, San Francisco, CA). The polyclonal antibody was raised against a peptide of the C-terminus 1–21 amino acids of rat TTP and cross-reacted with mouse liver TTP (14). Proteins (40 mg per lane for ETS or 100 mg per lane for diet studies) were then subjected to electrophoretic separation under denaturing and reducing conditions and transferred onto a nitrocellulose membrane. Immunoreactive protein was detected by chemiluminescence by using goat antirabbit IgG conjugated to horseradish peroxidase (Bio-Rad, Hercules, CA) with exposure to Kodak X-OMAT XRP film (Rochester, NY). Quantitative densitometric analysis of the image was performed using an AlphaImager™ 2000 Documentation and Analysis System (Alpha Innotech Corporation, San Leandro, CA). The O.D. value represents the sum of all pixels minus the background within the specified area. For all experiments, a single band was detected for TTP corresponding to 32 kDa. This M.W. is consistent with the published apparent M.W. for mouse TTP (14).

Lipid oxidation and environmental pollutants result in the production of unsaturated aldehydes such as 4-HNE. Lung and liver homogenates from ETS and air-exposed animals were separated by electrophoresis (10% SDS-gel, reducing conditions) and after transfer onto polyvinylidene difluoride membrane probed with rabbit anti4-HNE antibody (Oxis International Inc., Portland, OR, 1:1000). Immunoreactive protein was visualized as described above.

Protein carbonyls in bronchoalveolar lavage fluid. Oxidative modification of proteins in mouse lung lavage was determined using an ELISA method described previously (36). Briefly, after derivatization of carbonyl groups with dinitrophenylhydrazine (DNPH), proteins were adsorbed onto 96-well ELISA plates, captured with a commercially available anti-DNPH antibody, and detected with a horseradish peroxidase /hydrogen peroxide, phenylenediamine system (37).

Statistical analysis. Data are expressed as mean ± SD and were analyzed for statistical significance by Student's *t*-test, or ANOVA and Fisher's LSD using StatView 5.0 (SAS Institute, Inc., Cary, NC). Liver α-tocopherol concentrations were log transformed to normalize the variances between groups for the two diet studies. Differences were considered significant at $P < 0.05$.

RESULTS

Growth and food intake. In the diet studies, final body weights, weight gains (g/d), and diet consumed (g/d) were similar for all animals, except for the weight gain in diet study 1 (Table 3). Mice fed the High E diet gained more weight than those fed the Low E diet ($P = 0.02$) because of an initial low weight gain in one animal in the Low E group. Weight gain for this animal was similar to that of the other mice at the time of sample collection. In mice fasted for 24 h, livers weighed more in nonfasted than in fasted mice, irrespective of whether the mice were fed the High E ($P = 0.0013$) or Low E diet ($P = 0.0004$).

Plasma and hepatic vitamin E and TTP levels. (i) Responses to dietary vitamin E. Mice fed the High E diet had hepatic α-tocopherol concentrations ~40 times higher ($P < 0.0001$) and plasma α-tocopherol concentrations ~8 times higher ($P < 0.0001$) than those of mice fed the Low E diet (Figs. 1, 2). In the animals fed the Low E diet that were fasted for 24 h prior to sacrifice, no effect of fasting was observed on either plasma or hepatic α-tocopherol concentrations (Fig. 2). However, in mice fed the High E diet, fasting significantly decreased hepatic ($P = 0.003$) and plasma α-tocopherol concentrations ($P = 0.0003$) (Fig. 2).

In contrast to the 40-fold increase in hepatic α-tocopherol, mice fed the High E diets had hepatic TTP levels that were only 20 ($P = 0.02$) and 25% ($P = 0.002$) higher compared with those fed the Low E diet in studies 1 and 2, respectively (Figs. 1, 2). Hepatic TTP levels were unaffected by fasting in mice fed either the High E or Low E diet (Fig. 2).

(ii) Responses to oxidative stress. Exposure of mice to ETS for 3 d caused increased oxidative stress to proteins and lipids. Figure 3A shows increased formation of protein carbonyls in the lung lavage of animals exposed to ETS ($P = 0.007$). These results and the greater amount of 4-HNE adducts in lung tissue with ETS exposure vs. air ($P < 0.01$) (Fig. 3B) demonstrate pulmonary oxidative stress. The increase in lung 4-HNE in ETS-exposed mice seems to be transient, as adduct formation returned to control levels on day 3. Exposure to ETS also caused a significant increase in 4-HNE in liver ($P = 0.005$), indicative of systemic oxidative stress. Furthermore, exposure to ETS was associated with a 40% decrease in the lung α-tocopherol concentration ($P = 0.001$; Fig. 4A). However, hepatic α-tocopherol concentrations (Fig. 4B) and TTP levels were unaffected by ETS exposure (Fig. 4C).

TABLE 3
Growth and Dietary Intake Parameters of Mice Fed Low and High E Diets[a]

	Experiment 1		Experiment 2			
			Low E		High E	
Diet	Low E	High E	Fasted	Nonfasted	Fasted	Nonfasted
Final weight (g)	23.1 ± 1.1[#]	24.8 ± 1.2*	24.4 ± 1.3	23.4 ± 1.3	25.5 ± 0.8	25.9 ± 2.2
Liver weight (g)	1.5 ± 0.1	1.6 ± 0.2	0.9 ± 0.2[§]	1.4 ± 0.0[†]	0.9 ± 0.1[§]	1.5 ± 0.1[†]
Gain/d (g)	0.2 ± 0.03	0.2 ± 0.03	0.1 ± 0.02	0.1 ± 0.01	0.2 ± 0.05	0.2 ± 0.10
Diet/d (g)	3.7 ± 0.3	3.9 ± 0.2	3.8 ± 0.2	3.8 ± 0.2	3.9 ± 0.2	3.7 ± 0.2

[a]Values are means ± SD for High E ($n = 6$) and Low E ($n = 7$). For experiment 1, the final weight was significantly greater in mice fed the High E (*) vs. the Low E (#) diet ($P = 0.02$). For experiment 2 ($n = 3$ for each treatment), in mice fasted for 24 h, liver weights were significantly higher for nonfasted (†) compared with fasted mice [High E: $P = 0.0013$ (§); Low E: $P = 0.0004$ (§)] by ANOVA and Fisher's LSD test.

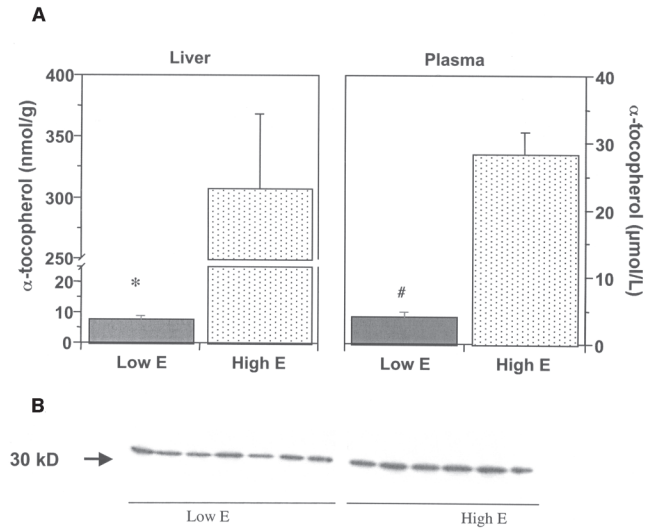

FIG. 1. Plasma and hepatic vitamin E levels and α-tocopherol transfer protein (TTP) concentrations in response to dietary vitamin E (A) Mice fed High E ($n = 6$) compared with Low E ($n = 7$) diets showed higher hepatic (*) and plasma (#) α-tocopherol concentrations, respectively (means ± SD, $P \leq 0.0001$). (B) Western blots of hepatic TTP from the livers of mice described in (A). Hepatic TTP levels were 20% higher ($P = 0.02$) in mice fed the High E diets (30,864 ± 5,199 pixels/mm^2) compared with those fed the Low E diet (24,570 ± 3,239 pixels/mm^2).

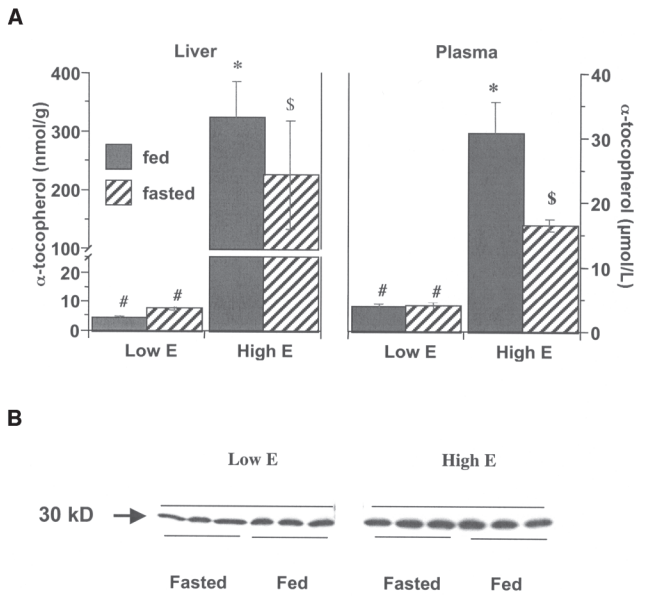

FIG. 2. Effect of fasting on plasma and hepatic vitamin E levels and TTP protein concentrations. (A) Hepatic and plasma α-tocopherol concentrations in mice (means ± SD, $n = 3$ for each of the four treatments) fed Low or High E diets followed by a 24-h fast or nonfast. Hepatic and plasma α-tocopherol concentrations were significantly lower in the Low E (#) compared with the High E diet-fed animals ($P < 0.0001$, diet effect) (*,$). Mice fed the High E diet that were fasted had significantly lower hepatic and plasma α-tocopherol concentrations than nonfasted mice [$P = 0.003$ for hepatic (* vs. $), and $P = 0.0003$ for plasma α-tocopherol (* vs. $), ANOVA and Fisher's LSD test]. (B) Western blots of hepatic TTP from the livers of mice described in (A). Hepatic TTP levels were 25% higher ($P = 0.002$) in mice fed the High E diets (40,404 ± 3,920) compared with those fed the Low E diet (29,545 ± 4,431). Hepatic TTP levels were unaffected by fasting. For abbreviation see Figure 1.

DISCUSSION

Hepatic TTP levels in mice were approximately 20% higher in response to the 100-fold greater dietary α-tocopherol levels in the High E compared with the Low E diet. This relatively small increase in TTP occurred despite a 40-fold increase in hepatic α-tocopherol in mice fed the High E diet. Plasma α-tocopherol levels increased only eightfold in the nonfasted mice fed the High E compared with the Low E diet (Figs. 1, 2). Clearly, plasma α-tocopherol concentrations do not increase to the extent they increase in the liver in response to dietary vitamin E. These data suggest that although liver α-tocopherol increased, plasma α-tocopherol levels were limited by the marginal increase in hepatic TTP and/or by the capabilities of liver-secreted lipoproteins to accept additional amounts of α-tocopherol (38).

Hepatic TTP levels were 20 and 25% higher in diet studies 1 and 2, respectively, in mice fed the High E diet compared with those fed the Low E diet. Although the levels of dietary vitamin E in our study were not identical to those used by Shaw and Huang (17), the direction and magnitude of changes in hepatic TTP levels were similar between the two studies. The authors (17) observed that TTP levels were *ca.* 25% higher in mice fed vitamin E-containing diets (for both their control and High E diets) compared with those fed a vitamin E-deficient diet, whereas no changes were observed in TTP mRNA levels (17). Using gene chip microarrays, Barella *et al.* (39) have also found a lack of significant difference in hepatic TTP mRNA expression in rats fed vitamin E-sufficient vs. vitamin E-deficient diets. Although Kim *et al.* (16) used diets and an animal species (rat) similar to those used by Shaw and Huang (17), the responses to vitamin E deficiency and supplementation did not agree for either hepatic TTP or TTP mRNA levels between the two studies. Reasons for these discrepancies have not been determined and warrant further investigation.

Fechner *et al.* (18) saw a significant increase in TTP mRNA levels in rats that consumed a vitamin E-deficient diet for 5 wk and were then fasted, refed vitamin E, and fasted again. However, this effect of fasting was evaluated only in animals fed a vitamin E-deficient diet and not in animals receiving dietary vitamin E. In contrast, we found that fasting for 24 h prior to sacrifice had no effect on the regulation of hepatic TTP levels in mice fed either low or high levels of dietary vitamin E. The significant changes in TTP mRNA levels observed by Fechner *et al.* (18) may be due to changes in vitamin E status or to changes in the animals' feeding vs. fasting state. Hormonal signals or aspects of the diet other than vitamin E levels may also regulate hepatic TTP levels (17).

Although no changes in hepatic TTP levels occurred with fasting, we observed lower hepatic and plasma α-tocopherol concentrations in fasted compared with nonfasted animals fed the High E diet, but not the Low E diet. Fasted animals that are receiving a High E diet will have a dramatic decrease in food

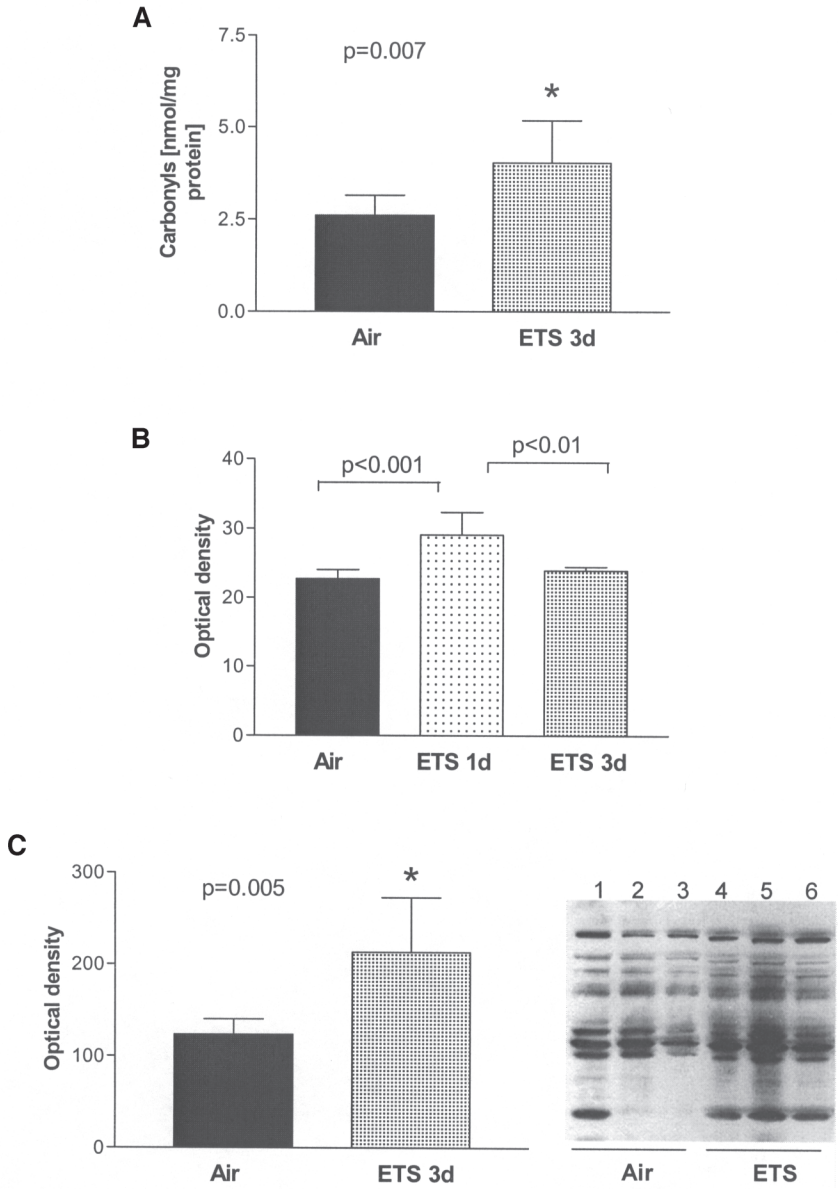

FIG. 3. Pulmonary and systemic oxidative stress in environmental tobacco smoke (ETS)-exposed mice. (A) Protein carbonyls in the lung lavage of mice exposed to ETS (3 d) vs. air (mean ± SD, $n = 8$). The protein carbonyl concentration was significantly higher in ETS-exposed animals ($P = 0.007$, Student's *t*-test). (B) 4-Hydroxy-2-nonenal (4-HNE) adduct formation in lung tissue of mice exposed to ETS (1 d and 3 d) vs. air (mean ± SD, $n = 8$). 4-HNE formation significantly increased after one day of ETS exposure but returned to control values by day 3. (O.D. 22.8 ± 1.2, 29.1 ± 3.2, and 23.9 ± 0.5 for air, ETS 1 d, and ETS 3 d, respectively, $P < 0.01$, ANOVA). (C) 4-HNE adduct formation in the liver tissue of mice exposed to ETS (3 d) vs. air (mean ± SD, $n = 6$). 4-HNE formation significantly increased after 3 d of ETS exposure (O.D. 123.6 ± 16.4 vs. 213.2 ± 59.4, $P = 0.005$, Student's *t*-test). A representative blot of liver homogenates from animals exposed to ETS and filtered air is shown (air: lanes 1–3; ETS: lanes 4–6).

intake and decreased delivery of vitamin E to both the liver and plasma. Increased metabolism of α-tocopherol may also play a role in the decreased hepatic and plasma α-tocopherol concentrations in these animals. Indeed, serum concentrations of α-carboxyethyl hydroxychroman (α-CEHC), a metabolite of α-tocopherol, have been shown to increase ~19-fold in individuals supplemented with 500 IU *RRR*-α-tocopherol per day for 29 d compared with unsupplemented individuals (40). Urinary α-CEHC is detectable at "low" vitamin E intakes (~5–10 mg/d) (41,42) in unsupplemented individuals and increases ~20-fold with supplementation of 800 mg/d (43). Hence, hepatic metabolism of α-tocopherol to α-CEHC in the mice may have been up-regulated with the high dietary levels of vitamin E.

We also considered that increased oxidative stress might up-regulate TTP. ETS exposure causes oxidative stress both because of the radicals in the smoke and through induction of airway- and systemic inflammatory-immune processes (22). Using deuterium-labeled vitamin E, Traber *et al.* (24) and

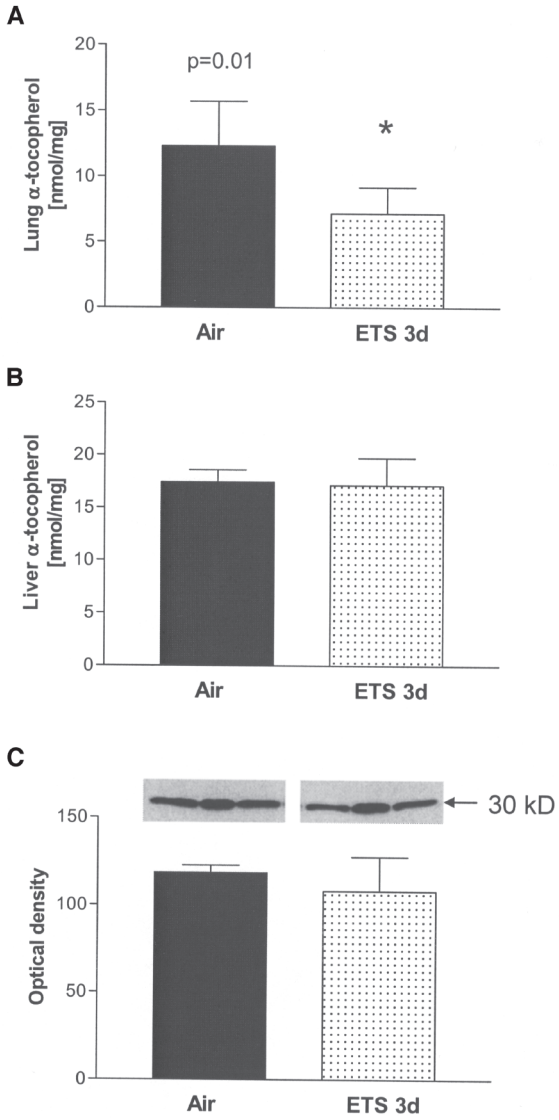

FIG. 4. Effect of ETS on pulmonary and hepatic vitamin E levels and TTP protein concentrations. (A) Pulmonary α-tocopherol concentrations in mice exposed to ETS (3 d) vs. air (mean ± SD, $n = 6$). Lung α-tocopherol concentrations decreased after 3 d of ETS exposure ($P = 0.001$, Student's *t*-test). (B) Hepatic α-tocopherol concentrations in mice exposed to ETS vs. air (mean ± SD). For hepatic tissue, ETS: $n = 5$, and air: $n = 4$. Hepatic α-tocopherol concentrations were similar by Student's *t*-test. (C) Western blots of hepatic TTP in mice exposed to ETS vs. air. No significant changes in TTP protein expression were observed ($P = 0.4$). Blots are of three representative liver homogenates from animals exposed to either ETS or air for 3 d. For abbreviations see Figures 1 and 3.

Bruno *et al*. (25) showed that cigarette smokers had a higher rate of vitamin E disappearance, yet total plasma α-tocopherol concentrations were similar in smokers and nonsmokers. We therefore hypothesized that the oxidative stress of cigarette smoking might increase hepatic TTP. Higher TTP levels could then potentially maintain plasma α-tocopherol. ETS-exposed mice exhibited increases in the oxidative modification of proteins (carbonyl formation) and lipids (HNE adducts) and a decrease in lung α-tocopherol. However, ETS exposure did not change hepatic α-tocopherol or up-regulate hepatic TTP (Fig. 4). Our exposure protocol mimics an acute ETS exposure. Although we showed increased formation of HNE adducts in the liver, it is possible that the ETS exposure regime [3 d (6 h/d) at 60 mg^3 TSP] used in this study did not cause a sufficient amount of systemic oxidative stress to deplete α-tocopherol stores and increase hepatic TPP expression. We did show, however, that exposure to ETS caused increased oxidative stress in the lung.

Thus, TTP plays an important role in the regulation of plasma levels of vitamin E. Together with Shaw and Huang (17) and Barella *et al.* (39), our study shows that the changes in hepatic TTP levels are minimal compared with changes in dietary or hepatic vitamin E levels. TTP appears to be normally expressed at sufficient levels to aid trafficking of newly absorbed dietary vitamin E. In our study, mice consuming the low vitamin E diet received half of the recommended vitamin E for mice [11.5 instead of 22 mg *RRR*-α-tocopheryl acetate/kg chow; (33)], similar to the low vitamin E diets used by others (44). TTP expression may therefore be optimized for sufficient vitamin E transport even under dietary vitamin E restrictions.

Under the conditions of oxidative stress used in this study, TTP was not up-regulated to compensate for the higher turnover or oxidative loss of vitamin E. Again, this may be due to optimal levels of TTP in the liver. However, we cannot exclude the possibility that higher levels of oxidative stress result in significant modulations in liver TTP levels. Therefore, additional studies at lower dietary and hepatic α-tocopherol concentrations are warranted.

ACKNOWLEDGMENTS

We gratefully acknowledge the technical assistance of David Blatt and Heather Vaule with these studies. The *RRR*-α-tocopheryl acetate for the diets was a gift from Dr. Brent Flickinger, ADM Nutraceuticals (Decatur, IL). This work and D.L.B. were supported in part by a Linus Pauling Institute pilot project grant. M.G.T., C.C., and B.S. were supported in part by grants from the Tobacco-Related Disease Research Program (7RT-0160), USDA (2003-00915), and the National Institutes of Health (ES011985).

Effects of Orlistat Therapy on Plasma Concentrations of Oxygenated and Hydrocarbon Carotenoids

Isabella Sundl[a], Elisabeth Pail[b], Karin Mellitzer[b], Hermann Toplak[b], and Brigitte M. Winklhofer-Roob[a,*]

[a]Human Nutrition & Metabolism Research and Training Center Graz, Institute of Molecular Biosciences, Karl-Franzens University, 8010 Graz, Austria, and [b]Department of Internal Medicine, Medical University, 8036 Graz, Austria

ABSTRACT: Orlistat is a lipase inhibitor that is applied for treating obesity. Lipases are required for digestion and absorption of dietary lipids and fat-soluble vitamins and carotenoids. The aim of this study was to compare the effects of orlistat therapy on plasma concentrations of oxygenated (β-cryptoxanthin, lutein/zeaxanthin) and hydrocarbon (α-, β-carotene, lycopene) carotenoids. Six patients with a body mass index (BMI) ≥ 30 kg/m^2 received 360 mg/d orlistat over 4.5 mon. Plasma carotenoid concentrations were determined at baseline (T_0) and after 3 (T_3) and 4.5 mon ($T_{4.5}$) along with anthropometric, dietary, and biochemical indices, including plasma lipids, retinol, α- and γ-tocopherols, and FA. Baseline BMI was 32.7 ± 1.97 kg/m^2. Five of six patients lost weight; the average weight loss was 3.6 ± 2.4% ($P = 0.47$). There were no significant changes in dietary carotenoid intakes. In contrast, plasma α- and β-carotene concentrations decreased significantly from T_0 to $T_{4.5}$ by 45% ($P = 0.006$) and 32% ($P = 0.013$), respectively. Plasma lycopene decreased from T_0 to T_3 but increased again from T_3 to $T_{4.5}$, while β-cryptoxanthin and lutein/zeaxanthin concentrations did not change. There were no significant alterations in tocopherol, retinol, and FA concentrations. In conclusion, even though weight loss was not significant, orlistat therapy was associated with significant decreases in plasma concentrations of the highly lipophilic hydrocarbon carotenoids, α- and β-carotene.

Paper no. L9725 in *Lipids 41*, 113–118 (February 2006).

The prevalence of overweight and obesity has grown progressively over the past two decades in both developing and industrial countries (1). Since 1991, the proportion of obese inhabitants increased from 12 to 21% in the United States, and there are 300 million obese adults worldwide (1,2). Given the strong association between obesity and several chronic diseases such as cardiovascular disease and diabetes mellitus (3), these changes will have major health implications in the near future.

One of the options for long-term treatment of obesity is orlistat, a potent inhibitor of gastric and pancreatic lipases. Lipases hydrolyze TG into absorbable MG and FFA and are thus instrumental in the digestion and absorption of dietary fats from the gastrointestinal tract (4). Orlistat binds to the active site of lipases, resulting in the inhibition of enzyme activity and, subsequently, impaired formation of mixed micelles. Along with impaired absorption of dietary fat, the absorption of fat-soluble vitamins (5), carotenoids (6), and dietary FA (7) is affected.

The absorption of highly lipophilic compounds such as carotenoids is impaired in patients with clinically overt fat malabsorption, e.g., in patients with cystic fibrosis (8), and in the presence of minimally impaired lipase activity (9). Depending on the chemical structure and subsequent lipophilicity of different carotenoids, the absorption may be affected to different extents. As a consequence, the oxygenated carotenoids β-cryptoxanthin, lutein, and zeaxanthin may be more easily absorbed than the hydrocarbon carotenoids α- and β-carotene and lycopene (10,11).

Different carotenoids exert different biological actions and functions, including antioxidant and immunoenhancing effects, protection against cardiovascular disease and certain types of cancer (lycopene for prostate cancer), and maintenance of normal vision (lutein for age-related macular degeneration) (12). However, the relative importance of the individual carotenoids has not been clearly established.

The aim of our study was to investigate the effects of treatment with the lipase inhibitor orlistat on carotenoid status in general and, more specifically, to compare the effects on hydrocarbon carotenoids with those on oxygenated carotenoids. In addition, the effects on other fat-soluble compounds such as retinol, α- and γ-tocopherol, and FA were analyzed.

EXPERIMENTAL PROCEDURES

Patients. Consecutive patients who attended the Outpatient Clinic for Diabetes and Metabolism at the Department of Internal Medicine, Medical University of Graz, and who had a body mass index (BMI) > 30 kg/m^2 were eligible for enrollment in the study. Patients were excluded if one or more of the following criteria were present: pregnancy, lactation, cholestasis, chronic malabsorption, and chronic alcoholism. The study protocol was approved by the Ethics Committee of the Medical University of Graz, and written informed consent was obtained from the patients. The six patients enrolled included five postmenopausal women and one man, aged 59.5 ± 3.78 yr (min, 54 yr; max, 65 yr). One patient smoked on average four cigarettes per day, while the others were nonsmokers. Two patients suffered from combined hyperlipidemia and showed elevated TG and LDL cholesterol concentrations. Demographic data are presented in Table 1.

TABLE 1
Anthropometric Data and Serum Cholesterol Concentrations (mean ± SD) During Orlistat Therapy[a] (*n* = 6)

	Time points		
	T_0	T_3	$T_{4.5}$
Weight (kg)	95.2 ± 11.0	91.4 ± 10.4	91.8 ± 10.7
BMI (kg/m^2)	32.7 ± 1.97	31.4 ± 1.48	31.5 ± 1.65
Waist (cm)	110 ± 4.51	106 ± 7.82	107 ± 4.90
Hip (cm)	121 ± 5.32	119 ± 4.27	119 ± 4.72
Waist/hip ratio	0.912 ± 0.068	0.887 ± 0.082	0.898 ± 0.066
Body fat (%)	41.9 ± 4.62	42.1 ± 3.78[b]	43.2 ± 2.74[b]
Total cholesterol	7.77 ± 1.18	7.15 ± 0.969	7.23 ± 0.492

[a]There were no significant differences between T_0, T_3, and $T_{4.5}$ for any of the variables studied. BMI, body mass index.
[b]n = 5.

Study design. In a single-center observational study, patients received 120 mg orlistat three times per day for 4.5 mon in addition to dietary advice and recommendations regarding physical activity as part of an established intervention program. Patients were advised to take the medication along with each fat-containing main meal during or up to 1 h after the meal. Patients were not allowed to take any vitamin and carotenoid supplements 2 mon prior to and during the trial. They were recommended to follow a weight-reducing diet including ≤30% of calories from fat, 10–15% from protein, and ≥50% from carbohydrates. Patients were monitored at the monthly visits for their dietary intake. Compliance with the study medication was checked by interview and pill count. The study period was based on the usual length of coverage of costs of obesity treatment with orlistat for patients with a BMI > 30 kg/m^2 by the major local health care provider.

Anthropometric assessment. At T_0, T_3, and $T_{4.5}$ anthropometric variables including weight, height, waist and hip circumference were measured, and the waist/hip ratio was calculated. Body fat was determined by bioimpedance analysis (BIA) using Bodystat Quadscan 4000 (Eumedics, Purkersdorf, Austria).

Dietary assessment. At T_0 patients completed a food frequency questionnaire (FFQ) for assessment of dietary habits over the past 6 mon prior to study entry. At T_3 and $T_{4.5}$ they recorded all food items and beverages consumed during the preceding 5 d. Intake of carotenoids was calculated using the food composition databases of Souci, Fachmann, and Kraut (13) and REGAL (14). Intake of energy, protein, fat, carbohydrates, and vitamins was calculated using the Austrian database Ernährungswissenschaftliches Programm (dato Denkwerkzeuge, Vienna, Austria, 1997).

Analytical methods. (i) Sample collection. At T_0, T_3, and $T_{4.5}$, venous blood was drawn after an overnight fast into plastic tubes containing either EDTA or lithium heparin (BD Vacutainer, Belliver Industrial Estate, Plymouth, United Kingdom), protected from light using aluminum foil, and centrifuged immediately at 1500 × *g* at 8°C for 10 min. Plasma was separated, divided into aliquots, collected in Eppendorf tubes, and stored at –80°C until determination of plasma carotenoids, retinol, tocopherols, and FA. Routine clinical chemistry indices, including total cholesterol, HDL, and TG, were determined in the fresh samples at T_0, T_3, and $T_{4.5}$ at the laboratory core facility of the University hospital (Clinical Institute of Medical and Chemical Laboratory Diagnostics) using a Hitachi analyzer (COPD test kit; Roche Diagnostics, Vienna, Austria). LDL was calculated using the formula of Friedewald *et al.* (15).

(ii) Determination of carotenoids, retinol, and tocopherols. The determination of retinol, tocopherols, and carotenoids was performed as described by Aebischer *et al.* (16). Briefly, 200 µL of EDTA plasma was diluted with deionized distilled water and deproteinized with 400 µL absolute ethanol. To extract lipophilic compounds, 800 µL of a solution of 350 mg BHT in 1000 mL *n*-hexane were added, centrifuged, and the clear supernatant transferred by a dispenser/dilutor system (Micro Laboratory 500B Dilutor; Hamilton, Martinsried, Germany) to an Eppendorf tube to be dried on a Speed Vac (Savant, Farmingdale, NY). The residue was then redissolved in a mixture of methanol/1,4-dioxane (1:1), diluted with acetonitrile, and injected into the HPLC system (Hewlett-Packard 1100A; Agilent, Vienna, Austria). Separation was achieved on a reversed-phase column; the mobile phase was a mixture of 684:220:68:28 acetonitrile/THF/methanol/water (by vol) containing 2.5 mg/L L(+)-ascorbate and 280 mg/L ammonium acetate, and the flow rate was 1.6 mL/min. α-Carotene, β-carotene, lutein/zeaxanthin, and β-cryptoxanthin were detected by a UV detector (JASCO, Model UV-1570; Biolab, Vienna, Austria) at 450 nm, and lycopene was detected at 472 nm; retinol and tocopherols were detected by a fluorescence detector (JASCO, Model FP-920; Biolab) at 330 nm excitation and 470 nm emission wavelength (retinol) and at 298 nm excitation and 328 nm emission wavelength (γ- and α-tocopherol). The areas under the HPLC peaks were quantified on an HP Chemstation (Hewlett-Packard 35900E; Agilent). *All-trans*- and *cis*-β-carotene were measured, and total β-carotene was calculated as the sum of *all-trans*- and *cis*-β-carotene. The tocopherol and carotenoid standards were a kind gift of the Vitamin Research Department of Hoffmann La-Roche (now DSM Nutritional Products), Basel, Switzerland. The CV within-run was 3.9% for retinol, 5.2% for γ-tocopherol, 5.0% for α-tocopherol, 5.7% for lutein/zeaxanthin, 5.4% for β-cryptoxanthin, 5.6% for lycopene, 4.7% for α-carotene, 6.0% for *cis*-β-carotene, and 5.1% for *all-trans*-β-carotene. All determinations were performed in duplicate, and all samples were processed in the same run. Six plasma samples of the patients were processed along with two control samples from a plasma pool obtained from healthy subjects to be used for long-term quality control, and along with a standard solution.

(iii) Determination of FA. The determination was based on an esterification procedure and a subsequent GC analysis of the FAME as described by Sattler *et al.* (17). Briefly, 100 µL of internal standard (heptadecanoic acid) was added to 450 µL of the EDTA plasma and kept at –80°C for a minimum of 30 min. The deep-frozen suspension was freeze-dried on a lyophilizer (VirTis, Gardiner, NY). Then, boron trifluoride/methanol complex and toluene were added. After transesterification at 110°C for 90 min, the FAME were extracted three times with *n*-hexane. The extracts

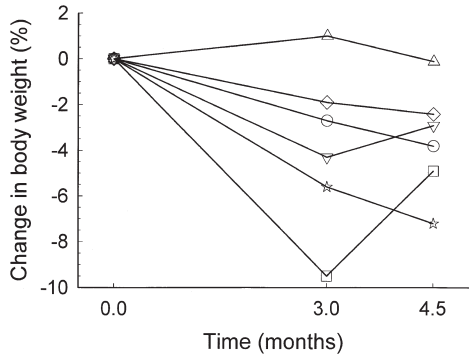

FIG. 1. Changes in body weight (% of baseline) in the individual patients during orlistat therapy.

were dried in a Speed Vac (Bachhofer, Reutlingen, Germany), redissolved in dichloromethane, and subjected to GC analysis (Hewlett-Packard 5890 Series II; Agilent). Separation of FAME was achieved on a DB-23 column, 30 m length, 0.250 mm diameter (Agilent); the mobile phase was a mixture of helium and hydrogen gas. The oven temperature at injection was 150°C and was then raised to 255°C. The areas under the GC peaks were quantified by integration, and the internal standard described above was used for calculation of the amounts of FA. CV (within-run) for the different FA were between 0.38 and 8.28%. All determinations were done in duplicate and in the same run, along with a control sample from the plasma pool.

Statistical analysis. All statistical analyses were performed on SigmaStat 3.0 (SPSS, Erkrath, Germany). Changes over time were analyzed using one-way repeated measures ANOVA. To isolate the time points that differed from the others, all-pairwise multiple comparison procedures (Tukey tests) were used.

RESULTS

Effects of intervention. All study subjects completed the 4.5-mon study period. Compliance with orlistat therapy was 100%, as checked by interview and pill count. One patient reported steatorrhea and diarrhea after she had not adhered to the dietary advice of reduced fat intake. Additional side effects were not reported.

Anthropometry. Changes in body weight showed substantial interindividual variability. While all patients except one showed a significant weight loss during the initial 3 mon, only four of six lost weight during the following 1.5-mon of therapy (Fig. 1). Overall, changes in weight, BMI, body fat, and hip and waist circumference were not statistically significant (Table 1). Body fat could not be measured in one patient due to problems with the technical equipment (BIA analyzer; Eumetics) at T_3 and in another one due to phlebitis at $T_{4.5}$.

Dietary assessment. The study subjects showed a high percentage of energy intake from fat at T_3 (38.5 ± 5.95%) and at $T_{4.5}$ (37.3 ± 5.19%). The average daily energy intake was 7729 ± 1639 kJ at T_3 and 8327 ± 2194 kJ at $T_{4.5}$. Dietary intakes of carotenoids calculated from FFQ at T_0 and from 5-d food records at T_3 and $T_{4.5}$ are presented in Table 2. There were no changes in dietary intakes of the different carotenoids during orlistat therapy, but wide ranges of consumed fruits and vegetables among the patients were observed (Table 2). There was no significant correlation between weight loss and energy intake ($P = 0.78$ at T_3 and $P = 0.26$ at $T_{4.5}$).

TABLE 2
Dietary Intake[a] (mean ± SD) of Carotenoids (mg/d) and Fruits and Vegetable Servings (servings/d) Estimated by FFQ (T_0) and 5-d Food Records (T_3 and $T_{4.5}$) ($n = 6$)

	FFQ	5-d food records	
	T_0	T_3	$T_{4.5}$
α-Carotene	0.487 ± 0.298	0.671 ± 0.734	0.959 ± 0.881
β-Carotene	3.77 ± 2.56	3.11 ± 2.23	3.73 ± 3.40
Lycopene	3.50 ± 2.65	1.69 ± 1.25	1.38 ± 1.56
β-Cryptoxanthin	0.492 ± 0.296	0.587 ± 0.663	0.517 ± 0.868
Lutein/zeaxanthin	4.58 ± 3.91	2.64 ± 1.51	1.77 ± 1.42
Servings of fruits and vegetables per day	5.20 ± 3.61	2.77 ± 1.88	2.60 ± 1.37

[a]There were no significant differences between T_3 and $T_{4.5}$ for any of the variables studied. FFQ, food frequency questionnaire.

Lutein/zeaxanthin: cholesterol	0.045 ± 0.005	0.043 ± 0.013	0.047 ± 0.025	NS

[a]Repeated measures ANOVA. [b–j]Significant differences by Tukey *post-hoc* tests are indicated with similar superscripts. NS, not significantly different.

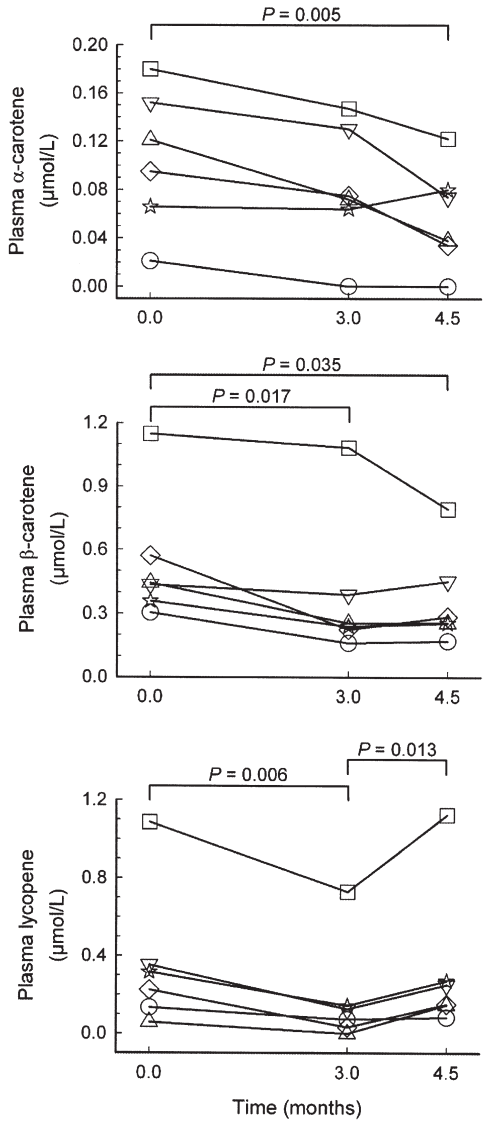

FIG. 2. Changes in plasma concentrations of α- and β-carotene and lycopene in the individual patients during orlistat therapy. *P* values were obtained by repeated measures ANOVA and Tukey all-pairwise multiple comparison procedures (for details see text and Table 3). Similar symbols indicate similar subjects.

Plasma carotenoids. Mean plasma concentrations and standardization for cholesterol of the different carotenoids at the three time points are presented in Table 3, and changes in plasma carotenoid concentrations of the individual patients are presented in Figure 2. Plasma α-carotene, β-carotene, and lycopene concentrations showed significant changes across the three time points (Fig. 2) (one-way repeated measures ANOVA), whereas β-cryptoxanthin and lutein/zeaxanthin did not. The Tukey all-pairwise multiple comparison procedure showed a significant decrease for α-carotene from T_0 to $T_{4.5}$ ($P = 0.005$), and for β-carotene from T_0 to T_3 ($P = 0.017$) and T_0 to $T_{4.5}$ ($P = 0.035$). Plasma lycopene concentrations decreased significantly from T_0 to T_3 ($P = 0.006$), and increased again from T_3 to $T_{4.5}$ ($P = 0.013$). Similar findings were observed for carotenoids standardized for cholesterol (Table 3). There were significant correlations between the carotenoid intakes and plasma concentrations for β-carotene at T_3 ($P = 0.04$), for lycopene at $T_{4.5}$ ($P = 0.02$), and for β-cryptoxanthin at T_3 ($P = 0.02$).

Serum lipids, plasma fat-soluble vitamins, and FA. Changes in total cholesterol (7.77 ± 1.18 at T_0, 7.15 ± 0.969 at T_3, and 7.23 ± 0.492 at $T_{4.5}$), HDL-cholesterol (1.45 ± 0.385 at T_0, 1.42 ± 0.258 at T_3, and 1.44 ± 0.395 at $T_{4.5}$), LDL-cholesterol (5.03 ± 0.705 at T_0, 4.86 ± 1.20 at T_3, and 4.64 ± 0.490 at $T_{4.5}$), and TG (2.84 ± 1.42 at T_0, 2.89 ± 1.93 at T_3, and 2.53 ± 0.991 at $T_{4.5}$) were not significant. Changes in plasma retinol (2.41 ± 1.13 at T_0, 2.51 ± 0.801 at T_3, and 2.29 ± 0.756 at $T_{4.5}$), α-tocopherol (37.2 ± 8.66 at T_0, 37.6 ± 4.54 at T_3, and 36.4 ± 6.15 at $T_{4.5}$) and γ-tocopherol (3.53 ± 2.27 at T_0, 3.01 ± 1.10 at T_3, and 2.62 ± 1.12 at $T_{4.5}$) were also not significant. In addition, plasma FA concentrations did not change significantly.

DISCUSSION

This is the first study showing plasma concentrations of the different hydrocarbon and oxygenated carotenoids during orlistat therapy and therefore allowing for comparison of the effects of orlistat based on the chemical structure of carotenoids.

Plasma α-carotene, β-carotene, and lycopene concentrations showed significant changes across the three time points, whereas β-cryptoxanthin and lutein/zeaxanthin did not. These results indicate that plasma concentrations of the hydrocarbon carotenoids α- and β-carotene and lycopene are more severely affected by orlistat-induced inhibition of gastrointestinal lipase activity than those of the less hydrophobic oxygenated carotenoids β-cryptoxanthin and lutein/zeaxanthin. The decrease in plasma α-carotene concentrations by 45% to 0.058 μmol/L and in plasma β-carotene by 32% to 0.369 μmol/L resulted in plasma concentrations that were about 76 and 60% lower for α-carotene and 59 and 43% lower for β-carotene compared with those of healthy Swiss (18) and Austrian subjects (19), respectively. In contrast, plasma concentrations of α- and β-carotene were comparable whereas plasma lycopene concentrations were lower during orlistat therapy in our study compared with serum concentrations of healthy subjects participating in the NHANES III (Third National Health and Nutrition Examination Survey) study (20). It seems unlikely that the changes in plasma concentrations in the present study were due to changes in intakes of α- and β-carotene, given that dietary recommendations focused on high intakes of fruits and vegetables, which are associated with higher intake of carotenoids. Unfortunately, prospective dietary records, in addition to FFQ, were not available at baseline to allow for assessment of prospective dietary intake data. There was a substantial difference in the consumption of fruits and vegetables recorded by FFQ and 5-d food records, respectively, suggesting that intakes might have been overestimated in FFQ.

Intestinal absorption of fat-soluble compounds such as carotenoids is facilitated when ingested along with dietary lipids (11). The study subjects showed a high percentage of energy intake from fat, which contrasted the recommended dietary regimen but is expected to have facilitated efficient absorption of

lipophilic compounds. In the absence of changes in dietary habits and lack of significant weight loss, the decrease in α- and β-carotene concentrations observed in our study can be explained by impaired lipase activity and subsequently reduced intestinal absorption during orlistat therapy. The significance of intestinal absorption of dietary lipids to facilitate specifically the absorption of carotenoids is further underlined by a recent study showing decreased plasma concentrations of carotenoids when olestra, an indigestible sucrose polyester containing 6–8 FA per molecule, was used to replace one-third of energy from fat. This effect could not be prevented by carotenoid supplements (21).

In the present 4.5-mon long-term study, a one-third reduction of β-carotene concentrations was observed during 360 mg/d orlistat therapy. These results are in agreement with a 6-mon long-term study showing a 22–40% reduction by using 90–720 mg/d orlistat (22). In contrast, 180 and 360 mg/d orlistat in a 2-yr long-term study did not show a significant effect (23).

Plasma concentrations of retinol were within the normal range and did not change during orlistat therapy. Both single-dosing (5,24) and long-term treatment with orlistat (22–25) did not alter plasma retinol concentrations, which can be explained by homeostatic control of plasma retinol concentrations.

The decrease in plasma α- and γ-tocopherol concentrations in the present 4.5-mon study was not significant. Other groups found impaired absorption of α-tocopherol taken along with orlistat in a single-dose test situation (5,24), whereas long-term treatment with orlistat did not alter plasma tocopherol concentrations (24,25).

In the present study, 4.5-mon orlistat therapy was not associated with statistically significant changes in plasma FA patterns, in contrast to 12-mon orlistat therapy in another study on 75 patients (7). There were also no significant changes in serum lipids during orlistat therapy. Although the cholesterol- and TG-lowering effect was smaller in our study compared with some other orlistat trials (23,26), it was comparable to those obtained in randomized placebo-controlled trials (7,27) that showed a decrease in plasma lipids that did not reach statistical significance. However, it cannot be ruled out that the findings of the present study could be due to the small number of study subjects (possible type II error), and extension of the study period might have allowed for significant changes to occur in FA patterns.

Taken together, significant changes in α- and β-carotene as well as in lycopene were observed even in the presence of relatively low weight losses. The latter were 0.1–7.2% (3.6 ± 2.4%) over 4.5 mon of orlistat therapy in the study patients compared with weight losses of 6.8–9.8% over 6 mon in other trials (20,26,28). However, there was a wide range in weight losses in the present as well as in previous studies (20,23,26,28), suggesting that some patients respond more favorably than others to orlistat (29).

Epidemiological evidence suggests that high intake of carotenoids and plasma concentrations in the upper normal range are associated with lower risk of cardiovascular disease and certain types of cancer (12). A recent study demonstrated that plasma α-carotene and γ-tocopherol concentrations are lower in patients with coronary heart disease compared with healthy controls (30). Given the preventive effects of carotenoids, a decrease in plasma concentrations during orlistat therapy may add an additional risk factor for obese patients, who are at increased risk for degenerative diseases. This seems even more important in view of the fact that the study patients showed low carotenoid status already prior to orlistat therapy, which, at least in part, can be explained by unfavorable dietary habits. Dietary intake of both α- and β-carotene was considerably lower in our study patients than in nonobese healthy male subjects living in the same area (19). This is even more striking because with one exception the study patients were females, who, in general, consume a diet higher in carotenoids compared with males (31).

It has been suggested that plasma concentrations of fat-soluble vitamins should be monitored and multivitamin supplements should be taken during orlistat therapy (20,22–25). However, high intake of carotenoids from fruits and vegetables during orlistat therapy might prove even more beneficial and contribute to the overall success of orlistat therapy, given that it would avoid possible unwanted effects of β-carotene supplements on the one hand (32), and facilitate lower total calorie and fat intake on the other.

ACKNOWLEDGMENTS

This study is part of the master's thesis of Isabella Sundl, presented at the Institute of Nutritional Sciences, Faculty of Natural Sciences, University of Vienna in July 2003. Isabella Sundl wishes to thank Professor Ibrahim Elmadfa for accepting her to perform this work at the IMB and Michaela Maritschnegg for technical advice and assistance. The authors wish to thank the study patients for their collaboration in this study.

Isabella Sundl developed the study design under the supervision of Brigitte M. Winklhofer-Roob and Hermann Toplak. Elisabeth Pail, Karin Mellitzer, and Hermann Toplak recruited and investigated the patients and collected the blood samples. Isabella Sundl carried out the analyses of the blood samples and the dietary records and performed the statistical analysis under the supervision of Brigitte M. Winklhofer-Roob. Isabella Sundl and Brigitte M. Winklhofer-Roob had primary responsibility for writing the manuscript, but all the other authors provided editorial comments on the draft. None of the authors had any conflict of interest.

ABSTRACT: PUFA are susceptible to oxidation. However, the chain-reaction of lipid peroxidation can be interrupted by antioxidants. Whether an increased concentration of PUFA in the body leads to decreased antioxidant capacity and/or increased consumption of antioxidants is not known. To elucidate the relationship between plasma total antioxidant capacity (TAC), the concentration of antioxidant vitamins, and the proportion of PUFA in red blood cells (RBC), plasma TAC was measured by a Trolox equivalent antioxidant capacity assay in blood samples from 99 Icelandic women. Concentrations of tocopherols and carotenoids in the plasma were determined by HPLC, and the FA composition of RBC total lipids was analyzed by GC. Plasma TAC and the plasma concentration of α-tocopherol correlated positively with the proportion of total n-3 PUFA, 20:5n-3, and 22:6n-3 in RBC, whereas the plasma lycopene concentration correlated negatively with the proportion of total n-3 PUFA and 20:5n-3. On the other hand, plasma TAC correlated negatively with the proportion of n-6 PUFA in RBC. Plasma TAC also correlated positively with the plasma concentration of α-tocopherol, alcohol consumption, and age. Both the plasma concentration of α-tocopherol and age correlated positively with the proportion of n-3 PUFA in RBC; however, n-3 PUFA contributed independently to the correlation with plasma TAC. Because the proportion of n-3 PUFA in RBC reflects the consumption of n-3 PUFA, these results suggest that dietary n-3 PUFA do not have adverse effects on plasma TAC or the plasma concentration of most antioxidant vitamins.

Paper no. L9813 in *Lipids 41*, 119–125 (February 2006).

PUFA are prone to oxidation, with increased susceptibility to oxidation being linked to the degree of unsaturation (1). The more unsaturated n-3 PUFA, EPA (20:5n-3) and DHA (22:6n-3), are thought to be more susceptible to oxidation than the n-6 PUFA arachidonic acid (AA, 20:4n-6), but recent findings also suggest that n-3 PUFA may decrease or protect against oxidative stress (2,3). Several human studies show that increased consumption of n-3 PUFA or fish oil leads to increased oxidation. For example, healthy smokers receiving 4 g of fish oil supplements per day for 3 wk had increased oxidation of plasma LDL (4), and long-term intervention with high doses of n-3 PUFA (850–882 mg EPA or DHA) for 1 yr, following an acute myocardial infarction, increased lipid peroxidation, measured as the thiobarbituric acid–malondialdehyde complex (5). Other studies show no effect of n-3 PUFA, or fish oil, on various indices of oxidation. For example, there was no change in the resistance of red blood cells (RBC) to hemolysis in normo- and hypertriglyceridemic subjects receiving 6 g of fish oil per day for 6 wk (6) or in plasma malondialdehyde in ulcerative colitis patients receiving 4.5 g of n-3 PUFA per day for 2 mon (3). In the latter study, fish oil n-3 PUFA decreased oxidation, as assessed by plasma chemiluminescence (3), and in another recent study, EPA decreased oxidative stress, as measured by urinary 8-isoprostane levels, in patients with lupus nephritis (2). Discrepancies among results from studies evaluating the effects of fish oil or n-3 PUFA on oxidation may be related to the different methods used to assess oxidation as well as the amount of n-3 PUFA in the diet (6–8), the duration of treatment, whether the subjects were under oxidative stress (3) or not (9), and lifestyle factors such as smoking (10) and drinking (11).

The body stores antioxidants that can be mobilized to neutralize reactive oxygen species and that are important for interrupting the chain reaction of lipid peroxidation. Scavenging antioxidants, such as α-tocopherol and β-carotene, have a high redox potential but are consumed in the process of oxidation. That increased PUFA consumption may decrease antioxidant status was demonstrated by the classic means of inducing vitamin E deficiency in animals, which is by feeding fish oil (12). Lower plasma vitamin E levels were also seen in women after receiving fish oil supplements containing 1.680 mg EPA, 720 mg DHA, and 6 IU of vitamin E for 3 mon (13) and in healthy men after receiving fish oil concentrate (15 g/d) fortified with 15 mg vitamin E for 10 wk (14). However, daily supplementation with 2.5 g EPA and 1.8 g DHA, without added vitamin E, for 5 wk had no effect on plasma α- and γ-tocopherol levels in healthy women (15). Further, supplementation of 2.1 g of fish oil, without added vitamin E, for 1 mon increased the plasma concentrations of α-tocopherol and β-carotene in healthy women (7).

Results from studies evaluating the effect of n-3 PUFA on antioxidant capacity differ. Animal studies show both an increase (16) and a decrease (17) in plasma total antioxidant capacity (TAC) following fish oil feeding. When healthy humans

Abbreviations: AA, arachidonic acid; $ABTS^{\bullet+}$, 2,2´-azinobis (3-ethylbenzothiazoline) radical cation; PI, peroxidizability index; RBC, red blood cells; TAC, total antioxidant capacity; TIBC, total iron-binding capacity.

supplemented their diets with fish oil and vitamin E, it had no effect on plasma TAC (18). Neither was there an effect of long-term DHA supplementation on plasma TAC in patients with X-linked retinitis pigmentosa (19). In contrast, treatment with fish oil n-3 PUFA increased microsomal lipid peroxidation inhibition in patients with lupus nephritis (3), and a negative correlation was found between antioxidant capacity, measured as anti-radical defense capacity against hemolysis in whole blood, and low fish consumption in healthy humans (20).

From these studies, there is no clear indication of whether dietary n-3 PUFA increase oxidation, decrease the plasma concentration of antioxidants or affect the antioxidant capacity in the body. Thus, the present study was performed to evaluate whether the proportion of PUFA in RBC from Icelandic women, who exhibit a wide range in proportions of n-3 PUFA in the RBC, was correlated with plasma TAC and antioxidant vitamin concentration, taking into account several potential confounding factors.

SUBJECTS AND METHODS

Subjects. Participants in this study were 99 female relatives of cancer patients enrolled in a larger study on genetic and environmental risk factors in breast cancer performed by the Icelandic Cancer Society. All women enrolled in the larger study at the time of recruitment for participation in the present study (March 2001–March 2003) were invited to participate in the present one. All participants signed an informed consent form prior to enrollment in the study. The study was approved by the National Bioethics Committee in Iceland (99–084-B1-S1), and the Data Protection Authority in Iceland was notified of the processing of personal data (216/2001). Participants donated blood after an overnight fast. Information on putative confounding factors (smoking habits, alcohol intake, fish liver oil intake, body weight and height) was obtained by a standardized lifestyle questionnaire. Smoking habits were recorded as cigarettes smoked per day. Alcohol consumption was recorded as grams of ethanol per day, where 10 g of ethanol equaled one bottle of beer (330 mL), one glass of white or red wine (125 mL), one drink of liquor (30 mL), or one drink of spirits (30 mL). Continuous fish oil supplement intake for the past 2 yr was recorded. Fish liver oil was not specified according to origin.

Plasma TAC. TAC was measured in EDTA plasma using a photometric method described by Rice-Evans and Miller (21). Plasma samples were prepared immediately after blood collection, flushed with nitrogen, and stored at –70°C until analyzed within 3 wk. The method measures the inhibitory effect of plasma antioxidants on the absorbance of 2,2´-azinobis (3-ethylbenzothiazoline) radical cation ($ABTS^{\bullet+}$) generated by activation of metmyoglobin (myoglobin equine heart; Sigma-Aldrich, Steinheim, Germany) with H_2O_2. Trolox (Fluka Chemie, Buchs, Switzerland), a water-soluble analog of α-tocopherol, was used as a standard, and units of activity were expressed as mmol/L of Trolox equivalents. Each plasma sample was measured in duplicate. The interassay CV was 3.0%.

Plasma tocopherols and carotenoids. Tocopherols and carotenoids were measured in EDTA plasma flushed with nitrogen and stored at –70°C until analysis was performed. Aliquots were rapidly thawed at room temperature and were protected from light. Plasma concentrations of α- and γ-tocopherol, α- and β-carotene, β-cryptoxanthin, and lycopene were determined by RP-HPLC (HPLC system series 200, Perkin-Elmer) using a method described by Su *et al.* (22). Samples were extracted with hexane after precipitating the proteins with ethanol, then evaporated under nitrogen and redissolved in chloroform. After vortexing for 40 s and adding acetonitrile/methanol (1:1, vol/vol), samples were vortexed for a further 40 s. The mobile phase consisted of methanol with 0.05% ammonium acetate, acetonitrile with 0.1% triethylamine, and chloroform. Three linear gradient steps were programmed. Samples were injected onto a reversed-phase C18 5-μm particle diameter column. α- and γ-Tocopherols were monitored at 292 nm and α- and β-carotene, β-cryptoxanthin, and lycopene at 450 nm. Ratios of peak areas of the samples to peak areas of an internal standard were compared with those of a certified serum standard (standard reference material 968c; NIST, Gaithersburg, MD). Each sample was analyzed in duplicate. The interassay CV was 3.4% for α-tocopherol, 4.1% for γ-tocopherol, 18.1% for α-carotene, 9.1% for β-carotene, 3.8% for β-cryptoxanthin, and 6.6% for lycopene.

Body iron status. Serum iron was measured with the ferrozine dye-binding method (Roche Iron kit; Roche Diagnostics, Mannheim, Germany). Total iron-binding capacity (TIBC) in serum was measured as the sum of measured serum iron and unsaturated iron-binding capacity of transferrin (Roche Diagnostics) or indirectly with a transferrin-immunoassay (Transferrin ver. 2; Roche Diagnostics). Serum transferrin saturation was calculated as serum iron/serum TIBC × 100. Serum ferritin was measured with an electrochemiluminescence immunoassay (Elecsys Ferritin reagent kit; Roche Diagnostics).

Lipid extraction and FA analysis of RBC. RBC were isolated on Histopaque from venous blood and washed three times with saline. RBC, in the presence of the antioxidant BHT (20 mg/L) and nitrogen, were kept at –70°C until analysis. Total lipids where extracted from RBC using chloroform/isopropanol as described by Rose and Oklander (23) with some modifications. Briefly, total lipids of RBC were extracted with chloroform/isopropanol (1:2, vo/vol), and BHT (5 mg/100 mL) was added to the extraction medium. The FA of RBC total lipids were methylated for 45 min at 110°C using 14% boron trifluoride/methanol (Merck, Hohenbrun, Germany). The FAME were analyzed using GC (Hewlett-Packard HP 7673; Hewlett-Packard, Palo Alto, CA) equipped with a Chrompack CP-Sil 8CB PEG column (30 m × 250 μm i.d. × 0.25 μm film thickness). The oven temperature was programmed to have an initial oven temperature of 150°C for 4 min, then rising at 4°C/min to 230°C and at 20°C/min to 280°C, then isothermal for 4 min. The injector and detector temperatures were maintained at 280 and 300°C, respectively. Hydrogen was used as the carrier gas. The FAME peaks were identified and calibrated against those of commercial standards (Sigma, St. Louis, MO; Nu-Chek-Prep, Elysian, MN). PC diheptadecanoyl (17:0) and heneicosanoic acid (21:0) methyl ester (Sigma) were used as internal and external standards,

respectively. The results are expressed as g/100 g of total FA. Each sample was analyzed in duplicate.

Statistical analysis. Mean levels of plasma TAC were compared between groups (smokers/nonsmokers, fish oil intake/no fish oil intake) using unpaired *t*-tests, and the results are expressed as mean values ± SD. In univariate analyses, the association between variables was evaluated using Pearson's correlation coefficient (*r*). Multiple regression modeling was applied to evaluate the association between PUFA and TAC, taking into account the effects of potential confounding factors. The significance level was set at $P < 0.05$. The statistical analysis was performed with SPSS 11.5 for Windows.

RESULTS

The associations among plasma TAC, plasma concentration of antioxidant vitamins, iron status, and proportions of FA in RBC from Icelandic women were examined, and potential confounding factors were taken into account. Characteristics of the subject group are summarized in Table 1. Mean levels of plasma TAC, concentrations of plasma tocopherols and carotenoids, and iron status are shown in Table 2. Women consuming fish oil supplements continually for 2 yr ($n = 37$) did not differ in plasma TAC (1.1 ± 0.1 mmol/L vs. 1.1 ± 0.2 mmol/L, respectively) or indices of iron status (data not shown) from women not consuming fish oil supplements ($n = 62$), but had higher plasma concentrations of α-tocopherol (29 ± 10 μmol/L vs. 25 ± 7 μmol/L, respectively, $P < 0.05$) and lower plasma concentrations of γ-tocopherol (2.7 ± 0.8 μmol/L vs. 3.1 ± 1.0 μmol/L, respectively, $P < 0.05$). There was no difference in plasma TAC, plasma concentrations of most of the antioxidant vitamins, or indices of iron status between smokers ($n = 24$) and nonsmokers ($n = 75$). Only the plasma concentration of β-cryptoxanthin was lower in smokers than in nonsmokers (0.08 ± 0.08 μmol/L vs. 0.14 ± 0.12 μmol/L, respectively, $P < 0.05$) and correlated negatively with the number of cigarettes smoked per day ($r = –0.200$, $P < 0.05$).

The FA composition and peroxidizability index (PI) of RBC total lipids are shown in Table 3. Women consuming fish oil supplements continually for 2 yr had a higher proportion of n-3 PUFA in the RBC than women not consuming fish oil supplements (13.1 ± 2.0 g/100 g vs. 11.3 ± 1.4 g/100 g, respectively, $P < 0.0001$). Women who smoked had a lower proportion of n-3 PUFA in the RBC than did women who did not smoke (11.16 ± 0.32 g/100 g vs. 12.17 ± 0.22 g/100 g, respectively, $P < 0.05$).

TABLE 1
Characteristics of Participants

	n	Mean ± SD	Range
Age (yr)	99	45.8 ± 12.1	18–73
Weight (kg)	98	71.9 ± 12.5	51–118
Height (cm)	99	167.7 ± 6.2	155–184
BMI[a] (kg/m^2)	98	25.6 ± 4.0	18.1–39.4
Smoking (cigarettes/d)	24	9.6 ± 6.7	2–30
Alcohol (g/d)	77	3.4 ± 3.8	0.2–20

TABLE 2
Plasma Total Antioxidant Capacity (TAC), Concentrations of Plasma Tocopherols and Carotenoids, Serum Concentration of Iron, Total Iron-Binding Capacity (TIBC), Transferrin Saturation, and Ferritin in Samples from 99 Icelandic Women

	Mean ± SD
TAC (mmol/L)	1.10 ± 0.16
α-Tocopherol (μmol/L)	26.94 ± 8.78
γ-Tocopherol (μmol/L)	2.97 ± 0.97
α-Carotene (μmol/L)	0.08 ± 0.12
β-Carotene (μmol/L)	0.35 ± 0.37
β-Cryptoxanthin (μmol/L)	0.13 ± 0.11
Lycopene/(μmol/L)	0.59 ± 0.43
Iron (μmol/L)	16.4 ± 7.7
TIBC (μmol/L)	65.9 ± 13.7
Transferrin saturation (%)	25.8 ± 11.8
Ferritin (μg/L)	46.3 ± 41.1

Correlations between plasma TAC and plasma concentrations of antioxidant vitamins and the proportion of FA in RBC are shown in Table 4. Plasma TAC correlated positively with the proportions of total n-3 PUFA (Fig. 1), 20:5n-3, and 22:6n-3 in RBC (Table 4). The plasma concentration of α-tocopherol also correlated positively with the proportions of total n-3 PUFA, 20:5n-3, and 22:6n-3 in RBC, whereas the plasma concentration of lycopene correlated negatively with the proportions of total n-3 PUFA and 20:5n-3 (Table 4). Analysis of population quartiles revealed a difference in plasma TAC between the subpopulations with the lowest ($P < 0.05$) and the second lowest ($P < 0.05$) proportions of n-3 PUFA in RBC and the subpopulation with the highest proportion of n-3 PUFA in RBC (1st quartile, 1.04 ± 0.18 mmol/L; 2nd quartile, 1.03 ± 0.14

[a]Pearson's correlation coefficient (*r*).
[b]Correlation between variables statistically significant. For abbreviations see Tables 2 and 3.

mmol/L; 3rd quartile, 1.14 mmol/L; 4th quartile 1.17 ± 0.17 mmol/L).

There was a negative correlation between plasma TAC and the proportions of total n-6 PUFA, 20:4n-6, and 22:4n-6 in RBC (Table 4). In a multivariate analysis including both the proportions of n-3 and n-6 PUFA in RBC as independent variables, only the proportion of n-3 PUFA in RBC showed an independent contribution to the association with plasma TAC.

Plasma TAC and the concentration of α-tocopherol correlated positively with age ($r = 0.296$, $P < 0.005$, and $r = 0.396$, $P < 0.0001$, respectively), whereas the plasma concentration of lycopene correlated negatively with age ($r = -0.437$, $P < 0.0001$). The proportions of total n-3 PUFA (Fig. 2), 20:5n-3, and 22:6n-3 in RBC correlated positively with age ($r = 0.539$, $P < 0.0001$; $r = 0.551$, $P < 0.001$; and $r = 0.438$, $P < 0.0001$, respectively). In a multivariate analysis with age and the proportion of total n-3 PUFA in RBC as independent variables, only the proportion of n-3 PUFA in RBC showed an independent contribution to the association with plasma TAC.

There was a positive correlation between plasma TAC and alcohol consumption ($r = 0.328$, $P < 0.005$). There was also a positive correlation between plasma concentrations of both α-tocopherol and lycopene and alcohol consumption ($r = 0.319$, $P < 0.005$, and $r = 0.275$, $P < 0.05$, respectively). In addition, there was a positive correlation between the proportions of n-3 PUFA in RBC and alcohol consumption ($r = 0.45$, $P < 0.001$). Because plasma TAC correlated positively with both the proportion of total n-3 PUFA in RBC and alcohol consumption, we examined whether either or both of these variables were independent contributors to the association with plasma TAC. In a multivariate model, with the proportion of n-3 PUFA in RBC and alcohol consumption as independent variables, neither variable showed a significant independent contribution to the model, although the overall relationship with plasma TAC was statistically significant ($r = 0.374$, $P < 0.005$). However, when the analysis was limited to women who consumed less than 6 g of ethanol per day (68 of 79 participants who responded to the question about alcohol intake), there was a positive correlation between plasma TAC and the proportion of n-3 PUFA in RBC ($r = 0.257$, $P < 0.05$), but there was no correlation between plasma TAC and alcohol consumption (data not shown).

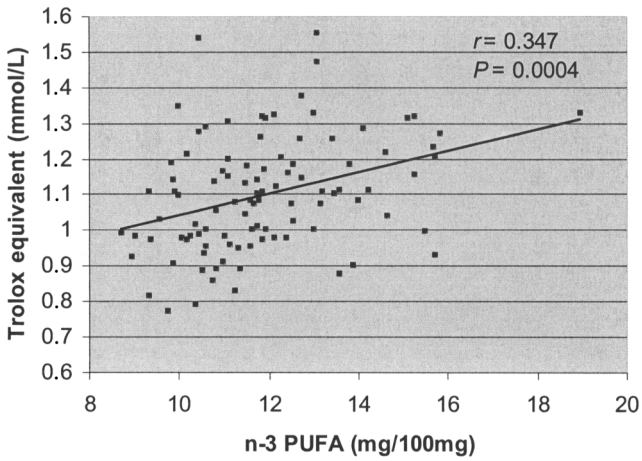

FIG. 1. Association between plasma total antioxidant capacity (TAC) and the proportion of total n-3 PUFA in red blood cell (RBC) total lipids from 99 Icelandic women. The association was evaluated using Pearson's correlation coefficient (*r*). Each sample was measured in duplicate.

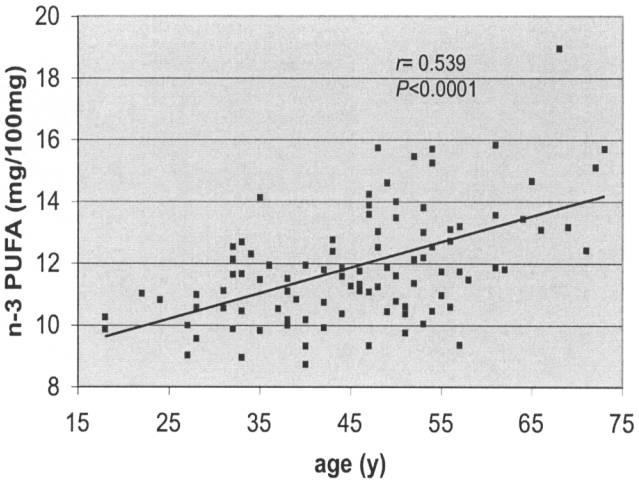

FIG. 2. Association between the proportion of total n-3 PUFA in RBC total lipids and age (yr) of 99 Icelandic women. The association was evaluated using Pearson's correlation coefficient (*r*). Each sample was measured in duplicate. For abbreviation see Figure 1.

There was a positive correlation between plasma TAC and both the plasma concentration of α-tocopherol and serum ferritin (Table 5). In a multivariate analysis with the concentration of ferritin in serum, the concentration of α-tocopherol in plasma, and the proportion of n-3 PUFA in RBC, only n-3 PUFA showed an independent contribution to the association with plasma TAC.

DISCUSSION

Because n-3 PUFA are highly unsaturated and believed to be prone to oxidation, they may lead to lower antioxidant capacity and increased consumption of antioxidants in the body. The only indication in the current study of increased consumption of antioxidants in the body with increased n-3 PUFA was the negative correlation between plasma lycopene concentration and the proportion of n-3 PUFA in RBC. On the other hand, the positive correlation between both plasma TAC and α-tocopherol and the proportion of n-3 PUFA in RBC indicates that n-3 PUFA are associated with higher antioxidant capacity in plasma and an increased concentration of one of the antioxidant vitamins.

The correlation found between plasma TAC and the proportion of n-3 PUFA in RBC may have depended on the wide range in the proportion of n-3 PUFA in RBC from the women participating in the study. No assessment was made of dietary intake in the present study. However, because the proportion of n-3 PUFA in RBC has been shown to reflect the dietary intake of n-3 PUFA in the preceding weeks or months (24), the high proportion of n-3 PUFA in RBC from many of the women probably reflects their intake of fish and/or fish oil. A high proportion of the women (37.4%) in the present study consumed fish oil supplements regularly, and one dietary survey (25) revealed that 36% of women in Iceland consumed fish at least three times a week in 2002.

Our results showing a positive correlation between plasma TAC and n-3 PUFA in RBC are in line with results showing that fish oil n-3 PUFA increase the antioxidant status in ulcerative colitis patients (3). However, our results are not in accordance with results from two intervention studies that show no effect of dietary fish oil supplements (18) or DHA supplementation (19) on plasma TAC, although in both studies supplementation resulted in increased plasma concentration of EPA and/or DHA. The discrepancy between the results from the present association study and the two intervention studies is not easily explained. One important factor that is different in all three studies is the consumption and/or plasma concentration of α-tocopherol. In the intervention studies participants consumed 206 mg/d (18) and 16.75 mg/d (19) of vitamin E, with intervention in the former study leading to an increased concentration of α-tocopherol in plasma but in the latter study to a trend toward reduced plasma α-tocopherol levels. In our study, women with a higher proportion of n-3 PUFA in the RBC had a higher concentration of α-tocopherol in the plasma. Thus, the differences in plasma concentrations of α-tocopherol do not explain the discrepancy between the results from the present association study and the two intervention studies.

The negative correlation seen between plasma TAC and the proportion of n-6 PUFA in RBC is probably explained by a strong negative correlation found between the proportions of n-3 and n-6 PUFA in RBC ($r = –0.643$, $P < 0.0001$). Although dietary n-3 PUFA supplementation is often thought to decrease the proportion of n-6 PUFA in phospholipids, this is not always the case (26,27), and when n-3 PUFA were added to the diet with n-6 PUFA, there was an increase in both n-3 and n-6 PUFA in the RBC in piglets (28). Our results, showing a strong negative correlation between n-3 and n-6 PUFA in RBC in a population with a mixed intake of n-3 and n-6 PUFA, indicate that in women with the highest proportion of n-3 PUFA in the RBC, there is enough n-3 PUFA in their diet to replace n-6 PUFA in the RBC.

The positive correlation between the plasma concentration of α-tocopherol and the proportion of n-3 PUFA in the RBC seen in the present study is in line with results from another

study showing an increased α-tocopherol concentration with the intake of fish oil supplements (18), which often have α-tocopherol added to them. The positive correlation between the plasma TAC and plasma concentration of α-tocopherol was expected, as α-tocopherol is known to contribute, although minimally, to the antioxidant capacity in the TEAC assay (21). The positive correlation between plasma TAC and the proportion of n-3 PUFA in the RBC is only partly explained by the positive correlation between plasma TAC and the concentration of α-tocopherol in plasma, as in a multivariate analysis with both the proportion of n-3 PUFA in RBC and α-tocopherol concentration in the plasma as independent variables, the proportion of n-3 PUFA in the RBC was an independent contributor to the correlation with plasma TAC.

The positive correlation between plasma TAC and age in the present study is in accordance with results from other studies (29,30). However, the positive correlations between plasma TAC and the plasma concentration of α-tocopherol and age are probably explained by the positive correlation between the proportion of n-3 PUFA in RBC and age (Fig. 2). The higher proportion of n-3 PUFA in the RBC of older birth cohorts may be due to a higher intake of fish oil supplements by older women than younger ones (data not shown). The higher proportion of n-3 PUFA in the RBC of older birth cohorts may also be due to greater fish consumption, as a dietary survey in Iceland in 2002 showed more fish consumption among older birth cohorts than younger ones (25). A trend toward a positive correlation between the proportion of n-3 PUFA in plasma phospholipids in Icelanders and age has previously been reported (31).

The positive association of plasma TAC with alcohol consumption in the present study is in line with results from intervention studies showing increased plasma TAC with wine consumption (32–36). However, the highest alcohol consumption in this study (two glasses of wine, beer, or spirits per day) was much lower than the consumption in an intervention study by van der Gaag *et al.* (37) (four glasses/d of red wine, beer, or spirits over a 3-wk period) that had no effect on TAC. About 20% of the participants did not respond to the question about alcohol consumption. Whether the women who did not respond to the question consumed more alcohol than the ones who did, and whether inclusion of their alcohol consumption would have affected the outcome of the study are not known. Also not known is whether the positive association between plasma TAC and alcohol consumption in the present study is linked to the intake of phenolic compounds, as has been suggested in other studies (34,38,39), as no distinction was made between beverages with or without phenolic compounds.

The results from the present study demonstrate a positive correlation between plasma TAC and the plasma concentration of α-tocopherol and the proportion of n-3 PUFA in RBC total lipids from 99 Icelandic women and a negative correlation between the plasma concentration of lycopene and the proportion of n-3 PUFA in RBC. A high proportion of n-3 PUFA in RBC reflects the dietary intake of n-3 PUFA from fish oil supplements and/or fish. Thus, the results suggest that dietary intake of n-3 PUFA may be accompanied by an increase in plasma TAC and does not lead to adverse effects on plasma concentrations of most of the antioxidant vitamins.

ABSTRACT: Plant sterols, incorporated into spreads and other food sources, have been shown to lower serum cholesterol concentrations. The effect of phytostanol supplementation in softgel form has not been assessed. Our objective was to examine the effects of sitostanol as sitostanol ester in softgel form on serum lipid concentrations in hypercholesterolemic individuals. Thirty hypercholesterolemic adults were supplemented with 1.6 g of free phytostanol equivalents as phytostanol ester (2.7 g stanol esters) or placebo per day for 28 d in a randomized, double-blind, parallel study design. Phytostanol supplementation resulted in a significant decrease in total cholesterol (TC) (–8%) and LDL-cholesterol (–9%). There were no alterations in concentrations of HDL-cholesterol or TG. Nor were the ratios of LDL/HDL or TC/HDL altered significantly. Thus, use of phytostanol ester softgel supplements improved serum total and LDL-cholesterol concentrations in hypercholesterolemic individuals.

Paper no. L9721 in *Lipids 41*, 127–132 (February 2006).

Dietary approaches to lowering heart disease risk factors are of interest to many in the population. The use of naturally occurring plant sterols is one such approach. Plant sterols are essential components of plant cell membranes with a structure similar to animal-derived cholesterol (1). Among the most abundant plant sterols are sitosterol, campesterol, and stigmasterol, which differ in their side chain configuration. Phytostanols are the completely saturated forms of phytosterols (2) and are not as abundant in nature. The Western diet contains approximately 100–300 mg sterols and 20–50 mg stanols per day (3), with the main sources being cooking oils, legumes, and seeds. Although cholesterol absorption from foods is as high as 20–80%, plant sterol absorption is likely less than 5% and stanol absorption less than 3% (3).

Plant sterol/stanol-enriched margarines are available on the market in many countries, and the ability of these products to lower circulating cholesterol concentrations is supported by multiple human feeding trials in normo- and hypercholesterolemic adults (3–7). Decreases in total and LDL-cholesterol concentrations of up to 15% have been observed.

Side effects of plant sterols/stanols appear to be rare and include reduced absorption of β-carotene, lycopene and α-tocopherol (8–10) as well as mild gastrointestinal complaints. Furthermore, the results of supplementation with plant sterol-/stanol ester-containing foods in combination with cholesterol-lowering medications, such as cerivastatin (11) and other statins (12), not only suggest a lack of increased side effects but also an increase in cholesterol-lowering ability equivalent to doubling the statin intake.

High-fat foods or spreads may not be the most appropriate form of phytostanol supplementation (13). Recently, the ability of phytosterols/stanols to reduce heart disease risk factors in non- or low-fat matrices has been investigated with differing results (14–18). Jones *et al.* (15) demonstrated that phytosterols added to nonfat milk or a low-fat beverage did not lower cholesterol levels to a greater extent than the control beverage. However, further research by this and other groups has demonstrated that phytosterols have total cholesterol (TC)- and LDL-lowering ability in a variety of media, including low-fat milk, yogurt, bread, cereal, and jam (14–18).

Although there is great potential for the phytosterol/stanol enrichment of a variety of foods, it is not always convenient for the consumer to incorporate a particular food into their daily diet because of cost, travel, or taste preferences. Thus, phytosterol/stanol softgel supplements have recently become available. These products are more convenient for most consumers. Although TC and LDL reduction is supported by studies investigating efficacy of food-based phytosterol/stanol-enriched products, there have been no published studies investigating lipid modification with phytosterol/stanol softgel supplements.

The purpose of this study was to examine whether supplementation with phytostanol ester softgel capsules for 28 d alters lipoprotein-cholesterol concentrations in men and women with elevated cholesterol. The hypothesis tested was that when a phytostanol ester dietary supplement is provided to moderately hypercholesterolemic adults for 4 wk, lipoprotein cholesterol profiles will be beneficially altered.

MATERIALS AND METHODS

Subjects. This study received ethical approval by the Research Ethics Board of the University of Guelph, Guelph, Ontario, Canada. Thirty adults (9 females, 21 males; aged 33–70 yr) with mild to moderate hypercholesterolemia (TC > 5.0 mmol/L

*To whom correspondence should be addressed at RGB Consulting, 34 Yale St., London, Ontario, Canada N6A 3Y4. E-mail: jconquer@uoguelph.ca

Abbreviations: BMI, body mass index; BP, blood pressure; CVD, cardiovascular disease; TC, total cholesterol.

or 193 mg/dL) were selected for this study. Subjects were screened, after 12 h of fasting, for TC concentrations. Inclusion criteria included TC concentrations greater than 5.0 mmol/L (193 mg/dL), aged 18–70 yr, body mass index (BMI; kg/m^2) > 18 and < 34. Individuals were excluded if they were pregnant and/or lactating, were using hormone replacement therapy, had diabetes, were using cholesterol-lowering medication or had used cholesterol-lowering medication within the past 3 mon, had a past myocardial infarction or heart surgery, were allergic to the treatment, or had used street drugs within the past 3 mon. Subjects were randomly assigned, using a standard random number table, into the two treatment groups on the basis of serum cholesterol concentrations.

Protocol. This study was a randomized, double-blind, placebo-controlled clinical trial. All subjects were free living throughout the trial duration and were advised to maintain regular eating and exercise habits. At baseline, subjects reported to the laboratory after a 12-h overnight fast to receive orientation training, to have a baseline blood sample taken and for various anthropometric measurements such as height, weight, blood pressure (BP), and heart rate. Subjects were randomized, using a standard random number table, into 4 blocks based on TC levels—5.0–5.99 mmol/L (193–231 mg/dL), 6.0–6.99 mmol/L (232–270 mg/dL), 7.0–7.99 mmol/L (271–309 mg/dL), and 8.0 mmol/L (310 mg/dL) and greater—to receive either placebo or phytostanol supplements (BENECOL® SoftGels, McNeil Nutritionals, LLC, Fort Washington, PA). Although the capsules were not identical, the supplements were packaged in opaque bags by someone not involved with the study, to ensure that both the researchers and subjects remained blind. General feedback from subjects was that they did not know what treatment they were receiving, and the lack of availability of BENECOL® Softgel supplements in Canada made it difficult for subjects to have seen the capsules prior to the study.

Each group received instructions to consume 3 softgel (glycerin) capsules with breakfast and with dinner daily for 28 d. The placebo capsules contained 500 mg corn oil/capsule (0.75 mg phytostanol and 0.9 mg phytosterol per capsule). The label claim indicated that consumption of 6 phytostanol ester softgel capsules per day would result in supplementation of 2.0 g phytostanol as phytostanol esters per day. Results from an independent testing laboratory indicated that the phytostanol ester capsules contained 266 mg phytostanol equivalents and 5 mg phytosterol equivalents per capsule for a total of 1.6 g phytostanol equivalents (2.7 g stanol esters) and 30 mg phytosterol equivalents per day. GC analysis of the phytostanol ester softgel capsules indicated that they comprised 65% sitostanol, 34% campestanol, 1% sitosterol, and less than 1% campesterol.

Subjects received instructions on how to record all food eaten for 3 d on study days 1–3 and 26–28. During the study, one individual in the treatment group dropped out for reasons unrelated to the study. Subjects returned to the laboratory on day 29 after an overnight fast (12 h) for various anthropometric measurements and a blood sample. All food records were returned at this time. Subjects were provided with a phone number to contact study personnel throughout the study duration.

Analysis. Venous blood samples were collected, in 10 mL vacutainer tubes with no additive (Becton Dickinson Vacutainer System, Franklin Lake, NJ), from fasting subjects on days 0 and 29 of the trial. Serum was obtained after 15 min of centrifugation at 775 × *g* at 4°C (Universal 32R; Hettich Zentrifugen, Tuttlingen, Germany) and frozen at –20°C until analysis. All samples from each subject were sent to the Guelph General Hospital (Guelph, Ontario) and analyzed within the same analytic run. Serum TC and HDL-cholesterol, as well as serum TG concentrations, were determined quantitatively with a within-run percent variability of <3% using a Synchron CX9® system (Beckman Coulter, Fullerton, CA). TC and TG were determined with a Synchron CX Multi calibrator, the former at a ratio of 1 part sample to 100 parts reagent (Beckman Coulter 467825) and the latter at a ratio of 1 part sample to 100 parts reagent (Beckman Coulter 445850); for both the change in absorbance at 520 nm was determined. HDL-cholesterol was determined quantitatively with a Synchron systems CX Lipid calibrator at a ratio of 1 part sample to 93 parts reagent (Beckman Coulter 6520207); the change in absorbance at 520 nm was determined. The within-run percent variability was <3%. TG was quantitatively determined using a Synchron CX9® system with Synchron® systems CX Multi calibrator (Beckman Coulter). A ratio of 1 part sample to 100 parts reagent (Beckman Coulter 445850) was used. The change in absorbance at 520 nm was determined. The within-run percent variability was <3%. LDL-cholesterol was determined by the Friedewald equation (19). Conversion of mmol/L to mg/dL is based on multiplication of 38.67 for TC, LDL- and HDL-cholesterol and 88.57 for TG.

At each visit total body weight was assessed using a calibrated medical scale (Acculab SV-100, Edgewood, NY) accurate to 0.1 kg. In addition, height, BP (Oscillometric Blood Pressure monitor UA-767CN; Life Source, Milpitas, CA; accuracy of ±2%), and resting heart rate (Oscillometric Blood Pressure monitor UA-767CN; accuracy of ±5%) were taken at each visit. All pre- and post-experiment measurements were taken at approximately the same time of day by the same investigator. For BP and heart rate measurements, the cuff was placed approximately 2.5 cm above the elbow joint. All manufacturers' directions were followed. Subjects sat in a chair for 5 min prior to measurement. One reading was taken from the left arm. Approximately 30 s afterward, one measurement was taken from the right arm. The average of the two measurements was used.

Phytostanol and phytosterol levels in the supplement (BENECOL® and placebo) were determined as follows by Enviro-Test (Edmonton, Alberta, Canada). An internal standard of 2.5 mg/mL cholestanol (C-2882; Sigma, St. Louis, MO) in propanolol (HPLC grade) was prepared and stored at 4°C. A system suitability standard of 0.5 mg/mL cholestanol and 0.5 mg/mL stigmastanol (5–4297; Sigma) was prepared and stored at 4°C. The softgel capsules to be analyzed were sliced to expose centers and placed in a 250-mL volumetric flask. THF (200 mL) was added, and the mixture was sonicated in a 50°C ultrasonic bath for 90 min. The mixture was left to cool at room temperature. Then 1.0 mL was pipetted into a screw-cap test

tube and evaporated under nitrogen at room temperature. Next, 5.0 mL of internal standard, 15.0 mL of 95% ethanol, and 5.0 mL of concentrated KOH solution [60.09 KOH pellets (85%) in 40 mL distilled water] was added. The tubes were capped and samples were mixed vigorously using a vortex mixer for 60 s and then sonicated in a 70°C ultrasonic bath in a fume hood for 5 min. Tubes were removed from the bath, mixed vigorously using a vortex mixer for 60 s, and sonicated at 70°C for 60 min. After cooling to room temperature, tubes were mixed vigorously using a vortex mixer for 60 s to disperse the saponified solution uniformly and 2.0 mL was transferred to a screw-cap test tube. Distilled water (3.0 mL) and 6.0 mL hexane were added to each test tube containing saponified solution, and the solution was mixed vigorously using a vortex mixer for 60 s and centrifuged at 345 × *g* for 3 min. The top lipid layer was transferred to a silylation vial and was evaporated under nitrogen at 70°C. After cooling to room temperature, 200 μL silylation reagent [bis(trimethylsilyl)trifluoroacetamide/trimethylchlorosilane, (99:1, w/w) and 100 μL pyridine were added. The tubes were left to silylate for 15 min at 70°C and cooled to room temperature. Samples were transferred to GC vials containing GC vial inserts for small volumes. Final GC sample preparations are stable in the GC vials for 72 h. GC (HP 5890 series II; Hewlett-Packard) column conditions were as follows: Column HP-5, 30 m long, 0.32 mm i.d., 0.25 μm film thickness; temperature program 300°C isothermal, 12 min; injector temperature 300°C; detector temperature 310°C, FID; helium 10–12 psi; make-up flow 20 mL/min; split ratio 1:50; injection volume 1 μL; syringe 10 μL. Stanol or sterol amount (mg/10 softgels) = [(area stanol)/(std amt) (df)]/area std, where area stanol = area of the stanol peak in the chromatogram, std amt = amount of the internal standard (mg), area std = area of the internal standard peak in the chromatogram, and df = dilution factor (200). Total stanols (mg) = amount sitostanol (mg) + amount campestanol (mg)

Statistical methods. Based on a power of 80% and a Type I error rate of $\alpha = 0.05$, a sample size of 13 participants per group was required to detect an estimated difference of 0.96 mmol/L. An approximate SD of 0.87 mmol/L has been observed in adults from previous work in this laboratory. That is,

$$n = \frac{(Z_\alpha + Z_\beta)^2 \times 2\sigma^2}{\Delta^2} \quad [1]$$

$$n = \frac{(1.96 + 0.84)^2 \times 2 \times 0.87^2}{0.96^2} = 13 \quad [2]$$

where Δ = change between subject's data at baseline and at day 28.

Data are expressed as means with SE. Assumptions for normality and homogeneity were tested and met with the exception of TG concentrations, which required log transformation. Comparison between groups was carried out with a two-sample *t*-test (20). Within-groups changes were analyzed using a two-sample paired *t*-test (20). *P* values less than 0.05 are considered significant.

RESULTS AND DISCUSSION

To our knowledge, this study is the first in which moderately hypercholesterolemic subjects, on self-selected diets, were supplemented with a softgel form of phytostanol esters. Previous studies have examined the effect of phytostanols/phytosterols in food sources such as margarine, or low-fat alternates such as bread, milk and other liquids (3–7,14–18).

Thirty subjects started the supplementation trial; 29 subjects completed the entire study. One study member dropped out for reasons unrelated to the study. Compliance was determined by capsule count at the end of the study. Average compliance for the treatment group was 95.5% and for the placebo group was 97.1%

All subjects were able to tolerate the phytostanol supplements with little or no adverse effects. Adverse effects reported, in the placebo group only, included a rash. Subjects reported that they were not aware of which supplementation group they were in despite the nonidentical appearance of the study capsules.

Three-day dietary analyses results are presented in Table 1. There were no differences in dietary consumption of total calories and cholesterol or percent protein, fat, carbohydrate, or alcohol between groups. In the control group, consumption of carbohydrate increased and alcohol decreased toward the end of the study (days 26–28) as compared with the beginning of the study (days 1–3).

[c]Beats per minute.

Baseline measurements for all subjects are given in Tables 2 and 3. Ages ranged from 33 to 70 yr and were balanced for gender (10 males in each group). The average age for the study was 53.7 (±10.1) yr. The average BMI was 27.5 ± 3.4 kg/m^2. BP ranged from 106 to 167 mmHg (systolic) and 76–105 mmHg (diastolic) and TC levels from 5.0 to 8.2 mmol/L (193–317 mg/dL). There were no differences in baseline values between the groups and subjects were randomized based on screening TC values (data not shown).

There were no differences in weight, resting heart rate, or BP at baseline between the two groups. Furthermore, there was no effect of phytostanol supplementation on weight, resting heart rate, or BP (Table 2). There was a slight, but significant decrease in weight in the control group over the 28-d study period.

Concentration of TC, HDL, LDL and TG did not differ between control and phytostanol-supplemented study groups at baseline (Table 3). Phytostanol supplementation resulted in a significant decrease in TC (–8%) and LDL-cholesterol (–9%). There were no alterations in concentrations of HDL-cholesterol or TG. Nor were the ratios of LDL/HDL or TC/HDL altered significantly. Thus, supplementation with approximately 1.6 g phytostanols in ester form (2.7 g stanol esters), as softgels, was effective in lowering circulating TC and LDL-cholesterol concentrations. The reduction of TC and LDL-cholesterol by phytostanols in this form is in agreement with results of other investigators in which phytostanols/phytosterols in high- and low-fat food forms were effective in reducing cholesterol concentrations (3–7,14–18).

The efficacy of phytostanols/phytosterols in lowering TC and LDL-cholesterol concentrations has been shown for both phytostanol and phytosterol, either esterified or nonesterified (reviewed in Refs. 3,13). Most studies have investigated the efficacy of these products in margarine form (4–7), as the use of a high-fat carrier was thought to be advantageous. Recently, the desire for lower-fat food carriers and/or alternative food choices has resulted in the investigation of the ability of phytosterols to lower cholesterol concentrations in food products such as bread, milk, juice, yogurt, and tortilla chips, among others (14–18,21). The addition of properly solubilized nonesterified plant sterols to low-fat milk was shown to result in decreased cholesterol absorption in mildly hypercholesterolemic men (14). Clifton *et al.* (16) showed that consumption of 1.6 g phytosterols per day as phytosterol esters, as part of many low-fat products, including milk, yogurt, bread, and cereal, all resulted in lowered cholesterol concentration, although the low-fat milk was the most effective (15% reduction vs. 5–9% for other products). Decreased LDL-cholesterol concentrations were observed in additional nonmargarine studies involving sterol ester fortification of bakery products (22), tortilla chips deep-fried in phytosterol-enriched oil (21), and chocolate (23). Not all studies involving nonmargarine food sources of supplemented phytosterol are supportive of cholesterol concentration lowering, however. Jones *et al.* (15) compared the cholesterol-lowering ability of a nonfat beverage vs. beverages with additional phytosterols. There was no additional cholesterol lowering as a result of phytosterol supplementation as compared with nonfat beverage consumption.

TABLE 3
Effect of Phytostanol Supplementation on Cardiovascular Disease Risk Factors in Moderately Hypercholesterolemic Adults[a]

[c]$P < 0.05$ vs. baseline.

Previous research demonstrated that Cytellin®, a nonesterified sitostanol drug in capsule form marketed by Eli Lilly, which was available in the United States from the 1950s to 1980s, significantly decreased TC and LDL-cholesterol at a recommended dose of 6–12 g per day (1). The present study showed that phytostanol ester in softgel form at a dose of 1.6 g per day is effective at lowering TC and LDL-cholesterol concentrations. After 28 d, TC concentrations were decreased by 8% and LDL-cholesterol concentrations by 9%. This translates into a 9–18% lower risk of cardiovascular disease (CVD) based on a 1–2% CVD risk reduction for each 1% reduction in LDL-cholesterol (24). This degree of reduction was comparable to reductions in LDL-cholesterol noted after consumption of sterol-enriched milk and yogurt for 3 wk (16), as well as 4-wk consumption of sterol-enriched chocolate (23), and is more than after consumption of sterol-enriched bread and cereal (16).

The label claim indicated that consumption of 6 softgel capsules per day resulted in supplementation of 2.0 g phytostanol as phytostanol esters (3.4 g stanol esters) per day. Results from an independent testing laboratory indicated that in reality a daily intake of 1.6 g per day of phytostanol as phytostanol esters was achieved. Other studies demonstrating TC and LDL-cholesterol concentration-lowering efficacy of phytostanols or phytosterols have used between 0.8 and 3 g per day (13). Thus, the doses used in this study, at either the label-indicated dose or the independent test dose, were well within levels previously shown to decrease serum TC and LDL-cholesterol values.

A recent meta-analysis of 18 clinical trials showed that consumption of plant sterols/stanols incorporated into spreads led to decreased LDL-cholesterol concentrations of 8–13% (10). Furthermore, it has been suggested that nonesterified phytostanols may provide better cholesterol-lowering potential than nonesterified phytosterols (4,6,25,26). This is perhaps owing to the decreased intestinal absorption of the hydrogenated phytostanols. Esterification, however, may result in similar cholesterol-lowering abilities of the sterols and stanols (7,27,28). It is likely that esterification of the stanol/sterol leads to higher incorporation into mixed micelles, thereby more effectively inhibiting dietary and bile cholesterol absorption as compared with nonesterified stanol or sterol powders.

The mechanism by which plant sterols/stanols exert their hypocholesterolemic action is not clearly understood. Plant sterols/stanols have been shown to decrease cholesterol absorption from the intestine (29–31). Cholesterol absorption may be inhibited by as much as one-third with phytostanol/sterol supplementation (30). Although the inhibition of cholesterol absorption may increase internal cholesterol synthesis, resulting decreased serum cholesterol concentrations suggest that the increased synthesis does not compensate for decreased absorption. The individuals in this study were told to consume the stanol ester-containing softgels with meals to take this into consideration. Although not specifically determined, it can be hypothesized that the phytostanol esters in the supplement inhibited cholesterol absorption from the accompanying meal and bile contents in the intestine. Furthermore, this study was not designed to determine whether results would differ if the capsules were taken on an empty stomach. Future studies could be designed to answer these and other questions, including optimal dosing (for example, a single daily dose vs. divided dosages).

In summary, the results of the present study show the efficacy of a softgel form of phytostanol esters in lowering TC and LDL-cholesterol in the absence of negative effects on HDL-cholesterol and fasting TG concentrations. Furthermore, these changes were noted in the absence of dietary modification and were in the same order of magnitude as those reported in various studies in which individuals consumed phytostanol- and/or phytosterol-enriched nonmargarine food products for 3–4 wk. We conclude that the use of phytostanol ester softgel supplements by mildly to moderately hypercholesterolemic subjects may be useful in sole or adjunct LDL-cholesterol-lowering therapy, thus reducing CVD risk.

ACKNOWLEDGMENTS

We acknowledge the assistance of the many undergraduate volunteers of the Human Nutraceutical Research Unit at the University of Guelph. We would like to thank Dr. Peter Jones from the Departments of Food Science and Human Nutritional Sciences, University of Manitoba, and his graduate students Adrielle Houweling, Amira Kassis, and Suhad Abumweis from the School of Dietetics and Human Nutrition, McGill University for graciously analyzing the composition of the phytostanol ester capsules. We also thank the Scottish Rite Charitable Foundation for funding this investigation.

ABSTRACT: The dose-dependent hypocholesterolemic and antiatherogenic effects of dietary apple polyphenol (AP) from unripe apple, which contains approximately 85% catechin oligomers (procyanidins), were examined in male Sprague-Dawley rats (4 wk of age) given a purified diet containing 0.5% cholesterol. Dietary AP at 0.5 and 1.0% levels significantly decreased the liver cholesterol level compared with that in the control (AP-free diet-fed) group. Dietary AP also significantly lowered the serum cholesterol level compared with that in the control group. However, the HDL cholesterol level was significantly higher in the 1.0% AP-fed group than in the control group. Accordingly, the ratio of HDL-cholesterol/total cholesterol was significantly higher in the 0.5% AP-fed group and 1.0% AP-fed group than in the control group. Moreover, the atherogenic indices in the 0.5 and 1.0% AP-fed groups were significantly lower than those in the control group. The activity of hepatic cholesterol 7α-hydroxylase tended to be increased by dietary AP in a dose-dependent manner. In accord with this observation, dietary AP increased the excretion of acidic steroids in feces. Dietary AP also significantly promoted the fecal excretion of neutral steroids in a dose-dependent manner. These observations suggest that dietary AP at a 0.5 or 1.0% level exerts hypocholesterolemic and antiatherogenic effects through the promotion of cholesterol catabolism and inhibition of intestinal absorption of cholesterol.

Paper no. L9825 in *Lipids 41*, 133–139 (February 2006).

Many polyphenolic compounds such as catechin and its derivatives, oligomeric catechins (procyanidins), may have beneficial effects on human health and preventive effects against diseases such as life-style-related diseases, without causing severe side effects.

A high level of plasma cholesterol has been ranked as one of the greater risk factors contributing to the incidence and severity of coronary heart disease. Previous studies showed that tea catechin exhibited hypocholesterolemic (1) and hypolipidemic effects (2) in experimental animals. Moreover, a combination of niacin-bound chromium and natural grape seed procyanidins, having 54% dimeric, 13% trimeric, and 7% tetrameric oligomeric procyanidins, also decreased total cholesterol and LDL levels in hypercholesterolemic subjects (3). Thus, dietary procyanidins, which are catechin oligomers, and catechin may prevent cardiovascular heart disease through hypocholesterolemic effects.

Humans consume approximately 28 mg of polyphenols/d from various plant foods and beverages (4). The total polyphenol level in a typical fruit serving of 200 g is 50–500 mg (5), and apples contain over 200 mg per serving of polyphenols. Thus, apples can serve as a major source of dietary polyphenols. Boyer and Liu (6) summarized various health benefits of apple phytochemicals; however, that review only showed functions of ripe apple and monomeric polyphenols. Unripe apples contain significantly higher levels of procyanidins than ripe apples (7); however, these procyanidins have not been used in foods yet. The procyanidins in unripe apple are 2–14mer oligomeric (−)-epicatechins, and they constitute over 60% of the total polyphenols in apples (7). Scheme 1 shows structures of procyanidins in apple polyphenol (AP) from unripe apple. The regulative effects of dietary procyanidins on lipid metabolism, especially on cholesterol metabolism, have not been completely evaluated yet. However, our recent study showed that

p-Coumaroylquinic acid		1.5
Sum		17.3

dietary procyanidins exerted hypolipidemic and antiobesity effects in experimental animals in which obesity was induced by consumption of high levels of lard (8). Therefore, the consumption of high doses of procyanidins may contribute to improvement of the lipid profile in hypercholesterolemic subjects. Here we examined the dose-dependent hypocholesterolemic effect of dietary purified AP [containing oligomeric (–)-epicatechin] from unripe apple in rats fed cholesterol to evaluate the preventive effects against atherogenesis and cardiovascular heart disease. We also examined the dose-dependent antioxidative effect of dietary AP.

EXPERIMENTAL PROCEDURES

Chemicals. The composition of dietary AP is shown in Table 1. AP contains approximately 85% procyanidins. This material was purified and provided by Asahi Brewery Co., Ltd. (Tokyo, Japan). [4-^{14}C]Cholesterol (52 mCi/mmol) was obtained from New England Nuclear (Boston, MA). Radioactive cholesterol was purified by TLC before use.

Animals and diets. Male Sprague-Dawley strain rats (3 wk old, CLEA Japan, Co., Ltd. Tokyo, Japan) were housed individually in a room with controlled temperature (20–23°C) and light (0800–2000). After rats were acclimatized for 1 wk, they were divided into four groups consisting of eight or nine rats each and given the following diets containing 0.5% cholesterol, as shown in Table 2: polyphenol-free diet (control); 0.2% AP-supplemented diet (AP-0.2); 0.5% AP-supplemented diet (AP-0.5); 1.0% AP-supplemented diet (AP-1.0). Each diet was prepared according to the AIN93 recommendations (9). The group fed the diet without polyphenol was given the diet at the level consumed by the AP-1.0 group under pair-feeding conditions because dietary polyphenol may cause a slight reduction in food intake. After 30 d, rats were anesthetized lightly using diethylether and bled from the abdominal aorta, and various tissues were quickly excised. Plasma was prepared by centrifugation after allowing blood to clot at room temperature. The liver was excised immediately and microsomes were prepared at 4°C. Ten days before the rats were killed, feces were collected for 2 d from each rat and then lyophilized and subsequently analyzed for the levels of neutral and acidic steroids in feces.

The samples were stored at −80°C until analyses. The animal experiments were conducted according to the guidelines of the ethical committee for experimental animal care at Hirosaki University.

Measurement of hepatic cholesterol 7α-hydroxylase (CYP7) activity. The activity of hepatic CYP7 was measured by the modified method of Van Cantfort *et al.* (10). The level of microsomal protein was measured by the method of Bradford (11).

Lipid analyses. Liver and serum lipids were extracted by the method of Folch *et al.* (12), and the levels of phospholipids, cholesterol, and TG in liver and serum were measured as described previously (13). The levels of serum TG and HDL-cho-

lesterol were measured using TG-E and HDL-cholesterol-E tests (Wako Pure Chemical Industries, Ltd., Tokyo, Japan), respectively. HDL-cholesterol-E test is commercial kit based on the theory of Burstein *et al.* (14) and is applied to various animal experiments.

Analysis of steroids excreted into feces. The levels of fecal neutral and acidic steroids were analyzed by GLC using 5α-cholestane (neutral steroids analysis) and 23-nordeoxycholic acid (acidic steroids analysis) (Steraloids, Wilton, NH) as internal standards according to the modified method of Sugano *et al.* (15). Briefly, fecal steroids were extracted by hot ethanol and separated into neutral or acidic steroids after deconjugation in an autoclave using 1.25 M NaOH. Neutral steroids were extracted by diethyl ether, and then acidic steroids were extracted by diethyl ether after acidification by additon of HCl. Neutral steroids were analyzed on a Shimadzu GC-14B gas chromatograph with an FID using an EC-1 column (0.25 mm × 30 m, film thickness 0.25 μm; Alltech Inc., Deerfield, IL) after trimethylsilylation. The oven and injector temperatures were 270 and 300°C, respectively. Acidic steroids were analyzed on the same column with an FID after methylation by diazomethane and followed by acetylation by acetic anhydride. The oven and injector temperatures were 280 and 320°C, respectively.

Analysis of tissue lipoperoxide and α-tocopherol levels. Liver and serum lipoperoxides were measured by the method of Fukunaga *et al.* (16) as TBARS. The levels of serum and liver α-tocopherol were measured by the method of Ueda and Igarashi (17).

Northern hybridization analyses. Total RNA was isolated from fresh liver (100–200 mg) using the RNeasy Midi Kit according to the manufacturer's instructions (Qiagen, Valencia, CA). mRNAs encoding CYP7 and glyceraldehyde-3-phosphate-dehydrogenase (GAPDH, used as an invariant control) were analyzed by Northern hybridization with the respective oligonucleotide probes described below. Preparation and hybridization of ^{32}P-labeled DNA probes were carried out as described by Sambrook and Russel (18). The rat cDNA probes for CYP7 and GAPDH were prepared by ^{32}P-labeling a 300-bp fragment (DDBJ/Genebank accession number J05430) amplified using CYP7 oligonucleotide primers (upstream primer, 5′-GAGTGATGTTTGAAGCAACTGGC-3′; downstream primer, 5′-GTTCGCTTCTTCCAACCACG-3′) and a 700-bp fragment (DDBJ/Genebank accession number AB017801) amplified using GAPDH oligonucleotide primers (upstream primer, 5′-GCCATCAACGACCCCTTCATT-3′; downstream primer, 5′-CGCCTGCTTCACCACCTTCTT-3′), respectively.

RNA was separated by electrophoresis in a 1.2% agarose gel containing 2.2 M formaldehyde and 20 mM MOPS. After electrophoresis, RNA was blotted onto a nylon membrane (Hybond-N+, Amersham Pharmacia Biotech, Little Chalfont, Bucks, United Kingdom).

Quantification of the band intensities. The hybridization signals were visualized and the band intensity was quantified using a Bio-Imaging Analyzer BAS 1000 (Fuji Photo Film, Tokyo, Japan). Quantified mRNA levels of CYP7 were divided by those of GAPDH for normalization.

Statistical analyses. All values are presented as mean ± SE. Statistical comparisons between groups were analyzed by Duncan's new multiple-range test (19) and Super ANOVA software (Abacus Concepts, Berkeley, CA). Statistical significance was defined as $P < 0.05$.

RESULTS

Growth and liver weight. On average, a rat weighing 96 g was fed 16.5 g of purified diet per day and gained 147–158 g of body weight during 30 d (Table 3). The weight gain in the AP-0.2 group was significantly higher than that in the control group; however, no such increase was seen in the AP-0.5 and AP-1.0 groups. The average liver weight in the AP-0.5 group was significantly lower than that in the control group.

Lipid levels in liver and serum. The level of liver TG tended to be lowered by dietary AP in a dose-dependent manner compared with that in the control group, although the decrease was not significant (Fig. 1). Dietary AP at the levels of 0.5 and 1.0% significantly lowered the liver cholesterol level compared with that in the control group. There was no significant difference in the liver phospholipid level among the groups.

Dietary AP tended to decrease the serum TG level, although the effect was not significant (Fig. 2). The level of serum phospholipid was highest in the AP-1.0 group among all of the groups. Dietary AP significantly decreased the level of serum cholesterol compared with that in the control group. The level of HDL-cholesterol in the AP-1.0 group was significantly higher than that in the control group, although HDL-cholesterol was lower in the AP-0.2 group than in the control group. The ratio of HDL-cholesterol/total cholesterol was significantly higher in the AP-0.5 and AP-1.0 groups than in the control group. Moreover, the atherogenic indices (the ratio of non-HDL

TABLE 3
Growth Parameter[a]

Group	Initial body weight (g)	Weight gain (g)	Food intake (g/30 d)	Liver weight (g/100 g B.W.)
Control	96 ± 2	147 ± 3[a]	496 ± 3	3.5 ± 0.1[a]
AP-0.2	96 ± 2	158 ± 3[b]	497 ± 3	3.3 ± 0.1[a,b]
AP-0.5	96 ± 2	148 ± 3[a,b]	497 ± 5	3.2 ± 0.1[b]
AP-1.0	96 ± 2	153 ±4[a,b]	497 ± 7	3.3 ± 0.1[a,b]

[a]Data are presented as mean ± SE of 8 or 9 rats in each group. Values without a common superscript letter are significantly different at $P < 0.05$ (Duncan's new multiple-range test). B.W., body weight; for other abbreviation see Table 1.

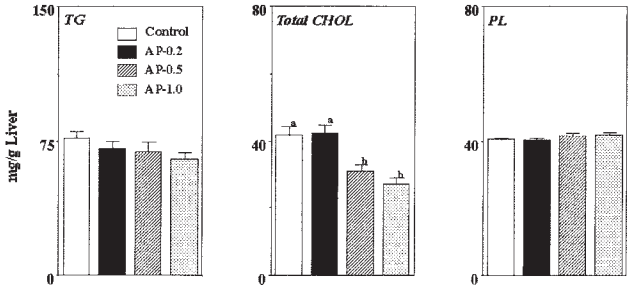

FIG. 1. Dose-dependent effect of dietary AP on liver lipid levels. Each value represents the mean ± SE for data obtained from 8 or 9 animals. Values without a common superscript letter are significantly different at $P < 0.05$. Abbreviations: AP, apple polyphenol; Control, rats fed AP-free diet; AP-0.2, rats fed 0.2% AP-supplemented diet; AP-0.5, rats fed 0.5% AP-supplemented diet; AP-1.0, rats fed 1.0% AP-supplemented diet; total CHOL, total cholesterol; PL, phospholipids.

cholesterol/HDL cholesterol) in the AP-0.5 and AP-1.0 groups, but not in the AP-0.2 group, were significantly lower than that in the control group.

TBARS and α-tocopherol levels in serum and liver. The level of TBARS in the liver tended to be lowered in a dose-dependent manner by consumption of AP compared with the level in the control group (control, 49.33 ± 3.63 nmol/g; AP-0.2, 46.88 ± 4.28 nmol/g; AP-0.5, 43.35 ± 1.91 nmol/g; and AP-1.0, 42.14 ± 1.34 nmol/g). Dietary AP at the 0.2 and 0.5% levels also significantly lowered the serum TBARS level compared with that in the control group (control, 1.29 ± 0.07 nmol/mL; AP-0.2, 1.09 ± 0.02 nmol/mL; AP-0.5, 1.09 ± 0.05 nmol/mL; and AP-1.0, 1.18 ± 0.03 nmol/mL). On the other hand, dietary AP increased the level of α-tocopherol in a dose-dependent manner (control, 1.93 ± 0.13 μg/mL; AP-0.2, 2.14 ± 0.16 μg/mL; AP-0.5, 2.16 ± 0.15 μg/mL; and AP-1.0, 3.09 ± 0.19 μg/mL). Such an effect did not necessarily occur in the liver, although dietary AP at the 0.2% level significantly increased the level of liver α-tocopherol compared with that in the control group (control, 25.83 ± 1.11 μg/g; AP-0.2, 28.78 ± 1.62 μg/g; AP-0.5, 27.57 ± 2.06 μg/g; and AP-1.0, 25.85 ± 1.38 μg/g).

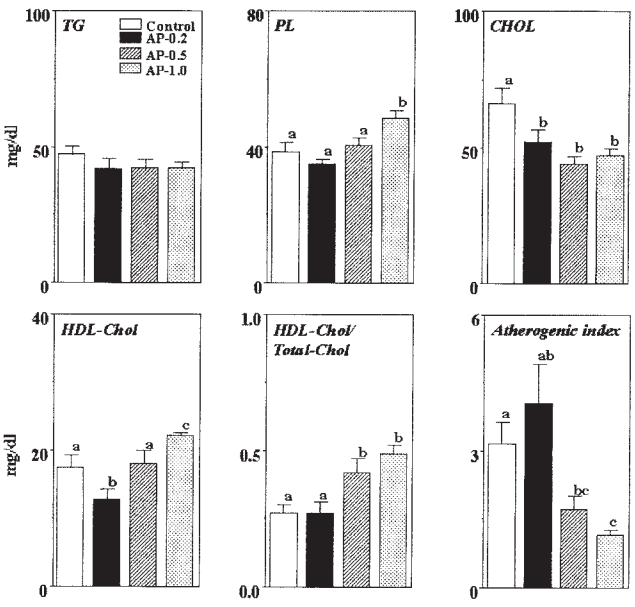

FIG. 2. Dose-dependent effect of dietary AP on serum lipid levels. Each value represents the mean ± SE for data obtained from 8 or 9 animals. Values without a common superscript letter are significantly different at $P < 0.05$. HDL-cholesterol-E test, which is a commercial kit based on the theory of Burstein *et al.* (14), was used for HDL-cholesterol analysis. For abbreviations see Figure 1.

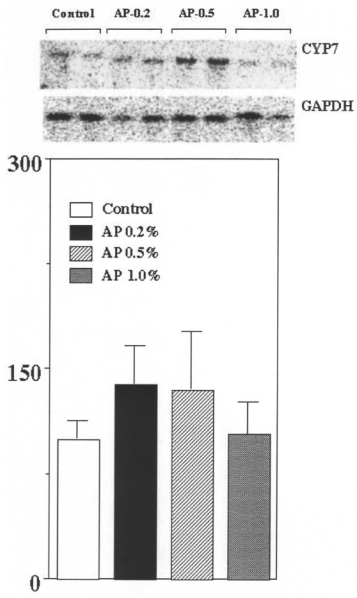

FIG. 3. Dose-dependent effect of dietary AP on hepatic cholesterol 7α-hydroxylase (CYP7) mRNA levels in rats fed 0.5% cholesterol for 30 d. Each value represents the mean ± SE for data obtained from 8 or 9 animals. The value of the CYP7 mRNA signal was normalized to the value of the glyceraldehyde-3-phosphate-dehydrogenase (GAPDH) signal, and each value is expressed relative to the average value for the rats fed the control diet, which was set to 1. For other abbreviations see Figure 1.

Hepatic CYP7 activity. The hepatic CYP7 activity was significantly higher in the AP-0.5 and AP-1.0 groups than in the control group (control, 15.7 ± 2.7 pmol/min/mg protein; AP-0.2, 19.2 ± 2.6 pmol/min/mg protein; AP-0.5, 23.8 ± 1.6 pmol/min/mg protein; and AP-1.0, 22.4 ± 2.0 pmol/min/mg protein)

Level of CYP7 mRNA. The level of CYP7 mRNA in the liver tended to be higher in the AP-0.2 and AP-0.5 groups than in the control group; however, the increases were not significant and no increase was seen in the AP-1.0 group (Fig. 3).

Fecal steroid excretion. The levels of steroids excreted into the feces are summarized in Figure 4. The level of neutral steroids excreted into the feces was increased by consumption of AP in a dose-dependent manner. Dietary AP, especially in the AP-0.5 and AP-1.0 groups, also increased the excretion of acidic steroids into feces compared with that in the control group.

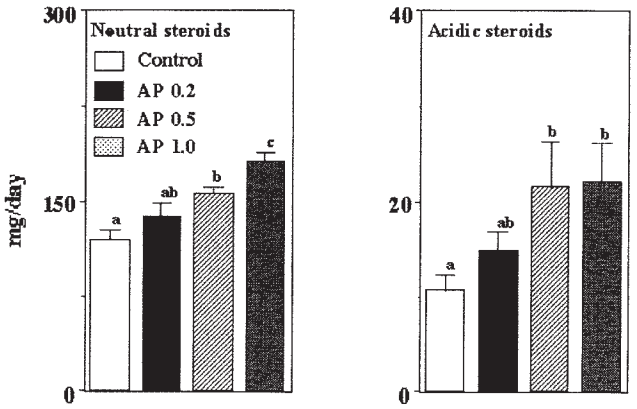

FIG. 4. Dose-dependent effect of dietary AP on neutral and acidic steroid excretion into feces. Each value represents the mean ± SE for data obtained from 8 or 9 animals. Values without a common superscript letter are significantly different at $P < 0.05$. For abbreviations see Figure 1.

DISCUSSION

Many reports show various health benefits of dietary apple or beverages from apple because it has phytochemicals such as polyphenol or pectin (6). Owing to the many studies on the biological activities of apple, the antioxidative effects of AP are now well known (20,21). On the other hand, Leontowicz *et al.* (22,23) and Aprikian *et al.* (24,25) report detailed and interesting data concerning the regulative effects of apple on lipid profiles. However, direct evidence of the regulative activities on lipid metabolism by AP has not been completely shown until now because these studies used juice or extracts from ripe apple. Moreover, the biological activity of procyanidins, which is high in apple, also has not yet been completely evaluated.

Therefore, we examined the dose-dependent hypocholesterolemic and antioxidative effects of dietary purified AP from unripe apple, which contained 84.9% (−)-epicatechin oligomers (procyanidins), in rats fed 0.5% cholesterol in this study. Our dose level of AP to rats is between 0.2 and 1.0%, and these levels are high; however, the elucidation of dietary functions of polyphenols such as tea catechin containing a high level of (−)-epigallocatechin gallate were carried out with the dose levels of 0.5, 1.0, or 2.0% in recent studies (26). No toxic effects were reported in these studies. Therefore, we also evaluated the effects of a high dose of AP on lipid metabolism in rats in this study.

Dietary AP increased weight gain at the 0.2% level and lowered liver weight at the 0.5% level; however, no impairment of hepatic functions (glutamic-oxaloacetic transaminase, glutamic pyruvic transaminase, and lactate dehydrogenase, data not shown) was observed at the 0.5 or 1.0% AP level, and thus a high dose of (−)-epicatechin oligomers such as that in AP appears not to be toxic. Shoji *et al.* (27) also reported that an acute oral-toxicity test, and a 90-d subchronic-toxicity test showed no significant hematological, clinical, chemical, histopathological, or urinary effects at a dose of 2 g/kg. Therefore, a high dose of AP, at 1.0% may exert no side effects or toxic effects.

Antioxidative activity of dietary AP was observed in these animal experiments, as already shown in many *in vitro* studies (6, 20, 21). Similar observations were made in human studies using grape seed extracts (28) or cocoa powder (29). The antioxidative action of dietary AP was significant in serum when the rats were given AP at the 0.2 or 0.5% level. This effect may be related to the free radical-scavenging action of metabolites from dimers and trimers of AP, which are soluble polyphenols in water and alcohol, incorporated into chylomicrons although their bioavailabilities are not necessarily high. Effects of monomeric polyphenols such as (−)-epicatechin and chlorogenic acid as shown in Table 2 also cannot be ignored; however, they are present at very low levels compared with the procyanidins in the AP that we used. Moreover, Lotito and Frei (30) showed that monomeric polyphenols in ripe apple and extracts from ripe apple did not exert antioxidative effects *in vivo* as shown in *in vitro* studies. Contrary to this report, Facino *et al.* (31) observed that diets supplemented with procyanidins from *Vitis vinifera* (grapes) enhanced plasma antioxidative activity in rats. Therefore, the plasma antioxidative activity in rats fed AP should be evaluated.

The level of serum α-tocopherol was higher in AP-fed groups than in that in control group. Dietary (+)-catechin and BHT markedly increased the level of α-tocopherol in rats by a mechanism independent of tocopherol-ω-hydroxylase, which is a key enzyme in tocopherol catabolism (32). Therefore, the metabolites of procyanidins, rather than internal α-tocopherol, may play critical free radical-scavenging roles. However, α-tocopherol level in liver was decreased in a dose-dependent manner, although their levels were higher than that in control group. These observations were not shown in serum α-tocopherol level. We must carry out a supplementary examination to elucidate this contradiction.

Dietary AP at levels of 0.5 and 1.0% significantly lowered the level of cholesterol in the liver compared with that in the control group. These effects may be related to the modulation of hepatic CYP7 activity by consumption of AP. The effects of dietary polyphenol on hepatic cholesterol catabolism have not been completely elucidated yet. However, the consumption of Lung Chen tea, which is a type of Chinese green tea, tends to lower the hepatic CYP7 and liver cholesterol levels in rats fed 1% cholesterol (33). Moreover, the consumption of a 4% Lung Chen tea solution significantly increased the excretion of fecal acidic steroids compared with that in the control (no consumption of tea) group. Sable *et al.* (34) also observed that fecal excretion of bile acids and neutral steroids increased in hamsters fed apple. Similar to this observation, the fecal excretion of acidic steroids was significantly higher in the AP-0.5 and AP-1.0 groups than in the control group in our study, reflecting the modulation of hepatic CYP7 activity. The polyphenolic compounds in Lung Chen tea are catechin monomers such as (−)-epicatechin, (−)-epicatechin gallate, (−)-epigallocatechin, and (−)-epigallocatechin gallate. Therefore, the metabolites of procyanidins from AP, which are oligomers of (−)-epicatechin, as well as catechin monomer, may modulate hepatic CYP7 activity and consequently increase the excretion of acidic steroids

into feces. This effect of dietary procyanidins must contribute to the decrease of the cholesterol level in the liver. The level of CYP7 mRNA was not necessarily associated with the hepatic CYP7 activity, although the consumption of 0.2 and 0.5% AP tended to increase the level of CYP7 mRNA. Therefore, dietary AP may modulate the expression of CYP7 in liver; additional evidence will be needed to determine the precise relationships among dietary AP, cholesterol catabolism, and the expression of CYP7 mRNA, because the level of CYP7 mRNA was not consistent with the activity of hepatic CYP7 in this study.

Dietary AP may exert a hypocholesterolemic effect through promoting the excretion of neutral steroids into the feces. Tea catechins exert a hypocholesterolemic effect through the inhibition of lymphatic cholesterol absorption in rats (35). This observation was attributed to the reduction of cholesterol solubility in mixed micelles by tea catechins. Moreover, an earlier study also showed that dietary crude tea catechin powder decreased plasma total cholesterol, cholesterol ester, VLDL-cholesterol + LDL-cholesterol, and atherogenic index through the increase of fecal excretion of total lipids and cholesterol in rats fed lard and cholesterol (36). Thus, dietary procyanidins from apple may exert hypocholesterolemic effects through the inhibition of intestinal absorption *via* the reduction of the micellar solubility of cholesterol.

These results suggest that it is possible that dietary purified procyanidins from unripe apple exert cholesterol-lowering effects in liver and serum through the combination of the activation of hepatic cholesterol catabolism and the inhibition of intestinal cholesterol absorption.

Solvents such as water, alcohol, and acetone can extract low- and intermediate-MW polyphenolic compounds such as hydrolyzable tannins and procyanidins (37). However, high-MW compounds remain insoluble in the same solvents (37). In their review, Bagchi and Preuss (38) estimate that monomeric polyphenol, and oligomeric procyanidin fractions, which are soluble in water and alcohol, may be partially absorbed from the intestine and detected in all tissues and plasma. On the other hand, high-MW procyanidin fractions, which are insoluble in water and alcohol but soluble in aqueous acetone, may be excreted in the feces and not detected in the plasma or tissues (38). Therefore, the soluble fractions in AP may affect hepatic cholesterol catabolism, whereas the insoluble fractions in AP may promote cholesterol excretion by inhibiting intestinal absorption.

The metabolic pathway of procyanidins has not been completely elucidated. For example, Baba *et al.* (39) observed that procyanidins B2 were absorbed and excreted in urine, and a portion of the procyanidins B2 is degraded to (−)-epicatechin and to the metabolized conjugated and/or methylated (−)-epicatechin internally in the rat. Sano *et al.* (40) also observed that procyanidins B1 were detected in human serum 2 h after intake. Similarly, the absorption of orally administered procyanidins B2 and B3 from Cinnamomi cortex in rat plasma was reported (41). On the other hand, Tsang *et al.* (42) reported that the metabolites from (−)-epicatechin and low amounts of the procyanidin dimers (B1, B2, B3, and B4) as well as the trimer (C2) and an unknown trimer in rats given grape seed extract; however, they indirectly estimate that procyanidins are not depolymerized to monomers after consumption. Moreover, some reports estimate that the metabolites such as phenolic acids from procyanidins metabolized by intestinal microflora contribute to various biological activities of dietary procyanidins because many phenolic acids were excreted into urine (43,44). Therefore, further experiments are needed to elucidate why dietary AP exerts hypocholesterolemic and antioxidative effects.

Effects of Margarine and Butter Consumption on Distribution of *trans*-18:1 Fatty Acid Isomers and Conjugated Linoleic Acid in Major Serum Lipid Classes in Lactating Women

Alam M. Shahin[a], Michelle K. McGuire[a,*], Nicole Anderson[a], Janet Williams[a], and Mark A. McGuire[b]

[a]Department of Food Science and Human Nutrition, Washington State University, Pullman, Washington 99164-6376, and [b]Department of Animal and Veterinary Sciences, University of Idaho, Moscow, Idaho 83844-2330

ABSTRACT: *Trans* FA (TFA) have at least one *trans* double bond and comprise several isomers and types, including many of the CLA (e.g., *c*9,*t*11-18:2 CLA). Some TFA may have adverse effects (e.g., cardiovascular disease), whereas some are thought to have beneficial effects (e.g., anticarcinogenicity). The presence of TFA in human tissues and fluids is related to dietary intake, although this relationship is not completely understood—especially in regard to serum lipid fractions. This study was conducted as part of an investigation designed to test the influence of butter (B), "low TFA" margarine (LT), and regular margarine (RM) on milk fat content. Here we tested the secondary hypothesis that consumption of B, LT, and RM by lactating women would result in differential distribution of TFA and CLA in major serum lipid classes. Breastfeeding women (n = 11) participated in this randomized Latin-square study consisting of five periods: intervention I (5 d), washout I (7 d), intervention II (5 d), washout II (7 d), and intervention III (5 d). Extracted serum lipid was separated into cholesterol ester (CE), TAG, and phospholipid (PL) fractions and analyzed for total and isomeric TFA and CLA concentrations. Data indicate that TAG consistently contained the highest concentration of total *t*-18:1. No interaction between treatment and fraction was found for any of the *t*-18:1 isomers identified. Absolute concentration of each *t*-18:1 isomer was greatest during the RM period, regardless of fraction. On a relative basis, concentrations of *t*10-18:1 and *t*12-18:1 were most responsive to treatment in the CE fraction. The concentration of *c*9,*t*11-18:2 CLA was highest in the TAG fraction and lowest in the PL fraction, regardless of treatment. In summary, these results indicate (i) that there is a differential distribution of some isomeric TFA and CLA among human serum lipid fractions and (ii) that dietary TFA intake influences absolute and relative concentrations of some of the isomers in selected fractions.

Paper no. L9501 in *Lipids 41*, 141–147 (February 2006).

Trans FA (TFA) are present in a variety of foods; some are derived from natural sources such as dairy products (1), but most come from products that contain commercially hydrogenated oils (2). The most prevalent TFA in partially hydrogenated vegetable oils (PHVO) tends to be *t*10-18:1, and the major TFA isomer in dairy products is *t*11-18:1 (3,4). Metabolic studies show that some TFA have adverse effects on coronary heart disease (CHD) risk factors, increasing LDL cholesterol while decreasing HDL cholesterol (5–8). A positive correlation also has been found between TFA intake and cholesterol level and CHD death rate (5,9–11). In addition to influencing risk of CHD, some TFA may have adverse effects on fetal and infant growth and development. For example, Rosenthal and Doloresco (12) demonstrated that TFA impaired the microsomal desaturation and chain elongation of the EFA to their long-chain polyunsaturated metabolites. These long-chain FA with 20 and 22 carbon atoms, such as arachidonic acid and DHA, are of great physiological importance during perinatal development. Some TFA have also been shown to depress milk fat concentration when administered to dairy cows or humans (13,14). Estimates of TFA intake among Americans vary, but data from Kris-Etherton and colleagues (15) suggest that TFA intakes range from 2.6 to 12.8 g/d. Allison *et al.* (16) reported that the U.S. population consumes 5.3 g/d TFA, representing 2.6% of total energy intake and 7.4% of energy from fat. In view of the potential deleterious effects of some TFA, the Institute of Medicine recently recommended that the TFA intake be a low as possible (17).

It is noteworthy that CLA were excluded from this recommendation, although many of CLA isomers are TFA. In general, CLA refers to a group of PUFA that exist as positional and stereoisomers of conjugated octadecadienoic acid (18:2). The predominant CLA isomer in foods is *c*9,*t*11-CLA, also called rumenic acid (18), and is found primarily in ruminant-derived foods such as beef, lamb, and dairy products (19–21). Data suggest that CLA intake in the U.S. population averages approximately 151 and 212 mg/d in females and males, respectively, with the majority (68%) coming from dairy products (22). Synthetic mixtures of CLA also can be readily purchased as nutritional supplements and are composed primarily of the *c*9,*t*11- and *t*10,*c*12-18:2 isomers. Unlike most other TFA, numerous beneficial health effects have been attributed to CLA, including those related to its potential antiadipogenic, antidiabetogenic, anticarcinogenic, and antiatherosclerotic properties (23–26). For this reason, CLA was not considered by the Institute of Medicine to be a TFA that should be avoided.

Present address of first author: Department of Nutrition and Food Sciences, University of Vermont, Burlington, VT 05405-0570.

Abbreviations: B, butter; CE, cholesterol ester; CHD, coronary heart disease; LT, "low TFA" margarine; MTBE, methyl tert-butyl ether; PHVO, partially hydrogenated vegetable oil; PL, phospholipid; RM, regular margarine; TFA, *trans* FA.

The FA composition of the diet has been shown to influence the FA composition of serum lipid fractions such as TAG, cholesterol ester (CE), and phospholipid (PL) as well as that of adipose tissue (27,28). However, very few studies have reported the individual TFA isomers in plasma, let alone in each lipid fraction (29,30). We recently reported (31) a combination of methods that could be used to methylate the CLA content of various plasma lipid fractions. However, we did not identify any of the *t*-18:1 isomers in the plasma lipid fractions. Doing this is important, because it is possible that the distribution of various TFA among the lipid fractions might have implications on human health. The influence on health of the incorporation of TFA might be different according to whether TFA are incorporated preferentially into the CE or the PL fraction. Thus, the overall objective of this study was to determine the effect of diet on the distribution of isomeric *t*-18:1 and CLA in the major plasma lipid fractions of humans. This study was part of a larger investigation designed to test the effect of the consumption of butter (B), low-TFA margarine (LT), and regular margarine (RM) on milk fat content. Results of this study have been published elsewhere (14). Thus, we were able to test the hypothesis that consumption of these commonly consumed fats by lactating women would alter the distribution of TFA isomers and CLA in major human serum lipid classes. We also tested the hypothesis that consumption of RM would increase the concentration of most of the *t*-18:1 isomers in each lipid class.

MATERIALS AND METHODS

Materials. Heneicosanoate (21:0), a mixture of 19 FAME, a mixture of CLA isomers (FFA; 80% *c*9,*t*11-18:2, 17% *c*9,*c*11-18:2, and 1% *t*9,*t*11–18:2) and a *t*-18:1 mixture (*t*6-, *t*7-, *t*9-, *t*11-, *t*12-, and *t*13-18:1) were purchased from Matreya (Pleasant Gap, PA). Sodium methoxide in methanol (0.5 N) and methyl acetate were obtained from Sigma-Aldrich Co. (St. Louis, MO). Silica Maxi-Clean™ cartridges (600 mg) were purchased from Alltech Associates, Inc. (Deerfield, IL). All chemicals and reagents used were of analytical grade.

Subjects. All procedures were approved by the Washington State University Institutional Review Board, and all participants provided written consent for themselves and their infants. Healthy, lactating women (n = 12) from 2 to 12 mon postpartum were recruited from the Pullman, WA, and Moscow, ID, areas. However, serum samples from only 11 subjects were analyzed in this study, as there was insufficient serum from one subject. Baseline data pertaining to these subjects are presented in Table 1. All women were self-reported to be healthy and were, on average, 26.7 ± 1.2 yr of age.

Study design and dietary interventions. This study was designed as a randomized Latin-square study consisting of five periods: intervention I (5 d), washout I (7 d), intervention II (5 d), washout II (7 d), and intervention III (5 d). Initial data analyses (not shown) suggested that there were no carryover effects from one intervention period to the next; thus, only data from the intervention periods (not washout periods) are presented here.

TABLE 1
Demographic Variables and Anthropometric Measurements of Women and Infants[a]

Variables	Mean ± SEM
Maternal	
Age (yr)	26.7 ± 1.2
Time postpartum (mon)	6.1 ± 1.0
Weight (kg)	70.5 ± 4.3
Height (cm)	167.7 ± 1.7
BMI (kg/m^2)	24.9 ± 1.2
Body fat[b] (%)	31.3 ± 2.0
Infant	
Weight (kg)	7.9 ± 0.5
Length (cm)	66.9 ± 1.7

[a]Anthropometric measurements were taken at time of enrollment; n = 11.
[b]Body fat was measured by dual energy X-ray absorptiometry. BMI, body-mass index.

During each intervention period, subjects consumed diets high in either B, RM, or LT. During the B period, subjects maximized their consumption of B and minimized their intake of PHVO. During the RM period, subjects maximized their consumption of RM and minimized their intake of dairy fats. During the LT period, subjects maximized their intake of LT and limited their intake of both dairy fats and PHVO. To facilitate compliance with these requests, subjects were provided with 454 g of either butter (Darigold® Sweet Cream Butter, Grade AA; Darigold, Inc., Seattle, WA), regular margarine (Gregg's™ Gold-n-Soft® margarine; Ventura Foods, City of Industry, CA), or margarine labeled as containing no TFA (Saffola Soft Margarine®;Ventura Foods) during the corresponding intervention period.

In addition, subjects consumed one "breakfast" muffin and one "lunch" muffin daily, each made with 37.8 ± 1.0 g of the appropriate fat. Four different types of muffins were prepared and systematically rotated for variety and enhanced subject compliance. Breakfast and lunch muffins were consumed before 1000 and 1600 h, respectively, except on day 5 of each intervention period, when subjects ate the breakfast muffin 1 h before the blood collection time, and the lunch muffin before 1200 h. Data concerning the nutrient and FA intake from the study muffins are summarized in Table 2. Total fat intakes were 123.1, 120.8, and 125.6 g/d during B, LT, and RM periods, respectively. No dietary restriction was imposed during the washout periods, and subjects were allowed to eat according to their choices.

Blood collection. Nonfasting maternal blood (20 mL) was collected by venipuncture on the last day of each intervention between 0800 and 1000 h. Blood was drawn approximately 1 h after consumption of the breakfast muffin. Serum samples were aliquoted and frozen for later analyses.

Lipid extraction, fractionation, and transmethylation. Lipids were extracted according to the method of Ingalls et al. (32) as modified by us (31). Extracted lipid (1.25 mg) was fractionated in quadruplicate using silica cartridges and combined after fractionation. Briefly, the column was loaded with 1.5 mg of plasma lipid; CE and TAG fractions were eluted with a combination of hexane/methyl tert-butyl ether (MTBE) (200:3, 12

[b]Values derived from biochemical analyses. ND, not detectable.

mL for CE followed by 12 mL for TAG). After removal of TAG, the column was acidified with 12 mL hexane/acetic acid (100:0.2). Finally, the PL fraction was eluted with 20 mL MTBE/methanol/ammonium acetate (pH 8.6; 10:4:1, by vol). TAG and PL fractions were dried under nitrogen at 45°C and transmethylated using sodium methoxide and methyl acetate for 10 min at room temperature; CE fractions were transmethylated similarly for 1 h (33).

Analysis of FAME. FAME were analyzed on a gas chromatograph (Hewlett-Packard 6890 Series) with auto injector fitted with an FID (Agilent Technologies, Wilmington, DE). FA profiles were determined by split injection (20:1) onto an SP-2560 fused-silica capillary column (100 m × 0.25 mm i.d., 0.2 μm film thickness; Supelco, Inc. Bellefonte, PA) using a programmed temperature gradient method (34). The helium carrier gas pressure was constant, and the injector and detector temperatures were 255°C. The initial oven temperature was 70°C and was held for 4 min. Following injection of the sample, the oven temperature was increased at 4°C/min to 170°C and held for 3 min. The oven temperature was then increased at 1°C/min to 185°C and held for 20 min and then increased at 3°C/min to 215°C and then 10°C/min to 230°C and held for 10 min, after which it was returned to 70°C. Identities of total *t*-18:1 isomers (sum of *trans* 6/8, *t*9, *t*10, *t*11, and *t*12 isomers), *c*9,*t*11-18:2 CLA, and other FA were established by comparing retention times to a 19 FAME standard mixture, and a CLA mixture containing 80% *c*9, *t*11-18:2; 17% *c*9,*c*11-18:2, and 1% *t*9,*t*11-18:2, respectively. Heneicosanoate (21:0) was added as an internal standard after serum fractionation to quantify the FAME concentration. We could identify only one CLA isomer that corresponded to the *c*9,*t*11-18:2 standard; *t*10,*c*12-18:2 was below the detection limit of our method. Similarly, only the major *t*-18:1 isomers (*trans* 6/8, *t*9, *t*10, *t*11, and *t*12 isomers) were identified in this study.

Statistical analyses. Standard descriptive statistics and ANOVA were performed using the Statistical Analysis System (Version 6.2; SAS, Cary, NC). The model used to test the stated hypotheses included the following factors: treatment, lipid fraction, and treatment × lipid fraction. Main effects and differences between means were considered significant at $P < 0.05$. Interactions were considered significant at $P < 0.05$.

RESULTS

Effects of treatment and lipid fraction on saturated and cis-FA. Effects of treatment on FA concentrations of lipid fractions are presented in Table 3. There was an interaction between treatment and fraction for the following FA: 14:0, 15:0, 16:0, 16:1, 17:0, and *c*9,*c*12,*c*15-18:3, whereas 12:0, *c*9-18:1, and *c*9,*c*12-18:2 had significant independent effects of both fraction and treatment ($P < 0.05$). Myristoleic acid (14:1), 18:0, and *c*5,*c*8,*c*11,*c*14-20:4 had a significant effect of fraction only ($P < 0.05$). During all periods, the predominant FA in CE was *c*9,*c*12-18:2 followed by *c*9-18:1. Oleic acid (*c*9-18:1) was the

predominant FA in the TAG fraction, except during the RM period when *c*9,*c*12-18:2 was instead. Palmitic acid (16:0) was the principal FA in the PL fraction, except during the RM period when it was *c*9,*t*12-18:2. Thus, although there were some relatively consistent trends as to which FA was the major one in each fraction, this was somewhat dependent on fraction and dietary treatment.

Effects of treatment and lipid fraction on total t-18:1 and t-18:1 isomers. The effects of treatment and lipid fraction on TFA are also presented in Table 3. There was no interaction between treatment and fraction on total *t*-18:1 concentration (defined as the sum of *t*6/8-, *t*9-, *t*10-, *t*11-, and *t*12-18:1). The TAG fraction contained the highest concentration of total *t*-18:1 followed by PL and CE (Fig. 1). There was also an independent effect of treatment ($P < 0.05$) in that consumption of RM resulted in higher total *t*-18:1 concentrations compared with the B and LT treatment periods.

We examined the effects of treatment and fraction on TFA isomers in two ways: (i) as absolute values (mg/g lipid) (Table 3) and (ii) as relative values (percentage of total *t*-18:1) (Table 4). When absolute values were considered, we found no interaction between treatment and fraction for any of the *t*-18:1 isomers identified. However, significant independent effects ($P < 0.05$) of fraction and treatment were evident for each isomer. In general, the concentration of each *t*-18:1 isomer was highest in the TAG fraction and lowest in the CE fraction and tended to be greatest during the RM period, regardless of fraction.

When each TFA was considered as a percentage of total *t*18:1, it was clear that the *t*10-18:1 isomer was the predominant TFA in the TAG fraction, regardless of dietary treatment. However, *t*11-18:1 was the second-most abundant during the B and RM period, whereas *t*9-18:1 was second-most abundant during the LT period. For the PL fraction, *t*12-18:1 was the most abundant during the LT and RM periods, with *t*11-18:2 being prominent during B consumption. The TFA profile of the CE fraction appeared to be most influenced by dietary treatment: *t*6/*t*8-18:1, *t*11-18:1, and *t*12-18:1 were the predominant TFA during B, LT, and RM periods, respectively.

Effects of treatment and lipid fraction on c9,t11-18:2 CLA. There was no interaction between treatment and fraction on

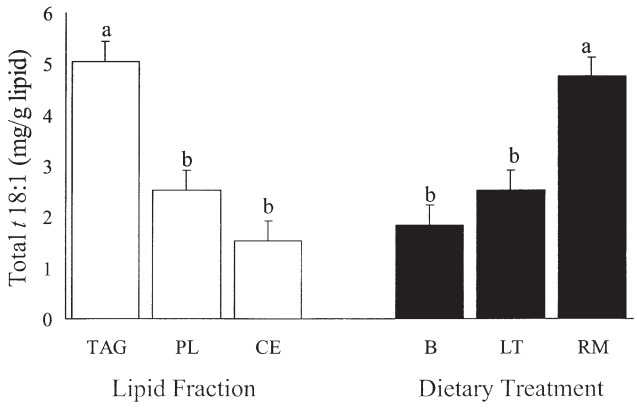

FIG. 1. Distribution of total serum *t*18:1 FA among lipid fractions [TAG; phospholipid (PL); and cholesterol ester (CE)] and by treatment (butter, B; "low TFA" margarine, LT; and regular margarine, RM). Each bar represents a mean ± SEM. Means within the lipid fraction or treatment groups not sharing a common letter differ significantly ($P < 0.01$).

*c*9,*t*11-18:2 CLA, nor was there an overall treatment effect. Nonetheless, consumption of B significantly increased the *c*9,*t*11-18:2 CLA content of the TAG fraction without changing the CLA content of the other fractions. There was a significant effect of fraction on *c*9,*t*11-18:2 CLA ($P < 0.05$), such that its concentration was highest ($P < 0.01$) in TAG (0.55 ± 0.04 mg/g lipid) followed by CE (0.31 ± 0.04 mg/g lipid) and PL (0.18 ± 0.44 mg/g lipid).

DISCUSSION

This study was conducted as a part of a larger investigation designed to test the influence of B, LT, and RM on milk fat in humans. In the present study we analyzed the distribution of *t*-18:1 isomers and *c*9,*t*11-18:2 CLA in major serum lipid fractions. Data indicate that the *t*-18:1 isomers and *c*9,*t*11-18:2 CLA were not equally distributed in TAG, PL, and CE fractions of serum lipid. The overall concentration of individual *t*-18:1 isomers was highest in the TAG fraction followed by PL and CE in each intervention period, respectively. Thus, it appears that the incorporation of *t*-18:1 isomers into serum lipid fractions is somewhat selective. Furthermore, overall concentration of total *t*-18:1 was also highest in the CE, TAG, and PL fractions during RM compared with the B and LT periods.

The results presented here for total TFA distribution among serum lipid fractions are in agreement with those of Vidgren *et al.* (35), who also reported a higher proportion of total TFA in the TAG fraction followed by PL and CE. Similarly, Schrock and Connor (36) reported the highest incorporation of total TFA into the TAG fraction followed by PL and CE in rabbits. However, in these studies isomeric TFA distributions were not reported. Recently, Mansour *et al.* (29) conducted a crossover intervention trial in which free-living subjects ($n = 10$) consuming moderate fat (25.6 ± 2.2% of energy from margarine) and then very low fat (9.9 ± 1.4% of energy from lean beef) diets were studied. The PL fraction contained more than 60% of the *trans*-18:1 isomers in plasma lipid in all subjects. The authors suggested that the measurement of *trans*18:1 in the plasma PL fraction could be used to estimate the presence or absence of TFA intake since it contained a greater amount of TFA compared with other fractions. Our results show that the FA concentration in CE tended to be most responsive to alterations in dietary TFA intake. Further, data suggest that incorporation of TFA isomers into individual lipid fractions is somewhat selective. Emken *et al.* (37) have also reported a selective discrimination in the incorporation of the *t*11-18:1 isomer compared with the *t*9-18:1 isomer in the TAG, CE, and FFA fractions.

We also studied the incorporation of CLA into lipid fractions. Recently, we reported (31) that the TAG fraction as opposed to the fractions CE and PL contained the highest percentage of CLA in human plasma. Thus, the present study confirms these findings and also supports those of others (38,39). We found that the effect of *c*9,*t*11-18:2 CLA intake on the amount of *c*9,*t*11-18:2 CLA in the lipid fractions was variable, with the TAG fraction appearing to be most responsive. However, this study was unable to take into account the endogenous conversion of *t*11-18:1 to *c*9,*t*11-18:2 CLA, which has been shown to occur (40). Clearly, stable isotope studies will be required to understand the partitioning of these FA, their precursors, and their metabolites in the body. Animal investigations also indicate that CLA accumulates predominantly in neutral lipids (41,42). In contrast, results from a recent study in Greek adults suggest that the majority of CLA is present in the PL fraction (43). Although most of the human studies indicate that CLA accumulates in the TAG, the discrepancy among study results remains unresolved.

In summary, these findings support our hypotheses that (i) concentrations of isomeric TFA and CLA in human serum lipid fractions are not equally distributed and (ii) maternal consumption of RM increases the level of *t*-18:1 isomers in the major lipid fractions. Interestingly, concentrations of CLA were less influenced by diet, although the conversion of *t*11-18:1 to *c*9,*t*11-18:2 CLA could not be accounted for here. Further studies are required to understand the biological significance of these findings.

ACKNOWLEDGMENTS

This work was supported by USDA National Research Initiative competitive grants program, the Washington State Dairy Products Commission, and the Western Dairy Center. The authors would like to extend their appreciation to the women and infants who participated in this project. We also would like to recognize Darigold, Inc. and Ventura Foods for donating the butter and "low *trans*" margarine used in the study.

ABSTRACT: Low linolenic acid soybean oil (LLSO) has been developed as a substitute for hydrogenated soybean oil to reduce intake of *trans* FA while improving stability and functionality in processed foods. We assessed the dietary impact of substitution of LLSO for hydrogenated soybean oil (HSBO) used in several food categories. All substitutions were done using an assumption of 100% market penetration. The impact of this substitution on the intake of five FA and *trans* FA was assessed. Substitution of LLSO for current versions of HSBO resulted in a 45% decrease in intake of *trans* FA. Impacts on other FA intakes were within the realm of typical dietary intakes. No decrease in intake of α-linolenic acid was associated with the use of LLSO in place of HSBO because LLSO substitutes for HSBO that are already low in α-linolenic acid.

Paper no. L9868 in *Lipids 41*, 149–157 (February 2006).

As of January 2006, food manufacturers in the United States are required to comply with a new Food and Drug Administration regulation to label products with their *trans* FA content in the Nutrition Facts panel (1). This new regulation responds to the recognition among scientists that *trans* FA have unfavorable effects on blood cholesterol levels and thus increase the risk for coronary heart disease (2). The 2005 Dietary Guidelines for Americans recommend that consumers keep their intakes of *trans* FA as low as possible (3). Food manufacturers have already begun to respond by reformulating foods that contain hydrogenated vegetable oils, the main source of *trans* FA in the diet, to contain other oils with lower or no *trans* FA.

Using traditional breeding methods, developers have created a new variety of soybean that produces oil with a reduced level of α-linolenic acid (18:3n-3). Such soybean oil requires less or no hydrogenation to be used in many processed foods, thus providing opportunities for consumers to reduce their intakes of *trans* FA. It is possible that using this new soybean oil to reformulate foods could result in changes in the intake of other FA. The purpose of this study was to estimate the impact of replacing hydrogenated soybean oil (HSBO) in several current food applications with low linolenic acid soybean oil (LLSO) or a hydrogenated version of low linolenic soybean oil (H-LLSO) on the intakes of total *trans* FA and of five FA.

The key difference in composition of oil between low linolenic acid soybeans and traditional soybeans is the α-linolenic acid content: about 2.5% vs. about 7% of FA. Changes in other FA are small and within the range of variability of traditional soybean oil. However, because traditional soybean oil must be hydrogenated to be used in many food applications whereas LLSO can be used without hydrogenation, the FA content of foods made with LLSO will be different, most notably with respect to *trans* FA, compared with foods made with HSBO.

MATERIALS AND METHODS

Food consumption and composition data sources. Detailed food consumption data for the U.S. population were obtained from the USDA's Continuing Survey of Food Intakes by Individuals (CSFII), 1994–1996, and 1998 (4). Each person reported food intakes for two nonconsecutive days. For these analyses, an average daily intake over the 2 d was computed for each of five FA: palmitic, stearic, oleic, linoleic (all-*cis* isomer), and α-linolenic (all-*cis* isomer), and for total *trans* FA (the sum of *trans* isomers of oleic acid, linoleic acid, and α-linolenic acid).

The CSFII (4) is a large survey specifically designed to allow the estimation of food and nutrient intakes by the U.S. population. The CSFII and its predecessor surveys have been used by the U.S. Department of Agriculture for more than 70 yr to estimate food and nutrient intake and to evaluate the impact of proposed policy changes. Households and individuals were surveyed in all four seasons and on all days of the week. Approximately 16,000 individuals participated in the surveys. The CSFII 1998 added intake data from 5,559 children ages birth through 9 yr to the intake data collected from 4,253 children of the same ages participating in the CSFII 1994–96.

Because the CSFII database does not have *trans* FA compositions for the HSBO component of foods, we extrapolated from the USDA's database of the FA profiles, including *trans*-FA, of 214 foods (5). When this database did not provide the FA profiles for specific versions of HSBO used to prepare certain foods, these FA were estimated, using information from the fats/oils industry (Banks, D., personal communication). The methods used to assign these FA profiles to HSBO in foods are described in detail below.

Exponent's proprietary software program, FARE™(developed by Durango Software, LLC, Bethesda, MD), was used to

Abbreviations: CSFII, Continuing Survey of Food Intakes by Individuals; H-LLSO, hydrogenated low linolenic acid soybean oil; HSBO, hydrogenated soybean oil; LLSO, low linolenic acid soybean oil.

analyze the CSFII data and estimate the intakes of total fat and FA from soybean oil in the diet (E_t) using the formula below. The intake of each food reported by each CSFII respondent $(Fc)_i$ (g/person/d) was multiplied by the soybean oil content of the food (SBO_f) (g/100 g food). Daily intakes of FA from soybean oil were calculated by multiplying the soybean oil intake by the assigned FA content of that soybean oil (FA_s), as described below. Mean and 90th percentile per capita dietary intakes for the total population and for eight age/sex groups were calculated as g/d:

$$E_t = \sum_i (\mathrm{Fc})_i (\mathrm{SBO}_f)_i (\mathrm{FA}_s)_i \quad [1]$$

where i = number of different food types consumed daily, Fc = amount of food consumed (g/d), SBO_f = soybean oil in food (g/100 g food), and FA_s = FA content of soybean oil (g/d).

Other publicly available statistical software programs such as SAS can be used to evaluate data from CSFII. The FARE™ software is currently used by the Center for Food Safety and Applied Nutrition (CFSAN) within the U.S. Food and Drug Administration.

We used a five-step process to determine the potential impact of substitution of LLSO for current versions of HSBO, as described below in detail.

Step One: Determination of current total fat intake and intake of five FA and trans FA. In using the CSFII database described above, the first step was to determine the mean and 90th percentile intakes of total fat, five FA, and total *trans* FA from all foods for the population and for eight age/sex groups.

Step Two: Determination of current total soybean oil intake and the categories of foods that are the major contributors to the dietary intake of soybean oil. The second step was to determine the mean and 90th percentile intakes of soybean oil. This was accomplished by identifying all foods in the CSFII surveys that contained soybean oil, whether hydrogenated or not, and multiplying the amount of soybean oil in the food by the amount of food consumed.

The categories of foods that contain hydrogenated (or partially hydrogenated) soybean oils were established by examining the FA composition of foods in the USDA *trans* FA database whose only added fat was provided by soybean oil and applying the following criteria: soybean oil-containing foods with *trans* FA concentrations greater than about 5% and α-linolenic acid levels less than about 4% were considered to be made with hydrogenated or partially hydrogenated soybean oil. The food categories of meat, poultry and fish mixtures, and egg dishes were divided into those prepared commercially or in restaurants vs. those prepared in the home. Foods in these categories that were prepared commercially or in restaurants were assumed to be prepared using HSBO, whereas those prepared in the home were assumed to be prepared with unhydrogenated, bottled soybean oil.

Step Three: Assignment of FA compositions to the soybean oils currently used in foods. In step three, a FA composition was assigned to all soybean oils currently used in foods. This step allowed the determination of baseline FA intake from soybean oils in all foods. The soybean oils used in foods can be unhydrogenated or hydrogenated to different degrees. Unhydrogenated soybean oil was assigned the FA composition presented in USDA's *trans* FA database, line #107, which describes a salad dressing made with unhydrogenated soybean oil. This FA profile was assumed to represent all unhydrogenated soybean oil (see Table 1). HSBO can have a number of FA compositions depending on the extent of hydrogenation. For example, light hydrogenation results in a small reduction in α-linolenic acid in soybean oil, whereas heavy hydrogenation results in virtually complete loss of α-linolenic acid and the creation of high proportions of *trans* FA. Changes in other FA in soybean oil also occur as a result of hydrogenation.

Since it is not possible to know the precise FA compositions for the various HSBO used in the several thousand foods made with soybean oil, we estimated a soybean oil FA composition for each category of food. We used the USDA *trans* FA database to assign FA compositions to the different types of soybean oils used in different food categories.

TABLE 1
FA Compositions of Low Linolenic Acid Soybean Oil Before and After Hydrogenation, and Comparator Soybean Oils

	% FA[a] (g/100 g fat)					
Soybean oil	16:0	18:0	18:1*c*	18:2n-6	18:3n-3	Total/*trans* FA
LLSO[b]	10.2	4.6	21.9	54.4	2.4	0.4
LLSO-hydrogenated[c]	10.2	11.3	40.0	3.1	0	30.3
USDA *trans* FA database, #107[d]	10.1	3.6	21.2	51.3	6.8	0.7
USDA *trans* FA database #107, hydrogenated[c]	10.1	10.2	38.7	3.1	0	31.4
All purpose, industrial, hydrogenated USDA/FNIC#04652[e]	10.8	12.1	30.2	4.4	0.2	32.8

[a]Values determined as % FA were converted to % fat by multiplying by 0.96.
[b]Low linolenic acid soybean oil (LLSO) was extracted and analyzed for FA composition using standard AOCS GC method #Ce 1b-89 (6).
[c]A mathematical modeling procedure was applied to derive the FA composition of the oil after theoretical hydrogenation (7).
[d]Item #107 in the USDA *trans* FA database (5) is a salad dressing made with unhydrogenated soybean oil as the only source of fat. Its FA composition is assumed to represent that of all unhydrogenated soybean oil used in this study.

Potato products							
French fries (fast food and home)	Avg. of #81, 82, 83	11.1	9.3	30.2	15.1	0.8	20.1
Potato chips and puffs	(Banks, D., personal communication)	10.8	5.4	34.1	27.5	0.8	17.3
White potatoes, mashed, stuffed, puffs	#88	10.7	6.7	30.0	15.0	1.5	30.4
Creamy salad dressings	(Banks, D., personal communication)	10.2	5.1	25.9	34.6	2.7	14.4
Bread	Avg. of #7, 9, 47	11.9	5.8	24.7	35.9	3.0	5.2
Salty snacks from grain products	Avg. of #174, 175, 176, 177	11.2	10.4	30.7	8.9	0.3	31.1
Crackers	#27	9.6	7.3	31.5	4.6	0.3	36.1
Grain mixture dishes (burritos,enchiladas, tacos, other ethnic mixed dishes)	Hydrogenated #107 (Table 1)	10.1	10.2	38.7	3.1	0	31.4
Egg dishes (commercial/restaurant)	Avg. of #81, 82, 83	11.1	9.3	30.2	15.1	0.8	20.1

[a]Corresponds to food items as numbered in Reference 5.
[b]Values from the USDA *trans* FA database (5), expressed as g FA per g of food, were converted to g FA per 100 g fat by dividing the g FA per 100 g food by the g of total fat (expressed per 100 g food). H-LLSO, hydrogenated LLSO; for other abbreviations see Table 1.

The FA profiles for the soybean oils in 10 food categories that use hydrogenated oils (food categories in which LLSO was substituted for HSBO in subsequent analyses) are presented in Table 2. The FA profiles for the soybean oils used in other foods are presented in Table 3 (the remaining food categories for which no soybean oil substitutions were made). The sources of the data are presented in both tables. These FA compositions are based either on a single, representative food in the USDA *trans* FA database whose only added fat ingredient is soybean oil, or are an average of several similar foods whose only fat ingredients are soybean oil. For example, the FA composition of stick margarine is represented by item #88 in the USDA *trans* FA database, while averaging items #81, 82 and 83 represents the FA composition of French fries. In the case of grain mixture dishes, an HSBO similar to that used in baked goods was used. In the case of commercial/restaurant-prepared meat/poultry/fish mixtures and egg dishes, an HSBO like that used to prepare French fries was used. No examples of potato chips made only with soybean oil were identified in the USDA *trans* FA database, and the USDA reported wide variability in the composition of soybean oils used in creamy salad dressings. For these foods, information was obtained from the fats/oils industry (Banks, D., personal communication). In the case of baked goods, the FA composition of an HSBO, suitable for baked goods, was applied to all foods in that broad food category. Table 1 explains how this FA composition was derived.

Step Four: FA consumption from soybean oil. Once the FA profiles for the soybean oils currently used in all food categories in the CSFII database were assigned, an analysis was performed to provide the baseline intakes of five FA and *trans* FA from soybean oil for the total population at the mean and 90th percentile, and by age/sex groups.

Step Five: Determination of the impact of substitution of LLSO for HSBO in 13 categories of foods on intake of total trans FA and five FA. The final step was to analyze the impact on FA intake if LLSO were substituted for existing versions of HSBO. It was assumed that foods currently made with unhydrogenated soybean oils would continue to use existing varieties of soybean oils because manufacturers would be unwilling to pay a higher price for an oil whose additional stability is not needed. Thus, foods such as mayonnaise and oil and vinegar salad dressings were not included in the substitution analysis. Categories of foods that provided <0.2 g/d of soybean oil (<1% of the total) were not modified in the evaluation of the impact of substitution by LLSO since these categories would not contribute meaningful levels of individual FA to the overall intake.

Because the soybean oils used in baked goods typically must be heavily hydrogenated, LLSO *per se* would not be able to provide the needed functionality. However, since it is possible that LLSO could be hydrogenated to be used in baked goods, it was assumed that a hydrogenated version of LLSO

[a]Corresponds to food items as numbered in Reference 5. For abbreviations see Tables 1 and 2.

(H-LLSO) could be substituted for HSBO used in baked goods. The FA composition of LLSO is provided in Table 1. A hypothetical FA composition for H-LLSO was derived by applying a formula to achieve the same solid fat index as in regular HSBO for bakery applications (Table 1). The FA composition of unhydrogenated soybean oil as provided in the USDA FA database (line #107) can be compared with the estimated hydrogenated composition when this formula is applied to the original composition. This calculated composition of HSBO is very close to that for a hydrogenated, industrial soybean oil provided in the USDA Nutrient Composition Database (8).

Thus, in this analysis LLSO was substituted for existing versions of HSBO used in 9 food categories (other than baked goods) and H-LLSO for existing versions of HSBO used in baked goods. It was assumed that there would be 100% substitution of LLSO or H-LLSO for current versions of HSBO for the 10 categories of foods identified for substitution. These results were then compared against baseline values of intakes of FA from soybean oil currently used in all foods.

RESULTS

The baseline analysis indicated that per capita total fat intake by Americans was 72.8 g/d at the mean and 122.1 g/d at the 90th percentile (Table 4). Table 4 also shows the overall population intakes of individual FA, including *trans* FA. The population mean *trans* FA intake was 5.6 g/d, and at the 90th percentile, 10.4 g/d. Table 4 also shows the intakes of FA expressed as % energy. *Trans* FA provided 2.6% energy at the mean and 3.1% at the 90th percentile. The population mean intake of α-linolenic acid was 0.9 g/d (0.4% energy), and 1.6 g/d (0.5% energy) at the 90th percentile. Tables 5 and 6 provide the intakes of total fat and FA by age/sex groups in g/d. Data expressed as % energy by age/sex groups were essentially identical to those determined for the total population, as shown in Table 4, and are not shown in Tables 5 and 6.

To validate the results of our baseline analysis, we compared our results with those reported by Allison *et al.* (9). In that study, the CSFII 1989–1991 database was analyzed for total fat and FA, including *trans* FA. A comparison of our results with those of Allison *et al.* is shown in Table 7.

The small differences in FA intakes between the results of this study and those reported in the Allison *et al.* study could be due to small changes in the American diet between the time the two survey databases were collected, 1989–1991 and 1994–1998. Another possible explanation is that we applied a somewhat more hydrogenated nature to the soybean oils in our analysis vs. those used by Allison *et al*. This would account for

the fact that we estimated slightly less α-linolenic and linoleic acids and slightly more *trans* FA than those reported by Allison *et al*. The lack of published data for the compositions of HSBO used in specific foods may also contribute to the minor differences observed in Table 5. This lack of published data requires estimations about the FA compositions of various soybean oils, and it is not surprising that different analyses provide somewhat varied results. Overall, there was good agreement between the results of this study and those of Allison *et al*.

Table 8 provides data on the mean and 90th percentile intake of soybean oil for the total population and by age/sex groups. Population mean intake was 21.8 g/d, and at the 90th percentile, 44.3 g/d. These data show that soybean oil contributes about one-third of the intake of total fat in the U.S. diet.

As shown in Table 9, the top 10 food categories containing HSBO account for 14.7 g of the 21.8 g/d mean total soybean oil consumption. These 10 food categories were the targets of LLSO or H-LLSO substitution in subsequent analyses.

Table 10 shows the mean and 90th percentile per capita intakes of FA from soybean oil by the U.S. population. The analysis was repeated for age/sex groups, and the results by age for males and females are presented in Tables 11 and 12, respectively. The mean intake of *trans* FA from soybean oil was 3.6 g/d (1.7% energy), and at the 90th percentile was 8.0 g/d (2.4% energy). These data form the baseline reference against which the effects of substitution of LLSO on intake of FA from soybean oil are measured.

Tables 13–15 provide data on the mean and 90th percentile per capita intakes of FA from soybean for the U.S. population and by age/sex groups after LLSO was substituted for HSBO in nine categories of foods and H-LLSO was substituted for HSBO in baked goods. These substitutions resulted in a decrease in mean *trans* FA intake from soybean oil from 3.6 to 1.1 g/d (1.7 to 0.5% energy), and at the 90th percentile, from 8.0 to 3.4 g/d (2.4 to 1.0% energy) (Tables 10 and 13). Tables 11 and 14 show the impact of this substitution on the FA intakes of males, and Tables 12 and 15 show the impact on that of females. Males ages 9–19 and 20–49 yr at the 90th percentile had baseline *trans* FA intakes from soybean oil of 10.5 g/d. These are the highest levels of *trans* FA intakes from soybean oil observed in this analysis. After substitution with LLSO and H-LLSO, *trans* FA intakes from soybean oil in these two age/sex groups decreased to 3.9–4.1 g/d, about a 62% reduction. Females ages 9–19 and 29–49 yr at the 90th percentile had baseline *trans* FA intakes from soybean oil of 7.9 and 7.1 g/d, respectively. After LLSO and H-LLSO substitution, *trans* FA intakes from soybean oil decreased to 3.4 and 2.9 g/d for females in the 9–19 and 20–49 yr age/sex groups, respectively, or reductions of about 57%.

Intake of α-linolenic acid, an essential ω-3 FA, from soybean oil did not decrease at the mean or 90th percentile intakes as a result of substitution of LLSO for HSBO in the nine categories and H-LLSO in baked goods. The mean baseline intake of α-linolenic acid from soybean oil was 0.6 g/d, and at the 90th percentile was 1.3 g/d. After LLSO and H-LLSO substitution as described above, there were 0.1 and 0.2 g/d increases at the mean and 90th percentile, respectively (Table 10 vs. 13).

[a]For footnote see Table 4.

All age/sex groups at both mean and 90th percentile intakes showed either no change or small increases in intakes of α-linolenic acid from soybean oil as a result of substitution of LLSO and H-LLSO for current versions of HSBO (Table 11 vs. 14 and Table 12 vs. 15).

Substitutions of LLSO and H-LLSO caused very small changes in the remaining FA, generally less than 2 g/d, with the exception of intake of linoleic acid from soybean oil, which approximately doubled at both the U.S. population mean and 90th percentile intakes (Table 10 vs. 13). These same results also were observed for all age/sex groups at both the mean and 90th percentiles of intake (Table 11 vs. 14; Table 12 vs. 15).

Figure 1 shows the overall dietary impact of substitution of LLSO or H-LLSO for HSBO in 10 food categories, expressed as % energy. Substitution of LLSO or H-LLSO resulted in an overall reduction in *trans* FA intake of about 1.2% energy (2.5 g/d) at the mean and about 1.4% energy (4.6 g/d) at the 90th percentile. Thus, postsubstitution, the total *trans* FA intake decreased from 2.6 to 1.4% energy at the mean, and from 3.1 to 1.7% energy at the 90th percentile. Changes in intakes of other FA were small, within 1% energy, with the exception of linoleic acid, which could increase by about 2–2.5% energy. This increase in linoleic acid intake results from the fact that LLSO has a linoleic acid content of about 54% whereas the linoleic acid content of partially HSBO is reduced due to the hydrogenation of linoleic acid to oleic and/or stearic acids as well as to *trans* FA.

Total *trans* FA	5.6	5.3

DISCUSSION

This analysis shows that substitution of LLSO and H-LLSO for HSBO can result in meaningful decreases in consumer intakes of *trans* FA from soybean oil with no reduction in intake of α-linolenic acid, an essential ω-3 FA. HSBO has been a major source of *trans* FA in the diet. As estimated in this study, HSBO provided 3.6 g/d *trans* FA at the mean intake (1.7% energy), and 8.0 g/d at the 90th percentile (2.4% energy). The total diet provided 5.6 g/d *trans* FA at the mean and 10.4 g/d at the 90th percentile (2.6 and 3.1% energy, respectively). Other sources of *trans* FA in the diet include other hydrogenated vegetable oils and animal products. However, since soybean oil provides about 80% of the total intake of vegetable oils in the U.S. diet, and since the *trans* FA in animal products are inherent, it is reasonable to target *trans* FA intake reduction at HSBO. This substitution analysis shows that substitution of LLSO for HSBO in nine food categories and use of H-LLSO in the baked goods category can result in a *trans* FA content of the diet of 1.4% energy at the mean and 1.7% energy at the 90th percentile. These

levels approach those recommended by the Dietary Guidelines Advisory Committee (3).

Soybean oil is among the richest and most abundant sources of α-linolenic acid in the American diet (10). This study showed that soybean oil contributed 0.6 g/d on average (67%), and 1.3 g/d at the 90th percentile (81%), to total α-linolenic acid intake. Canola and flax seed oil have higher concentrations of α-linolenic acid than soybean oil, but the consumption of these oils by Americans is small. Nuts such as walnuts are also rich sources, but again, intakes are low. This analysis has shown that substitution of LLSO or H-LLSO for HSBO in 10 food applications does not result in a lowering in the dietary intake of α-linolenic acid. Although the α-linolenic acid content of LLSO is 2.4%, lower than the level in unhydrogenated soybean oil (about 7%), LLSO is intended to substitute for a variety of HSBO, which are as low in α-linolenic acid as LLSO, if not lower. As shown in Table 2, the estimated α-lino-

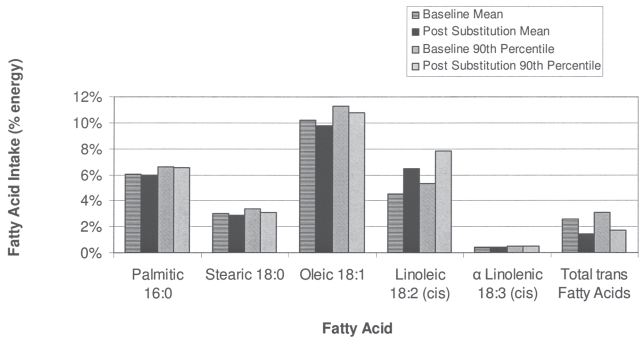

FIG. 1. Total dietary intake of FA: baseline vs. post-LLSO, H-LLSO substitution and U.S. per capita mean and 90th percentile (% energy). LLSO, low linolenic acid soybean oil; H-LLSO, hydrogenated LLSO.

lenic acid composition of the HSBO used in processed foods ranges from zero to 3.9%. Thus, when the impact of substitution is considered across this range of HSBO, it becomes clear why LLSO had no impact on intake of α-linolenic acid.

Changes in intakes of other FA associated with substitution of LLSO and H-LLSO for HSBO were within the range of normal and nutritious dietary intakes. It is important to note that use of LLSO or H-LLSO did not raise the intake of saturated FA but did raise the intake of linoleic acid by a few grams per day on average. Thus, the overall combination of effects on FA intake, i.e., a reduction in *trans* FA, no increase in saturated FA, an increase in linoleic acid, and no decrease in α-linolenic acid, is consistent with the 2005 Dietary Guidelines for Americans (3).

This analysis assumed 100% market penetration of LLSO for current versions of HSBO in nine food categories and of H-LLSO in baked goods. This assumption allows one to see the extremes of substitution on FA intakes. It is likely that the marketplace will use LLSO and H-LLSO at less than 100% penetration and use other substitutes for HSBO besides LLSO and H-LLSO; thus the actual impact on FA intakes will likely be somewhat different from that estimated here. As more options to replace hy-

drogenated oils become available on the market, it will be important to estimate their potential impact on the FA composition of the diet.

A High-Saturated Fat Diet Enriched with Phytosterol and Pectin Affects the Fatty Acid Profile in Guinea Pigs

Gemma Brufau[a], Miguel Angel Canela[b], and Magda Rafecas[a,*]

ABSTRACT: This paper presents the results of a study whose aim was to test the effects of several doses of pectin and phytosterols on the body weight gain and the FA content in female guinea pigs. The treatments resulted from supplementing with pectin and plant sterol a guinea pig diet (rich in saturated FA), following a 3×3 factorial design, with three levels of pectin (0, 3.67 and 6.93%) and three levels of phytosterols (0, 1.37, and 2.45%). Seventy-two female Dunkin Hartley guinea pigs were randomly assigned to the treatment groups (8 animals/group), the duration of the treatment being 4 wk. Pectin dietary intake led to a significant increase in body weight ($P < 0.001$), food consumption ($P = 0.025$), and feed efficiency ($P < 0.001$), but no influence of phytosterols on weight gain or food consumption was detected. We found a significant negative effect of the addition of phytosterols on lauric, myristic, and palmitic acid contents in feces, and a positive effect on their concentration in plasma and liver, but no significant effect on stearic acid content. Apparent FA absorption was assessed by calculating the ratio of FA in feces and diets that the absorption of the different FA could be compared, and the negative effect of phytosterol supplementation on these ratios, especially for lauric and myristic acids, was established.

Paper no. L9877 in *Lipids 41*, 159–168 (February 2006).

During the past several decades, reduction in fat intake has been the main focus of dietary recommendations. In particular, it has been recommended to "choose a diet low in saturated fat and cholesterol and moderate in total fat" to prevent coronary heart disease (CHD) (1,2). Thus, there is a shift going on in nutrition, from the elimination of nutrient deficiencies, toward the possibility of improving health and quality of life. This awareness has lead to the development of functional foods, claiming beneficial effects for consumers. Several studies have shown that the ingestion of bioactive substances, such as soluble fibers (guar gum, psyllium, pectin, and oat products) and phytosterols (stanols and sterols) may have a positive lipidemic effect. As a consequence, they have been incorporated into some foods to reduce LDL-cholesterol levels and therefore prevent the development of CHD (3,4).

The cholesterol-lowering efficacy of plant sterol and stanol esters in food products has been confirmed in a great number of studies (5–10). Several mechanisms have been suggested to explain the action of phytosterols on lipid metabolism. For instance, β-sitosterol and sitostanol reduce plasma total-cholesterol levels through several mechanisms, such as competitively blocking cholesterol absorption from the intestinal lumen (11,12), displacing cholesterol from bile salt micelles (13), increasing bile salt excretion (14), or hindering the cholesterol esterification rate in the intestinal mucosa (15,16). Daily consumption of moderate quantities of phytosterols also has been shown to reduce plasma total-cholesterol by 5 to 13% and LDL-cholesterol by 7 to 16%, in both hyper- (17,18) and normocholesterolemic (19) individuals, without affecting HDL-cholesterol or TAG concentrations.

On the other hand, it is well known that including in the diet soluble viscous fibers such as pectin or guar gum as well as nonfermentable viscous fibers such as psyllium helps to lower plasma cholesterol concentrations (20–24). The soluble fiber action is mainly effected by binding bile acids, thus provoking a reduction in bile acid reabsorption of the small intestine.

Nevertheless, a separate examination of the effect of both phytosterols and pectin on the different FA is needed because there are different pathways of absorption for short-chain and long-chain FA. As early as 1935, Hughes and Wimmer (25) suggested that FA may be absorbed by different routes, according to their chain length. Since then, a number of studies (26) have established the role of the lymph and portal blood absorption pathways.

Finally, it is important to note that the consumption of vegetable shortenings is increasing because of their use in ready-to-eat foods (27) and in deep-fat frying. This is an undesirable development, because the intake of *trans* FA and saturated FA (SFA), which are two of the most important components of Western diets (28,29), is related to an increased risk of cardiovascular disease (1,2).

Therefore, the aim of the present study was to examine the effects of several doses of pectin and phytosterols on FA content in female guinea pigs fed a diet rich in SFA and cholesterol. The comparison of fecal and dietary levels allows us to examine the effects of this type of supplementation to a diet enriched with SFA on the apparent absorption (30–33) of the different FA. It has been reported (34,35) that results regarding apparent absorption were similar to those obtained using stable isotopes. Moreover, it is also important to determine the FA content in some biological tissues, such as liver and plasma.

The guinea pig was chosen as the animal model owing to its similarities with humans (LDL/HDL ratio, distribution of

Abbreviations: CHD, coronary heart disease; MUFA, monounsaturated FA; SFA, saturated FA.

cholesterol pools, and activities of main enzymes regulating cholesterol metabolism), and because guinea pigs respond to dietary treatments by changing plasma cholesterol concentrations in the same way as humans do (36).

MATERIALS AND METHODS

Materials. All FAME standards (12:0, 14:0, 16:0, 18:0, 18:1n-9, 18:2n-6, 18:3n-3, 19:0, and 21:0), with purity greater than 99%, were purchased from Sigma Chemical Co. (St. Louis, MO). The identification of FAME was made with FAME Mix, C_4–C_{24} (Supelco, Bellefonte, PA).

Boron trifluoride in methanol (1.7 mol/L) and *n*-hexane were purchased from Merck (Darmstadt, Germany), and sodium chloride and anhydrous sodium sulfate from Panreac (Barcelona, Spain). Sodium methylate (0.5 mol/L) was prepared by dissolving 17 g of sodium in 1 L of dry methanol.

Diets. Nine isocaloric diets, designed to meet all the nutritional requirements for guinea pigs, were prepared by Mucedola SRL (Settimo Milanese, Italy). The composition of all diets was similar, except for the content of pectin and phytosterols. Pectin was purchased from CP Kelco (Atlanta, GA). We used GENU-type Freeze pectin, which is a high (methyl) ester pectin (containing more than 50% of the carboxylic acid as methyl esters). This kind of pectin is a mixture of high-ester pectin extracted from citrus peel and α-amylolytic enzyme complex, which is standardized by addition of sucrose. Plant sterols were esterified with unsaturated FA (Raisio, Helsinki, Finland).

The treatments resulted from the addition of pectin and plant sterols, following a 3×3 factorial design, with three levels of pectin, denoted by PE0 (0%), PE1 (3.67%), and PE2 (6.93%), and three levels of phytosterols, denoted by PH0 (0%), PH1 (1.37%), and PH2 (2.45%). The chemical composition of the diets is shown in Table 1. The FA content in each diet was determined by the method proposed by Lopez-Lopez *et al.* (37).

Table 2 shows the content (μg/mg) of seven FA (12:0, 14:0, 16:0, 18:0, 18:1n-9, 18:2n-6, and 18:3n-3) in the nine diets. The presentation of results in this article is restricted to these seven FA, selected by their accumulation pattern and the differences observed in feces. The addition of pectin did not affect the total FA content but, since phytosterols were esterified with unsaturated FA, the FA profile was modified.

The SFA fraction ranged from 84 to 96% of the total FA content of the diet. The monounsaturated FA (MUFA) fraction was much smaller, but the most variable, ranging from 2 to 11% owing to the variations in the oleic acid content (Table 2). The PUFA fraction fluctuated from 1 to 5% of the total FA content. The main SFA was lauric acid (40–47%), followed by myristic acid (about 16%) and palmitic and stearic acids, with similar levels (9–10%). Also relevant was the presence of short-chain SFA, essentially 8:0 and 10:0, which accounted for 10% of the total FA content; however these are not reported in Table *2*, since their content in feces was below 1%. Oleic acid was the main unsaturated FA, presenting also the highest variation across diets (2–10%).

Animals. Seventy-two female Dunkin Hartley guinea pigs, supplied by Harlan Interfauna Ibérica (Barcelona, Spain) and weighing 300–350 g, were randomly assigned to the treatment groups (8 animals/group). The duration of the treatment was 4 wk. The guinea pigs were housed two per cage in a light-cycle room (light from 0800 to 2000), with free access to feed and water. They were killed by heart puncture after halothane anesthesia. Blood samples were obtained by means of an intracardiac extraction, and liver was extracted after the sacrifice and homogenized. Feces were collected with a 2-d periodicity and freeze-dried immediately. All procedures were approved by the Animal Care and Use Committee of the University of Barcelona.

FA analysis. The FA content in feces and in diets was determined with the method of Lopez-Lopez *et al.* (37). To determine the FA concentration in liver and plasma, we used a

PE2/PH2	6.9	2.45	18.1	19.5	29.2	11.8	6.7

[a]All diets had been enriched with 0.33% of cholesterol.
[b]Added on top of the basal diet. The plant sterol ester mixture was mixed into the feed and comprised 6.4% brassicasterol, 24.9% campesterol, 1.0% campestanol, 18.5% stigmasterol, 45.6% β-sitosterol, 1.8% sitostanol, 0.9% Δ5-avenasterol, and 1.0% other sterols. PE0, PE1, PE2, pectin levels of 0, 3.67, and 6.93%, respectively; PH0, PH1, and PH2, phytosterol levels of 0, 1.37, and 2.45%, respectively.
[c]Protein content was casein; fat was hydrogenated coconut oil; sugars were corn starch, dextrose, and sucrose; and insoluble fiber was cellulose.
[d]Vitamin and mineral mixes were adjusted to meet National Research Council requirements for guinea pigs. A detailed composition of the vitamin and mineral mix has been reported by Krause and Newton (36).

method described elsewhere (38) but with some modifications to adapt it to our samples, followed by a double methylation to obtain FAME.

(i) Determination of FA content in feces. First, 25 μL of internal standard (21:0, 466 μg/mL) was added to 50 mg of freeze-dried fecal homogenate. Then, a small magnetic stirring bar was added and the sample was saponified with 1 mL of sodium methylate (0.5 mol/L) and heated in a water bath at 90°C for 15 min. The tubes were removed from the water bath and cooled in another water bath at room temperature. Then, 1 mL of boron trifluoride/methanol (1.7 mol/L) was added. Next, the tubes were placed in the water bath at 90°C for 15 min and subsequently cooled as before; 400 μL of *n*-hexane was then added. The tubes were shaken, and 1 mL of a saturated solution of sodium chloride in distilled water was added, followed by centrifugation. The clear *n*-hexane top layer, containing the FAME, was transferred to another tube, and a small quantity of anhydrous sodium sulfate was added. The tubes were stored at −20°C until the contents were injected into the gas chromatograph.

(ii) Determination of FA content in liver. Hepatic homogenate (between 0.8 and 1.0 g) was weighed into a 32 × 210 mm tube, and 200 μL of internal standard (21:0, 466 μg/mL) was added. Just before homogenization, 20 mL of chloroform/methanol (2:1, vol/vol) was added. The tube contents were homogenized (30 s, 12,000 rpm) in a Polytron PT 3000 (Kinematica, Lucerne, Switzerland), keeping the tubes in an ice bath. The extract was filtered through a Whatman No. 1 filter paper into a 50 mL screw-capped tube, and the residue was re-extracted twice (10 mL) with the same solvent. Next, 10 mL of water was added to the tube and, after centrifugation (20 min, 750 × *g*), the chloroform phase was filtered through anhydrous sodium sulfate (Whatman No. 1 filter paper), which was then washed twice with 10 mL of chloroform. The lipid extract obtained was dried in a vacuum rotary evaporator at 30°C, and re-extracted five times with 2 mL of diethyl ether. The tubes were dried first by a slight nitrogen stream and then by keeping the flask in a vacuum desiccator at 10 mmHg overnight.

After lipid extraction, a small magnetic stirring bar was added, and the samples were saponified with 2.5 mL of sodium methylate (0.5 mol/L) and heated in a water bath (90°C, 20 min). After that, the tubes were cooled in a water bath at room temperature, and 3 mL of boron trifluoride/methanol (1.7 mol/L) was added. Next, they were placed in the water bath at 90°C for 20 min, subsequently cooled as before, and 2 mL of *n*-hexane was added. The tubes were shaken, and 3 mL of a saturated solution of sodium chloride in distilled water was added, followed by centrifugation. The clear *n*-hexane top layer, containing the FAME, was transferred to another tube, and a small quantity of anhydrous sodium sulfate was added. The tubes were stored at −20°C until the contents were injected into the gas chromatograph.

(iii) Determination of FA content in plasma. Plasma (100 μL) was added to a tube containing 25 μL of internal standard (19:0, 996 μg/mL). Then, 3 mL of chloroform/methanol (2:1, vol/vol) was added and mixed. After that, 0.75 mL of 0.8% aqueous NaCl was added, mixing again. After centrifugation (7 min, 1025 × *g*), the chloroform phase was transferred to another tube, and the aqueous one was washed with 3 mL of chloroform. The lipid extract obtained was dried with a slight nitrogen stream, keeping the flask in a vacuum desiccator at 10 mmHg overnight. The double methylation was done in the same way as in hepatic samples, but instead of using 2.5 mL of sodium methylate and 3 mL of boron trifluoride/methanol, 1 mL of each was used. FAME were obtained by adding 400 μL of *n*-hexane to tubes, followed by 1 mL of a saturated solution of sodium chloride in distilled water. The clear *n*-hexane top layer, containing FAME, was transferred, adding a small quantity of anhydrous sodium sulfate. The tubes were stored at −20°C until injection into the gas chromatograph.

GC conditions. FAME were analyzed with an Agilent 4890D gas chromatograph, equipped with an FID. The separation of FAME was done in a fused-silica column (60 m × 0.20 mm i.d., 0.2 μm). The split-splitless injector was used in split mode with a ratio of 1:30. Injector and detector temperatures were kept at 270 and 300°C, respectively. For feces analysis the oven temperature was programmed as follows: an initial period of 5 min at 100°C, followed by an increase of 4°C/min, up to 235°C, and a final period of 2 min at this temperature. In liver samples the oven program started with a period of 5 min at 140°C, followed by an increase of 1.8°C/min until 180°C, followed by another increase of 7.5°C/min until 235°C. Finally, for FAME determination in plasma samples, the initial temperature was 170°C (11 min), being for the rest the same as in liver samples.

[a]Mean of consumption (g/d/animal) ± SD.
[b]Mean of body weight (g) ± SD. For abbreviations see Table 1.

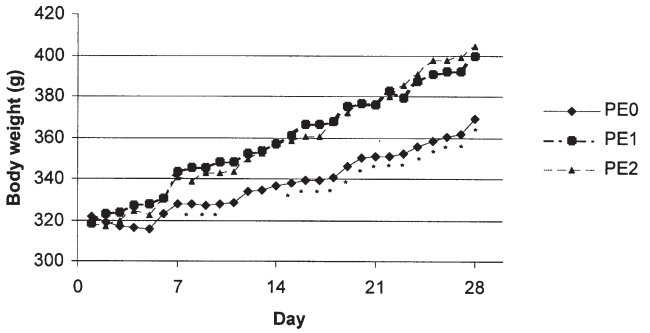

FIG. 1. Mean body weight curves for different pectin levels. PE0, PE1, and PE2, pectin levels of 0, 3.67, and 6.93%, respectively. An asterisk (*) means significant differences among diets ($P < 0.05$).

Helium was used as the carrier gas. Chromatographic peaks were identified by comparing the retention times with those of known standards and by cochromatography. FAME quantification was performed by the internal standard addition method.

Statistical analysis. The effects of the treatments on body weight gain and FA content were tested by two-way ANOVA with the amount of pectin and phytosterols as factors. Since an assumption of homogeneity of variance in the case of food consumption (Table 3), where coefficients of variance range from 4 to 43%, was unrealistic, we used the Kruskal–Wallis test to assign a significance level to the pectin supplementation effect.

On the other hand, since the FA profile of the diets changes with phytosterol supplementation, as a result of esterification, the phytosterol effect can be confounded with a diet effect, especially for the MUFA and PUFA. To account for these diet effects, we performed the statistical analysis, for the different FA considered, for both the content and the tissue/diet ratio. For the liver, dividing the numbers of Table 5 (see below) by those of Table 1 gives a set of percentages that can be interpreted as the percentages of the different FA that are incorporated into liver. For plasma, assuming unit density, the ratio comes in a 1/100 scale since the results in plasma are given in µg/mL whereas those in liver are given in µg/100 mg, but the interpretation is the same.

The significance of the differences in FA content and incorporation ratios was also tested by two-way ANOVA. We used SPSS 11.0 (Erkrath, Germany) in the calculations. As usual, $P < 0.05$ was considered significant.

RESULTS

Food intake and body weight. Guinea pigs were healthy throughout the feeding period except for four animals (6%) from groups PE0/PH2, PE1/PH0, PE1/PH2, and PE2/PH1 that died. No relation was found between the diets and the death of these animals. These deaths were taken into account in all measurements, such as body weight, food intake, and FA concentrations. Treatment means (±SD) of food consumption and body weight are shown in Table 3. Although no relevant effect of phytosterol supplementation was detected, we observed a decrease in food consumption from PE1 to PE2, and an increase in body weight from PE0 to PE1. Overall significance tests on pectin effect gave $P = 0.025$ for food consumption and $P < 0.001$ for body weight.

As shown by the curves of Figure 1, all groups gained weight during the study. The differences in weight increase in successive periods were tested. Whereas the pectin effect was significant ($P < 0.001$) from the second week, as shown in Figure 1, the phytosterol effect was not significant (data not shown). Feed efficiency was significantly higher ($P < 0.001$) in the animals fed with pectin than in those fed without, but the phytosterol effect again was nonsignificant.

Fecal FA. The mean content in feces of the seven FA of Table *2* can be seen in Table 4. Comparing the figures in Table 4 with those in Table 2 reveals that the total FA was lower in feces than in the diet, suggesting that fat was better absorbed than the other components of a guinea pig standard diet. Nevertheless, there was a great variability in absorption across the FA spectrum.

Using the ratio of the mean content in feces divided by the content in diet, for the different components of the FA spectrum, we have a rough assessment of apparent absorption. First, we found an overall ratio of 0.35 for total FA. The ratios of the SFA fraction were clearly related to chain length. Thus, the short-chain SFA (8:0 and 10:0) were almost completely absorbed. For the medium- and long-chain SFA, the ratios ranged from 0.12 in lauric acid to 1.07 in stearic acid, with intermediate values for myristic (0.36) and palmitic (0.74) acids. Palmitic and stearic acids were the only ones for which the fecal content was higher than the diet content. MUFA and PUFA ratios must be evaluated more cautiously, since we were dealing with a diet containing highly SFA. Anyway, the ratios for these three FA as reported in Tables 2 and 4 were similar (around 0.16).

Such a variability in fat absorption calls for a separate analysis of the supplementation effects on the different FA. The effect of phytosterol supplementation on the lauric acid content in feces is illustrated in Figure 2, which is a plot of lauric acid content as a function of the phytosterol level, for different levels of pectin. The curves corresponding to levels PE0 and PE1 are remarkably parallel and can be easily related to the variation of the lauric acid content of the diet. The curve corresponding to level PE2 is clearly different, suggesting that high

[a]FA content expressed as μg/mg of total fecal content (SD in parenthesis). For abbreviations see Tables 1 and 2.

levels of pectin supplementation modulated the effect of phytosterol supplementation, although the small sample size did not allow us clarify this point. The ANOVA test yielded $P < 0.001$ for the phytosterol effect and indicated no significance for the pectin and the interaction effect. Since part of the phytosterol effect could be attributed to the increase of lauric acid content in the diet, one could choose to test the ratio of apparent absorption mentioned above. The result was then $P = 0.044$, which is still significant.

The results of myristic acid, not plotted, were very similar, giving again $P < 0.001$ for the feces content and $P = 0.017$ for the ratio of apparent absorption. Looking at the variation in these ratios, one could see that the phytosterol supplementation decreased the amount of lauric and myristic acid that was excreted by 20%, thus increasing the apparent absorption.

The effect of phytosterol supplementation on palmitic acid content is illustrated in Figure 3. The comparison of the curves shows again the combined effect of phytosterol and pectin supplementation. Here, the decrease in the second part of the curve that is related to pectin level PE2 contrasts with the increase in the palmitic acid content of the diet (Table 2). The test of significance for the phytosterol effect was $P = 0.014$. Although there was a decrease in the feces/diet ratio, from 0.89 in the control diet to 0.70 in the PH2/PE2 diet, the test for this ratio indicated no significant difference, so the conclusions about the phytosterol effect cannot be so firm as for palmitic acid. The results for stearic acid, not plotted here, presented a similar pattern, although the supplementation effects were not significant.

For oleic acid in feces, we found no effect of the addition of pectin, but a significant positive phytosterol effect ($P < 0.001$) correlated with the variation in the content of this FA in the diet. Nevertheless, when looking at the feces/diet ratio, the effects were opposite, so the combined phytosterol and pectin supplementation produced a decrease of 20% with respect to the control diet (PE0/PH0). The results for linoleic acid were similar, with a decrease in the feces/diet ratio of 30%.

Finally, the results of linolenic acid were somewhat different. For the content in feces, we found the same highly significant positive phytosterol effect but a significant negative pectin effect ($P = 0.021$). For the feces/diet ratio, we found negative effects. The pectin effect, in particular, was almost significant ($P = 0.083$).

FA content in liver. Table 5 is a summary of the FA content in liver (μg/100 mg) for the different treatment groups. The SFA fraction, which dominated the FA profile, was quite stable (54–58%). Second came the PUFA fraction, which was more variable (19–29%), and then the MUFA fraction (14–23%).

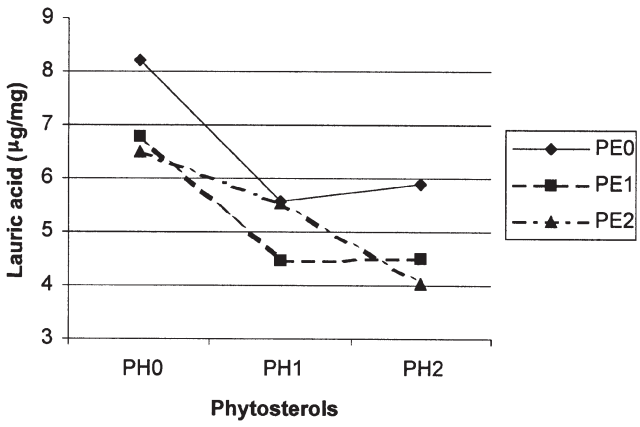

FIG. 2. Concentration (μg/mg) of lauric acid in total feces. PH0, PH1, and PH2, phytosterol levels of 0, 1.37, and 2.45%, respectively; for other abbreviations see Figure 1.

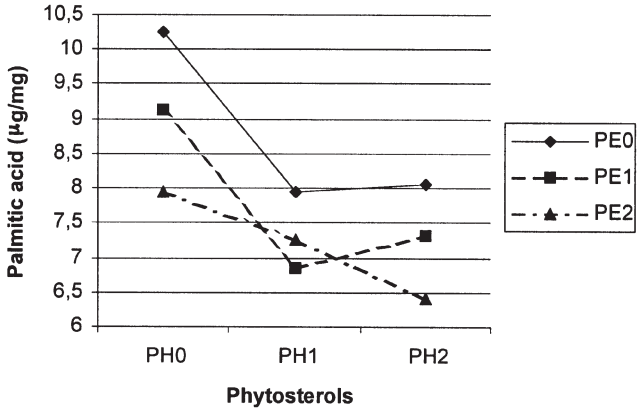

FIG. 3. Concentration (µg/mg) of palmitic acid in total feces. For abbreviations see Figures 1 and 2.

We consistently found, across the different components of the SFA fraction, a nonlinear effect of supplementation, an increase from PH0 to PH1, and a slight decrease from PH1 to PH2. The same effect, but generally weaker, was found for the pectin supplementation. In particular, the highest SFA levels were found when the intermediate doses were combined (PE1/PH1), showing an increase in the SFA liver incorporation ratio from 1.3% in group PE0/PH0 to 2% in group PE1/PH1. The effect of phytosterol on the incorporation ratio was significant ($P < 0.001$), but the pectin effect was not.

Although lauric acid (12:0) was the main component of the FA profile of the diet, it was a minor component in the liver (3–6%), whereas myristic acid (14:0) was more abundant (10–14%). The phytosterol effect on the incorporation ratio was significant in both cases ($P < 0.001$ and $P = 0.002$, respectively), and the pectin effect was not significant. Except for higher doses of pectin (PE2), the phytosterol effect was approximately linear.

Palmitic acid (16:0) was one of the major components of the FA profile in the liver (16–20%). The results for palmitic acid were not significant, although the pectin/phytosterol interaction was almost significant ($P = 0.089$). The content of stearic acid (18:0) was a bit higher (18–23%). Both pectin ($P = 0.002$) and phytosterol ($P = 0.003$) had significant positive effects on this ratio.

The increase in the relative content of oleic acid (18:1n-9) in the diet (2.5–10%) was correlated with the increase in the liver samples (12–16%), but this effect was not significant. The results of linoleic acid (18:2n-6), the last of the major components of the FA profile (12–21%), had a similar pattern, but they were very significant ($P < 0.001$). Finally, for the n-3 PUFA fraction, only linolenic acid was reported, since others were not detected in the diet. The percentage of the n-3 PUFA fraction remained quite stable (11–13%) and was unaffected by changes in these FA in diet.

FA content in plasma. Table 6 is a summary of the FA content in plasma (µg/mL). The percentage of SFA (53–63%) was more variable than in liver, but the levels were similar. Here, palmitic acid was the major component (20–23%), followed by stearic acid (12–14%), myristic acid (10–15%), and lauric acid (4–7%). The percentages of MUFA (19–26%) and PUFA (14–28%) were correlated with the contents of oleic acid and of linoleic and linolenic acids, respectively, in the diet.

The supplementation effects on the total FA content were very clear. As in liver, both pectin and phytosterol supplementation had a nonlinear effect, and the FA content was higher at intermediate doses. As a consequence, the maximal FA content was found when combining intermediate doses (PE1/PH1). For the total FA content, the pectin effect was significant ($P = 0.002$),

[a]FA content expressed as μg/mL of plasma (SD in parenthesis). For abbreviations see Table 1.

whereas the phytosterol effect was not, but both effects were significant for the total SFA content ($P = 0.012$ and $P = 0.050$, respectively). Much more significance was found in the plasma/diet ratio, especially for the phytosterol effect ($P < 0.001$). In absolute terms, the type of supplementation used in this study could increase by 50% the total FA content (from 1409 μg/mL in group PE0/PH0 to 2182 μg/mL in group PE1/PH1), without increasing the content in the diet. A similar increase was found in the total SFA content. This pattern was consistently found in all SFA fraction. The effects were stronger for stearic acid and weaker (in decreasing order) for myristic, lauric, and palmitic acids.

The results for oleic acid were again nonsignificant. For linoleic acid, the pectin effect showed the same pattern as in the SFA fraction and was significant ($P = 0.007$). The phytosterol effect was confounded with a diet effect, being positive when the plasma content was used for the comparison, but negative for the plasma/diet ratio. The levels of n-3 PUFA in plasma were very low.

DISCUSSION

Although many research groups in the last 50 years have studied the role of phytosterols and pectin as cholesterol-lowering compounds (7,9,10,20,39–42) few studies have been conducted to determine how these compounds may affect FA metabolism. In the present study, we examined the effect of phytosterol supplementation, added to a diet rich in SFA, on the content of certain FA in plasma and liver and how this effect can be changed when pectin is also supplemented. We decided to add these compounds to a SFA-enriched diet since most of the studies used low-fat products as carriers (43,44). However, to our knowledge, no data are available about the effects of the addition of phytosterols and/or pectin to a Western diet (rich in SFA and cholesterol) (28,29).

In our study, we found a negative effect of pectin supplementation on food consumption, and no effect of phytosterol supplementation. Dietary pectin intake also resulted in a significant body weight increase, which agreed with some results described previously (23), although others (21,45,46) did not find such an effect. We found an increase in feed efficiency at higher doses of pectin, contrary to the results of other studies (45,46). The unexpected increase in feed efficiency and body weight may be due to an early breakdown of this fiber in the gut, although we used high-esterified pectin, which is less fermentable than low-esterified (47,48). This might be explained by taking into account the possible interaction between pectin and the source of added fat, since it has been reported that pectin may cause mucosal proliferation in the lower intestinal tract (49), and this effect can be modulated by the source of fat administered (50,51). Further studies are necessary to clarify the interactions between sources of fat and doses of pectin with different degrees of esterification.

On the other hand, our results are consistent with a previous study (52), in which no effect of different doses of phytosterols on body weight was observed. Despite the high amount of fat in diets enriched with phytosterols (Table 1), our results indicate that slight differences in composition of diets had no effect on growth.

Since the supplementation, whose effects are examined in this paper, was made to a standard guinea pig diet, we deal here with a highly SFA profile. This allows us to emphasize our conclusions on SFA profile but calls for some caution when extending the conclusions about MUFA and PUFA absorption to diets with a completely different FA profile.

Whereas the absorption rates of the MUFA and PUFA examined in this paper look quite uniform, with a feces/diet ratio

of about 0.16, those of SFA are clearly related to the chain length, showing big differences from the short-chain FA (8:0 and 10:0) to long-chain FA. Such a variety suggests that any approach to fat absorption must account for the specificities of the different FA, especially of those related to chain length.

The results for lauric and myristic acid are similar and consistent with the fact that both are medium-chain SFA, so that they should have a similar absorption pathway. The concentration of lauric acid in feces is shown in Figure 2, where the interpretation of the curves corresponding to levels PE0 and PE1 is straightforward: Although the decrease in the first segment can be partly attributed to a decrease in the dietary supply of these FA, the second segment shows that at least for the highest doses, phytosterol supplementation has a negative effect on the fecal content of lauric and myristic acids. When relating the feces content to the diet content, we find a significant positive effect on apparent absorption, suggesting that phytosterols added to a diet enriched with SFA increase the absorption of these FA. Although the conclusions about absorption rates for palmitic acid cannot be so firm, the results point in the same direction, that of a negative effect of phytosterol supplementation. Moreover, the results in plasma and liver agreed with their apparent absorption, in which a significant association was also found between SFA and phytosterol intake.

Unsaturated FA are much less abundant in the diets used in this study, and the results for them are not so clear but point in the same direction, toward a positive effect on FA absorption.

On the other hand, the influence of the dietary fiber intake on SFA is not clear. Whereas some authors (53) reported that the effects of dietary fiber intake might counteract the effects of saturated fat intake and thus reduce CHD events, others (39,54,55) did not find any differences in SFA content in biological samples after fiber ingestion. A recent study (56) reported a liver weight gain in rats fed with a fiber mixture. However, in our study, we did not find a direct effect on FA concentrations after fiber feeding, although pectin modulated the phytosterol effect on FA absorption (results not statistically significant).

The main animal studies (3,57–60) show that dietary phytosterols inhibit the atherosclerotic process, although others (61–65) report an association between increased plasma levels of phytosterols and increased risk of CHD in phytosterolemic and nonphytosterolemic subjects. It remains to be shown whether the high serum plant sterol levels caused by long-term plant sterol ester consumption are harmful. However, taking into account that SFA as lauric, myristic, and palmitic acids have been associated with cardiovascular risk (54,66,67), our results may agree with those who found a potential atherosclerotic effect of plant sterols in the way that they are capable to increase biological SFA concentrations.

ACKNOWLEDGMENTS

This study was supported by Programa Nacional de Recursos y Tecnologías Alimentarias (FIT-060000-20003-68). Europastry provided the proximate analysis of the animal feeding. Gemma Brufau has received a Fundació Pedro i Pons grant.

ABSTRACT: As tools for mechanistic studies on lipid metabolism, with the long-term goal of developing a drug for the treatment of lipid disorders, thia FA with the sulfur atom inserted at positions 3–9 from the carboxyl group were fed to male Wistar rats for 1 wk to determine their impact on key parameters in lipid metabolism and hepatic levels of thia FA metabolites. Thia FA with the sulfur atom in even positions decreased hepatic and cardiac mitochondrial β-oxidation and profoundly increased hepatic and cardiac TAG levels. The plasma TAG level was unchanged and the hepatic acyl-CoA oxidase activity increased. In contrast, thia FA with the sulfur atom in odd positions, especially 3-thia FA, tended to increase hepatic and cardiac FA oxidation and acyl-CoA oxidase and carnitine palmitoyltransferase-II activities, and decreased the plasma TAG levels. The effects seem to be related to differences in the catabolic rate of the thia FA. Differences between the two groups of acids were also observed with respect to the regulation of genes involved in FA transport and catabolism. Feeding experiments with 3- and 4-thia FA in combination indicated that the 4-thia FA partly attenuated the effects of the 3-thia FA on mitochondrial FA oxidation and the hepatic TAG level. In summary, the position of the sulfur atom in the alkyl chain, especially whether it is placed in the even or odd position, is crucial for the biological effect of the thia FA.

Paper no. L9770 in *Lipids 41*, 169–177 (February 2006).

Thia FA are modified FA with a sulfur atom inserted in the backbone of a normal FA. In 3-thia FA the sulfur atom is located in the β-position of the alkyl chain, thereby making it non-β-oxidizable. Tetradecylthioacetic acid (TTA), the best-described 3-thia FA, has been extensively tested over the last decade in various animals (1,2), and has recently been subjected to a clinical trial, where it was shown to modify dyslipidemia in HIV-infected humans (3). In many aspects, TTA has properties similar to natural FA, but also has the capacity to profoundly affect lipid metabolism. In test animals TTA has diverse and beneficial effects, including lowering plasma lipids, improving antioxidant status, reducing hyperglycemia, and improving insulin action (reviewed in Ref. 2). These remarkable properties suggest that TTA may have the potential to be used in the prevention and treatment of obesity and obesity-related disorders in humans.

Although the underlying mechanism is not fully understood, TTA is thought to exert its hypolipidemic effect by increasing hepatic FA oxidation, primarily hepatic mitochondrial FA oxidation, and thereby reducing the availability of FA for VLDL synthesis and secretion (4). Research has shown that TTA can enter cells and be activated to its CoA ester (5). TTA is a substrate for carnitine palmitoyltransferase (CPT)-I and CPT-II, and can enter the mitochondria, but the β-oxidation of TTA is blocked since TTA-CoA is not a substrate for acyl-CoA dehydrogenase (6). TTA can be incorporated into several lipid classes but accumulates mostly in the hepatic phospholipids (7). TTA can also be desaturated (8) and elongated (9), and, like a variety of other lipid-like compounds, it transcriptionally activates peroxisome proliferator-activated receptors (PPAR) (10,11). TTA is catabolized by ω-hydroxylation followed by ω-oxidation and oxidation to sulfoxide (12–14). The end products, short sulfoxy dicarboxylic acids, can be detected in the urine of treated animals.

Shifting the position of the sulfur atom toward the methyl end of the alkyl chain renders the thia FA β-oxidizable. The 4-thia FA can undergo one cycle of mitochondrial β-oxidation, but the alkyl-thioacryloyl-CoA formed in the process are poor substrates for both mitochondrial hydratase (15) and for CPT-II (16). Consequently, they accumulate in the mitochondrial matrix, where they inhibit normal FA oxidation (17). 4-Thia FA tend to enlarge the mitochondria but do not promote the proliferation of mitochondria and peroxisomes like the non-β-oxidizable FA (18). In contrast to the effect obtained with the 3-thia FA TTA, administration of 4-thia FA increases the hepatic level of TAG (19), with the formation of numerous fat droplets in the liver cells (18). Thus, intake of 4-thia FA appears to cause a pathological condition, and it may be used as an experimental drug for studies on fatty liver in animal models.

Because of the profound differences between the effects of the 3-thia FA TTA and the 4-thia FA on lipid metabolism, it was of interest to conduct a more extensive study of the consequences of inserting the sulfur atom at different positions in the carbon chain, ranging from the 3- to the 9-position, while keeping the total chain length of the thia FA constant. A survey of

Abbreviations: ACBP, acyl-CoA binding protein; ACO, acyl-CoA oxidase; CMC, carboxymethyl cellulose; CPT, carnitine palmitoyltransferase; DTA, dodecylthioacetic acid; PPAR, peroxisome proliferator-activated receptor; TTA, tetradecylthioacetic acid.

TABLE 1
Formulas and Trivial Names of the Studied Thia FA[a]

	Abbreviation	Formula	Trivial name
S in odd position	14-Carbon 3-thia	$CH_3(CH_2)_{11}\mathbf{S}CH_2C(O)OH$	Dodecylthioacetic acid (DTA)
	3-Thia	$CH_3(CH_2)_{13}\mathbf{S}CH_2C(O)OH$	Tetradecylthioacetic acid (TTA)
	5-Thia	$CH_3(CH_2)_{11}\mathbf{S}(CH_2)_3C(O)OH$	Dodecylthiobutanoic acid
	7-Thia	$CH_3(CH_2)_9\mathbf{S}(CH_2)_5C(O)OH$	Decylthiohexanoic acid
	9-Thia	$CH_3(CH_2)_7\mathbf{S}(CH_2)_7C(O)OH$	Octylthiooctanoic acid
S in even position	4-Thia	$CH_3(CH_2)_{12}\mathbf{S}(CH_2)_2C(O)OH$	Tridecylthiopropanoic acid
	6-Thia	$CH_3(CH_2)_{10}\mathbf{S}(CH_2)_4C(O)OH$	Undecylthiopentanoic acid
	8-Thia	$CH_3(CH_2)_8\mathbf{S}(CH_2)_6C(O)OH$	Nonylthioheptanoic acid

[a]The thia FA contain 16 carbon atoms with a sulfur atom inserted at different positions in the alkyl chain except for the shorter 3-thia FA DTA, which contains 14 carbon atoms.

the compounds studied in this work is given in Table 1. Of particular interest was how the thia FA would affect gene regulation. Because the 3-thia FA TTA is known to modulate FA transport and catabolism, this issue was one of the main subjects of this study. Additionally, only limited knowledge is available with regard to the metabolic fate of such diverse thia FA, which potentially may have a great impact on their metabolic functions. We therefore determined the level of metabolites of some thia FA. It was previously shown that a similar degree of hypolipidemic effect was not achieved with administration of 3-thia FA with alkyl chains several carbon atoms shorter than that of TTA compared to treatment with TTA (20). However, a 3-thia FA with an alkyl chain two carbons shorter than that of TTA reduced the plasma lipids in the same order as TTA (20). Because this shorter 3-thia FA is the proposed β-oxidation product of the 16-carbon 5-thia FA used in the current experiment, it was of interest to compare the effects of these two thia FA on lipid metabolism.

The long-term goal of studies on thia FA with lipid-lowering effects is to provide a drug with lipid-lowering properties for the treatment of obesity and obesity-related disorders. The screening of thia FA with the sulfur atom in positions 3–9 showed that among thia FA with the sulfur atom in odd positions, the 3-thia FA possessed the most potent biological effects. The thia FA with the sulfur atom in even positions reduced mitochondrial β-oxidation concomitantly with an elevated amount of TAG in the liver and heart. These thia FA obviously are of no clinical significance regarding treatment of obesity-related disorders, but may become important for studies on hepatic lipidosis in animal models. In addition, thia FA with a sulfur atom in odd or even positions are powerful tools in mechanistic studies on the regulation of FA metabolism, and in the present study, we showed that the 4-thia FA partially abolished the biological effects of the 3-thia FA. Thus, the position of the sulfur atom is of major importance for the effects of FA oxidation and lipid levels in the liver and plasma.

MATERIALS AND METHODS

Preparation of thia FA: General procedure. The thia FA (Table 1) were synthesized essentially as previously described (21). Two equivalents of KOH were dissolved in methanol, about 25 mL per g KOH. To the solution, in a stream of argon, was added one equivalent of ω-mercaptocarboxylic acid, $HS(CH_2)$-*n*C(O)OH, and then dropwise one equivalent of the appropriate alkyl bromide, $CH_3(CH_2)m$Br (with $n + m$ being 15 or 13), at room temperature and under constant stirring. Finally, the solution was kept at the reflux temperature for 8–12 h. A sufficient amount of water was then added to dissolve the precipitated KBr, whereupon the pH was adjusted to about 1.5 with HCl. The acidified solution was set aside at about 20°C for 1 to 2 d to allow the thia FA to precipitate and to facilitate the following filtration. The collected acid was washed with water until the filtrate was odorless and was then dried in air. The acid was finally purified by subsequent crystallization from diethyl ether and methanol and dried in an oil pump vacuum. The m.p. was determined with a Perkin-Elmer m.p. apparatus, and all acids had a m.p. range of ±0.5°C. The purity of the compounds was further verified by titration with sodium hydroxide in an inert atmosphere. The solvent was ethanol, and phenolphathalein was used as an indicator. The calculated M.W. of all the FA varied from the theoretical formula weight by 1–5% (data not shown). Mass spectrophotometry verified the molecular structures (data not shown). The analytical methods showed a successful synthesis, with >95% purity of the compounds.

Animals and treatments. Male Wistar rats (Mol:Wist) from Mollegard Breeding Laboratory (Ejby, Denmark), weighing 170–210 g, were housed in pairs in metal wire cages, and both received the same treatment. The rats were kept in a 12-h light/dark cycle at a temperature of 20 ± 3°C and a RH of 65 ± 15% and were acclimatized for at least 1 wk under these conditions prior to the start of the experiments. Thia FA (Table 1) were suspended in 0.5% sodium carboxymethyl cellulose (CMC) and were administered by orogastric intubation once a day for 7 d at doses of 150 (only one group) or 300 mg/d/kg body weight. In one group, the rats were fed 4-thia FA at a dose of 150 mg/d/kg body weight for 4 d and thereafter were fed the 3-thia FA TTA and the 4-thia FA for 7 more days, both at a dose of 150 mg/d/kg body weight. Control rats received palmitic acid suspended in CMC at a dose of 300 mg/d/kg body weight. Each experimental group being fed the thia FA consisted of 4 rats, and the control group consisted of 8 rats. The rats had free access to tap water and standard rat pellet food (rat and mice standard diet No. 1; B&K Universal, Nittedal, Norway). At the end of the feeding period, the animals were fasted for 12 h and

anesthetized subcutaneously with a 1:1 mixture of Hypnorm™ (fentanyl citrate 0.315 mg/mL and fluanisone 10 mg/mL; Janssen Animal Health, Beerse, Belgium) and Dormicum® (midazolam 5 mg/mL; Hoffmann-La Roche, Basel, Switzerland). Cardiac puncture was performed to collect blood samples, and the liver and heart were dissected. Parts of liver and heart were immediately frozen in liquid N_2 while the rest of the liver and heart were chilled on ice for homogenization. The protocol was approved by the Norwegian State Board of Biological Experiments with Living Animals. At the end of the feeding period, no difference in weight gain between the groups could be detected (data not shown).

Homogenization and preparation of subcellular fractions. The liver and heart from the rats were homogenized individually in ice-cold sucrose solution (0.25 M sucrose in 10 mM HEPES buffer, pH 7.4, and 1 mM EDTA) using a Potter–Elvehjem homogenizer. Subcellular fractions were prepared as previously described (22). The procedure was performed at 0–4°C, and the fractions were stored at −80°C. Protein was assayed using the BioRad protein assay kit (BioRad, Heraules, CA) with BSA as standard.

Lipid analysis. TAG in the postnuclear fractions of the liver and heart and in the plasma were measured using the Technicon Axon system (Miles, Tarrytown, NY) with the TAG enzymatic kit (Boehringer Mannheim GmbH, Mannheim, Germany).

To measure the hepatic FA composition, the lipids were extracted from subcellular fractions with 2:1 chloroform/methanol (23). The lipid extracts were added to heneicosanoic acid (21:0) as the internal standard and transesterified in 12% BF_3 in methanol (vol/vol) (24). To remove the neutral sterols and unsaponifiable material, the extracts of FAME were heated in 0.5 mol/L KOH in an ethanol/water solution (9:1, vol/vol). The recovered FA were reesterified using BF_3/methanol. The methyl esters were quantified as previously described (25).

Enzyme assays. The CPT-I and CPT-II activities were measured in the postnuclear fraction using palmitoyl-CoA and [methyl-^{14}C]L-carnitine as substrates (26), and the acyl-CoA oxidase (ACO) activity was measured spectrophotometrically in the postnuclear fraction by a coupled assay using palmitoyl-CoA as substrate (27). Palmitoyl-CoA and palmitoyl-L-carnitine oxidation were measured in the postnuclear fraction as acid-soluble products of [1-^{14}C]palmitoyl-CoA and [1-^{14}C]palmitoyl-L-carnitine, respectively (28).

RNA purification and analysis. Total cellular RNA was isolated by the guanidinium–thiocyanate method (29). Hybridization and preparation of hybridization probes were performed as described earlier (30). The DNA probes were purified fragments of cloned rat genes: CPT-II, 1600 bp *Xho*I/*Xba*I fragment of pBKS-CPT II.4 (31); mitochondrial 2.4-dienoyl-CoA reductase, 632 bp *Pst*I/*Eco*RI insert in pGEM-4Z (32); ACO, 1400 bp *Pst*I fragment of pMJ125 (33); acyl-CoA binding protein (ACBP), 458 bp *Eco*RI fragment of pRL-cACBP –E2b (34). Rat P0 rRNA, 1046 bp *Bam*HI/*Xho*I fragment in pBluescript II SK (z29530, provided by Anders Molven, Bergen, Norway) was used as the control.

Presentation of results. The results are reported as means ± SEM from 4–8 animals in each group. Statistical analyses was performed by one-way ANOVA and Dunnet's *post hoc* test, with the level of statistical significance set at $P < 0.05$. Rats treated with palmitic acid served as the controls.

RESULTS

Thia FA affect the liver weight and hepatic, cardiac, and plasma lipids. It is well documented that peroxisome proliferators can induce hepatomegaly, and previously it was reported that administration of 3-thia FA to rats increased the liver weight (18). Table 2 shows that, in this respect, the 3-thia FA TTA was comparable to the 3-thia FA with two carbon atoms less in the alkyl chain. Thia FA with the sulfur atom in positions 4, 6, or 8 also increased the relative liver weights. 4-Thia FA are known to cause hepatic lipidosis (18), and this study demonstrated that thia FA with the sulfur atom in even positions (4-, 6-, and 8-thia FA) increased the hepatic levels of TAG (Table 3). The 4- and 6-thia FA also increased the TAG level in the heart (Table 3). Hepatic and cardiac TAG levels were unchanged in rats treated with thia FA with the sulfur atom in odd positions, except for the 7-thia FA, which reduced the hepatic TAG level (Table 3). In agreement with previous studies (35,36), the 3-thia FA significantly decreased plasma TAG levels (Table 3). Shifting the position of the sulfur atom further away from the carboxylic end reduced this hypolipidemic effect. Thia FA with the sulfur atom in even positions did not affect the plasma TAG levels (Table 3).

Thia FA change the hepatic and cardiac oxidation of FA. As shown in Figures 1A and 1B, the 3-thia FA increased mitochondrial FA oxidation in the liver and heart. This increase was diminished as the sulfur atom was moved further away from the carboxylic end. In contrast, thia FA with the sulfur atom in an even position decreased mitochondrial FA oxidation in the liver and heart (Figs. 1A, 1B).

Thia FA with the sulfur atom in even or odd positions appeared to enhance the hepatic and cardiac ACO activities, with the 3-thia FA being the far most potent of the thia FA (Fig. 2A). The hepatic

[a]Measurements were taken in plasma or the postnuclear fractions of liver or heart tissues. The values represent the mean ± SEM for 4 animals in each experimental group and 4 to 8 animals in the control group. *$P < 0.05$ compared with the control (palmitic acid). ND, not determined; for other abbreviations see Table 1.

CPT-I and CPT-II activities were increased only in rats fed the 3-thia FA, whereas the cardiac activities of CPT-I and CPT-II remained unchanged (Figs. 2B, 2C).

3- and 5-Thia FA are recovered in hepatic subcellular fractions. In the liver of rats fed the 3-thia FA TTA, this acid was found in equal amounts in the postnuclear, mitochondrial, and peroxisomal fractions (Fig. 3). Likewise, the desaturated product of TTA was found in equal amounts in the different fractions (Fig. 3). In rats fed the shorter (14-carbon) 3-thia FA dodecylthioacetic acid (DTA) or the 5-thia FA, both these acids were recovered in the postnuclear, mitochondrial, and peroxisomal fractions (Fig. 3). This could be explained by the ability of the shorter 3-thia FA to be elongated to a 5-thia FA, and of the 5-thia FA to be chain shortened by one round of β-oxidation. With both diets, there was a higher accumulation of the shorter 3-thia FA DTA than of the 5-thia FA.

The effect of a 3-thia FA is modulated by a 4-thia FA. To further examine the mechanisms behind the opposing effects of 3- and 4-thia FA, an experiment was conducted in which rats were fed a mixture of the 3-thia FA TTA and a 4-thia FA. The rats were first fed the 4-thia FA for 4 d and thereafter with a mixture of the two 3- and 4-thia FA for 7 more days, both at a dose of 150 mg/d/kg. These rats were compared with rats fed 3-thia FA, 4-thia FA, or palmitic acid (control). Figures 4A and 4B show for the first time that the 4-thia FA attenuated the 3-thia FA-mediated increase in mitochondrial FA oxidation. The re-

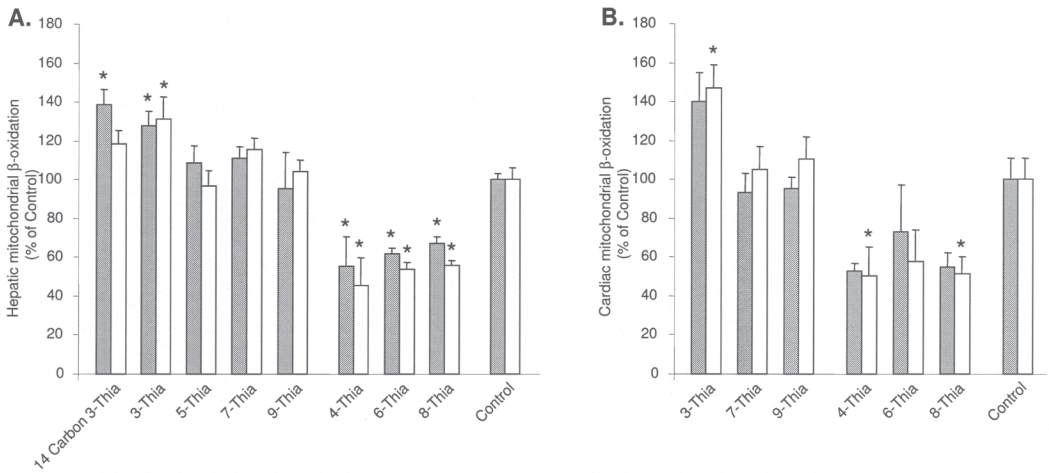

FIG. 1. Mitochondrial FA oxidation in liver (A) and heart (B) in rats fed different thia FA at a dose of 300 mg/d/kg body weight for 7 d. All thia FA (*n*-Thia) contained 16 carbon atoms with a sulfur atom inserted at various positions in the alkyl chain, except for the shorter 3-thia FA, which consisted of 14 carbons and the sulfur atom. The data are presented as the mean ± SEM for 4 animals in each experimental group and 4 to 8 animals in the control group, and as the percentage of control [liver: 1.12 ± 0.04 and 2.02 ± 0.05 nmol/min/mg protein; and heart: 0.57 ± 0.06 and 0.58 ± 0.06 nmol/min/mg protein when palmitoyl-CoA (shaded bars) and palmitoyl-carnitine (open bars) were used as substrates, respectively]. Measurements were performed in the postnuclear fractions of liver or heart tissue. *Significantly different from the control ($P < 0.05$).

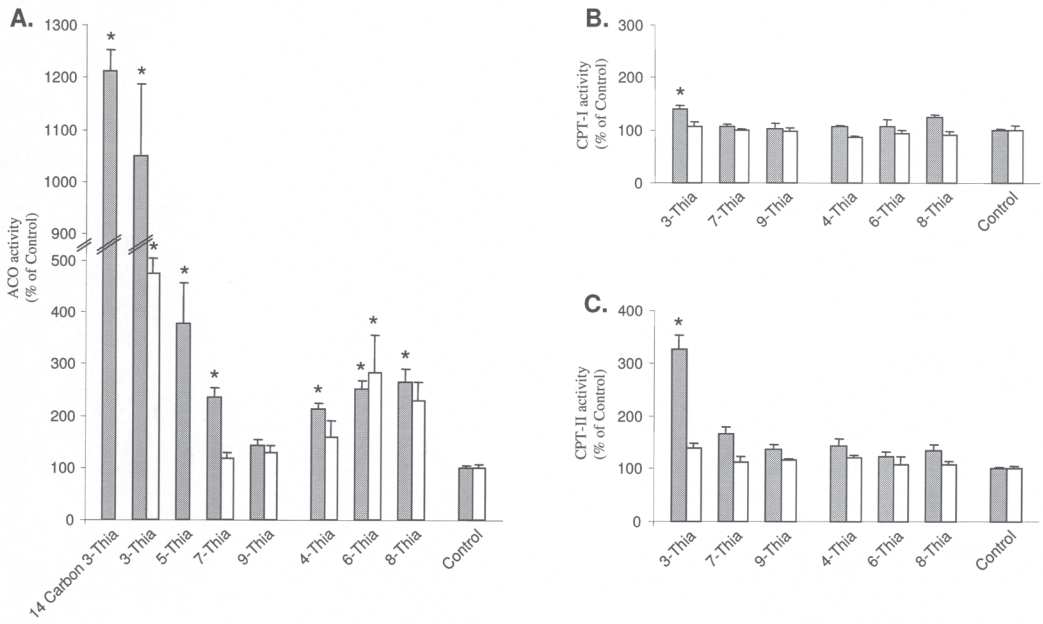

FIG. 2. Activities of acyl-CoA oxidase (ACO) (A), carnitine palmitoyltransferase (CPT)-I (B), and CPT-II (C) in the liver and heart of rats fed different thia FA at a dose of 300 mg/d/kg body weight for 7 d. Nomenclature of the thia FA is as in Figure 1. The data are presented as the mean ± SEM for 4 animals in each experimental group and 4 to 8 animals in the control group and as the percentage of control [ACO: 16.6 ± 0.6 and 0.81 ± 0.05 nmol/min/mg protein; CPT-I: 2.04 ± 0.05 and 1.73 ± 0.15 nmol/min/mg protein; and CPT-II: 10.6 ± 0.3 and 1.00 ± 0.13 nmol/min/mg protein in the liver (shaded bars) and heart (open bars), respectively]. Measurements were performed in the postnuclear fractions. *Significantly different from the control ($P < 0.05$).

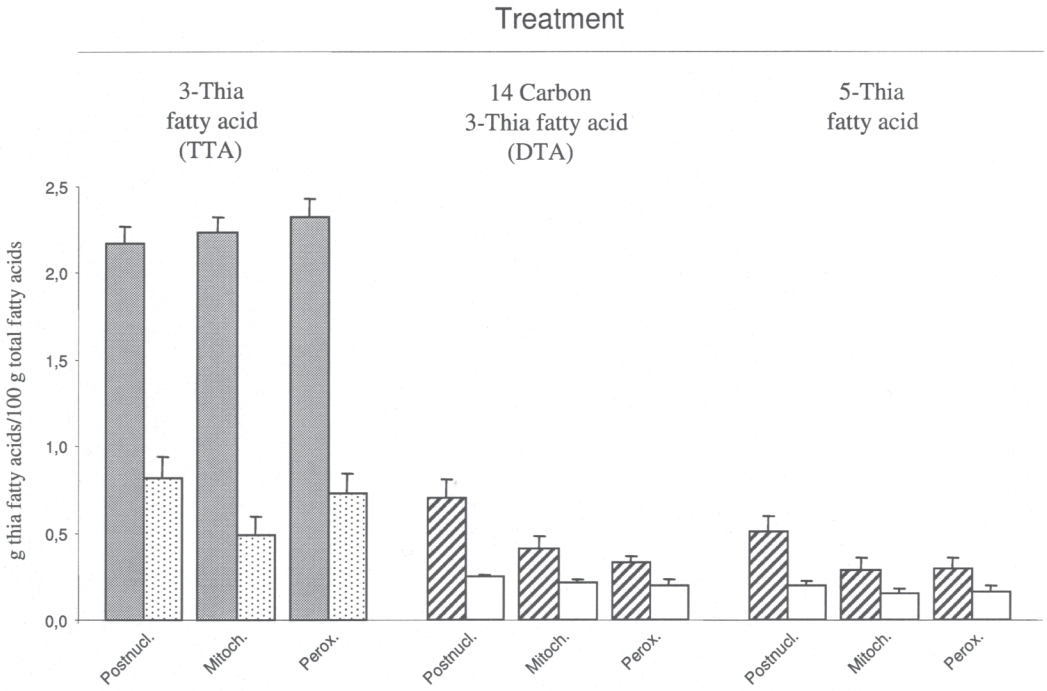

FIG. 3. Accumulation of thia FA in subcellular fractions of the liver of rats fed thia FA at a dose of 300 mg/d/kg body weight for 7 d. The thia FA denoted as 3- and 5-thia FA contained 16 carbon atoms, whereas the shorter 3-thia FA contained 14 carbon atoms. Measurements were performed in the postnuclear, mitochondrial, and peroxisomal fractions of the liver tissue, and the results are presented as grams thia FA per 100 g of the total amount of FA found in the liver, as determined by GC. Thia FA recovered: 3-thia FA (tetradecylthioacetic acid, TTA) (shaded bars); monounsaturated 3-thia FA [TTA:1 (n-8)] (dotted bars); 14-carbon 3-thia FA (dodecylthioacetic acid, DTA) (striped bars); 5-thia FA (open bars). The values represent the mean ± SEM for 4 rats in each group.

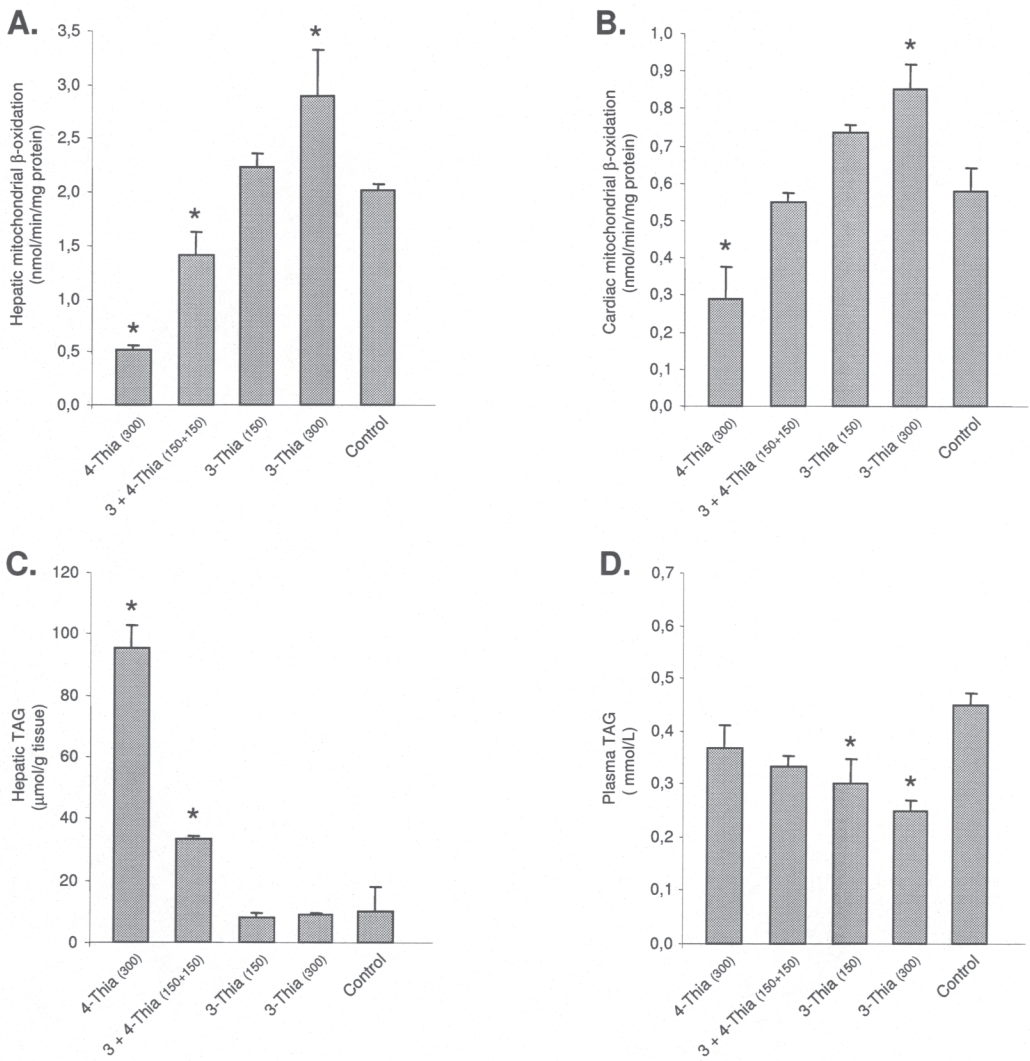

FIG. 4. Effects of 3- and 4-thia FA, and a combination of 3- and 4-thia FA, on (A) hepatic mitochondrial β-oxidation, (B) cardiac mitochondrial β-oxidation, (C) hepatic TAG levels, and (D) plasma TAG levels. (In A and B, palmitoyl-carnitine was used as substrate.) 3-Thia and 4-Thia denote 3- and 4-thia FA, respectively, both with 16 carbon atoms, and the dose in mg/d/kg body weight is given in parentheses. Values are presented as the mean ± SEM. *Significantly different from the control ($P < 0.05$).

duced hepatic FA oxidation was reflected in the elevated hepatic TAG level when feeding a mixture of 3- and 4-thia FA (Fig. 4C). It is noteworthy that the mixture of 3- and 4-thia FA abolished the plasma TAG-lowering effect of the 3-thia FA (Fig. 4D). The 4-thia FA increased the ACO activity and tended to increase the CPT-II activity, although less efficiently than the 3-thia FA (Table 4). Giving rats a combination of 3- and 4-thia FA resulted in higher activities of ACO and CPT-II than did giving the 4-thia FA alone (Table 4). Furthermore, the mixture of 3- and 4-thia FA had an additive effect on the CPT-II activity compared with the lowest dose of the 3-thia FA alone. The gene expression of ACO was increased several fold by the 3-thia FA and tended to be increased by the 4-thia acid, whereas the gene expression of CPT-II was modestly increased by both 3- and 4-thia FA (Table 4). The gene expressions of the mitochondrial 2.4-dienoyl-CoA reductase and ACBP increased with 3-thia FA feeding but were not affected by the 4-thia FA (Table 4). Feeding a combination of 3- and 4-thia FA did not attenuate the 3-thia FA-induced increase in the gene expressions of 2.4-dienoyl-CoA and ACBP (Table 4).

DISCUSSION

Thia FA can generally be viewed as normal FA that at the same time possess some abnormal properties because of the presence of a sulfur atom. This paradoxical statement is based on their normal behavior with respect to transport, activation, esterification, elongation, and desaturation. These compounds apparently act as substrates for most of the lipid-handling enzymes in the cell. In contrast, they are much less susceptible to catab-

TABLE 4
Effect of 3- and 4-Thia FA on Hepatic Enzyme Activities and mRNA Levels[a]

	Control	4-Thia FA	3- and 4-Thia FA	3-Thia FA	3-Thia FA
Dose (mg/d/kg body weight)		300	150 + 150	150	300
Enzyme activities			nmol/min/mg protein		
ACO	16.1 ± 0.6	34.4 ± 1.9*	115 ± 3*	114 ± 16*	201 ± 26*
CPT-II	10.6 ± 0.3	15.1 ± 1.5	23.2 ± 2.4*	16.4 ± 0.9	34.7 ± 2.9*
mRNA levels			relative values		
ACO	1.00 ± 0.10	3.04 ± 0.36	4.51 ± 1.27*	6.95 ± 0.79*	8.77 ± 1.98*

[a]The thia FA contain 16 carbons with sulfur at the 3- or 4-position. Enzyme activities were measured in the postnuclear fractions of liver tissue, and the mRNA levels were measured in total RNA samples extracted from liver tissue. The values represent the mean ± SEM for 4 animals in each group. *$P < 0.05$ compared with the control (palmitic acid). ACO, acyl-CoA oxidase; CPT, carnitine palmitoyltransferase; ACBP, acyl-CoA binding protein.

olization by β-oxidation than the natural FA, and they profoundly affect the oxidation of other FA in the cell. Obviously, the catabolism of thia FA is a decisive factor in determining their biological effects, and this catabolism will be affected by the length of the carbon chain and the position of the sulfur atom. By inserting the sulfur atom in even or odd positions in the carbon chain, two groups of thia FA with distinct features can be identified.

From the data presented in this paper, two important trends can be discerned when the position of the sulfur atom is shifted from the carboxylic end toward the methyl end of the molecule. First, thia FA with the sulfur atom in even or odd positions have opposing effects on the mitochondrial FA oxidation of natural FA. Second, feeding even or odd thia FA increases the ACO activity, a key enzyme involved in the peroxisomal catabolism of FA, with the highest enzyme activity observed after feeding the 3-thia FA. For these acids with the sulfur in odd positions, the ACO activity gradually decreases as the sulfur atom is located farther away from the carboxylic group. This trend is also observed for the plasma and hepatic TAG levels.

3-Thia FA are blocked for β-oxidation, whereas the 5-, 7-, and 9-thia FA will be blocked for further β-oxidation after one, two, or three cycles of oxidation, respectively, until they become shorter 3-thia FA. The hepatic contents of thia FA with the sulfur in odd positions and of their metabolites have recently been analyzed (9), demonstrating that the particular 3-thia FA TTA was recovered in the greatest amount. The 5- and 7-thia FA and their metabolites were recovered in gradually decreasing amounts as the sulfur atom was located closer to the methyl end of the molecule, indicating a more rapid catabolism as the metabolites of shorter carbon chains were formed. Thus, the decrease in biological potency of these thia FA may be related to a diminished effective concentration of the active compound.

In the present experiment, metabolites of the shorter 3-thia FA (DTA) and the 5-thia FA were identified in the nuclear, mitochondrial, and peroxisomal fractions, demonstrating relatively similar levels of metabolites in these fractions (Fig. 3). After feeding the 5-thia FA, both the parent product (0.19 wt%) and the shortened β-oxidized product, 3-thia FA DTA (0.50 wt%), were found in the rat liver (Fig. 3). Presently, it is difficult to assess which of these two compounds is the more active species, or whether they are equally effective. Strangely enough, after feeding the 3-thia FA DTA (equal to the β-oxidized product of the 5-thia FA), the content of this FA in rat liver was no more than 0.70 wt% (Fig. 3) and was comparable to the amount found when feeding the 5-thia FA. However, the biological potency of this compound was stronger than that of the 5-thia FA and was comparable to that of the 3-thia FA TTA (2.17 wt%, Fig. 3). Also in the heart, the shorter 3-thia FA was found in lower amounts than was TTA (20). The reason for this discrepancy is presently not known but may be related to several factors. The biological effect may be determined by an active pool of thia FA or their metabolites in a specific cellular compartment. However, because there were no differences among the contents of the 3-thia FA DTA and of the 5-thia FA in the postnuclear, mitochondrial, and peroxisomal fractions, compartmentalization of the thia FA and their metabolites is probably of minor importance to explain their biological activities. Second, the pharmacokinetics may be different for the thia FA, and especially for the two 3-thia FA. The biological effects of the thia FA may be determined by their *in vivo* concentrations shortly after feeding when these concentrations may be of the same magnitude. Thereafter, the shorter 3-thia FA may have a more rapid catabolism, resulting in a lower recovery of this FA when the animals are killed and analyzed. This may also explain the difference in biological effects after feeding rats the shorter 3-thia FA and the 5-thia FA, even though the hepatic amounts of the shorter 3-thia FA and the 5-thia FA were comparable at the time of analysis and were independent of which thia FA was fed to the rats. The possibility also exists that the shorter 3-thia FA is inherently a more biologically active compound than the other acids.

Thia FA with the sulfur atom in an even position efficiently inhibited mitochondrial FA oxidation in both the liver and heart (Figs. 1, 4). In transfection experiments, the 4-thia FA was found to be a PPARα ligand, although the potency was lower than for the odd-positioned thia FA (Gudbrandsen, O.A., Rost, T., Wergedahl, H., and Berge, R.K., unpublished manuscript). Inherently, the 4-thia FA should, at least to a certain extent, increase FA oxidation. The inhibitory effect of this 4-thia FA can

probably be explained by the formation of a metabolite acting as an inhibitor of mitochondrial FA oxidation (16). This inhibitor, a thioacrylic acid, should theoretically be formed during β-oxidation of all the thia FA with a sulfur atom in an even position, although with gradually shorter carbon chains. Because these acids are equally effective in inhibiting FA oxidation (Fig. 1A), provided the different thioacrylic acids are formed in comparable amounts, the length of the carbon chain does not seem to be decisive for this inhibitory effect.

Thia FA modulated the expression of genes involved in FA transport and catabolism to a variable degree. As PPARα ligands, the 3-thia FA increased the expression of PPARα-regulated genes (Table 4). 4-Thia FA feeding increased, or tended to increase, some of these genes (ACO and CPT-II), whereas others were not affected. When 3- and 4-thia FA were fed together, no additive effect attributable to the 4-thia FA could be detected. ACO activity was affected in a specific manner, determined by the position of the sulfur (Fig. 2A). The increase in ACO activity observed after feeding the odd-positioned thia FA was gradually diminished by moving the sulfur atom toward the methyl end of the molecule. In contrast, the relatively modest effect exerted by feeding the even-positioned thia FA did not seem to be influenced by the position of the sulfur atom.

When interpreting the data obtained from feeding the even-positioned thia FA, one should consider that the hepatic level of TAG is increased (Fig. 4, Table 3) and that the FA composition will be changed, as found in the liver of rats fed 4-thia FA (9). It may be argued that this increase in hepatic lipids may affect the gene expression of specific genes such as ACO and CPT-II in a PPARα-independent manner. The implications are that the metabolic changes exerted by the 4-thia FA and similar acids are due to disturbed lipid metabolism affected by a significantly reduced oxidation of the FA.

The importance of mitochondrial FA oxidation is further emphasized by the results from the experiments in which rats were fed a combination of equal amounts of both 3- and 4-thia FA. This combination resulted in diminished FA oxidation as compared with feeding the 3-thia FA alone. However, 3-thia FA-stimulated oxidation was not completely abolished. Apparently, the inhibitor formed can only partially attenuate the effect of the 3-thia FA, probably due mainly to the increased CPT-II activity. As expected, the rate of FA oxidation observed with the 3- and 4-thia FA, and the combination of these, was reflected in the amount of hepatic TAG, resulting in a reduced hepatic lipidosis when they were combined as compared with feeding the 4-thia FA alone (Figs. 4A–4C). A similar trend was found in the plasma TAG level, although to a lesser extent (Fig. 4D), as the combination of 3- and 4-thia FA decreased the hepatic FA oxidation and abolished the plasma TAG lowering effect of 3-thia FA.

It is reasonable to assume, although difficult to assess directly, that the position of the sulfur atom in the molecule is of minor importance for the direct interaction between the thia FA and regulatory factors such as PPAR. Because of the significant differences in the catabolic rates, this factor is probably more important for the observed differences in metabolic effects. The main regulatory target of these metabolites is mitochondrial FA oxidation, which to a large extent determines how hepatic and plasma lipid metabolism is affected. Thus, 3-thia FA and other acids with the sulfur atom in odd positions increase FA oxidation mainly through a PPAR-mediated mechanism dependent on the actual cellular level of the thia FA present. Thia FA with the sulfur atoms in even positions appear to have metabolic effects governed mainly by significantly reduced FA oxidation in the liver, with a concomitant accumulation of hepatic lipids.

In summary, the results from this study demonstrate the importance of the position of the sulfur atom in the carbon chain when modifying a FA. This position appears to have consequences for the catabolism of the modified FA, which in turn influence interactions with regulatory factors and gene regulation. Among the thia FA with the sulfur atom in odd positions, the 3-thia FA possessed the most potent biological effects, and in the future they may be candidates for use as lipid-lowering drugs for the treatment of obesity and obesity-related disorders. In fact, the 3-thia FA TTA has already been used in a clinical study to treat dyslipidemia in HIV-infected humans on antiretroviral therapy (3). The thia FA with the sulfur atom in even positions reduced the mitochondrial β-oxidation concomitant with an elevated amount of TAG in the liver and heart, and in rats fed the combination of 3- and 4-thia FA, the 4-thia FA partially abolished the biological effects of the 3-thia FA.

ABSTRACT: CLA has been shown to induce or suppress excess liver lipid accumulation in various animal models. Interestingly, the state of insulin resistance may be an important modulator of this effect. The objective of the current study was to determine how feeding a dietary CLA mixture would affect liver lipid accumulation in insulin-resistant/obese and lean rats in relation to liver function, lipidemia, liver TAG and phospholipid FA composition, and expression of hepatic markers of FA transport, oxidation, and synthesis. Six-week-old *fa/fa* and lean Zucker rats (n = 20/genotype) were fed either a 1.5% CLA mixture or a control diet for 8 wk. CLA supplementation reduced liver lipid concentration of *fa/fa* rats by 62% in concurrence with improved liver function (lower serum alanine aminotransferase and alkaline phosphatase) and favorable modification of the serum lipoprotein profile (reduced VLDL and LDL and elevated HDL) compared with control-fed *fa/fa* rats. The *fa/fa* genotype had two-thirds the amount of CLA (as % total FA) incorporated into liver TAG and phospholipids compared with the lean genotype. In both genotypes, CLA altered the hepatic FA profile (TAG greater than phospholipids) and these changes were explained by a desaturase enzyme index. Liver-FA-binding protein and acyl CoA oxidase, markers of FA transport and oxidation, respectively, were expressed at higher levels in CLA-fed *fa/fa* rats. In summary, these results illustrate a strong relationship between the state of insulin resistance and liver lipid metabolism and suggest that CLA acts to favorably modify lipid metabolism in *fa/fa* Zucker rats.

Paper no. L9722 in *Lipids 41*, 179–188 (February 2006).

Nonalcoholic fatty liver disease (NAFLD) is a condition that begins with simple hepatic steatosis and may then progress to nonalcoholic steatohepatitis, cirrhosis, and end-stage liver disease (1,2). Hepatic steatosis is defined as excess accumulation of lipid, specifically TAG, in the liver, which may lead to degenerative changes in liver cells. Often, the first clinical signs of hepatic steatosis are abnormal liver function tests. Although, the exact etiology of NAFLD is not known, it is associated with insulin resistance. Consequently, it has been proposed that hepatic steatosis be included as another feature of the metabolic syndrome (1,3). Disturbingly, obesity, insulin resistance, and hepatic steatosis are occurring in children and adolescents at significant rates (4,5). Thus, the investigation of nutritional factors, such as CLA, that may prevent or ameliorate these conditions becomes increasingly relevant.

CLA is a term that describes positional (carbon 7–12) and geometric (*cis-cis*, *cis-trans*, *trans-cis*, and *trans-trans*) isomers of octaecadienoic acid (18:2) (6). CLA induces hepatic steatosis in normal-weight mice (7,8) but ameliorates hepatic steatosis in insulin-resistant obese rats (9–12). These differing outcomes may be due to various factors including species-specific and age-related responses, varying levels and duration of CLA supplementation, and the background diet. However, the response to dietary CLA may also be different in normal vs. obese insulin-resistant states as evidenced in human studies. In men with metabolic syndrome and people with type 2 diabetes, CLA supplementation worsens measures of insulin resistance (13–15), whereas one study in healthy people reported that CLA supplementation improved insulin sensitivity (16).

Thus, the objective of the current 8-wk study was to determine the effects of a CLA mixture (1.5%, w/w) on liver lipid accumulation in relation to (i) liver function, (ii) lipidemia, (iii) liver TAG and phospholipid (PL) FA composition, and (iv) markers of hepatic FA transport, oxidation, and synthesis in 6-wk-old *fa/fa* and lean Zucker rats. Supplementation with a 1.5% (w/w) CLA mixture has been previously shown to improve glucose tolerance in hyperglycemic Zucker Diabetic Fatty (ZDF) rats (17). The *fa/fa* rat has a mutation in the leptin receptor and is an appropriate model for studying hepatic steatosis in the presence of obesity (18,19).

MATERIALS AND METHODS

Animals and diets. Following a 5- to 7-d acclimation period, *fa/fa* (fa) and lean (ln) 6-wk-old Zucker rats (n = 20/genotype; Charles River, St. Constant, Québec, Canada) were randomly assigned to receive either the CLA (faCLA and lnCLA groups) or control (faCTL and lnCTL groups) diet for 8 wk. The diet

formulation was based on the AIN-93G diet (Table 1) (20). The FA distributions of the CLA and CTL diets are shown in Table 2. The dry ingredients for the diets were premixed and stored at 4°C. The CLA oil was aliquoted and stored at –20°C. Fresh batches of the diet, containing oil, were prepared weekly and stored at –20°C until used. Rats were given new feed cups with fresh feed three times per week. Feed consumption (corrected for spillage) and weekly body weights were recorded.

Tissue collection. With cessation of the study period, rats were fasted overnight and euthanized by CO_2 asphyxiation and cervical dislocation according to the Canadian Council on Animal Care Guidelines (21). Trunk blood was collected and immediately placed on ice until centrifuged to separate the serum fraction, which was stored at –80°C. Dissected organs including liver were weighed, immediately frozen in liquid nitrogen, and subsequently stored at –80°C.

Liver lipid concentration. Total liver lipid was separated by chloroform/methanol extraction (22), and total lipid was calculated by weight.

Fasting serum biochemistry. Enzymatic kits were used to quantify serum FFA (#1383175; Roche Diagnostics, Mannheim, Germany), TAG (#DCL 210–75; BioPacific, North Vancouver, Canada), cholesterol (#DCL225–26; BioPacific), alanine aminotransferase (ALT) (#318–10; BioPacific), and alkaline phosphatase (#245; Sigma, St. Louis, MO). Relative serum lipoprotein (VLDL, LDL, HDL) levels were determined using nondenaturing PAGE (23).

FA analysis. Lipids were extracted using a modified Bligh and Dyer extraction procedure (24). Briefly, 0.50 g of liver was added to 10 mL of chloroform/methanol (2:1, vol/vol) with 0.01% BHT (Sigma-Aldrich, Oakville, Ontario, Canada) and extracted and separated by TLC as previously described (25). All solvents were from Fisher Scientific (Nepean, Ontario, Canada).

The two lipid classes were methylated separately using a sodium methoxide ($NaOCH_3$)-based procedure (15 min at 50°C) to ensure that isomerization of double bonds in the conjugated PUFA did not occur (26). Analyzing the PL fraction required the use of two methylating agents since there is no one methylating agent that is appropriate for analyzing both CLA and the FA found in sphingomyelin [i.e., sphingomyelin FA are not methylated by $NaOCH_3$ and CLA is isomerized by acid-based methylating agents (27)]. Thus, a duplicate PL fraction was also methylated with methanolic hydrochloric acid (mHCl) for 2 h at 80°C. The results from the two methylation procedures were combined based on quantification by the internal standard 1,2-dipentadecanoyl-*sn*-glycero-3-phosphocholine (Avanti, Alabaster, AL) added to duplicate samples in equal amounts. For GC, $NaOCH_3$-methylated samples were separated on a Chrompack CP-select CB column (100 m × 0.25 mm diameter and 0.25 μm film thickness; Varian Canada Inc., Mississauga, Ontario) using a Varian CP-3800 GC with FID. The column was operated at 45°C for 4 min, the temperature was raised to 175°C at 13°C/min, held for 27 min, raised again to 190°C at 1°C/min, held for 38 min, raised again to 215°C at 4°C/min, held for 10 min, and finally raised to 240°C at 4°C/min and held for 5 min. Total run time was 121.5 min, and samples were run with a 10:1 split ratio. The mHCl-methylated samples were separated on a DB225MS column (30 m × 0.25 mm diameter and 0.25 μm film thickness; Agilent Technologies Canada Inc., Mississauga, Ontario) using a Varian 3400 GC with FID. The temperature program was 70°C for 1 min,

the temperature was raised to 180°C at 20°C/min, held for 8.5 min, raised to 220°C at 3°C/min, held for 15 min, and finally raised to 240°C at 20°C/min and held for 10.5 min. Total run time was 55 min, and samples were run with a 20:1 split ratio. Individual FA results are expressed as the percentage of total FA. The Δ^9 desaturase index [(16:1n-7 + 18:1-n9)/(16:0 + 18:0)] was calculated based on the FA results.

Reverse transcription-polymerase chain reaction (RT-PCR) for analysis of mRNA. Markers of hepatic FA transport, oxidation, and synthesis [liver-FABP (L-FABP), acetyl CoA oxidase (ACO), and acetyl CoA carboxylase (ACC) mRNA levels, respectively] were assessed by RT-PCR using previously published procedures (28). Briefly, total RNA was isolated using TRIzol (Invitrogen Corp., Burlington, Ontario, Canada). The RNA was resuspended in RNase-free water, and concentration determined by spectrophotometric absorbance at 260 nm. Reverse transcription of 1 μg RNA was conducted (after removal of possible genomic DNA contamination with DNase I) according to the protocol (25 cycles of amplification and 62°C annealing temperature) recommended for the Access RT-PCR system (Promega, Madison, WI). The sequences for the PCR primers (Invitrogen Life Technologies, Burlington, Ontario, Canada) were ACO (sense) 5′-TTCGAGGCTTGGAAACCACT-3′, ACO (antisense) 5′-CTGGGCGTATTTCATCAGCA-3′, ACC (sense) 5′-AGGATCTTAAGGCCAACGCA-3′, ACC (antisense) 5′-TTGGGATCTGCAATGTCTGG-3′, L-FABP (sense) 5′-CGGCAAGTACCAAGTGCAGA-3′, L-FABP (antisense) 5′-CTGCTTGACCTTTTCCCCAG-3′, and the housekeeping gene, L32 ribosomal protein (sense) 5′-TAAGCGAAACTGGCGGAAAC-3′ and L32 ribosomal protein (antisense) 5′-GCTCGTCTTTCTACGATGGCTT-3′. The Gene Bank accession numbers were M13501, AB004329, NM022193, and M13501 for L-FABP, ACO, ACC, and L32, respectively. Vistra green (Amersham, Baie d'Urfe, Québec, Canada) was used to visualize RT-PCR products on 2% agarose gels by electophoresis. Relative band intensity was quantified by scanning the gel (Storm Fluorimager, Amersham) and results are expressed as arbitrary units.

Statistical analysis. Two-way ANOVA was used to determine significant main effects (genotype, lipid, and genotype × lipid interaction), and Duncan's multiple range test was used for means testing (SAS 6.04; SAS Institute, Cary, NC). Data are presented as mean ± SEM unless otherwise indicated. For mRNA and lipoprotein data, differences were assessed by contrasts of preplanned comparisons. The significance level was $P < 0.05$.

RESULTS

Liver lipid content and function. The *fa/fa* rats weighed 58% more than lean rats (567 ± 10 vs. 358 ± 6 g) and consumed 43% more feed than lean rats (1539 ± 27 vs. 1078 ± 22 g), but there were no differences due to dietary treatment (data not shown). The *fa/fa* rats had greater liver weight, relative liver weight, and liver lipid concentration compared with lean rats (Table 3, Fig. 1). Dietary CLA reduced liver weight by 40%, relative liver weight by 37%, and liver lipid concentration by 62% in the faCLA rats compared faCTL rats. In fact, the relative liver weight of faCLA rats was equivalent to that of the lean rats (Table 3). This was paralleled by 54 and 64% reductions in fasting serum ALT and alkaline phosphatase (markers of liver function), respectively, in faCLA rats compared with faCTL rats. Although the faCLA rats still had a twofold higher serum ALT than the lean controls, serum alkaline phosphatase was not different between faCLA, lnCTL, and lnCLA rats (Fig. 2).

Lipidemia. The *fa/fa* rats had higher fasting serum FFA (0.62 ± 0.03 vs. 0.27 ± 0.02 mmol/L), TAG (16.55 ± 0.94 vs. 3.90 ± 0.31 mmol/L), and cholesterol (7.80 ± 0.56 vs. 3.16 ± 0.12 mmol/L) compared with the lean rats. There was no effect of CLA on fasting serum FFA or TAG; however, fasting serum cholesterol was 37% lower in faCLA rats compared with faCTL rats (Table 3). The *fa/fa* rats had elevated fasting serum VLDL and LDL and reduced HDL compared with the lean rats. Dietary CLA reduced fasting serum VLDL by 60% and LDL by 41% in faCLA rats compared with faCTL rats (Fig. 3). Fasting serum HDL in faCLA rats was elevated to a level comparable with lean rats.

Liver FA composition. (i) CLA isomers. The faCLA rats had only two-thirds the CLA isomers present in liver TAG and PL compared with lnCLA rats, as a percentage of total FA (Fig. 4).

TABLE 3
Characteristics of *fa/fa* and Lean Zucker Rats Fed 0 or 1.5% CLA for 8 wk[a]

					Pr > *F*

[a]Means ± SEM for $n = 10$/group; main effects from ANOVA: Geno = genotype (*fa/fa* vs. lean rats), Lipid (0 vs. 1.5% CLA), and Geno × lipid = lipid × genotype interaction; means with different superscript letters are significantly different ($P < 0.05$) by Duncan's multiple range test; faCLA = *fa/fa* rats fed 1.5% CLA, faCTL = *fa/fa* rats fed 0% CLA, lnCLA = lean rats fed 1.5% CLA, lnCTL = lean rats fed 0% CLA; bwt = body weight; NS = not significantly different.

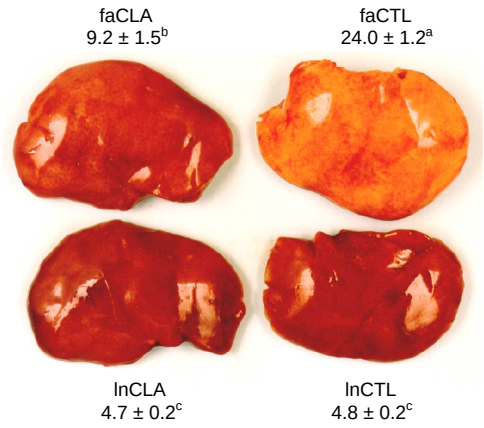

FIG. 1. Hepatic steatosis and liver lipid concentration (%). The pale color of faCTL liver portrays hepatic steatosis, which was confirmed by analysis of liver lipid concentration; values are means ± SEM for $n = 10$ rats/group; means with different superscript letters are significantly different ($P < 0.05$) by Duncan's multiple range test; faCLA = *fa/fa* rats fed 1.5% CLA, faCTL = *fa/fa* rats fed 0% CLA, lnCLA = lean rats fed 1.5% CLA, lnCTL = lean rats fed 0% CLA.

The faCLA rats had less *c*9,*t*11/*t*8,*c*10 CLA in liver TAG, and less *c*11,*t*13 CLA in liver PL compared with lnCLA rats. The dominant isomers in liver TAG were *c*9,*t*11/*t*8,*c*10, whereas in liver PL the isomers reported were equally distributed in the faCLA rats. In contrast, lnCLA rats had a greater proportion of *c*11,*t*13 compared with the other isomers.

(ii) Liver TAG. The *fa/fa* rats had higher total saturated FA (SFA) (40.7 ± 0.6 vs. 27.9 ± 1.0%) and monounsaturated FA (MUFA) (38.6 ± 2.7 vs. 24.5 ± 1.2%) and lower PUFA (18.0 ± 2.5 vs. 44.1 ± 2.1%) than lean rats. CLA feeding resulted in a lower proportion of MUFA and a higher proportion of PUFA in liver TAG of *fa/fa* rats (Table 4). The Δ^9 desaturase index was reduced in faCLA rats compared with faCTL rats. The PUFA/SFA ratio was lower in *fa/fa* rats compared with lean rats (0.45 ± 0.07 vs. 1.61 ± 0.12) and unchanged by dietary CLA treatment. The faCLA rats had a lower proportion of n-9 (18:1n-9) and a higher proportion of n-6 (18:2n-6, 20:4n-6) and n-3 (18:3n-3, 20:5n-3, 22:5n-3, 22:6n-3) FA in liver TAG compared with faCTL, resulting in a pattern more similar to lean rats. Interestingly, the n-6/n-3 ratio was lowest in faCLA compared with faCTL and lean rats.

(iii) Liver PL. The *fa/fa* rats had higher SFA (45.1 ± 0.4 vs. 42.7 ± 0.4%) and MUFA (6.18 ± 0.43 vs. 5.29 ± 0.19%) and lower PUFA (45.9 ± 1.3 vs. 49.0 ± 0.7%) and PUFA/SFA ratio (1.02 ± 0.04 vs. 1.15 ± 0.03) compared with lean rats. CLA-fed rats had a lower proportion of MUFA (5.05 ± 0.21 vs. 6.43 ± 0.34%) and a lower Δ^9 desaturase index compared with CTL-fed rats (Table 5). The faCLA rats had a lower Δ^9 desaturase index compared with faCTL and lean rats. The faCLA and lean rats had similar proportions of n-9 (18:1n-9) FA, which were lower than the faCTL group. The *fa/fa* rats had a smaller proportion of total n-6 (due to 18:2n-6) FA than lean rats. CLA-fed rats had more 18:2n-6 than CTL-fed rats, and faCLA rats had more 20:3n-6 than faCTL rats. Arachidonic acid (20:4n-6) was not affected by genotype or diet. Total n-3 FA were not changed, but CLA-fed rats had a greater proportion of 22:5n-3 than CTL-fed rats.

Hepatic gene expression. The faCLA rats had higher L-FABP mRNA levels and a trend ($P = 0.0589$) toward greater ACO mRNA levels compared with faCTL rats (Fig. 5). There was no difference in ACC mRNA levels within the *fa/fa* genotype. In lean rats, there were no differences in L-FABP, ACO, and ACC mRNA levels.

DISCUSSION

CLA isomers were incorporated into liver and affected liver lipid metabolism. Although the effects of dietary CLA on tissue CLA incorporation and FA composition have been investigated in rodent models, there is a lack of information comparing the response in normal vs. obese insulin-resistant states. In the present study, the *fa/fa* rats had just two-thirds the percentage of CLA in liver TAG and PL compared with lean rats (Fig. 4), suggesting that CLA metabolism (e.g., oxidation, storage) is altered in the obese insulin-resistant state. It has been shown by others that *t*10,*c*12 CLA is metabolized to a greater extent

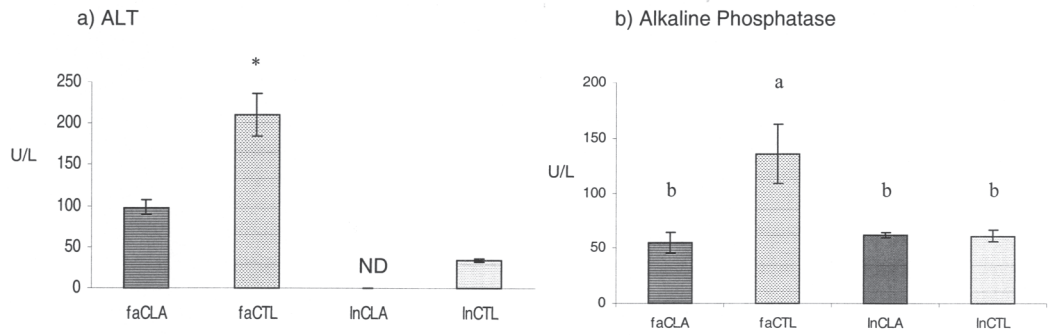

FIG. 2. Fasting serum (a) alanine aminotransferase (ALT) and (b) alkaline phosphatase. Results expressed as means ± SEM for $n = 10$ rats/group; * denotes faCTL different from faCLA and lnCTL ($P < 0.05$); means with different superscript letters are significantly different ($P < 0.05$) by Duncan's multiple range test. ND = not determined; U/L = units per liter; for other abbreviations see Figure 1.

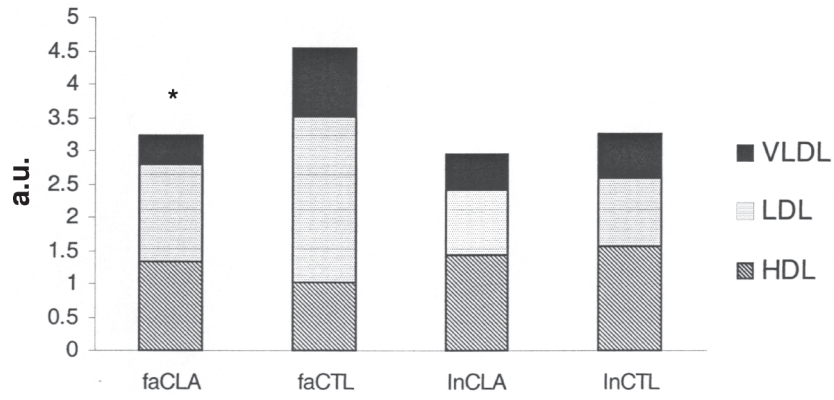

FIG. 3. Fasting serum lipoproteins. Results expressed as means for arbitrary units for lipoprotein bands for $n = 10$ rats/group except $n = 9$ for lnCLA; * denotes faCLA different from faCTL for VLDL, LDL, and HDL using pairwise comparisons ($P \leq 0.05$); a.u., arbitrary units; for other abbreviations see Figure 1.

than other isomers (30), and both the *fa/fa* and lean genotypes had more *c*9,*t*11/t8,*c*10 CLA than *t*10,*c*12 CLA in liver TAG (Table 4). Interestingly, the lnCLA rats had proportionally more *c*11,*t*13 in liver PL (Fig. 4), but, given the relatively small percentage of CLA found in liver PL, the biological significance of this remains to be determined.

The present study demonstrated that a dietary CLA mixture ameliorates hepatic steatosis (62% less total lipid; Fig. 1) in *fa/fa* Zucker rats, consistent with other studies using rat models of obesity and insulin resistance (9–12). Although the progression of NAFLD was not monitored by histology in this study, fasting serum ALT and alkaline phosphatase were lower (54 and 64%, respectively) in *fa/fa* CLA-fed rats compared with *fa/fa* CTL-fed rats (Fig. 2), illustrating the influence of excessive fat accumulation on declining liver function. In people with the metabolic syndrome, interventions that improve insulin sensitivity (e.g., weight loss, oral antihyperglycemic agents) are potential therapies for the treatment of hepatic steatosis and may improve liver function tests (31). One possible reason for the species-specific effect of CLA on insulin resistance may be differences in liver lipid content mediated by CLA. For example, CLA supplementation in mice results in hepatic steatosis and worsening of insulin resistance (7), whereas in the *fa/fa* Zucker rat, reduction of hepatic steatosis by CLA appears to be associated with improved insulin sensitivity (12,32). To date, the effects of CLA supplementation on hepatic steatosis in humans have not been reported.

Circulating lipids portray a balance between liver lipid processing and peripheral lipid storage and release. Supplementation with a CLA mixture did not alter fasting serum TAG or FFA in male (present study; Table 3) or female (32) *fa/fa* Zucker rats. However, circulating TAG and FFA were reduced by CLA supplementation in ZDF rats (CLA mixture) (33), OLETF (Otsuka Long Evans Tokushima Fatty) rats (CLA mixture) (9), normal mice (*c*9,*t*10 or *t*10,*c*12) (34), and ob/ob mice (*c*9,*t*10 but not *t*10,*c*12) (35). It is noteworthy that in the present study, the circulating FFA and TAG levels in the *fa/fa* CLA-fed rats did not change despite the central role of the liver in lipid processing and the dramatic reduction in liver lipid concentration.

In the present study, CLA supplementation reduced fasting serum total cholesterol (Table 3) and VLDL and LDL fractions

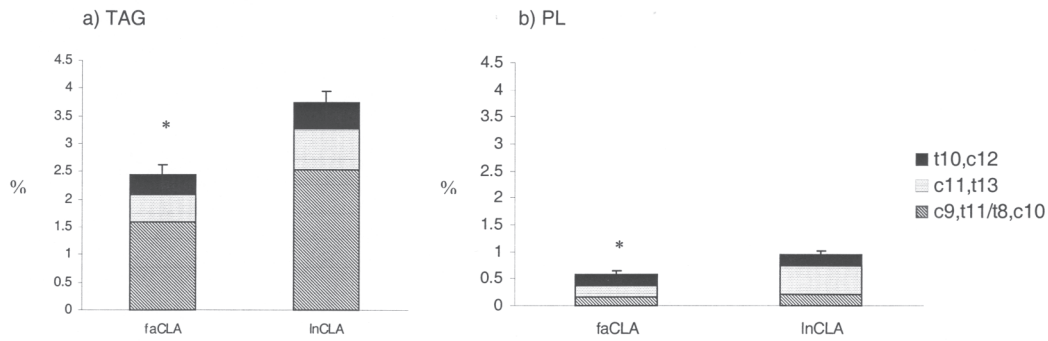

FIG. 4. CLA isomers in (a) TAG and (b) phospholipids (PL) from liver. Results (% of total FA) expressed as means for separate CLA isomers and means ± SEM for total CLA for $n = 5$ rats/group; * denotes faCLA different from lnCLA ($P < 0.05$) for total CLA (TAG and PL), *c*9,*t*11 (TAG) and *c*11,*t*13 (PL); *c*9,*t*11/*t*8,*c*10 = sum of *c*9,*t*11 and *t*8,*c*10 because these isomers coelute (29); for other abbreviations see Figure 1.

[a]Means ± SEM for $n = 5$ rats/group; main effects from ANOVA: Geno = genotype (*fa/fa* vs. lean rats), Lipid (0 vs. 1.5% CLA), and Geno × lipid = lipid × genotype interaction; means with different superscript letters are significantly different ($P < 0.05$) by Duncan's multiple range test; faCLA = *fa/fa* rats fed 1.5% CLA, faCTL = *fa/fa* rats fed 0% CLA, lnCLA = lean rats fed 1.5% CLA, lnCTL = lean rats fed 0% CLA; NS = not significantly different. Only FA present at >0.25% composition are reported.
[b]Δ^9 DS index = [(16:1n-7 + 18:1n-9)/(16:0 + 18:0)].

(Fig. 3) in *fa/fa* Zucker rats; the HDL level in *fa/fa* Zucker rats was elevated to the level of lean rats (Fig. 3). Others have reported that serum total cholesterol was reduced in OLETF rats (10) and peroxisome proliferator activated receptor α (PPARα)-null mice fed CLA mixtures (36) and in hamsters fed the *t*10,*c*12 isomer (37). In OLETF rats, dietary CLA reduced hepatic microsomal TAG transfer protein activity, which is involved in lipoprotein packaging (9), and this would contribute to reduced circulating VLDL. In healthy adults, 80:20 *c*9,*t*11/*t*10,*c*12-CLA supplementation lowered fasting plasma VLDL-cholesterol but did not affect HDL- and LDL-cholesterol (38). However, in men with the metabolic syndrome, fasting plasma HDL-cholesterol was unfavorably decreased by supplementation with a CLA mixture or *t*10,*c*12 CLA (13) but not *c*9,*t*11 CLA (14). In insulin-resistant humans, HDL carries much more TAG and is catabolized by endothelial lipase to a much greater extent compared with non-insulin-resistant persons (39).

CLA is a PPARα-ligand, and both L-FABP and ACO contain PPAR response elements (40). In the present study, the mRNA levels of hepatic PPARα did not change (data not shown). However, CLA-fed *fa/fa* rats had higher mRNA levels of PPAR-responsive genes that are markers of hepatic FA transport (L-FABP) and oxidation (ACO, $P = 0.0589$; Fig. 5) concomitant with reduced liver lipid. It is unclear why CLA supplementation did not alter these PPAR-responsive genes in the lean rats. Interestingly, the genes involved in FA oxidation (peroxisomal and mitochondrial) and transport are elevated in the liver of CLA-fed mice and rats, independent of whether CLA induces or ameliorates hepatic steatosis (8,10,31,41–43). Furthermore, up-regulation of genes for FA oxidation can occur independently of PPARα activation, based on studies using mice deficient in both PPARα and stearoyl CoA desaturase 1 (SCD1) (44). All together, the mechanism by which CLA induces or protects against hepatic steatosis in mice and rats, respectively, appears to be independent of PPARα and FA oxidation. Regulation of FA synthesis or elongation may play a greater role.

Sterol regulatory binding protein (SREBP)-1 up-regulates FA synthesis and elongation genes, including ACC and SCD1

(isoform of Δ^9 desaturase). SREBP-1 and/or its target genes have been implicated in CLA-induced fatty liver in mice (7,8,33,35). This raises the question whether CLA amelioration of fatty liver in CLA-fed *fa/fa* rats involves inhibition of SREBP-1 pathway and/or its target genes. However, in the current study, CLA did not alter ACC, a SREBP target gene, in either genotype. It is possible that CLA could be affecting ACC phosphorylation and/or other enzymes of FA synthesis. For example, CLA supplementation decreased activity of other lipid synthesis enzymes including FA synthase *in vitro* (45) and hepatic microsomal phosphatidate phosphohydrolase in OLETF rats (10).

The current study shows that CLA decreases liver Δ^9 desaturase activity in both normal lean and obese insulin-resistant rats based on the FA composition of TAG and PL (Tables 4 and 5). SCD (+/+) mice have greater liver lipid content and circulating TAG, FFA, and cholesterol than SCD (–/–) mice (44). Furthermore, SCD1 deficiency prevents hepatic steatosis and hyperlidemia in PPARα-deficient mice. SCD1 plays a key role in hepatic TAG and VLDL synthesis, as 18:1 (product of SCD activity) is essential for TAG and cholesterol ester synthesis. Thus, in the present study, reduction of hepatic Δ^9 desaturase activity may be contributing in part to the mechanism for amelioration of hepatic steatosis and improvement in lipoprotein profile in CLA-fed *fa/fa* rats.

Other desaturase enzymes may also play an important role in mediating hepatic lipid levels. In the current study, *fa/fa* insulin-resistant rats had hepatic steatosis and lower percentages

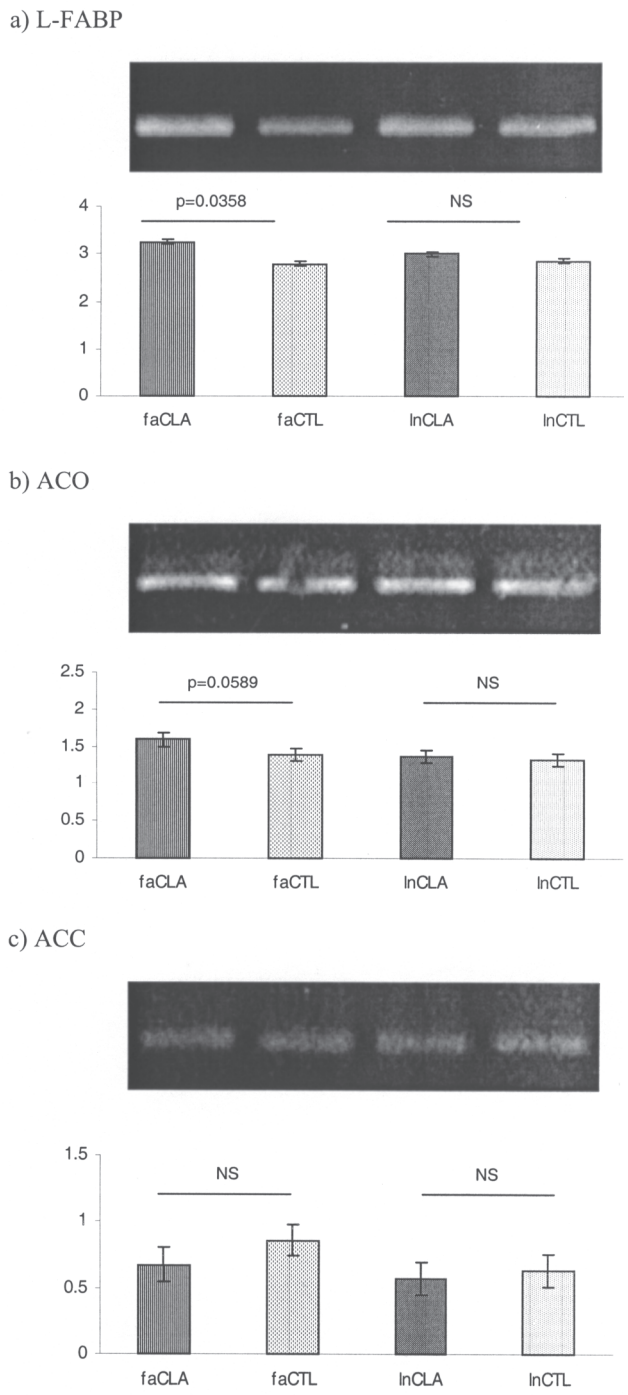

FIG. 5. Reverse transcription-polymerase chain reaction for mRNA levels of enzymes involved in (a) FA transport (L-FABP = liver FABP), (b) peroxisomal FA oxidation (ACO = acyl CoA oxidase), and (c) FA synthesis (ACC = acetyl CoA carboxylase). Results expressed as means for arbitrary units for $n = 10$ rats/group except $n = 9$ rats/group for L-FABP; *P*-values from preplanned comparisons using the housekeeping gene as a covariate; NS, not significantly different; for other abbreviations see Figure 1.

of longer-chain FA (18:3n-3, 20:4n-6, 20:5n-3, 22:5n-3, and 22:6n-3) in liver TAG, suggesting reduced activity of Δ^6-, Δ^5-desaturase, and/or enzymes of Sprecher's pathway compared with lean rats. Reduction of hepatic steatosis by CLA feeding in *fa/fa* rats was associated with a liver FA profile that resembled that of the lean rats. Investigations in mice support a role for impaired Δ^6 desaturation in the development of hepatic steatosis. Feeding 18:3n-6 (product of Δ^6-desaturation) plus CLA prevented the fatty liver normally induced by CLA in mice, possibly through altered eicosanoid metabolism (46). Thus, it is reasonable to speculate that amelioration of fatty liver by CLA in the *fa/fa* model was mediated by enhanced long-chain FA synthesis, with possible implications for eicosanoid production.

In summary, these results illustrate a strong relationship between the state of insulin resistance and liver lipid metabolism and suggest that CLA acts to favorably modify lipid metabolism in *fa/fa* Zucker rats, a model of insulin resistance and obesity. CLA reduced hepatic steatosis in the *fa/fa* Zucker rat, concomitant with reduced circulating ALT and alkaline phosphatase, improved lipoprotein profile, elevated markers of FA transport and oxidation, and altered liver FA profiles, thus implicating a role for altered liver desaturase activities.

ACKNOWLEDGMENTS

We would like to acknowledge Dairy Farmers of Canada and Natural Sciences and Engineering Research Council (NSERC) for funding to CGT and PZ, Manitoba Institute of Child Health, a division of The Children's Foundation of Manitoba, Inc., for funding to MO, NSERC for awarding a Postgraduate Scholarship to ADN, Marilyn Latta and Dennis Labossiere for their technical assistance with GC, Dr. John Kramer (Agriculture and Agrifood Canada, Guelph, Ontario) for analyzing CLA oil used for diet preparation, Dan Chateau for statistical expertise, Laura Burr and Melissa Zirk for technical assistance, and Jennifer Zahradka and the staff of the Animal Holding Facility (University of Manitoba) for assistance with animal care.

ABSTRACT: Lysobisphosphatidic acid (LBPA) is highly accumulated in specific domains of the late endosome and is involved in the biogenesis and function of this organelle. Little is known about the biosynthesis and metabolism of this lipid. We examined its FA composition and the incorporation of exogenous FA into LBPA in the human monocytic leukemia cell line THP-1. The LBPA FA composition in THP-1 cells exhibits an elevated amount of oleic acid (18:1n-9) and enrichment of PUFA, especially DHA (22:6n-3). DHA supplemented to the medium was efficiently incorporated into LBPA. In contrast, arachidonic acid (20:4n-6) was hardly esterified to LBPA under the same experimental conditions. The turnover of DHA in LBPA was similar to that in other phospholipids. Specific incorporation of DHA into LBPA was also observed in baby hamster kidney fibroblasts, although LBPA in these cells contains very low endogenous levels of DHA in normal growth conditions. Our results, together with published observations, suggest that the specific incorporation of DHA into LBPA is a common phenomenon in mammalian cells. The physiological significance of DHA-enriched LBPA is discussed.

Paper no. L9882 in *Lipids 41*, 189–196 (February 2006).

During atherogenesis, peripheral blood monocytes traverse the arterial endothelium and differentiate into macrophages. Much of the vessel wall lesion of atherosclerosis is composed of macrophages that have become engorged with cholesterol (1,2). Cells acquire cholesterol by receptor-mediated endocytosis of LDL or oxidized LDL. After endocytosis, LDL and oxidized LDL are first transported to early endosomes and then late endosomes/lysosomes (3). The molecular mechanism of cholesterol transport from late endosomes/lysosomes is not well understood. The characteristic feature of the late endosome is the accumulation of internal membranes (4). Recently it was shown that these internal membranes are highly enriched with a unique phospholipid (PL), lysobisphosphatidic acid (LBPA), also called bis(monoacylglycerol) phosphate (5,6). Antibodies against LBPA, when internalized from the medium, alter both the organization of internal membranes and the membrane traffic from late endosomes (7,8). These results suggest that LBPA-rich internal membrane domains contribute to membrane sorting and/or trafficking from late endosomes. Accumulation of cholesterol in late endosomes in Niemann–Pick type C (NPC) cells and in drug-treated cells that mimic NPC impaired membrane traffic from late endosomes (9–11). Treatment of the cells with anti-LBPA antibody also resulted in a massive accumulation of cholesterol in late endosomes, suggesting that the characteristic network of LBPA-rich membranes contained within multivesicular late endosomes regulates cholesterol transport (9).

LBPA is a structural isomer of phosphatidylglycerol. Whereas phosphatidylglycerol binds two acyl groups to one glycerol moiety, LBPA binds one acyl group to each glycerol moiety. In addition, LBPA has an *sn*-1, *sn*-1′ glycerophosphate backbone, instead of *sn*-3 stereoconfiguration, which is a common structure of all other PL (12,13). The FA composition of LBPA varies among cell types. In baby hamster kidney (BHK) cells, more than 90% of FA in LBPA is oleic acid (OA; 18:1) (6,14) whereas pulmonary alveolar macrophages efficiently incorporate arachidonic acid (AA; 20:4) (15–17). DHA (22:6) is selectively incorporated into LBPA in rat uterine stromal cells (18). DHA attracts special attention since epidemiological, animal, and clinical studies all indicate that DHA has potent anti-inflammatory and antiatherogenic properties (19,20). It is reported that membranes enriched with DHA-containing PL exclude cholesterol (21–24). Phorbol ester-treated THP-1 monocytes are a widely used model in studying cholesterol homeostasis in human macrophages (25–27). In the present study, we characterized the content, distribution, and FA composition of LBPA in THP-1 cells. Our results indicate that LBPA selectively incorporates DHA into THP-1 cells. Our results also suggest that the preferential incorporation of DHA is a common phenomenon in LBPA.

MATERIAL AND METHODS

Materials. DHA and AA were from Sigma (Saint Quentin Fallavier, France). Tissue culture media were from Eurobio (Les Ulis, France). [9,10-^{3}H]OA (23 Ci/mmol), [5,6,8,9,11,12,14,15-^{3}H]AA (200 Ci/mmol), [4,5-^{3}H]DHA (23 Ci/mmol), [1-^{14}C]DHA (54 mCi/mmol), and [1-^{14}C]EPA (20:5n-3) (54 mCi/mmol) were from PerkinElmer Life Science (Paris, France). All other lipids were purchased from Avanti Polar Lipids (Alabaster, AL). Anti-Lamp-1 mouse monoclonal antibody was obtained from Developmental Studies Hybridoma Bank at the University of Iowa (Iowa City, IA). Anti-EEA1 mouse monoclonal antibody was from Transduction Laboratories (Lexington, KY). Anti-CD63 mouse monoclonal antibody was obtained from Cymbus Biotechnology (Southampton, United Kingdom). Alexa Fluor 488 conjugated anti-mouse IgG was from Molecular Probes (Eugene, OR). Anti-LBPA mouse monoclonal antibody was obtained as described (7). Alexa Fluor 546 conjugated anti-LBPA antibody was prepared according to the manufacturer's instruction (Molecular Probes).

Cell culture. Human monocytic leukemia cell line THP-1 was obtained from RIKEN Bioresource Center (Tsukuba, Japan). Cells were grown in RPMI 1640 medium containing 10% (v/v) FCS, 2 mM L-glutamine, 100 units/mL penicillin, and 100 μg/mL streptomycin. Cells were grown in suspension in 75-cm^2 flasks at 37°C in an atmosphere of 5% CO_2 and subcloned periodically to maintain a cellular density around 2×10^5 cells/mL

Differentiation to a macrophage phenotype was induced by culturing 10–12 $\times$ 10^6 cells per 100-mm diameter dish in the presence of 100 nM phorbol myristate acetate (PMA) for 72 h. Where indicated, cells were differentiated in the presence of 5 μM AA or DHA. Medium was changed for the last 24 h. FA were added from ethanolic stock solutions, the final ethanol concentration being 0.025%. When radioactive FA were incorporated, cells were differentiated for 2 d in the presence of 100 nM PMA and then labeled with radioactive FA in complete medium for 24 h at 37°C in the presence of PMA. At the end of incubation, the medium was aspirated, cells were washed twice with PBS and scraped in PBS for lipid analysis. For immunofluorescence, cells were grown on glass-bottomed 35-mm dishes. Baby hamster kidney (BHK-21) cells were grown and maintained as described (28).

Lipid extraction and separation of lipids on TLC. Cells were collected by centrifugation and resuspended in methanol. Total lipids were extracted using the procedure of Folch *et al.* as described previously (18,29): 2 vol of chloroform were added to the methanolic cell suspension and after sonication and vortexing for 5 min, 0.9 vol of 0.88% KCl was added. Samples were vortexed and centrifuged for 10 min at 1500 $\times$ *g*. The chloroform layer was collected, and the aqueous phase was washed once with 2 vol of chloroform. The two chloroform layers were combined, dried under vacuum, and stored in chloroform at –20°C. Extracted lipids were spotted on a silica gel 60 TLC plate (20 $\times$ 20 cm, 0.25 mm; Merck AG, Darmstadt, Germany), which was developed in chloroform/methanol/40% methylamine (65:22:3, by vol). PL were revealed under UV light after spraying with 0.05% 2′,7′-dichlorofluorescein in methanol and were identified by comparison with authentic standards spotted on the same plate. For radioactive samples, the labeled compounds were detected and integrated using a Berthold LB 511 (Wildbad, Germany) TLC analyzer and identified by their R_f values as compared with those observed for standards. The silica gel containing lipids was scraped and lipids extracted using 2 $\times$ 2 mL chloroform/methanol/water (5:5:1, by vol). Water was added to the combined extracts to obtain 10:10:9 (by vol) chloroform/methanol/water mixture. The samples were vortexed and centrifuged, and the chloroform layer was collected. The solvent was then removed under nitrogen, and the dried lipids were resolubilized in chloroform.

HPLC. Purification of LBPA was carried out on a Nucleosil 5NH2, 250 $\times$ 4.6 mm column using a Hewlett-Packard 1100 HPLC system equipped with a quaternary pump and a diode array detector as previously described (18). The mobile phase was acetonitrile/methanol/water/50% methylphosphonic acid (730:250:15:0.3, by vol; pH adjusted to 6.2 with 28% NH_4OH) with a flow rate of 1.2 mL/min. The absorbance was monitored at 205 and 210 nm, and eluting lipids were identified by comparison with authentic standards. When radioactive lipids were analyzed, the detector was coupled with continuous-flow liquid scintillation counting using a Radiomatic Flow One β detector. The detector was operated with Ultima-Flow M (Packard) at a flow rate of 2.5 mL/min in a 400 μL cell. In some experiments, radioactive FAME were separated by reversed-phase HPLC using a 4.6 $\times$ 250 mm Ultrabase C18 column (SFCC-Shandon, Eragny, France) with 5 μm spherical particles as previously described (30,31). The mobile phase was acetonitrile/water (80:20 vol/vol), and the flow rate was 2.0 mL/min. The absorbance was monitored at 210 nm. Peaks were identified by comparing retention times with authentic standards.

GC. The FA composition of total lipids, PL classes, and purified LBPA was determined by GC after transmethylation using 5% H_2SO_4 in methanol (100°C, 90 min). FAME were analyzed with a Hewlett-Packard 5590 gas chromatograph. The capillary column was an SP2380 (0.32 mm, 30 m; Supelco, Bellefonte, PA). The temperature was programmed from 145 to 225°C at 1.2°C/min. Helium was used as a carrier gas. FAME were identified by comparison with the relative retention times of known standards. The percentage and mass of each FA were calculated using an internal standard (pentadecanoic acid methyl ester) as described previously (18,30).

Immunofluorescence. All manipulations were performed at room temperature. Cells were first washed with PBS and then were fixed with 3% paraformaldehyde in PBS for 20 min, quenched with 0.1 M NH_4Cl and then blocked with 0.2% gelatin in PBS. Cells were then permeabilized by treatment with 50 μg/mL digitonin for 5 min followed by incubation with the first monoclonal antibodies. After 30 min of incubation with Alexa Fluor 488 conjugated anti-mouse IgG, cells were washed with PBS and further incubated with Alexa Fluor 546 conjugated anti-LBPA monoclonal antibody. The specimens were mounted with Mowiol and examined under a Zeiss LSM

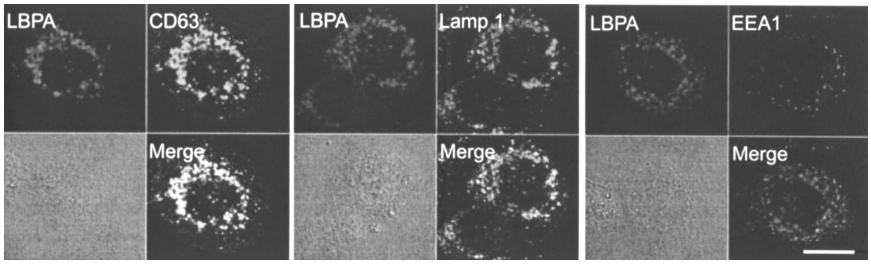

FIG. 1. Intracellular distribution of lysobisphosphatidic acid (LBPA) in THP-1 macrophages examined by immunofluorescence. THP-1 cells were grown for 3 d in the presence of 100 nM phorbol myristate acetate (PMA). Cells were then fixed and permeabilized as described in the Materials and Methods section. Cells were then doubly labeled with anti-LBPA antibody and various endosome markers as indicated. Bar, 10 μm.

510 confocal microscope equipped with C-Apochromat 63XW Korr (1.2 n.a.) objective.

Data analysis. Data are expressed as mean ± SD. Statistically significant difference was tested using Student's *t*-test for paired samples.

RESULTS

LBPA in THP-1 cells. In the present study, we characterized LBPA in the cultured macrophage cell line THP-1. LBPA was purified from THP-1 total lipid extracts, using a first separation from total lipids by TLC, and a further separation by HPLC as described previously (18). The proportion of LBPA compared with other PL was determined on the basis of FA content in the different PL classes. Expressing the results as a percentage of total PL, based on the FA amount in each PL class, LBPA represents 1.4 ± 0.7% (mean ± SD) of the total PL, phosphatidylcholine (PtdCho) 51.7 ± 3.5%, phosphatidylethanolamine (PtdEtn) 23.8 ± 7.0%, sphingomyelin 6.0 ± 1.3%, and phosphatidylinositol/phosphatidylserine 16.3 ± 2.3%. The low proportion of LBPA was also found in THP-1 cells before differentiation into macrophages (data not shown).

The intracellular distribution of LBPA was then measured using a specific monoclonal antibody (7). In Figure 1, THP-1 macrophages were doubly labeled with anti-LBPA and anti-CD63 monoclonal antibodies, anti-LBPA and anti-Lamp 1 monoclonal antibodies, or anti-LBPA and anti-EEA1 monoclonal antibodies, as described in the Materials and Methods section. CD63 is a member of the four-time membrane-spanning proteins (tetraspanins) and is enriched in the internal membranes of multivesicular late endosomes (32,33). Lamp-1 is localized in the limiting membranes of late endosomes (7,34). LBPA was not co-localized with the early endosome marker, EEA1 (35). Co-localization of LBPA with late endosome markers indicates that, similar to other cell types (7,36), LBPA is enriched in late endosomes in THP-1 macrophages.

[a]Total lipids were obtained from THP-1 macrophages [3 d of differentiation with 100 mM of phorbol myristate acetate (PMA)] without (control cells) or with 5 μM of FA. Phospholipids (PL) were separated by TLC and analyzed as described in the Materials and Methods section. The FA composition is expressed as mol% of total FA, and represents means ± SD from three separate experiments. PtdEtn, phosphatidylethanolamine; PtdCho, phosphatidylcholine; LBPA, lysobisphosphatidic acid; MUFA, monounsaturated FA. Trace means <1% of total FA. Significant differences with respect to the values of unsupplemented cells were determined using Student's *t*-test and are indicated with asterisks. *$P < 0.05$; **$P < 0.01$.

TABLE 2
Percent Distribution[a] of Radioactivity in Lipids from THP-1 Macrophages Labeled for 24 h with [^{3}H]AA, [^{3}H]OA, [^{14}C]DHA, or[^{14}C]EPA

	Percentage of total radioactivity in PL			
Radioactive FA	ChoGpl	EtnGpl	PtdIns/PtdSer/Cer*P*Cho	LBPA
DHA	19.5 ± 4.2	66.3 ± 4.1	6.5 ± 3.0	6.4 ± 1.1
AA	19.0 ± 2.7	69.4 ± 7.5	13.6 ± 0.8	0.8 ± 0.3
EPA	16.1 ± 2.7	72.7 ± 8.5	9.7 ± 2.2	1.6 ± 0.4
OA	63.8 ± 0.1	21.8 ± 0.1	4.2 ± 0.3	7.5 ± 0.1
DHA/AA	1.0	1.0	0.5	8.0

[a]Values refer to averages ± SD of three different experiments. Total lipids were obtained from THP-1 cells differentiated 2 d with 100 nM of PMA and the last 24 h, with 100 nM PMA plus 0.5 μCi/mL of radioactive FA. PL classes were separated by TLC and analyzed as described in the Materials and Methods section. OA, oleic acid; ChoGpl, cholineglycerophospholipids; EtnGpl, ethanolamineglycerophospholipids; PtdIns, phosphatidylinositol; PtdSer, phosphatidylserine; Cer*P*Cho, sphingomyelin; for other abbreviations see Table 1.

LBPA is enriched with DHA in THP-1 cells. Table 1 shows the FA composition of LBPA and two major PL classes, PtdCho and PtdEtn, in THP-1 macrophages. The FA composition of PtdCho and PtdEtn obtained in this experiment is close to that reported by others (37). PtdEtn contains a high level of monounsaturated FA (MUFA) and is enriched with PUFA compared with PtdCho, which is mainly constituted of saturated FA and MUFA. The major FA in LBPA were saturated FA and MUFA, especially 18:1, which represents 26% of the total FA. However, the PUFA content in LBPA was relatively high. n-3 and n-6 PUFA together account for 20% of the total FA in LBPA, whereas this proportion was 26% in PtdEtn and less than 5% in PtdCho. The main PUFA of LBPA were AA (20:4n-6) and DHA (22:6n-3), which were found in similar proportions. It is noteworthy that DHA accounts for 33% of the total PUFA in LBPA. This percentage is higher than those in PtdEtn and PtdCho (20 and 17%, respectively) whereas AA represents around 35% of the total PUFA regardless of the PL class. Moreover, DHA was the only n-3 PUFA representative in LBPA. In contrast, PtdEtn contained both EPA (20:5n-3) and docosapentaenoic acid (22:5n-3) in addition to DHA. We have also analyzed PL from undifferentiated THP-1 cells (data not shown) and found similar FA compositions, indicating that PMA treatment and the differentiation of monocytes into macrophages had no significant effect on cellular FA composition.

DHA is selectively incorporated into LBPA in THP-1 cells. We then asked whether exogenously added FA alter FA composition of LBPA, PtdCho, and PtdEtn. As shown in Table 1, after DHA supplementation, the proportion of this FA was significantly increased in the three PL compared with their respective controls. Interestingly, the highest increase of DHA was found in LBPA with a 4.5-fold increase vs. a 3- and 2.8-fold increase, respectively, in PtdCho and PtdEtn. This increase of DHA in LBPA was compensated for by a significant decrease in the proportion of AA and a less marked decrease of stearic acid (18:0) and OA. In contrast, incorporation of DHA did not significantly decrease the percentage of AA in PtdCho and PtdEtn. In supplemented cells, DHA accounted for more than 90% of the total n-3 PUFA in LBPA as compared with 70% in PtdEtn. Determination of the FA amounts revealed that the cellular LBPA content was not affected by incubation with DHA (0.26 ± 0.12 vs. 0.27 ± 0.12 nmol/10^6 cells, in control and supplemented cells, respectively). After AA supplementation, the proportion of AA was significantly increased in PtdCho and PtdEtn, and levels of linoleic acid were also increased, with a compensatory decrease in MUFA. In contrast, no increase of AA and its retroconversion products was observed in LBPA.

	Percentage of total radioactivity in PL			
FA	ChoGpl	EtnGpl	PtdIns/PtdSer/Cer*P*Cho	LBPA
[^{14}C]DHA 5 μM	23.6 ± 4.2	64.5 ± 4.7	4.7 ± 0.7	7.2 ± 0.6
+ AA 5 μM	24.0 ± 2.7	63.7 ± 3.1	4.2 ± 0.2	8.0 ± 0.1
[^{3}H]DHA 10 nM	22.3 ± 0.7	61.9 ± 0.8	7.0 ± 0.3	8.8 ± 0.8
+ AA 5 μM	25.0 ± 1.6	58.8 ± 1.5*	6.9 ± 0.3	9.3 ± 0.7

[a]Values refer to averages ± SD of triplicates. Total lipids were obtained from THP-1 cells differentiated 2 d with 100 nM of PMA and the last 24 h, with 100 nM PMA plus 5 μM [^{14}C]DHA or 10 nM [^{3}H]DHA in the absence or presence of 5 μM AA. PL were separated by TLC and analyzed as described in the Materials and Methods section. For abbreviations see Tables 1 and 2.

TABLE 4
Percent Distribution[a] of Radioactivity in PL from BHK Cells Labeled for 24 h with [^{3}H]AA, [^{3}H]OA, or [^{3}H]DHA

	Percentage of total radioactivity in PL			
Radioactive FA	ChoGpl	EtnGpl	PtdIns/PtdSer/Cer*P*Cho	LBPA
DHA	5.8 ± 0.8	76.1 ± 4.2	13.9 ± 3.6	3.0 ± 0.6
AA	7.0 ± 0.6	70.3 ± 0.9	21.3 ± 0.1	0.4 ± 0.1
OA	38.7 ± 2.6	45.8 ± 3.7	10.7 ± 2.1	4.5 ± 0.5
DHA/AA	0.8	1.1	0.7	7.5

[a]Values refer to averages ± SD of three different experiments. Total lipids were obtained from baby hamster kidney (BHK) cells labeled for 24 h with 0.5 μCi/mL of radioactive FA. PL were separated by TLC and analyzed as described in the Materials and Methods section. For other abbreviations see Tables 1 and 2.

Altogether, these results show that DHA is preferentially incorporated into LBPA.

The apparent selectivity of LBPA for DHA was further examined by comparing the incorporation of several radioactive FA into PL classes. Radiolabeled OA, AA, EPA, and DHA were incubated with THP-1 macrophages for 24 h, and the distribution of cellular radioactivity was determined after separation of the lipid and PL classes by TLC (Table 2). For OA and DHA, nearly 5% of the incorporated radioactivity was found associated with LBPA, which represents less than 1% of the total PL in terms of mass. This is indicative of a high rate of incorporation of these FA in LBPA, when compared with AA. Indeed, DHA was eightfold more efficiently incorporated than AA into LBPA (Table 2). After incubation with EPA, a precursor of DHA, LBPA was only slightly labeled. EPA was metabolized to DHA, with 2% of radioactive EPA being converted to DHA as shown in total cellular lipids. This proportion increased up to 40% in LBPA (data not shown), indicating that DHA, which was derived from EPA, was preferentially esterified into LBPA. These results, together with those presented in Table 1, show that regardless of the source of DHA (i.e., formed either by elongation/desaturation or by direct addition), DHA was incorporated selectively into LBPA in THP-1 macrophages.

We next examined whether the selectivity for DHA still would be observed if DHA was coincubated with AA. This condition mimics the *in vivo* situation where both FA are present at comparable levels and could therefore compete for uptake and incorporation mechanisms. THP-1 macrophages were incubated with 5 μM [^{14}C]DHA (0.3 μCi/mL) in the absence or presence of 5 μM AA. Total incorporation of radioactive DHA was not affected by the presence of exogenous AA (92.8 ± 0.06% of initially added radioactivity vs. 92.9 ± 0.21% in the control experiment). In addition, the distribution of incorporated radioactivity to total PL was not significantly altered (85.3 ± 5.1% of cellular radioactivity vs. 87.6 ± 4.4% in the control). As shown in Table 3, the percentage of DHA incorporated into LBPA was not modified in the presence of 5 μM AA. We have also incubated macrophages with 10 nM [^{3}H]DHA (0.3 μCi/mL) together with a 500 times higher concentration of AA (5 μM). In this condition, coincubation with AA reduced the cellular uptake of DHA (83.6 ± 2.5% of initially added radioactivity vs. 95.2 ± 5.2% in the control, $P \leq 0.05$) but not its distribution in total PL (82.2 ± 1.8% of cellular radioactivity vs. 85.3 ± 3.7% in controls). Of interest, the percentage of DHA incorporated into ethanolamineglycerophospholipids (EtnGpl) was slightly decreased whereas it was not changed into LBPA (Table 3). These results indicate the LBPA selectivity for DHA even when a high level of AA is available for incorporation.

DHA is selectively incorporated into LBPA in BHK cells. Selective incorporation of DHA into LBPA has been reported in several cell types (18,38). The results in pulmonary macrophages are controversial. Whereas Huterer and Wherrett (38) showed the efficient incorporation of DHA, Waite and colleagues (17) reported that LBPA is a reservoir of AA. The FA composition of LBPA varies among cell types. In BHK cells, more than 90% of FA in LBPA is OA (18:1) (6). To determine whether selective incorporation of DHA into LBPA is a common phenomenon, we measured the incorporation of radioactive FA in BHK cells. Radioactive DHA and OA were efficiently incorporated into LBPA whereas, as observed in THP-1 cells, AA was not significantly incorporated with a DHA/AA ratio of around 8, as shown in Table 2 for THP-1 cells (Table 4).

DHA turns over similarly in PtdCho, PtdEtn, and LBPA in THP-1 cells. The present results, together with previous reports, confirm the selective ability of LBPA to incorporate DHA and suggest that this selectivity is extended to most cell types, regardless of their DHA content in LBPA. The reason for the preferential incorporation of DHA into LBPA is not understood. It has been suggested that the turnover of certain FA, such as AA and OA, is high in LBPA of pulmonary alveolar macrophages (15). Conversely, one might suggest that the turnover of DHA in LBPA is particularly slow compared with that in other PL, allowing its accumulation in that pool. This possibility was examined in THP-1 cells by following the removal of DHA from PL after the cells had been supplemented with DHA. As shown in Figure 2, after 3 d of supplementation, the DHA content was increased by 400% in LBPA, 280% in PtdEtn, and 220% in PtdCho compared with nonsupplemented control cells. After DHA removal, the DHA content decreased progressively back to the initial value in all PL. The data show no significant difference of DHA turnover in LBPA compared with PtdCho and PtdEtn.

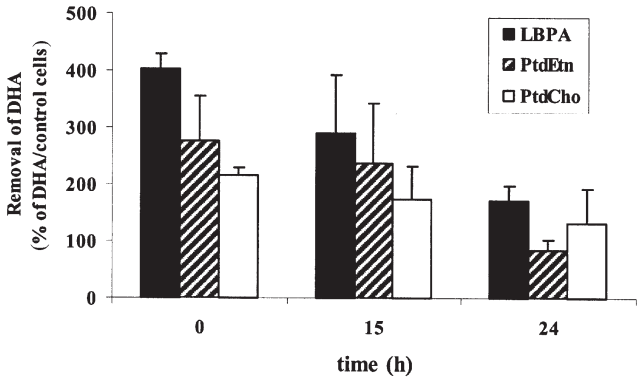

FIG. 2. Turnover of DHA in various phospholipids in THP-1 macrophages. THP-1 cells were grown for 3 d in the presence of 100 nM PMA and 5 μM DHA (time 0). DHA was then removed and cells were further incubated for various intervals in normal medium. Lipids were then extracted, and DHA composition was measured by GC. DHA content without supplementation represents 100%. PtdEtn, phosphatidylethanolamine; PtdCho, phosphatidylcholine; for other abbreviations see Figure 1.

DISCUSSION

The present study was undertaken to characterize LBPA in THP-1 macrophages in the context of related investigations on the putative role of LBPA in cholesterol homeostasis. We first showed that LBPA is almost exclusively localized in late endosomes in THP-1 macrophages, which is important regarding its involvement in LDL-derived cholesterol transport. Lipid composition of monocytic THP-1 cells already has been reported, but no data were available for differentiated macrophages, in particular for LBPA content and FA composition. Our data indicate that LBPA represents 1–2% of total PL in THP-1 macrophages and accumulates in late endosomes. This proportion is not different from peritoneal macrophages in which LBPA was also reported to be a minor PL (15). In contrast, in pulmonary alveolar macrophages, LBPA constitutes roughly 15–18% of the total cellular PL (15,16). It has been postulated that the presence of a large quantity of the precursor phosphatidylglycerol in lung surfactant could account for such a high level of LBPA in alveolar macrophages (39). Most other mammalian cell types, including human fibroblasts (39), polymorphonuclear leukocytes (16), BHK cells (6,14), PC12 cells (40), and rat uterine stromal cells (18) contain low amounts of LBPA. A striking accumulation of LBPA, however, is found in tissues from patients suffering from genetic lipidosis such as Niemann–Pick disease (41) as well as rat organs treated with drugs that induced lysosomal lipid storage (14,42–44).

The FA composition of LBPA in THP-1 macrophages resembles that of other cell types in terms of the elevated amount of OA (18:1n-9) and enrichment in PUFA. The proportion of OA was found to constitute 30–50% of total FA of LBPA in uterine stromal cells (18) and pulmonary alveolar macrophages (15–17), reaching more than 80% in BHK cells (6,14). With respect to PUFA, our data suggest an enrichment in DHA, as reported for PC12 cells (40) and uterine stromal cells (18). This is strikingly different from the situation observed in pulmonary alveolar macrophages. The latter cells contain mostly n-6 FA, mainly linoleic acid (18:2n-6) and AA, but have only a trace amount of DHA in their LBPA (15–17). In rat testis, 22:5n-6 accounts for more than 70% of the total FA of LBPA (18). It thus appears that while PUFA are consistently reported as being substantial constituents of LBPA, the specific composition of the PUFA varies depending on the cell type. This supports the idea that FA composition of LBPA could depend on the cellular function of this PL, as described for AA-containing LBPA in rabbit pulmonary macrophages (17).

Our results show that both THP-1 and BHK cells efficiently incorporated DHA into LBPA by comparison with other FA such as OA and AA. It should be noticed that although the percentage of DHA incorporation was not significantly different from that of OA in BHK cells, OA represents more than 80% of the endogenous FA in LBPA of those cells. In contrast to DHA, incorporation of AA into LBPA was very inefficient in both THP-1 and BHK cells. Preferential incorporation of DHA into LBPA has been reported in other cell types. In pulmonary alveolar macrophages, DHA was more efficiently incorporated than AA into LBPA despite a much lower endogenous content of DHA (0.5 vs. 7%) (38). In uterine stromal cells, where AA makes up about 6% of the total FA in LBPA (18), no labeling was detected after incubation with radioactive AA, while DHA was readily incorporated. Our present data further show that the high incorporation of DHA into LBPA was not affected by the presence of a high level of AA, which brings out further evidence for selectivity of LBPA toward DHA. One interesting point is that, whereas AA and DHA were found in similar amounts in LBPA in THP-1 macrophages, only exogenous DHA, but not AA, was incorporated in this PL. This suggests that DHA turnover in LBPA is much more rapid than that of AA. The specific localization of LBPA in late endosomes may also be important in this respect. It is possible that in these acidic compartments, FA metabolism differs from what is typically described for cellular membrane PL. For example, it is not known whether all FA can equally reach these compartments or whether classical acyltransferases are efficient. This is an important difference with EtnGpl that are enriched in both n-3 and n-6 PUFA and can also incorporate AA at a high rate. It should be noted that both EtnGpl and LBPA show high affinity for DHA, which raises the question of a potential relationship between these PL. Preliminary data using plasmalogen EtnGpl-deficient human skin fibroblasts showed that the DHA content in LBPA was not changed in these cells compared with controls, arguing against a role of plasmalogens as a reservoir of DHA during LBPA remodeling. From our present data, we can exclude a difference in turnover of DHA in LBPA compared with other PL to explain DHA enrichment and high incorporation. It may be alternatively proposed that the selective incorporation of DHA into LBPA reflects a DHA-specific transacylase activity (13,45) or is related to the unique cellular localization of LBPA. Further experiments will be necessary to elucidate the molecular mechanisms of the preferential incorporation of DHA into LBPA.

The physiological relevance of DHA enrichment of LBPA must also be addressed. LBPA is almost exclusively localized in membranes of late endosomes that are essential compartments of the endocytic pathway and participate in LDL-derived cholesterol distribution. The content of DHA in biological membranes has been shown to influence membrane properties such as fluidity, fusion, and raft formation (24). Importantly, it has been reported that membranes enriched with DHA-containing PL exclude cholesterol (21–23). These properties may be advantageous for the removal of cholesterol from late endosomes. DHA has interesting medical implications since its dietary presence has been positively linked to the prevention of numerous human afflictions including cancer and heart disease (46–49). However, little is known about the molecular mechanisms of action of DHA. Future study of DHA in LBPA may shed a revealing light on the biological role of this unique FA.

METHOD

Characterization of Hair Lipid Images by Argon Sputter Etching–Scanning Electron Microscopy

Yoshinori Masukawa[a], Hiroto Tanamachi[b], Hisashi Tsujimura[a], Akira Mamada[b], and Genji Imokawa[a,*]

Kao Corporation, [a]Tochigi Research Laboratories, Haga, Tochigi, 321-3497 Japan, and [b]Tokyo Research Laboratories, Tokyo, 131-8501 Japan

ABSTRACT: Hair lipid images, as visualized by argon sputter etching–scanning electron microscopy (ASE–SEM), reveal convex structures with a stitch pattern (SP) at the cell membrane complex (CMC) in the transverse hair plane. Based on interindividual variation, different features of the convex SP were classified into Types 0 to 4 with the corresponding scores 0 to 4. Observations using hair fibers collected from 27 Japanese females revealed significant positive correlations between the scores and the levels of exogenous lipids, which suggests that exogenous lipids internalized at the CMC predominantly constitute the convex SP. Intraindividual variation with different levels of exogenous lipids among hair fibers derived from individual females may be relevant to the uneven physicochemical properties of hair fibers on the scalp. Observations of 380 hair fibers collected from Japanese (Mongoloid), German and American (Caucasoid) females aged 3 to 77 yr demonstrated similar age-related changes in the lipid images, which represent an increase and then a decrease in levels of exogenous lipids with increasing age. This suggests that age-related changes in exogenous lipids are attributable to alterations in sebum excreted during aging and that this elicits age-related changes in physical parameters, which affect human hair texture.

Paper no. L9887 in *Lipids 41,* 197–205 (February 2006).

Human hair fibers are composed mainly of proteins (>90% dry hair weight) and lipids (1–9%). Each hair fiber consists of a central medulla surrounded by more tightly packed, spindle-shaped cortical cells, with 5 to 10 layers of flat, overlapping scale-like cuticle cells and with the cell membrane complex (CMC) located in the intercellular spaces between cuticle and cortical cells (1). Structures such as the cuticle, the cortex, the medulla (absent in some fibers), and the CMC are common among hair fibers of different races (2–5), although their diameters, shapes, and colors are different (1,6). Squalene (SQ), wax esters (WEs), triglycerides (TGs), free fatty acids (FFAs), cholesterol (CH), ceramides (CERs), and cholesterol sulfate (CS) comprise the free lipids, whereas 18-methyl eicosanoic acid is a bound lipid within hair fibers (7–14). Since hair lipids exist at the CMC and at the cuticle surface, they seem to play roles in the physicochemical characteristics of hair fibers, including the chemical diffusion barrier, the water-holding property, and the cell cohesion (14–17). The composition of hair lipids is changed by effects of daily weathering such as shampooing, conditioning, exposure to sunlight, and brushing (18), and by chemical oxidation such as bleaching (Masukawa, Y., Tsujimura, H., Tanamachi, H., Narita, H., and Imokawa, G., unpublished data). However, the reports of age-related changes in hair lipids are few (16,19,20).

We established a novel method for visualizing hair lipids at the CMC using argon sputter etching–scanning electron microscopy (ASE–SEM) (21). This method provides characteristic images consisting of a circular pattern (CP) and/or a stitch pattern (SP) at the cortex in a transversely polished hair plane, without complicated procedures such as are needed for transmission electron microscopy (2–5). The CP and the SP are formed at melanin granules and the CMC, respectively, as convex structures. The convex formation of the SP is ascribed to CMC lipids, which may ooze out from the inside to the surface of the hair plane as a result of the heat generated during the ASE and which may be chemically changed into immobilized structures as a part of the CMC. This effect allows us to characterize the distribution of hair lipids at the CMC using the novel ASE–SEM methodology (21). However, it remains to be clarified which lipids among free hair lipids [such as SQ, WEs, TGs, FFAs, CH, CERs and CS (7–13)] are the predominant contributors to the convex SP in ASE–SEM images of hair fibers.

With this new methodology (21), the variation of the convex SP in ASE–SEM images was examined in this study by using hair fibers from 27 Japanese females, and the ASE–SEM images were then classified and scored based on the frequency and strength of the convex SP. These scores were compared with the levels of hair lipids. Further, age-related changes in the convex SP in ASE–SEM images were evaluated using 380 hair fibers from Japanese (Mongoloid), German and American (Caucasoid) females (3–77 yr old). We now report that higher levels of exogenous lipids within hair fibers predominantly induce greater convex SP and that the resulting hair lipid profiles change with aging in all races tested.

MATERIALS AND METHODS

Chemicals. Epon 812 resin, 25% glutaraldehyde, and osmium tetroxide were purchased from TAAB (Reading, United Kingdom). As authentic lipids, SQ, palmityl palmitate, tripalmitin, palmitic acid, CH, β-cholestanol (BC), and CS were purchased from Sigma (St. Louis, MO). Ceraminde/*N*-palmitoyl-DL-dihydrosphingosine (CER/PDS) and ceramide/*N*-myristoyl sphingosine (CER/MS) were from Funakoshi (Tokyo, Japan) and from Avanti Polar Lipids (Alabaster, AL), respectively. Hexane, chloroform, methanol, and pyridine of infinity pure grade were from Wako Pure Chemicals Industries (Tokyo, Japan). Methanol of HPLC grade was from Kanto Reagents (Tokyo, Japan) and was used to prepare the mobile phase solution for LC connected to MS analysis. *N*-Trimethylsilylimidazole was from GL Science (Tokyo, Japan) and was used to derivatize hair lipids. Ultra-pure water prepared using a Milli-Q purification system (Millipore, Bedford, MA) was used for all analytical procedures. All other chemicals were of the highest analytical grade commercially available.

Materials. Scalp hair fibers from the proximal root end were kindly provided by 27 Japanese females (designated as No. 1 to No. 27) who had not treated their hair with chemical reactions such as permanent waving, bleaching, or coloring for at least 6 mon. In a second experiment, a total of 380 hair fibers, each of which was cut just at the proximal root end for each individual, were collected from 380 females [153 Japanese (Mongoloid) ranging from 3 to 68 yr old, 169 Germans (Caucasoid) from 18 to 77 yr old, and 58 Americans (Caucasoid) from 10 to 65 yr old]. None of the 380 females had treated their hair with chemical reactions such as permanent waving, bleaching, or coloring for at least 2 mon before collection.

For observations using ASE–SEM, hair fibers were washed with *n*-hexane for 5 min to remove the surface lipids and then were air-dried. In contrast, in preparation for analyzing hair lipid contents, hair fibers (*ca*. 20 mg) were washed successively with plain shampoo for 1 min and with tap water for 10 min. This procedure was repeated twice. The fibers were then dried at room temperature for more than 48 h, and, after washing with *n*-hexane for 5 min, their weight was measured accurately. The washing with *n*-hexane for 5 min was determined based on our previous experiment on the effects of *n*-hexane incubation time of hair fibers on extracted lipid contents (20), which suggested that the lipids present on the inside of the hair are removed under *n*-hexane incubation for more than 5 min.

ASE–SEM observations. In all hair fibers, the region 1-cm distant from the proximal root end was observed by ASE–SEM according to previously reported procedures (21). Thus, each hair fiber was embedded in Epon 812 resin, and each resin-embedded hair block was transversely polished with a diamond knife (MT6740; DiATOME Ltd., Biel, Switzerland) and was exposed to ASE (Hitachi Ion Sputter E-1030, Hitachinaka, Japan). Each specimen was then etched under conditions of a pressure of 6 to 7 Pa, a current of 6 mA, a voltage of 0.3 kV, a working distance of 30 mm, and a time of 360 s. After coating with Pt-Pd using the same instrument (Hitachi Ion Sputter E-1030), the polished hair planes were observed using a Hitachi S-4300 field emission scanning electron microscope with an accelerating voltage of 5 kV.

Analysis of hair lipids. Hair lipids were analyzed as previously reported (18). All analyses were performed in duplicate, and their average values are expressed as mg/g hair. Small pieces of hair fibers were cut with scissors and were immersed successively in chloroform/methanol (2:1, 1:1, 1:2, vol/vol) and chloroform/methanol/water (18:9:1, by vol) for 24 h. Each filtrate of solvent mixtures was dried under a nitrogen stream, and the residue was then dissolved in chloroform/methanol. Although there are several molecular species of CERs in human hair (12), CER/PDS was determined as a representative target because it is one of the predominant molecules in the hair fibers.

Levels of SQ, WEs, TGs, and FFAs were determined by TLC coupled to FID, using an Iatroscan MK-5 analyzer (Iatron Laboratories, Tokyo, Japan), a silica gel-coated Chromarod SIII (Iatron Laboratories), and a microdispenser (Drummond Scientific Co., Broomall, PA,). The level of CS was determined by LC–MS using an Agilent 1100 Series LC/MSD SL system equipped with ChemStation software (Agilent Technologies, Palo Alto, CA) and an L-Column ODS 2.1 mm i.d. × 150 mm (Chemical Evaluation and Research Institute, Tokyo, Japan). The mass spectrometer, using electrospray ionization, was operated in selected ion monitoring (SIM) mode with $m/z = 465$ for CS. Levels of CH and CER/PDS followed by trimethylsilylation were determined by GC–MS using an Agilent 6890 Series GC coupled to an Agilent 5973 mass selective detector, equipped with ChemStation software (Agilent Technologies) and an Ultra Alloy #1 metal capillary column of 30 m × 0.25 mm i.d. and a film thickness 0.15 μm. The internal standards BC and CER/MS were added to the lipid samples containing CH and CER/PDS, and they were then trimethylsilylated. The mass spectrometer was operated in electron impact mode, and the ions $m/z = 443$, 445, 313, and 342 in SIM were detected for trimethylsilylated-CH, trimethylsilylated-BC, trimethylsilylated-CER/PDS, and trimethylsilylated-CER/MS, respectively.

Statistical analyses. Correlation coefficients between the scores of the ASE–SEM images and each level for hair lipids were determined using Excel Tahenryo-Kaiseki version 3.0 software (Esumi, Tokyo, Japan).

RESULTS

ASE–SEM images of hair fibers from Japanese females. Representative ASE–SEM images of a transversely polished hair plane are shown in Figure 1. In SEM images without ASE, the hair plane can be visualized only as an even surface; when ASE treatment is performed on the hair plane prior to SEM observation, a characteristic image, consisting of the convex CP that reflects melanin granules and the convex SP that reflects lipid portions of the CMC at the cortex, is observed (21). Our preliminary observations by ASE–SEM revealed that, whereas the convex CP were always formed in all hair fibers, the convex SP varied among different hair fibers. Therefore, using ASE–SEM, we

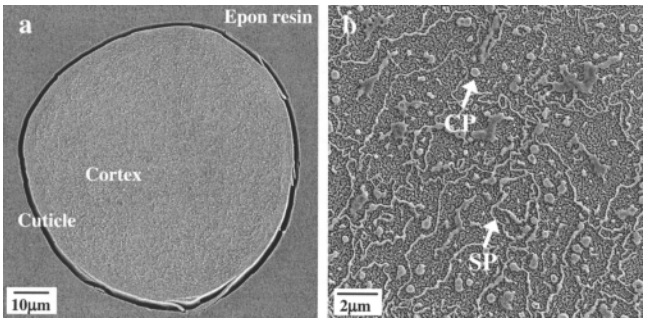

FIG. 1. Representative argon sputter etching–scanning electron microscopy (ASE–SEM) images of a transversely polished hair plane embedded in Epon resin. (a) A whole hair plane image, where cuticle, cortex, and Epon resin are observed. (b) A magnified image for part of the cortex in image a, where a circular pattern (CP) and a stitch pattern (SP) are observed.

characterized the variation of the convex SP in hair fibers derived from 27 Japanese females. ASE–SEM images are shown in Figure 2 for Japanese female No. 2, in Figure 3 for No. 13, and in Figure 4 for No. 24. In all hair planes of No. 2, ASE–SEM images consisted of both convex CP and SP (Fig. 2), which resembled those observed previously in virgin hair fibers (21). Convex CP but not convex SP were observed in ASE–SEM images in all hair planes of No. 13 (Fig. 3), which were almost the same as those in hair fibers delipidized by incubation with chloroform/methanol/water prior to the ASE procedures (21). In the ASE–SEM images of hair fibers of No. 24, convex CP were commonly observed in all hair fibers, but the convex SP in the hair plane varied in membranous morphology as well as in their 3D structures among the five fibers observed (Fig. 4). In some fibers, convex SP were observed sparsely over the hair planes (Fig. 4a,c), whereas in others, convex SP were observed densely and homogeneously (Fig. 4b,d,e). These observations demonstrate that there are individual variations and differences in the convex SP even among fibers derived from the same person.

Based on the variation in convex SP, ASE–SEM images were classified into Types 0 to 4 and scored with a 0 to 4 grading system, respectively, as shown in Table 1. Representative ASE–SEM images corresponding to Types 0 through 4 are depicted in Figure 5. For Type 0 (score = 0) convex SP characteristically were not detectable (Fig. 5a). All ASE–SEM images in Figure 3 were classified as Type 0. Type 1 (score = 1) was assigned according to a characteristic in which a thin convex SP was seen sparsely (Fig. 5b). The ASE–SEM image for Figure 4c was classified as Type 1. For Type 2 (score = 2) a thin convex SP was observed over most of the plane (Fig. 5c). The ASE–SEM image for Figure 4a was classified as Type 2. Type 3 (score = 3) was assigned by a characteristic in which both thin and thick convex SP were observed over all of the plane (Fig. 5d). The ASE–SEM image for Figure 4e was classified as Type 3. Type 4 (score = 4) was assigned according to a characteristic in which a thick convex SP was observed all over the plane (Fig. 5e). The ASE–SEM images for all fibers in Figure 2 and for Figure 4b and 4d were classified as Type 4. The types of ASE–SEM images and their scores for 27 Japanese females according to this classification are listed in Table 2. Since the averages and the SE of the scores reflect inter- and intraindividual variation, respectively, their values (as shown in Table 2) allow us to evaluate the differences in ASE–SEM images among females, as well as among fibers from each female.

Relationship between ASE–SEM images and lipid composition. Levels of SQ, WEs, TGs, FFAs, CH, CER/PDS, and CS in 27 Japanese females were determined using the proximal root regions, which were close to the observation sites of the ASE–SEM images for each female, by TLC–FID, GC–MS and LC–MS (18), as listed in Table 3. The lipid analyses demonstrated that although the lipid composition varied among the females tested, the levels of exogenous lipids (SQ, WEs, TGs, and FFAs) were in general greater than endogenous ones (CH, CER/PDS, and CS); and FFAs and WEs were predominantly present. These findings are in agreement with our previous re-

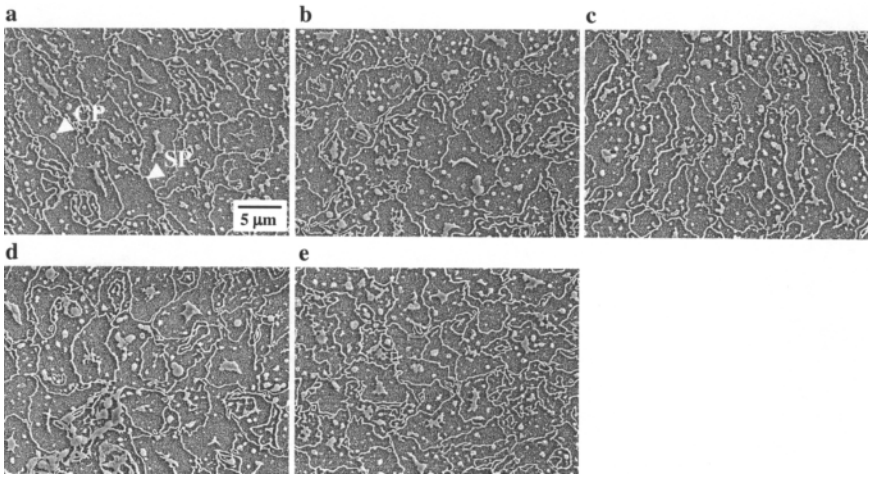

FIG. 2. ASE–SEM images in Japanese female No. 2. The images a–e, which include a CP and an SP, were obtained from five different hair fibers from the same scalp. For abbreviations see Figure 1.

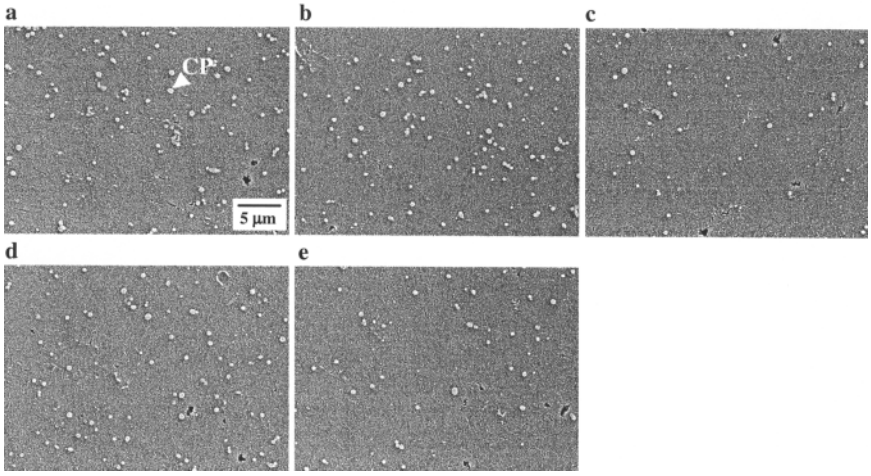

FIG. 3. ASE–SEM images in Japanese female No. 13. The images a–e, which include a CP, were obtained from five different hair fibers from the same scalp. For abbreviations see Figure 1.

ports (18,20). Table 4 shows the correlation coefficients between the average scores of the ASE–SEM images (Table 2) and the levels of hair lipids (Table 3) for 27 Japanese females. The average scores had significant positive correlations with the levels of WEs (R = 0.846), FFAs (R = 0.813), SQ (R = 0.530) and TGs (R = 0.424), and significant negative correlations with the levels of CH (R = −0.892) and CER/PDS (R = −0.688). The level of CS did not correlate with the average scores. A relationship between the average scores and the levels of WEs, which had the highest positive correlation, is shown in Figure 6. This correlation indicates that hair fibers with higher average scores in the ASE–SEM images contain higher levels of WEs as well as other exogenous FFAs, SQ, and TGs.

Characterization of ASE–SEM images in relation to aging. Individual hair fibers cut just at the proximal root end were collected from 380 females, consisting of 153 Japanese (Mongoloid), 169 Germans and 58 Americans (Caucasoid), and the transverse hair planes at the 1-cm region from the proximal root end were then observed using ASE–SEM. Table 5 shows the types of ASE–SEM images obtained from the hair fibers of 153 Japanese females. No females with Type 3 or Type 4 in their

TABLE 1
Scores and Features in Type 0 to Type 4[a] of Classification of ASE–SEM Images

	Score	Feature
Type 0	0	No convex SP is detectable.
Type 1	1	Thin convex SP is observed sparsely.
Type 2	2	Thin convex SP is observed mostly over the plane.
Type 3	3	Thin and thick convex SP is observed all over the plane.
Type 4	4	Thick convex SP is observed all over the plane.

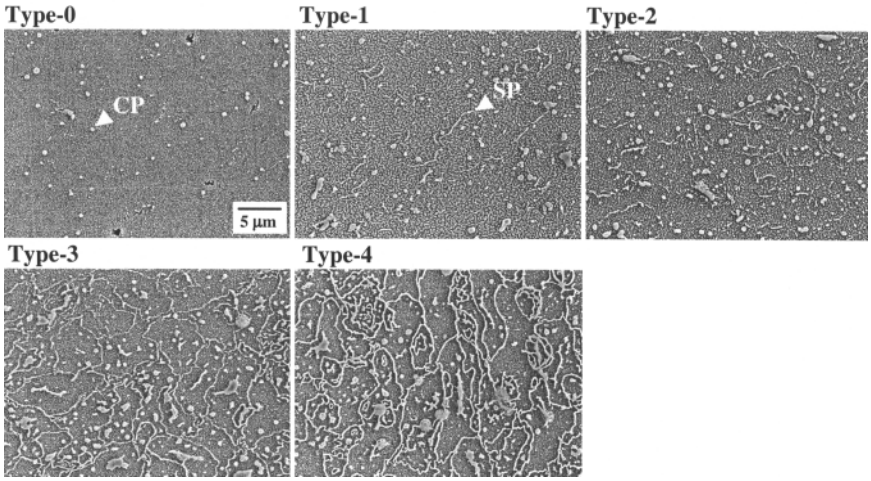

FIG. 5. Representative ASE–SEM images corresponding to Types 0–4. For abbreviation see Figure 1.

hair fibers were observed in the youngest group aged 0 to 9 yr. However, in the younger female group aged 10 to 29 yr, the percentages of Type 3 or Type 4 sharply increased, and in the older female group aged 50 to 69 yr, the percentages of Type 3 or Type 4 decreased (Table 5). Changes in the percentages of Type 0 or Type 1 according to aging were inversely related to those of Type 3 or Type 4. Table 6 shows the types of ASE–SEM images from the hair fibers of 169 German females. Changes in the types of ASE–SEM images for German females with aging are almost identical to those for Japanese females, although we had no individuals in the youngest German female group aged 0 to 9 yr. Thus, the percentages of females with Type 3 or Type 4 were greater in the younger group than in the older group, while those with Type 0 or Type 1 were greater in

[a]See Figure 5. For abbreviation see Table 1.

the older group than in the younger group (Table 6). There was a marked increase in the percentages of German females with Type 0 or Type 1 with aging, probably because only German females included the oldest group, aged 70 to 79 yr (Tables 5, 6). Table 7 shows the types of ASE–SEM images from the hair fibers of 58 American females. Changes in the types of ASE–SEM images for American females with aging (Table 7) were almost identical to those for Japanese and German females, although we had no individuals in the youngest group aged 0 to 9 yr or in the oldest group aged 70 to 79 yr.

The average scores for the hair fibers from all 380 females tested are shown in Table 8. Although the ASE–SEM images of the youngest female group aged 0 to 9 yr were taken only of Japanese, the average score of the ASE–SEM images in the youngest female group was found to be the lowest. Common characteristics associated with age-related changes were observed in all races (Mongoloid and Caucasoid); younger females aged 10 to 29 yr had higher scores and older females aged 50 to 69 yr showed lower scores (Table 8). In the oldest females aged 70 to 79 yr, who were only Germans, a marked decrease in the average score was observed dependent on aging.

DISCUSSION

Our previous study, which used the proximal root regions of hair fibers collected from 44 different Japanese females (1 to 81 yr of age), revealed that the lipid composition of hair in females varies from person to person as well as with age (20). The predominant variation was a negative correlation between exogenous lipids (SQ, WEs, TGs, and FFAs) and endogenous

lipids (CH and CERs), which suggests that endogenous lipids might serve as a barrier against the penetration of sebum-derived exogenous lipids. In addition, age-related changes in the composition of exogenous hair lipids are found, which seem to reflect an increased sebum secretion during adolescence (20). On the other hand, we recently established the ASE–SEM method to visualize hair lipids at the CMC in hair fibers (21). In ASE–SEM images, the convex SP in a transversely polished hair plane would be considered an indicator of the localization of hair lipids, based on the fact that whereas virgin hair fibers have convex SP in their polished hair planes, solvent-treated hair fibers lack convex SP (21).

The present study reveals that the convex SP in ASE–SEM images among females includes not only inter- but also intraindividual variation among hair fibers. Since a convex SP is associated with hair lipids, these variations reflect differences in hair lipids among females as well as among fibers derived from each female. We used the interindividual variation among females to determine which lipids predominantly contribute to the convex SP. According to characteristics in frequency and

strength of the convex SP, ASE–SEM images were classified into Type 0 through 4, and scored as 0–4, respectively, as shown in Table 1 and Figure 5. When relationships between the average scores obtained from ASE–SEM images and the measured levels of hair lipids were evaluated for 27 Japanese females, we found significant positive correlations between the scores and the levels of WEs, FFAs, SQ, and TGs (as listed in Table 4). This indicates that a convex SP is attributable to the levels of exogenous lipids such as WEs, FFAs, SQ, and TGs. The contribution of exogenous lipids to the formation of convex SP is corroborated by our previous study, which showed that, although delipidized hair fibers had no convex SP in ASE–SEM images, treatment with FA and wax esters induced the reappearance of convex SP in the hair plane (21). We also found significant negative correlations between the average scores and the levels of endogenous lipids such as CH and CER/PDS, as listed in Table 4, in which higher levels of endogenous lipids in hair fibers correlated with fewer convex SP in ASE–SEM images. Since the higher levels of endogenous lipids are paralleled by lower levels of exogenous lipids that have penetrated into the hair fibers, these negative correlations may support the possibility that a convex SP is mainly composed of exogenous lipids that have penetrated from the surface against the possible barrier function regulated by endogenous lipids.

The present study also suggests the notion of an internalized site for exogenous lipids consisting of sebum excreted at the hair follicle and diffused within a hair fiber. Although the existence of exogenous lipids within hair fibers is well known (7–9,11,13,20), such an internalized site has not been hitherto reported. However, our study indicates that exogenous lipids, such as SQ, WEs, TGs, and FFAs, are mainly associated with the convex formation of SP at the CMC in ASE–SEM images, which suggests in turn that the internalization of exogenous lipids within hair fibers mainly occurs at the CMC.

Furthermore, the intraindividual variation of the convex SP suggests another implication about the heterogeneous features of hair fibers growing on the scalp. Since levels of exogenous lipids had been previously determined using bundles of hair and by conventional analytical methods (7–13,18,20), their variation along a single hair fiber on the scalp had not been detectable. However, the observed intraindividual variation in the convex SP seen in this study suggests that ASE–SEM can roughly measure the variation in levels of exogenous lipids along hair fibers derived from the scalp. Thus, because the contents of exogenous lipids seem to be closely related to physicochemical properties such as hydrophobicity, water holding, and elasticity of hair fibers, the determination of the variation in the levels of exogenous lipids by ASE–SEM would be helpful when considering the properties of scalp hair fibers. If a female has variations in the levels of exogenous lipids among her hair fibers, her scalp hair can be considered physicochemically uneven, which might result in heterogeneous properties, including its texture and appearance.

Taken together, the advantages of the ASE–SEM method can be summarized as follows: (i) The interindividual variation can be useful for characterizing exogenous lipids among individuals, which may contribute to understanding different hair fibers in relation to age, sex, and race, (ii) the intraindividual variation also can be useful for characterizing exogenous lipids among fibers derived from an individual, which may allow us to clarify physicochemical properties of scalp hair fibers. In this study, results from 380 hair fibers from 380 females revealed that levels of exogenous lipids, which reflect convex SP, changed in relation to aging. The youngest females aged 0 to 9 yr (only Japanese) have lower levels of exogenous lipids, whereas hair from younger females aged 10 to 29 yr tends to contain higher levels of exogenous lipids. Further, older females aged 50 to 69 yr, and in particular, the oldest females aged 70 to 79 yr (only Germans), have lower levels of exogenous lipids. The age-related changes in the levels of exogenous lipids agree with our previous study that described hair lipid composition and its variation in Japanese females aged 1 to 81 yr (20). These changes seem to be similar regardless of racial origin tested. Since sebaceous excretion is known to increase during adolescence in females and then decrease gradually after menopause (22,23), the lower levels of exogenous lipids may be ascribed to a reduced excretion of sebum in the youngest or oldest females.

Changes in hair with aging have been reported by other groups with respect to the level of cholesterol (19), water content (16), diameter, and physical properties (24). As for the physical properties, Naruse and Fujita examined hair fibers collected from 81 Japanese females aged 2 to 91 yr with stress-strain curves; the physical parameters, such as breaking strength, breaking extension, and breaking energy, showed the highest values in 15–20 yr-old women and then gradually decreased with aging (24). These changes in the physical parameters of female hair are similar to those of the levels of exogenous lipids in this study. This suggests that age-related changes in exogenous lipids may be associated with changes in physical parameters of female hair, such as hydrophobicity, water holding and elasticity, which affect their texture with respect to moisture content, smoothness, and flexibility.

ACKNOWLEDGEMENTS

We would like to express our cordial gratitude to Dr. Katsumi Kita of the Kao Corporation for his invaluable encouragement in this study. Our sincere thanks are also due to Miho Suzuki of the Hitec Corporation for technical support in the SEM observations.

Lower Weight Gain and Higher Expression and Blood Levels of Adiponectin in Rats Fed Medium-Chain TAG Compared with Long-Chain TAG

Hiroyuki Takeuchi*, Osamu Noguchi, Seiji Sekine, Aiko Kobayashi, and Toshiaki Aoyama

Division of Healthcare Science, Research Laboratory, Nisshin Oillio Group, Yokosuka, Kanagawa 239-0832, Japan

ABSTRACT: Previous studies demonstrated that, compared with long-chain TAG (LCT), dietary medium-chain TAG (MCT) could improve glucose tolerance in rats and humans. It has been well established that adiponectin acts to increase insulin sensitivity. The effects of dietary MCT on adiponectin serum concentration and mRNA levels in adipose tissue were studied in rats. Male Sprague-Dawley rats were fed a diet containing 20% MCT or LCT for 8 wk. After 6 wk of dietary treatment, an oral glucose tolerance test was performed. Rats fed the MCT diet had less body fat accumulation than those fed the LCT diet ($P < 0.01$). The cell diameter of the perirenal adipose tissue, one of the abdominal adipose tissues, was smaller ($P < 0.01$) in the MCT diet group. The serum adiponectin concentration was higher ($P < 0.01$) in the MCT diet group than in the LCT diet group. The adiponectin content in the perirenal adipose tissue was higher ($P < 0.01$) in the MCT diet group. The MCT-fed group had a higher adiponectin mRNA level in their perirenal adipose tissue ($P < 0.05$). The increase of the plasma glucose concentration after glucose administration (area under the curve) was smaller ($P < 0.01$) in the MCT diet group than in the LCT diet group. These findings suggest that dietary MCT, compared with LCT, results in a higher serum adiponectin level with transcriptional activation of the adiponectin gene in rats. We speculate that improved glucose tolerance in rats fed an MCT diet may be, at least in part, ascribed to this higher serum adiponectin level.

Paper no. L9779 in *Lipids 41*, 207–212 (February 2006).

Medium-chain TAG (MCT) are edible oils consisting of medium-chain FA. The digestion, absorption, and metabolism of MCT are markedly different from those of long-chain TAG (LCT) (1). Animal and human studies have provided evidence that MCT impact not only lipid metabolism (1–4) but also glucose metabolism (5,6). Han *et al.* (5) found improved glucose tolerance and insulin sensitivity in MCT-fed rats, compared with LCT. Eckel *et al.* (6) reported that an MCT diet, compared with an LCT diet, increased insulin sensitivity in both diabetic patients and nondiabetic subjects.

Adiponectin (also known as ACRP30, apM1, and AdipoQ) is one of the adipocytokines secreted by mature adipocytes that circulate in high concentrations in the blood (7). It is well established that adiponectin acts to increase insulin sensitivity (8). A high-fat diet increased the adipocyte size of the adipose tissue, and at the same time decreased the adiponectin mRNA levels in mice (9). These studies indicate that the suppression of adipocyte hypertrophy might lead to a higher plasma adiponectin level, resulting in protection against insulin resistance (10).

Previous studies showed that the cell size of adipose tissue was significantly smaller in animals fed MCT than in those fed LCT (3,11,12). We hypothesized that dietary MCT might increase serum adiponectin concentration by transcriptional activation of the adiponectin gene in adipose tissue, resulting in improved glucose tolerance. Therefore, we investigated the effects of dietary MCT on the serum adiponectin concentration and adiponectin mRNA level in adipose tissue of rats.

MATERIALS AND METHODS

Animals and diets. All animals were treated in accordance with the guidelines for the care and use of laboratory animals (Notification of the Prime Minister's Office in Japan). The experimental plan was approved by the Laboratory Animal Care Committee of the Research Laboratory, Nisshin Oillio Group. Male Sprague-Dawley rats (Japan SLC, Hamamatsu, Japan) were individually housed in stainless steel wire cages and allowed free access to sterilized water. The temperature of the animal room was set at 23 ± 1°C, with RH of 50 ± 5% and illumination from 0800 to 2000 h. The animals were also allowed free access to a commercial stock diet before the experiment.

Eight-week-old rats were randomized into two groups. Each group of rats ($n = 10$ or 9) was allowed free access to the experimental diet containing 20% of one of the test oils for 8 wk. The experimental diets contained the following ingredients (g/kg): cornstarch, 249.955; casein, 200; test oil, 200; soybean oil, 30; AIN-93G mineral mix (13), 35; AIN-93 vitamin mix (13), 10; cellulose, 269.5; L-cystine, 3; choline bitartrate, 2.5; and TBHQ, 0.045. The soybean oil, MCT, and rapeseed oil were purchased commercially (Nisshin Oillio Group, Tokyo, Japan). The rapeseed oil was used as the LCT. The FA compositions of the test

oils (Table 1) were determined by GLC (6890 series; Agilent Technologies, Palo Alto, CA) with a capillary column (SP2340; Supelco, Bellefonte, PA) (4). The digestible energy of the two diets was calculated as the gross energy fed minus the energy in feces. The energies of the diets and feces were determined using a bomb calorimeter (CA-4P, Shimadzu, Kyoto, Japan).

At the end of the feeding period, the rats were killed by decapitation after 6 h of food deprivation. In a separate experiment, we confirmed that rats were not hungry after 6 h of food deprivation. Blood was collected to obtain serum, which was stored at −80°C until use. The abdominal adipose tissues (perirenal, epididymal, and mesenteric) were carefully removed using scissors and weighed. Carcass samples were obtained by removing the abdominal adipose tissues and liver and were stored at –80°C until analyses.

Glucose tolerance test. After 6 wk of dietary treatment, an oral glucose tolerance test was performed. The animals were food-deprived for 6 h. Blood samples were obtained from the tail vein using heparinized syringes at 0, 30, 60, 90, 120, and 180 min after the oral administration of 2 g glucose/kg body wt. The area under the curve (AUC) for glucose and insulin was determined using the trapezoidal rule (14).

Analyses. The carcass fat content was analyzed by a method reported previously (15). The adipose cell size was determined in osmium-fixed cells as described by Hirsch and Gallian (16). Briefly, adipose tissue samples were placed in plastic vials containing osmium tetroxide and collidine for immediate fixation. Postfixation, connective tissue and debris were removed *via* filtering through 250 and 25 μm nylon mesh screens with saline. The cell size was determined using a laser scattering particle-size analyzer (LA-500, Horiba, Kyoto, Japan). The fat cell number was calculated using the following formula: number of cells/g = average cell size (pL) × 0.95 (ng lipid/1 pL) × g/10^9 ng (17). This product was then multiplied by the number of grams of tissue to get the fat cell number.

The adiponectin levels in the serum and adipose tissue were measured by an ELISA kit (Otsuka Phamaceutical, Tokyo, Japan) according to the manufacturer's instructions. The adiponectin in the adipose tissue was extracted with 10 mmol/L HEPES containing 1 mmol/L EDTA and 1% NP-40. The plasma glucose and insulin concentrations were determined by using a colorimetric assay kit (Wako Pure Chemical, Osaka, Japan) and ELISA kit (Shibayagi, Shibukawa, Japan), respectively.

The mRNA levels of adiponectin, retinoid X receptor (RXR), peroxisome proliferator-activated receptor γ (PPARγ), liver receptor homolog-1 (LRH-1), tumor necrosis factor α (TNF-α), and cAMP response element binding-protein (CREB) binding protein (CBP) in the perirenal adipose tissue were measured by quantitative real-time PCR (LightCycler PCR; Roche, Basel, Switzerland). The total RNA from the adipose tissue (80–100 mg) was extracted from each adipose tissue using RNeasy Lipid Tissue Mini (Qiagen, Hilden, Germany). Reverse transcription (RT) (1 μg of total RNA) was performed with the SuperScript First-Strand Synthesis System for RT-PCR (Invitrogen, Carlsbad, CA). The following sense and antisense primers were used (GenBank accession numbers are in parentheses): adiponectin (AY033885), nucleotides 130–148 and 250–268; RXR (L06482), nucleotides 908–927 and 1037–1056; PPARγ (AF156665), nucleotides 1269–1288 and 1417–1436; LRH-1 (NM 021742), nucleotides 1350–1369 and 1478–1497; CBP (AY462245), nucleotides 5123–5142 and 5222–5241; TNF-α (X66539), nucleotides 150–168 and 291–309; β-actin (NM 031144), nucleotides 939–958 and 1095–1114. The data were analyzed according to the comparative cycle threshold method and were normalized by the β-actin expression in each sample.

Statistical analysis. Data were expressed as mean ± SEM. The results were analyzed by the *F*-test for equality of variance, and significant differences between the diet groups were determined by the Student's or Welch's *t*-test. Differences with a value of $P < 0.05$ were considered significant. A statistical software package (Toukei version 2; Esumi, Tokyo, Japan) was used for all of the statistical analyses.

RESULTS

Body weight, food intake, and body fat mass. The body weight gain was significantly lower in the rats fed the MCT diet than in those fed the LCT diet (Table 2). There was no significant difference in food and digestible energy intake between the two diet groups. The weight of the abdominal adipose tissue was significantly lower in the MCT diet group than in the LCT diet group. The carcass fat content was also significantly lower in the MCT-fed rats.

Cell size, cell number, and adiponectin content of adipose tissues. The weight of the perirenal adipose tissue was significantly lower in the rats fed the MCT diet than in those fed the LCT diet (Table 3). The cell diameter of the perirenal adipose tissue in the rats fed the MCT diet was smaller than those fed the LCT diet. However, the cell numbers of the two groups were the same. The adiponectin content (expressed as per gram of adipose tissue and per 10^6 cells) in the perirenal tissue was significantly higher in the MCT diet group than in the LCT diet group.

Serum adiponectin, leptin, glucose, and insulin. The serum adiponectin concentration was significantly higher in the rats fed the MCT diet than in those fed the LCT one (2.6 ± 0.2 vs.

5.1 ± 0.5 mg/L, Table 4). There was no significant difference in the serum leptin concentration between the two diet groups. The rats fed the MCT diet had a significantly lower serum glucose concentration than those fed the LCT diet. The type of dietary fat did not affect the insulin concentration.

Adiponectin, RXR, PPARγ, LRH-1, TNF-α, and CBP mRNA in adipose tissue. There was no significant difference in β-actin expression between the LCT and MCT groups (100 ± 7 vs. 98 ± 8% of LCT diet group). The adiponectin mRNA level in the perirenal adipose tissue was significantly higher in the rats fed the MCT diet than in those fed the LCT diet (129 ± 9 vs. 100 ± 8% of LCT diet group, Table 5). The RXR and PPARγ mRNA levels were also significantly higher in the rats fed the MCT diet. The rats fed the MCT diet tended (P = 0.06) to have a higher LRH-1 mRNA level than those fed the LCT diet. The TNF-α and CBP mRNA levels of perirenal adipose tissue were found to be similar between the two diet groups.

Oral glucose tolerance test. The plasma glucose concentration before glucose administration was not significantly different between the two diet groups (Fig. 1A). The plasma glucose

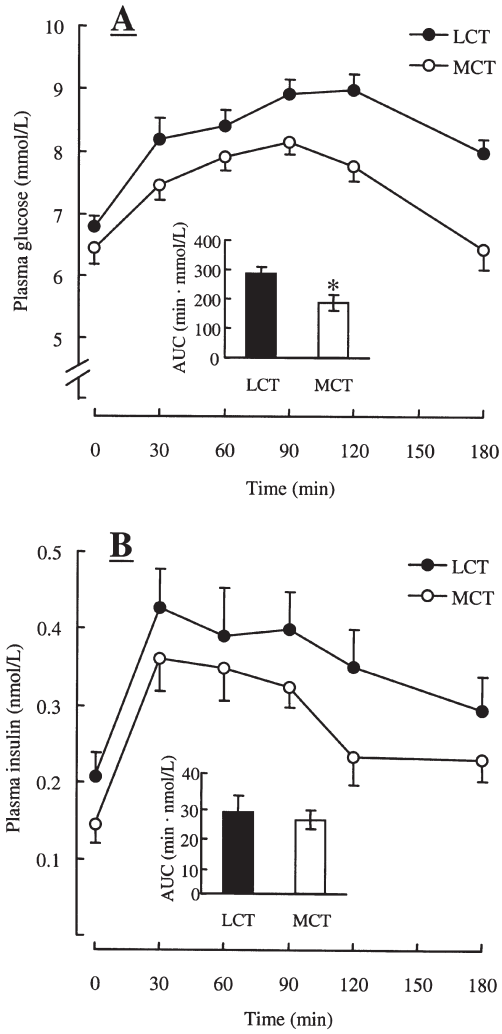

FIG. 1. Plasma glucose (A) and insulin (B) responses after oral administration (2 g glucose/kg body wt) in rats fed long-chain TAG (LCT) or medium-chain TAG (MCT) for 6 wk. The areas under the curve (AUC) during the 180 min period after oral glucose administration were determined using the trapezoidal rule. Values are means ± SEM, n = 10 (LCT) or 9 (MCT).

concentration gradually increased after glucose administration, and the levels reached peaks after 90 min in the MCT diet group and 120 min in the LCT diet group. For 180 min after glucose administration, the plasma glucose levels appeared to be lower at all time points in the MCT diet group than in the LCT diet group. The increase in the plasma glucose concentration during the 180 min period after oral glucose administration (AUC) was significantly lower in the rats fed the MCT diet than in those fed the LCT one.

There was no significant difference in the plasma insulin level before glucose administration between the two diet groups (Fig. 1B). The plasma insulin levels of the two groups increased immediately (30 min), and then decreased gradually. The plasma insulin levels also appeared to be lower at all time points in the MCT diet group than in the LCT diet group. However, the increase of the plasma insulin concentration during the 180 min period after glucose administration (AUC) was not significantly different between the two diet groups.

DISCUSSION

Here, we demonstrated that rats fed a diet containing MCT had a higher serum adiponectin concentration than rats fed a diet containing LCT. Adiponectin is a protein exclusively secreted by adipocytes (7). We also observed that rats fed the MCT diet had a higher adiponectin content and mRNA level in their perirenal adipose tissue than those fed the LCT diet. These results indicate that the intake of MCT, compared with LCT, might promote adiponectin production by an increase of the mRNA expression in adipose tissue, resulting in the elevation of the plasma adiponectin concentration. To our knowledge, this is the first time that the effect of MCT on the serum concentration and mRNA level of adiponectin has been reported. The link between adiponectin and visceral adiposity and insulin resistance has been discussed (8). Therefore, we focused on abdominal adipose tissues in the present study.

In this study, the effects on adiponectin expression and blood levels of 8-wk consumption of LCT and MCT diets were compared. We did not have data on adiponectin expression and blood levels before intake of the test diets. The adiponectin levels in rats fed a standard chow diet (Labo MR Stock; Nosan Corporation, Yokohama, Japan) at the age of 8 and 16 wk were 3.9 ± 0.4 and 2.9 ± 0.4 mg/L, respectively (obtained from a separate experiment). Much more research is needed to clarify the changes in adiponectin expression and blood levels of adiponectin by intake of a MCT diet.

Results from animal and human studies show that adiponectin increases insulin sensitivity (8,9,18–25). Low adiponectin levels have been strongly implicated in the development of insulin resistance in mouse models of both obesity and lipoatrophy (9). Adiponectin knockout mice exhibited severe diet-induced insulin resistance with reduced insulin signaling activity in muscle (19). The administration of adiponectin improves glucose metabolism and insulin sensitivity in animal models of obesity and insulin resistance (9,20,21). In humans, circulating adiponectin concentrations are significantly lower in cases of obesity, type 2 diabetes, and insulin resistance (22). Lindsay *et al.* (23) demonstrated that plasma adiponectin levels were lower in Pima Indians, a unique cohort with a high prevalence of obesity, with diabetes. They also demonstrated that the plasma levels of adiponectin are strongly correlated with insulin sensitivity as evaluated by the glucose disposal rate (24). These studies show that adiponectin plays a key role in the prevention of diabetes mellitus (25).

The suppression of adipocyte hypertrophy leads to a higher plasma adiponectin level (10). In the present study, the cell size of the perirenal adipose tissue in the rats fed the MCT diet was smaller than that in rats fed the LCT diet. It is likely that the higher expression and serum level of adiponectin in the MCT group resulted from the suppression of adipocyte hypertrophy, rather than being a result of the MCT *per se*. On the other hand, PPARγ ligands prevent adipocyte hypertrophy and increase the expression and plasma concentration of adiponectin (26,27). Unsaturated FA are natural ligands for PPARγ. However, saturated FA, including medium-chain FA, are poor PPARγ ligands compared with unsaturated FA (28). Hence, it may be difficult to explain the transcriptional activation of the adiponectin gene in the MCT diet group by the ligand action of medium-chain FA.

MCT are metabolized differently from LCT (1). On one hand, ingested MCT are more easily degraded to FA and glycerol by pancreatic lipase compared with LCT and are absorbed directly into the portal circulation and transported to the liver for rapid oxidation. On the other hand, absorbed LCT flow into the veins *via* lymphatic vessels and are transported to peripheral tissues, such as adipose tissues and muscle tissues. Therefore, the fast rate of oxidation of MCT increases energy expenditure and results in less body fat accumulation (13,29,30). We have reported larger diet-induced thermogenesis in rats fed MCT than in those fed LCT (30). Diet-induced thermogenesis occurs mainly in brown adipose tissue regulated by the sympathetic nervous system (31,32). Thus, the fast oxidation rate of MCT might relate to the activity of the sympathetic nervous system and uncoupling protein. In this study, we also observed less body fat accumulation in the MCT diet group than in the LCT diet group. The mass of adipose tissue is dependent on the size and number of its adipocytes (33). Previous studies reported that the adipocyte size (but not adipocyte number) was smaller in the MCT-fed than in the LCT-fed rats, using rats with >250 g body weight (3,11,12). In the present study using 8-wk-old rats, we also observed a smaller adipocyte size in the MCT diet group, whereas the adipocyte number was not affected by dietary fat. However, Hashim and Tantibhedyangkul (33) investigated the effects of feeding a MCT diet on the development of adipose tissue in postweanling rats. They reported that the MCT-fed rats had a smaller size and number of adipocytes than the LCT-fed rats. The effect of dietary MCT on adipocyte number may depend on the age of the animals.

Animal studies have already shown that insulin action is modulated by the type of fat (34). In these studies, saturated fat significantly increased insulin resistance, and unsaturated FA significantly improved it (35). MCT used in this study contained medium chain length saturated FA. However, this study

showed improved glucose tolerance in rats fed a diet containing MCT, compared with LCT rich in unsaturated FA. Previous studies also demonstrated that dietary MCT improve glucose tolerance in rats and humans (5,6). These results indicate the possibility of modulating insulin sensitivity by changing the length of the dietary saturated FA.

Little is known about the mechanism of higher adiponectin expression by suppression of adipocyte hypertrophy. In this study, mRNA levels related to adiponectin gene expression were determined. RXR and PPARγ mRNA levels were significantly higher in the rats fed the MCT diet. The PPARγ/RXR heterodimer directly bound to the peroxisome proliferator-activated receptor-responsive element (PPRE) and increased the promoter activity in cells. Previous studies demonstrated that TNF-α suppresses the gene expression of PPARγ and adiponectin (27,36). The TNF-α mRNA level in perirenal adipose tissue was not affected by the type of dietary fat in the present study. A future study should be designed to clarify the mechanism.

It has been reported that serum leptin concentration is positively correlated with subcutaneous fat (37). It must be noted that serum leptin levels did not seem affected despite the lower body fat in rats fed the MCT diet. However, the reason for this contradiction is unknown.

In conclusion, we demonstrated higher serum adiponectin levels and higher levels of adiponectin mRNA in perirenal adipose tissue in rats fed a diet containing MCT as compared with LCT. These findings suggest that dietary MCT, compared with LCT, causes higher serum adiponectin level with transcriptional activation of the adiponectin gene in rats. We speculate that improved glucose tolerance in rats fed an MCT diet may be, at least in part, ascribed to higher serum adiponectin level. In this study, we investigated the effect of a diet containing 20% of MCT on adiponectin in rats. It is difficult to administer a 20% MCT diet to human. Further study on the effects of partial substitution of MCT for LCT is necessary.

ACKNOWLEDGMENTS

We would like to thank Yumiko Ishikawa for her conscientious assistance with the animal care.

[a]Institute of Brain Chemistry and Human Nutrition, London Metropolitan University, London, United Kingdom, and [b]School of Nutritional Sciences, The Hebrew University of Jerusalem, Israel

ABSTRACT: The synthesis of docosahexaenoic (DHA, 22:6n-3) and Osbond acid (OA, 22:5n-6) is regulated by the heterodimer of peroxisome proliferator-activated receptor and retinoid X receptor (RXR). 9-*Cis* retinoic acid, a metabolite of vitamin A, is the most potent ligand of RXR. We tested whether vitamin A deficiency impairs DHA and OA synthesis in rats fed a vitamin A- and α-linolenic acid (ALA)-sufficient (VASALAS), vitamin A-sufficient and ALA-deficient (VASALAD), vitamin A–deficient and ALA-sufficient (VADALAS), or vitamin A- and ALA-deficient (VADALAD) diet. After 7 wk of feeding, liver and colon choline (CPG) and ethanolamine (EPG) phosphoglyceride FA were analyzed. The VADALAS compared with the VASALAS rats had elevated levels of both DHA ($P < 0.05$) and OA ($P < 0.005$) in liver CPG and EPG. In contrast, the VADALAD group had a lower DHA ($P < 0.01$) and higher OA ($P < 0.005$) level in CPG and EPG of both tissues than their VASALAD counterparts. ALA deficiency reduced DHA and enhanced OA levels in liver and colon CPG and EPG in both the vitamin A-sufficient (VASALAS vs. VASALAD) and -deficient (VADALAS vs. VADALAD) rats ($P < 0.005$). The study demonstrates that ALA deficiency reduced DHA and enhanced OA levels in tissue membranes, and dietary vitamin A deficiency has a profound effect on membrane DHA and OA in rat tissues. Both vitamin A and DHA are involved in a myriad of vital physiological functions pertaining to growth and development and health. Hence, there is a need for a further study to unravel the mechanism by which vitamin A influences membrane DHA and OA.

Paper no. L9853 in *Lipids 41*, 213–219 (March 2006).

DHA (20:6n-3) is a major constituent of neural and retinal membrane lipids (1,2). In addition, it is present in appreciable proportions in other cell and subcellular membranes (3,4).

Membrane DHA is obtained either preformed from animal products, particularly from fish, shellfish, and fish oil, or from α-linolenic acid (ALA, 18:3n-3) by *de novo* synthesis. It is generally accepted that the synthesis of DHA from ALA involves a series of elongation and desaturation steps in endoplasmic reticulum followed by a final single step β-oxidation reaction in the peroxisomes (5–7) (Scheme 1). Osbond acid (OA, 22:5n-6) is also thought to be synthesized from its precursor FA, linoleic acid (LA, 18:2n-6), by the same pathway, following elongation, desaturation, and β-oxidation reactions.

The activation of peroxisome proliferator-activated (PPAR) and retinoid X (RXR) receptors is imperative for the proliferation of peroxisomes and activation of the key enzymes involved in peroxisomal β-oxidation. On activation by a specific ligand, PPAR form a heterodimer complex (PPAR-RXR) with activated RXR and subsequently bind to specific DNA sequences and initiate inducible transcriptional activity (8–11). The heterodimer PPAR-RXR also has been shown to up-regulate the activity of Δ6 and Δ5 desaturases (12), enzymes that are vital for the synthesis of the long-chain n-6 and n-3 FA, including DHA and OA.

PPAR are members of the intracellular type II nuclear hormone receptor superfamily. Three subtypes have been identified, $PPAR_{\alpha}$, $PPAR_{\beta}/PPAR_{\delta}$, and $PPAR_{\gamma}$ (13). They are acti-

Mineral mix, AIN-76 (170915)	35.0	35.0
Calcium carbonate, $CaCO_3$	4.0	4.0
Vitamin A (IU)	0	19825
Vitamin mix, Teklad (40060)	10.0	10.0
Ethoxyquin (antioxidant)	0.016	0.016

TABLE 2
Percent FA Composition of the α-Linolenic Acid (ALA)-Deficient (ALAD) and -Sufficient (ALAS) Diets

FA	ALAD (% of total FA)	ALAS (% of total FA)
14:0	1.12	0.976
16:0	21.85	19.44
18:0	2.31	2.49
18:1n-9	18.81	19.25
18:2n-6	53.09	49.21
18:3n-3	0.31	6.82
18:2n-6/18:3n-3	170:1	7:1

vated by polyunsaturated, conjugated, and branched FA, eicosanoids, and synthetic ligands such as fibrates (14). In contrast to PPAR, RXR is activated primarily by 9-*cis* retinoic acid, which is a metabolite of vitamin A (8,9), and by phytanic acid with a low affinity (15).

Previously (16), we showed that vitamin A deficiency enhances OA and reduces DHA levels in liver and colon choline (CPG) and ethanolamine (EPG) phosphoglycerides in rats fed a diet deficient in n-3 and sufficient in n-6 FA. The finding was rather intriguing since vitamin A deficiency would have been expected to reduce the levels of both DHA and OA owing to a reduction of activation of RXR and consequently impaired peroxisomal proliferation. In the current study, we have investigated the effect of vitamin A deficiency on levels of DHA and OA in liver and colon phosphoglycerides in rats fed a diet sufficient or deficient in n-3 FA.

EXPERIMENTAL PROCEDURES

Animals. Pathogen-free, weanling male Wistar rats (n = 24) were obtained from the Harlan laboratory, The Weizmann Institute of Science, Rehovot, Israel. They were housed in metal cages in a room with controlled temperature (22 ± 2°C), RH (65 ± 5%), and light (0800–2000 h).

Diets. Twenty-four rats were randomly distributed into four groups and fed one of the following diets: vitamin A- and α-linolenic acid (ALA)-deficient (VADALAD, n = 6), vitamin A-deficient and ALA-sufficient (VADALAS, n = 6), vitamin A-sufficient and ALA-deficient (VASALAD, n = 6), or vitamin A- and ALA-sufficient (VASALAS, n = 6). The diet, which was obtained from ICN Nutritional Biochemicals (Costa Mesa, CA) (cat. no. 960220) contained 9% fat, 20% protein, and 60% carbohydrate (Tables 1 and 2). With the exceptions of vitamin A and n-6 and n-3 FA, the four diets had optimal and comparable amounts of vitamins and trace elements. The linoleic acid/ALA ratio of the ALA-sufficient diet was 7:1 and that of the ALA-deficient, 170:1. The rats had free access to their respective diets and water. Their food consumption was monitored daily, and they were weighed every other day.

After they were fed for 7 wk, at which time the liver vitamin A concentration of the deficient group was lower than 5 μg/g liver, the rats were sacrificed by decapitation and colon and liver tissues were removed for analyses. All procedures were conducted with full compliance to the guidelines of the Ethics Committee and Policy of Animal Care and Use of the Hebrew University.

Analysis of lipids and FA. A method modified from Folch *et al.* (17) was used to extract liver and colon total lipids. The tissues were homogenized in chloroform and methanol (2:1 vol/vol) containing 0.01% BHT as an antioxidant under N_2. Phosphoglyceride classes were separated by TLC on silica gel plates (Merck KGaA, Darmstadt, Germany) by the use of these developing solvents: Chloroform, methanol, and water (60:30:4 by vol) containing 0.01% BHT. CPG and EPG bands were detected by spraying with a methanolic solution of 2,7-dichlorofluorescein (0.01% wt/vol) and identified by the use of authentic standards.

FAME were prepared by heating the CPG and EPG with 5 mL of 15% acetyl chloride in methanol in a sealed vial at 70°C for 3 h under N_2. FAME were separated by a gas–liquid chromatograph (HRGC MEGA-2 Series; Fisons Instruments, Milan,Italy) fitted with a BP-20 capillary column (30 m × 0.32 mm i.d., 0.25 μm film; SGE Ltd., Milton Keynes, United Kingdom). Hydrogen was used as a carrier gas. It has a broad minimum van Deemter profile, which is vital for optimal performance, as compared with helium and nitrogen. In addition, it has faster diffusion and lower viscosity than the latter gases. The injector, oven, and detector temperatures were 235, 210, and 260°C. The FAME were identified by comparison of retention times with authentic standards and interpretation of ECL values. Peak areas were quantified by computer software (EZChrom Chromatography Data System; Scientific Software, Inc., San Ramon, CA).

Analysis of liver vitamin A. The liver specimen, 100 mg, was thoroughly minced, flushed with nitrogen, and saponified with a 50% ethanolic potassium hydroxide (BDH Chemicals, Poole, United Kingdom) for 25 min at 60°C. The saponified sample was cooled, diluted with de-ionized water, and neutralized with hydrochloric acid (BDH Chemicals). Extraction of vitamin A was carried out with 2 mL of hexane for 5 min on a Rotamixer Shaker (Baird and Tatlock, Ramford, Essex, United Kingdom). After centrifugation at 800 × g for 15 min, the upper organic layer containing vitamin A was transferred to a brown glass tube and subsequently evaporated to dryness on a water bath at 37°C under a stream of nitrogen. The re-

[a]VADALAD, vitamin A- and ALA-deficient; VADALAS, vitamin A-deficient and ALA-sufficient; VASALAD, vitamin A-sufficient and ALA-deficient; VASALAS, vitamin A- and ALA-sufficient.

sulting vitamin A residue was redissolved in 100 μL methanol (BDH Chemicals) and a 25-μL aliquot taken for analysis. The entire extraction procedure was carried out under subdued light.

The extracted vitamin A was separated by HPLC (Agilent 1100 series; Agilent Technologies, Waldbronn, Germany) connected to a 250 × 4.6 mm and a 5 μ SphereClone ODS reversed-phase column (Phenomenex, Macclesfield, Cheshire, United Kingdom) and detected at 325 nm with a multiple wavelength diode array detector (Agilent 1100 series). It was eluted with acetonitrile/dichloromethane/methanol (75:15:10). Retinyl acetate was used as an internal standard. Vitamin A concentration was computed from a linear graph of retinol external standards. ChemStation data system version A10.01 (Agilent Technologies) was used for peak area measurement and quantification.

Data analyses. The data are expressed as mean ± SD. The Kruskal–Wallis one-way ANOVA nonparametric method was used to compare liver and colon FA levels of the four dietary groups. Differences between two dietary groups were analyzed by the Mann–Whitney U nonparametric test. All the statistical analyses were performed by the use of SPSS software for Windows, Release 10 (SPSS, Chicago, IL).

RESULTS

Food consumption and weight gain. The food consumption of the VADALAD and VADALAS groups was lower ($P < 0.05$) than that of the VASALAD and VASALAS groups (Table 3). No difference in food consumption was found between VADALAD and VADALAS, and between VASALAS and VASALAD, respectively.

Consistent with change of the food consumption, the weight gain of the VADALAD and VADALAS groups was lower ($P < 0.005$) than that of the VASALAD and VASALAS groups (Table 3). No difference in weight gain was observed between VADALAD and VADALAS, and between VASALAS and VASALAD, respectively. Moreover, no difference in liver somatic index was found among VADALAS, VASALAS, VADALAD, and VASALAD groups.

Liver FA. (i) CPG. The FA composition of liver CPG is presented in Table 4. The mean DHA level in CPG of the VADALAS group was significantly higher than that of the VASALAS ($P < 0.05$), VASALAD ($P < 0.005$), and VADALAD ($P < 0.005$) groups. In addition, the VADALAD rats had a lower level of DHA in CPG compared with the VASALAD ($P < 0.05$) and VASALAS ($P < 0.005$) groups. Of the two vitamin A-sufficient groups, VASALAS and VASALD, the former had a higher DHA level ($P < 0.01$).

As was expected, the proportion of OA, which is a biochemical marker of n-3 FA deficiencies, was increased by ALA deficiency both in the vitamin A-sufficient (VASALAD vs. VASALAS, $P < 0.005$) and -deficient (VADALAD vs. VADALAS, $P < 0.005$) rats. Surprisingly, vitamin A deficiency enhanced the level of OA in the ALA-sufficient (VADALAS vs. VASALAS; $P < 0.005$) and ALA-deficient (VADALAD vs. VASALAD; $P < 0.005$) groups.

(ii) EPG. The mean liver EPG FA composition is given in Table 5. Consistent with the manifestations of n-3 FA insufficiencies, ALA deficiency decreased DHA level in both the vitamin A-sufficient (VASALAD vs. VASALAS, $P < 0.005$) and -deficient (VADALAD vs. VADALAS, $P < 0.005$) groups. The decrease in DHA was associated with a concomitant increase in OA (VASALAD vs. VASALAS, $P < 0.005$) and (VADALAD *vs* VADALAS, $P < 0.005$). As in CPG, the EPG of vitamin A-deficient rats regardless of their ALA status had a significantly elevated proportion of OA.

Colon FA. (i) CPG. Table 6 shows colon CPG FA of the four groups of rats. The VADALAS animals had a higher level of DHA than those of the VASALAS ($P < 0.05$), VADALAD ($P < 0.01$), and VASALAD ($P < 0.005$) rats. In contrast to the VADALAS, the VADALAD rats had reduced DHA compared with the VASALAD rats ($P < 0.01$). Vitamin A deficiency increased the level of OA in the ALA-deficient, VADALAD, ($P < 0.05$) but not in the ALA sufficient, VADALAS, rats.

(ii) EPG. Percent FA composition of colon EPG is given in Table 7. ALA deficiency significantly reduced the level of DHA in the vitamin A-sufficient (VASALAD vs. VASALAS, $P < 0.005$) and -deficient (VADALAD vs. VADALAS, $P < 0.005$) rats. Vitamin A deficiency reduced DHA in the ALA-deficient (VADALAD vs. VASALAD) but not in the ALA-sufficient (VADALAS vs. VASALAS, $P > 0.05$) rats. The level of OA significantly increased in the ALA-deficient compared with the ALA-sufficient groups (VADALAD vs. VADALAS, $P < 0.005$; VASALAD vs. VASALAS, $P < 0.005$). Although vitamin A deficiency in both the VADALAS and VADALAD groups was associated with an increase in OA, the difference with their corresponding vitamin A-sufficient counterparts did not reach a stastically significant level (VADALAS vs. VASALAS, VADALAD vs. VASALAD, $P = 0.078$).

DISCUSSION

Consistent with our previous findings in rats (18) and chicks (19), the vitamin A-deficient groups, regardless of the ALA content of their diet, consumed less food compared with their vitamin A-sufficient counterparts. The reduction of food intake and consequent lower weight gain of the vitamin A-deficient animals were most likely due to vitamin A deficiency-induced atrophy of the gustatory apparatus (20,21) and a loss of taste (20–22). The increase in OA and the concomitant reduction of DHA in the ALA-deficient rats, regardless of vitamin A status, suggest that dietary ALA and LA may be the primary sources of membrane DHA and OA, respectively. These findings are analogous to some reports about n-3 FA deficiencies (23,24).

This partial investigation of the effect of vitamin A defi-

ciency on FA composition in liver membrane lipids of rats fed an ALA-deficient diet, consistent with our previous study (16), demonstrated that vitamin A deficiency leads to a reduction in DHA and a concomitant increase in OA in liver CPG and EPG. The reduction in DHA was predicted since vitamin A deficiency was expected to impair peroxisomal proliferation and inhibit the activity of acyl-CoA oxidase owing to an insufficiency of 9-*cis* retinoic acid, which is the potent ligand of RXR. However, the vitamin A deficiency-induced increase in OA was unexpected and rather intriguing. Both DHA and OA are thought to be synthesized by a common shared microsomal-peroxisomal pathway involving chain elongation and desaturation reactions in the endoplasmic reticulum followed by a final one-step β-oxidation reaction in the peroxisomes (5,25). Consequently, an impairment of peroxisomal proliferation would have been expected to lead to a reduction in both OA and DHA. The contrasting effects of vitamin A and ALA deficiency on the proportions of DHA and OA in liver CPG and EPG seemed to lend credence to the proposition that the two FA are synthesized by independent pathways involving n-6- and n-3-specific enzymes (6,7) or to the suggestion that the desaturation of n-6 and n-3 involves two distinct Δ6 desaturases (26). Indeed, Infante *et al.* (27) reported that the straight-chain acyl-CoA oxidase knockout mouse had decreased DHA and increased threefold OA in liver. Our enhancement of OA and reduction of DHA levels in VADALAD rats, similar to their findings, can be explained by hypothesizing that DHA and OA are synthesized by a carnitine-dependent multifunctional mitochondrial synthase residing in the outer mitochondrial membrane, and beyond this, that there is another redundant microsomal pathway that is only suitable for OA synthesis (6,7). In contrast to the rats fed the VADALAD diet, which had reduced DHA and enhanced OA levels, the levels of both DHA and OA were enhanced in the rats that were fed VADALAS diet. Paradoxically, this finding is consistent with the conventional microsomal-peroxisomal and additional carnitine-dependent multifunctional mitochondrial pathways (5–7,26). These effects of vitamin A deficiency on membrane DHA and OA may have been mediated by enhanced peroxisomal proliferation and the consequential activation of peroxisomal enzymes, including acyl-CoA oxidase, activity of Δ6 and Δ5 desaturases, or incorporation. The current wisdom is that peroxisomal proliferation is mediated by PPAR-RXR complex after the activation of RXR by 9-*cis* retinoic acid, and it is difficult to envisage how this could be induced under vitamin A deficiency. However, the studies that reported that 9-*cis* retinoic acid is a potent ligand of RXR were conducted *in vitro* (28–30). Consequently, it is possible that the finding may not be portable to an *in vivo* physiological environment. Indeed, Lawrence *et al.* (31) have reported significantly higher induction of peroxisomal β-oxidation in vitamin A-deficient than -sufficient rats that were treated by the potent peroxisomal proliferator, nafenopin. Similarly, in a communication by Sohlenus *et al.* (32), the vitamin A-deficient mice untreated by the peroxisomal proliferator had about 40% higher volume and number of liver peroxisomes compared with their sufficient counterparts; the authors did not discuss this finding. Interestingly, Werner and DeLuca (33) were unable to detect 9-*cis* retinoic acid in tissues of vitamin A-deficient rats that were given a physiological amount of radioactive all-*trans* retinol. It is plausible that vitamin A deficiency may enhance the synthesis of OA and/or DHA through the induction of peroxisomal proliferation and the activation of β-oxidation without the involvement of 9-*cis* retinoic acid. On the other hand, both DHA and OA can be synthesized in another carnitine-dependent multifunctional mitochondrial pathway (6,7,27). There is evidence that DHA was still the predom-

inant FA in straight-chain acyl-CoA oxidase null mice, and its amount was comparable to that in their corresponding wild-type animals (27). The characteristics of these multifunctional pathways are that the enzyme-bound products are recycled back as substrates until the desired final product is formed. In these recycling reactions, alternative *cis*-desaturations and elongation of the enzyme-bound acyl intermediates would introduce the methylene-interrupted double-bond structure of the final products. The enhanced DHA and OA suggest that a termination reaction catalyzed by an acyl carrier protein-connected carnitine acyltransferase might be preferential for the release of DHA or OA from enzyme in vitamin A-deficient rats.

Although vitamin A deficiency has been shown to enhance the activity of Δ5 (34,35) and Δ9 (36) desaturases, such influence was not apparent in this study. This difference could be a reflection of the rat strain (37) or diet used.

From the present study, it is evident that dietary vitamin A deficiency has a profound effect on membrane DHA and OA in rat tissues. It increases the proportions of OA consistently regardless of the level of dietary ALA. In contrast, the effect on DHA is dependent on dietary ALA level; it is reduced when dietary ALA is limiting and is enhanced when ALA is adequate. Both vitamin A and DHA are involved in a myriad of vital physiological functions pertaining to growth and development and health. Hence there is a need for a further study to unravel the mechanism by which vitamin A influences membrane DHA and its n-6 counterpart, OA.

Unité de Recherche Animal Fonctionnalité des Produits Animaux, Nancy-Université, 54000 Nancy, France

ABSTRACT: The effects of season, geographic source (Lake Geneva, Rhine River), and rearing system (extensive, semiextensive, and intensive systems) on the lipid content and FA composition of fillets of *Perca fluviatilis* were studied. Significant differences in the total lipid content were found between fish coming from the Rhine River and Lake Geneva (1.21 and 1.48%, respectively). Seasonal effects were investigated quarterly for perch sampled in the Rhine River. Intensively reared perch displayed a higher lipid content (1.48%) than the other farmed perch, i.e., 1.26% for a semiextensive system and 1.16% for an extensive system. No significant difference in lipid content was found (i) between lacustrine fish and intensively reared fish or (ii) among fish from the Rhine River and the semiextensive or extensive rearing systems. The main FA were 22:6n-3 (DHA, 21.3–37.1% of total FA), 16:0 (17.7–20.2%), 20:5n-3 (EPA, 9.2–13.2%), 18:1 (8.0–11.5%), 20:4n-6 [arachidonic acid (ARA), 1.9–10.7%], 16:1 (4.3–6.0%), and 18:2n-6 (2.1–6.0%). In comparison with perch coming from the Rhine River, the lacustrine fish were characterized by higher total n-6 PUFA and a lower proportion of both total monounsaturated FA (MUFA) and total n-3 PUFA. Among rearing systems, extensively farmed fish had higher n-6 PUFA and lower n-3 PUFA contents. Wild fish showed higher ARA and 18:2n-6 than farmed fish. They also had significantly more EPA (12.5–13.2%) than farmed perch (9.2–10.9%). For DHA, no difference existed between (i) the lacustrine fish (31.9% of total FA) and the intensively reared fish (33.0%) and (ii) the Rhine (37.1%) and semiextensively reared fish (36%). Effects of size, diet composition, and environmental conditions on the total lipid contents and FA composition are discussed.

Paper no. L9867 in *Lipids 41*, 221–229 (March 2006).

Beneficial effects of fish consumption on human health, e.g., stroke reduction and prevention of hypertension, cancer, heart disease, or depression, have been demonstrated previously (1). These health benefits appear to be related to the high content of PUFA (15–36% of the total FA), particularly n-3 PUFA such as DHA (22:6n-3) and EPA (20:5n-3) (2). Clearly, both the FA composition and lipid content of fillets could be influenced by many parameters, such as genetic factors, geographic origin or domestication level, food availability and quality, and season (3–5). Moreover, it is well established that nutritional quality differs between wild and reared fish (2), but also among different rearing systems (6).

Aquaculture of the Eurasian perch, *Perca fluviatilis*, is a diversification route for inland aquaculture. Perch fillets are considered a dietetic product because of their low fat and high DHA contents (7). In addition, the Eurasian perch is very adaptable, which allows for a wide variety of rearing systems in aquaculture. However, the effects of such different rearing systems on the nutritional quality of perch still remain unclear. Moreover, perch is a very common species inhabiting very different biotopes and large geographic areas (8). All these different environmental conditions could be responsible for differences in the quality of perch at large. However, no information about the variability of the nutritional quality regarding the geographic source is currently available. The purpose of the present paper was threefold. First, it was intended to study the variability of fillet lipids and the FA contents of Eurasian perch from two geographic sources, namely, the Rhine River and Lake Geneva, and from three rearing systems, ranked as intensive, semiextensive, and extensive. Second, a comparison between wild and farmed perch was carried out. Third, the effect of season on the nutritional quality of wild perch was assessed. In addition, the relationship between the nutritional quality of fish and the composition of the fish diet was assessed using stable isotope analysis.

MATERIALS AND METHODS

Fish collection. Live fish from the Rhine River (Boven-Hardinxveld, The Netherlands) and Lake Geneva (Lugrin, France) were sampled in July and October of 2002 and in January and April of 2003. We assumed that differences in nutritional quality could be found in wild fish living in two very different natural systems. Thus, these two sites were selected on the basis of their very different physicochemical water parameters (9). Fish were collected according to the normal practice used by professional fishermen for perch fishing (net for Lake Geneva and fish pot for the Rhine River) to provide a wild reference base corresponding to the fish consumed in each area. Nets and fish pots were submerged for 3 to 5 d. Farmed perch were collected during the period of market consumption, i.e., in October 2003. They were sampled from three different rear-

[a]Each sample of food was analyzed in triplicate. Bio-Optimal ST and Ecolife 15 were from BioMar (Brande, Denmark).
[b]Results are expressed as the percentage of wet weight.
[c]Only FA > 1% of total FA are shown.

ing systems: an extensive system (pond, Gelucourt, France), a semiextensive system (tank, Lindre, France), and an intensive system (water recirculating system, Lucas Perches pilot farm, Hampont, France). In the extensive system, fish lived on natural prey. Fish from the semiextensive system were fed both natural food and an artificial food, Bio-Optimal ST (BioMar, Brande, Denmark). In the intensive system, fish were exclusively fed an artificial food, Ecolife 15 (BioMar) (Table 1). All fish were slaughtered by thermoshock immediately after collection. Fish were filleted 48 h post mortem, i.e., after rigor mortis (10), and the fillets were stored at −20°C awaiting lipid extraction.

Lipid extraction and FA composition. Both fillets of each fish were crushed together to homogenize the samples and to avoid any effect related to the heterogeneity of lipid distribution. Total lipids (expressed as a percentage of the fillet weight) were extracted with dichloromethane/methanol (2:1, vol/vol) according to Folch *et al.* (11) as modified by Chen *et al.* (12). BHT (0.1%) was added to the dichloromethane/methanol as an antioxidant. FA of the total lipids were converted to methyl esters with BF_3–methanol (14%) (13) and stored at −80°C. The FA composition was assessed using GLC on a fused-silica capillary column 30 × 0.25 mm i.d. and 20 µm film thickness (SUPELCOWAX™ 10; Sigma-Aldrich, St Quentin Fallavier, France). The instrument conditions were as follows: initial temperature: 140°C; heating rate: 4°C/min; final temperature: 240°C; injector temperature: 260°C; detection temperature: 260°C; carrier gas: helium; sample injection: 1 µL; total time of analysis: 26 min. FAME mixtures No. 189-19 and PUFA 3 (Sigma Chemical Company, St. Louis, MO) were used as standards. Only FA > 1% of total FA are reported in this study.

Stable isotope analysis. Diet is the primary determinant of animal isotopic composition (14). Thus, to characterize the place of perch in the trophic web and obtain some indirect information on the composition of their diet, a stable isotope analysis (^{13}C and ^{15}N) was carried out; 20 fish from the Rhine River, 20 fish from Lake Geneva (5 fish per season), and 5 fish from each rearing system were randomly selected. After lipid extraction, samples were dried for 48 h at 60°C. Isotopic ratios were determined by a coupled system of an elemental analyzer (NA 1500NC; Carlo Erba, Rodano, Italy) and a mass spectrometer (IRMS) (delta S; Finnigan, Bremen, Germany). Abundances of the ^{13}C and ^{15}N isotope were expressed in δ notation as the deviation from standards in parts per thousand (‰) according to the following equation: $\delta X = [(R_{sample}/R_{standard}) - 1] \times 1000$, where X represents either ^{13}C or ^{15}N and R is the corresponding ratio $^{13}C/^{12}C$ or $^{15}N/^{14}N$. The R standard values were based on PeeDee Belemnite (PDB) for ^{13}C and atmospheric N_2 for ^{15}N. The measurement errors for carbon and nitrogen were 0.20 and 0.25‰, respectively.

Statistical analysis. Data were treated with an ANOVA (unbalanced hierarchical ANOVA) using the statistical package SAS (SAS/STAT, 1989; SAS Institute Inc., Cary, NC) according to a mixed procedure and a univariate procedure. Seasonal effects were nested within site effects (site: DF of factor = 4; DF of residual = 370; season(site): DF of factor = 6; DF of residual = 370). The significance level was fixed at 5% using Bonferonni's *t*-test.

To characterize the effect of food on the muscle FA composition, a hierarchical clustering analysis using the aggregation criteria of Ward was performed using SPAD 5.5 software (SPAD, Paris, France). The $\delta^{13}C$ and $\delta^{15}N$ values were used as active variables. This data analysis allowed classes of fish to be characterized by a particular $\delta^{13}C$ or $\delta^{15}N$ value. Afterward, a factorial discriminant analysis (StatBoxPro 5.0; GrimmerSoft, Neuilly-Sur-Seine, France), using as discriminant factor the classes had previously created by the hierarchical clustering analysis, was performed on the major FA (16:0, 18:0, 16:1, 18:1, 18:2n-6, 20:4n-6, 20:5n-3, 22:6n-3) to assess whether the classification of fish realized according to the $\delta^{13}C$ or $\delta^{15}N$ values was related to the FA composition.

RESULTS

Nutritional quality and geographic source of wild perch. Overall, lipid contents of the perch fillet varied between 1.16 and 1.48% (Table 2). A significant difference in the total lipids of perch muscle was observed between fish collected from the Rhine River (1.21%) and Lake Geneva (1.43%). A difference in the weight of fish was reported between fish in these two natural systems, with bigger fish being found in the Rhine River. However, no linear relationship ($r^2 = 0.02$, $P > 0.05$, data not shown) was found between the mean total fillet lipid content and the weight of fish sampled in both natural environments at each season.

Total saturated FA (SFA) accounted for 25.5 and 25.1% of the total FA in the Rhine River and Lake Geneva fish, respectively (Table 2). Palmitic acid (16:0) was the main SFA, con-

[c]Only FA > 1% of total FA are shown. Values are adjusted mean ± SE. Values in the same row having different roman superscript letters are significantly different ($P < 0.05$).

tributing approximately 73–75% of the total SFA. The total SFA content displayed no significant difference between the two origins, although the 16:0 and 18:0 contents were significantly different.

The total monounsaturated FA (MUFA) content for fish coming from the Rhine River (14.1 ± 0.3%) was significantly higher than that from the lacustrine perch (12.5 ± 0.3%). Furthermore, no significant relationship was found between the mean MUFA content and the total lipid content ($P > 0.05$) (Fig. 1). Oleic acid (18:1) was the primary MUFA (57–66% of total MUFA) and showed no significant difference between fish from the Rhine River and Lake Geneva.

Arachidonic acid (ARA, 20:4n-6) accounted for 71 and 75% of the total n-6 PUFA in fish coming from the Rhine River and Lake Geneva, respectively (Table 2). The total n-6 PUFA content, ARA, and linoleic acid (18:2n-6) were significantly lower for fish from the Rhine River than for the lacustrine fish. Furthermore, there was a positive linear relationship between the lipid content and n-6 PUFA (Fig. 1).

DHA (22:6n-3) and EPA (20:5n-3) were identified as the main n-3 PUFA. DHA was the dominant FA in all fish, whatever their origin (between 21 and 37% of total FA) (Table 2). The n-3 PUFA content varied significantly between natural sites and was negatively related to the lipid content (Fig. 1). Fish from Lake Geneva had lower DHA and higher EPA than their counterparts from the Rhine River.

Nutritional quality and rearing systems. For each rearing system, no significant linear relationship between the weight of reared fish and the lipid content or FA was found. The rearing system had an effect on the total lipid content (Table 2). Indeed, fish from the intensive rearing system displayed a significantly higher lipid content (1.48%) than did the other farmed perch (1.26% for the semiextensive system and 1.16% for the extensive system).

The total SFA content of farmed perch varied between 25.1 and 27.8% of the total FA and was significantly lower in the intensive system. 16:0 accounted for 71–76% of the total SFA content.

No difference in the total MUFA content was noticed between the different rearing systems. Oleic acid was dominant

and increased significantly as the level of farming intensified.

The n-6 PUFA contents exhibited a significant difference between the rearing systems (Table 2). The lowest total n-6 PUFA level was found in fish from the semiextensive system (7.0% of total FA), whereas fish from the extensive system had a higher n-6 PUFA content (17.6% of total FA).

Concerning the n-3 PUFA, the lowest values were found in fish from the extensive system, whereas the highest values were assessed in fish from the semiextensive and intensive systems (Table 2). The semiextensively farmed fish showed a higher proportion of DHA (36.9%) and a lower level of EPA (9.2%) in comparison with the other farmed fish.

Comparison between wild and farmed perch. The total lipid content in farmed perch showed significant differences from wild fish, but these differences depended on the rearing system and the natural system considered (Table 2). Two different groups could be formed according to their similar lipid content, namely, (i) fish from the Rhine River and from the extensive and semiextensive systems, and (ii) fish sampled from Lake Geneva and from the intensive system.

The most important differences in FA composition between the wild and farmed fish were in their MUFA and PUFA contents (Table 2). The farmed fish had a higher MUFA content than did wild fish (16–19% vs. 12–14% of total FA). This was particularly obvious for oleic acid (10–11.5% vs. 8–8.2% of total FA). ARA was identified as the primary n-6 PUFA in fish coming from the Rhine River, Lake Geneva, and the extensive system (71, 75, and 61% of total n-6 PUFA respectively), i.e., fish fed with natural food, whereas linoleic acid was predominant in fish reared in the semiextensive and intensive systems (66 and 69% of n-6 PUFA, respectively). The wild fish displayed significantly more EPA (13.2–12.5% of total FA) than the farmed perch (9.2–10.9%), whereas no difference was found for DHA between (i) the lacustrine and intensively farmed fish, and (ii) the Rhine River and semiextensively farmed fish.

Seasonality of the nutritional quality in wild perch fillets. The season had a significant effect on the total lipid content of fish from the Rhine River (Table 3), whereas no effect was detected for perch sampled from Lake Geneva (Table 4). A slightly positive linear relationship was reported between the mean lipid content and the mean weight of fish by season for the Rhine River ($r^2 = 0.83$, $P = 0.046$, data not shown), but not in fish from Lake Geneva ($r^2 = 0.61$, $P > 0.05$, data not shown), probably because of their low weight heterogeneity.

Seasonal variability in the FA composition was greater for fish sampled from the Rhine River, probably because of the high size heterogeneity compared with those sampled from Lake Geneva (Tables 3, 4). In this study, the proportion of 16:0 remained constant throughout the year. However, the proportion of SFA exhibited some variability, with the lowest value in January and the highest in July.

Concerning the total MUFA content, no seasonal variation appeared in lacustrine fish, whereas the MUFA content of Rhine River fish reached a minimum in October 2002 (11% of total FA) and a maximum in January 2003 (17.4% of total FA). Moreover, a positive relationship ($r^2 = 0.94$, $P = 0.015$, data not shown) was found between the total lipid content and the MUFA content of fish sampled from the Rhine River.

The n-6 PUFA content varied significantly between seasons

[a]Values are mean ± SE. For abbreviations see Table 2.
[b]Only FA > 1% of total FA are shown. Values are adjusted mean ± SE. Values in the same row having different roman superscript letters are significantly different ($P < 0.05$).

in both sites. ARA showed no seasonal variation for the lacustrine fish (9.2–9.7% of total FA), whereas the proportion in fish from the Rhine River was significantly higher in October and April (7.1 and 6.9% of total FA, respectively) than in July (5.8% of total FA). Moreover, no significant linear relationship was found between the n-6 PUFA content and total lipids at both sites ($P > 0.05$, results not shown).

The proportion of DHA in fish from the Rhine River remained constant throughout the year, whereas the EPA level was higher in July. However, in the lacustrine system, perch had a significantly lower proportion of DHA in July than in January and April, whereas the proportion of EPA displayed the reverse tendency.

Relationship between fish diet composition and nutritional quality. No significant relationship ($P > 0.05$) was established between the size of fish and the $\delta^{13}C$ or $\delta^{15}N$ values in both wild systems. The stable isotopic analyses clearly showed a difference in the $\delta^{13}C$ or $\delta^{15}N$ between fish from each system (reared vs. wild systems) (Fig. 2). This was confirmed by the hierarchical clustering representation, which showed five classes (Fig. 3). Classes 1 and 2 contained fish from the Rhine River. Classes 3 and 4 corresponded to fish sampled from Lake Geneva and the extensive system, respectively. Class 5 was composed of fish farmed in the intensive and semiextensive systems, i.e., fish that had been fed artificial food. Furthermore, results of the factorial discriminant analysis clearly showed that these five classes formed with hierarchical clustering analysis were successfully identified with the FA composition of muscle (96% of total variability explained by planes 1–2) (Fig. 4A). The discrimination according to these five classes, i.e., fish from the different aquatic systems (wild and reared), was mainly realized according to the ARA, DHA, and 18:2n-6 contents of fillets (Fig. 4B). Moreover, it clearly showed that the FA composition of perch reared in the semiextensive and intensive systems was highly correlated with the diet composition (Tables 1, 2). Thus, all of these results suggest that differences in the nutritional quality of fish from different aquatic systems (wild or reared) were mainly the result of different diets.

DISCUSSION

Variability of total lipid content according to the geographic source and rearing system. The lipid contents in perch fillets measured in the present study are in agreement with the litera-

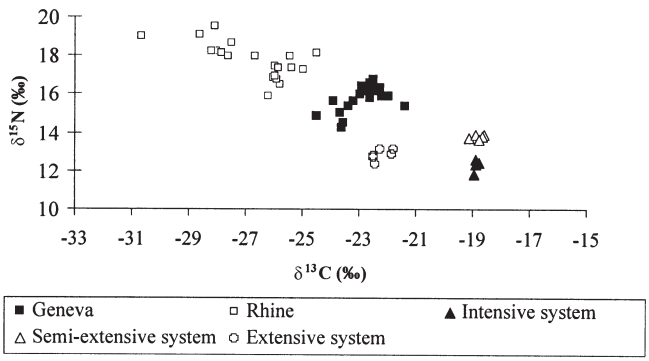

FIG. 2. Stable isotope values ($\delta^{13}C$ and $\delta^{15}N$) of fish fillets in natural and rearing systems.

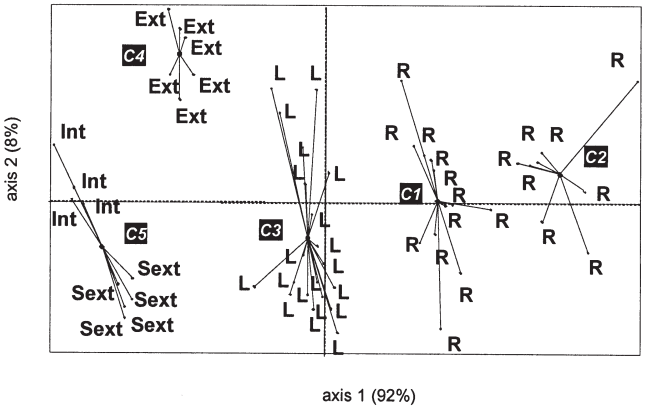

FIG. 3. Hierarchical clustering representation for stable isotope values ($\delta^{13}C$ and $\delta^{15}N$) of fish in natural and rearing systems. C1, 2, 3, 4, and 5 = class 1, 2, 3, 4, and 5; R = fish from the Rhine River; L = fish from Lake Geneva; Ext = fish from the extensive system; Sext = fish from the semiextensive system; Int = fish from the intensive system.

ture (7,15). The lipid content was variable, but the range of variation was low. The higher lipid content found in Lake Geneva fish could be related to their diet or to a lower annual water temperature compared with the Rhine River (10.5 vs. 16°C, respectively) (9). Indeed, according to Corraze *et al.* (16), the increase in lipid content at low temperatures could be the result of a greater deposit of dietary lipids. But other factors (such as genetics and lipid metabolism) also could be implicated in the lipid content in muscle, as suggested by Henderson and Tocher (17).

The higher lipid content in fish from the intensive system was related to the dietary lipid content (Table 1). However, Xu *et al.* (18) showed that an increase in fat content of the diet (11.7; 15; 19.3%) had no consequence on the lipid content of the muscle of perch, as was also found by Mathis *et al.* (15). In our study, the lipid contents of the diets for the intensively and semiextensively farmed perch (17.0 and 10.0%, respectively) were similar to those tested by Xu *et al.* (18) and Mathis *et al.* (15), but an effect on intramuscular lipid content was highlighted. Furthermore, according to Gardeur (unpublished data), among the 12 different dietary and environmental factors tested, only one interaction, i.e., between water temperature and dietary lipid sources (fish oil or rapeseed oil), led to significant differences in the muscle lipid content of intensively reared perch.

Fish from the intensive system are domesticated fish (sixth generation, or F6), with the origin of genitors (F0) being Neuchatel Lake (Switzerland). Thus, the close geographic origin of fish from Lake Geneva and fish used in the intensive rearing system could suggest that the fish actually belong to the same population, explaining their similar lipids content.

Moreover, even if the amount of food consumed had not been determined in our experiment, this factor could be implicated in the difference in fillet lipid contents reported here. Indeed, this factor was important in determining the lipid content in *Dicentrarchus labrax* (19). But according to Mathis *et al.* (10), no effect of feeding rate on the total lipid content of perch

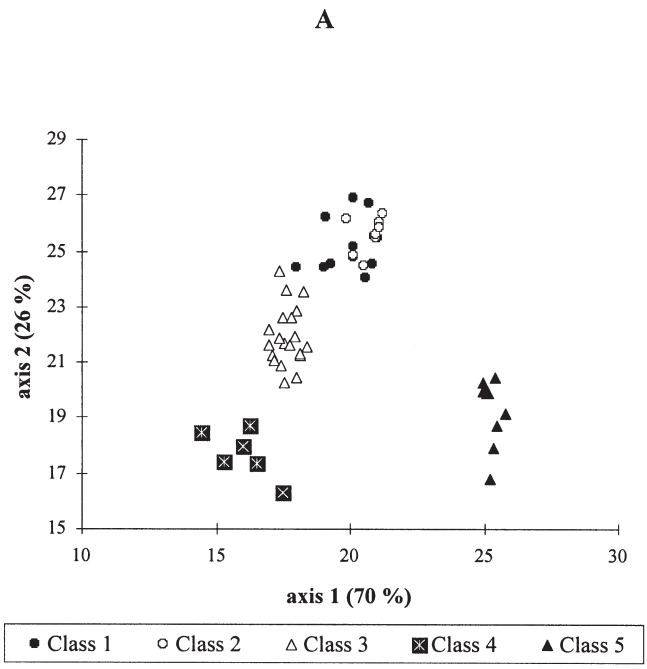

FIG. 4. 2-D plot of the FA profiles of muscle in fish sampled in all systems with a factorial discriminant analysis using classes derived from the hierarchical clustering representation as the discriminant factor. (A) Results of the factorial discriminant analysis for FA variables; (B) results of the factorial discriminant analysis for individuals.

fillets was found in intensive rearing conditions.

Variability of the FA composition according to the geographic source and rearing system. The total SFA content reported here is in agreement with other studies in which SFA represent less than 30% of the total FA (20). Moreover, the 16:0 content (73–75% of the total SFA content) was slightly lower than those reported by Xu and Kestemont (7) and Xu *et al.* (18)

in perch (78–82%), but higher than those reported in the sander *Sander lucioperca* (65%) (21).

The difference in the MUFA content between fish from the Rhine River and Lake Geneva was not related to the lipid content but might be explained by the difference in the dietary FA composition of wild perch. For both wild and farmed fish, particularly salmonids, it is well established that the FA composition of fillets reflects the composition of the fish diet (22). The stable isotope analysis tended to support this pattern: A difference in the diet composition might have been responsible for the difference in the FA composition of fish coming from each system (natural and farmed).

In this study, the n-3 PUFA content was negatively related to the total lipid content. When the total lipid content increases, TAG are accumulated, whereas the cellular phospholipids, which are rich in n-3 PUFA and particularly in DHA, remain constant (23,24). Therefore, phospholipids and DHA decrease proportionally with a higher lipid content, as reported in the present study.

The higher ARA values in wild fish and in fish from the extensive system compared with farmed fish are consistent with findings from other researchers (25,26) and are related to the composition of their natural prey (27). Furthermore, the composition of the commercial food available in the semiextensive and intensive systems, which showed a high proportion of linoleic acid and a low level of ARA, explains the fillet FA composition of the farmed perch. Moreover, the higher linoleic acid content found in the extensive system could suggest a diet composition rich in this FA.

A higher DHA content in wild fish, in comparison with the farmed counterparts, has already been described (4,20,26). However, the opposite results were found in the gilthead sea bream *Sparus aurata* (28), although for the same species, Grigorakis *et al.* (25) found no difference, as was also found in the white seabream (29). Effects of geographic origin, environment, and strain could be important in the FA composition of wild and reared fish.

In freshwater fish, the n-3/n-6 ratios range from 1 to about 4 (30). In perch filet, our results showed that this ratio varied according to the source but always ranged at the higher level (5.9 ± 0.1%, 7.1 ± 0.3%, 5.8 ± 0.1% for fish from the Rhine River and from the semiextensive and intensive rearing systems, respectively). These high values impart to perch a good nutritional value among all the freshwater fish. Differences in n-3/n-6 ratios existed between wild and farmed fish. Indeed, some authors have found a higher n-3/n-6 ratio in wild fish than in farmed counterparts (20,25,26,29), but the amplitude of these differences between wild and farmed fish depended on the dietary FA composition. Indeed, the level of n-3 PUFA in the diet could vary greatly according to the dietary lipid source and *in fine* to induced variations in the n-3/n-6 ratio in fillets (31,32). However, the overall nutritional quality of perch depended both on the rearing system and on the geographic source of the fish, as well as on the important lipid classes.

In this study, fish from natural systems and from the extensive system consumed natural prey, whereas fish from the intensive system were exclusively fed an artificial food. In the semiextensive system, fish could eat both natural and artificial food. The lack of similarity in the FA profiles between fish from the natural system and from the extensive rearing system still remains unclear. The stable isotope analysis showed that extensively reared fish possessed stable isotope values different from fish from the Rhine River and Lake Geneva. This suggests a different diet composition between fish from natural and extensive systems, e.g., a lower level of n-3 PUFA and a higher level of n-6 PUFA, particularly in linoleic acid, for prey from the extensive system compared with those from the Rhine River and Lake Geneva. However, factors other than food could be important, such as environmental conditions, as suggested by Njinkoue *et al*. (33), or some intrinsic factor (strain or lipid metabolism).

Effect of season on the total lipid content and FA composition of wild perch. The seasonal variation in lipid content primarily affects the tissue where fat stores are preferentially accumulated (34,35). Perch deposit lipids in the perivisceral tissue rather than in the muscle (18). This suggests that the muscle lipid content would remain constant throughout the year, as reported in this study, particularly for fish sampled from Lake Geneva. The higher weight of fish collected in the Rhine River in January might explain the higher total lipid content found in this period, because of the linear relationship between the weight of fish from the Rhine River and the lipid content. It thus appears that in this study, the apparent seasonality of the total lipid content in fillets of fish from the Rhine River is size related, although other factors, such as temperature or diet composition (33), could explain this variation.

The seasonal variations in FA composition also have been described as species dependent or FA dependent (36). For example, significant differences between the seasons were reported in the FA composition of the common sole *Solea solea* (35), in the sardine *Sardinops melanostictus* (37), in the Japanese catfish, *Silurus asotus* (38), and in the wild crappie, *Pomoxis* spp. (39). In our study, the relationship between the MUFA content and lipid content of fish was previously found by Mathis *et al.* (40). Consequently, for fish from the Rhine River, the increase in lipid content in January induced a higher proportion of MUFA, thereby increasing the relative proportion of MUFA, presumably in TG.

In perch coming from the Rhine River, the proportion of EPA varied according to the season, whereas the DHA content remained almost constant irrespective of the season. However, for lacustrine perch, the seasonal variation in EPA (low in July, i.e., end of the spawning period; high in January and April) and DHA (high in July) could suggest a selective mobilization of EPA and/or a specific retention of DHA during gonad development, as has been found in the European whitefish *Coregonus macrophthalmus* (41). Other hypotheses could be suggested, such as quantitative or qualitative changes in the diet composition of perch between the summer and winter, as was observed for the sardine *Sardinops melanostictus* (37). However, in the present study, the stable isotope analysis was not sufficient to decisively link seasonal variation in the FA composition with

variation in the diet composition. Indeed, it has been reported in the bivalve *Pecten maximus* that seasonal variations in metabolism can cause changes in the isotopic composition unrelated to changes in the diet (14). A gut content analysis could give complementary data, allowing us to study whether the seasonality of the fillet FA composition is linked to variations in the prey consumed.

The aim of this work was to compare the nutritional quality of perch fillets coming from different sources (wild, reared) that are available on the market. We showed that the nutritional quality of the perch varied according to the geographic source, rearing system, and season. All these variations were mainly correlated with the diet composition of the fish. However, the high n-3 PUFA content and n-3/n-6 ratio identify this species as a product of high nutritional quality. Further experimental studies should be developed to assess, independently of diet, the true effect of the season, geographic source, and rearing system.

ACKNOWLEDGMENTS

The authors are grateful to Claire Hognon and Laetitia Louis (Laboratory of Animal Sciences, Nancy) for their help in the determinations of FA composition. In addition, thanks to Patrick Ribière for his help in the filleting process and to the CNRF (Centre National de Recherche Forestière)–INRA (l'Institut National de la Recherche Agronomique) Champenoux (France), for the stable isotope analysis.

[a]University of Joensuu, Department of Biology, FIN-80101, Joensuu, Finland, and [b]Department of Plant and Animal Sciences, Nova Scotia Agricultural College, Truro, Nova Scotia, B2N 5E3, Canada

ABSTRACT: The American marten (*Martes americana*) is a boreal forest marten with low body adiposity but high metabolic rate. The study describes the FA composition in white adipose tissue depots of the species and the influence of food deprivation on them. American marten ($n = 8$) were fasted for 2 d with 7 control animals. Fasting resulted in a 13.4% weight loss, while the relative fat mass was >25% lower in the fasted animals. The FA composition of the fat depots of the trunk was quite similar to other previously studied mustelids with 14:0, 16:0, 18:0, 16:1n-7, 18:1n-9, and 18:2n-6 as the most abundant FA. In the extremities, there were higher proportions of monounsaturated FA (MUFA) and PUFA. Food deprivation decreased the proportions of 16:0 and 16:1n-7, while the proportion of long-chain MUFA increased in the trunk. The mobilization of FA was selective, as 16:1n-7, 18:1n-9, and particular n-3 PUFA were preferentially mobilized. Relative mobilization correlated negatively with the carbon chain length in saturated FA (SFA) and n-9 MUFA. The Δ9-desaturation of SFA enhanced the mobilization of the corresponding MUFA, but the positional isomerism of the first double bond did not correlate consistently with relative mobilization in MUFA or PUFA. In the marten, the FA composition of the extremities was highly resistant to fasting, and the tail tip and the paws contained more long-chain PUFA to prevent the solidification of lipids and to maintain cell membrane fluidity during cooling.

Paper no. L9885 in *Lipids 41*, 231–240 (March 2006).

The American marten (*Martes americana*) is a boreal forest marten, together with the Japanese marten (*M. melampus*), the sable (*M. zibellina*), and the European marten (*M. martes*; 1,2). The American marten occupies a large part of North America (3), inhabiting forests or landscape mosaics with seasonal snow cover (4). The species prefers loose snow with access to subnivean spaces, which has been interpreted as a strategy to minimize energy loss (5). Metabolic costs are a major factor determining the seasonal habitat choice for the American marten. This could be due to the high energetic costs associated with the elongated body shape (6–8). The most important food items in the diet of the American marten are voles, birds, fish, ungulate carcasses, insects, fruits, and berries (9).

The American marten has a low body fat content (approximately 5%) possibly as an adaptation to maintain the lean body shape required for hunting in the burrows of rodents (10). Furthermore, the species does not experience clear seasonal cycles in its body fat content (11). Due to its small gastric ventricle, the American marten has only a limited capacity to consume large amounts of food during a single meal, making fat deposition difficult. The high-protein diet and the high energetic costs of foraging are additional causes for the limited fat storage capacity. However, it has been established that the species can withstand at least 5 d of fasting by entering a state of protein conservation using fat and protein in a ratio of 1.56:1 (12). The plasma concentrations of particular amino acids increase and the excretion of urea decreases in fasted marten probably owing to a high turnover of proteins and urea nitrogen recycling (13). These results indicate that the American marten must be able to mobilize some of its fat reserves effectively for short periods of time. In fact, the periods of naturally occurring fasting are relatively short for the marten, as they are also known to leave their nests daily during the winter with the exception of the harshest weather conditions (14).

In addition to fur, the subcutaneous (sc) fat layer may offer thermal insulation for the marten in the boreal climate. There must also exist a temperature gradient from the skin to the core of the body affecting the FA composition. The challenge of the ambient temperature is even more pronounced on the extremities, such as on the bare food pads and the tip of the tail. Unlike the sc or intra-abdominal (iab) fat depots, the fats of the footpads have to maintain cell membrane fluidity, and it can be hypothesized that they would experience only minor changes in FA composition during food scarcity. For instance, iab fat depots of the semiaquatic American mink (*Mustela vison*) are preferentially mobilized instead of sc fat probably owing to the significance of the sc fat layer as insulation during aquatic predation (15; Nieminen, P., Käkelä, R., Pyykönen, T., and Mustonen, A.-M., unpublished data).

Abbreviations: BM, body mass; BMI, body mass index; DBI, double bond index; DI, desaturation index; dia, diaphragmatic; iab, intra-abdominal; mes, mesenteric; MUFA, monounsaturated FA; om, omental; rp, retroperitoneal; sc, subcutaneous; SFA, saturated FA; TACL, total average chain length; UFA, unsaturated FA; VLCFA, very long chain FA; WAT, white adipose tissue.

The aim of this study was to describe (i) the FA composition of different white adipose tissue (WAT) depots of the American marten and (ii) the effects of a 48-h fasting period on FA composition. The fasting period of 2 d was considered suitable because, according to previous studies (12), it is significantly shorter than what the species can withstand.

EXPERIMENTAL PROCEDURES

For these experiments 15 American marten (9 males and 6 females) born between 1993 and 2004 were randomly divided into two experimental groups. All the animals were housed singly in standard cages (85 × 30 × 46 cm) with wooden nest boxes (24 × 32 × 35 cm) suspended above ground in an unheated shed at the Canadian Centre for Fur Animal Research, Nova Scotia Agricultural College, in Truro, Nova Scotia, Canada (45.37°N, 63.27°W). Before the experiment the animals were fed for several months with standard fur animal feed (metabolizable energy 1200–1300 kcal kg fresh wt^{-1}; protein minimum 11.0–12.0%, fat 3.0–7.5%, carbohydrates maximum 10.0–11.0%; 16). The marten were provided about 200 g feed or 250 kcal $animal^{-1}$ d^{-1}. They are known to require about 80 kcal d^{-1} when at rest (17). The fasting experiments were conducted January 5–7, 2005. Half of the animals (n = 8) were put on a total 2-d fast, while the other half (n = 7) was fed using the diet and procedure described above. The fed group was fasted overnight before the sampling. Water was available for both experimental groups *ad libitum* during the whole of the study period.

Body masses (BM) were recorded on the first day of the experiment and at sampling, and the body lengths at sampling. Body mass indices (BMI) indicating body adiposity of mustelids (15) were calculated with the formula BMI = BM (kg) × [body $length^3$ (m)]$^{-1}$. The animals were anesthetized with an intramuscular injection of xylazine (Rompun™ 0.17 mL kg^{-1}) and ketamine hydrochloride (Ketalean™ 0.09 mL kg^{-1}). Blood samples were obtained by cardiac punctures using sterile evacuated blood collection tubes with EDTA as an anticoagulant, and the animals were euthanized with an intracardiac injection of pentobarbital (Euthanyl™ 0.44 mL kg^{-1}). The blood was stored on ice until centrifugation at 1000 × g for 15 min at 4°C, after which the plasma was removed. The livers and WAT samples were dissected. The WAT samples collected were as follows: sc interscapular, sc rump, sc ventral, iab omental (om), iab mesenteric (mes), iab diaphragmatic (dia), iab retroperitoneal (rp), intermuscular, tail tip, front paw, and rear paw. The fat samples of the paws were obtained from the tissues situated ventral to the metacarpal and metatarsal bones. At the same time, muscle and kidney samples were obtained for other substudies, and the spleen and pancreas were weighed. All the samples were placed into vials, frozen immediately with liquid nitrogen, and stored at −80°C. The carcasses were also frozen and the different adipose depots dissected and weighed at a later date.

The FA compositions of WAT, plasma, and liver were determined from total lipids. Subsamples of WAT and liver were transmethylated according to Christie (18) by heating with 1% methanolic H_2SO_4 under a nitrogen atmosphere. The same procedure was used for the plasma samples (50 μL); these were first evaporated to near dryness under nitrogen flow and then methylation solvents were added immediately. The FAME that formed were extracted with hexane. The dried and concentrated FAME were analyzed by a gas–liquid chromatograph (GC-FID and GC-MS, 6890N network GC system with autosampler, FID detector, and model 5973 mass selective detector; Agilent Technologies Inc., Palo Alto, CA). The injection volume was 2 μL, and the split ratio 1:20. The injectors were set at 250°C, and the FID and mass interphases were at 250 and 200°C, respectively. Helium was used as a carrier gas (1.8 and 1.0 mL min^{-1} for FID and mass detecting lines, respectively). The obtained peaks were reintegrated manually. The FAME were identified based on retention time, MS, and comparisons with authentic (Sigma, St. Louis, MO) and natural standards of known composition and published reference spectra (http://www.lipidlibrary.co.uk/masspec.html). Quantifications were based on FID responses. The peak areas of the FID chromatograms were converted to mole percentages by using the theoretical response factors (19) and calibrations with quantitative authentic standards. The FA were marked by using the abbreviations: [carbon number]:[number of double bonds] n-[position of the first double bond calculated from the methyl end] (e.g., 22:6n-3). The iso- and anteiso-isomers were abbreviated as *i* and *ai*. If not stated otherwise, PUFA were methylene-interrupted. The FA results are represented as mol%.

The double bond index (DBI) and the total average chain length (TACL), indicating the mean number of double bonds and the mean number of carbon atoms per molecule, respectively, were calculated according to standard formulae (20). The Δ9-desaturation index (Δ9-DI), the ratio of the most important potentially endogenous Δ9-monounsaturated FA (MUFA) to the corresponding saturated FA (SFA), was calculated as [(mol% 14:1n-5) + (mol% 16:1n-7) + (mol% 16:1n-9) + (mol% 18:1n-9) + (mol% 18:1n-7)]/[(mol% 14:0) + (mol% 16:0) + (mol% 18:0)]. The very long chain FA (VLCFA) were calculated as the sum of all FA with a chain length ≥24 carbons (i.e., 24:0 + 24:1n-9; Ref. 21). Relative mobilization was calculated by the formula: [(mol% in the fed animals) – (mol% in the fasted animals)]/(mol% in the fed animals). The FA composition and relative mobilization were also determined for the pooled sc (scapular, rump, and ventral combined) and iab (om, mes, rp and dia combined) fat depots and compared with the results obtained from the extremities.

Multiple comparisons between the experimental groups were performed with one-way ANOVA followed by the Duncan's *post hoc* test. Comparisons between the two experimental groups were performed with the Student's *t*-test for independent samples or, for nonparametric data, with the Mann–Whitney U test. Correlations were calculated using the Spearman correlation coefficient (r_s). A P value less than 0.05 was considered to be statistically significant. The results are presented as mean ± SE.

TABLE 1
Effects of Fasting on the FA (mol%) in Total sc and iab Fats, Fats of the Extremities, and Plasma and Liver of the American Marten[a] (mean ± SE)

[a]An asterisk (*) indicates a significant difference between the fed and fasted animals (*t*-test, Mann–Whitney U test, $P < 0.05$); dissimilar superscripts indicate that the values of subcutaneous (sc), intra-abdominal (iab), and extremity fats of the fed group differ at $P < 0.05$ (one-way ANOVA). Δ9-DI = Δ9-desaturation index, VLCFA = very long chain FA (chain length ≥ 24 C), UFA = unsaturated FA, SFA = saturated FA, DBI = double bond index, TACL = total average chain length.

RESULTS

The average initial (fed: 884 ± 70 g, fasted: 849 ± 63 g) or final (fasted: 734 ± 56 g) BM of the marten did not differ between the experimental groups. The fasted marten lost approximately 113 g or 13.4% of BM during the 2-d fasting period. The absolute or relative masses of the different fat depots did not differ between the experimental groups (sc interscapular: fed 0.27 ± 0.05 vs. fasted 0.15 ± 0.04 g; sc rump: 0.16 ± 0.05 vs. 0.15 ± 0.05 g; sc ventral: 1.29 ± 0.57 vs. 0.61 ± 0.16 g; iab om: 4.94 ± 1.66 vs. 1.93 ± 0.61 g; iab mes: 2.44 ± 0.78 vs. 1.19 ± 0.24 g; iab dia: 0.68 ± 0.27 vs. 0.33 ± 0.11 g; iab rp: 5.58 ± 2.18 vs. 3.29 ± 1.79 g; intermuscular: 8.03 ± 0.85 vs. 7.52 ± 0.57 g; total fat percentage: 2.74 ± 0.56 vs. 2.06 ± 0.24%, $P > 0.05$). The total fat mass (23.4 ± 4.4 vs. 15.2 ± 2.2 g) was lower in the fasted animals ($P < 0.05$). The calculated BMI correlated strongly with the total fat mass ($rs = 0.604$, $P < 0.05$) and the fat percentage ($rs = 0.804$, $P < 0.01$). The initial BMI did not differ between the experimental groups, but the BMI was significantly lower in the fasted animals at the end of the study (12.9 ± 0.7 vs. 10.6 ± 0.2 kg $(m^3)^{-1}$; $P < 0.05$). Many of the marten in the fasted group were physically active and exhibited stereotypical behavior and signs of stress, such as hair biting.

The most abundant FA (≥1 mol%) in the sc and iab fat depots of the marten were 12:0, 14:0, 16:0, 18:0, 16:1n-7, 18:1n-9, 18:1n-7, 20:1n-11, 20:1n-9, 22:1n-11, 18:2n-6, and 22:6n-3 (Table 1). In the extremities the pattern was mostly the same, but the proportions of 12:0, 20:1n-11, and 20:1n-9 were clearly lower, whereas the proportions of 14:1n-5, 20:4n-6, and 20:5n-3 were higher than in the trunk fat. Generally, the extremities had higher proportions of unsaturated FA (UFA) than the iab or sc depots. In fact, the DBI, Δ9-DI, total PUFA, and the sums of 4n- and 5n-PUFA were all higher in the extremities. In the plasma and livers the proportions of SFA and particular PUFA were higher than in any of the fat depots; in particular, the proportions of 16:0 and 18:0 were two to three times higher than in the WAT, and also the proportions of 20:4n-6 and 20:5n-3 were elevated. On the other hand, the proportions of certain monoenes, especially 18:1n-9 and 18:1n-7, were fairly low in the plasma and livers.

Food deprivation caused numerous differences in the proportions of FA in the fat depots (Tables 1–3). The sum of SFA decreased in the sc scapular and iab rp depots and in the pooled trunk fats, mostly owing to significant decreases in the proportion of 16:0, whereas the proportions of 18:0, 19:0, 20:0, 22:0, and 24:0 mostly increased in the fasted animals. Also the proportions of most MUFA were higher in the fasted group in most fat depots with the exception of 16:1n-7, the proportions of which decreased in all sc and iab tissues. In the PUFA the proportions of 20:2n-6, 20:3n-6, 22:4n-6, 22:4n-3, 22:5n-6, and 22:5n-3 increased, whereas the proportions of 18:3n-3 and 18:4n-3 were lower in the fasted marten. In the pooled trunk fats, the proportions of 4n- and 5n-PUFA increased due to fasting. In a similar manner, the proportions of n-6 PUFA and VLCFA as well as the TACL were higher in the fasted group in the pooled sc and iab fats. In the extremities, the effects of fasting were minor. In plasma, the proportions of several SFA,

[a]An asterisk (*) indicates a significant difference between the fed and the fasted animals (*t*-test, Mann–Whitney U test, $P < 0.05$). For abbreviations see Table 1. The sums include also minor FA not presented in the table.

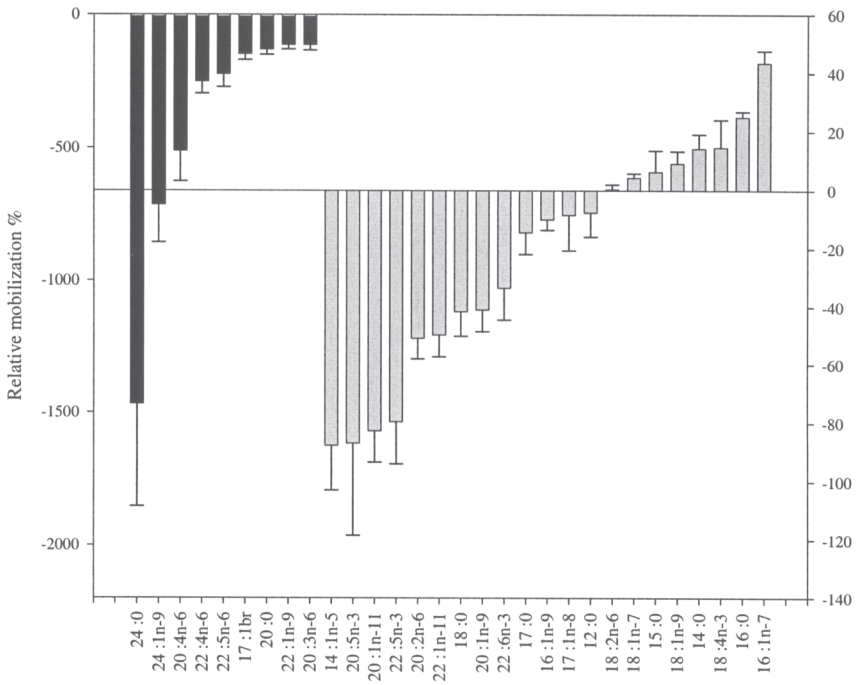

FIG. 1. *In vivo* relative mobilization of the most abundant FA in pooled adipose tissues of the American marten fasted for 2 d (mean + SE). Positive (+) values indicate that the proportion of a FA is lower compared with the fed control group, and negative (–) values signify that the proportion of a FA has increased compared with the fed control group. Black bars are plotted against the left Y-axis and gray bars against the right Y-axis.

MUFA, and, in particular, 2n-PUFA increased, while the proportions of 5n-PUFA decreased and the total percentage of the VLCFA increased. In the liver, the total proportion of SFA, 3n-, and 5n-PUFA was lower in the fasted animals. After 2 d of fasting, most FA were highly preserved in the fat depots (Fig. 1). The most important FA that had high relative mobilization were 16:1n-7, 16:0, 18:4n-3, and 14:0, whereas several long-chain MUFA and PUFA, such as 24:1n-9 and 20:4n-6, had mostly low relative mobilization, along with 14:1n-5, 17:0, 18:0, 20:0, and 24:0. Relative mobilization did not differ between the various iab and sc depots.

Relative mobilization of SFA correlated negatively with the chain length when all trunk WAT were analyzed as a whole (r_s = –0.327, $P < 0.01$; Fig. 2a). The same was observed in the n-9 MUFA (r_s = –0.350, $P < 0.01$; Fig. 2b) but not in the n-5, n-7, or n-11 MUFA. The influence of chain length on the relative mobilization of PUFA was tested by comparing PUFA with the same degree of unsaturation and position of the first double bond but with a different chain length. The difference was statistically significant in six out of eight pairs (16:2n-4 vs. 18:2n-4; 18:2n-6 vs. 20:2n-6; 18:3n-6 vs. 20:3n-6; 18:3n-3 vs. 20:3n-3; 18:4n-3 vs. 20:4n-3; and 20:4n-3 vs. 22:4n-3) in the way that the PUFA with the longer chain length had a lower mobilization rate (*t*-test, $P < 0.05$).

When SFA and corresponding MUFA with the same chain length were compared with each other, relative mobilization increased with Δ9-desaturation in four out of seven cases (16:0 vs. 16:1n-7; 18:0 vs. 18:1n-9; 19:0 vs. 19:1n-10, and 20:0 vs. 20:1n-11, *t*-test, $P < 0.05$; Fig. 2c). The influence of unsaturation on relative mobilization of PUFA was investigated by comparing PUFA with the same chain length and position of the first double bond but with a different double bond number. The difference was significant in three out of six pairs (18:3n-3 vs. 18:4n-3; 20:2n-6 vs. 20:3n-6; 20:3n-6 vs. 20:4n-6; Fig. 2d) in the way that the PUFA with the higher number of double bonds had the lower relative mobilization rate (*t*-test, $P < 0.05$).

The influence of positional isomerism on the relative mobilization of MUFA was tested by comparing MUFA of the same chain length but different position of the double bond. The difference was statistically significant in five out of seven pairs (*t*-test, $P < 0.05$) in the way that the MUFA with the double bond closer to the methyl end of the molecule had a lower (18:1n-5 vs. 18:1n-7; 20:1n-9 vs. 20:1n-11; and 22:1n-9 vs. 22:1n-11) or a higher mobilization rate (14:1n-7 vs. 14:1n-9 and 16:1n-7 vs. 16:1n-9). When comparing PUFA with the same chain length and unsaturation but with a different position of the first double bond, the difference was statistically significant in four out of six pairs (*t*-test, $P < 0.05$) in the way that the PUFA with the first double bond closer to the methyl end of the molecule had a lower (18:3n-3 vs. 18:3n-6; 18:2n-6 vs. 18:2n-7; and 22:5n-3 vs. 22:5n-6) or a higher mobilization rate (20:4n-3 vs. 20:4n-6).

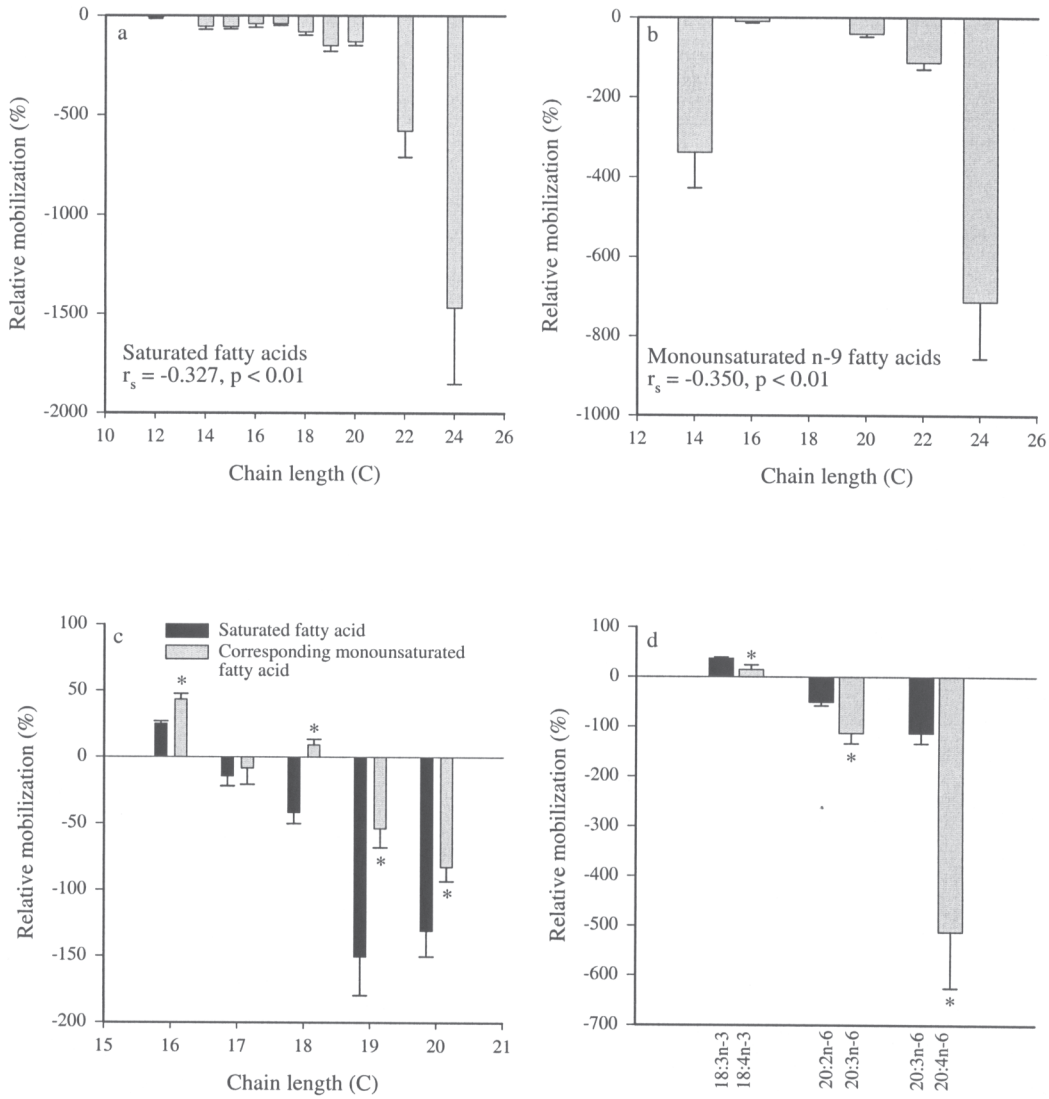

FIG. 2. Effects of FA structure on relative mobilization in the American marten after 2 d of fasting (all trunk white adipose tissues analyzed as a whole; mean + SE). (a) Relative mobilization of saturated FA of different carbon chain length. (b) Relative mobilization of n-9 monounsaturated FA of different carbon chain length. (c) The influence of Δ9-desaturation on relative mobilization. * = Significant difference in relative mobilization between saturated and monounsaturated FA (*t*-test, $P < 0.05$). (d) Effect of double bond number on relative mobilization of selected PUFA. * = Significant difference in relative mobilization between PUFA with different degrees of unsaturation (*t*-test, $P < 0.05$).

DISCUSSION

Body fat content and rate of weight loss. The rate of BM loss in the fasted American marten was 13.4% or 6.7% d^{-1}. This is slightly higher than the BM loss of 4.8% d^{-1} observed previously after a 5-d fasting period (12). At the same time, the BMI of the fasted marten of this study decreased by 18.5%. The total fat percentage of the marten was very low, approximately 2.7% for the fed animals and only a little more than 2% for the fasted animals. The data of the fed control animals fit quite well the previous report of Buskirk and Harlow (11). They measured a 2.4% body fat content in skinned American marten in Alaska, whereas in Wyoming the whole body fat content was approximately 5.6% in winter. The rate of BM loss in the marten was relatively high compared with a close relative, the farmed sable, which lost about 16% or 4.0% d^{-1} of its BM during a 4-d wintertime fasting period (Mustonen, A.-M., Puukka, M., Saarela, S., Paakkonen, T., Aho, J., and Nieminen, P., unpublished data). The sable had an 8.0% body fat content. The body fat percentage of the captive marten of this study was even more different from the farmed American mink, which can have a body fat content as high as 35–38% in the winter (15). Fasted mink lose weight at a rate of approximately 3.0% after a 2-d fasting period, which is about 4.5 times less than the weight loss rate of the marten was.

The smaller initial body fat percentage compared with the sable or the mink could be an explanation of the more rapid weight loss of the marten. Marten have been previously fasted for 5 d with fat as the principal source of metabolic energy (12). Yet the use of proteins is already quite significant at this point of fasting. It is conceivable that some body proteins could have been lost during the fasting procedure of the present study, as the total BM of the fasted marten decreased by 113 g, of which fat accounted for approximately 8.2 g. A major part of the BM loss probably consisted of intestinal contents, but also body proteins and carbohydrates could have contributed to the observed BM loss. However, plasma urea and ammonia levels as well as plasma, liver, and muscle protein concentrations remained stable during fasting while the liver, muscle, and kidney glycogen stores decreased (Nieminen, P., Rouvinen-Watt, K., and Mustonen, A.-M., unpublished data). These data indicate that the marten were still within phase II of fasting at the end of the experiment.

As an additional result, the clearly positive correlation between the BMI and the total fat mass or the body fat percentage indicates that the BMI can be used as an accurate and easily measured tool to approximate the body condition and fat content of American marten. To determine the condition of an individual marten, this can be supplemented by measuring the om fat mass (22). In fact, the correlation between the calculated BMI and the different fat depots was the most significant between the BMI and the om fat mass ($r_s = 0.828$, $P < 0.01$). The observation that the marten in the fasted group were physically active, many of them exhibiting stereotypical behavior and signs of stress, may be quite relevant to their rapid rate of body mass loss. This is most likely due to increased energy expenditure caused by accelerated locomotor activity as observed previously in fasted mink (23). In a similar manner, it has been observed that physical activity increases in the least weasel (*Mustela nivalis*) due to food deprivation (24).

Site-specific FA composition of the American marten. Generally, the FA composition in the sc and iab depots of the American marten was very similar to previous findings on other mustelids, the sable and the mink (25,26; Nieminen, P., and Mustonen, A.-M., unpublished data; Nieminen, P., Käkelä, R., Pyykönen, T., and Mustonen, A.-M., unpublished data). The most abundant FA in the fat depots of the marten were 14:0, 16:0, 18:0, 16:1n-7, 18:1n-9, and 18:2n-6. The proportions of total MUFA and PUFA in the trunk fat depots (42–43% and 22–23%, respectively) were closer to those observed previously in the farmed sable (40–45% and 20–25%) than to those in the farmed mink (50–55% and 10%). In this respect, the American marten is very similar to its Siberian relative, the sable, wheras both differ from the more distantly related mink. However, it must be recalled that the FA composition of the diets affecting the tissue FA percentages was probably dissimilar between the species of these experiments and could have caused some of the observed differences.

Proportions of MUFA and PUFA were much higher in the extremities than in the trunk of the marten. This was especially evident in the tip of the tail, with many n-3 PUFA, such as 20:3n-3, 20:5n-3, and 22:6n-3, in higher proportions than in the trunk. Furthermore, there was a simultaneous increase in the sum of n-3 PUFA in all the extremity tissues. The longer-chain 20- and 22-carbon PUFA were detected at higher proportions in the paws. In addition, the indices of unsaturation, the Δ9-DI, DBI and UFA/SFA ratio, were higher in the extremities, especially in the tail tip.

Previously, the FA composition of the extremities of mustelids has been studied in the mink and the sable (Mustonen, A.-M., Käkelä, R., and Nieminen, P., unpublished data; Mustonen, A.-M., and Nieminen, P., unpublished data). In this respect, the American marten is quite similar to the mink, as both species have decreased proportions of SFA and increased desaturation in the periphery. The differences between the fat depots of the trunk and the extremities are less pronounced in the sable, yet sables also have increased proportions of n-3 PUFA and VLCFA in their peripheral tissues. In general, the m.p. of mammalian fats are approximately 30–40°C, whereas the least insulated parts of the body, such as paw pads and the tail tip, may cool significantly more, down to 0°C in some conditions. The higher proportion of UFA in the periphery is probably crucial to prevent the solidification of lipids to maintain the fluidity of cell membranes. In fact, similar FA gradients have been detected from other boreal and arctic mammalian species, such as the European otter (*Lutra lutra*; 27), the blue fox (*Alopex lagopus*; 26), and beavers (*Castor fiber* and *C. canadensis*; 28). For instance, the adipose depots under the footpads of the otter have significantly more MUFA than the fat tissues of the trunk (27). Also, in the American marten, this phenomenon must be taken as an adaptation to the cold winter environment the species experiences in its natural habitat.

Effects of food deprivation on the relative mobilization of FA. In the fat depots of the trunk, the 2-d fasting period induced significant changes in the FA composition. In the SFA the proportions of long-chain FAs, especially 18:0, 20:0, and 22:0, increased with very few exceptions in most of the WAT depots, whereas the proportion of 24:0 increased especially in the iab fat. Simultaneously, the proportions of 16:0 decreased in all the studied fat tissues. Furthermore, the percentages of 18:3n-3 decreased in both pooled sc and iab fats, and the proportion of 18:4n-3 decreased in the iab fat, whereas the percentages of many n-6 PUFA, such as 20:2n-6, 20:3n-6, 20:4n-6, 22:4n-6, and 22:5n-6 increased. This caused an elevation in the sum of n-6 PUFA in both pooled sc and iab fats. At the same time, the proportion of 22:6n-3, an important FA for biological membranes (29), was unaffected by fasting. The conversion of various n-3 PUFA into the biologically important 22:6n-3 can be an explanation to the stable proportion of 22:6n-3 despite of fasting.

An increase in the proportion n-6 PUFA would be considered undesirable from the point of view of the human cardiovascular system as it causes harmful alterations in eicosanoid production (30). As the proportions of n-3-derived prostaglandins and eicosanoids decrease, unwanted proinflammatory changes in the immune response as well as cardiac arrhythmias and increased platelet aggregation may ensue. However, despite

this general effect of fasting on n-6 PUFA, the effects of positional isomerism on the relative mobilization of PUFA were inconsistent and no definite conclusions on the effects of fasting on n-3 and n-6 PUFA can be drawn from these data. The apparent increase in the proportion of n-6 PUFA can be caused by the analysis of FA from total lipids. There could have been a relative increase in the proportion of membrane phospholipids in comparison with storage TAG during fasting in the marten with a low body fat content. For instance, the increased proportion of phospholipids can be an explanation for the observed increases in 18:0 and 20:4n-6 in the fasted animals.

After 2 d of fasting, most of the relatively abundant FA were preserved in the fat depots. The anatomically different adipose tissues of the marten were very similar in this respect, as no significant differences in the mobilization rates of individual FA were found between the different WAT depots. Likewise, rats (*Rattus norvegicus*; 31) do not experience fat depot-associated differences in relative mobilization. The FA that were preferentially mobilized by the fasted marten were 16:1n-7; short-chain SFA, especially 14:0 and 16:0; 18:1n-9; and, in some of the fat depots, particular n-3 PUFA (18:4n-3).

The structure of FA may partly dictate the selectivity of FA mobilization. In the case of the American marten, short-chain FA were more readily mobilized over long-chain FA in all FA classes (SFA, MUFA, and PUFA). Shorter FA molecules are hypothesized to be situated peripherally in lipid droplets and can thus be more easily accessible to lipases (32). As a result, the proportion of longer-chain FA increases as the shorter-chain FA are mobilized for energy production. The same could be observed in the negative correlation between relative mobilization and chain length in all the fat depots of the trunk: the longer the carbon chain, the more obvious the preservation of a FA in an adipose tissue depot.

For a particular chain length, relative mobilization of FA increases with the number of double bonds in the rat (31). The same could be observed in the marten, as the mobilization of MUFA was higher than that of their corresponding SFA in 71% of the studied cases. However, in PUFA the effect was the opposite, as relative mobilization decreased with the number of double bonds in 50% of the cases. In this study, the effects of positional isomerism on relative mobilization were quite vague. This suggests that relative mobilization of FA during fasting is not as straightforward in all mammalian species as suggested by previous *in vitro* (32) and *in vivo* studies (31).

Ecophysiological implications. According to Buskirk (22), the American marten has limited fat reserves in the winter (2.4% of skinned carcass) and the om fat mass is considered the best indicator of body energy content. This would indicate that marten do not have enough stored body fat available to fast for long periods when foraging is impossible, e.g., during severe weather. To cope with this, marten may use microhabitats to avoid extremely cold temperatures. Furthermore, Thompson (33) suggests that marten reduce energy loss during winter by reducing activity, by eating large prey, and by being active during the warmest part of the day.

Despite its very low body adiposity, the American marten has adaptations to withstand short periods of food deprivation encountered in nature especially in the winter. According to Buskirk (22), if a marten had a body fat content of 2.37%, approximately the same as in the fed marten of this study, it would take 70 h for the animal to metabolize its fat reserves completely, putting the marten of this experiment still within the phase II of fasting. In fact, the marten were able to mobilize all their principal adipose tissue depots of the trunk during food deprivation. The FA mobilized were almost the same in sc and iab fats, indicating that as a terrestrial species the American marten is not very dependent on sc fat for insulation and can use it as an energy reserve for intermittent fasting. The principal FA mobilized were relatively short-chain SFA (14:0 and 16:0) and MUFA (16:1n-7 and 18:1n-9), and in the case of the iab fat, n-3 PUFA, especially 18:3n-3 and 18:4n-3. In contrast to this, the FA composition of the extremities was very resistant to fasting and contained significantly more long-chain PUFA than the depots of the trunk. This is probably an adaptation to maintain cell membrane fluidity and prevent freezing and solidification of these parts of the body most susceptible to cooling and frostbite.

ACKNOWLEDGMENTS

Effects of Conjugated Linoleic Acid and Troglitazone on Lipid Accumulation and Composition in Lean and Zucker Diabetic Fatty (*fa/fa*) Rats

Angela A. Wendel and Martha A. Belury*

Department of Human Nutrition, The Ohio State University, Columbus, Ohio 43210

ABSTRACT: Dietary CLA has been shown to enhance glucose tolerance in several animal models, but in mice it induces insulin resistance and lipodystrophy. In this study, the effects of 2 wk of diet supplementation with either 1.5% CLA or 0.2% troglitazone (TZD), an insulin-sensitizing thiazolidinedione, on glucose tolerance, lipid accumulation, and composition of both lean and Zucker diabetic fatty (*fa/fa*; ZDF) rats were examined. Compared with lean rats, which maintained normal glucose tolerances after 2 wk of feeding regardless of diet, ZDF rats fed a control diet (CON) had significantly worsened glucose tolerance. ZDF rats fed CLA and TZD diets, however, maintained normal glucose tolerances. In contrast to the significantly elevated lipid levels in ZDF rats fed the CON diet, concentrations of plasma FFA and TG in ZDF rats fed CLA and TZD diets were normalized. A similar reduction of plasma lipid levels was observed in lean rats fed CLA and TZD compared with lean rats fed the CON diet. Although ZDF CON rats developed significant hepatic steatosis, both CLA- and TZD-fed rats had hepatic TG levels similar to those of lean rats. Both lean and ZDF rats fed the CLA diet had reduced adipose mass compared with respective genotype controls; however, TZD had no effect. Ratios of 16:1/16:0 and 18:1/18:0 FA, surrogate markers for stearoyl-CoA desaturase-1 (SCD-1) activity, were reduced in livers of ZDF rats fed CLA and TZD diets. These results show that, like TZD, CLA normalizes glucose tolerance and plasma lipids and also improves hepatic steatosis and FA composition in ZDF rats. The effects of CLA and TZD on hepatic lipid composition suggest that the effects of these two agents on glucose tolerance may be associated with a reduction in SCD-1.

Paper no. L9849 in *Lipids 41*, 241–247 (March 2006).

CLA refers to a group of PUFA that exist as positional and stereoisomers of octadecadienoic acid (18:2). CLA is found naturally in foods derived from ruminants, such as beef, lamb, and dairy products, and in supplement form (e.g., Tonalin™). Due to the potential health benefits of CLA, a great deal of research has been devoted to this group of PUFA. CLA acts as an anticarcinogenic (1) and anti-atherosclerogenic agent, as a modulator of immune function and body composition, and as a possible antidiabetic agent (2). In the treatment of diabetes, CLA improves glucose tolerance and insulin sensitivity, as well as fasted glucose and insulin levels in several rodent models of obesity and diabetes (3–7). Further, CLA reduces plasma FFA (3,5–8) and plasma (3,6–8) and hepatic (9) TG concentrations, which are thought to contribute to insulin resistance and subsequent increased hepatic glucose production (10). The decrease in hepatic TG and altered lipid metabolism by CLA may be attributed, in part, to the reduction of stearoyl-CoA desaturase-1 (SCD-1), a rate-limiting enzyme in the desaturation of palmitoyl- (16:0) and stearoyl-CoA (18:0) FA that is essential to TG formation. Previous research has shown that CLA reduces SCD-1 mRNA expression and activity in several different *in vitro* and *in vivo* models (11–14). Nevertheless, the mechanism and the relative efficacy of CLA to improve glucose tolerance, insulin sensitivity, and the associated lipid metabolism have not been fully elucidated.

Similarly, treatment with thiazolidinediones, insulin-sensitizing agents used in type 2 diabetes therapy, lowers fasting glucose and insulin concentrations, corrects plasma lipid levels (15), and reduces hepatic TG levels (16). Thiazolidinediones also have been shown to decrease SCD-1 expression and activity (17,18), which may contribute to the reductions in lipid levels. Additionally, thiazolidinediones function as a high-affinity ligand for the nuclear receptor peroxisome proliferator activated receptor-γ (PPARγ). PPARγ, in turn, stimulates the differentiation, proliferation, and lipid accumulation of adipocytes, thereby increasing adiposity (19). The induction of adipocyte differentiation promotes lipid accumulation in adipose tissue and prevents lipid accumulation in peripheral tissues such as liver, muscle, and pancreas. The ability of thiazolidinediones to prevent steatosis in nonadipose tissues, as well as other indirect mechanisms, may contribute to the activity of thiazolidinediones as insulin sensitizers (20).

Our group reported that, following 11 d on experimental diets, Zucker diabetic fatty (ZDF) rats fed diets supplemented with either CLA or a thiazolidinedione had similar fasting glucose levels as lean rats, whereas ZDF rats fed a control diet had elevated fasting glucose levels (5). Because glucose metabolism and insulin sensitivity are associated with reduced steatosis (21) and decreased SCD-1 activity (22,23), the objective of this study was to compare the effects of CLA and a thiazolidinedione on lipid composition and metabolism in the liver. The impact of CLA on glucose tolerance, plasma lipid levels, and hepatic lipid accumulation, composition, and SCD-1 activ-

ity was compared with this known type 2 diabetes agent in both lean and ZDF rats, as many of the antidiabetic effects of CLA and thiazolidinediones are similar.

MATERIALS AND METHODS

Materials. Diet components were obtained from Dyets, Inc. (Bethlehem, PA). The CLA oil (Pharmanutrients, Inc., Lake Bluff, IL) was ~90% CLA with the following composition: 42% *c*9, *t*11- and *t*9, *c*11-CLA; 43.5% *t*10, *c*12-CLA; 1% *c*9, *c*11-CLA; 1% *c*10, *c*12-CLA; 1.5% *t*9, *t*11- and *t*10, *t*12-CLA; 0.5% linoleate; 5.5% oleate; and 5% unidentified. The use of this mixed isomer form of CLA is most relevant regarding the impact of CLA on the management of type 2 diabetes as this source of CLA is currently available commercially for use in humans (e.g., Tonalin™). The thiazolidinedione troglitazone (TZD) was obtained from Parke-Davis (Ann Arbor, MI).

Animals and experimental diets. Six-week-old, male, obese, Zucker diabetic fatty (ZDF/Gmi-*fa/fa*) rats (n = 24) and lean littermates (ZDF/Gmi-+/?; n = 12) were purchased from Genetic Models, Inc. (Indianapolis, IN). Prior to beginning experimental diets, rats were determined to be normoglycemic by a fasting glucose measurement. Rats were then randomized by genotype and body weight and assigned to one of three isocaloric, modified AIN-76 diets containing 6.5% fat for 14 d (from 8–10 wk of age). Corn oil (5%) was used in all diets, and research-grade, tocopherol-stripped lard was used to balance caloric density so that diets contained either 5% corn oil/1.5% lard/no CLA (CON); 5% corn oil/1.5% CLA (CLA); or 5% corn oil/1.5% lard/0.2% TZD. Each diet group contained 8 ZDF rats and 4 lean rats. All procedures were in accordance with institution guidelines and approved by the Purdue Animal Care and Use Committee. A glucose tolerance test was conducted on day 11 of dietary intervention after an overnight (16 h) fast as previously reported (5). Glucose areas under the curve (AUC) are expressed as positive incremental AUC calculated using the trapezoidal rule (24). After 14 d on experimental diets, rats were euthanized by CO_2 and cervical dislocation. Blood was collected immediately in heparinized test tubes for plasma analyses as described below. Liver and adipose tissues were harvested, weighed, and immediately frozen and stored at –80°C.

Analysis of TG and FFA. Plasma FFA were determined using a colorimetric kit (NEFA C; Wako Chemicals, Richmond, VA). Lipids were extracted from tissues with chloroform/methanol (2:1, vol/vol) and 0.2 vol 0.88% KCl. To measure TG concentrations, lipid extracts were further processed as previously described by Denton and Randle (25) with alterations by Frayn and Maycock (26). In brief, phospholipids were removed with silicic acid, and the remaining lipids were saponified with 80% KOH/ethanol (5:95, vol/vol). Addition of 0.15 M $MgSO_4$ stopped the saponification; and after centrifugation, the supernatants, as well as plasma, were analyzed for TG by colorimetric enzymatic hydrolysis (Triglyceride GPO-Trinder reagents; Sigma, St. Louis, MO).

FA analyses. Lipid extracts were separated into neutral lipids and phospholipids by the silica column procedure described by Hamilton and Comai (27). In brief, neutral and phospholipids were separated by PrepSep Si columns (Fisher Scientific, Fair Lawn, NJ) by eluting extracts with methyl *tert*-butyl ether/acetic acid (100:0.2, vol/vol) and methyl *tert*-butyl ether/methanol/ammonium acetate (pH 8.6) (5:8:2, by vol), respectively. FAME of the fractions were prepared by incubating the fractions with 1,1,3,3-tetramethylguanidine at 100°C and analyzed by GC using a 30-m Omegawax 320 capillary column (Supelco, Sigma-Aldrich, St. Louis, MO). The helium flow rate was 30 mL/min, and the oven temperature was programmed to start at 175°C for 4 min and increase to 220°C at a rate of 3°C/min.

Statistical analyses. Data are expressed as least square means ± SE. Effects of genotype (lean and ZDF) and diet (CON, CLA, and TZD) were analyzed by two-way ANOVA using the MIXED procedure of Statistical Analysis System (SAS V8; Cary, NC). Differences of $P < 0.05$ were considered significant.

RESULTS

Glucose tolerance. A glucose tolerance test was administered after 11 d on experimental diets. There were no differences in the AUC among any of the lean diet groups. Although ZDF rats fed the CON diet had significantly worsened glucose tolerance as indicated by elevated AUC, ZDF rats fed CLA or TZD diets maintained an AUC similar to that of lean rats (Fig. 1).

Plasma FFA and TG levels. Plasma FFA concentrations were reduced by CLA and TZD treatment in both lean and ZDF rats. Plasma FFA levels were similar between lean and ZDF rats fed the CON diets, but were significantly reduced in lean

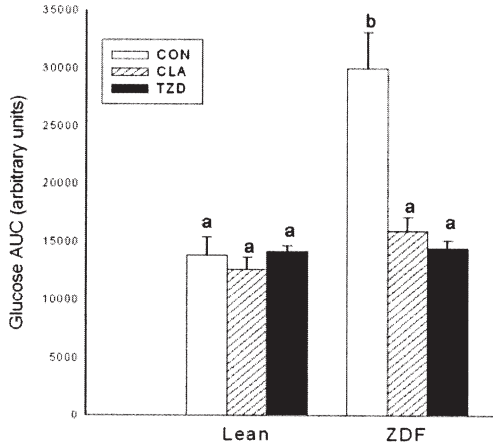

FIG. 1. Effect of dietary CLA and troglitazone (TZD) on glucose tolerance test in lean and Zucker diabetic fatty (ZDF) rats. Rats were fed either a control (CON; open bars), 1.5% CLA (hatched bars), or 0.2% TZD (closed bars) diet for 14 d. A glucose tolerance test was administered on day 11 of experimental diets after a 16-h fast as described in the Materials and Methods section. Values represent least squares mean (LSM) ± SE. Values with different superscripts are significantly different ($P < 0.05$). AUC, area under the curve.

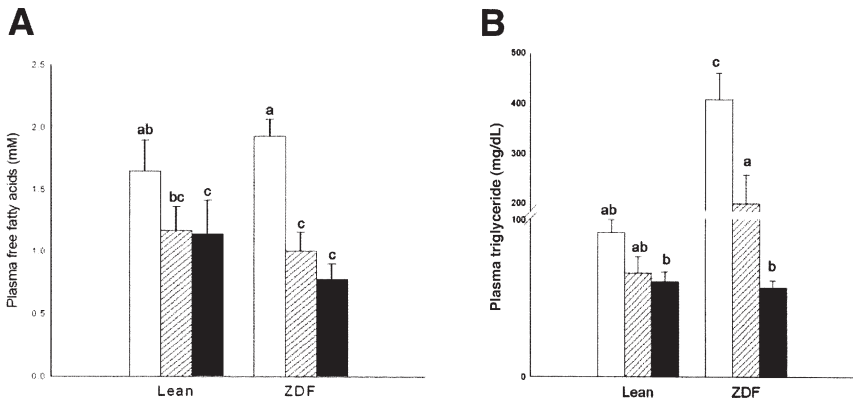

FIG. 2. Effect of dietary CLA and TZD on plasma (A) FFA and (B) TG levels in lean and ZDF rats. Rats were fed either a control (CON; open bars), 1.5% CLA (hatched bars), or 0.2% (closed bars) diet for 14 d. FFA and TG levels were measured as described in the Materials and Methods section. Values represent LSM ± SE. Values with different superscripts are significantly different ($P < 0.05$). For abbreviations see Figure 1.

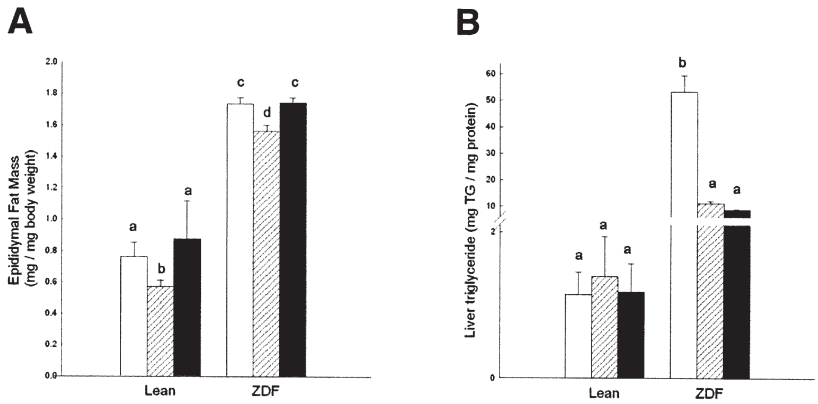

FIG. 3. Effect of dietary CLA and TZD on (A) epididymal fat mass and (B) liver TG levels in lean and ZDF rats. Rats were fed either a control (CON; open bars), 1.5% CLA (hatched bars), or 0.2% TZD (closed bars) diet for 14 d. TG levels were measured as described in Materials and Methods section. Values represent LSM ± SE. Values with different superscripts are significantly different ($P < 0.05$). For abbreviations see Figure 1.

TZD and in ZDF CLA and TZD rats. The plasma FFA concentration in lean rats fed CLA was similar to the reduced levels but was not statistically lower compared with lean CON (Fig. 2A). Plasma TG levels did not differ among diet groups of lean rats (Fig. 2B). Although the plasma TG concentrations of ZDF rats fed the CON diet were significantly elevated compared with lean rats fed the CON diet, both CLA and TZD treatments in ZDF rats reduced plasma TG. Additionally, lean and ZDF rats fed the TZD diet had significantly lower plasma TG levels than ZDF rats fed the CLA diet.

Epididymal fat mass and liver TG concentrations. Regardless of dietary group, ZDF rats had significantly more epididymal fat mass than all the lean diet groups following 14 d on experimental diets (Fig. 3A). Rats fed the CLA diet, whether the lean or ZDF group, had lower epididymal fat mass than the CON and TZD-fed rats within their respective genotype group. Liver TG concentrations in lean rats were not altered by diet (Fig. 3B). ZDF rats fed the CON diet had significantly elevated levels of TG in their livers, but CLA and TZD treatment maintained TG levels in ZDF rats similar to those of lean rats.

Liver FA composition. As expected, compared with rats fed the CON and TZD diets, rats fed the CLA diet, regardless of genotype, accumulated greater amounts of both isomers in both the neutral lipid and phospholipid fractions of the liver (Tables 1, 2). In both lipid fractions of the liver, all ZDF rats had significantly reduced levels of arachidonic acid (20:4) compared with lean animals. While dietary treatment had no effect on arachidonic acid levels in lean rats, arachidonic acid levels were significantly higher in ZDF rats fed CLA and TZD (Tables 1, 2). Ratios of palmitoleate (16:1)/palmitate (16:0) and oleate (18:1)/stearate (18:0) were used as an index of SCD activity. Compared with lean rats, all ZDF rats had elevated SCD in-

dices in both lipid fractions of the liver; however, the increase was partially rescued by both CLA and TZD treatment in the ZDF rats (Tables 1, 2).

DISCUSSION

Of the prospective health benefits of CLA, the potential antidiabetic effects may be the most controversial due to conflicting data. This report agrees with others that have shown CLA attenuates insulin resistance and glucose intolerance in diabetic or obese rat models (3–6,28). However, other groups have shown that CLA induces insulin resistance and hyperglycemia primarily in mouse models (7,29–31). In mice, insulin resistance develops in parallel with severe lipoatrophy and hepatic steatosis (29). Consequently, the ablation of adipose tissue caused by CLA results in lipid accumulation in peripheral tissues, such as liver, as well as decreases in adipocytokines, such as leptin and adiponectin (29,32,33), all of which may contribute to insulin resistance. Tsuboyama-Kasaoka *et al.* (34) demonstrated that feeding CLA with a high-fat diet partially preserves adipose mass and prevents hyperinsulinemia and hepatomegaly. These results suggest that the ability of CLA to enhance insulin sensitivity is dependent on maintaining a certain level of adipose mass and therefore preventing a marked reduction in adipocytokines and lipid accumulation in peripheral tissues, especially the liver.

In the present study, the effects of dietary CLA and TZD were compared in obese (Gmi-*fa/fa*) and lean (Gmi-+/?) ZDF rats. In contrast to lean rats that are nonobese and otherwise phenotypically "normal," ZDF rats have a mutated, nonfunctional leptin receptor (35). ZDF rats are therefore leptin resistant, obese, and develop hyperlipidemia, hyperleptinemia, insulin resistance, and hyperglycemia in a pattern similar to type 2 diabetes (36,37). As in mice and other animal models (38,39),

both lean and ZDF rats fed CLA had significantly reduced adipose mass. However, the reduction in adipose in either genotype was not sufficient to induce lipoatrophy and subsequent hepatic steatosis as observed in mice (29,34). Although liver TG were significantly elevated in ZDF CON rats, liver TG of ZDF rats fed CLA were similar to lean rats. TZD, a PPARγ agonist, did not affect adipose mass in this 2-wk study but, consistent with another report (16), reduced liver TG. Notably, liver TG levels in lean rats were not affected by either treatment. These results support previous reports that CLA reduced adipose mass and hepatic steatosis in ZDF and Zucker rats (4,9,40). Furthermore, CLA was as effective as TZD in lowering liver TG and did not induce hepatic steatosis in lean rats. The prevention and reduction of hepatic steatosis is important for the ability of CLA to improve glucose tolerance, as hepatic steatosis contributes to insulin resistance and increased hepatic glucose production. Additionally, despite ZDF rats being leptin resistant, a condition that contributes to hepatic steatosis (41), CLA was able to prevent hepatic steatosis. Nagao *et al.* (9) showed that CLA increased adiponectin, an insulin-sensitizing adipocytokine, and suggested that the increase may have prevented the development of hepatic steatosis. Although adiponectin levels were not measured in this study, others have shown that CLA enhances adiponectin levels in ZDF rats (28).

The decrease in liver TG by CLA treatment in ZDF rats may also be partially attributed to the reduction of SCD-1. SCD-1 is important in lipid metabolism as it catalyzes the Δ-9 desaturation predominantly of palmitoyl- (16:0) and stearoyl-CoA (18:0) to palmitoleoyl- (16:1) and oleoyl-CoA (18:1), respectively. These monounsaturated FA are integral components of phospholipids, TG, wax esters, and cholesterol esters (42). Therefore, the regulation of SCD-1 is crucial in the formation of these lipid fractions and essential for TG synthesis. Decreases in SCD-1 expression or activity have been associated with reduced TG levels in plasma and liver (43–45), as well as increased insulin sensitivity (22,23). These effects also may be due to increased β-oxidation, which occurs with reduced SCD-1 expression (22). Both CLA (11–14) and thiazolidinediones (17,18) have been reported to reduce SCD-1 expression and activity or alter FA composition, specifically decreasing monounsaturated FA, indicating a reduction of SCD-1 activity. In this study, CLA and TZD treatment decreased the SCD-1 indices in neutral and phospholipid fractions in livers of ZDF rats, suggesting a reduction of SCD-1 activity. Although ZDF rats lack responsiveness to leptin, a regulator of SCD-1 (46), CLA and TZD reduced SCD-1 indices, indicating these effects are independent of a leptin:leptin receptor-mediated mechanism. However, perhaps due to the unresponsiveness to leptin, ZDF rats, regardless of diet, had significantly higher SCD-1 indices than lean rats. Conversely, lean rats respond to leptin and had relatively low SCD-1 indices, which were not further reduced by either diet. This suggests that despite the presence of down-regulators of SCD-1, such as leptin, CLA, or TZD, other regulatory mechanisms maintain a basal level of SCD-1 activity. Synthesis of hepatic TG and cholesterol ester are dependent on SCD-1 activity, and therefore maintenance of the activity of this enzyme is crucial to lipid homeostasis (43).

Impairments in insulin sensitivity have been closely linked to increases in plasma FFA and TG concentrations. Studies in which both glucose metabolism and lipid accumulation were measured suggest that a reduction in plasma, as well as tissue, TG correlates with improved glucose tolerance and insulin sensitivity (47). Thiazolidinediones act, in part, by promoting uptake of circulating FFA and storage in the adipose tissue, thus lowering plasma FFA and allowing for improved insulin sensitivity. Previous research showed that CLA reduced plasma TG and FFA levels in both rats and mice (3,4,6–8,48). The exact mechanism by which CLA is able to reduce plasma TG and FFA is largely unknown, but the enhanced uptake of circulating FFA due to increased lipid oxidation has been suggested as a possible mechanism (8,49). The present study shows that CLA decreased plasma FFA and TG in both lean and ZDF rats and to the same degree as TZD (except ZDF-CLA plasma TG). Other studies have reported that CLA improved fasting glucose and hyperinsulinemia in obese or diabetic rats (4–6). Accordingly, we report that CLA normalized glucose tolerance in ZDF rats. Importantly, in this study, CLA was as effective as TZD in improving glucose tolerance, and CLA did not affect glucose tolerance in nonobese, lean rats.

[a]Department of Preventive Medicine and Public Health, University of Navarra, E-31008 Pamplona, Spain, [b]Department of Clinical Sciences, University of Las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain, and [c]Department of Physiology and Nutrition, University of Navarra, Pamplona, Spain

ABSTRACT: The aim of this dynamic prospective follow-up study was to assess the association between olive oil consumption and the likelihood of weight gain or the incidence of overweight or obesity in a large Mediterranean cohort of 7,368 male and female Spanish university graduates (the SUN Project) who were followed for a median period of 28.5 mon. A validated Food Frequency Questionnaire was administered at baseline, and respondents also completed a follow-up questionnaire after 28.5 mon. Changes in participants' consumption of olive oil and their weight were assessed during follow-up. A higher baseline consumption of olive oil was associated with a lower likelihood of weight gain, although the differences were not statistically significant. The adjusted difference in weight gain (kg) was –0.16 [95% confidence interval (CI): –0.42 to +0.11] for participants in the upper quintile of olive oil consumption (median: 46 g/d) compared with those in the lowest quintile (median: 6 g/d). For participants with a high baseline consumption of olive oil whose olive oil consumption also increased during follow-up, we found a slightly increased but nonsignificant risk of incidence of overweight or obesity (adjusted odds ratio = 1.19, 95% CI: 0.73 to 1.95). Our study, carried out in a sample of free-living people, shows that a high amount of olive oil consumption is not associated with higher weight gain or a significantly higher risk of developing overweight or obesity in the context of the Mediterranean food pattern.

Paper no. L9879 in *Lipids 41*, 249–256 (March 2006).

The role of diet on ischemic heart disease has been studied for almost a century, and substantial evidence about the protection provided by some nutrients and foods is currently available (1,2). One of the most influential seminal works came from the Seven Countries Study (3), which introduced the concept of the cardioprotective properties of the food habits in Mediterranean populations, where olive oil is the main source of fat (1,4). For the last few decades, several population studies have supported its potential cardioprotective effect. The Mediterranean dietary pattern has consistently been associated with a lower mortality from all causes in prospective studies (5–7), and also to a lower incidence of nonfatal coronary events in two case-control studies (8–10). In fact, the U.S. Food and Drug Administration has endorsed olive oil consumption for cardiovascular prevention (11).

However, some criticism (12) has been raised about recommending virgin olive oil consumption to protect from cardiovascular diseases because it is presumed to increase the risk of overweight or obesity. This presumption is based on the nutritional content of olive oil (100% fat). Currently, obesity is one of the most important public health problems (13), and the possibility of increasing population levels of obesity could hinder the promotion of a fat-rich traditional Mediterranean food pattern in which the source of fat is mainly monounsaturated FA (MUFA) provided by olive oil.

Olive oil is an energy-dense food that provides a large amount of fat in the diet. In contrast. carbohydrate-rich diets (i.e., those reducing fat intake) have been associated with substantial weight gain, and low-carbohydrate diets (i.e., those relatively rich in fat) have become increasingly popular. Hence, it is necessary to better assess the role of the high-fat/low-carbohydrate approach in overweight and obesity among free-living subjects (14,15).

The purpose of our study was to address more precisely the question of whether the promotion of healthy lipids such as olive oil would increase the obesity epidemic. Here, we estimate the association between total olive oil consumption and the likelihood of weight gain or of becoming overweight or obese in a longitudinal study with high between-subjects variability conducted in a Mediterranean country, where olive oil is usually consumed. This setting provides a unique opportunity to test this hypothesis following one of the research recommendations for obesity issued by the American Heart Association in its Prevention Conference VII (16).

METHODS

Study population. The SUN Project (Seguimiento Universidad de Navarra, i.e., Follow-up University of Navarra) is a large Spanish longitudinal study (a prospective cohort) that was designed in collaboration with the Harvard School of Public Health using a methodology similar to that used in large U.S. cohorts such as the Nurses' Health Study (17) and the Health Professionals Follow-up Study (18).

*To whom correspondence should be addressed at Department of Preventive Medicine and Public Health, University of Navarra, C/ Irunlarrea nº1, 31080 Pamplona (Navarra), Spain. E-mail: mamartinez@unav.es

Abbreviations: BMI, body mass index; CI, confidence interval; FFQ, food frequency questionnaire; MET, metabolic equivalent(s); MUFA, monounsaturated fatty acids; OR, odds ratio(s).

The SUN cohort is followed up using biennial mailed questionnaires, with a follow-up rate exceeding 90% for the first 2-yr period (19,20). The recruitment of participants started in December 1999 and is permanently open. All participants had a university degree (at least college) at the onset of the study. The data set of the SUN project incorporated 17,170 participants up to December 2004. Recruitment is ongoing, as this is a dynamic cohort study. Previous analyses of this cohort were published earlier, when the number of recruited participants was smaller (21).

For the present analyses, we included participants who had already been followed up after a median of 28.5 mon (n = 9,000). Participants who reported excessively high or low values for total energy intake (less than 800 kcal/d in men and 600 kcal/d in women or more than 4,200 kcal/d in men and 3,500 kcal/d in women), missing values in variables of interest in the analysis, and pregnant women were excluded, leaving a total of 7,368 participants available for analyses.

The study was approved by the Human Research Ethics Committee at the University of Navarra. Voluntary completion of the first self-administered questionnaire was considered to imply informed consent.

Assessment of dietary and nondietary exposures. Dietary and nondietary exposures were assessed through a self-administered questionnaire (baseline questionnaire) including a 136-item food frequency questionnaire (FFQ) previously validated in Spain (22). This questionnaire also included different questions related to lifestyle, with 46 items for men and 54 items for women. Sociodemographic variables (sex, age, marital status, university degree, and employment) anthropometric data (weight, height, body image, and weight change), health-related habits (e.g., smoking status, alcohol consumption, and physical activity), and medical history information (medication use, cholesterol level, blood pressure, and family history of several diseases) were also collected. The reproducibility and validity of the self-reported weight was assessed in a representative subsample of the cohort (n = 70). The mean relative error in self-reported weight was 1.5%. The correlation coefficient between measured and self-reported weight was 0.991 [95% confidence interval (CI): 0.986–0.994] (23). We inquired about 17 activities to quantify the amount of physical activity, and a metabolic equivalent index (MET-h/wk) was computed (24).

Nutrient scores were calculated as frequency × nutrient composition of a specified portion size, where frequencies were measured in nine categories (6+/d, 4–6/d, 2–3/d, 1/d, 5–6/wk, 2–4/wk, 1/wk, 1–3/mon, and never or almost never for each food item). Nutrient intake scores were computed using an *ad hoc* computer program specifically developed for this aim. A trained dietitian updated the nutrient data bank using the latest available information included in food composition tables for Spain (25,26).

Assessment of variables of interest. Body mass index (BMI) was calculated as weight in kilograms divided by the square of height in meters. Information on weight was collected at baseline and in the follow-up questionnaire (after a median of 28.5 mon of follow-up). The outcomes at the end of follow-up were: (i) incident overweight or obesity (participants with a baseline BMI value lower than 24.9 kg/m^2 and with a BMI ≥ 25 kg/m^2 after follow-up), and (ii) change in weight after 28.5 mon of follow-up. A careful procedure, combining several items in the FFQ, was used to assess the exposure to olive oil consumption. Baseline total olive oil consumption was calculated from the nutrient score of olive oil consumption in the FFQ, also taking into account the amount and type of olive oil used for cooking or frying and the use of olive oil as a salad dressing or a spread on bread or other foods. Information on changes in olive oil consumption (consistent, increased, or reduced) was collected in the follow-up questionnaire.

Statistical analysis. We estimated the association between quintiles of baseline olive oil consumption (our sample was categorized into 5 groups, from low consumption—first quintile, Q1—to high consumption—last quintile, Q5—and the subsequent change in weight using linear regression models. We considered the lowest quintile (Q1) of total baseline olive oil consumption to be the reference category of exposure and weight change during follow-up as the outcome. Therefore, each regression coefficient can be interpreted as the mean difference in weight gain between the upper categories of olive oil consumption (Q2 to Q5) and the lowest category (Q1).

In addition, logistic regression models were fit to assess the relationship between baseline olive oil consumption as the exposure and the risk of incident overweight or obesity (BMI ≥ 25 kg/m^2) as the outcome. Odds ratios (OR) and their CI were calculated for each of the four upper quintiles considering the lowest quintile of baseline olive oil consumption (Q1) as the reference category. In consequence, the OR represent an estimation of relative risks. They indicate how much more likely it is that someone who is exposed to upper levels of olive oil consumption (Q2 to Q5) develop overweight or obesity (BMI ≥ 25 kg/m^2) as compared with someone who is exposed to the lowest level (Q1). Tests of linear trends across increasing quintiles of intake were calculated by assigning the median intake to each quintile and treating the quintiles in each model as continuous variables.

All dietary intakes were adjusted for total energy intake using the residuals method (27). We fit a crude model (univariate, i.e., without any adjustment), an age- and gender-adjusted model, and a multivariate-adjusted model including the following variables: total energy intake (kcal/d), energy-adjusted fiber intake (g/d), energy-adjusted vegetable consumption (g/d), physical activity during leisure time (MET-h/wk), smoking status (never smoked, smoker, or former smoker), snacking between meals (yes/no), TV viewing (h/wk), and baseline BMI (kg/m^2) (for models using overweight or obesity as the outcome) or baseline weight (for models using weight change). We evaluated all first-order multiplicative interactions (effect modifications) through product terms.

To assess the joint exposure to both baseline total olive oil consumption and changes in olive oil consumption during follow-up (increased vs. consistent or reduced), we considered participants with both low baseline olive oil consumption (lowest tertile) and no increment in consumption (consistent or reduced)

during follow-up as the reference category. We built five other categories combining both exposures, i.e., baseline total olive oil consumption (three categories: low, moderate, and high) and changes in olive oil consumption during follow-up (two categories: consistent or reduced vs. increased). To these combined categories we applied the same statistical procedures previously described for analyzing only baseline consumption as the exposure (linear regression models for weight change and logistic regression models for incident overweight or obesity). All *P* values presented are two-tailed; $P < 0.05$ was considered statistically significant.

RESULTS

Olive oil consumption was higher among women, participants with a lower baseline weight, and current and former smokers. Higher olive oil consumption was associated with a higher vegetable consumption. As expected, participants with higher olive oil consumption exhibited a higher total fat intake ($P < 0.001$) (41% of total energy intake in the fifth quintile) because of increased MUFA intake (20% of total energy in the fifth quintile) (Table 1).

The results for the association between baseline consumption of olive oil and subsequent weight change (as a continuous outcome) were not significant (Table 2). However, we found negative point estimates for the fourth and fifth quintiles of energy-adjusted olive oil consumption that did not change after further adjustment for age and gender or after multivariate adjustment, suggesting that a higher baseline consumption of olive oil was associated with a *lower* likelihood of weight gain, although differences were not statistically significant.

During a median follow-up of 28.5 mon, we observed 405 new (incident) cases of overweight or obesity (BMI ≥ 25 kg/m^2) among 5,356 participants initially free of overweight or obesity. No significant association was observed between olive oil consumption and the risk of developing overweight or obesity during follow-up. The crude results did not substantially change when we used a multivariate logistic regression model to adjust for age, gender, total energy intake, fiber intake, vegetable consumption, leisure-time physical activity, smoking, snacking between meals, TV viewing, and baseline BMI (Table 3).

When we assessed the joint exposure to baseline consumption (tertiles of olive oil) and subsequent changes in consumption during follow-up (dichotomous: increased vs. consistent or reduced), we observed an increase in average weight after follow-up in all categories of olive oil consumption. However, when we compared weight change across categories of olive oil consumption, the highest weight gain was observed precisely for those with the lowest baseline consumption who also did not increase their consumption during follow-up (mean weight gain: +0.85 kg). The lowest weight gain was observed among those in the moderate category of baseline olive oil consumption who increased their consumption during follow-up (+0.42 kg). To control for potential confounding in these comparisons, we used multivariate linear regression modeling (Table 4). We found a significantly lower weight gain among

[a]T1–T3: Lowest to highest tertile of olive oil consumption.
[b]Additional adjustment for total energy intake (kcal/d), energy-adjusted fiber intake (g/d), energy-adjusted vegetable consumption (g/d), leisure-time physical activity (MET-h/wk), smoking status (never smoked, smoker, or former smoker), snacking between meals (yes/no), TV viewing (h/wk), and baseline BMI (kg/m^2). For abbreviations see Tables 1–3.

participants with moderate baseline consumption who increased their consumption during follow-up than among participants in the reference category (low baseline + no increment). The adjusted difference in weight gain was −0.37 kg (95% CI: −0.73 to −0.01). Similarly, participants with high baseline olive oil consumption and no increment in consumption during follow-up experienced a statistically significant lower weight gain than participants in the reference category (adjusted difference = −0.30 kg; 95% CI: −0.53 to −0.06). No significant differences in weight gain were found between those with the highest baseline consumption who also increased their consumption and the reference category (Table 4). Moreover, the Pearson correlation coefficient between baseline olive oil consumption and subsequent body weight change (both as continuous variables) was −0.020 ($P = 0.081$).

In Table 5 we show the results for the risk of becoming overweight or obese when we restricted our analyses only to those participants initially free of overweight or obesity ($n = 5,356$). We found no significant differences in the risk of developing overweight or obesity for the categories built according to the joint exposure to baseline consumption and changes in consumption of olive oil compared with those in the reference category (both baseline consumption and consistent or reduced change during follow-up). For those with the highest baseline consumption who also increased their consumption during follow-up, the OR was 1.19 (95% CI: 0.73 to 1.95). When we repeated all these analyses (both linear and logistic regression modeling), excluding those participants with prevalent cancer or cardiovascular disease, we obtained very similar results (data not shown).

We used energy-adjusted olive oil consumption (27) throughout all the previous analyses. However, we also repeated all the analyses without adjusting for total energy intake, and the only noticeable change was observed among those who had high baseline olive oil consumption and who also increased their consumption during follow-up. Their adjusted OR for overweight or obesity changed from 1.19 (95% CI: 0.73 to 1.95) to 1.33 (95% CI: 0.69 to 2.56).

DISCUSSION

In this 28.5-mon follow-up study of a large, free-living Mediterranean cohort with high between-subjects variability in olive oil consumption, we did not find a significant positive association between olive oil consumption and weight gain or between olive oil intake and the risk of overweight or obesity. In fact, most point estimates for weight change suggested an inverse association, i.e., lower weight gain for those with higher olive oil consumption, and therefore with a higher proportion of their total energy coming from lipids (mainly from MUFA).

In spite of the high caloric density represented by olive oil consumption, our results could be partially explained by different FA displaying differential effects on weight gain through differences in sensitivity to neurotransmitters, to the intestinal peptide enterostatin, or to specific influences of FA on thermogenesis (28,29). Additionally, between-nutrient interactions may be important, because olive oil in Mediterranean countries is consumed within a bread-rich dietary pattern, where it is commonly used for dressing legumes, vegetables, and salads. In this context, a possible interaction between starch and lipids in the upper part of the small intestine after fat intake, which may slow the rate of starch digestion and reduce the glycemic response, has been reported (30). Other reasons to support our results are based on the fact that, as the dietary fat load is increased, proportionate increases occur in fecal fat losses (31). Moreover, high levels of olive oil consumed might not be completely absorbed and digested (32).

The promotion of a Mediterranean diet with a high percentage of fat from olive oil consumption to protect from cardiovascular diseases presents some unclarified questions for public health. A major reason for concern is that the prevalence of obesity in the Mediterranean population is one of the highest in Europe. In consequence, some authors have viewed the recommendation of following an olive oil-rich Mediterranean diet as one of the major causes responsible for this fact (12). However, this view is not based on reliable epidemiological evidence, and, to our knowledge, this is the first *prospective* large-sample

study that has specifically assessed the role of olive oil on the risk of weight gain in a Mediterranean country. The confirmation of a lack of weight gain among our participants exposed to high levels of olive oil consumption should allay fears that the promotion of lipid-rich Mediterranean food patterns may lead to increased overweight or obesity in the population.

Additionally, our results demonstrated that although participants who consumed high amounts of olive oil (upper quintile) had a very high total fat intake (around 41% of total calories), their percentage of total calories derived from saturated fats was lower, whereas their consumption of vegetables was higher.

Our data are consistent with four cross-sectional studies in which no relationship or a very weak association was observed between olive oil consumption and obesity or weight gain (33–36). Recently, Trichopoulou *et al*. (36) showed that adherence to a Mediterranean diet score (including the ratio of monounsaturated to saturated lipids) was essentially unrelated to BMI in a large Greek cohort. However, none of these previous studies used a prospective design and their analyses were only cross-sectional, having the inherent threat of a reverse causation bias. Thus, if subjects who watch themselves gaining weight tend to restrain from consuming olive oil because they believe in a weight-gaining effect of olive oil, any cross-sectional analysis will find an *inverse* association, but this association would be the result of a bias. Our study is less susceptible to this bias because of the longitudinal prospective design we followed.

The results from this study confirm, with a greater number of individuals and with a specific focus on olive oil consumption rather than on the Mediterranean dietary pattern, the results previously obtained in our cohort (37) by addressing not only weight gain but also the risk of developing overweight or obesity.

A potential limitation in our study is that most of the results we report here are not statistically significant, thus raising the issue that perhaps this study might have been unable to capture a positive or negative relationship owing to low statistical power and a type 2 error. The statistical power of our dichotomous analyses (overweight or obesity as the outcome) for a relative risk ≥2.00 is higher than 95% (the power would be 53% if the relative risk were 1.5, and we would have insufficient statistical power only for relative risks lower than 1.5). However, the statistical power approached 100% when we treated weight changes as continuous variables to apply linear regression modeling. It is precisely in this highly powered analysis, using a continuous variable (weight change) as the outcome, that we found results suggesting, in any case, that higher olive oil consumption was related to *lower* weight gain.

Because of the observational nature of our study, we cannot exclude residual confounding because it could theoretically affect the observed lack of association. We controlled for potential confounding by taking into account most known risk factors for obesity that are plausibly also associated with olive oil consumption. We also acknowledged that our estimates of total energy intake or of the consumption of some foods, as measured by the FFQ, may present some degree of measurement error, which is to be expected in nutritional epidemiology (22,38); therefore, the variance in total energy intake may be seen as large. This large variability is usual in most studies of nutritional epidemiology (39,40); however, it might limit our ability to capture a positive or negative relationship. In addition, a further potential limitation of our study is the reliance on self-reported body weight. Nevertheless, a substudy in our cohort showed that self-reported weight can be considered valid among highly educated participants (23), as other similar cohorts have also shown (41). Our cohort is nonrepresentative of the general population because all participants have attained a high educational level. However, this potential limitation to generalization of the results is not a sufficiently strong reason to limit the validity of our findings, because it is implausible to think that the effects of olive oil on weight gain depend on participants' educational level (42).

Therefore, with these results we can provide evidence that the risk of obesity is not increased in subjects who follow an olive oil-rich Mediterranean food pattern. The belief that olive oil consumption increases the risk of obesity in Mediterranean populations is not supported by any reliable evidence. However, epidemiological evidence supports the major role of a sedentary lifestyle as a more likely explanation for the increasing obesity epidemic in Mediterranean countries (43,44).

ACKNOWLEDGMENTS

We are indebted to the participants of the SUN Study for their continued cooperation and participation. The Department of Health of the Navarre Regional Government (PI41/2005) and Spanish Ministry of Health (Fondo de Investigaciones Sanitarias, projects PI042241, PI040233, and G03/140, Red Temática de Dieta y Enfermedad Cardiovascular) are gratefully acknowledged for supporting the present study. We would like to thank other members of the SUN Study Group: María Seguí-Gómez, Alvaro Alonso, Raquel Pajares, Miguel Delgado-Rodríguez, Manuel Serrano-Martínez, Arancha Tortosa, Zenaida Vázquez, Amelia Marti, Francisco Guillén-Grima, and our advisors from the Department of Nutrition of the Harvard School of Public Health: Alberto Ascherio, Walter C. Willett, and Frank B. Hu, who helped us design the SUN cohort study.

ABSTRACT: Soy isoflavones may impede atherogenic processes associated with cardiovascular disease. Research suggests that the postprandial generation of TG-rich remnants contributes to the development of atherosclerosis. The purpose of the current study was to determine if 39 g soy (85 mg aglycone isoflavones, treatment) compared with 40 g milk protein (0 mg aglycone isoflavones, control) in combination with a high-fat meal can modify postprandial, atherogenic-associated events and biomarkers for oxidative stress, inflammation, and thrombosis. Fifteen healthy men (20–47 yr) participated in a double-blind cross-over meal-challenge study occurring on two nonconsecutive days. The study meals consisted of two high-fat apple muffins consumed with either a soy or milk shake (229 mL, 41% fat, 41% carbohydrate, and 18% protein). Blood samples were obtained at baseline (fasted) and hours two, four, and six postprandial. Plasma TG significantly increased in both treatment and control meal challenges compared with baseline. There were no significant differences ($P > 0.05$) between treatment (soy) and control (milk) for *ex vivo* copper-induced LDL oxidation, serum C-reactive protein, serum interleukin-6 (IL-6), serum fibrinogen, or plasma lipids (total cholesterol, HDL, LDL, TG). IL-6-concentrations significantly decreased as a function of time during either meal challenge ($P = 0.005$). These data suggest that consumption of soy or milk protein in conjunction with a high-fat meal does not acutely modify postprandial oxidative stress, inflammation, or plasma lipid concentrations in young, healthy men.

Paper no. L9840 in *Lipids 41*, 257–265 (March 2006).

Cardiovascular disease (CVD) has been the leading cause of death in the United States for almost a century. Nearly 2,600 Americans die of CVD each day, an average of 1 death every 34 s (1). More than 20 years ago, Zilversmit (2) suggested that the postprandial generation of TG-rich remnants contributed to the development of atherosclerosis. Investigators have proposed that Western populations exist in a predominantly chronic postprandial state due to frequent meal consumption throughout the day (3) and this lengthened hyperlipidemic state may contribute to prolonged vascular injury and the initiation and development of atherosclerosis (3). LDL oxidation increases risk of atherosclerosis (4,5), and investigators suggest that postprandial LDL are more easily oxidized than fasting LDL (6). Reactive oxygen species produced in the vessel wall in response to initial endothelial injury can also mediate adverse downstream cellular responses associated with atherosclerosis and CVD, such as inflammation, platelet aggregation, thrombosis, and DNA damage (7–10).

High-fat meals have been shown to increase glucose, insulin (11), and TG concentrations (11,12), impair (13–18) or have minimal effect (19) on endothelial function; increase postprandial lipid hydroperoxides (biomarkers of oxidative stress) (20,21); and reduce the time needed to oxidize LDL particles (22). Additionally, meals high in fat have been shown to increase pro-inflammatory cytokines interleukin-6 (IL-6) and tumor necrosis factor-α (TNF-α) plasma concentrations (23) and either increase (24) or have no effect (16) on C-reactive protein (CRP), a biomarker of systemic inflammation and CVD risk (25–27). Fibrinogen and factor VII (VII-c) play a role in atherosclerotic plaque development (28) and are CVD hemostatic risk biomarkers (29). Studies report postprandial-induced activation of plasma factor VII-c (30) but not fibrinogen concentrations (30,31) following a high-fat meal. Collectively, these data encourage investigators to explore the health benefits of consuming specific foods or nutrients that decrease meal-induced oxidative stress and inflammatory and hemostatic processes.

Consumption of soy-containing foods may, in part, explain the low incidence of CVD and hormone-dependent cancers in the Asian population (32). Western consumption of soy products has surged since 1999 when the FDA released a health claim for the cholesterol-lowering potential of soy products (33,34). Genistein and daidzein are the predominant isoflavones in soy foods and have been shown to protect against LDL oxidation by reducing formation of preformed lipid hydroperoxides (35), decreasing tyrosine nitration (36,37), and increasing lipoprotein particle antioxidant potential owing to their lipophilic phytoestrogen structures (38–42).

Abbreviations: AUC, area under the curve; BMI, body mass index; CRP, C-reactive protein; CVD, cardiovascular disease; HI, high isoflavone; IL-6, interleukin-6; LI, low isoflavone; NRL, Nutrition Research Laboratory; $PGF_{2\alpha}$, prostaglandin $F_{2\alpha}$; T0, time point hour 0, pre-meal challenge; T2, T4, T6, time point hours 2, 4, 6 post-meal challenge, respectively; TC, total cholesterol; TNF-α, tumor necrosis factor-α.

Although these CVD-protective mechanisms are promising, intervention studies with soy protein and isoflavones lasting 1–2 mon have yielded conflicting results. For instance, some studies report a reduction in the susceptibility of LDL to oxidative stress (42–44), whereas others show no effect on *in vivo* or *ex vivo* oxidative stress markers (45–47). Genistein is a potent inhibitor of tyrosine kinase activity (48), and platelets possess several protein-tyrosine kinase domains that undergo phosphorylation when activated. Results from *in vitro* studies show genistein is able to block thrombin-induced human platelet aggregation by inhibiting tyrosine kinase activity (49,50) and there is considerable interest in the ability of soy isoflavone phytopharmaceuticals potentially to modulate IL-6 gene expression and activity (51). Very few studies have examined the effect of soy and/or isoflavones on inflammatory (IL-6, CRP, TNF-α) or coagulation (fibrinogen) biomarkers (52–55), and none are postprandial (6-h post-meal) studies. For instance, Jenkins and co-workers (54) reported an increase in IL-6 concentration following a 1-mon soy intervention; other investigations showed no effects of diets high in tofu (52) or isoflavones (53,55) on fibrinogen (52,53,55) or factor VII-c concentrations (53,55). On the other hand, isolated soy protein and isoflavones have favorable effects on endothelial vasoactivity and function, as assessed with brachial artery reactivity measurements (56–58).

To date, the postprandial effects of soy consumed with a meal inducing oxidative stress (e.g., high fat) have not been determined. Therefore, the purpose of this study was to determine if 39 g soy protein (85 mg isoflavones, treatment) consumed in combination with a high-fat meal decreased postprandial oxidative stress, inflammation, and hemostatic risk factors compared with a high-fat meal supplemented with 40 g milk protein (0 mg isoflavones, control).

SUBJECTS AND METHODS

Study protocol. Fifteen healthy, nonvegetarian men 20–47 yr of age were recruited to participate in a double-blind cross-over study. On average (mean ± SD), the subjects were 28 ± 9 yr, 180 ± 25 cm tall, 83 ± 10 kg (pre-milk treatment), and 83 ± 11 kg (pre-soy treatment). Exclusion criteria included: (i) regular use (>3 times per week) of a vitamin or mineral supplement in the previous 3 mon; (ii) regular consumption of soy protein (≥2 servings of 6.25 g/d); (iii) known existence of metabolic disorders (thyroid disease, diabetes, liver or renal disease); (iv) use of oral prescription medications (including any antibiotic use within the previous 3 mon) (12); (v) obesity [body mass index (BMI) > 30 kg/m^2); (vi) cigarette smoking within the last 3 yr (59); (vii) known food allergies (soy protein, milk protein, peanuts); (viii) a strict vegetarian status (60); (ix) regular alcohol consumption (>2 drinks/d; 1 drink = 12 oz beer, 6 oz wine, or 1.5 oz distilled alcohol); or (x) regular use of vitamin or herbal supplement (>3 times/wk) with antioxidant capacity.

Participants signed a Human Subjects Informed Consent Form approved by the Montana State University Internal Review Board prior to additional screening and participation in the study. Eligible subjects reported to the NRL at 0700 on two separate, nonconsecutive days in a fasted state (no food or beverage, with the exception of water, for 10 h), and had refrained from any strenuous physical activity or alcohol consumption for at least 24 h prior to the study date. Weight and height were recorded and a fasted blood sample (prechallenge meal; T0) was drawn *via* venipuncture. Participants were given 20 min to consume the high-fat challenge meal. Blood was subsequently drawn at hours 2 (T2), 4 (T3), and 6 (T6) postprandially. Participants remained on-site for the entire 6 h.

The study meal consumed following the baseline blood draw included two high-fat apple crumb muffins made in the Food Science Laboratory on the campus of Montana State University, and either a soy (treatment) or milk (control) protein shake. The soy beverage was made with SUPRO®SOY (Solae™, St. Louis, MO) isolated soy protein, water-washed to retain the naturally occurring isoflavones. The soy shake provided 39.0 g of soy protein (85 mg aglycone isoflavones). The placebo beverage was made with milk protein isolate and provided 40 g of casein/whey combination (0 mg aglycone isoflavones). A banana (100 g) was added to both shakes. The nutrient composition (Nutritionist Pro™ Version 1.2; First DataBank Inc., San Bruno, CA) of the two apple crumb muffins was: 130 mJ, 42.0 g total fat (68.2% of total calories), 26.2 g saturated fat (66.3% of total fat), 6.7 g polyunsaturated fat, 40.6 g carbohydrates (29.2% of total calories), 3.6 g protein (2.6% of total calories), and 33.8 mg cholesterol. Subjects were allowed water *ad libitum* throughout the day. The challenge meal, consisting of two muffins and a soy or milk shake with a banana, was 41% fat, 41% carbohydrate, and 18% protein (Table 1).

Participants were given instructions on how to weigh and record all food and beverages (excluding water) consumed on the 3 d prior to the study date. Diet records were analyzed using the Nutritionist Pro™ Version 1.2 software package. Additionally participants completed a 3-d activity log for the 3 d just

prior to each study date. The Bouchard Three Day Physical Activity Record (61) was used to approximate mean energy expenditure and to assess compliance with the study protocol. The procedure for recording the data was thoroughly explained to the subjects, and a list of activities along with their corresponding ratings was provided.

Assessment of oxidative stress. Isolation of LDL occurred through a sequential density-gradient ultracentrifugation in an Optima TLX Ultracentrifuge (Beckman Instruments, Palo Alto, CA) (62). A 0.5 mL volume of plasma and 0.5 mL of 0.9% sodium chloride solution were centrifuged for 2.5 h (435,680 × *g*; 16°C). The VLDL layer was discarded. A volume of 0.5 mL of 16.7% sodium chloride was added to the remaining HDL and LDL and spun for 2.5 h (435,680 × *g*; 16°C) (63). The isolated LDL was desalted using prepackaged columns (Econo-Pac 10 DG; Bio-Rad, Richmond, CA) filled with bio-Gel P6 desalting gel and subsequently collected and analyzed for protein concentration (63,64). The protein concentration of the LDL eluate was determined using a bicinchoninic acid protein assay kit (Pierce, Rockford, IL) adapted to a 96-well microplate (65,66). All standards and samples were analyzed in duplicate at 562 nm (μQuant Universal Microplate Spectrophotometer; Bio-Tek Instruments, Winooski, VT). Isolated and desalted LDL samples were diluted with PBS to achieve a final concentration of 0.10 mg protein/mL (67). One hundred microliter (100 μL) volumes of samples (isolated, desalted, and adjusted for protein concentration) and of blanks (PBS) were incubated in separate wells of a 96-well microplate (Costar; Corning Incorporated, Corning, NY) with 10-μL volumes of 500 mM cupric chloride solution; and the absorbance was read every 10 min for 8 h at 234 nm at 37°C (μQuant Universal Microplate Spectrophotometer). Samples were analyzed in duplicate. Lag time was calculated with an Excel (Microsoft Corporation, Redmond, WA) spreadsheet. The point of intersection of a best-fit line drawn tangent to the propagation phase was defined as the lag time or duration of the lag phase. An increase in lag time is considered beneficial owing to the increased resistance of the LDL to oxidation. The mean of the lag times for duplicate sample wells was used for statistical analysis. The inter- and intra-assay CV were 4 and 2%, respectively.

Assessment of inflammatory and hemostatic risk biomarkers. To determine CRP serum concentrations, frozen (−80°C) blood samples from T0, T2, T4, and T6 for each treatment were thawed. CRP concentrations were determined *via* a nephelometric method using a BN ProSpec (Dade-Behring, Deerfield, IL; instrument located at Bozeman Deaconess Laboratory, Bozeman, MT). The sensitivity of the CRP assay was 0.0175 mg/dL with a range of 0–0.3 mg/dL for a healthy adult.

Blood samples for IL-6 were collected at T0, T2, T4, and T6 for each diet treatment into a serum separator (Becton-Dickson) and allowed to clot for 30 min. Samples were then centrifuged for 10 min at approximately 1000 × *g*, with subsequent storage at −80°C until analysis. Thawed samples were analyzed *via* a Quantikine® Human IL-6α Immunoassay diagnostic kit (R&D Systems Inc., Minneapolis, MN). IL-6 standards and sample concentrations were measured at 450 nm (Model ELIU808IU microplate reader; BioTek). The inter- and intra-assay CV were 4.2 and 7.5%, respectively. The range for the minimum detectable dose for IL-6 with the Quantikine® ELISA was 0.016–0.110 pg/mL (mean = 0.039 pg/mL). Fibrinogen was analyzed in duplicate (bovine fibrinogen reagent hemoalliance reagent) for T0, T2, T4, and T6 for each diet treatment. Blood samples were collected into citrate (0.129 mol/L of citrate/citric acid, 1:10 total volume) and immediately analyzed on an ACL9000 Coagulation Analyzer (Beckman Coulter, Fullerton, CA; instrument located at Bozeman Deaconess Laboratory, Bozeman, MT). .

Assessment of plasma lipid concentrations. Plasma total cholesterol (TC), HDL, and TG concentrations were determined using the Dimension® Automated Chemistry Analyzer (Dade-Behring) (Bozeman Deaconess Hospital). The Friedewald equation (68) was used to calculate the plasma LDL concentration. All samples were run in one continuous batch. Interassay CV for the "low" and "high" LDL control samples were 3.53 and 2.62%, respectively.

Statistical analysis. Power calculations from a pilot project designed to assess the effects of soy protein on postprandial oxidative stress indicated future studies of the effect of soy protein consumption on oxidative stress should use no less than 15 subjects ($\alpha = 0.05$; $\beta = 0.80$). A two-way ANOVA with repeated measures was used to assess treatment (soy vs. milk) differences (lag time, IL-6, CRP, fibrinogen, and blood lipids) for the four time points analyzed using the SPSS (Chicago, IL) statistical program. Differences in baseline values among the time points were assessed with a Bonferroni multiple comparison test. A paired *t*-test was used to determine significance between the means of weight, BMI, energy expenditure, energy intake, and selected macro- and micronutrients between the two treatment types (soy vs. milk). The α level was set at 0.05. Data for all lipid (TC, HDL, LDL, TG) and inflammatory (fibrinogen, IL-6, CRP) variables were analyzed with the incremental and net area under the curve (AUC) (69) methods to assess treatment effects during the postprandial period (data not shown).

RESULTS

Subjects. The following analyses include 15 subjects with complete data for both treatment types. No subjects dropped or withdrew from the study. No significant differences were found for weight between the two study days. There were no significant differences in the nutrient composition of the challenge meals, except that, by design, the treatment meal (soy) was significantly higher in the soy protein compared with the control meal (milk), and whey/casein protein was significantly higher in the control meal vs. treatment meal (Table 1). Energy intake and expenditure, carbohydrate, protein, total fat and selected micronutrients for the 3 d prior to the testing days were not significantly different; however, a significant difference was found for saturated FA intake ($P = 0.04$) (Table 2).

Blood lipid assessment. No significant treatment effect was found for plasma lipid concentrations (TC, HDL, LDL, and

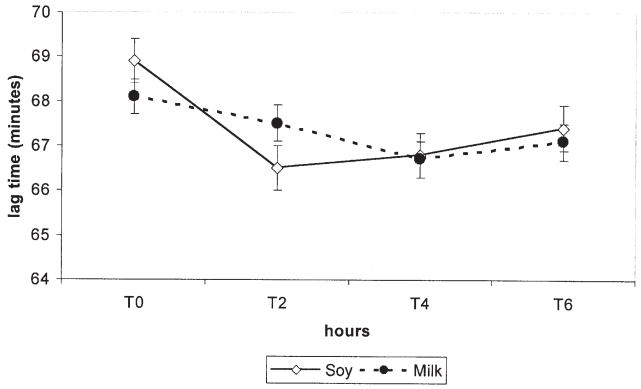

FIG. 1. Postprandial copper-induced LDL oxidation with a challenge meal containing soy and milk protein.

difference ($P > 0.05$) for LDL oxidation between the main effects (protein type, time points) or their interaction on LDL oxidation (lag time) (Fig. 1).

DISCUSSION

The results of our study suggest that biomarkers associated with the development of atherosclerosis (oxidative stress, inflammation, thrombosis, and hyperlipidemia) are minimally affected in healthy men consuming a controlled challenge meal high in total and saturated fat, with either 39 g soy or 40 g milk protein. The composition of the challenge meal was chosen to elicit a hyperlipidemic response to produce an atherogenic environment, while maintaining a constant polyunsaturated to saturated fat ratio between the two treatment days. As expected, we observed significant increases in plasma TG concentrations, which show that the high-fat meal did elicit a hyperlipidemic response. Previous research by Ceriello *et al*. (22) demonstrated that a high-fat meal can elicit meal-induced oxidative stress assessed *via ex vivo* copper-induced LDL oxidation in diabetic individuals. However, diabetes is often characterized by dyslipidemia with an elevated TG concentration and abnormally low HDL levels (70), and postprandial LDL in Type 2 diabetes are more easily oxidized than fasting LDL or from controls (59). The inclusion of healthy young men in our study may have precluded us from identifying a postprandial effect of soy consumption on oxidative stress, inflammation, coagulation, and hyperlipidemia.

In the current study we chose to use 39 g soy protein and 85 mg isoflavones based on previous studies that have evaluated the chronic intake of soy and oxidative stress (43,44,71). *In vitro* data have demonstrated that soy isoflavones act as antioxidants when incubated with plasma from fasted adult, human volunteers. For instance, LDL-oxidation resistance increases in the presence of at least 2.5 (72) to 50 μM (36) of genistein and daidzein. On the other hand, the antioxidant potential of soy *in vivo* remains unclear, as human intervention studies have produced mixed results (43,44,46,47,71). For instance, Jenkins *et al*. (44) investigated the effects of a soy-based breakfast cereal (36 g/d soy protein and 168 mg total isoflavones/100 g) consumed daily for 3 wk on blood lipids and oxidized LDL in 25 hyperlipidemic individuals. The treatment diet significantly reduced LDL oxidation (*ex vivo* assessment) compared with the control diet ($P < 0.05$) (44). In a separate study, Jenkins *et al*. (43) demonstrated with 31 hyperlipidemic men and postmenopausal women that a diet providing 33 g soy protein with 86 mg isoflavones for 1 mon along with a low-fat metabolic diet favorably reduced oxidative stress, as indicated by significantly decreased conjugated dienes ($P < 0.001$). These studies suggest that soy and isoflavone consumption can positively modify the *ex vivo* oxidative stress profile of hyperlipidemic individuals.

In a randomized cross-over study, normolipidemic men and women ($n = 24$) consumed a high isoflavone (15 g soy protein, 56.0 mg isoflavones) (HI) and a low isoflavone (15 g soy protein, 1.9 mg isoflavones) (LI) burger for 17 d each with a 25-d wash-out period. Plasma isoprostane concentrations [8-epi-prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$)], an *in vivo* biomarker of whole-body lipid peroxidation, were significantly reduced following the HI diet as compared with the LI diet (326 ± 32 ng/mL vs. 405 ± 50 ng/mL, respectively; $P = 0.028$). Additionally, lag time for copper ion-induced LDL oxidation was significantly longer with the HI diet than with the LI diet (48 ± 2.4 and 44 ± 1.9 min, respectively; $P = 0.017$). Although the aforementioned studies provide support that moderate isoflavone intake (56–86 mg/d) is effective in reducing oxidative stress in healthy (71) and hyperlipidemic (43,44) adults, two recent, well-designed human feeding studies found soy consumption had no effect on *in vivo* and *ex vivo* biomarkers of oxidative stress (46,47).

In a double-blind, parallel arm study, Engelman *et al*. (46) provided 14 postmenopausal women with 40 g soy protein/d (86 mg isoflavone/d) and compared oxidative stress biomarkers with 14 women not consuming soy protein after 6 wk. No significant changes were found for any of the *in vivo* oxidative stress indexes (plasma protein carbonyls, oxidized LDL, and 8-epi-$PGF_{2\alpha}$). Similarly Vega-López and co-workers (47) reported no significant effect on oxidative stress biomarkers with the daily consumption of soy protein (25 g/1000 kcal) and soy isoflavone (50 mg/1000 kcal).

Although our study design differed from these investigations (46,47), in that it tested the effects of soy on postprandial (0–6 h post-meal), and not long-term (>1 wk), oxidative stress, our results were similar in that we found no effect of soy on oxidative stress measurements (e.g., LDL oxidation or lag time). On the other hand, investigators have suggested that soy protein may exert beneficial effects on oxidative systems and biomarkers not reported in our study, or others (46,47). Thus, investigations continue to explore the relationships between soy protein and oxidative stress.

Our study did not find a significant difference between treatment and control (soy vs. milk) in IL-6, CRP, or fibrinogen serum concentrations. Very few studies have examined the effect of soy and/or isoflavones on inflammatory (IL-6, CRP, TNF-α) or coagulation (fibrinogen) biomarkers (52–55), and none are postprandial (6-h post-meal) studies. For example, 41 hypercholesterolemic men and postmenopausal women consuming either a

low-fat control diet or a diet low (10 mg/d isoflavones) and high (70 mg/d isoflavones) in soy protein showed increased IL-6, but not CRP or TNF-α serum concentrations with the high-isoflavone diet (54). Dent *et al.* (53) reported no difference in fibrinogen, factor VII-c, or coagulant activity in perimenopausal women consuming a low (4 mg isoflavone), high (80 mg isoflavone), or control-whey diet isoflavones after 24 wk. These results agree with a shorter (17 d) feeding trial (55) and with a study of 45 healthy men consuming either lean meat or tofu (soy-containing product) for 1 mon (52). Tsai *et al*. (16) reported no significant changes in CRP at 2, 4, or 6 h after a standard high-fat meal. In contrast, Aljada and co-workers (24) showed that a mixed meal high in fat (50% total kcal) significantly ($P < 0.05$) increased plasma CRP at 3-h post-meal challenges. Although these studies suggest soy may have a minimal effect on inflammatory, fibrinolytic, or coagulation biomarkers, isolated soy protein and isoflavones have been shown to have favorable effects on endothelial function, as assessed with brachial artery reactivity measurements (56–58). Further, that IL-6 significantly decreased as a function of time during either meal challenge in our study indicates IL-6 is a sensitive biomarker in the postprandial period. Furthermore, it may be that significant IL-6 changes were not observed as a result of the timing of the blood draws. Future studies should include more frequent blood draws immediately after the meal consumption (e.g., every 30 min). The timing of blood draws for the current study was based on capturing the peak TG response to ensure an atherogenic environment in response to the high-fat meal (73). Additionally, CRP and fibrinogen may be more sensitive measures of systemic inflammation and hemostatic changes following a long-term dietary intervention and therefore would be minimally affected by a single meal challenge.

Our study had several limitations. Most importantly, the use of *ex vivo* LDL oxidation as our biomarker of oxidative stress limits our ability to evaluate the acute antioxidant effect of soy consumption. At the time this study was conducted, LDL oxidation was the primary biomarker used in soy and oxidative stress studies (43,44,71). To our knowledge, no studies have been published regarding the postprandial antioxidant effects of soy, but studies with other bioactive food components have found significant changes with the *ex vivo* LDL oxidation assessment (74–76). Thus, evidence exists to support the inclusion of LDL oxidation as an assessment parameter.

Although our meal challenges significantly increased TG concentrations, whether the hyperlipidemic state produced was enough to create an oxidative stress environment that could increase risk for atherosclerosis is not clear. Thus, additional biomarkers of antioxidant systems and responses such as F_2-isoprostane or glutathione peroxidase should be included in future studies. This would clarify whether the meal challenge has in fact induced prolonged oxidative stress *in vivo*, and if so, whether these are more sensitive biomarkers to use in postprandial oxidative stress studies.

An additional limitation is the significant difference in the saturated fat intake between the milk and soy treatment days for the 3 d prior to the meal challenges. That plasma TG concentrations significantly increased with both treatments suggests that the significant difference in saturated fat intake did not result in significantly different hyperlipidemic states between the two meal challenge days.

The final limitation of this study relates to the use of young, healthy men. An indication of their health status is the low serum CRP levels of the subjects. Future studies focused on evaluating the acute antioxidant effect of bioactive food components should consider the use of "non-healthy" or "at risk" participants. Engelman *et al*. (46) demonstrated a significant correlation between BMI and oxidative stress (serum $PGF_{2\alpha}$, $r = 0.33$; serum oxidized LDL, $r = 0.34$). Others have also shown that people with diabetes (77) or who smoke (78) have increased *in vivo* oxidative stress as reflected by elevated urinary isoprostane concentrations. Individuals with elevated oxidative stress and inflammatory profiles would be appropriate subjects to include in future studies.

Despite the controversy surrounding the antioxidant and anti-inflammatory effects of soy consumption, future studies continue to be warranted to elucidate whether long-term soy consumption can modify chronic disease risk by minimizing postprandial oxidative stress and inflammatory excursions. Future studies should include individuals with elevated oxidative stress and inflammatory profiles such as smokers and diabetic and/or obese individuals. This acute study did not elicit significant oxidative stress, inflammation, or hyperlipidemic changes between soy and milk protein.

ACKNOWLEDGMENTS

Our sincerest appreciation to the participants. Dietary protein was graciously donated by The Solae Company (St. Louis, MO). The project described was supported by NIH Grant Number P20 RR16455-02 from the INBRE-BRIN (IDeA Networks of Biomedical Research Excellence–Biomedical Research Infrastructure Network) Program of the National Center for Research Resources.

Oleate-Induced Formation of Fat Cells with Impaired Insulin Sensitivity

Weisheng Xie, James A. Hamilton, James L. Kirkland, Barbara E. Corkey, and Wen Guo*

Obesity Research Center, Boston University School of Medicine, Boston, Massachusetts 02118

ABSTRACT: Exogenous FA cause lipid accumulation in preadipocytes. We investigated whether the fat cells thus formed are metabolically distinct from adipocytes differentiated with standard methylisobutylxanthine, dexamethasone, and insulin (MDI) hormonal cocktail by comparing their expression of adipogenic genes, accumulation of TAG, lipogenesis, lipolysis, glucose uptake, and the effects of insulin on selected metabolic activities. Cells exposed to oleate began to accumulate TAG in parallel or prior to the induction of adipogenic genes, whereas cells treated with MDI expressed adipogenic genes before TAG accumulation. Oleate-treated fat cells also showed exaggerated basal lipolysis and weak response to insulin in both lipolysis regulation and glucose uptake. These findings were associated with increased basal phosphorylation of perilipin, increased Glut-1 but decreased Glut-4 expression, and reduced insulin-induced Akt phosphorylation. We suggest that this unique fat cell phenotype might be a mimetic of what can happen to fat cells formed *in vivo* under the influence of circulating FA and might be a useful model for *in vitro* studies of obesity-related insulin resistance in adipocytes.

Paper no. L9836 in *Lipids 41*, 267–271 (March 2006).

Exogenous FA have been shown to enhance preadipocyte differentiation, but the metabolic functions of fat cells thus formed have not been reported (1,2). We now show that fat cells formed by treating 3T3-L1 preadipocytes with oleic acid (oleate), while expressing adipocyte-specific genes to some extent, exhibit impaired insulin sensitivity in several important metabolic aspects as compared with MDI (methylisobutylxanthine, dexamethasone, and insulin)-induced adipocytes.

METHODS

Cells culture. 3T3-L1 Preadipocytes were treated with DMEM containing 10% FBS and 17 nM insulin +/– FA (oleate, palmitate, linoleate, 0.5 mM, all complexed to BSA at a 3:1 molar ratio). Control adipocytes were differentiated by treatment with an MDI hormone cocktail for 48 h and then switched to DMEM with 10% FBS and 17 nM insulin (3). All cells were incubated in low-glucose (5 mM) DMEM with 0.5% BSA for 24 h before metabolic experiments.

Cell cycle analysis. After treatments, cells were trypsinized and fixed with 70% ethanol. Samples were stained with propidium iodide (5 μg/mL in PBS with 20 μg/mL RNase) for 30 min at 37°C and then analyzed using FACScan flow cytometry (BD Biosciences, San Jose, CA).

Lipolysis, lipogenesis, glucose uptake, Western analysis, and statistical analysis. These steps were performed as previously described (4,5). RNA isolation and reverse transcription were done as described before (4). Real-time PCR was done by mixing 2 μL of first strand cDNA with an adequate amount of water and 10 μL TaqMan universal PCR master enzyme mix from Roche (Brunburg, NJ) using the Rotor-Gene 3000A instrument (Corbett Robotics, San Francisco, CA).

RESULTS AND DISCUSSION

Oleate-induced growth arrest and lipid accumulation. Figure 1A shows the changes in cell morphology before and after being treated with oleate, linoleate, and a mixture of palmitate, linoleate, and oleate (PLO, 1:1:1 molar ratio) for 4 d. All FA were added at 0.5 mM with 0.14 mM BSA. Palmitate alone added at the same concentration was found to induce apoptosis (data not shown). For comparison, a microphotograph of cells differentiated with standard MDI protocol is also shown (7 d post-differentiation). These results indicated that all the exogenous FA caused intracellular lipid accumulation, with oleate being the most efficient in forming large, coalescent lipid droplets. Since oleate is mitogenic in selected cell types (6–8), we performed fluorescence-activated cell sorting (FACS) analysis to assess whether this might occur in our cell systems. As shown in Figure 1B, a similar cell population distribution pattern was found for postconfluent preadipoctyes before and after being treated with oleate or MDI: ~75–80% at G1/G0, ~15% at G2/M and ~5% at S phase. Such a distribution pattern is typical for growth-arrested fibroblasts (9). To further test whether the cells maintained at a growth-arrested state after being treated with oleate, we performed real-time PCR analysis for the expression of G0S2 gene, a novel marker for growth arrest and differentiation in 3T3-L1 cells (10). As shown in Figure 1C, treatment with FA or MDI increased G0S2 mRNA substantially as compared with growing preadipocytes. Together, these data suggest that treating 3T3-L1 preadipocytes with oleate alone or in combination with other FA resulted in the formation of fat cells that mimic

FL2-A, propidium iodide.

the adipocytes differentiated with the standard MDI protocol. We then further characterized this new type of fat cells at the molecular and metabolic levels.

Expression of adipogenic genes. As shown in Figure 2A, oleate induced a gradual increase in expression of the key adipogenic transcription factors, peroxisome proliferator-activated receptor-γ (PPARγ) and C/EBPα (CCAAT/enhancer-binding protein-α), in preadipocytes. After being normalized to the maximal expression level at maturation (day 7), the time courses of PPARγ and C/EBPα induction in cells treated with oleate were similar to that in cells treated with MDI, except that PPARγ expression was induced to a greater extent in the former during the early phase (day 0–2, Fig. 2A). Figure 2B shows that oleate also induced expression of selected differentiation marker genes, including FA binding protein (aP2), CD36, DAG acyltransferase-2 (DGAT-2), and glycerol-3-phosphate dehydrogenase (GPDH). Compared with MDI, oleate had a similar induction of GPDH, two- to threefold less CD36 and DGAT2 but two- to threefold more *aP2*. This suggests that fat cells formed after the two different treatments were similar but not identical and that MDI might be a more potent inducer for adipogenesis. Oleate, on the other hand, might specifically increase steady-state aP2 mRNA *via* alternative mechanisms as previously reported (11). Treatment with a combination of PLO gave a similar induction as that induced by oleate alone.

TAG accumulation. In the absence of oleate or MDI, little TAG was found in preadipocytes (Fig. 2C), consistent with a previous report that insulin alone does not induce adipogenesis (12). Cells treated with oleate began to accumulate TAG within 24 h, which reached a plateau at day 3–4 (Fig. 2C). On the other hand, TAG was undetectable in MDI-treated cells in the first 3 d but began to accumulate rapidly thereafter. These results indicate that TAG accumulation was tightly associated with adipogenesis in MDI-treated cells but not in oleate-treated cells.

Metabolic characterization. As shown in Figure 3A, cells treated with oleate or MDI both showed a higher basal lipogenesis rate as compared with the untreated preadipocytes. Insulin further stimulated lipogenesis two- to threefold (Fig. 3A), indicating that the insulin-sensitive lipogenic pathway was developed to a similar extent in both cell types. On the other hand, Figure 3B shows that oleate-treated cells had a greater basal glucose uptake than the MDI-treated cells. However, glucose uptake in the oleate-treated cells was not responsive to insulin stimulation at or near physiological concentration (170 nM) and only moderately responsive at supraphysiological concentration (1.7 μM), as compared with cells treated with MDI that showed a 3.5-fold increase in response to 170 nM insulin but with no further increase when insulin was increased to 1.7 μM. This difference suggests that the insulin signaling pathways were not activated properly in oleate-treated cells. Figure 3C shows that oleate-treated cells also had a greater basal lipolysis as compared with cells treated with MDI. However, isoproterenol-stimulated lipolysis was blunted, indicating dampened sensitivity to β-agonist as compared with that in the MDI-treated cells. Insulin also had no effect on isoproterenol-stimulated lipolysis in oleate-treated cells although it greatly suppressed that in the MDI-treated cells (Fig. 3C).

Altered metabolic characteristics are associated with

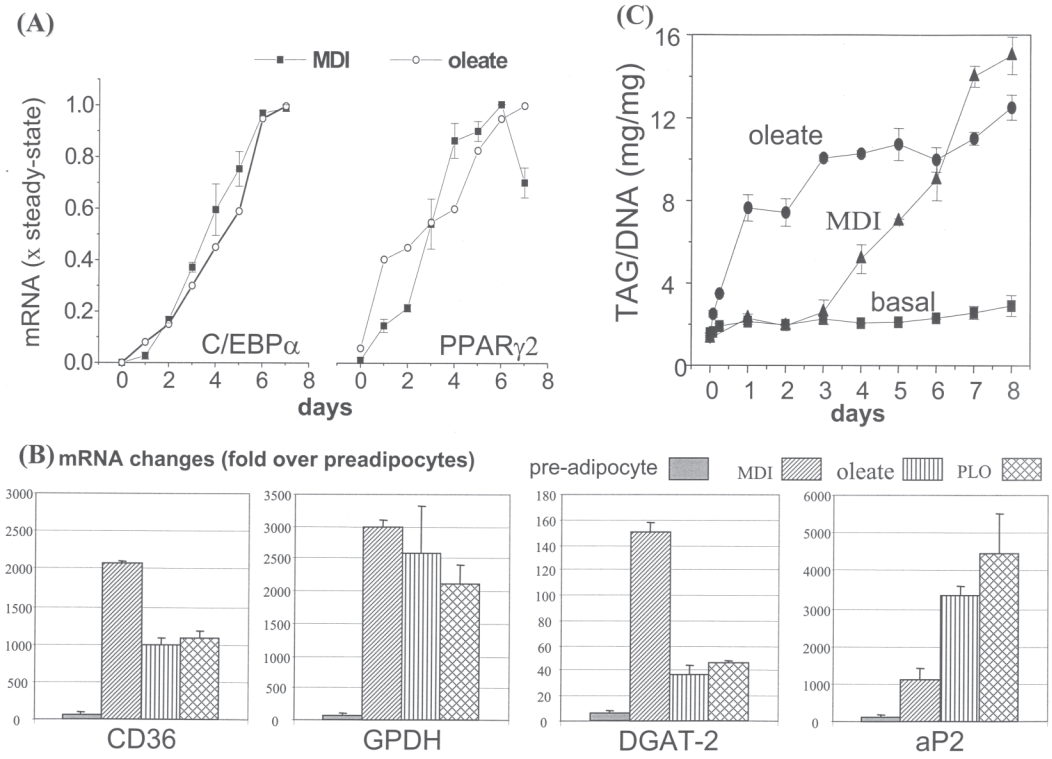

FIG. 2. Effects of FA on adipogenic gene expression and TG storage. (A) Time-dependent expression of CCAAT/enhancer-binding protein-α (C/EBPα) and peroxisome proliferator-activated receptor-γ (PPARγ) in preadipocytes treated with oleate or MDI, normalized to the steady-state expression levels on day 7; (B) time-dependent TAG accumulation (mean ± SE, $n = 3$); (C) mRNA expression of selected adipogenesis-related genes on day 7. GPDH, glycerol-3-phosphate dehydrogenase; DGAT-2, DAG acyltransferase-2; aP2, FA binding protein; for other abbreviations see Figure 1.

changes in the expression or phosphorylation of key functional proteins. First, we measured the expression/phosphorylation of perilipin, a protein that coats the lipid droplets in fat cells and facilitates lipolysis when phosphorylated (13). Consistent with the exaggerated basal lipolysis (Fig. 3C), we found that oleate-treated cells had a higher level of basal perilipin phosphorylation than MDI-treated cells (Fig. 4A). Second, we measured the expression of Glut-1 and Glut-4, the transporter proteins

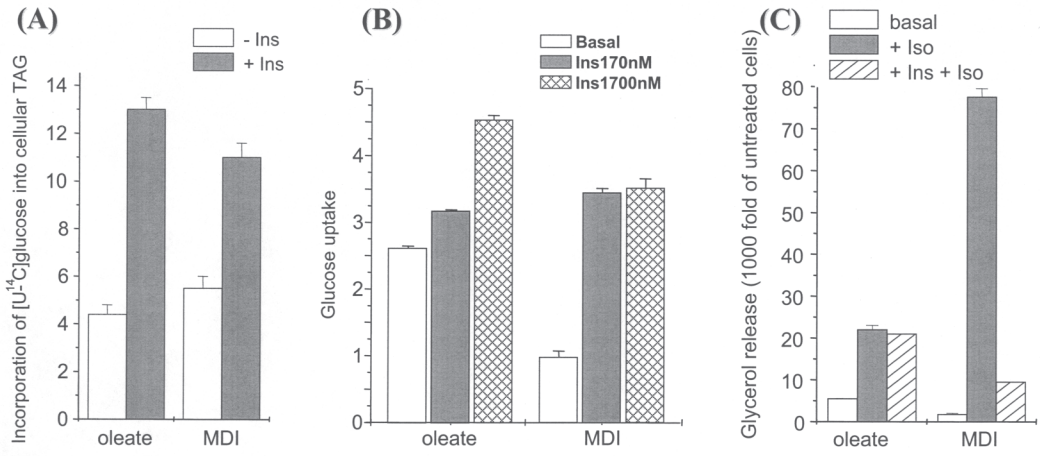

FIG. 3. Effects of oleate on metabolic functions and cellular response to insulin. (A) Incorporation of [U-^{14}C] glucose into cellular lipids, (B) uptake of 2-deoxy [2,6-^{3}H] glucose, (C) glycerol release, with or without insulin (170 nM, Ins) or isoproterenol (0.5 μM, Iso). Results are presented as fold changes over the untreated cells, for which the basal rates of lipogenesis, glucose uptake, and glycerol release were 0.82 pmol/μg DNA/min, 0.06 nmol/μg DNA/min, and 0.8 pmol/μg TAG/min, respectively (mean ± SE, $n = 3$, Duncan's test). For abbreviation see Figure 1.

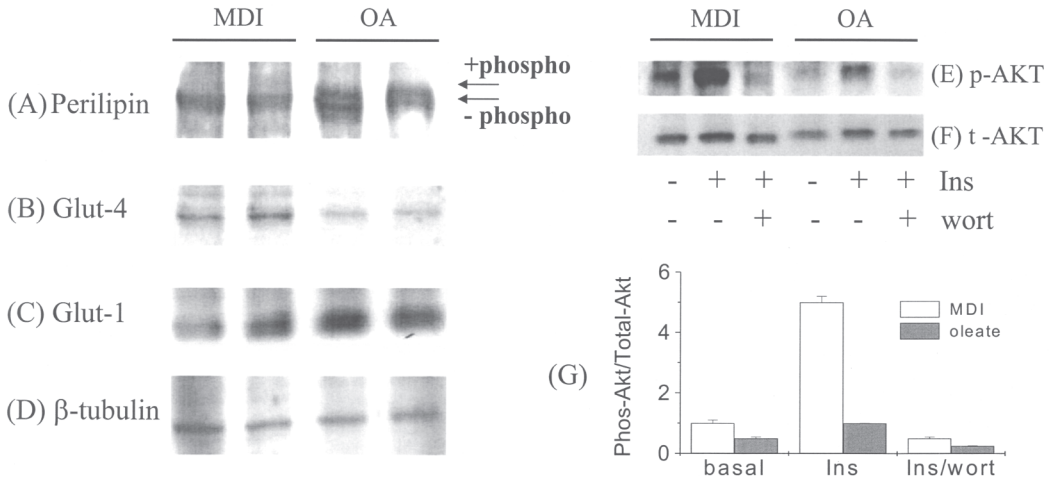

FIG. 4. Western analysis of selected proteins as labeled. Cells were prepared as in Figure 2 and used directly (A–D) or after incubation with insulin (170 nM, 15 min) with or without wortmanin (500 nM, wort) (E,F). Cells were lysed using RIPA buffer containing inhibitors for proteases and phosphatases, and 20 μg crude protein lysate of each sample was loaded for electrophoresis. Results are representative of three independent experiments. OA, oleate; p-AKT, phosphorylated protein kinase B; t-AKT, total protein kinase B protein; for other abbreviations see Figures 1 and 3.

that control the basal and insulin-stimulated glucose uptake, respectively (12). As shown in Figures 4B and 4C, oleate-treated cells had a greater expression of Glut-1 but less of Glut-4 compared with MDI-treated cells. This is consistent with the elevated basal, but dampened insulin-stimulated, glucose uptake in the former (Fig. 3B). Finally, we showed that insulin-stimulated protein kinase B (Akt) phosphorylation was also dampened in oleate-treated cells (~twofold), compared with a more sensitive response in MDI-treated cells (~fivefold) (Fig. 4E–G). This might also contribute to the poor insulin sensitivity with regard to lipolysis and glucose uptake in oleate-treated cells, based on the pivotal role of Akt in control of insulin signaling (14). The insulin-stimulated lipogenesis, on the other hand, appeared to be normally developed in these cells (Fig. 3A).

In summary, we showed that oleate induced the formation of a unique fat cell phenotype that exhibited some of the features of adipocytes, as shown by the expression of adipogenic genes, active lipogenesis, and lipolysis. However, these cells were also relatively insensitive to insulin and β-agonist. It is almost certain that they also differ from normal adipocytes in other functional aspects that still remain to be determined. Because elevation of blood FA concentration is common after a high-fat diet, and high-fat diets are known to be associated with increased fat cell formation *in vivo* (15–18), it is possible that fat cells thus formed may bear similar features to those of oleate-treated preadipocytes *in vitro*, with augmented fat storage but impaired hormonal sensitivity. In this regard, this work might provide a useful *in vitro* model for studying the effects of FA on adipose tissue development.

Coexistence of Phosphatidylcholine-Specific Phospholipase C and Phospholipase D Activities in Rat Cerebral Cortex Synaptosomes

Melina V. Mateos, Romina M. Uranga, Gabriela A. Salvador*, and Norma M. Giusto

Instituto de Investigaciones Bioquímicas de Bahía Blanca, Universidad Nacional del Sur and Consejo Nacional de Investigaciones Científicas y Técnicas, CC 857, B8000FWB Bahía Blanca, Argentina

ABSTRACT: DAG derived from phosphatidylcholine (PtdCho) acts as a lipid second messenger. It can be generated by the activation of phospholipase D (PLD) and the phosphatidic acid phosphohydrolase type 2 (PAP2) pathway or by a PtdCho-specific phospholipase C (PtdCho-PLC). Our purpose was to study PtdCho-PLC activity in rat cerebral cortex synaptosomes (CC Syn). DAG production was highly stimulated by detergents such as Triton X-100 and sodium deoxycholate. Ethanol and tricyclodecan-9-yl-xanthate potassium salt decreased DAG generation by 42 and 61%, respectively, at 20 min of incubation. These data demonstrate that both the PLD/PAP2 pathway and PtdCho-PLC contribute to DAG generation in CC Syn. PtdCho-PLC activity remained located mainly in the synaptosomal plasma membrane fraction. Kinetic studies showed K_m and V_{max} values of 350 μM and 3.7 nmol DAG × (mg protein × h)$^{-1}$, respectively. Western blot analysis with anti-PtdCho-PLC antibody showed a band of 66 KDa in CC Syn. Our results indicate the presence of a novel DAG-generating pathway in CC Syn in addition to the known PLD/PAP2 pathway.

Paper no. L9873 in *Lipids 41,* 273–280 (March 2006).

Phosphatidylcholine (PtdCho) is the most abundant class of glycerophospholipids in mammalian cell membranes, where it plays key roles in membrane structure, cell death, and cellular signaling (1). This phospholipid is also an important source of second lipid messengers such as lysophosphatidylcholine, phosphatidic acid (PtdOH), arachidonic acid, and DAG.

PtdCho hydrolysis can be elicited by growth factors, cytokines, neurotransmitters, hormones, and other extracellular signals (2–5). In response to several stimuli, DAG can be generated from PtdCho by subsequent activation of phospholipase D (PLD) and PtdOH phosphohydrolase type 2 (PAP2) or by a PtdCho-specific phospholipase C (PtdCho-PLC) (2,6). In contrast to DAG generated from phosphatidylinositol (4,5) bisphosphate ($PtdInsP_2$) by PtdIns-PLC activity, the wave of DAG elicited from PtdCho hydrolysis is generated more slowly and proceeds without elevation of intracellular Ca^{2+}. PtdCho-PLC activation might be related to a sustained activation of Ca^{2+}-independent protein kinase C (PKC) isoforms suggesting its involvement in slow and extended cell responses such as proliferation and differentiation (6,7).

PtdCho-PLC activity has been previously described in several rat tissues (8) as well as in rat platelets (9), and it has been isolated and characterized in bull seminal plasma (10). PtdCho-PLC activity is involved in many cellular events such as glutamate-induced nerve cell death (11) and in Fas-induced apoptosis (12,13). PtdCho-PLC also can be activated during cell mitogenic responses that are triggered by platelet-derived growth factor (14,15), thromboxane A_2 (16), and lipopolysaccharide (LPS) (17), leading to the activation of the mitogen-activated protein kinase pathway. Furthermore, PtdCho-PLC seems to be acting downstream Ras but upstream Raf-1 during mitogenic signal transduction (18,19).

Studies from our laboratory demonstrated the presence of the PLD/PAP2 pathway and its regulation by insulin in rat cerebral cortex (CC) synaptosomes (Syn) (20,21). Mammalian PLD isoforms (PLD1, PLD2) are present in neurons and in glial cells, and these enzymes are implicated in basic cellular functions such as vesicular trafficking as well as in brain development (22). However, the PtdCho-PLC pathway has not been thoroughly studied in the central nervous system (CNS), and no evidence has been reported to date about its presence in synaptic endings and its involvement in signal transduction events. In view of its wide distribution and its implication in such diverse cell responses, the aim of this work was to analyze PtdCho-PLC activity in rat CC Syn.

MATERIALS AND METHODS

Wistar-strain adult rats (4 mon old) were kept under constant environmental conditions and fed on a standard pellet diet *ad libitum* until decapitation.

1-[^{14}C]Palmitoyl-2-[^{14}C]palmitoyl-*sn*-glycero-3-phosphocholine ([^{14}C]DPPtdCho) (111 mCi/mmol), 1,2-dipalmitoyl-*sn*-glycero-3-phospho[methyl-^{3}H]choline ([^{3}H-choline] DPPtdCho) (43 Ci/mmol), and Omnifluor were obtained from New England Nuclear-DuPont (Boston, MA). Triton X-100 (T X-100), sodium deoxycholate (DOC), tricyclodecan-9-yl-xanthate potassium salt (D609), and 1,6-bis(cyclohexyloximinocarbonylamino)hexane (RHC80267) were obtained from Sigma-Aldrich (St. Louis, MO). Polyclonal anti-PtdCho-PLC antibody (Ab) raised against *Bacillus cereus* PtdCho-PLC was generously provided by Dr. Howard Goldfine, University of Pennsylvania (Philadelphia, PA). All other chemicals were of the highest purity available.

Preparation of synaptosomal fraction. Total homogenates were prepared from the CC of 4-mon-old rats. Rats were killed by decapitation and CC was immediately dissected (2–4 min after decapitation). All proceedings were in accordance with *Principles of Use of Animals and Guide for the Care and Use of Laboratory Animals* (National Institutes of Health regulation).

The synaptosomal fraction (Syn) was obtained as previously described by Cotman (23) with slight modifications (20). Briefly, CC homogenate was prepared in the following way: 20% (wt/vol) in a buffer containing 1 mM EDTA, 10 mM HEPES buffer (pH 7.4) in the presence of 1 mM DTT, 2 μg/mL leupeptin, 1 μg/mL aprotinin, 1 μg/mL pepstatin, and 0.1 mM PMSF.

The CC homogenate was centrifuged at 1,800 × *g* for 7.5 min using a JA-21 rotor in a Beckman J2-21 centrifuge, and the supernatant was carefully poured into another tube. The supernatant was subsequently centrifuged at 15,000 × *g* for 20 min to obtain the crude mitochondrial pellet (CM). The CM was washed and resuspended with 3 mL of the isolation medium and loaded onto a 8.5% Ficoll medium (6 mL) and 13% Ficoll medium (6 mL) discontinuous gradient. The Ficoll solutions were prepared in the isolation medium. The sample loaded onto the discontinuous gradient was centrifuged at 120,000 × *g* for 30 min using a SW 28.1 rotor in a Beckman L5-50 ultracentrifuge. The myelin fraction band was at the interface between the isolation medium and the 8.5% Ficoll medium, the Syn band at the interface between the 8.5% and the 13% Ficoll medium, and the free mitochondrial fraction was the pellet below the 13% Ficoll medium. Syn was centrifuged at 33,000 × *g* for 20 min using a JA-21 rotor in a Beckman J2-21 centrifuge and resuspended in the assay buffer.

Preparation of Syn plasma membrane (SPM). SPM isolation was performed according to a protocol previously described by Igbavboa *et al.* (24) with slight modifications. Briefly, the Syn fraction from one CC was resuspended in 4 mL of cold lysis buffer (5 mM Tris buffer, pH 8.5). The lysed suspension was vortex-mixed vigorously and incubated for 1 h at 4°C with repeated vortex mixing every 15–20 min. After 1 h the suspension was centrifuged at 33,000 × *g* for 30 min using a JA-21 rotor in a Beckman J2-21 centrifuge. The soluble fraction (Sol) from lysed Syn was collected; the pellet was resuspended in 4 mL of cold distilled water, layered onto 12 mL of 0.75 M sucrose containing 10 mM HEPES and 0.25 mM EDTA (pH 7.4), and centrifuged at 73,000 × *g* for 30 min using an SW 28.1 rotor in a Beckman L5-50 ultracentrifuge. The SPM suspension at the interface was removed and centrifuged at 33,000 × *g* for 30 min in a JA-21 rotor in a Beckman J2-21 centrifuge. The SPM pellet was resuspended in the assay buffer. To establish the purity of Syn subfractions, a 5′ nucleotidase assay was performed according to Widnell and Unkeless (25).

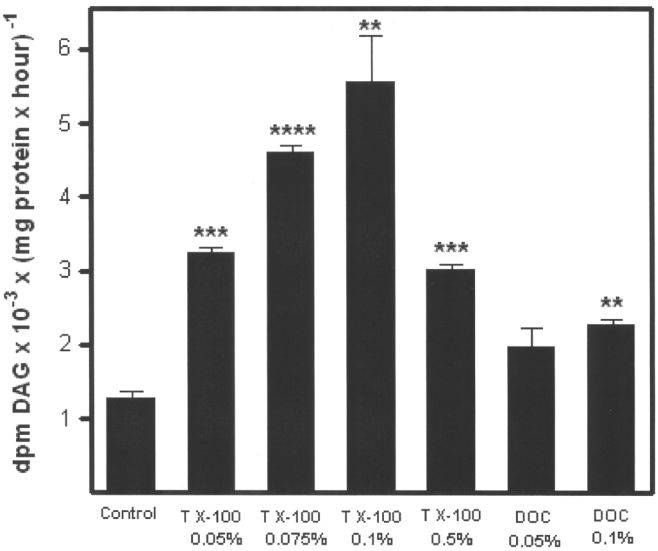

FIG. 1. Effect of detergents on synaptosomal DAG generation from phosphatidylcholine (PtdCho). Rat cerebral cortex (CC) synaptosomes (Syn) were incubated in a buffer containing 0.1 M Tris (pH 7.2) in the presence of 0.125 mM dipalmitoylphosphatidylcholine (DPPtdCho) (40,000 dpm of [^{14}C]DPPtdCho per assay) and different concentrations of Triton X-100 (T X-100; 0.05, 0.075, 0.1, and 0.5%) or sodium deoxycholate (DOC; 0.05 and 0.1%) as described in the Materials and Methods section. After 20 min, the enzyme reaction was stopped and lipids were extracted and isolated as described in the Materials and Methods section. Results are compared with the control condition without detergent, and the enzyme activity is expressed as dpm DAG × 10^{-3} × (mg protein × h)$^{-1}$. Each experiment was performed twice, using a pool of three animals on each occasion. Data are the mean ± SD of four samples (**$P < 0.01$; ***$P < 0.005$; ****$P < 0.001$).

Determination of PtdCho-PLC activity. PtdCho hydrolysis by PtdCho-PLC was determined using lipid vesicles containing [^{14}C]DPPtdCho and cold DPPtdCho to yield 40,000 dpm and 0.125 mM per assay. These lipid vesicles (100 μL) were added to 100 μL of Syn, SPM, or Sol (150 μg of protein) in a final volume of 200 μL in a buffer containing 0.1M Tris (pH 7.2). The reaction was incubated at 37°C for 5 or 20 min and stopped by the addition of 5 mL of chloroform/methanol (2:1, vol/vol). Blanks were prepared identically, except that membranes were boiled for 5 min before being used. Lipids were extracted and separated as described below.

Determination of PLD activity. To assay PLD activity, transphosphatidylation reaction was measured in Syn and SPM. Lipid vesicles were prepared as described above and the assay was conducted in the presence of 2% ethanol. The reaction was incubated at 37°C for 5 or 20 min and stopped by the

addition of 5 mL of chloroform/methanol (2:1, vol/vol). Lipids were extracted and separated as described below.

Determination of sphingomyelin synthase (SMS) activity. SMS activity was assayed as described for PtdCho-PLC, but lipid vesicles were prepared with [^{3}H-choline]-DPPtdCho as labeled substrate. The reaction was incubated at 37°C for 5 or 20 min and stopped by the addition of 5 mL of chloroform/methanol (2:1, vol/vol). Lipids were extracted and separated as described below.

Extraction and isolation of lipids. Lipids were extracted according to Folch *et al.* (26). Briefly, the lipid extract was washed with 0.2 vol of 0.05% $CaCl_2$ and the lower phase was obtained after centrifugation at 900 × *g* for 5 min. Neutral lipids (MAG, DAG, and FFA) were then separated by 1-D TLC using silica gel G plates (Merck, Darmstadt, Germany) in a mobile phase consisting of hexane/diethyl ether/acetic acid (50:50:2.6, by vol). PtdCho was retained at the spotting site. Lipids were visualized by exposure of the plate to iodine vapors. DAG spots were scraped off for counting by liquid scintillation.

Phosphatidylethanol (PtdEth) was separated by 1-D TLC on silica gel H (Merck) and developed with chloroform/methanol/acetone/acetic acid/water (50:15:15:10:5, by vol) up to 70% of the plate. Then the plate was rechromatographed up to the top using hexane/diethyl ether/acetic acid (70:30:2.6, by vol) as described by Salvador and Giusto (27). Radioactivity of lipid spots was determined as previously described.

Sphingomyelin (SM) was separated by 1-D TLC on silica gel H (Merck) and developed with chloroform/methanol/27% ammonia (65:25:5, by vol). Radioactivity of lipid spots was determined as previously described.

Western blot assay of PtdCho-PLC. Syn samples were resuspended in Laemmli buffer and boiled for 3 min. Protein (60 µg) was loaded and resolved in a 10% SDS-PAGE following Laemmli (28) and transferred to a polyvinylidene difluoride (PVDF) membrane using a Mini Trans-Blot cell electroblotter (Bio-Rad Life Science Group, Hercules, CA) for 1 h. Membranes were blocked with 5% nonfat dry milk in Tris-buffered saline (20 mM Tris, pH 7.5, 150 mM NaCl) containing 0.1% Tween-20 (2 h at room temperature) and then incubated with rabbit polyclonal anti-PtdCho-PLC Ab overnight at 4°C. Immunoreactions were detected with polyclonal horseradish peroxidase conjugated to total antirabbit Ab (Santa Cruz Biotechnology, Santa Cruz, CA) followed by incubation with enhanced chemiluminescence substrates (New England Nuclear-Dupont).

Other methods. Protein concentration was determined according to Bradford (29).

Statistical analysis. Statistical analysis was performed using Student's *t*-test.

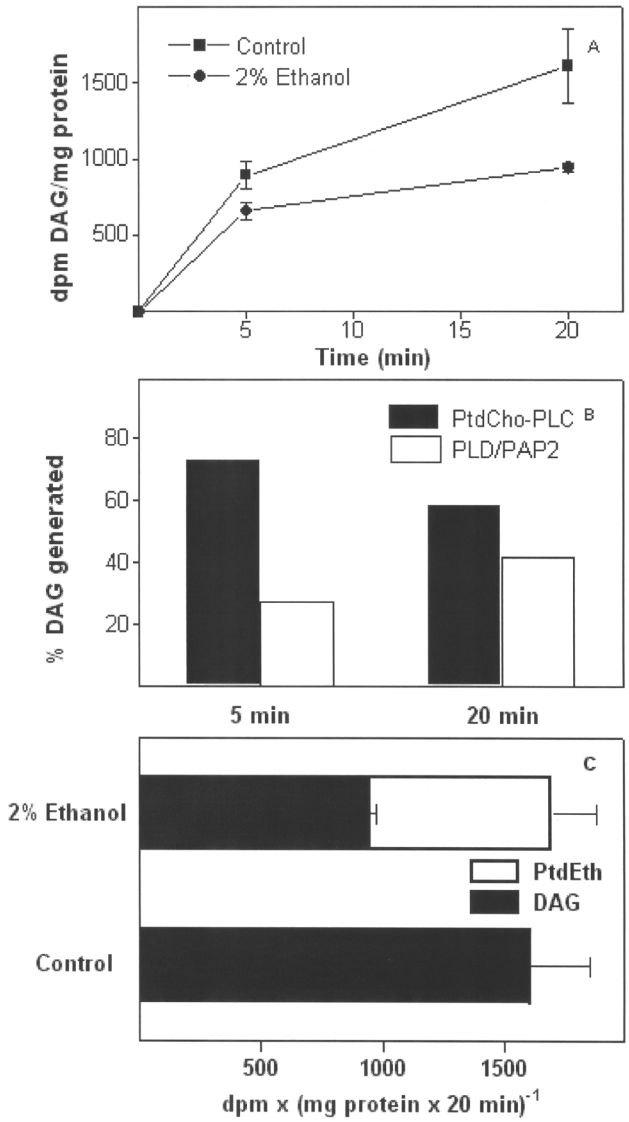

FIG. 2. (A) Contribution of PtdCho-PLC (PtdCho-specific phospholipase C) and phospholipase D/phosphatidic acid phosphohydrolase type 2 (PLD/PAP2) pathways to synaptosomal DAG generation. The enzyme assay was carried out as described in Figure 1 in a buffer containing 0.1% T X-100 with 2% ethanol and without ethanol (control condition). DAG generation was evaluated as a time function (5 and 20 min), and results are expressed as dpm DAG/mg protein. (B) Contribution of PtdCho-PLC and PLD/PAP2 pathways to synaptosomal DAG formation as a time function. Results are expressed as the percentage of the total DAG generated. (C) Synaptosomal phosphatidylethanol (PtdEth) formation. PtdEth production was measured as described in the Materials and Methods section. DAG and PtdEth levels obtained in Syn incubated with 2% ethanol are compared with DAG levels obtained under control condition at 20 min incubation. Results are expressed as dpm × (mg protein × 20 min)$^{-1}$. Each experiment was performed twice, using a pool of three animals on each occasion. Data are the mean ± SD of four samples. For other abbreviations see Figure 1.

RESULTS

Effect of detergents on DAG generation in CC Syn. The effect of detergents such as DOC and T X-100 on synaptosomal DAG generation was studied. Syn were incubated in the presence of 0.125 mM DPPtdCho (40,000 dpm of [^{14}C]DPPtdCho per assay) and in different concentrations of T X-100 (0.05, 0.075, 0.1, and 0.5%) or DOC (0.05 and 0.1%) as described in the Materials and Methods section. The effect of these tensioactive

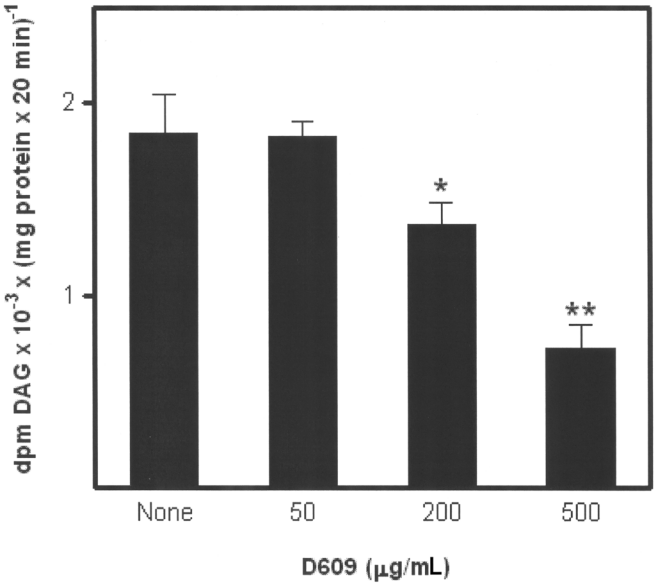

FIG. 3. Effect of tricyclodecan-9-yl-xanthate potassium salt (D609) on synaptosomal DAG formation. Syn were preincubated at 4°C for 20 min in the presence of different concentrations of D609 (50, 200, and 500 μg/mL). The enzyme reaction was carried out as described in Figure 2. Results are compared with the control condition, in which samples were preincubated without the inhibitor, and are expressed as dpm DAG × (mg protein × 20 min)$^{-1}$. Each experiment was performed twice, using a pool of three animals on each occasion. Data are the mean ± SD of four samples (*$P < 0.025$; **$P < 0.01$). For abbreviation see Figure 1.

agents on synaptosomal DAG generation is shown in Figure 1. Both detergents stimulated DAG generation at all concentrations assayed when the activity was compared with the control condition (without any detergent). The major DAG generation was observed with 0.1% T X-100: DAG formation increased by 330% with respect to the control condition. At the same concentration, DOC increased DAG generation by only 77% with respect to the control condition. Based on these results, all subsequent experiments were conducted in the presence of 0.1% T X-100.

Contribution of PtdCho-PLC and PLD/PAP2 pathways to synaptosomal DAG generation. To study the contribution of PtdCho-PLC and PLD/PAP2 pathways to synaptosomal DAG generation, ethanol was used as a marker of PLD activity. The enzyme assay was conducted in the presence of 2% ethanol, and DAG generation was evaluated as a time function (5 and 20 min) and compared with the control condition (without ethanol) (Fig. 2A).

Figure 2B shows the contribution of PtdCho-PLC and PLD/PAP2 pathways to DAG formation in CC Syn. At 5 min incubation, 73% of the total DAG generated is originated by PtdCho-PLC activity while the remaining 27% is generated by the PLD/PAP2 pathway. At 20 min incubation, 58% of DAG is generated by PtdCho-PLC activity and 42% is from the PLD/PAP2 pathway, respectively. In the presence of ethanol, DAG and PtdEth levels correlated to total DAG levels generated under control condition (Fig. 2C), indicating that PtdOH generated by PLD was converted to PtdEth.

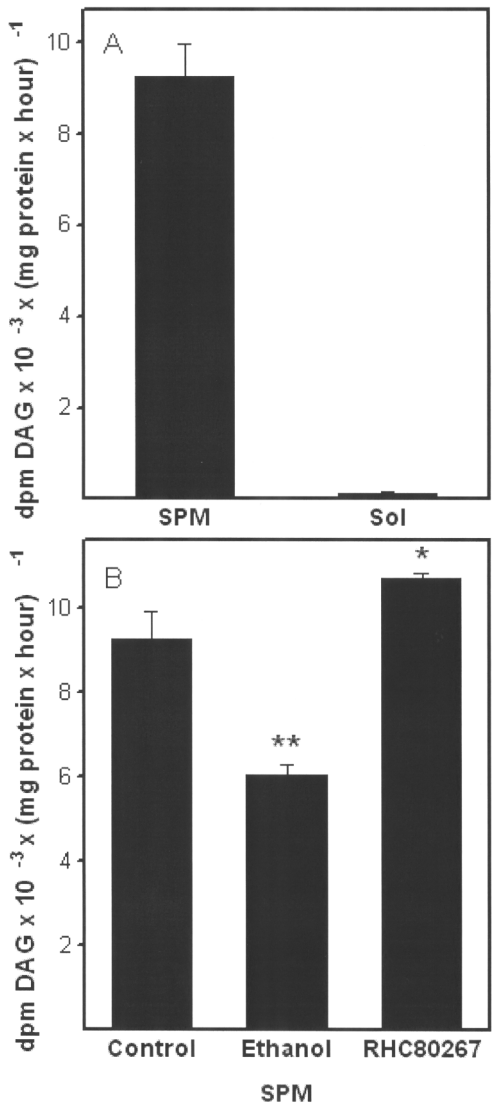

FIG. 4. (A) Localization of PtdCho-PLC activity. DAG formation was measured in the synaptosomal plasma membrane (SPM) and soluble fractions (Sol) obtained from Syn. SPM and Sol were isolated as described in the Materials and Methods section, and the enzyme reaction was carried out as described in Figure 2. (B) Effect of ethanol and 1,6-bis(cyclohexyloximinocarbonylamino)hexane (RHC80267) on DAG generation in SPM. DAG formation was measured under control conditions and in the presence of either 2% ethanol or 30 μM RHC80267 using SPM as the enzyme source. Results are expressed as dpm DAG × 10^{-3} × (mg protein x h)$^{-1}$. Each experiment was performed twice, using a pool of three animals on each occasion. Data are the mean ± SD of four samples (*$P < 0.025$; **$P < 0.01$). For other abbreviations see Figure 1.

Effect of D609 on DAG formation. To evaluate the effect of the PtdCho-PLC inhibitor D609, Syn were preincubated at 4°C for 20 min in the presence of increasing concentrations of D609 (50, 200, and 500 μg/mL) before starting the enzyme reaction. Results in Figure 3 show that D609 inhibited DAG formation in a dose-dependent manner: 50 μg/mL had no effect on DAG generation whereas 200 μg/mL decreased DAG formation by

TABLE 1
Protein and 5′ Nucleotidase Distribution in Total Homogenate, Synaptosomes, Synaptosomal Plasma Membrane, and Soluble Fractions Prepared from Rat Cerebral Cortex[a]

Subcellular fraction	mg protein/g CC	5´ Nucleotidase activity	Nucleotidase activity/ TH nucleotidase activity
TH	145.8	352 ± 56	1
Syn	12.02	684 ± 96	1.94
SPM	2.56	1500 ± 2.4	4.26
Sol	8.7	40 ± 16	0.11

[a]Subcellular fractions were prepared as described in the Materials and Methods section. The 5′ nucleotidase activity is expressed as nmol Pi × (mg protein × h)$^{-1}$. Data are the mean ± SD of four samples. TH, total homogenate; Syn, synaptosomes; SPM, synaptosomal plasma membrane; Sol, soluble fraction; Pi, inorganic phosphorus.

26% and 500 μg/mL decreased DAG formation by 61% with respect to the control condition (without the inhibitor).

Localization of PtdCho-PLC activity. For determining the localization of PtdCho-PLC activity, PtdCho hydrolysis was measured in the plasma membrane fraction and in the Sol, obtained after the lysis of Syn. SPM and Sol were isolated as described in the Materials and Methods section, and the enzyme reaction was carried out as previously described.

Figure 4A shows that PtdCho-PLC activity was present in the SPM fraction whereas enzyme activity was negligible in Sol. These results are evidence that PtdCho-PLC is located in the SPM fraction. To evaluate the contribution of the PLD/PAP2 pathway to DAG formation in SPM, enzyme assays were carried out in the presence of 2% ethanol (Fig. 4B). At 20 min incubation, ethanol inhibited DAG generation by 35%. These results demonstrated that 65% of DAG was generated by PtdCho-PLC activity and 35% was from PLD/PAP2 pathway in the plasma membrane fraction.

As DAG lipase, which is a very active enzyme, is also located in the plasma membrane, DAG formation was evaluated in the presence of the DAG lipase inhibitor, RHC80267. DAG formation in the presence of 30 μM RHC80267 was increased by 16% in SPM with respect to the control condition (Fig. 4B). The activity of 5′ nucleotidase was measured in Syn, SPM, Sol, and total homogenate (TH), for evaluating purity of fractions (Table 1). The specific activity of 5′ nucleotidase in SPM was 4.26-fold higher than the specific activity present in TH.

Determination of PtdCho-PLC K_m and V_{max}. To determine PtdCho-PLC K_m and V_{max} values, enzyme reactions were carried out in the presence of increasing concentrations of exogenous DPPtdCho. DAG generation was measured using 50, 75, 125, 200, 300, 500, 700, and 900 μM of DPPtdCho (150,000 dpm per assay) in the presence of 2% ethanol. DAG generation increased linearly up to 200 μM DPPtdCho; at higher concentrations PtdCho-PLC showed a saturation behavior (Fig. 5A). K_m and V_{max} values calculated from a Lineweaver-Burk plot were 350 μM and 3.7 nmol DAG × (mg protein × h)$^{-1}$, respectively (Fig. 5B).

Detection of synaptosomal PtdCho-PLC by Western blot assay. Synaptosomal proteins were resolved in a 10% SDS-PAGE and transferred to a PVDF membrane. The membrane was then incubated with a polyclonal Ab raised against *B. cereus* PtdCho-PLC (Fig. 6). *Clostridium perfringens* PtdCho-PLC (line A, Fig. 6) was used as a positive control for the Ab since the N-terminal domain of this protein shows structural similarity to *B. cereus* PtdCho-PLC (30). CC Syn from adult rats (line B) showed a band corresponding to 66 kDa.

DISCUSSION

DAG was discovered as a lipid second messenger through its involvement in PKC activation (31,32). At present there is increasing interest in the question as to whether DAG derived from PtdCho may function as a lipid second messenger and regulate PKC analogous to DAG derived from $PtdInsP_2$. Among the pathways that generate lipid second messengers from PtdCho, PtdCho-PLC is one of the least characterized. It has been reported that PtdCho-PLC is involved in the activation of the nuclear transcription factor κB in response to the tumor necrosis factor α (TNF-α) (33,34) as well as in the activation of the signal transducer and activator of transcription 6 (STAT6) induced by interleukin-4 (35). In immune responses and inflammatory processes, PtdCho-PLC may play important roles because it co-localizes with perforin-carrying granules and it is involved in natural killer (NK)-mediated lytic activity (36). In addition, PtdCho-PLC inhibition blocks interleukin-6 and TNF release in LPS-stimulated human alveolar macrophages (17). However, little is known about PtdCho-PLC implications in signal transduction pathways in CNS.

In this work we studied the existence of the PtdCho-PLC pathway in rat CC Syn. Tensioactive agents such as T X-100 and DOC stimulated synaptosomal DAG formation. Maximal DAG generation was observed at 0.1% T X-100, and DAG formation increased by 330% with respect to the control condition (Fig. 1). Our results agree with data regarding PtdCho-PLC activity in rat platelets (9). However, rat platelet PtdCho-PLC activity was highest at 0.01% DOC.

To corroborate the source of synaptosomal DAG generation, ethanol was used as a marker of PLD activity. It is known that PLD in the presence of primary alcohols, such as ethanol or 1-butanol, not only catalyzes PtdCho hydrolysis yielding PtdOH but also catalyzes a competitive transphosphatidylation reaction leading to the formation of either PtdEth or phosphatidylbutanol with the accompanying suppression of DAG formation from PtdOH (37,38). In the presence of 2% ethanol, DAG formation decreased by 27 and 42% at 5

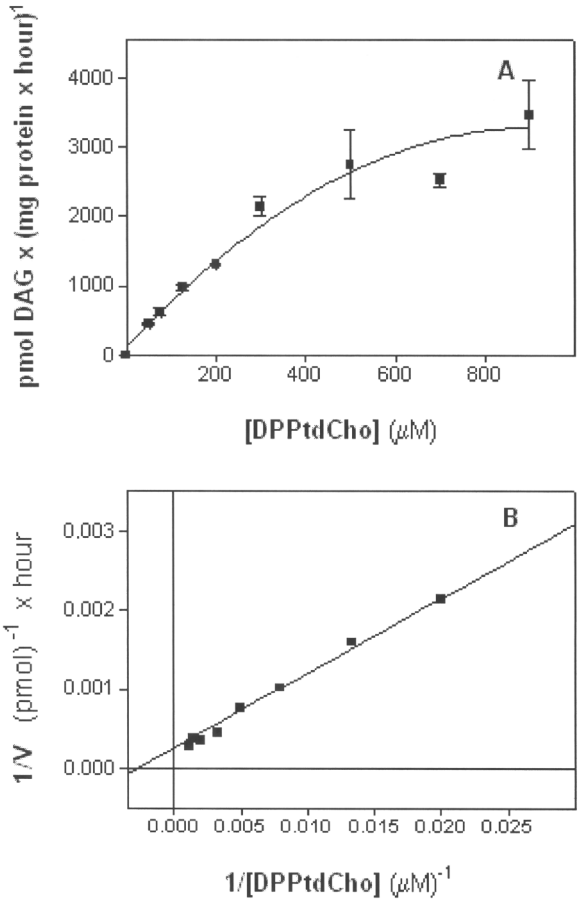

FIG. 5. (A) Determination of PtdCho-PLC K_m and V_{max}. Enzyme reactions were carried out in the presence of increasing concentrations of exogenous dipalmitoylphosphatidylcholine (DPPtdCho; 50, 75, 125, 200, 300, 500, 700, and 900 μM), 150,000 dpm of [^{14}C]DPPtdCho per assay in the presence of 2% ethanol, and 0.1% T X-100. Results are expressed as pmol DAG × (mg protein × h)$^{-1}$. (B) Lineweaver-Burk plot from the data in Figure 5A. Each experiment was performed twice, using a pool of three animals on each occasion. Data are the mean ± SD of four samples. For other abbreviations see Figure 1.

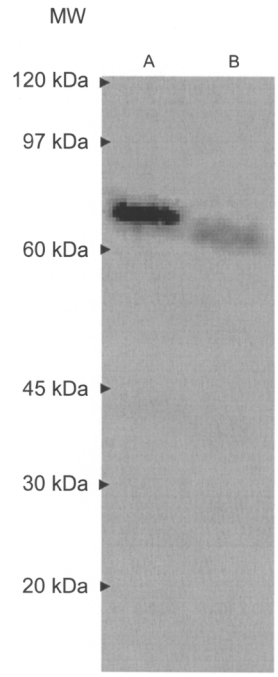

FIG. 6. Detection of synaptosomal PtdCho-PLC by Western blot assay. Synaptosomal proteins (60 μg) were resolved in a 10% SDS-PAGE and transferred to a polyvinylidene difluoride membrane. The membrane was then incubated with rabbit polyclonal anti-PtdCho-PLC antibody (Ab), and immunoreactions were detected with polyclonal horseradish peroxidase conjugated to total antirabbit Ab. *Clostridium perfringens* PtdCho-PLC was used as a positive control for the anti-PtdCho-PLC Ab (A). Synaptosomal proteins from adult rats (4-mon-old) were loaded on the second line (B). For other abbreviations see Figure 1.

and 20 min, respectively (Fig. 2A). Consequently, the PtdCho-PLC contribution decreased from 73 to 58% as a time function. This decrease in DAG generation induced by ethanol demonstrates that PLD/PAP2 and PtdCho-PLC pathways differentially contribute to DAG production as a time function in CC synaptic endings (Fig. 2B). Our experiments suggest that PtdCho-PLC could be activated upstream from the PLD/PAP2 as it has been reported in other experimental systems (12,13,39).

For additional confirmation of the origin of DAG in CC Syn, enzyme assays were conducted in the presence of D609. This antiviral and antitumoral potassium xanthate is widely accepted as a selective inhibitor of PtdCho-PLC (15,40–42), and it has been proposed that it behaves as a competitive inhibitor of the enzyme (41,43). D609 inhibited synaptosomal DAG generation in a dose-dependent manner (Fig. 3). At 20 min of incubation, 500 μg/mL D609 decreased DAG formation by 61%, which was correlated with the PtdCho-PLC contribution observed in the presence of 2% ethanol.

Previous studies suggest that some of the biological events that had been attributed to PtdCho-PLC could be due to SMS (44,45). SMS is an enzyme involved in SM and ceramide metabolism that transfers a phosphocholine group from PtdCho to ceramide to generate SM and DAG (46,47). However, the kinetics of DAG production by SMS is significantly different from that of DAG production by PtdCho-PLC or PLD/PAP2 pathways because SMS-mediated DAG production is a slow process. Moreover, when [^{3}H-choline]DPPtdCho was used as a labeled substrate, no SM formation from PtdCho was detected under our experimental conditions (data not shown).

Experiments performed in the SPM and Sol fractions from Syn provide evidence that PtdCho-PLC is located in the plasma membrane (Fig. 4A). PtdCho-PLC localization in the membrane fraction is in accordance with previously published data observed in NK cells (36) and in NIH-3T3 fibroblasts (15). The inhibition of DAG generation by ethanol demonstrates that both PLD/PAP2 and PtdCho-PLC pathways contribute to DAG generation in SPM.

Although the molecular structure of eukaryotic PtdCho-PLC is still unknown, Clark *et al.* (48) demonstrated that antibodies prepared to *B. cereus* PtdCho-PLC cross-react with a

PtdCho-PLC from mammalian cells. Detection of synaptosomal PtdCho-PLC by Western blot assay with a polyclonal Ab raised against *B. cereus* PtdCho-PLC showed a band corresponding to 66 kDa (Fig. 6). Using also a polyclonal Ab directed to *B. cereus* PtdCho-PLC, a 66 kDa band was detected in NIH-3T3 fibroblasts (15) and in human NK cells (36). Our results also correlate to those obtained by Sheikhnejad and Srivastava (10), who determined the M.W. of an isolated PtdCho-PLC from bull seminal plasma by SDS-gel electrophoresis and reported two bands of 69 and 55 kDa.

Our experiments demonstrate the existence of a novel synaptosomal DAG generation pathway, thus confirming the first evidence for the presence of PtdCho-PLC in rat CC Syn. The existence of this novel lipid second messenger pathway in CNS is the starting point for the study of its involvement in neuronal signal transduction.

ACKNOWLEDGMENTS

This research was supported by the Consejo Nacional de Investigaciones Cientificas y Técnicas (CONICET), Secretaría General de Ciencia y Tecnología, Universidad Nacional del Sur and Agencia Nacional de Promoción Científica y Tecnológica (FONCyT), Argentina. N.M. Giusto and G.A. Salvador are research members of the CONICET, and M.V. Mateos and R.M. Uranga are research fellows of the CONICET. The authors thank Dr. Howard Goldfine for generously providing the anti-PtdCho-PLC antibody.

Diacylglycerol Acyltransferase Activity and Triacylglycerol Synthesis in Germinating Castor Seed Cotyledons

Xiaohua He, Grace Q. Chen, Jiann-Tsyh Lin, and Thomas A. McKeon*

Western Regional Research Center, USDA, Albany, California 94710

ABSTRACT: The central importance of storage lipid breakdown in providing carbon and energy during seed germination has been demonstrated by isolating the genes encoding the enzymes involved in FA β-oxidation. In contrast, little is known about the ability of germinating seeds to synthesize TAG. We report that castor cotyledons are capable of TAG synthesis. The rate of incorporation of ricinoleic acid into TAG reached a peak at 7 d after imbibition (DAI) (1.14 nmol/h/mg) and decreased rapidly thereafter, but was sustained at 20 DAI in cotyledons and true leaves. The castor DAG acyltransferase (RcDGAT) mRNA and protein were expressed throughout seed germination at levels considerably enhanced from that in the dormant seed, thus indicating new expression. Significant degradation of the RcDGAT protein was observed after 7 DAI. The DGAT activity was found to be predominantly a function of the level of the intact RcDGAT protein, with the rate of TAG synthesis decreasing as degradation of the RcDGAT protein proceeded. A possible mechanism for the degradation of the RcDGAT protein is discussed. The induction of DGAT mRNA and protein, the capacity for TAG synthesis *in vitro* and in tissue slices, and the differing TAG composition of dormant seed TAG vs. cotyledonary TAG provide strong circumstantial evidence for active TAG synthesis by cotyledons. However, we have not yet determined the physiological significance of this capability.

Paper no. L9856 in *Lipids 41*, 281–285 (March 2006).

Castor plants (*Ricinus communis*) are grown for their seeds, which, at maturity, contain up to 60% of oil. Nearly 90% of the TAG FA content is ricinoleic acid, a hydroxy FA that has numerous industrial uses (1). Unlike the majority of oil crops, castor seeds store oil in a living endosperm rather than the embryo. During castor seed germination, storage oil in the endosperm is converted to sucrose *via* successive pathways of β-oxidation, the glyoxylate cycle, the partial tricarboxylic acid cycle, and gluconeogenesis for utilization by the developing embryo (2).

Although the breakdown of storage lipids is the most striking metabolic event occurring during oilseed germination (3), it is evident from data presented in previous studies that germinating seeds may also be able to synthesize TAG. In 1975, Harwood reported that all the enzymes required in FA and glycerolipid synthesis were present and active in soybean cotyledons during seed germination (4). The synthesis of TAG has also been shown to occur during seed germination of some plants, such as the pea (5), cucumber (6), and soybean (7). These observations suggest the presence of DAG acyltransferase (DGAT) in germinating seeds. Recently, we identified a cDNA encoding DGAT from castor seed (RcDGAT) based on its homology to other plant-type DGAT1 cDNA (8) and investigated the expression of the RcDGAT gene and DGAT activity in developing seeds (9). In this study we extend our examination of the RcDGAT gene and protein to cotyledons of germinating castor to elucidate the function of RcDGAT in the germination process and in plant development.

EXPERIMENTAL PROCEDURES

Growth conditions. Castor (*Ricinus communis* L.) seeds, PI 215769, were obtained from the USDA Germplasm Resources Information Network, Southern Regional Plant Introduction Station (Griffin, GA). Plants were germinated and grown in the greenhouse at temperatures ranging between 28 (day) and 18°C (night), with supplemental metal halide lighting used to provide a 15-h day length (1000–1250 μeinstein/m^2/s). The time of planting was considered to be time zero in developmental studies.

Northern blot analysis. RNA samples were extracted from germinating castor bean cotyledons and true leaves using the method of Gu *et al.* (10). Five micrograms of total RNA was applied to each lane in a 1% agarose gel with 2% formaldehyde. The probe used for hybridization was generated by PCR labeling with digoxigenin (DIG-dUTP) using RcDGAT cDNA as the template and the primers: 5′-AAGACCCCATGGCGATTCTCGAAACGCCAGAA-3′ and 5′-CTGGAGCTTCAGAACCCTCTCAA-3′. Northern analysis was performed based on the DIG Application Manual for Filter Hybridization (Roche Molecular Biochemicals, Mannheim, Germany).

Microsomal preparations. Leaf samples were collected from developing seedlings. Microsomes were isolated as described by Lu *et al.* (11). Briefly, leaves were homogenized in buffer containing 400 mM sucrose, 100 mM Hepes-NaOH (pH 7.5), 10 mM KCl, 1 mM $MgCl_2$, 5 mM EDTA, 2 mM DTT, and a protease inhibitor cocktail tablet per 10 mL (Boehringer Mannheim, Indianapolis, IN). The homogenate was cen-

Abbreviations: DAI, days after imbibition; DGAT, diacylglycerol acyltransferase; RcDGAT, diacylglycerol acyltransferase from *Ricinus communis*.

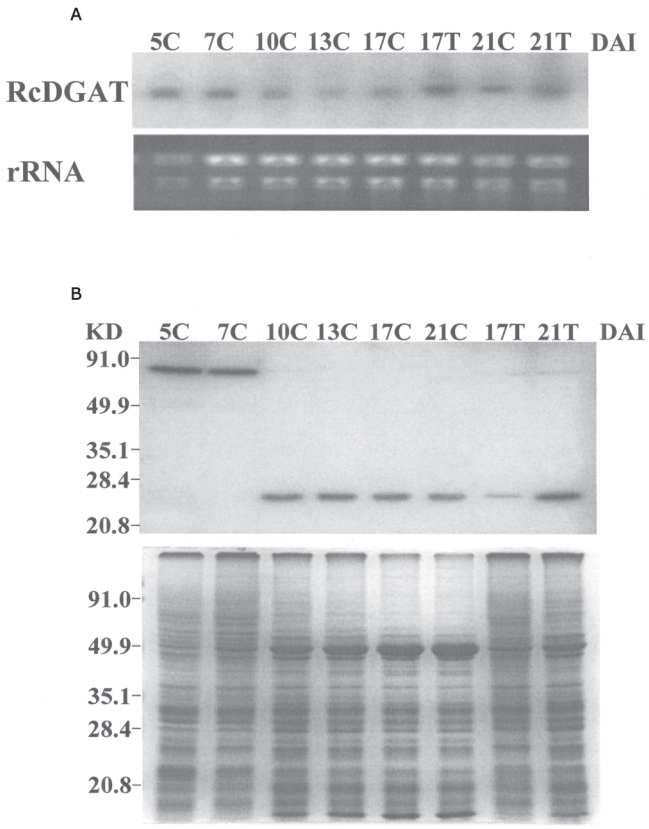

FIG. 1. Expression of castor DAG acyltransferase (RcDGAT) in germinating seedlings. RNA and protein samples were extracted from the cotyledon (C) or true leaves (T) at different stages of seed development from 5–21 d after imbibition (DAI). (A) Total RNA (5 μg) was loaded in each well of the gel for the northern blot analysis and hybridized to the RcDGAT cDNA probe. Ribosomal RNA (rRNA) was stained with ethidium bromide to show equal loading. (B) Total protein (30 μg) was used in SDS-PAGE. Top panel: The western blot was incubated with antibodies against peptide in the C-terminus of RcDGAT. Bottom panel: Duplicate protein gel stained with Coomassie Brilliant Blue R-250 is shown for equal loading of protein.

trifuged at 10,000 × *g* for 10 min to remove cell debris, and the supernatant was spun again at 100,000 × *g* for 90 min. The pellet was resuspended in the homogenizing buffer (microsomal fraction), and the protein concentration was determined using Bradford reagent (BioRad, Hercules, CA). These microsomal preparations were stored at −80°C and used for western blot and DGAT activity assay.

Western blot analysis. Thirty micrograms of microsomal protein from cotyledons and true leaves was separated by SDS-PAGE and electrotransferred to a polyvinylidene difluoride membrane. The membrane was incubated with the anti-RcDGAT antibodies developed previously (9) at 1:5000 dilution, followed by horseradish peroxidase-conjugated goat-anti-rabbit secondary antibodies (Amersham Pharmacia, Piscataway, NJ) at 1:3000 dilution. Horseradish peroxidase activity was visualized by chemiluminescence using the ECL kit (Amersham, Arlington Heights, IL).

In vitro DGAT assay. The DGAT assay was performed as in Cases *et al.* (12) with minor modifications. The [1-^{14}C]ricinoleoyl-CoA was synthesized according to McKeon *et al.* (13). Assay mixtures (100 μL) contained 0.1 M Tris-HCl (pH 7.0), 20% glycerol, 400 μM 1,2-diricinolein prepared previously (14), and 20 μM [^{14}C]ricinoleoyl-CoA (200,000 cpm). Reactions were started by the addition of 100 μg microsomal protein. The reactions were incubated for 15 min at 30°C with shaking and stopped by the addition of 1 μL 10% SDS. The 1,2-diricinolein was prepared as a 10 mM stock in 0.5% Tween-20. Lipids were extracted from assay mixtures using chloroform/methanol as previously described (15). The molecular species of TAG products were separated using C18 HPLC (25 × 0.46 cm, 5 μm, Ultrasphere C18; Beckman Instruments Inc., Fullerton, CA) (16). DGAT activity was determined based on the ^{14}C-label incorporated into the TAG products from [^{14}C]ricinoleoyl-CoA.

Feeding cotyledons and true leaves with exogenous FA. Castor seedling leaves (0.15 g) were sliced into 1 × 5 mm^2 pieces and incubated at 25°C with gentle shaking for 2 h in 1 mL of 0.1 M sodium phosphate buffer (pH 7.2) containing FA (2 mM cold ricinoleic acid and 1.0 μCi [^{14}C]ricinoleic aicd). Assays were terminated by removing the incubation buffer and washing the samples three times with water. The lipids were extracted and analyzed as described below to measure the amount of label incorporated into TAG.

Lipid analysis. Lipids were extracted from 0.15 g of leaves at each developmental stage according to the method of Christie *et al.* (17). Samples were finally stored in methanol with 0.01% BHA at −20°C prior to HPLC analysis. Lipid classes and molecular species of TAG were separated by HPLC as we reported previously and identified by co-chromatography with a lipid standard, matching the retention times from the UV detector (absorbance at 205 nm) and flow scintillation analyzer (18).

RESULTS AND DISCUSSION

Expression of RcDGAT in leaves during castor bean germination. Northern analysis of RNA isolated from cotyledons and the first true leaves showed that RcDGAT was expressed at the transcriptional level in all samples tested (Fig. 1A). This result is in agreement with previous reports for *Arabidopsis* (11,19). In contrast, in immature castor seeds, the RcDGAT protein was not detectable until 1–2 wk after we were able to detect the RcDGAT mRNA. To determine whether the same transcription–translation "uncoupling" occurs in germinating seed, we performed western blot analysis of microsomal proteins from cotyledon and true leaf samples using antibodies against a 15-amino acid peptide in the C-terminus of RcDGAT (9). We detected a significant amount of RcDGAT protein in cotyledon samples at 5–7 d after imbibition (DAI), with most present as full-length protein (~60 kDa) as opposed to the partially degraded form prominent in developing seed (~50 kDa) (9). Previously, we found only trace amounts of mRNA and DGAT protein in the mature, dormant castor seed (9), so we conclude that their presence in the germinating cotyledon is a result of

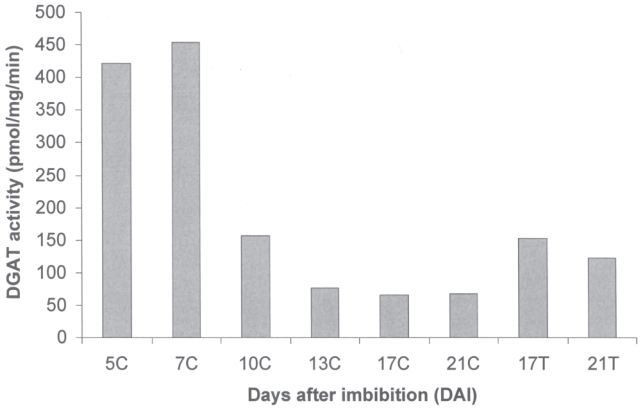

FIG. 2. DAG acyltransferase (DGAT) activities in the C and T from 5 to 21 DAI. Microsomal fractions were used for the DGAT assay. DGAT activities were measured based on the [^{14}C]-label incorporated into the TAG products. Data represent one of three independent experiments. For other abbreviations see Figure 1.

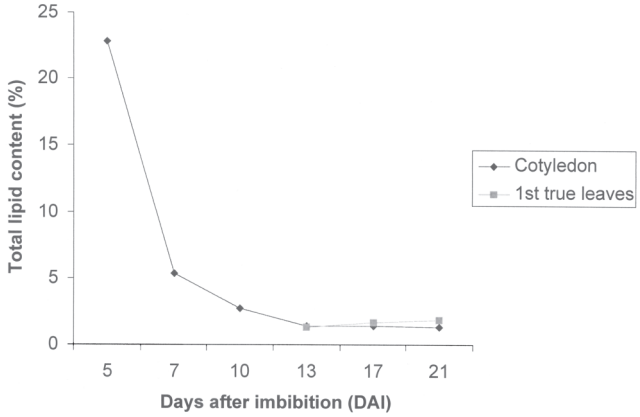

FIG. 3. Changes of lipid content in the cotyledon and true leaves during castor germination. Lipid content was measured as the percentage of total lipids to fresh weight. At each time point, 0.5 g of leaf sample was used to analyze for lipid content. For abbreviation see Figure 1.

new expression, not carryover. However, RcDGAT protein was rapidly degraded after 7 DAI. From 10 DAI, almost all RcDGAT protein in the cotyledons had degraded, whereas only small amounts remained intact in true leaf samples at 17 and 21 DAI (Fig. 1B). We do not know whether degradation of RcDGAT protein during seed germination reflects the *in vivo* situation or whether proteolysis occurred during preparation of the protein extract. However, adding protease inhibitors to the extraction buffer did not block protein degradation (data not shown).

Change of DGAT activity in germinating castor beans. To examine the effect of RcDGAT protein degradation during seed germination, we measured DGAT activity in an *in vitro* assay using microsomes isolated from cotyledons and true leaves (Fig. 2). The highest enzyme activities in cotyledons were detected at 5–7 DAI, the time at which most of the RcDGAT was still present as intact protein. Enzyme activities decreased significantly in cotyledons at 10 DAI and in true leaves at 17 and 21 DAI. In these samples, only small amounts of RcDGAT protein were intact, with most degraded to ~28 kDa. We found much lower enzyme activity in cotyledons at 13–21 DAI (about 6–7 times lower than the activity at 7 DAI), and at these times, almost all RcDGAT protein had been degraded based on western blot analysis (Fig. 1B). This indicates that DGAT activity corresponds directly to the amount of full-length RcDGAT protein. The level of full-length RcDGAT protein is likely to be regulated specifically by proteases in the seedlings since the total amount of protein produced did not differ significantly in cotyledons during seed germination (Fig. 1B).

Change of lipid content during seed germination. The germinating castor bean has a considerable supply of oil to provide energy for growth and development of the seedling. We investigated the lipid content of cotyledons during castor bean germination. The results are shown in Figure 3. We observed a dramatic decrease of the total lipid content at the early stages. The value then changed from 23% of the fresh weight at 5 DAI to 5% at 7 DAI, with a slower decline from 7–13 DAI. At 13 DAI, the lipid content was 1% and remained at this low level thereafter. The lipid contents in the first true leaves were relatively stable from their appearance at 13 (1.3%) to 21 DAI (1.8%). These results suggest that at the early stage of germination, mobilization of storage oil for transfer into the embryo dominates the metabolism in cotyledons, but beyond 13 DAI, the lipid content represents some combination of residual mobilized lipids and *de novo* synthesized lipids.

Rate of TAG synthesis in castor seedling leaves. We showed that the DGAT gene is expressed in seedling tissues. Although lipid biosynthesis is clearly important for membrane production, DGAT has generally been considered to implement a diversion of membrane lipid synthesis to oil production in seeds. Detection of DGAT activity suggests the possibility of *de novo* synthesis of TAG in cotyledons. To determine whether germinating castor bean leaves are capable of synthesizing TAG, we examined the incorporation of [^{14}C]ricinoleic acid into TAG

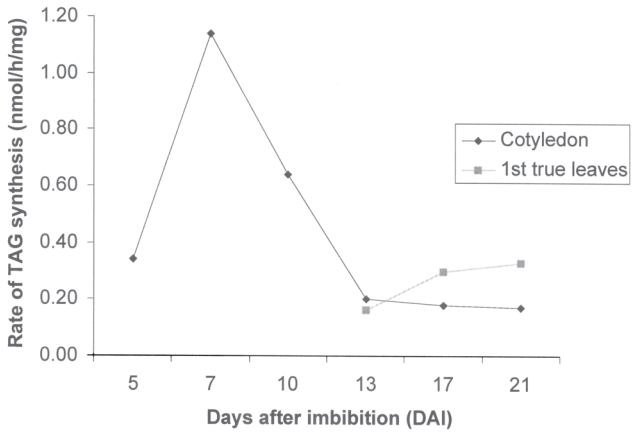

FIG. 4. Rate of ^{14}C-TAG synthesis in germinating castor seedlings. The cotyledon or true leaves (0.15 g) were sliced into small pieces and incubated with ^{14}C-labeled ricinoleic acid in 1 mL of 0.1M sodium phosphate buffer (pH 7.2) at 25°C for 2 h. The rate of ^{14}C-TAG synthesis was calculated as nanomoles of ^{14}C-ricinoleic acid found in TAG per hour in each milligram of tissue. Data represent one of three independent experiments. For abbreviation see Figure 1.

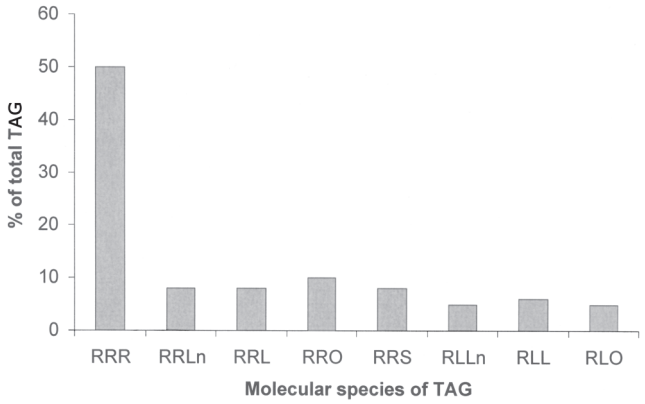

FIG. 5. Molecular species of TAG identified from castor cotyledons at 7 DAI and their contents. The data shown represent each molecular species of TAG as a percentage of total TAG. Abbreviations: R, ricinoleic acid; Ln, linolenic acid; L, linoleic acid; O, oleic acid; S, stearic acid; for other abbreviations see Figure 1.

(Fig. 4). Sliced cotyledons or true leaves were incubated in buffer containing exogenous [^{14}C]ricinoleic acid. The rate of incorporation of ^{14}C from ricinoleic acid into TAG reached a peak at 7 DAI and rapidly declined after that. At 13 DAI, the incorporation rate was one-sixth that at 7 DAI and remained at a low rate to 21 DAI. We noticed that the flux of carbon from ricinoleic acid into TAG was slightly higher in growing true leaves than in senescing cotyledons after 13 DAI. To identify the representative molecular species of TAG that incorporated ricinoleic acid, a TAG fraction was collected from cotyledons at 7 DAI and separated by HPLC on a C18 column. We observed that about 50% of TAG labeled with ^{14}C was triricinolein, indicating that germinating castor cotyledons are not only capable of TAG synthesis, but also of producing oils with characteristics similar to mature castor (Fig. 5).

Castor beans store oil in a living endosperm, which is laterally attached to the cotyledons. The stored oil is mobilized from endosperm into the cotyledons during the first several days of germination. Over the same period, the activities of many enzymes involved in the pathway, including the β-oxidation pathway, the glyoxylate cycle, the tricarboxylic acid cycle, and gluconeogenesis, increase dramatically in the endosperm and the level of sugars (mainly sucrose) increases correspondingly (3). Huang and Beevers (20) reported that the accumulation of sucrose was much higher in endosperm lacking an embryo than with the embryo because in intact seedlings, sugars were absorbed by cotyledons, then used by the growing embryo at 5 DAI. This suggests that the major product of storage oil mobilization during germinative growth is sucrose. Our observations of lipid accumulation at 5 DAI showed that cotyledons contain about 23% lipids (Fig. 3), and 30–35% of that is TAG containing ricinoleate (data not shown). At 5 DAI, the oil reserves are depleted and the endosperm detaches from the cotyledons. The origin of the ricinoleic acid and TAG in the cotyledons is not clear. Since the FA composition differs from the stored oil, TAG is probably not transported directly from endosperms. Therefore, we tested the oleoyl-12-hydroxylase activity in the microsomal fraction of castor cotyledons at 5 DAI using [^{14}C]oleoyl-CoA as substrate (21). When using the method described previously (21), we detected a low level of oleoyl-12-desaturase activity but found no hydroxylase activity, even up to 0.5 mg of microsomal protein. This result suggests that the ricinoleic acid present in the cotyledon is directly mobilized from the endosperm. The appearance of radiolabel in TAG in the feeding experiment clearly indicated that during seed germination, cotyledons have the capacity for *de novo* synthesis of TAG, with the rate of TAG synthesis reaching a peak at 7 DAI and declining rapidly. From 13 DAI, cotyledons and true leaves maintained a basal level of TAG synthesis. These results are consistent with the change of RcDGAT protein and activity during germination (Fig. 1B, Fig. 2), except the rate of TAG synthesis at 5 DAI is much lower than that predicted based on the profile of the DGAT activity assay. One possible explanation for this discrepancy is that the FA content in the cotyledon at 5 DAI is much higher than at any other time point, and labeled exogenous FA could easily be diluted, resulting in an apparently low incorporation of [^{14}C] into TAG.

We have accumulated several different lines of evidence that we believe support the idea that castor cotyledons can carry out TAG biosynthesis. The induction of DGAT mRNA and protein, the capacity for TAG synthesis *in vitro* and in tissue slices, and the differing TAG composition of dormant seed TAG vs. cotyledonary TAG provide strong circumstantial evidence for active TAG synthesis by cotyledons. However, demonstration of such activity is not proof of physiological relevance, so we can only speculate about the underlying meaning of our observations of TAG synthesis in cotyledons from germinating seeds. We suggest that at early stages of germination, when plant photoautotrophism is not fully established, the TAG synthesized and stored in leaves provides a source of energy that maintains seedling development. During the germination of castor beans, storage fats in the endosperm are converted to sucrose with high efficiency, which can result in the accumulation of sugars. In seedlings grown on high levels of sucrose, levels of FA have been observed to be much higher than seedlings grown on low levels of sucrose (22). Since energy mobilization is of importance in early seedling development, it is possible that excess sugar production is channeled into TAG for storage or utilization to prevent osmotic effects. Three enzymes, i.e., DGAT1, DGAT2 (23), and PDAT (24), have been reported to have the ability to catalyze the final step of TAG synthesis. Whether DGAT2 and PDAT are involved in the TAG synthesis we observed in extracts from germinating seeds is not known, but we believe that RcDGAT is one of the rate-limiting enzymes for TAG synthesis in castor seed (9). Still, how this enzyme is regulated during the senescence of leaves is not at all clear. Figure 1B shows unambiguously that the RcDGAT protein is expressed throughout seedling development. A significant degradation of the RcDGAT protein is observed in cotyledons and true leaves after 10 DAI, and changes in enzyme activities closely reflect those of intact protein levels. If there is TAG biosynthesis during germination, then our data

suggest that TAG biosynthesis is regulated by the level of active RcDGAT protein, and proteolytic degradation of the protein regulates its activity. This is in contrast to DGAT expressed in castor seed development, during which the DGAT is partially degraded yet remains active. RcDGAT degradation may be associated with the accumulation and release of endopeptidases from ricinosomes during seed germination. In the castor bean, cysteine endopeptidase is a marker for ricinosomes (25), organelles found exclusively in plant tissues undergoing developmentally determined programmed cell death (26). The castor bean cotyledon represents a senescing tissue, programmed to die during germination after its cellular material has been mobilized for transfer into the embryo. The decline in measurable DGAT activity suggests that targeted proteolytic degradation may be one method for controlling DGAT activity in castor tissue.

ABSTRACT: Raman spectroscopy has been used for the first time to predict the FA composition of unextracted adipose tissue of pork, beef, lamb, and chicken. It was found that the bulk unsaturation parameters could be predicted successfully [R^2 = 0.97, root mean square error of prediction (RMSEP) = 4.6% of 4 σ], with *cis* unsaturation, which accounted for the majority of the unsaturation, giving similar correlations. The combined abundance of all measured PUFA (≥2 double bonds per chain) was also well predicted with R^2 = 0.97 and RMSEP = 4.0% of 4 σ. *Trans* unsaturation was not as well modeled (R^2 = 0.52, RMSEP = 18% of 4 σ); this reduced prediction ability can be attributed to the low levels of *trans* FA found in adipose tissue (0.035 times the *cis* unsaturation level). For the individual FA, the average partial least squares (PLS) regression coefficient of the 18 most abundant FA (relative abundances ranging from 0.1 to 38.6% of the total FA content) was R^2 = 0.73; the average RMSEP = 11.9% of 4 σ. Regression coefficients and prediction errors for the five most abundant FA were all better than the average value (in some cases as low as RMSEP = 4.7% of 4 σ). Cross-correlation between the abundances of the minor FA and more abundant acids could be determined by principal component analysis methods, and the resulting groups of correlated compounds were also well-predicted using PLS. The accuracy of the prediction of individual FA was at least as good as other spectroscopic methods, and the extremely straightforward sampling method meant that very rapid analysis of samples at ambient temperature was easily achieved. This work shows that Raman profiling of hundreds of samples per day is easily achievable with an automated sampling system.

Paper no. L9812 in *Lipids 41*, 287–294 (March 2006).

Government dietary guidelines in the United Kingdom (UK) are based on the assumption that nutritional or dietary management, and in particular management of dietary lipid intake, can help reduce mortality and morbidity from cardiovascular disease (CVD). At present, UK Department of Health guidelines (1994) recommend that the contribution of lipid intake to total dietary energy should be reduced from about 40 to 30% of dietary energy intake and that the contribution from saturated FA in particular should be reduced from 15 to 10% of total energy intake (1). They also recommend that the ratio of PUFA to saturated FA in the diet should be increased (1). Many studies have identified the involvement of a high intake of saturated fat with increased risk of CVD (2–4), and specific saturated FA are now recognized to have hypercholesterolemic effects. In a review of studies investigating the cholesterolemic effects of individual FA, Kris-Etherton and Yu (5) concluded that the saturated FA 12:0–16:0, were hypercholesterolemic but that the unsaturated FA were hypocholesterolemic, with PUFA being more potent than monounsaturated FA. The essential n-3 FA, such as 18:3 α-linolenic acid, have also been demonstrated to have health benefits by lowering blood lipid concentrations and reducing the risk of platelet aggregation and thrombosis (6). Finally, in recent years there has been much interest and research on the potential health benefits of consumption of CLA, and the anticarcinogenic and antiatherosclerotic properties of some isomers of CLA have been demonstrated in animal studies and models (7–10).

The net result of all the foregoing is that it is becoming increasingly important to measure the abundance of individual FA in the complex mixtures of lipids that are found in foods. This is particularly true for samples that have been deliberately treated to move their FA composition away from "typical" values. For example, the saturated nature of animal lipids has adversely influenced their perception by consumers; this has led to research aimed at reducing the high level of saturated FA and increasing the proportion of PUFA in both meat and milk lipids through dietary manipulation (11–14).

This paper is part of a series that investigate the feasibility of applying Raman spectroscopy to the analysis of FA-based fats and oils (15–18). In previous experimental studies, the correlation between particular bands in the Raman spectra of solid and liquid samples of pure FAME (15) and properties such as average chain length was investigated. This experimental work on FAME was complemented by density functional calculations, which allowed the underlying reasons for the experimentally determined structure/spectra correlations to be explored (16,17). Application of the same approach to real foodstuffs (clarified butterfat) showed that even with mixed TG, rather than simple model FAME, bulk composition parameters, e.g., chain length or iodine value, could be determined from Raman spectra (18). Furthermore, in addition to bulk or average properties, it was also possible to build multivariate calibration models that allowed the abundance of individual FA to be determined (18). The ability to monitor levels of desirable/undesirable components is obviously important in dietary lipids.

Here we extend the work on butterfat to investigation of adipose tissue; the aim is to find whether Raman spectra can still be used to predict FA composition when the samples are drawn from a much broader range of sources, including tissue from different species.

EXPERIMENTAL PROCEDURES

Samples. The samples used in this investigation were subcutaneous adipose tissue dissected from above the *Longisimus dorsi* in the position of the 12th rib for beef, lamb, and pork, and from above the breast for chicken. As it is well known that the FA composition varies between the inner and outer surfaces of adipose tissues, care was taken when dissecting the samples to note the outer (next to skin) and inner (next to muscle) surfaces of the adipose tissue. Samples were obtained from a number of research sources and were all dissected within 48 h of slaughter.

GC. GC was the primary analysis method in this study. Subsamples (*ca.* 0.2–0.5 g) of adipose tissue were dissected from the regions, on each surface of the samples, that had been Raman probed. These samples were then extracted three times in 10 mL of 2:1 chloroform/methanol. FAME were prepared from the extracted fat according to the British Standard method (British Standards Institute BS 684-2.34) and were analyzed by GC (18). Aliquots of FAME in heptane (0.1 μL) were injected *via* a septa programmable injector at 250°C onto a GC column (WCOT CP Sil-88; i.d. 0.25 mm; length 50 m; film thickness 0.2 μm) supplied by Varian Inc. (Middelburg, The Netherlands) fitted in a Varian 3400 gas chromatograph (GC). An FID was used, and the heating program was ramped as follows to improve separation of the FA peaks: 50°C for 1.0 min, 50 to 140°C at 20°C min^{-1}, 140 to 225°C at 5°C min^{-1}, and finally 225°C for 10.0 min. Pure FAME, obtained from Sigma-Aldrich (Poole, UK), were used to prepare internal and external standards to establish retention times and peak identification. The following acids, as well as all FA 20 carbons in length, were undetectable in at least one species: 12:0, 14:1*c*Δ9, 15:1*c*Δ10, 17:1*c*Δ10, and 18:2*t*Δ9,12. Only FA detectable in more than half the samples were investigated. The total combined abundance of PUFA was determined by summing the relative abundances of all the PUFA including those only detected in pork and chicken (half of the samples).

Raman spectroscopy. Raman measurements were carried out using a 785 nm excitation wavelength (typically 100–120 mW at the sample, 10 cm^{-1} resolution, 180° geometry) generated by a home-built spectrometer previously described (19). Raman spectra of 8–10 samples of each of the four species were recorded. The sample was mounted on a rotating stage, oriented with the surface perpendicular to the incident radiation. The laser was line focused on the surface of the sample while the stage was rotated, giving an approximate coverage of 1.5 cm^2. Spectra were accumulated from both sides (outer and inner) to give two separate spectra for each sample, yielding a total of 16–20 spectra per species. Wavelength calibration was carried out using a neon emission lamp. The spectrograph was calibrated for Raman shift using a 50:50 (vol/vol) acetonitrile/toluene mixture [comparing to frequency standards from the American Standard Testing Method (ASTM E 1840 (1996)]. The Raman signal was recorded from 270 to 1900 cm^{-1}, the region containing the C–C, C=C, C–O and C=O, stretches and the C–H bends, in two sequential 60-s accumulations.

The non-Raman background in the raw data was removed, and the spectra were normalized and mean-centered as previously described (18). Standard partial least squares (PLS) analysis was carried out between the Raman data and FA profiles (using PLS2 to simultaneously model the full range of FA) using The Unscrambler™ v9.1 (Camo, Trondheim, Norway) and leave-one-out cross-validation to confirm the predictive ability of the model generated. During the PLS analysis of the data the Uncertainty Test was used to select the wavenumber shifts correlated with the measured parameter and reject wavenumber shifts not contributing to the prediction. To test the predictive ability of the models on unknown samples, calibrations were generated using PLS2 with test set validation. The data set was prepared by removing a subset of 10 randomly selected spectra and the model constructed from the remaining 63 samples and validated using the subset of 10. All species were represented in the test set.

RESULTS AND DISCUSSION

Figure 1 shows the average Raman spectrum of adipose tissue from each of the species used in this experiment. The major bands have been assigned previously, but for convenience they are numbered on the Figure and the most important assignments are given in Table 1. The differences between the average adipose tissue spectrum of each species, as shown in Figure 1, are larger than the differences between the butterfats obtained under various feeding regimes that were studied previously (18). The average FA profiles of the four species studied and the corresponding average bulk properties are given in Tables 2 and 3, respectively. The data in Figure 1 show that the samples are partly melted because the spectra show features similar to those characteristic of both liquid FAME (which give only broad unresolved features in several spectral regions) and solid FAME (which typically display sets of narrow, well-defined bands (15). The differences between solid and liquid FAME are particularly noticeable at *ca.* 1000–1200 cm^{-1}, and in the spectra shown in Figure 1 there are sharp solid-phase peaks on top of underlying broad liquid-phase bands in this spectral range.

Since the Raman spectra contain readily identifiable bands associated with particular groups, such as C=C bonds or CH_2 groups, it would be expected that the Raman spectrum of a mixed sample, being an ensemble average of the spectra of the individual FA chains present, would reflect the bulk sample properties. For example, the determination of unsaturation (measured as C=C per chain or per gram, i.e., in molar or molal units, respectively) is the most widely investigated aspect of the Raman spectra of lipids. In the adipose tissue samples investigated here, the level of unsaturation (the number of *cis* un-

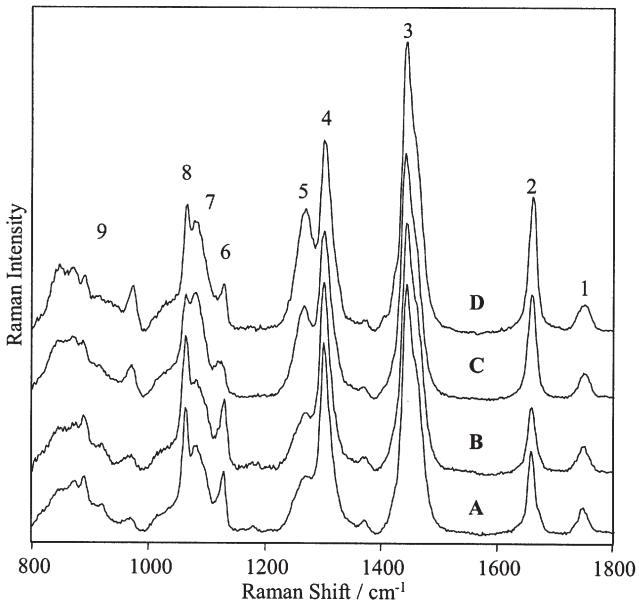

FIG. 1. Average Raman spectra for each species: (A) beef, (B) lamb, (C) chicken, and (D) pork. The numbering of the bands refers to the band positions and assignments given in Table 1. saturated bonds per chain, i.e., molar unsaturation) was well-predicted using standard PLS2 methods, which gave a correlation coefficient of $R^2 = 0.97$ and a root mean square error of prediction (RMSEP) of 4.6% of the range. In contrast, it was not possible to find a good prediction model for *trans* unsaturation; the best model gave $R^2 = 0.52$ and RMSEP = 18% of the range. This poor *trans* prediction ability is due to the low range of relative abundances of *trans* unsaturated bonds in the adipose tissue (0.031, compared with 0.24 bonds per FA for *cis* unsaturated bonds). However, it has previously been demonstrated that Raman spectroscopy is capable of accurately predicting *trans* content in samples with a larger range of *trans* values (20). Total unsaturation (sum of *cis* and *trans*) was predicted with similar accuracy to the *cis* content, primarily because the low *trans* unsaturation meant that it was the well-predicted *cis* contribution that dominated total unsaturation.

In addition to unsaturation, another major compositional parameter is the average chain length. It was found that, as was the case for butterfats and model FAME, the Raman spectra could be used to predict average chain length satisfactorily, $R^2 = 0.92$ and RMSEP = 6.9% of the range. Since the chain length is the sum of the number of saturated and unsaturated C–C bonds and both chain length and unsaturation were modeled satisfactorily in this sample set, it would be expected that the third parameter, number of saturated C–C bonds, could also be modeled. However, it was found that even the best model gave an unsatisfactory correlation, $R^2 = 0.58$, for the average number of C–C bonds per chain. Although this result appears anomalous, it is a straightforward consequence of the fact that the number of saturated bonds per chain varied very little between samples ($\sigma = 0.07$, compared with 0.24 for unsaturated bonds), which made it difficult to model. In effect, the number of saturated bonds was almost constant in all the tissue samples so that modeling the increase in double bonds effectively also measured the increase in chain length over a constant baseline value of *ca.* 15.5 saturated C–C bonds per chain. In sample sets with a larger range of saturated C–C values it should be possible to obtain a better calibration.

The ability to predict bulk composition parameters from Raman spectra is not surprising if the spectra of individual FA are simply regarded as the sum of the contributions from individual entities, because incremental structural changes would be expected to give incremental increases in the intensities of the associated vibrational bands. For example, addition of CH_2 groups into the chain would be expected to increase the intensities of the vibrations associated with the methylene groups, such as the CH_2 twist and scissoring bands. However, if this model were strictly accurate, it would be impossible to determine relative proportions of the individual constituents in samples containing mixtures of different FA since there would be many ways of preparing different mixtures with the same bulk properties, which would therefore give the same overall spectrum. However, experimental and theoretical studies on model FAME showed that, whereas many of the vibrational modes did show the expected incremental changes with changing structure, there were some bands that did not follow a smooth progression and potentially might allow the variation in indi-

[a]Mean weight percentage of total FA (g/100 g FA) for all samples used within investigation.
[b]SD of the % total mass of lipid from the mean.
[c]Least squares regression correlation coefficient (validation).
[d]Root Mean SE of prediction (RMSEP) as absolute value and as percentage of mean (RMSEP % of μ) and sample range (RMSEP % of 4 σ).
[e]Root Mean SE of estimate (RMSEE), determined by test set validation, removing a subset of 10 samples.
[f]The isomers for 18:1*t* are not well resolved, so the figure is for an undifferentiated mixture of isomers.
[g]These FA are unassigned due to difficulty in unambiguously identifying the different 20-carbon unsaturated FA under the experimental conditions used in this study.
[h]PUFA represents the combined abundances of all measured FA with ≥2double bonds in the chain. FA groups, as determined by grouping in principal components analysis: Group 1 = 18:3*c*Δ9,12,15; 18:2*c*Δ9,12; 20:xa ; Group 2 = 18:2*t*Δ9,12; 18:1*c*Δ9, 18:3Δ6,9,12; 16:1*c*Δ9; Group 3 = 16:0, 18:1*t*Δ9; 15:0, 17:1*c*Δ10; 14:0; 14:1*c*Δ9; 17:0; Group 4 = 20:xb; 20:xc*; Group 5 = 20:0, 18:0. *Here the symbols 20xa–c stand for three different 20-carbon FA, which could be distinguished in the GC but could not be unambiguously identified.

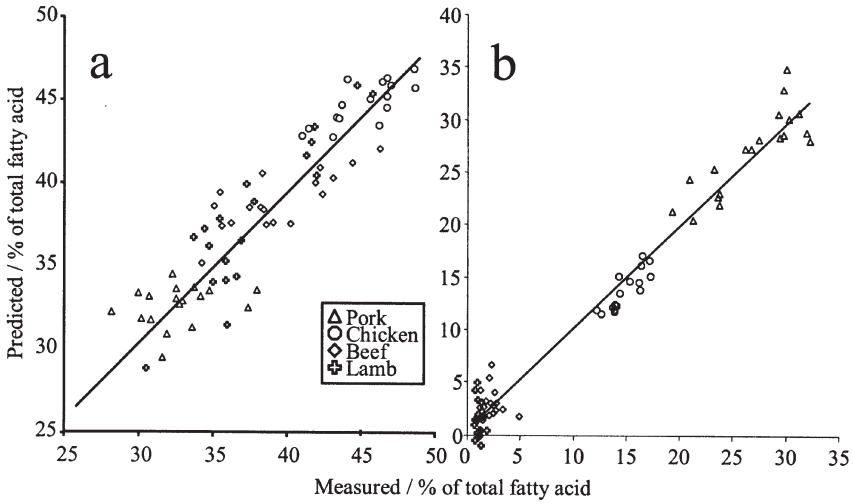

FIG. 2. Partial least squares (PLS) regression validation plot for (a) percentage of 18:1*c*Δ9 and (b) percentage of 18:2*c*Δ9,12 compared with total FA content (g/100 g FA) in subcutaneous adipose tissue predicted from Raman spectra against the percentage of total FA measured by GC.

vidual constituents to be determined, even in mixed samples with the same bulk composition (15,17).

Previously it was found that PLS1 regressions of Raman data against the amounts of individual FA in butterfat samples (18) (determined by GC as percentage of total FA) could be used to predict the relative proportions of the major FA in butterfat. In the previous study PLS1 regressions were used to create individual calibration models for each FA; in this study PLS2 was used so that we could generate a single model that predicted all the FA in the profile. The PLS2 approach gives slightly reduced prediction accuracy but it is preferable owing to its inherent simplicity. Table 4 shows the results for a PLS2 regression carried out for 73 samples of subcutaneous adipose tissue. The samples were taken from four different species, which ensured the extent of variation of each individual FA was acceptably large, but they were not separated according to

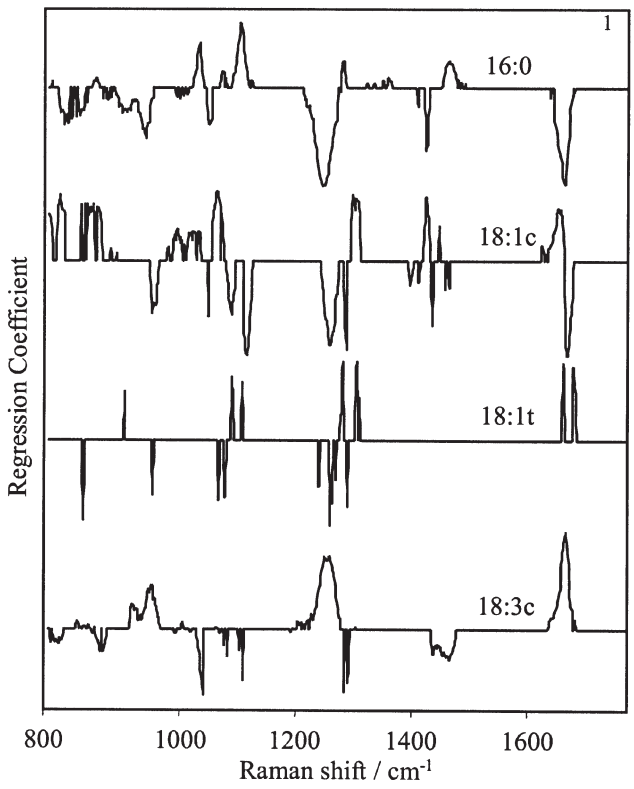

FIG. 3. PLS regression coefficients used to predict, from the Raman spectra of intact tissue at 19–21°C, the percentage of total FA content of 16:0, 18:1*c*Δ9, 18:1*t*, and 18:3*c*Δ9,12,15 in subcutaneous adipose tissue, as determined by GC. For abbreviation see Figure 2.

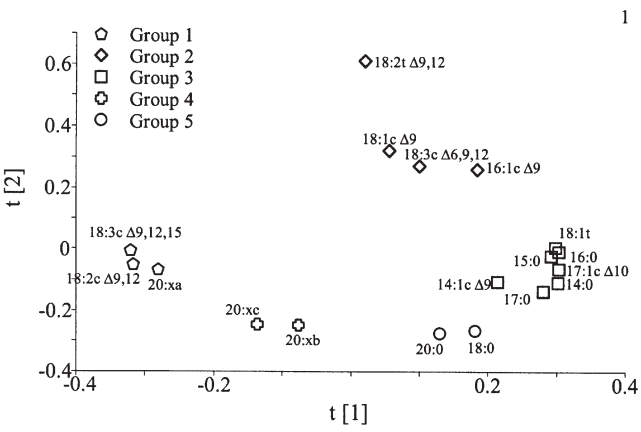

FIG. 4. Principal components analysis loading plot for the GC data, showing the groups of interrelated FA present in adipose tissue. Group 1 = 18:3*c*Δ9,12,15, 18:2*c*Δ9,12,20xa; Group 2 = 18:2*t*, 18:1*c*Δ9, 18:3*c*Δ6,9,12, 12:0, 16:1*c*Δ9; Group 3 = 16:0, 18:1*t*, 15:0, 17:1*c*Δ10, 14:0, 14:1*c*Δ9, 17:0; Group 4 = 20:xb 20:xc; Group 5 = 20:0, 18:0. Here the symbols 20xa–c stand for three different 20-carbon FA, which could be distinguished in the GC but could not be unambiguously identified.

species for the purpose of regression. The Table shows that the four most abundant FA analyzed had regression correlation coefficients ranging from R^2 = 0.80 to 0.97, with standard errors of prediction ranging from 4.7 to 11.3% of the range (4 σ). Example regression plots of the most common FA (18:1*c*Δ9) and that of the FA with the largest range (18:2*c*Δ9,12) are shown in Figure 2. Of all the moderately abundant (>3%) FA, 18:1*c*Δ9 gave the poorest correlation (due to the relatively narrow range of values, range = 14% of the mean, compared with 98% of the mean for 18:2*c*Δ9,12) but it is clear from Figure 2 that even in this worst case the scatter in the plot is still reasonably small with no systematic error apparent. This is reflected in the prediction error of 6.4% of the mean, which is acceptably low for a rapid, nondestructive analytical method. These FA are of particular interest as they confer the predominant chemical and physical characteristics of the lipids within the adipose tissue and furthermore have important consequences in health and nutrition. For example, 16:0 is known to be hypercholesterolemic, whereas the *cis* unsaturated acids lower cholesterol (in particular, LDL).

The loadings used to predict the proportion of selected FA from the Raman spectrum are presented in Figure 3. The pattern of bands used to predict each FA agrees well with well-established assignments of the bands in the Raman spectrum of FAME. The saturated FA 16:0 has positive correlation coefficients in positions known to arise from saturated modes (e.g., 1440, 1300, 1130, and 1060 cm^{-1}) whereas bands related to unsaturated modes are negative (e.g., 1270 and 1660 cm^{-1}). Conversely, the unsaturated FA would be expected to have positive coefficients for unsaturated modes and negative coefficients for saturated modes. The weighting plot for 18:3*c*Δ9,12,15 shows the expected pattern, such as large positive bands at 1660 (*cis* C=C stretch) and 1270 cm^{-1}. The 18:1*t* FA shows some of the expected bands such as positive bands at the *trans* C=C stretch position (1670–1680 cm^{-1}), but the correlation is less obvious than the 18:3*c*Δ9,12,15, which is hardly surprising given the low abundance in the sample and the corresponding high prediction error. The weighting plot for 18:1*c*Δ9 is complicated by the occurrence of strong negative and positive components, which, although they presumably arise from changes in saturation from the mean values, are so close to those values (18:1*c* is the predominant FA in adipose samples) that the model can only find a very complex relationship between the abundance of 18:1*c* and the spectra.

Surprisingly good predictions were obtained for a number of the less abundant FA, with 15:0 and 17:0 giving R^2 = 0.82 and RMSEP = 10.5% of the range, despite being present in relative abundances of 0.5% of the total FA content. It seems highly unlikely that these low-abundance compounds give distinct characteristic signals that are detectable under our experimental conditions, since the intensity of even the strongest bands in a FA present at <1% would be similar to the noise in the data, and the differences that would allow the particular FA to be distinguished from similar compounds in the tissue would be expected to be much smaller again. A more convincing explanation is that this good modeling ability arises from an underlying correlation between the low-abundance FA and much more abundant ones whose signals would be expected to be detectable. Since the adipose tissue is a product of biosynthetic pathways, such cross-correlation might be expected. In this study the samples were dissected from four animal species (two ruminant and two nonruminant) with a selection of breeds from within each species to minimize cross-correlation. Moreover, a range of experimental programs and commercial suppliers was used to reduce the influence of feeding regimes. The consequence is that the cross-correlation is significantly less than that in the butterfat samples previously studied (18), so the correlation determined within this sample set is more widely applicable.

One way of explicitly including the cross-correlation in the analysis and simplifying the data is to carry out a principal components analysis (PCA) and divide all the FA into groups according to which others their abundance correlates with. Figure 4 shows such a plot for the FA in this study. The FA abundances for each of the five groups found in the PCA analysis of the data were then summed, and the Raman spectra were used to model the variation between the FA groups. The results of these regressions of the FA groups are summarized in Table 4, with details of contributing FA given in the footnote. The one obvious group is the FA set comprising 18:2*t*Δ9,12; 18:1*c*Δ9; 18:3Δ6,9,12; 12:0; and 16:1*c*Δ9 while another large group contains highly *cis* unsaturated compounds 18:2*c*Δ9,12, 18:3*c*Δ9,12,15, and 20xa (which is one of the unassigned 20-carbon unsaturated FA). The Raman spectra were able to predict the total abundance of all of these groups with some success. In fact, the least well-modeled group is the one constituting the largest fraction of the sample, although this may be attributed to the lower range of values relative to the mean abundance (range < 0.66 σ) that this group shows (in the remaining groups the range was >1.5 σ).

A further useful group that can be defined, though not cross-correlated by relative abundance, is the combined proportion of PUFA. This group of FA, as detailed above, is of extreme interest because of their relevance to health issues. Raman spectroscopy was able to model this group well (R^2 = 0.97, RMSEP = 4.0% of 4 σ). One individual FA that is of particular interest is the EFA 18:3*c*Δ9,12,15, which was well modeled (R^2 = 0.932) with good prediction accuracy (7.6% of 4 σ). Using a PLS1 regression allows models to be optimized for any given FA. In this case, using PLS1 regression to predict 18:3*c*Δ9,12,15 gave a slightly better result than PLS2 (R^2 = 0.946, RMSEP = 5.8% of 4 σ). As already alluded to, Raman spectroscopy is able to predict the relative abundances of several FA that influence the level of cholesterol in the blood including 14:0 and 16:0, which increase cholesterol, and the unsaturated FA, which are important in reducing cholesterol. Unfortunately the limitations of the GC method used did not allow calculation of the cholesterolemic index, but the results suggest that Raman could be used to predict this important parameter. One FA of interest, CLA, was not detected in large quantities in concentrate-fed ruminants, most probably because it was not sufficiently resolved from the more abundant 18:3Δ9,12,15

on the GC column used in this study. However, it has been previously demonstrated that Raman spectroscopy can be used to predict the relative abundance of CLA in butterfats from grass-fed cows, where higher concentrations are found (18).

Overall, the prediction ability for the FA in this study on adipose tissue (average R^2 = 0.74 and average RMSEP = 12.0% of 4 σ for the 18 most abundant FA) was significantly better than was found in experiments carried out on clarified butter samples analyzed at 55°C [average R^2 = 0.68, and average RMSEP = 18.5% of 4 σ for the 18 most abundant FA (18)]. This improvement is not due to higher signal-to-noise ratios in the adipose spectra but seems to stem from the fact that the spectra of the adipose tissue were recorded at temperatures within the melting range whereas those of the butterfat were recorded on fully melted samples (although the slightly larger range of abundances for the FA in the adipose samples may also have contributed). Since the Raman spectrum of each FA changes with physical state, recording spectra in a temperature range that allows the adoption of different physical states, i.e., within the melting range, gives information that is simply lost at temperatures where all the components have melted. In this case the adipose tissue was run at 21 ± 2°C (ambient temperature), which allowed the higher m.p. TG to solidify and give rise to characteristic sharp bands that can easily be distinguished from the broader bands of the liquid constituents (shorter-chain or unsaturated components).

The results shown in Table 4 compare favorably with other published investigations that used spectroscopic techniques to predict FA composition. A number of papers investigating the use of NIR spectroscopy to predict FA composition of foodstuffs (21–24) found that it is possible to predict the proportion of the major unsaturated FA well (R^2 typically ≥0.95 for the most abundant unsaturated FA) but that the prediction ability is reduced as the proportion of the FA decreases and the saturation increases. Velasco *et al.* (23) found the NIR regression correlation coefficients for saturated FA such as palmitic and stearic acids in rapeseed were lower (<0.8) that those for unsaturated FA, which were between 0.84 and 0.98 (25). Kohler and Kallweit (21) found that the NIR regression correlation coefficients for the 15 major FA in sheep intramuscular fat ranged from r = 0.57 to 0.90 (R^2: 0.32–0.81). When FTIR was used to predict the FA composition of dissected but unextracted adipose tissue (26) it gave poor correlation coefficients for the main FA (R^2 = 0.69–0.79) although much better correlations (R^2 = 0.91–0.98) were found if the tissue was extracted before analysis. Similarly, NIR analysis had poorer prediction ability for the less significant FA compared with Raman analysis (21).

It is clear that Raman has the advantage of giving correlation coefficients as high as the best of the other spectroscopic methods, and it can do this without the need for prior solvent extraction steps in the analysis. The most common method of determining the FA profile of adipose tissue and similar TG systems is to use GC; typically, 100-m capillary columns and temperature ramps are required to obtain effective separation and identification of isomers. Since this GC method requires time-consuming, destructive sample extraction and transmethylation, the ability to use Raman spectroscopy, with a simple calibration, on unextracted, dissected tissue is a significant advantage.

Thus, Raman spectroscopy can accurately predict the bulk properties of adipose tissue and a detailed FA profile of the 18 most abundant FA found in neat adipose tissue with an accuracy at least as good as that of other spectroscopic methods but with extremely straightforward sampling. The bulk unsaturation parameters could be predicted successfully (*cis*: RMSEP = 4.7% of 4 σ; total PUFA RMSEP = 4.0% of 4 σ) but *trans* unsaturation was not so well modeled (RMSEP = 18% of 4 σ). For the individual FA, the average RMSEP of the 18 most abundant FA was 11.9% of 4 σ while the prediction errors for the five most abundant FA were all better than the average value (in some cases as low as RMSEP = 4.7% of 4 σ). Of particular note was the ability of Raman spectroscopy to predict quantities important in human health, such as the proportion of 18:3*c*Δ9,12,15 present, or the total proportion of PUFA. The accuracy of the prediction, although as good as other spectroscopic methods, does not approach that of conventional GC methods: This method is not intended as an alternative to established chromatographic methods for high-accuracy profiling. The approach is predominantly aimed at on-line applications, in which the lower accuracy is compensated by the ability to make rapid, noncontact measurements with no additional sample preparation.

Fluorescent Image Analysis of Lipid Hydroperoxides in Fish Muscle with 3-Perylene Diphenylphosphine

Chatchawan Chotimarkorn, Toshiaki Ohshima, and Hideki Ushio*

Department of Food Science and Technology, Tokyo University of Marine Science and Technology, Tokyo, Japan 108-8477

ABSTRACT: A fluorescent image analysis method was developed to evaluate lipid hydroperoxide formation in fish muscle. The lipid hydroperoxides generated in white and dark fish muscles during storage at 5–6°C oxidized 3-perylene diphenylphosphine located in the tissue to yield the fluorescent derivative, 3-perylene diphenylphosphine oxide (3-PeDPPO). 3-PeDPPO thus obtained was determined by digital fluorescent image analysis. The 3-PeDPPO fluorescence intensity of white and dark muscle increased during low-temperature storage (0–24 h) and was clearly correlated with total lipid hydroperoxide levels in muscle extracts, which were determined by using HPLC based on a triphenylphosphine oxidation method (R^2 = 0.954). These results suggest that 3-PeDPPO fluorescence, coupled with fluorescent image analysis, is a novel tool for direct determination of lipid hydroperoxides in fish muscle without a need for extraction of lipid.

Paper no. L9892 in *Lipids 41*, 295–300 (March 2006).

Lipid peroxidation is a major cause of the deterioration of fatty fish during storage because of its high content of PUFA. Several methods have been proposed to quantify hydroperoxides in food and biological systems, including an iodometric assay (1), complexation of Fe(III) (2), enzymatic reaction (3), and chromatographic techniques (4–6). Some significant investigations of lipid peroxidation have been carried out by reducing hydroperoxides with a triarylphosphine possessing a fluorophore instead of the phenyl group of triphenylphosphine (TPP), such as diphenyl-1-pyrenylphosphine (DPPP), and quantifying the resultant formation of the arylphosphine oxide by its intense fluorescence (7). However, DPPP has fluorescence excitation and emission wavelengths in the UV region, possibly causing lipid peroxidation when irradiated by itself. Recently developed advanced image analysis methods support visual subjective tests in the routine evaluation of food quality. Fluorescent image analysis is a selective and sensitive method that offers several advantages, including easy and accurate identification of structures, quantification at low concentrations, high analysis speed, and rapid sample preparation and determination (8). Although direct image analysis on cultured cells with DPPP oxide fluorescence has been reported (9–11), fluorescent compounds such as tocopherols will also interfere with the DPPP image analysis of meats because of overlapping fluorescence emissions. In this study, a novel fluorescent probe, 3-perylene diphenylphosphine (3-PeDPP) (12,13), was applied to a fluorescent image analysis for the quantification of lipid hydroperoxide (LOOH) generated in fish muscle during low-temperature storage.

In our previous reports, fluorescence intensity increased dramatically when 3-PeDPP was oxidized to 3-perylene diphenylphosphine oxide (3-PeDPPO), the corresponding oxidation product of 3-PeDPP, which has an excitation wavelength at 440 nm (12,13). In the present study, the 3-PeDPP fluorescent probe showed better selectivity in combination with fluorescent image analysis for quantification of LOOH. Successful measurement allows the possible application of 3-PeDPP with fluorescent image analysis as a novel tool to detect LOOH formation in fish muscle directly and satisfactorily.

MATERIALS AND METHODS

Chemicals. 3-PeDPP was prepared from 3-bromoperylene and TPP and identified as previously described (12,13), based on the method of Akasaka *et al.* (7). The purified 3-PeDPP was kept as the solid under nitrogen gas (N_2) in the dark at −20°C until use. The solution of 3-PeDPP was freshly prepared before the experiment to prevent 3-PeDPP oxidation. 2-Thiobarbituric acid and 2,6-di-*tert*-butyl-*p*-cresol (BHT) were purchased from Tokyo Kasei Kogyo Co. Ltd. (Tokyo, Japan). Cumene hydroperoxide (CumOOH) and TPP were purchased from Sigma-Aldrich Japan (Tokyo, Japan). Dimethyl sulfoxide was purchased from Wako Pure Chemical Industries (Osaka, Japan). PBS powder was purchased from Nissui Pharmaceutical Co., Ltd. (Tokyo, Japan). Other organic solvents and chemical reagents were of analytical grade and used without further purification. Commercial tuna oil (T.C. Union Food Co., Ltd., Bangkok, Thailand), soybean oil (Miyazawa Yakuhin Co., Ltd., Tokyo, Japan), and cashew nut oil (extracted in the laboratory) were used as sample oils. These oils were purified by open column chromatography on Spherical silica gel 60 40–50 μm (Kanto Chemical Co. Inc., Tokyo, Japan) by using *n*-hexane followed by 7% of diethyl ether in *n*-hexane.

Preparation of white and dark muscles. A sample of yellowtail (*Seriola quinqueradiata*) was purchased from a local fish market. The specimen was separated into white muscle and

Abbreviations: a.u., arbitrary units; CumOOH, cumene hydroperoxide; DPPP, diphenyl-1-pyrenylphosphine; LOOH, lipid hydroperoxide; 3-PeDPP, 3-perylene diphenylphosphine; 3-PeDPPO, 3-perylene diphenylphosphine oxide; TPP, triphenylphosphine; TPPO, triphenylphosphine oxide.

dark muscle, taken separately from the fillet under the lateral line, and these were immediately cut into two pieces, about 10 g each, in sizes of 4.0 × 2.0 × 0.6 cm. Pieces of white and dark muscles were placed in an empty petri dish (60 × 15 mm polystyrene; Becton Dickinson Labware, Franklin Lakes, NJ), one piece per dish, and stored in the dark at 5–6°C.

Determination of total lipid content. Total lipid content in white and dark muscle was determined by the method of Bligh and Dyer (14).

Determination of PV by iodometric method. PV of oils was determined by an iodometric method according to AOCS Official Method Cd 8-53 (15).

Determination of LOOH with 3-PeDPP. Oil samples were prepared by dissolving 5–10 mg of sample in 25 mL of a mixture of chloroform and methanol (1:1, vol/vol). Then 2.9 mL of the oil solution was mixed with 0.1 mL 3-PeDPP in methanol at a final concentration of 75 μM in a glass reaction vessel (Reacti-vial; Pierce, Rockford, IL). The vial was tightly capped and kept at room temperature for 30 min in the dark. The fluorescence due to 3-PeDPPO was measured at excitation and emission wavelengths of 440 and 470 nm, respectively, with a model RF-1500 spectrofluorometer (Shimadzu, Kyoto, Japan).

Determination of LOOH based on TPP oxidation. On the basis of TPP oxidation, LOOH levels were determined by HPLC as described by Nakamura and Maeda (16). Lipids were extracted from stored samples by chloroform/methanol (2:1, vol/vol) containing 0.05% (wt/vol) BHT, which was added to prevent lipid peroxidation during extraction. Lipid samples (50 mg) were dissolved in 10 mL of cyclohexane in a glass reaction vessel and reacted with 800 μM TPP at 30°C for 30 min in the dark. Triphenylphosphine oxide (TPPO), a reaction product of TPP and LOOH, was separated by HPLC on a Mightysil RP-18GP column (4.6 × 250 mm, 3 μm film thickness; Kanto Chemical Co. Inc., Tokyo, Japan) using a mixture of CH_3CN and water (9:1 vol/vol) as a mobile phase at a flow rate of 1.0 mL per min and detected at 260 nm with an SPD 10Av UV-vis detector (Shimadzu). The content of LOOH was calculated from the peak area of TPPO and was expressed as nanomoles LOOH per gram of muscle. A calibration curve was used to convert peak area into concentration of CumOOH equivalent (μM). Finally, levels of LOOH were expressed as nanomoles of CumOOH equiv/gram of fish muscle (nmol CumOOH equiv/g muscle).

Determination of TBARS. Accurately weighed fish muscle (2.5 g) was homogenized in 10.0 mL of PBS (275–285 mOsm/kg, pH 7.4) using an Ace homogenizer model AM-3 (Nihonseiki Kaisha, Tokyo, Japan). The homogenate was used for TBARS assay. The TBARS were determined by the method of Rice-Evan *et al.* (17). Absorption was measured at 532 nm with a UV-vis spectrophotometer (model UV-1700; Shimadzu) and using a molar extinction coefficient of 156×10^3 M^{-1} cm^{-1} for calculating TBARS concentration (17). TBARS were expressed as nanomoles of malondialdehyde per gram muscle.

Analysis of LOOH by fluorescent image analysis. For fluorescent image analysis, the white and dark muscle sections (about 0.5 mm thickness) were individually taken at appropriate intervals (0–24 h) and stained in a mixture of PBS (8,000 mg/L of NaCl, 200 mg/L of KCl, 1,150 mg/L of $NaHPO_4$ and 200 mg/L of KH_2PO_4, 275–285 mOsm/kg, pH 7.4) and DMSO (9:1, vol/vol) containing 3-PeDPP at a final concentration of 1.2 μM for 30 min at room temperature in the dark. The fluorescent images of LOOH generated in fish muscle were obtained with an Olympus IX70 inverted microscope (Olympus, Tokyo, Japan) equipped with an Olympus 40X UApo/340 (40-fold, N.A. = 0.90; Olympus, Tokyo, Japan) as an objective lens and an Olympus UMNBV cube filter unit (420–440 nm excitation, 475 nm emission). Image data were digitally acquired with an Olympus model C-3040 Camedia digital camera equipped with a NY-2000S eyepiece-mount adapter (MeCan Imaging Inc., Saitama, Japan) according to the manufacturer's instruction. The acquired data were converted into 8-bit gray-scale digital data by measuring mean gray scale pixel densities with ImageJ software (National Institutes of Health, Bethesda, MD). The resulting mean pixel densities were used as fluorescence intensities at arbitrary units (a.u.).

Statistical analysis. Student's *t*-test was used to distinguish significant differences among the mean values. A statistically significant difference was declared at $P < 0.05$.

RESULTS

Detection of LOOH with 3-PeDPP. The reaction for 3-PeDPPO formation is shown in Scheme 1. In the present study, under a temperature of 37°C and with incubation for 0–40 min, 3-PeDPP was also oxidized to 3-PeDPPO in various oils and oxidized oils (Fig. 1A). 3-PeDPP at a final concentration of 75 μM in the reaction solutions was reacted with tuna oil, soybean oil, and cashew nut oil containing a range of 2–13 nanoequivalents CumOOH per 3 mL cuvette in a solution of chloroform/methanol (1:1, vol/vol) with continuous stirring and darkness at room temperature. The fluorescence intensity increased

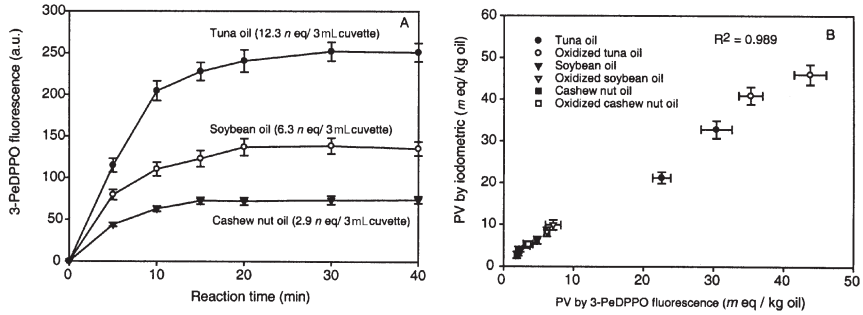

FIG. 1. (A) Time course of 3-perylene diphenylphosphine oxide (3-PeDPPO) formation with different concentrations of lipid hydroperoxide in various oil samples. The vertical bars represent the SD for data from 3-PeDPPO fluorescence (n = 3). (B) Relationship between PV obtained by the iodometric method and by the 3-PeDPPO-fluorescence method. The vertical bars represent the SD for data obtained by iodometric method (n = 3). The horizontal bars are the SD for data obtained by 3-PeDPPO fluorescence method (n = 3). Abbreviation: a.u., arbitrary units.

exponentially for 10 min due to the formation of 3-PeDPPO, which was stable within 30 min (Fig. 1A).

The PV of various oils and oxidized oils were determined by using the 3-PeDPPO fluorescence and the iodometric method. The oxidized oils were prepared by incubating the oils in an air oven set at 40°C for 1 h. Figure 1B shows a good linear regression between the results obtained by a traditional iodometric method and the proposed novel 3-PeDPP assay (R^2 = 0.989).

Application of 3-PeDPPO fluorescence image analyses of fish muscle lipid oxidation. The results for the total lipid content from white and dark muscles of yellowtail revealed no significant differences (8.2 and 8.5% for white and dark muscle, respectively). The contents of total LOOH and TBARS in white and dark muscle of yellowtail stored at 5–6°C for 0–24 h were determined (Fig. 2). Dark muscle contained a significantly higher amount of total LOOH and TBARS compared with white muscle ($P < 0.05$) from 6 to 24 h under storage at 5–6°C. The total LOOH contents in the muscle increased from 24.3 ± 2.8 to 174.0 ± 23.7 and from 53.5 ± 10.2 to 485.0 ± 30.7 nmol per g of white and dark muscle, respectively. The TBARS contents in the muscle also increased from 1.2 ± 0.08 to 3.8 ± 0.91 and from 2.2 ± 0.07 to 11.5 ± 2.0 nmol per g of white and dark muscle, respectively.

The digital images of 3-PeDPPO fluorescence in white and dark muscle slices stored at 5–6°C for 0–24 h are shown in Figure 3. Strong fluorescence due to 3-PeDPPO was observed in white and dark muscle after 12 and 6 h, respectively. 3-PeDPPO fluorescence determined through digital image analysis is shown in Figure 4. Strong fluorescence (7.9 ± 2.7 to 130.4 ± 17.2 a.u.) due to 3-PeDPPO was observed in the dark muscle, whereas weak fluorescence (3.6 ± 1.1 to 61.5 ± 17.2 a.u.) was obtained in the white muscle. The fluorescent analysis data also showed a good correlation with total LOOH content obtained by the TPP oxidation method (R^2 = 0.954) (Fig. 5).

DISCUSSION

The reaction of triarylphosphine with hydroperoxide or a hydroperoxy group seems to be a general phenomenon of triarylphosphines having a fluorophore instead of the phenyl group of TPP or fluorescent probes based on fluorophores in TPP analogs (18). Fluorescence detection based on a fluorophore in TPP analogs with a HPLC method of post-column

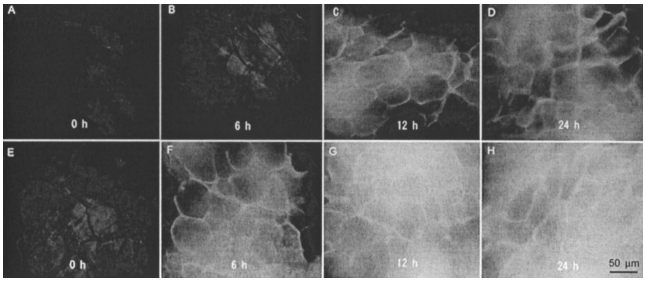

FIG. 3 . Typical 3-PeDPPO fluorescence images from 1.2 µM 3-perylene diphenylphosphine-labeled fish muscle slices. The visible light lines in the panels delineate cell membranes of white (panels A–D) and dark (panels E–H) muscle during storage at 5–6°C, respectively. For abbreviation see Figure 1.

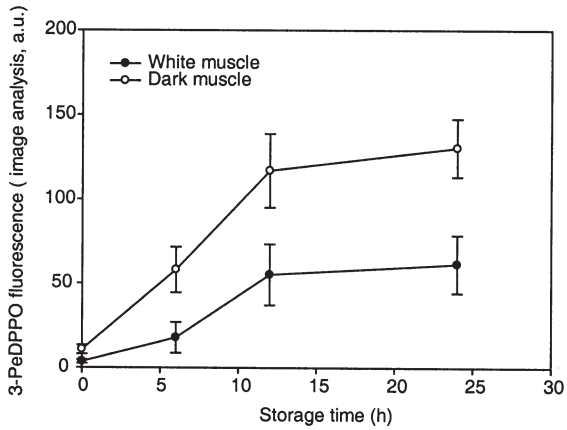

FIG. 4. 3-PeDPPO fluorescence intensity (a.u.) from fluorescent image analysis of white and dark muscle (Fig. 3) during storage at 5–6°C. The vertical bars are the SD of 3-PeDPPO fluorescence in each image field. For abbreviations see Figure 1.

derivatization was developed for improving the specificity and sensitivity over the other available methods (5,18,19). However, these methods need uniformity of oil samples; and complicated sample preparation procedures, such as homogenization and lipid extraction of oil-containing materials, are necessary before determination of LOOH. Moreover, LOOH are difficult to measure accurately because of their short lifetime.

Direct fluorescent image analysis is a selective and sensitive method that offers several advantages such as easy and accurate identification of structures and rapid preparation and determination (8). Direct fluorescent image analysis without sample preparation procedures was carried out with a fluorescent probe based on the fluorophore in TPP analogs such as DPPP oxide fluorescence (9–11) and had several advantages such as the possibility of continuous observation of oxidation in cells in a nondestructive manner. However, the disadvantage of DPPP oxide image analysis may be that DPPP oxide has a fluorescence emission wavelength of 380 nm in the UV region, causing lipid peroxidation and cell death by itself. Moreover, the presence of tocopherol analogs will interfere with DPPP oxide image analysis of lipid-containing fluorescent compounds because of overlapping fluorescence.

3-PeDPP is a nonfluorescent compound, but when it is oxidized to 3-PeDPPO, the resultant oxidation products exhibit dramatically increased fluorescence intensities, with excitation (440 nm) and emission (470 nm) wavelengths (12,13). This increase in fluorescence intensity is due to decreases in steric hindrance around the phosphorus atom and increases in electron density on the phosphorus atom (20).

The fluorescence intensity due to 3-PeDPPO increased proportionally with increasing concentration of hydroperoxides generated in homogeneous solutions, as well as in nonhomogeneous solutions, such as phospholipid liposome models oxidized with the free radical generator 2,2′-azobis(2-amidinopropane)dihydrochloride and photosensitized oxidation (12). 3-PeDPP as the fluorescent probe coupled with fluorescent image analysis enabled us to observe the fluorescence due to the reaction between 3-PeDPP and LOOH in cell membranes and thin slices of liver and heart tissues in a nondestructive manner (12).

As shown in Figure 1A, the fluorescence intensity of 3-PeDPPO increased dramatically with higher reaction times and amounts of LOOH from various types of oil. For the 3-PeDPPO fluorescence method, 5–10 mg of lipid was sufficient for a single assay, but the iodometric method required the use of oil on a gram scale for the determination. In our previous report (13), the kinetic profiles of LOOH formation were investigated by both 3-PeDPPO fluorescence and ferric-xylenol orange methods during autoxidation of refined tuna oil at 40°C. In the present study a linear correlation (coefficient of determination R^2 = 0.989) was found between lipid hydroperoxide contents in various oils and oxidized oils as determined by 3-PeDPPO fluorescence and by the iodometric method. (Fig. 1B). This result suggests that 3-PeDPPO fluorescence could be used as a sensitive tool for quantitative determination of trace

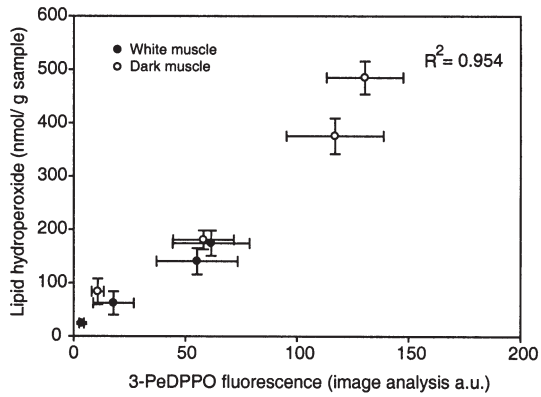

FIG. 5. Relationship between lipid hydroperoxide levels in white and dark muscle during low-temperature storage determined by HPLC based on oxidation of triphenylphosphine and by 3-PeDPPO fluorescence (a.u.) from image analyses. Data are represented as mean ± SD (n = 3). The horizontal bars are the SD for data obtained by the 3-PeDPPO fluorescence method, and the vertical bars represent the SD for the triphenylphosphine method. For abbreviations see Figure 1.

amounts of LOOH in various oils, which supports the performance of the 3-PeDPP assays.

It is well established that lipid peroxidation is an important contributor to postmortem deterioration of fish quality during storage. Fish meat is more susceptible to oxidative degradation than other meats during storage because of the abundance of PUFA in the tissues. LOOH are the primarily oxidative products of unsaturated FA (21). Changes in the content of LOOH generated in white and dark muscles of yellowtail during low-temperature storage were successfully measured by the proposed 3-PeDPPO fluorescence image analyses, which were linearly correlated with the data by HPLC methods based on TPP oxidation (16).

The present results showed the enhanced production of LOOH and secondary lipid peroxidation product (TBARS) in dark muscle of yellowtail during low-temperature storage (0–24 h at 5–6°C) in comparison with those in white muscle (Fig. 2A and 2B, respectively). The results were in agreement with previous reports that the levels of the lipid peroxidation products in dark muscle were higher than those in the white muscle in wild and cultured yellowtail (22,23) and herring (24). This observation is due to the high contents of myoglobin in muscle intracellular structure or red muscle fibers (25). During the handling and storage of fish, a number of biochemical changes occur, leading to the formation of metmyoglobin (26,27). Metmyoglobin formation is positively correlated with lipid peroxidation (28,29), and high concentrations of myoglobin and other heme compounds in dark meats function as prooxidants in the muscle tissue (30).

Digital image analysis techniques are generally used to uncover information from image data. The information is derived by transforming the digital image or by directly extracting data values from the image. We carried out fluorescent image analysis for evaluation of LOOH formation in thin sections of yellowtail white and dark muscle during storage at 5–6°C. The visible light lines in Figure 3 delineate the cell membranes of white and dark muscle cross-sections during low-temperature storage. Strong fluorescence of 3-PeDPPO was observed in cell membranes of dark muscle after 6 h of low-temperature storage, but low fluorescence intensity of 3-PeDPPO was obtained in cell membranes of white muscle (Fig. 3). Moreover, the image analysis data also showed the good correlation with the data for LOOH by HPLC based on the TPP oxidation method (R^2 = 0.954, Fig. 5). Thus, 3-PeDPPO fluorescence in combination with fluorescent image analysis was successfully used to estimate 2-D LOOH formation in fish muscle during storage.

[b]Department of Chemistry, Sichuan Normal University, Chengdu 610066, China

ABSTRACT: In investigating the preparation of 2-acylglycerol by debenzylation of 1,3-di-*O*-benzyl-2-*O*-acylglycerol, twelve 1,3-di-*O*-benzyl-2-*O*-acylglycerols were synthesized. 2-*O*-Acyl moieties with one or more protons at the carbon atom adjacent to carbonyl group were found to migrate from C-2 to C-1 of the glycerol moiety during hydrogenation under Pd/C at room temperature.

Paper no. L9872 in *Lipids 41*, 301–303 (March 2006).

A number of methods are available to prepare 2-*O*-protected glycerols. The method based on 1,3-*O*-benzylideneglycerol (1,2) results in low yields (3) owing to competitive formation of 1,2-*O*-benzylideneglycerol isomer, and its use would be expected to be restricted to 2-protecting groups stable to acid. The method based on 1,3-di-*O*-tritylglycerol is also unsuitable for acid-labile 2-protecting groups (4). The method based on 1,3-di-*O*-benzylglycerol (Fig. 1) appears to be compatible with different protecting groups. This method is the mildest and cheapest strategy to prepare 2-*O*-acylglycerols and has been used to prepare 2-*O*-acetyl, benzoyl, and *p*-toluenesulfonyl glycerol (5,6).

In our research on preparing 2-*O*-acylglycerols *via* debenzylation of 1,3-di-*O*-benzyl-2-*O*-acylglycerols, we found that some acyl groups migrated to a limited extent (acetyl) or entirely (stearyl) (Fig. 1). The intramolecular migration of acyl groups in MAG and DAG has been studied (7,8). Bases or acids catalyze this reaction (9,10). There is also a report on the solid-state isomerization of partial acylgycerols (11). The acyl migration under various conditions of a palmitoyl group in 1,2-dipalmitoyl-*sn*-glycerol to form 1,3-dipalmitoylglycerol was studied (12). However, the acyl migration during hydrogenation under Pd/C and the role of acyl characters on this migration were not reported. To investigate the parameters affecting the preparation of 2-acylglycerol from 1,3-di-*O*-benzyl-2-*O*-acylglycerol, twelve 1,3-di-*O*-benzyl-2-*O*-acylglycerols were synthesized and the acyl migration during debenzylation was studied.

EXPERIMENTAL PROCEDURES

Instrumentation. ^{1}H NMR spectra were obtained on a Bruker Avance 600 NMR spectrometer (Bruker, Rheinstetten, Germany) and Varian Unity Inova 400 WB Superconducting NMR Spectrometer (Varian Inc., Palo Alto, CA). Chemical shifts (δ) are given in ppm relative to internal standard tetramethylsilane and coupling constants in Hertz (Hz).

Materals and reagents. Silica gel for column chromatography (Silica gel H 200–300 mesh) and for TLC plates (Silica gel GF_{254} 10–40 μm) was purchased from Qingdao Haiyang Chemical Ltd., Co. (Qingdao, China). All products were purified by silica gel column chromatography before NMR analysis.

*1,3-Di-O-benzylglycerol (**1**)*. A solution of sodium hydroxide (30 g, 0.75 mol) in water (100 mL) was added over 10 min to benzyl alcohol (110 g, 1.06 mol). The mixture was cooled to 25°C, and then epichlorohydrin (30.6 g, 0.331 mol) was added under vigorous stirring over 30 min. Stirring was continued for 16 h. The mixture was then diluted with water (200 mL) and extracted with EtOAc (3 × 400 mL). The EtOAc layer was washed with water (500 mL), dried over anhydrous Na_2SO_4, and evaporated to give a liquid, which was distilled under reduced pressure to afford 56.3 g of **1** with a yield of 63%.

*General procedure for preparation of 1,3-di-O-benzyl-2-O-acylglycerol (**2a–2l**)*. A solution of 1 equiv acyl chloride in $CHCl_3$ was added to a mixed solution of 1 equiv 1,3-*O*-benzylglycerol and 1.1 equiv Et_3N in $CHCl_3$. The mixture was stirred for 2 h at room temperature and then washed with 1 M HCl (aq) and brine, dried over anhydrous Na_2SO_4, and evaporated to give **2a–2l** as a pale yellow liquid (Table 1).

*General procedure for preparation of 1-O-acylglycerol or 2-O-acylglycerol (**3a–3l**)*. A mixture of **2** and 5% Pd/C (10 mol%) in ethanol was stirred at room temperature under H_2 for 12 h, and filtered. The filtrate was evaporated to give **3** as a pale yellow liquid with yield >98% (Table 2).

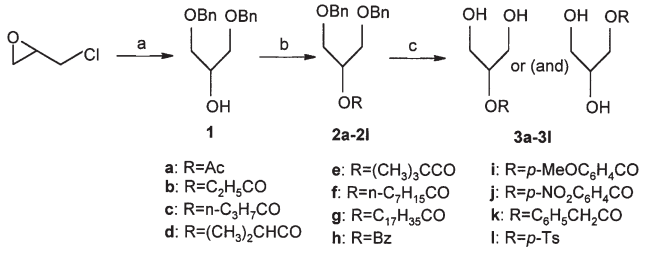

FIG. 1. Synthesis of 2-acylglycerol from 1,3-di-*O*-benzyl-2-*O*-acyl glycerol. Reaction a: Benzyl alcohol (BnOH), NaOH, MeOH, reflux 8 h, 63% yield; reaction b: acyl chloride, Et_3N, $CHCl_3$, 76–96% yield; reaction c: H_2, 5% Pd/C, 12 h, >98% yield. *p*-Ts = *p*-toluenesulfonyl.

RESULTS AND DISCUSSION

The substituents on the phenyl ring of the acyl groups (**2i** and **2j**) as well as steric hindrance (**2d** and **2e**) have no effect on acyl migration in 1,3-di-*O*-benzyl-2-*O*-acylglycerol under hydrogenation. The length of the side chain in an aliphatic acyl group has little effect on acyl migration (**3a–3d**, **3f**, **3g**). Thus, 2-*O*-acyl groups with one or more protons at the C-2 position in the acyl moiety are inclined to migrate during debenzylation. It could be estimated that H-2 in the acyl moiety may be encountered in the acyl migration. The proposed mechanism, as depicted in Figure 2, is different from the migration of 2-*O*-acyl to

Very Long Chain Fatty Acid Methyl Esters in Transesterified Palm Oil

Chiew Wei Puah[a,b], Yuen May Choo[a,*], Ah Ngan Ma[a], and Cheng Hock Chuah[b]

[a]Malaysian Palm Oil Board (MPOB), Bandar Baru Bangi, 43000 Kajang, Selangor, Malaysia, and [b]Department of Chemistry, Faculty of Science, University of Malaya, Lembah Pantai, 50603 Kuala Lumpur, Malaysia

ABSTRACT: Some unidentified minor compounds have been observed in the residue from short-path distillation of transesterified palm oil that are not detected in the original palm oil. A method combining short-path distillation to enrich the unknowns with fractionation using solid-phase extraction is described. The fractionated components were identified using GC coupled with MS. The transesterified palm oil was found to contain methyl esters of up to C_{32} carbon atoms. In the very long chain FAME with carbon numbers ≥20, both even and odd carbon numbers accounted for 0.26 wt%, with C_{24} and C_{26} being the major ones present in the residue after short-path distillation of transesterified palm oil.

Paper no. L9884 in *Lipids 41*, 305–308 (March 2006).

Very long chain FA (VLCFA) with more than 20 carbon atoms are present in most common seed oils, albeit in small amounts (1). Sunflower oil contains three main saturated VLCFA: arachidic (20:0), behenic (22:0), and smaller amounts of lignoceric (24:0) acids. These FA account for 1–3% of the total FA in sunflower seeds (2). Recent analytical instrumentation has proved the occurrence of straight-chain odd-numbered FA as minor constituents in practically every natural fat (3). A detailed review of these VLCFA has been reported (4). Christie (5) also reported that all the possible odd-numbered homologs with 2–36 carbon atoms have been found in nature in esterified form.

Transesterification is a direct conversion of FA-containing lipids to alkyl esters by alcohol in the presence of a catalyst. The alkyl esters (particularly methyl esters) are produced from vegetable oils such as rapeseed oil (6,7), soybean oil (8,9), sunflower oil (10), and palm oil (11,12).

The FAME in palm oil and its products are expected to closely resemble the corresponding FA composition of crude palm oil (CPO), with up to C_{20} (13). VLCFA with more than 20 carbon atoms have not been reported in palm oil (14). However, some unidentified compounds have been observed in transesterified palm oil that are not found in the original oil. The main problems in identifying the minor components in transesterified palm oil are caused by their relatively low concentrations. Thus, they are unable to be detected using the current method of GC alone. An effort was made in this study to enrich the minor components using short-path distillation by removal of the bulk methyl esters.

A further enrichment was carried out using solid-phase extraction (SPE) to separate the mixture into groups of components. This can eliminate the interfering components and thus concentrate other trace components. Identification of the components was carried out using GC coupled with MS (GC–MS). The identification of FAME using GC has been described as a reliable tool, as the FAME show highly predictable behavior in GC, as reviewed by Ackman (15). Thus, the identification of very long chain FAME (VLCFAME) using GC–MS as the spectra provides complete information and makes possible the full identification of the methyl esters. If GC retention data are added, it is possible to be 90% certain of the identity of the FA. Some limited information on the positions of structural features, such as the double bond in polyenic FA, branch points, and oxygenated groups, also may be obtained (16). For separation of a mixture of methyl esters with a high molar mass, GC can be used up to C_{40} (4). Even- and odd-numbered methyl esters of up to 31:0 are available commercially; thus, we were able to carry out comparisons of retention times with standards.

EXPERIMENTAL PROCEDURES

Materials. CPO was obtained from the MPOB Palm Oil Mill Technology Centre in Labu, Negeri Sembilan, Malaysia.

Standard and chemical reagents. All solvents and chemicals used for transesterification, SPE, and analyses were of analytical or chromatographic grade, purchased from Merck (Darmstadt, Germany). A FAME mix (189201AMP) and saturated straight-chain FAME (ME7–1KT) were purchased from Supelco (Bellefonte, PA).

Method. The CPO was transesterified to palm oil methyl esters using the method described by Choo *et al.* (17). CPO (1 kg) was weighed into a (2-L) three-necked round-bottomed flask, and methanol (500 mL) was added to the flask. Sodium hydroxide (5.5 g) was dissolved in methanol and added to the flask. The mixture was refluxed at a temperature of 60–70°C for 1 h. The glycerol layer was separated and the methyl esters were washed with hot water until neutral. The methyl esters were dried with anhydrous sodium sulfate and subsequently pumped dry. The methyl esters were then subjected to short-path distillation (Pope Scientific Inc.) at a temperature of 150°C and pressure of <1.0 mTorr with a flow rate of 6.0–8.5 mL/min

Abbreviations: CPO, crude palm oil; VLCFA, very long chain fatty acid(s); VLCFAME, very long chain FAME.

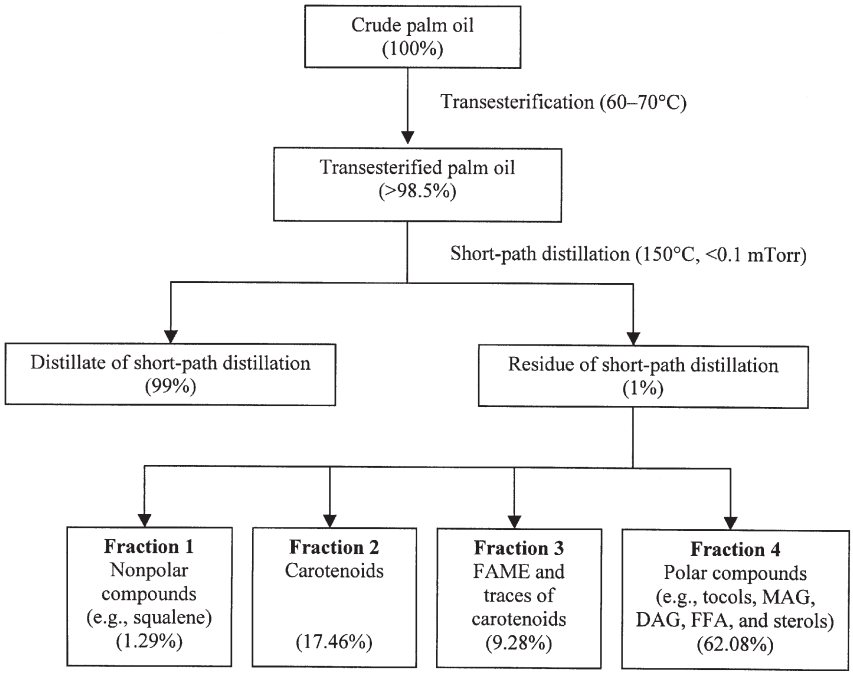

FIG. 1. Flow diagram of the enrichment and fractionation of methyl esters.

to obtain (i) distilled methyl esters and (ii) residue enriched with minor components. The residue was blanketed with nitrogen and stored in the dark at –20°C before use to prevent deterioration by heat, light, and air.

SPE. A Strata SI-1 1000 mg/6 mL (55 µm, 70 Å) silica gel column (Phenomenex, Torrance, CA) was rinsed with 2.0 mL of *n*-hexane. A 21.65-mg quantity of residue was weighed accurately and dissolved in 1.0 mL of *n*-hexane. The sample was transferred into the silica column and rinsed with 3.0 mL of *n*-hexane and eluted as fraction 1. The subsequent fractions 2 and 3 were eluted with 6.0 mL of *n*-hexane/toluene (85:15, vol/vol) each. Fraction 4 was eluted with 10.0 mL of methanol. The solvent was allowed to flow under gravity at a flow rate of 0.75 mL/min. The eluate was dried under nitrogen.

GC-FID. The sample was weighed accurately into a 2-mL GC vial. Then 1.0 mL of methylene chloride was pipetted into the vial. The instrument used was a Hewlett-Packard gas chromatograph, model 5890, series II (Avondale, PA), equipped with an FID and on-column injector. A fused-silica capillary column, BPX 5 (15 m × 0.32 mm) coated with (5% phenyl)-polysilphenylene-siloxane, film thickness of 0.25 µm (SGE, Austin, TX), was used. GC conditions were: injector temperature, 245°C; detector temperature, 370°C; initial oven temperature, 100°C; initial holding time, 1 min; ramping rate, 10°C/min; final temperature, 300°C; carrier gas (He) flow rate, 2 cm^3/min; column pressure, 14.5 psi; injection volume, 1 µL. Quantification was carried out using a five-point external standard calibration assay, with R^2 values > 0.99.

GC–MS. The instrument used was a Hewlett-Packard gas chromatograph, model 6890 series, coupled with a Hewlett-Packard mass selective detector, model 6890 series. The capillary column used was an HP-5MS coated with (5%-phenyl)-methylpolysiloxane (Agilent Technologies, Palo Alto, CA). The injector temperature was 245°C and the GC–MS interphase temperature was 280°C. The initial temperature of 100°C was held for 1 min and the final temperature of 280°C was held for 16 min. The ramping rate was 10°C/min. The mode of ionization was EI with an ionization voltage of 70 eV.

RESULTS AND DISCUSSION

The FAME in palm oil and its products are expected to closely resemble the corresponding FA composition of CPO. This paper reports the presence in transesterified palm oil of VLCFAME that include even and odd carbon number identified by (i) enriching the minor components by removing the bulk methyl esters using short-path distillation and (ii) consequent fractionation of the residue using SPE. Figure 1 shows a flow diagram of the enrichment and fractionation of the methyl esters. The yield in the figure shows the mean value of three replicates.

The presence of methyl esters in the residue obtained by short-path distillation of transesterified palm oil was confirmed with IR spectra. It showed the presence of a carbonyl functional group for esters, with C=O stretching at 1735 cm^{-1}. In addition, the C–H stretching for $–CH_3$ and $–CH_2–$ were shown at 2925 and 2855 cm^{-1}, respectively. These indicate the presence of saturated alkyl moieties in the residue.

The residue was then subjected to SPE for further isolation into groups of components. A total of four fractions were collected, with recovery ~90% (Fig. 1). When the fractions were analyzed, we found that the residue could be separated into four groups of components.

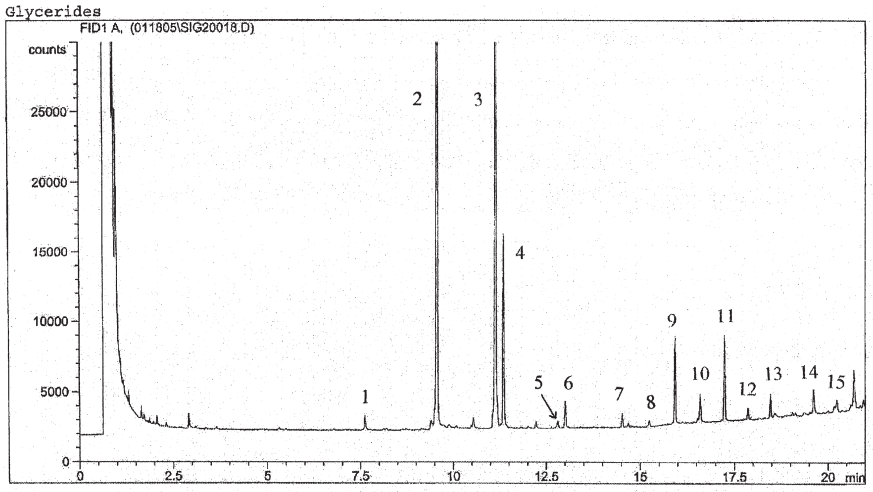

FIG. 2. Gas chromatogram of fraction 3.

The gas chromatogram of fraction 3 (Fig. 2) illustrates at least 15 identifiable peaks with good baseline separation. The mass spectra of the peaks show the characteristic peak in MS for saturated straight-chain methyl esters at *m/z* 74. This most abundant peak is the McLafferty rearrangement ion that involves a γ-hydrogen transfer followed by β-cleavage. The molecular ion at 382 is clearly seen for methyl esters of 24 carbon atoms. The ion at *m/z* 351, $[M - 31]^+$, arises following a simple homolytic cleavage of the methoxy bond to yield a commonly observed acylium ion. This ion confirms that the peak is indeed a methyl ester. Another abundant ion at *m/z* 87 shows a simple cleavage mechanism or fission of the bond between C3 and C4. An ion at *m/z* 339, $[M - 43]^+$, represents the loss of a C3 unit (carbons 2–4) *via* a complex rearrangement. Other prominent ions, including a $C_nH_{2n-1}O_2^+$ series (87, 101, 115, 129, 143, etc.) and the alkyl ion (57, 71, 85, etc.), also show the saturated straight-chain methyl ester.

The relative (%) concentration of the FAME identified in the residue of transesterified palm oil after short-path distillation is shown in Table 1. The quantification was carried out using a five-point external standard calibration assay, with R^2 values > 0.99. The residue from short-path distillation of transesterified palm oil was found to contain 2.50 wt% FAME ranging from C_{14} to C_{32} carbon atoms. The VLCFAME of >20 carbon atoms consisting of even and odd carbon numbers accounted for 0.26 wt%, with C_{24} and C_{26} being the major ones.

TABLE 1
Relative (%) Concentration of Methyl Esters Identified in Residue from the Short-Path Distillation of Transesterified Palm Oil

Peak no.	FAME	Relative concentration[a] (%)
1	14:0	0.54 ± 0.02
2	16:0	47.39 ± 0.05
3	18:1	34.02 ± 0.10
4	18:0	6.501 ± 0.005
5	20:1	0.27 ± 0.02
6	20:0	1.02 ± 0.03
7	22:0	0.54 ± 0.04
8	23:0	0.36 ± 0.01
9	24:0	2.89 ± 0.01
10	25:0	1.02 ± 0.04
11	26:0	3.06 ± 0.08
12	27:0	0.48 ± 0.05
13	28:0	0.933 ± 0.002
14	30:0	0.856 ± 0.008
15	32:0	0.12 ± 0.02

[a]Mean value of three replicates.

FAME of the residue from the short-path distillation of transesterified palm oil were satisfactorily separated from other interfering components for characterization and identification. However, because the ester moiety has similar properties, it was a challenge to isolate every individual constituent of the methyl esters. Nonetheless, GC–MS is considered a reliable and adequate tool for the identification of methyl esters (18).

The results of the present study clearly show that 2.50 wt% of FAME ranging from C_{14} to C_{32} carbon atoms, with both even and odd carbon atoms, were present in the residue from the short-path distillation of transesterified palm oil, whereas the VLCFAME with carbon atoms >20 accounted for 0.26 wt%.

ACKNOWLEDGMENTS

The authors wish to thank the Director General of the MPOB for permission to publish this paper. Thanks are also extended for the MPOB Research Graduate Assistantship awarded to Chiew Wei Puah to conduct her postgraduate studies. REVIEW

Natural Neo Acids and Neo Alkanes: Their Analogs and Derivatives

Valery M. Dembitsky*

Department of Medicinal Chemistry and Natural Products, School of Pharmacy, The Hebrew University of Jerusalem, Jerusalem 91120, Israel

ABSTRACT: This review presents more than 260 naturally occurring (as well as 47 synthesized) neo fatty (carboxylic) acids, neo alkanes, and their analogs and derivatives, isolated and identified from plants, algae, fungi, marine invertebrates, and microorganisms, that demonstrate different biological activities. These natural metabolites are good prospects for future chemical preparations as antioxidants, and also as anticancer, antimicrobial, and antibacterial agents. Described also are some synthetic bioactive compounds containing a tertiary butyl group(s) that have shown high anticancer, antifungal, and other activities. Applications of some neo fatty (carboxylic) acid derivatives in cosmetic, agronomic, and pharmaceutical industries also are considered. This is the first review to consider naturally occurring neo fatty (carboxylic) acids, neo alkanes, and other metabolites containing a tertiary butyl group(s) [or *tert*-butyl unit(s)].

Paper no. L9944 in *Lipids 41*, 309–340 (April 2006).

This review is a comprehensive survey of neo fatty (carboxylic) acids and/or their derivatives obtained from living organisms. FA constitute the most abundant class of natural compounds and are components of complex lipids. FA differ in their number of olefinic bonds, the extent of branching, the length of the hydrocarbon chain, and the number of functional groups (1–5). Acid- or base-catalyzed hydrolysis of complex lipids yields the free FA. These long- or short-chain acids are generally referred to by their common names, which in most cases reflect their sources. Natural FA can be saturated, unsaturated, or branched. The saturated (branched) acids have higher m.p. than unsaturated acids of corresponding size (6).

Branched fatty (carboxylic) acids and/or their derivatives, e.g., amides, alcohols, and aldehydes, whose ends are remote from the carboxylic (or $–NH_2$, -OH, and –CHO) group, as shown in Figure 1, are usually described by the terms *iso*-, *anteiso*-, or *neo*-. The sterically hindered structures of neo acids provide them with certain performance advantages over the unhindered FA. Natural biogenic neo acids and/or alkanes containing a tertiary butyl group(s) are produced by different organisms (bacteria, fungi, plants, marine invertebrates, and animals) for a specific purpose, usually involving the survival of the species. Research into the natural occurrence of neo acids is relatively new with much attention in the past focusing on the pharmaceutical impact of synthetic ones. Neo (saturated tertiary and/or trialkylacetic) acids are synthetically produced and have been available since the early 1960s (6,7).

Discussions of the physical and chemical properties of neo acids, their manufacture, economic aspects, storage and handling, toxicity, and applications have been reviewed (5,8–10).

Neo acids and/or their derivatives show different biological activities, including anticarcinogenic, antifungal, antibacterial, antimicrobial, and others (11).

Neo alkanes are produced by soil cyanobacteria (12), marine algae (13), and some microorganisms (14,15). They have been isolated from plant species and also have been discovered in ancient sediments and oils (16,17). Aromatic and related compounds containing a tertiary butyl group(s), which are produced by many plants, are of considerable interest for chemistry, nutrition, commerce, and human health (18) and are considered in this review..

This paper is a comprehensive survey of neo acids, neo alkanes, and their analogs and derivatives that are deemed as naturally occurring. Also, this is the first article to review natural neo fatty (carboxylic) acids, neo alkanes, and other metabolites containing a tertiary butyl group(s) [or *tert*-butyl unit(s)].

FIG. 1. The *iso*-, *anteiso*-, and *neo*-fatty (carboxylic) acids isolated from living organisms.

*Address correspondence at Dept. of Medicinal Chemistry and Natural Products, School of Pharmacy, P.O. Box 12065, The Hebrew University of Jerusalem, Jerusalem 91120, Israel. E-mail: dvalery@cc.huji.ac.il

Abbreviations: 6FP, 6-formylpterin; CDH, choline dehydrogenase; DC-A, discodermin A; EC_{50}, concentration having an effect on 50% of the population; LC_{50}, concentration having a lethal effect on 50% of the population; PAF, platelet-activating factor.

OCCURRENCE OF NEO ACIDS AND DERIVATIVES IN NATURE

Pivalic acid (**1**), a simple carboxylic acid with methyl side chains, is usually used in the form of its chloride as an intermediate in the manufacture of pharmaceuticals (ampicillin, amoxycillin, cephalosporins), pesticides, and organic peroxide compounds (19). Other names for pivalic acid include: 2,2-dimethyl propionic acid, dimethylpropionic acid, α,α-dimethyl propionic acid, *tert*-pentanoic acid, neopentanoic acid, trimethylacetic acid, and versatic acid 5.

Pivalic acid was detected in snake fruit (*Salacca edulis*) (20); white- and yellow-fleshed peaches, peento peach, and nectarine (21); in the phenolic fractions from Koshu and Zenkoji grapes (22); in *Capsicum annuum* var. *annuum* fruits (23); in commercial plain sufu [fermented soybean (*Glycine max*) curds] (24); in tobacco leaf material (25); in the volatile, neutral and acidic constituents of Virginia tobacco (26); and in the volatile flavor of a wheat flour and butter mixture, and roux cooked to 100°C (27). Pivalic acid also was detected in ripe and unripe golden empress melon (*Cucumis melon*) (28) and *Michelia alba* (29), and in the exotic fruit *Spondias mombin* from French Polynesia (30).

It also was detected in the Japanese fish sauce Ishiru (31), in three brands of Philippine fish sauces (patis) (32), in fish sauce (33), and in volatile flavor components in snow crab cooker effluent and effluent concentrate (34).

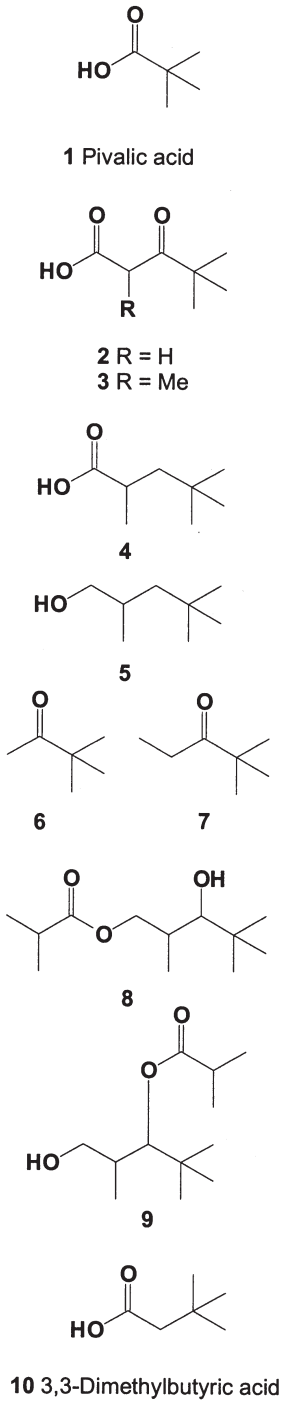
Numerous bacterial strains able to degrade pivalic acid have been isolated, including members of families Rhodocyclaceae, Comamonadaceae, and Oxalobacteraceae; and two pathways have been proposed (35). After activation with a CoA-forming ligase, a pivalyl-CoA mutase is considered to isomerize the quaternary compound. In contrast to the originally proposed pathway, recent studies showed that 3-methylbutyryl-CoA is the product. In an alternative pathway, strain PIV-34-1, a member of Oxalobacteraceae that is closely related to genus *Herbaspirillum*, was proposed to degrade pivalate *via* an anaerobic oxidation of the methyl group, with dimethylmalonate as the initial product (35).

Some metabolites of pivalic acid—pivaloylacetic acid (**2**,**3**), methyl-neopentylacetic acid (**4**), 2,4,4-trimethyl-1-pentanol (**5**), and 4,4-dimethyl-3-pentanone (**6**)—were isolated from extract of *Mycobacterium austroafricanum* IFP 2173 during investigation of the catabolic pathway of isooctane (36).

2,2-Dimethyl-3-pentanone (**7**) was produced by the toxic fungi *Stachybotrys chartarum*, *Aspergillus* spp., and *Penicillium* spp. (37). A mixture of five fungi—*Aspergillus versicolor, Fusarium culmorum, Penicillium chrysogenum, Ulocladium botrytis,* and *Wallemia sebi*—produced many volatile organic compounds, including two neo metabolites, (**8**,**9**) (38).

Simple neohexanoic (3,3-dimethylbutanoic) acid (**10**) was isolated from volatile constituents of *Hemerocallis citrina* (daylily, Liliaceae) (39); and it was also detected in *Ferula gummosa* essential oil (40). Traditional herbal medicines based on *F. gummosa* have been used for treatment of intestinal disorders in Iran, and *F. gummosa* essential oil showed spasmolytic activity. Neohexanoic acid was detected in Saint-Maure soft cheeses obtained from goat's milk (41).

Pivalic acid was found in samples of the Cl-Na-Ca type stratal waters of petroleum deposits (Neftechala, Azerbaidzhan) (42). Pivalic acid and a homologous series of low M.W. monocarboxylic acids (C_2 to C_{12}) and γ-lactones (C_5 to C_{12}) were detected in Miocene to Pliocene sediments of Shinjo Basin (43). More than 50 monocarboxylic acids, including pivalic acid, neohexanoic acids, and neopentyl 3,3-dimethylbutanoate (**12**), were detected in the water-soluble organic com-



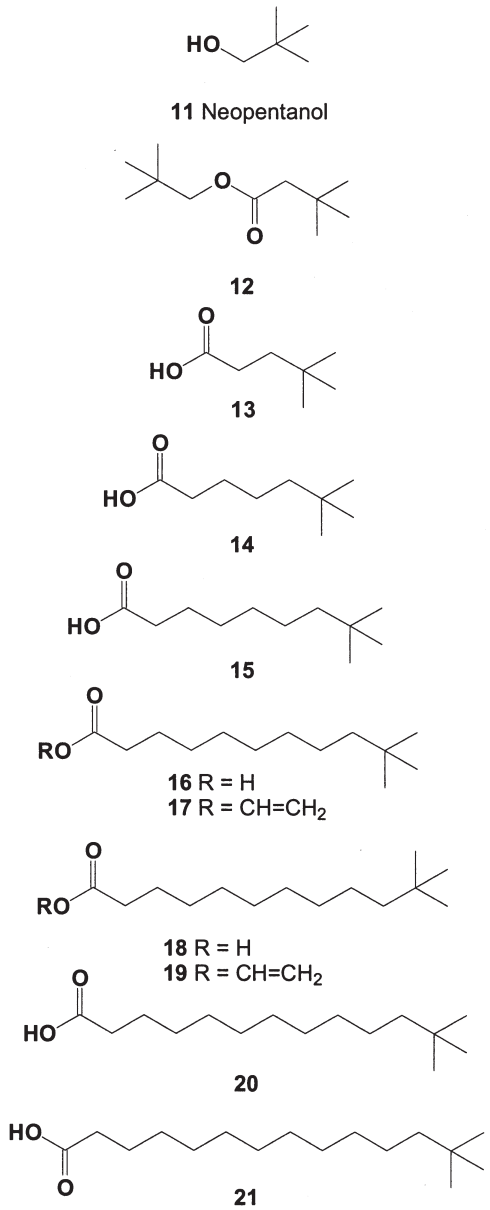
pounds of Murchison and EET96029.20 carbonaceous meteorites (44). The distribution of low M.W. monocarboxylic acids was studied in three CM2 Asuka carbonaceous chondrites (A-881280, A-881334, and A-881458) that were recovered from Antarctica by the 29th Japanese Antarctic Research Expedition in 1988. More than 30 monocarboxylic acids were isolated, including aliphatic and aromatic acids with various structural isomers, including neohexanoic acid (45).

Echinacea, the purple coneflower, is the best known and researched herb for volatile constituents, and neopentanol (**11**) was detected in three *Echinacea* species (46). Pivalic acid, neohexanoic acid, and neopentanol were isolated from sheep wool extracts, and it was shown that these compounds are hair growth stimulants (47), and from *Inula viscosa* extract (48). Sweet olive (*Osmanthus fragrans*) is a flower native to China that is valued for its delicate fragrance, and neopentanol was isolated from the top note of *O. fragrans* (49). Volatile components of pine nuts were recovered by simultaneous distillation and extraction after Soxhlet extraction. One hundred eighteen components, including 26 hydrocarbons, 17 esters, 16 aldehydes, 12 ketones, 31 alcohols, 11 bases, 2 acids and neopentanol were identified (50).

The neo FA having structures **13**–**16** and **20** have been isolated as minor components from the glycolipids fraction of the freshwater sponges, *Ephydatia syriaca*, *Nudospongilla* sp., and *Cortispongilla barroisi* (51). Neononanoic (**16**) and neodecanoic acids (**18**) and its ethenyl esters (**17** and **19**), respectively, were found in lubricating oils of animal and vegetable origin (52-54).

Neohexadecanoic acid (13,13-dimethyltetradecanoic acid) (**21**) was isolated from both wood and bast (inner bark) of *Daphne bholua* (also known as "Jacqueline Postill," and a bush used in Nepal for paper manufacture) along with other FA. Bast contained more unsaturated FA than wood (55). The composition of higher FA and diterpenic acid mixtures was determined by HPLC in fir and cedar chlorophyll-carotene paste from needles, in fir balsamic paste from needles, and in fir bark lipid constituents. The main unsaturated acids found in the samples were linoleic, oleic, and linolenic; the main saturated acids were palmitic acid and 14-methylhexadecanoic acid, and among branched FA 13,13-dimethyltetradecanoic acid (**21**) was detected. The mixtures of diterpenic acids contained mainly abietic, dehydroabietic, neoabietic, levopimaric, palustric, isopimaric, sandaracopimaric, and pimaric acids (56). The total content of FA and rosin acids in pine needles was 2.2–2.3%, of which rosin acids account for 92–93%. The content of FA in needles decreases and that of rosin acids increases with increasing age of needles. Among 38 rosin acids and FA isolated from pine needles, 13,13-dimethyltetradecanoic, palmitic, stearic monomethyl pinifolate, and neoabietic acid were dominant compounds. (57). FA mixtures isolated from the balsams of *Picea excelsa* and *P. sibirica* contain large amounts 7-hexadecenoic, 4,7,10-hexadecatrienoic, 6,9,12,15-octadecatetraenoic, and 11,14-eicosadienoic acids. All studied Soviet balsams and rosins of different conifers contained 13,13-dimethyltetradecanoic acid (**21**) as a minor compound (58). The composition of FA of Bulgarian extractive colophony and pine resin from *Pinus silvestris* and *P. nigra* was studied, and some branched acids—11-methyl-dodecanoic, 12-methyltridecanoic, 13-methyltridecanoic, 12-methyltetradecanoic, 13,13-dimethyltetradecanoic (**21**), and 14-methylpentadecanoic—were detected (59). Neohexadecanoic acid was also isolated from the mixture of saturated FA in tall oils from the Segezha and Kotlass pulp mills (60).

Neopalmitic acid (**21**) was found in some marine invertebrates. Phospholipids and FA of the shell, chitin, and chitosan of the crab *Paralitodes camtshatica* were studied (61). PC, PE, and PS were found in the shell, and PC in chitin, and diphosphatidylglycerols in chitosan. The shell had more FA than did chitin and chitosan, and the most prominent FA in the shell were 9-octadecenoic acid (22%), *iso*-palmitic acid (10%), 9,12-octadecadienoic acid (10%), and 6-hexadecenoic acid. The



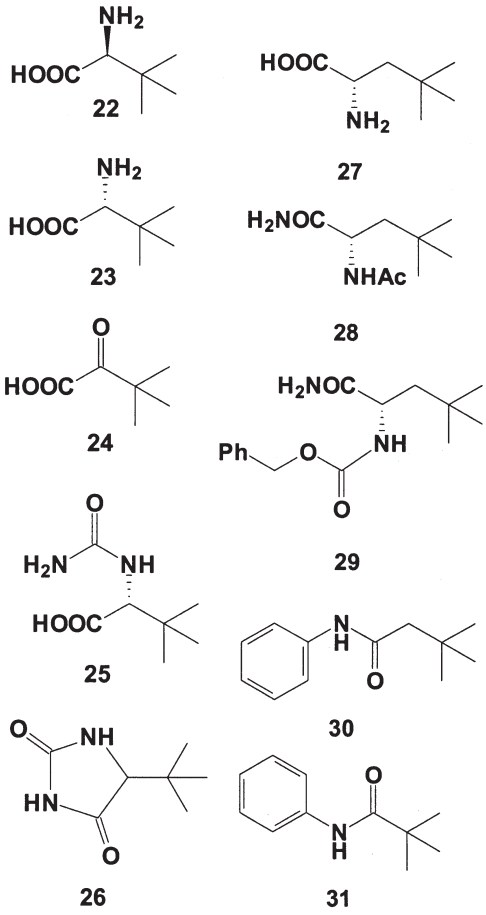
most prominent FA in the chitin were neopalmitic acid (**21**) (22%), 9-octadecenoic acid (19%), myristic acid (12%), and 6-hexadecenoic acid (12%). The most prominent FA in chitosan were 9,12-octadecadienoic acid (18%), palmitic acid (16%), and nondecylic acid (9%) (61). Neopalmitic acid (**21**) was also found in the crayfish, *Astacus astacus* (62).

(2*R*)-2-Amino-3,3-dimethylbutanoic acid (**22**) was produced by 54 soil bacteria taken on Hat Yai campus of Prince of Songkla University (Thailand) when grown at 30 and 45°C (63). (2*S*)-2-Amino-3,3-dimethylbutanoic acid (**23**) and 2-oxo-3,3-dimethylbutanoic acid (**24**) were obtained by transamination with transaminase-producing yeast and bacteria such as *Arthrobacter* sp., *Brevibacterium* sp., *Brevibacterium lineus*, *Brevundimonas* sp., *Candida* sp., *Candida utilis*, *Corynebacterium ammoniagenes*, *Cryptococcus* sp., *Cryptococcus flavus*, *Flavobacterium heparinum*, *Hansenula* sp., *Hansenula jadinii*, *Issatchenkia orientalis*, *Micrococcus* sp., *Micrococcus luteus*, *Nocardioides simplex*, *Pedobacter heparinus*, *Pichia* sp., *Schizosaccharomyces* sp., and *Schizosaccharomyces pombe* (64).

A novel *Pseudomonas putida* strain produced optically pure chiral amino acids and their derivatives (**23**) including N-(aminocarbonyl)-3-methyl-L-valine (**25**) and 5-(1,1-dimethylethyl)-2,4-imidazolidinedione (**26**) (65). Microbial peptide amidases obtained from soil microorganisms in a double screening were used for the production of peptides and neo N-terminal-protected amino acids and racemate splitting of N-protected amino acid amides, D-amino acids, and Nα-protected D-amino acid amides (**27**–**29**) (66). Two amides (**30**) and (**31**) were found in an extract of the root bark of *Viburnum prunifolium* (67).

The marine bacterial community (EM4, including the genera *Marinobacter, Bacillus,* and *Erwinia*) produced several neo compounds—2,4,4-trimethyl-2-penten-3-ol (**32**), 2,4,4,6,6-pentamethylheptanoic acid (**33**), 2,4,4,6,6-pentamethylheptanoic acid (**34**), 2,4,4,6,6-pentamethyl-3-oxo-heptanoic acid (**35**), 2,4,4,6,6-pentamethyl-5-oxo-heptanoic acid (**36**), 2,4,4-trimethylpentanoic acid-1,1-dimethylethyl ester (**37**), and 2,2,4,6,6,8,8-heptamethyl-3-nonanone (**38**)—by direct oxidation of 2,2,4,4,6,8,8-heptamethylnonane (68). The volatile oils isolated by steam distillation from the leaves, stems and flowers of *Paederia foetida* (Malaysia) led to a new neo kyowanoic N (3,5,5-trimethylcaproic, **39**) acid (69).

Pivaloylcarnitine (**40**), pivaloylglycine (**41**), and free pivalic acid (**1**) were present in human urine samples after administration of S-1108 (70). Metabolism of pivaloylcarnitine and pivaloyl-CoA, as well as carnitine homeostasis in man were studied and reviewed (71). *tert*-Valeraldehyde (or pivalaldehyde, **42**) was isolated from among 39 alcohols, 31 aldehydes, 28 ketones, 17 esters, 7 lactones, 4 phenols, 3 furans and furanones, 29 hydrocarbons, and 14 other compounds from black tea (72); it was also present in cigar smoke (73). Raw and smoked black bream (*Brama raii*) and rainbow trout (*Oncorhynchus mykiss*) contain some neo compounds (**43**–**45**) (74). The volatile oil of *Lysimachia foenum-graecum*, grown in Jinxiu County of Guangxi Zhuang Autonomous Region, contains compound **45** (75).



Dimbunol (**46**) was among 85 constituents of the essential oil of fresh flowers of *Elaeagnus angustifolia* (76). Dimbunol is a competitive inhibitor of choline dehydrogenase (CDH)—more so than ethylcholine mustard aziridinium ion—and is an effective irreversible inhibitor of both CDH and choline transport in mice (77). 2,2-Dimethylpropionamide (**47**) was produced by *Pseudomonas putida* and by a strain of *Agrobacterium radiobacter* that was capable of converting nitriles to amides (78,79). 2-Methyl-2-propanol (**48**) was produced by seven *Pseudomonas* strains belonging to six different species: *Ps. brenneri*, *Ps. libanensis*, *Ps. graminis*, *Ps. lundensis*, *Ps. putida*, and *Ps. rhodesiae* (80). Rare 2,2-diethylbutyric acid (**49**), also known as NSC 407528 and NSC 938, was found in a natural anaerobic ecosystem (81).

During genetic engineering of *Streptomyces hygroscopicus* and other microorganisms for production of polyketides and other natural products, an unusual neo acid, 4-*tert*-butylcyclohexanecarboxylic acid (**50**) (also known as NSC 176105, NSC 176107, and NSC 48094), was isolated (82). Derivatives of bicyclo[3.1.0]hexan-2-one (**51**) were detected in essential oil of *Paulownia tomentosa* flowers (83); compounds **51** and **52** were found among volatile components of the marine red alga *Corallina officinalis* (84), and compound **51** has been isolated from the roots of *Aristolochia asclepiadifolia* (85).

An anticoagulant coumarin derivative, named pivalylindandione (**53**) (other names: pindone, pival, or pivalyl), was iso-

lated from biological and bait materials (e.g., slugs, snails) more than 50 years ago (86). More recently, it has been shown that pivalylindandione has insecticidal and blood coagulation properties (87–91).

Two *cis*- and *trans*-isomers derivatives of cyclohexanol (**54, 55**) were obtained by transformations of four alicyclic ketones of an axenic strain of *Chlorella pyrenoidosa* (92).

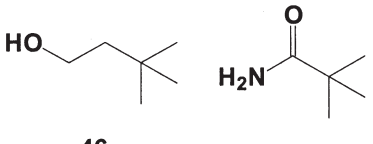
Laingolide (**56**), a novel 15-membered macrolide containing a lactam group, was isolated from the cyanobacterium *Lyngbya bouillonii*, collected on Laing Island (Papua-New Guinea) (93). Two macrolide derivatives, laingolide A (**57**) and madangolide (**58**), have been from obtained from the same organism (94).

Investigation of the blue-ring sea hare *Stylocheilus longicauda* led to the isolation of two chlorinated complex proline esters, makalika ester (**59**) and makalikone ester (**60**) (95).

Several biologically active metabolites with condensed ring systems and containing a *tert*-butyl unit belonging to sesquiterpenes (**61**–**68**) have been obtained from the leaves of *Ginkgo biloba* (96–99). Ginkgo is a traditional herb that has been used for disease treatment for more than 2,500 years (100). Extracts from its leaves were used in ancient China, whereas in the Western world they have been used only since the 1960s, when it became technically possible and feasible to isolate the essential substances of *Ginkgo biloba* (101).

The terpene trilactones of *Ginkgo biloba* leaves, containing mainly ginkgolides (A,B,C,J,M,K,L, **61**–**67**, respectively) and bilobalide (**68**), are selective platelet-activating factor (PAF) antagonists and have neuroprotective effects. Compound **62** especially has the greatest potentcy among these terpene trilactones and is now used as the PAF antagonist for the prevention and treatment of thrombus, illness of blood vessels of heart and brain, arrhythmia, asthma, bronchitis, senile dementia, and allergic reaction (102–104).

Ypaoamide (*Z*) (**69**), a new herbivore antifeedant metabolite, was isolated from the extract of a mixed cyanobacterial assemblage that was composed of *Schizothrix calcicola* and *Lyngbya majuscule* (105). Ypaoamide is a structurally novel cyanobacterial metabolite.



46 47

48 49

Ypaoamide (*E*) (**70**) was isolated from a cyanobacterial bloom and a massive die-off of juvenile rabbitfishes (*Siganus argenteus* and *S. spinus*). The microbial assemblage was composed primarily of the marine cyanobacterium *Schizothrix calcicola* with sparsely distributed strands of *Lyngbya majuscula*. Palatability of the crude organic extract of this mixed cyanobacterial assemblage was evaluated in feeding assays using the parrotfish *Scarus schlegeli* and the sea urchin *Echinometra mathaei* in outdoor tanks on Guam. Bioassay-guided fractionation resulted in the isolation of ypaoamide B, a new, broadly acting feeding deterrent compound (106,107).

Teleocidins are potent tumor promoters, having a nine-membered lactam structure. Teleocidins and their small-molecular-sized active congeners (indolactams) are known to exist in an equilateral position between at least two conformational states, the twist and the sofa form. Three teleocidin derivatives (**71**–**73**) with a *tert*-butyl unit are produced by the actinomycete, *Streptoverticillium blastmyceticum* NA34-17 (108–111).

The antibiotics bottromycin A2 (**74**) and B (**75**) are produced by *Streptomyces* sp. strain No. 3668-L2 (112,113), *Kitasatoa purpurea* strain KA-281 (114), and *Micromonospora chalcea* strain FERM-P 1823 (115). Bottromycins showed similar antibacterial spectra, except that bottromycin A was 3–4 times stronger than bottromycin B. They were effective against six antibiotic-resistant strains of *Staphylococcus aureus*, *Streptococcus pyogenes, Micrococcus flavus, Bacillus subtilis, B. cereus, B. megaterium, B. anthracis, Corynebacterium xerosis*, and *Mycobacterium phlei* in concentrations of 0.03–3 μg/mL.

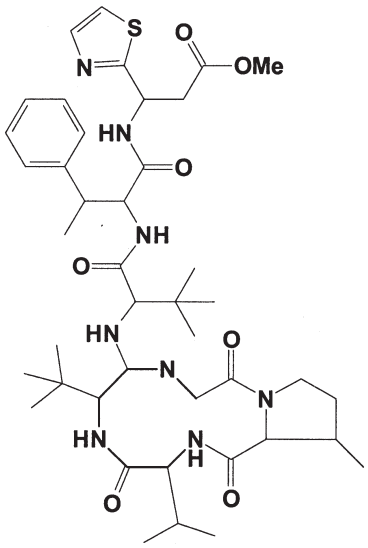
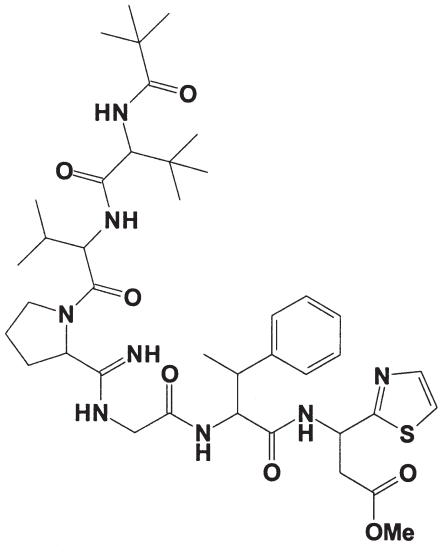
Goldfish toxicity was used to direct the fractionation of a chemical-rich extract of *Lyngbya majuscula* from Curaçao, resulting in the isolation of a metabolite, (**76**), as an exceptionally potent ichthyotoxin (LD_{50} = 0.05 μg/mL).

Bioassay-guided fractionation of organic extracts from two *Lyngbya majuscula* collections led to the isolation of a new secondary metabolite, antillatoxin B (**77**), an unusual N-methyl homophenylalanine analog of the potent neurotoxin antillatoxin. Antillatoxin B exhibited significant sodium channel-activating (EC_{50} = 1.77 μM, where EC_{50} refers to that concentration having an effect on 50% of the population) and ichthyotoxic (LC_{50} = 1 μM, where LC_{50} is that concentration having a lethal effect on 50% of the population) properties (118,119). The potent cytotoxic agent hemiasterlin (**78**) was identified from the sponge *Hemiasterella minor* (120). Antimiotic peptides, hemiasterlin (**79**), hemiasterlin methyl ester (**80**), dihydrohemiasterlin (**81**), and criamides A (**82**) and B (**83**) were isolated from Indian Ocean sponge *Cymbastela* sp. (121,122).

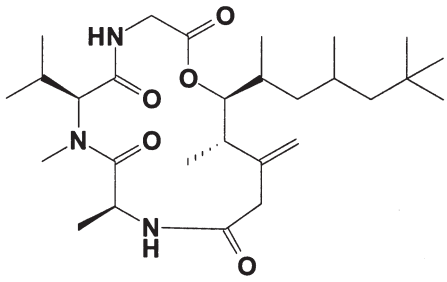
A reinvestigation of the sponge *Auletta* sp. yielded the novel and known cytotoxic compounds, milnamide A, C, and D (**84**–**86**), hemiasterlin, jasplakinolide, and geodiamolides A, D,



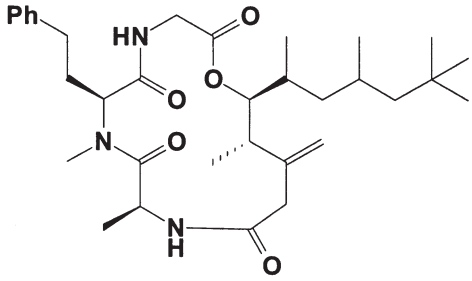
74 Bottromycin A_2



75 Bottromycin B



76 Antillatoxin A



77 Antillatoxin B

E, and G, and milnamide B (known as hemiasterlin, **78**) (123). Milnamides A and D were also found in methanolic extract of the marine sponge *Cymbastela* sp. (124).

A depsipeptide, polydiscamide A (**87**), composed of 13 amino acids including a novel amino acid 3-methylisoleucine, was isolated from a Caribbean sponge of the genus *Discodermia* (125). This compound inhibits the *in vitro* proliferation of the cultured human lung cancer A549 cell line. Microspinosamide (**88**), a new cyclic depsipeptide incorporating 13 amino acid residues, was isolated from extracts of an Indonesian collection of the marine sponge *Sidonops microspinosa*. The tridecapeptide (**88**) incorporates numerous uncommon amino acids, and it is the first naturally occurring peptide to contain a β-hydroxy-*p*-bromophenylalanine residue. Compound **88** inhibited the cytopathic effect of HIV-1 infection in an XTT (kit assay)-based *in vitro* assay with an EC_{50} value of 0.2 μg/mL (126).

The unique polytheonamides A (**89**) and B (**90**) are highly cytotoxic polypeptides with 48 amino acid residues. They have been isolated from the marine sponge, *Theonella swinhoei*. Elucidation of the structure of polytheonamide B resulted in an unprecedented polypeptide structure: an N-terminal glycine blocked with a 5,5-dimethyl-2-oxo-hexanoyl group, the presence of eight *tert*-leucine, three β-hydroxyvaline, six γ-N-methylasparagine, two γ-N-methyl-β-hydroxyasparagine, and β,β-dimethyl-methionine sulfoxide residues. More significantly, there is a sequence of alternating D- and L-amino acids. Polytheonamide A is an epimer of polytheonamide B, differing only in the stereochemistry of the sulfoxide of the 44th residue (127). Polytheonamides A and B are quite unusual in that one peptide molecule contains nine amino acids with *tert*-butyl units (!).

Three tetradecapeptides named halicylindramides A–C were isolated from the Japanese marine sponge *Halichondria cylindrata*; halicylindramide B (**91**) and C (**92**) contain *tert*-butyl units. In these tetradecapeptides the N-terminus is blocked by a formyl group and the C-terminus is lactonized with a threonine residue. Halicylindramides A–C have antifungal activity against *Mortierella ramanniana* and cytotoxic activities against P388 murine leukemia cells (128).

Two collections of the marine cyanobacterium *Lyngbya* sp. from Guam and Palau both afforded the potent cytotoxins apratoxin A (**93**) and B (**94**) and E-dehydroapratoxin A (**95**). According to SAR studies on this novel family of depsipeptides, these compounds showed toxic activity against some yeast species. The key structural elements responsible for the cytotoxicity of these toxins were identifiedAll analogs displayed weaker cytotoxicity than compound **93**, but to different extents (129).

The structure of the antimicrobial peptide discodermin A (**96**) isolated from the marine sponge *Discodermia kiiensis*

were elucidated in 1984 (130). Ten years later, the known discodermins A–D were isolated from same sponge together with a cytotoxic and antimicrobial tetradecapeptide discodermin E (**97**) (131) and three novel tetradecapeptides, named F (**98**), G (**99**), and H (**100**) (132). The effects of discodermin A (DC-A), a marine bioactive peptide extracted from the sea sponge *D. kiiensis*, on the vascular smooth muscle cells and tissues were reported (133). Analysis with a confocal laser microscope showed that DC-A (0.1–30 μM) permeabilized the plasma membrane of A10 cells to the nonpermeable fluorescent agents ethidium homodimer-1 and calcein in a concentration-dependent manner. In vascular tissue treated with 30 μM DC-A, addition of a micromolar concentration of Ca^{2+} evoked a sustained contraction in the presence of ATP, suggesting that DC-A increased the permeability of the membrane to Ca^{2+} and ATP. These results suggested that DC-A had a permeabilizing effect on the plasma membrane, possibly by interacting with plasma membrane phospholipids with its six successive hydrophobic amino acid residues at N-terminal.

Several steroids containing a tertiary butyl group have been isolated from plants, marine algae, and invertebrates.

Wallenone (**101**), a C_{32} tirucallane-type triterpene, was isolated from the leaves of *Gyrinops wala* (Thymelaeaceae, small tree grown on Ceylon) (134). More recently, the same compound was isolated from the ethyl acetate extract of the dried leaves of *Esenbeckia stephani* (Rutaceae) (135).

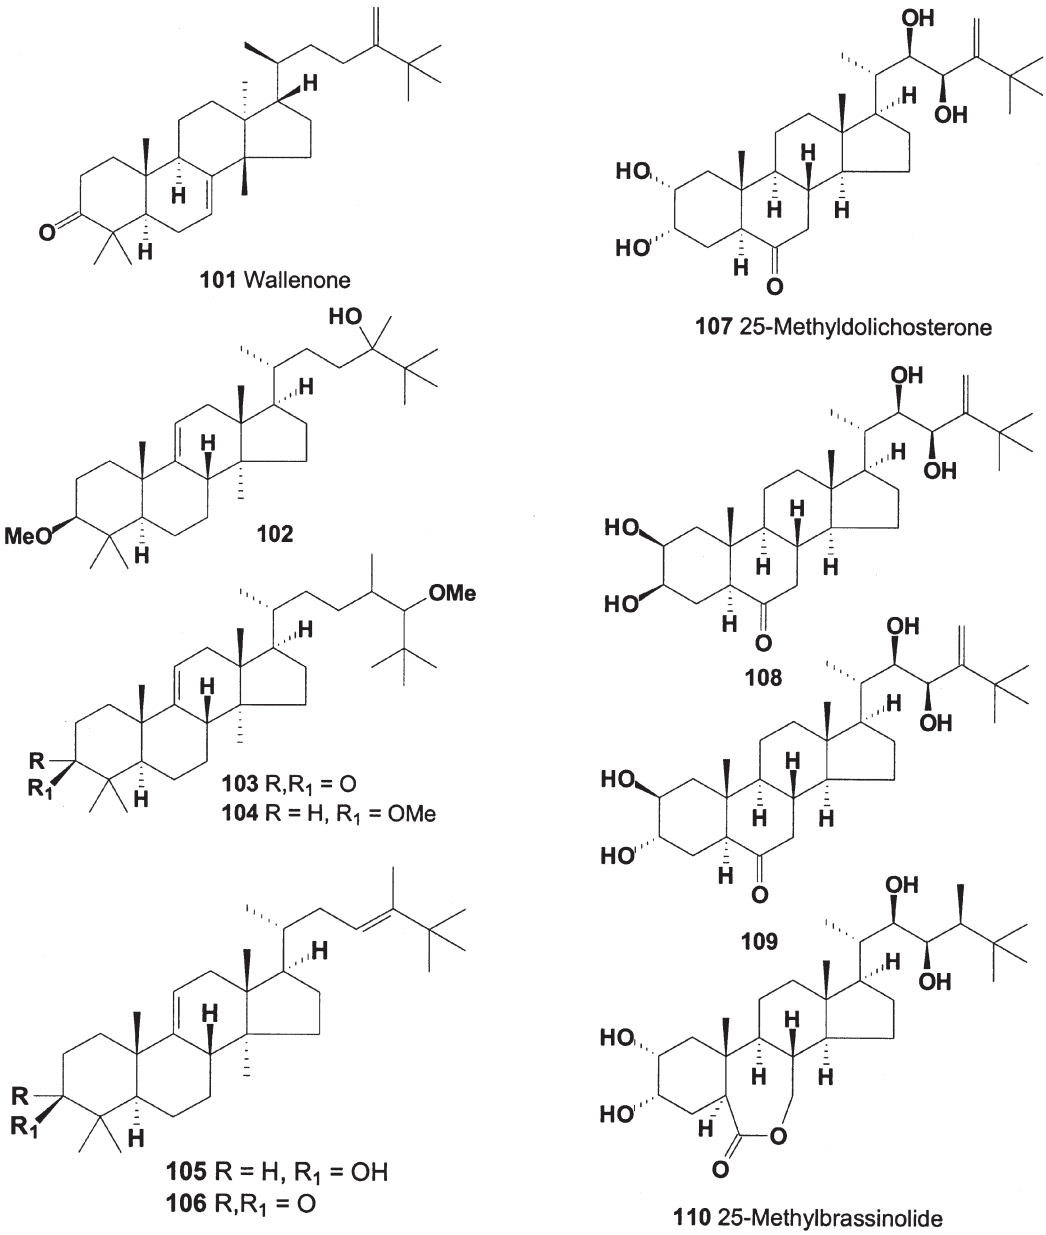
Three triterpenoids, 3β-methoxy-24-methyl-lanost-9(11)-en-24-ol (**102**), 24ξ-methoxy-24,25-dimethyl-lanost-9(11)-en-3-one (**103**), and 3β,24ξ-dimethoxy-24,25-dimethyllanost-9(11)-ene (**104**), were isolated from *Neolitsea pulchella* (Lauraceae, Hong Kong, also known as Neolitsea) (136,137). Two triterpenoids, 24,25-dimethyl-9(11),23-lanostadienol (**105**) and 24,25-dimethyl-lanosta-9(11),23-dien-3-one (**106**), were obtained from the stems of *Quercus* spp. (*Q. bambusaefolia, Q. championi, Q. myrsinaefolia*) (138).

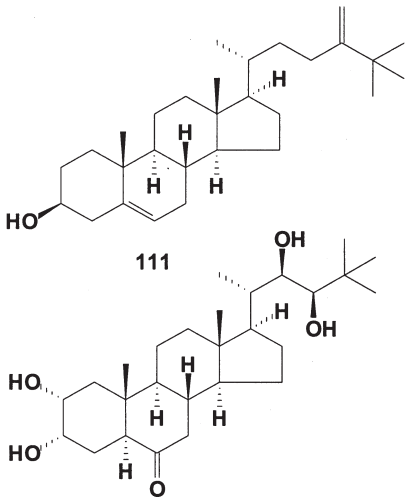
Several phytosterols with a tertiary butyl group, namely, 25-methyldolichosterone (**107**), 2,3-diepi-25-methyl-dolichosterone (**108**), 25-methyl-2-epidolichosterone (**109**), 25-methyl-brassinolide (**110**), 24-methylene-25-methyl-cholesterol (**111**), and brassinone (**112**) were identified in immature seed of *Phaseolus vulgaris*. 24-Methylene-25-methylcholesterol is considered closely correlated biogenetically with 25-methyl-dolichosterone (139–142). Compound (**110**) was a more potent plant-growth regulator than brassinolide itself (143).

In 1949, Bergmann and Feeney (144) discovered haliclonasterol (25-methyl-24ξ-ergosta 5,7,22- rien-3β-ol; **113**) in marine sponges belonging to genus *Haliclona*. They were studying the sterol composition of acetone extracts from the sponges *H. variabilis*, *H. permollis, H. coerulescens, H. viridis, H. rubens*, and *H. longleyi* and showed that haliclonasterol was present in all investigated species (144). Haliclonasterol was also detected in the marine green algae *Monostroma nitidum* and *Enteromorfa*



linza (145), and other species belonging to the phylum Chlorophyta (146,147). It also was found in other sponge species (148), and in three sea anemones, *Palythoa mammilosa*, *Zoanthus proteus*, and *Condylactis gigantean* (149). For the first time an axinyssasterol (**114**) and (3β,24*E*)-25-methyl-stigmasta-5,24(28)-dien-3-ol (**115**) were identified from a *Pseudoaxinyssa* species by Li and Djerassi (150). In the Australian sponge *Trachyopsis* sp., 64% of the total sterols was axinyssasterol (151). (3β,22*E*,24ξ)-28,28-Dimethyl-stigmasta-5,22,25-trien-3-ol acetate (**116**) and (3β,22E)-25-methyl-stigmasta-5,22-dien-3-ol (**117**) were obtained from an EtOH extract of the sponge *Halichondria* sp. (152,153), and compound **117** was also found in specimens of the sponge *Trachyopsis aplysinoides* from Sri Lanka inshore waters (154).

The antimicrobial halistanol (**118**) and its trisulfate (**119**) were isolated from the Okinawan sponge *Halichondria* cf. *moorei* more then 25 years ago (155). More recently, halistanol trisulfate was found in different sponge species (148,156–159). Halistanol trisulfate has a relatively low critical micelle concentration of 14.5 μM and strong hemolytic potency with an EC_{50} of 6.67 μM. As expected of a detergent, it inhibits the growth of Gram-positive but not Gram-negative bacteria (160). Halistanol sulfate E (**120**) was present in an extract of the marine sponge, *Epipolasis* sp. (161). Halistanol trisulfate and a new sterol sulfate, Sch 572423 (**121**), were detected in a marine sponge *Topsentia* sp.; both metabolites were identified as $P2Y_{12}$ inhibitors with IC_{50} of 0.48 and 2.2 μM, respectively (162). Some sponge steroids contain sulfate groups in positions 3α and 2β. This series of compounds includes compound **122**, a possible biogenetic precursor of halistanol sulfate (148). The tris-(2-aminoimidazolium) salt of halistanol sulfate (**123**) was isolated as an antimicrobial agent from a Japanese specimen of *Topsentia* sp. (163).



112 Brassinone

Several marine steroids with a tertiary butyl group were isolated as glycosides. Two novel triterpene glycosides, eryloside C (**124**) and eryloside D (**125**), from a sponge of the genus *Erylus*, collected at a depth of 500 m isouth of New Caledonia (an island off the northeast coast of Australia), were reported (164), and another glycoside termed eryloside E (**126**) was isolated from the marine sponge *E. goffrilleri* (165). The crude extract of sponge *E. nobilis* from Jaeju Island (Korea) exhibited moderate cytotoxicity (LC_{50} 317 μg/mL) against the human leukemia cell line K562. From this extract a new triterpenoid trisaccharide, designated erylosides I (**127**) and J (**128**), were obtained (166).

These compounds possessed C_{32} aglycone based on the carbon framework of lanostane. The sugar portions were proven to be branched assemblies of one unit each of L-arabinose, L-galactose, and 2-*N*-acetyl-L-glucosamine (**127**) or two units of L-arabinose and one unit of 2-*N*-acetyl-D-glucosamine (**128**) (166).

Some natural bioactive metabolites contain pivalic acid (**1**) in their structure. Bryostatins, a structurally novel family of marine macrolides, were first discovered by Pettit and co-workers in the bryozoan invertebrate *Bugula neritina* (167). These interesting anticarcinogenic compounds are also found in smaller quantities in the marine organisms *Lissodendoryx isod-*

ictyalis, Aplidium californium, and *Amathia convoluta* (168). Each organism was discovered to have *B. neritina* growing within its biomass.

Twenty bryostatins have so far been isolated from these two organisms, which are indigenous to the Gulf of Mexico (Florida), Gulf of Aomori (Japan), and Radio Island Jetty near Morehead, North Carolina (USA) (168–170). All bryostatins possess a 20-membered macrolactone in which there are three remotely functionalized pyran rings interconnected by an (*E*)-disubstituted alkene and a methylene bridge. In several bryostatins such as 10, 14, 16, 17, 18, and 20 (**129–131,132a,b,** and **133**), pivalic acid is present.

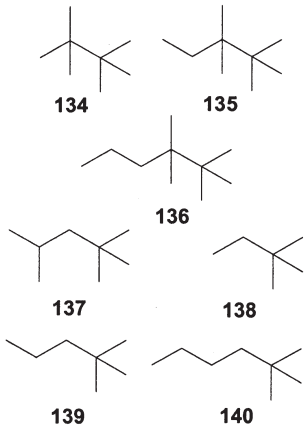
OCCURRENCE OF NEO ALKANES AND DERIVATIVES IN NATURE

Highly branched alkanes have been found in bacteria, cyanobacteria, plants, invertebrates, and other animals. They also are found in sediments, meteorites, and other geological samples (16,17).

Analysis of volatile components of the marine red alga *Corallina elongata* led to the identification of 141 components including three neo alkanes, 2,2,3,3-tetramethylbutane (**134**), 2,2,3,3-tetramethylpentane (**135**), and 2,2,3,3-tetramethylhexane (**136**) (12). Neo alkanes **137**–**140** were produced by *Pseudomonas oleovorans* GPo1 and *Corynebacterium urealyticum* CIP-I-2126 (14,15).

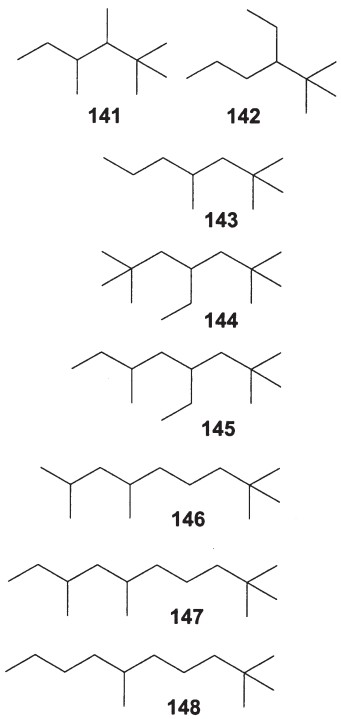
Analysis of the cultured soil cyanobacterium *Microcoleus vaginatus* from the Negev Desert found that this microorganism produced an unusual mixture of four normal and more than 60 branched alkanes, as well as a number of FA, cyclic and unsaturated hydrocarbons, aldehydes, alcohols, and ketones, including some neo alkanes (**141–148**) (13).

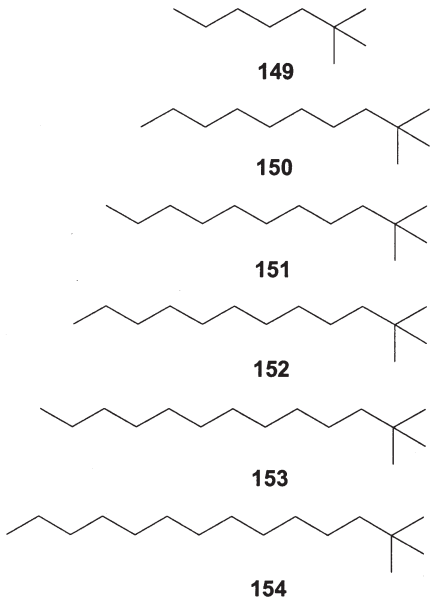
Some neo alkanes (**137**,**149–160**) have been isolated from plants. In cooked samples of black-salsify (*Scorzonera hispanica*), a member of the Asteraceae family, were found 114 com-



ponents, including two neo alkanes (**137** and **155**) (171). From the volatile oils of *Houttuynia cordata* 'Chameleon' was identified 2,2-dimethylheptane (**149**) (172). The volatiles from fresh flowers and leaves of *Gentiana lutea*, *G. punctata* (yellow *Gentiana* spp.), and *G. asclepiadea* (Gentianaceae Juss.) were analyzed by GC/MS and 81 compounds identified, including 2,2-dimethyldecane (**150**) (173,174); compound **150** was also found in dehulled sesame seeds and in volatile compounds of black tea (175).

2,2-Dimethylundecane (**151**) was extracted with a mixture of *n*-pentane, methylene chloride and diethyl ether from samples of Cuban sugarcane molasses (176). Two neo alkanes, 2,2-dimethyldodecane (**152**) and 2,2-dimethyl-ridecane (**153**), were present in alcohol extracts of the fruits of *Averrhoa carambola*; and 2,2-dimethyltetradecane (**158**) was isolated from essential oil of *Plectranthus coleoides* (177,178). The highly branched alkane 2,2,4,6,6-pentamethylheptane (**156**)



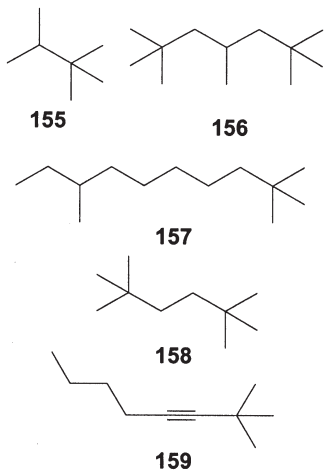


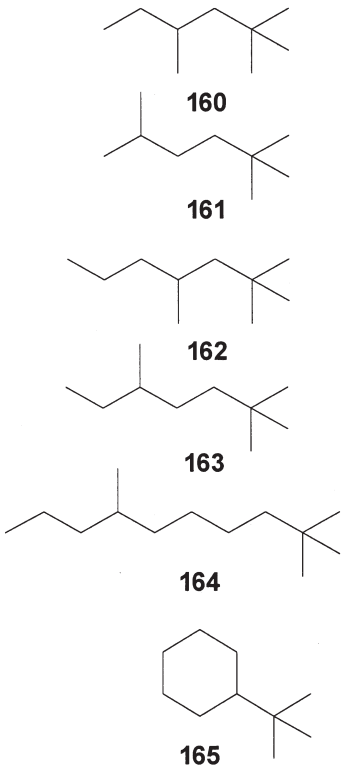
was identified in ginseng root oils; it also was found among volatiles from litter and soil associated with *Ceratiola ericoides*, and in the essential oil of *Anthemis montana* (Asteraceae) (179–181). Two other neo alkanes, 2,2,5,5-tetramethylhexane (**158**) and 2,2,8-trimethyldecane (**157**), were isolated from the volatile components of fresh, tree-ripened apricots (*Prunus armeniaca*), plums (*Prunus salicina*), and their interspecific hybrids (182).

2,2,4,6,6-Pentamethylheptane (**156**) was isolated from the mycelium of the fungus *Tuber borchii* (Ascomycete) grown in a sterile liquid medium (183).

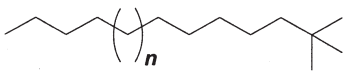
The rare acetylenic neo alkane 2,2-dimethyl-3-octyne (**159**) was detected in essential oil of *Paulownia tomentosa* flowers (83). The neo alkanes **156** and **160** were detected in fresh-cut fruits of pineapple (*Ananas* sp.) (184).

Some neo alkanes and other volatile compounds have been isolated from food products. 2,2,4,6,6-Pentamethylheptane (**156**) and four alkanes (C_{15}–C_{17}, C_{19}) were present among volatile components from freshly picked out meat of blue crab

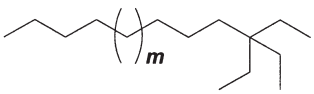




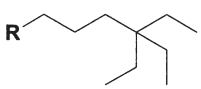
(*Callinectes sapidus*) and processing by-product, and in freshly boiled crayfish tail meat and hepatopancreas (185,186). Alkanes **137** and **156** were present in cooked beef from the local Spanish cattle breeds, Asturiana, Avilena, Parda Alpina, Pirenaica, Retinta, Rubia Gallega, and Morucha, and in raw beef from Asturiana de los Valles, Morucha, Parda Alpina, Pirenaica, and Retinta cattle breeds (187,188). 2,2,5-Trimethylhexane (**161**) was detected in flavor and aroma volatiles of Colonnata bacon, a traditional delicacy (189,190).



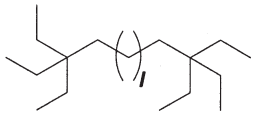
166-175 *n* = 1,2,4,6,8,10,12,14,16



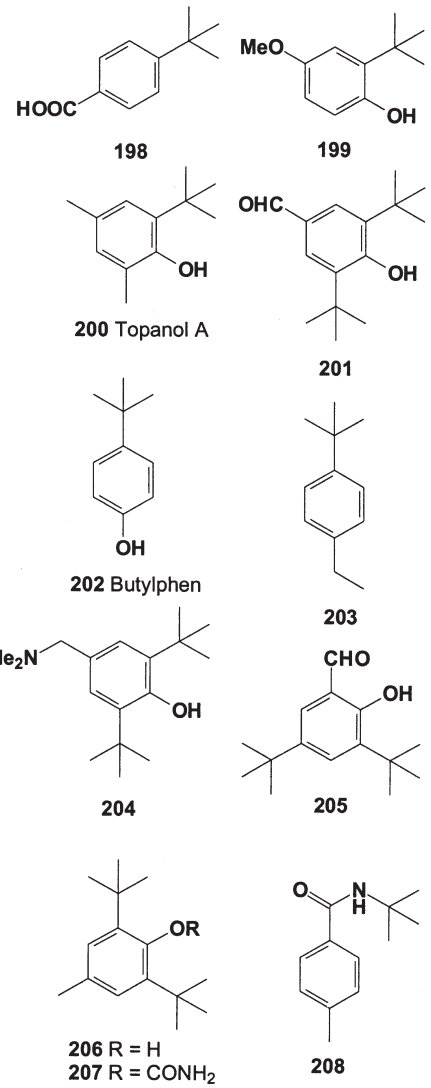
176-183 *m* = 1,2,4,6,8,12,14,16



184-191 R = C_{27}-C_{39}



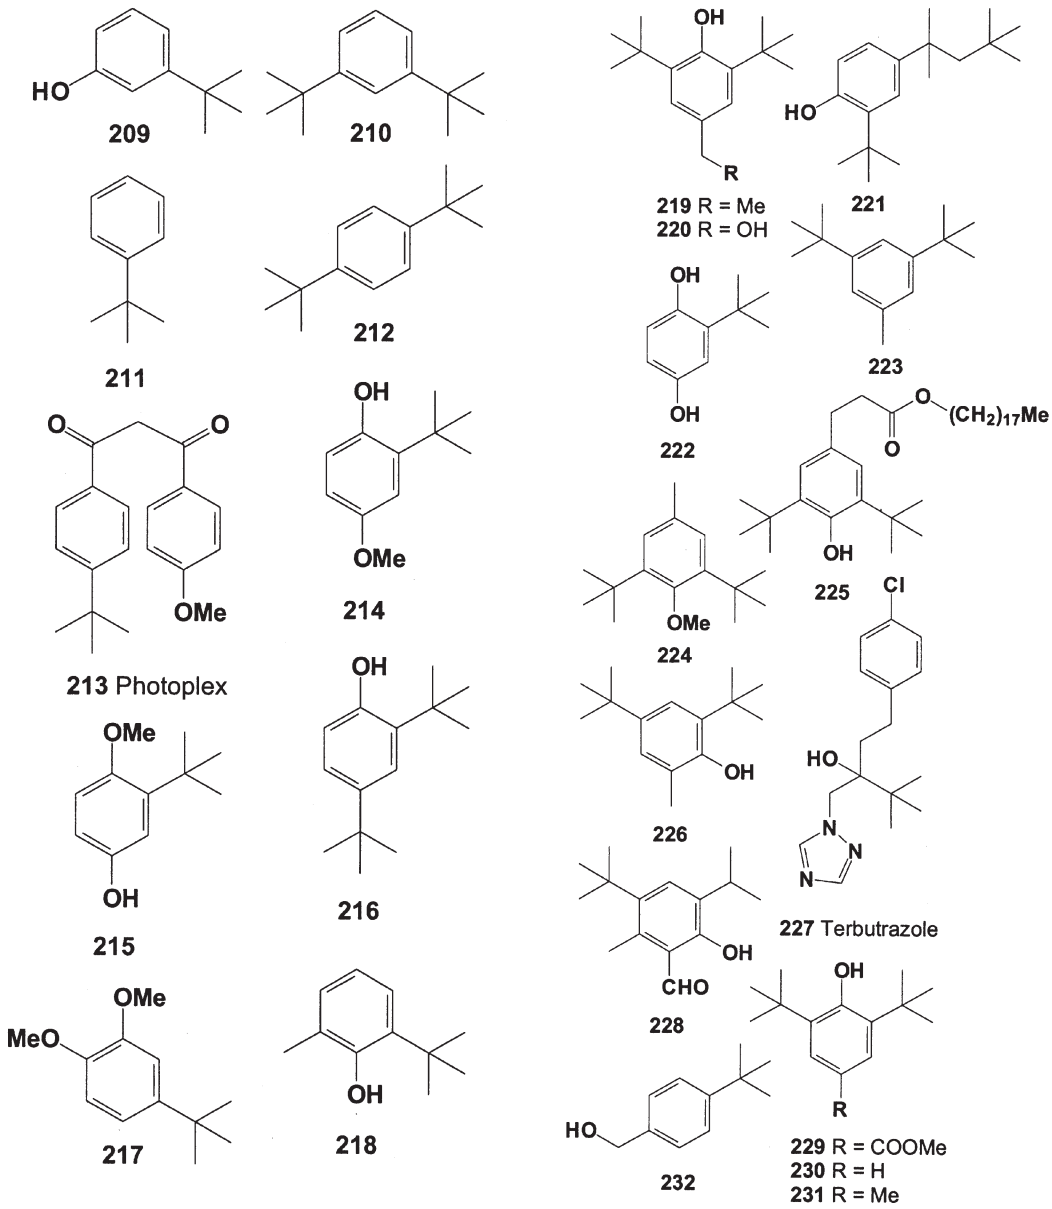
192-197 *l* = 1,4,6,8,10,12



Among 81 compounds, alkane **156** was detected in the volatile flavors of six types of cheese: Parmigiano Reggiano, Fontina, Mahon, Comte, Beaufort, and Appenzeller, and compounds **150** and **151** were isolated from Cheddar and Swiss cheeses during ripening for 9 weeks at 11 and 21°C, respectively (191,192). The aroma fraction of Parmesan cheese was studied in 21 samples of certified origin and aging. Volatile compounds were isolated by means of GC and GC/MS. One hundred sixty-seven compounds were identified: 23 hydrocarbons, including compound **150**, 19 aldehydes, 19 ketones, 29 alcohols, 24 esters, and 25 acids, and 28 other compounds that represented other classes of substances (192,193).

The volatile compounds generated in meat from Iberian and lean pigs after four different treatments (raw, refrigerated, cooked, and refrigerated cooked meat) were analyzed. The different treatments showed different volatile profiles, and all fractions contained the neo alkane **156** (194).

Chicken fat was cooked to 80°C and extracted using supercritical carbon dioxide at 40°C and each of three pressures: 10.3, 20.7, and 31.0 MPa. Of the 318 volatile compounds detected, 99 were classified, including neo alkanes **161**–**164** (195,196).



Raw and smoked black bream (*Brama raii*) and rainbow trout (*Oncorhynchus mykiss*) contained neo alkane **156** (74). The same compound was detected in volatile components of eight cultivars of potato after microwave baking (197). Coryneform bacteria produced *tert*-butylcyclohexane (**165**) (198).

Branched alkanes, such as dimethylalkanes and monomethylalkanes, are common in organic geological samples. At present, the sources of these identified compounds are not well known. Some short-chain (C_{16}–C_{21}) dimethylalkanes (**166–168**) and monomethylalkanes were identified in cyanobacterial cultures, fungi, and marine algae (12–15,199). 2,2-Dimethyldocosane was tentatively identified in the desulfurized polar fraction of an Oligocene anhydrite (200), and a pseudohomologous family of 2,2-dimethylalkanes (C_{16}–C_{28}) (**166–175**) was tentatively identified in Cenomanian and Turonian black shales of Canada (201). Unusual pseudohomologous series of branched alkanes with one (**176–183**) or two quaternary (**192–197**) carbon atoms were present in the extractable organic matter of Cenomanian and Turonian black shales of Pasquia Hills (Saskatchewan, Canada) (202). The 3,3-diethylalkanes ranged from C_{15} to C_{39} (**184–191**) with C_{max} at 27, and only odd carbon-numbered pseudohomologs were detected in the sulfide deposits of the Rainbow field (Mid-Atlantic Ridge) (203). The origin of these compounds remains unclear, although a bacterial origin is favored.

OTHER NATURAL METABOLITES CONTAINING A TERTIARY BUTYL GROUP(S)

Some aromatic compounds containing *tert*-butyl unit(s) can be components of natural antioxidants, and they have been isolated from plants, marine algae, and fungi (204,205).

4-*tert*-Butylbenzoic acid (**198**) and 4-methoxy-2-*tert*-butylphenol (**199**) were found among volatile substances in

TABLE 1
Distribution of Aromatic and Other Metabolites with a Tertiary Butyl Group(s)

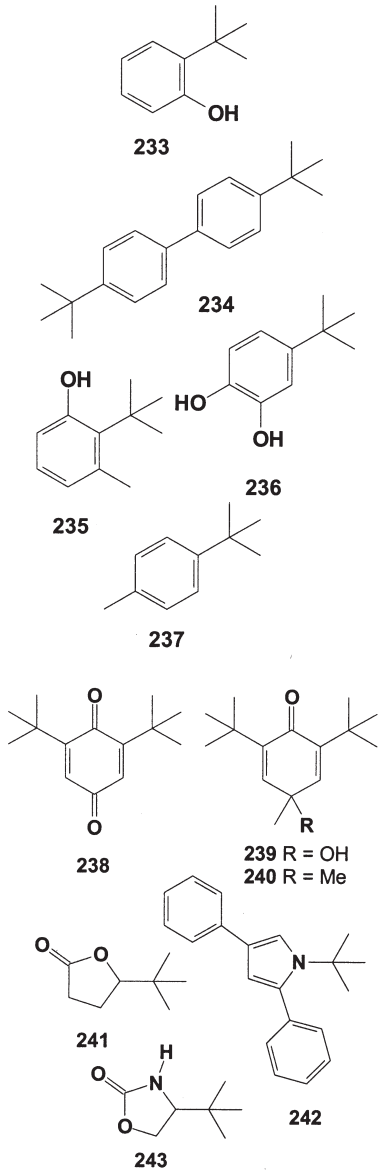
fruits of *Zizyphus jujube* (206). The well-known antioxidant topanol A (**200**) was found in dry and fresh flowers of *Aloe vera* (207), and identified from the green alga *Enteromorpha compressa* and the red alga *Hypnea musciformis* (208). The 4-formyl-2,6-di-*tert*-butylphenol (**201**) was among 62 compounds detected in odors of apple trees (209). Butylphen (**202**) and compound **204** were detected in the volatiles of fresh flowers from nine natural populations of four *Lamium* species: *L. album, L. galeobdolon, L. garganicum, L. maculatum*, and *L. purpureum* (210). Thirty-three components have been identified in the odors emitted by fresh flowers of *Fissistigma shangtzeense*, which is found in Guangxi and the southwest of Yunnan province of China, including 3,5-di-*tert*-butylsalicylic aldehyde (**205**) (211). Essential oil from flowers of *Robinia pseudoacacia* contained approximately 51% α-limonene, 12% γ-terpinene, and 7% 2,6-di-*tert*-butyl-4-methylphenol (**206**), and minor compound **207** (212). Floral fragrance oils related to pollination were studied in three cacao species of *Theobroma* and one *Herrania* species (Sterculiaceae) in Costa Rica, and N-*tert*-butyl-4-methylbenzamide (**208**) was found (213).

Two fungal species, *Penicillium commune* and *Paecilomyces variotii*, were cultivated on pine wood and on a combination of

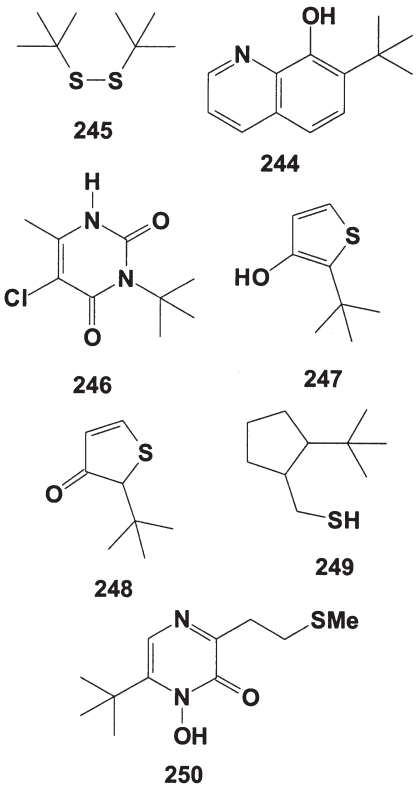


gypsum board and mineral wool, and both fungal species produced *p-tert*-butyl-ethylbenzene (**203**) (214).

About 40 natural aromatic compounds containing *tert*-butyl unit(s) (**198**–**237**) have been isolated from plant, marine algae, and fungi, their distribution in nature shown in Table 1. Occurrence other metabolites with *tert*-butyl unit(s) (**238**-**250**) shown in Table 1.

Some novel natural metabolites with a tertiary butyl group(s) have been discovered in plant species and fungi. Two new sulfur-containing derivatives, *tert*-Bu-3-[(1-methylpropyl)dithio]-2-propenyl malonate (**251**) and *tert*-Bu-3-[(1-methylthiopropyl)thio]-2-propenyl malonate (**252**) were isolated from the roots of *Ferula persica* var. *latisecta* grown in Iran (268).

The roots of *Toona ciliata* (Brazil) yielded a new 9,10-dihydrophenanthrene, which was identified as 9,10-dihydro-9-hydroxy-9-(*tert*-butoxycarbonylmethyl)-10-oxo-phenanthrene (**253**) (269).



Among four furanocoumarins isolated from the roots of *Angelica dahurica* (grown in South Korea) was a new bioactive oxypeucedanin hydrate-3″-*tert*-Bu ether (**254**) (270).

The essential oil steam distillation of the aerial parts of *Saussurea arenaria*, *S. iodostegia* and *S. japonica* led to a 4-*tert*-butoxyanisole (**255**) (271). A derivative of 1(2H)-pentalenone (**256**) was extracted from and detected in aged flue-cured tobacco leaves (272).

Two stereoisomers (**257** and **258**) were produced by the filamentous fungus *Penicillium citreo-viride* (273). S-*tert*-Butyl-L-cysteine (**259**) was obtained by the cleavage of alliin by C-S-lyase isolated from ramson, the wild garlic (*Allium ursinum*) (274). Compound **260** was obtained by biotransforming *cis*-2-methyl-3-oxobutanoic acid ethyl ester with bakers' yeast at 30°C for 48 h (275). The volatile amines **261** and **262** were detected in dry bakery yeast autolyzate (276). Three cyclohexanol derivatives (**263**–**265**) and compound (**266**) were detected in essential oil of medicinal herb extract (277).

BIOLOGICAL ACTIVITIES OF NEO ACIDS AND DERIVATIVES

Many natural metabolites and synthesized compounds (**267**–**289**) containing a tertiary butyl group(s) show biological activity, and some of them used in clinical medicine. Some synthesized compounds with *tert*-butyl unit(s) for which activity has been demonstrated activities are considered next.

Photoplex (**213**) has other names: escalol 517, eusolex 9020, neoheliopan 357, parsol 1789, parsol A, parsol RTM 1789, and uvinul BMBM. It has a broad spectrum of protective proper-

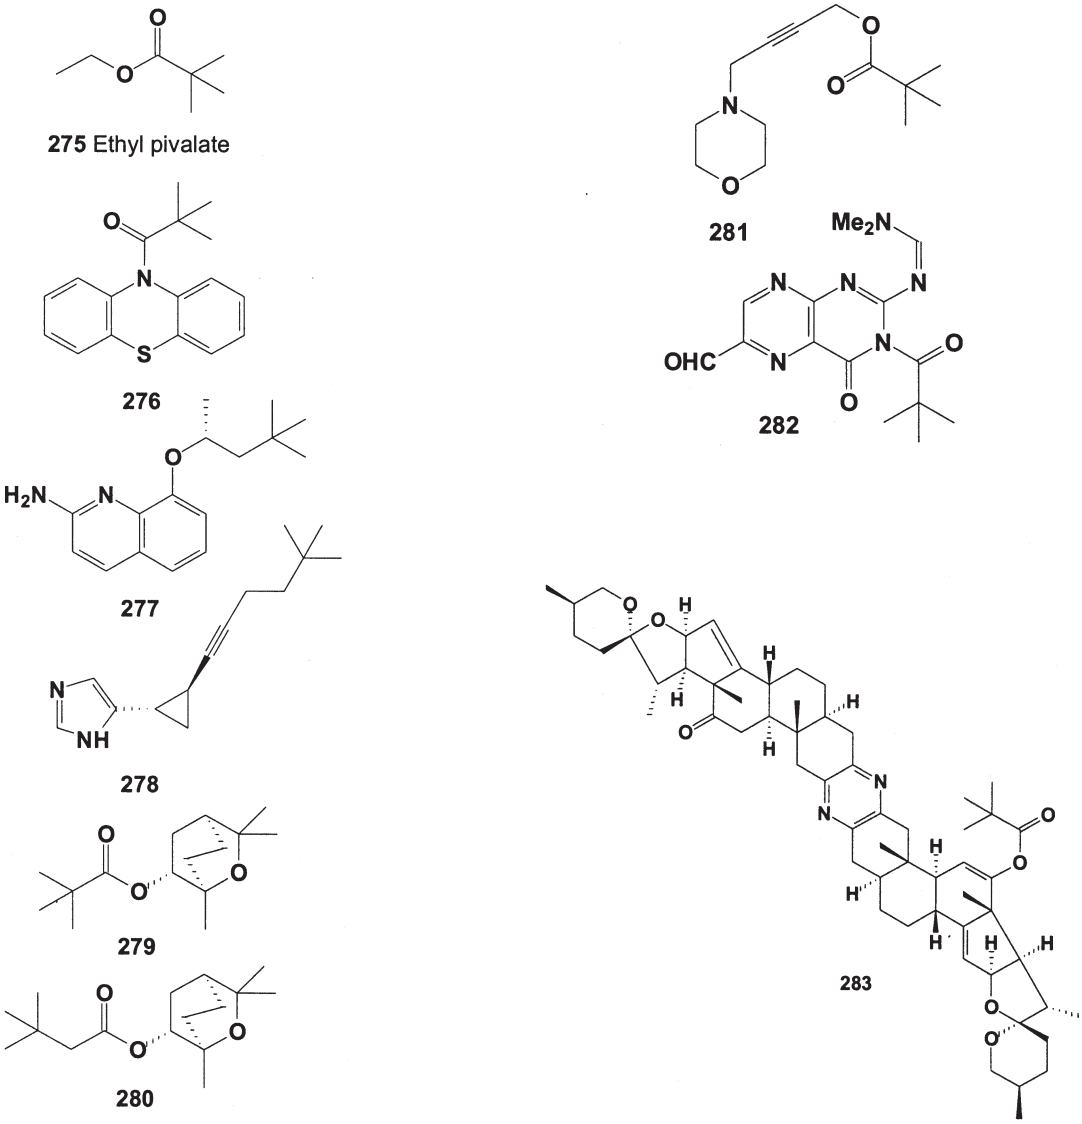
ties toward human skin, and it is used in clinic dermatology (278,279).

A novel biphenolic compound, bis(2-hydroxy-3-*tert*-butyl-5-methylphenyl)-methane (GERI-BP002-A, **234**), that was isolated from the fermentation broth of *Aspergillus fumigatus* F93 (222) is cytotoxic to human solid tumor cells. Effective doses that cause 50% inhibition of cell growth *in vitro* against non-small cell lung cancer cell A549, ovarian cancer cell SK-OV-3, skin cancer cell SK-MEL-2, and central nerve system cancer cell XF498 are 8.24, 10.60, 8.83, 9.85 μg/mL, respectively.

Neo FA (**14** and **267**–**272**) were prepared and showed strong bactericidal properties (280). 12,12-Dimethyltridecanoic acid (**21**) and 18,18-dimethylnonadecanoic acid (**273**) exhibited synergistic effects in combination with tetramethylthiuram-disulfide, and strongly enhanced the effect of conventional antimicrobial agents that act inside the cell membrane (281). A novel derivative of butyric acid, pivalyloxymethyl butyrate (pivanex, or AN-9, **274**) has been shown, *in vitro*, (i) to induce cy-



todifferentiation and inhibit the proliferation of leukemic cells; and (ii) to inhibit the growth and formation of Lewis lung carcinoma colonies in semisolid agar. AN-9 is a potential anti-neoplastic agent (282) that induces cell death by apoptosis (283).

Ethyl pivalate (**275**) has demonstrated antitumor activity against Ehrlich L-1210 leukemia (284). Compound pivaloylphenothiazine, **276**, showed 24.3% inhibition of Ehrlich-type tumors in male mice (285). 2-Amino-8-alkoxy quinoline (**277**) was synthesized and had properties as a melanin-concentrating hormone receptor-1 (MCHr1) antagonist (286).

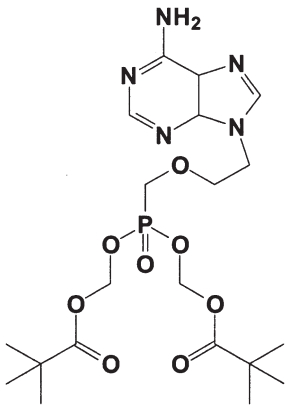
Dimethylpentynylcyclopropylimidazole (**278**) (GT-2331 or Cipralisant), a potent histamine H3 antagonist, was prepared, and biological activity was also reported (287,288). The alkyl esters of 2-endo-hydroxy-1,8-cineole (**279** and **280**) were synthesized, with yields of 57.8-98.0%. The antimicrobial and bactericidal activities of these synthetic esters against bacteria (*Staphylococcus aureus, Escherichia coli*, and *Pseudomonas fluorescens*) were reported (289). As a result, the *tert*-Bu acetate of compound **280** showed the highest antimicrobial and bactericidal activities against all kinds of the test bacteria (289).

The 4-morpholino-2-butynyl pivalate (**281**) was synthesized and of the eight examples it had the highest antitumor activity and low toxicity to fibroblasts (290).

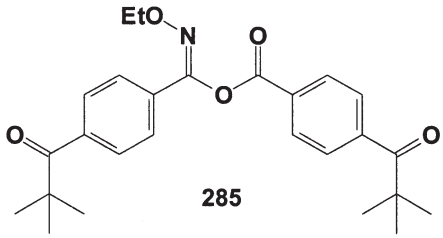
A novel variant of 6-formylpterin (6FP), 2-(N,N-dimethylamino-methylene-amino)-6-formyl-3-pivaloyl-pteridine-4-one (6FP-tBu-DMF, **282**) was synthesized, and photodynamic effects on a pancreatic cancer cell line (Panc-1 cells) were observed (291). A cephalostatin analog (**283**) was highly effective in inhibiting cell growth in various human cell lines (292).

Antiviral agent **284** showed strong activity against human hepatitis B virus and herpes viruses 1, 2, and 5 (293). Pivaloylbenzoyl N-alkoxypivaloylbenzimidates (**285** and **286**) were prepared and used as antidiabetic and anticholesterolemic agents (294).

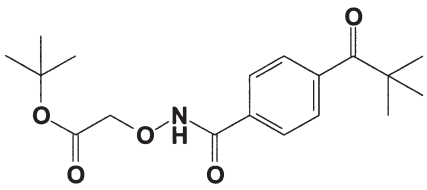
Following oral administration in mice, organ levels of pivampicillin (**287**) were three- to fourfold greater than the levels of ampicillin. The *in vitro* antibacterial activity of compound **287** against a number of Gram-negative and Gram-positive bacteria was similar to that of ampicillin. Also compound **287** was less sensitive than ampicillin to inactivation by streptococcal β-lactamase (295).



284 Hepsera



285



286

Pivmecillinam (**288**) is a pivaloyloxymethyl ester of a new penicillin analog that is hydrolyzed after absorption by nonspecific esterases to release mecillinam. Comparable studies suggested that standard doses of pivmecillinam were unlikely to be effective in the majority of cases of urinary infection by fecal streptococci (Micrococcaceae) (296). The *O*-pivaloyltyrosine derivative (**289**) was prepared, and it showed elastase-inhibiting activity at IC_{50} of 0.84 μM (297).

APPLICATION OF NEO ACIDS AND DERIVATIVES

Different pivalic acid derivatives and/or compounds with a tertiary butyl group(s) are produced and used in the cosmetic, agronomic, and perfume industries. Skin creams and lotions contain a pivaloylascorbic acid (**290**) and pivaloyl derivates (**291**-**293**) as well as derivatives of vitamin E, including vitamin E acetate, vitamin E nicotinate, and vitamin E orotate. These cosmetics have little irritating effect on skin, and they condition the skin for a long period of time (298,299). Two seco-theaspiranes (**294**,**295**) with pronounced blackcurrant notes were synthesized as odor and odorous substances and used in cosmetics (300).

Derivatives of neo FA (**296**–**300**) are used in the cosmetic industry, for example, by L'Oreal (France) (301). An amide of a trialkylacetic acid (**301**), amides of neo FA (**302**,**303**) and a

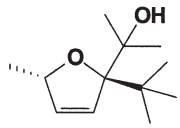
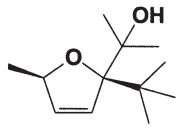
293 R,R_1,R_2 = Pivaloyl



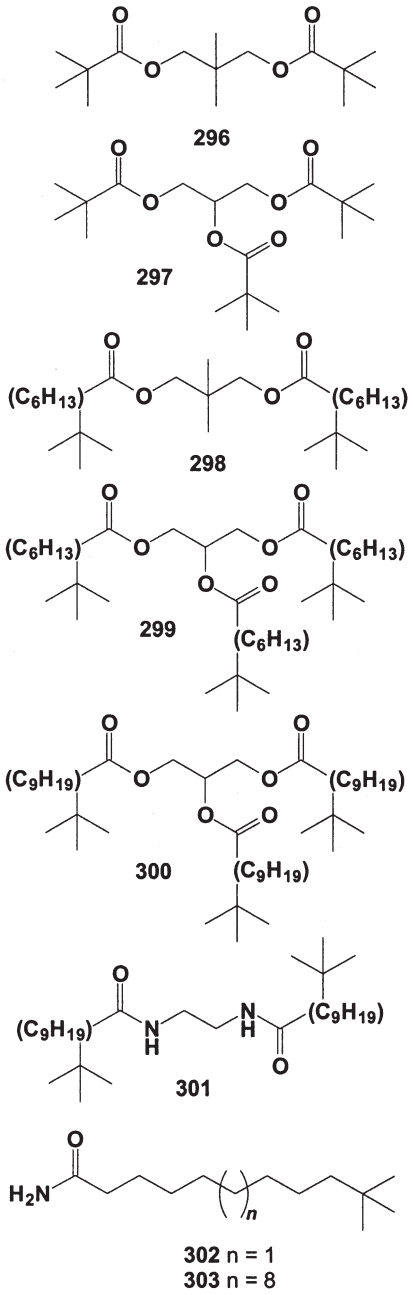
294

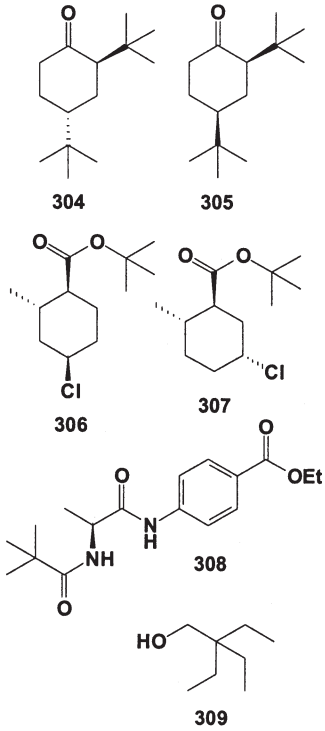


295

polyamine were used with a particulate carrier (e.g., detergent builder or filler) or liquid medium (e.g., aqueous nonionic surfactant solution) in a composition that was added to fabrics in a laundry bath to impart antistatic properties to fabrics after laundering and automatic machine drying (302,303).

2,4-Di-*tert*-butylcyclohexanones **304** and **305** have been synthesized and used as components in perfume. Compound **304**) has a mild, soft, floral-woody and violet-like scent. An equal mixture of *cis*- and *trans*-isomers of compound **04** has a mild, soft, floral-woody and violet-like scent. The *cis*-isomer





of **304** by has a highly diffusible cyclamen-like and floral scent; the *trans*-isomer of compound **304** has an orris-like woody scent (304).

The most biologically active forms of the insect attractant trimedlure, a synthetic lure used to attract male Mediterranean fruit flies, are the *tert*-Bu esters of *cis*-4- (**306**) and *trans*-5-chloro-*trans*-2-methyl-cyclohexanecarboxylic (**307**) acids (305).

The peptide analog of insect juvenile hormone ethyl pivaloyl-D-alanyl-*p*-aminobenzoate (**308**) had pronounced systemic activity in sunflowers for controlling *Dysdercus cingulatus* (306). This compound can enter the plant through the leaves or the roots, and is translocated throughout the plant in an active form. There was nearly maximal activity at 500–1000 μg (**308**)/plant, and activity remained for up to 14 d.

2,2-Diethylbutyric acid (**49**) forms stable dispersions and is used to achieve long-lasting fragrance or aroma at room temperature in a paint-scenting additive mixture. This mixture has good coverage ability, and its fresh fragrance lasts for over 180 d (307). 2,2-Diethyl-1-butanol (**309**) has been used as a minor ingredient in aquatic ink (308).

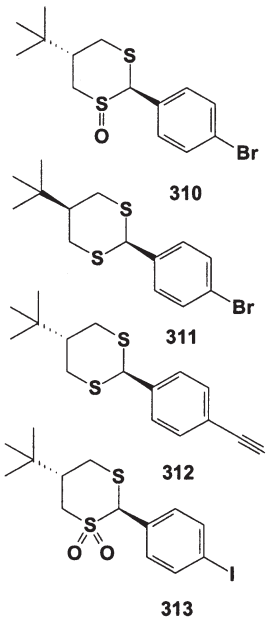
The 1,3-dithianes and 1,3-dithiane 1,1-dioxides (**310**–**313**) are more effective insecticidal compounds in the dithiane series than known halogenated compounds (hexachlorocyclohexanes, polycholorobornanes, and chlorinated cyclodienes) against the housefly (LD_{50} from 0.36 to 0.0095 μg/g) (309).

CONCLUSION

Neo fatty (carboxylic) acids as well as other metabolites containing a tertiary butyl group(s) belong to a rare group of natural products. In the last 100 years fewer than 300 representatives from this rare and unique group of secondary metabolites have been identified. However, many different natural and synthesized compounds with *tert*-butyl group(s) show high biological activities. Simple aromatic compounds with *tert*-butyl group(s) demonstrated good antioxidant and fungicidal properties. The presence of *tert*-butyl amino acids that are incorporated into structures of natural peptides and/or natural alkaloids found in cyanobacteria, and marine invertebrates, or free *tert*-butyl amino acids found in some fungi, and microorganisms are worthy of note.

Neo acids and derivatives have a low order of toxicity and are used by different chemical companies for synthesis of novel biologically active compounds in the fields of agronomy, medicine, and cosmetics.

Novel natural neo FA and their analogs and derivatives have



been discovered and evaluated for their biological activity. It seems certain that some possess anticarcinogenic, antifungal, antiviral, and/or antibacterial properties. Certainly other important neo FA derivatives, and/or metabolites with *tert*-butyl unit(s) possessing biological activity also will be discovered and/or synthesized.

Gestational Diabetes Mellitus Enhances Arachidonic and Docosahexaenoic Acids in Placental Phospholipids

Demetris Bitsanis[a,*], Kebreab Ghebremeskel[a], Therishnee Moodley[a], Michael A. Crawford[a], and Ovrang Djahanbakhch[b]

[a]Institute of Brain Chemistry and Human Nutrition, London Metropolitan University, London N7 8DB, United Kingdom, and [b]Academic Department of Obstetrics and Gynaecology, Bart's and The Royal School of Medicine at Newham University Hospital, London E13 8SL, United Kingdom

ABSTRACT: In previous studies, we reported that neonates of women with gestational diabetes mellitus (GDM) have reduced blood levels of arachidonic acid (AA) and docosahexaenoic acid (DHA) that were unrelated to maternal status. Since both AA and DHA are selectively transferred from maternal to fetal circulation by the placenta, we have investigated whether the FA composition of the placenta is altered by GDM. Thirty-six women, 11 with and 25 without GDM, were recruited from Newham General Hospital, London. The women with GDM had higher levels of di-homo-γ-linolenic ($P < 0.05$), docosatetraenoic (n-6 DTA; $P < 0.0001$), docosapentaenoic n-6 ($P < 0.005$), total n-6 ($P < 0.005$), docosapentaenoic (n-3 DPA; $P < 0.005$), and total n-3 ($P < 0.01$) FA, as well as higher levels of AA ($P < 0.05$) and DHA ($P < 0.01$), in placental choline phosphoglycerides (CPG) compared with the healthy women who served as controls. Similarly, the women with GDM had elevated n-6 DTA ($P < 0.005$), AA, total n-6 metabolites ($P < 0.05$), DHA, total n-3 metabolites, and total n-3 FA ($P < 0.005$) in ethanolamine phosphoglycerides (EPG). In contrast to CPG and EPG, the placental TG of the women with GDM had higher linoleic acid ($P < 0.05$) and lower AA, n-6 metabolites, and n-3 DPA ($P < 0.01$). The placenta is devoid of desaturase activity, and it is thought to be reliant on maternal circulation for both AA and DHA. Hence, the enhanced levels of the two FA in the placenta of the GDM group suggests that these FA are taken up from the maternal circulation and retained after esterification into phosphoglycerides instead of being transferred to the fetus. Further study is needed to elucidate the mechanism involved and the effect of the phenomenon on postnatal growth and development of the offspring.

Paper no. L9904 in *Lipids 41,* 341–346 (April 2006).

Both first- and second-phase insulin secretion increase in the later part of pregnancy (1) to compensate for pregnancy-induced insulin resistance and to maintain normal carbohydrate tolerance. Some women, 3–5% (2,3), fail to respond to the changes in insulin resistance and develop a transient diabetes, gestational diabetes mellitus (GDM), that resolves after delivery.

In human (types 1 and 2) and experimental diabetes, the activity of Δ-6 and Δ-5 desaturase, enzymes that are vital for the synthesis of arachidonic acid (AA) and DHA, is impaired (4–6), and the levels of both desaturases are reduced in membranes (7–9). AA and DHA are vital for the structure and function of cell and subcellular membranes (10), and the requirement for these FA increases during pregnancy (11,12).

Although the fetus and neonate are able to synthesize AA from linoleic acid (LA) and DHA from α-linolenic acid (13–17), the rate of synthesis is not fast enough to support optimal growth and development (18–20). Consequently, it is now acknowledged that the fetus is reliant on the mother for an optimal supply of these nutrients. In pregnancy complicated with diabetes, owing to the impairment of AA and DHA synthesis in the mother, there may be an imbalance between the fetal requirement and maternal supply. Indeed, there is evidence that AA and DHA levels are compromised in neonates of women who have type 1 (21), type 2 (22), and gestational (23,24) diabetes. Compared with healthy controls, the women with GDM had lower AA and DHA levels in red cells (25) but not in plasma (26). Because the maternal plasma AA and DHA, which is the main source for the fetus, was normal in the women with GDM, it is unclear whether the observed compromise in the level of the two FA in the neonates (23,24) was due to reduced supply, impaired transfer, or both. The aim of this study was to investigate whether GDM alters the placental FA profile.

MATERIALS AND METHODS

Subjects. Thirty-six women, 11 women with GDM and 25 women who were healthy controls, with uncomplicated singleton pregnancies were recruited on admission for delivery at the Newham General Hospital, London, UK. The women with GDM comprised four of African descent and seven of Asian descent. Of the control women, six were Caucasian, six African, and 13 Asian. The mean pre-pregnancy body mass index (BMI) and age of the control and GDM groups were 25.9 ± 4.4 and 28.6 ± 5.4 (range 20–41) and 30.1 ± 3.5 and 32.6 ± 3.3 (range 27–37), respectively. The women in the control group did not have a family history of diabetes, high

Abbreviations: AA, arachidonic acid; BMI, body mass index; CPG, choline phosphoglycerides; DHGLA, di-homo-gamma-linolenic acid; DPA, docosapentaenoic acid; DTA, docosatetraenoic acid; EPG, ethanolamine phosphoglycerides; GDM, gestational diabetes mellitus; LA, linoleic acid; LCPUFA, long-chain PUFA.

blood pressure, or other chronic disorders. Ethical approval from the East London Health Authority and written consent from the subjects were obtained.

Diabetes diagnosis, treatment, and outcome. As part of the antenatal care, and because of the high prevalence of type 2 diabetes in this borough of East London, all of the women were assessed for the presence of the disease at 16 wk of gestation. In addition, those women considered to be at high risk of GDM were screened with an oral glucose tolerance test at gestation week 28. Women were considered to be at risk if they had a BMI greater than 30, polycystic ovary syndrome, or a history of GDM, insulin resistance, pregnancy-induced hypertension, stillbirth, or macrosomia. Blood sugar levels were determined after an overnight fast. Those with a glucose concentration of greater than 7 mmol/L were given a high-energy carbohydrate supplement, Polycal (Nutricia Zoetermeer, The Netherlands), equivalent to 75 g glucose load by diluting 113 mL of Polycal to 200 mL with water. GDM was diagnosed if the glucose concentration at 120 min was greater than 7.8 mmol/L.

Subsequent to diagnosis, four of the GDM subjects were treated with diet, four with insulin, one with both insulin and diet, and two did not receive any treatment. None of the subjects in either the GDM or healthy control groups had obstetric or clinical complications, and they all delivered at term. The gestational age, birth weight, and head circumference of the babies of the women in the GDM group were 37.7 ± 0.7 wk, 3251.8 ± 674.6 g, and 33.6 ± 1.7 cm, and the corresponding values for the babies of the women in the healthy control group were 39.7 ± 1.1 wk, 3342.8 ± 597.4 g, and 33.7 ± 1.3 cm.

Sample collection. Immediately after delivery, the placentas were cleaned of traces of blood and weighed. A representative sample was taken from the same area of each placenta, washed several times in cold saline to remove all traces of blood, and stored at –70°C until analysis.

Extraction and analysis of total lipids. Total lipids were extracted by the method of Folch *et al.* (27) from placental homogenates in chloroform/methanol (2:1 vol/vol) containing BHT (0.01% wt/vol) under nitrogen. The total lipid extract was dried under a stream of nitrogen, dissolved in a known volume of chloroform/methanol, and transferred carefully to a preweighed trident vial. Subsequently, the total lipid solution in the vial was dried under a stream of nitrogen to a constant weight. The weight of the total lipid extracted from a known weight of placenta was computed by subtracting the weight of the empty vial from the weight of the vial and total lipid.

Analysis of FA. The total lipid was dissolved in chloroform/methanol (2:1 vol/vol) and an aliquot was taken for FA analysis. The different classes of phospholipids were separated by TLC on silica gel plates with the use of the developing solvents chloroform/methanol/methylamine (65:35:15 by vol), containing 0.01% BHT. Similarly, TG were separated from cholesterol esters and FFA by TLC on silica gel plates with the developing solvents petroleum spirit/diethyl ether/formic acid/methanol (85:15:2.5:1 by vol), containing 0.01% BHT. The separated lipid bands were visualized by spraying the developed plate with a methanolic solution of 2,7-dichlorofluorescein (0.01% wt/vol).

FAME were prepared by heating the lipid fractions in 4 mL of 15% acetyl chloride in methanol for 3 h at 70°C, in a sealed vial under nitrogen. FAME were separated by GLC (HRGC MEGA 2 series; Fisons Instruments, Italy) fitted with a capillary column (30 m × 0.32 mm i.d., 0.25-μm film, BP20). Hydrogen was used as a carrier gas, and the injector, oven, and detector temperatures were 235, 250, and 178°C, respectively. FAME were identified by comparison of retention times with authentic standards and calculation of equivalent chain length values. Peak areas were quantified by a computer chromatography data system (EZChrom Chromatography Data System; Scientific Software Inc., San Ramon, CA).

Statistical analysis. The data are expressed as median and interquartile ranges. The Mann-Whitney U nonparametric test was used to investigate significant differences in demographic and fatty acid data between the two groups of subjects, and between the diabetic and nondiabetic Asian women. Kruskal–Wallis nonparametric ANOVA and the Mann–Whitney U test were used to investigate a statistical difference in AA and DHA between Caucasian, African, and Asian subjects in the control group. $P < 0.05$ was considered to be significant. All of the analyses were performed with the use of the statistical software SPSS for Windows, version 11.5.

RESULTS

Placental weight and total lipids. There was no difference in placental weight between the GDM (640 ± 176.7 g) and the healthy control (573 ± 148.6 g) groups ($P > 0.05$). However, the placental total lipids were elevated in the GDM (15.8 ± 1.0 mg/g) group compared with the control group (14.2 ± 2.3 mg/g) ($P < 0.005$).

Placental FA composition. The median percentage FA of placental choline phosphoglycerides (CPG) and ethanolamine phosphoglycerides (EPG) and TG of the women with and without gestational diabetes mellitus is presented in Tables 1, 2, and 3, respectively.

CPG. The women with GDM had higher levels of stearic ($P < 0.0001$), di-homo-γ-linolenic acid (DHGLA; $P < 0.05$), AA ($P < 0.05$), docosatetraenoic acid (n-6 DTA; $P < 0.0001$), docosapentaenoic acid (n-6 DPA; $P < 0.005$), n-6 metabolites ($P < 0.005$), total n-6 FA ($P < 0.005$), docosapentaenoic acid (n-3 DPA; $P < 0.005$), DHA ($P < 0.01$), n-3 metabolites ($P < 0.01$), and total n-3 FA ($P < 0.01$) compared with the controls. In contrast, the proportions of palmitic, total saturated, and palmitoleic FA were lower in the GDM group ($P < 0.0001$).

EPG. Similar to the CPG, the EPG of the GDM group had elevated proportions of n-6 DTA ($P < 0.005$), AA, n-6 metabolites ($P < 0.05$), DHA, total n-3 metabolites, and total n-3 FA ($P < 0.005$) compared with the control group. However, the GDM group had reduced palmitic ($P < 0.01$), palmitoleic, oleic, total monounsaturated FA, LA ($P < 0.0001$), and DHGLA ($P < 0.05$).

[a]For abbreviations, see Table 1.
[b]Values marked with asterisks are significantly different from the control group: *$P < 0.05$; **$P < 0.01$.

TG. In contrast to CPG and EPG, GDM had a negligible effect on placental TG FA composition. Nevertheless, compared with the controls, the GDM group had higher LA ($P < 0.05$), and lower DHGLA, AA, n-6 metabolites, and n-3 DPA ($P < 0.01$).

Ethnicity. There was no difference in the levels of placental AA and DHA in CPG, EPG, and TG between the Caucasian, African, and Asian subjects in the control group ($P > 0.05$).

DISCUSSION

In our previous communications, we reported that red cells of women with GDM at diagnosis (25), and plasma (24) and red cells (23) of their neonates at birth, had an abnormal FA composition. The two questions that arose from these studies were the following: (i) Is the abnormality a generalized phenomenon, or is it restricted to red cells of the mothers with GDM and plasma and red cells of their newborn babies? (ii) Why do the seemingly nondiabetic healthy babies of women with GDM have abnormal blood AA and DHA? The current study was undertaken to help address these questions.

The placenta is a very important tissue to investigate in relation to maternal-fetal AA and DHA status and balance. First, the human placenta is a vascular organ rich in phospholipids (28–30), which in turn are rich in PUFA, particularly AA (31). Second, the placenta lacks desaturase activity (13), and is thought to be primarily dependent on maternal circulation for the supply of these vital FA. Consequently, diabetes-induced abnormality in supply and/or uptake would be expected to alter placental AA and DHA composition.

In contrast to plasma (26) and red cells (25), the placenta of the women diagnosed with GDM had higher levels of both AA and DHA compared with the control subjects. The AA level was elevated by 11 and 6%, and the DHA level by 38% and 29%, respectively, in CPG and EPG of the diabetics. These differences between the two groups were unlikely to have been a reflection of their dietary background because the level of AA was reduced by 30% and the level of DHA was unaltered in placental TG of the GDM relative to that of the control group.

The GDM group comprised four Africans and seven Asians, and the control group comprised six Caucasians, six Africans, and 13 Asians. It is conceivable that the observed difference between the two groups could be due to the ethnic imbalance of the populations studied. However, the difference in the pattern of the major FA in CPG, EPG, and TG between the GDM and control Asian women was similar to that of the total GDM and control groups. In addition, there was no difference in either of the two FA between the Asian, African, and Caucasian subjects in the control group. This is consistent with our previous study (31), which showed that ethnicity had no significant effect on placental AA and DHA.

There are no published data on placental FA of women with GDM. However, the placentas of women with type 1 diabetes have been reported to have reduced DHA and normal AA levels compared with those of nondiabetics (32). The contrast between our findings and those of Lakin and colleagues (32) could be a reflection of the two different disease entities. In the latter study, FA of placental total lipids (phospholipids and TG), rather than of the individual lipid fractions, were determined. Hence, it is conceivable that the real effect of diabetes on the FA composition of the individual phospholipids might have been masked by the disproportionate contribution of the neutral lipids, primarily TG.

The higher levels of AA and DHA in CPG and EPG of the GDM group could not be explained by enhanced synthesis because the placenta is thought to be devoid of desaturase activity (13). As maternal circulation is the primary source of placental AA and DHA, our data suggest that the uptake of these two FA is enhanced in gestational diabetes. Consistent with this proposition, there is evidence of alteration of the transporters and transport of long-chain PUFA (LCPUFA) in experimental animals (33,34), a higher incorporation of AA into TG of placental tissue in insulin-dependent diabetes mellitus pregnancy (35), and enhanced expression of the liver FA-binding protein in placental homogenates of women with GDM (36). Indeed, Bonen *et al.* (37) hypothesized that the intramuscular accumulation in human obesity and type 2 diabetes is attributable to an increased rate of LCPUFA transport as the result of an increase in the FA transporters, FA translocase (FAT/CD36), and/or plasma-membrane–associated FA-binding protein (FABPpm).

The lower level of AA in the placental TG in contrast to that in CPG and EPG in the GDM group could indicate that the TG AA was selectively transferred to the fetus. Bonet *et al*. (38) showed a 10-fold preference in uptake of FA from TG compared with uptake of albumin-bound FA by isolated placental trophoblasts. Also, it could be that the TG was used for eicosanoid production (39), hydrolyzed and re-esterified into phosphoglycerides, or both.

The question is whether the abnormal FA composition of the placenta of the women in the GDM group, which was manifested by higher levels of AA and DHA in CPG and EPG, would help explain the reduced levels of the two FA in the newborn offspring of women with GDM reported by Min *et al.* (23) and Thomas *et al.* (24). The fetus and neonate are able to synthesize AA and DHA (14–17). However, because of the slow rate of synthesis and the consequent inability to support optimal development (18,19), it is acknowledged that maternal circulation is the major source of AA and DHA for the fetus. The enhanced levels of the two FA in the placenta and the concomitant reduction of levels in the fetus suggest that the two FA are taken up by the placenta and retained after esterification into phosphoglycerides instead of being transferred to the fetus. The amount retained is likely to be significant because, in the placenta, phospholipids account for about 80% of total lipids, EPG and CPG for 60% of the phospholipids, and LCPUFA for 40% of the phospholipid FA (28–30).

The limitations of this study were the ethnic heterogeneity of the subjects and the lack of FA intake data of the mothers. Nevertheless, in spite of these shortcomings, the investigation reveals that, in contrast to fetal blood, the placentas of women with pregnancy-induced transient diabetes mellitus exhibit elevated levels of the vital FA AA and DHA. The mechanism involved and the effect of this phenomenon on long-term fetal growth and development remain to be elucidated.

ACKNOWLEDGMENTS

The financial support of Mother & Child Foundation, Vice Chancellors' Development & Diversity Programme, and The Worshipful Company of Innholders is gratefully acknowledged. We also thank the mothers for participating in the study and the nursing staff for their support.

Effect of Diacylglycerol on the Development of Impaired Glucose Tolerance in Sucrose-Fed Rats

Shinichi Meguro*, Noriko Osaki, Noboru Matsuo, and Ichiro Tokimitsu

Biological Science Laboratories, Kao Corporation, Tochigi, Japan

ABSTRACT: The effects of DAG oil and TAG oil on impaired glucose tolerance in rats that were fed a diet containing high levels of sucrose were compared. Male Wistar rats (8 wk old and 32 wk old) were fed either high-sucrose (57.5% sucrose w/w) or control diets containing either 10% (w/w) DAG or TAG oil with a similar FA composition for 48 wk in 8-wk-old rats and for 24 wk in 32-wk-old rats. Plasma lipids, the size of the islets of Langerhans, and insulin, glucose, and adipocytokine levels were measured. An oral glucose tolerance test (OGTT) was carried out during the study period. For rats in both age groups that were fed a high-sucrose diet, the DAG oil group had lower plasma glucose and insulin response in an OGTT, and lower homeostasis model assessment-R levels, than the TAG oil group. Furthermore, in 8-wk-old rats that were fed a high-sucrose diet, the DAG oil group accumulated less visceral fat and showed decreases of plasma adiponectin and suppressed increases of plasma insulin, leptin, and the size of islet of Langerhans compared with the TAG oil group. No difference in the OGTT was found between the DAG and TAG oil groups in either age group of rats fed a control diet. In conclusion, these results suggest that DAG oil ingestion prevents the high-sucrose-diet–induced development of impaired glucose tolerance compared with TAG oil ingestion.

Paper no. L9829 in *Lipids 41*, 347–355 (April 2006).

In industrialized societies, type 2 diabetes is a common cause of morbidity and mortality. The disease is characterized by impaired glucose tolerance and insulin resistance, which is frequently accompanied by visceral fat obesity (1–3). The typical Western diet is very high in fat and sucrose and is considered to be a major factor in the development of impaired glucose tolerance, insulin resistance, and visceral fat obesity. Foods that are designed to prevent and reduce visceral fat obesity may help to avoid diet-induced diabetes characterized by impaired glucose tolerance and insulin resistance.

DAG, a natural component of various edible oils, contains only two esterified FA chains, in contrast to the three FA chains in TAG. DAG oil is an edible oil containing approximately 80–90% DAG. Most of the DAG (70%) is the 1,3-DAG isoform, and its energy value is practically the same as ordinary oil containing TAG (4–6). Results of studies in animals and humans have revealed that DAG oil has metabolic characteristics that are distinct from those of TAG oil with a similar FA composition, and that these characteristics can be beneficial in preventing and managing the accumulation of visceral fat and the postprandial elevation of triglyceride in serum and chylomicrons (4,5,7–16). In addition, the long-term ingestion of DAG oil instead of TAG oil decreases the serum triglyceride and glycohemoglobin A_{1c} (HbA_{1c}) levels in type 2 diabetic patients with hypertriglyceridemia. It also suppresses the increase in fasting blood glucose and insulin levels in high-fat, high-sucrose-diet–fed C57BL/6J mice, and in blood glucose levels in an oral glucose tolerance test (OGTT) in Otsuka Long-Evans Tokushima Fatty (OLETF) rats (9,10,17,18). These results suggest that the ingestion of DAG oil not only prevents the accumulation of visceral fat but also suppresses the development of abnormal carbohydrate metabolism.

Impaired glucose tolerance is accompanied by visceral fat accumulation that develops in normal rats fed sucrose instead of starch as a carbohydrate source, and depends on both the amount of sucrose and the length of time for which it is used in the diet (19–25). In addition, impaired glucose tolerance is also induced with aging (26,27). The objectives of this study were to investigate the effect of the long-term ingestion of DAG oil, in comparison with TAG oil, on impaired glucose tolerance as well as on visceral fat accumulation in high-sucrose-diet–fed young (8-wk-old) and old (32-wk-old) rats.

EXPERIMENTAL PROCEDURES

Test oils. The DAG oil was prepared by esterifying glycerol with FFA derived from rapeseed oil and soybean oil by the method of Huge-Jensen *et al.* (28). The TAG oil was blended from rapeseed oil, safflower oil, and perilla oil. The FA composition of both oils is shown in Table 1. The FA composition of the DAG oil was very similar to that of the TAG oil. The DAG concentration of the DAG oil was 85.01/100 g and the ratio of 1(3),2- to 1,3-DAG was 34.5:65.5.

Animals and experimental design. Male Wistar rats (8 wk old and 32 wk old) were purchased from CLEA Japan (Tokyo, Japan). They were maintained in a temperature-controlled environment (23 ± 2°C) on a 12-h light/dark cycle. After an acclimatization period of 7 d, each group (8-wk-old or 32-wk-old) of rats was divided into four groups (n = 6/group), so that the body weight of each group was approximately equal, and the rats were transferred to individual cages. The 8-wk-old and

[a]Percentage by weight.

32-wk-old rats were fed with control or a high-sucrose diet including 10% TAG or DAG oil, respectively (Table 2). The 8-wk-old and 32-wk-old rats were maintained on these diets for 48 and 24 wk, respectively. All rats were allowed access to water and food ad libitum. The energy values for each diet were calculated from the macronutrient composition using values of 4 kcal/g, 4 kcal/g, 9.3 kcal/g, and 9.2 kcal/g for carbohydrate, protein, DAG oil, and TAG oil, respectively. Mesenteric, epididymal, perirenal, and retroperitoneal white adipose tissues as visceral fat, as well as the liver and pancreas, were dissected from each rat at the end of the study period. The food intake for each rat was recorded every 3–4 d. Body weights of all rats were recorded at weekly intervals. Animal experiments were performed with the approval of the Ethics Committee for Experimental Animals of the Kao Corporation.

Plasma lipids and adipocytokines. At weeks 0, 20, and 44 after initiation of the experiment for the 8-wk-old rats, and at weeks 0 and 20 after initiation of the experiment for the 32-wk-old rats, blood samples were withdrawn from the jugular vein after an 18-h fast. Plasma was obtained by centrifugation at 1500 × *g* for 15 min at 4°C. Plasma triglyceride and nonesterified FA (NEFA) levels were determined enzymatically using L-type Wako TG-H and NEFA-HA tests, respectively (Wako, Osaka, Japan). Plasma leptin and adiponectin were measured by means of a leptin enzyme-linked immunosorbent assay (EIA) kit (Morinaga, Yokohama, Japan) and an adiponectin EIA kit (Otsuka, Tokushima, Japan).

OGTT. At weeks 5, 9, 13, 21, 29, and 45 after initiation of the experiment for the 8-wk-old rats, and at weeks 5, 9, 13, and 21 after initiation of the experiment for the 32-wk-old rats, rats were fasted for 20 h and blood samples were taken from the tail vein for the determination of fasting glucose and insulin levels. An oral glucose challenge (2 g/kg) was administered to unrestrained animals, and blood samples were taken at 30, 60, 90, and 120 min after glucose ingestion. Blood glucose was measured using ACCU-CHEK Comfort (Roche Diagnostics, Basel, Switzerland). Plasma insulin was measured by means of a rat insulin EIA kit (Morinaga). The homeostasis model assessment-R (HOMA-R) was estimated using the following formula: HOMA-R = fasting insulin (μU/mL) × fasting glucose (mg/dL)/405.

Size of islet of Langerhans in pancreas. At the end of the study period, the pancreas was rapidly removed, washed with saline, fixed in 10% buffered formalin, and embedded in paraffin. Each paraffin-embedded block was sectioned and stained with Gomori's aldehyde fuchsin trichrome (29). Each stained section was photographed with an Olympus DP70 camera (Olympus Co. Ltd., Tokyo, Japan). The number of islets was counted and the diameter of islets was measured using Scion Image (Scion Co. Ltd., Frederick, MD).

Statistical analysis. The data are represented as the means ± standard deviation, and statistical differences in body weight, visceral fat weight, liver weight, energy intake, plasma lipid level, plasma adipocytokine level, plasma insulin level, blood glucose level, HOMA-R level, and islet diameter between the groups were determined using the student t-test. Repeated measures ANOVA was used to investigate changes in blood glucose, plasma insulin, and HOMA-R over time and in the OGTT. A statistical model was constructed using the effect of oil, time, and the interaction of oil × time. In all analyses, a significant difference was defined as $P < 0.05$. These statistical calculations were

performed with StatView for Windows, version 5.0 (SAS Institute, Cary, NC).

RESULTS

Energy intake, body weight, and general observation. In 8-wk-old rats, the average energy intake during the study period in groups fed the control diet with TAG oil, the control diet with DAG oil, the high-sucrose diet with TAG oil, and the high-sucrose diet with DAG oil was 68.15 ± 4.17, 64.58 ± 4.16, 69.79 ± 2.87, and 67.73 ± 2.98 kcal/d/rat, respectively. In 32-wk-old rats, the average energy intake during the study period in groups fed the control diet with TAG oil, the control diet with DAG oil, the high-sucrose diet with TAG oil, and the high-sucrose diet with DAG oil was 71.7 ± 3.81, 68.69 ± 2.01, 79.45 ± 5.87, and 77.45 ± 6.06 kcal/d/rat, respectively. No differences were found in energy intake between the TAG and DAG oil groups. In addition, time-course changes in body weight in 8-wk-old rats and 32-wk-old rats that were fed control or high-sucrose diets containing TAG or DAG oil during the study period were measured at weekly intervals; no differences were found between the TAG and DAG oil groups. All of the rats remained healthy during the study period.

Visceral fat and liver weight. The visceral fat (perirenal, retroperitoneal, mesenteric, and epididymal fat) weight and the liver weight in the rats in each group of this study are shown in Table 3. In the 8-wk-old rats fed with a high-sucrose diet, total visceral fat weight was lower in the DAG oil group compared to that in the TAG oil group, whereas no difference in total visceral fat weight was noted between the DAG and TAG oil groups in the 32-wk-old rats fed with a high-sucrose diet. The liver weight was similar between the DAG and TAG oil groups. In rats of either age group fed a control diet, no differences in the total visceral fat weight or liver weight was found between the DAG and TAG oil groups.

Plasma lipids and adipocytokines. Plasma lipid and adipocytokine levels in the rats in each group of this study are shown in Table 4. In the 8-wk-old rats fed a high-sucrose diet, the elevation in triglyceride and leptin levels were suppressed at week 20 and the reduction in adiponectin levels was suppressed at week 44 in the DAG oil group compared to those in the TAG oil group. In contrast, in the 32-wk-old rats fed a high-sucrose diet, no differences were noted in the plasma lipid and adipocytokine levels between the DAG and TAG oil groups. In both 8-wk-old and 32-wk-old rats fed a control diet, no differences in plasma lipid and adipocytokine levels were found between the DAG and TAG oil groups.

Glucose, insulin, and HOMA-R. Time-course changes in fasting blood glucose levels, plasma insulin levels, and HOMA-R levels in the rats in each group of this study are shown in Figure 1. In the 8-wk-old rats fed a high-sucrose diet, the elevation in fasting plasma insulin and HOMA-R levels were suppressed in the DAG oil group compared to those in the TAG oil group. In addition, in the 32-wk-old rats fed a high-sucrose diet, the HOMA-R level was lower in the DAG oil group compared to that in the TAG oil group.

OGTT. Time-course changes in blood glucose and plasma insulin levels in an OGTT at weeks 5, 9, 13, 21, 29, and 45 after initiation of the experiment in the case of the 8-wk-old rats, and at weeks 5, 9, 13, and 21 after initiation of the experiment in the case of the 32-wk-old rats, for each group of this study, are shown in Figure 2. In the 8-wk-old rats fed a high-sucrose diet, the elevation in blood glucose levels was suppressed at weeks 9, 13, and 21, and the elevation in plasma insulin levels was

[c]$P < 0.05$ vs TAG oil group. NEFA, nonesterified FA.

suppressed at weeks 13, 21, and 29 in the DAG oil group compared to the TAG oil group. In the 32-wk-old rats fed a high-sucrose diet, the elevation in blood glucose levels was suppressed at week 5, and the elevation in plasma insulin levels was suppressed at weeks 5 and 21 in the DAG oil group compared to the TAG oil group. However, in rats in either age group fed a control diet, no differences were noted between the DAG and TAG oil groups.

Size of islets of Langerhans in pancreas. The distributions of size of the islets of Langerhans in the pancreas in the rats in each group of this study are shown in Figure 3. In the 8-wk-old rats fed a high-sucrose diet, smaller islets appeared more frequently and the average diameter of the islets was smaller in the DAG oil group compared to the TAG oil group. In contrast, in the 32-wk-old rats fed a high-sucrose diet and either 8-wk-old or 32-wk-old rats fed a control diet, no differences were noted in the distribution and islet diameter between the DAG and TAG oil groups.

DISCUSSION

The accumulation of visceral fat is associated with the development of hyperinsulinemia and insulin resistance (19,23,30–32). The replacement of TAG oil with DAG oil in the diet was found to suppress the accumulation of visceral fat and the elevation in plasma insulin levels in 8-wk-old rats fed a high-sucrose diet. Murase *et al.* reported that the amount of visceral fat and the insulin levels were increased in C57BL/6J mice fed a high-fat, high-sucrose diet, compared to mice fed a control diet, but the replacement of TAG oil with DAG oil in the high-fat, high-sucrose diet suppressed these increases (9,10). Muzumdar *et al.* reported that the age-related elevation of the plasma insulin levels was suppressed by the surgical removal of visceral fat and by limitations in food intake in Sprague-Dawley (SD) rats (33). Thus, DAG oil suppressed the high-sucrose-diet–induced increase in plasma insulin levels, and this effect may have been due to the suppression of visceral fat accumulation as the result of DAG oil ingestion. In addition, the replacement of TAG oil with DAG oil in the diet suppressed the high-sucrose-diet–induced increase in HOMA-R levels. HOMA-R levels are a known index of insulin resistance (34–36). Furthermore, the use of DAG oil suppressed the high-sucrose-diet–induced increase in plasma leptin at week 20 in 8-wk-old rats compared with the TAG oil group. In obese individuals, the elevation of plasma leptin levels induces leptin resistance, and this event is generally thought to trigger insulin resistance (37). These results suggest

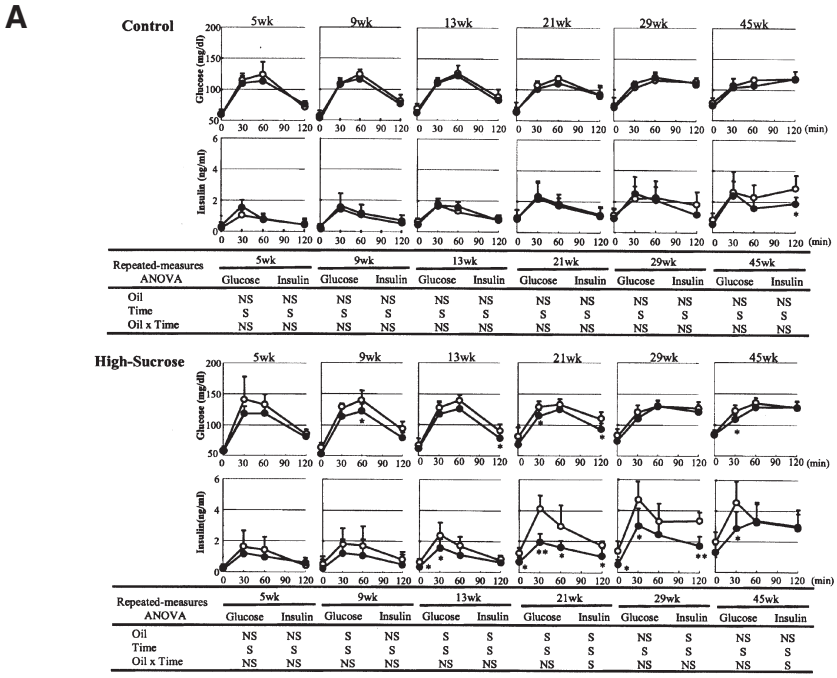
FIG. 1. Time-course changes in fasting blood glucose, plasma insulin, and HOMA-R levels in 8-wk-old rats (A) and 32-wk-old rats (B) fed control or high-sucrose diets containing TAG or DAG oil. Closed circles indicate DAG oil and open circles indicate TAG oil. Values are means ± SD (n = 6/group). A statistical model of the repeated measures ANOVA was constructed using the effect of oil, time, and interaction of oil × time: effect significant, S ($P < 0.05$), or not significant, NS. *$P < 0.05$ versus TAG oil group. HOMA-R: fasting insulin (μU/mL) × fasting glucose (mg/dL)/405.

that DAG oil might prevent the high-sucrose-diet–induced development of hyperinsulinemia and insulin resistance compared to TAG oil.

Compared with TAG oil, DAG oil suppressed the elevation in blood glucose levels in an OGTT in rats fed a high-sucrose diet, suggesting that DAG oil prevents the development of impaired glucose tolerance. However, this effect was not noted at week 29 (at age 37 wk) or later in the 8-wk-old rats, or at week



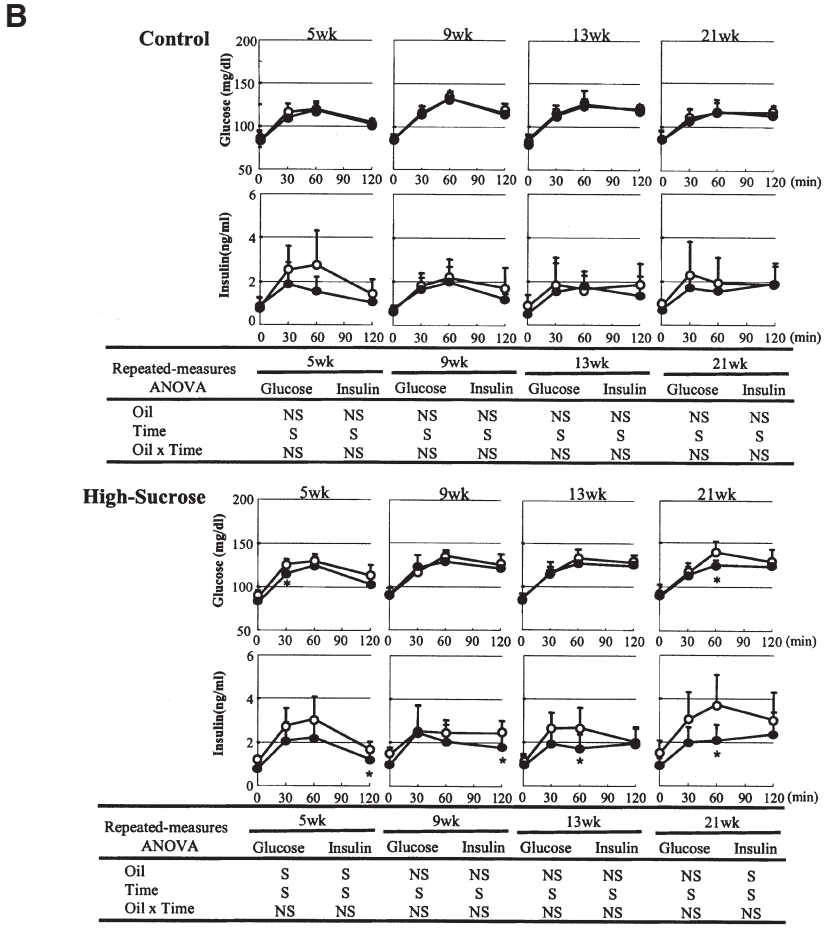


FIG. 2. Time-course changes in blood glucose and plasma insulin levels in an oral glucose tolerance test (OGTT) at weeks 5, 9, 13, 21, 29, and 45 after initiation of the experiment in the 8-wk-old rats (A) and at weeks 5, 9, 13, and 21 after initiation of the experiment in the 32-wk-old rats (B) fed control or high-sucrose diets containing TAG or DAG oil. Closed circles indicate DAG oil and open circles indicate TAG oil. Values are means ± SD (n = 6/group). A statistical model of the repeated measures ANOVA was constructed using the effect of oil, time, and interaction of oil × time: effect significant, S ($P < 0.05$), or not significant, NS. *$P < 0.05$ versus TAG oil group. **$P < 0.01$ versus TAG oil group.

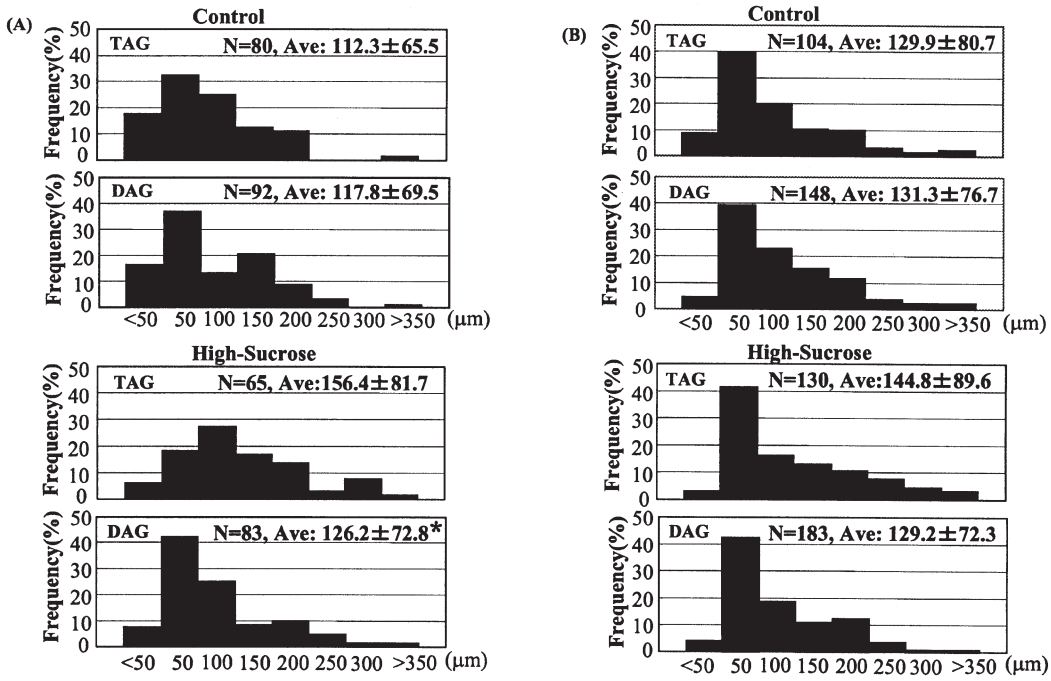

FIG. 3. The size distribution of islets of Langerhans in the pancreas in 8-wk-old rats (A) and 32-wk-old rats (B) fed control or high-sucrose diets including TAG or DAG oil. The distribution of size of islet (μm) is represented every 50 μm diameter size. *N*, total number of islets observed (n = 6/group); ave., the average diameter size (μm) observed for all islets; values represented as means ± SD. *$P < 0.05$ versus TAG oil group.

9 (at age 41 wk) or later in the 32-wk-old rats, and the reason for this is not clear. The ingestion of a high-sucrose diet is known to lead to impaired glucose tolerance in normal rats (21,24,25). In addition, impaired glucose tolerance is also induced by aging (26,27). Fink *et al.* reported that serum insulin and blood glucose levels were increased in elderly subjects (69 ± 1 yr old), compared to young subjects (37 ± 2 yr old) in an OGTT, and that this caused a decrease in peripheral glucose disposal with aging (38). Matthaei *et al.* reported that insulin-stimulated glucose incorporation in rat adipocytes was suppressed with aging (39). In the current study, the suppression of the development of impaired glucose tolerance by DAG oil ingestion disappeared at the age of 37 wk and 41 wk in 8-wk-old rats and 32-wk-old rats, respectively. Therefore, the promotion of impaired glucose tolerance with aging might have a stronger influence than the DAG oil–induced suppression of impaired glucose tolerance.

Murata *et al.* reported that when SD rats were fed a DAG or TAG oil diet for 14 d, the activities of β-oxidation-related enzymes in the liver, acyl-CoA dehydrogenase, acyl-CoA oxidase, enoyl-CoA hydrase, and 3-hydroxyacyl-CoA dehydrogenase, were increased with the DAG oil additive dose (40). Murase *et al.* also reported that DAG oil with high-fat, high-sucrose-diet–fed C57BL/6J mice, compared with TAG oil, increased the expression of lipid metabolism–related genes and β-oxidation activity in the liver and small intestine (9,10). These findings suggest that the effect of the suppression of visceral fat accumulation in 8-wk-old rats fed a high-sucrose diet containing DAG oil might be due to DAG oil activating more β-oxidation-related enzymes in the liver and small intestine compared with TAG oil. On the other hand, in this study, the use of DAG oil suppressed the high-sucrose-diet–induced decrease in the plasma adiponectin levels at week 44 in 8-wk-old rats, compared to TAG oil. A decrease in plasma adiponectin levels is accompanied by obesity and diabetes (41–44). It has been reported that adiponectin regulates glucose and lipid metabolism and activates energy expenditure by activating AMP kinase (45,46). Furthermore, Fruebis *et al.* reported that adiponectin treatment induced weight loss without decreasing food intake in mice consuming a high-fat, high-sucrose diet (47). Thus, the suppression of the decrease in plasma adiponectin levels in 8-wk-old rats fed a high-sucrose diet containing DAG oil compared with those fed a high-sucrose diet containing TAG oil may also contribute to the suppression of visceral fat accumulation by the activation of energy expenditure.

In this study, not only plasma analysis but also histological analysis has been conducted to accurately verify the effect of DAG oil on the development of high-sucrose-diet–induced hyperinsulinemia and impaired glucose tolerance. DAG oil suppressed the high-sucrose-diet–induced increase in the size of islets of Langerhans in the pancreas, compared to TAG oil. Huo *et al.* (48) reported that the development of insulin resistance in C57BL/6J mice fed a high-sucrose, high-fat diet induced an increase in the size of the islets of Langerhans in the pancreas compared with mice fed a control diet. In this study, in 8-wk-

old rats fed the high-sucrose diet, a reduction in blood glucose levels after an OGTT was observed at weeks 9, 13, and 21 in the DAG oil group compared to those in the TAG oil group, as shown in Figure 2A. This finding suggests that DAG oil prevents the high-sucrose-diet–induced development of impaired glucose tolerance. Hypertrophy of islet size in the high-sucrose diet was reduced in the DAG oil group versus the TAG oil group, perhaps because blood glucose levels are better regulated with less hyperinsulinaemia. In addition, in rats fed the high-sucrose diet, the suppression of visceral fat accumulation was observed in the DAG oil group versus the TAG oil group. Ikeda *et al.* (49) reported that obesity was readily induced, hyperglycemia and hyperinsulinemia developed, and the size of the islets of Langerhans in the pancreas significantly increased in obese-hyperglycemic Wistar fatty rats compared with lean Wistar rats. Thus, the suppression of the high-sucrose-diet–induced increase in the size of islets by DAG oil ingestion, compared with TAG oil ingestion, may have been due to the suppression of visceral fat accumulation and of the development of hyperinsulinemia and impaired glucose tolerance.

Sugimoto *et al.* reported the possibility that the replacement of ordinary oil in the diet with DAG oil induced an impaired glucose tolerance in normal rats and Wistar fatty rats that were fed a high-sucrose diet for 12 and 5 wk, respectively (50,51). The findings herein were not consistent with the results reported by Sugimoto *et al.*, and the reason for the discrepancy is not clear. Yamamoto *et al.* reported that the ingestion of DAG oil for 12 wk by type 2 diabetic patients with hypertriglyceridemia decreased the serum HbA_{1c} levels, compared with patients who ingested TAG oil (17). In an animal study, Mori *et al.* (18) reported that the long-term consumption of DAG oil instead of TAG oil in OLETF rats suppressed the increase in blood glucose levels in an OGTT. Murase *et al.* also reported that DAG oil suppressed the high-fat, high-sucrose-diet–induced increase in blood glucose and insulin levels compared with C57BL/6J mice that were fed TAG oil (9,10). These reports suggest that DAG oil consumption might suppress the development of abnormal carbohydrate metabolism, consistent with the results reported in this study. Further detailed experiments might be required to clarify and validate this conclusion.

In this study, we demonstrated that the ingestion of DAG oil suppressed the high-sucrose-diet–induced increase in blood glucose and plasma insulin response in an OGTT, and in HOMA-R levels, compared with TAG oil ingestion. These findings suggest the possibility of the prevention and improvement of impaired glucose tolerance and insulin resistance via the use of DAG oil.

Rat Adult Offspring Serum Lipoproteins Are Altered by Maternal Consumption of a Liquid Diet

J.S. Pennington and S.N. Pennington*

Department of Biochemistry and Molecular Biology, Brody School of Medicine, East Carolina University, Greenville, North Carolina, 27858

ABSTRACT: Palatable liquid diets for the administration of ethanol (EtOH) to animals have proven to be a major advance for the study of the effects of EtOH consumption under conditions of isocaloric nutrition of the control animals. Using a liquid diet, the original aim of the reported studies was to examine the effect of maternal EtOH consumption during pregnancy on the lipoprotein (Lp) profiles of the adult offspring measured by means of nuclear magnetic resonance spectroscopy. However, initial data suggested that compared to a maternal chow diet, the basal maternal liquid diet (without EtOH) had a significant effect on specific serum Lp of the adult offspring. The adult offspring of mothers who had consumed a basal liquid diet without EtOH exhibited significant increases in their plasma triglycerides (TG) and cholesterol content compared to adult offspring whose mothers consumed a chow diet. Further, there were significant increases in the offspring's VLDL and low density Lp (LDL) subfractions' particle number, regardless of whether the maternal liquid diet was ad libitum–fed, pair-fed, or EtOH-containing. The increase in offspring plasma TG was due to increases in specific VLDL subfraction particle numbers and not to increased TG content per particle. Similarly, the increase in plasma cholesterol was the result of elevated level of the very small LDL particles but not to an increased amount of cholesterol per LDL particle. These findings should be further examined in light of the widespread use of liquid diets in research to administer EtOH, especially for studies of fetal alcohol syndrome.

Paper no. L9904 in *Lipids 41*, 357–363 (April 2006).

Various experimental protocols have been used to administer ethanol (EtOH) to animals. During studies of the effects of alcohol on the liver, Lieber's laboratory (1–3) administered EtOH to rats by modification of a liquid diet used for the study of amino acid deficiencies as described by Forbes and Vaughan (4). These studies provided the initial approach to a solution to the problem of isocaloric nutrition of control animals. Over the next several years, Lieber and DeCarli elaborated the widespread usage of liquid diet formulations. This technique is now widely employed in alcohol research, and although other drinking paradigms are still used, the administration of EtOH via a liquid diet has become the gold standard, especially for fetal alcohol syndrome (FAS) research.

Abbreviations: EtOH, ethanol; FAS, fetal alcohol syndrome; IDL, intermediate density lipoproteins; Lp, lipoproteins.

Ongoing studies in our laboratory examining the molecular causes of maternal diet–induced metabolic changes in the offspring (5–9) led to an unexpected finding as to the effect of a maternal liquid diet on the plasma lipoproteins (Lp) of the adult offspring as determined by NMR spectroscopy. Compared to the progeny of chow-fed mothers, adult rat offspring whose mothers consumed a commercial liquid diet based upon a formulation developed by Lieber and associates (but without EtOH), exhibited prominent increases in their circulating levels of VLDL triglycerides plus increased LDL-associated cholesterol. The offsprings' response to maternal liquid diet consumption varied among the subfractions in the various Lp components and, for some parameters, was sex-dependent.

EXPERIMENTAL PROCEDURES

Rat model. Virgin, Harlan-derived Sprague Dawley female rats 150–175 g (Harlan, Indianapolis, IN) ($n = 84$) were maintained on a 12-h day/12-h night cycle. The animals were fed commercial lab chow with a balanced liquid diet (Dyets, Inc., Bethlehem, PA) being available either *ad libitum* for 5 d prior to mating or at the start of pregnancy (sperm plug = day 0). The liquid diet was based upon the Lieber and DeCarli formulation (10) for dosing rats with EtOH. Each animal was randomly assigned to one of seven groups: Group 1 had EtOH added (36% of calories) to the liquid diet with 12% fat content (EtOH-fed, low fat), and Group 2 had EtOH added (36% of calories) to the liquid diet with 35% fat content (EtOH-fed, high fat). Group 3 was pair-fed an amount of the liquid diet with 12% fat isocaloric with that consumed by Group 1 in the previous 24 h, and Group 4 was pair-fed an amount of the liquid diet with 35% fat isocaloric with that consumed by Group 2 in the previous 24 h. Group 5 was *ad libitum*–fed the liquid diet with 12% fat without EtOH, and Group 6 was *ad libitum*–fed the liquid diet with 35% fat without EtOH. Group 7 females were fed *ad libitum* rat chow and tap water throughout their pregnancies. The surrogate group of pregnant animals was also fed *ad libitum* lab chow and tap water (see Fig. 1). The compositions of the liquid and chow diets are given in Table 1. All of the liquid diets contained comparable amounts of protein because of the known effect of maternal dietary protein levels on fetal development (11–14).

The pregnancies were allowed to go to term with the mothers being returned to commercial rat chow on day 20 of their

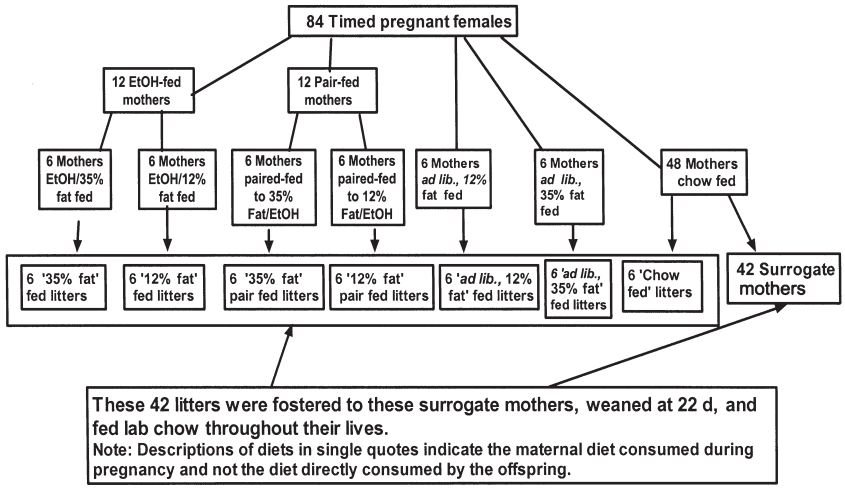

FIG 1. Diagram of the breeding paradigm used to generate the offspring utilized in the studies. Numbers in boxes indicate the minimum number of pregnant animals utilized. EtOH, ethanol.

pregnancy such that each female received the experimental or control diet for 20 d. At or before 2 d of age, the neonates were culled to four males and four females per litter, whenever possible, and surrogate-fostered to chow-fed mothers who had delivered within the previous 48 h. The surrogate-fostered pups were weaned at 22 d of age and fed commercial rat chow *ad libitum*. All pregnant animals were handled regularly to minimize stress, and they were weighed at 3-d intervals to maintain the isocaloric liquid diet pair feedings. The total experimental paradigm was run twice.

The East Carolina University Animal Care and Use Committee approved all animal procedures. The East Carolina University animal research facilities and program are accredited by the American Association for Accreditation of Laboratory Animal Care.

NMR studies. For the NMR studies, whole blood (0.50 mL) was collected via a tail vein from male and female offspring in 0.65-mL tubes containing EDTA (0.5 mg/tube). The animals were fasted for 8 h prior to the blood sample being collected to minimize circulating chylomicron levels. The samples were spun at room temperature at 10,000 rpm for 20 s using a microcentrifuge, and the resulting plasma super-

natants (0.25 mL) were removed to 0.65-mL centrifuge tubes and immediately frozen in liquid nitrogen. The samples were transported on solid CO_2 to the laboratory of Dr. James Otvos (LipoScience, Raleigh, NC) for assay using the commercial LipoProfile NMR-based assay. This proprietary assay uses whole plasma in a single run at 46°C utilizing a 360 MHz NMR spectrometer.

Free FA assay. Nonesterified FA in plasma were analyzed by use of an assay kit (#990-75401) purchased from Waco Chemicals (Richmond, VA).

Statistical analyses of data. All assays were run in at least duplicate, and the results averaged to determine mean values. For all experiments, the value of *n* for each analysis was ≥ 6, including one animal of each sex, from each of six litters of a given maternal dietary treatment. Group means and standard errors, as well as *post hoc* testing of significant differences between means of the treatment groups, were calculated using the general linear model procedure of the SAS/PC statistical program (SAS Inc., Cary, NC). Statistically significant differences between group means was determined using a three-way ANOVA (maternal diet × offspring sex × offspring age) with $P < 0.05$ accepted as significant. Significant differences between individual groups were determined by the use of the least squared means test.

RESULTS

Compared to the offspring of mothers who consumed a chow diet during pregnancy, the offspring of liquid diet–fed mothers had increased amounts of the primary lipids associated with the VLDL, intermediate density Lp (IDL), and LDL fractions (Fig. 2). The low level of TG associated with the chylomicron fraction in both groups reflects the fact that the animals were food-deprived overnight before samples were taken. There were no significant differences in the results as a function of offspring age (data not shown). Initiating the liquid diet consumption 5 d prior to or at the start of the pregnancy had no significant effect on maternal consumption of the diet or on the offspring's outcome (data not shown). Varying the fat content of the maternal liquid diet did not appear to significantly alter the outcome (Fig. 3).

There were significant increases in the overall numbers of circulating VLDL, IDL, and LDL particles in the plasma of offspring of mothers who consumed the liquid diet (Fig. 4). But, other than an increase in the HDL fraction (Fig. 5), no significant differences were seen in the particle size of the Lp fractions. The increases in offspring Lp particle numbers occurred regardless of whether the maternal liquid diet was *ad libitum*–fed, pair-fed, or EtOH-containing. For example, offspring serum LDL particle content increased regardless of the maternal liquid diet composition or amount fed (Fig. 5).

The liquid diet altered the TG content of the individual VLDL subgroups in a distinct manner (Fig. 6A). Plasma VLDL subfractions 6, 4, 3, and 1 from the offspring of liquid diet–fed mothers had significantly higher TAG levels. VLDL subfraction particle concentration differences, shown in Figure 6B, illustrate that the increase in the number of TG-containing Lp particles was not uniformly distributed across the VLDL subfractions. Although there appeared to be little difference in the numbers of chylomicron particles (due to the animals being starved prior to blood being drawn), maternal consumption of the liquid diet significantly increased the number of circulating particles in the offspring's VLDL subgroups ($VLDL_6$, $VLDL_4$, $VLDL_3$, and $VLDL_1$). This finding is in contrast to the effect of maternal EtOH consumption, in which the increase in VLDL particle numbers and TG content was in the $VLDL_6$ particle (data not shown).

Dividing the TG content of each VLDL fraction (Fig. 6A)

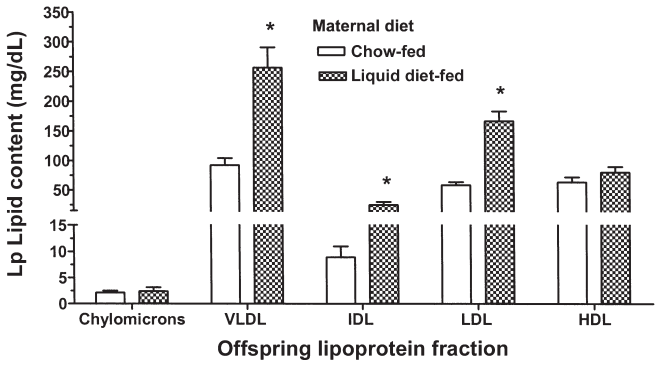

FIG 2. Combined data for adult male and female (90–150 d of age) offspring plasma TG associated with the chylomicron and VLDL lipoprotein (Lp) fractions as well as the cholesterol content of the intermediate density Lp (IDL), LDL, and HDL. In this and all other figures, the bars represent group mean values with SEM shown as a positive error bar. In this figure and all subsequent figures, an asterisk (*) indicates a group mean value for the offspring of liquid diet–fed mothers that is significantly different ($P < 0.05$) from that of the offspring of chow-fed mothers. TG were the primary lipid fraction associated with the chylomicron and VLDL fractions; cholesterol was the major lipid associated with all other Lp fractions.

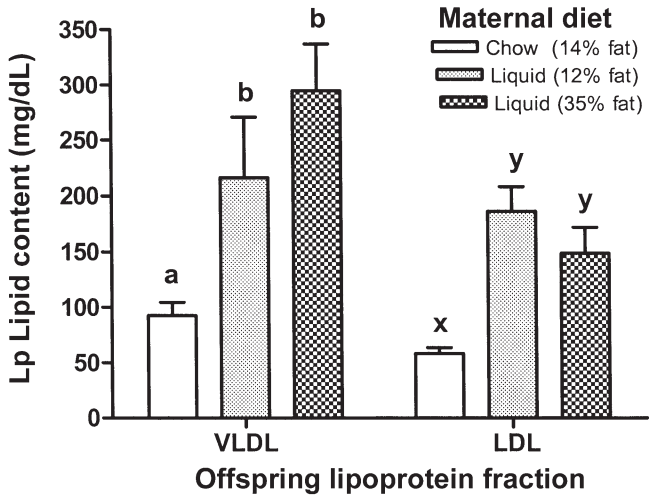

FIG 3. Comparison of the plasma VLDL TG content and LDL cholesterol content for offspring of chow-fed mothers with those of offspring from mothers consuming the liquid diet containing either 12% or 35% of calories as fat. For each Lp fraction, values for the maternal diets with a different letter are significantly different ($P < 0.01$). For abbreviation see Figure 2.

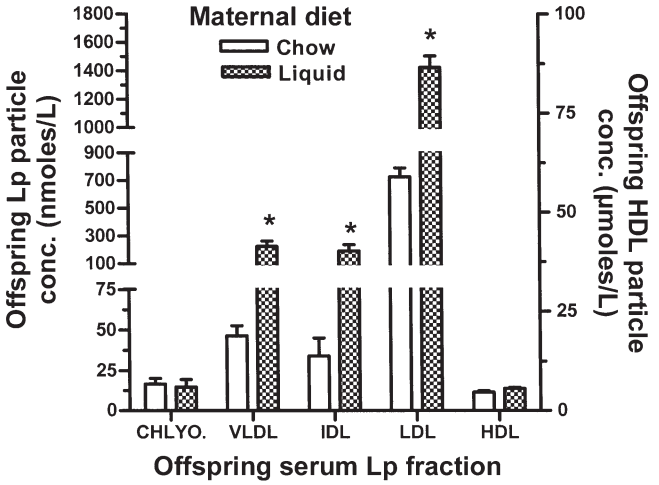

FIG 4. Effect of a maternal liquid diet on the plasma Lp particle concentrations of the offspring. The maternal liquid diet resulted in significant increases in the number of circulating VLDL, IDL, and LDL particles but no changes in the number of chylomicrons or HDL particles. Note the difference in the units for the right-hand y-axis (number of HDL particles). For abbreviations see Figure 2.

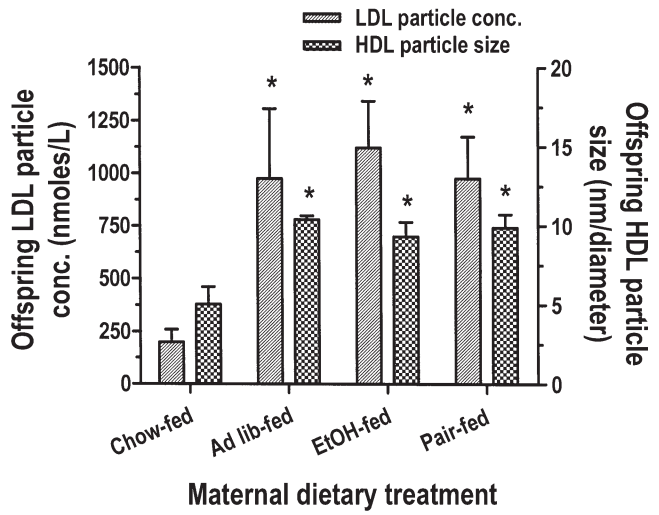

FIG 5. Comparison of serum LDL particle concentrations (left-hand axis) and HDL particle sizes (right-hand axis) from the offspring of chow-fed mothers to those for offspring of mothers consuming the liquid diet either *ad libitum* with EtOH, or pair-fed to the EtOH-fed mothers. The asterisk (*) indicates mean values that are significantly different from the same parameter in the progeny of chow-fed mothers. For abbreviation see Figure 1.

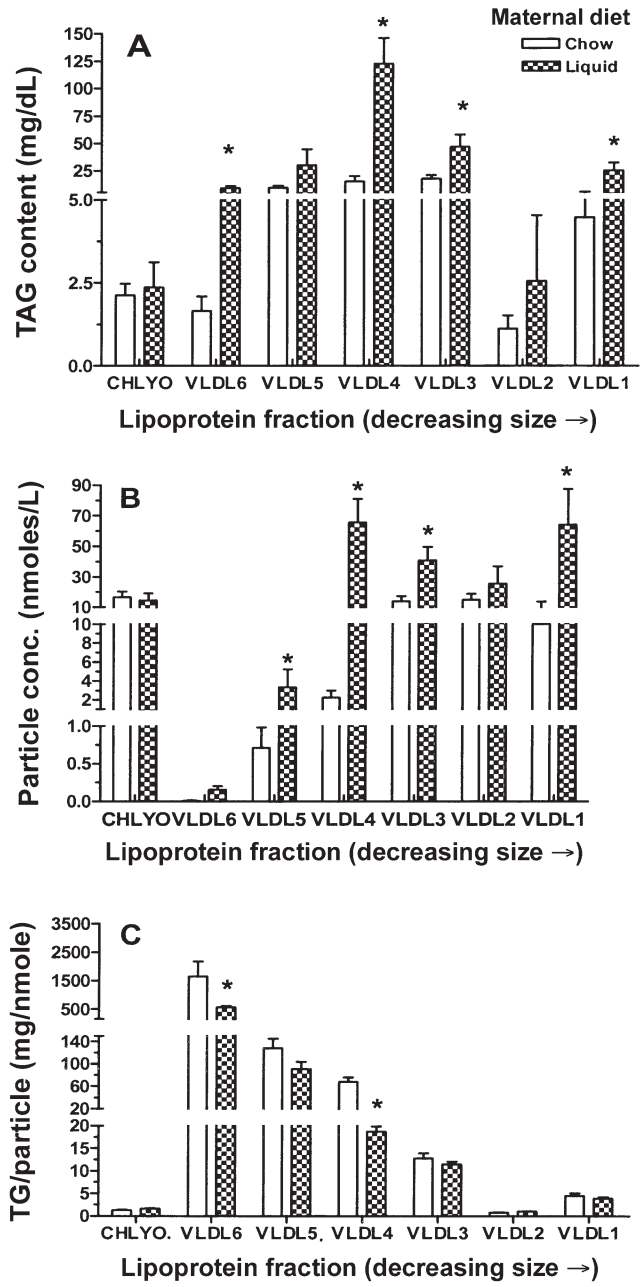

FIG 6. Comparison of (A) Lp particle concentration and (B) particle TG content for the chylomicron and individual VLDL subfractions, as well as (C) the ratio of TG/particle for each fraction for the offspring of chow-fed and liquid diet–fed mothers. For abbreviation see Figure 2.

by the number of particles in that VLDL fraction (Fig. 6B) illustrated that the TG concentration per Lp particle was either comparable or lower in all fractions for the offspring of liquid diet–fed mothers (Fig. 6C). Thus, the increase in plasma VLDL TG content for the offspring of liquid diet–fed mothers was the result of the large rise in the number of VLDL particles and not the result of an increased amount per VLDL particle.

Similar results were seen for the comparison of the offsprings' LDL particle numbers and plasma cholesterol concentration, except here the increases were associated with the smallest LDL particle (Fig. 7).

Sex-specific differences in the Lp subfraction distribution of both the TG- and cholesterol-rich Lp were also found. For example, male and female offspring whose mothers had consumed the liquid diet had different responses with respect to the amount of TG associated with the $VLDL_4$ subfraction (Fig. 8). We have previously reported what appeared to be sex-specific, maternal EtOH-induced changes in the TG content of the offspring's VLDL fraction (15).

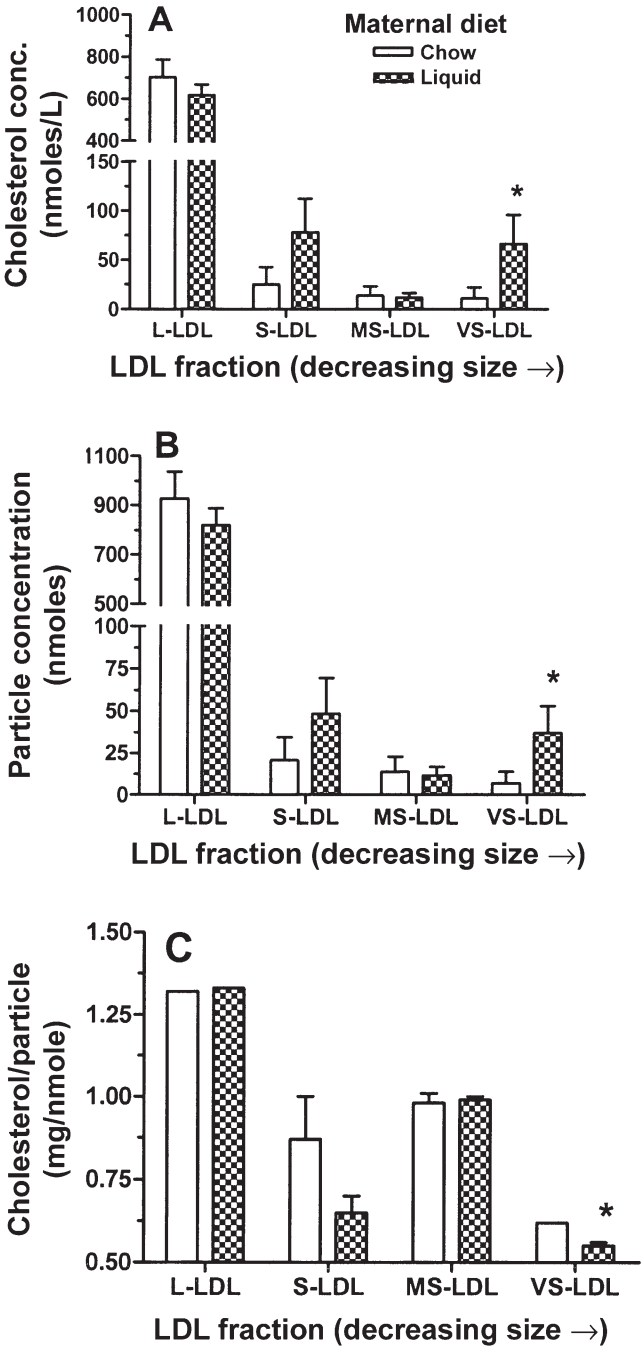

FIG 7. Comparisons of (A) LDL particle concentration and (B) particle cholesterol content for the individual LDL fractions, as well as (C) the ratio of cholesterol/particle for each LDL fraction for the offspring of chow-fed and liquid diet–fed mothers. L-LDL = large LDL, S-LDL = small LDL, MS-LDL = medium small LDL, and VS-LDL = very small LDL.

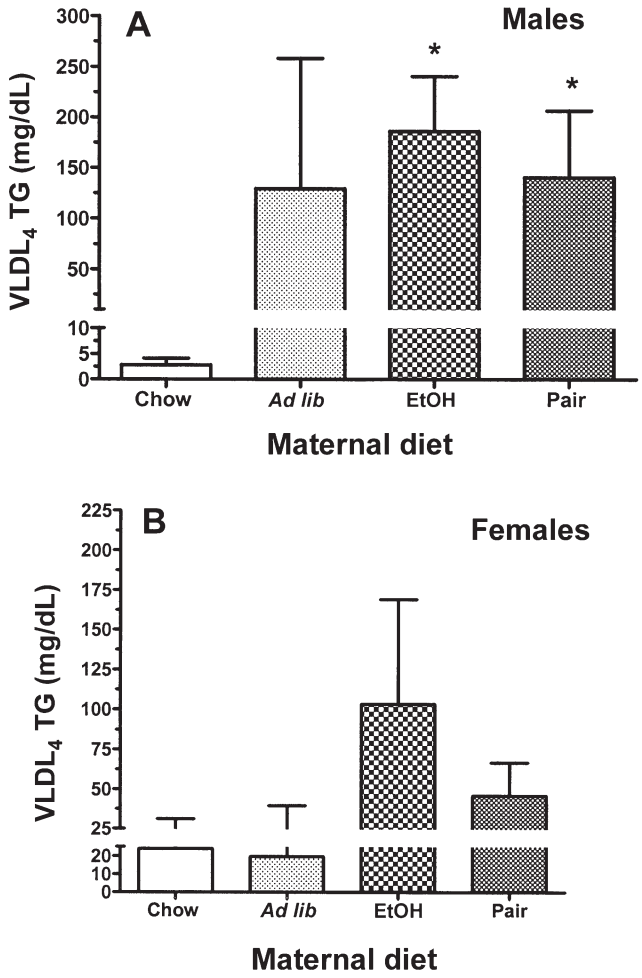

FIG 8. An example of a sex-specific difference in the offspring's Lp associated with the maternal liquid diet. (A) There were significant increases in the amount of TG associated with $VLDL_4$ for the male offspring of mothers who consumed the liquid diet. (B) The female offspring showed no significant differences as a function of maternal diet except that the female offspring of mothers who consumed EtOH in the liquid diet showed a tendency to have increased TG. For abbreviations see Figures 1 and 2.

DISCUSSION

The observations reported here suggest that *in utero* exposure to a maternal liquid diet based upon the Lieber formulation can significantly alter the adult offspring's Lp. Studies to examine the effects of maternal EtOH on the adult offspring's insulin sensitivity showed significant differences in the plasma Lp of the offspring whose mothers consumed the liquid diet, even without EtOH. The Lieber diet formulation has been used in hundreds of studies, and although other drinking paradigms are still used, the administration of EtOH via the liquid diet formulation has become the gold standard, especially for FAS research.

It is known that the source and amount of maternal dietary calories consumed during pregnancy can affect the offspring's development and growth (12,16–18). Further, intake of individual proteins from different dietary sources has been shown to alter Lp particle composition and metabolism (19–22). Also, simple dietary sugars, but not starch, have been shown to modulate the response to protein (23).

The current results suggest that maternal consumption during pregnancy of a liquid dietary formulation widely used in the study of the fetal effects of EtOH can cause significant,

long-term changes in the offspring's plasma Lp. Not only did the maternal liquid diet appear to be associated with increases in the offspring's TG and cholesterol levels but the increases appeared to result from changes in specific lipoprotein subfractions. Based on current research (24–27), such maternal diet–induced differences could reflect important changes in the offspring's Lp metabolism.

Evaluation of the increased lipid content of individual Lp subfractions and the changes in the particle numbers of those subfractions suggests that the increase in offspring plasma lipid levels were the result of increases in specific Lp subfraction particle numbers and not of increases in the amount of lipid per particle. Thus, the increase in offspring plasma TG associated with maternal consumption of the liquid diet was the result of a significant increase in the number of VLDL particles, and not the result of an increase in the amount of TG per particle.

The differences observed in the $VLDL_4$ subfraction may result from sex-related differences in the offspring's response to the maternal diet for this fraction (see Fig. 8). There are known sex-related differences in Lp profiles (28,29), and similar differences were seen in the current studies. That is, in general, females offspring had lower levels of Lp (data not shown). Further, certain of the changes observed here were sex-specific, specifically with regard to which Lp subfraction was involved, but the magnitude of the overall increases in TG and cholesterol was significant for both male and female offspring.

For LDL, the increase in offspring cholesterol associated with maternal consumption of the liquid diet was also the result of a significant increase in the number of very small LDL particles and not due to an increase in the amount of cholesterol per particle, the value of which actually decreased in the offspring of liquid diet–fed mothers. An increase in the number of the more athrogenic very small LDL particles would suggest that these offspring may be at increased risk for cardiovascular disease.

The development of a rapid, single-scan NMR method (30–34) has proven to be a powerful tool for the study of Lp and their role in the pathophysiology of cardiovascular disease. The ability to simultaneously determine plasma Lp particle numbers, particle size distribution, and the concentration of the major lipid component associated with each particle size range is an invaluable tool. It is well-recognized that catabolism within an Lp class, such as removal of TG from large VLDL particles by lipoprotein lipase, results in smaller particles that can differ in their metabolic rates and athrogenicity. Also, the exchange of lipid moieties and proteins between Lp may occur, leading to changes in Lp metabolism. Thus, unless one is able to determine the types and amounts of Lp in circulation at a given time, it is difficult to deduce what changes have occurred as the result of an experimental treatment. Because of this metabolic interaction/exchange between Lp, the ability of the NMR method to determine multiple parameters for all major Lp in a single sample is extremely valuable.

The variation in the distribution of TG across the VLDL subfractions observed here demonstrates the significant advantage of using NMR spectrometry to investigate plasma Lp. Only NMR analyses provide such detailed data without extensive sample preparation, including difficult fractionation of the plasma Lp, and even then, with other methods there is a high likelihood that much detail about lipid distribution would be lost.

Although nutritional or chemical differences between the maternal liquid diets and the chow diet are potential mechanisms that could be responsible for the differences observed in the offspring's Lp, such differences are not immediately apparent in the diet formulations (35) and, in fact, significant research (cited earlier) has been carried out to minimize differences between the Lieber-DeCarli formulation and chow diets designed for reproduction and growth. Thus, if the reported increases in the offspring's Lp and associated lipid levels are proven accurate, the results would raise significant questions about the role of the Lieber-DeCarli diet in alcohol research and especially in such studies related to fetal plasma lipids. Whatever their cause, the magnitude of the observed differences suggests that such changes could have significant metabolic consequences for the offspring.

ABSTRACT: A group of Angus beef cattle was removed from temperate pastures and fed a very low β-carotene cereal-based ration in a feedlot for over 300 d. Half the group was supplemented weekly with retinyl palmitate (at the rate of 60,000 IU vitamin A/100 live weight (LW)/day), sufficient to offset clinical vitamin A deficiency; the other half received no supplement. Blood was sampled from all animals at biweekly intervals to assess β-carotene and vitamin A status. Adipose tissue was sampled by biopsy on three occasions throughout the experimental period and at slaughter to assess FA composition. Muscle was sampled at slaughter to determine the intramuscular fat content. The mean plasma concentration of β-carotene of all animals fell from an initial value of 20.1 to 5.2 μg/mL at 14 d, to 1.4 μg/mL at 35 d, and to zero at 105 d. Mean vitamin A in plasma was not significantly different between the treatment groups initially. The values then rose to almost twice their initial values by 35 d, but subsequently fell to below initial values by day 119. Thereafter, plasma vitamin A of the supplemented group was significantly greater than that of the unsupplemented group ($P < 0.05$). Muscle samples at slaughter from supplemented animals contained significantly ($P < 0.01$) more intramuscular lipid (13.0 vs. 9.6%). Major changes occurred over time in FA composition in both groups. Saturated FA decreased as monounsaturated FA increased over the first 60 d. An index of desaturation of FA was significantly lower ($P < 0.001$) in the vitamin A-supplemented group than in the nonsupplemented group. M.P. of the adipose tissue of nonsupplemented animals was 32.3°C, significantly less ($P < 0.05$) than that of supplemented animals (34.1°C). Feeding vitamin A was associated with less intramuscular fat but with a less desirable (less unsaturated, more solid) FA profile.

Paper no. L9903 in *Lipids 41*, 365–370 (April 2006).

Intramuscular fat (IMF) deposition and the desaturation of fat have a major influence on the quality of beef. The expression of both traits is partly influenced by the genes controlling adipocyte differentiation (1) and by stearoyl-CoA desaturase (SCD) activity (2), but both traits are also subject to environmental (chiefly, dietary) factors. Cattle reared on pastures do not grow to maturity or fatten as rapidly as those reared on high-energy cereal-based diets, and they have higher levels of saturated FA (SFA) (3). Differences both in fattening and in the degree of saturation between pasture-fed and cereal-fed animals can be partly attributed to either inhibition of adipocyte differentiation or SCD gene expression by vitamin A derived from dietary β-carotene (2).

Japanese cattle are chiefly cereal-fed, reared on low β-carotene and vitamin A diets to produce animals with high marbling (i.e., IMF). Studies of cattle under these conditions have found that marbling scores are negatively related to blood vitamin A (4,5). Although historically Australian beef cattle have been reared on pastures and thus consume varying quantities of provitamin A (β-carotene), it is now relatively common in Australia (near 30% in 2003) to fatten animals with low-carotene cereal rations (6). The residual effects of prior feeding on pastures, however, may well affect the vitamin A status of cereal-fed animals for some time or alternatively, lack of vitamin A may lead to deficiency. The present experiment was designed to determine the effect of rations low in provitamin A and vitamin A on IMF deposition and FA desaturation in cattle after rearing on pasture.

MATERIALS AND METHODS

Animals and management. Twenty, 12-mon-old Angus steers, all progeny of one sire with a high propensity for marbling, were used in the study. The steers were removed from pasture and placed in feedlot facilities of the Department of Primary Industries, Rutherglen, Victoria, for 10 mon. In the feedlot, they were fed standard commercial feedlot rations without vitamin A, composed of triticale and wheat as the grain source (95 and 5%, respectively), canola meal as the protein source, and triticale straw as the fiber source. A premix containing all essential vitamins and minerals, except vitamin A, was added to the ration. The steers were fed three rations: a 12.8% protein ration for the first 100 d, a 7.5% protein ration for the next 100 d, and finally a 2.0% protein ration for the last 100 d. Similar to values from other published sources (7), laboratory analysis showed that the β-carotene content of the feed rations did not exceed 5 mg/kg dry matter. Prior to grain feeding, the steers were allocated to two treatment groups: vitamin A nonsupplemented (A−) and vitamin A supplemented (A+), with each

Abbreviations: IMF, intramuscular fat; MUFA, monounsaturated FA; SCD, stearoyl-CoA desaturase; SFA, saturated FA.

group comprising 10 animals. The allocation to treatment groups was based on feedlot entry weight; animals were ranked by live weight (LW) and then allocated alternately to either group. During the feeding period, blood was sampled biweekly for plasma vitamin A (retinol) and β-carotene concentration. Adipose tissue was sampled by biopsy on three occasions. Ultrasound scans every 50 d provided indirect measures of IMF. All the steers were kept in one pen, and once a week the (A+) group was taken to an adjacent pen and briefly fed feed supplemented with retinyl palmitate at the rate of 60,000 IU vitamin A/100 kg LW/d. At the start of the trial, the mean weight (± SEM) of all cattle was 354.9 ± 6.1 kg. The Animal Ethics Committee of the Department of Primary Industries, Rutherglen, approved of all measurements and sampling of tissues from cattle (application number 200104).

Biopsy sampling. Fat samples were removed by biopsy conducted at day 0, day 150, and day 268 of the experiment by methods described elsewhere (8). In brief, a 3–5 cm incision was made at a site at the base of the tail of a restrained animal that had received local anesthetic at the marked site. Three to five gram of fat was removed using a scalpel and the wound was treated with antibiotic powder before closure with surgical metal staples. The animals were injected with Terramycin® (Pfizer, Australia), and the sampling site was protected against dust and flies with Stockholm Tar® (Joseph Lyddy, Waproo Pty. Ltd., Canterbury, Victoria, Australia). Fat samples were placed in a sieve, washed with deionized water, then placed in vials prior to freezing in liquid nitrogen for storage at −80°C.

Ultrasound scanning procedures. Intramuscular fat prior to slaughter was assessed by ultrasound scanning of musculus longissimus dorsi between the 12th and 13th rib position of animals in both treatment groups. A certified scanner using an Aloka 500V with a 3.5-MHz, 17.2-cm linear array transducer measured IMF in individual animals every 50 d (9).

Vitamin A and β-carotene determination. Vitamin A (retinol) and β-carotene levels in blood were determined as described elsewhere (10,11). In brief, the proteins in the blood plasma (500 μL) were precipitated with 500 μL of ethanol. α-Tocopherol acetate was added as an internal standard. After vortexing, retinol and β-carotene were extracted with 600 μL of hexane, samples were centrifuged at 10,000 × *g* for 3 min, and 400 μL of hexane extract was dried under a stream of nitrogen. The residue was resuspended in a mobile phase of methanol/hexane/water (90:8:2, by vol) and run on a high-performance liquid chromatograph (model 1100; Hewlett-Packard, Palo Alto, CA). Separation was achieved using a Spherisorb ODS column (5 μm, C18 250 × 4.6 mm), protected by a precolumn guard cartridge. The mobile phase was used at a flow rate of 2.0 mL/min. Analytical standards of β-carotene, retinal, and α-tocopherol acetate (internal standard) were obtained from Fluka (Buchs, Switzerland). The β-carotene content of the various ingredients of feed rations was determined by methods published elsewhere (12).

IMF content, FA composition, and m.p. Muscle samples (musculus longissimus dorsi) were trimmed of all visible fat, and a subsample (~100 g) was homogenized in a food processor. Fat content was extracted from an accurately weighed subsample (~2 g) of the homogenized muscle using chloroform/methanol (2:1, vol/vol) as the solvent (13,14). FA composition of adipose tissue lipids was determined by GC. Methyl esters of FA were prepared under acid-catalyzed conditions from subsamples of adipose tissue (~20 mg) as described elsewhere (4). Individual FA were identified and quantified with use of a Hewlett-Packard gas chromatograph (5890A II) fitted with a capillary column (BPX70; SGE, Melbourne, Australia). The system allowed for the identification of *cis/trans* isomers. Unsaturated FA reported herein were identified relative to the carboxyl end (Δ convention). Total SFA and total monounsaturated FA (MUFA) were expressed as the sum of the individual FA (ΣSFA and ΣMUFA). A desaturation index was calculated from the sum of the saturated species (ΣSFA) and from the sum of the *cis* monounsaturated species (Σ*cis* MUFA). The index was calculated as ΣSFA × 100/(ΣSFA + Σ*cis* MUFA). At the time of subsampling adipose tissue for FA analysis, similar subsamples were used to determine m.p. as described elsewhere (13).

Slaughter measurements. The animals were transported approximately 1000 km to a meat works at Murray Bridge, South Australia, 2 d before the slaughter. After arrival at the meat works, the steers had *ad libitum* access to water and hay. Liver samples were collected on the slaughter floor and muscle samples in the boning room on the following day.

Statistical analyses. Least squares ANOVA for the entire data set was initially carried out. A model including LW and plasma vitamin A at day 0 as covariates and treatment (supplemented vs. unsupplemented vitamin A) was initially fitted to the data. Since these covariates were not significant for any of the traits measured, a formal model was deemed unnecessary and a simple *t*-test was used to compare treatment means.

RESULTS

Plasma β-carotene and vitamin A (retinol) levels altered considerably when cattle were removed from pasture and fed a cereal diet in the feedlot (Fig. 1). Plasma β-carotene (mean of all animals) was 20.1 μg/mL when the animals were removed from pasture and entered the feedlot. This value fell abruptly to 5.2 μg/mL by day 14, when half the animals began supplementation with vitamin A, and continued to decrease. The value was still positive at day 77, but fell to zero by day 90 and thereafter (Fig. 1). Plasma retinol of both groups increased considerably with the low-carotenoid cereal diet by day 35, then fell over the next two measurements, before increasing again at day 77. Both groups then decreased to lower than initial values by day 90, when β-carotene reached zero. Despite similar responses by both groups, the supplemented group demonstrated a significantly higher level of plasma retinol ($P < 0.05$) than the unsupplemented group at day 105 and remained significantly higher for the remainder of the experiment. Thus, there was no significant difference between the plasma retinol concentrations of both groups at day 0, but there was a highly significant difference at day 294.

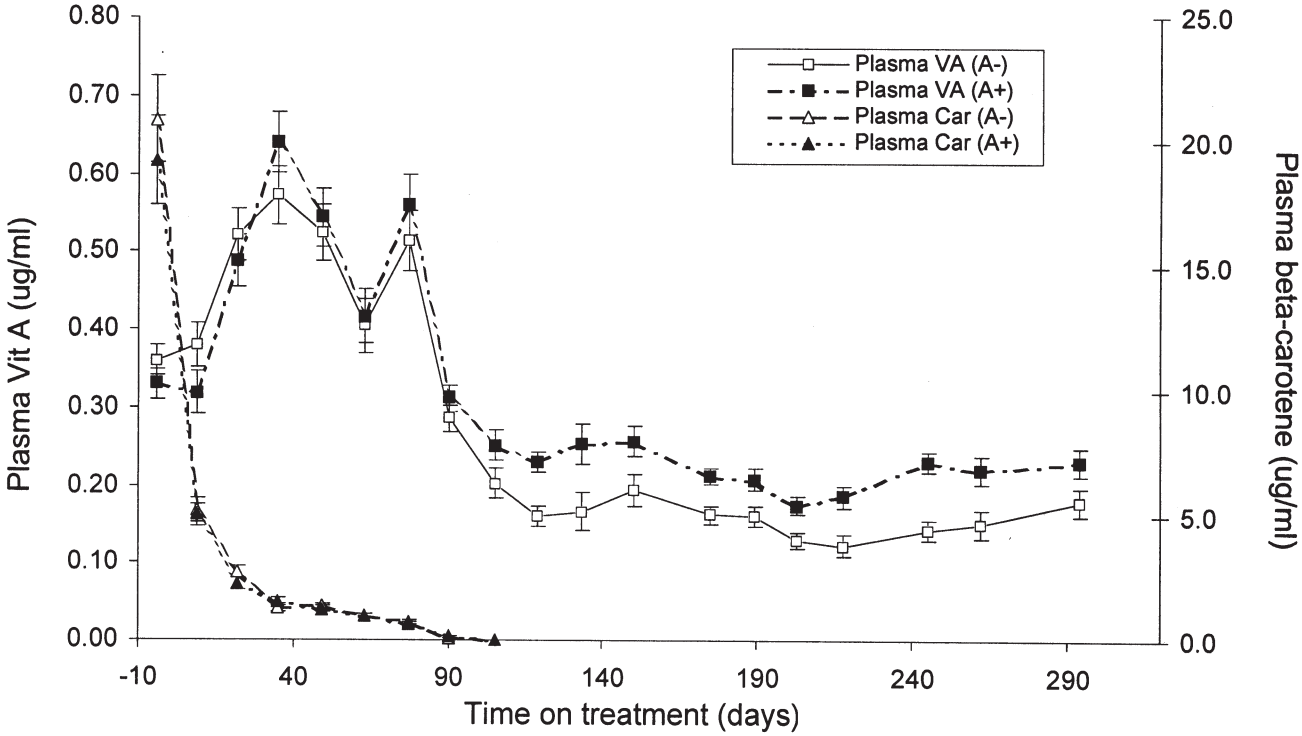

FIG. 1. Plasma vitamin A (retinol) and plasma β-carotene after pasture-fed cattle were transferred to a carotene-free cereal diet in the feedlot, half of which were supplemented with dietary vitamin A (A+); the remainder were unsupplemented (A–). Plasma vitamin A was significantly greater ($P < 0.05$) in A+ animals than in A– animals after day 105.

The IMF content as determined by ultrasound scanning of the two groups of cattle prior to cereal feeding was 3.2 and 3.0% for the unsupplemented and supplemented groups, respectively (Table 1). The mean (± SE) IMF content of tissue collected at slaughter as measured by solvent extraction was 9.6 ± 0.8% (wet weight) in animals from the supplemented group and 13.0 ± 0.6% (wet weight) in animals from the unsupplemented group. The effect of supplementation of cattle with vitamin A was associated with a 26% reduction in IMF concentration. The difference between the values was highly significantly ($P = 0.0025$). LW, LW gain, and rib fat depth showed no difference between treatments.

Both treatment groups, A– and A+, became less saturated and more monounsaturated after cereal feeding commenced (Table 2). The major contributor to this decrease in SFA was the decrease in stearic acid (18:0), which fell by 8%. There was little change in the 14:0 and 16:0 levels. Associated with this decrease in stearic acid was an increase in the content of oleic acid (18:1 *c*9), the product of C18 desaturation. Most of these changes occurred by day 150, although there was some further change by day 270. These changes in FA species also altered the m.p., causing it to decrease by at least 9°C between day 0 and day 270.

TABLE 1
Mean Values of Intramuscular Fat Content (%) from Unsupplemented (A–) and Supplemented (A+) Cattle After Removal from Pasture (day 0) and After Cereal Feeding in the Feedlot

Treatment Animals	A– ($n = 10$)	A+ ($n = 10$)	Significance

[a]Mean ± SE.
[b]Values with different superscripts differ significantly at $P < 0.05$ at least.
[c]ΣSFA, total saturated FA.
[d]Σ*cis* MUFA, total *cis* monounsaturated FA.

Between treatments, total SFA in unsupplemented animals decreased from 52.08 to 43.85%, while supplemented animals decreased to 46.97%, a value significantly higher than that of the unsupplemented animals. Simultaneously, total *cis* MUFA of unsupplemented animals increased significantly to 54.37% from 43.15%, while supplemented animals only increased to 51.56%. CLA was significantly higher in the nonsupplemented animals after 270 d of cereal feeding. Supplementation with vitamin A lessened the degree of desaturation as assessed by an index that included the major SFA and MUFA. This was also demonstrated by the difference in m.p. between treatment groups. In the nonsupplemented animals, the average m.p. was 32.3°C, significantly lower than that of supplemented animals at 34.1°C ($P < 0.05$). The effect of vitamin A supplementation on the desaturation of SFA was exemplified in the difference of the degree of desaturation that occurred after 270 d of cereal feeding with and without vitamin A supplementation (Table 2). Desaturation indices rose from approximately 39% to in excess of 51%. At 268 d, unsupplemented animals had a value of 55.81%, significantly greater ($P < 0.05$) than that of supplemented animals at 53.02%.

Desaturation indices were inversely related ($P < 0.001$) to plasma vitamin A levels (Table 3) after 268 d of cereal feeding. Plasma vitamin A and the index of desaturation in unsupplemented animals measured 0.149 μg/mL and 55.81%, respectively, and in supplemented animals measured 0.220 μg/mL and 53.10%, respectively. The difference between treatments of the various parameters was significantly different in all cases ($P < 0.05$ or greater). The difference in vitamin A status between treatments at the end of cereal feeding was further demonstrated by slaughter liver vitamin A and β-carotene levels, which were significantly different between treatments ($P < 0.001$).

TABLE 3
Mean Values of Plasma Vitamin A and FA Desaturation Index of Unsupplemented (A–) and Supplemented (A+) Cattle After Removal from Pasture (day 0) and After 268 d of Cereal Feeding in the Feedlot[a]

Treatment	A–	A+	
Animals	*n* = 10	*n* = 10	Significance
Plasma vitamin A (μg/mL)—day 268	0.149 ± 0.023[b]	0.220 ± 0.011	$P < 0.05$
Desaturation index (% total FA)—day 268	55.81 ± 0.97	53.02 ± 0.61	$P < 0.001$
Liver retinol (μg/g)—at slaughter	12.4 ± 3.8	223.4 ± 26.0	$P < 0.001$
Liver β-carotene (μg/g)—at slaughter	0.04 ± 0.01	0.50 ± 0.10	$P < 0.001$

[a]Liver vitamin A and liver β-carotene at slaughter are also shown.
[b]Mean ± SE.

DISCUSSION

It has been recognized for some years that differentiation of animal fat cells is controlled by communication between individual cells or between cells and the extracellular environment (1). Most effects have been determined in cell lines and primary cultures, where various hormones, cytokines, and growth factors have been shown to have positive and/or negative effects on adipocyte differentiation. Retinoic acid, a particularly potent form of vitamin A, is one such agent; it has been shown to inhibit adipocyte differentiation of adipocyte cell lines and primary preadipocytes (15–17). Livestock animal studies in Japan (4) showed that in a small number of cattle (4 per treatment), animals injected with vitamin A showed visibly less muscular fat (marbling) than those that did not receive vitamin A. In the experiment, 15-mon-old steers with a starting serum vitamin A level of nearly 0.4 μg/mL were fed a vitamin A-free diet. Without supplementation, this value fell to approximately 0.07 μg/mL after 15 mon. The unsupplemented group had a significantly higher marbling score than the steers injected with 20 mL vitamin A palmitate (303 mg as vitamin A alcohol) every 2 mon, whose serum vitamin A was maintained above 0.3 μg/mL for most of the measurement period.

In the present experiment, plasma vitamin A levels were very similar to the Japanese study mentioned above (4), prior to a period of cereal feeding (0.33 and 0.36 μg/L), and IMF, determined from muscle samples removed at slaughter, was 35% higher in the nonsupplemented animals. Vitamin A levels rose soon after cereal feeding commenced to values in excess of 0.5 μg/mL before decreasing to below initial values by 90 d. This rise in plasma vitamin A in the absence of either vitamin A or β-carotene in the diet was maintained until plasma β-carotene could no longer be detected, indicating vitamin A was being formed by cleavage of β-carotene in the body stores by the enzyme 15,15′-dioxygenase. This enzyme normally acts in the small intestine with dietary carotene, but the enzyme is also present in the liver (18,19). In previous studies from this laboratory, increased IMF was observed in young sheep fed a cereal diet, similar to the cattle herein. Half the lambs were fed provitamin A (β-carotene) by inclusion of green feed in their diet (20). At slaughter, the lambs on the low provitamin A (41 mg/d) diet had a mean IMF level of 6.3%. The lambs on the high provitamin A (890 mg/d) diet had a mean level of 4.9%. This 29% increase in nonsupplemented animals was a significant response, not dissimilar to that in the cattle herein.

In the cattle of the present experiment and in the Japanese cattle referred to above, the supplements of vitamin A amounted to 60,000 and 35,000 IU/100 kg LW/d, respectively. These intakes of vitamin A are relatively small, however, compared with those of cattle grazing green pastures, which can range from 100,000 to 400,000 IU vitamin A/100 kg LW/d derived from β-carotene (200–800 mg β-carotene/kg dry matter). Thus, the effects of vitamin A in a grazing animal would be far greater than in animals fed cereal in a feedlot with or without supplementation (<5 mg β-carotene/kg dry matter). This is demonstrated in grass-fed cattle, even when selected for IMF, as they only achieve IMF levels of approximately 5.8% at a LW of 550 kg (21). This is comparable to the 13.0% IMF content of the unsupplemented cattle of similar breed and LW in the experiment reported here. In animals receiving a limited supplement of vitamin A herein, IMF was measured at 9.6%, a value that was anticipated based on an intermediate level of provitamin A (carotene) or vitamin A intake.

Coincident with the increase in IMF was an increase in ΣMUFA in adipose tissue. At the end of cereal feeding, there was also a significant increase in ΣMUFA when vitamin A was not supplemented in the diet compared with that of supplemented animals. FA desaturation of adipose tissue increased as animals moved from a high provitamin A pasture diet to a low vitamin A cereal diet. CLA, a FA synthesized in cattle by biohydrogenation in the rumen and in adipose tissue from *trans* vaccenic acid by the action of a desaturase enzyme (22), was also significantly higher in the nonsupplemented animals. The significantly higher value of desaturation in nonsupplemented animals was inversely associated with vitamin A status in terms of plasma and liver vitamin A levels, and also liver β-carotene. High IMF and high MUFA are both properties that attract premium prices for beef.

The propensity of herbivores to deposit lipid in muscle is dependent on an interaction between genetic factors displayed differently by the species or breed and environmental factors such as dietary β-carotene. Angus, Hereford, Wagyu, and Jersey breeds mature earlier than other European breeds or tropical cattle and have higher IMF levels when reared on cereal feeds in the feedlot (3,23). At pasture, however, the differences in IMF are small (3,21). Although on occasion this can be partly attributed to lesser energy intake and growth rate, the lower IMF content of pasture feeding compared with cereal feeding can also be attributed to β-carotene consumption. Lower fat deposition with carotene diets can be explained by the negative effect of retinoic acid, a potent form of vitamin A (1) that is capable of inhibiting differentiation of preadipocytes. Retinoic acid has also been shown to inhibit Δ^9-desaturase activity in rats (24) and to regulate SCD gene 1 expression (2). The enzyme is present in cattle adipose tissue (25) and is significantly higher in Jersey cattle that absorb more β-carotene than other breeds and form less retinoic acid (11). Genetic polymorphisms in the SCD gene have been associated with breed differences in FA profile within the Wagyu breed (26). Studies suggest SCD transcriptional activity may account for some of these breed differences (27).

Thus, removing vitamin A from the diet or restricting its intake in the present experiment increased IMF and brought about significant increases in MUFA. Despite these differences, no significant differences were recorded in LW gain or rib fat depth, suggesting a repartitioning of fat throughout the body under different intakes of vitamin A.

ACKNOWLEDGMENTS

The donation by Dr Ian Partridge of Hoffman-La Roche of the supply of retinyl palmitate is greatly appreciated.

Differential Effect of Lysophospholipids on Activities of Human Plasma Paraoxonase1, Either Soluble or Lipid-Bound

Cheon Ho Park[a], Su Duy Nguyen[a], Mee Ree Kim[b], Tae-Sook Jeong[c], and Dai-Eun Sok[a,*]

[a]College of Pharmacy and [b]Department of Food and Nutrition, Chungnam National University, Yuseong-Gu, Daejon 305-764, Korea, and [c]Lipid Metabolism Laboratory, Korea Research Institute of Bioscience and Biotechnology, Daejon 305-333, Korea

ABSTRACT: Interaction of paraoxonase1 (PON1) with lysophospholipids was examined with respect to activity regulation and binding property. Paraoxonase activity of purified PON1 was partially inhibited by palmitoyl-lysophosphatidylglycerol (palmitoyl-lysoPG) and lysophosphatidylinositol (lysoPI), which had a stimulatory effect on arylesterase and diazoxonase activities. The selective inhibition of paraoxonase activity by palmitoyl-lysoPG, characterized by noncompetitiveness and charge interaction, was also observed with HDL- or dimyristoylphosphatidylcholine (DMPC)-bound PON1. Meanwhile, lysophosphatidylcholine (lysoPC) stimulated all three activities of purified PON1, although it stimulated DMPC-bound or HDL-bound PON1 to a lesser extent. The stimulatory action of lysophospholipids was observed around their CMC, suggesting that micelle formation of lysophospholpids might be involved in the stimulation of PON1 activity. Presumably in support of this, the tryptophan fluorescence intensity of PON1 was increased by lysophospholipids at concentrations required for the stimulation of PON1 activity. Separately, lysoPC stimulation was less remarkable for DMPC-bound PON1 than for either dimyristoylphosphatidylserine (DMPS)- or dimyristoylphosphatidylglycerol-bound PON1, suggesting a tight association between PON1 and DMPC. In support of this, the stimulatory role of apolipoprotein A-I was less prominent for DMPC-bound PON1 than for DMPS-bound PON1. Taken together, these data suggest that the inhibition of paraoxonase activity by lysoPG or lysoPI may be due to binding to a site distinct from the active center, whereas the stimulation by lysophospholipid may be ascribed to the micelle formation around the lipid-associable region of PON1.

Paper no. L9909 in *Lipids 41,* 371–380 (April 2006).

Paraoxonase1 (PON1), which is bound to HDL, has the ability to hydrolyze organophosphate compounds, carboxylic acid esters, and some lactone compounds (1–7). In addition to interest in a potential use of PON1 in detoxification of toxic organophosphates (5,8), interest in the enzyme has arisen from the idea that PON1 may exert antiatherogenic properties through antioxidant action (3,9–12). In animal and human model experiments, a lower serum level of PON1 was suggested to be associated with an increased risk of atherosclerosis (10,13–16). However, recent findings (17,18) do not support this theory of antioxidant activities of PON1. Nonetheless, PON1 was found to inhibit macrophage cholesterol biosynthesis and atherogenesis, probably through its phospholipase-A2–like activity (11), and also to inhibit oxidized LDL-induced monocyte chemoattractant protein-1 production in endothelial cells (12). Further, PON1 was reported to enhance HDL-mediated macrophage cholesterol efflux via ATP-binding cassette A1 transporter in association with increased HDL binding to the cells (19). Very recently (20), the antiatherogenic properties of HDL-associated PON1 was proposed to involve lysophosphatidylcholine (lysoPC) release in macrophages. Thus, it has been of much interest to clarify whether and/or how the PON1 molecule interacts with lipoproteins or lipid membranes. Although earlier studies demonstrated the stimulation of PON1 arylesterase activity by phospholipids or lysoPC (21–23), the structural relationship for the interaction of PON1 with various lipids has not been established.

Two substrates, paraoxon and phenylacetate, have been employed in the routine assay of PON1 activity (1,4). However, it has been suspected that the binding sites for the two substrates may not overlap exactly with each other (24,25). Furthermore, PON1 exhibits a substrate-dependent polymorphism; the Q(A) isozyme and the R(B) isozyme impart different catalytic activity toward paraoxon, in contrast to the same rate for phenylacetate hydrolysis (5,15,19,26). In support of this, a recent structural analysis indicates that the paraoxon-binding subsite may be not identical to the phenylacetate-binding subsite (27). Somewhat consistent with these findings, there have been reports on greater loss of paraoxonase activity, compared to arylesterase activity, in sera of aging persons or patients with oxidative stress-related diseases (28–33). Our recent data demonstrated that monoenoic acids such as oleic acid and palmitoleic acid caused a preferential inhibition of paraoxonase activity of PON1 (34), in contrast to polyunsaturated or saturated FA, which inhibit both activities to a similar extent (34,35). Also, monooleoylated lysophosphatidylglycerol (lysoPG) demonstrated a selective inhibition of paraoxonase activity, in contrast to a slight stimulation of paraoxonase activity by monooleoylated lysoPC (34). Thus, the structural requirement of lysophospholipids for the inhibition or stimulation of PON1 activities

needs further study. Furthermore, there is no further information on the effects of lysophospholipids on the activities of PON1 bound to lipid bilayer or HDL, or the cooperative roles between lysoPC and apolipoprotein A-I (apo A-I) in the regulation of lipid-bound PON1 activity.

In this study, we examined the effect of various lysophospholipids on activities of PON1, either soluble or phospholipid-bound, and proposed the possible mechanisms responsible for the inhibitory or stimulatory action of lysophospholipids.

EXPERIMENTAL PROCEDURES

Chemicals. All materials including apo A-I (human plasma) were purchased from Sigma Chemical Co. (St. Louis, MO) unless otherwise noted. Diazoxon was from Chem Service (West Chester, PA). Phospholipids and lysophospholipids were provided by Avanti Polar Lipids, Inc. (Alabaster, AL).

Purification of PON1. PON1 was purified using human plasma from normolipidemic volunteers according to a slight modification of the published procedures (1,22,35,36). Briefly, PON1 was purified from human plasma by (pseudo)affinity chromatography using Cibacron Blue 3GA, DEAE-Sephacel chromatography, Sephacryl S-200-HR gel chromatography, and finally affinity chromatography using concanavalin A–Sepharose. The purified PON1 (740-fold purification), expressing a specific activity of 1251 mmol/min/mg protein and 781 nmol/min/mg protein in the hydrolysis of phenylacetate and paraoxon, respectively, was found to belong to phenotype A type (ratio approximately 1.6) on the basis of the dual substrate method (24).

Assay of PON1. Unless otherwise noted, arylesterase activity of PON1 was determined by monitoring the change of absorbance at 270 nm in 0.5 mL of 50 mM Tris buffer (pH 7.4 + 1 mM $CaCl_2$) containing 1 mM phenylacetate, except the purification procedure, where 10 mM phenylacetate was used (1,22,35). Paraoxonase activity and diazoxonase activity were determined by monitoring the change of absorbance at 405 nm in the same buffer containing 1 mM paraoxon (22), and the change of absorbance at 270 nm in the same buffer containing 1 mM diazoxon (5), respectively. One unit of arylesterase or diazoxonase activity is expressed as 1 μmol of product generated from substrate per min, and 1 unit of paraoxonase activity as 1 nmol of *p*-nitrophenol produced from paraoxon per min.

Preparation of HDL. Serum HDL was isolated from fasted normolipidemic human volunteers by ultracentrifugation at a density ranging between 1.063 and 1.121 g/mL as previously described (9), and dialyzed against 10 mM phosphate buffer (pH 7.4) containing 150 mM NaCl and 1 mM Ca^{2+} at 4°C.

Preparation of liposome and liposome-bound PON1. For the preparation of liposome, each phospholipid, dissolved in chloroform/methanol, was evaporated in a glass vial under vacuum, and suspended in 0.4 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM $CaCl_2$ using a dismembrator (Branson sonifier 250). For the preparation of liposome-associated PON1 (21), A-type PON1 (75 arylesterase units/mL) in the buffer (0.6 mL) containing 1 mM $CaCl_2$ was added to the lipid suspension, and the mixture was incubated under stirring for 4 h at room temperature. Finally, the mixture was centrifuged (100,000*g*, 90 min), and the pellet was washed with the same buffer containing 1 mM $CaCl_2$ to remove the remaining soluble enzyme. The recovery of PON1 activity was estimated to be approximately 50%.

Effect of lysophospholipids on PON1 activities. Purified PON1 was incubated with phenylacetate (1 mM), paraoxon (1 mM), or diazoxon (1 mM) in the presence of each lysophospholipid of various concentrations in 0.5 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+} at 25°C. One arylesterase unit /mL (0.8 μg protein/mL) of PON1 was used for the hydrolysis of phenylacetate or diazoxon, and 7.5 arylesterase units/mL (6 μg protein/mL) of PON1 was used for paraoxon hydrolysis.

Effect of lysophospholipids on liposome-bound PON1 activities. Liposome-bound PON1 (1.6 arylesterase units/mL) was incubated with phenylacetate (1 mM) or paraoxon (1 mM) in the presence of each lysophospholipid of various concentrations in 0.5 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+} at 25°C.

Effect of lysophospholipids on HDL-bound PON1 activities. HDL was incubated with 1 mM of phenylacetate or paraoxon in the presence of each lysophospholipid in 0.5 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+} at 25°C. The activity of PON1 in HDL used was 1 arylesterase unit/mL for arylesterase activity determination and 7.5 arylesterase unit/ml for paraoxonase activity determination. Separately, 100 μl of HDL (8 mg protein/mL) was preincubated with bee PLA_2 (1.5 unit) in 0.4 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+} at 25°C for 30 min, and then the aliquot (1 μL) was taken into 0.5 mL of the above buffer to determine activity of arylesterase and paraoxonase in the presence of palmitoyl-lysoPC.

Effect of apo A-I on arylesterase activity of liposome-bound PON1. Liposome-bound PON1 (1.6 arylesterase units/mL) was preincubated with apo A-I in 0.1 mL of 10 mM PBS buffer (pH 7.4) containing 1 mM Ca^{2+} at 37°C for 30 min, and then the aliquot was taken for the assay of arylesterase activity in the presence or absence of palmitoyl-lysoPC.

Effect of apo A-I on arylesterase activity of PON1 exposed to dimyristoylphosphatidylserine (DMPS). Purified PON1 (2.5 arylesterase units) was preincubated with sonicated DMPS (0.2 mM) in 0.1 mL of the above buffer containing 1 mM Ca^{2+} at 25°C for 5 min. Then apo A-I was added to the mixture. After another10 min incubation, the aliquot was taken for the assay of remaining activity in the presence or absence of palmitoyl-lysoPC.

Kinetic analysis of inhibition of PON1 paraoxonase activity by palmitoyl-lysoPG. PON1 (7.5 arylesterase units) was incubated with paraoxon of various concentrations in the presence of palmitoyl-lysoPG (3 or 10 μM) in 0.5 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+}, and the inhibition was analyzed by Lineweaver-Burk plot as described previously (35).

Other analyses. Fluorescence emission spectra of PON1 were monitored using a PerkinElmer 550-55 fluorimeter at room temperature (37) with excitation wavelength at 280 nm and emission wavelength at 340 nm (slit width 5 nm). Change in fluorescence was calculated according to the following equation: the relative change of fluorescence = $(I_x - I_o)/I_o$, where I_x is the fluorescence intensity of PON1 in the presence of lysophospholipid and I_o is the fluorescence intensity of PON1 in the absence of lysophospholipid.

RESULTS

Selective inhibition of PON1 paraoxonase activity by lysoPG or lysophosphatidylinositol (lysoPI). Previously (34), oleoylated lipids such as oleic acid or monooleoyl-lysoPG had been reported to partially inhibit PON1 paraoxonase activity. However, the structural requirement of lysophospholipids for the regulation of PON1 activities was not established. First, to see the structural requirement for the inhibition of paraoxonase activity by lysoPG, paraoxonase activity of purified PON1 was determined in the presence of lysoPG with various acyl chains (C_{14}–C_{18}). As demonstrated in Figure 1, the most potent was palmitoyl-lysoPG, which had a maximal inhibition (I_{max}) of 22%, followed by myristoyl-lysoPG (I_{max} = 18%) and stearoyl-lysoPG (I_{max} = 16%). Myristoyl-lysoPG was almost equipotent to oleoyl-lysoPG (I_{max} = 18%). When the dose-dependent effect of palmitoyl-lysoPG, the most potent, on paraoxonase activity was examined (Fig. 2A), the 50% maximal inhibitory concentration of palmitoyl-lysoPG was estimated to be ~3 μM, lower than its CMC value (38,42). In contrast, palmitoyl-lysoPG stimulated arylesterase and diazoxonase activities (Fig. 2A). It is noteworthy that the stimulatory action of palmitoyl-lysoPG tended to increase up to 30 μM, higher than its CMC value (38), and palmitoyl-lysoPG at 30 μM enhanced arylesterase and diazoxonase activities by 25% and 35%, respectively ($P < 0.01$). Thus, palmitoyl-lysoPG was found to be a selective inhibitor of paraoxonase activity of PON1, somewhat different from oleic acid, a preferential inhibitor of paraoxonase activity (34). In a separate study, in which three PON1 activities were examined in the presence of liver lysoPI, it was also found (Fig. 2A) that liver lysoPI (10 μM) inhibited paraoxonase activity partially (24%), while the activities of arylesterase and diazoxonase were augmented slightly (9–14%) by 10 μM lysoPI ($P < 0.05$). Meanwhile, negatively charged lipids such as lysophosphatidylserine (lysoPS) or phosphatidic acid did not inhibit paraoxonase activity.

Binding site for inhibitory palmitoyl-lysoPG. Although the inhibitory action of palmitoyl-lysoPG was exerted at relatively low concentrations with a 50%-maximum inhibitory concentration of approximately 3 μM, the maximal inhibition degree was restricted to ~22% (Fig. 2A). Moreover, the inhibition degree (~22%) did not differ significantly according to the paraoxon concentration (0.25–2.0 mM) in repeated experiments. When the marginal inhibition was subjected to Lineweaver-Burk plot analysis, palmitoyl-lysoPG (3 μM or 10 μM) appeared to express a mixed type of noncompetitive pattern in the inhibition of paraoxonase activity (Fig. 3), supporting the notion that the inhibitory action of palmitoyl-lysoPG might be exerted at a site different from the active center of PON1. From kinetic analysis, the K_i value of palmitoyl-lysoPG is estimated to be 41.2 ± 3.8 μM, much smaller than the K_m value (1.42 ± 0.2 mM) of substrate. Moreover, the inhibitory action of palmitoyl-lysoPG on paraoxonase activity, time-independent, was almost fully (>90%) suppressed by 1 M NaCl, in contrast to no suppressive effect of salt on the stimulation of arylesterase activity by palmitoyl-lysoPG (Park, C.-H., *et al.*, unpublished data).

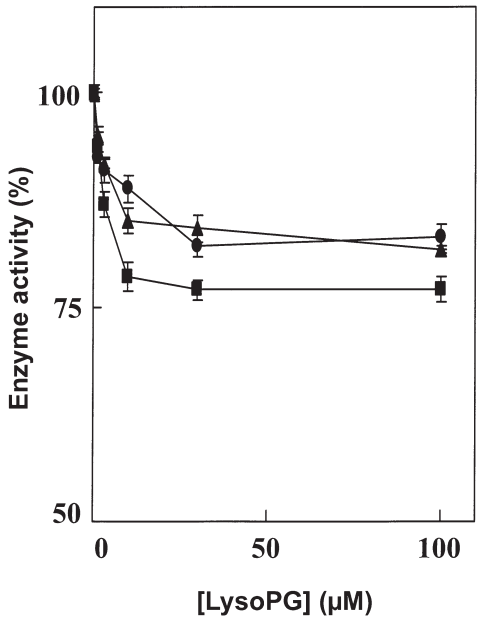

FIG. 1. Inhibitory effect of lysophosphatidylglycerol (lysoPG) on paraoxonase activity of purified paraoxyonasel (PONI). Purified PON1 (7.5 arylseterase unit/mL), A type, was incubated with paraoxon (1 mM) in the presence of lysoPG (1–100 μM) in 0.5 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+} at 25°C, and the formation of product was monitored at 405 nm as described previously (22). ▲, stearoyl-lysoPG; ■, palmitoyl-lysoPG; ●, myristoyl-lysoPG. Data are expressed as a mean ± SD (bar) value of triplicate assays, presented as a relative value (%) of control activity, which was obtained in the absence of lysophospholipids.

Stimulation of PON1 activities by lysophospholipids. When the effect of various lysophospholipids (10 μM) on arylesterase activity was examined, it was found that palmitoyl-lysoPC, liver lysoPI, and monooleoyl-lysoPS enhanced arylesterase activity by 47%, 10%, and 8%, respectively. In addition, nonionic detergents such as monolaurylglycerol (1–10 mM), Tergitol-10 (1–100 μM), or Triton X-100 (1–100 μM) showed no significant stimulation (<5%) of arylesterase activity. Thus, palmitoyl-lysoPC was the most efficient in stimulating arylesterase activity. The stimulatory effect of lysophospholipids on three PON1 activities, arylesterase, paraoxonase, and diazoxonase, was investigated in more detail. In further study of the effect of palmitoyl-lysoPC on these three activities (Fig. 2B), it was found to express a concentration-dependent increase of all three activities up to 30

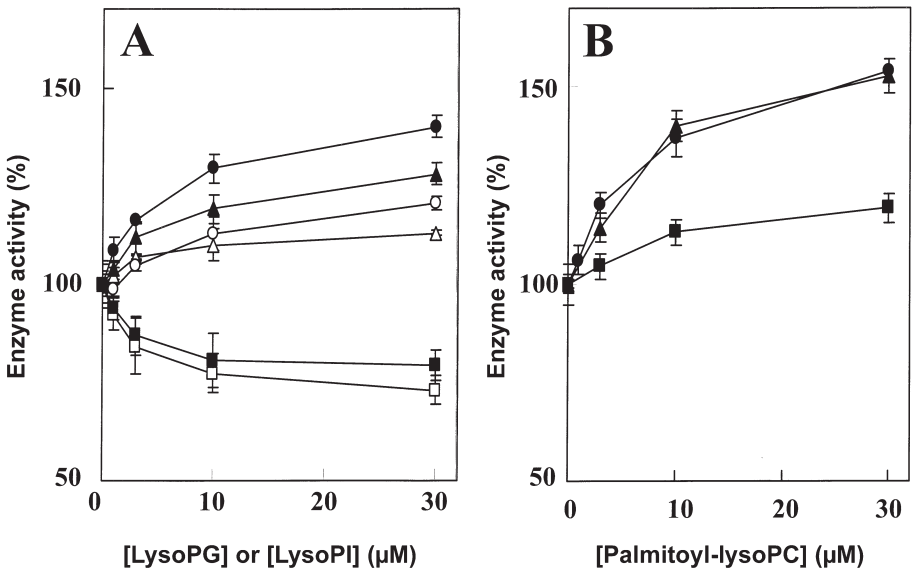

FIG. 2. Inhibitory effect of lysophospholipids on activities of purified PON1. (A) Purified PON1 was incubated with 1 mM of phenylacetate (triangle), paraoxon (rectangle), or diazoxon (circle) in the presence of palmitoyl-lysoPG (filled symbols) or liver lysophosphatidylinositol (lysoPI) (open symbols) in 0.5 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+} at 25°C. (B) The same experiment was done in the presence of palmitoyl-lysophosphatidylcholine (lysoPC). One arylesterase unit/mL was used for assay of the hydrolysis of phenylacetate and diazoxon, whereas 7.5 aryleterase units/mL were used for assay of hydrolysis of paraoxon. Data are expressed as a mean ± SD (bar) value of triplicate assays, presented as a relative value (%) of control activity, which was obtained in the absence of lysophospholipids. Control activity was ΔO.D. 0.081/min for paraoxonase activity, ΔO.D. 0.37/min for arylesterase activity, and ΔO.D. 0.35/min for diazoxonase activity. For abbreviations see Figure 1.

μM, above its CMC value. At concentration as low as 10 μM, palmitoyl-lysoPC stimulated the activities of arylesterase, paraoxonase, and diazoxonase by 47 %, 14%, and 40%, respectively. Thus, arylesterase and diazoxonase activities were more sensitive to the palmitoyl-lysoPC stimulation, compared to paraoxonase activity ($P < 0.05$).

Effect of lysophospholipids on Trp fluorescence of PON1. According to a previous report (27), PON1 is known to contain three helical regions, of which two helices (H1 and H2) are associable with amphiphilic phospholipids. Since the maximal stimulatory effect of lysophospholipids on arylesterase activity was observed at or above their CMC values (Fig. 2), the lysophospholipid stimulation was thought to be due to the micelle formation around some polypeptide regions, probably helical regions. Actually, three of four Trp residues reside in or close to helical regions (H2 and H3) of PON1. Therefore, the effect of lysophospholipids on the fluorescence spectrum of Trp residues in PON1 was examined. As demonstrated in Figure 4, each lysophospholipid enhanced Trp fluorescence intensity of PON1 in a concentration-dependent manner up to 30 μM with a sharp inflection at 10 μM, suggesting that some Trp residue–containing regions of PON1 might be exposed to a relatively low level of lysophospholipids. In contrast, Triton X-100, an amphiphile, failed to enhance PON1 Trp fluorescence even above its CMC value (Fig. 4A). A related study indicates that lipids, which show an enhancing effect on PON1 Trp fluorescence, seem to stimulate arylesterase activity effectively (Nguyen, S.D., *et al.*, unpublished data). The concentration-dependent effect of lysophospholipids on the fluorescence spectrum indicates that the concentration of lysophospholipids required for a remarkable increase in Trp fluorescence intensity is close to that for

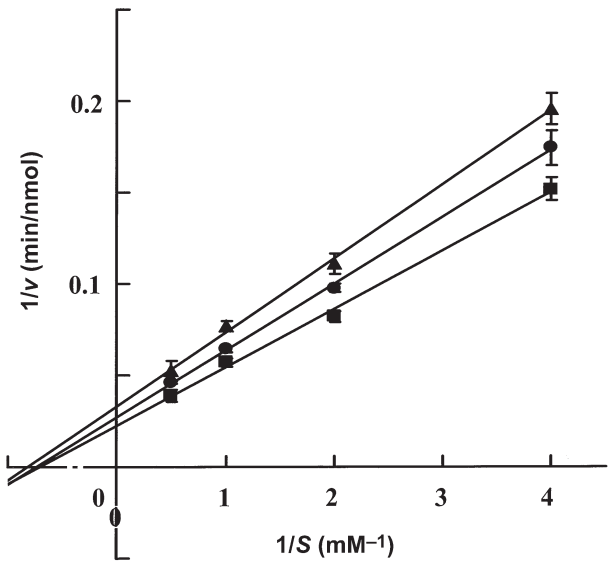

FIG. 3. Lineweaver-Burk double-reciprocal plot for partial inhibition of paraoxonase activity by palmitoyl-lysoPG. PON1 (7.5 arylesterase units/mL) was incubated with paraoxon of various concentrations (0.25–2 mM) in the presence or absence of palmitoyl-lysoPG (3 or 10 μM) in 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+} at 25°C. ■, control; ●, 3 μM ; ▲, 10 μM. For abbreviations see Figure 1.

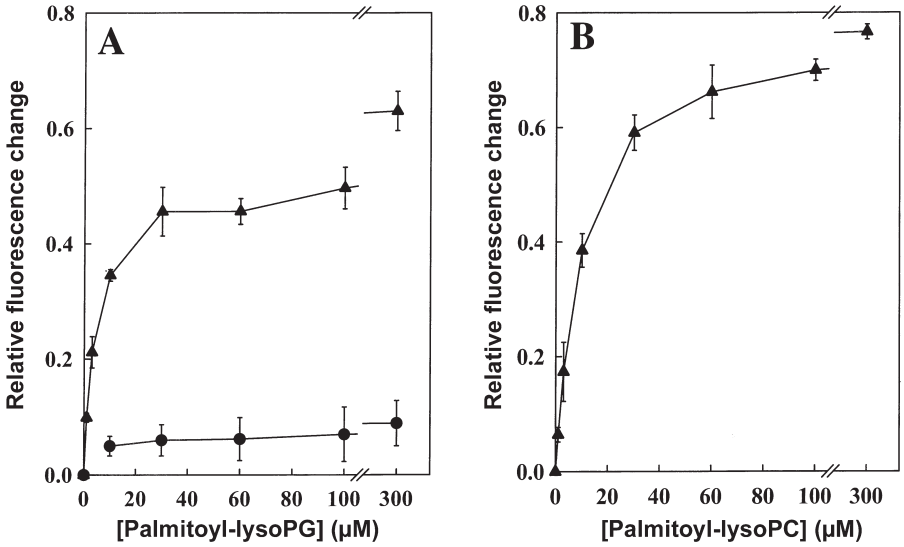

FIG. 4. Effect of lysophospholipids on the fluorescence of PON1. (A) PON1 (6 arylesterase units; 4.8 mg) was incubated with palmitoyl-lysoPG at various concentrations (0, 1, 3, 10, 30, 60, 100, or 300 μM) in 1 mL Tris buffer (pH 7.4) containing 1mM Ca^{2+}. Triton X-100 was used as control (filled circle). (B) The same experiment was done in the presence of palmitoyl-lysoPC. Fluorescence emission spectra of PON1 were monitored using a PerkinElmer 550-55 fluorimeter at room temperature, with the excitation wavelength at 280 nm and the emission wavelength at 340 nm (slit width 5 nm). Change in fluorescence was calculated as described in this paper. Data are expressed as a mean ± SD (bar) value of triplicate assays. For abbreviations see Figures 1 and 2.

the stimulation of PON1 arylesterase activity (Fig. 2). These data indicate that the stimulatory action of lysophospholipids is due to their association around the polypeptide region containing at least one Trp residue.

Effect of lysophospholipids on liposome-bound PON1. Previous studies showed that anchoring of the PON1 N-terminus to phospholipids was important for PON1 activity (21,23). Therefore, the prior binding of the N-terminus to phospholipid micelles was expected to result in the decreased response of PON1 to further stimulation by lysophospholipid. In this regard, the effect of lysophospholipids on dimyristoylphosphatidylcholine (DMPC) liposome– or DMPS liposome–bound PON1 activities was investigated. As shown in Fig. 5A, DMPC liposome–bound paraoxonase activity was inhibited partially (approximately 22%) by palmitoyl-lysoPG (10 μM), and the inclusion of 1 M NaCl restored the lost activity to 93% of control level, similar to the finding with purified PON1. Arylesterase activity of DMPC-bound PON1 was not altered remarkably by palmitoyl-lysoPG (1–10 μM), contrasting with the finding for purified PON1 arylesterase (Fig. 2A). Thus, DMPC-anchored arylesterase was resistant to palmitoyl-lysoPG stimulation. Furthermore (Fig. 5A), palmitoyl-lysoPG inhibited DMPS-bound paraoxonase activity by 43% while stimulating arylesterase activity by 28% ($P < 0.05$). Thus, the effect, inhibitory or stimulatory, of palmitoyl-lysoPG on PON1 activities seems to be more remarkable for DMPS-bound PON1, compared to DMPC-bound PON1.

When the effect of palmitoyl-lysoPC on liposome-bound PON1 activities was examined (Fig. 5B), palmitoyl-lysoPC (10 μM) enhanced DMPC-bound paraoxonase activity and DMPC-bound arylesterase activity by 13% and 23%, respectively ($P < 0.05$). Thus, compared to purified PON1 activities, DMPC-anchored PON1 activities were less sensitive to the stimulatory effect of palmitoyl-lysoPC, reflecting that the polypeptide regions of PON1 that are associable with palmitoyl-lysoPC were already occupied by DMPC. In support of this, PON1 associated with dipalmitoyl phosphatidylcholine (DPPC), which is more nonpolar, was less responsive to palmitoyl-lysoPC than DMPC-associated PON1. Further, palmitoyl-lysoPC (10 μM) augmented DMPS-bound paraoxonase and arylesterase activities by 41% and 83%, respectively; these increases are much greater than the values achieved with purified PON1.

Effect of lysophospholipids on HDL-bound PON1. The effect of lysophospholipids on HDL-bound PON1 activities was examined. As demonstrated in Fig. 6A, palmitoyl-lysoPG at relatively low concentrations (1–10 μM) inhibited HDL-paraoxonase activity with a maximal inhibition of ~15% ($P < 0.05$), but it had no remarkable effect on HDL-associated arylesterase activity. A similar result was also observed with soybean lysoPI. Thus, palmitoyl-lysoPG or liver lysoPI inhibited HDL-associated PON1 paraoxonase activity selectively, similar to the finding with purified PON1. Separately (Fig. 6B), palmitoyl-lysoPC (30 μM) was observed to enhance HDL-bound arylesterase activity by ~13% ($P < 0.05$), but showed no effect on HDL-paraoxonase activity, indicating that HDL-associated PON1 was less responsive to palmitoyl-lysoPC compared to DMPC-bound PON1. Accordingly, it was supposed that the polypeptide regions of PON1 that are associable with palmitoyl-lysoPC might be intimately

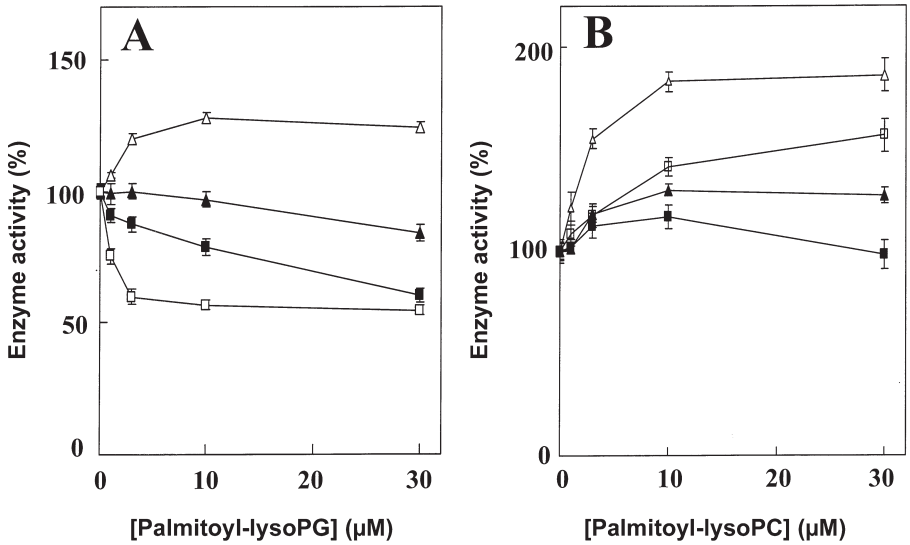

FIG. 5. Effect of lysophospholipids on activities of liposome-bound PON1. (A) Liposome-bound PON1 was incubated with 1 mM of phenylacetate or paraoxon in the presence of palmitoyl-lysoPG (1–30 μM) in 0.5 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+} at 25°C. (B) The same experiment was done in the presence of palmitoyl-lysoPC. The amount of dimyristoylphosphatidylcholine (DMPC) (filled symbols) or dimyristoylphosphatidylserine (DMPS) (open symbols)-bound PON1 used is 0.5 arylesterase unit/mL for the hydrolysis of phenylacetate (triangle) and 3 arylesterase units/mL for paraoxon hydrolysis (rectangle). Data are expressed as a mean ± SD (bar) value of triplicate assays, presented as a relative value (%) of control activity, which was obtained in the absence of lysophospholipids. For abbreviations see Figures 1 and 2.

bound to HDL lipid. In an attempt to test this possibility, HDL was pretreated with bee PLA_2 to generate phosphatidylcholine-deficient HDL. Then, the PLA_2-pretreated HDL, after 500-fold dilution, was subjected to the stimulation by palmitoyl-lysoPC. The prior treatment of HDL with PLA_2 led to ~47% loss of arylesterase activity, and the subsequent exposure of PLA_2-pretreated HDL to palmitoyl-lysoPC (30 μM) recovered > 95% of the lost activity (Fig. 6B). Likewise, the prior treatment of HDL with PLA_2 led to ~50% loss of paraoxonase activity, and the subsequent treatment with palmitoyl-lysoPC (30 μM) recovered > 90% of the lost activity. Thus, the site responsible for palmitoyl-lysoPC stimulation seems to be occupied by phosphatidylcholine in HDL.

Effect of apo A-I on arylesterase activity of PON1 associated with phospholipids. Earlier (21,23), PON1 N-terminus had been reported to bind to phosphatidylcholine optimally presented in association with apo A-I. Therefore, it was supposed that activity of HDL-bound PON1 might be maximally expressed by phosphatidylcholine recruited by apo A-I. To test this, the effect of apo A-I, in combination with lysoPC, on arylesterase activity of PON1 bound to DMPS, dimyristoylphosphatidylglycerol (DMPG), or DMPC was examined. When DMPS-bound PON1 was preincubated with apo A-I for 30 min before the determination of arylesterase activity (Fig. 7A), the arylesterase activity was enhanced by apo A-I (0.3–10 μM) with a maximal stimulation of 174%. The preincubation with apo A-I followed by palmitoyl-lysoPC (10 μM) further augmented PON1 arylesterase activity up to 210%, higher than the levels achieved with apo A-I alone (174%) or 10 μM palmitoyl-lysoPC alone (178%), which suggests that apoA-I and palmitoyl-lysoPC might cooperate to maximize the arylesterase activity when they are bound to DMPS. A similar result was also observed with DMPG-bound arylesterase activity, although to a lesser extent. Meanwhile, the stimulatory effect of apo A-I (10 μM) on DMPC-bound arylesterase activity was restricted to 19%, which is less than the effect (25%) achieved with palmitoyl-lysoPC alone (10 μM). In comparison, DMPS-bound arylesterase (74% stimulation) was much more responsive to apo A-I stimulation or palmitoyl-lysoPC stimulation than DMPC-bound arylesterase (19% stimulation), leading to the assumption that arylesterase activity of PON1 may not be fully expressed in DMPS liposome. In related experiment to address this notion (Fig. 7B), the preincubation of PON1 with DMPS (200 μM) resulted in 47% loss of arylesterase activity, and the subsequent inclusion of apo A-I (1–10 μM) in the mixture containing PON1 and DMPS (200 μM) restored the lost activity with a full recovery (100% of control). Further, the inclusion of palmitoyl-lysoPC (10 μM), in combination with apo A-I (≥ 3 μM), augmented the activity up to 140%, far beyond that (100%) achieved with apo A-I alone. Similarly, the preincubation of PON1 with DMPS (200 μM) led to 20% loss of paraoxonase activity, and the subsequent inclusion of apo A-I (1–10 μM) in the mixture restored the lost activity with a full recovery. Further, the inclusion of palmitoyl-lysoPC (10 μM), in combination with apo A-I (3–10 μM), augmented the activity to

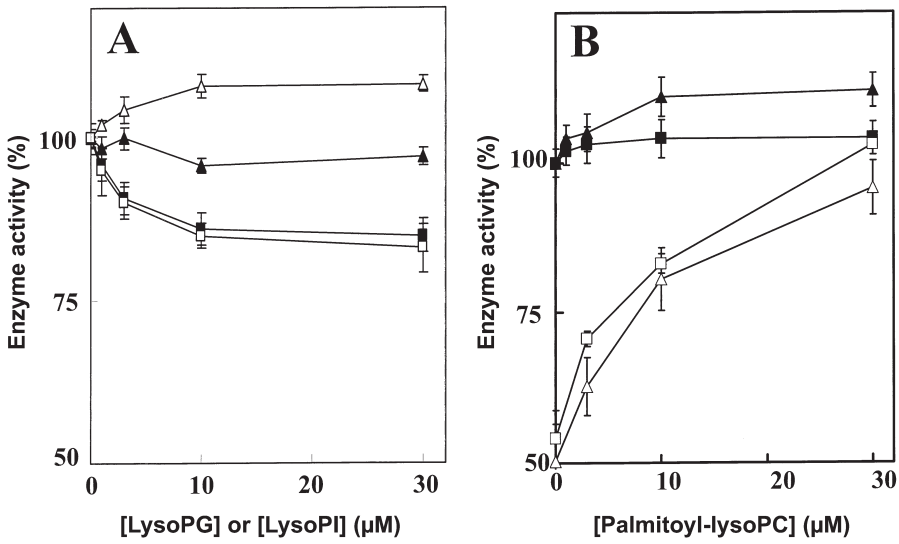

FIG. 6. Effect of lysophospholipids on HDL-associated PON1 activities. (A) HDL was incubated with 1 mM of phenylacetate, diazoxon, or paraoxon in the presence of palmitoyl-lysoPG (filled symbols) or lysoPI (open symbols) in 0.5 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+} at 25°C. The activity of PON1 in HDL used is 1 arylesterase unit/mL for arylesterase activity (triangle) and 7.5 arylesterase unit/mL for paraoxonase activity (rectangle). (B) HDL was incubated with 1 mM of phenylacetate or paraoxon in the presence of palmitoyl-lysoPC in the same buffer. Data are presented as a relative value (%) of control activity, which was obtained in the absence of lysophospholipids. The activity of PON1 in HDL used is 1 arylesterase unit/mL for arylesterase activity (filled triangle) and 7.5 arylesterase unit/mL for paraoxonase activity (filled rectangle). Separately, 100 μl of HDL (8 mg protein/mL) was preincubated with bee PLA_2 (1.5 unit) in 0.5 mL of 50 mM Tris buffer (pH 7.4) containing 1 mM Ca^{2+} at 25°C for 30 min, and then an aliquot (1 μL) was taken into 0.5 mL of the same buffer containing palmitoyl-lysoPC (0–30 μM) for the determination of arylesterase activity (open triangle) and paraoxonase activity (open rectangle). Data are expressed as a mean ± SD (bar) value of triplicate assays, presented as a relative value (%) of control activity of HDL, which was preincubated in the absence of PLA_2. For abbreviations see Figures 1 and 2.

120%. In a separate experiment, the preincubation of PON1 with DMPC (200 μM) led to a 30% increase of arylesterase activity, and the subsequent inclusion of apo A-I (1–10 μM) in the mixture failed to further enhance the activity. Also, no further increase was observed with the combination of palmitoyl-lysoPC (10 μM) and apo A-I (3–10 μM).

DISCUSSION

There have been reports on the interaction between PON1 molecule and lipids (9,21,23,34,35,39). Our present data may add to the knowledge concerning the interaction of PON1 with phospholipids as well as lysophospholipids. From the arguments over the phospholipase-like activity of PON1 solutions (17–20), some researchers question whether the potential phospholipase activity of PON1 might influence the present results. However, this possibility is excluded as a result of the findings that purified PON1 used here did not hydrolyze DMPC, and that the stimulation of PON1 arylesterase activity by DMPC was not influenced by PAF hydrolase inhibitor (Nguyen, S.D., *et al.*, unpublished data).

The effect, inhibitory or stimulatory, of lysophospholipids on PON1 activity depends on their structure. Moreover, the effect of negatively charged lysophospholipids on PON1 activities differed according to the type of substrate; lysoPG or lysoPI inhibited paraoxonase activity partially, but stimulated arylesterase and diazoxonase activities, representing a selective inhibition of paraoxonase activity. This may support the notion that the paraoxon-binding subsite does not coincide with the phenylacetate-binding subsite (27,40). Further, the possibility that the selective inhibition of paraoxonase activity by lysoPG or lysoPI may occur at a site different from the active center may be suggested by the noncompetitive nature of the partial inhibition of paraoxonase activity by palmitoyl-lysoPG.

One structural feature of lysophospholipids related to the inhibition of paraoxonase activity is their negatively charged regions with bases such as glycerol or inositol. In addition, the size of the acyl chain in lysoPG is important; the palmitoyl group is the most effective. Meanwhile, an oleoyl group is not necessary for the selective inhibition of paraoxonase activity, which is somewhat different from previous suggestion (34). The inhibitory action of lysoPG at concentrations below its CMC value, a characteristic feature expressed by a monomer portion of amphiphiles (38,41,42), implicates palmitoyl-lysoPG monomer in such an inhibition. In addition, there is no relationship between the inhibitory potency of lysoPG series and their CMC values (41,42). Moreover, the inhibitory action of palmitoyl-lysoPG was suppressed by 1 M NaCl, contrary to the promoting effect of high salt concentration on micelle formation (38,41). Such a selective inhibition

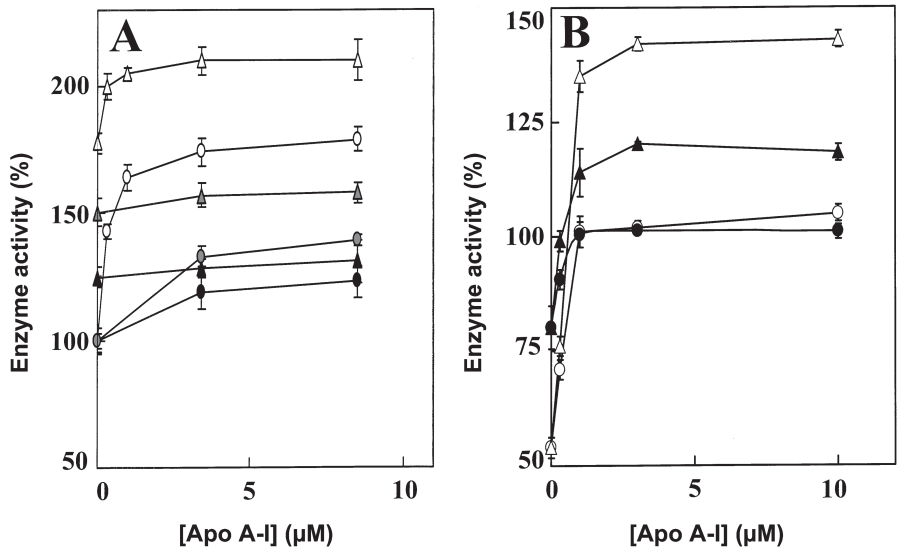

FIG. 7. Effect of apolipoprotein A-I (apo A-I) on PON1 activities associated with phospholipids. (A) Liposome-bound PON1 (1.6 arylesterase unit/mL) was preincubated with apo A-1 (0.3–8.5 μM) in 0.1 mL of 10 mM PBS buffer (pH 7.4) containing 1 mM Ca^{2+} at 37°C for 30 min, and an aliquot was taken for the assay of arylesterase activity in the presence (triangle) or absence (circle) of palmitoyl-lysoPC (10 μM). DMPC (filled symbols); DMPS (open symbols); dimyristoylphosphatidylglycerol (DMPG) (shaded symbols). (B) Purified PON1 (2.5 arylesterase units/mL) was preincubated with DMPS (0.2 mM) in 0.1 mL of the same buffer containing 1 mM Ca^{2+} at 25°C for 5 min, and then apo A-1 (0.3–10 μM) was added to the mixture. After further incubation for 10 min, aliquots were taken for the assay of arylesterase activity (open symbol) and paraoxonase activity (filled symbol) in the presence (triangle) or absence (circle) of palmitoyl-lysoPC (10 mM). Data are expressed as a mean ± SD (bar) value of triplicate assays, presented as a relative value (%) of control activity, which was preincubated in the absence of phospholipid. For abbreviations see Figures 1, 2, and 5.

by palmitoyl-lysoPG was also observed with HDL- or DMPC-bound paraoxonase activity in studies where the N-terminal sequence of PON1 was anchored to phospholipids (21). In this respect, the N-terminal sequence of PON1 molecule is not likely implicated in the inhibition of paraoxonase activity by palmitoyl-lysoPG.

Previous reports (21,23,27) have demonstrated that the anchoring of the PON1 N-terminus to lipid is important for the maintenance of PON1 arylesterase activity. The same mechanism may account for the stimulation of PON1 arylesterase activity by some phosphatidylcholines (23,27). In agreement with this, the stimulatory action of palmitoyl-lysoPC was the more remarkable for purified PON1 than for DMPC-bound PON1 and HDL-associated PON1. In further support, the stimulatory effect of palmitoyl-lysoPC was still less pronounced in PON1 associated with DPPC, which is more nonpolar than DMPC. This might explain why PON1 activity in PLA_2-modified HDL, which is phosphatidylcholine-deficient, became more responsive to the palmitoyl-lysoPC stimulation than HDL-associated PON1. However, a recent study (27) indicates that besides the N-terminal signal sequence, the H1 helix, H2 helix, and its loop, which lie in the interphase between the HDL hydrophobic interior and exterior aqueous phase, also contribute to the association of PON1 with HDL lipids. Further, a very recent report (43) indicates that there is no noticeable difference of specific arylesterase activity between truncated variant PON1 devoid of the N-terminal 20 amino acid residues bound to apo A-I rHDL and intact PON1 bound to apo A-I rHDL, which suggests that the N-terminus of PON1 may not be involved in the stimulation mechanism. From this, it is conceivable that the stimulation of PON1 by lipids may be due to their binding to the interphase of PON1, which is associable with lipids (27). The possible interaction between lysophospholipid and the PON1 interphase may be implied from the enhancing effect of lysophospholipids on the fluorescence intensity of Trp residues in the PON1 molecule. PON1 contains four Trp residues, with three of these being placed in or close to the interphase region (22,27). Probably in support of this, the stimulation of PON1 activity by lysophospholipids was observed at their concentrations corresponding to those required for the enhancement of the Trp fluorescence.

Earlier studies showed that the efficient binding of PON1 N-terminal region to HDL required the coexistence of apo A-I (21,23,44). Further, the binding of the N-terminal sequence to phospholipids in the presence of apo A-I was crucial for the maximal activity of PON1 (21). Thus, apo A-I might contribute to full expression of PON1 activity by promoting micelle formation of phospholipids around the N-terminal signal sequence and/or the interphase of PON1. This might be extended to explain why PON1 associated with HDL that is rich in apo A-I differed from DMPC liposome–bound PON1 in its response to palmitoyl-lysoPC. The interface of DMPC-bound PON1 is still available for the interaction with phospholipids recruited by apo A-I, whereas the interface of PON1 is already associated with lipids in the HDL particle. The positive effect of apo A-I

or palmitoyl-lysoPC was more remarkable for DMPS-bound PON1 than for DMPC-bound PON1. Further, the stimulating effect of apo A-I or palmitoyl-lysoPC on DMPS-bound arylesterase activity was far beyond their effect on purified PON1 activity. A plausible explanation for this is that apo A-I or palmitoyl-lysoPC may exert an additional effect by selectively binding to the contact region between PON1 and DMPS lipid, and restoring the activity of DMPS-bound PON1, which is in a state of suppressed catalysis.

The low response of DMPC-bound PON1 to apo A-I may be ascribed to the limited role of apo A-I for DMPC-bound PON1 in activated state. However, the stimulation of purified PON1 by palmitoyl-lysoPC was not further enhanced by apo A-I, because palmitoyl-lysoPC alone can maximally stimulate the activity through micelle formation around the N-terminal region and/or the interphase. From the finding that the maximal stimulation of purified PON1 arylesterase activity by palmitoyl-lysoPC is similar to that achieved with the combination of DMPC and apo A-I, it is likely that the same polypeptide region may be implicated in the stimulation of PON1 activity by phospholipids or lysophospholipids.

Taken together, the inhibition of PON1 paraoxonase activity was exhibited by lysoPG and lysoPI, which could bind to a specific site different from the catalytic site, whereas the stimulation of three PON1 activities was expressed commonly by lysophospholipids that are associable with the N-terminal region and/or the interphase. Therefore, paraoxonase activity and arylesterase activity of HDL would be significantly altered in pathological states that are accompanied by PLA_2 hydrolysis of phospholipids (45–49), in which a considerable level of lysophospholipids could be generated. This might be more prominent in atherosclerotic plaques containing proinflammatory stimuli such as lysophosphatidylcholine (50) or in phospholipid-deficient HDL (51). In addition, the distribution or amount of apo A-I in HDL particles (23) might be another factor that affects PON1 activities in HDL. It remains to be clarified in further studies whether or how the possible interaction between PON1 and lysophospholipids can affect the potential antiatherogenic function of PON1 *in vivo*.

METHOD

Analysis of Triacylglycerols of Seeds and Berries of Sea Buckthorn (*Hippophaë rhamnoides*) of Different Origins by Mass Spectrometry and Tandem Mass Spectrometry

Baoru Yang[a,b,*] and Heikki Kallio[a]

[a]Department of Biochemistry and Food Chemistry, University of Turku, Turku, Finland, and [b]Aromtech Ltd., Veturitallintie 1, 95410 Kiviranta/Tornio, Finland

ABSTRACT: TAG of seeds, berries, and fruit pulp/peel of different subspecies of sea buckthorn (*Hippophaë rhamnoides*) were analyzed by MS and tandem mass spectrometry (MS/MS). The seeds contained mainly TAG with acyl carbon number (ACN) of 52 with 2–6 double bonds (DB) (20–30%), and TAG of ACN 54 with 3–9 DB (70–80%). In the pulp/peel fraction, the major TAG were species with ACN:DB of 48:1 to 48:3 (19–49%), 50:1 to 50:4 (31–41%), and 52:1 to 52:6 (9–19%). The molecular weight species of whole berries largely resembled those of fruit pulp/peel with additional species of ACN 54 from the seeds (5–24%). Subspecies (ssp.) *sinensis* differed from ssp. *mongolica* and *rhamnoides* by having a higher proportion of TAG of ACN 52 (27% vs. 21% and 22%, $P < 0.05$) and a lower proportion of ACN 54 (71% vs. 79% and 78%, $P < 0.01$) in seed TAG. Seed TAG of ssp. *mongolica* contained a higher proportion of more unsaturated species compared with those of the two other subspecies. Berry TAG of ssp. *mongolica* had the highest proportion of molecular species of ACN 48 due to the higher proportion of palmitic and palmitoleic acids and the lower seed content of the berries. Overall, palmitic acid favored the *sn*-1 and *sn*-3 positions. The order of preference of unsaturated FA for the *sn*-2 position depended at least partially on the FA combination of TAG. Seed TAG of ssp. *mongolica* contained a higher proportion of α-linolenic acid in the *sn*-2 position than those of ssp. *sinensis*. In berry TAG, ssp. *mongolica* had the highest proportions of palmitoleic and linoleic acids in the *sn*-2 position, and the lowest proportion of oleic/*cis*-vaccenic acid in the *sn*-2 position, among the three subspecies.

Paper no. L9806 in *Lipids 41*, 381–392 (April 2006).

Sea buckthorn (*Hippophaë rhamnoides* L.) is increasingly recognized as an important potential source of bioactive ingredients for functional foods, nutraceuticals, and personal-care products. Sea buckthorn berries are characterized by a high content of water-soluble antioxidants and vitamins in the berry juice and flesh. The uniqueness of the composition of the sea buckthorn berry also lies in the fact that both the seed and the fruit flesh/peel contain oil. The seeds of sea buckthorn typically contain 6–11% oil, whereas the oil content in the fruit flesh and peel varies considerably from 0.5 to 5% with its origin (1,2). Oils from seeds and fruit flesh/peel of sea buckthorn have clearly distinct FA compositions; seed oil is rich in linoleic (18:2n-6) and α-linolenic (18:3n-3) acids, whereas oil from fruit flesh and peel contains a high level of palmitoleic acid (16:1n-7) (2). In addition, oils from the seeds and the fruit soft parts (flesh/peel) can be differentiated by the high content of carotenoids usually found in the latter (1).

The health effects of sea buckthorn seed oil and pulp oil have been extensively documented in the literature in various languages. Topical use of sea buckthorn oils promotes the healing of wounds, burns, scalds, and different types of dermatitis of the skin (1). Dietary intake of sea buckthorn oils has been shown to increase antioxidation capacity, enhance the function of the immune system, and improve the health of the skin, the mucous membranes, and the cardiovascular system (1,3–5).

As a major class of active compounds, FA play an important role in the nutritional effects of sea buckthorn oils. Both the composition of FA and their distribution in TAG influence the nutritional value of oils and fats. After ingestion of oils, the FA in the secondary (*sn*-2) position of TAG have a different metabolic fate compared with those in the primary (*sn*-1 and *sn*-3) positions, resulting in different nutritional and health effects (6,7).

Sea buckthorn oils have been used in China and Russia as ingredients for health-care products for more than half a century. Health-care and personal-care products based on sea buckthorn oils have become increasingly popular in Western countries. This has resulted in an increased demand for sea buckthorn oil in these countries. Selection of the sea buckthorn oils most suitable for specific applications and maintenance of the stable quality of the oils are extremely challenging due to the great variation in their composition depending on the origin of the berries and the oil production technology. Because of the compositional variation among the oils from different sources, the FA composition alone is not always enough to establish the authenticity of sea buckthorn oil. Structural features of TAG of seed and fruit flesh/peel of sea buckthorn provide valuable information for distinguishing sea buckthorn oils from adulterations.

In the present study, the pattern of molecular weight distribution and regioisomers of TAG of seeds, berries, and fruit

Abbreviations: ACN, acyl carbon number; DB, double bond; CID, collision induced dissociation; MS/MS, tandem mass spectrometry; MTBE, methyl *t*-butyl ether; ssp., subspecies.

flesh/peel fraction of three major subspecies of sea buckthorn were determined. The aim was to reveal the structural features of TAG common to the species, as well as the differences among the subspecies.

MATERIALS AND METHODS

Berries. Wild berries of *Hippophaë rhamnoides* ssp. *sinensis* were collected from their natural growth sites in Shanxi, Shaanxi, Qinghai, and Gansu provinces of China in 1997. Berries of three cultivars (Ruet, Luchezarnaya, and Dar Katuni) of *H. rhamnoides* ssp. *mongolica* were collected from the research station of the Institute of Botany, Siberian Branch of the Russian Academy of Science, Novosibirsk, Russia, in 1997. Wild berries of *H. rahmnoides* ssp. *rhamnoides* were picked in autumn 1999 from five natural growth sites on the Baltic coast of southwest Finland. The berries were loosely frozen immediately after picking.

Extraction of lipids. Frozen berries were lyophilized to a constant weight before manual separation of seeds from fruit pulp and peel. Oil was extracted from seeds, berries, and the fruit flesh/peel fraction as previously described (2). Briefly, a sample of 1 g was crushed in liquid nitrogen and extracted with 3 × 30 ml of a solvent mixture of chloroform/methanol (2:1, vol/vol). The extract was purified by repeated washing with a 0.88% potassium chloride water solution and methanol/water (1:1, vol/vol) before the solvents were removed using a rotary film evaporator. The total lipids extracted were dissolved in chloroform and stored at –20°C until analyzed.

Separation of TAG from total lipids. Triacylglycerols were isolated from total lipids on a Sep-Pak silica cartridge as previously described (2,8). After evaporation of chloroform to dryness under nitrogen, total lipids were reconstituted in hexane. Total lipids were applied on a preconditioned Sep-Pak silica cartridge. After elution of hydrocarbons, wax esters, and steryl esters with 15 ml hexane/MTBE (methyl *t*-butyl ether) (200:2, vol/vol), TAG were eluted with 20 ml of hexane/MTBE (96:4, vol/vol). After evaporation of solvents under nitrogen, the TAG were dissolved in hexane and stored at –20°C until analyzed.

Analysis of FA composition of TAG. TAG was transesterified by sodium methoxide catalysis (9). The FAME were analyzed by GC using a PerkinElmer (San Jose, CA) Autosystem equipped with a programmed split/splitless injector and a flame ionization detector A silica capillary column NB-351 (length 25 m, i.d. 0.32 mm, d_f 0.2 μm, HNU-Nordion Ltd, Helsinki, Finland) was used for GC analysis. The flow rate, split ratio, and temperature programs for the oven, injector, and detector for GC analysis were as reported previously (2).

Mass spectrometric analysis of molecular weight distribution of TAG. Mass spectrometric analysis of molecular weight distribution was carried out on the TAG of the following samples, four analyses each: seeds of ssp. *sinensis* (from three natural growth sites in Shanxi, Qinghai, and Gansu, China), ssp. *rhamnoides* (from three natural growth sites in Vaasa and Pyhämaa, Finland), and ssp. *mongolica* (three commercial varieties); whole berries of ssp. *sinensis* (from four natural growth sites in Shanxi, Shaanxi, Qinghai, and Gansu, China), ssp. *rhamnoides* (from five natural growth sites in Hirsilahti, Siikajoki, Vaasa, and Pyhämaa, Finland), and ssp. *mongolica* (three commercial varieties); and seedless fruit pulp/peel of ssp. *sinensis* (from one natural growth site in Shanxi, China) and ssp. *rhamnoides* (from one natural growth site in Pyhämaa, Finland).

Molecular weight distribution of TAG was analyzed using a Finnigan (San Jose, CA) MAT TSQ-700 triple-quadrupole mass spectrometer equipped with a Finnigan MAT ICIS II data system. CI with ammonia in negative-ion mode was used according to parameters previously optimized and controlled regularly in the laboratory (10). The pressure of the reactant gas ammonia was 8500 mtorr and the ion source temperature was 200°C in order to produce abundant $[M - H]^-$ ions without formation of interfering fragments. The electron energy was 70 eV and the filament current was 400 μA. Samples were introduced to the ion source on a rhenium wire of a direct exposure probe. A rapid desorption of the sample using a high heating rate (40 mA s^{-1}) was used to minimize the thermal degradation of unsaturated TAG, and hence to eliminate the need for quantitative correction of different molecular weight species (10).

Under the selected analytical condition, $[M - H]^-$ ions were generated from deprotonation of TAG from chemical ionization. The $[M - H]^-$ ions were analyzed by scanning the mass range of *m/z* 500–1000. The calculation program includes automatic correction of the $[M - H]^-$ ions for ^{13}C isotope species; $[M - H]^-$ ion species that are less abundant than the ions that are smaller by two mass units (with one more double bond), in particular, would display significant quantitative error without corrections (10). The relative abundances of TAG with different molecular weights were determined according to the intensity of $[M - H]^-$ ions of different *m/z* values. The numbers of total acyl carbons and of the double bonds in the acyl chains of TAG were calculated according to the *m/z* value of $[M - H]^-$ ions and the FA composition analyzed by GC.

Tandem mass spectrometry (MS/MS) analysis of regioisomers of TAG. Regioisomers of major acyl carbon number: double bond (ACN:DB) species of TAG of the following samples were analyzed by MS/MS, four analyses for each ACN:DB species: seeds of ssp. *sinensis* (from three natural growth sites in Shanxi, Qinghai, and Gansu, China), ssp. *rhamnoides* (from three natural growth sites in Vaasa and Pyhämaa, Finland), and ssp. *mongolica* (three commercial varieties); and whole berries of ssp. *sinensis* (from three natural growth sites in Shanxi, Qinghai, and Gansu), ssp. *rhamnoides* (from three natural growth sites in Hirsilahti and Pyhämaa, Finland), and ssp. *mongolica* (three commercial varieties).

Regioisomers of TAG were analyzed by determining the molecular weights of FA in the primary (*sn*-1 and *sn*-3) positions and the secondary (*sn*-2) position. Negative-ion MS/MS with ammonia CI and argon collision-induced dissociation

(CID) was carried out with a Finnigan MAT TSQ-700 triple-quadrupole mass spectrometer equipped with a Finnigan MAT ICIS II data system (10,11). The conditions for CI were as described in the previous section. The pressure of the collision gas was 1.8 mtorr and the collision energy was 15 eV. TAG samples (1 µl, approximately 1 mg/mL) dissolved in hexane were placed on a rhenium wire at the end of a direct insertion probe. The solvent was allowed to evaporate and the rhenium wire and the probe were introduced directly into the ion source. The probe was heated to 300°C at the maximum heating rate (300°C/min). The scan time for each individual scan was 8 s, and a total of 10–12 spectra were obtained. The first and the last spectra were discarded, and the rest were summed and displayed.

The CI of TAG produced a complex mixture of ions within the ion source. The first quadrupole of the mass spectrometer transmitted ions of one particular *m/z* value. The selected $[M - H]^-$ ions (parent ions) entered the second (RF-only) quadrupole, collided with argon, and were fragmented. The fragment ions were then analyzed by the third quadrupole and displayed in daughter-ion spectra. These CID spectra were used to deduce the structural information about TAG regarding the FA and their distribution in TAG molecules.

The ions $[M - H]^-$, $[RCOO]^-$, and $[M - H - RCOOH - 100]^-$ in the CID spectra were taken into account in the calculation. The *m/z* value of $[M - H]^-$ and the FA composition of TAG determined by GC gave information about the ACN:DB of TAG. The molecular weights of the FA were interpreted according to the *m/z* values of the $[RCOO]^-$ ions. These, together with the results of GC analysis, were used to identify the FA within the specific ACN:DB species of TAG. Empirical correction factors for the abundance of $[RCOO]^-$ ions were used on the basis of regular analysis of reference TAG containing the following FA: 18:0 (1.0); 18:1n-9 (1.1); 18:2n-6 (1.2); 18:3n-3 (1.3); 16:0 (1.1); and 16:1n-7 (1.3). The FA 18:1n-7 was assumed to have the same correction factor as 18:1n-9. Under the selected conditions of analysis, the dependence of the correction factors of these FA on the positions of FA in TAG was minimal and was thus not taken into account. The proportions of FA within TAG were calculated according to the corrected relative abundance of $[RCOO]^-$ ions in the CID spectra. Iterated calculation of all possible FA combinations of TAG within a specific molecular weight species was carried out according to the ACN:DB (*m/z* value of $[M - H]^-$ ion) and the proportions of FA to achieve a result with the lowest error (excess or shortage of FA). On the basis of the results of the iterated calculation, the proportions of the FA were further corrected to reduce the errors introduced during the MS/MS analysis. These corrected relative abundances of FA were then used in the calculation of the regioisomers (11,14).

The differentiation of FA in the primary positions from that in the secondary position of TAG was based on the preferential formation of $[M - H - RCOOH - 100]^-$ ions from FA located in *sn*-1 and *sn*-3 positions (11). For TAG with a FA combination A/B/A, a standard curve can be established of the ratio $[M - H - B - 100]^-/[M - H - A - 100]^-$ (typically ranging from 0.1 to 0.8) with a gradual change in composition of the TAG from 100% *sn*-A-B-A to 100% *sn*-A-A-B + *sn*-B-A-A. Experience has shown that the standard curve depends mainly on the parameters of MS/MS. The influence of the FA with 16 and 18 carbons and 0–3 double bonds was minor, and thus not taken into account in the calculation. The curve was measured and regularly controlled with the TAG pair 1,2-di-(*cis*-9-octadecenoyl)-3-hexadecanoyl-*sn*-glycerol and 1,3-di-(*cis*-9-octadecenoyl)-2-hexadecanoyl-*sn*-glycerol. An experimental equation based on the standard curve, the relative abundance of $[M - H - RCOOH - 100]^-$ and the corrected proportions of the FA were used for differentiating the FA in the secondary position from those in the primary positions of TAG (11–15).

Automatic calculation of data of MS and MS/MS analyses. In the present study, the proportions of ACN:DB species, the proportions of FA combinations, and proportions of regioisomers within each ACN:DB species of TAG were calculated automatically using the software TAGS-100/MSPECTRA (Nutrifen Oy, Naantali, Finland) based on the mathematical principles described previously (14,16).

Statistical analysis. The sea buckthorn samples analyzed in the present study were taken from larger sample groups of sea buckthorn, which were shown by earlier investigations to follow a normal distribution within the subspecies (2,8).

Due to the relatively high deviation in the analysis, the proportions of regioisomers from four repeated analyses were used directly for statistical analysis of the data (n = number of growth sites/varieties × 4 repeats). Some minor regioisomers appeared only in some of the four repeated runs; during the calculation a value of zero was assigned to the missing peaks.

The data analysis was carried out using the statistical program SPSS 11.0 for Windows. One-way ANOVA and independent sample t-test were used in the comparison of the analyzed results of positional distribution of FA in TAG with the random distribution, as well as in the comparison of the molecular weight distribution and regioisomers of TAG among the subspecies. The data from the three subspecies were combined when comparing the analyzed results of positional distribution of FA in TAG with the random distribution. Differences reaching a minimum confidence level of 95% ($P < 0.05$) were defined as being statistically significant.

RESULTS

FA composition of TAG of seeds and berries. The FA compositions of TAG of seeds and berries of three different subspecies are summarized in Table 1. Seed TAG of ssp. *sinensis* contained a higher proportion of oleic acid and a lower proportion of α-linolenic acid compared with those of ssp. *rhamnoides*. In berry TAG, the proportion of palmitic and palmitoleic acids was higher in ssp. *mongolica* than in ssp. *sinensis* and *rhamnoides*. This was accompanied by a lower proportion of oleic acid (4%, vs. 17% in ssp. *sinensis* and *rham-*

noides) and α-linolenic acid (4%, vs. 9% in ssp. *sinensis* and *rhamnoides*) in ssp. *mongolica*.

Molecular weight distribution of seed TAG. The molecular weight distributions of seed TAG of different subspecies of sea buckthorn are summarized in Figure 1. The major ACN species in sea buckthorn seed TAG were 54 (70–80%) and 52 (20–30%) followed by trace amounts of 50 and 56, regardless of the subspecies. Seeds of ssp. *sinensis* contained slightly more palmitic acid, which resulted in a higher proportion of ACN 52 species (27%) and a lower proportion of ACN 54 species (71%) compared with ssp. *mongolica* (21% for ACN 52, 79% for ACN 54) and *rhamnoides* (22% for ACN 52, 78% for ACN 54) ($P < 0.01$ for ACN 52, $P < 0.001$ for ACN 54).

The level of saturation within both the ACN 52 and ACN 54 groups also showed a regular pattern among the three subspecies (Fig. 1). In the ACN 52 group, the proportions of 52:4, 52:3, and 52:2 were significantly higher in TAG of ssp. *sinensis* compared with those of ssp. *mongolica* (9.1% vs. 5.6%, $P < 0.05$; 5.8% vs. 3.0%, $P < 0.05$; and 2.9% vs. 0.9%, $P < 0.01$, respectively). The corresponding values of ssp. *rhamnoides* fell somewhere between the other two subspecies, with higher proportions of 52:4 and 52:2 compared with ssp. *mongolica* ($P < 0.01$; $P < 0.05$), and lower proportions of 52:3 and 52:2 compared with ssp. *sinensis* ($P = 0.05$; $P < 0.05$). The proportion of 52:6 was highest in ssp. *mongolica* and lowest in ssp. *sinensis*; the difference between the two subspecies reached a statistically significant level (4.0% vs. 2.7%, $P = 0.05$).

For the ACN 54 group, the TAG of ssp. *monogolica* seeds contained a significantly higher proportion of 54:9 (6.5%), 54:8 (17.0%), and 54:7 (20.8%) compared with those of ssp. *sinensis* (2.3%, $P < 0.01$; 8.3%, $P < 0.01$; and 14.9%, $P < 0.001$, respectively) and *rhamnoides* (3.9%, $P < 0.01$; 12.5%, $P < 0.1$; and 19.3%, $P < 0.1$, respectively). The proportions of 54:5, 54:4, and 54:3 were highest in ssp. *sinensis* and lowest in ssp. *mongolica* (15.7% vs. 11.2%, $P < 0.05$; 9.1 vs. 3.9%, $P < 0.05$; 3.8% vs. 1.5%, $P < 0.05$, respectively). Ssp. *rhamnoides* again fell between ssp. *sinensis* and *mongolica*, differing from both subspecies in the proportion of 54:8 and 54:7 (Fig. 1). Statistically significant differences were also found between ssp. *rhamnoides* and *mongolica* in the proportions of 54:9 and 54:3 as well as between ssp. *sinensis* and *rhamnoides* in the proportion of 54:4 (Fig. 1).

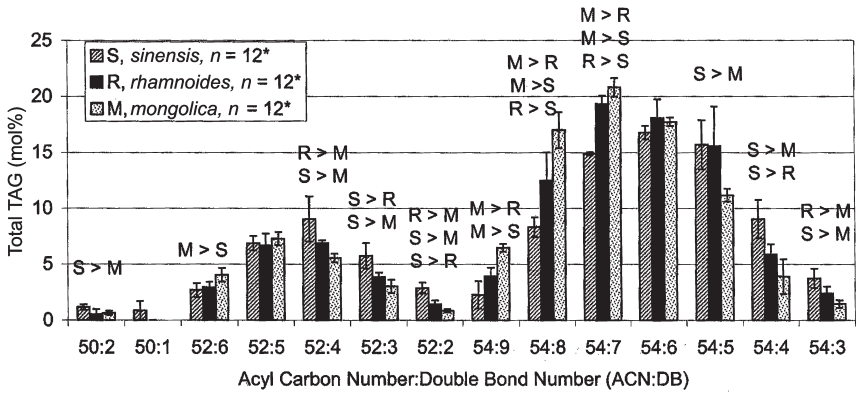

FIG. 1. Molecular weight species of TAG of seeds of three subspecies of sea buckthorn (mol%). Differences among the subspecies are indicated only when the difference reached a statistically significant level ($P < 0.05$). *n = number of natural growth sites (or varieties) × number of repeats (4); ssp. *sinensis*, three natural growth sites in Shanxi, Qinghai, and Gansu, China; ssp. *rhamnoides*, three natural growth sites in Vaasa and Pyhämaa, Finland; ssp. *mongolica*, three commercial varieties from Russia.

Positional distribution of FA in seed TAG. Regioisomers of seven major ACN:DB species 52:3 through 52:5 and 54:5 through 54:8 of seed TAG were analyzed by MS/MS. The results are summarized in Table 2.

ACN:DB 52:3. The FA combination 16:0/18:2/18:1 constituted on average 95% of the ACN:DB group 52:3, the proportion being higher in ssp. *rhamnoides* than in ssp. *mongolica* (98.0% vs. 92.4%, $P < 0.05$). Due to the low content of stearic acid and palmitoleic acid in sea buckthorn seed oil, TAG with FA combinations 16:0/18:3/18:0, 16:1/18:2/18:0, and 16:1/18:1/18:1 existed in trace amounts only.

Linoleic acid (18:2n-6) was mainly in the *sn*-2 position, whereas palmitic acid (16:0) was preferentially located in the *sn*-1/3 positions. FA of 18:1 did not show a clear preference between the primary and secondary positions.

Comparing the three subspecies (Table 2), the proportion of 1(3)-palmitoyl-2-oleoyl/vaccenoyl-3(1)-linoleoyl-*sn*-glycerols (*sn*-16:0-18:1-18:2 + *sn*-18:2-18:1-16:0) in the 52:3 group was higher in ssp. *mongolica* than in ssp. *rhamnoides* (48.9% vs. 30.1%, $P < 0.05$). This difference was accompanied by a higher proportion of TAG with 18:2 in the *sn*-2 position (*sn*-16:0-18:2-18:1 + *sn*-18:1-18:2-16:0) in ssp. *rhamnoides* compared with ssp. *mongolica* (64.4% vs. 39.6%, $P < 0.05$) and *sinensis* (64.4% vs. 56.5%, $P = 0.05$). In addition, differences among the subspecies were also recognized in some minor regioisomers. The proportion of 1(3)-palmitoyl-2-stearyl-3(1)-linolenoyl-*sn*-glycerols (*sn*-16:0-18:0-18:3 + *sn*-18:3-18:0-16:0) was higher in ssp. *mongolica* compared with ssp. *rhamnoides* (2.6% vs. 0.2%, $P < 0.01$) and *sinensis* (2.6% vs. 0.9%, $P < 0.05$); the proportion of 1(3)-palmitoleoyl-2-oleoyl/vaccenoyl-3(1)-oleoyl/vaccenoyl-*sn*-glycerols (*sn*-16:1-18:1-18:1 + *sn*-18:1-18:1-16:1) was highest in ssp. *sinensis* (1.8% vs 0.2% and 0.3%, $P < 0.05$).

ACN:DB 52:4. Two major FA combinations, 16:0/18:3/18:1 and 16:0/18:2/18:2, together accounted for 96–97% of 52:4 TAG.

Within the combination 16:0/18:3/18:1, 18:1 FA and α-linolenic acid ($P = 0.07$) were preferentially located in the secondary position, whereas palmitic acid was mainly found in the primary positions, differing significantly from random distribution. In the FA combination 16:0/18:2/18:2, 1(3)-palmitoyl-2-linoleoyl-3(1)-linoleoyl-*sn*-glycerols (*sn*-16:0-18:2-18:2 + *sn*-18:2-18:2-16:0) accounted for 72%, 80%, and 87%, respectively, in the three subspecies, showing a clear dominance of linoleic acid in the *sn*-2 position.

Ssp. *rhamnoides* differed from ssp. *mongolica* by having higher proportions of 1(3)-palmitoyl-2-linolenoyl-3(1)-oleoyl/vaccenoyl-*sn*-glycerols (*sn*-16:0-18:3-18:1 + *sn*-18:1-18:3-16:0, 22.5% vs. 12.6%, $P < 0.05$) and 1-linoleoyl-2-palmitoyl-3-linoleoyl-*sn*-glycerol (*sn*-18:2-16:0-18:2, 15.9% vs. 7.0%, $P < 0.05$) and a lower proportion of 1(3)-palmitoyl-2-oleoyl/vaccenoyl-3(1)-linolenoyl-*sn*-glycerols (*sn*-16:0-18:1-18:3 + *sn*-18:3-18:1-16:0, 16.0% vs. 28.3%, $P < 0.05$).

ACN:DB 52:5. The most abundant FA combination of the 52:5 group was 16:0/18:3/18:2, accounting for an average of 93% of 52:5 TAG of the samples analyzed (Table 2).

Ssp. *sinensis* had a higher proportion of the combination 16:1/18:2/18:2 (6.3% vs. 4.8%, $P < 0.05$) and a lower proportion of the combination 16:0/18:3/18:2 (92.5% vs. 94.5%, $P < 0.01$) than ssp. *mongolica*. The proportion of the combination 16:0/18:3/18:2 was also lower in ssp. *rhamnoides* compared with the value in ssp. *mongolica* (91.7% vs. 94.5%, $P < 0.05$).

Within the most abundant FA combination, 16:0/18:3/18:2, 18:2 was the preferred FA in the *sn*-2 position. The FA 16:0 and 18:3 were mainly located in the primary (*sn*-1/3) positions.

Within the FA combination 16:1/18:2/18:2, ssp. *sinensis* had a higher proportion of 1(3)-palmitoleoyl-2-linoleoyl-3(1)-linoleoyl-*sn*-glycerols (*sn*-16:1-18:2-18:2 + *sn*-18:2-18:2-16:1) than ssp. *mongolica* (5.6% vs. 3.2%, $P < 0.05$).

ACN:DB 54:5. The 54:5 TAG group consisted of three different FA combinations: 18:2/18:2/18:1, 18:3/18:1/18:1, and 18:3/18:2/18:0. Within each of the FA combinations, the distribution of the FA between primary and secondary positions did not differ significantly from random distribution (Table 2).

Ssp. *mongolica* had a lower proportion of the FA combination 18:2/18:2/18:1 compared with ssp. *sinensis* (55.5 % vs. 61.7% within 54:5, $P = 0.06$) and *rhamnoides* (55.5% vs. 65.0% within 54:5, $P < 0.001$). This was accompanied by a higher proportion of the FA combination 18:3/18:2/18:0 (18.3% in ssp. *mongolica* vs. 11.5% in *rhamnoides,* $P < 0.01$, and vs. 6.1% in ssp. *sinensis*, $P < 0.001$). The differences between ssp. *sinensis* and *rhamnoides* in the proportion of the FA combinations 18:3/18:2/18:0 (6.1% vs. 11.5%) and 18:3/18:1/18:1 (32.1% vs. 23.4%) were also statistically significant ($P < 0.05$).

Differences were also found among the subspecies in the proportion of 1(3)-linolenoyl-2-oleoyl/vaccenoyl-3(1)-oleoyl/vaccenoyl-*sn*-glycerols (*sn*-18:3-18:1-18:1 + *sn*-18:1-18:1-18:3; *sinensis* > *rhamnoides*, $P < 0.05$) and 1(3)-linoleoyl-2-linoleoyl-3(1)-oleoyl/vaccenoyl-*sn*-glycerols (*sn*-18:2-18:2-18:1 + *sn*-18:1-18:2-18:2; *rhamnoides* > *mongolica*, $P < 0.05$).

ACN:DB 54:6. The dominating FA combinations of this group were 18:3/18:2/18:1 and 18:2/18:2/18:2. In addition, 18:3/18:3/18:0 was present in trace amount in some of the samples analyzed (Table 2).

Within the FA combination 18:3/18:2/18:1, 18:1 clearly dominated in the *sn*-2 position, whereas 18:2 was mostly found in the primary positions. The FA 18:3 did not discriminate between the primary and secondary positions.

The proportion of TAG with the FA combination 18:3/18:3/18:0 was higher in ssp. *rhamnoides* than in ssp. *sinensis* (2.2% vs. 0.4%, $P < 0.05$). A difference was seen in the proportion of 1(3)-oleoyl/vaccenoyl-2-linoleoyl-3(1)-linolenoyl-*sn*-glycerols (*sn*-18:3-18:2-18:1 + *sn*-18:1-18:2-18:3) between ssp. *sinensis* and *mongolica* (11.5% vs. 1.1%, $P < 0.05$).

ACN:DB 54:7. ACN:DB 54:7 was the most abundant TAG group in the seed of ssp. *rhamnoides* (19.3% of seed TAG) and *mongolica* (20.8% of seed TAG). Of the two FA combinations in this TAG group, 18:3/18:2/18:2 dominated over

sn-18:3-18:2-18:3*	54.3 ± 10.8[a]	63.0 ± 6.7[b]	55.7 ± 9.4[a]
TAG with *sn*-2 18:1	22.5 ± 6.8	19.5 ± 1.0	20.1 ± 0.5
TAG with *sn*-2 18:2	34.6 ± 8.7	38.7 ± 4.3	36.8 ± 2.0
TAG with *sn*-2 18:3	17.3 ± 1.8[a]	21.2 ± 2.8[ab]	23.0 ± 1.9[b]

[a]Values in bold are molar percentage of total TAG; other values represent molar percentages within each acyl carbon number:double bond (ACN:DB) group. [b]*n* = number of natural growth sites (or varieties) × number of repeats (4); ssp. *sinensis*, three natural growth sites in Shanxi, Qinghai, and Gansu, China; ssp. *rhamnoides*, three natural growth sites in Vaasa and Pyhämaa, Finland; ssp. *mongolica*, three commercial varieties from Russia. [a–c]Means ± SD with different superscripts within a row differ significantly ($P < 0.05$). Asterisks indicate statistically significant difference from random system, $*P < 0.001$; $**P < 0.05$.

18:3/18:3/18:1 (69.4% vs. 30.6% of 54:7 TAG). In the former combination, linoleic acid was mainly found in the *sn*-2 position (Table 2). α-Linolenic acid, on the contrary, preferred the primary (*sn*-1/3) positions. This was shown as an overall ratio of 3.5:1 between the two types of regioisomers in the samples analyzed.

In the FA combination18:3/18:3/18:1, oleic/vaccenic acids were the preferred FA in the *sn*-2 position (Table 2).

When comparing the three subspecies, the only statistically significant difference found was a higher proportion of 1-linoleoyl-2-linolenoyl-3-linoleoyl-*sn*-glycerols in ssp. *sinensis* than in ssp. *mongolica* (18.0% vs. 10.9% of 54:7, $P < 0.05$).

ACN:DB 54:8. In the seeds of ssp. *sinensis,* ACN:DB 54:8 species (8.3% of seed TAG) accounted for less than half of that of ssp. *mongolica* (17.0%). The proportion in ssp. *rhamnoides* (12.5 % of seed TAG) fell between the other two subspecies. The only FA combination in this group was 18:3/18:3/18:2. Linoleic acid was preferred in the *sn*-2 position (Table 2).

Ssp. *rhamnoides* differed from the other two subspecies in its higher proportion of *sn*-18:3-18:2-18:3 ($P < 0.05$) and its lower proportion of 1(3)-linoleoyl-2-linolenoyl-3(1)-linolenoyl-*sn*-glycerols (*sn*-18:2-18:3-18:3 + *sn*-18:3-18:3-18:2, $P < 0.05$).

Molecular weight distribution of TAG of whole berries. Figure 2 presents the molecular weight distribution of the TAG of whole berries (A) and fruit pulp/peel (B) of different subspecies. The major ACN of TAG from the whole berries were 48, 50, 52, and 54. Ssp. *sinensis* and *rhamnoides* showed similar patterns of molecular weight distribution of TAG, which clearly differed from that of ssp. *mongolica*. Overall, ssp. *mongolica* had a higher proportion of TAG with 48 acyl carbons (47.6% in ssp. *mongolica* vs 22.1% in ssp. *sinensis* and 23.3% in ssp. *rhamnoides*), whereas ssp. *sinensis* and *rhamnoides* were more abundant in TAG with ACN 52 (21.6% and 22.4% vs. 10.2%) and 54 (20.1% and 17.4% vs. 5.8%). Statistically significant differences among the subspecies were found in the proportions of most of the molecular weight species detected (Fig. 2A).

Comparing the molecular weight distribution of TAG from whole berries (Fig. 2A) and fruit flesh/peel (Fig. 2B), it is clear that the TAG of 54 acyl carbons were mostly from the seeds. Seed content is known to be lower in berries of ssp. *mongolica* than in berries of ssp. *sinensis* and *rhamnoides* (2,17). Thus, the difference observed in the molecular weight distribution of TAG among the subspecies was partially due to the different seed content in the berries. In addition, the differences in molecular weight species also reflected variations in overall FA composition of TAG (2,8,17) as well as FA combination in TAG molecules among the subspecies.

The major ACN:DB species of TAG of the whole berries (i.e., mainly of fruit flesh and peel) were 48:1, 48:2, 50:2, and 50:3, followed by 52:2, 52:3, and 52:4. TAG of ACN:DB species 48:1, 48:2, 50:2, and 50:3 constituted together up to 46%, 49%, and 71% of berry TAG of ssp. *sinensis*, *rhamnoides*, and *mongolica,* respectively.

Positional distribution of FA in berry TAG. Positional distributions of FA of the four most abundant ACN:DB species (48:1, 48:2, 50:2, and 50:3) were analyzed in berry TAG because these were the most important molecular weight species of TAG from the fruit pulp/peel. The results are summarized in Table 3.

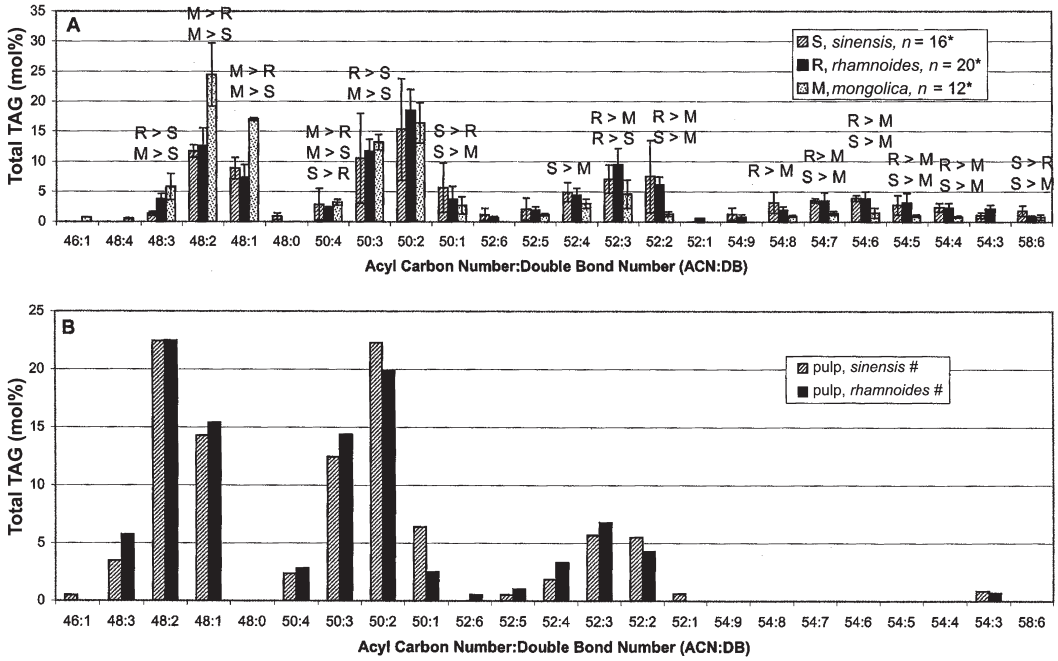

FIG 2. Molecular weight species of TAG of (A) whole berries of three subspecies and (B) fruit flesh/peel of two subspecies of sea buckthorn (mol%). Differences among the subspecies are indicated only when the difference reached a statistically significant level ($P < 0.05$). *for whole berries, n = number of natural growth sites (or varieties) × number of repeats (4); ssp. *sinensis,* four natural growth sites in Shanxi, Shaanxi, Qinghai, and Gansu, China; ssp. *rhamnoides,* five natural growth sites in Hirsilahti, Siikajoki, Vaasa, and Pyhämaa, Finland; ssp. *mongolica,* three commercial varieties from Russia. #ssp. *sinensis,* average of four analyses of one sample from a natural growth site in Shanxi, China; ssp. *rhamnoides,* average of four analyses of one sample from a natural growth site in Pyhämaa, Finland.

ACN:DB 48:1. This group consisted of TAG of only one FA combination, 16:1/16:0/16:0 (Table 3). The dominating regioisomer was 1-palmitoyl-2-palmitoleoyl-3-palmitoyl-*sn*-glycerol (*sn*-16:0-16:1-16:0), representing 82–87% of TAG of ACN:DB 48:1 in the three subspecies. Palmitoleic acid (16:1n-7) was the preferred FA in the *sn*-2 position, whereas 16:0 was favored in the *sn*-1/3 positions.

ACN:DB 48:2. This group consisted of only TAG with the FA combination 16:1/16:1/16:0. Molecular species with palmitoleic acid in the *sn*-2 position (*sn*-16:1-16:1-16:0 + *sn*-16:0-16:1-16:1) were by far the major regioisomers of this group (Table 3). The minor molecular species with palmitic acid in the *sn*-2 position represented less than 10% of the TAG of this ACN:DB group.

Compared with ssp. *sinensis*, ssp. *mongolica* had a higher proportion of regioisomers with 16:1 in the *sn*-2 position (98.4% vs. 86.1%, $P < 0.05$) and a lower proportion of regioisomers with 16:0 in the *sn*-2 position (1.6% vs. 13.9%, $P < 0.05$). The corresponding values of ssp. *rhamnoides* fell between the other two subspecies, almost statistically different ($P = 0.07$) from those of ssp. *mongolica*.

ACN:DB 50:2. Two major FA combinations, 16:1/16:0/18:1 (92.8%, 92.6%, and 63.6% of 50:2, respectively, in the three subspecies) and 16:0/16:0/18:2 (6.3%, 6.5%, and 34.6% of 50:2, respectively, in the three subspecies), were identified in this ACN:DB group. In addition, traces of TAG with the FA combination 16:1/16:1/18:0 were present (about 1% of 50:2 on average).

Of the three subspecies, ssp. *mongolica* had the lowest proportion of TAG of the FA combination 16:1/16:0/18:1 (92.8% and 92.6% in ssp. *sinensis* and *rhamnoides*, respectively, vs. 63.6% in ssp. *mongolica*, $P < 0.001$) and the highest proportion of the combination 16:0/16:0/18:2 (34.6% in ssp. *mongolica* vs. 6.3% in ssp. *sinensis* and 6.5% in ssp. *rhamnoides*, $P < 0.001$) within the group 50:2. The proportion of 1(3)-palmitoyl-2-palmitoleoyl-3(1)-oleoyl/vaccenoyl-*sn*-glycerols (*sn*-16:0-16:1-18:1 + *sn*-18:1-16:1-16:0) was highest in ssp. *rhamnoides* (46.0% vs. 22.5% in *sinensis,* $P < 0.01$; 46.0% vs. 31.1% in ssp. *mongolica*, $P = 0.05$). The highest proportion of 1(3)-palmitoleoyl-2-oleoyl/vaccenoyl-3(1)-palmitoyl-*sn*-glycerols (*sn*-16:1-18:1-16:0 + *sn*-16:0-18:1-16:1) was found in ssp. *sinensis* (62.2% vs. 41.7%, $P < 0.05$ compared with ssp. *rhamnoides*; 62.2% vs. 25.0%, $P < 0.001$ compared with ssp. *mongolica*).

Being more abundant in TAG with the FA combination 16:0/16:0/18:2, ssp. *mongolica* contained higher proportions of both types of regioisomers within this combination, compared with the other two subspecies ($P < 0.001$) (Table 3).

ACN:DB 50:3. This group consisted of TAG of two FA combinations, 16:1/16:1/18:1 and 16:1/16:0/18:2. Within the combination 16:1/16:0/18:2, linoleic acid was favored in the *sn*-2 position, whereas palmitic acid was mainly located in the *sn*-1/3 po-

[a]Values in bold are molar percentage of total TAG; other values represent molar percentages within each ACN:DB group. [b]*n* = number of natural growth sites (or varieties) × number of repeats (4); ssp. *sinensis*, three natural growth sites in Shanxi, Qinghai, and Gansu, China; ssp. *rhamnoides*, three natural growth sites in Vaasa and Pyhämaa, Finland; ssp. *mongolica*, three commercial varieties from Russia. [a–c]Means ± SD with different superscripts within a row differ significantly ($P < 0.05$) *Asterisk indicates statistically significant difference from random system, $P < 0.001$.

sitions ($P < 0.001$ compared with random distribution). Palmitoleic acid did not show a clear discrimination between primary and secondary positions. This was shown as a higher average proportion of 1(3)-palmitoleoyl-2-linoleoyl-3(1)-palmitoyl-*sn*-glycerols (*sn*-16:1-18:2-16:0 + *sn*-16:0-18:2-16:1, 27.0% of 50:3) and 1(3)-palmitoyl-2-palmitoleoyl-3(1)-linoleoyl-*sn*-glycerols (*sn*-16:0-16:1-18:2 + *sn*-18:2-16:1-16:0, 20.1% of 50:3) than of 1(3)-palmitoleoyl-2-palmitoyl-3(1)-linoleoyl-*sn*-glycerols (*sn*-16:1-16:0-18:2 + *sn*-18:2-16:0-16:1, 5.8% of 50:3) ($P < 0.001$). It is worth noticing the high deviation in the analysis results for this group.

Among the three subspecies, ssp. *mongolica* had the lowest proportion of TAG of the FA combination 16:1/16:1/18:1 (25.0% vs. 60.9% in ssp. *sinensis* and 55.5% in ssp. *rhamnoides*, $P < 0.001$) and the highest proportion of those with the FA combination 16:1/16:0/18:2 (75.0% vs. 39.1% and 44.5% in ssp. *sinensis* and *rhamnoides*, respectively, $P < 0.001$) (Table 3). Concerning the regioisomers, ssp. *mongolica* was richer in 1(3)-palmitoyl-2-palmitoleoyl-3(1)-linoleoyl-*sn*-glycerols (*sn*-16:0-16:1-18:2 + *sn*-18:2-16:1-16:0, 33.1% vs. 9.9%, $P < 0.01$) and poorer in 1(3)-palmitoleoyl-2-palmitoleoyl-3(1)-oleoyl/vaccenoyl-*sn*-glycerols (*sn*-16:1-16:1-18:1 + *sn*-18:1-16:1-16:1, 18.5% vs. 39.2%, $P < 0.01$) compared with ssp. *rhamnoides*. Differences were also found between ssp. *mongolica* and *sinensis*, the latter being richer in *sn*-16:1-18:1-16:1 (6.5% vs. 29.6%, $P < 0.05$).

TAG with sn-2 unsaturated FA. On average TAG with linoleic acid in the *sn*-2 position represented about 37%, and those with *sn*-2 oleic/vaccenic acid and α-linolenic acid about 21% each, of the molecular weight species of seed TAG analyzed (Table 2). The proportion of TAG with α-linolenic acid in the *sn*-2 position was higher in seed TAG of ssp. *mongolica* than in those of ssp. *sinensis* (23.0% vs. 17.3%, $P < 0.05$).

The TAG with palmitoleic (50.8% vs. 24.5% in ssp. *sinensis* and 31.6% in ssp. *rhamnoides*, $P < 0.01$ among three subspecies) and linoleic (9.5% vs. 2.2% in ssp. *sinensis* and 3.8%

in ssp. *rhamnoides*, $P < 0.001$) acids in the *sn*-2 position represented a higher proportion of berry TAG of ssp. *mongolica* compared with the other two subspecies. The situation was reversed in the case of TAG with oleic/vaccenic acid in the *sn*-2 position (5.0% in ssp. *mongolica* vs. 13.2% in ssp. *sinensis* and 9.5% in ssp. *rhamnoides*, $P < 0.01$) (Table 3).

DISCUSSION

The research group in our department has earlier reported the molecular weight distribution and FA combinations of supercritical CO_2-extracted seed oil and pulp oil of sea buckthorn (18), as well as molecular weight species of seed oil of wild sea buckthorn in Finland (19). The former was a qualitative analysis by capillary supercritical fluid chromatography-atmospheric pressure chemical ionization mass spectrometry, and the latter a quantitative analysis using chemical ionization mass spectrometry. The reported results were in agreement with the findings of the present study.

Using an enzymatic method, Ozerinina *et al.* investigated the TAG of seeds of three different cultivars of *H. rhamnoides* ssp. *mongolica*, Dar Katuni, Maslichnaya, and Shcherbinka-1 (20) and the mesocarp of four different origins (21). The FA of the primary and secondary positions were differentiated. TAG with linoleic acid in the *sn*-2 position represented 46–49% of the total seed TAG, whereas those with linolenic and oleic/vaccenic acids in the *sn*-2 positions represented 28–33% and 11–16%, respectively. In the mesocarp of Siberian, Central Asian, and Baltic berries, the major TAG species were of ACN:DB 48:1, 48:2, and 48:3 with 16:1 in the *sn*-2 position, whereas 50:1 and 50:2 with 18:1 in the *sn*-2 position dominated in the mesocarp of Caucasian berries. Caucasian berries also differed from berries from the other three sources in their lower proportion of TAG with palmitoleic acid in the *sn*-2 position. The authors suggested that sea buckthorn from the four sources could be divided into two different groups according to the different mechanisms of TAG biosynthesis in berry mesocarp. The botanical status of the berries was not defined. According to the geographical distribution of natural populations of sea buckthorn, the Siberian, Central Asian, Baltic, and Caucasian berries belong to ssp. *mongolica*, *turkestanica*, *rhamnoides*, and *caucasica*, respectively.

Vereshchagin *et al.* (22) also reported the existence of two different systems of TAG synthesis in sea buckthorn fruit mesocarp. Berezhnaya *et al.* (23) studied changes in TAG composition in the mesocarp of developing sea buckthorn fruit.

In the present study, the molecular weight distributions of TAG in the seeds and the berries of ssp. *sinensis*, *rhamnoides*, and *mongolica* and the fruit pulp/peel of ssp. *sinensis* and *rhamnoides* were analyzed by MS and MS/MS. As shown in many applications during the past years (10–14,16,18,24–27), regardless of the relatively high deviations, the MS and MS/MS procedures applied in this study, combined with the automatic calculation program, represent a fast method for the determination of regioisomers of TAG.

TAG of ACN 54 comprised 70–80% of seed TAG (including species not listed in Table 2). The rest (20–30%) were TAG of ACN 52 (C18/C18/C16). In the whole berries, the profile of TAG molecular weight species were more diversified, because they contain TAG from both the fruit flesh/peel and seeds. TAG of ACN 48 and 50 were the major species found in the fruit pulp and peel of sea buckthorn.

Clear differences were found among the subspecies in molecular weight distribution, FA combinations, and regioisomers of TAG in both seeds and berries. This is the first time that TAG of both seeds and berries of different species of sea buckthorn have been studied and compared.

In seed TAG, palmitic acid was mainly found in the ACN 52 group. Most of the palmitic acid of the ACN:DB species 52:3, 52:4, and 52:5 of seed TAG was located in *sn*-1/3 positions regardless of the FA combinations. This is in accordance with the common knowledge of the positional distribution of FA in natural TAG of vegetable origin (28).

The two most abundant TAG regioisomers in the seeds of the three subspecies were 1(3)-linolenoyl-2-linoleoyl-3(1)-linoleoyl-*sn*-glycerols and 1(3)-linolenoyl-2-oleoyl/vaccenoyl-3(1)-linoleoyl-*sn*-glycerols. In the former species, linoleic acid, and in the latter oleic/vaccinic acid, preferentially occupied the *sn*-2 position. In the combination 18:3/18:3/18:1, 1,3-dilinolenoyl-2-oleoyl/vaccenoyl-*sn*-glycerol was the preferred regioisomer . It is generally known that linoleic acid is preferentially located in the *sn*-2 position, whereas oleic and α-linolenic acids are equally distributed in *sn*-1, -2, and -3 positions in TAG of plant origin (28). The results of the present study suggest that the positional distribution of unsaturated FA depends on the FA combination as far as specific TAG molecules are concerned.

This can be further demonstrated by comparing the positional distribution of 18:1 in TAG of ACN:DB 54:6 and 54:5. In the former group, in which the major FA combination was 18:3/18:2/18:1, 18:1 was mostly located in the *sn*-2 position of glycerol. In contrast, in the ACN:DB 54:5 group, in which the major FA combinations were 18:2/18:2/18:1 and 18:3/18:1/18:1, oleic acid did not preferentially occupy the secondary position of glycerol.

It is generally accepted that both the FA composition and the positional distribution of FA in TAG molecules play a role in the nutritional properties and physiological effect of oils and fats (6,7). FA located in the primary and secondary positions of TAG have different metabolism fates after ingestion. FA in the *sn*-2 position remain as a part of monoacylglycerols directly absorbed by the intestine, whereas those in *sn*-1/3 positions are released before absorption. The *sn*-2 FA of ingested fats and oils were largely found to be in the *sn*-2 position of chylomicron TAG. Saturated FA in *sn*-1/3 positions are inferiorly absorbed compared with those in the *sn*-2 position due to the *sn*-1/3 specific actions of digestive lipase and the formation of insoluble salts in the gut (6,7). Although TAG with *sn*-2 palmitic acid are recommended fat species for infant formula, some saturated FA in the *sn*-2 position of TAG may enhance the fat absorption and unfavorably influence

postprandial lipid metabolism in adults (29). Dietary *sn*-2 long chain polyunsaturated FA may be absorbed with high efficiency compared with those in *sn*-1/3 positions (30).

Linoleic and α-linolenic acids are essential FA in the human diet. Oleic acid is a major FA of the Mediterranean diet, and is generally considered beneficial to humans. Studies carried out *in vivo* and *in vitro* have indicated that palmitoleic acid may play an important role in human health. Information on the positional distribution of these FA in TAG of sea buckthorn provides important guidelines for applications of sea buckthorn oils. Linoleic, α-linolenic, and oleic acids together accounted for around 86% of the total FA of sea buckthorn seed oil. TAG with these FA in the *sn*-2 position constituted 75–81% of the ACN:DB species analyzed, indicating the favorable position of the oil as a dietary source of beneficial FA. Seed TAG of ssp. *mongolica* contained a higher proportion of regioisomers with α-linolenic acid in the *sn*-2 position than those of ssp. *sinensis*. In the major ACN:DB species of berry TAG analyzed, ssp. *mongolica* was the richest in regioisomers with palmitoleic and linoleic acids in the *sn*-2 position and the poorest in those with *sn*-2 oleic/vaccenic acid among the three subspecies. These differences should be considered when raw materials are selected for sea buckthorn oil for specific nutritional needs.

Industries producing food and health-related products using sea buckthorn oils often face great challenges in raw material selection due to the extremely high variation in composition of sea buckthorn oils from different sources. Often, authentication is difficult. Analysis of TAG with the fast MS and MS/MS methods described in the present study could offer a solution to this problem for the future.

ACKNOWLEDGMENTS

The authors would like to express their sincere thanks to Mr. Jukka-Pekka Suomela, Dr. Juha-Pekka Kurvinen, and Ms. Marjukka Sillanpää for their help during the MS analysis and the data handling process.

NMR Characterization of Dihydrosterculic Acid and Its Methyl Ester

Gerhard Knothe*

National Center for Agricultural Utilization Research, Agricultural Research Service, U.S. Department of Agriculture, Peoria, IL 61604

ABSTRACT: Cyclopropane FA occur in nature in the phospholipids of bacterial membranes, in oils containing cyclopropene FA, and in *Litchi sinensis* oil. Dihydrosterculic acid (2-octyl cyclopropaneoctanoic acid) and its methyl ester were selected for ^{1}H and ^{13}C NMR analysis as compounds representative of cyclopropane FA. The 500 MHz ^{1}H NMR spectra acquired with $CDCl_3$ as solvent show two individual peaks at –0.30 and 0.60 ppm for the methylene protons of the cyclopropane ring. Assignments were made with the aid of 2D correlations. In accordance with previous literature, the upfield signal is assigned to the *cis* proton and the downfield signal to the *trans* proton. This signal of the *trans* proton is resolved from the peak of the two methine protons of the cyclopropane ring, which is located at 0.68 ppm. The four protons attached to the two methylene carbons α to the cyclopropane ring also show a split signal. Two of these protons, one from each methylene moiety, display a distinct shift at 1.17 ppm, and the signal of the other two protons is observed at 1.40 ppm, within the broad methylene peak. The characteristic peaks in the ^{13}C spectra are also assigned.

Paper no. L9832 in *Lipids 41*, 393–396 (April 2006).

FA containing a cyclopropane structure (Fig. 1; shown as methyl esters), the most common of which contain 17 and 19 carbons, occur in seed oils such as Sterculiaceae, Malvalaceae, Bombaceae, and Tiliaceae that contain cyclopropene FA, and also frequently in bacterial cell membranes (1). Among these compounds are dihydrosterculic acid (x = 7, y =7 in Fig. 1; systematic name 2-octyl cyclopropaneoctanoic acid; sterculic acid is the corresponding cyclopropene FA), lactobacillic acid (x = 9, y = 5 in Fig. 1), and dihydromalvalic acid (x = 6, y = 7). Dihydrosterculic acid has also been reported in significant amounts (41%) in *Litchi sinensis* (lychee) seed oil (2), and its isolation and absolute configuration have been reported (3).

Numerous authors (3–12) have reported not only on the synthesis of cyclopropane FA but also analytical data for these compounds, with the signals of the methylene protons in the ^{1}H NMR spectra being assigned early, including distinguishing the *cis* and *trans* protons (4,5). Selected ^{1}H NMR data contained in the literature are compiled in Table 1. The ^{1}H NMR analytical data for the salient signals do not always agree, and in some cases assignments are incomplete. Although the ^{13}C NMR signals of cyclopropenoid FA have been assigned (13,14), those of cyclopropane FA were reported but no assignments made. Therefore, in light of the significant interest in long-chain compounds containing cyclopropane moieties, commercially available dihydrosterculic acid and its methyl ester were selected for NMR analysis as representatives of the class of cyclopropane FA. Full ^{1}H and ^{13}C NMR data are reported along with assignments of key peaks.

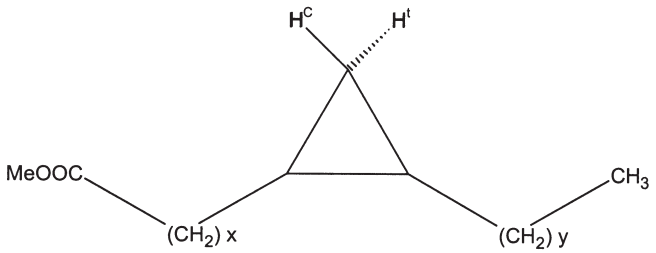

FIG 1. General structure of *cis*-cyclopropane FAME. The protons of the methylene unit in the cyclopropane are identified as *cis* and *trans* by the labels H^c and H^t, respectively.

EXPERIMENTAL PROCEDURES

Methyl dihydrosterculate and dihydrosterculic acid (synthetic material) were purchased from Matreya LLC (Pleasant Gap, PA). NMR spectra were acquired with $CDCl_3$ as solvent (approximately 40 mg sample dissolved in about 1 mL solvent) on a Bruker (Billerica, MA) Avance 500 spectrometer operating at 500 MHz (^{1}H) or 125 MHz (^{13}C). All chemical shifts are reported relative to the chloroform peak (7.29 ppm for ^{1}H NMR). Besides NMR, GC-MS analyses were carried out, using an Agilent Technologies (Wilmington, DE) 6890 GC with HP-5MS capillary column coupled to a 5973 mass selective detector, showing about 99% purity of the sample. The GC-MS results coincided well with the spectrum found by a library search (Wiley library) and literature data (3).

RESULTS AND DISCUSSION

Figure 2 depicts the ^{1}H NMR spectrum of methyl dihydrosterculate in the region of –0.5 to 2.5 ppm. The spectrum of the corresponding acid is virtually identical in this region. Expansions of the peaks at –0.30 and 0.60 ppm and the coupling constants for these signals are also shown in Figure 2.

Table 2 lists the peaks in both the ^{1}H and ^{13}C NMR spectra as well as their assignments.

In previous literature, the ^{1}H NMR spectra of cyclopropane FA or FAME have been shown to exhibit several upfield signals assignable to the cyclopropane moiety (4,5). Corresponding data are compiled in Table 1. The data show that compounds with the cyclopropane ring in *cis* configuration show different shifts than those with *trans* configuration. An earlier study using molecular models and resulting interpretation showed that *trans* cyclopropane compounds do not show the upfield peak at about –0.3 to –0.35 ppm, because in this case the methylene protons in the cyclopropane ring would be equivalent (4). The same study (4) also details earlier disagreeing assignments of the protons in the cyclopropane moiety. The downfield peak at –0.3 to –0.35 ppm can be assigned to the *cis* proton of the methylene moiety in the cyclopropane ring. The majority of data for the *cis* compounds imply that a second peak at about 0.55–0.60 ppm exists, assignable to the *trans* proton of the cyclopropane methylene unit, which agrees with earlier literature (4,5). For the *trans* compounds, two data entries given in Table 1 agree on a peak at 0.11–0.12 ppm and a peak at 0.33–0.35 ppm, although the patterns differ.

However, some data show an overlap with a peak slightly downfield (0.60–0.70 ppm) caused by two protons. Also, the data do not give the same patterns of the various peaks. Furthermore, the methylene protons in the FA chain were usually reported to be contained in the usual broad methylene peak at 1.1–1.5 ppm, with the exception of a separate peak around 1.60–1.70 ppm caused by two protons (assigned to C3 in the chain, relative to the carboxyl moiety [7]). In one case (11), however, an unassigned separate multiplet at 1.11 ppm caused by two protons was reported.

To clarify this matter, in the present work, the ^{1}H (500 MHz) and ^{13}C spectra of dihydrosterculic acid and its methyl ester (Fig. 2) as well as 2D homo- and heteronuclear correlations were acquired with $CDCl_3$ as solvent. Peaks at –0.30 ppm, 0.60 ppm, and 0.68 ppm were observed, agreeing with some literature data (3,8,12), and correlated with ^{13}C NMR shifts at 10.93 for the methylene moiety of the cyclopropane ring as well as 15.75 and 15.78–15.79 for the methine car-

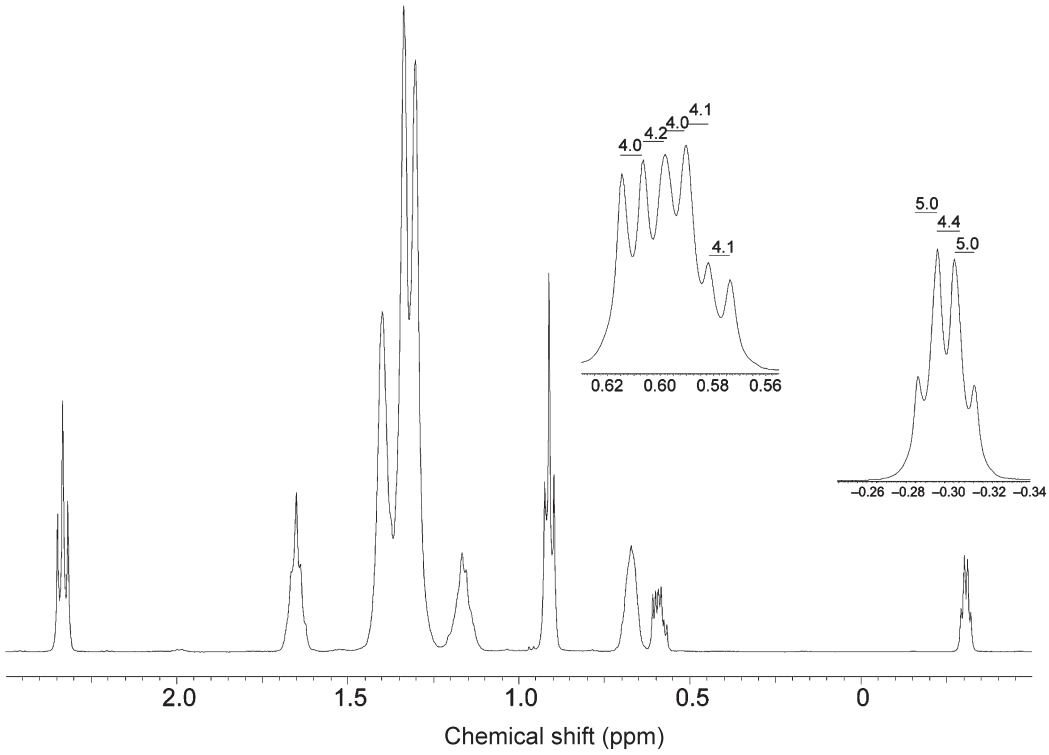

FIG 2. ^{1}H NMR spectrum of methyl dihydrosterculate (500 MHz, $CDCl_3$) in the region –0.5 to 2.5 ppm. The peaks at around 0.60 ppm and –0.30 ppm are expanded, and the coupling constants (Hz) are inscribed in these expansions.

bons. In other reports (3,7,11–12), the two peaks observed in the present work at 0.60 and 0.68 ppm apparently were not resolved. In the present work, 2D homonuclear correlation showed that the peaks at –0.30 and 0.60 ppm are assigned to the two C3 protons of the cyclopropane ring—*cis* and *trans*, respectively—and that the two methine protons resonate slightly downfield at 0.68 ppm.

The methylene peaks at 1.65 ppm and 1.17 ppm need to be investigated also. In agreement with most data in Table 1, the peak at 1.65 ppm is caused by only two protons. Two-dimensional homonuclear correlation shows clear correlation with the triplet caused by the protons attached to C2, indicating that this signal is assigned to the C3 methylene protons. On the other hand, the peak at 1.17 ppm, which was not resolved or listed separately in the previous literature, with one exception (11), correlates with the signal of the methine protons at

TABLE 2

1.25–1.45 (22H; br)[b]	22.71	22.70	CH_2 α to terminal CH_3 (-$\underline{CH_2}$-CH_3; ω-2)
1.65 (2H)	24.70	24.98	MeOOC-CH_2-$\underline{CH_2}$ or HOOC-CH_2-$\underline{CH_2}$
1.17 (2H; br), 1.40	28.68, 28.74	28.68, 28.73	CH_2 α to cyclopropane ring
1.25–1.45 (22H; br)[b]	29.09	29.18	CH_2 at C4 (MeOOC-CH_2-CH_2-$\underline{CH_2}$-)
	29.30, 29.37, 29.43	29.31, 29.37, 29.45	CH_2
	29.70	29.69	CH_2; 2 carbons
	30.13, 30.23	30.13, 30.22	CH_2
	31.94	31.94	-$\underline{CH_2}$-CH_2-CH_3 (ω-3)
2.33 (t, 2H)	34.06	34.13	HOOC-$\underline{CH_2}$- or MeOOC-$\underline{CH_2}$-
3.70 (s, 3H; ester only)	—	51.40	COO$\underline{CH_3}$
—		174.31	$\underline{C}$OOH or $\underline{C}$OOCH$_3$

[a]All spectra were obtained in $CDCl_3$ at 500 MHz (^{1}H NMR). For abbreviations see Table 1.
[b]This integration value contains two protons (resonating at 1.40 ppm) attached to the carbons α to the cyclopropane ring; see signal at 1.17 ppm. Also, the range 1.25–1.45 ppm appears twice to reflect the different signals in ^{13}C NMR correlating with this signal range.

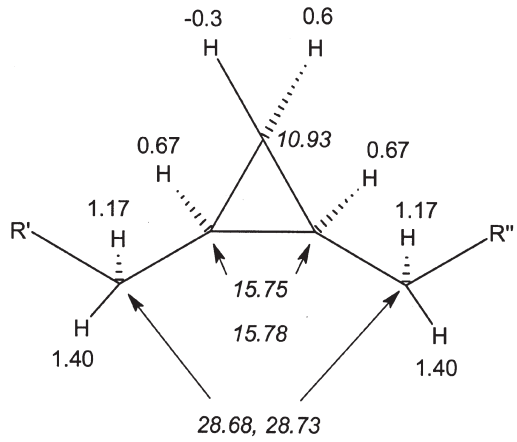

FIG 3. Assignments of chemical shifts (ppm; ^{13}C shifts are italicized) to the cyclopropane moiety in methyl dihydrosterculate. $R = -(CH_2)_6-COOMe$ and $R = -(CH_2)_6-CH_3$.

0.68 ppm and is therefore assigned to methylene protons · to the cyclopropane ring. However, the peak at 1.17 ppm is caused by two protons. In heteronuclear correlation, it correlates with ^{13}C NMR signals at 28.68 and 28.73 ppm. These two ^{13}C NMR peaks also correlate with the downfield region at 1.40 ppm, the broad methylene peak. The implication is that, likely due to shielding effects of the cyclopropane ring and similar to the differing shifts of the methylene protons in the cyclopropane ring, one proton each of the two methylene units · to the cyclopropane ring (at C8 and C11 of the FA chain) is responsible for the peak at 1.17 ppm. The downfield correlation is caused by the two other protons of these methylenes. A similar observation was made for FA with terminal cyclopentene moieties in which the signals of the methylene protons in the chain and the cyclopentene ring α to the "junction" carbon were split (15).

Table 2 contains not only information on the ^1H spectra but also on the ^{13}C spectra. The ^{13}C NMR signals not discussed above are assigned by general correlation with known data (14). The numerous methylene signals in the ^{13}C NMR spectra were not assigned to individual carbon atoms. Additionally, the assignments relating to the cyclopropane ring are depicted in Figure 3.

ABSTRACT: Poikilothermic organisms accumulate highly unsaturated FA (HUFA) in their lipids at reduced temperatures to maintain cell membrane fluidity. In this study we investigated the effect of temperature on temporal trajectories of FA of fasting *Daphnia pulex* cultured on a HUFA-free diet. *Daphnia pulex* populations were maintained for 1 mon at 22 and 11°C and were fed the chlorophyte *Ankistrodesmus falcatus*. We observed conversion of C_{18} FA precursors to EPA (20:5n3) and arachidonic acid (ARA; 20:4n6) in *D. pulex*. We showed that long-term exposure to cold temperature causes a significant increase in EPA. HUFA such as ARA and EPA are highly conserved during starvation. Therefore, *D. pulex* has the biosynthetic capacity to adjust and to maintain the content of HUFA required to survive at low temperatures.

Paper no. L9889 in *Lipids 41,* 397–400 (April 2006).

Species in the genus *Daphnia* are eurythermal organisms with a wide geographical distribution (1) that exposes them to dramatic changes in temperature. *Daphnia pulex*, for example, can be cultivated at constant temperatures ranging between 2°C and 30°C (2). Many poikilothermic animals adapt to changing environmental temperatures by modifying the degree of unsaturation of their lipids (3,4). Highly unsaturated FA (HUFA) are defined as PUFA that have more than three double bonds and carbon chain lengths of C_{20} or longer (5). The high degree of unsaturation of HUFA imparts to them the property of low m.p. The accumulation of HUFA in the lipids of poikilothermic organisms at reduced temperatures can therefore be explained as an adaptation to maintain cell membrane fluidity and thus membrane function.

When *Daphnia* feed on diets containing HUFA, for example, EPA (20:5n3) or arachidonic acid (ARA; 20:4n6), their lipids become enriched with these FA (6,7). However, *Daphnia* appear unable to accumulate large amounts of docosahexaenoic acid (DHA; 22:6n3), which they readily convert to EPA (6,8). *Daphnia* can use α-linolenic acid (ALA; 18:3n3) and linoleic acid (LIN; 18:2n6) as precursors for the synthesis of EPA and ARA, respectively (6,9,10). However, *de novo* rates of FA synthesis in *Daphnia* have been shown to be less than 2% (11).

Short-term (48 h) exposure to cold temperatures (4–5°C) did not cause appreciable changes in HUFA levels of *D. pulex* (8) or *D. magna* (9). These observations indicate either that *Daphnia* exposed to cold temperatures must be highly dependent on dietary HUFA, or that enzymes involved in the HUFA synthesis need longer adaptation periods to reach full activity. We hypothesize that *D. pulex* has the biosynthetic capacity to adjust and maintain the HUFA content necessary to survive at low temperatures. Bychek *et al.* (12) recently showed that cultures of *D. magna* are able to tolerate brief (24 h) spells of fasting with very little change in lipid metabolism. Here we investigate the effect of temperature on temporal trajectories of FA of fasting *D. pulex* (hereafter referred to as *Daphnia*) grown exclusively on a HUFA-free diet.

MATERIAL AND METHODS

Culture conditions. The chlorophyte *Ankistrodesmus falcatus* (AF; strain UTCC63) was cultured in modified CHU-10 medium (13). Algae were cultured in semicontinuous chemostats at 22°C under both a General Electric Cool-White® 40-watt and a Phillips F40T12 40-watt Plant-and-Aquarium® fluorescent lamp with a combined emission of 220 μmol m^{-2} $s^{-1}$of photosynthetically active radiation. Specimens of *Daphnia pulex* (Carolina Biological Supply Company, Burlington, NC) were cultured in glass aquaria at 22°C (DA22) or 11°C (DA11) under a 12-h light–12-h dark cycle, and the *D. pulex* were fed *ad libitum* with AF that were concentrated by centrifugation before feeding. *Daphnia* were maintained under these constant conditions for 1 mon prior to their use in starvation experiments.

Starvation experiments. Tap water was preconditioned to remove chlorine and ammonia and was filtered through a 0.2-μm Sartorius membrane filter to remove most bacteria. *Daphnia* were separated from algae by pouring them onto a 350-μm mesh nylon sieve and by repeatedly rinsing them with filtered water to finish the cleaning process. Clean *Daphnia* were kept in filtered water for 24 h to provide a standard time for hind-gut clearance. *Daphnia* were counted and distributed equally among 500-mL flasks filled with 400 mL of filtered

Abbreviations: AF, *Ankistrodesmus falcatus*; ALA, α-linolenic acid; ARA, arachidonic acid; DA11, *Daphnia pulex* cultured at 11°C; DA22, *Daphnia pulex* cultured at 22°C; HUFA, highly unsaturated FA; LIN, linoleic acid; MUFA, monounsaturated FA; TFA, total FA content.

water to obtain homogenous groups. Nongravid mid-sized animals (subadults) were selected to avoid the release of neonates during the experiment (14). *Daphnia* that were pre-adapted to 11 and 22°C for 1 mon had a similar average dry weight on Day 0 of the starvation experiment (17.7 and 18.1 μg/animal, respectively). Twenty-one flasks were stocked with *Daphnia* that were pre-adapted to 11°C (75 animals/flask). Twenty-four flasks were stocked with animals that were pre-adapted to 22°C (100 animals/flask). *Daphnia* were starved at original culture temperatures under constant dim fluorescent lighting conditions. Each day, three flasks were chosen randomly, and live *Daphnia* were collected from them. All animals were counted to determine the survival rate. When the survival rate fell below 50%, the experiments were terminated to guarantee a sufficient tissue mass for FAME analysis. DA22 could be collected only from 12 flasks because the survival rate decreased abruptly to 16.4% on Day 4. The average survival rate for DA11 was 85.8% on Day 6. *Daphnia* were frozen (at −85°C) after removing as much water as possible so as to minimize bacterial contamination, then they were freeze-dried and weighed prior to FA analysis.

FAME analyses. FAME of algae and *Daphnia* were extracted by grinding freeze-dried tissues in 2:1 (vol/vol) chloroform/methanol (15). FA were transmethylated with boron trifluoride in methanol (14% w/w). FAME concentrations were quantified on a Hewlett-Packard 6890 gas chromatograph with the following configuration: splitless injection; column = Supelco SP-2560 100 m × 0.25 mm i.d. × 0.20 μm thick film; oven = 140°C (hold for 5 min), then to 240°C at 4°C min^{-1}, hold for 12 min; carrier gas = helium, 1.2 mL/min; detector = FID at 260°C; injector = 260°C; run time = 42 min/sample.

Statistical analysis. All results are presented as mean ± SE. Independent samples collected on Day0/1, Day2/3, and Day4/5 were grouped prior to one-way ANOVA. ANOVA was followed by a Tukey test when a significant ($P < 0.05$) difference was found. Percentage data were arcsine transformed (16).

RESULTS AND DISCUSSION

Effects of growth temperature on the FA composition of Daphnia that were fed Ankistrodesmus falcatus. The FA compositions of AF, DA11, and DA22 are presented in Table 1. The lipid content of AF was 26% of its dry weight. HUFA as ARA, EPA, or DHA could not be detected in lipids extracted from AF. However, with 44.3% ALA and 15.9% LIN, total FA content (TFA) of AF contained two important precursors required for the synthesis of HUFA. AF was therefore a suitable diet to investigate the biosynthetic capacity for HUFA in *Daphnia*. In contrast to their diet, *Daphnia* grown at 11 and 22°C contained HUFA (ARA and EPA). The content of EPA was clearly influenced by temperature, because a significantly higher level of EPA was found in DA11 (12.7%) compared with DA22 (3.1%). *Daphnia* are clearly able to increase the proportion of EPA in their lipids to maintain cell membrane fluidity at low temperatures. However, for optimal growth and reproduction, additional dietary EPA might be required (17,18).

[a]Results are means ± SE. Values within a row with a different superscripted letter are significantly different ($P < 0.05$). nd = not detected. DA22, *Daphnia pulex* cultured at 22°C; DA11, *D. pulex* cultured at 11°C; SAFA, saturated FA; MUFA, monounsaturated FA.

ARA is an important precursor for signaling molecules including prostaglandins, prostacyclins, and thromboxanes (5). In contrast to EPA, DA11 and DA22 contained similar levels of ARA (2–3%). Therefore, the biosynthesis of ARA is unaffected by the difference in temperature within this range. We suggest that EPA and ARA were produced by conversion of dietary LIN and ALA precursors, especially at the lower temperature. In nature, *Daphnia* might therefore play an important role in trophic upgrading (19) of FA, thereby improving the nutritional quality of algae for subsequent use by higher trophic levels (e.g., invertebrate predators and fish). We cannot exclude the possibility that ultratrace amounts of dietary HUFA or HUFA of bacterial origin (gut bacteria) were accumulated by *Daphnia*. However, it is unlikely that EPA, at levels greater than 10% of TFA, would be derived from bacteria, particularly as care was taken to remove bacteria from the water and to clear the gut of the *Daphnia*. DHA was not detected in these *D. pulex*, confirming the results of Bychek *et al.* (12) and Farkas *et al.* (9) on *D. magna*.

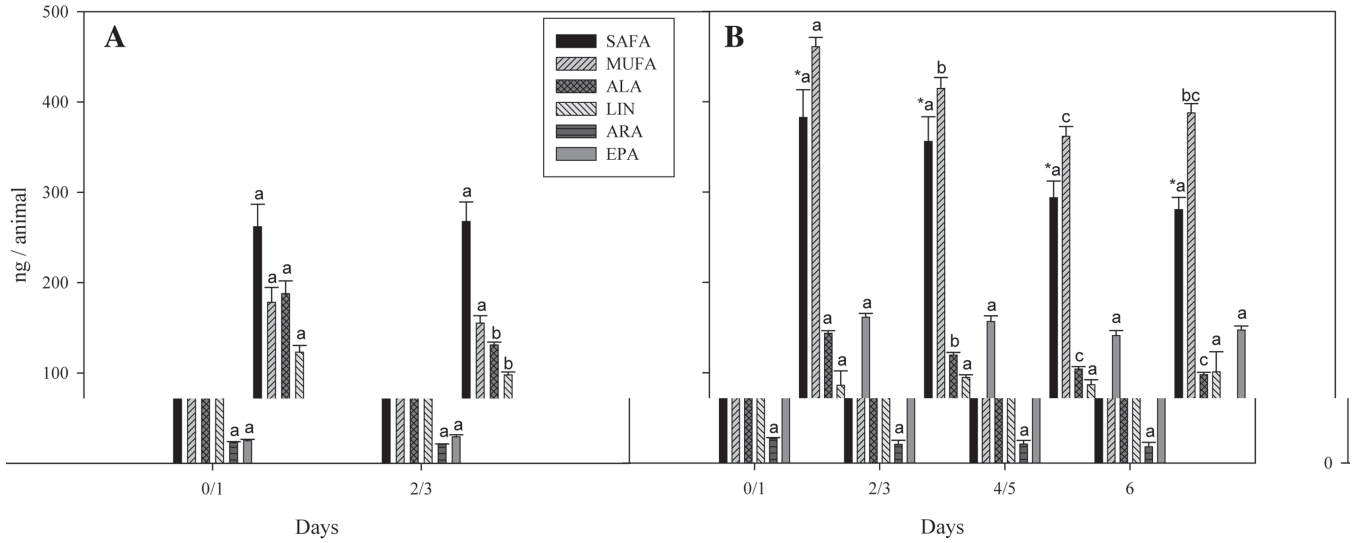

FIG. 1. Temporal trajectories of FA in fasting *Daphnia pulex* kept at (A) 22 and (B) 11°C. Results are means ± SE. Significant differences between means were determined by one-way ANOVA followed by Tukey's multiple comparison test. Values of the same FA with a different superscripted letter are significantly different ($P < 0.05$). An asterisk indicates that there was a statistically significant difference ($P = 0.031$), but the power of the performed test (0.56) was below the desired power of 0.80. ALA, α-linolenic acid; ARA, arachidonic acid; LIN, linoleic acid; MUFA, monounsaturated FA; SAFA, saturated FA.

DA11 had a significantly higher content of monounsaturated FA (MUFA), 36.3%, compared with DA22, which had 23.3%. The higher level of MUFA in DA11 might be explained by cold-induced expression of Δ9-desaturase as observed in carp (20), and can be described as a further adaptation to maintain cell membrane fluidity because MUFA have a significantly lower m.p. compared with their saturated analogs (21).

Effect of temperature on temporal trajectories of FA in fasting Daphnia. DA11 had a higher TFA on Day 0/1 (1272 ng/animal) compared with DA22 (821 ng/animal). The lower TFA in DA22 might be explained by the higher metabolic rate compared with DA11 ($Q_{10} = 2$; ref. 22). The term Q_{10} is defined as the increase in the rate of metabolic activity caused by a 10°C increase in temperature (23). If the rate doubles, Q_{10} is 2. TFA values decreased during starvation to 1061 and 779 ng/animal in DA11 and DA22, respectively. The insignificant decrease of TFA in DA22 during starvation suggests that only minor lipid reserves were available, which is confirmed by the high mortality of these animals within the first 3 d. ARA and EPA are important structural components of membrane glycerolipids, and were highly conserved during starvation in both DA11 and DA22 (Fig. 1). This agrees with Kainz *et al.* (24), who noted that EPA and ARA are highly retained in zooplankton. ALA decreased significantly in both treatments after being metabolized in order to resist starvation or after conversion to EPA. A significant decrease was also observed for LIN in DA22; however, no changes were observed in DA11.

In nature, periods of food shortage occur that can, temporarily, result in starvation conditions for zooplankton (25–27). Several effects of starvation on the biochemical composition of *Daphnia* have been described (14,28). However, we show, for the first time, trajectories of FA concentrations in starved animals under different temperature regimes. After further laboratory calibration, characteristic levels of selected FA in fasting *Daphnia* might be better defined, providing more quantitative assessments about the condition of field-derived *Daphnia* specimens.

FA can be used as trophic markers of dietary composition (29). However, our data indicate that such studies require detailed information about the effect of temperature on the extent of dietary FA conversion in different organisms.

Conclusions. We showed that long-term exposure of *D. pulex* to cold temperature causes a significant increase in EPA. HUFA, such as ARA and EPA, are highly conserved during starvation. Therefore, *D. pulex* has the biosynthetic capacity to adjust and to maintain the content of HUFA required to survive at low temperatures.

Effects of Storage Time and Added Antioxidant on Fatty Acid Composition of Red Blood Cells at –20°C

Anna R. Magnusardottir and Gudrun V. Skuladottir*

Department of Physiology, Faculty of Medicine, University of Iceland, IS-101 Reykjavik, Iceland

ABSTRACT: The stability of PUFA in venous red blood cells (RBC) of women aged 25 to 55 years (n = 12) was investigated during storage at –20°C. The RBC sample from each participant was divided into seven portions: one baseline with the antioxidant BHT, another without BHT, samples without BHT stored for 2, 4, 9, or 17 wk, and samples with BHT stored for 17 wk. No difference was found in proportions of PUFA at baseline and after storage for 2 and 4 wk without BHT, and 17 wk with BHT. After 9 wk without BHT the proportion of 22:6n-3 in RBC was lower, and after 17 wk without BHT proportions of all PUFA were lower than at baseline. High proportion of 22:6n-3 in RBC at baseline was associated with more stable concentration of total FA in RBC without BHT during 17 wk. The findings indicate that PUFA in RBC from healthy women are stable at –20°C for 4 wk without BHT and for at least 17 wk with BHT.

Paper no. L9878 in *Lipids 41,* 401–404 (April 2006).

Red blood cell (RBC) membrane lipids are a good indicator of dietary fat intake (1,2), as well as a biomarker of disease risk (3,4,5). RBC membrane is rich in PUFA, and a mature RBC is filled with hemoglobin containing iron, which might induce production of free radicals and lipid peroxidation of RBC membrane lipids (6).

Some centers for health service have access to only a –20°C or –30°C freezer, and human studies have shown that venous RBC stored at –20°C without addition of antioxidant had unchanged FA composition after 4 wk compared to baseline (7). Storage of RBC samples for more than 4 wk before FA analysis is often unavoidable, but lower proportion of long-chain PUFA has been found after 6 mon compared to baseline (8). The stability of PUFA in RBC may be affected by the physiological or pathological state of the individual. PUFA in RBC from healthy individuals were more stable during storage at –20°C than PUFA in RBC from patients with schizophrenia (9) and autism (10). Addition of the antioxidant BHT to RBC samples before freezing has been shown to preserve the PUFA composition for 1 yr at –50°C (7) and for 2 yr at –80°C (8) in healthy individuals.

The present study was undertaken to investigate at –20°C whether PUFA composition of RBC is stable for more than 4 wk without addition of antioxidant, and if addition of BHT preserves the PUFA content even longer.

MATERIALS AND METHODS

Subjects. Nonfasting venous blood samples from healthy women (n = 12) aged 25 to 55 yr were collected in tubes containing EDTA. RBC were isolated immediately by centrifuging whole blood at 1300 × g for 10 min at 4°C, and washed three times with isotonic saline solution. The RBC sample from each participant was divided into seven portions: one baseline sample with and another without addition of the antioxidant BHT, samples without BHT stored at –20°C for 2, 4, 9, or 17 wk, and one sample with BHT stored at –20°C for 17 wk. BHT dissolved in methanol (500 mg/L) was added to RBC sample at a final concentration of 42 mg/L. No methanol was added to the RBC samples without BHT. Baseline RBC samples with or without BHT were lipid-extracted within 3 h of collection, and FA were analyzed.

Analysis of RBC total lipid fatty acids. RBC total lipids were extracted as described by Bligh and Dyer (11) except isopropanol was used instead of methanol (isopropanol/chloroform 2:1, v/v). BHT (50 mg/L) was added to the extraction medium. The FA were transmethylated for 45 min at 110°C using 14% boron trifluoride/methanol (Sigma Chemical Co., St. Louis, MO). The FAME were analyzed using GC (Agilent 6890 N, Agilent, Palo Alto, CA) equipped with a Chrompack CP-SIL 8CB column (25 m × 250 μm i.d. × 0.12 μm film thickness). The oven temperature was programmed to have an initial temperature of 150°C for 4 min, then rising 4°C/min to 230°C, then 20°C/min to 280°C, and then held isothermal for 4 min. The injector and detector temperatures were maintained at 280°C and 300°C, respectively. Hydrogen was used as the carrier gas. The FAME peaks were identified and calibrated against those of commercial standards (Sigma Chemical Co.; Nu-Chek-Prep, Elysian, MN). PC diheptadecanoyl (17:0) and heneicosanoic acid (21:0) methyl ester were used as internal and external standards, respectively. The intra- and interassay CV for analytical variation (measurement error) were, respectively, 1.13% and 1.46% for 18:2n-6, 2.09% and 1.95% for 20:4n-6, 2.38% and 2.08% for 22:6n-3, 1.29% and 1.09% for 16:0, 1.78% and 0.85% for 18:0, and 0.91% and 0.92% for 18:1n-9.

Statistical analysis. The effect of storage time and added antioxidant, and interaction between storage time and added antioxidant, were evaluated with the ANOVA for repeated measures and Tukey–Kramer *post-hoc* test in the SAS program (Mixed procedure in SAS for Windows, V8). $P < 0.05$ was considered significant. Multiple linear regression was used to evaluate the association of age or proportion of indi-

[d]mg/L red blood cells (RBC). MUFA, monounsaturated FA; SFA, saturated FA.

vidual FA in RBC lipids at baseline with the change in concentration of total FA in RBC lipids after 17 wk of storage at –20°C without added antioxidant.

RESULTS

The FA composition of RBC at baseline and stored at –20°C for 2, 4, 9, or 17 wk with or without BHT are shown in Table 1. RBC without BHT contained lower proportion of 22:6n-3 after 9 wk, and higher proportions of all saturated FA (SFA) and monounsaturated FA (MUFA), and lower proportions of all n-6 and n-3 PUFA after 17 wk than at baseline. The concentration of total FA in RBC without BHT was lower after 9 wk of storage than at baseline (Table 1).

Figure 1 shows the concentrations of six main FA in RBC at all time points with or without BHT as a percentage of the concentration at baseline without BHT. In RBC without BHT the concentrations of 20:4n-6 and 22:6n-3 were lower after 4 wk, and the concentrations of 18:2n-6 and 18:1n-9 were lower after 9 wk of storage than at baseline. After 17 wk the concentrations of 16:0 and 18:0 were also lower than at baseline. Addition of BHT preserved the FA composition and concentration of total FA (Table 1) and prevented the decrease in concentrations of individual FA in RBC during 17 wk of storage (Figure 1).

The relationship between change in concentration of total FA in RBC after 17 wk of storage without BHT and the proportion of 22:6n-3 at baseline without BHT is shown in Figure 2. The two variables were strongly associated. Multivariate model analysis showed that age and other FA proportions in RBC at baseline had no effect on the change in total FA during 17 wk without BHT.

DISCUSSION

In the present study the PUFA composition and total FA concentration were stable in washed venous RBC from healthy women during 4 wk storage at –20°C without addition of antioxidant, which supports the findings reported previously (7). However, after 9 wk the proportion of 22:6n-3 and total FA concentration was lower, and after 17 wk without addition of antioxidant all PUFA proportions were lower than at baseline. On the other hand, addition of BHT did preserve FA proportions and concentrations of venous RBC for at least 17 wk at –20°C. BHT has been shown to preserve FA composition of RBC for at least 1 yr at lower temperature (7,8).

Studies on vulnerability of n-3 and n-6 PUFA in RBC to peroxidation have been inconsistent, some showing similar (12,13,14), others increased (15,16), and yet others decreased (17) peroxidation of RBC lipids high in n-3 PUFA compared

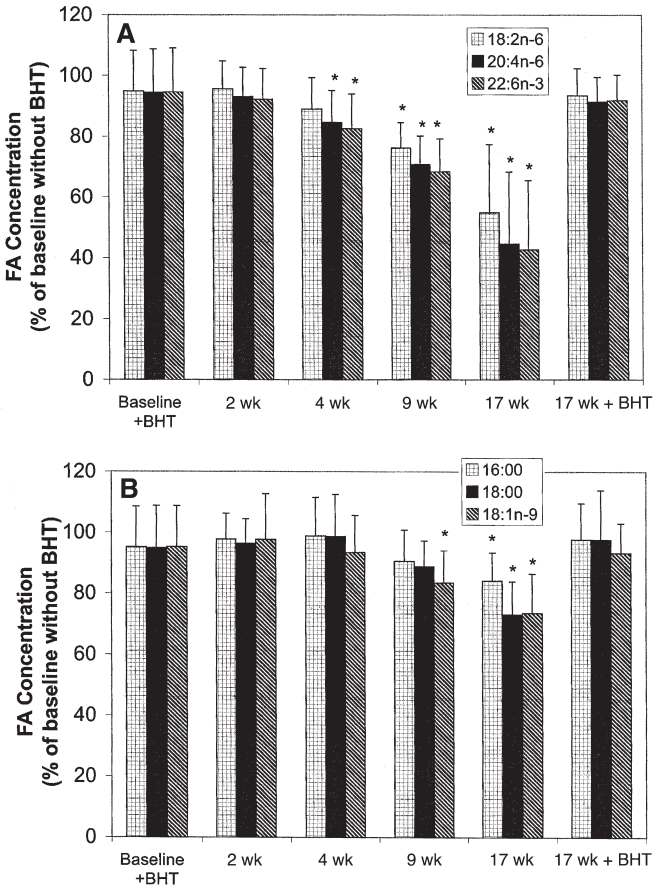

FIG. 1. Concentrations (% of baseline without BHT) of (A) 18:2n-6, 20:4n-6, and 22:6n-3 and (B) 16:0, 18:0, and 18:1n-9 in RBC of healthy women at baseline with BHT, and after 2, 4, 9, or 17 wk storage at –20°C with or without BHT. See Table 1 for number of subjects in each time point. *$P < 0.05$, compared with baseline without BHT, ANOVA for repeated measures and Tukey–Kramer *post-hoc* test.

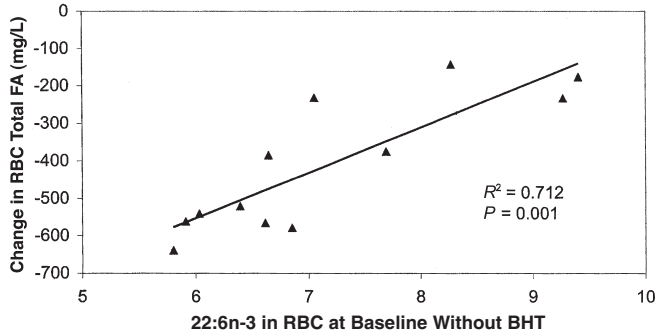

FIG. 2. Correlation between change in total FA concentration (mg/L) in red blood cells (RBC) of healthy women (n = 12) from baseline to 17 wk at –20°C without BHT and proportion (% of total FA) of 22:6n-3 in RBC at baseline without BHT.

with n-6 PUFA. In the present study, the proportion of 22:6n-3 at baseline was positively correlated to the change in concentration of total FA in RBC without BHT during 17 wk at –20°C (Fig. 2), even though n-3 PUFA deteriorated faster than n-6 PUFA (Table 1). A positive association has been found between proportion of n-3 PUFA in RBC and concentration of α-tocopherol in plasma of Icelandic women (18), and vitamin E has been shown to prevent lipid peroxidation of n-3 PUFA in animal RBC (19). Therefore we cannot exclude the possibility that antioxidants such as α-tocopherol or antioxidative enzymes naturally present in RBC may be confounding factors, and explain the correlation observed in our study. However, RBC high in n-3 PUFA have also been shown to be more resistant to hemolysis (16,20), which is one of the factors inducing lipid peroxidation of PUFA during cold storage (21). In the present study the decrease in total FA concentration during 17 wk storage without BHT was 35 ± 15% (mean ± SD), and in half the women the decrease was about 60% (over 500 mg/L, Fig. 2), where the baseline proportion of 22:6n-3 was under 7%.

In capillary RBC with low 22:6n-3 content at baseline, the decrease was 45% after 4 wk at –20°C without BHT (7). The present study indicates that the loss of RBC total FA concentration was not due only to lipid peroxidation of PUFA, as the concentration of SFA was also decreased (Fig. 1). One of the explanations for loss of total FA concentration might be that the extraction of lysophospolipids and partly degraded PL, which increase with hemolysis, was incomplete by the solvent used. Addition of BHT before storage of the RBC at –20°C prevented the degradation, probably by contributing to maintenance of the integrity of the membrane.

The findings in this study indicate that high content of 22:6n-3 in venous RBC of healthy women is associated with less deterioration of lipid FA content during storage at low temperature without addition of antioxidant. Whether RBC membranes with high content of 22:6n-3 are more resistant to deterioration in storage, because of α-tocopherol or other natural antioxidants, remains to be investigated.

Effect of Antiretroviral Agents on Triglyceride Levels in HIV-1-Infected Pregnant Women

Sir:

Today women represent the population segment with the greatest increase in HIV infection. Despite the association between the use of antiretroviral (ARV) medications and adverse metabolic events (1–3), no study has prospectively evaluated lipid profile in pregnant women using these drugs. We carried out a controlled, prospective cohort study from September 2001 to March 2003 on 45 HIV-infected pregnant women who had not previously used ARV medications to investigate the effect of ARV on triglycerides.

The women were divided into ZDV group (zidovudine) and TT group (ZDV + lamivudine + nelfinavir) according to the criteria established by the Perinatal HIV Guidelines Working Group (4). Pregnant women with a personal history of hyperlipidemia or who were taking other medications causing secondary lipemic abnormalities were excluded. The study was approved by the Research Ethics Committee of the institution, and the subjects gave informed consent to participate. The groups were similar with respect to maternal age, body mass index, race, smoking habit, and alcohol drinking. Blood samples were obtained four times during pregnancy at equidistant time intervals after a 12–14-hour fast into a vacutainer without anticoagulant and processed in duplicate for the determination of total cholesterol and fractions and triglycerides by automated enzymatic methods using the Cobas Integra 400 apparatus of Roche (Basel, Switzerland).

Median maternal age was 24 years for the ZDV group, and 27 years for the TT group. Our findings demonstrate that TG concentration was higher in the TT group than in the ZDV group from the sixth week after the beginning of ARV treatment (Table 1).

One of the positive points of the present study was the homogeneous patient sample investigated, because several risk factors are associated with the development of dyslipidemias, with emphasis on obesity, smoking habit, alcohol drinking, and a personal and family history of diabetes mellitus and dyslipidemia. Similarly, the study was characterized by homogeneous maternal age and body mass index.

It has been demonstrated that the gestational period is associated with important phsyiological changes in lipid metabolism. The first is progressive stimulation of lipolysis and ketogenesis during pregnancy (5), and the second is a gradual increase in TG concentrations with the evolution of pregnancy, which is more constant during the third trimester of gestation, when concentrations of 1.5 to 2 times above pregestational levels occur. In the present study, TG concentration was higher in the TT group than in the ZDV group. This fact may be explained by the association between TG levels and viral burden detected in the present patient series, as also observed by Hadigan *et al.* (6). According to these investigators, this result suggests metabolic abnormalities correlated with the presence of the virus in the organism and may also represent a direct or even indirect effect of the virus, with a worsening of lipid control associated with the clinical improvement and weight gain provided by these drugs. Our study demonstrates higher elevation of TG levels in TT group. However, doubts persist about whether pregnancy might potentiate the lipid effects of ARV drugs such as the risk of pancreatitis and premature atherosclerosis. The prospective follow-up of these women on a long-term basis may permit important interventions.

TABLE 1
Triglyceride Concentration in HIV-Infected Pregnant Women at Four Periods During Pregnancy

Triglyceride	ZDV[a] (n = 20)	TT[a] (n = 25)	P^b
14–20 wk	101.1 ± 8.25	119.3 ± 11.01	0.21
21–26 wk	134.6 ± 10.90	177.1 ± 12.31	0.02
27–32 wk	146.8 ± 10.17	197.7 ± 14.92	0.01
33–38 wk	175.5 ± 13.94	226.6 ± 17.43	0.03

[a]Data are reported as mean ± SEM. ZDV, pregnant women using zidovudine; TT, pregnant women using zidovudine, lamivudine, and nelfinavir.

ABSTRACT: Variation in brain FA composition, particularly decreased DHA (22:6n-3), affects neurodevelopment, altering visual, attentional, and cognitive functions, and is implicated in several neuropsychiatric disorders. To further understand how specific brain processes and systems are affected by variation in brain DHA content, we sought to determine whether specific brain regions were differentially affected by treatments that alter brain DHA content. Adult male Long-Evans rats were raised from conception using diet/breeding treatments to produce four groups with distinct brain phospholipid compositions. Total phospholipid FA composition was determined in whole brain and 15 brain regions by TLC/GC. Brain regions exhibited significantly different DHA contents, with the highest levels observed in the frontal cortex and the lowest in the substantia nigra/ventral tegmental area. Increased availability of DHA resulted in increased DHA content only in the olfactory bulb, parietal cortex, and substantia nigra/ventral tegmental area. In contrast, treatment that decreased whole-brain DHA levels decreased DHA content in all brain regions except the thalamus, dorsal midbrain, and the substantia nigra/ventral tegmental area. Alterations in DHA level were accompanied by changes in docosapentaenoic acid (n-6 DPA, 22:5n-6) content; however, the change in DHA and n-6 DPA was nonreciprocal in some brain regions. These findings demonstrate that the FA compositions of specific brain regions are differentially affected by variation in DHA availability during development. These differential effects may contribute to the specific neurochemical and behavioral effects observed in animals with variation in brain DHA content.

Paper no. L9925 in *Lipids 40*, 407–414 (May 2006).

Long-chain PUFA (LC-PUFA) are synthesized from two independent and nutritionally essential PUFA, α-linolenic acid (18:3n-3) and linoleic acid (18:2n-6), by chain elongation and desaturation. Mammals are not able to introduce a double bond in the n-3 or n-6 position of the FA chain, but they have the enzymes to elongate the essential FA to biologically important n-3 and n-6 LC-PUFA such as EPA (20:5n-3), DHA (22:6n-3), arachidonic acid (20:4n-6), and docosapentaenoic acid (n-6 DPA, 22:5n-6). The relative availability of these LC-PUFA depends on the dietary intake of essential FA or the LC-PUFA themselves (1).

LC-PUFA are found in all cell membranes and play an important role in the structure of neuronal cells in the central nervous system, where they are in particularly high concentration. Within the lipid bilayer of the cell membrane, phospholipids containing LC-PUFA are localized preferentially around membrane proteins. Accordingly, variation in LC-PUFA composition of synaptic membranes can affect neuronal function by altering the physicochemical properties of the membrane, and thus the structure and function of receptors, transporters, and ion channels (2). LC-PUFA also serve as precursors for inter- and intracellular signals such as prostaglandins and thromboxanes, and modulate gene expression at the transcriptional level, most likely through the activation of transcription factors (3). Variation in brain FA composition, particularly decreased DHA, affects neurodevelopment, altering visual, attentional, and cognitive functions in human and animals, and is implicated in several neuropsychiatric disorders, such as schizophrenia, depression, and attention deficit hyperactivity disorder (for review see 4–9).

To further understand how specific brain processes and systems are affected by variation in brain DHA content, we sought to determine whether the phospholipid FA compositions of specific brain regions are differentially affected by treatments that alter brain DHA levels. Diet and breeding protocols were used to produce four groups of rats with distinct brain phospholipid FA compositions (10), and importantly alterations in DHA content in a range similar to those reported in clinical populations with neuropsychiatric disorders (7–9). The effects of these treatments were examined in 15 specific brain regions of adult male rats. We will show that specific regions of the rat brain have distinct FA compositions, that specific regions exhibit different changes in DHA content as a result of manipulation of DHA availability, and that the compensatory change in n-6 DPA differs between brain regions.

MATERIALS AND METHODS

Animals and diet/breeding procedures. All experiments were conducted in accordance with the NIH Guide for the Care and Use of Laboratory Animals (11) and were approved by the University of Kansas Medical Center Institutional Animal Care and Use Committee.

[a]Harlan Teklad TD00235, composition supplied by the manufacturer. The basal mix is modified from AIN-93G (12) for use at the rate of 930 g/kg of diet prepared by adding 70 g/kg of the selected oils.
[b]Harlan Teklad TD94046 (AIN 93G-MX).
[c]Harlan Teklad TD94047 (AIN-93-VX).
[d]A triacylglycerol oil produced by algae containing 42.57% DHA by weight.

Long-Evans rats used for breeding (females >10 wk old and male proven breeders; Harlan, Indianapolis, IN) were obtained at least 5 d prior to the commencement of any treatments. Rats were housed in a temperature- and humidity-controlled animal facility with a 12-h light-dark cycle (on at 0600), given food and water *ad libitum*, and were handled regularly.

Rats were raised from conception using diet/breeding treatments designed to modulate brain DHA content. The ALA group was raised from conception on a purified diet prepared by adding 7% by weight of pure soybean oil (without partial hydrogenation) as a source of α-linolenic acid, the dietarily essential precursor of DHA, to a baseline diet (Harlan Teklad Basal Diet TD00235). The ALA diet was identical to Harlan Teklad AIN-93G and meets all current nutrient standards for rat pregnancy and growth (12). The ALA + DHA group was raised on a diet formulated with soybean oil and preformed DHA (DHASCO™, a triacylglycerol oil produced by algae containing 42.57% DHA; Martek Biosciences Corp, Columbia, MD) substituted on an equal weight basis for soybean oil such that DHA accounted for 0.7% of the total fat in the diet by weight. The low-ALA and low-ALA 2nd generation groups were the first and second generations, respectively, raised on a diet formulated with sunflower oil (7% by weight), which contains negligible α-linolenic acid compared with soybean oil. The nutritional composition of the experimental diets is presented in Table 1; FA composition of all diets, in Table 2.

Individually housed dams were placed on the respective diets at the time of initial mating. Prior to purchase, rats were fed Harlan Teklad Global 19% Protein Rodent Diet #2018S. Rats received Teklad Rodent Diet (W) #8604 for 5–7 d during acclimatization between purchase and mating. The female offspring of low-ALA dams used to generate low-ALA 2nd generation offspring (each from a different litter) were maintained on the low-ALA diet throughout their lifetime and were mated on postnatal day 70 (± 5 d). Litters were culled to 8 on postna-

tal day 1. Pups were weaned on postnatal day 21, group-housed (3 per cage), and placed on the maternal diet. On postnatal day 70, male offspring were euthanized by decapitation. Rats (n = 5 per group, each from a different litter) were used for analysis of FA composition in specific brain regions. Additional rats from the same litters (n = 3–6 per group, each from a different litter) were used for determination of whole-brain FA composition. Brains were rapidly removed, frozen on dry ice, and stored at –70°C for determination of FA composition.

FA analysis. Specific brain regions were isolated bilaterally by free-hand dissection on ice according to a modification of the method of Glowinski and Iversen (13) and weighed, a procedure taking roughly 10 min per brain. Whole-brain analyses were performed using one hemisphere of each brain. Tissues were then homogenized in methanol using a PRO250 homogenizer (4–5 mL for individual regions depending on weight, 10 mL for hemispheres). An aliquot of each homogenate was removed and extracted with chloroform-methanol (14). The methanol contained 50 mg/L of butylated hydroxytoluene as an antioxidant. The lipid extracts in organic solvents were washed with 0.15 M potassium chloride (15), and the organic solvents that remained were evaporated under nitrogen. Phospholipids were isolated from other lipid classes by TLC (silica gel G plates, 10 × 20 cm, Analtech, Inc., Newark, DE) in hexane:diethyl ether:acetic acid (80:20:1, by vol) (16). The band containing phospholipids was removed completely from the plate and transmethylated with boron trifluoride methanol (Sigma Chemical, St. Louis, MO) to yield FAME (17). Individual FAME were separated and the relative areas determined with a Varian 3400 gas chromatograph with a SP-2330 capillary column (30 m, Supelco, Belfonte, PA). The instrument was programmed for an instrument-controlled time gradient from 140°C to 208°C at the rate of 4°C/min. The injector and detector temperatures were 250°C and 300°C, respectively. Helium was used as a carrier gas at a flow rate of 21 cm/s. Individual peaks were integrated using Varian Star (v. 6) software as area percent of total FA (including plasmalogens and unidentified peaks) and identified by comparison to authentic standards (NHI-C, NHI-F, NHI-D, Supelco, Inc.; n-6 DPA, Nu-Chek-Prep, Elysian, MN) and biological mixtures (PUFA 1 and PUFA 2, Supelco, Inc.).

Data analysis. Results are presented as the mean ± SEM. Data were analyzed for statistically significant effects of the diet/breeding procedures on each FA measured by two-way ANOVA, with factors of overall brain DHA content (produced by the diet/breeding procedures) and brain region, followed by one-way ANOVA for each brain region and by Tukey's test (Systat, v. 10.2). Significance was assumed at $P < 0.05$. Regression analyses were performed using data from individual samples. Differences between slopes were determined by assessment of the confidence interval for differences between regression coefficients (18).

RESULTS

Effects of diet/breeding treatments on whole-brain phospholipid FA composition. Whole-brain total phospholipid FA composition of ALA rats was similar to that previously reported (19–22), with DHA representing 13.4% of total FA. The diet/breeding treatments used in this study produced four groups of rats with distinct phospholipid FA compositions (Table 3). DHA contents of the low-ALA and low-ALA 2nd generation groups were 77% and 66% of ALA, respectively ($P < 0.05$). In accordance with this change in DHA content, n-6

[a]Total phospholipid FA composition is expressed as the mean ± SEM (n = 3–6 per group). Data were analyzed by repeated measures ANOVA and Tukey's test. *$P < 0.05$ vs. ALA. †$P < 0.05$ vs. ALA + DHA. ‡$P < 0.05$ vs. low-ALA.
[b]Previously reported in (10).

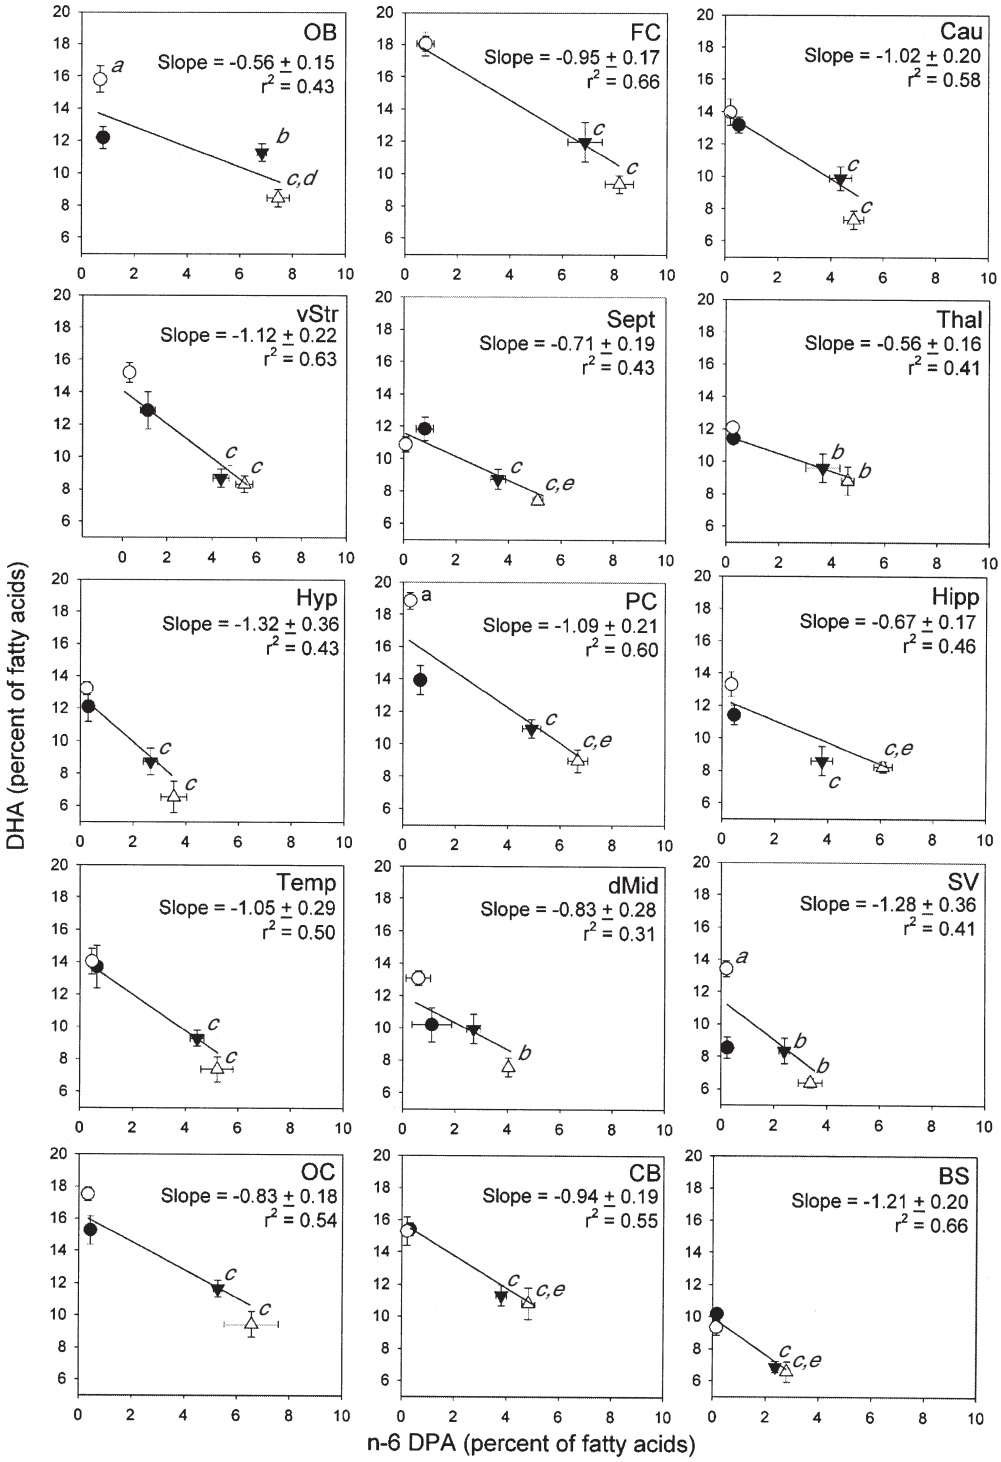

FIG. 1. Effects of diet/breeding treatments on the DHA and n-6 DPA contents of specific brain regions. Total phospholipid DHA content was determined for each of 15 brain regions of rats raised from conception using diet/breeding treatments that produced four distinct whole-brain phospholipid FA compositions. Brain regions are presented in rostro-caudal order. Data are presented as the mean ± SEM (n = 5 per group). Treatment groups: ○, ALA + DHA; ●, ALA; ▼, low-ALA; △, low-ALA 2nd generation. Significant differences by ANOVA and Tukey's test ($P < 0.05$): [a]DHA content different than ALA; [b]n-6 DPA content different than ALA; [c]DHA and n-6 DPA content different than ALA; [d]DHA content different than low-ALA; [e]n-6 DPA content different than low-ALA. For simplicity, significant differences between the ALA + DHA group and the low-ALA and low-ALA 2nd generation groups are not indicated; however, regional DHA contents in the ALA + DHA group were different than the low-ALA and low-ALA 2nd generation groups for all brain regions except low-ALA Sept, Thal, dMid, CB, and BS. Regional n-6 DPA contents for the ALA + DHA group were different than the low-ALA and low-ALA 2nd generation groups in all instances. Significant differences ($P < 0.05$) between regression slopes for some regions were detected using differences between confidence intervals of regression coefficients. OB, olfactory bulb; FC, frontal cortex; Cau, caudate-putamen; vStr, ventral striatum (nucleus accumbens and olfactory tubercle); Sept, septal area; Thal, thalamus; Hyp, hypothalamus; PC, parietal cortex; Hipp, hippocampus; Temp, temporal lobe; dMid, dorsal midbrain; SV, substantia nigra/ventral tegmental area; OC, occipital cortex; CB, cerebellum; BS, brainstem.

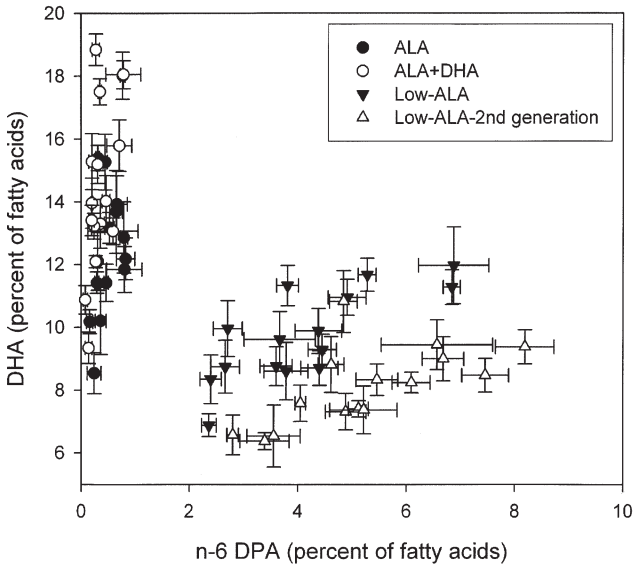

FIG. 2. Relationship between regional phospholipid DHA and n-6 DPA within treatment groups. DHA and n-6 DPA contents were determined for each of 15 brain regions. Data points represent each of the 15 individual brain regions examined expressed as the mean ± SEM (n = 5 per group). Regression analysis for ALA animals indicated a slope of 2.80 ± 0.79 (r^2 = 0.37). Slopes for ALA + DHA, low-ALA, and low-ALA 2nd generation groups were 2.27 ± 0.87 (r^2 = 0.30), 0.9 ± 0.15 (r^2 = 0.74; $P <$ 0.05 vs. ALA), and 0.60 ± 0.12 (r^2 = 0.57, $P <$ 0.05 vs. ALA and low-ALA), respectively.

DPA content was increased to 780% of ALA in the low-ALA group ($P < 0.05$) and was further increased to 1200% of ALA in the low-ALA 2nd generation group ($P < 0.05$ vs. low-ALA). In the ALA + DHA group, the ratio of DHA to n-6 DPA was significantly increased to 237% of ALA ($P < 0.05$).

Alterations in the levels of several additional FA were observed, including palmitic acid (16:0), vaccenic acid (18:1n-7), oleic acid (18:1n-9), arachidonic acid (20:4n-6), and 22:4n-6. These differences were primarily observed between the ALA + DHA and low-ALA 2nd generation groups; however, vaccenic acid in the low-ALA group and 22:4n-6 in the low-ALA 2nd generation group were different than ALA.

Regional variation in brain DHA and n-6 DPA contents in ALA rats. DHA and n-6 DPA were the primary phospholipid FA affected by the diet/breeding treatments in whole brain; thus, results for specific brain regions are presented only for these FA. In ALA rats, specific brain regions exhibited a range of DHA contents ($P < 0.05$ by ANOVA). Frontal cortex exhibited the highest DHA content (18.0%), which was roughly twofold that detected in the substantia nigra/ventral tegmental area (8.5%), the brain region with the lowest DHA content (Fig. 1). Brain n-6 DPA content also varied between brain regions ($P < 0.05$) with olfactory bulb, frontal cortex, and ventral striatum having the highest n-6 DPA contents (0.8%), which was four-fold that observed in the substantia nigra/ventral tegmental area and brain stem (0.2%). Across brain regions, DHA contents were positively correlated with n-6 DPA contents (slope = 2.80, $r^2 = 0.37$) (Fig. 2).

Effects of diet/breeding treatments on FA composition in specific brain regions. In the ALA + DHA group, the inclusion of preformed DHA in the diet resulted in significantly increased DHA content in the olfactory bulb (130% of ALA), parietal cortex (135% of ALA), and substantia nigra/ventral tegmental area (157% of ALA) (Fig. 1). DHA content of all other brain regions was not different than ALA. No significant changes in regional n-6 DPA content were detected.

In the low-ALA group, the significant (23%) decrease in whole-brain DHA content resulted in significant decreases to between 66% and 79% of ALA in 11 of the 15 brain regions examined. Frontal cortex was the most affected (66% of ALA), whereas decreases in the olfactory bulb, thalamus, dorsal midbrain, and substantia nigra/ventral tegmental area were not of sufficient magnitude to reach statistical significance. Significant increases in n-6 DPA content were observed in all brain regions where decreases in DHA were observed.

In the low-ALA 2nd generation group, the multigenerational treatment with the diet lacking α-linolenic acid resulted in a trend toward greater regional decreases in DHA content than observed in the low-ALA group; however, this further decrease reached statistical significance only in the olfactory bulb ($P < 0.05$ vs. low-ALA). n-6 DPA content was significantly increased in all brain regions compared with ALA ($P < 0.05$) and was significantly greater in low-ALA 2nd generation rats compared with low-ALA DHA rats in the septal area, parietal cortex, hippocampus, cerebellum, and brain stem ($P < 0.05$).

The relationship between regional DHA and n-6 DPA contents for each brain region across treatments was examined by regression analysis (Fig. 1). Hypothalamus (slope = –1.31) and substantia nigra/ventral tegmental area (slope = –1.28) exhibited the steepest slopes, indicating the greatest change in DHA content relative to n-6 DPA, and were significantly different ($P < 0.05$) from the olfactory bulb and thalamus (slope = –0.56), which had greater change in n-6 DPA content relative to the change in DHA content across the range of treatments. Significant differences between regression slopes ($P < 0.05$) were detected between the confidence intervals for slopes for some brain regions.

Regression analysis of the relationship between regional DHA and n-6 DPA contents within each treatment group indicates that DHA and n-6 DPA content exhibited a positive correlation (Fig. 2). The regression slopes for DHA vs. n-6 DPA in the ALA and ALA + DHA groups were not significantly different, consistent with the similar whole-brain DHA content in these groups. In agreement with the decrease in DHA content observed in whole brain and the compensatory incorporation of n-6 DPA under conditions with lower availability of DHA, the slopes for the low-ALA and low-ALA 2nd generation groups were significantly lower than the ALA slope ($P < 0.05$). Likewise, slopes for the low-ALA and low-ALA 2nd generation groups were different from each other ($P < 0.05$). However, the positive correlation within each treatment group was retained.

DISCUSSION

Adequate availability of DHA is important for optimal brain development and appears to affect visual, cognitive, and attentional processes (4–6). In addition, a growing body of epidemiological and clinical evidence suggests that low levels of n-3 LC-PUFA, particularly DHA, may contribute to the development or severity of neuropsychiatric disorders such as schizophrenia (7,8) and attention deficit hyperactivity disorder (9), with early development as a period of particular vulnerability. Accordingly, DHA was included in infant formula in 2002 and several n-3 PUFA supplements are marketed to pregnant and nursing women. Brain FA composition, including DHA content, can vary depending on the availability of specific FA (23–25); however, relatively little is known about the effects of such variation on the FA composition of specific brain regions. This study evaluated the phospholipid FA composition of specific brain regions in four groups of rats with distinct whole-brain phospholipid FA compositions.

The DHA content of rat brain observed in this study is similar to that reported in numerous previous studies (e.g., 19,20,22,26). In agreement with previous studies in rodents (27,28), the FA composition of specific regions exhibited significant variation in DHA content, with higher levels of DHA in regions such as the frontal cortex and lowest levels in regions such as the substantia nigra/ventral tegmental area. However, the regional distribution of DHA in the rodent differs from that reported in the 4-wk-old baboon (29), where the range of DHA levels in brain regions was smaller and the highest DHA levels were observed in basal ganglia, discrepancies that likely reflect both species and maturational differences.

The decrease in whole-brain DHA content in the low-ALA group in this study is similar to that observed in previous studies with rats raised from conception on diets formulated with sunflower oil (26). Decreases in brain DHA content of greater magnitude have been produced in first-generation models using diets formulated with oils such as peanut and safflower, which contain even less α-linolenic acid than sunflower oil (30). Similarly, the DHA content of the low-ALA 2nd generation group in this study, produced by breeding two generations of rats on a diet formulated with sunflower oil, resulted in a smaller decrease in DHA level than that observed in other studies using multiple-generation models (20,22,31). Again, this discrepancy is probably caused by differences in the formulation of the diets and perhaps strain differences. The decreases in DHA content in this study are similar to the 15–50% decreases relative to normal controls observed in tissues from patients with neuropsychiatric disorders such as ADHD (32,33) and schizophrenia (34–37) and are thus likely to model these clinical conditions.

In concordance with previous studies that examined the effects of decreased brain DHA in specific regions of the rodent brain (20,27,28), the present data clearly demonstrate that brain regions respond differentially to treatments that alter DHA accretion over the course of development. Under conditions of increased availability of DHA from the inclusion of preformed DHA in the diet, only three brain regions (olfactory bulb, parietal cortex, and substantia nigra/ventral tegmental area) exhibited significant increases in DHA content, a change that was not reflected in a detectable alteration in whole-brain DHA level. Under sufficiently strenuous conditions of reduced DHA availability, all brain regions except thalamus exhibited depletion of DHA content, with frontal and temporal cortices, caudate-putamen, and hypothalamus exhibiting the greatest depletion under the low-ALA 2nd generation treatment condition. Over the range of treatments examined in this study, substantia nigra/ventral tegmental area and parietal cortex exhibited the greatest range of DHA contents, whereas brain stem, thalamus, cerebellum, and septal area exhibited the least. Previous studies using multigeneration treatments with α-linolenic acid–deficient diets suggest that the variation in brain phospholipid DHA content most likely represents changes in the composition of phosphatidylethanolamine and phosphatidylserine, the phospholipid species that contain the highest concentrations of DHA (38). With regard to specific cell types, oligodendrocytes are most affected followed by neurons, whereas astrocytes are least affected (39). It is likely that these specific phospholipid subtypes and cell types are similarly affected in this study, particularly in the low-ALA 2nd generation group; however, the actual effects of the FA compositions of these phospholipid subclasses and cell types over a range of brain DHA contents and in specific brain regions have yet to be determined. Likewise, it must be noted that this study assessed the effects of variation in the availability of DHA during development in young adult rats. Differences between the regional distribution of DHA between neonatal baboons (29) and adult rodents (20,27,28) suggest that DHA accretion in specific brain regions may occur at different rates during different phases of development. Accordingly, the present observations may not be valid at time points in development other than adulthood.

Incorporation of n-6 DPA into phospholipids under conditions with decreased availability of DHA is well established (23). As expected, variation in the availability of DHA during development resulted in inversely related changes in regional DHA and n-6 DPA contents in all brain regions. However, consistent with the nonreciprocal replacement of DHA by n-6 DPA reported in rat cortex (40) and retina (41), the significant differences among regional DHA/n-6 DPA regression slopes across treatments suggests that the quantitative relationship between the incorporation/loss of DHA and the loss/incorporation of n-6 DPA differed among regions. Reciprocal substitution of n-6 DPA for DHA appears to occur in brain regions where the DHA/n-6 DPA regression slope across treatments was close to –1, such as the caudate nucleus, parietal cortex, and temporal lobe. However, the compensatory changes in these FA were not reciprocal in other regions, such as the olfactory bulb, parietal cortex, and substantia nigra/ventral tegmental area, where the increases in DHA produced by the diet containing preformed DHA were not accompanied by a commensurate decrease in n-6 DPA. On the other hand, in brain regions such as the thalamus, septal area, and hippocampus (where the regression slope was greater than –1), the low-ALA and low-ALA 2nd genera-

tion treatments produced greater incorporation of n-6 DPA than decreases in DHA. Finally, whereas the relationship between DHA and n-6 DPA across treatments appears linear for some brain regions (e.g., dorsal midbrain), this may not be the case in others (e.g., olfactory bulb).

Differences in the change in phospholipid FA composition of specific brain regions may contribute to the neurobiological effects associated with decreased availability of DHA during development. For example, function of systems associated with the midbrain, which has relatively low levels of DHA in rats raised on the ALA diet, are altered by treatments that decrease accretion of DHA during development. Substantial decreases in brain DHA content (–75%) alter function of the mesolimbic and mesocortical dopamine systems (42), and changes in motor activity, a parameter relevant to dopaminergic function, have been observed in animals with various levels of DHA depletion (e.g., 6,26,43,44) or increased DHA (45). Interestingly, a moderate decrease in brain DHA content resulted in increased locomotor activity, whereas a greater decrease in DHA resulted in decreased activity (10,26,46), perhaps caused by differing degrees of DHA depletion in different brain regions. Altered evoked visual and auditory cortical potentials are also reported in rats with a moderate decrease (–20%) in brain DHA content (47). Similarly, performance in an olfactory discrimination task was decreased in rats with a 79% decrease in brain DHA content (22,48), consistent with the depletion of DHA and substantial incorporation of n-6 DPA observed in the olfactory bulb in the low-ALA 2nd generation group. In view of the relative lack of effect of the low-ALA treatment on DHA content in olfactory bulb, it is interesting to hypothesize that olfactory function might be less affected by treatments that produce only a modest decrease in whole-brain DHA content. The specific relationship between regional FA composition and functional effects, however, must be determined by systematic study over a range of brain DHA contents.

In summary, the present findings demonstrate that the phospholipid DHA contents of specific brain regions are differentially affected by diet/breeding treatments that alter brain DHA accretion over the course of development. Compensatory changes in n-6 DPA content are also regionally specific and appear to be nonreciprocal with DHA in some brain regions. These differential effects on regional LC-PUFA composition may underlie the neurochemical and behavioral effects resulting from variation in DHA availability and suggest that different neurochemical alterations may occur with changes in brain DHA content of various magnitudes.

Departments of [a]Public Health and [b]Food Safety and Food Quality, Ghent University, Ghent, Belgium

ABSTRACT: The intake of fat, saturated and monounsaturated FA (SFA and MUFA), and omega-6 and omega-3 PUFA has been estimated in 641 Belgian women (age 18–39 y). Their food intake was recorded using a 2-d food diary. The PUFA included were linoleic (LA), alpha-linolenic (LNA), arachidonic (AA), eicosapentaenoic (EPA), docosapentaenoic (DPA) and docosahexaenoic (DHA) acids. The mean total fat intake corresponded to 34.3% of total energy intake (E). The mean intake of the FA groups corresponded to 13.7%, 13.1%, and 6.0% of E, for SFA, MUFA, and PUFA, respectively. The mean intake of LA was 5.3% of E and of LNA was 0.6% of E, with a mean LA/LNA ratio of 8.7. The mean intake of AA was 0.03% of E. The mean intake of EPA, DPA, and DHA was 0.04%, 0.01%, and 0.06% of E, respectively. According to the Belgian recommendations, the total fat and SFA intake was too high for about three-quarters of the population. The mean LA and overall n-6 PUFA intake corresponded with the recommendation, with part of the population exceeding the upper level. Conversely, the population showed a large deficit for LNA and n-3 PUFA. The major food source for LA and LNA was fats and oils, followed by cereal products. The main sources of long-chain PUFA were fish and seafood, and meat, poultry, and eggs. From a public health perspective, it seems desirable to tackle the problem of low n-3 PUFA intake.

Paper no. L9945 in *Lipids 41*, 415–422 (May 2006).

Advances in the knowledge concerning physiological functions of dietary PUFA, in particular omega-3 PUFA, have led to an increased interest in the food sources and the level of dietary intake of these nutrients. Alpha-linolenic acid (LNA, C18:3n-3) is a plant-derived omega-3 FA. Together with linoleic acid (LA, C18:2n-6), LNA is one of the two essential FA in the human diet; LA and LNA cannot be synthesised by the human metabolism. LNA can be desaturated and elongated in the human body to its longer-chain relatives, long-chain n-3 PUFA (LC n-3 PUFA), but the efficiency of this conversion is reduced by high intake levels of LA, which competes more effectively than LNA for desaturation and elongation enzymes because LA is abundantly present in Western diets (1). There is evidence to suggest that the conversion rate of dietary LNA to LC n-3 PUFA is insufficient to achieve adequate levels, even when the LNA intake is increased (2,3). Nevertheless, a British study suggested that women may possess a greater capacity for LNA conversion than men (4,5). LC n-3 PUFA are not synthesised by plants, but they are present in animals and in the marine food chain, EPA (C20:5n-3), docosapentaenoic acid (DPA, C22:5n-3), and DHA (C22:6n-3) being the most abundant in the human diet. It is via planktivorous fishes that LC n-3 PUFA enter the marine food chain and accumulate in seafood (2). Therefore, seafood products are excellent food sources of LC n-3 PUFA.

For more than 30 years, a lot of fundamental clinical and epidemiological research work has been done with regard to the relationship between n-3 FA and health, showing the potential role of n-3 PUFA from the diet in the prevention of several diseases, in particular cardiovascular diseases (1,6,7). Moreover, the importance of an adequate intake of DHA, particularly during pregnancy, is stated, given the role of DHA in the development of visual functions and the nervous system. Because LC n-3 PUFA cannot be formed by human cells to a significant extent, most of the n-3 FA accumulated in the fetal tissue must originate from the maternal diet (8,9). The knowledge about the beneficial effects of these FA has led to the formulation of dietary reference intakes for the absolute amount of PUFA, but also for the balanced intake of n-6 and n-3. In 2003, the Belgian Health Council formulated recommendations for FA intake for the Belgian population, expressed in percentages of total energy intake (Table 1) (10). However, there is a lack of information on the current dietary intakes and sources for the Belgian population. One of the reasons for this has been the lack of a sufficiently complete food composition database (FCDB) for FA (11). Up to now, dietary intake assessments of individual n-6 and n-3 PUFA on a population level can be found for Japan (12,13), France (14), Norway (15), Australia (11,16), and Germany (17).

The aim of this study is to determine the total intake of fat, FA groups, and in particular n-6 and n-3 PUFA in a population sample of Belgian women of reproductive age, and to compare these intakes with the current Belgian recommendations (10). In addition, the main food sources of these FA have been identified.

Abbreviations: AA, arachidonic acid; DPA, docosapentaenoic acid; E, total energy intake; FCDB, food composition database; long-chain PUFA (LC PUFA); linoleic acid (LA); alpha-linolenic acid (LNA); MUFA, monounsaturated FA; SFA, saturated FA.

TABLE 1
Recommended Daily Intakes of Fat and FA, Formulated by the Belgian Health Council (10)[a]

	Recommendations (%E)
Fat	< 30
SFA	< 10
MUFA	> 10
PUFA	5.3–10.0
18:2n-6	> 2.0
20:4n-6	—
Σn-6 PUFA	4.0–8.0
18:3n-3	> 1.0
Σ(20:5n-3, 22:6n-3)	> 0.3
Σn-3 PUFA	1.3–2.0

[a]Σn-6 PUFA = 18:2n-6 + 20:4n-6; Σn-3 PUFA = 18:3n-3 + 20:5n-3 + 22:5n-3 + 22:6n-3; %E, percent of total energy intake.

MATERIALS AND METHODS

Population sample. The data reported in this paper are from a large epidemiological survey that included women aged 18 to 39 y. A total of 4,000 women were randomly selected from the population register of Ghent, a medium-sized city (a population of 229,000 inhabitants) in Flanders, the Dutch-speaking, northern part of Belgium. They were invited to participate in the study by postal mail and were asked to reply by use of an enclosed postcard. Not less than 2,634 subjects declined the invitation to participate, and 424 invitation letters were declared undeliverable by the postal service. Women who were pregnant, who had moved to another city, who did not speak Dutch, who were unable to come to the research center, or who were unable to volunteer within the planned period of the fieldwork were excluded from the study. In total, dietary data were collected for 641 women. The primary objective of the survey was to evaluate food and nutrient (in particular iron) intake in a group of Belgian women of reproductive age. Dietary assessment was done on the basis of a 2-d food record, using diaries with a semistructured, open-entry format and consisting of six eating occasions: breakfast, lunch, dinner, and morning, afternoon, and evening snacks. The women were asked to give a detailed description of the foods eaten, if possible to give a brand name and to estimate the amounts using natural measures (e.g., pieces, slices) or household measures (e.g., coffee spoon, cup). Experienced dietitians used a standardized protocol, including a manual on household weights and measures, to convert the estimated amounts into weights. In addition, a general sociodemographic questionnaire was administered. Data were gathered during the year 2002 (January 29 to December 22), thereby covering the different seasons. The study was approved by the Ethical Committee of the Ghent University Hospital. Only the data from the 2-d food record are used in this study for assessing the intake of total fat and important dietary FA.

FCDB. A specific FCDB was developed on the basis of existing food composition data. Of all the different food items in the study (n = 1,063), 75.1% contained fat (n = 799). Total fat contents for these foods were available from the Belgian FCDB (18) and the Dutch FCDB (19). For the establishment of a detailed FA database, including SFA, MUFA, PUFA, LA, LNA, AA, EPA, DPA, and DHA, the following eight different existing food composition tables were used: an extended version of the Dutch FCDB (20) (for 457 food items); a specific French FCDB (14) (for 115 food items); the British McCance & Widdowson's FCDB (21) (for 59 food items); the USDA National Nutrient Database (22) (for 51 food items); the Finnish FCDB (23) (for 12 food items); the Canadian Nutrient File (24) (for 9 food items); the Danish FCDB (25) (for 6 food items); and the German Food Composition and Nutrition Table (26) (for 1 food item). Furthermore, food composition information from industries was used for 43 food items, mostly specific varieties of margarine, cheese, and dressings. Finally, for 46 composite food items, the FA composition was calculated using both local recipes describing the different ingredients and their proportions, and the FA composition of the ingredients as found in one of the FCDB. Detailed FA profiles for the 799 food items were then compiled using the listed databases by applying the proportional share of each FA (group) in the total fat content as found in the database of origin, to the total fat content of the food as listed in the local FCDB (18,19).

Statistics. The population intake is calculated and expressed as means, standard deviations, and different percentiles (P5, P50, P95). All statistics are based on the mean of 2 d for each individual. The intakes are expressed in absolute amounts (g or mg per d) as well as in percentage of total energy intake. The percentages of the n-6 and n-3 PUFA provided by the different food items were calculated. These percentages were calculated as population proportions, as defined by Krebs-Smith *et al.* (27). The population proportion is calculated by summing the amount of a certain FA from a certain food item for all individuals and then dividing that by the sum of that FA from all food items for all individuals. The food items were grouped in eight different food groups, each consisting of several subgroups, as presented by Astorg *et al.* (14).

RESULTS

The intakes of total fat, SFA, MUFA, and PUFA of Belgian women (n = 461) are given in Table 2 in grams per day (g/d) and in percentage of total energy intake (%E). This table also shows the energy intake (kJ/d). The intakes of individual PUFA expressed in mg/day and in %E can be found in Table 3. The mean E of the study population was 8,338 kJ. On average, 34.3%E was provided by fat intake. The mean intake of SFA and MUFA was very similar, respectively 13.7% and 13.1%E, whereas the mean intake of PUFA was less than half of it, being 6.0%E (Table 2). Flemish women consumed on average 11.92 and 1.44 g (5.28 and 0.64%E) of LA and LNA, respectively, per day. As a consequence, the LA/LNA ratio was fairly high: 8.7 on average, with 50% of the population having a ratio over 10.1 (Table 4). The mean daily intake for AA amounted to 55.9 mg (0.03%E). Mean intakes for EPA, DPA and DHA were 77.8 mg/d (0.04%E), 25.3 mg/d (0.01%E) and 131.2 mg/d (0.06%E), respectively (Table 3). The average total n-6 PUFA intake (sum of LA and AA, presented as ∑n-6PUFA) was 11.97 g/d (5.33%E). Mean total n-3 PUFA intake (sum of LNA, EPA, DPA, and DHA, presented as ∑n-3 PUFA) was 1.67 g/d (0.75%E). As a result, the mean ratio of ∑n-6 PUFA to ∑n-3

For abbreviations, see Table 1.

PUFA was 7.8. The 5th and 95th percentiles of this ratio show a quite high variation (Table 4). The contribution of the LC n-6 derivates to the ∑n-6 PUFA was on average very low, only 0.5%. For the ∑n-3 PUFA, the LC fraction accounted for 14.0%. Furthermore, the LC PUFA intake is skewed to the right, as shown by the median intakes being much lower than the mean intakes (Table 3). A large proportion of the study population had no intake of the LC PUFA on both recorded days, whereas others had rather high intakes.

The percentages of fat, SFA, MUFA, total PUFA, and individual n-6 and n-3 PUFA provided by different food types are presented in Tables 5 and 6. The major food sources contributing to total fat intake were dairy products, sweet products, fats and oils, and meat, poultry, and eggs. Dairy products and sweet products were the main contributors to SFA intake, whereas fats and oils were the primary source of MUFA and PFUA (Table 5). Fats and oils were the main sources for LA (31%) and especially of LNA (45%), followed by cereal products. In the group of fats and oils, margarines and fatty sauces (dressings, etc.) were the major subgroups. Breads was the most important subgroup in the groups of cereal products. The intake of AA was mainly contributed to the diet by meat, poultry, and eggs, which contributed more than half of the intake. The subgroup eggs was responsible for more than 25% of the overall AA intake. The second important contributor was fish and seafood, accounting for 17.8%, with molluscs and crustacean as the most important subgroup, followed by fatty fish. For the three different LC n-3 PUFA taken into consideration in this study, a nearly equivalent pattern is found concerning the contribution of the different food groups to the mean intake. Fish and seafood contributed 87.3%, 66.0%, and 80.0%, respectively, of EPA, DPA, and DHA. The most important subgroup was fatty fish, which accounted for almost half

[a]Σn-6 = C18:2n-6 + C20:4n-6.
[b]Σn-3 = C18:3n-3 + C20:5n-3 + C22:5n-3 + C22:6n-3.

of the overall intake of EPA, DPA, and DHA. For EPA, the subgroup molluscs and crustacean were also quite important (accounting for 23.9%). A substantial part of the DPA intake was contributed by poultry (13.0%), meat and meat dishes (12.1%), and eggs (6.1%). This group contributed also to the DHA intake (for 11.8%), with eggs as the major subgroup (6.1%). Since fortification of margarines with LC n-3 PUFA and since the use of eggs in pastry and desserts, as well as in certain snacks, these food items also contribute a bit to the intake of LC n-3 PUFA intake.

DISCUSSION

Some methodological shortcomings related to this study have to be mentioned. First, it has to be said that extreme intakes (low and high) are likely to be exaggerated because the consumption data were derived only from a 2-d food record. Two days are not enough to give a picture of the usual intake on an individual level, especially for nutrients abundantly present in foods that are not consumed on a daily basis, such as seafood products. There is a high within- and between-subject variance

for these nutrient intakes over different days. Nelson *et al.* (28) calculated the days needed to assess the individual PUFA intake with a good correlation ($r \geq 0.9$) between the observed and the true mean intake. For women older than 18 y, at least 30 d should be necessary. Nevertheless, the 2-d food record yields unbiased estimates of the mean food consumption of a population sample.

Second, at the level of the food composition data, a point of discussion is that PUFA, in particular the long-chain PUFA, are present in only small amounts in individual foods, but accumulate to significant levels of biological importance in the context of a whole diet. For most foods, these low values often round down to zero when reported to a single decimal place, and so it is likely that FA concentrations will be consistently underreported in FCDB (29). Furthermore, for some items it was not easy to find the FA composition. Quinoa, for example, was only mentioned in the German FCDB (26). We were obliged to use eight different databases in order to determine the FA composition of all food items, which is not an ideal situation. Moreover, a very recent Australian study (11) noted that the meat and poultry category of foods was a significant source of LC n-3 PUFA. The authors stated that the modest amount of PUFA in muscle tissue phospholipids of lean meat needs to be taken into account when determining dietary PUFA intakes. The majority of LC n-3 PUFA in meat is DPA. According to Howe *et al.* (11), the LC n-3 PUFA content of meat products has been underestimated up to now. Because of the limitations of available data about the FA content of these food items, LC n-3 intake from meat, poultry, and eggs, especially DPA intake, could have been underestimated, but this is not likely to have resulted in a significant underestimation of the mean EPA and DHA intake, given that these two FA are mainly brought by fish and seafood. Moreover, the Belgian recommendation considers only EPA and DHA for the evaluation of LC n-3 PUFA intake. Therefore, the evaluation of the intake data against the Belgian recommendations is not influenced by the possible underestimation of DPA during the intake assessment.

The recommendations formulated by the Belgian Health Council regarding fat and FA (Table 1), were used to evaluate the intakes of this study population. It is recommended that the total fat intake not exceed 30% of E per day. Three-quarters of the population exceeded the tolerable upper intake limit for total fat (30%E) and SFA (10%E), whereas MUFA and PUFA corresponded to the recommendations. In contrast to the intakes of LA and ∑n-6 PUFA, which fit the recommendations for the major part of the population, the mean and median intakes of LNA and ∑n-3 PUFA fell well below the recommended intake (1%E for LNA). The same is true for LC n-3 PUFA. The recommended minimum is expressed for the sum of EPA and DHA, and is at least equal to 0.3%E. The mean intake for EPA + DHA was 0.10%E, and the median was 0.20%E. It can be concluded that the study population has an important deficit for these FA.

Published data of mean dietary intake of PUFA in adult women, expressed in g/d or mg/d, are presented in Table 7.

Nevertheless, the comparisons must be interpreted with caution as survey methods can vary. Moreover, non-negligible differences exist in the age and the total energy intake of the population.

The women of the studies in France, Norway, and Australia seemed to consume less LA, whereas the women in Germany and Japan consumed quite similar levels (11,12,14–17). Conversely, higher absolute LA intake levels were found in another Belgian and a Dutch study with a smaller sample size (30,31) (Table 7). Another pattern was found for LNA. The absolute intake of LNA determined in this study is quite high when compared with other studies, with exception of the Japanese and German studies (12,17) and a study done in pregnant Canadian women (32). In all the other studies, a lower LNA intake was determined. This is remarkable, because even in the present study a comparison of the LNA intake with the Belgian recommendations showed a deficit of this FA in the diet of the Belgian women. Astorg *et al.* (14) translated the mean LNA intake of the female population group in their study into %E; it was 0.38%E. Comparing this with the Belgian recommended minimum level, the French women have an even worse deficit than the Belgian women. Correspondingly, the mean LA/LNA ratio of the French women is far higher (11.10) than the one found in this study. Whereas the essential n-6 PUFA intake seemed rather high in comparison with other studies, the opposite applies to the mean absolute intake of AA, the only LC n-6 PUFA taken into consideration in this study. Most of the other studies found a mean absolute AA intake that was two to three times higher than the mean AA intake determined in this study. Nevertheless, the intake of the food sources that contribute the most AA to the diet are equal compared with those found in the French and the Australian studies (14,16); they are (1) meat, poultry, and eggs (accounting for more than 50% of the AA intake), and (2) fish and seafood. So a probable explanation is that the AA concentration of these food items is underestimated in the FCDBs that were used in this study.

A large variation is found in the intake estimations of LC n-3 PUFA between studies and countries. As for LA and LNA mean intake, the mean LC n-3 PUFA intake is comparable with the results found in the German study (17), as well as with the results of the Dutch study (31). A larger absolute intake of EPA, DPA, and DHA is found in France and especially in Norway and Japan, probably due to larger seafood consumption. In this study, the average seafood consumption of the women (calculated as a mean of the 2 d) was 27.0 (± 44.9) g/d. Welch *et al.* (33) reported the seafood consumption in 10 European countries for men and women between 35 and 74 years old. For women, a mean seafood consumption of 15.9 g/d and 19.9 g/d was found in two German cities, and a mean of 13.3 g/d and 13.4 g/d in two Dutch cities (33). In comparison, French women have a mean seafood consumption ranging between 35.0 g/d and 52.4 g/d, depending on the region where they live; the mean intake of seafood for Norwegian women was 42.9 g/d in south and east Norway and 63.3 g/d in north and west Norway (33). Johansson *et al.* (15) reported a mean intake of 57 g of fish per day for Norwegian women. These results show that the higher seafood consumption in the latter two countries is clearly the main reason for the higher LC n-3 PUFA intake.

Comparisons of food sources of fat and FA are not easy, because the definitions of food groups are not the same in the different studies. The definition of the food groups in this study is based on the French study of Astorg *et al.* (14), so the results of these two studies are quite comparable. The comparison with other results must be seen as an indication.

The main sources for LA found in this study were fats and oils (31.4%), followed by cereal products (16.4%). The important contribution of fats and oils to the LA intake was also found in the French and the Australian studies (accounting for 33.5% and 21.9%, respectively) (14,16), as well as in the Japanese study (13). For AA, the intake was mostly contributed by meat, poultry, and eggs, followed by fish and seafood. The same results were found by the French and Australian authors: meat, poultry, and eggs accounted for 67.2% and 70.15%, respectively, followed by fish and seafood (11.1% and 27.2%, respectively). In the Japanese study, chicken, eggs, and pork together contributed 50.6% to the AA intake.

In the present study, fats and oils were by far the major contributor to LNA intake (45%), especially fatty sauces and margarines. This is at variance with the French study, where fats and oils were only a minor contributor (10%), the major ones being dairy products, fruits and vegetables, and meat, poultry, and eggs (14). Fatty sauces and margarines seem to be much less consumed in France than in Belgium.

In this study, fish and seafood were the major contributors to the EPA, DPA, and DHA intake, representing respectively 87.3%, 66.0%, and 80.0%. In Norway, fish was also the major source (respectively, accounting for 55%, 43%, and 57%), followed by cod liver oil, which was used by 36% of the survey subjects (15). In contrast, cod liver oil, being rich in LC n-3 PUFA, was not consumed by the Belgian women included in this study. In the French data, fish and seafood were the major sources for EPA and DHA (72.0% and 64.7%, respectively) (14), but meat, poultry, and eggs were the first contributor of DPA intake (55%). In Norway, meat and fish were the main sources of DPA (43% each) (15). In the present study, the contribution of meat, poultry, and eggs to the DPA intake was lower (31%). A very recent Australian publication described in detail the contribution of meat sources to the intake of LC n-3 PUFA (11). Their analyses showed that fish and seafood contributed 49.7%, 15.4%, and 69.9% to the intake of, respectively, EPA, DPA, and DHA. On the other hand, meat, poultry, and game products provided, respectively, 44.8%, 73.2%, and 19.6%. This shows that an underestimation of the LC n-3 PUFA content of meat can be crucial, since the consumption of meat and meat products is large compared with that of fish and seafood.

CONCLUSION

In conclusion, analysis showed that the mean intake of total fat and SFA of Belgian women exceeded the Belgian recommendations. With regard to the PUFA intake, the mean intake of n-6

PUFA seemed to be sufficient. In contrast, the mean intakes of LNA and LC n-3 PUFA were far too low. When considering these facts together, it seems advisable to explore ways to investigate food-based strategies to decrease the SFA intake and also increase the n-3 PUFA intake; this is a counterargument to the intake of supplements. Although such supplements can be an easy solution for some women, the presence of other nutrients in food sources of EPA and DHA, such as important amino acids and trace elements, must also be considered. This conclusion is in accordance with one of the conclusions in a recent Dutch report, which stated that an excessive intake of the unfavorable types of fat, such as SFA, increases the likelihood of developing cardiovascular disease by 25%, whereas eating fish once or twice a week reduces this risk 25% (34).

A previous study in Belgium of consumer awareness and beliefs related to n-3 PUFA, their health benefits, and their food sources showed that awareness is poor and beliefs often wrong (35). Nutrition education should play an important role in convincing people of this dietary shift.

ACKNOWLEDGMENTS

The authors gratefully acknowledge financial support from the Belgian Science Policy through the SPSD II project CP/02/56, the Institute for the Promotion of Innovation through Science and Technology in Flanders (IWT-Vlaanderen), and the National Fund for Scientific Research/Flemish Division (Fund No G.0152.01). The dieticians Mrs. M. Bellemans and Mrs. M. De Maeyer (Department of Public Health, Ghent University) are thanked for their important contribution to the fieldwork and the data input of the food consumption data. The reviewers of this paper are thanked for their useful and detailed remarks and suggestions.
