Experimental system. The experiment was conducted at the School of Aquaculture, University of Tasmania. Atlantic salmon parr were obtained from Wayatinah Salmon hatchery (SALTAS, Tasmania, Australia), and 14 fish per tank were randomly stocked into three 300-L tanks in a partial recirculation system (24). The tanks were held at a constant temperature of 19°C in 30 ppt seawater (24) with a photoperiod of 16:8, light/dark. The water was treated through physical, biological, and UV filters. Dissolved oxygen, pH, ammonia, nitrate, and nitrite were monitored daily to ensure water quality remained within parameters recommended for Atlantic salmon (25). A commercially extruded feed (Skretting, Tasmania, Australia) was fed to excess twice a day (0900–1000 and 1600–1700 h) by automatic belt feeders. The salmon had an initial weight of 139.6 + 1.5 g (mean ± SE; $n = 6$), were grown for 105 d, and reached an average final weight of 510.2 ± 13.2 g. Salmon weighing 420.2 ± 6.3 g, $n = 3$, maintained at 15°C and with a similar history and fed on the same diet, provided a reference group that represented baseline temperature conditions.

Sampling. On the last day (day 104) of the trial, fish were killed by a blow to the head after immersion in anaesthetic (benzocaine, 100 mg/L) and two fish were sampled from each tank. Samples of gill tissue were dissected from the first gill arch. Red (average sample weight 1.3 ± 0.2 g, $n = 6$) and white muscle (average sample weight 2.4 ± 0.1 g, $n = 6$) samples were taken from below the dorsal fin. Samples were immediately frozen and stored at –80°C until analysis. Salmon at 15°C were similarly sampled. The experiment was conducted in accordance with the University of Tasmania Animal Ethics guidelines (Investigation A0007719).

Lipid extraction, fractionation, and FA analysis. Samples were freeze-dried and extracted by a modified Bligh and Dyer protocol (26). A single-phase extraction, $CHCl_3$/MeOH/H_2O (1:1:0.9, by vol), was used to yield a total lipid extract (TLE).

Lipid classes were analyzed by an Iatroscan MK TLC-FID analyzer (Iatron Laboratories, Tokyo, Japan). Samples were spotted onto silica gel SIII Chromarods (5 mm particle size) and developed in a glass tank lined with pre-extracted filter paper. The solvent system used for the lipid separation was hexane/diethyl ether/acetic acid (60:17:0.1, by vol) (27). After development for 25 min, the Chromarods were oven-dried and analyzed immediately to minimize adsorption of atmospheric contaminants. Lipid classes were quantified by DAPA software (Kalamunda, Western Australia, Australia). The FID was calibrated for each compound class: PC; cholesterol; cholesteryl ester; oleic acid; hydrocarbon (squalene); wax ester (derived from fish oil); TAG (derived from fish oil); and DAG ether (purified from shark liver oil). To analyze the PL fraction, a second solvent system, chloroform/methanol/water (80:35:3 by vol), was used (28). The Iatroscan was calibrated with PC with equivalent response factors assumed across the PL classes. Retention factors were measured for each phospholipid and compared with standards (Sigma-Aldrich).

An aliquot of TLE was transmethylated in methanol/chloroform/hydrochloric acid (10:1:1, by vol) for 1 h at 100°C. After addition of water, the mixture was extracted three times with hexane/chloroform (4:1, vol/vol) to obtain FAME. FAME were concentrated under nitrogen and treated with N,O-bis(trimethylsilyl)-trifluoroacetamide (50 mL, 60°C, 1 h) to convert hydroxyl groups to their corresponding trimethyl silyl ethers. Samples were made up to a known volume with an internal injection standard (23:0 or 19:0 FAME) and analyzed by GC using an Agilent Technologies 6890N gas chromatograph (Palo Alto, CA) equipped with an HP-5 cross-linked methyl silicone fused-silica capillary column (50 m × 0.32 mm i.d.) and an FID. Helium was used as the carrier gas. Samples were injected, by a split/splitless injector and an Agilent Technologies 7683 Series auto sampler in splitless mode, at an oven temperature of 50°C. After 1 min the oven temperature was raised to 150°C at 30°C min^{-1}, then to 250°C at 2°C min^{-1} and finally to 300°C at 5°C min^{-1}. Peaks were quantified by Agilent Technologies GC ChemStation software. Individual components were identified by mass spectral data and by comparing retention time data with those obtained for authentic and laboratory standards. GC results are typically subject to an error of ±5% of individual component area. GC-MS analyses were performed on a Finnigan Thermoquest GCQ GC-MS fitted with an on-column injector with Thermoquest Xcalibur software (Austin, TX). The GC was fitted with a capillary column similar to that described above.

Fractionation of lipid classes was accomplished by silicic acid column chromatography. The TLE was applied to a 1 g column of silicic acid (preheated to 100°C, 1 h) and separated into neutral lipids, glycolipids, and PL in a stepwise elution of chloroform (10 mL), acetone (20 mL), and methanol (10 mL), respectively (29).

Membrane lipid analysis: ESI-RP-LCMS. PL species were analyzed by LCMS by negative ion ESI. A Waters Alliance 2690 high-performance liquid chromatograph fitted with a Nova-Pak RP C18 column (3.9 × 150 mm) was coupled to a Finnigan LCQ ion trap mass spectrometer fitted with an electrospray source. The mobile phase gradient was methanol/0.25 M ammonium acetate (pH 5), (96:4 vol/vol) to methanol/0.25 M ammonium acetate (pH 5)/hexane (86:4:10 by vol) at 20 min, then to methanol/hexane (80:20 vol/vol) at 25 min, which was held for 10 min. The flow rate was 1 mL min^{-1}. Alternating normal scans in the range *m/z* 600–950 and data-dependent

MS/MS product ion scans were acquired. The MS/MS scans isolated the strongest ion observed, and a collision energy of 40% was applied with all product ions monitored. The capillary temperature was 275°C, sheath gas pressure 600 kPa, auxiliary gas pressure 275 kPa, and the needle voltage was 4 kV. Minor molecular species (>0.1 across all tissues) are not included to simplify the analysis. PL species and regiospecificity were identified by MS and MS/MS breakdown products according to published data (10).

Storage lipid analysis: ^{13}C NMR spectroscopy. Acyl group positional distributions on TAG were determined quantitatively by ^{13}C NMR on a 400 MHz Varian (Palo Alto, CA) Inova Wide Bore spectrometer, with either a Broadband 10 mm probe or a 3 mm MAS Nanoprobe at 25.0 ± 0.1°C. A π pulse at 100.516 MHz, 128 K acquisition with 2.5 s relaxation delay and full nuclear Overhauser effect enhancement and decoupling sequence was employed. Samples were dissolved in 99.96% deuterated chloroform ($CDCl_3$) with *ca.* 0.025 M $Cr(acac)_3$ [tris(acetylacetonato)chromium(III)] as a relaxation agent and brought to a volume of 0.6 mL. TAG fractions that were <10 mg were dissolved in 20–35 μL of $CDCl_3$/$Cr(acac)_3$ in a glass rotor and filled to a total volume of 40 μL and spun at 3.000 ± 0.002 kHz. The number of transients collected was 512 to 8192. A 0.12 Hz Gaussian and a 0.15 Hz Lorentzian window function was applied to the free induction decay prior to transformation, and polynomial baseline correction and drift correction were applied to each spectrum. Peak chemical shifts were referenced to $CDCl_3$ at 77.16 ppm (30).

Statistical analysis. Mean values were reported plus or minus the SEM. Percentage data were arcsin transformed prior to analysis. Normality and homogeneity of variance were confirmed, and a comparison between means was achieved by one-way ANOVA. Multiple comparisons were achieved by Tukey-Kramer HSD (honestly significant difference). Significance was accepted as probabilities of 0.05 or less. Statistical analysis was performed using SPSS (statistical package for social science) for windows version 11 (SPSS, Chicago, IL).

RESULTS

Lipid class. TAG accounted for the largest proportion of the lipid in the diet (88.2%) and in the tissues (81.9–94.1%) (Table 1). The red muscle had significantly ($P < 0.05$) higher percentage of TAG compared with the gill and white muscle, but diet was not significantly different from any sampled tissue. The PL value varied across the tissues and was significantly ($P < 0.05$) higher in the gills (15.8%) and the white muscle (15.5%) than in red muscle (4.8%). The diet contained 8.4% PL and was not significantly different from any tissues. FFA were significantly ($P < 0.01$) higher in the diet (1.7%).

FA profiles of total lipid. The major (>10%) dietary FA were 16:0, 18:1n-9, EPA, and DHA, with 14:0 and 16:1n-7 present at moderate percentage abundances (5–10%) (Table 1). Of all the FA, 16:0, 18:1n-9, and DHA were at high proportions across all tissues, whereas 14:0, 16:1n-7, and EPA were present at moderate percentages. In addition, 18:0 was present at moderate abundance in white muscle and gills. The TLE FA profile of the three tissues reflected closely the profiles of the diet. This was judged by the small statistical difference between the diet and the tissues. There were no significant differences in the relative percentage of monounsaturated FA (MUFA) in any tissue or the diet. The major exception was EPA, which showed a significantly ($P < 0.01$) lower percentage in all the salmon tissues compared with the diet.

A significantly ($P < 0.05$) lower unsaturated FA/saturated FA (UFA/SFA) ratio in the white muscle and significantly ($P < 0.05$) lower n-3/n-6 ratios were observed in all tissues compared with the diet. There was a significant percentage reduction in total n-3 PUFA ($P < 0.01$), total n-6 PUFA ($P < 0.05$), and total PUFA ($P < 0.01$) in white muscle compared with the diet and red muscle.

15°C fish. Lipid class and FA profiles for fish grown at a water temperature of 15°C are shown in Table 2. These fish had a very similar history, and results are included to provide comparison with the fish grown at the elevated temperature of 19°C. The lipid class profiles for the 15°C fish are very similar to 19°C fish (Table 1). The FA profiles showed that in the red and white muscle there was decreased SFA and increased n-3 PUFA and total PUFA in the 15°C fish (Fig. 1).

Lipid class composition of PL. The major (>10%) phospholipid classes in all samples were PE and PC (Table 3). Both PE and PS were significantly ($P < 0.05$) lower in all tissues compared with the diet. PI was significantly ($P < 0.05$) higher in red muscle. Unidentified PL (UPL) consisted of several very polar peaks, which may have included sphingomyelin and lysophosphatidyl derivatives. UPL was significantly higher in all salmon tissues ($P < 0.05$) compared with the diet.

FA profiles of PL. The major (>10%) dietary polar lipid FA (PLFA) were 16:0, 18:1n-9, 20:5n-3, and 22:6n-3, with 14:0, 16:1n-7, and 18:2n-6 present at moderate percentages (5–10%) (Table 3). The major PLFA for the gills were 16:0, 18:0, and 18:1n-9, with 14:0, 16:1n-7, and 22:6n-3 also present in moderate abundance. The major PLFA for white muscle were 16:0, 18:0, 18:1n-9, and 22:6n-3 with 14:0, and 20:5n-3 also present in moderate abundance. The major FA for red muscle PL were 16:0, 18:1n-9, and 22:6n-3, with 14:0, 18:0, and 20:5n-3 also present in moderate abundance.

Accumulation of PUFA was not observed in the PL fraction. This was shown by the decrease in total PUFA percentage across all tissues compared with the FA profile of the 19°C fish. Over 50% of the PLFA in the gill and white muscle were saturates (especially 16:0: 34.4 and 37.1%, respectively), which were significantly ($P < 0.01$) higher than in the red muscle.

Gill PLFA showed a statistically higher percentage of MUFA, especially 18:1n-9 (17.7%), 18:1n-7 (3.9%), and total MUFA (30.2%). This coincided with significantly ($P < 0.01$) lower relative abundances of n-3, n-6, and total PUFA. Lower percentages of n-3, n-6, and total PUFA occurred in the white muscle compared with red muscle.

A significantly ($P < 0.01$) lower percentage of DHA was present in the gills (5.2%) than white muscle (10.5%), but red muscle was significantly ($P < 0.05$) higher (20.1%). The

[h] "Other n-6 PUFA" include 20:2n-6, 20:3n-6, 22:4n-6, and 24:5n-6.
[i] "Other PUFA" include 16:2n-4, 16:3n-4, and 18:2n-9.
[j] Determined by TLC-FID. SFA, saturated FA; MUFA, monosaturated FA; DPA, docosapentaenoic acid; ST, sterol; PL, polar lipid; WW, wet weight; UFA, unsaturated FA; *c*, *cis*.

UFA/SFA ratio was significantly ($P < 0.05$) lower in the gill and white muscle fractions. The n-3/n-6 ratio was significantly ($P < 0.05$) lower in the gills compared with the red and white muscle ($P < 0.05$).

Regiospecific analysis of the membrane lipids. The major PL (>10%) species for the gills were PC 16:0/18:1 (denotes 16:0 at *sn*-1 and 18:1 at *sn*-2 on the PC molecule), PE 18:0/18:1, and PE 18:0/22:6, with moderate percentages (5–10%) of PC 16:0/22:6 and PE 16:0/22:6 (Table 4). The gills had the highest proportion of SFA/MUFA, MUFA/MUFA, and MUFA/PUFA profiles (Fig. 1). The major PL species for white muscle was PE 18:0/22:6, with moderate percentages of PC 16:0/18:1, PC 16:0/22:6, and PE 18:0/20:5. The major PL species for red muscle were PC 16:0/22:6, PE 16:0/22:6, and

[a]Mean values across the row not sharing a common superscript were significantly different ($P < 0.05$) as determined by Tukey–Kramer HSD; $n = 6$. For abbreviations see Table 1.
[b]Other SFA includes 15:0, 17:0, 20:0, 22:0, and 24:0.
[c]Includes 18:3n-3 (minor component).
[d]Other MUFA includes 16:1n-9, 16:1n-5, 18:1n-5, 20:1n-7, 22:1n-9, 22:1n-11, and 24:1n-9.
[e]Other n-3 PUFA include 21:5n-3 and 24:6n-3.
[f]Other n-6 PUFA include 20:2n-6, 20:3n-6, 22:4n-6, and 24:5n-6.
[g]Other PUFA include 16:2n-4, 16:3n-4, and 18:2n-9.
[h]Determined by TLC-FID.

PE 18:0/22:6, with moderate percentages of PE 18:0/20:5 and PE 18:1/22:6.

Faint signals of phosphatidylglycerol (PG) species were detected by LCMS, in particular PG 16:0/18:2, PG 16:0/18:1, PG 18:0/18:2, and PG 18:0/18:1, in some samples. Small amounts of PG 16:0/18:1 were found in all samples, as was sphingomyelin.

Regiospecific analysis of storage lipid: ^{13}C NMR. Where random distribution of a FA occurs across the TAG molecule, 33% of any FA would be expected at the *sn*-2 position. Since the TAG molecule has a symmetric plane, the relative proportions at the *sn*-1 and *sn*-3 positions cannot be identified by ^{13}C NMR. DHA had a high affinity with the *sn*-2 position (62.1–68.3% across the tissues). Docosapentaenoic acid (DPA) (37.3–39.6%) and 18:4n-3 (42.1–46.3%) also had an affinity to the *sn*-2 position. EPA (34.2–36.0% *sn*-2) and 20:4 (32.6–35.3% *sn*-2) had even distribution across the molecule and did not show a preferred regiospecific position (Table 5).

[j]Determined by TLC-FID. UPL, undetermined polar lipid; UFA, unsaturated FA; for other abbreviations see Table 1.

EPA and 18:4n-3 abundances at the *sn*-2 position were significantly ($P < 0.01$) higher in the tissues relative to the diet, whereas that of DPA was significantly ($P < 0.01$) lower. The percent distribution of all the FA did not show significant differences across the three tissues. However, there were significant increases ($P < 0.01$) in EPA and 18:4n-3 and a significant decrease in DPA ($P < 0.01$) in the *sn*-2 position relative to the diet.

DISCUSSION

This is the first detailed examination of the lipid profile of Atlantic salmon at an elevated temperature (19°C). We describe the effect elevated temperature has on the composition of storage and structural lipids of three key tissues in seawater Atlantic salmon. The water temperature of 19°C was considerably above the optimum although representative of environ-

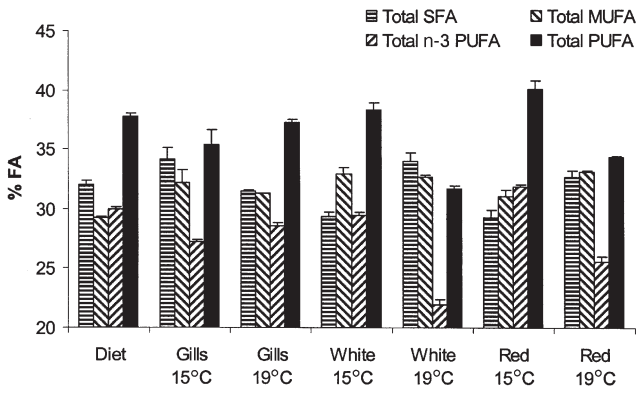

FIG. 1. Abundances of SFA, MUFA, Total ω3 PUFA and Total PUFA From the Total Lipid Extract (TLE) for the Diet, Red Muscle, White Muscle and Gills from Atlantic Salmon Salmo Salar Grown at 15 and 19°C. Values are Means with ± SE.

mental conditions now experienced by an established industry in Tasmania, Australia (23). As often observed, the FA profile of fish, particularly the storage (TAG) fraction, is strongly influenced by diet (31,32). Many studies performed at lower temperatures have shown that salmon accumulate n-3 (with a corresponding reduction in SFA) (21,22,33). We observed, in the red and white muscle, lower levels of total n-3 PUFA and total PUFA and higher SFA in the FA profile in the TLE of the 19°C fish compared with fish grown at 15°C (Fig. 1).

Environmental factors, particularly temperature, have a more significant influence on the structural lipid (PL) fraction (15,18,34,35). Elevated temperature-raised fish had higher SFA in the PLFA and lower levels of n-3, n-6, and total PUFA in the gill and white muscle. These changes suggest adaptation of the cell membrane structure has occurred, which could be explained as a response to the elevated water temperature. In other species it has been shown that there is more PUFA present and less SFA in fish that live in colder temperatures (36). Consideration of both membrane and storage lipids, including regiospecificity, allowed further examination of these adaptive changes.

Membrane lipids. Phospholipids, the membrane lipids that form the cell bi-layers, consist of two FA moieties on a glycerol backbone generally with one of five different functional phosphatidyl head groups attached. Specific FA chains can be attached at either the *sn*-1 or *sn*-2 positions. Fish phospholipids generally contain 16:0 and 18:1n-9 at the *sn*-1 position and 20:5n-3 and 22:6n-3 at the *sn*-2 position (32). This generalization is dependent on the phospholipid class and also on the particular tissue (32). In the present study 16:0 [33.4, 17.0, and 39.3%: gill, white muscle, and red muscle (G,W,R), respectively] and 18:0 (41.1, 23.6, 28.1%: G,W,R) were the major PLFA at the *sn*-1 position with 18:1 (8.9, 3.6, 7.7%: G,W,R) present at low percentages as determined by LCMS. The major PLFA at the *sn*-2 position were 22:6n-3 (46.1, 35.1, 60.7%: G,W,R), 20:5n-3 (13.6, 11.5, 14.2%: G,W,R) and 18:1 (29.2, 11.5, 8.5%: G,W,R).

In the present study the PLFA profile showed a reduced number of statistical differences between tissue FA profiles in the gills and white muscle when compared with the TLE FA profile. This observation is consistent with the PL profile being more functional (membrane structure role) and therefore more adaptive to environmental change and also less influenced by diet. The PLFA profile is also very dependent on the particular tissue analyzed.

Phospholipids generally contain high levels of 16:0, 18:1n-9, 20:5n-3, and 22:6n-3 as principal FA in the membrane bilayer (32). The PLFA fractions from the present study on Atlantic salmon contained these principal FA, as well as an enhanced percentage of 18:0 with a significantly lower percentage ($P > 0.01$) of 18:2n-6 compared with the diet. Significantly lower percentages ($P > 0.05$) of n-3, n-6, and total PUFA occurred in the gills and white muscle in the PLFA compared with red muscle and the diet (Table 3). The relative percentage of DHA was lower in the gill (5.2%) and in white muscle (10.5%), but was significantly higher ($P > 0.05$) in red muscle (20.1%). In the gill, the percentages of n-3, n-6, and total PUFA were lower, leading to higher percentages of 16:0, 18:1, and 18:0 FA, which are important pulmonary surfactants (37). Higher percent levels of DHA in the gill TAG may be attributed to the presence of residue blood in the gill tissue. The reduction of PUFA in white muscle is most likely due to the effect of elevated temperature.

The regiospecific distribution of membrane PL cannot be determined by traditional FA analysis. ESI-RP-LCMS provides a rapid method to compare relative percentages of the individual intact lipids across tissues. There is only limited work published on phospholipid molecular species distribution in salmonoid tissues determined by tandem MS (10,38). These studies, on the distribution of individual molecular species across phospholipid species, focused on the liver (38) and head kidney (10) tissues. We examined the molecular species distribution of the gill, white and red muscle and also compared them with the diet.

The principal molecular species in muscle PC in most fish is 16:0/22:6 (9). Increased PC 16:0/22:6 tends to fluidize the membrane and reduce the temperature sensitivity of electrolyte permeation (18). PC 16:0/22:6 is the predominant lipid in the PC fraction of the muscle tissues of Atlantic salmon, but not in the gills. The PI fraction was relatively high in 18:0 and low in PUFA, which was predominantly 20:4n-6; this has previously been observed in fish and was suggested as being due to a role in eicosanoid metabolism (9).

Studies on the molecular diversity of wild Atlantic cod muscle showed that SFA/PUFA and MUFA/PUFA dominated, especially PC 16:0/20:5, PC 16:0/22:6, PE 16:0/22:6, and PE 18:1/22:6 (8). The PUFA/PUFA totaled between 21 and 38% in the PC and PE fractions for cod (8). Our results showed very little PUFA/PUFA, 0.5% PC, 1.8% PE, and 4% total for white muscle and 2.7% PC, 4.7% PE, and 8.4% total in red muscle. This finding is consistent with the elevated water temperature and lower PUFA percentages noted earlier for the FAME profiles. The SFA/PUFA species dominated (42.7–64.2%) throughout the tissues, with the gill showing low (28%) levels of SFA/MUFA.

Storage lipids. Along with the structural membrane bi-layer function, lipids play an important role in energy storage in fish (39) in the form of TAG. Fish oil, which is predominantly TAG, is nutritionally important for the supply of n-3 LC-PUFA in the human diet. However, in salmon it is recognized that dietary TAG are hydrolyzed to FFA in the gastrointestinal tract prior to absorption. The regiospecific position of the dietary lipids is less important in fish than in mammals, including humans. It is well documented that consuming quantities of LC-PUFA in the form of TAG is nutritionally beneficial (40), with recent reports suggesting the position of the LC-PUFA on the glycerol backbone is also important in human nutrition (1). In general, fish oils have SFA and MUFA preferentially located at the *sn*-1 and *sn*-3 positions on the glycerol backbone, whereas LC-PUFA are generally preferentially located in the *sn*-2 position (32).

The original speculation that TAG structure might influence lipid absorption was based on observed differences in fat absorption by infants fed breast or formulated milk (3). It was shown that palmitate (16:0) in the *sn*-2 position is generally not hydrolyzed by pancreatic lipase, and the remaining MAG was well absorbed. However, when palmitate was in the *sn*-1 and *sn*-3 positions, it was hydrolyzed to form FFA, which were poorly absorbed (3). The same argument could be used for the delivery of LC-PUFA in human diet. LC-PUFA of TAG from Atlantic salmon are largely at the *sn*-2 position and are not hydrolyzed by pancreatic lipases and therefore can be absorbed into the intestinal mucosal cells of the small intestine.

It has also been shown that in whale oil EPA and DHA in the *sn*-1 and *sn*-3 positions showed a steric hindrance to pancreatic lipase hydrolysis, which may decrease their intestinal absorption (41). Therefore, fish oil with large quantities of LC-PUFA in the *sn*-2 position will be nutritionally more desirable since they are at the preferred position for absorption into the body.

The effect of regiospecific distribution of the TAG molecule on absorption and metabolism has not been thoroughly investigated in fish oils due to the wide diversity of molecular species. There have been few studies showing the relative percentages of EPA and DHA across the glycerol backbone in marine oils. Available results include fish oil (DHA 79% and EPA 53%, *sn*-2 position) (42); salmon oil (DHA 72.6% and EPA 37.8%, *sn*-2) (43); this study (DHA 62.1–68.3% and EPA 34.2–36.3%, *sn*-2), and cod liver oil (DHA 74.4% and EPA 39.7%, *sn*-2) (43). Seal oil shows contrasting regiospecificity (DHA 4.4% and EPA 4.4%, *sn*-2) (42).

There was no significant difference in the regiospecific composition of TAG across the three tissues in Atlantic salmon in the present study. The majority of DHA for all tissues is at the *sn*-2 position (62.1–68.3%), which is slightly lower compared with the 15°C fish (68.4–69.7%) and other literature for salmon oil (72.6%) (43). Our results suggest a reduced percentage of DHA at the *sn*-2 position at elevated temperature, but further work is needed to ascertain this effect. EPA showed a significant increase ($P < 0.01$) in percentage at the *sn*-2 position (34.7–36.0%) compared with the diet (23.4%). The percentages of EPA at the *sn*-2 position are comparable with results

from previous work on Atlantic salmon (44). Interestingly, the proportions of 18:4n-3 at the *sn*-2 position (42.1–46.3%) significantly ($P < 0.05$) increased compared with the diet (35.0%). The significant ($P < 0.05$) changes observed in the regiospecific distribution of DPA, 18:4n-3, and EPA, in salmon tissues compared with diet, showed that this distribution is not just a reflection of diet. Further biosynthesis or some adaptive changes have taken place in the storage of lipids as TAG in Atlantic salmon.

Temperature effects. Temperature has a major influence on the membrane and storage lipids of ectothermic animals such as Atlantic salmon, which need to adapt to seasonal and occasional abrupt changes in environmental temperature (15,17,18,31). To counteract these changes, membrane lipids may adapt in several ways: by altering the unsaturation and chain length of the FA (45); by changing the distribution of FA within the phospholipid molecules (33,46); and by altering the composition of the polar head group of the phospholipids (16,47). Gill FA profiles have been shown to vary with environmental temperature (48). In general, colder temperatures lead to an increase in unsaturation in gill lipids, thus maintaining its membrane fluidity (33,49).

Introducing a double bond to 18:0 changes the m.p. from about 70 to 20°C (39), with additional double bonds further reducing m.p. (22:6n-3, –45°C; 20:5n-3, –52°C) (39). By exploiting the diversity of the lipid structure, Atlantic salmon changes its membranes to provide physical properties to suit the environmental temperature. Since different mixtures of phospholipid molecular species, which share the same overall FA composition, can display a marked difference in physical properties, remodeling of molecular species may also help fish adapt to differences in temperature.

It is well documented that tissue FA composition of salmon, especially muscle tissue, reflects closely the FA composition of their diet (31–33,50–52). In the present study of salmon grown at 19°C, we observed significant differences between diet and tissue profiles. A significantly higher ($P < 0.05$) percentage of 16:0 occurred in white muscle, with a significantly ($P < 0.05$) higher percentage of 18:0 also observed in white muscle as well as the gills. The major differences were a significantly ($P < 0.05$) lower percentage of PUFA, in particular EPA, across all tissues compared with the diet. It has been shown that LC-PUFA, especially DHA, showed preferential deposition and retention at lower temperatures (5–15°C), regardless of the concentration present in diet (33,50,51). Comparing these results with those for fish grown at 15°C (Table 2) shows the higher temperature increased the percentage of SFA while reducing total PUFA and n-3 PUFA, particularly DHA (Fig 1). These findings indicate that there was a major adaptation of the total body lipid that was due to the higher temperature. In our study, at the elevated water temperature, there were also significantly ($P < 0.05$) lower percentages of n-3 PUFA and total PUFA in white muscle tissue. It is presently unclear and remains to be validated whether the PUFA have been directed preferentially toward metabolism, presumably for energy production, rather than to storage in muscle tissue in the form of TAG.

Cold climate has been associated with an increase in the proportions of PE and decreased proportions of PC in fish (46,49). Our results show PE was the major phospholipid in Atlantic salmon grown at 19°C. The ratio of UFA/SFA provides an assessment of the proportion of both MUFA and PUFA to SFA, and the ratio will be unchanged if MUFA replace PUFA (22). At lower temperatures, there is an accumulation of UFA and a reduction of SFA, which leads to an increase in the UFA/SFA ratio (22). As mean water temperature increases, a reduction in the UFA/SFA ratio for Atlantic salmon occurs at 10°C (4.0 UFA/SFA ratio) (35), at 11°C (3.4) (50), and at 12°C (2.5) (53). A trial looking at dietary lipids at two temperatures (2 and 8°C) showed a high UFA/SFA ratio for the muscle fraction where the diet was most like a commercial diet (high-fat fish oil). The trial separated both the polar and neutral lipids with UFA/SFA being 7.1 at 2°C and 7.0 at 8°C for PL and 5.9 at 2°C and 5.3 at 8°C for the neutral lipids (22). Our 15°C fish had a higher UFA/SFA ratio (2.4) in the red and white muscle, which is due to an accumulation of UFA (especially PUFA) in the muscle at the lower temperatures. Our results for fish grown at an elevated temperature are consistent with these patterns with UFA/SFA ratios of 0.7–1.6 observed for the PL and 1.9–2.2 for the TLE, the latter also largely neutral (TAG) lipid (81–94% of TLE). At 19°C a significant ($P < 0.05$) decrease in UFA/SFA occurred in the white muscle for the TLE fraction, with a highly significant ($P < 0.05$) decrease in the white muscle and gill tissues also occurring in the PL.

A study looking at Atlantic salmon cell culture and the effect on phospholipid class and its metabolism showed that temperature significantly affected the incorporation of PUFA in a phospholipid class (49). There was higher PUFA incorporation into PC at 10°C than at 22°C, clearly showing temperature to have an important consequence for membrane structure and possibly for function (49). In cell culture there was an increase in levels of PUFA, altered distribution of PUFA within the phospholipid classes, and decreased metabolism of C_{18} PUFA for cells grown at 10°C compared with those at 22°C (49). It has also been shown, in the marine dinoflagellate *Crypthecodinium cohnii* grown at different temperatures (16–27°C), that at the lower temperature there was a decrease in SAT/SAT and an increase in SAT/PUFA species (14).

On average, there is more PUFA present and less SFA in species of fish that live in colder regions (36,49). High levels of SFA in diets have been associated with poor human health, and recommendations have been made to reduce SFA levels in diets (54). It is also well known that eating foods containing MUFA and specific n-3 and n-6 LC-PUFA have associated health benefits (55–58). As a source of these MUFA and PUFA, fish and especially fish oil have been traditionally the major resource. Increased SFA in white muscle has implications for the salmon aquaculture industry in regions where water can reach temperatures of 19°C and beyond in the warmer months. The results also suggest a reduction in the need for dietary PUFA over these warmer months. Economically this would be advantageous to the aquaculture industry due to the high cost involved with supplying LC-PUFA-rich fish oil in the diet. Con-

versely, if harvest occurs over these warmer months, the percentage of LC-PUFA in these fish will be lower and will reduce the nutritional quality of the product with respect to n-3 LC-PUFA content. The precise physiological significance of the phospholipid distribution and how incorporation of these results into feed formulation may occur remains to be developed. With new methods such as LCMS and ^{13}C NMR becoming more accessible and automated, regiospecific analysis can be routinely applied in investigations of marine oils. Such information, as it becomes available, will ultimately provide improved understanding on the distribution, function, and bioactivity of LC-PUFA-containing oils.

ACKNOWLEDGMENTS

The authors gratefully acknowledge Keith Irwin for technical assistance at UTAS, Danny Holdsworth for management of the CSIRO GC-MS facility, Rhys Hauler at Skretting (Tasmania, Australia) for the supply of feeds, and Harry King at SALTAS Wayatinah salmon hatchery for the supply of fish. Matthew Miller was supported by an Australian postgraduate award (APA) and a CSIRO Food Futures Flagship postgraduate award. Dr Howard Knapp and two anonymous referees are thanked for their helpful comments on the manuscript.

Convenient and Efficient Syntheses of 4-Hydroxy-2(*E*)-nonenal and 4-Oxo-2(*E*)-nonenal

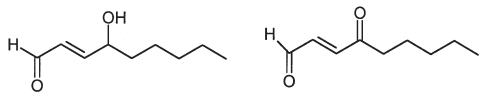
Reshma F. Kurangi[a], Santosh G. Tilve[a], and Ian A. Blair[b]

[a]Department of Chemistry, Goa University, Taliegao Plateau, Goa, India, and [b]Center for Cancer Pharmacology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania 19104-6160, USA

ABSTRACT: Lipid peroxidation products 4-hydroxy-2(*E*)-nonenal (HNE) and 4-oxo-2(*E*)-nonenal (ONE) were conveniently synthesized using Wittig and Horner-Wardsworth-Emmons (HWE) reaction. Wittig or HWE reaction between an easily prepared phosphorane or phosphonate with glyoxal dimethyl acetal gave a protected 4-oxo-2(*E*)-nonenal. Hydrolysis gave 4-oxo-2(*E*)-nonenal, whereas reduction followed by hydrolysis gave 4-hydroxy-2(*E*)-nonenal.

Paper no. L10054 in *Lipids 41*, 877–880 (September 2006).

Lipid peroxidation in biological systems produce many degradation products including 4-hydroxy-2(*E*)-nonenal (HNE) **1** and 4-oxo-2(*E*)-nonenal (ONE) **2** (1,2). These are well known for their genotoxic and cytotoxic effects (1,3–5). The extreme cytotoxicity of HNE is a manifestation of its ability to inhibit several enzymes like protein kinase C, adenylate cyclase, glyceraldehyde-3-phosphate dehydrogenase, and others through modification of nucleophilic amino acid residues (6–9). HNE has been shown to induce apoptosis (10,11) and to cause changes in global gene expression (12). HNE readily modifies nucleophilic protein side chains and DNA bases and its bifunctionality results in protein cross-linking (13,14).



1 **2**

There is increasing evidence that HNE is casually involved in most of the pathophysiological effects associated with inflammatory and oxidative stress in cells and tissues (15,16). HNE is thought to play a significant role in neurodegenerative diseases, in particular Alzheimer's disease (17–20) and Parkinson's disease (21–23). In addition to studies on its toxicity, protein and DNA adducts of HNE are commonly used as a biomarker for the occurrence and/or the extent of lipid peroxidation (24).

ONE is an even more potent electrophile and therefore more neurotoxic and highly protein reactive (5). Thus, both HNE and ONE participate in the formation of DNA adducts, making it possible to assess the role of lipid peroxidation in mutagenesis and carcinogenesis (2).

We required substantial amounts of these compounds for our study. Previous procedures for HNE preparation employed variations in the Grignard reaction (25–30), isomerization of 2-yne-1,4-diols with ruthenium catalyst (31), a method via 1,3-bis(methylthio)allyl-lithium (32), a sequence of addition/elimination/substitution reaction performed on the corresponding saturated aldehyde (33,34), epoxidation of 3(*Z*)-nonenol, oxidation, and isomerization (35). A method for chiral synthesis for HNE is also reported (36) which involves Sharpless epoxidation, reaction with an unstable Wittig reagent followed by isomerization (36). The methods for the synthesis of ONE employed lithiation of furan using *n*-BuLi, alkylation using *n*-pentyliodide, followed by either methoxylation using bromine in methanol, ring cleavage and isomerization (37), or oxidative ring opening of furan using PCC (38). We report herein a simple and convenient method for the preparation of HNE **1** and ONE **2.**

EXPERIMENTAL PROCEDURES

^{1}H NMR and ^{13}C NMR spectra were recorded on 300-MHz and 400-MHz Bruker instruments. The multiplicities of carbon signals were obtained from a distortionless enhancement by polarization transfer (DEPT) experiment. Chemical shifts (ppm) are relative to the internal standard Me_4Si (0 ppm). IR spectra were recorded on a Shimadzu FT-IR spectrophotometer (KBr pellet or neat sample). TLC was performed on silica gel G (13% $CaSO_4$ as binder). Triethylphosphonoacetate was purchased from Aldrich Chemical Company (Sigma-Aldrich, Mumbai, India), and Glyoxal dimethyl acetal was purchased from Lancaster (Lancaster, A Clariant Group Company, Chennai, India).

The stable Wittig reagent ethyl (triphenylphosphoranyliden)acetate **3a** was acylated with hexanoyl chloride to provide acylated Wittig reagent **4a** (39). The Wittig reagent **4a** on decarboxylative hydrolysis provided acyl Wittig reagent 1-(triphenylphosphoranylidene)-2-heptanone **5a** (Scheme 1).

The diethyl-2-oxoheptylphosphonate **5b** was prepared by acylating triethyl phosphonoacetate to obtain **4b**. Hydrolysis and decarboxylation of **4b** gave phosphonate **5b** (Scheme 2).

On condensation of **5a** or the anion of phosphonate **5b** with glyoxal dimethyl acetal, an α,β-unsaturated ketone **6** was formed, which on deprotection gave ONE **2** and after reduction followed by deprotection gave HNE **1** (Scheme 3).

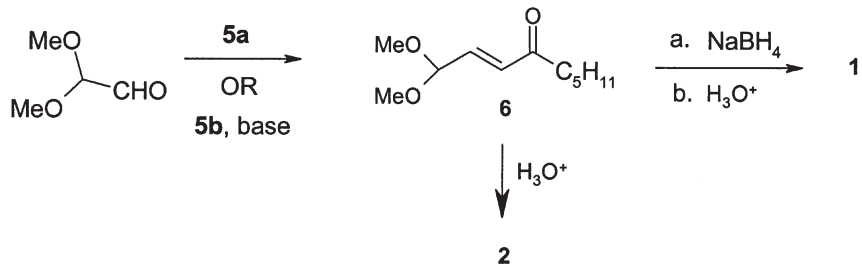

SCHEME 3

*Preparation of Wittig reagent (**5a**).* The stable Wittig reagent **3a**, 5.2 g (14.8 mmol), dissolved in toluene (15 mL) was added to hexanoyl chloride 1 g (7.4 mmol). The yellow solid obtained, after stirring for 5.0 h at room temperature, was filtered. The product obtained after concentration of the filtrate under reduced pressure was 3.1 g (**4a**, yield 93.5%). IR (KBr): ν_{max} 2949.16, 2927.94, 2850.00, 1662.64, 1556.55, 1103.28, 752.20, 692.40 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ_{ppm} 0.63 (t, 3H, J = 7.1 Hz, CH_3), 0.83 (t, 3H, J = 6.8 Hz, CH_3), 1.28 (m, 4H, CH_2), 1.59 (m, 2H, CH_2), 2.84 (t, 2H, J = 7.6 Hz, CH_2CO), 3.70 (q, 2H, J = 7.1 Hz, CH_2), 7.40–7.65 (m, 15H, ArH). A solution containing 1.70 g (3.8 mmol) of phosphorane **4a** in a mixture of trifluoroacetic acid (15 mL) and water (2.5 mL) was heated under reflux for 6.0 h. The reaction mixture was then poured onto ice and basified with 2% sodium bicarbonate solution. This was followed by extraction with diethyl ether (3 × 10 mL). The combined organic extracts were dried over anhydrous Na_2SO_4 and evaporated under reduced pressure. The residue was purified by column chromatography using ethyl acetate/hexanes (1:5 vol/vol) to obtain 0.71 g (yield 50%) of **5a**. IR (KBr): ν_{max} 2927.56, 1537.25, 1436.00, 1392.31, 1195.14, 751.21, 749.51, 719.45 cm^{-1}. ^1H NMR ($CDCl_3$, 400 MHz) δ_{ppm} 0.80 (t, 3H, J = 7.0 Hz, CH_3), 1.25 (m, 4H, 2 × CH_2) 1.58 (m, 2H, CH_2), 2.22 (t, 2H, J = 7.1 Hz, CH_2CO), 4.37 (br s, 1H, $CH{=}PPh_3$), 7.2–7.6 (m, 15H, ArH).

*Preparation of **5b**.* A solution of hexanoyl chloride 5.8 g (43.12 mmol) in dry toluene (21 mL) was slowly added over a period of 2.0 h. to a cold solution (5°C) of triethyl phosphonoacetate (9.7 g, 43.12 mmol), $MgCl_2$ (4.1 g, 43.12 mmol), and triethylamine (13.06 g, 129.4 mmol) in toluene (125 mL). The reaction was stirred for 6.0 h at room temperature; the reaction was then quenched into an ice-cold solution of 10% H_2SO_4 (125 mL). The two layers were separated and the aqueous layer was extracted with ethyl acetate (4 × 25 mL). The combined organic extracts were dried over Na_2SO_4. The product **4b** obtained after filtration and concentration of the organic layer was 13.3 g (yield 96.18%). The compound was judged as pure by observation of a single spot on TLC (ethyl acetate/hexanes 2:3 vol/vol). A solution of **4b** (13.3 g, 43.4 mmol) and *p*-toluenesulfonic acid (0.21 g, 1.2 mmol) in H_2O (175 mL) was heated under reflux for 3.0 h. The reaction mixture was extracted using diethyl ether (3 × 50 mL). The combined organic extracts were dried over Na_2SO_4. The product obtained after filtration and solvent evaporation under reduced pressure was purified by silica gel column chromatography (ethyl acetate/hexanes, 1:5 vol/vol) to obtain 8.1 g (yield 74.7%) of **5b**. IR (neat): ν_{max} 2958.00, 2932.00, 1708.04, 1254.75, 1025.21, 964.45 cm^{-1}. ^1H-NMR ($CDCl_3$, 300 MHz) δ_{ppm} 0.81 (t, 3H, J = 6.9 Hz, CH_3), 1.20 (m, 4H, 2 × CH_2), 1.27 (t, 6H, J = 7.0 Hz, OCH_2CH_3), 1.52 (m, 2H, CH_2CH_2CO), 2.55 (t, 2H, J = 6.9 Hz,

CH_2CO), 3.00 (d, 2H, J = 22.8 Hz, $COCH_2P$), 4.06 (q, 2H, J = 7.0 Hz, OCH_2CH_3), 4.11 (q, 2H, J = 7.0 Hz, OCH_2CH_3).

*Preparation of α,β-unsaturated ketone (**6**) from **5a.*** A solution containing glyoxal dimethyl acetal 4.0 g (10.7 mmol) and Wittig reagent **5a** 1.8 g (11.7 mmol) in methanol (20 mL) was heated at reflux for 3.0 h. The solvent was removed under reduced pressure and the residue was chromatographed (column chromatography, hexanes), giving 1.26 g (yield 59.03%) of **6** as an oil. IR (neat): ν_{max} 2956.87, 2933.73, 1709.00, 1680.00, 1130.29, 1058.92, 979.84 cm^{-1}. ^{1}H-NMR ($CDCl_3$, 300 MHz) δ_{ppm} 0.8 (t, 3H, J = 6.75 Hz, CH_3), 1.2 (m, 4H, 2 × CH_2), 1.56 (m, 2H, CH_2), 2.5 (t, 2H, J = 7.35 Hz, CH_2CO), 3.2 (s, 6H, OCH_3), 4.9 (d, 1H, J = 4.2 Hz, C*H*$(OCH_3)_2$), 6.3 (d, 1H, J = 16.2 Hz, =C*H*CO), 6.55 (dd, 1H, J = 16.2 & 4.2 Hz, CH=C*H*-CH). ^{13}C-NMR ($CDCl_3$) δ_{ppm} 14.20 (C9), 22.41 (C8), 23.71 (C7), 31.40 (C6), 40.65 (C5), 52.90 (C1), 101.10 (OCH_3), 132.10 (C2), 139.90 (C3), 200.46 (C4).

*Preparation of α,β-unsaturated ketone (**6**) from **5b.*** A solution of 1 g (25 mmol) of NaOH in 2 mL of H_2O was added to the mixture of 0.58 g (2.3 mmol) of **5b**, 0.35 g (3.3 mmol) of glyoxal dimethyl acetal, 0.04 g of tetrabutylammonium iodide in 3 mL of dichloromethane. After 30 min of stirring at 28°C, the reaction mixture was extracted with dichloromethane (3 × 5 mL). After drying all the combined organic layers over Na_2SO_4, filtration, and concentration, the resulting residue was passed through a silica gel column (hexanes) to obtain 0.43 g (yield 92.45%) of **6**.

*Preparation of **2.*** A solution containing α,β-unsaturated ketone **6** (0.1 g, 0.5 mmol) and citric acid (0.1 g) in water (10 mL) was stirred at room temperature for 2.0 h and then extracted in chloroform (3 × 10 mL). Combined organic extracts were concentrated to obtain 0.062 g (yield 80%) of the product. IR (neat): ν_{max} 2956.87, 2933.73, 2872.00, 1701.00, 1680.00, 1350.00, 1130.00, 1058.00 cm^{-1}. ^{1}H-NMR ($CDCl_3$, 300 MHz) δ_{ppm} 0.9 (t, 3H, J = 7.00 Hz, CH_3), 1.28 (m, 4H, 2 × CH_2) 1.61 (m, 2H, CH_2), 2.56 (t, 2H, J = 7.00 Hz, CH_2CO-), 6.35 (dd, 1H, J = 17.00 and 7.00 Hz, =CH-CHO), 6.6 (dd, 1H, J = 17.00, =CHCO), 9.78 (d, 1H, J = 7.00 Hz, CHO).

*Preparation of **2.*** To the stirred solution of **6** (0.1 g, 0.5 mmol) in dichloromethane (2 mL) was added 0.152 g of montmorillonite K-10 (40) and stirred at room temperature for 30 min. The reaction was filtered, the residue was washed with dichloromethane (2 × 5 mL), and the combined filtrate concentrated under vacuum to give 0.071 g (92%) of pure 4-ONE.

*Preparation of **1.*** Sodium borohydride 0.0208 g (0.55 mmol) was added to the solution of 0.1 g (0.5 mmol) of **6** in 5 mL absolute ethanol. After stirring the reaction for 2.0 h at 28°C, the solvent was removed under vacuum. To the residue, water (5 mL) was added and then extracted in diethyl ether (3 × 5 mL). The combined organic extracts were dried over anhydrous sodium sulfate, filtered, and concentrated under vacuum to obtain 0.097 g (96%) of the protected HNE. IR (neat): ν_{max} 3442.94 (br), 2931.80, 2858.51, 1130.29, 1053.13, 970.19 cm^{-1}.

To the stirred solution of the above protected HNE (0.0813 g, 0.4 mmol) in dichloromethane (2 mL) was added 0.123 g of montmorillonite K-10 and stirred at room temperature for 30 min. The reaction was filtered, the residue was washed with dichloromethane (2 × 5 mL), and the combined filtrate was concentrated under vacuum to give 0.064 g (83.5%) of pure HNE

IR (neat): ν_{max} 3442.94 (br), 2931.80, 2858.51, 1693.50, 975.98, 734.88. ^{1}H-NMR ($CDCl_3$, 300 MHz) δ_{ppm} 0.91 (t, 3H, J = 7.00 Hz, CH_3), 1.33 (m, 5H, 2 × CH_2 and C*H*CHOH), 1.65 (m, 2H, C*H*$_2$CH$_2$CHOH), 2.62 (t, 1H, J = 7.1 Hz, HC*H*CHOH), 4.45 (m, 1H, C*H*OH), 6.33 (m, 1H, CHOC*H*=), 6.84 (dd, 1H, J = 4.8, J = 15.6 Hz =C*H*CHOH), 9.6 (d, 1H, J = 7.1 Hz, CHO).

RESULTS AND DICUSSION

Previously described methods (25–38) mostly require anhydrous, inert, and/or cryogenic reaction conditions, use of organometallic reagent, and are used only for the preparation of either HNE or ONE. We required large amounts of both ONE and HNE for our studies so we visualized a convergent approach. The first approach using phosphorane gives us the key intermediate **6** in slightly low yield (59%) due to its decomposition on silica gel column. The latter phosphonate approach (Horner-Wardsworth-Emmons) was the most efficient method giving **6** in 92.5% yield. ONE was obtained from **6** using citric acid for hydrolysis in 74% overall yield. Use of montmorillonite K-10 (40) provided ONE in 83% overall yield. HNE was obtained from **6** by reduction with $NaBH_4$ followed by deprotection using montmorillonite K-10 in 80.7% overall yield. Both our methods are advantageous over the earlier methods in terms of overall yield, simplicity of procedures, availability of the chemicals, and also are easily scalable. In both methods the unsaturated ketone **6** has exclusive *E* geometry.

ACKNOWLEDGMENTS

The authors are thankful to University Grants Commission, India, and the United States National Institutes for Health (RO1-CA CA 91016) for their financial support. We also thank the National Institute of Oceanography, Goa and Indian Institute of Science, Bangalore, for the analysis of samples.

REVIEW

Anticancer Activity of Natural and Synthetic Acetylenic Lipids

Valery M. Dembitsky*

Department of Medicinal Chemistry and Natural Products, School of Pharmacy, The Hebrew University of Jerusalem, Jerusalem, Israel

ABSTRACT: This review is a comprehensive survey of acetylenic lipids and their derivatives, obtained from living organisms, that have anticancer activity. Acetylenic metabolites belong to a class of molecules containing triple bond(s). They are found in plants, fungi, microorganisms, and marine invertebrates. Although acetylenes are common as components of terrestrial plants, fungi, and bacteria, it is only within the last 30 years that biologically active polyacetylenes having unusual structural features have been reported from plants, cyanobacteria, algae, invertebrates, and other sources. Naturally occurring aquatic acetylenes are of particular interest since many of them display important biological activities and possess antitumor, antibacterial, antimicrobial, antifouling, antifungal, pesticidal, phototoxic, HIV-inhibitory, and immunosuppressive properties. There is no doubt that they are of great interest, especially for the medicinal and/or pharmaceutical industries. This review presents structures and describes cytotoxic and anticancer activities only for more than 300 acetylenic lipids and their derivatives isolated from living organisms.

Paper no. L10086 in *Lipids 41*, 883–924 (October 2006).

Natural acetylenic lipids and their derivatives have been isolated from a wide variety of plant species, cultures of higher fungi, and marine invertebrates (1–8). Many of them display important biological activities, including antitumor, antibacterial, antimicrobial, antifungal, phototoxic, and other chemical and medicinal properties (9,10). Currently, about half of all prescribed medicines are extracted or derived from terrestrial plants and microorganisms. Most of the synthetic drugs, it should be noted, were originally inspired by novel compounds discovered in terrestrial organisms (11–13). Plants have been used worldwide since antiquity for treatment of various human ailments. Their use is still quite prevalent in developing countries in the form of traditional/folkloric medicine.

Intensive chemical and pharmacological studies during the last five decades have led in many cases to validation of traditional claims and facilitated identification of the traditional medicinal plants and of their active principles. Biological activities of acetylenes and related compounds from higher plants have been studied intensively in recent years, and their activity in various organisms is now well documented. More than 1000 acetylenic metabolites have been isolated from plants, fungi, microorganisms, and marine invertebrates and identified (1–5,14–17).

In the past several decades, natural acetylenic compounds have been isolated from a wide variety of macro- and microalgal species, freshwater and marine cyanobacteria, and other aquatic organisms. Extensive pharmacological screening performed on aquatic species resulted in discovery of novel antitumor agents (1,5,6). The purpose of this review is to summarize antitumor and cytotoxic properties of 318 terrestrial and aquatic acetylenic natural products, belonging to diverse structural classes, including aliphatic and cyclic polyketides, terpenes, steroids, lipids, carotenoids, and peptides. The species yielding these bioactive compounds comprise a taxonomically diverse group of terrestrial and aquatic organisms (1,18–20).

ACETYLENIC METABOLITES FROM PLANT SPECIES

Two polyacetylenes, heptadeca-3-oxo-4,6-diyne-9,10-diol (panaxacol **1**) and its dihydro derivative (dihydropanaxacol **2**) were isolated from callus of the *Panax ginseng*. Both compounds inhibited the growth of Yoshida sarcoma cells in tissue culture, and have been synthesized (21–24). Panaxyne (**3**) (tetradeca-13-ene-1,3-diyne-6,7-diol) was isolated from the Korean red ginseng (25,26). The ED_{50} (dose that is effective in 50% of test subjects) value of panaxyne for cytotoxicity against L-1210 cell was 11 μg/mL. The cytotoxic activity of the compound was lower than that manifested by other ginseng polyynes, which was presumably due to a lack in the panaxyne molecule of an essential structural part (hept-1-en-4,6-diyne-3-ol). Another polyacetylene compound isolated from *P. ginseng* possessed a diyne-ene and an epoxy moiety (27). Tetradeca-13-ene-1,3-diyne-6,7-epoxide (panaxyne epoxide **4**) revealed cytotoxic activity against L-1210 cells (27).

The content of some polyacetylenes in *P. ginseng* is quite high. Thus, panaxydol (**5**), panaxynol (falcarinol) (**6**), and panaxytriol (**7**) are present in red ginseng powder at concentrations of 297, 250, and 320 μg/g, respectively. The antitumor alcohols panaxydol and panaxynol, isolated from a powder of the root of P. ginseng, inhibited the growth of various kinds of cultured tumor cell lines (28–32).

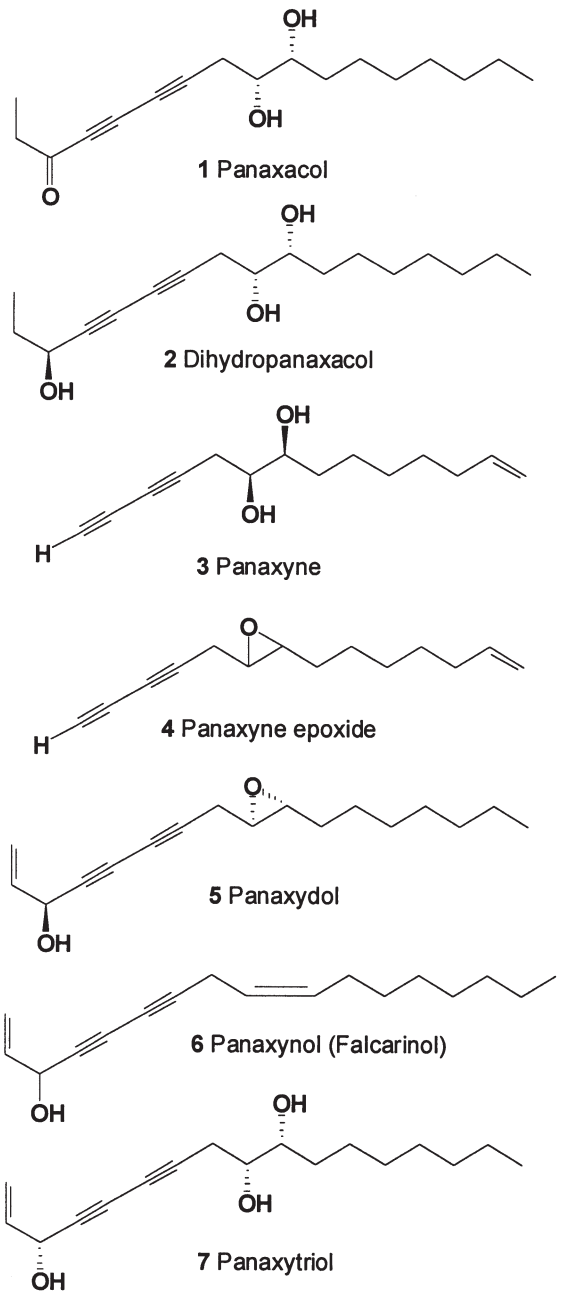
Abbreviations: A549, lung carcinoma cells; COX, cyclo-oxygenase; ED_{50}, dose that is effective in 50% of test subjects; HeLa, cervical cancer cells; IC_{50}, concentration that is inhibitory to 50% of the test subjects; KB, KB carcinoma cells; L-1210, murine leukemic cells; LC_{50}, concentration lethal to test animals in a given time, usually 4 h; LOX, lipoxygenase; MK-1, human gastric adenocarcinoma; P388, murine lymphocytic leukemia; PA, phosphatidic acid; PC, phosphatidylcholine; PQ, panaquinquecol.



The α-cyclodextrin complexes of **5** and **6** inhibited growth of various kinds of cultured cell lines in a concentration-dependent fashion. Their inhibitory activity was much stronger against malignant cells than against normal cells. ATPase activities of cells from Sarcoma 180 and rat liver were slightly inhibited by panaxydol (**5**). Activities of 5′-nucleotidase and succinate cytochrome C reductase in Sarcoma 180 cells and in rat liver, respectively, were significantly inhibited in a dose-dependent manner by panaxynol (**6**) (33).

To investigate the cytotoxic mechanism of polyacetylenes against cancer cell lines, the effects of these compounds were tested on cell membranes (rat erythrocytes and murine leukemic L-1210 cells) as well as on artificial lipid bilayers (34). Panaxydol and panaxynol caused concentration-dependent hemolysis, whereas panaxytriol produced no lysis. With liposomes composed of phosphatidylcholine (PC) and phosphatidic acid (PA), all three polyacetylenes suppressed osmotic behavior to the same degree. Panaxytriol gave its least suppression with liposomes of PC, PA, and cholesterol. Electron microscopic observations demonstrated that panaxydol caused nonspecific injury to L-1210 cells by affecting the cell membrane, nuclear envelope, and mitochondria. The cytotoxicity of polyacetylenes may thus be related to membrane damage. A relatively polar panaxytriol had little effect on the cholesterol of lipid bilayers. Panaxytriol (**7**), from *P. ginseng*, showed antiproliferative effects against several kinds of tumor cells, mitomycin C (MMC), and a human gastric carcinoma cell line, MK-1 (35). Panaxytriol also inhibits human breast carcinoma cells (Breast M25-SF, 180 mM) *in vitro* and the growth of B16 melanoma transplanted into mice (36).

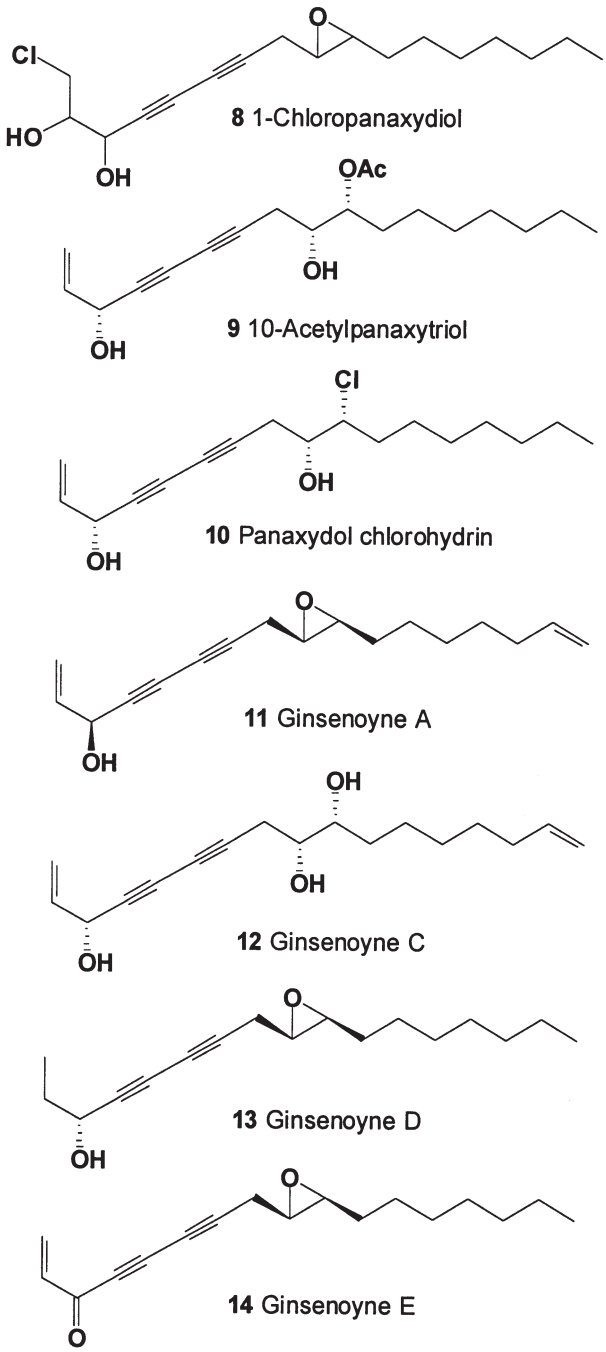
Panaxydol (**5**), panaxynol (falcarinol) (**6**), and panaxytriol (**7**) inhibited the synthesis of DNA, RNA, and protein in lymphoid leukemia L-1210 cells incubated with the drugs for 4–16 h (25). Falcarinol showed anti-inflammatory activity; had a marginal effect on cyclo-oxygenase (COX) activities [IC_{50} (concentration that is inhibitory to 50% of the test subjects) values > 100 μM]; and inhibited 5-lipoxygenase (5-LOX: IC_{50}, 2 μM), two isoforms of 12-LOX (leukocyte-type, 1 μM and platelet-type, 67 μM), and 15-LOX (4 μM) (37–39).

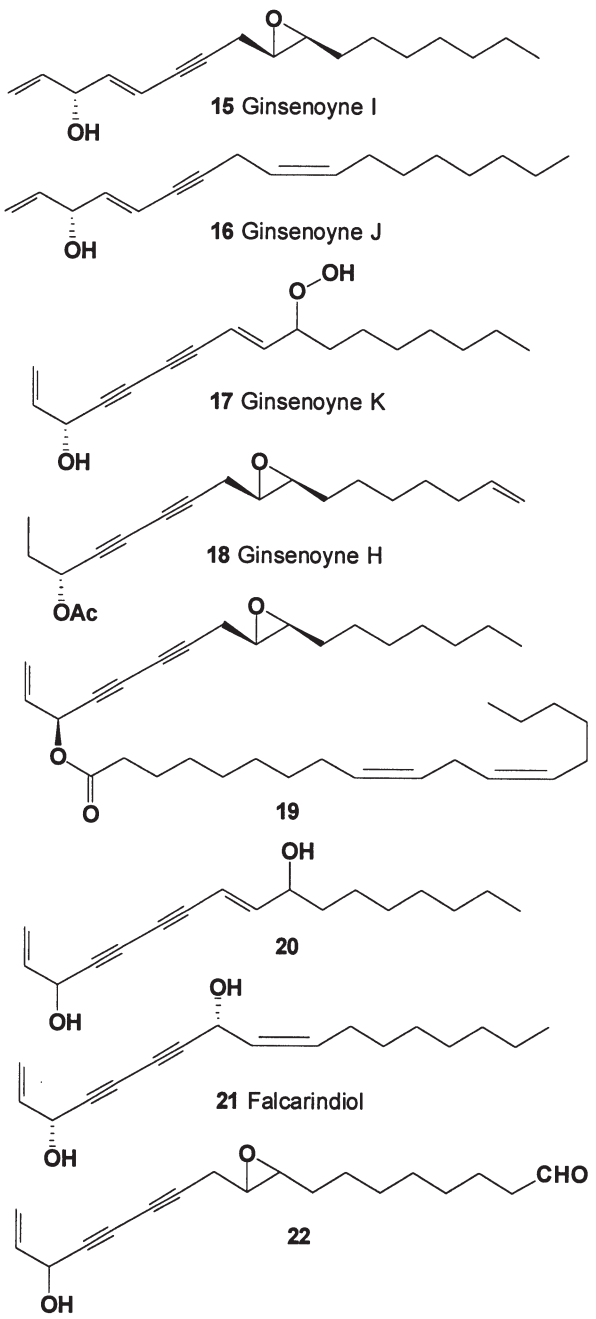
Panaxytriol (**7**), from red ginseng *(P. ginseng*), was studied to detect its effects on the growth and cell cycle of tumor cell lines (40,41). It showed both significant cytotoxicity toward and inhibition of DNA syntheses in various tumor cells. For P388D1, a mouse lymphoma cell line, IC_{50} values for cytotoxicity and inhibition of DNA synthesis were 3.1 and 0.7 μg/mL, respectively. Also panaxytriol exhibited antiproliferative activity toward the tumor cell lines MK-1, HeLa, and B16F10 (40,41). The cytotoxic effect of panaxytriol was both time- and dose-dependent. It also induced the cell cycle arrest of P388D1 at the G2/M phase. In particular, flow cytometry data indicated that the proportion of cells arrested in the G2/M phase increased from 9 to 26 and 48%, respectively, after 24 and 36 h exposure to panaxytriol at 5 μg/mL. A similar decrease was found for the cells arrested at the G0/G1 phase.

A series of other polyacetylene compounds of ginseng origin, including chlorine-containing chloropanaxydiol (**8**) and panaxydol (**5**), were tested for cytotoxic activities in different cell and tissue cultures (42–44). Chloropanaxydiol (**8**) showed inhibitory activity against leukemia cells (L-1210) in tissue culture and exhibited fungicidal properties. The heptadeca-1-ene-4,6-diyne-3,9-diol 10-acetate [10-acetyl panaxytriol (**9**) from Korean ginseng roots] showed strong cytotoxic activity against L-1210 cells (ED_{50} = 1.2 μg/mL) (45). Acetylenic compounds **3–7** and **10–19** from the root of *P. ginseng* were tested for their cytotoxic activities on murine and human malignant cells (DT, NIH/3T3, L-1210, HeLa, T24, and MCF7 cells) *in vitro* (46). Most of them showed more potent cytotoxicity than 5-fluorouracil and cisplatin. Of the active compounds, panaxydol was found to be most efficient (IC_{50} DT cells, 0.65 μM; 3T3 cells,

1.3 μM; L-1210 cells: 0.19 μM). Compound **19** inhibited growth of L-1210 line cells at an IC_{50} of 14 μg/mL (47).

Other isolated polyacetylenic alcohols—panaxynol (**6**) and heptadeca-1,8-diene-4,6-diyne-3,10-diol (**20**) (*Saposhnikoviae radix*: Fang Feng in Chinese Medicine) and falcarindiol (**21**) (from *Peucedani radix*, Qian Hu), 9,10-epoxy-16-hydroxy-octadeca-17-ene-12,14-diyne-1-al (**22**) (from *Foeniculi fructus*, bitter fennel) as well as panaxydol **5**, panaxynol (**6**), and panaxytriol (**7**) (from *Panax ginseng)*—inhibited the growth of cells from a human gastric adenocarcinoma cell line, MK-1, in a dose-dependent manner (48–51).





Three new cytotoxic polyacetylenes, panaquinquecol-1 (PQ-1: **23**), PQ-2 (**24**), and PQ-3 (**25**), from *Panax quinquefolium* exhibited strong cytotoxic activities against leukemia cells (L-1210) in tissue culture (52). Anticancer agents panaquinquecol 4 (PQ-4) (**26**), panaquinquecol 5 PQ-5 (**27**), and panaquinquecol 6 (PQ-6) (**28**) were isolated from root extracts of *P. quinquefolium* as active ingredients and had IC_{50} values of 0.5, 10, and 0.5 μg/mL, respectively, against murine leukemia L-1210 (53). C_{17}-Polyacetylenes PQ-4 (**26**) and PQ-6 (**28**) and a C_{14}-polyacetylene PQ-5 (**27**) were isolated from dried roots of *P. quinquefolium* (54). The cytotoxic activity of C_{17}-polyacetylenes **26** and **28** against leukemia cells (L-1210)

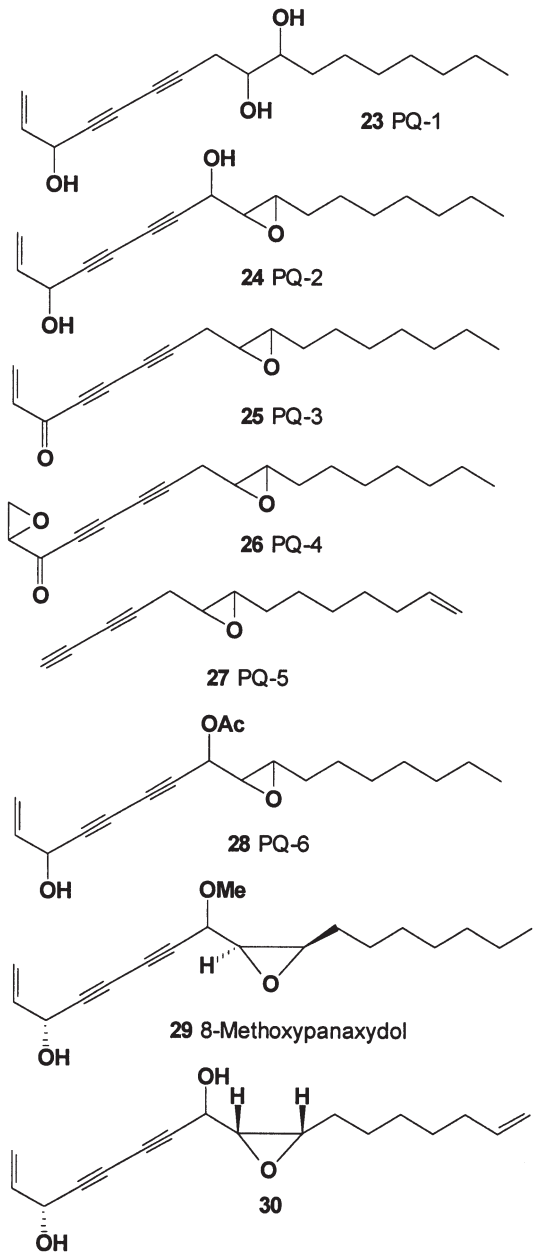
was about 20 times higher than that of the C_{14}-polyacetylene (**27**). Panaxydol (**5**), heptadeca-1,8-diene-4,6-diyne-3,10-diol (**20**), and 8-methoxy-panaxydol (**29**) from *Acanthopanax senticosus* roots seemed to induce various pro-apoptosis mechanisms in animal cells (55–62). Compound **29** was preferably used in treating leukemia.

Anticancer agents 1,16-heptadecadiene-4,6-diyne-3,9,10-triol (**12**) and compound **30,** which inhibited L-1210, Ehrlich, and HeLa cell lines with IC_{50} of 0.2, 1.3, and 2.1 μg/mL, respectively, have been isolated from Japanese ginseng (63). C_{17}- and C_{14}-polyacetylenes (**31**) and (**32**: PQ-8), from the dried roots of *P. quinquefolium*, showed strong cytotoxic activity (IC_{50} = 0.1 and 0.5 μg/mL, respectively) against leukemia cells (L-1210) in tissue culture (64). Falcarinol (**6**), falcarindiol (**21**), and falcarinolone (**34**) from the Chinese crude drug Toki (the roots of *Angelica acutiloba* var. *acutiloba*, Umbelliferae) inhibited AcOH-induced writhing in mice (65). Falcarindiol also showed antinociceptive activities in the retrograde injection test of bradykinin into a carotid artery of rats. Bioactive crepenynic acid (**33**) was obtained from crude extracts of *Crepis rubra* (66–69). Three compounds, **6**, **21**, and **34**, have also been isolated from carrots and other root crops, and their phytoprotective, cytotoxic, and allergic properties reviewed (70,71). *Dendropanax arboreus* is native to North America. It has spread from Mexico, across Central America, to northern South America and the West Indies. Its major ingredient that was responsible for *in vitro* cytotoxicity was falcarinol (**6**). Several other related compounds, including dendroarboreols A (**35**) and B (**36**), dehydrofalcarinol (**37**), dehydrofalcarindiol (**38**), and (**40**) were proven to be effective (72–74). Their cytotoxic effects are shown in Table 1.

TABLE 1
***In vitro* Cytotoxicity[a] Potencies of Different Compounds (LOX melanoma mouse; ref. 72)**

Compound	GI_{50}[b] (μg/mL)	TGI[b] (μg/mL)	LC_{50}[b] (μg/mL)
6	0.22	0.76	3.8
21	0.66	2.2	7.6
35	4.6	14.0	25.0
36	0.5	1.9	7.6
37	0.4	1.3	4.8
38	2.1	3.0	10.0
40	0.44	1.4	4.7

[a]In National Cancer Institute's 60-cell-line human tumor screening panel; data reported (molarity) are overall panel averages of quadruplicate tests, unless otherwise noted.
[b]GI_{50}, drug-treated cells' net growth is 50% of untreated controls; TGI, no net growth of drug-treated cells; LC_{50}, 50% net cell death in drug-treated cells vs. starting levels.



The active component *cis*-1,9,16-hepta-decatriene-4,6-diyne-3,8-diol (**39**) has been isolated from *Dendropanax arboreus* extract (75,76). The same compound has recently been found in the hairy root culture of *Ambrosia maritima*; it showed cytotoxic action against tumor cell lines LS174T (IC_{50}, 14.8 μg/mL), SKCO1 (IC_{50}, 13.3 μg/mL), COLO320DM (IC_{50}, 9.6 μg/mL), WIDR (IC_{50}, 10.9 μg/mL), MDA231 (IC_{50}, 37.6 μg/mL), and MCF7 (IC_{50}, 5.8 μg/mL) (77).

Acetylenic compounds **41–44**, including two chlorine-containing metabolites, **41** and **42**, are inhibitors of HL-60 cells (Table 2) and were isolated from the leaves of *Artemisia lactiflora* (Compositae, Thailand) (78–80). Compounds **44**, **46**, and **47** were evaluated for their ability to inhibit 12-LOX, and **46** and **47** showed moderate activity at 30 μg/mL. Compound **44** was tested on a series of colorectal and breast cancer cell lines, and its IC_{50} values ranged from 5.8 to 37.6 μg/mL. Compound **41** showed inhibitory activity against *Staphylococcus aureus* (ATCC) at concentrations in the range of 64–128 μg/mL.

The inhibitory effects of a diacetylenic spiroketal enol ether epoxide [AL-1 (**45**) from white mugwort, Asteraceae; *Artemisia lactiflora*] on a variety of tumor promoter-induced biological responses such as oxidative stress as well as tumor

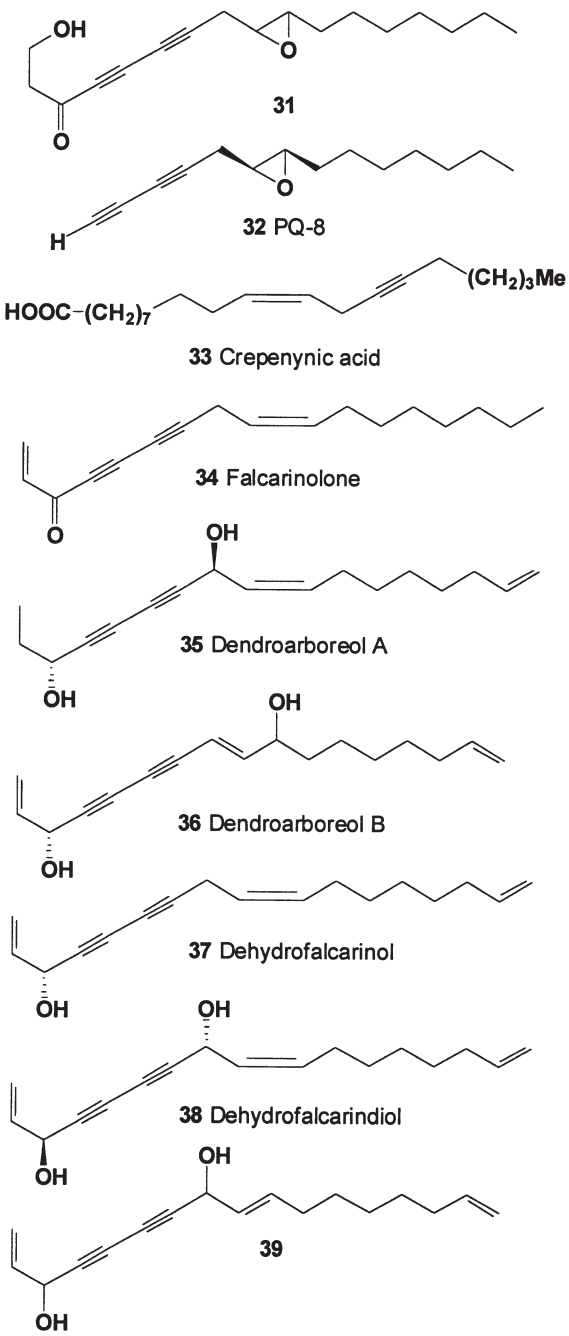


TABLE 2
Inhibitory Effects of Some Polyacetylenes on TPA-Induced O_2^- Generation[a] (ref. 78)

Compounds	10 (μM)	50 (μM)	100 (μM)	IC_{50} (μM)

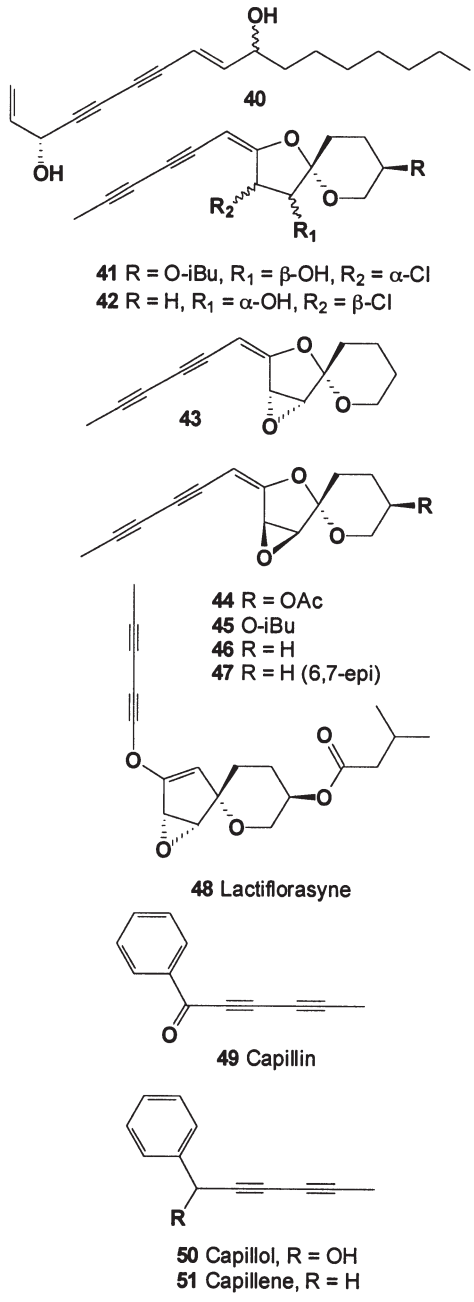
47	NT	55	78	43.0

[a]The maximal SD for each experiment was 5% from at least duplicate tests. NT, not tested; TPA, 12-*O*-tetradecanoylphorbol-13-acetate. IC_{50}, concentration that is inhibitory to 50% of test subjects.



promotion in ICR mouse skin were reported (81). AL-1 (**45**) strongly inhibited tumor promoter-induced Epstein-Barr virus activation in Raji cells (IC_{50} 0.5 μM), the effect being comparable with or even stronger than that of curcumin, a well-known antioxidative chemopreventive from turmeric. The cytotoxic compound lactiflorasyne (**48**) containing a spiro system has been isolated from the flowers and leaves of *A. lactiflora* (81–83).

Capillin (**49**) was isolated from *Artemisia capillaris* (fragrant wormwood), and its inhibitory activity on carcinogenic Epstein-Barr virus demonstrated (84-86). Capillin, capillol (**50**), and capillene (**51**) were obtained from extracts of *A. sco-*

TABLE 3
Cytotoxicity[a] of Gummiferol (54) Isolated from *Adenia gummifera* (ref. 103)

Cell line	ED_{50} (μg/mL)	Cell line	ED_{50} (μg/mL)

KB	0.3	U-373	0.05
KB-V-	0.4		

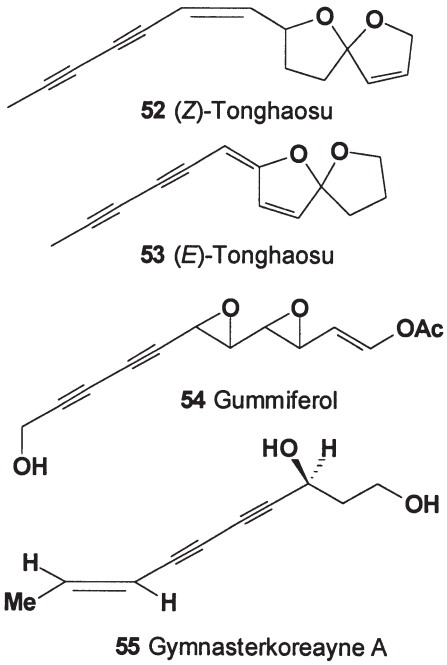
[a]Key to cell lines used: BC1, human breast cancer; HT-1080, human fibrosarcoma; LUC-1, human lung cancer; MEL-2, human melanoma; COL-1, human colon cancer; KB, human oral epidermoid carcinoma; KB-V+, multidrug-resistant KB assessed in the presence of vinblastine (1 μg/mL); KB-V–, multidrug-resistant KB assessed in the absence of vinblastine; P388, murine lymphoid neoplasm; A-431, human epidermoid carcinoma; LNCaP, hormone-dependent human prostate cancer; ZR-75-1, hormone-dependent human breast cancer; U-373, human glioblastoma. ED_{50}, dose that is effective in 50% of test subjects

paria (redstem wormwood) (87,88), from aerial parts of *A. variabilis* (89), and from the essential oil of *Santolina rosmarinifolia* (Holy flax, Compositae) (90). Concentrations (1–10 μM) of capillin (**49**) from *A. monosperma* inhibited cell proliferation of four human tumor cell lines—colon carcinoma HT29, pancreatic carcinoma MIA PaCa-2, epidermoid carcinoma of the larynx HEp-2, and lung carcinoma A549—by inducing DNA fragmentation and cell death (91). The oil content increased in the aerial parts of *A. scoparia* from the rosette stage to budding (from 0.21 to 2.5%) and flowering (0.23 to 2.6%). Concomitantly the capillene (**51**) content increased from 42.4 to 79.8% and that of capillin (**49**) decreased from 45.0 to 4.4% (92). Capillene and capillin were the main components in both the roots and leaves of *A. capillaris* growing at riverside sites (93).

German chamomile (*Matricaria recutita,* Asteraceae) oils containing ≥1% by wt of natural *cis*- and *trans*-spiro ether polyynes were obtained by steam distillation of fresh chamomile. Isolated compounds were named as *Z*-tonghaosu (**52**) and *E*-tonghaosu (**53**) (94–96), and they showed inhibiting activity on human lung cancer cell line as well as insecticidal and considerable antifeedant properties (97–102). A new polyacetylenic diepoxide compound, gummiferol (**54**), was isolated from the leaves of *Adenia gummifera* (Passifloraceae) by KB (carcinoma cells) cytotoxicity-guided fractionation. It exhibited cytotoxic actions on KB cell lines and a broad cytotoxic spectrum against 10 other human cancer cell lines (Table 3) (103). *Adenia gummifera* is used to improve animal health in Tanzania.

Polyacetylenic compounds isolated from roots of *Gymnaster koraiensis* (Compositae) included the gymnasterkoreaynes A to F (compounds **55–62**, respectively) as well as 1,9,16-heptadecatrien-4,6-diyn-3,8-diol (**59**) and 1,9,16-heptadecatrien-4,6-diyn-8-ol (**60**), and were separated by bioassay-guided fractionation using the L-1210 tumor cell line as a model for cytotoxicity (104).

Gymnasterkoreaynes A–F are linear diacetylenes and are



structurally related to falcarinol, panaxynol, panaxydiol, and panaxytriol. In isolated form, gymnasterkoreaynes B (**56**), C (**58**), F (**62**), and 1,9,16-heptadecatrien-4,6-diyn-8-ol (**60**) exhibited significant cytotoxicity against L-1210 tumor cells with ED_{50} values of 0.12–3.3 μg/mL (Table 4). In addition, gymnasterkoreaynes A–F showed considerable antiproliferative activity against various cancer cells, inhibition of NO production, and inhibition of acyl-CoA:cholesterol acyltransferase (105).

The antitumor acetylenic compounds 2-*cis*-dehydro-matricaria acid (**63**), 2-*trans*-dehydromatricaria acid (**64**), *cis*-dehy-

58	2.1	**62**	3.1

[a]For abbreviation see Table 3.

dromatricaria Me ester (**65**), and *trans*-dehydromatricaria Me ester (**66**) were obtained from roots of *Solidago virga-aurea* (Compositae) (106,107), and also from other species (108–111).

Polyacetylene (–)-17-hydroxy-9,11,13,15-octadecatetraynoic acid (**67**), referred to as minquartynoic acid, from *Minquartia guianensis* stem bark showed cytotoxic activity against P388 murine lymphocytic leukemia *in vitro*. The P388 ED_{50} of the pure compound was 0.18 μg/mL, and it was also active in the brine shrimp larvicidal bioassay with an LC_{50} of 5.06 μg/mL (95% confidence interval 3.68–6.98 μg/mL). These biological activities could account for the alleged efficacy of the plant in folk usage (112,113).

More recently, minquartynoic acid was isolated from the air-dried bark of *Coula edulis* (114), the twigs of *Ochanostachys amentacea* (both plants belonging to the Olacaceae) (115,116), and from *Minquartia guianensis* bark (117). In addition, acetylenic acids **68** and **69** were isolated from the twigs of *O. amentacea* (115,116), and their cytotoxic activities determined (Table 5). Minquartynoic acid (**67**) also showed moderate *in vitro* activity against *Plasmodium falciparum* and *Leishmania major* and strongly inhibited phytohemagglutinin A-induced proliferation of human lymphocytes (118).

A dichloromethane extract of celery root (*Apium graveolens*) yielded falcarinol (**6**), falcarindiol (**21**), panaxydiol (**70**), and 8-OMe-falcarindiol (**71**) (119). Its nonpolar extracts as

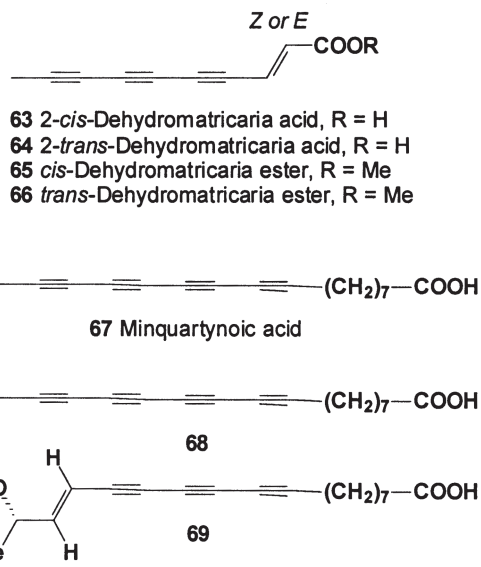
[b]Key to cell lines used: BC1, human breast cancer; Lu1, human lung cancer; Col2, human colon cancer; KB, human oral epidermoid carcinoma; KB-V+, multidrug-resistant KB assessed in the presence of vinblastine (1 μg/mL); KB-V–, multidrug-resistant KB assessed in the absence of vinblastine; LNCaP, hormone-dependent human prostate cancer; SW626, human ovarian cancer; SKNSH, human neuroblastoma cancer; M109, mouse lung cancer.



well as those obtained from roots and bulbs of carrots, fennel, parsley, and parsnip were separated by HPLC. All species contained polyacetylenes, although carrots and fennel only in minor amounts. In addition, by using the annexin V-PI assay, the cytotoxicity of the compounds **6**, **21**, **70**, and **71** was evaluated. Falcarinol proved to be the most active, with a pronounced toxicity against an acute lymphoblastic leukemia cell line CEM-C7H2 (IC_{50} = 3.5 mg/mL).

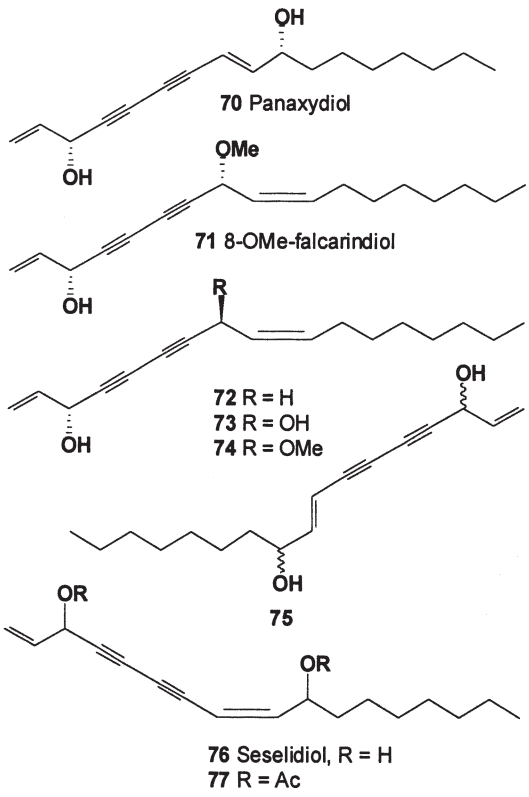
Polyacetylenes (**72–75**) from *Apium graveolens* showed medium-level cytotoxicity against certain leukemia, lymphoma, and myeloma cell lines with IC_{50} values of approximately 30 μM (Table 6). Only falcarinol showed much higher activity against one cell line, CEM-C7H2, with an IC_{50} value of 3.50 μM. Colorectal carcinoma cell lines were less sensitive to polyacetylenes in general, with IC_{50} values above 100 μM for compound **73** against both cell lines and for compound **74** against HT2912 cells. However, compound **74** also displayed medium-level activity against HRT-18 cells, and compounds **72** and **75** displayed medium-level activities against both cell lines (IC_{50} values between 30 and 64 μM).

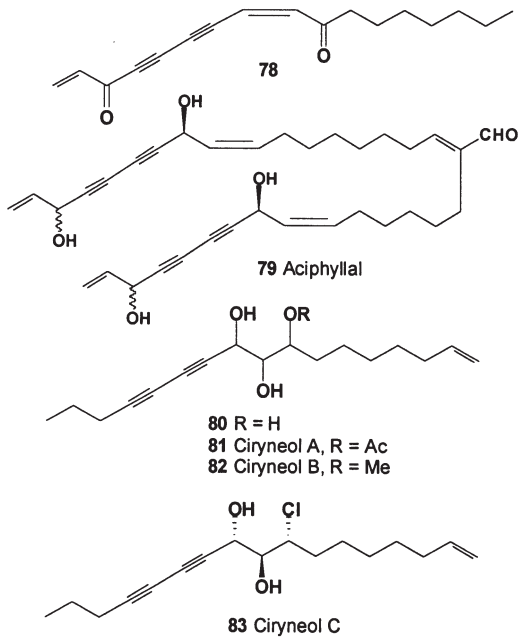
Seselidiol (**76**) has been isolated from the roots of *Seseli mairei* (120). Seselidiol, its acetate (**77**), and compound **78** showed moderate cytotoxicity against KB, P388, and L-1210 tumor cells (Table 7).

TABLE 6
Cytotoxicity[a] of Polyacetylenes Isolated from *Apium graveolens*

Compound	A	B	C	D	E
72	3.5	30.1	27.4	42.3	63.9
73	29.8	31.8	29.6	>100	>100
74	31.8	32.1	29.3	34.7	>100
75	29.2	29.5	27.8	29.8	32.3

[a]IC_{50}, μg/mL (ref. 119). Abbreviations: A, CEM-C7H2 (human lymphoblastic leukemia); B, U937 (human monocytic lymphoma); C, RPMI (human nasal epithelial cells); D, HRT-18 (adenocarcinoma); E, HT2912 (human brain neoplasm). For other abbreviation see Table 2.





The novel dimeric C_{34}-polyacetylene aciphyllal (**79**) was isolated from the New Zealand subalpine herb (giant speargrass) *Aciphylla scott-thomsonii* (Apiaceae, tribe Apieae) by Perry and co-workers (121) and synthesized by Patnam and coworkers (122). This was the first report on very long chain polyacetylenes (up to C_{45}) isolated from marine sponges. Aciphyllal showed weak cytotoxic activity against P388 cells (IC_{50} > 25 μg/mL) and antifungal activity against *Trichophyton mentagrophytes*.

The polyacetylene compounds heptadeca-1-ene-l,13-diyne-8,9,10-trio1 (**80**) and ciryneols A–C (**81–83**) were isolated from *Cirsium japonicum* (Compositae). These compounds inhibit the growth of KB cells *in vitro* (123–125). Ciryneol C (**83**) was also isolated from *C. rhinoceros* (126). *Scurrula atropurpurea* (Loranthaceae), a parasitic plant that attacks the tea plant *Thea sinensis* (Theaceae), is called "benalu teh" in Indonesia, and the whole plant (stems and leaves) has been traditionally used for the treatment of cancer in Java (Indonesia). Three acetylenic acids—octadeca-8,10-diynoic (**84**), (*Z*)-octadec-12-ene-8,10-diynoic (**85**), and octadeca-8,10,12-triynoic (**86**) acids—were isolated from aqueous acetone extracts of stems and leaves. All compounds showed inhibitory activity against cancer cell invasion (MM1) *in vitro* (Table 8) (127,128). Five C_{16}-acetylenic FA—hexadec-8-ynoic (**87**), hexadec-10-ynoic (**88**), hexadeca-8,10-diynoic (**89**), hexadeca-6,8,10-triynoic (**90**), and hexadeca-8,10,12-triynoic (**91**) acids—were prepared, and their inhibitory activity against cancer cell invasion was examined (129). The results indicated that the natural C_{18}-triyne FA (**86**) and the synthetic C_{16}-triyne FA (**90** and **91**) inhibit cancer cell invasion in spite of their simple chemical structures.

Bioassay-directed fractionation of the dried roots of *Asparagus cochinchinensis* (Asparagaceae) led to the isolation of some active compounds (130–132), including a new acetylenic

TABLE 7

derivative, 3″-methoxyasparenydiol (**92**), and asparenydiol (**93**). These compounds demonstrated moderate cytotoxicities in a panel comprised of KB, Col-2, LNCaP, Lu-1, and human umbilical vein endothelial cells (HUVEC) cells, with IC_{50} values ranging from 4 to 20 μg/mL (Table 9). The dried roots of *A. cochinchinensis* are used in Laos to treat chronic fever (Lao name of plant: Kheua Ya Nang Xang). The plant has a long history of use for treating fever, cough, kidney diseases, and benign breast tumors in China.

From the rhizomes of *Atractylodes lancea* were isolated bioactive compounds **94–99** (133–136). Only **94** showed strong inhibition of 5-LOX and COX-1 activity [IC_{50} (5-LOX) = 3.4 μM; IC_{50} (COX-1) = 1.1 μM]. The activity of the other compounds is shown in Table 10. Crude extracts of seven species of the genus *Argyranthemum* were tested for potential cytotoxic and antimicrobial activities (137,138). *Argyranthemum adauctum, A. foeniculaceum*, and *A. frutescens* were effective against both Gram-positive and Gram-negative bacteria and showed cytotoxic activity against HeLa and Hep-2 cell lines. Cytotoxic activity of **100–110** against HeLa and Hep-2 cells is shown in Table 11.

Some identified compounds from *Angelica* species showed antimicrobial, anticancer, antitumor, analgesic, anti-inflammatory, hepatoprotective, and nephroprotective activities. The $CHCl_3$ extract from *A. japonica* root showed high inhibitory activity on human gastric adenocarcinoma (MK-1) cell growth. From this extract, a new furanocoumarin named japoangelone and four furanocoumarin ethers of falcarindiol, named japoangelols A (**111**, ED_{50}, 8.5 μg/mL), B (**112**, ED_{50}, 7.2 μg/mL), C

(**113**, ED_{50}, 7.4 μg/mL), and D (**114**, ED_{50}, 8.4 μg/mL) were isolated and tested. In addition, three other polyacetylenes were isolated and tested in the MTT assay: panaxynol (ED_{50}, 0.3 μg/mL), falcarindiol (**21**) (ED_{50}, 3.2 μg/mL), and 8-OMe-falcarindiol **71** (ED_{50}, 3.2 μg/mL). Moderate activity of compounds **111**–**114** against HeLa and B16F10 cell lines were also reported (139,140).

A few acetylenic phytosterols have been found. The first acetylenic sterols (**115–117**) from *Gymnostemma pentaphyl-*

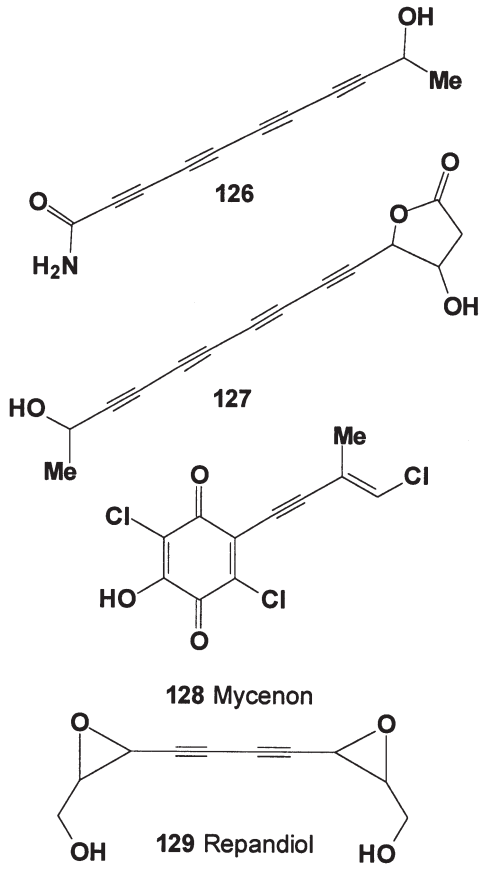
lum (Cucurbitaceae) were isolated by Akihisa and co-workers in 1989 (141).

Acetylenic sterols having a same structure (except for the side chains) as the anticancer agent spinasterol (**118**) were isolated from *Pueraria* roots (*P. mirifica* from Thailand and *P. lobata* from Korea) (142). These plants are used as a rejuvenating folk medicine in Thailand and China. The ethanol extracts had significant antiproliferative effects on breast cancer cell lines, including MCF-7, ZR-75-1, MDA-MB-231, SK-BR-3, and Hs578T. Spinasterol inhibited the growth of some breast cancer cell lines (MCF-7, MDA-MB-231) in a dose- and time-dependent manner, as well as the growth of ovarian (2774) and cervical cancer cells (HeLa) (142). The occurrence of spinasterol has also been reported in *Cucurbita moschata* (143), *Conyza blinii* (144), *Gypsophila oldhamiana* (145), *Gordonia ceylanica* (146), and *Acacia cedilloi* (147). The anticancer activity of spinasterol was demonstrated *in vivo* in studies that showed that it greatly decreased the incidence of skin tumors without co-carcinogen or co-tumor promoter activities (148).

FUNGAL ACETYLENIC METABOLITES

Fungal species produce many different acetylenic metabolites, but only few of them show cytotoxic, antitumor, and/or related activities (149–154). Two glutamyl peptides, γ-glutamyl-L-2-aminohex-4-ynoic acid (**119**) and γ-L-glutamyl-L-erythro-2-amino-3-hydroxyhex-4-ynoic acid (**120**), were isolated from the fruit bodies of *Tricholomopsis rutilans* (155–157). Derivatives of these amino acids showed antiviral, anticholesterol, and anticancer activities (158–166).

Mycomycin (**121**), isolated in 1950 by Jenkins (167), is used not only as a therapeutic agent for tuberculosis (168–170) but also for treatment of late-stage inoperable primary hepatocellular carcinoma (171,172). More recently, antibiotic 07F275 [also known as mycomycin (**121**)], which belongs to the allenic polyacetylene family, has been produced by submerged fermentations of fungal culture LL-07F275 (173). Acetylenic metabolites named drosophilins C (**122**) and D (**123**) have been isolated from fungal culture of *Drosophila subatrata* (now classified as *Psathyrella subatrata*) (174–176). These compounds showed antibacterial, antimicrobial, and antifungal activities, and they inhibited bacteriophage growth (174–180). Tricholomenyns A (**124**) and B (**125**) were isolated from the fruiting bodies of *Tricholoma acerbum* (181,182). The tricholomenyns efficiently inhibit mitosis of T-lymphocyte cultures and are potent as anticancer agents.



Two bioactive polyynes, 10-hydroxyundeca-2,4,6,8-tetraynamide (**126**) and 3,4,13-trihydroxy-tetradeca-5,7,9,11-tetraynoic acid-γ-lactone (**127**), were isolated from cultures of the fungus *Mycena viridimarginata* (183,184). Compound **126** was highly active against Gram-positive and Gram-negative bacteria, yeasts, filamentous fungi, and Ehrlich ascites carcinoma. Compound **127** had similar though less pronounced biological activities. A novel chlorinated benzoquinone antibiotic, mycenon (**128**), was isolated from the culture broth of a basidiomycete, *Mycena* sp., and shown to inhibit isocitrate lyase (EC 4.1.3.1) (185).

Repandiol (**129**), a new cytotoxic diepoxide [(2*R*,3*R*,8*R*, 9*R*)-4,6-decadiyne-2,3:8,9-diepoxy-1,10-diol], was isolated from the mushrooms *Hydnum repandum* and *H. repandum* var. *album* (186–188). Repandiol displayed pronounced cytotoxic effects against various tumor cells. It was found to form interstrand cross-links of DNA, linking deoxyguanosines on opposite strands primarily within the 5′-GNC and 5′-GNNC sequences preferred by diepoxyoctane. However, repandiol was a significantly less efficient cross-linker than diepoxy-alkanes (diepoxyoctane and diepoxybutane) (189).

BACTERIAL AND CYANOBACTERIAL ACETYLENIC METABOLITES

Microorganisms produce a large variety of biologically active substances representing a vast diversity of fascinating molecular architecture not available in any other living systems. During the last two decades, quite a few active compounds having an enediyne unit have been isolated and identified from soil bacteria and identified. In 1987, Lederle (190–193) and Bristol-Myers (194,195) groups revealed unprecedented molecular architecture of a new class of natural products, the so-called enediyne anticancer antibiotics. The enediynes are characterized by the presence of an unsaturated core with two acetylenic groups conjugated to a double bond or to an incipient double bond. They are categorized into two subfamilies possessing either 9-membered ring chromophore cores or 10-membered rings.

Calicheamicin γ_1 (**130**), the most prominent member of the calicheamicins, was isolated from *Micromonospora echinospora* ssp. *calichensis* and is a remarkable piece of engineering by Nature, which has perfectly constructed the molecule to endow it with its extraordinary chemical and biological properties (196). One can mention, in particular, its efficiency in the biochemical prophage induction assay at concentrations <1 pM, high antibacterial activity, and extreme potency against murine tumors such as P388 and L-1210 leukemias and solid neoplasms such as colon 26 and B16 melanoma with optimal doses of 0.15–5.0 μg/kg.

The esperamicins represent a class of antitumor antibiotics revealing extremely high cytotoxicity. A family of potent esperamicins showing a broad spectrum of antimicrobial and antitumor activities in murine systems has been identified in cultures of *Actinomadura verrucosospora* (193,194). The esperamicins are characterized by the presence of a particular central core. Unusual features of the core include a bicyclo[7.3.1] ring system, an allylic trisulfide attached to the bridging atom, a 1,5-diyn-3-ene as part of the ring system, and an α-3-unsaturated ketone in which the double bond is at the bridgehead of the bicyclic system. Esperamicin A_1 (**131**) contains four sugars attached to the bicyclic core and an aromatic chromophore attached to one of the sugars. Cytotoxicities of esperamins A_1 (**131**), C (**133**), and D (**134**) are presented in Table 12. Another compound, esperamicin P (**132**), isolated from a fermentation broth of *A. verrucosospora* was found to differ from esperamicin A_1 by possessing a methyl tetrasulfide moiety instead of a methyl trisulfide (197). It was active against xenografted tumors in mice and exhibited antimicrobial activity. It also showed antitumor activity against cultured cell lines with IC_{50} values (in μg/mL) of 0.01 against A549 human lung and A549 (VP-resistant) cells; 0.02 against B16-PRIM murine

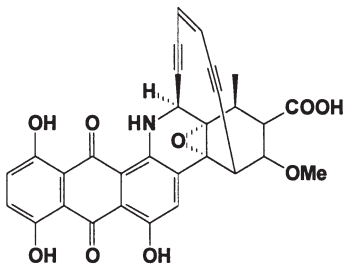
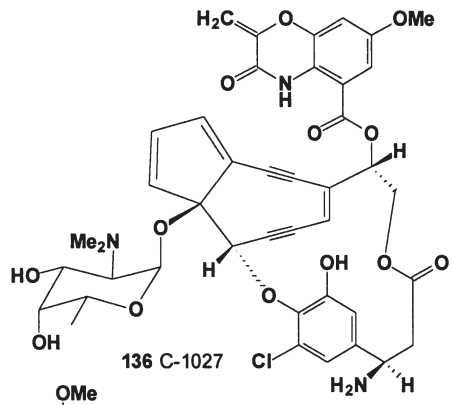
melanoma cells, and <0.002 against HCT-116 human colon and HCTNP35 (VP-resistant human colon) cells (197).

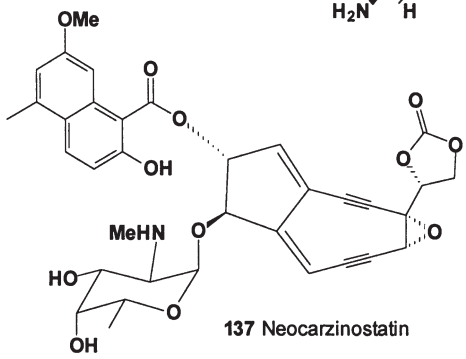
Dynemicin A (**135**), a new antibiotic with 1,5-diyn-3-ene and anthraquinone subunits, was isolated from the culture broth of *Micromonospora chersina* sp. nov. M956-1 (198). It was especially active against Gram-positive bacteria, prolonged the life span of mice inoculated with P388 leukemia, and displayed significant activity against P388 leukemia and 316 melanoma in mice.

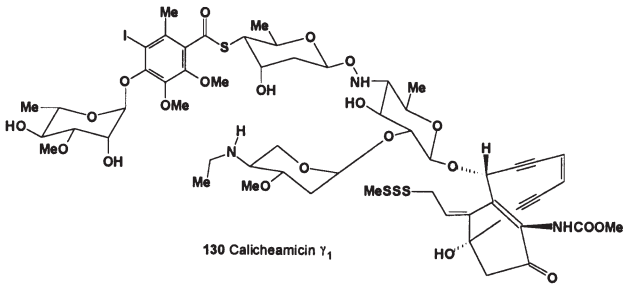
Antitumor antibiotic C-1027 (**136**) isolated from *Streptomyces globisporus* (199–202) showed pronounced cytotoxicity against KB carcinoma cells (IC_{50} 0.1 ng/mL) (203) and was effective as an antitumor drug in experiments on tumor-bearing mice (204–206). The metabolites, belonging to a steadily growing enediyne family, now comprise nine natural products: neocarzinostatin (**137**), which was isolated from *S. carzinostaticus* (207–213), kedarcidin (**138**) from *Actinomycete* L585-6 (214–218), maduropeptin (**139**) from *Actinomadura madurea* (219,220), and N1999A2 (**140**) from *Streptomyces* sp. AJ9493 (221–223). The representatives of this group are probably the most potent anticancer agents discovered. Some of them are 5–8000 times more effective than adriamycin, an antibiotic widely used for antitumor treatment (224,225).

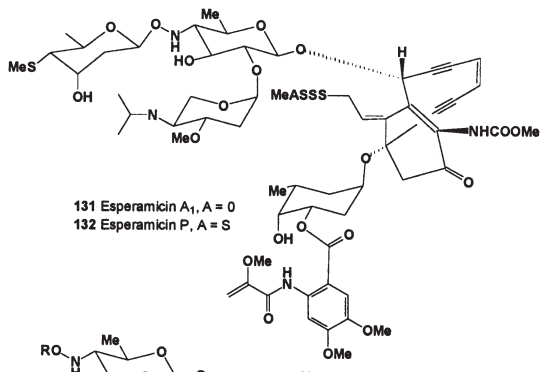
Neocarzinostatin (**137**) showed antibacterial activity (LD_{50}, μg/mL) against Gram-positive organisms: *Bacillus subtilis*, 32;

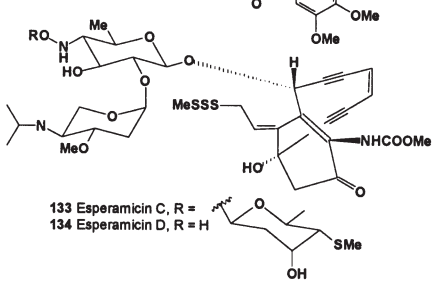












Staphylococcus aureus, 16; *S. aureus*, 32; *S. aureus*, 8; *S. aureus*, 16; *Sarcina lutea*, 2; and *S. lutea*, 2. In mice with ascitic sarcoma 180, 3.2 mg/kg daily was tolerable. The LD_{50} was 30 mg/kg. In doses of 0.1–3.2 mg/kg/d, neocarzinostatin inhibited tumor growth with a therapeutic index (also known as the therapeutic ratio or margin of safety) of 32; ranges of 0.8–3.2 μg/kg/d gave 100% survival. Doses of 0.2–3.2 mg/kg/d in leukemia SN-36-bearing mice significantly prolonged survival of animals.

Kedarcidin (**138**) showed antitumor activity against implanted P388 leukemia (3.3 μg/mL/kg), and B16 melanoma (2 μg/kg) in mice. It was also effective against Gram-positive, but not against Gram-negative, bacteria (226,227). The antibiotic maduropeptin (**139**) was active against Gram-positive bacteria and highly cytotoxic to tumor cells. It produced significant prolongation of survival of mice implanted with P388 leukemia and B16 melanoma (228). Antibiotic N1999A2 (**140**) strongly inhibited growth of various tumor cell lines (with IC_{50} values varying from 10^{-12} to 10^{-8} M) and bacteria (229). For details on the chemistry and biological activities of this family of antibiotics see recent publications (230–233).

140 N1999A2

Cyanobacteria include nearly 2,000 species, growing as single cells, filaments of cells, or through various colonial associations (234–239). This indicates a high degree of biological adaptation, which has enabled these organisms to thrive and compete effectively in nature. Many of them produce toxic secondary metabolites, in particular nerve and liver toxins, as a form of defense against herbivores. At the same time, some cyanobacterial species represent a source of interesting active metabolites, including acetylenic compounds that possess selective cytotoxicities and that may prove useful for development into commercial drugs (240–246). The ubiquitous tropical cyanobacterium *Lyngbya majuscula* is a prolific producer of bioactive metabolites: Approximately 30% of all natural products reported from marine cyanobacteria have been isolated from this species. The plethora of structurally diverse secondary metabolites isolated from *L. majuscula* exhibits a variety of bioactivities including antifeedant, molluscicidal, antiproliferative, and immunosuppressive properties. More than half of the known secondary metabolites of the species are either cyclic or linear lipopeptides, some of them having an acetylenic unit.

The linear lipopeptides named apramides A (**141**), B (**142**), and G (**143**) have been isolated from the cytotoxic fraction of *L. majuscula* collected at Apra Harbor (Guam). Apramide G showed cytotoxic activity, with IC_{50} values of 33 and 11 ng/mL against KB and LoVo cells, respectively (247,248). Four new metabolites have been isolated from *L. majuscula* collected at Boca del Drago Beach, Bocas del Toro, Panama. These compounds were assigned the trivial names dragonamide (**144**), pseudodysidenin, dysidenamide, and nordysidenin. Dragonamide exhibited cytotoxic activity against P388, A-549, HT-29, and MEL-28 cells (IC_{50} > 1 μg/mL) (249). Carmabin A (**145**), a linear lipotetrapeptide, was isolated from the *n*-BuOH extract of *L. majuscul*a. By using the MRC-5 human embryonic lung cell line in the confluent and proliferating states (cytotoxicity assessment assay, Syntex Discovery Research), curacin A and carmabin produced the following IC_{50} values: 6.58 μg/mL (crude extract with curacin A), 0.98 μg/mL (fraction with curacin A), 0.003 μg/mL (pure curacin A); 4.8 μg/mL (crude extract with carmabin), 0.6 μg/mL (fraction with carmabin A), and 0.06 μg/mL (pure carmabin A) (250). Hexane and butanol extracts of *Symploca hydnoides* showed cytotoxic activity against HT-29 human colon cancer cells. A new depsipeptide, malevamide C (**146**), was isolated from the cyanobacterium *S. laete-viridis*, collected near the south shore of Oahu, Hawaii (251). At a concentration <2 μg/mL, this compound was found to be active against P388, A-549, and HT-29 cancer cells. The malevamide contains some unusual amino and hydroxy acids and several methylated and dimethylated residues. Other unusual moieties include 3-amino-2-methylhexanoic acid and 3-amino-2-methyl-7-octynoic acid.

Of a new series of depsipeptides, antanapeptins A–D, two [antanapeptin A (**147**) and D (**148**)] containing acetylenic acid were isolated from *L. majuscula* of the Antany Mora collection (Madagascar) (252). Both metabolites showed moderate cytotoxic activity against neuroblastoma-2A cells in mice.

A new cyclodepsipeptide [named pitipeptolide A (**149**)], isolated from *L. majuscula* collected at Piti Bomb Holes (Guam reefs), an area known for its periodic blue-green algal blooms, appears to be uniquely distinguished in this particular collection of Dr. Valerie Paul and colleagues by the presence of a 2,2-dimethyl-3-hydroxy-7-octynoic acid residue (253). This compound exhibited weak cytotoxicity against LoVo cancer cells but possessed moderate antimycobacterial activity and stimulated elastase activity.

Yanucamides A (**150**) and B (**151**) were isolated from lipid extracts of *L. majuscula* and *Schizothrix* sp. collected at Yanuca Island (Fiji) (254). Both compounds contain a unique 2,2-dimethyl-3-hydroxy-7-octynoic acid. Ulongapeptin (**152**), a cyclic depsipeptide with a β-amino acid, 3-amino-2-methyl-7-octynoic acid, was isolated from a Palauan marine *Lyngbya* sp. The compound was cytotoxic against KB cells with an IC_{50} value of 0.63 μM (255).

Four new depsipeptides have been isolated from the marine cyanobacterium *Lyngbya semiplena* collected from Papua New Guinea. The wewakpeptins represent an unusual arrangement of amino and hydroxy acid subunits compared with known

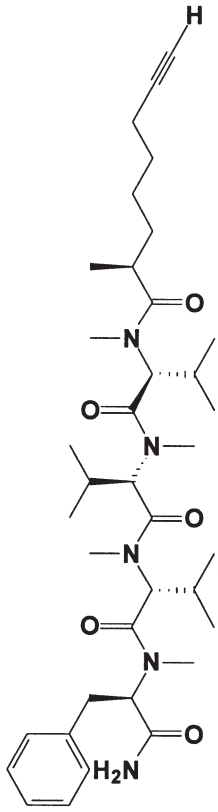
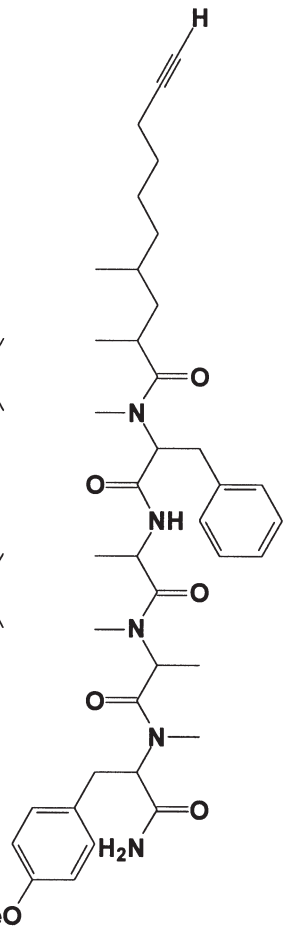
143 Apramide G



144 Dragonamide



145 Carmabin A

peptides of cyanobacterial origin and possess a bis-ester, a 2,2-dimethyl-3-hydroxy-7-octynoic acid residue. Wewakpeptins A (**153**) and C (**154**) were the most cytotoxic among these four depsipeptides, with an LC_{50} value of approximately 0.4 μM for both the NCI-H460 human lung tumor and the mouse neuroblastoma-2A cell lines (256–258).

Guineamide C (**155**) is a novel cyclic depsipeptide isolated and characterized from a Papua New Guinea collection of *L. majuscula* (257). Guineamide C possesses moderate cytotoxicity to a mouse neuroblastoma-2A cell line with an IC_{50} value of 16 μM. A cyclic depsipeptide, georgamide (**156**), was isolated from an unidentified cyanobacterium (Australia) (258). Its constituent units were five amino acid residues (L-Thr, L-Pro, L-Val, N-Me-L-Val, and N-Me-L-Phe), as well as two hydroxy carboxylic acids, 2(*S*)-hydroxy-3(*R*)-methylpentanoic acid and 2,2-dimethyl-3-hydroxy-7-octynoic acid, which are also present in wewakpeptins A and B (258).

METABOLITES OF MACRO- AND MICROALGAL SPECIES

The structures of octadec-5-yne-7*Z*,9*Z*,12*Z*-trienoic acid (liagoric acid) (**157**), 7-hydroxy-5-yne-9*Z*,12*Z*-dienoic acid (**158**), and glyceryl octadec-5-yne-7*Z*,9*Z*,12*Z*-trienoate (**159**) isolated from *Liagora farinosa* are presented here. These compounds showed acute toxicity toward *Eupomacentrus leucostictus* at concentrations from 5 to 8 μg/mL. At a concentration of 31 μM, liagoric acid inhibited COX activity (259,260).

The family Caulerpaceae includes hundreds of multishaped species of marine green macroalgae, from grape-like *Caulerpa racemosa* to feathery *C. sertularioides, C. taxafolia*, and *C. mexicana,* and to the solid-bladed *C. prolifera.* Some of them are very invasive. The most devastating representative of this genus, *C. taxifolia*, has received the nickname "killer alga." Its aquarium strain was accidentally released in the wastewater from the Oceanographic Museum at Monaco, from whence it rapidly invaded the Mediterranean Sea; it is also present along the southern Californian and Australian coasts. *Caulerpa taxifolia,* like other species of *Caulerpa*, is coenocytic, representing a gigantic cell and containing millions of nuclei. The ethanolic extract of *C. prolifera* showed antitumor activity against Ehrlich ascites carcinoma *in vitro* (261). In contrast to other plants that produce a variety of toxins, but in reduced amounts, *C. taxifolia* synthesizes a single major secondary metabolite, caulerpenyne (**160**), in enormous quantities (varying from 1.9 to 10% of algal dry mass, depending on season). This sesquiterpene is toxic to herbivores, such as sea urchins, and to submarine flora.

Caulerpenyne is cytotoxic to several cell lines. In particular, it induces inhibition of SK-N-SH (neuroblastoma) cell proliferation with an IC_{50} of 10 μmol/mL after either long-time incubation (24 h) or after 2 h (262). In this respect, caulerpenyne is as efficient as other antitumor drugs, such as oxaliplatinul and paclitaxel (=Taxol). After a short incubation *in vitro*, caulerpenyne blocked polymerization of pure tubulin with an IC_{50} of 21 μM, presumably by inducing its aggregation (262). A detailed study of its antitumor efficiency and selectivity was performed on eight cancer cell lines of human origin. It produced growth-inhibitory effects in all cases, with some variability among the cell lines. Cells of colorectal cancer origin were the most sensitive to caulerpenyne, with IC_{50} values from 6.1 to 7.7 μM (263). As to the major mechanism underlying caulerpenyne cytotoxicity, available data are controversial: Both inhibition at the G2/M phase (263) and absence of the effect (262) were reported. On the other hand, the particular action of the compound on the microtubular network assayed both in the *in vitro* tubulin system and on the SK-N-SH cell line (262) could be of great importance in the future search for novel antimitotic agents.

Conventional antimitotics either stabilize (Taxol) or depolymerize (*Vinca* alkaloids) microtubules but do not induce tubulin aggregation. Tubulin may represent just one of the targets of caulerpenyne. After taking into account an early and strong cytotoxic effect of caulerpenyne, involvement of other antiproliferative mechanisms was suggested (262). Indeed, caulerpenyne was reported to block phospholipase A_2 activity and selectively inhibit stimulation of mitigen-activated kinase (MAPK) (262).

Caulerpenyne is produced in somewhat lower amounts by other Caulerpaceae and has been isolated from several *Caulerpa* species from the Mediterranean Sea (*C. prolifera*), the Pacific Ocean, and the Caribbean Sea (*C. prolifera, C. racemosa, C. lanuginosa*) (262–264). Though caulerpenyne represents a major toxic metabolite of *Caulerpa*, its numerous derivatives (**163–168**), including furocaulerpin (**169**), an acetylenic sesquiterpenoid possessing a furan ring, could contribute to the cytotoxicity of the species. It should be noted that,

upon wounding, *C. taxifolia* and other *Caulerpa* species, within seconds, induce transformation of caulerpenyne into highly reactive, and thus potentially more toxic, aldehydes of the oxytoxin family (265,266).

Some of the minor caulerpenyne metabolites (**161–164**) were shown to inhibit, *in vitro*, the growth of marine bacteria and marine ciliates (Protozoa) (267). The toxicity of pure compounds (**163–168**) was also evaluated on three models: mice (lethality), mammalian cells in culture (cytotoxicity), and sea urchin eggs (disturbance of cell proliferation).

These caulerpine analogs were found to be more or less toxic, with variations of efficiency depending on the assay (265,266). Bioactive furocaulerpin (**169**), an acetylenic sesquiterpenoid possessing a furan ring, was isolated from the marine alga *C. prolifera* (268).

Three carotenoids with an acetylenic unit, named diadinochromes A (**170**) and B (**171**) and diatoxanthin (= cynthiaxanthin: **172**), were isolated from the freshwater red tide organism *Peridinium bipes* (Dinophyceae). Diadinochrome A was cytotoxic to HeLa cells, whereas the other two compounds exhibited anticancer activity. Extracts of *P. bipes* exerted an inhibitory effect on the growth of *Microcystis aeruginosa* (269–271). Tsushima and co-workers (272) studied 51 carotenoids, including carotenoids with acetylenic unit(s): amarouciaxanthin B (sidnyaxanthin), crassostreaxanthin A, diatoxanthin, halocynthiaxanthin, heteroxanthin, mytiloxanthin, mytiloxanthinone, pectenols A and B, and pectenolone. Acetylenic carotenoids showed different cytotoxic activity against Raji cells (human neoplasm).

Quantitative carotenoid analysis of the microalga *Euglena viridis* revealed the presence of β,β-carotene (5% of total carotenoids), mixed with some β,ε-carotene, the β,ε-carotene-derived siphonein (siphonaxanthin 19-dodecenoate, 8%), the allenic neoxanthin (4%), and acetylenic carotenoids >86% (273–276). Those included the mono-acetylenic diatoxanthin (**172**) (major, 61%), diadinoxanthin (**174**, rearranged to diadinochrome, 12%), heteroxanthin (**173**, 1%), and the diacetylenic 3,4,7,8,3′,4′,7′,8′-octadehydro-β,β-carotene (**175**, 6%). The significance of the presence of siphonein and diacetylenic carotenoids for algal chemosystematics was briefly discussed. Heteroxanthin was also found in *Euglena gracilis* (274,275), and Xanthophyceae species (276). The principal crystallizable xanthophylls of *Tribonema aequala* were diatoxanthin, heteroxanthin, and diadinoxanthin (277).

Carotenoids of two members of the Raphidophyceae (chloromonads), *Gonyostomum semen* and *Vacuolaria virescens*, and of two tentative members of the same class (*Chattonella japonica* and *Fibrocapsa japonica)* were analyzed (278).

Group I (*G. semen* and *V. virescens*) showed a similar carotenoid pattern, comprised of diadinoxanthin (54–60% of total carotenoids), dinoxanthin (8–17%), β,β-carotene (7%), and heteroxanthin (7%), as well as neoxanthin (*G. semen*, 3%),

an epoxidic monoacetate (*G. semen*, 12%), an epoxidic carotenol, possibly 9′-*cis*-diadinoxanthin (*V. virescens*, 8%), an epoxidic diacetate (*V. virescens*, 2%), and vaucheriaxanthin 3,19-diacetate (*V. virescens*, 8%). Characteristic features common to the carotenoids encountered are a high proportion of epoxidic carotenoids (78–86%), allenic carotenoids (24–82%), acetylated carotenols (18–81%), and acetylenic carotenoids (61–67%; Group I only). The xanthophycean cultured alga *Pleurochloris meiringensis* contains heteroxanthin, diadinoxanthin, and β-carotene (279). Carotenoids extracted from freshwater red tide plankton were shown to include β-carotene (8.1%), peridinin (26.5%), dinochrome A (14.3%), dinochrome B (2.7%), dinoxanthin (1.7%), diadinochrome A (**170**, 2.7%), diatoxanthin (**172**, 6.8%), and 13′-*cis*-7′,8′-dihydroneoxanthin-20′-al 3′-β-lactoside (4.7%). Some of the isolated carotenoids were shown to be cytotoxic to mouse tumors (272).

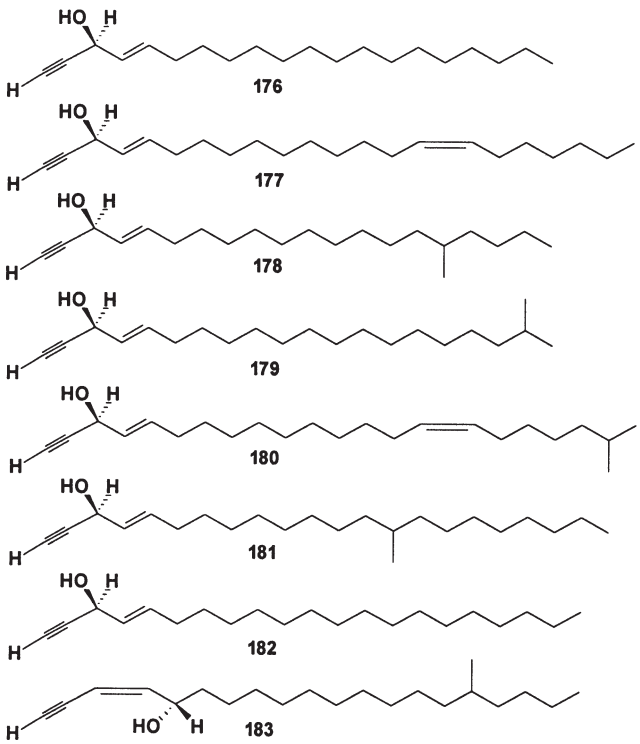
MARINE AND FRESHWATER SPONGES (PORIFERA)

These invertebrates are quite vulnerable and are characterized by a lack of physical defenses. To resist predators and bacteria, to protect themselves from fouling, and to compete for space, they have developed effective mechanisms of chemical defense by extruding, in particular, very toxic secondary metabolites. In fact, the sponges produce the highest quantity of secondary metabolites compared with all other marine invertebrates (280–287). Some of the released compounds are of high structural complexity, exhibit unique modes of action, and are active in extremely low doses. It is no wonder that the sponges are a rich source of biologically active chemical molecules and potentially valuable pharmacological compounds. These porous organisms are known for their ability to serve as harbors for bacteria. Thus, many active compounds produced by the sponges are bactericides (more than 200 antibiotics have been isolated from this source), while others could be of bacterial origin. Intensive search for new classes of biologically active molecules led to a discovery of a series of antitumor compounds from marine sponges and the microorganisms associated with them (286,287).

More than 100 polyacetylenic metabolites have been identified in different sponge species (288), and some of these possess pronounced antitumor activities. Antitumor bioassay-guided fractionation of the organic extract of the marine Brown Bowl Sponge (*Cribrochalina vasculum)* resulted in the isolation of several closely related cytotoxic acetylenic alcohols (**176–183**) (289). Isolated compounds selected from this series showed selective *in vitro* antitumor activity against H-522 non-small cell lung line and IGROV-1 ovarian line. Five acetylenic alcohols (**176**, **177**, **179**, **180**, and **182**) with immunosuppressant and antitumor activity were isolated from the sponge *C. vasculum* and characterized (290,291). The alcohols displayed immunosuppressive activity in mixed lymphocyte reaction and CV-1 cytotoxicity assays (Table 13). In *in vitro* tests on P388 leukemia cells and on cells from human lung (A549) and colon (HT-29) tumors, these compounds had IC_{50} values that varied from 0.86 to 90 μg/mL.

Chromatographic separation of solvent-partitioned fractions of the extract of *Haliclona* sp. yielded two new compounds, halicynones A (**184**) and B (**185**), along with the known compounds triangulyne A (**186**), triangulyne E (**187**), and pellynols A (**188**), B (**189**), C (**190**), D (**191**), and I (**192**) (0.011–0.11% of dry weight). The isolated polyacetylenes were tested for cytotoxicity (292–294). Cultured HCT-116 cells were found to be very sensitive to compounds **188** (IC_{50} 0.026 μg/mL), **189** (0.12 μg/mL), **190** (0.127 μg/mL), **191** (0.103 μg/mL), and **192** (<0.008 μg/mL), whereas the acetylenic ketones **184** and **185** were not effective (IC_{50} > 78 μg/mL). The unusually high cytotoxicities of **188–192** and lack of activity of **184** and **185** suggest that not only a relatively rigid, rod-like structure of the



molecule but also the presence of 1-yn-3-ol were required for this type of biological activity of the above compounds. Pellynols A–D, I, and F (**193**), having a terminal 1-yn-3-ol, showed strong cytotoxicity against several melanoma and ovarian cancer cell lines (IC_{50} 0.08–2.0 μg/mL) (293,294). Pellynic acid (**194**) inhibited inosine monophosphate dehydrogenase with an IC_{50} of 1.03 pg/mL.

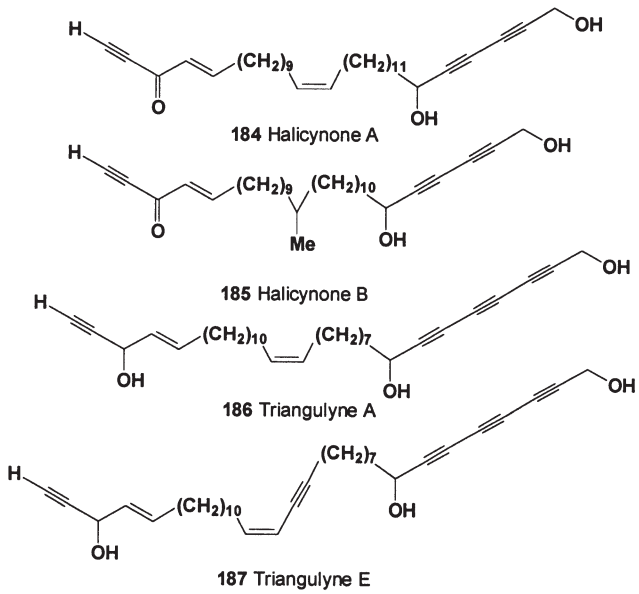
Acetylenic alcohols, strongylodiols A–D (**195–198**), were obtained from the Okinawan marine sponge belonging to the genus *Strongylophora*. Each of these compounds was an enantiomeric mixture in a different ratio and showed cytotoxic activity toward human T lymphocyte leukemia (MOLT-4) cells (295,296).

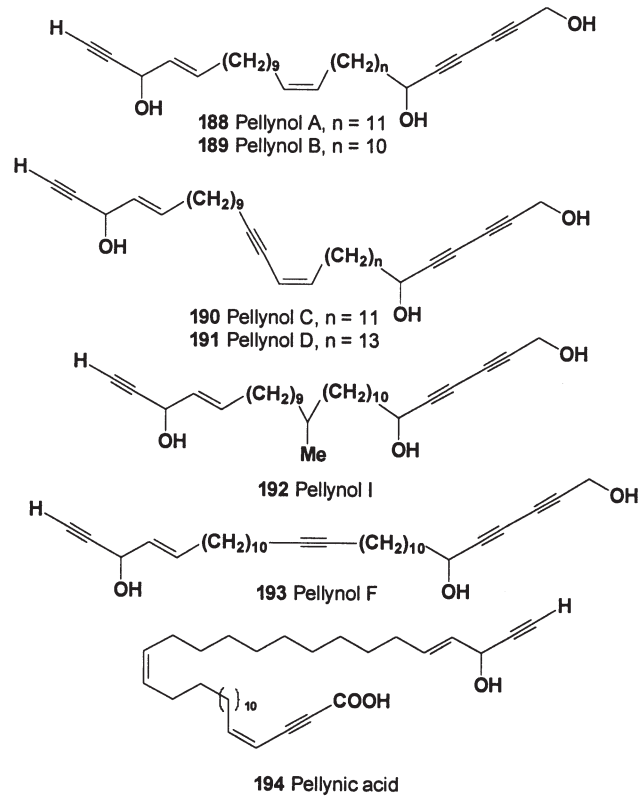
Polyacetylenes with cytotoxic activities against human tumor cell lines (A549, SK-OV-3, SK-MEL-2, XF498, and HCT15) have been isolated from the marine sponge *Petrosia* sp. and given the trivial names of dideoxypetrosynols A–D (**199–202**) (297,298). Compound A (**199**) inhibited DNA replication (299), and a mechanism of its action on cultured human SK-MEL-2 skin melanoma cells has been suggested (300). It is worthy of mention that dideoxypetrosynols B (**200**), D (**201**), and C (**202**) revealed, depending on the test used, cytotoxic activities one order of magnitude higher than those found for doxorubicin (Table 14).

Lembehyne A (**203**), a novel long-chain polyacetylene, was isolated from the Indonesian marine sponge *Haliclona* sp. (301). Lembehyne A induced bipolar neuritogenesis of Neuro-2A cells at 1 μg/mL. Acetylcholinesterase activity of Neuro-2A was also increased by treatment with **203**. Furthermore, the cell cycle of Neuro-2A cells was specifically blocked by **203** at the G1 phase. Lembehynes B (**204**) and C (**205**), which possess different types of long carbon-chain parts compared with that of lembehyne A, also exhibited neuritogenic activity against a neuroblastoma cell line, Neuro-2A. This indicates the importance of a particular stereochemistry (presence of a hydroxyl group at C-3) of lembehynes for the revealed activity (302–304). A new long-chain acetylene named fulvinol (**206**) was isolated from the sponge *Reniea fulva* from Algeciras Bay (Spain), and it exhibited cytotoxicity against four tumor cell lines (ED_{50} = 1 μg/mL) (305).

Adociacetylenes A–D (**207–210**) were isolated as new polyacetylenes from the Okinawan marine sponge *Adocia* sp. (306). Adociacetylenes A, C, and D exhibited inhibitory activity in the *in vitro* endothelial cell-neutrophil leukocyte adhesion assay. All acetylenes were highly cytotoxic to P388, A-549, HT-29, and MEL-28 melanoma cells.

Two acetylenic compounds, petrosynol (**211**) and petrosolic acid (**212**), from the Red Sea sponge *Petrosia* sp. inhibited reverse transcriptase of HIV virus (307,308). The sponge *Strongylophora durissima* yielded two new acetylenic derivatives, durissimols A and B (**213**), and duryne (**214**) (309–311). Among them, durissimol B and duryne showed potent cytotoxicity against human gastric tumor (NUGC) cells. Duryne, a cytotoxic metabolite that inhibits the growth of both mouse and human tumor cell lines *in vitro,* was previously isolated from the marine sponge *Cribrochalina dura* (310,311).





A new C_{43} acetylenic alcohol, vasculyne (**215**), was isolated by cytotoxicity-guided fractionation of the Caribbean sponge *Cribrochalina vasculum* (312). Vasculyne yielded average GI_{50}, TGI, and LC_{50} values of 0.2, 0.7, and 6.7 mg/mL, respectively (where GI_{50} is the concentration required for 50% inhibition of cancer cell growth and TGI is the concentration required for total inhibition of cancer cell growth), and exhibited

modest differential cytotoxicity toward the melanoma and colon tumor cell-line subpanels when determined for a panel of 60 human tumor cell lines, representing nine tumor tissue types, used by the National Cancer Institute (NCI). Structurally, **215** is closely related to the C_{30} compound duryne, previously isolated from the Caribbean sponge *C. dura.*

Osirisynes A–F (**216–221**, respectively), highly oxygenated C_{47} polyacetylenes, have been isolated from the sponge *Haliclona osiris* collected from Guam (313,314). These compounds are characterized by the presence of a diacetylenic carbinol and an α-acetylenic carboxylic acid. Osirisynes A–F exhibited moderate cytotoxicity against a human leukemia cell-line (KS62), with LC_{50} values of 25, 48, 52, 25, 20, and 22 μM for **216–221**, respectively. In addition, **218**, **220**, and **221** inhibited

[b]A549, human lung cancer; SK-OV-3, human ovarian cancer; SK-MEL-2, human skin cancer; XF498, human central nervous system cancer; HCT15, human colon cancer. Doxorubicin, also known as adriamycin, is one of the most commonly used chemotherapeutic drugs and exhibits a wide spectrum of activity against solid tumors, lymphomas, and leukemias.

Na^+/K^+-ATPase and reverse transcriptase at concentrations of l μg/mL.

A novel acetylenic compound, taurospongin A (**222**), was isolated from the Okinawan marine sponge *Hippospongia* sp. (315), and amino acid analysis of the hydrolysis products of **222** showed the presence of taurine. Two fragments, trihydroxylamide and an unsaturated fatty acid methyl ester, were obtained by methanolysis to elucidate the lengths of the methylene chains. Metabolite **222** showed inhibitory activity against c-erbB-2 kinase (IC_{50} 28 μg/mL).

Callyspongamide A (**223**), a cytotoxic polyacetylenic amide, has been isolated from the marine sponge *Callyspongia fistularis* collected in the Red Sea. Callyspongamide A is an amide derivative of a C_{17}-polyacetylenic acid and phenethylamine. It showed a moderate cytotoxicity against HeLa cells with an IC_{50} value of 4.1 μg/mL (316).

Investigation of the organic extract of a Red Sea sponge, *Callyspongia* sp., resulted in the isolation and identification of

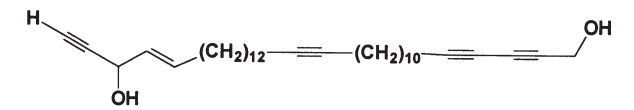
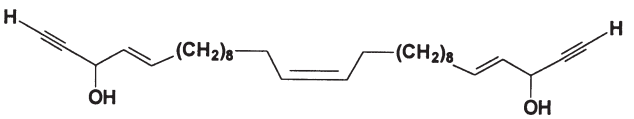
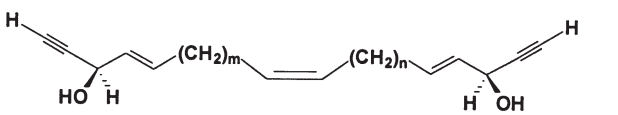
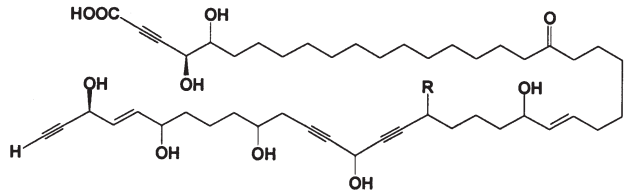
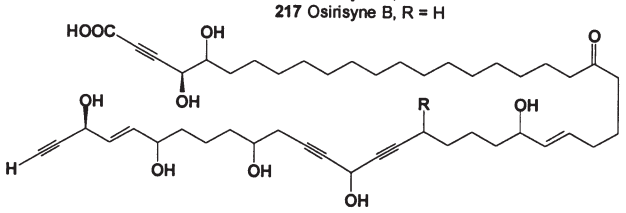
three new C_{22}-polyacetylenic alcohols, callyspongenols A–C (**224–226**), together with siphonchalynol (**227**) (317,318). All compounds showed moderate cytotoxicity against P388 and HeLa cells. The cytotoxicity of compounds **224–227** against HeLa and P388 cells is presented in Table 15. Previously, siphonochalynol (**227**) was isolated from the sponge *Siphonochalina* sp. (318).

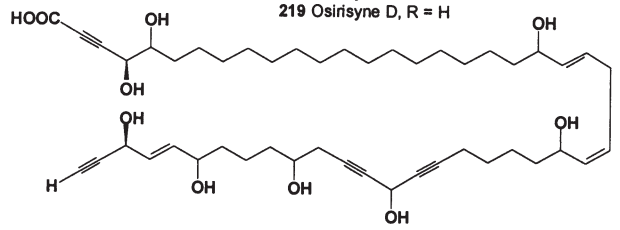


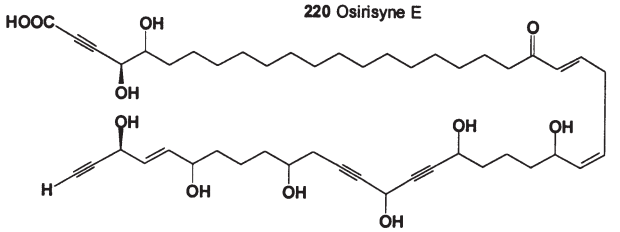












Three new acetylenic metabolites (**228–230**) were isolated from the sponge *Stelletta* sp. collected from Gagu-Do, Korea (319). These compounds exhibited no significant antimicrobial activity and displayed only weak cytotoxicity against the human leukemia cell-line K562 with LC_{50} values of 43.5, 51.3, and 62.5 µg/mL for **228**–**230**, respectively.

(7*E*,13ξ,15*Z*)-14,16-Dibromo-7,13,15-hexadecatrien-5-ynoic acid (**231**) and its methyl ester (**232**), also known as NSC 300263, were isolated from the sponge *Xestospongia muta*. The ED values of **231** for 50% inhibition in *in vivo* PS and L-1210 cell culture evaluations were 24 and 34 µg/mL, respectively, and the corresponding doses of **232** were 29 and 34 µg/mL (320). Similar brominated fatty acids (**233** and **234**)

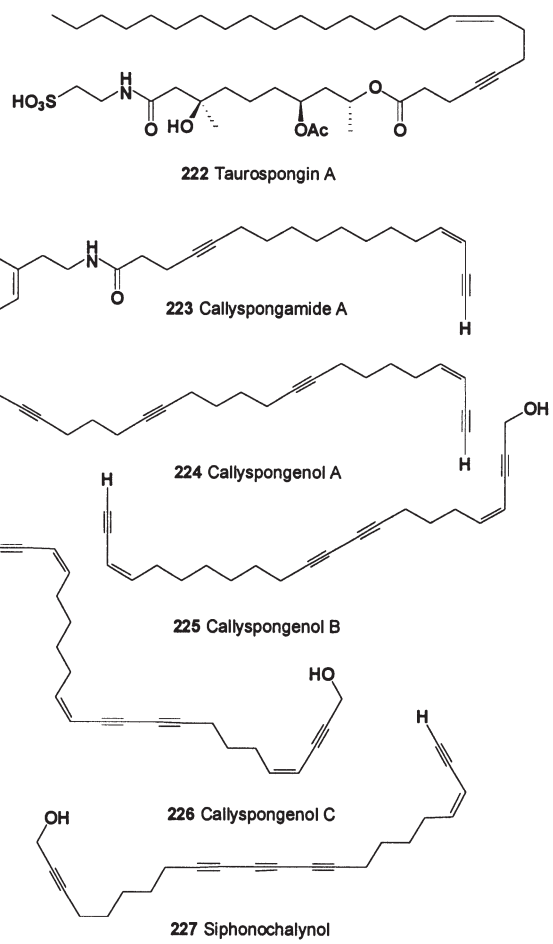
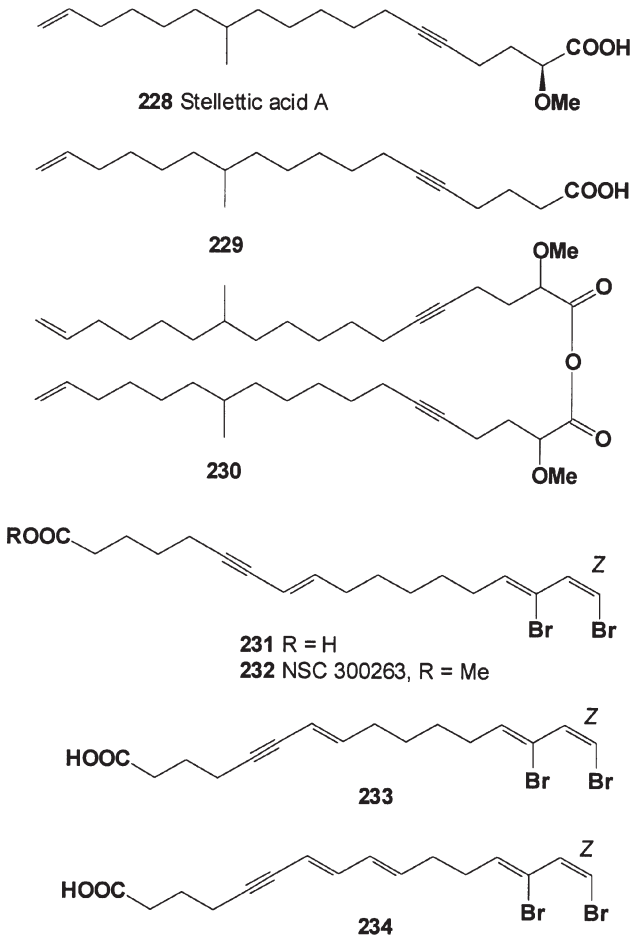
[b](Also known as doxorubicin). Positive cytotoxicity control.





were isolated from an Indonesian sponge, *Oceanapia* sp. (321). Their common structural feature is a (13*E*,15*Z*)-14,16-dibromodiene terminus. Both compounds are unstable oils. The mixture exhibits mild cytotoxicity toward KB cells. A methanol-soluble extract of the frozen marine sponge *Petrosia* sp. showed significant activity in the brine shrimp larvae lethality bioassay (LD_{50} 30 μg/mL), and cytotoxic activities against a panel of human solid-tumor cells. A number of very long chain C_{46} polyacetylenic alcohols from the marine sponge *Petrosia* sp., named petrocortynes (**235–240**), have been identified. These compounds showed different cytotoxic activities human tumor cells (Table 16) (322).

Acetylenic enol ethers of glycerols, including bioactive compounds **241–246**, have been isolated from a sponge of the genus *Petrosia*. Compounds **241** and **243** exhibited weak cytotoxicity against a human leukemia cell-line (K-562) (323). Bioactivities of glyceryl enol ether compounds **241, 242,** and **244**, of the yne-diene series, exhibited weak cytotoxicity against the human leukemia cell-line K-562 (LC_{50} 9.2, 57, and 29 μg/mL for **214, 242,** and **244**, respectively), whereas **244–246**, possessing the yne-ene group, were less active (LC_{50} > 100 μg/mL).

The marine sponge *Prianos osiros*, from Pohnpei (Micronesia), yielded a new cytotoxic acetylenic carotenoid, 3,3′,5,19′-tetrahydroxy-7′,8′-didehydro-γ,ε-carotene-8-one (**247**) (324), which was cytotoxic toward cultured human colon tumor cells, HCT 116 (IC_{50} 4.38 μg/mL). Two new carotenoids, the neoplasm inhibitors 19-hexanoyl-oxymytiloxanthin (**248**) and 19-butanoyloxymytiloxanthin (**249**), have been isolated from the marine sponge *Phakellia stelliderma* collected in Okinawa. Both compounds showed mild cytotoxic activity against P388 mouse leukemia cells (325).

Callipeltoside A (**250**), the first member of a novel class of

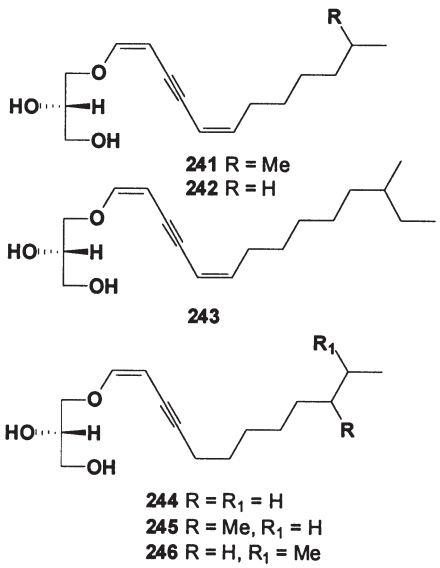
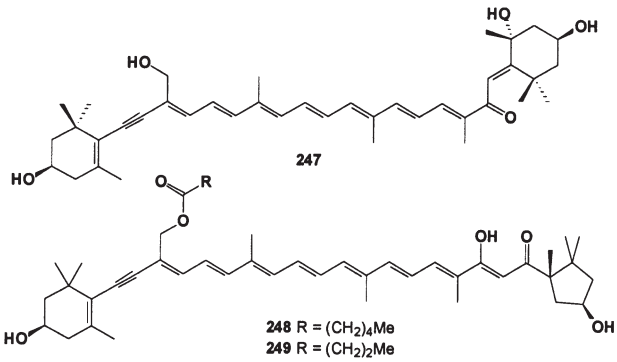
marine glycoside macrolides, was isolated from the lithistid sponge *Callipelta* sp. by Minale and co-workers in 1996 (326). Preliminary biological assays indicated that this marine natural product exhibited cytotoxic activity against NSCLC-N6 human





bronchopulmonary non-small-cell lung carcinoma and P388 cell lines. Callipeltosides A (**250**), B (**251**), and C (**252**) are moderately cytotoxic against NSCLC-N6 cells, with IC_{50} values of 10.0, 15.1, and 30.0 µg/mL, respectively (327).

A novel macrolide, spongidepsin (**253**), has been isolated from the Vanuatu marine sponge *Spongia* sp. (328). The structure of **253** contains 9-hydroxy-2,4,7-trimethyltetradeca-14-ynoic acid and *N*-methyl-phenylalanine residues joined in a 13-membered ring. Spongidepsin showed cytotoxic activity against J774.A1, WEHI-164, and HEK-293 cancer cell lines, with an IC_{50} value in the submicromolar range (see Table 17).

New acetylenic sterols, gelliusterol A (**254**: 26,27-bisnorcholest-5-en-23-yn-3-β-7,α-diol), its corresponding 7-ketone, gelliusterol B (**255:** 26,27-bisnorcholest-5-en-23-yn-3-β-ol-7-one), and gelliusterols C (**257**: cholest-5-en-23-yn-3-β-7-one) and D (**258**: cholest-5-en-23-yn-3-β-25-diol-7-one), were isolated from an unidentified species of sponge, *Gellius* sp. (329). Biological evaluation of gelliusterols A, B, and C was performed on cancer cell lines P388, HT-29, A-549, DU-145, and MEL-28. Gelliusterols A and B exhibited moderate activity, with IC_{50} values greater than 1 μg/mL. An activity of 0.5 μg/mL was observed with gelliusterol C against HT-29, while the other cell lines gave IC_{50} values above 1 μg/mL. The quantity of gelliusterol D (**258**) and **259** was insufficient for biological testing (330,331). Previously, bioactive compound (**256**) was isolated from sponge *Calyx podatypa* by Doss and Djerassi (332).

SOFT CORALS AND OTHER COELENTERATES

The old phylum Coelenterata, now included in the phylum Cnidaria, contains the corals, jellyfish, hydras, and sea anemones. Soft corals can be found worldwide in tropical environments, and they can contain symbiotic dinoflagellate algae (Zooxanthellae) that provide the coral with food in return for a safe environment. The defense of soft corals is based mainly on their stinging cells. At the same time, some fish and molluscs are attracted by the fleshy body of the soft corals. Thus, they release poisonous secondary metabolites (mostly terpenes) to deter potential predators, as well as to protect themselves from algal and bacterial colonization. In addition, the soft corals are territorial and will defend their territory by releasing toxic compounds inhibiting the growth of neighboring animals and algae (333–338). Some corals' secondary metabolites showed antibacterial, antifungal, cytotoxic, and anticancer activities.

The genus *Montipora* is very rich in acetylenic compounds, and many of them are cytotoxic and/or possess antifungal and antibacterial properties. Two polyacetylene carboxylic acids, montiporic acids A (**260**) and B (**261**), were isolated from the eggs of the scleractinian coral *M. digitata* (339). Montiporic acids A and B were not only antibacterial against *Escherichia coli* but also cytotoxic against P388 murine leukemia cells, with IC_{50} values of 5 and 12 μg/mL, respectively.

Coral metabolites **262–275** and four known diacetylenes (**260**,**261**) have been isolated from the methanolic extract of the stony coral *Montipora* sp. (340). The compounds exhibited significant cytotoxicity against a small panel of human solid tumor cell lines (see Table 18). Compounds **262–270** appear to share a common 2,4-diyne moiety as a biosynthetic precursor. Compounds **271–275** are similar to compounds **262–270** in having a diyne group, but the position at which it is found is different. 2,4-Diynes are encountered more frequently in corals, and this may raise a question of the origin of **271–275**.

Compound **271** showed significant cytotoxicity against human skin cancer and human ovarian cancer cell lines. In gen-

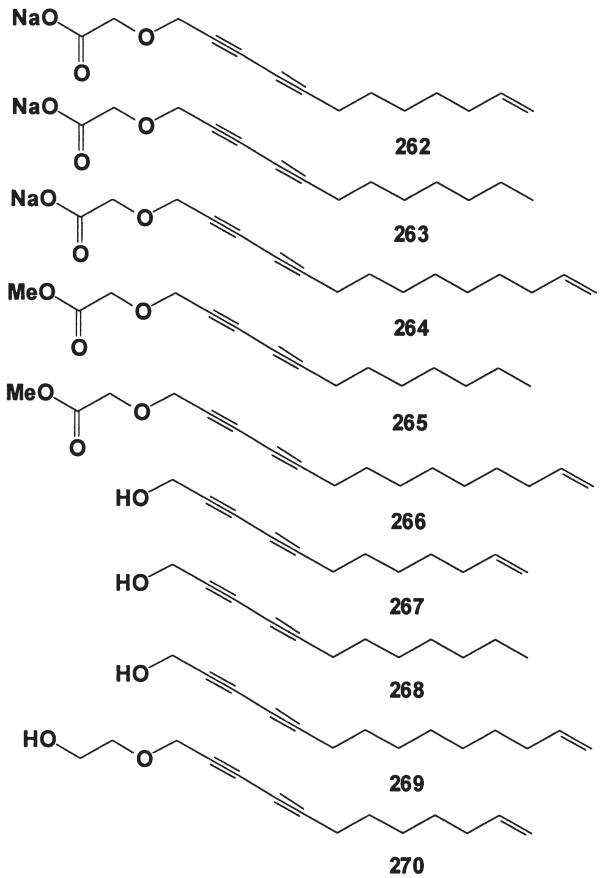
eral, diacetylenes with the α-hydroxy ketone functionality (**271**-**273**) were more active. The *trans*-isomer (**274**) was more active than the *cis*-isomer (**275**), as in the case of montiporynes A–D (**276–279**). Montiporyne A (**276**), an analog of **275**, showed significant cytotoxicity toward human solid tumor cell lines and cell cycle inhibition of the HCT116 cell.

Six acetylenic compounds, montiporynes A–F (**276–281**, respectively), with cytotoxic activities against human solid tumor cell lines SK-OV-3, SK-MEL-2, XF498, and HCT15, have been isolated from the stony coral *Montipora* sp. (Table 19) (341). Polyacetylenes **282–285**, found in three species of the hermatypic corals, *Montipora* sp., *M. mollis*, and *Pectinia lactuca*, represent metabolites of coelenterates that exhibit ichthyotoxicity and inhibit the growth of some bacteria, fungi, and fish (342).



MARINE AND FRESHWATER MOLLUSKS

The mollusks (=molluscs) are members of the large and diverse phylum Mollusca, which includes eight living classes: Caudo-

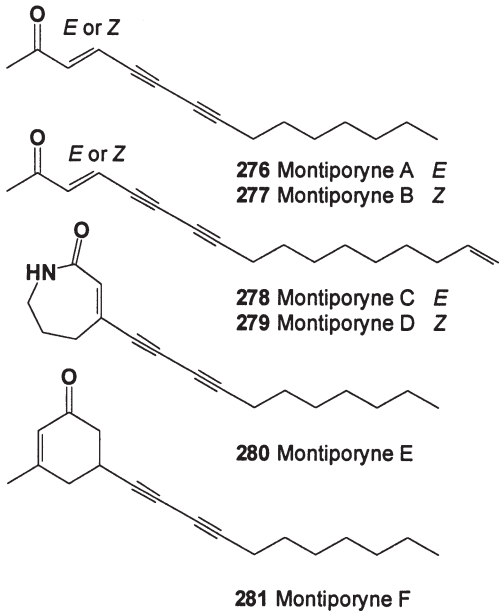


TABLE 19

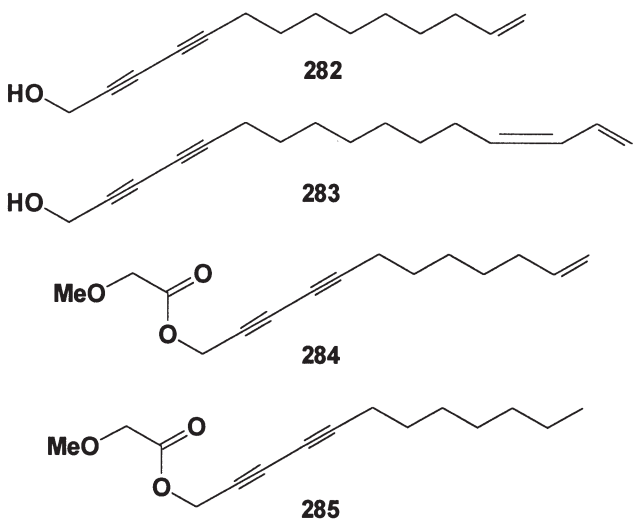
[b]A549, human lung cancer; SK-OV-3, human ovarian cancer; SK-MEL-2, human skin cancer; XF498, human CNS cancer; HCT15, human colon cancer. Compounds were assayed in two separate batches.

foveata (deep-sea wormlike creatures), Aplacophora (solenogasters, deep-sea wormlike creatures), Polyplacophora (chitons), Monoplacophora (deep-sea limpet-like creatures), Scaphopoda (tusk shells), Cephalopoda (squids, octopuses, nautilus, and cuttlefish), Bivalvia (clams, oysters, scallops, and mussels), and Gastropoda (nudibranchs, snails and slugs, limpets, and sea hares) (343,344). Only the two last classes (Bivalvia and Gastropoda) have been well studied and have been of great interest from the pharmaceutical point of view (345,346).

The ethanol extract of the mucous secretion from the opisthobranch mollusk *Oxynoe olivacea* was examined and found to contain two novel ichthyotoxic metabolites, oxytoxins 1 (**167**) and 2 (**168**) (347,348). The structures of the two compounds are closely related to the metabolites previously isolated from the alga *Caulerpa prolifera*. The activity of the most stable compound was studied to investigate the possibility of a further biological role for these metabolites, which represent an uncommon example of bioactive molecules produced *in vivo* from a dietary precursor. Another acetylenic bioactive metabolite, caulerpenyne (**160**), was isolated from the mesogastropod *Littorina irrorata*, which used the macrophytes



Caulerpa prolifera and *Cymopolia barbata* for its diet (348).

Cytotoxic carotenoids, named crassostreaxanthins A (**286**) and B (**287**) and apoalloxanthinal (**288**), were isolated from the oyster *Crassostrea gigas* (Ostreidae) (349), and apocarotenoid **292** was isolated from the marine shellfish *Mytilus coruscus* (350). Acetylenic carotenoids [**172, 173, 289–291**, 7,8-didehydro-β-cryptoxanthin (**292**), 6-epi-heteroxanthin (**293**), and **294**] have been isolated from three species of Chinese freshwater corbicula clams (*Corbicula japonica*, *C. sandai*, and *Corbicula* sp. (351).

The antimutagenic and anticancer effects of carotenoids (β-carotene, cynthiaxanthin (= diatoxanthin), astaxanthin and halocynthiaxanthin, mytiloxanthin, and halocynthiaxanthin) isolated from marine and freshwater bivalve mollusks *Crassostrea gigas* and *Corbicula fluminea* against *S. typhimurium* (TA98) and cancer NCI-H87, HeLa, HT-29, MG-63 cell lines were reported (352).

Several cytotoxic acetylenic carotenoids (**172, 173, 289, 291**), isomytiloxanthin (**295**), 19′-(hexanoyloxy)-isomytiloxanthin (**296**), hydroamarouciaxanthin B (**297**), pyrrhoxanthinol (**298**), and halocynthiaxanthin (**299**) have been identified from muscle of *Mytilus edulis* (353–357). Diatoxanthin (**172**), alloxanthin (= pectenoxanthin: **289**), and pectenolone from *Pectene maximus* (358) and *Patinopectene yessoensis* (359), pectenols A and B from *Mytilus coruscus* (360), crassostreaxanthins A and B (**286** and **287**) from *Crassostrea gigas* (361), and a series of carotenoids with a 5,6-dihydro-β-end group from *Fusinus perplexus* (362) have been reported as the principal carotenoids in marine shellfish. Carotenoids in eight species of freshwater and sea mollusks from Russia were investigated (363). The following compounds have been isolated from the named organisms: alloxanthin, mytiloxanthin, isomytiloxanthin, and the halocynthiaxanthin ether from *Modiolus modiolus* and *Crenomytilus grayanus*; alloxanthin and mytiloxanthin from *Mytilus galloprovincialis*; alloxanthin, mytiloxanthin, isomytiloxanthin, halocynthiaxanthin ether, and pectenolone from *Mizuhopecten yessoensis* have been isolated (363,364).

Marine depsipeptides are natural bio-oligomers composed of hydroxy and amino acids linked by amide and ester bonds; many of them show very promising biological activities, including anticancer, antibacterial, antiviral, antifungal, anti-inflammatory, anticlotting, and antiantherogenic properties. Depsipeptides have shown the greatest therapeutic potential as anticancer agents (365–367).

The depsipeptides onchidin (**300**) and onchidin B (**301**) were isolated from the pulmonate mollusk *Onchidium* sp. Onchidin contains the β-amino acid, 3-amino-2-methyl-7-octynoic acid, and onchidin B, the β-hydroxy acid, 3-hydroxy-2-methyl-7-octynoic acid. The onchidins are known to be cytotoxic, but no details were given in regard to this activity (366,367). The chemical makeup suggests that the compounds originate from cyanobacteria and that they are transmitted *via* herbivorous mollusks to *Philinopsis speciosa* (368,369). Combined extracts [(EtOH and $CHCl_3$/MeOH (1:1)] of the mollusk *P. speciosa* yielded kulolide-1 (**302**), kulolide-2, kulolide-3,

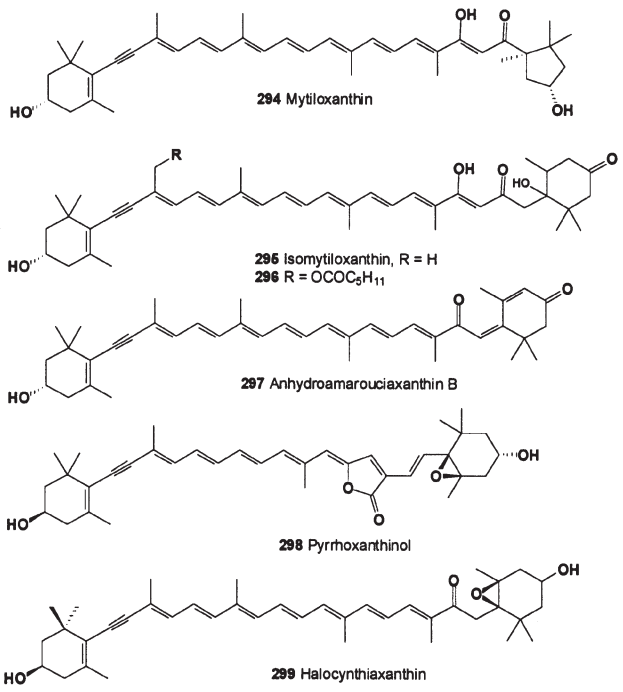
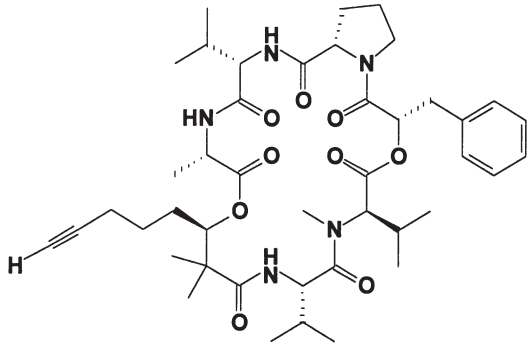
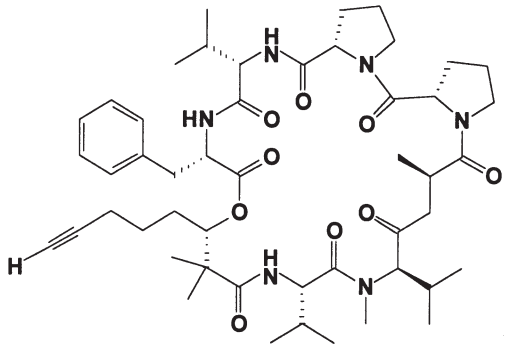
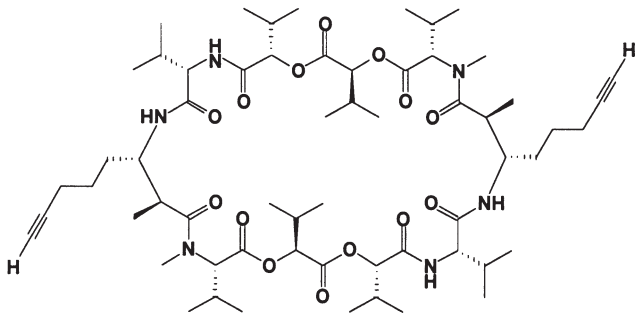
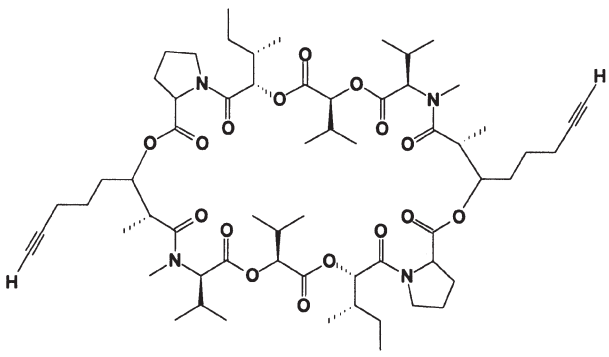
293











kulokainalide-1 (**303**), kulomo'opunalide-1 (**304**), kulomo'opunalide-2 (**305**), and tolytoxin 23-acetate.

Kulolide (**302**), a cyclic depsipeptide, was isolated from a cephalaspidean mollusk, *Philinopsis speciosa* (368,369). Kulolide is made up of five amino acid residues, one each of L-Ala, L-Pro, and N-Me-L-Val and two of L-Val, and two carboxylic acids, L-3-phenylacetic acid and the unprecedented (*R*)-3-hydroxy-2,2-dimethyl-7-octynoic acid. Kulolide was active against L-1210 leukemia cells and P388 murine leukemia cells, with IC_{50} values of 0.7 and 2.1 μg/mL, respectively. Kulolide caused morphological change of rat 3Y1 fibroblast cells at a concentration of 50 μM. In addition to five new depsipeptides related to kulolide-1 (**302**), further examination of the mollusk *Philinopsis speciosa* has yielded a linear peptide, pupukeamide, and an unprecedented macrolide, tolytoxin-23-acetate.

Kulolide-1 (**302**) caused morphological changes to rat fibroblast cells at a concentration of 50 μM. Less than 0.1% contamination with tolytoxin might account for this activity. Peptides **303–305** showed only moderate cytotoxicity against P388 cells.

The unusual cyclodepsipeptide dolastatin 17 (**306**) was isolated from the Papua New Guinea sea hare *Dolabella auricularia* (Gastropoda, Orthogastropoda, Aplysiidae) and found to contain an acetylenic β-amino acid, designated dolayne. Dolastatin 17 exhibited significant human cancer cell growth inhibitory activity (GI_{50} 0.45–0.74 μg/mL range) (370,371).

STARFISH AND OTHER ECHINODERMS

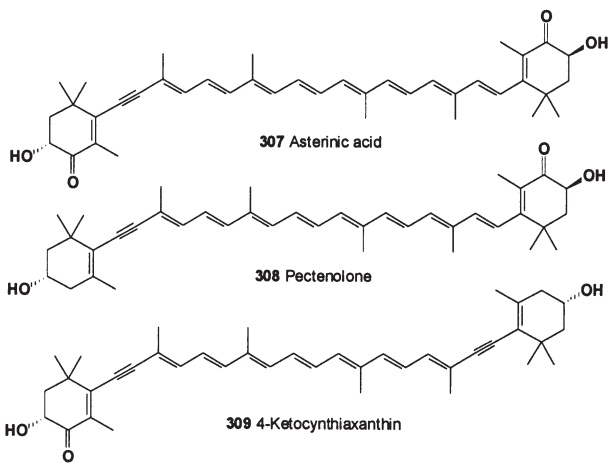
Echinoderms ("spiny skin" in Greek: including starfish, brittle stars, crinoids, sea urchins, and sea cucumbers) are radially symmetrical invertebrates that are only found in the sea (372–374). More than 6,500 species have been recorded in the phylum Echinodermata. A variety of biologically active substances have been isolated from the echinoderms: carotenoids, ether lipids, glycolipids, saponins, naphthoquinones, porphyrins, and others; some of the isolated metabolites contain the acetylenic unit (375–377). Several substances unique to echinoderms have also been reported, some of which show high potential as new medicaments.

From the calyx and arms of *Lamprometra klunzingeri* (family Mariametridae, class Crinoidea, Echinodermata), collected in the Red Sea, the cytotoxic carotenoids diadinochrome (**170**), alloxanthin (pectenoxanthin = **289**), cynthiaxanthin, and asterinic acid (**307**) have been isolated (378).

Asterinic acid (**307**) was found in the following echinoderms from the Adriatic Sea: *Coscinasterias tenuispina, Marthasterias glacialis, Paracentrotus lividus,* and *Sphaerechinus granularis* (379). The cytotoxic acetylenic carotenoids diatoxanthin, and alloxanthin were present in the gonads of Australian and Japanese species of the echinoids *Heliocidaris erythrogramma* and *H. tuberculata* (380); in the sea urchin *Pseudocentrotus depressus* (381); in the sea urchin *Peronella japonica* (382); in seven species of sea urchins, belonging to the orders Cidaroida, Echinothurioida, Diadematoida, and Arbacioida, as well as pectenolone (**308**) and 4-keto-cynthiaxanthin (**309**) (383).

Asterinic acid was isolated from *Asterias rubens*, *Acanthaster planci*, *Coscinastrias acutispina*, *Leiaster leachii*, *Asterias amurensis*, *Ophidiaster ophidianus*, *Asterina panceri*, *Asteropecten aurantiacus*, and *Marthasterias glacialis* (384–389). Mytiloxanthin was found in *Ophiocomina nigra* (390); and derivatives of the cytotoxic acetylenic carotenoids, (3*S*,4*S*,3′*S*,5′*R*)-4-hydroxymytiloxanthin, (3*S*,4*S*,3′*S*,4′*S*)-4,4′-dihydroxydiatoxanthin, (3*S*, 4*S*,3′*S*,4′*S*)-4,4′-dihydroxyalloxanthin, (3*S*,3′*S*,4′*S*)-4-keto-4′-hydroxydiatoxanthin, and (3*S*,3′*S*,4′*S*)-4-keto-4′-hydroxyalloxanthine were isolated from the starfish *Asterina pectinifera* and *Asterias amurensis* (391).

Carotenoid content of the seven species of sea cucumber (*Stichopus japonicus*, *Holothuria leucospilota*, *H. moebi*, and *H. pervicax* of the order Aspidochirotida, *Cucumaria japonica*, *C. echinata*, and *Pentacta australis* of the order Dendrochirotida) was reported (392). β-Carotene, β-echinenone, canthaxanthin, phoenicoxanthin, and astaxanthin were common in all the sea cucumbers examined. Alloxanthin, diatoxanthin, and pectenolone were isolated as minor carotenoids. The bluish vi-



307 Asterinic acid

308 Pectenolone

309 4-Ketocynthiaxanthin

olet pigment in the dorsal skin of *Asterias rubens* was isolated as an amorphous powder (393). Asterinic acid (**307**) and four derivatives of alloxanthin, diatoxanthin, and mytiloxanthin were isolated and their structures elucidated. More detailed information on the carotenoids and other bioactive compounds was also reported (394,395).

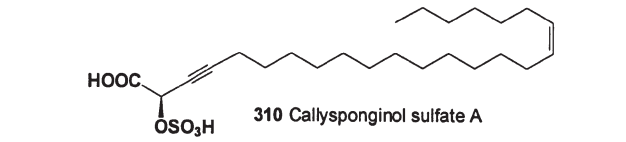
TUNICATES (OR SEA SQUIRTS)

Tunicates (urochordates) are small, box-like filter-feeding animals that live either alone or in colonies cemented to the sea floor. Many species of tunicata produce bioactive compounds (396). Callysponginol sulfate A (**310**), a sulfated C_{24} acetylenic fatty acid from the marine sponge *Callyspongia truncata*, is a membrane type 1 matrix metalloproteinase (MT1-MMP) inhibitor. Compound **310** inhibited MT1-MMP with an IC_{50} value of 15.0 mg/mL (397), and sodium 1-(12-hydroxy)octadecanyl sulfate was isolated from a marine tunicate as a matrix metalloproteinase 2 (MMP2) inhibitor (398). This compound inhibited MMP2 with an IC_{50} value of 9.0 μg/mL.

Four cytotoxic straight-chain polyacetylenic alcohols (**311–314**) were isolated from a marine ascidian (phyllum Chordata, subphyllum Urochordata) collected off Vigo, along the Atlantic coast of northwestern Spain (399). This is the first finding of acetylenic lipids from an organism belonging to phylum Chordata.

The carotenoids of the muscles and tunic of the tunicates *Halocynthia aurantium*, *H. roretzi, Styela clava*, and *S. plicata* were isolated and identified (400,401). Antimutagenic activities of the carotenoids toward *S. typhimurium* TA 98 and cytotoxic activity for cancer cell lines were detected. Total carotenoid contents in the muscle of tunicata ranged from 18.65 to 2.39 mg percent. The major carotenoids of *H. roretzi*, *H. aurantium*, *S. plicata*, and *S. clava* were cynthiaxanthin (25.1–42.2%), halocynthiaxanthin (9.7–26.3%), diatoxanthin (8.0–18.7%), and β-carotene (7.7–21.7%). Diadinochrome, mytiloxanthin, diatoxanthin, alloxanthin, pectenolone, and halocynthiaxanthin were isolated from *H. roretzi* (400,401). Halocynthiaxanthin (**299**), with few side effects at 2 μg/mL, inhibited growth of HeLa, COLO32ODM, HGC-27, PANC-I, and GOTO cells, *in vitro* (402). Halocyanthiaxanthin (5 μg/mL), from the sea squirt *H. roretzi*, caused complete suppression of human neuroblastoma GOTO cell proliferation, reducing the growth rate by 88.8% compared with the control. Furthermore, halocyanthiaxanthin also inhibited the growth of other human malignant tumor cells. Thus, halocyanthiaxanthin seems to be a promising antineoplastic agent (403).

Extracts of the colonial marine ascidian, *Polysyncraton lithostrotum*, collected from Namenalala Island, Fiji Islands,



310 Callysponginol sulfate A

317 Shishijimicin B, R = H, R_1 = iPr
318 Shishijimicins C, R = SMe, R_1 = Et

showed induction of the SOS repair response in a Biochemical Induction Assay (BIA) and potent cytotoxicity against a panel of human tumor cell lines. Bioassay-guided fractionation of the extract, following BIA activity, yielded namenamicin (**315**), a new enediyne antitumor antibiotic. DNA cleavage experiments showed that namenamicin cleaves DNA less specifically than calicheamicin (404). The MeOH and EtOH extracts of the tunicate, following reversed-phase HPLC, afforded shishijimicins A (**316**), B (**317**), and C (**318**), together with the known namenamicin (Table 20).

CONCLUDING REMARKS

Intensive searches for new classes of pharmacologically potent agents produced by bacteria, cyanobacteria, micro- and macroalgae, marine and freshwater invertebrates, plants, and fungi have resulted in the discovery of dozens of compounds possessing high cytotoxic activities. However, the preclinical and clinical development of many terrestrial- and aquatic-derived natural products into pharmaceuticals is often hampered by a limited supply from the natural source. Total synthesis is of vital importance in these situations, allowing for the production of useful quantities of the target compound for further biological evaluation.

ABSTRACT: One of the main biological systems that can be used as a model for studying the molecular mechanisms involved in membrane fusion is the formation of the nuclear envelope (NE). NE assembly to form the male pronucleus at fertilization occurs by binding of NE membrane precursor vesicles to chromatin and their fusion. MV_1 is an NE precursor vesicle population of low density, highly enriched in {18:0/20:4}PI. The modification of {18:0/20:4}PI to {18:0/20:4}DAG leads to NE formation, and the depletion of MV_1 from the total membrane precursors results in the inhibition of NE assembly. Here we show by ^{2}H NMR studies of various physiologically relevant model membranes made of {18:0/20:4}PI, {18:0/20:4}DAG, and saturated and unsaturated PC that membranes of composition similar to MV_1 exhibit dramatically enhanced fluidity and non-lamellar structures, thus providing a possible explanation for the essential role of MV_1 and the modification of PI to DAG in membrane precursor vesicles during NE assembly.

Paper no. L10023 in *Lipids 41*, 925–932 (October 2006).

The nuclear envelope (NE) is disassembled and reassembled at each mitosis in typical animal cells. Membrane vesicle precursors of different phospholipid compositions contribute to the membrane fusion leading to NE formation (1). Therefore, study of NE assembly combines and relates the study of membrane domains and regulation of membrane fusion.

Study of male pronuclear membrane formation in fertilized sea urchin egg extracts has revealed several novel features of assembly, especially regarding the role of phospholipids. The binding of NE vesicles to chromatin is ATP-dependent (1). When total precursor membrane vesicles are fractionated on a sucrose gradient, several vesicle populations can be resolved (2). The least dense, MV_1, is highly enriched in PI (3,4). This unusual precursor membrane vesicle plays an essential role in the assembly of the NE. *In vitro*, assembly can be triggered by either GTP hydrolysis or bacterial or eukaryotic phosphoinositide phospholipase C (PIPLC), and depletion of MV_1 from the cell-free system prevents NE assembly (4,5).

Fusion of membrane vesicles is a proteo-lipid phenomenon in which proteins are required for targeting and fusogenic lipids for destabilizing the local structure of the lamellar bilayer to induce fusion. Model membrane studies have shown that lipids such as DAG, PE, and PA are destabilizing fusogenic lipids, and that variation in their composition induces membrane fusion (6–9). Our EI–MS studies show that the major PI in the total membrane vesicle population is {18:0/20:4}PI, and its hydrolysis by bacterial PLC leads to production of {18:0/20:4}DAG (10). Moreover, we have recently shown that DAG derived from $PI(4,5)P_2$ hydrolysis is required to induce NE assembly (5).

Studies performed on the physical properties of membranes have been based largely on model systems, but these do not necessarily represent the composition of biological membranes (11). We have exploited deuterium solid-state NMR to study membrane fluidity and polymorphism of model systems that have similar composition to the NE precursor membrane vesicles. ^{2}H NMR is one of the most precise and direct methods to determine order parameters that depict the amplitude of intramolecular and molecular motions; the method therefore provides insight into the rigidity or fluidity of a particular membrane. These physical parameters are directly associated with the fusogenity and the mobility of membranes. Thus, the order parameters of biologically relevant model membranes can be informative as to their physiological roles.

A study concerning the physical properties of biologically relevant model membranes investigated the effect of calcium ions on phase separation in natural PC and PI liposomes (12). This study primarily used ESR methods. The effect of DAG on phase changes of phospholipid bilayers has been studied using x-ray diffraction techniques (13). However, in the latter study, {18:0/20:4}DAG, which is specifically relevant to NE assembly, was not used. Moreover, neither of these studies exploited deuterium-labeled solid-state NMR to study the physical properties of high levels of natural PI and natural DAG.

The specific role of large amounts of PI in membrane conformational changes has not been previously investigated by a non-invasive method such as solid-state NMR. Solution NMR studies have illustrated that MV_1 is composed of 80 mol % PI and 20 mol % PC (4). To investigate the physical properties of such an unusual bilayer, and the consequences of hydrolysis of the PI by PIPLC, we made various binary systems with

{18:0/20:4}PI/diplamitoylphosphatidylcholine (DPPC)-$^2H_{62}$ and {18:0/20:4}DAG/DPPC-$^2H_{62}$. Because DPPC has an elevated gel-to-fluid phase transition temperature, T_c, near 41°C, we also used deuterium-labeled palmitoyloleoylphosphatidylcholine (POPC), which has a T_c near –5°C. POPC has a 16:0/18:1 chain composition that is more representative of MV_1 PC composition.

We show that with increasing molar ratios of {18:0/20:4} DAG and {18:0/20:4}PI in DAG/DPPC and PI/DPPC binary model membranes, membrane fluidity is enhanced dramatically and non-lamellar structures are promoted. Similar results are obtained using POPC containing 80% DAG or PI. We propose a plausible explanation for the presence of PI domains to account for fusion events in NE assembly.

EXPERIMENTAL PROCEDURES

Lipids were purchased from Larodan Fine Chemicals (Sweden): D1-stearin-2 arachidonin ({18:0/20:4}DAG) and PI (liver, porcine; mainly composed of {18:0/20:4}). Note that the FA molecular composition of our binary model membranes is the same as the molecular composition of the NE membrane vesicles. Deuterium-labeled 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (DPPC-$^2H_{62}$) and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC-$^2H_{31}$) were purchased from Avanti Polar Lipids, Inc. (Alabama, U.S.A.). All solvents were purchased from Aldrich (Saint Quentin Fallavier, France), and 4-mm (50-µL) ZrO_2 rotors were purchased from Cortec (Paris, France).

Preparation of Multi-lamellar Vesicles. DPPC-$^2H_{62}$/PI, DPPC-$^2H_{62}$/DAG, POPC-$^2H_{31}$/PI, and POPC-$^2H_{31}$/DAG mixtures in chloroform were mixed by vortexing and dried down in a Speedvac for 20 min. The 1:4, 1:1, and 4:1 molar ratios were made for binary model membranes with DPPC. Only the 4:1 molar ratio was made when preparing binary mixtures with POPC. Pellets were resuspended in 200 µL of TN buffer (10 mM Tris-HCl, 150 mM NaCl, 15 mM $MgCl_2$, pH 7.2) and lyophilized. Lipid powders were dispersed in deuterium-depleted water at the required concentration to give 80% hydration (wt/wt). Hydration was completed by three 20-min freeze-thaw cycles. The samples were placed in 50-µL ZrO_2 rotors. Depending on samples, the amount of deuterated lipid ranged from 3 to 12 mg.

NMR Spectroscopy. Solid-state NMR was carried out on Bruker Avance DSX-500 and DSX-300 instruments (11.75 and 7.05 Tesla, respectively). ^{31}P NMR spectra were acquired at 202 MHz using a phase-cycled Hahn-echo pulse sequence with gated broadband proton decoupling (14). ^2H NMR experiments on deuterated lipids were performed at 46.1 MHz by means of a quadrupolar echo pulse sequence (15). Typical acquisition parameters were as follows: spectral window of 50 kHz for ^{31}P NMR and 250 kHz for ^2H NMR; π/2 pulse widths ranged from 3 to 5 µs depending on sample, interpulse delays were of 30–40 µs. A recycle delay of 5 s was used for ^{31}P NMR; for ^2H NMR experiments, it was set to 2 s. Typically, 2k–4k scans were recorded for the deuterium nucleus and 4k transients for the phosphorus nucleus. A line broadening of 50–300 Hz was applied prior to Fourier transformation. Phosphorus chemical shifts were referenced relative to 85% H_3PO_4 (0 ppm). Quadrature detection and digital filtering were used in all cases. Samples were allowed to equilibrate at least 30 min at a given temperature before the NMR signal was acquired; the temperature was regulated to ±1°C.

Calculations. The first spectral moment, M_1, was calculated according to the method of Davis (16) using a C++ routine analysis incorporated in Origin 7 software (S. Buchoux, CNRS, University of Bordeaux 1, IECB, Bordeaux, France, unpublished). To avoid zero values for spectra symmetrical relative to the origin a sign reversal was used for negative frequencies. In such a case M_1 can be used to directly estimate the carbon-deuterium bond order parameter S_{CD} according to the following equation:

$$\langle S_{CD} \rangle = \frac{\sqrt{3}}{\pi A_Q} M_1 \qquad [3]$$

Angular brackets represent the average overall deuterium-labeled positions in the perdeuterated palmitic chains in DPPC and POPC. A_Q is the static quadrupolar coupling constant, 167 kHz (17).

RESULTS

For the initial optimization of our studies we prepared model systems with molar ratios of PI or DAG in DPPC of 1:4, 1:1, and 4:1. Because pure DPPC membranes have a gel-to-fluid transition temperature around 40°C, we performed temperature scans from 0 to 60°C, by increasing or decreasing temperatures. Reproducible spectra were obtained independent of the thermal history of the sample. To investigate a more physiologically relevant model system we used POPC and applied the same procedures as with DPPC. In the case of POPC, only the 1:4 molar ratio between POPC and DAG or PI was prepared. We performed temperature scans from –15°C to 40°C, because the POPC gel-to fluid phase transition temperature occurs at about –5°C. Similar to DPPC-containing samples, the spectra obtained were independent of the thermal history of the sample.

Figure 1 shows selected ^2H NMR spectra in the presence of PI. The left panel shows control DPPC-$^2H_{62}$ spectra. A well-known axially asymmetric L_β, gel phase spectrum is detected at 20°C depicting the quasi-absence of intramolecular motions and a molecular tilt of approximately 30° with respect to the membrane normal (16). At 60°C a narrower axially symmetric spectrum is detected, representative of intramolecular disorder (gauche-trans isomerizations of chain segments, whole molecule wobbling) as in an L_α fluid phase. At 35°C, a two-phase spectrum is detected, illustrating the coexistence of gel and fluid phases on the NMR timescale (µs). Addition of PI induces, overall, a narrowing of all spectra. This is particularly clear for the sample containing 80% PI, for which the spectrum at 20°C is characteristic of a fluid phase. This narrowing phenomenon is also observed at high temperatures. For various amounts of PI, a more general view can be obtained when plot-

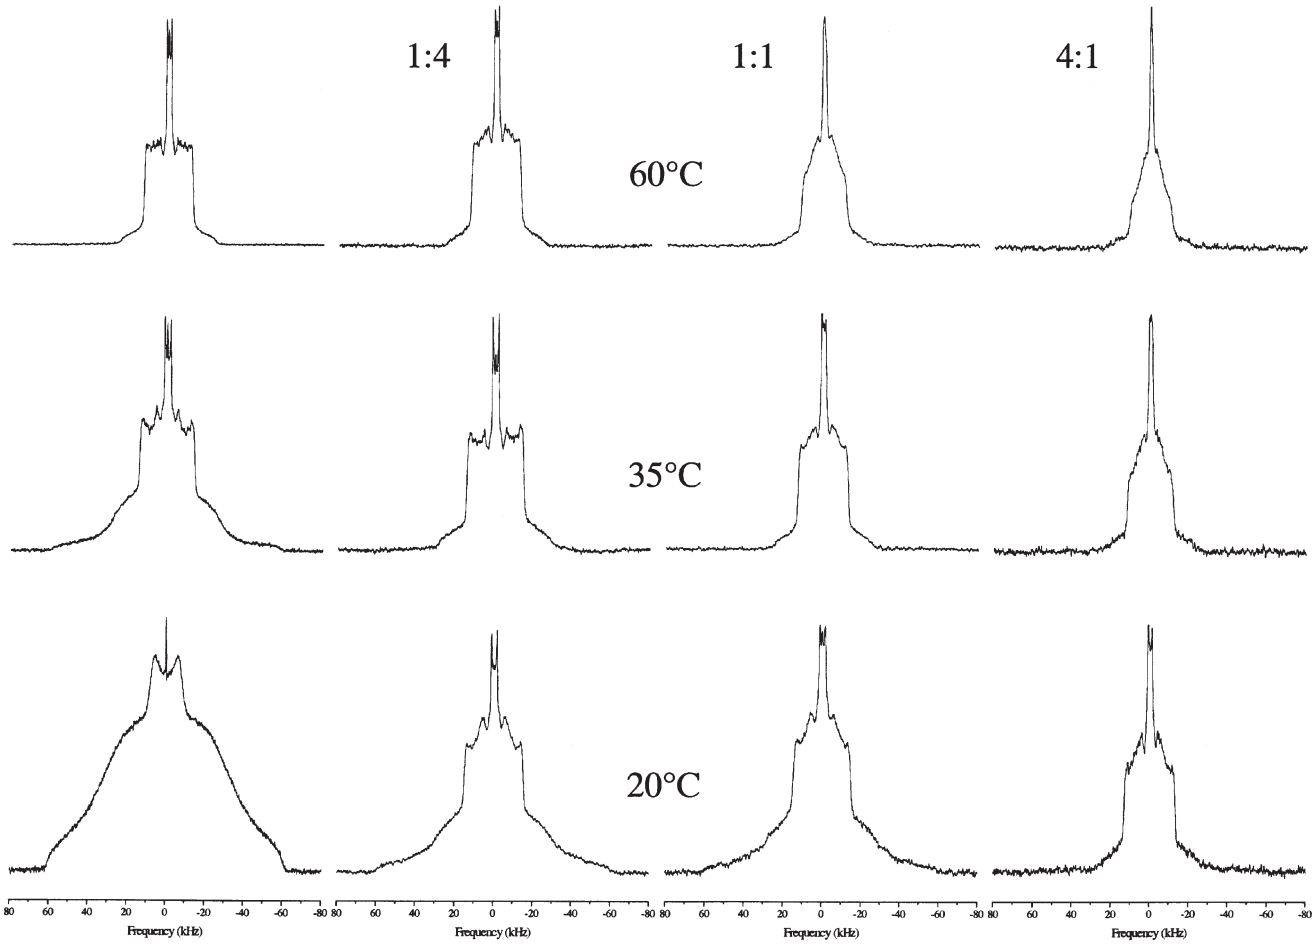

FIG. 1. Elevated amounts of PI in PI:DPPC induce membrane fluidity. Representative deuterium wide-line NMR spectra of DPPC-$^2H_{62}$ in the absence (left panel) or presence of PI. Temperatures and {18:0/20:4}PI:DPPC molar ratios are indicated. Sample hydration is 80%. Depending on DPPC amounts (3–12mg), each spectrum is the result of 1k to 4k scans. A Lorentzian filtering (LB) of 200 Hz was applied prior to Fourier transformation.

ting the first moment as a function of temperature (Fig. 2). Several effects are noted: reduction of molecular order at low temperatures, downshift of the gel-to-fluid phase transition, and molecular disorder in the fluid phase spectra. A clear dose-dependent effect is demonstrated.

We have translated M_1 into membrane order by plotting on a double-*Y* axis the orientation order parameter S_{CD} (Fig. 2). A value close to 1 represents membranes where almost no bond or molecule fluctuations are detected (ordered system). A zero value shows complete molecular disorder as in liquids. It is striking that elevated amounts of PI induce membrane disorder in a manner that the membrane at 15°C with 80% PI has the same fluidity as pure DPPC above its fluid phase transition temperature (40°C).

Figures 3 and 4 show the corresponding effect of DAG on DPPC-$^2H_{62}$ liposomes. Spectral features become narrower as the amounts of DAG are increased (Fig. 3). At high temperatures an isotropic line dominates the spectrum, indicating that the initial micrometer-size multi-lamellar vesicles have been converted into isotropic symmetries such as cubic phases or smaller tumbling objects (50–200 nm) (18,19). This is a clear indication that DAG modulates the vesicle size by inducing a highly curved interface. From the M_1-vs.-*T* graph (Fig. 4) we can see that at low temperatures, where values typical of a gel phase are detected, reduced membrane perturbations occur. A 10°C downshift of the gel-to-fluid phase transition temperature is detected, and there seems to be a saturation effect at 20 mol % DAG in DPPC. DAG readily promotes membrane disorder for amounts greater than 20 mol % and temperatures higher than 40°C. It should be noted here that the presence of the isotropic line for very high temperatures leads to an additional decrease of M_1 that cannot be attributed to disorder.

Figure 5 shows selected spectra of POPC-$^2H_{31}$ in the absence or presence of 80 mol % DAG (center) or PI (right). The features observed for pure DPPC in Figure 1 are also observed with POPC, but these are downshifted in temperature by approximately 45°C. Below –5°C, gel-phase spectra are detected; above this temperature, axially symmetric powder patterns characteristic of lamellar fluid phases are observed. This downshift in temperature is well known and is due to the presence of

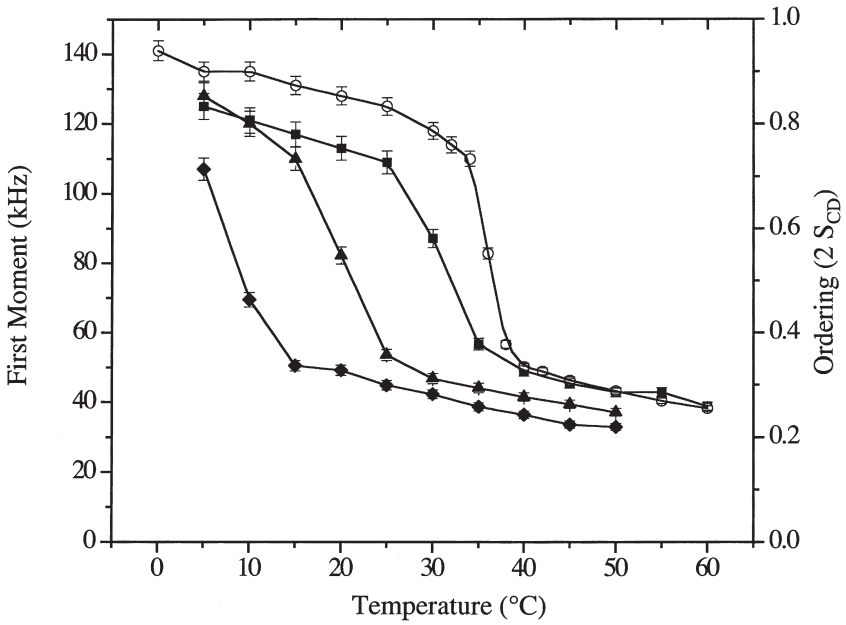

FIG. 2. Thermal variation of the first spectral moment of PI:DPPC membranes. Calculated from ^{2}H NMR spectra of DPPC-$^2H_{62}$ in the absence (empty circles) or presence of {18:0/20:4}PI; {18:0/20:4}PI:DPPC molar ratios of 1:4 (squares), 1:1 (triangles), and 4:1 (diamonds). Accuracy of calculations is ±3%. On the double *Y*-axis the C-D order parameter is shown as calculated from Equation [1] (see text). Twice $<S_{CD}>$ is plotted to express residual ordering information relative to the bilayer normal. A zero value is indicative of a fully disordered system, as in pure liquids, whereas a value of 1 reflects the absence of *gauche-trans* isomerization and molecular wobbling as in a very rigid membrane (ordered system).

the *cis* double bond at positions 9–10 in the *sn*-2 chain that hinders the close packing of acyl chains. In the presence of DAG (center panel), we note the appearance of a marked isotropic line that dominates spectra at high temperatures. With PI (right panel), the spectrum at –10°C is in the fluid phase and remains characteristic of this phase for increasing temperatures. In fact, to detect an ordered system the temperature had to be decreased to –15°C (data not shown). At 40°C, the spectrum in the presence of PI is much narrower that that of pure POPC, clearly indicating a greater disorder of the membrane. It is noteworthy that the deuterium-labeled lipid shows only one spectrum in the mixed system (independent of the PC/(PI or DAG) ratio). The spectrum is different from pure PC, indicating that the deuterated reporter lipid samples only one environment on the microsecond timescale of NMR. This shows that there is only one average homogeneous environment. A sample with coexisting rigid and fluid domains would have shown two spectra, one of them being the pure reporter (POPC or DPPC). This phenomenon is clearly not observed. In addition, the deconvolution of deuterium spectra was performed using the de-Pakeing algorithm (20), and the order parameter profile was plotted against the labeled carbon position. This shows that all chain positions, from the glycerol backbone near the interface to the bilayer center, are disordered in a similar way (data not shown).

In order to ascertain the effects detected by the chains of labeled POPC, we performed ^{31}P NMR experiments on new samples of unlabeled POPC with 80 mol % {18:0/20:4}PI or {18:0/20:4}DAG. Figure 6 shows that with high levels of DAG, the 40°C spectrum is characterized by a single isotropic line. This profile is also as observed with ^{2}H NMR (Fig. 5). However, at –5°C a broad feature is barely detected. The weak intensity is due to the low amount of lipids containing phosphorus (20% POPC only) that show a spectral feature with a wide distribution of frequencies, as also observed with ^{2}H NMR. For the PI:POPC model system, a spectrum typical of a fluid membrane is seen both at 40 and –5°C, as also detected with ^{2}H NMR (Fig. 5). Closer analysis of the spectra illustrates that although there are similar dynamics, the two lipids show two detectable chemical shift anisotropies that reflect the different nature of the lipid head groups (PI and PC).

The data in Figure 5 were used to calculate the first spectral moment, M_1. From the M_1-vs.-T graph in Figure 7, we observe that both DAG and PI with POPC produce effects similar to DPPC, except the temperatures are downshifted by approximately 45°C. PI greatly decreases the gel-to-fluid transition temperature of POPC and increases molecular disorder of the fluid-phase spectra. DAG also shifts the transition temperature, but to a lower extent. It readily promotes membrane disorder for temperatures higher than 0°C. As with DPPC-containing samples, it should be noted that the presence of the isotropic line for very high temperatures leads to an additional decrease of M_1 that cannot be attributed to disorder.

Temperatures and {18:0/20:4}DAG :DPPC molar ratios are indicated. Sample hydration is 80%. Experimental parameters are as in Figure 1.

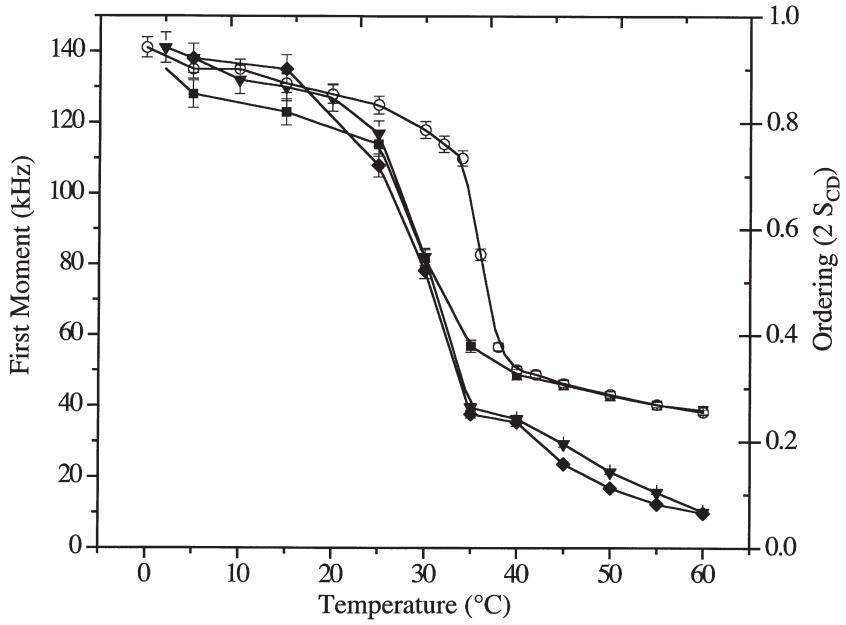

FIG. 4. Thermal variation of the first spectral moment of DAG:DPPC membranes, as calculated from ^2H NMR spectra of DPPC-$^2H_{62}$ in the absence (empty circles) or presence of {18:0/20:4}DAG; {18:0/20:4}DAG:DPPC molar ratios of 1:4 (squares), 1:1 (triangles), and 4:1 (diamonds). Other parameters are as in Figure 2.

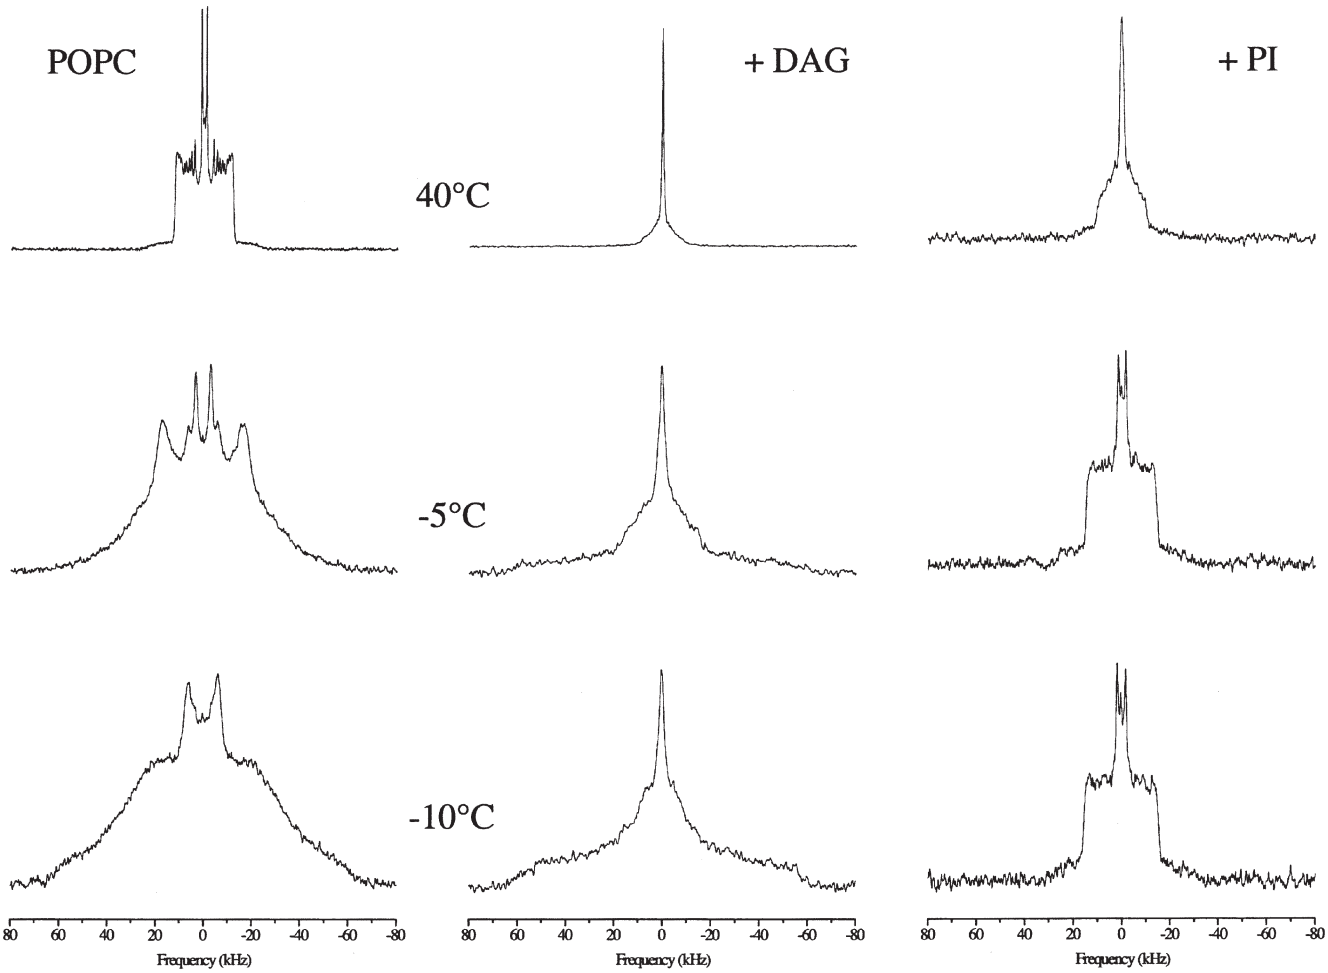

FIG. 5. Membrane perturbations with high levels of PI/POPC-$^2H_{31}$ and DAG/POPC-$^2H_{31}$. Representative deuterium wide-line NMR spectra of POPC-$^2H_{31}$ in the absence (left panel) or presence of 80 mol % DAG or PI. Temperatures are indicated on spectra. Sample hydration is 80%. Experimental parameters are as in Figure 1.

DISCUSSION

We have demonstrated by ^2H NMR studies that both polyunsaturated PI and DAG cause prominent perturbations of membrane fluidity and thermal behavior, both in saturated and unsaturated model membranes. To our knowledge, prior investigations using ^2H solid-state NMR illustrating perturbations in membrane fluidity and membrane disorder induced by high levels of {18:0/20:4}PI and {18:0/20:4}DAG lipids have not been reported. Moreover, we show that PI readily disorders membrane packing by providing fluid-phase conditions at temperatures as low as 15°C with DPPC or –10°C with POPC (sample with 80% PI). This is an important point because the physiological temperature of the sea urchin is close to 16°C. It should be noted that, typically when phase transitions are studied, experiments are performed at much higher temperatures that are not strictly physiologically relevant to biological systems. MV_1 FA composition is mainly {18:0/20:4}PI and {18:1/20:4}PC. Moreover, {18:0/20:4}PI is the main molecular species that undergoes lipid modification in our system (B. Larijani, unpublished data). Hence the study of this particular species became our prime interest. Nevertheless, the closest deuterated probes available commercially to perform our experiments were 16:0/16:0PC and 16:0/18:1PC.

We therefore used the closest binary composition to MV_1 ({18:0/20:4}PI/DPPC and{18:0/20:4}PI/POPC, 4:1 molar ratio) to study the physical properties of these systems. It should be noted that the initial experiments were performed with DPPC, but the physiological significance of the data relies on the experiments that were performed with POPC. We deduce from our data that these biological vesicles are very fluid even at low temperatures. PI provides a greater chain disorder of the membrane, which may result in a reduction of the membrane thickness (21,22). This effect could be promoted both by the PI head group and chains. It is however well documented that the augmentation of unsaturated bonds induces a greater disorder in lipid bilayers (23). We suggest that the role of this particular polyunsaturated PI is to promote such an effect, and it would be well-adapted for fusion events that require a dynamic membrane interior.

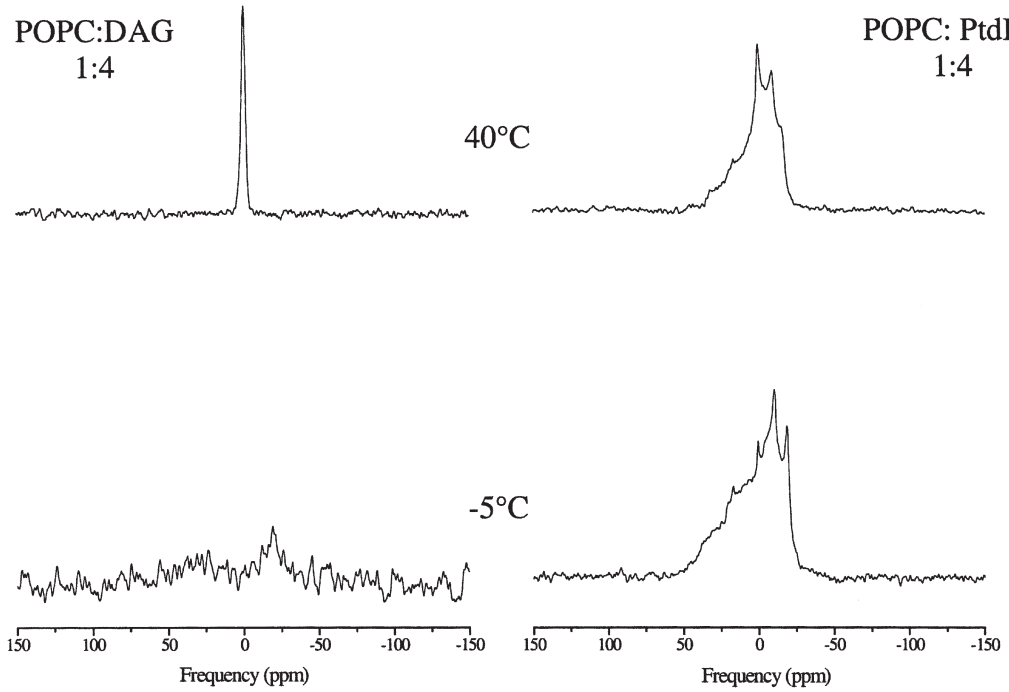

FIG. 6. Membrane perturbations with high levels of PI/POPC and DAG/POPC. Representative ^{31}P wide-line NMR spectra of POPC in the presence of 80 mol % DAG or PI. Temperatures are indicated on the spectra. Sample hydration is 80%. Each spectrum is the result of 4k scans. A Lorentzian filtering (LB) of 100–300 Hz was applied prior to Fourier transformation.

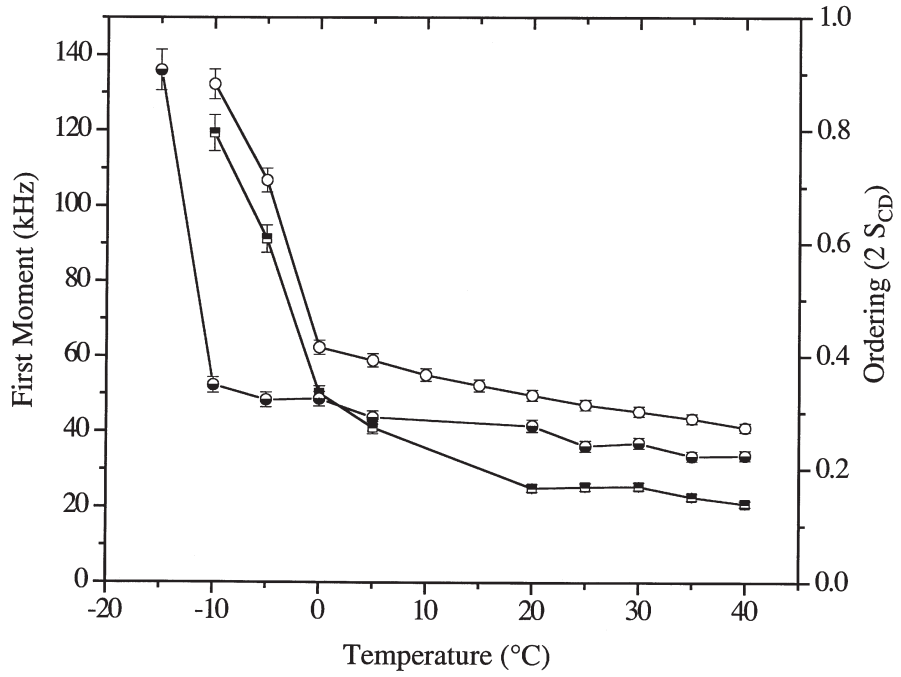

FIG. 7. Thermal variation of the first spectral moment of DAG:POPC-$^2H_{31}$ and PI:POPC-$^2H_{31}$ membranes (4:1 molar ratio), as calculated from ^2H NMR spectra of POPC-$^2H_{31}$ in the absence (empty circles) or presence of {18:0/20:4}DAG (half-filled squares) or {18:0/20:4}PI (half-filled circles). Other parameters are as in Figure 2.

In NE precursor membrane vesicles, the product of endogenous {18:0/20:4}PI hydrolysis by bacterial PIPLC is {18:0/20:4}DAG. We show in this study that unsaturated DAG does not affect rigid gel-phase membranes. However, it does induce disorder at higher temperatures, thus promoting under such conditions non-lamellar structures that are a prerequisite for induction of membrane fusion (24,25). This effect is detected independent of the chain composition of the host membrane; it occurs equally with both saturated and unsaturated PC.

From these studies we propose a model whereby both polyunsaturated PI and DAG are implicated in membrane fusion events, leading to NE assembly, in a sequential manner. The {18:0/20:4}PI in MV_1 would increase membrane fluidity thus "prompting" the membranes for fusion, and, following PLC hydrolysis of PI, highly curved structures (non-lamellar) would be formed in the presence of {18:0/20:4}DAG, thus triggering the fusion of the NE precursor membrane vesicles. Although the kinetics of membrane fusion leading to the induction of NE formation is protein-dependent we have shown in this study that lipids such as {18:0/20:4}PI can affect membrane dynamics when presented at elevated amounts such as in MV_1.

To verify this proposed model, the change in MV_1 conformation, upon PIPLC treatment, observed by ^{2}H NMR is being currently studied in our laboratories.

Markedly Raised Intake of Saturated and Monounsaturated Fatty Acids in Rats on a High-Fat Ketogenic Diet Does Not Inhibit Carbon Recycling of ^{13}C-α-Linolenate

Ameer Y. Taha, Mary Ann Ryan, and Stephen C. Cunnane*

Department of Nutritional Sciences, Faculty of Medicine, University of Toronto, Toronto, Ontario, Canada, M5S 3E2

ABSTRACT: Under various dietary and physiological conditions, carbon from α-linolenic acid (ALA) is extensively recycled into saturated and monounsaturated fatty acids. In this study we investigated whether carbon is still recycled from ALA when a dietary source of saturated and monounsaturated fatty acids is provided in excess. ^{13}C-labeled ALA was given to rats consuming a high-fat ketogenic diet and to rats consuming a low-fat control diet. In rats on the ketogenic diet, ^{13}C recycling from α-linolenate into several, but not all, saturated and monounsaturated fatty acids matched or exceeded that in the controls ($P<0.05$). We conclude that carbon recycling into saturated and monounsaturated fatty acids persists when the main end products of ALA recycling are provided in excess, using a ketogenic diet.

Paper no. L10028 in *Lipids 41*, 933–935 (October 2006).

Studies addressing the whole-body utilization of linoleic acid (LA) and α-linolenic acid (ALA) in young rats have shown that up to 80% of dietary derived LA or ALA normally disappears from the body; it is thought to be mostly or completely β-oxidized to CO_2 (1,2). In rats, recycling of exogenously administered ^{13}C-LA or ^{13}C-ALA into *de novo* products of lipid synthesis accounts for a significant proportion of the carbon skeleton of these fatty acids that is catabolized, but not completely oxidized to CO_2 (3,4). Approximately 50–60% is oxidized to CO_2, whereas the remaining 20–30% is recycled into *de novo* lipid products (3,4). This quantitative aspect of carbon recycling has been confirmed for ALA in particular, in the fetuses and infants of monkeys that were fed an LA-enriched diet throughout gestation and lactation (5). More recently, ALA recycling has also been confirmed in adult humans (6).

ALA recycling into *de novo* lipid products appears to be a preferential pathway of ALA utilization in tissues because it occurs regardless of dietary n-3 PUFA status (7,8). In young rats, ALA recycling into *de novo* lipid products is not altered by ALA deficiency during early development, a period when the demand for n-3 PUFA is thought to be at its highest (7). Conversely, adult rats fed a diet enriched with DHA continue to recycle exogenously administered ^{14}C-ALA into sterols and products of *de novo* fatty acid synthesis (8). These studies suggest that ALA recycling into sterols and saturated and monounsaturated fatty acids may possibly be an "obligatory" pathway for ALA utilization in rats (9).

It is not known, however, whether ALA recycling into *de novo* lipid products is maintained when the major fatty acid end products of ALA recycling, specifically saturated and monounsaturated fatty acids, are provided in the diet in excess. To elucidate further the nature of ALA recycling in liver, adipose, and brain, we investigated ^{13}C-ALA recycling into saturated and monounsaturated fatty acids in rats consuming a high-fat ketogenic diet. We hypothesized that, despite higher tissue incorporation of saturated and monounsaturated fatty acids in rats on a high-fat ketogenic diet, carbon recycling into products of *de novo* fatty acid synthesis would remain a major pathway of ALA utilization. This study was part of a previous study addressing the effects of the ketogenic diet on ketone body production and tissue fatty acid composition (10).

EXPERIMENTAL PROCEDURES

Animals and treatments. Male Wistar rats (Charles River, La Prairie, QC, Canada) aged 40–42 days received a low-fat control diet during the 10-day adaptation period. For the following 10 days, the control rats continued on the low-fat control diet, whereas the experimental group received a high-fat ketogenic diet (n = 8/group). The macronutrient profile of the control diet (by weight) was 8.2% fat, 9.2% protein, and 82.6% carbohydrate, whereas that of the ketogenic diet was 72.7% fat, 16.3% protein, and 11.0% carbohydrates. The control diet contained 79.3 g added fat/1000 g of diet of the following composition: palmitate (9.4%), stearate (4.2%), oleate (27.2%), LA (50.6%) and ALA (8.0%). The ketogenic diet contained 688.8 g fat/1000 added g of diet, including medium-chain fatty acids (<12 carbons; 11.3%), myristate (7.3 %), palmitate (23.9%), stearate (10.9%), oleate (25.7 %), LA (16.2%), and ALA (2.4%), as well as behenate, palmitoleate, and vaccinate, which collectively accounted for <2.3%.

After 9 d on the respective diets, six rats from each group were gavaged with 5 mg of ^{13}C-ALA dissolved in 100 μL of

*$P < 0.05$.

olive oil. The remaining two rats in each group were gavaged with 100 μL of olive oil and used as references for ^{13}C background during analysis of isotopic enrichment. Twenty-four hours after tracer dosing, all rats were sacrificed by an intraperitoneal injection of 1.3 μL/kg of sodium pentobarbital (MTC Pharmaceuticals, Cambridge, ON), and liver, brain, and perirenal adipose tissue samples were excised from each rat. Liver and brain were washed with saline and weighed immediately after extraction. Samples were stored at below −20°C until they were analyzed.

Lipid extraction and fatty acid analysis. As previously described (10), total lipids of homogenized samples of adipose, liver, and brain were extracted according to Folch *et al.* (11) and analyzed by gas-liquid chromatography, using a 30-m × 0.25-mm i.d. capillary column (J&W Scientific DB-23, Folsom, CA) in a Hewlett-Packard 6890 gas liquid chromatograph (Palo Alto, CA). Methyl esters of total fatty acid extracts from adipose tissue, liver, and brain were analyzed for ^{13}C enrichment by gas chromatography–combustion–isotope ratio mass spectrometry (Europa 20-20 with Orchid combustion interface, PDZ Europa, Crewe, Cheshire, UK), as described in detail elsewhere (12). The ^{13}C enrichment data are expressed as the amount of labeled fatty acid per gram of tissue (ng ^{13}C/g of tissue).

Statistical analysis: All data are presented as mean ± standard deviation. Statistical analysis was performed on Statistical Analysis Software (version 8.02, SAS Institute, Cary, NC). An unpaired Student's *t*-test was used to detect statistical significance at $P < 0.05$.

RESULTS

There were no significant differences in liver or brain weights between the control and ketogenic diet groups (10.6 ± 1.1 g in controls vs. 10.5 ± 0.7 g in ketogenic diet group for liver; 1.9 ± 0.1 g in controls vs. 1.8 ± 0.2 g in ketogenic diet group for brain). Fatty acid profiles of adipose tissue, liver, and brain reflected the differences in fatty acid composition of the control and ketogenic diets (Table 1). Compared to rats on the control diet, rats on the ketogenic diet had significantly higher percent composition of stearate (300%) in adipose tissue; higher concentrations (mg/g of tissue) of palmitate (41%), stearate (61%), and oleate (58%) in liver; and a higher concentration of palmitate (6%) in brain ($P<0.05$).

There was a two- to fourfold greater incorporation of ^{13}C from ALA into stearate and oleate in adipose tissue of rats on the ketogenic diet than in controls, but a 72% lower direct incorporation of ^{13}C-ALA ($P < 0.05$; Table 2). Despite the increase in liver concentrations of saturated and monounsaturated fatty acid species due to the high fat content of the ketogenic diet, recycling of ^{13}C-ALA into saturated and monounsaturated fatty acids in liver of rats that received the ketogenic diet did not differ significantly from controls ($P > 0.05$; Table 2). Moreover, the amount of ^{13}C-ALA itself incorporated into liver did not differ significantly between the two groups. In brain, carbon recycling from ^{13}C-ALA into palmitate was twofold higher in rats on the ketogenic diet ($P < 0.05$), even though brain content of palmitate was significantly raised by the high-fat ketogenic diet (Table 2).

DISCUSSION

This study shows that carbon recycling from ALA into saturated and monounsaturated fatty acids is not decreased even when intake and tissue levels of fatty acids produced during carbon recycling of ALA are raised by the high-fat ketogenic diet. Our results confirm that ALA recycling into products of *de novo* fatty acid synthesis occurs regardless of the saturated and monounsaturated fatty acid content of the diet or tissues.

ALA recycling into some, but not all, products of *de novo* fatty acid synthesis in adipose tissue and brain was more than twofold higher in rats on the ketogenic diet, despite the significant increase in the composition of stearate and oleate in adipose tissue and palmitate concentration in brain (Tables 1 and 2). The underlying pathway accounting for greater recycling of ALA, despite higher concentrations of fatty acid end products of ALA recycling, is not clear. However, greater incorporation

*$P < 0.05$.

of ^{13}C-ALA into stearate and oleate in the adipose of rats on the ketogenic diet does not reflect recycling in adipose tissue, because adipose tissue has minimal capacity to oxidize fatty acids (13). It is possible, however, that ^{13}C reflects recycling in liver and subsequent uptake by adipose tissue, because the concentrations of stearate and oleate were significantly higher in the liver of rats that received the ketogenic diet, relative to control rats (Table 1).

The different fatty acid content and composition of the control and experimental diets were unlikely to affect ALA partitioning toward elongation/desaturation products of ALA, because we previously showed that rats on a ketogenic diet appear to preferentially mobilize PUFA from adipose tissue to liver and brain, yet, tracer incorporation into DHA in all these tissues remained the same (10). Our findings are consistent with other studies showing that elongation/desaturation of ALA into DHA occurs regardless of dietary or tissue concentrations of n-3 or n-6 PUFA (5,8,14,15).

We conclude that carbon recycling from ALA into *de novo* products of fatty acid synthesis persists despite higher dietary intake and tissue concentrations of saturated and monounsaturated fatty acids and low to negligible incorporation of ALA into adipose tissue and brain. It now seems clear that, under experimental conditions ranging from extreme dietary and tissue depletion of n-3 fatty acids to raised intake and tissue content of saturates and monounsaturates, carbon recycling of ALA is consistently observed (7). The biological significance underlying this quantitatively important pathway remains to be established.

ABSTRACT: This study was conducted to determine effect of CLA and linoleic acid (LA) on cell differentiation, cellular glycerol-3-phosphate dehydrogenase (GPDH) activity, and FA accumulation in differentiating 3T3-L1 cells (3 isomers × 3 treatment periods × 4 doses). The cells were cultured in 24-well plates for proliferation until confluence. Then they were treated with media containing 0, 10, 35, or 70 mg/L (0, 35, 125, or 250 mmol/L, respectively) of LA, *cis*9,*trans*11- or *trans*10,*cis*12-CLA during early (day 0–2), intermediate and late (day 3–8), or overall (day 0–8) differentiation periods. Dexamethasone, methyl-isobutylxanthine, and insulin were supplemented to the media only for the early period to induce the differentiation. On day 8 of postconfluence the cells were harvested for Oil Red O staining, analysis of GPDH activity, and determination of the FA concentration. Cellular LA or CLA was found to accumulate in a dose-response manner, mainly during the intermediate/late period. Treatment with *trans*10,*cis*12-CLA lowered ($P < 0.05$) GPDH activity and the concentration of FA including palmitic acid (16:0) and palmitoleic acid (16:1), especially during the intermediate/late and overall periods, or whenever a high dose of 70 mg/L was applied. This also resulted in a higher ($P < 0.05$) ratio of saturated FA to monounsaturated FA. Treatment with LA or *cis*9,*trans*11-CLA lowered cellular FA only when they applied during the early period at a dose of 70 mg/L. The results demonstrated that the inhibitory effects of CLA on differentiation, GPDH activity, and FA accumulation of 3T3-L1 cells are dependent on the isomer type, treatment period, and dose.

Paper no. L9824 in *Lipids 41*, 937–949 (October 2006).

CLA are positional and geometric isomers of linoleic acid (LA) produced during biohydrogenation of FA by rumen bacteria such as *Butyrivibrio fibrisolvens* (1) or in body tissues from *trans*-11 octadecenoic acid by Δ^9-desaturase (2). In animal models, dietary CLA has induced positive effects that could be applied to enhance human health (3). Studies found that a mixture of synthetic CLA containing isomers of *cis*9,*trans*11 (c9,t11) and *trans*10,*cis*12 (t10,c12) decreased body fat mass in rats (4), a result that possibly reflected increasing energy expenditure (5) or decreasing adipocyte number (6). The effects of c9,t11- and t10,c12-CLA may be different on lipogenesis and adipogenesis of adipose tissues. It was reported that t10,c12-CLA had a better effect on decreasing body fat in mice than c9,t11-CLA (7).

Early *in vitro* studies found that a mixture of CLA in culture medium inhibited preadipocyte differentiation (8,9) but stimulated lipogenesis in 3T3-L1 preadipocytes (9). In studies using pure CLA, t10,c12-CLA attenuated lipogenesis in primary human adipocytes (10) and increased FA oxidation in 3T3-L1 cells (11). Brown *et al*. (12,13) reported that t10,c12-CLA decreased cellular TAG accumulation in differentiating human preadipocytes, and it functioned similarly in 3T3-L1 cells (14–16). However, McNeel *et al*. (17) found that cellular TAG concentration, glycerol-3-phosphate dehydrogenase (GPDH) activity, and peroxisome proliferator-activated receptor γ (PPARγ) were increased in either c9,t11- or t10,c12-CLA-treated human preadipocytes.

3T3-L1 cell lines have been used as models for study on the differentiation from preadipocytes to adipocytes (18). Dexamethasone, methyl-isobutylxanthine, and insulin (DMI) typically were used to induce the differentiation of the cells (19). Within 2 d of treatment with media containing DMI, the cells completed a postconfluent mitosis and formed a growth arrest. Treatment with DMI allowed the expression of transcription factors including PPARγ, which could reach a high level on day 4 of postconfluence, at which time the differentiation generally was completed (19). Therefore, the differentiating periods could be divided into early (day 0–2), intermediate (day 2–3), and late (from day 4) periods according to the appearances of differentiation markers. It is necessary to clarify the effect of CLA or LA on the cells in various differentiation periods and the doses applied in previous studies (13,14,16,17).

The present study was conducted to investigate the effects of LA, c9,t11- or t10,c12-CLA, of their treatment periods, and of their doses on the differentiation process in DMI-induced differentiating 3T3-L1 preadipocytes. As main indicators of differentiation and lipid accumulation, the Oil Red O-stained cell profile, cellular GPDH (EC 1.1.1.8) activity, and the concentration of the main cellular FA were compared among various treatments.

Abbreviations: DHAP, dihydroxyacetone phosphate; DMI, dexamethasone, methyl-isobutylxanthine, and insulin; GPDH, glycerol-3-phosphate dehydrogenase; LA, linoleic acid; MUFA, monounsaturated fatty acid(s); PPARγ, peroxisome proliferator-activated receptor γ; SCD, stearoyl-CoA desaturase; SFA, saturated fatty acids.

MATERIALS AND METHODS

Experimental design and cell culture. This is a 3 FA × 3 treatment periods × 4 doses cell culture experiment. The 3T3-L1 cell line was obtained from the American Type Culture Collection (Manassas, VA). Passages of the cells used in present study were seven or eight. The cells were seeded to 24-well plates at a density of 1.5×10^4 cells per mL of DMEM (Sigma Chemical, St. Louis, MO) containing 10% FBS (Sigma Chemical) in a humidified 5% CO_2 atmosphere at 37°C for proliferation until confluence was attained. The total 432 wells of confluent cell cultures were treated, respectively, with media containing 0, 10, 35, or 70 mg/L (0, 36, 125, 250 μmol/L, respectively) of LA, c9,t11-, or t10,c12-CLA during the early (day 0–2), intermediate/late (day 3–8), or overall (day 0–8) differentiation period. Each treatment included 12 replications. The media contained 0.1% ethanol used as carrier for FA. LA was obtained from (Sigma Chemical), and isomers of CLA were obtained from Matreya, Inc. (Pleasant Gap, PA) with a purity of more than 98% for both. The basic media for the intermediate/late period (day 3–8) was DMEM supplemented with 10% FBS. All the media including the control and the FA treatments during the early period (day 0–2) were supplemented with 0.1 μmol/L dexamethasone (Sigma Chemical), 1 mmol/L methyl-isobutylxanthine (Sigma Chemical), and 0.1 μmol/L insulin (bovine insulin; Sigma Chemical) that acted as the main factors (DMI) to induce initial differentiation.

Harvesting and counting cells. At the end of culture experiment (day 8), the cells in 5 wells per treatment (total 140 wells) were harvested for analysis of GPDH activity whereas the contents of the other 140 wells were harvested for FA analysis. The remaining 56 wells were stained with Oil Red O and Mayer's hematoxylin (Sigma Chemical) before being photographed. For counting and for analysis of FA, cells were harvested by washing them with warm PBS (pH 7.08) and then dissociating by incubation with PBS containing 0.25% trypsin and 100 mg/L EDTA. The cells were counted on a hemocytometer. For analysis of GPDH activity, the cells were washed with cold PBS (calcium- and magnesium-free). Then 0.5 mL Tris-EDTA (pH 7.5) was added to each well. The cells were collected mechanically and fractured by ultrasonication. After centrifugation at 12,800 × *g* for 5 min at <5°C, the supernatant was taken for analysis of GPDH activity. All the harvested cells and extracts were stored at –80°C until further analysis.

Staining and photographing cells. The cells, in duplicate per treatment (total 56 wells), were stained with Oil Red O and Mayer's hematoxylin. Briefly, 1 mL of cold, buffered formalin was added to the cell culture and kept at room temperature for 30 min. Then it was replaced with fresh 2 mL of cold, buffered formalin for 1 h at room temperature to achieve fixation. After washing with deionized water, 1 mL of 0.5% Oil Red O (Sigma Chemical) in isopropanol/deionized water (3:2) was added to the fixed cells for 1 h to stain the oil bodies in the cells. Then the cells were washed with deionized water, then counterstained with Mayer's hematoxylin (1 g/L; Sigma Chemical) for 3 min, and washed with deionized water again. The cell cultures were photographed by using a microscope digital camera.

GPDH (EC 1.1.1.8) activity and protein analysis. The GPDH activity assay was carried out following a previous method, with modifications (20). Cellular extract (100 μL) was added to mixture of the following: 50 μL of TEA solution (pH 7.5: composed of 0.5 M triethanolamine, 10 mM EDTA, and 10 mM 2-mercaptoethanol); 100 μL of 5 mmol/L dihydroxyacetone phosphate (DHAP); and 200 μL 0.5 mM NADH. The disappearance of NADH at 25°C was measured by a spectrophotometric method at 340 nm with a microplate spectrophotometer (Benchmark Plus; Bio-Rad, Hercules, CA). The activity of GPDH was expressed as units per min = [NADH (100 nmol) × change of OD_{340}]/[1.25 × time (min) × protein (mg)]. Protein content was measured with the modified method of Lowry *et al.* (21) with a modified Lowry protein assay kit (Pierce, Rockford, IL).

Extraction of cellular lipids. The cellular lipids were extracted by using a procedure reported by Jiang *et al.* (22) with modifications. The harvested cells were transferred into a test tube to which 7 mL of isopropanol was added and then homogenized for 3 min. Next, 5 mL of hexane was added and mixed, followed by 4 mL of water, and the tube contents were homogenized again. The mixture was then centrifuged at 2,000 × *g* at 5°C for 5 min. The upper layer was transferred to a new tube. The extraction was repeated twice with hexane. Then 7 mL of 0.47 M aqueous Na_2SO_4 was added to the extracted liquid and mixed. The solution was centrifuged again at 2,000 × *g* at 5°C for 5 min. The hexane layer was collected into a tube and evaporated under nitrogen in a 38°C water bath. The residue was flushed with nitrogen and stored at –80°C for further analysis.

Methylation and determination of FA. A combined base/acid methylation method (23) with modifications was used. Heneicosanoic acid (21:0) methyl ester was used as an internal standard by adding it to the tubes containing extracted cellular lipids (75 μL, 5 mg/mL Nu-Chek-Prep, Inc., Elysian, MN). Then 2 mL of sodium methoxide (0.5 mmol/L in methanol) was added to each tube, each tube was mixed completely and flushed with nitrogen, then placed in a 50°C water bath for 10 min. After that, 1 mL of boron trifluoride (14% in methanol) was added to each tube, and the tube reheated in a 50°C water bath for another 10 min. Then 5 mL water and 1 mL hexane were added and mixed completely. After standing for 10 min. the upper layer (hexane) was taken into a GC vial flushed with nitrogen and stored at –30°C until FA profiles were determined by GC. The FA profiles were analyzed on a Shimadzu gas chromatograph (GC-14B; Shimadzu Co., Kyoto, Japan) with an Rtx®-2330 capillary column (Bellefonte, PA; 30 m × 0.32 mm i.d. × 0.2 μm film thickness). The initial GC temperature was 100°C, then increased to 175°C at a rate of 25°C/min. After holding at 175°C for 5 min, the temperature was increased to 225°C at a rate of 5°C per min and held for 10 min. Helium was used as the carrier gas. The FA were identified by comparison with retention times of known FAME standards. The concentration of identified FA was then calculated based on the ratio of the FA to the internal standard.

Statistical analysis. ANOVA was carried out to determine the effect of the main treatments—LA and isomers of CLA, treatment periods, and doses—and their interactions on the cellular GPDH activity, FA concentration, and the ratio of satu-

rated FA to monounsaturated FA (24). ANOVA was also applied for analysis of the effect among all the combinations of the treatment periods and doses within the same LA or CLA, or among the LA and CLA. Tukey multiple tests were used to compare the means of the treatments. Analysis was made to determine the correlation between cellular GPDH activity and FA concentration, and between cellular GPDH activity and the ratio of saturated FA/monounsaturated FA (24). The significance level was set as $P < 0.05$.

RESULTS

Profile of Oil Red O-staining cells. The cells in the control group were generally differentiated to adipocytes, as indicated by a large proportion of Oil Red O-stained cells shown in the photographs (Fig. 1). Treatment with media containing DMI for 2 d (day 0–2), followed by a further culture in FBS-supplemented DMEM for lipid accumulation (day 3–8), could effectively induce differentiation and lipid accumulation in the confluent 3T3-L1 cells. Supplementation with t10,c12-CLA (10–70 mg/L) during the overall differentiation period (day 0–8) resulted in a much lower proportion of Oil Red O-stained cells than all the others did. Similarly, the treatment with t10,c12-CLA (10–70 mg/L) during the intermediate/late differentiation period (day 3–8) also led to a much lower proportion of Oil Red O-staining cells than all the others did. The treatment with a high dose (70 mg/L) of LA or CLA only during the early period also apparently produced a relative low proportion of Oil Red O-stained cells. However, the treatment with a high concentration of c9,t11-CLA (35 or 70 mg/L) during the overall period (day 0–8) led to a higher proportion of Oil Red O-staining cells containing large lipid drops compared with the others (Fig. 1).

Cellular GPDH activity. The cellular GPDH activity was significantly lowered in cells treated with 70 mg/L of t10,c12-CLA during the early and intermediate/late periods, and in those treated with doses of 35 and 70 mg/L during the overall period (Fig. 2). The cellular GPDH activities in the treatments under above conditions were only about half that of the control. However, the treatments with LA (35 and 70 mg/L) and c9,t11-CLA (10–70 mg/L) during the overall period led to a significantly higher cellular GPDH activity than that in the control. There was no significant difference in the cellular GPDH activity between the control and the treatments with LA and

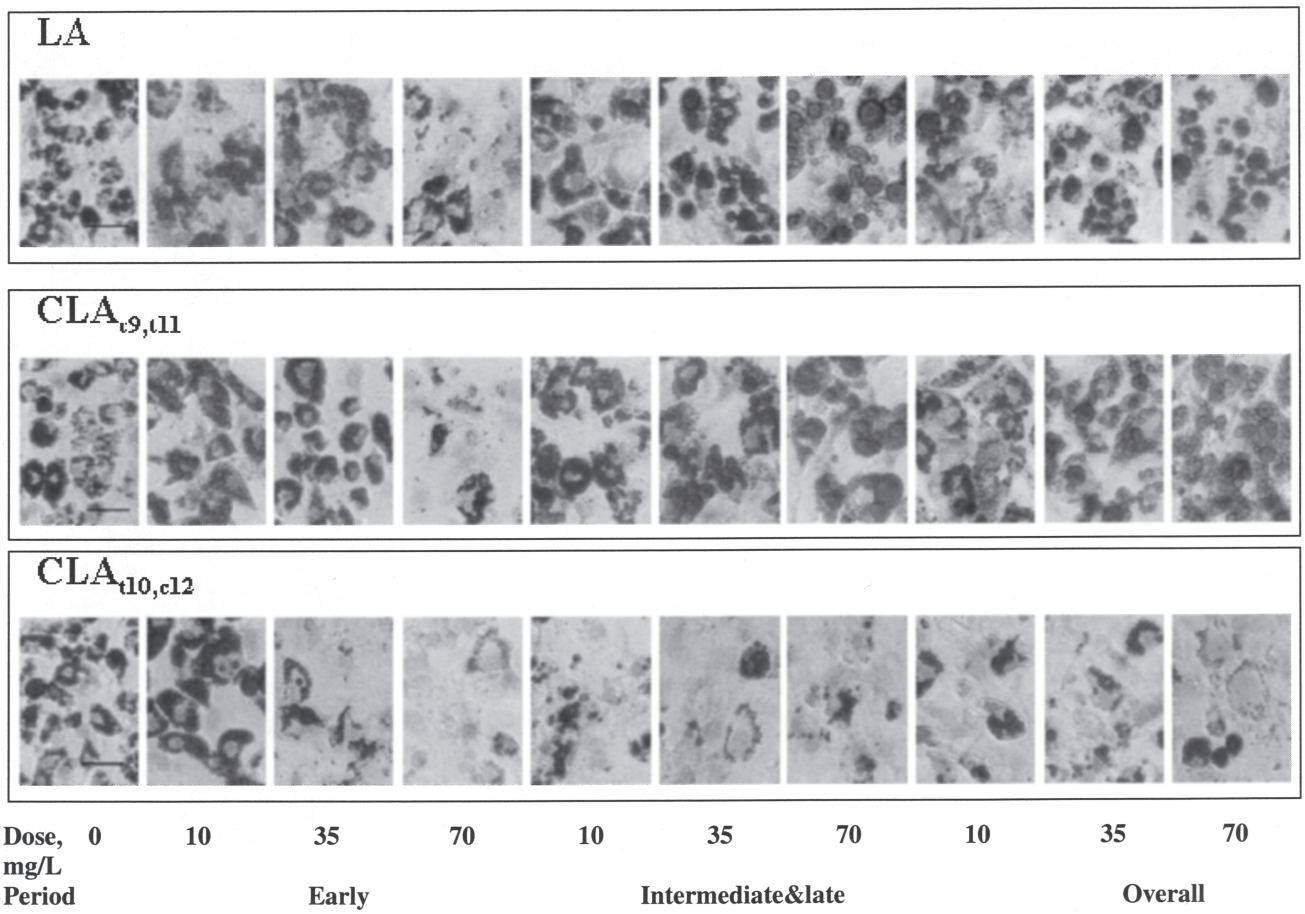

FIG. 1. Photographs of 3T3-L1 adipocytes on day 8 of postconfluence after treatment with or without various doses of CLA or linoleic acid (LA) during differentiation periods (Early: days 0–2; intermediate&late, days 3–8; overall, days 0–8). Cells were stained with Oil Red O and Mayer's hematoxylin. Bar = 50 μm.

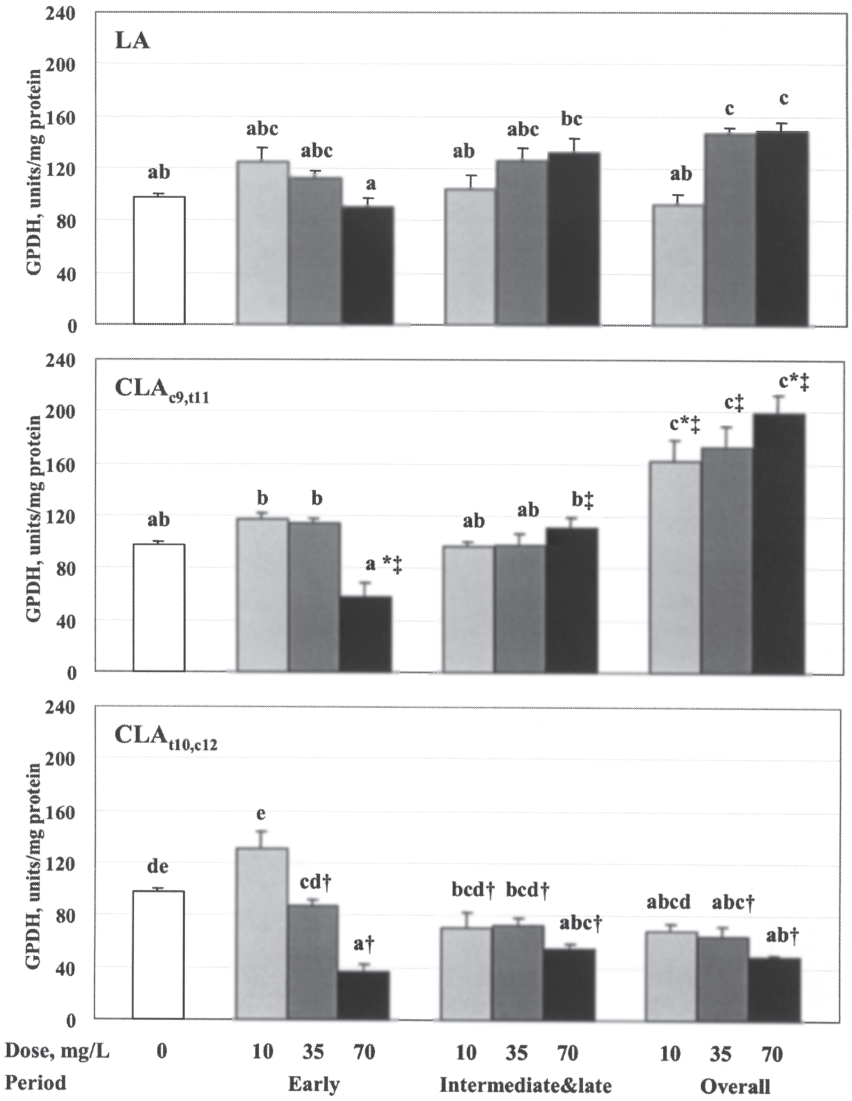

FIG. 2. Activity of glycerol-3-phosphate dehydrogenase (GPDH: EC1.1.1.8) in the 3T3-L1 adipocytes after treatment with or without various CLA or LA dosages during differentiation periods. In the groups treated with the same CLA or LA dosage, means (±SE, $n = 5$) without the same letter (a–e) differ significantly ($P < 0.05$). *, †, and ‡ indicate a significant difference when comparison is made of c9,t11-CLA vs. LA; t10,c12-CLA vs. LA; and c9,t11-CLA vs. t10,c12-CLA, respectively ($P < 0.05$). For abbreviation and terminology regarding periods see Figure 1.

c9,t11-CLA during the early and intermediate/late periods, although the activity in cells treated with 70 mg/L LA or c9,t11-CLA during the early period were relatively lower than that of the control.

A significant difference was also found in the GPDH activity between CLA and LA treatments (Fig. 2). Comparison of these treatments was based on the same treatment period with same dose. GPDH activities in the treatments of t10,c12-CLA were significantly lower than those of LA when doses of 35 and 70 mg/L were applied. However, treatment with c9,t11-CLA led to a higher ($P < 0.05$) GPDH activity compared with that of LA, especially when applied during the overall period.

Viability of the cells. The average density of the cells harvested on day 8 of postconfluence was between 9.5×10^4 and 12×10^4 cells/mL, which was six- to eightfold higher than that of cells on day 0 at the beginning (1.5×10^4 cells/mL). The treatment with CLA and LA during the various periods of differentiation did not significantly affect the final cell number, except relatively higher values were found for LA and c9,t11-CLA when they were applied during the intermediate/late period with a dose of 70 mg/L (Fig. 3).

Accumulation of LA or CLA. The accumulation of LA or CLA in cells treated with the corresponding FA was dose-dependent (Fig. 4). The accumulations of LA or CLA in the cells treated during the intermediate/late period were close to that in the cells treated during the overall period (day 0–8). However,

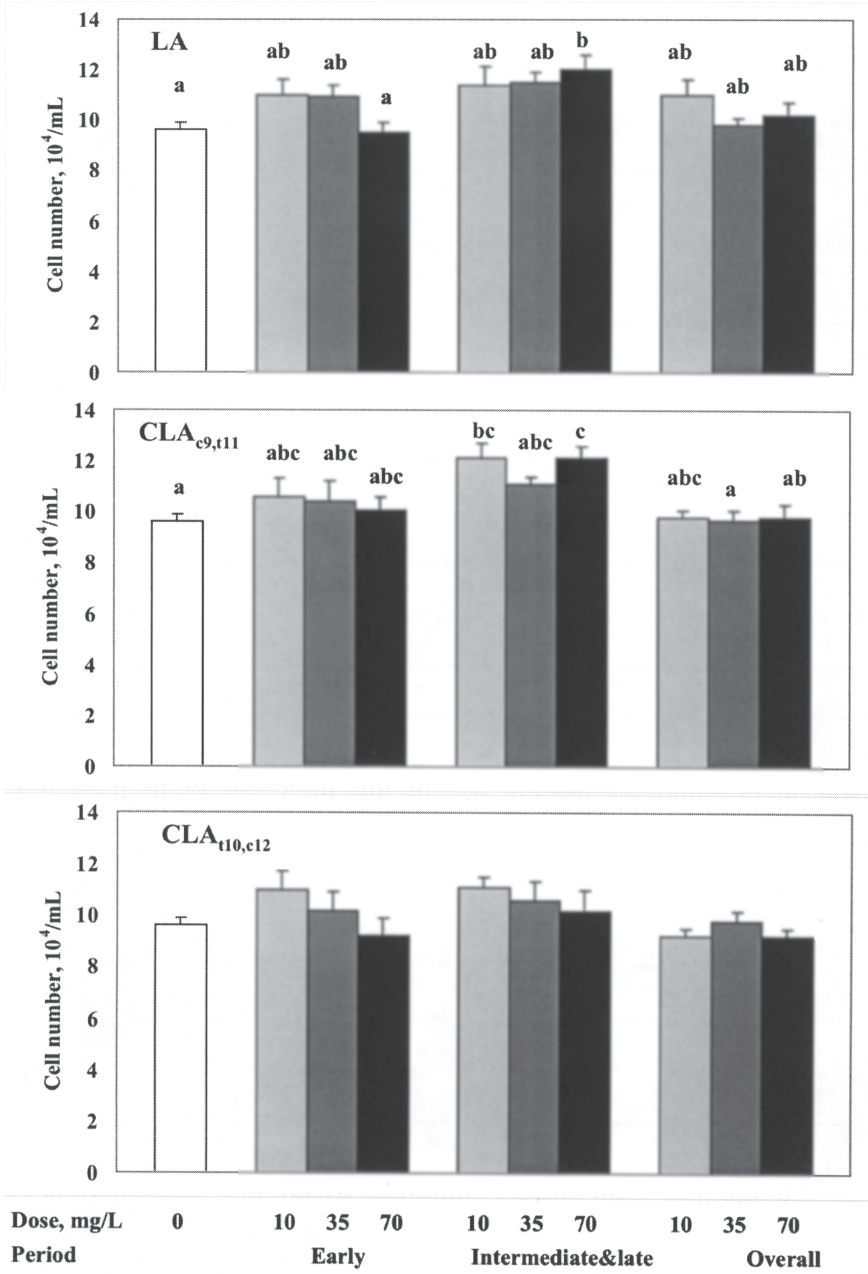

FIG. 3. Viability of cells after treatment with or without various CLA or LA dosages during differentiation periods. In groups treated with the same CLA or LA dosage, means (±SE, $n = 8$) without the same letter (a–c) differ significantly ($P < 0.05$). For abbreviation and terminology regarding periods see Figure 1.

the cells treated during the early period were very low in cellular concentrations of LA or CLA. The cellular concentrations of t10,c12-CLA were only about one-third of the LA or c9,t11-CLA accumulated in the cells treated with corresponding FA isomers, although the same dose was applied.

Concentration of main cellular FA. Comparisons of the sum of the main FA and of palmitic acid (16:0) and palmitoleic acid (16:1) are shown in Figures 5, 6, and 7, respectively.

The treatment with t10,c12-CLA during the overall and intermediate/late periods significantly decreased the total amount of the FA (Fig. 5), 16:0 (Fig. 6), and 16:1 (Fig. 7). The cellular concentration of 16:1 in the cells under these conditions was only 5–20% of that in the control group. The treatment with t10,c12-CLA during the overall (70 mg/L) and intermediate/late (35 and 70 mg/L) periods significantly decreased the cellular concentration of 16:0 FA (Fig. 6). However, treatment with 10 and 35 mg/L doses of t10,c12-CLA during the early period (day 0–2) had little effect on the synthesis of the main FA but with a 70 mg/L dose the FA and 16:0 and 16:1 FA were greatly lowered (Figs. 5–7).

The treatment with c9,t11-CLA during intermediate/late (35 and 70 mg/L) and the overall periods significantly increased

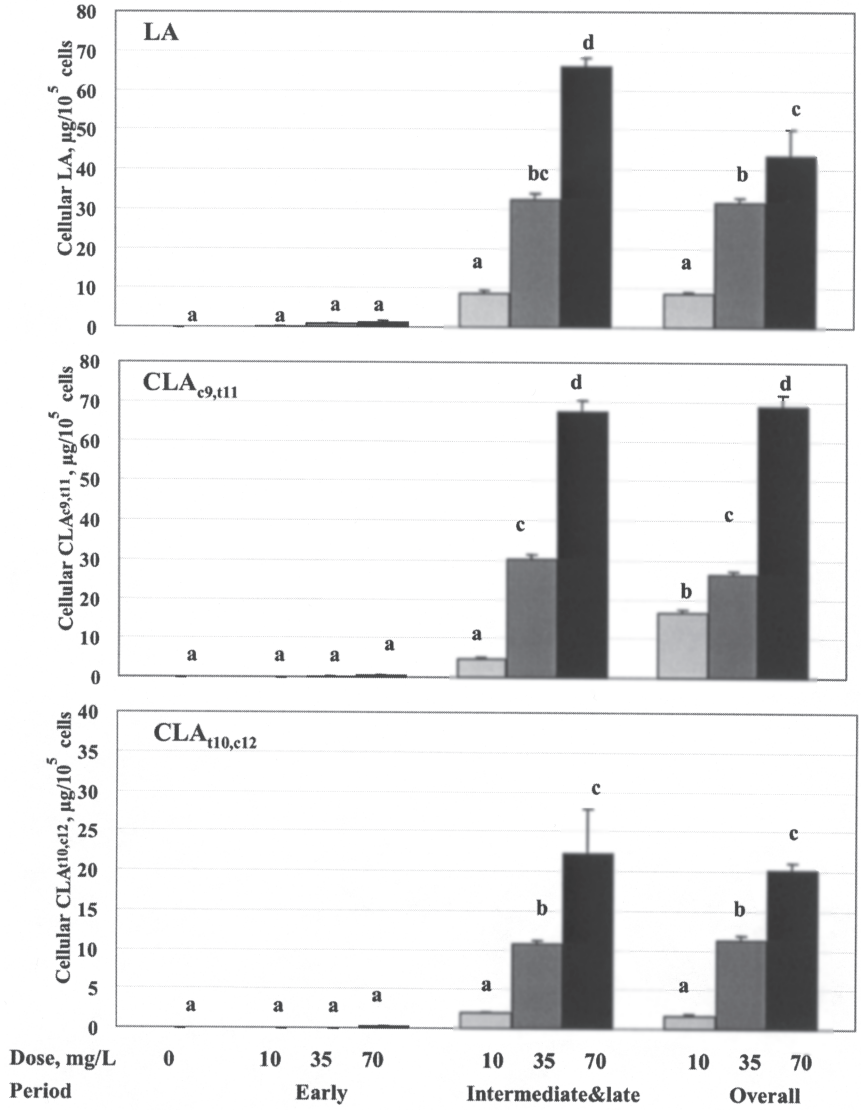

FIG. 4. Concentration of CLA or LA in the 3T3-L1 adipocytes after treatment with or without various CLA or LA dosages during differentiation periods. In groups treated with the same CLA or LA dosage, means (±SE, $n = 5$) without the same letter (a–d) differ significantly ($P < 0.05$). For abbreviation and terminology regarding periods see Figure 1.

the cellular amount of both the total and individual FA, especially that of 16:0 FA (Figs. 5–7). The concentration of 16:0 in the treatment with c9,t11-CLA was two- to threefold higher than that in the control when c9,t11-CLA was applied at doses of 35 and 70 mg/L during the overall and intermediate/late periods. The treatment with c9,t11-CLA during the early period did not significantly change the concentration of the main FA in the cells compared with that of the control, although a high dose of 70 mg/L had a tendency ($P < 0.1$) to decrease the cellular FA accumulation.

The treatment with LA during the overall (70 mg/L) and intermediate/late periods also significantly increased the amounts of total FA and 16:0 (Figs. 5 and 6). However, the treatment with a 70 mg/L dose during the early period significantly lowered the main FA accumulation in the cells, along with the decrease in the cellular 16:1 FA.

When comparison was made based on the same treatment period and dose, the treatments with t10,c12-CLA produced significantly lower cellular concentrations of the total or individual FA (Figs. 5–7) than with LA-treated cells during the overall and intermediate/late periods. By contrast, the treatments with c9,t11-CLA generally resulted in a higher cellular FA concentration than that of LA-treated cells during the overall period.

*Ratios of 16:0/16:1 and 18:0/18:1 FA***.** Treatment with LA and CLA doses of 10 and 35 mg/L during the early period had little effect on the ratios of 16:0/16:1 and 18:0/18:1, which ranged from1.4 to 1.8 (Fig. 8) and from 0.21 to 0.26 (Fig. 9),

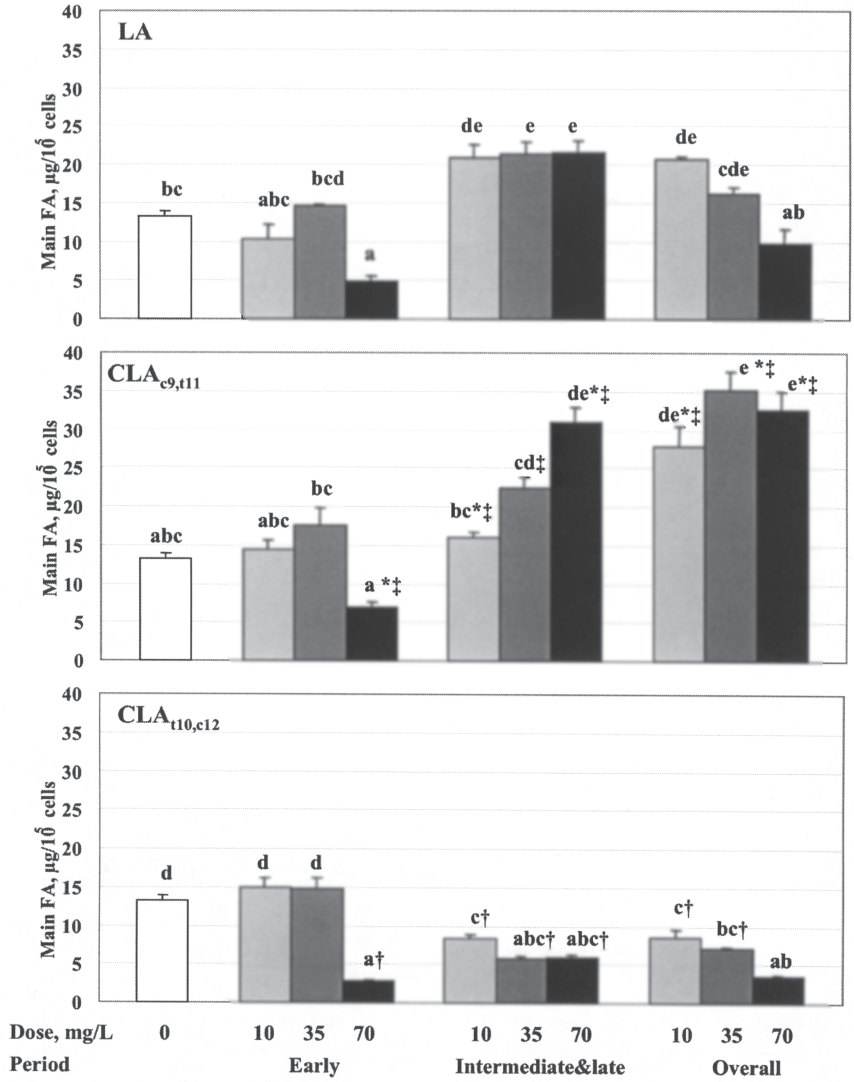

FIG. 5. Main FA in the 3T3-L1 adipocytes after treatment with or without various CLA or LA during differentiation periods. The "main FA" represent the sum of 16:0, 16:1, 18:0, and 18:1 detected in cellular lipids. In groups treated with the same CLA or LA dosage, means (±SE, n = 5) without the same letter (a–e) differ significantly ($P < 0.05$). *, †, and ‡ indicate a significant difference when comparison is made of c9,t11-CLA vs. LA; t10,c12-CLA vs. LA; and c9,t11-CLA vs. t10,c12-CLA, respectively ($P < 0.05$). For abbreviation and terminology regarding periods see Figure 1.

respectively. However, treatment with t10,*c12-CLA* during the overall and intermediate/late periods increased the ratios of 16:0/16:1 and 18:0/18:1 to 7.8-22 and 0.55-0.77, respectively. The treatment with t10,c12-CLA using a high dose of 70 mg/L during the early period also increased the ratios of 16:0/16:1 and 18:0/18:1 to 7.7 and 0.60 respectively. The treatment with a c9,*t11-CLA* dose of 10 or 35 mg/L during the overall and intermediate/late periods only moderately increased the ratios, wh*ereas* treatment with a dose of 70 mg/L significantly increased the ratios. Similarly, the treatment of LA during the overall and intermediate/late periods only led to a moderate increase in those ratios when a normal dose of 10 mg/L was applied. However, the ratios were significantly increased when a high dose of 70 mg/L was applied.

Correlation between cellular GPDH activity and accumulation of FA. Significant positive correlations were observed between the GPDH activity and the mainly synthesized FA concentration. Most of the coefficients were larger than 0.7 (Table 1). A significant negative correlation was observed between the GPDH activity and ratio of 16:0/16:1 and of 18:0/18:1, with correlation coefficients of –0.55 and –0.44, respectively.

DISCUSSION

The present study showed that t10,c12-CLA depressed differentiation and cellular lipid accumulation in differentiating 3T3-L1 cells, whereas c9,t11-CLA and LA enhanced them under certain conditions. The results are consistent with previous re-

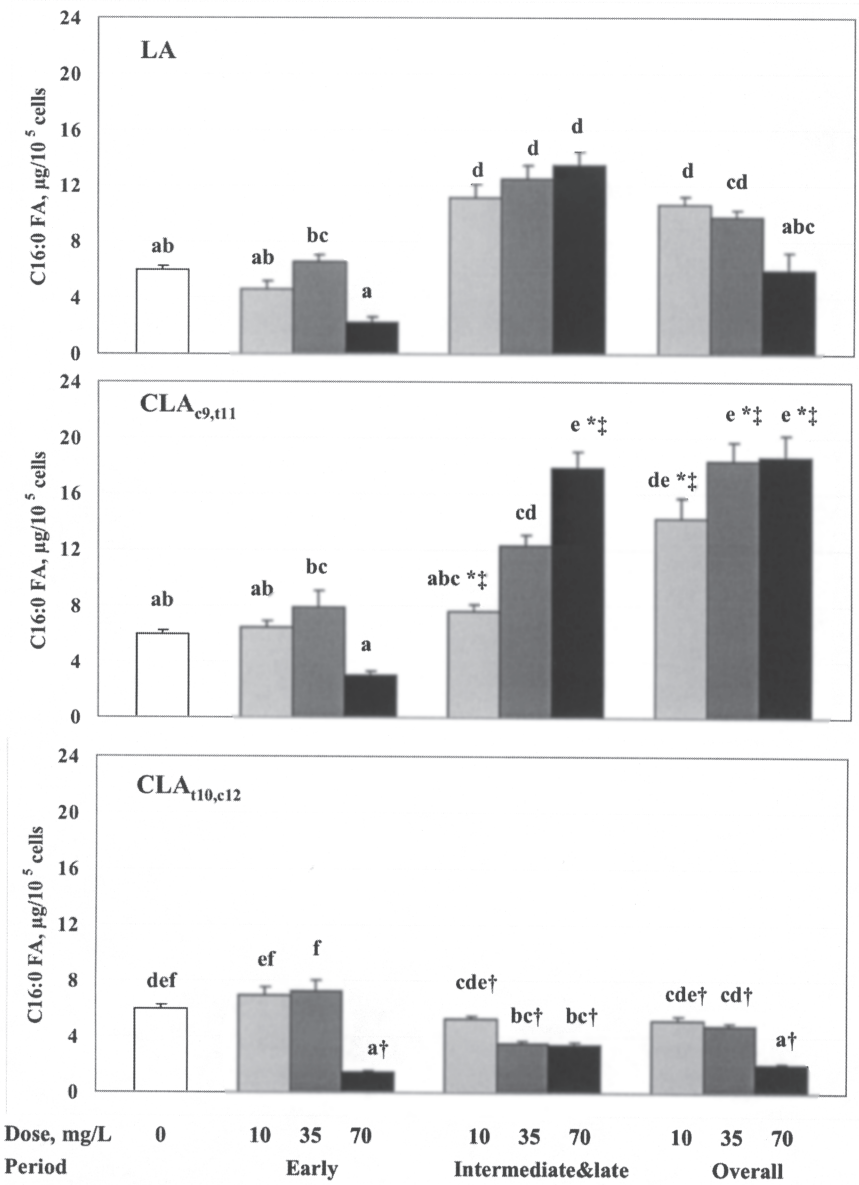

FIG. 6. Palmitic acid (16:0) in the 3T3-L1 adipocytes after treatment with or without various CLA or LA dosages during differentiation periods. In groups treated with the same CLA or LA dosage, means (±SE, $n = 5$) without the same letter (a–e) differ significantly ($P < 0.05$). *, †, and ‡ indicate a significant difference when comparison is made of c9,t11-CLA vs. LA; t10,c12-CLA vs. LA; and c9,t11-CLA vs. t10,c12-CLA, respectively ($P < 0.05$). For abbreviation and terminology regarding periods see Figure 1.

ports of *in vivo* studies showing that dietary CLA, especially t10,c12-CLA, lowered the body fat mass in animals and humans (7,25,26). The contrasting effects of these two CLA isomers were also seen in FA profiles and concentration of liver lipids from rats and mice (27,28). The results are in agreement with those studies using primary cultures of stromal vascular cells from human adipose tissue (10,13), which indicated that t10,c12- but not c9,t11-CLA decreased both the total TAG concentration and lipogenesis in the cells. Similarly, Kang *et al.* (14) reported that t10,c12-CLA inhibited differentiation of 3T3-L1 cells and resulted in lower TAG in the cells compared with the control. However, an *in vitro* study using human preadipocytes showed that c9,t11- and t10,c12-CLA increased differentiation and TAG concentration of the cells (17). The different effects found in *in vivo* studies may be due to the species and the degree of obesity in the animals whereas in *in vitro* studies, the differences may be related to treatment timing, length, dose, and the variation in cellular amount of incorporated CLA.

GPDH is the most important enzyme to catalyze the conversion of DHAP to glycerol 3-phosphate, which is a predominant substrate for TAG biosynthesis in adipocytes (20). GPDH was

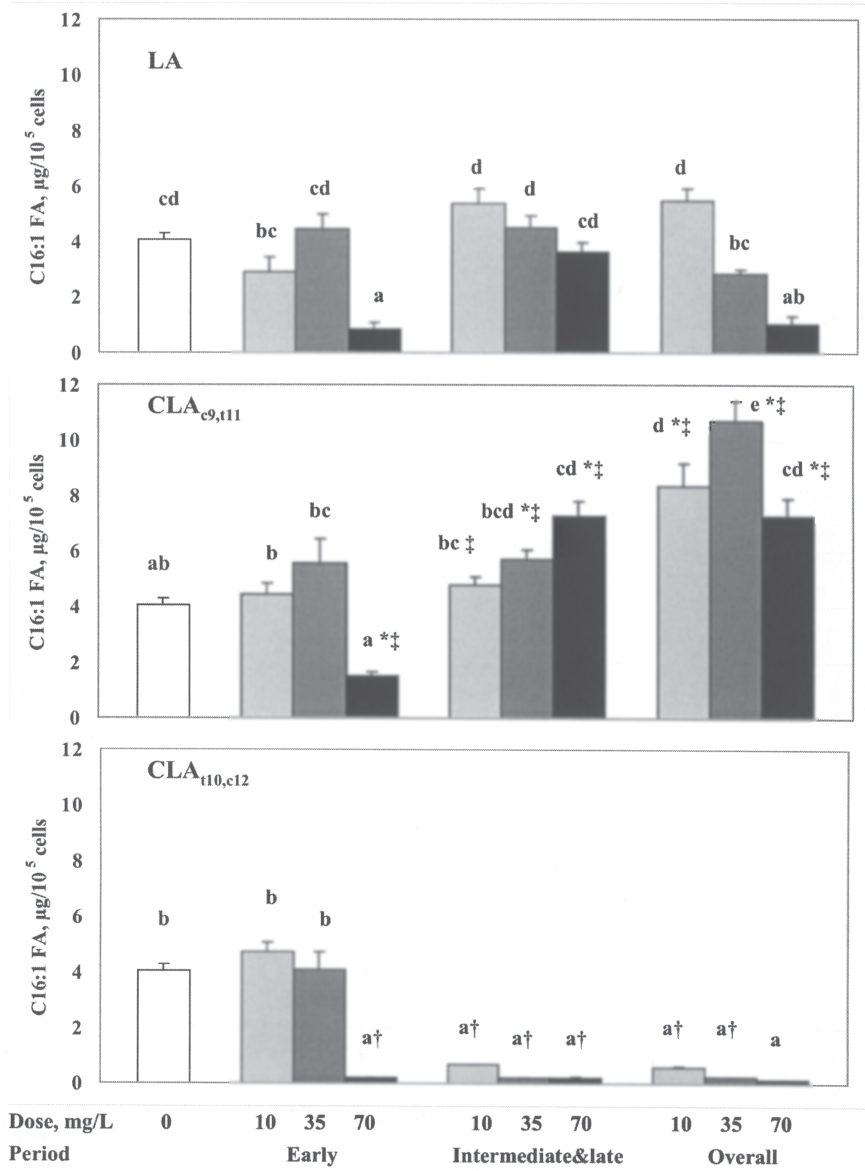

FIG. 7. Palmitoleic acid (16:1) in the 3T3-L1 adipocytes after treatment with or without various CLA or LA dosages during differentiation periods. In groups treated with the same CLA or LA dosage, means (±SE, $n = 5$) without the same letter (a–e) differ significantly ($P < 0.05$). *, †, and ‡ indicate a significant difference when comparison is made of c9,t11-CLA vs. LA; t10,c12-CLA vs. LA; and c9,t11-CLA vs. t10,c12-CLA, respectively ($P < 0.05$). For abbreviation and terminology regarding periods see Figure 1.

measured because it is a very important biochemical marker for the differentiation of preadipocyte to adipocyte and because its activity and gene expression increased greatly during the process (20,29). This study found that GPDH activity had a very significant ($P < 0.001$) positive correlation with the main synthesized FA in the cells. The treatment with a high dose of 35–70 mg/L of t10,c12-CLA during any of the differentiation periods led toa decrease in GPDH activity, whereas treatment with c9,t11-CLA and LA led to an increase. The effects are similar to those found in human adipocytes, in which chronic treatment with t10,c12-CLA resulted in a time-dependent decrease in mRNA expression of GPDH gene but not with c9,t11-CLA treatment (13).

In the present study, the FA concentration was measured as the main indicator of cellular lipid accumulation including those FA synthesized and incorporated from media. This method has been used in previous studies (9,30). The amount of CLA or LA incorporated into the cells was found to vary with timing and length of administration of the treatments and dosage. The concentration of CLA or LA incorporated into the cells increased as the dose applied increased. Treatment in the early period led to a very low accumulation of LA or CLA at

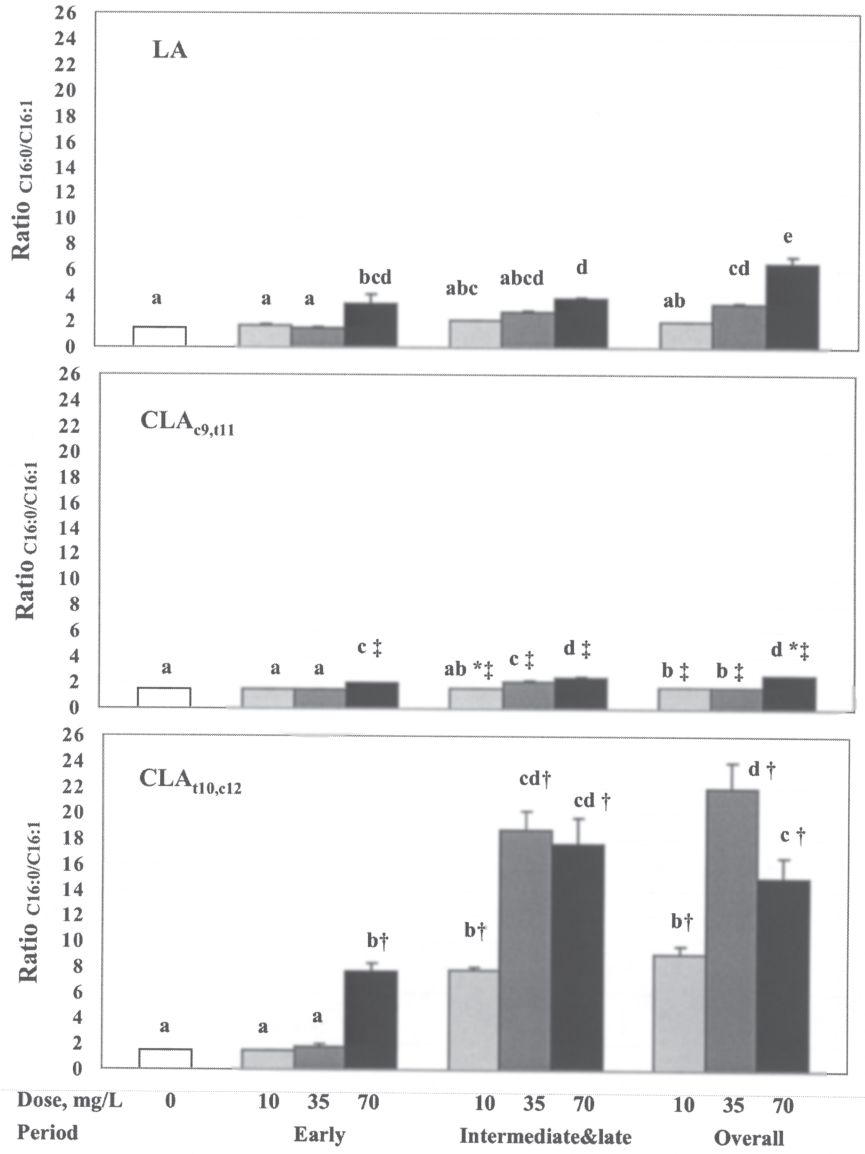

FIG. 8. Ratios of 16:0 to 16:1 FA in the 3T3-L1 adipocytes after treatment with or without various CLA or LA dosages during differentiation periods. In groups treated with the same CLA or LA dosage, means (±SE, $n = 5$) without the same letter (a–e) differ significantly ($P < 0.05$). *, †, and ‡ indicate a significant difference when comparison is made of c9,t11-CLA vs. LA; t10,c12-CLA vs. LA; and c9,t11-CLA vs. t10,c12-CLA, respectively ($P < 0.05$). For abbreviation and terminology regarding periods see Figure 1.

the end of experiment, which may be caused by the low incorporation of the FA and/or the possibility of turnover in the intermediate/late period. The amount of the main cellularly synthesized FA more reasonably reflected the *de novo* synthesis of lipids without being affected by the amount of CLA or LA incorporated directly from the media. It was also possible to calculate and compare the ratio of saturated FA/monounsaturated FA among cells treated with or without CLA through measuring the concentration of cellular individual FA. The FA ratios for 16:0/16:1 and 18:0/18:1 may relate to metabolic rate and physiological responses of the cells, because changes in these ratios affect membrane fluidity (31).

t10,c12-CLA decreased PPARγ and the expression of some adipogenic marker genes in 3T3-L1 adipocytes (14,16) and in human adipocytes (12,13), although a contradictory report indicated CLA increased the expression of these genes (17). The inhibition effect of t10,c12-CLA on the lipid accumulation of the adipocytes may be attributable to its specialized molecular structure. The small change in the structure of t10,c12-CLA, such as a-methylation, completely abolished its inhibitory effect on TAG accumulation and the expression of adipogenic marker genes (32). The decrease in FA concentration induced by t10,c12-CLA may be also due to an increase in FA oxidation in the cells (11). The present study found that the ratio of

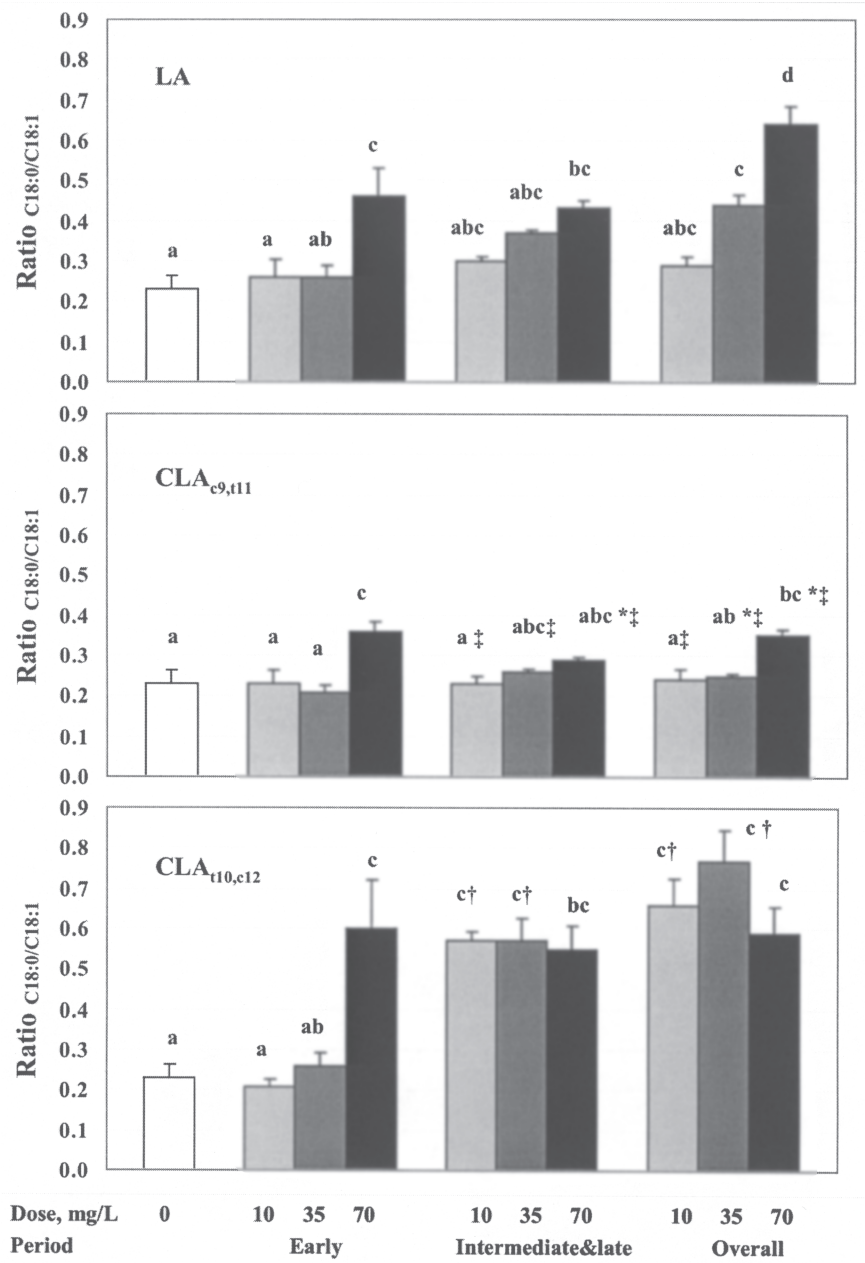

FIG. 9. Ratios of 18:0 to 18:1 FA in the 3T3-L1 adipocytes after treatment with or without various CLA or LA dosages during differentiation periods. In groups treated with the same CLA or LA dosage, means (±SE, $n = 5$) without the same letter (a–e) differ significantly ($P < 0.05$). *, †, and ‡ indicate a significant difference when comparison is made of c9,t11-CLA vs. LA; t10,c12-CLA vs. LA; and c9,t11-CLA vs. t10,c12-CLA, respectively ($P < 0.05$). For abbreviation and terminology regarding periods see Figure 1.

saturated FA to monounsaturated FA was greatly increased in cells treated with t10,c12-CLA. The results are consistent with those previous reports on t10,c12-CLA, such as its down-regulation of stearoyl-CoA desaturase (SCD) 1 gene expression and the inhibition of SCD activity in the cells (12,33).

Treatment with c9,t11-CLA under most of the experimental conditions used in the present study did not depress GPDH activity or FA accumulation in the cells. By contrast, treatment with c9,t11-CLA improved these, as did LA under certain conditions. Some of the previous studies found that c9,t11-CLA did not affect TAG accumulation and the expression in adipocytes of related genes (11,15), whereas others found that treatment with this CLA isomer increased TAG concentration, as did LA (13,14,17). The FA or their derivatives could be involved in the differentiation of preadipocytes to adipocytes as signal transduction molecules (34) and the gene expression of

TABLE 1
Correlations Between Cellular GPDH Activity and Concentration of FA or Ratio of SFA to MUFA in the 3T3-L1 Adipocytes After Treatment With or Without Various CLA or LA During Differentiation Periods[a] (*n* = 28)

Covariates	Coefficient	Significance of correlation
GPDH – 16:0 FA	0.76	<0.001
GPDH – 16:1 FA	0.73	<0.001
GPDH – 18:0 FA	0.65	<0.001
GPDH – 18:1 FA	0.78	<0.001
GPDH – 20:4 FA	0.44	0.018
GPDH – 22:6 FA	0.72	<0.001
GPDH – Ratio of 16:0/16:1 FA	–0.55	0.003
GPDH – Ratio of 18:0/18:1 FA	–0.44	0.018

the FA-binding protein aP-2 (35) or activate PPAR in the cells (36). They could be potential ligands for PPARÁ, the important adipogenesis marker mainly expressed during the intermediate/late differentiation period.

The timing, length, and dose of the treatment with CLA or LA affect cell differentiation. Effective doses of CLA or LA used in previous studies for cell culture were 25–100 μmol/L (13,14,16,17). The CLA or LA in the media could be incorporated into cellular TAG directly, which is confirmed in the present experimental conditions. Variation of incorporated CLA may affect the comparison result, when the cellular TAG was applied as the main lipid accumulation factor. Treatment with a relatively low concentration of CLA during the early period did not affect the differentiation and the accumulation of lipids. Similar results were found in PPARγ expression in 3T3-L1 cells treated with CLA (32). However, a high dose (70 mg/L) of CLA or LA depressed GPDH activity and FA accumulation when applied during the early differentiation period only. This could be due to the inhibitory effect of CLA or LA on SCD activity or to the initial activation of the differentiation factors (DMI), and the subsequent differentiation gene expression of adipogenic marker genes. It was found (36) that doses of 20–100 mmol/L LA might activate a chimera of the PPAR/human glucocorticoid receptor expressed in a cell line derived from the ovary of the Chinese hamster (36). The induction level was maximal when a dose of 150 μmol/L was applied. However, the dose of 300 μmol/L LA caused complete detachment of the cells. This indicated that the very high level of FFA could be toxic to the cells. Satory and Smith (9) reported that the inclusion of a mixture of CLA at 100 mg/L or at 356 μmol/L resulted in destruction of the 3T3-L1 cells. From our preliminary experiments, 70 mg/L of LA or CLA, especially c9, t11-CLA, was found to inhibit the proliferation of preadipocytes when supplied to media during the early proliferation period. However, viability of the cells was not affected during the differentiation period when the cell culture reached confluence (Fig. 3). This suggests that the cells under postconfluence condition could tolerate the CLA or LA dose used in the present study.

In conclusion, the present study indicated that inhibitory effects of CLA on differentiation, GPDH activity, and FA accumulation of 3T3-L1 cells are dependent on the isomer type, treatment period, and dose. t10,c12-CLA depressed the differentiation, the cellular GPDH activity, and FA accumulation in differentiating 3T3-L1 cells, whereas c9,t11-CLA and LA enhanced these under certain conditions. However, a high amount of c9,t11-CLA and LA, as well as t10,c12-CLA, also depressed the differentiation, cellular GPDH activity, and FA accumulation when they were applied during the early differentiation period.

Fatty Acids and Monoacylglycerols Inhibit Growth of *Staphylococcus aureus*

J.A. Kelsey[a], K.W. Bayles[b], B. Shafii[c], and M.A. McGuire[a,*]

[a]Department of Animal and Veterinary Science, and [c]Statistical Programs, College of Agriculture and Life Sciences, University of Idaho, Moscow, Idaho 83844, USA [b]Department of Pathology and Microbiology, University of Nebraska Medical Center, Omaha, Nebraska 68198, USA

ABSTRACT: *Staphylococcus aureus* causes a variety of human infections including toxic shock syndrome, osteomyelitis, and mastitis. Mastitis is a common disease in the dairy cow, and *S. aureus* has been found to be a major infectious organism causing mastitis. The objectives of this research were to determine which FA and esterified forms of FA were inhibitory to growth of *S. aureus* bacteria. FA as well as their mono-, di-, and triacylglycerol forms were tested for their ability to inhibit a human toxic shock syndrome clinical isolate (MN8) and two *S. aureus* clinical bovine mastitis isolates (305 and Novel). The seven most potent inhibitors across all strains tested by minimum inhibitory concentration analysis included lauric acid, glycerol monolaurate, capric acid, myristic acid, linoleic acid, *cis*-9, *trans*-11 conjugated linoleic acid, and *trans*-10, *cis*-12 conjugated linoleic acid. Some of these lipids were chosen for 48-h growth curve analysis with a bovine mastitis *S. aureus* isolate (Novel) at doses of 0, 20, 50, and 100 μg/mL except myristic acid, which was tested at 0, 50, 100, and 200 μg/mL. The saturated FA (lauric, capric, myristic) and glycerol monolaurate behaved similarly and reduced overall growth. In contrast, the polyunsaturated FA (linoleic and *cis*-9, *trans*-11 conjugated linoleic acid) delayed the time to initiation of exponential growth in a dose-dependent fashion. The results suggest that lipids may be important in the control of *S. aureus* during an infection.

Paper no. L10024 in *Lipids 41*, 951–961 (October 2006).

Staphylococcus aureus is a broad host range pathogen and a leading cause of infections in both humans and domesticated animals worldwide. Infections caused by *S. aureus* are extremely common and often life threatening, creating the potential for *S. aureus* to increase morbidity and mortality. *S. aureus* causes nearly any type of human infection including toxic shock syndrome (TSS), osteomyelitis, and mastitis (1,2). *S. aureus* also causes mastitis in dairy cattle, which is the most economically important disease to the dairy industry in the United States (3). Mastitis is also a common disease during human lactation, affecting 20% to 33% of women in developed and developing countries (4,5). *S. aureus* has been found to be the main infectious organism in cases of human mastitis (6,7).

Abbreviations: CLA, conjugated linoleic acid; GML, glycerol monolaurate; MIC, minimum inhibitory concentration; OD_{600}, optical density at 600 nm; TSB, tryptic soy broth; TSS, toxic shock syndrome.

Early reports (8,9) have characterized the ability of lipids to inhibit bacteria. Various FA and monoacylglycerols in trace amounts have an inhibitory effect on the growth of microorganisms (10). Both bacteriostatic (8,9,11) and bactericidal effects (8,12,13) have been observed. Lauric acid and glycerol monolaurate (GML) have been extensively characterized in their ability to inhibit the growth and toxin production of *S. aureus* (14,15). Other FA in milk have also been shown to inhibit bacterial growth including capric acid, myristic acid, linoleic acid, and linolenic acid. This inhibition of growth by FA has been demonstrated in several species of bacteria including *S. aureus*, *Streptococcus pneumoniae*, and *Streptococcus* group A (10,16). One of the hallmark signs of an infection caused by *S. aureus* bacteria is a release of FFA in the infected area as observed in intraperitoneal abscesses, skin infections, and mastitis across a variety of animal models (17–20). Increased concentrations of FFA in milk are common during mastitis in cows (21). Increases of 50% to 100% have been detected in FFA content of milk from cows with mastitis (22–26). However, despite the impact of mastitis on the health of the cow or woman, little is known about the effect of these FA on bacteria during an infection. To begin to investigate this, we hypothesized that certain FA and monoacylglycerols commonly found in milk would inhibit growth of *S. aureus*.

EXPERIMENTAL PROCEDURES

Bacterial strains and growth conditions. The bacterial strains used in this study represent two different human diseases caused by *S. aureus* and include *S. aureus* MN8, a well-characterized human TSS isolate (27), and two clinical bovine mastitis isolates, *S. aureus* Novel (28) and *S. aureus* 305 (29). Cultures of each strain were prepared by inoculating a single colony into 3 mL of tryptic soy broth (TSB) (VWR, Gibbstown, NJ, USA) before incubation at 37°C overnight with shaking at 250 rpm. All minimum inhibitory concentrations (MIC) were done in duplicate and cultured in 3 mL of TSB containing a serial dilution of each particular FA. Lipids (Sigma, St. Louis, MO, USA) were solubilized in ethanol before adding to TSB to get a final concentration of 0, 12.5, 25, 50, 100, and 200 μg/mL. A control tube containing TSB and an equivalent amount of ethanol was included. Culture tubes were inoculated 1:100 with the overnight culture of the *S. aureus* strain tested and incubated 24 h with continuous shaking

at 250 rpm to determine if growth occurred. The minimum concentration necessary to prevent turbid growth was considered the MIC and evaluated visually. Growth curves were performed in triplicate and used tryptic soy broth (25 mL) inoculated 1:100 with overnight culture of *S. aureus* Novel, adjusted to an optical density at 600 nm (OD_{600}) of 0.1 units. The cultures were allowed to grow for 2 h with continuous shaking at 250 rpm to reach the growth phase. Lipids including lauric acid, GML, capric acid, myristic acid, linoleic acid, and *cis*-9, *trans*-11 conjugated linoleic acid (CLA) were then added at 0, 20, 50, and 100 μg/mL concentrations (except myristic acid, which was tested at 0, 50, 100, and 200 μg/mL) and the incubation was continued at 37°C with continuous shaking at 250 rpm. Samples were taken frequently, and the OD_{600} was read after appropriate dilution (whenever the absorbance exceeded a value of 1.0, dilutions were made until the value was within the linear range, and the absorbance value was multiplied by the dilution factor to obtain the OD_{600} value) using a Perkin-Elmer MBA2000 spectrophotometer (Boston, MA, USA). We found 1 OD_{600} unit is equivalent to 2.25 ± 0.29 mg/mL dry weight of *S. aureus* Novel.

Statistics. Minimum inhibitory concentrations were conducted twice and reported as the mean of duplicate runs. Statistical analysis of growth curves used the typical parabolic pattern of bacterial population growth. Interestingly, in some of our experimental cultures, we observed a lag phase representing delay in onset of increased growth followed by a parabolic curve. The ideal description of bacterial growth in our system, therefore, should include both the linear lag phase and the parabolic growth phase in a jointed regression, allowing estimation of the joint points and the maximum growth achieved. The fitted model was of the form:

$$Y = \beta_o + \beta_1 t + \beta_2 t^2 \text{ for } t > t_o$$
$$Y = c \text{ for } t \leq t_o$$

where Y is the OD_{600}, t is time in h, t_o is the time joint point is reached (lag before exponential growth), c is a constant representing the value of OD_{600} during the lag phase, and β_o, β_1, and β_2 are regression coefficients associated with the intercept, slope, and inflection (maximum) point, respectively. A generalized nonlinear estimated algorithm was used for parameter estimation. Separate models were estimated for each of the FA tested. The adequacy of fit was determined by the significance of the parameter estimates, and their corresponding signs and magnitudes, examination of the model residuals, and the structure of correlation among estimated parameters. A full model dummy variable regression procedure was used to conduct preplanned contrasts to compare coincidence (equality) of estimated lines, joint points, and maximum values at specific doses. Contrasts of estimated lines included all parameter estimates. Significance was declared at $P < 0.05$. Statistical computations were performed using the PROC NLMIXED procedure of SAS (30).

RESULTS

Minimum inhibitory concentrations. The MIC of the major FA present in milk along with several of their monoacylglycerols, diacylglyerols, and triacylglycerols forms were determined for two *S. aureus* bovine mastitis isolates (strain 305 and Novel), as well as the TSS isolate, MN8 (Table 1). The lipids that were the most inhibitory were similar for all three strains (except oleic acid was not inhibitory to strain MN8) and included lauric acid, glycerol monolaurate (GML), linoleic acid, *cis*-9, *trans*-11 conjugated linoleic acid (CLA), *trans*-10, *cis*-12 CLA, capric acid, and myristic acid. As shown in Table 1, the majority of FFA and their triglycerides from C6:0 to C18:0 did not inhibit growth at the maximum concentration tested (200 μg/mL) except stearic acid, which was inhibitory to the Novel strain at 200 μg/mL.

Growth curves. Several of the FA shown to have inhibitory activity were further examined in batch cultures of the *S. aureus* Novel strain including capric acid, myristic acid, lauric acid, GML, linoleic acid, and *cis*-9, *trans*-11 CLA. Growth curves were performed using concentrations of 0, 20, 50, and 100 μg/mL, with the exception of myristic acid, which was tested at 0, 50, 100, and 200 μg/mL. Parameter estimates were significant, suggesting the models were reasonable and all parameters were required. The correlation among parameters was also examined and most showed < 0.95 correlation, indicating a lack of redundancy among parameters. For each dose of FA tested, the model followed data trends (data for *cis*-9, *trans*-11 CLA presented in Fig. 1). The expected lag phase followed by a parabolic curve was observed in all doses. Residuals were examined and found to be uniform and random with no discernible pattern (data not shown). The same procedure was used for all doses of the six FA tested, with very good agreement between the predicted model and the observed data (data not shown), similar to that presented for *cis*-9, *trans*-11 CLA.

Preplanned contrasts were conducted to compare growth curves, and we found that in the case of lauric acid, capric acid, linoleic acid, and *cis*-9, *trans*-11 CLA, growth curves at each dose differed from each other. In the case of GML, 0 μg/mL was not different than 20 μg/mL; however, the growth curves for 50 and 100 μg/mL differed from 0 and 20 μg/mL. In the case of myristic acid, the 200 μg/mL myristic acid growth curve differed from the growth curves for all other doses but the other growth curves were similar. To further describe how growth curves were different, contrasts of the joint points (measure of lag in the initiation of growth) and the maximum amount of growth achieved were conducted to compare these parameters at all doses.

When free lauric acid (50 and 100 μg/mL), a well-characterized inhibitory FA, was added to the growth medium (Fig. 2, top panel), the optical density of the culture increased initially but reached a maximum well below that seen in the untreated or 20 μg/mL lauric acid-supplemented cultures. Maximum growth of bacteria was 24.7 OD units at 0 μg/mL lauric acid and was re-

TABLE 1
Minimum Inhibitory Concentration (MIC) of Lipids on Strains of *Staphylococcus aureus*[a]

[a]Numbers reported represent the mean of duplicates. NI = no inhibition observed at any dose tested.
[b]All FA tested were in FFA form. FA were esterified at the *sn*-1 position for all monoacylglycerols and at the *sn*-1 and *sn*-3 position for diacylglycerols.
[c]CLA = conjugated linoleic acid.

duced to 8.8 OD units ($P < 0.01$) at 100 μg/mL lauric acid (Table 2). Contrasts indicated that maximum growth was different at all doses of lauric acid (Table 3). These reduced values remained constant throughout the culture duration. The 20 μg/mL lauric acid had a higher maximum growth than 0 μg/mL lauric acid.

Glycerol monolaurate supplementation (Fig. 2, bottom panel, and Table 2) resulted in both a lag in the initiation of growth and a reduction in maximum growth achieved at 100 μg/mL compared to 0 μg/mL. The maximum growth yield achieved at 20 μg/mL GML was not different than maximum growth yield at 0 μg/mL GML ($P > 0.05$, Table 3). Maximum bacterial growth was different at all other doses of GML. There was a lag in the initiation of growth (joint point) at 50 and 100 μg/mL GML compared to 0 μg/mL GML.

For capric acid (Fig. 3, top panel, and Table 4), we observed a similar growth pattern to lauric acid. At 100 μg/mL capric acid there was a lower maximal growth than 0, 20, or 50 μg/mL capric acid ($P < 0.05$, Table 3). There was no difference in maximum growth at 0, 20, or 50 μg/mL capric acid. Although there was a lag in the initiation of growth at 20 vs. 50 μg/mL capric acid ($P < 0.01$, Table 3) and 0, 20, or 50 vs. 100 μg/mL capric acid ($P < 0.05$), there was very little practical difference between the joint point estimations of 0.51, 0.52, 0.56, and −0.26 OD units for 0, 20, 50, and 100 μg/mL capric acid, respectively. Myristic acid was also tested, but at slightly higher concentrations including 0, 50, 100, and 200 μg/mL based on the higher MIC value. The results of myristic acid supplementation were similar to capric acid (Fig. 3, bottom panel, and Table 4). Maximum growth was not different at any dose. However, the time that maximum growth was achieved was different at 200 μg/mL myristic acid than all other doses. The time when growth was initiated (joint point) did not differ between 0 and 100 μg/mL myristic acid.

When *cis*-9, *trans*-11 CLA was added, there was a dose-dependent lag in the initiation of bacterial growth (Fig. 4, bottom panel). Results indicated that the lag was 3.3 h with 20 μg/mL CLA and extended to 15.5 h with 100 μg/mL CLA (Table 5). Contrasts revealed that each of the joint points were different from each other (Table 3). To determine if the effect was similar to other long-chain polyunsaturated FA tested, cultures were grown with linoleic acid supplemented at the same concentrations. A similar dose-dependent lag in the initiation of growth occurred with linoleic acid (Fig. 4, top panel, and Table 5) as was observed for *cis*-9, *trans*-11 CLA. Results indicated that the lag in growth initiation at 50 μg/mL linoleic acid was different than the joint point at 0 μg/mL linoleic acid. The lag was extended with 100 μg/mL linoleic acid to 15.2 h, which was also different from 50 μg/mL linoleic acid where growth was initiated at 8.4 h. Maximum growth was not affected by either CLA or linoleic acid.

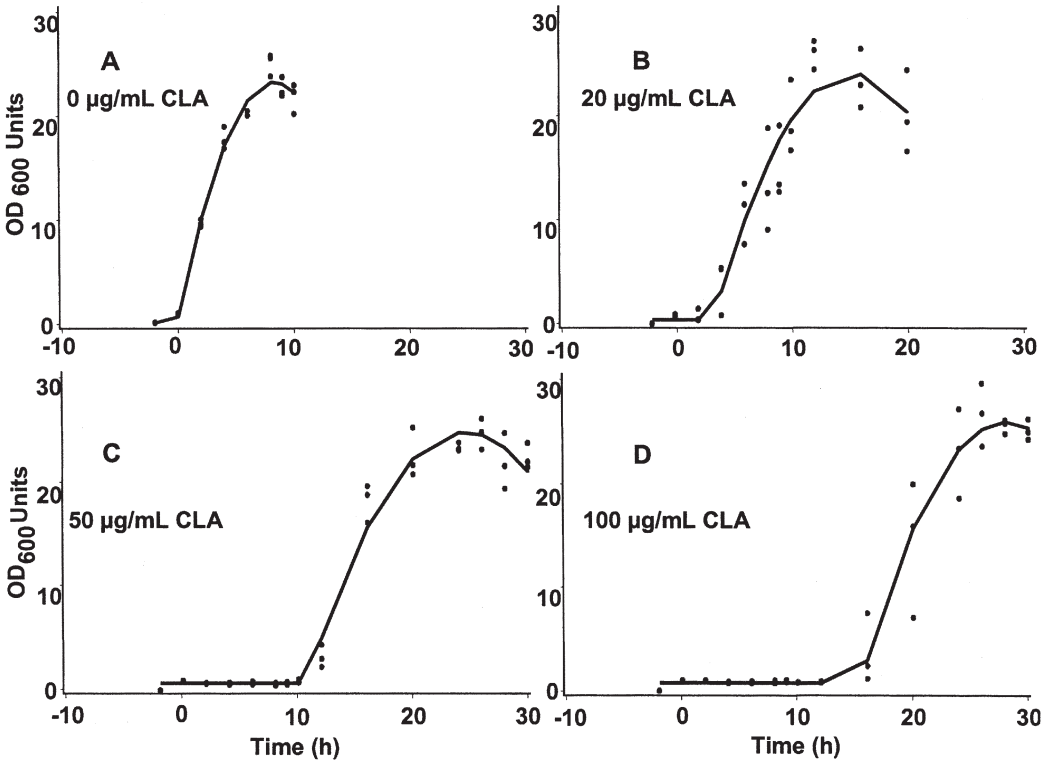

FIG. 1. Jointed nonlinear regression model fit to growth of *Staphylococcus aureus* Novel with 0 (A), 20 (B), 50 (C), or 100 µg/mL (D) of *cis*-9, *trans*-11 conjugated linoleic acid (CLA). Points are values for three replicates for each time of observation.

DISCUSSION

Fatty acids as antimicrobial agents. It has long been known that lipids have an inhibitory effect on bacteria (8,9). Trace amounts of FA have been shown to influence the growth of microorganisms in a very specific manner; certain FA such as lauric acid are more inhibitory than others (10). Kabara and coworkers (11) examined several specific straight-chain saturated FA and found lauric acid to be one of the most potent bacteriostatic FA when tested on gram-positive organisms in agreement with the present study results. They also investigated the effect of esterification and found that GML was the only monoacylglycerol more active than the FFA form, similar to our results (Table 1) where GML had the same or slightly lower MIC than lauric acid depending on the strain of *S. aureus* tested (11). The MIC of lauric acid (11) for *S. aureus* was higher (498 µg/mL) than what we observed (50 µg/mL). This may be due to differences in the sensitivity of *S. aureus* strains to certain lipids, as was found in the present study with 305 more sensitive than MN8 or Novel (Table 1). Kabara and coworkers (11) did not report what strain of *S. aureus* was used to determine their MIC (11). Our results indicate that certain FA and monoacylglycerols are more potent than others in their ability to inhibit bacterial growth similar to the previously described literature (8,9,12,13). In addition, we have demonstrated that *cis*-9, *trans*-11 and *trans*-10, *cis*-12 CLA can inhibit growth of *S. aureus* (Table 1). We are not aware of previous reports on the effect of CLA on the growth of *S. aureus.*

We observed a very specific growth curve response when different FA were tested. The saturated FA, capric acid, myristic acid, and more dramatically, lauric acid, inhibited growth of bacteria through a decrease in the maximal amount of growth achieved. However, the polyunsaturated FA, linoleic, and *cis*-9, *trans*-11 CLA achieved inhibition through a dose-dependent lag in the initiation of growth. Once started, growth proceeded in a similar pattern to control. Previous reports with other species of bacteria including *Lactobacillus helveticus*, *Clostridium sporogenes,* and *Bacillus subtilis* observed similar growth inhibition with linoleic acid (10,31).

Our research suggests that some saturated and polyunsaturated FA inhibit the growth of *S. aureus* bacteria but by different mechanisms. It was also noted that in studies (10) with *Clostridium botulinum* that there may be different mechanisms of inhibition by saturated and unsaturated FA. Kodicek and Worden (32) characterized the action of unsaturated FA (i.e., linoleic acid) as bacteriostatic and reversible by surface-active agents like sterols and lecithin in *Lactobacillus* (32). Nieman (10) suggested that the inhibitory properties of FA appear more pronounced with increased chain length and degree of unsaturation (10). Knapp and Melly (12) found bactericidal effects on *S. aureus* mediated by peroxidation of arachidonic acid. Chamberlain and coworkers (33) demonstrated that addition of oleic

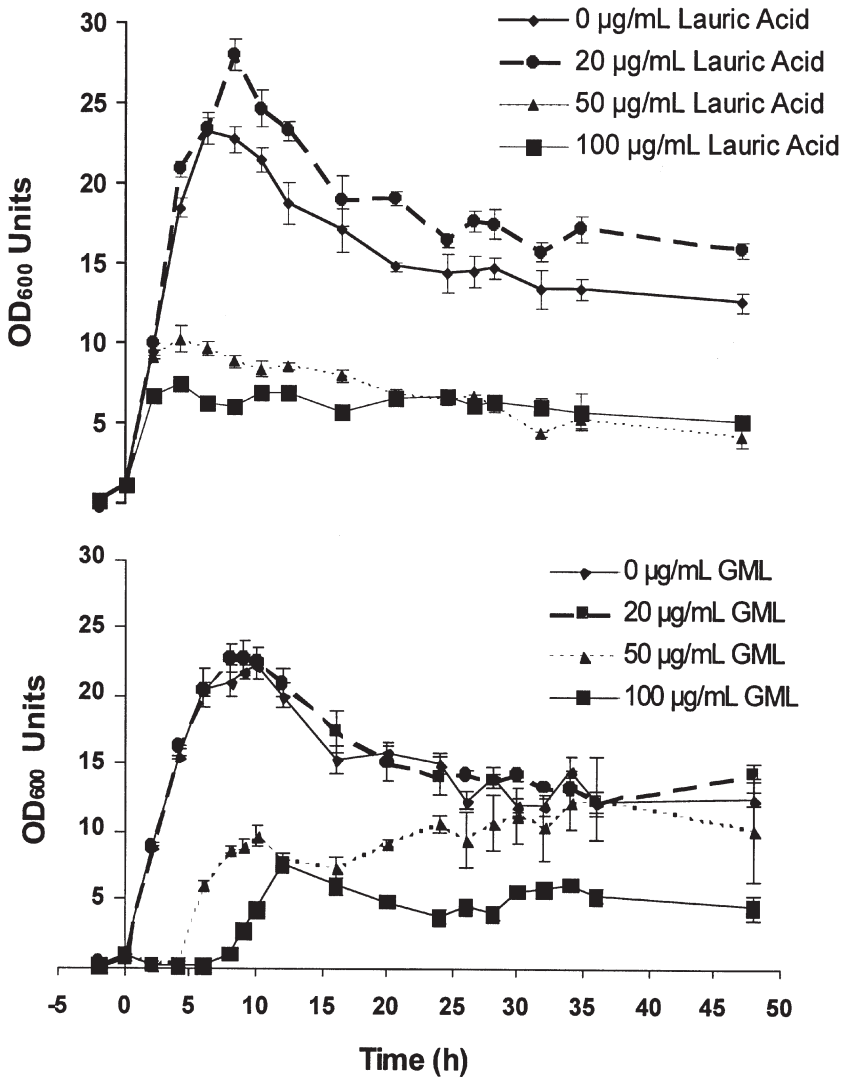

FIG. 2. Growth curves of *Staphylococcus aureus* Novel bacteria incubated with 0 (diamonds), 20 (circles), 50 (triangles), or 100 µg/mL (squares) of lauric acid (top panel) or glycerol monolaurate (bottom panel). Curves represent average of cultures performed in triplicate ± SE.

acid to the *S. aureus* resulted in increased membrane fluidity when measured by fluorescence polarimetry. This change in fluidity was detected as early as 30 s following treatment; however, significant killing occurred 45 min after treatment, indicating that oleic acid-induced killing was a multiple step process beginning with a change in fluidity of the membrane that may disrupt signal transduction cascades (33). Although proposed mechanisms (10) rely on models where the lipid interacts with the cell membrane to change permeability, more recent reports (34) indicate that some lipids including lauric acid and GML disrupt signal transduction cascades that inhibit the production of exoprotein virulence factors by *S. aureus* at concentrations lower than those required to affect growth. These observations support a multistep hypothesis to FA-induced inhibition.

FA release during infection. One indication of *S. aureus* infection is an increase in the concentration of FFA. This has been observed across a variety of infections in various animal models and in humans. Dye and Kapral (17) induced intraperitoneal abscesses in mice with *S. aureus* and found a substance produced in the abscess that was bactericidal, which was found in the lipid fraction, and further partitioning revealed it was the FFA portion. Once these FA were made into methyl esters, however, there was a loss of bactericidal activity (17). Further studies by Engler and Kapral (35) revealed a monoacylglycerol produced in intraperitoneal abscesses also had bactericidal activity. The 2-monoacylglycerol was the form originally produced; however, it spontaneously isomerized to a 1-monoacylglycerol. The FA moiety of the monoacylglycerol consisted of mostly palmitoleic acid and palmitic acid (35).

Patients with atopic dermatitis have recurring *S. aureus* skin infections and have a very different distribution of FA in their epidermis when compared to those without this condition (18). *In vitro* tests to evaluate the antimicrobial activity of human

stratum corneum lipids against *S. aureus* have only been done with extracts from the skin of healthy individuals. However, the FFA fraction has been found to be the most effective class of lipid against growth of *S. aureus* (19). Further studies found lauric acid and linoleic acid to be the most active of these FFA, similar to the present study results (20).

The concentrations of FA tested in the present study were well within the normal range found in bovine and human milk. The profiles of bovine and human milk are slightly different, with bovine milk containing a higher content of short-chain saturated FA and human milk containing a higher concentration of unsaturated long-chain FA (36). Increased concentrations of FFA in milk are common during mastitis in cows (21). Increases of 50% to 100% have been detected in FFA content of milk from cows with mastitis (22–26). The concentrations of individual FFA during mastitis ranged from approximately 17 to 312 μg/mL with lauric acid and linoleic acid present at 50 and 56 μg/mL (an increase of 20% and 60% over normal concentrations), respectively (37). The increase in FFA during infection of the mammary gland was not constant among all FA (4.7% increase in capric acid vs. 77.2% increase in stearic acid), presumably due to the amount of that particular FA present in milk fat and their preferential position on the triglyceride molecule. Preference for butyric acid, caproic acid, and caprylic acid is at the *sn*-3 position, while lauric acid, myristic acid, and palmitic acid are typically located at the *sn*-2 position (36). However, lipases secreted by *S. aureus* have no positional specificity and hydrolyze FFA at all positions on the triglyceride equally (38). Nair *et al.* (39) tested the antibacterial effect of caprylic acid and monocaprylin and showed these lipids were able to kill five different mastitis pathogens in milk. However, the doses used were ~7,200 or ~14,000 μg/mL caprylic acid and ~5,500 or ~11,000 μg/mL monocaprylin, well above the range of those lipids present even in the triglyceride fraction of milk. The doses of FA used in the present study (20, 50, 100, and 200 μg/mL) are within the physiological range of those specific FA released during a mastitis infection.

Impact on host/pathogen interaction. FA at lower concen-

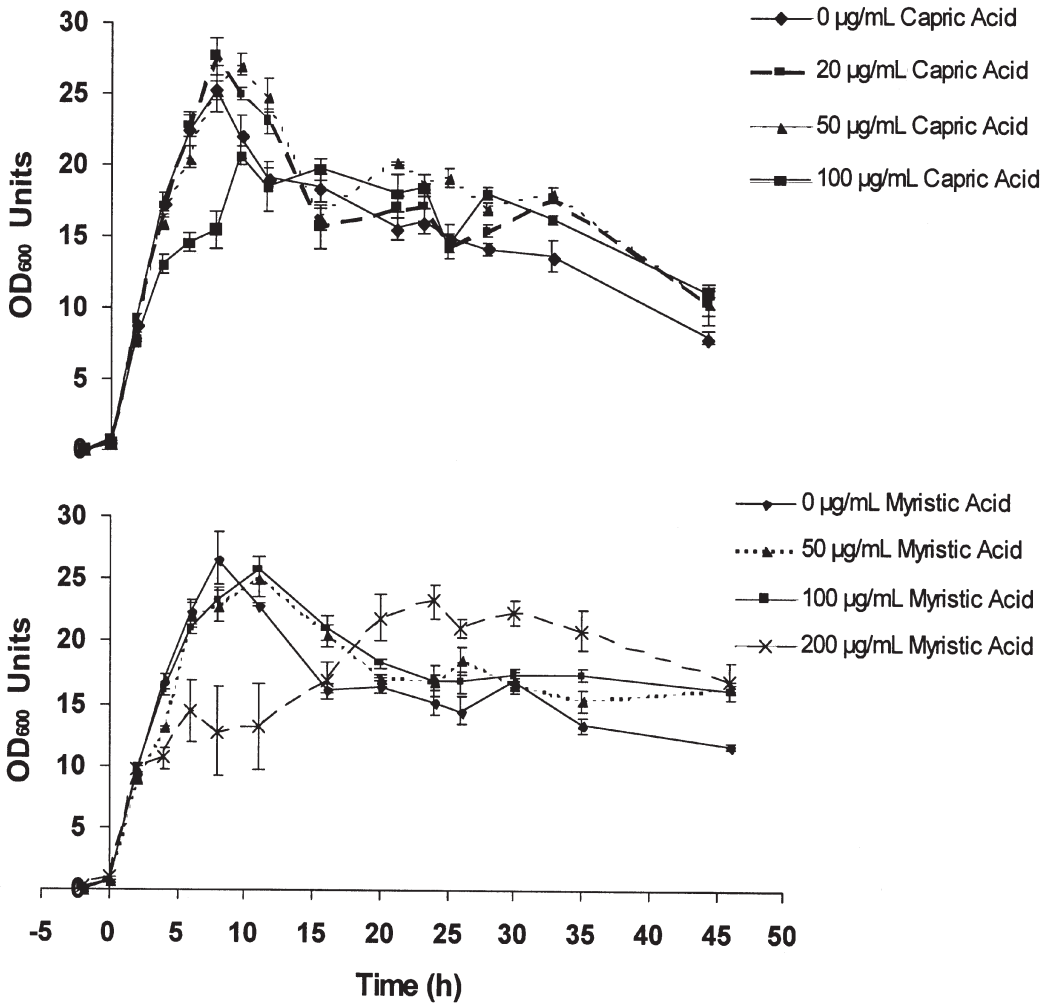

FIG. 3. Growth curves of *Staphylococcus aureus* Novel bacteria incubated with 0 (diamonds), 20 (circles), 50 (triangles), or 100 µg/mL (squares) of capric acid (top panel) or 0 (diamonds), 50 (triangles), 100 (squares), or 200 µg/mL (crosses) of myristic acid (bottom panel). Curves represent average of cultures performed in triplicate ± SE.

trations than those required for growth inhibition may also have other effects on the bacteria that are beneficial to the host. Lauric acid and GML have been more specifically analyzed in their ability to inhibit the growth and toxin production of *S. aureus*. Schlievert and coworkers (14) demonstrated the ability of GML to reduce the production of exotoxins by *S. aureus* at concentrations lower than those required for growth inhibition. The growth curves for the bovine mastitis *S. aureus* isolates followed a similar pattern to growth curves presented by Schlievert *et al.* (14) with human TSS isolates. Further work by Ruzin and Novick (15) found that free lauric acid at equimolar concentrations was just as effective as GML in blocking expression of protein A and TSS toxin-1 in *S. aureus.* Importantly, they found that active lipases secreted by *S. aureus* rapidly hydrolyze lauric acid from GML. This inhibition by lauric acid was at a dose of 20 µg/mL, a concentration 50-fold lower than that found in milk. Projan *et al.* (34) determined that GML inhibition of staphylococcal toxins occurred at the level of transcription. They also demonstrated that reduction of virulence factors was independent of the *agr* virulence regulatory system. Recently, GML was also shown to reduce three anthrax toxin components at the transcriptional level (40). We observed a difference in the pattern of growth inhibition between lauric acid (Fig. 2, top panel) and GML (Fig. 2, bottom panel). Lauric acid inhibited the maximum growth achieved by the bacteria whereas GML inhibited the growth of *S. aureus* through both a delay in the initiation of growth and a decrease in the maximum growth achieved. We speculate that this difference might be attributed to the amount of time it takes *S. aureus* to secrete active lipases able to cleave free lauric acid from the glycerol backbone of GML. Initially, GML inhibits the growth of *S. aureus* similarly to the polyunsaturated long-chain FA, creating a dose-dependent lag in the initiation of exponential growth. However, after 12 h, the pattern of growth is similar to that seen for lauric acid. Expression of lipases occurs normally during the postexponential phase of growth (41,42). However,

[a]Significance represents whether parameter estimate is different from zero. NS = not significant.
[b]Joint point = time (h) where exponential growth was initiated.
[c]Time to max = time (h) when maximal growth was achieved.
[d]Value at max = amount of growth (OD units) at the time when maximal growth was achieved.

some exoproteins including lipases may have individual specific regulatory mechanisms that may be induced by their substrates (41). The effect on *S. aureus* toxin production has been observed in lauric acid and GML; however, we are unaware of any reports in which these effects have been observed with polyunsaturated long-chain FA.

These results indicate that release of FFA or monoacylglycerols may be a mechanism to inhibit growth of *S. aureus* during an infection. At subinhibitory concentrations, these FA may also help to minimize damage to host tissues due to virulence factors such as toxins secreted by *S. aureus.*

REVIEW

Dietary *trans* Fatty Acids: Review of Recent Human Studies and Food Industry Responses

J. Edward Hunter*

Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221-0172

ABSTRACT: Dietary *trans* FA at sufficiently high levels have been found to increase low density lipoprotein (LDL)-cholesterol and decrease high density lipoprotein (HDL)-cholesterol (and thus to increase the ratio of LDL-cholesterol/HDL-cholesterol) compared with diets high in *cis* monounsaturated FA or PUFA. The dietary levels of *trans* FA at which these effects are easily measured are around 4% of energy or higher to increase LDL-cholesterol and around 5 to 6% of energy or higher to decrease HDL-cholesterol, compared with essentially *trans*-free control diets. Very limited data at lower levels of intake (less than 4% of energy) are available. Most health professional organizations and some governments now recommend reduced consumption of foods containing *trans* FA, and effective January 1, 2006, the U.S. Food and Drug Administration requires the labeling of the amounts of *trans* FA per serving in packaged foods. In response, the food industry is working on ways to eliminate or greatly reduce *trans* FA in food products. Current efforts focus on four technological options: (i) modification of the hydrogenation process, (ii) use of interesterification, (iii) use of fractions high in solids from natural oils, and (iv) use of trait-enhanced oils. Challenges to the food industry in replacing *trans* FA in foods are to develop formulation options that provide equivalent functionality, are economically feasible, and do not greatly increase saturated FA content.

Paper no. L10000 in *Lipids 41*, 967–992 (November 2006).

In recent years, dietary *trans* FA have raised health concerns largely from reports that high levels in the diet, compared with high levels of *cis* FA, have resulted in unfavorable effects on both low density lipoprotein (LDL)- and high density (HDL)-cholesterol. In response, most health professional organizations have recommended reduced consumption of foods containing *trans* FA, and the U.S. Food and Drug Administration (FDA) has issued regulations requiring the labeling of *trans* FA on packaged foods effective January 1, 2006. In addition, many food manufacturers who have used partially hydrogenated oils in their products have developed or are considering ways to reduce or eliminate *trans* FA from these products.

This review covers the following topics: (i) occurrence of *trans* FA in the U.S. food supply; (ii) review of human studies relating dietary *trans* FA to risk of coronary heart disease (CHD); (iii) review of studies relating dietary *trans* FA to other health conditions: cancer, maternal and child health, type 2 diabetes, and macular degeneration; (iv) dietary recommendations regarding *trans* and saturated FA by health professional organizations; and (v) recent food industry efforts to replace or reduce *trans* FA in foods. The possible relationship between dietary factors, such as *trans* and saturated FA, and CHD is important because CHD is the most common form of cardiovascular disease in the industrialized world. Key risk factors for CHD include positive family history (genetics), tobacco smoking, hypertension, diabetes, and elevated serum cholesterol.

OCCURRENCE OF TRANS FA IN THE U.S. FOOD SUPPLY

Unsaturated FA in foods can exist in either the *cis* or *trans* configuration (Scheme 1). In the *cis* form, the hydrogen atoms are on the same side of the double bond. In the *trans* form they are opposite. As a result of these orientations around the double bond, the *cis* FA has a bend in the carbon chain, whereas the *trans* FA has a straight carbon chain resembling that of a saturated FA. The term "positional isomer" is commonly used to refer to *cis* or *trans* FA if one or more of the double bonds have migrated to a new position in the FA chain. *Trans* FA (with double bonds at various positions in the FA chain) and *cis* positional isomers are formed during partial hydrogenation of fats and oils, a process used to impart desirable stability and physical properties to such food products as margarines and spreads, shortenings, frying fats, and specialty fats (e.g., for fillings, toppings, and candy). In addition, small amounts of *trans* FA occur naturally in foods such as milk, butter, and tallow as a result of biohydrogenation in ruminants.

Widespread use of partially hydrogenated vegetable oils in the United States during the past four or five decades has raised questions about possible health effects resulting from the consumption of *trans* FA present in these products. Among isomeric FA, recent interest has focused on *trans* FA rather than on positional isomers of *cis* FA. Accordingly, this review deals with effects of *trans* FA rather than positional isomers of *cis* FA.

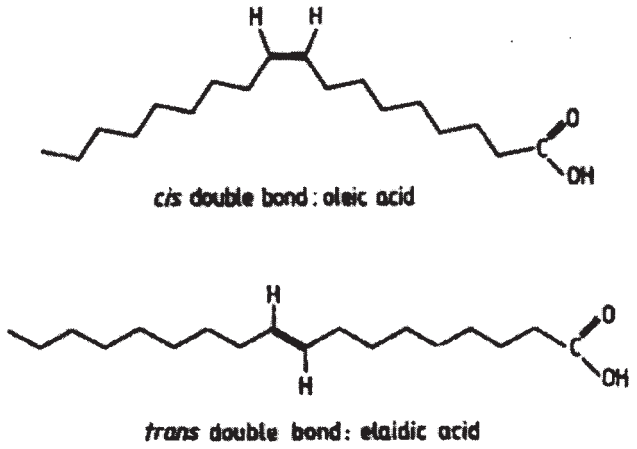

SCHEME 1

Typical levels of *trans* FA in food products containing partially hydrogenated oils are shown in Table 1. Frying oils used by restaurants and food service operations range in *trans* FA content from zero to about 35% of total FA. Some restaurants and food service operations currently use unhydrogenated oils (such as those used as salad oils) for frying, and such oils are *trans*-free. Until a few years ago, the fats used in the manufacture of retail margarines and spreads contained, on average, about 15–25% *trans* FA. Currently, most tub, liquid, and spray products contain no *trans* fat. The total fat content of many retail spreads, both tub and stick varieties, now averages about 55–60%. Thus, these spread products contain between 0 and 15% *trans* FA by weight. True margarines contain at least 80% fat (required by the FDA's standard of identity for margarines), but such products now represent only a small market share of the category of margarines and spreads. Most currently available baking shortenings typically contain about 15–30% *trans* FA, expressed as a percentage of total FA. In 2005, at least one marketed shortening was *trans*-free. Beef and dairy fat typically contain about 3% *trans* FA, also expressed as a percentage of total FA.

With regard to levels of consumption, Allison *et al.* (1) reported a mean intake of *trans* FA by the U.S. population of 2.6% of energy, or 5.3 g/person/d. This estimate was based on 24-h recalls and 2-d food records by over 11,200 subjects as part of the USDA's Continuing Survey of Food Intakes by Individuals (cited in Ref. 1). Consistent with these results, Harnack *et al*. (2) reported that the mean intake of *trans* FA in a population of adult subjects in the Minneapolis-St. Paul, Minnesota, USA, metropolitan area decreased from 3.0% of total energy in 1980–1982 to 2.2% of total energy in 1995–1997. The estimates of Harnack *et al.* were based on 24-h dietary recalls by more than 7,900 subjects participating in the Minnesota Heart Study, an ongoing observational epidemiologic study. These estimated intakes (1,2) of *trans* FA of 2–3% of total energy are smaller than those of saturated FA, which contribute 12–14% of energy intake (3–6). The intake of *trans* FA in 14 European countries has been reported to range from 0.5 to 2.1% of energy (7), somewhat less than the intake reported for the United States. This intake of *trans* FA in Europe also is considerably less than the intake of saturated FA in Europe, estimated to be 10–19% of energy (7).

TABLE 1
Typical Levels[a] of *trans* FA in Food Fats/Products

Food fat/product	*trans* FA content
Frying fats	0–35% of FA
Margarines/spreads	Fat: 0–25% of FA product: 0–15% by weight
Shortenings	0–30% of FA
Beef and dairy fat	3% of FA

[a]The levels of *trans* FA in various food products are expressed as a percentage of total FA.

Estimates of intake of *trans* FA based on reported consumption of foods (1,2,7) are considerably lower than estimates based on the availability from foods. The latter estimates consider market size, market share, and composition of products made from partially hydrogenated fats and oils and thus represent reasonable approximations of intake. Such estimates, however, do not take into account fats that are wasted or deliberately discarded. In 1986, Hunter and Applewhite (8) reported an estimate of *trans* FA available for consumption in the U.S. diet for 1984 of 7.6 g/person/d. A similar value, 8.3 g/person/d, was obtained independently by a Federation of American Societies for Experimental Biology (FASEB) Review Panel on *Trans* FA (9). Hunter and Applewhite (10) updated their estimate of *trans* FA availability in the U.S. diet for 1989 to be 8.1 g/person/d. Biomarker data are needed to assess *trans* FA intake more accurately. Current efforts by food manufacturers to eliminate or drastically reduce levels of *trans* FA in their products (to be discussed later in this review) are expected to reduce the intake of *trans* FA to levels well below those reported to date.

HUMAN STUDIES RELATING DIETARY *TRANS* FA TO RISK OF CHD

Review articles. (i) Reviews of studies reported prior to 1990. The year 1990 marked a period of renewed interest by many health professionals in the effects of dietary *trans* FA. That year, a study by Mensink and Katan (11) reported that high levels of *trans* FA in the diet increased the level of LDL-cholesterol and decreased the level of HDL-cholesterol compared with high levels of *cis* FA. Details of this study will be discussed subsequently.

Prior to the study by Mensink and Katan (11), numerous reviews and comprehensive studies showed that diets high in 18-carbon *trans* monoenes but adequate in EFA were not uniquely atherogenic (12–18). Many of these reviews and studies were considered in a comprehensive literature review by a special FASEB committee (9). This report concluded that there is "little reason for concern with the safety of dietary *trans* FA *both* at their present and expected levels of consumption *and* at the present and expected levels of consumption of dietary linoleic acid. . . ." A 1987 British Nutrition Foundation report on the safety of *trans* FA reached the same conclusion (19).

(ii) Reviews of studies reported since 1990. Reviews published after 1990 discussed the Mensink and Katan study (11)

and subsequent studies, suggesting that high dietary levels of *trans* FA increased CHD risk. A 1995 review (3) by Kris-Etherton and Nicolosi (before much of the *trans* fat literature was published) suggested that the association between *trans* FA intake and CHD risk is weak and inconsistent compared with the large body of evidence from epidemiologic observations and animal and human studies that supports a direct effect of saturated fat on CHD risk. These authors commented that some clinical studies were difficult to interpret because it was unclear whether the reported responses were due to the addition of *trans* FA to the diet or to a decrease in dietary unsaturated (i.e., cholesterol-reducing) FA. Kris-Etherton and Nicolosi (3) considered the current level of intake of *trans* FA to be safe; however, they supported the reduction of total fat intake (including reduced intake of *trans* and cholesterol-raising saturated FA) as part of national dietary guidelines to promote health and well-being.

Katan *et al*. (20) concluded that the effects of *trans* FA on raising plasma LDL-cholesterol levels were similar to those of saturated FA. These authors recommended that diets aimed at reducing the risk of CHD be low in both *trans* and saturated FA.

A comprehensive review by the American Society for Clinical Nutrition/American Institute of Nutrition Task Force on *trans* Fatty Acids (4) concluded that "compared with saturated FA, the issue of *trans* FA is less significant because the U.S. diet provides a smaller proportion of *trans* FA and the data on their biological effects are limited." The Task Force recommended that data be obtained that are comparable to those of saturated FA on the intake of *trans* FA, their biological effects and associated mechanisms of action, and their relation to disease.

Zock and Katan (21) reviewed 20 dietary trials comparing effects of butter and margarine on blood lipids. The authors reported that replacing butter by soft, low-*trans* margarines favorably affected the blood lipoprotein profile, which in turn might reduce the risk of CHD. Replacing butter by hard, high-*trans* margarines appeared to offer no benefit over butter.

Ascherio *et al*. (22) reported a linear relationship between the change in LDL/HDL ratio (a measure of CHD risk) and the percentage of energy from either *trans* FA or saturated FA in the diet. These authors also concluded that the adverse effect on LDL/HDL ratio of *trans* FA appeared to be stronger than that of saturated FA.

A subsequent review by Katan (23) indicated that since around 1990, *trans* FA went from a type of fat generally regarded as safe and possibly beneficial to one considered by many to be unfavorable for CHD risk. Katan felt that *trans* FA were at least as unfavorable as cholesterol-raising saturated FA. Wolfram (24) indicated that epidemiological studies have noted a strong association between intake of saturated and *trans* FA and plasma cholesterol levels and rates of CHD mortality worldwide.

A 2002 review by Schaefer (25) suggested that hydrogenated margarines and butter should be avoided, and that either oil or soft margarine low in *trans* FA should be used as a spread. Schaefer noted that in addition to having unfavorable effects on LDL- and HDL-cholesterol concentrations, there is evidence that increased *trans* FA consumption, in contrast with consumption of saturated fat, increases plasma concentrations of lipoprotein(a) [Lp(a)].

Mensink *et al*. (26) reported a meta-analysis of 60 controlled trials focusing on the effect of individual dietary FA on the ratio of total cholesterol to HDL cholesterol and on serum lipoproteins. These authors determined that this ratio was decreased most effectively (corresponding to decreased risk of CHD) when *trans* FA and saturated FA were replaced with *cis* unsaturated FA.

In contrast to the preceding reviews, Wilson *et al*. (27) concluded that the intake of *trans* FA does not pose as much of a health concern for Americans as does the intake of cholesterol-raising saturated FA. Although Wilson *et al.* encouraged efforts to minimize increased amounts of *trans* FA in the diet, they felt that *trans* FA at the current level of intake are a safe component of the diet. Wilson *et al*. suggested that consumers limit their intake of *trans* FA by lowering their intake of total fat within the context of a varied and healthful diet.

Similarly, a brief review by Steinhart *et al*. (28) noted that only a slight correlation between *trans* FA and CHD can be observed if *trans* FA are consumed instead of saturated FA. Nevertheless, the *trans* FA content of German margarines, cooking fats, and shortenings was reported to have decreased from 1992 to 1997, and estimated daily intakes of *trans* FA in Germany also decreased during this period.

The Institute of Medicine (IOM) of the National Academy of Sciences (29) reviewed effects of dietary *trans* FA as part of a report on reference intake levels of macronutrients. Citing the study of Ascherio *et al*. (22), the IOM report stated that, similar to saturated FA, there is a positive linear trend between *trans* FA intake and increased risk of CHD. The IOM report, however, did not establish a "Tolerable Upper Intake Level" above which long-term consumption might be undesirable for some individuals. The IOM noted that *trans* FA are unavoidable in ordinary diets and that eliminating them from the diet might result in inadequate intakes of certain nutrients and increase certain health risks. The report recommended that consumption of *trans* FA as well as saturated FA and cholesterol be as low as possible from a nutritionally adequate diet.

The most recent (2006) review, by Mozaffarian *et al*. (30), considers evidence for physiological and cellular effects of *trans* FA as well as the feasibility and potential implications of reducing or eliminating the consumption of *trans* FA in the United States. Consistent with other reviews, this article conveys risks associated with consumption of high levels of *trans* FA. In contrast to other reviews, the authors state that even low levels of consumption (1 to 3% of total energy intake) confer "a substantially increased risk . . . ." However, the references cited to support this statement were epidemiological and prospective studies and not controlled dietary trials in which the investigators fed *trans* FA at such levels. A controlled study by Lichtenstein *et al*. (31) found no significant effect on either LDL- or HDL-cholesterol when a diet containing *trans* FA at 3.3% of energy was fed for 35 d and compared with a control

diet with *trans* FA at only 0.6% of energy. Mozaffarian *et al*. expressed their view that consumption of *trans* FA at less than 0.5% of total energy may be necessary to avoid adverse effects. This would mean complete or near-complete avoidance of dietary *trans* FA, an extreme position compared with that expressed in the IOM report (29) and probably unlikely in the near future to meet with significant consumer acceptance.

Human trials reporting changes in blood lipid and lipoprotein levels with dietary trans FA. (i) Experimental studies. Prior to 1990, two comprehensive literature reviews (9,19) had concluded that there was little basis for concern about the consumption of *trans* FA at present and expected dietary levels. One study (of many) on which this conclusion was based was that of Mattson *et al*. (32). This study was particularly significant because it was the first to control carefully the FA composition of the diets. In this study, subjects were fed liquid formula diets high in *cis* or *trans* FA for 28 d. The FA intakes of both groups were the same except for the presence or absence of *trans* FA. The key result was that the subjects fed the high-*trans* diet had the same blood total cholesterol and TG levels as subjects fed the high-*cis* diet. At the time of this study, methodology for measuring HDL- and LDL-cholesterol and their apoproteins was not well established.

In a subsequent study by Mensink and Katan (11), blood lipoprotein levels were measured in young adult human subjects (mean age 26 yr) fed conventional food diets high in either *cis*, *trans*, or saturated FA. The study design resembled that used by Mattson *et al*. (32) in that the diets containing *cis* and *trans* FA had similar FA compositions except for the presence or absence of *trans* FA. In this study, the high-*trans* diet (10.9% of energy as *trans* FA) raised total and LDL-cholesterol and lowered HDL-cholesterol compared with the high-*cis* diet after 3 wk. Although the level of *trans* FA in the high-*trans* diet was unrealistically high (nearly 11% of energy), the authors concluded that the effect of *trans* FA on serum lipoprotein profiles was similar to that of cholesterol-raising saturated FA.

Since the Mensink and Katan study (11), numerous other human trials have been conducted that include measurement of LDL- and HDL-cholesterol [and occasionally Lp(a)] after feeding diets containing moderate or high levels of *trans* FA (31,33–61). Key study design parameters and results are summarized in Table 2. In essence, these studies demonstrated that diets high in *trans* FA raised LDL-cholesterol and lowered HDL-cholesterol compared with diets low in *trans* FA.

Three noteworthy studies (34,37,39) are discussed in more detail below. Zock and Katan (34) compared effects on blood lipoproteins of diets high in linoleic acid, *trans* FA, and stearic acid. In this study, the intake of *trans* FA was lower than that of the Mensink and Katan (11) study (7.7% of energy vs. 10.9% of energy). The lower level of *trans* FA raised total cholesterol and LDL-cholesterol and lowered HDL-cholesterol compared with the linoleic acid diet. The stearic acid diet similarly raised total and LDL-cholesterol and reduced HDL-cholesterol compared with the linoleic acid diet. Subsequently, Mensink *et al*. (33) reported that this *trans* FA diet raised Lp(a) levels compared with the linoleic acid and stearic acid diets.

In the first study by Judd *et al*. (37), moderate- and high-*trans* diets (3.8 and 6.6% of energy, respectively) resulted in increased plasma LDL-cholesterol levels compared with an oleic acid diet. These increases, however, were less than those observed with a saturated FA diet. The high-*trans* diet, but not the moderate-*trans* diet, resulted in a minor (statistically significant) reduction in HDL-cholesterol. The saturated diet, however, led to a slight increase in HDL-cholesterol.

Lp(a) levels were reported in a subsequent publication (40). Compared with the oleic diet, the *trans* diets had no effect on Lp(a) levels when all subjects were considered collectively. However, a subset with initially high levels of Lp(a) (≥30 mg/dL) responded to the high-*trans* diet with a slight (5%) increase in Lp(a) levels relative to the oleic and moderate-*trans* diets. Thus, the possibly unfavorable effects on Lp(a) of replacing *cis* with *trans* FA were restricted to high-*trans* intakes in subjects with high levels of Lp(a).

The second study by Judd *et al*. (39) included a high-carbohydrate diet to assess whether direct addition of *trans* FA to the diet had an independent cholesterol-raising effect. Also, a high-stearate diet was included to determine whether stearate and *trans* FA were neutral with regard to their effects on blood lipoproteins. Compared with a high-oleic diet, the high-*trans* (8% of energy) diet raised LDL-cholesterol to a greater extent than the high-saturated diet despite similar levels of *trans* plus saturated FA. In contrast, in the previous study (37), the increase in LDL-cholesterol after the high-*trans* diet was directionally (but not significantly) less than that observed after the high-saturated diet. Compared with the high-carbohydrate diet, both the moderate- (4% of energy) and high-*trans* diets and the saturated diet resulted in increased LDL-cholesterol levels. Both *trans* diets lowered HDL-cholesterol compared with the oleic diet but not compared with the carbohydrate diet. Also compared with the carbohydrate diet, the stearic acid diet had no effect on LDL-cholesterol but lowered HDL-cholesterol. The oleic acid diet had no effect on LDL-cholesterol but raised HDL-cholesterol.

The studies by Mensink and Katan (11), Zock and Katan (34), and Judd *et al*. (37,39) were consistent in that in all four studies, the *trans* FA and saturated FA treatments raised LDL-cholesterol levels compared with the control diet. The changes in LDL-cholesterol levels by *trans* FA and by saturated FA were similar. HDL-cholesterol levels in these studies were reduced consistently when the level of *trans* FA in the diet was 6.6% of energy or higher. In the second study by Judd and colleagues (39), the moderate-*trans* diet showed a reduction in HDL-cholesterol that was not seen in the first study (37).

(ii) Effect of dietary trans FA on LDL particle size. Mauger *et al*. (62), in an extension of the study by Lichtenstein *et al*. (31), reported that increasing the amounts of dietary *trans* FA resulted in decreased LDL particle size in a dose-dependent fashion. Mauger *et al*. cited studies reporting that small and dense LDL particles have been reported to be more atherogenic than larger, less dense particles. In contrast, Kim and Campos (63), in an epidemiological study of a Costa Rican population, found an association between intake of *trans* FA and large LDL

TABLE 2
Human Trials Reporting Changes in LDL-Cholesterol, HDL-Cholesterol, and Lipoprotein(a) with Dietary *trans* FA (TFA)

[a]Changes indicated were significant at $P \leq 0.05$ unless otherwise indicated. Abbreviations: TFA, *trans* FA; % en, % of energy; LDL-C, low density lipoprotein cholesterol; HDL-C, high density lipoprotein cholesterol; Lp(a), lipoprotein(a); OL, oleic acid; LA, linoleic acid; STE, stearic acid; SAT, saturated FA; CO, corn oil; SBO, soybean oil; SO sunflower oil; PHSBO, partially hydrogenated soybean oil; PHFO, partially hydrogenated fish oil; min, minimum (i.e., values apply only to test fat, not to total fat in diet; NS, not significant; NR, not reported.
[b]Based on 3-d food records.

particles. Campos *et al*. (64) previously had reported that large LDL particles were independently associated with increased risk of CHD in case control and prospective studies, after adjustment for established lipid and nonlipid risk factors. In an *in vitro* study, Mitmesser and Carr (65) found that the size of the apoB-100-containing lipoproteins (apoB-100 is the principal apolipoprotein of LDL) secreted by HepG2 cells pre-incubated with elaidic acid or CLA was smaller compared with those pre-incubated with oleic acid or linoleic acid, respectively. This *in vitro* study is consistent with the idea that *trans* FA enhance production of small LDL particles. On the other hand, Kim and Campos (63) stated, "It is possible that the atherogenic characteristics (of small LDL particles) *in vivo* may not be worse than the harmful effects of large LDL." Further research is needed to clarify effects of dietary *trans* FA on LDL particle size.

Collective consideration of human trials. Nine human studies reporting increases in LDL- and decreases in HDL-cholesterol levels when diets high in *trans* FA were compared with diets high in either oleic acid or linoleic acid (11,31,34–37, 39,41,42) have been compared collectively by Ascherio *et al*. (22). (There may have been minor differences among the diets besides the intake of *trans* vs. *cis* monounsaturated FA.) Control diets in these studies contained minute levels of *trans* FA (from zero to 0.7% of energy). Ascherio *et al*. graphed the changes in LDL/HDL ratio reported in these studies against the percentage of energy from either *trans* or saturated FA (Fig. 1). Two best-fit regression lines were plotted through the origin, one line representing the percentage of energy from *trans* FA and the other line, the percentage of energy from saturated FA. Six of the nine studies (11,34,35,37,39,42) allowed a comparison between *trans* and saturated FA. Both regression lines had positive slopes, indicating a positive association between intake of either category of FA and CHD risk. However, the slope of the regression line for *trans* FA was larger (by about twofold) than that for saturated FA. This difference in slopes led to the conclusion that *trans* FA have a more adverse effect on CHD risk than saturated FA (22). This conclusion was supported further by the greater effect on LDL/HDL ratio of *trans* FA compared with saturated FA in the six studies that allowed such a comparison.

Another way to look at these studies collectively is to consider the relationship between simply the change in LDL-cholesterol level or the change in HDL-cholesterol level (rather than the change in their ratio) with increasing level of *trans* FA in the diet (66). This is reasonable because changes in the LDL/HDL ratio do not permit determination of whether LDL, or HDL, or both were changing at a particular dietary level of *trans* FA.

Using data from the same nine studies, Figure 2 is a scatter diagram of the change in LDL-cholesterol with dietary level of *trans* FA. The relationship is directionally similar to that seen when the LDL/HDL ratio was plotted (Fig. 1). Importantly, however, considering these nine studies, the change in LDL-cholesterol was not statistically significant unless the dietary level of *trans* FA was around 4% of energy or higher. The change in HDL-cholesterol with increasing level of *trans* FA

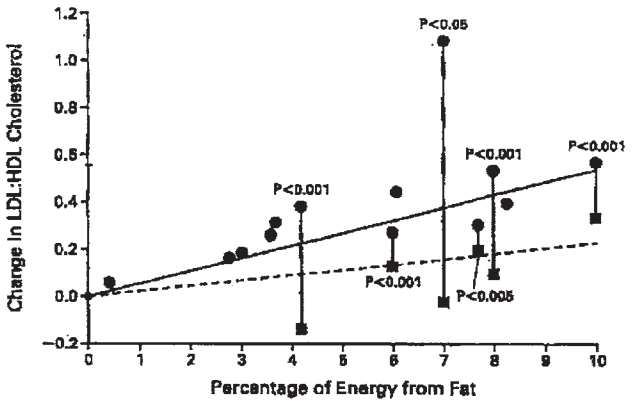

FIG. 1. Change in low density lipoprotein/high density lipoprotein (LDL/HDL) ratio with level of dietary *trans* FA or saturated FA. This graph was reported by Ascherio *et al*. (22) and compares collectively the LDL/HDL ratios against the percentage of energy as either *trans* fat (solid circles, solid line) or saturated fat (solid squares, dashed line) for nine studies (see text). This figure is adapted with permission, copyright© 1999, Massachusetts Medical Society.

in the diet (Fig. 3), with the exception of one study, was not statistically significant unless the dietary level of *trans* FA was higher than about 5–6% of energy. [*Note*: Numerous other human studies (Table 2) that have evaluated effects of *trans* FA on LDL- and HDL-cholesterol levels were excluded from consideration here because they did not compare effects of *trans* FA with those of isocaloric amounts of *cis* FA.]

In an effort to better define the dietary level of *trans* FA that raises LDL-cholesterol and lowers HDL-cholesterol, I considered weighted regression break point analysis and chi-squared analysis (66). Both of these analyses are statistical determinations to estimate possible threshold levels (i.e., "break points"). Weighted regression analysis uses sample size as a weight, thus giving more weight to larger samples. For LDL-cholesterol, a visual break point (the minimum level of *trans* FA resulting in a significant increase in LDL) appeared to exist at or below about 4% of energy as *trans* FA (Fig. 2). Weighted regression analysis, however, did not show quantitatively that 4% of energy is the break point, probably in part because there were only two data points below 3.8% of energy. Nevertheless, it seemed reasonable to expect that a break point might exist in the range of 3.3–4.2% of energy, where the difference between treatment and control LDL values was greatest. This range is consistent with a possible visual break point at or below 4% of energy, i.e., it raises the possibility that there may be a threshold effect of *trans* FA between 3.3 and 4.2% of energy.

In the case of HDL-cholesterol, more data were available below a visual break point estimated to be between 5 and 6% of energy (Fig. 3). However, the absence of data in the range of 4.2–6.6% of energy did not permit more precise estimation of a break point other than to suggest that it might fall in the range of 5–6%.

Chi-squared analyses indicated reasonable break points for effects of *trans* FA on LDL and HDL to be about 3.5 and 7.0% of energy, respectively (66). These latter values are similar to

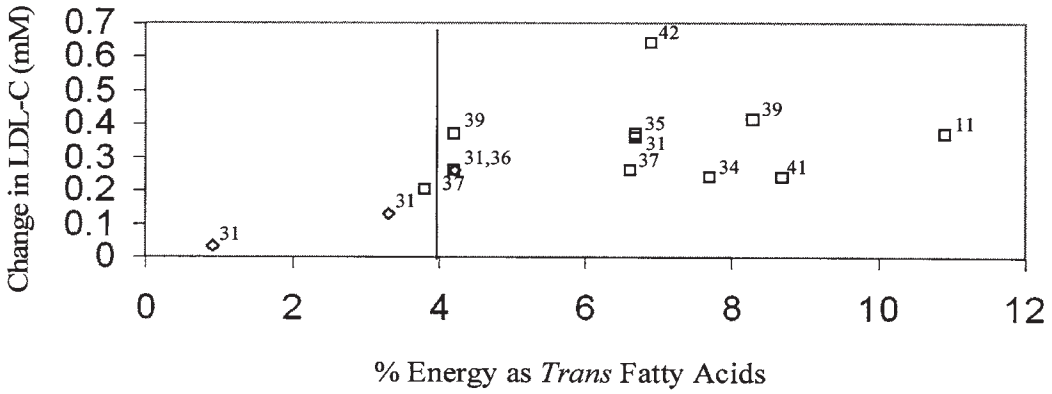

FIG. 2. Scatter diagram of the change in LDL-cholesterol (expressed as mM) with dietary level of *trans* FA (expressed as % energy) using data from the nine studies compared collectively by Ascherio *et al.* (22). Changes in LDL-cholesterol were calculated from the difference between a *trans* FA treatment and its corresponding control treatment. Open diamonds (◇) represent changes in LDL-cholesterol that were reported not to be statistically significant. Open squares (□) represent changes in LDL-cholesterol that were reported to be statistically significant. The number to the right of each point indicates the reference from which the data were taken.

the visual break point estimates of 4% of energy for LDL and 5–6% of energy for HDL.

It is recognized that the confidence in these visual and estimated break points is limited because of the small amount of data (14 treatments) available from the nine studies considered. In particular from Figure 2, there were only two dietary treatments below 4% of energy as *trans* FA. This is an insufficient amount of evidence at present to say whether or not *trans* FA at less than 4% of energy are harmful to humans, and possible biological effects below 4% of energy cannot be ruled out. On the other hand, showing this experimentally would be difficult and expensive and probably not feasible because of the large number of subjects (hundreds or thousands) required along with the difficulty of excluding effects of other FA (saturated, monounsaturated, and polyunsaturated) in the diet. In the case of HDL-cholesterol, lack of data also does not rule out possible biological effects below the apparent visual break point range of 5–6% of energy.

Also because of the limited amount of data available, it is not possible to determine with certainty whether the relation-

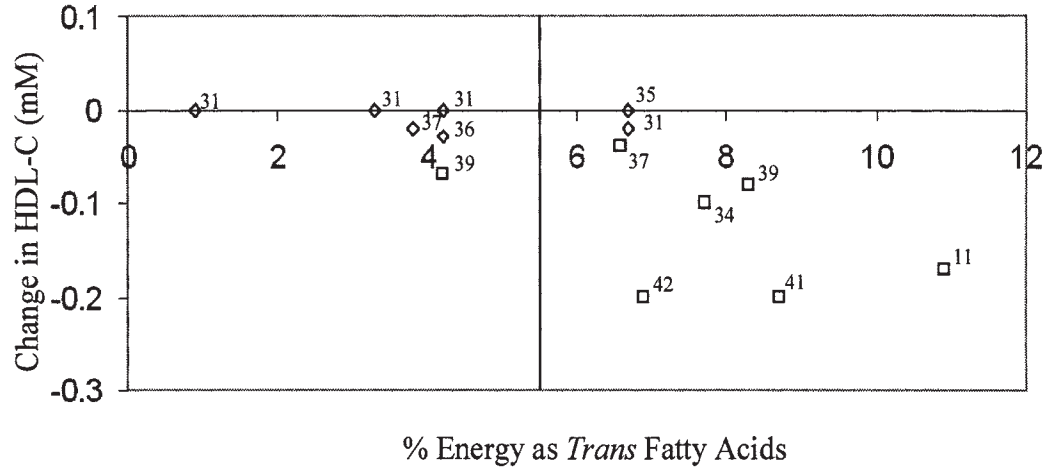

FIG. 3. Scatter diagram of the change in HDL-cholesterol (expressed as mM) with dietary level of *trans* FA (expressed as % energy) using data from the nine studies compared collectively by Ascherio *et al.* (22). Changes in HDL-cholesterol were calculated from the difference between a *trans* FA treatment and its corresponding control treatment. Open diamonds (◇) represent changes in HDL-cholesterol that were reported not to be statistically significant. Open squares (□) represent changes in HDL-cholesterol that were reported to be statistically significant. The number to the right of each point indicates the reference from which the data were taken.

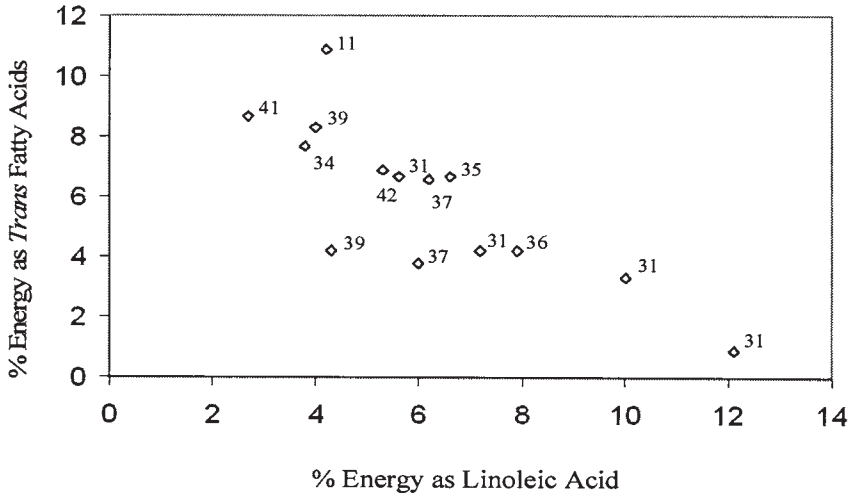

FIG. 4. Scatter diagram comparing the levels of *trans* FA and of linoleic acid used in the *trans* FA diet treatments of the nine studies compared collectively by Ascherio *et al.* (22). Each open diamond (◇) represents the level of dietary *trans* FA and the corresponding level of linoleic acid used in that same treatment. The number to the right of each point indicates the reference from which the data were taken.

ship between the change in LDL-cholesterol (or HDL-cholesterol) and dietary level of *trans* FA is linear, nonlinear, or includes a threshold below which there is no change in LDL-cholesterol with *trans* FA level. Ascherio *et al*. (22) assumed the relationship (considering the LDL/HDL ratio) is linear. Figure 2, however, indicates that the change in LDL-cholesterol may be greatest between 3.3 and 4.2% of energy as *trans* FA and, except for one data point, may be essentially constant between 4 and 11% of energy. However, what is important is not the shape of the curve but the finding that *trans* FA at or above 4% of energy consistently have resulted in significant increases in LDL-cholesterol compared with an essentially *trans*-free diet.

An additional way to consider the same studies is to compare the levels of *trans* FA and of linoleic acid used in the *trans* FA diet treatments (66). A scatter diagram (Fig. 4) indicates that higher dietary levels of *trans* FA were associated with lower levels of linoleic acid and vice versa. In some cases where high levels of *trans* FA (i.e., more than 6% of energy) were fed, the corresponding levels of linoleic acid, 2–4% of energy, while adequate to prevent a nutrient deficiency (e.g., scaly skin), may not have been sufficient to prevent the cholesterolemic effect of a high level of *trans* FA. According to the IOM report (29), an "adequate intake" of linoleic acid for men 31 to 50 yr old is 17 g/d. For men in this age range consuming 2800 kcal/d, this "adequate intake" of linoleic acid would be 5.5% of energy, well above the 2–4% of energy used in several studies. For women 31–50 yr old consuming a 2000 kcal/d diet, the reported "adequate intake" of 12 g/d (29) would provide 5.4% of energy, also above the level used in several studies.

Figure 5 plots the change in LDL/HDL ratio from the *trans* FA diet treatments (22) against the percentage of energy as linoleic acid instead of against the percentage of energy as *trans* FA (66). The regression line obtained is opposite in direction compared with that for the percentage of energy as *trans* FA (22). One interpretation of this difference in direction of the regression lines is that at a sufficient level of linoleic acid in the diet (i.e., 5–6% of energy or higher), *trans* FA may be less effective in increasing the LDL/HDL ratio. Alternatively, increasing dietary linoleic acid may lower the LDL/HDL ratio through the well-known effect of lowering LDL-cholesterol.

A possible physiological explanation for Figure 5 is that *trans* FA and linoleic acid might have opposite effects on the catabolism of the apoproteins of LDL and HDL. Matthan *et al*. (67) reported that dietary hydrogenated fat (i.e., *trans* FA) decreases the catabolism of LDL apoB-100 and increases the catabolism of HDL apoA-I. This could explain the corresponding increase in LDL-cholesterol and decrease in HDL-cholesterol associated with high dietary *trans* FA levels. Perhaps these catabolic effects of *trans* FA are reduced in the presence of sufficient linoleic acid. Additional studies would be needed to clarify whether the proportions of dietary linoleic acid and *trans* FA affect the catabolic rates of the apoproteins.

Note that even at dietary levels of *trans* FA between 4 and 11% of energy, the magnitude of the reported changes in LDL-cholesterol between *trans* and essentially *trans*-free diets was small, ranging from 0.20 to 0.64 mmol/L (equivalent to 7.7 to 25 mg/dL). Similar small changes in LDL-cholesterol might reasonably be expected in many people from the near elimination from the diet of industrially produced *trans* FA. Although small reductions in LDL-cholesterol in a population may benefit heart health, the suggestion by Mozaffarian *et al*. that the near elimination of industrially produced *trans* FA would decrease the number of CHD events each year by up to 228,000 (30) seems to be greatly exaggerated. Achieving such a major reduction in CHD events likely would require additional and more drastic lifestyle changes (e.g., elimination of smoking and greater participation in regular exercise) and more widespread use of cholesterol-lowering drugs.

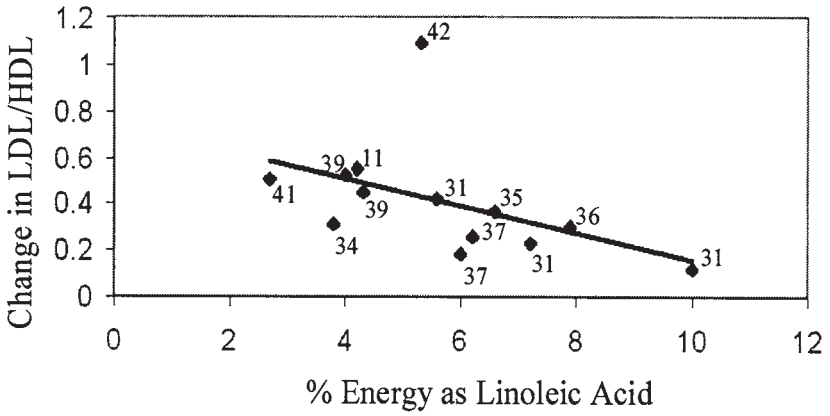

FIG. 5. Change in the ratio of LDL-cholesterol/HDL-cholesterol vs. the dietary level of linoleic acid using data from the nine studies compared collectively by Ascherio *et al.* (22). The slope for the best-fit regression line is –0.059, similar in magnitude (0.056) to that determined for the graph presented by Ascherio *et al.* (22; LDL/HDL ratio vs. % energy as *trans* FA) but opposite in sign. The number to the right of each point indicates the reference from which the data were taken.

In summary, it appears that at a sufficiently high dietary level, *trans* FA consistently raise LDL-cholesterol and reduce HDL-cholesterol levels compared with a diet essentially free of *trans* FA. The dietary levels of *trans* FA necessary to increase LDL-cholesterol appear to be around 4% of energy and higher and to decrease HDL-cholesterol, around 5–6% of energy or higher compared with control diets. Thus, high dietary levels of *trans* FA indeed increase CHD risk. On the other hand, because of limited available data, it was not possible to estimate precise break points for effects of *trans* FA on LDL or HDL. There is insufficient evidence at present to say whether *trans* FA at less than 4% of energy in the diet are or are not harmful to humans.

Studies on clotting tendency, blood pressure, LDL oxidation, flow-mediated vasodilation (FMD), and systemic inflammation. Results of studies assessing the effect of dietary *trans* FA on blood clotting tendency have been inconsistent. Wood *et al.* (43) reported that blood levels of thromboxane B_2, an indicator of increased *in vitro* platelet aggregation (i.e., a measure of increased clotting tendency), were unchanged in a group of human subjects fed high levels of hard margarine compared with subjects fed a baseline diet. Almendingen *et al.* (68) found that a diet containing 8.5% of energy from a margarine made from partially hydrogenated soybean oil resulted in higher levels of plasminogen activator inhibitor type 1 than a diet containing 8.0% of energy from a margarine made from partially hydrogenated fish oil. This finding suggested that partially hydrogenated soybean oil had unfavorable antifibrinolytic effects compared with partially hydrogenated fish oil. There were no differences between the diets in levels of factor VII, fibrinogen peptide A, β-thromboglobulin, D-dimer, or tissue plasminogen activator.

In other studies, Mutanen and Aro (69) reported no differences in coagulation and fibrinolysis between a high stearic acid diet (0.4% of energy as *trans* FA) and a high *trans* FA diet (8.7% of energy as *trans* FA). The same high stearic acid and *trans* FA diets also produced similar effects on platelet aggregation and endothelial prostaglandin I_2 production (70). Sanders *et al.* (71) saw no significant differences in factor VII coagulation activity after feeding single meals high in either oleic acid (0.07% of energy as *trans* FA) or elaidic acid (24.7% of energy as *trans* FA). A subsequent study (57) in which normocholesterolemic men were fed a high oleic acid diet (0.1% of energy as *trans* FA) or a high *trans* FA diet (9.6% of energy as *trans* FA) for 2 wk resulted in no differences in known hemostatic risk markers (fibrinogen and D-dimer concentrations, factor VII coagulant, plasminogen activator inhibitor type 1, and tissue plasminogen activity) for cardiovascular disease. Feeding a diet high in the ruminant *trans* FA vaccenic acid (1.1% of energy) similarly had no effect on the hemostatic variables factor VII coagulant activity and plasminogen activator inhibitor type 1 (59).

With regard to blood pressure, two studies with normotensive subjects showed no effect of *trans* FA (fed at up to 10.9% of energy) compared with oleic acid on either systolic or diastolic blood pressure (72,73). Similarly, high-*trans* diets containing up to 8.5% of energy as *trans* FA consistently have been reported to produce little or no effect on the susceptibility of LDL to oxidation (35,53,74,75).

FMD is defined as the increase in diameter of an artery, usually the brachial artery in the arm, after a provoked local increase in blood flow. Impaired FMD appears to be predictive of future coronary events. De Roos *et al.* (47,76) found that dietary replacement of saturated FA by *trans* FA for 4 wk reduced FMD by 29% and decreased HDL-cholesterol (Table 2). Replacement of monounsaturated fats by carbohydrates did not impair FMD, but it decreased HDL-cholesterol. Acute postprandial impairments of FMD by either *trans* or saturated FA were not found, suggesting that long-term effects are re-

sponsible for reported detrimental effects of *trans* FA on health.

Systemic inflammation is involved with a variety of neurological and degenerative conditions and is considered a nonlipid risk factor for CHD, insulin resistance, diabetes, and heart failure. Chronic systemic inflammation is tissue-destructive, and cardiovascular tissue is no exception. Low-grade systemic inflammation can be measured in blood with the inflammatory marker C-reactive protein (CRP). High levels of CRP have been associated with increased incidence of myocardial infarction and with stroke. Elevated concentrations of interleukin 6 (IL-6) and soluble tumor necrosis factor alpha receptors 1 and 2 (sTNF-R1 and sTNF-R2) have been associated with insulin resistance, diabetes, and heart disease.

Mozaffarian *et al*. (30,77–79) have suggested that dietary *trans* FA may influence systemic inflammation, which might partly account for the relationship between *trans* FA and heart disease. Mozaffarian *et al.* (78) investigated the relationship between *trans* FA intake (measured by food frequency questionnaires) and inflammatory markers in healthy female subjects. *Trans* FA intake was positively associated with sTNF-R1 and sTNF-R2 but not with IL-6 or CRP concentrations overall. *Trans* FA intake was associated with IL-6 and CRP in women with higher body mass index. In patients with established heart disease (79), *trans* FA levels of red blood cell membranes (a measure of dietary intake) were associated with activation of systemic inflammatory responses, including increased levels of IL-6 and TNF receptors. In a controlled feeding trial with 50 men, a high *trans* FA diet (8% of energy) raised plasma CRP levels compared with carbohydrate- or oleic acid-containing diets (80). Further investigation of dietary *trans* FA in relation to inflammation and the implications for coronary disease and other conditions is warranted.

In summary, a limited number of studies have reported no consistent effects of dietary *trans* FA on blood clotting tendency and no significant effects on blood pressure or LDL oxidation compared with dietary *cis* FA. Several studies have suggested a possible relationship between dietary *trans* FA and systemic inflammation, but the potential mechanism of such an effect is uncertain.

Epidemiologic and case-control studies. Several epidemiologic and case-control studies have reported associations between the intake of *trans* FA and the risk of developing CHD (81–89). Key study design aspects and results of these studies are summarized in Table 3. Results of the studies were consistent in that *trans* FA intake (usually assessed by a food frequency questionnaire) was positively associated with risk of CHD or with a major coronary event, particularly when relative risks between the highest and lowest quintiles of intake were considered.

On the other hand, in at least one study (83), individuals eating intermediate levels of *trans* FA had a lower risk of CHD compared with individuals eating the *lowest* level of *trans* FA. This study did not support a dose-response relationship. A limitation of epidemiologic studies is that they may show associations between two variables but they do not prove cause-and-effect relationships. The relatively low risk values reported for associations of *trans* FA intake and CHD risk (typically around 1.2–1.5, Table 3) are considered weak associations by many epidemiologists [Lilienfeld and Stolley (90); Rothman and Greenland (91)].

Dietary *trans* FA have been considered in relation to sudden death from cardiac causes in at least two case-control studies. A study by Roberts *et al*. (92) compared proportions of *trans* isomers of oleic and linoleic acid in adipose tissue obtained at autopsy from 66 subjects with sudden death from cardiac causes with adipose tissue from 286 healthy control subjects. No relationship was seen between combined *trans* isomers of oleic and linoleic acid and sudden cardiac death. When the individual FA were considered, *trans* oleic acid was negatively associated with risk of sudden cardiac death, and no association was seen with *trans* forms of linoleic acid. Overall, this study did not support the hypothesis that *trans* isomers increase the risk of sudden cardiac death. In contrast, a study by Lemaitre *et al*. (93; discussed in 94) reported that the level of total *trans* FA in red blood cell membranes (a biomarker of dietary intake) was associated with a modest increase in risk of primary cardiac arrest. However, when different *trans* isomers were assessed separately, the isomers of oleic acid were not associated with risk, whereas those of linoleic acid were associated with a threefold increase in risk. It seems doubtful, however, that *trans* 18:2 isomers are present at sufficient levels in typical U.S. diets to contribute uniquely and significantly to the risk of primary cardiac arrest (95). More work is needed to establish whether *trans* isomers are associated with an increased risk of sudden cardiac death.

A further limitation of epidemiologic studies is that self-reported dietary intake data are likely inaccurate. Mertz *et al*. (96) found that recall and food record data usually underestimate intake. A further complicating factor is that the *trans* FA contents of similar-appearing foods, such as tub margarines, can be highly variable among brands and even with the same brand over time. Thus, an assumed *trans* FA level for the category of "tub margarines" may not result in accurate calculation of *trans* FA intake levels over time.

Additionally, a recent report by Schatzkin *et al.* (97) does not recommend use of a food frequency questionnaire for evaluating relationships between absolute intake values and disease. This is because repeated applications of the questionnaire did not lead to improvement in proposed relationships being considered. The study by Schatzkin *et al.* (97) was part of the National Cancer Institute's "Observing Protein and Energy Nutrition" (OPEN) Study designed to assess dietary measurement error by comparing results from self-reported dietary intake data with four dietary biomarkers based on analysis of urine: doubly labeled water and urinary nitrogen, sodium, and potassium. A key finding was significant underreporting of energy and protein intakes by both men and women. Although the study by Schatzkin *et al*. (97) did not assess FA intake, this study nevertheless would raise questions about the strength of

TABLE 3
Epidemiological/Case Control Studies Relating Dietary *trans* FA and Risk of Coronary Heart Disease[a]

Reference	Study design	Subjects	TFA intake	Results	Comments
Troisi *et al.* (81)	Cross-sectional	748 men, aged 43–85 yr	Food frequency questionnaire; for entire sample, mean TFA intake was 1.6% of total energy	TFA intake directly related to total serum (r = 0.07, P = 0.04) and LDL-C (r = 0.09, *P* = 0.01).	Authors suggested increasing TFA intake from 2.1 to 4.9 g/d would correspond to a 27% increase in risk of MI.
Willett *et al.* (82)	Prospective cohort study among 85,095 women	431 women experiencing new CHD (nonfatal MI or death from CHD) over 8-yr follow-up period	Food frequency questionnaire; quintiles of mean TFA intakes: 1.3, 1.8, 2.2, 2.6, and 3.2% of energy (2.4, 3.2, 3.9, 4.5, and 5.7 g/d)	TFA intake directly related to risk of CHD (relative risk for highest vs. lowest quintile was 1.50 (p = 0.001 for trend).	Authors suggested consumption of partially hydrogenated vegetable oils may contribute to occurrence of CHD.
Ascherio *et al.* (83)	Case-control	239 MI patients, 282 population controls	Food frequency questionnaire; quintiles of mean TFA intake: 1.69, 2.48, 3.35, 4.52, 6.51 g/d	TFA intake directly related to risk of MI [relative risk for highest vs. lowest quintile was 2.44 (P < 0.0001 for trend)]. Increased risk evident only among individuals in top quintile of intake.	Patients not asked whether they changed their dietary intakes after their MI. LDL-C in this group may reflect recent dietary intakes rather than diet before MI.
Kromhout *et al.* (85)	Cohort study among men from 7 countries	12,763 men, aged 40–59 yr, over 25-yr follow-up period	Food composites collected and analyzed for TFA. Average TFA intakes: 0.05 to 1.84% of energy	Strong positive associations between 25-yr death rates from CHD and average intake of TFA (elaidic acid, r = 0.78, *P* < 0.001).	Authors suggested dietary TFA (also SFA and cholesterol) are important determinants of differences in population rates of CHD death.
Ascherio *et al.* (84)	Cohort study	43,757 men, aged 40–75, over 6-yr follow-up period	Food frequency questionnaire; median intakes (g/d) of quintiles: 1.5, 2.2, 2.7, 3.3, 4.3 (0.8 to 1.6% of energy, lowest to highest quintiles)	TFA intake directly associated with risk of MI (nonfatal and fatal). Relative risk for quintiles: 1.0, 1.20, 1.24, 1.27, 1.40, P = 0.01.	The association was attenuated after adjustment for dietary fiber.
Hu *et al.* (86)	Prospective cohort study	939 women with MI, aged 34–59 yr	Food frequency questionnaire; median intakes of quintiles (% of energy): 1.3, 1.7, 2.0, 2.4, 2.9	TFA intake directly associated with risk of CHD. Relative risk for quintiles: 1.0, 1.07, 1.10, 1.13, 1.27 (P= 0.02 for trend).	Authors reported that replacing 2% of energy intake from TFA with unhydrogenated, unsaturated fats would reduce CHD risk by 53%.
Pietinen *et al.* (87)	Cohort study	21,390 male smokers, aged 50–69 yr, over 6.1-yr follow-up period	Food frequency questionnaire; median intakes (g/d) of quintiles: 1.3, 1.7, 2.0, 2.7, 6.2	TFA intake significantly associated with risk of major coronary event. Relative risk for quintiles: 1.00, 1.10, 0.97, 1.07, 1.14 (P = 0.158 for trend).	Authors also reported positive association between TFA intake and risk of coronary death (*P* for trend = 0.004).
Tavani *et al.* (88)	Case-control	Italian women, aged 18–74 yr, 429 MI cases, 866 controls	Margarine intakes reported as no or low, medium, or high.	Medium or high intake of margarine associated with increased risk of MI [multivariate odds ratio (OR) = 1.5 vs. no or low intake. Association stronger for women aged 60–74 yr (OR = 2.4) and in current smokers (OR = 2.3).	Authors suggested the association with margarine could explain about 6% of MI in this population. Major limitation of this study: low intake of margarine by these Italian women.
Oomen *et al.* (89)	Prospective study	667 elderly Dutch men, aged 64–84 yr	Dietary surveys; average TFA intakes fell from 10.9 to 6.9 to 4.4 g/d from 1985 to 1990 to 1995 (4.3, 2.9, and 1.9% of energy)	TFA intake positively associated with 10-yr risk of CHD. Relative risk for a difference of 2% of energy in TFA intake at baseline was 1.28.	Authors suggested that high intake of TFA contributes to risk of CHD.
Lemaitre *et al.* (93)	Case-control	174 cardiac arrest patients, 285 controls, aged 25–74 yr	TFA levels in red blood cell membranes used as indicator of intake.	Higher TFA levels in red blood cell membranes associated with increased risk of primary cardiac arrest (relative risk = 1.47). *Trans* isomers of oleic acid not associated with risk, but those of linoleic acid associated with threefold increase in risk.	It seems unlikely that *trans* 18:2 isomers are present at sufficient levels in typical U.S. diets to contribute significantly to risk of primary cardiac arrest.

[a]Abbreviations: CHD, coronary heart disease; MI, myocardial infarction; TFA, *trans* FA; SFA, saturated FA; LDL-C, LDL-cholesterol; *r* = partial correlation coefficient (adjusted for various parameters including energy intake, age, body mass index, waist-to-hip ratio, smoking status, and alcohol intake).

the proposed relationship between CHD risk and *trans* FA intake because most studies reporting such a relationship used a food frequency questionnaire to assess *trans* FA intake. (Further information about the OPEN Study may be found at the NCI website: http://riskfactor.cancer.gov/studies/open/status.html)

Correlation coefficients between FA intake data estimated from food frequency questionnaires and plasma FA generally have been higher for PUFA as well as n-3 FA of marine origin than for saturated and monounsaturated FA. In a large population of free-living, middle-aged adults, Ma *et al*. (98) found correlation coefficients between dietary and plasma FA (expressed as the percentage of total FA) for phospholipid and cholesterol ester FA, respectively, to be as follows: total PUFA (r = 0.25 and 0.31), linoleic acid (r = 0.22 and 0.28), α-linolenic acid (r = 0.15 and 0.21), eicosapentaenoic acid (EPA, r = 0.20 and 0.23), docosahexaenoic acid (DHA, r =0.42 and 0.42), saturated FA (r = 0.15 and 0.23), and monounsaturated FA (r = 0.05 and 0.01). The correlations between diet and plasma FA held relatively constant regardless of whether subjects were overweight, had chronic diseases, were alcohol drinkers, or were cigarette smokers. In a population of Norwegian men, Andersen *et al*. (99) reported correlation coefficients between dietary FA and FA in total serum lipids to be: linoleic acid, 0.16; α-linolenic acid, 0.28; EPA, 0.51; DHA, 0.52; palmitic acid, 0.11; and monounsaturated FA, 0.08. In a group of British civil servants (men and women), Brunner *et al*. (100) reported correlations between dietary intakes and FA in serum cholesteryl esters to be: EPA, 0.54; linoleic acid, 0.38; total PUFA, 0.43; and total saturated FA, –0.01. Because plasma monounsaturated and saturated FA may arise from endogenous monounsaturated and saturated FA, as well as from the diet, food frequency questionnaires may not always provide reliable estimates of dietary monounsaturated and saturated FA.

Other studies. Muller *et al*. (101) and Pedersen *et al*. (102) developed regression equations to predict effects on serum total and LDL-cholesterol levels of dietary *trans* FA as well as individual saturated FA. The regression equations were based on consideration of four controlled studies. The food sources of *trans* FA were partially hydrogenated soybean oil and partially hydrogenated fish oil. *Trans* FA from these two sources differ with respect to chain length and number of *trans* bonds. The authors concluded that myristic acid (14:0) is the most hypercholesterolemic FA and that *trans* FA are less hypercholesterolemic than the saturated FA myristic and palmitic (16:0) acids. Hydrogenated fish oil was felt to be slightly more hypercholesterolemic than hydrogenated soybean oil. Separately, Lichtenstein *et al*. (31) reported predictive equations for total and LDL-cholesterol and also for HDL-cholesterol.

Kritchevsky (103) cited human data indicating that if the diet contains a high level of linoleic acid (e.g., 22–37% of total dietary FA) and a relatively low level of *trans* FA (e.g., 8–18% of total dietary FA), then the change in total serum cholesterol is much smaller than if the diet contains a low level of linoleic acid and a high level of *trans* FA. Such a relationship would be predicted according to equations presented by Muller *et al.* (101). The relationship is supported by data cited in Figures 4 and 5 (see also Ref. 66).

The *trans* fats used in studies considered thus far have contained principally *trans* 18:1 isomers as well as low levels of *trans* 18:2 isomers. These fats have been essentially free of *trans* 18:3 isomers. Vermunt *et al*. (104) recently investigated the effect of *trans* α-linolenic acid formed by deodorization of canola oil (105) on plasma lipids and lipoproteins. Eighty-five healthy men from three European countries consumed α *trans* FA-free diet for 6 wk followed by either a diet "high" or "low" in *trans* α-linolenic acid for 6 wk. Daily mean total *trans* α-linolenic acid intake was 1410 mg in the high-*trans* group and 60 mg in the low-*trans* group. The high *trans* α-linolenic acid diet did not change total, LDL-, or HDL-cholesterol levels, but it did result in statistically significant increases in the plasma LDL/HDL ratio and the total/HDL ratio compared with the low *trans* diet. The authors commented that whether the diet-induced changes in these ratios truly affect CHD risk remains to be established. These results, however, suggest the importance of selecting conditions for deodorization that minimize formation of *trans* α-linolenic acid isomers. A parallel study by Armstrong *et al*. (106) using the same high dietary level of *trans* α-linolenic acid found no effect on platelet aggregation and blood coagulation factors, including platelet thromboxane production, fibrinogen levels, factor VII, activated factor VIIa, or plasminogen activator inhibitor activity.

The level of *trans* α-linolenic acid produced by deodorization of canola or soybean oil depends on the time and temperature of the deodorization process (107). The canola oil used in the studies by Vermunt *et al.* (104) and Armstrong *et al*. (106) contained 4.5% *trans* α-linolenic acid and was produced by batch deodorization for 52.5 h at 205°C (105). In contrast, most canola oil produced in the United States has a *trans* α-linolenic acid level ranging from about 1.0 to 2.5% (personal communication, David Volker, J.M. Smucker Co., Cincinnati, OH). The lower (1.0%) level of *trans* α-linolenic acid typically is produced by a continuous deodorization process lasting up to about 5 min at about 240–270°C. The higher (2.5%) level typically is produced by batch deodorization for up to 2 h also at 240–270°C. Canola oil containing 2.5% *trans* α-linolenic acid would qualify for a label claim of zero *trans* FA in the United States, because a 14-g (1 tablespoon) serving of the oil would provide 0.35 g of *trans* FA. The U.S. FDA permits a label claim of zero *trans* FA if the food product contains less than 0.5 g of *trans* FA per serving.

The question has been raised as to whether *trans* FA from ruminant fats have similar metabolic effects to those from industrially hydrogenated fats. Controlled metabolic trials have not directly addressed this question. The predominant *trans* isomer of ruminant fats is vaccenic acid, an 18-carbon monounsaturated FA with its double bond at the 11-position of the carbon chain (18, *t*-11). In contrast, the *trans* isomers of industrially hydrogenated fats have their double bonds primarily at positions 9, 10, and 11 (108). Meijer *et al*. (109) reported that feeding vaccenic acid (in mixed TG) to hamsters resulted in a signifi-

cant increase in the LDL-/HDL-cholesterol ratio compared with feeding elaidic acid (18, *t*-9). This study suggested that elaidic acid might be preferable to vaccenic acid with respect to reducing CHD risk. On the other hand, an overview of effects of ruminant *trans* FA by Jakobsen *et al*. (110) noted that some epidemiological studies have suggested an innocuous or even protective effect of ruminant *trans* FA (81,86) whereas other such studies have not (88). Jakobsen *et al*. (110) concluded that controlled metabolic studies on effects of intake of total and specific ruminant *trans* FA on CHD risk factors are warranted. In addition, they suggested that epidemiological studies on the intake of ruminant *trans* FA and risk of CHD in populations with high intake of ruminant *trans* FA also are warranted.

In summary, since 1990, controlled human studies have found that sufficiently high levels of dietary *trans* FA increase LDL-cholesterol and decrease HDL-cholesterol compared with diets high in *cis* monounsaturated FA or PUFA. The dietary levels of *trans* FA necessary to detect this effect appear to be approximately 4% of energy or higher to increase LDL-cholesterol and approximately 5–6% of energy or higher to decrease HDL-cholesterol, compared with control diets that are essentially *trans*-free. There are very limited data at lower levels of intake (less than 4% of energy). In the United States, the intake of saturated FA is reported to be substantially higher (about 10–12% of energy) than the intake of *trans* FA (about 2–3% of energy). Also since 1992, several epidemiologic and case-control studies have reported a positive association between dietary *trans* FA and the risk of CHD. A major limitation of the epidemiologic studies may be inaccurate *trans* FA intake data. To date, no consistent effects of dietary *trans* FA compared with *cis* FA have been reported on blood clotting tendency, blood pressure, LDL oxidation, or sudden death, and it is not clear whether ruminant *trans* FA have different metabolic effects compared with industrially produced *trans* FA.

STUDIES RELATING DIETARY *TRANS* FA TO CANCER, MATERNAL AND CHILD HEALTH, TYPE 2 DIABETES, AND MACULAR DEGENERATION

Trans FA in relation to cancer. In contrast to the extensive literature on *trans* FA in relation to CHD, relatively few investigators have studied *trans* FA with respect to cancer. Ip and Marshall (111) reviewed comprehensively more than 30 reports addressing the strength and consistency of available scientific data on *trans* FA and cancer. One reviewed study (112) involved the treatment of a colon cancer-sensitive strain of rats with the colon carcinogen dimethylhydrazine and then compared tumor development after feeding diets containing either partially hydrogenated corn oil or high-oleic safflower oil. Overall, there was no evidence that cancer of the intestinal tract was differentially affected by fat type given to animals of either sex.

Ip and Marshall (111) also evaluated epidemiologic studies since around 1990 that have considered the influence of the intake of various types of FA on the development of cancer at different sites. For breast cancer, Ip and Marshall noted that the epidemiologic evidence shows only a slight to negligible effect of fat intake in general on breast cancer risk and no strong evidence that the intake of *trans* FA is related to increased risk. For colon cancer, evidence exists of increasing risk with the intake of saturated fat or animal fat and decreasing risk with increased intake of fiber and vegetable products. However, no evidence indicated that the intake of *trans* FA is related to an increased risk of colon cancer or rectal cancer. For prostate cancer, Ip and Marshall noted evidence that fat intake might be related to risk. Most of this evidence has focused on the consumption of saturated and animal fats. The intake of *trans* FA has not been correlated with prostate cancer risk.

Since the review by Ip and Marshall (111), two case-control studies have investigated an association between dietary *trans* FA and the development of cancer. Kohlmeier *et al*. (113) investigated the relationship between adipose tissue levels of *trans* FA and postmenopausal breast cancer in European populations in 209 cases and 407 controls. Adipose tissue levels of *trans* FA were used as a biomarker of dietary exposure. The adipose concentration of *trans* FA showed a positive association with breast cancer, suggesting a relationship between adipose stores of *trans* FA and postmenopausal breast cancer risk in European women. Dietary FA data, however, were not provided to relate to adipose tissue stores.

The other case-control study was conducted by Slattery *et al*. (114) to examine a possible association between dietary *trans* FA and colon cancer incidence in 1,993 cases and 2,410 control subjects. Dietary data were collected using a diet history questionnaire. The authors found a weak association between dietary *trans* FA and colon cancer risk in women (odds ratio = 1.5) but not in men (odds ratio = 1.2). Slightly stronger associations were observed in subjects aged 67 yr or older (odds ratios = 1.4 for men, 1.6 for women). The authors concluded that it seems prudent to avoid consuming partially hydrogenated fats, because no increased risk was observed for *cis* FA.

In recent years, a specific category of *trans* FA, conjugated linoleic acid (CLA, a group of isomers of linoleic acid, each with one *trans* bond), has been reported to have possible human health benefits, including controlling body fat gain, enhancing immunity, and reducing inflammation. Recent perspectives on CLA have been discussed by Pariza (115; see additional related articles in this *Am. J. Clin. Nutr.* supplement). CLA is not further discussed in this article so that the focus here can be on effects of *trans* FA produced as a result of partial hydrogenation of oils.

In summary, current scientific evidence does not support a convincing relationship between *trans* FA intake and the risk of cancer at specific sites. Two recent case-control studies have reported an association between the intake of *trans* FA and breast cancer or colon cancer risk. However, the accuracy of the intake values is subject to question.

Trans FA in relation to maternal and child health. Concerns about a possible relationship between dietary *trans* FA and maternal and child health have focused on whether *trans* FA may affect human fetal growth and infant development. It is well established that n-6 and n-3 long-chain PUFA play significant roles in growth and development. Linoleic acid (18:2n-6) and

α-linolenic acid (18:3 n-3) are EFA (i.e., they cannot be synthesized by humans) are precursors of other important long-chain PUFA. Specifically, arachidonic acid (20:4n-6) is derived from linoleic acid by desaturation and chain elongation reactions and is a component of membrane phospholipids, a precursor for eicosanoids, and a stimulant of growth and cell division. DHA (22:6 n-3) is obtained in the diet (e.g., from fish oils) or synthesized from α-linolenic acid (also by desaturation and chain elongation) and is a component of retinal and neural membrane phospholipids. As such, it is involved in visual and central nervous system function.

According to Carlson *et al*. (116), concerns have been expressed that *trans* FA could decrease fetal and neonatal tissue concentrations of n-6 and n-3 long-chain PUFA, thereby interfering with normal growth and development. Carlson *et al*. (116) concluded that a definitive answer to the question of whether *trans* FA affect fetal development is not possible because there are few studies in this area, observed effects have been small, results have been inconsistent, and confounding factors have not been excluded.

Noting that *trans* FA from the maternal diet can cross the placenta or be secreted into human milk, Craig-Schmidt (117) indicated that developing fetuses and nursing infants in the United States and Canada generally would be exposed to larger amounts of *trans* FA than would infants in other parts of the world. This is supported by larger amounts of *trans* isomers in human milk samples from the United States and Canada compared with human milk samples from various countries of Europe, Asia, or Africa.

Craig-Schmidt (117) also cited studies in which plasma *trans* FA levels were inversely related to birth weight and head circumference. She added that the hypothesis that dietary *trans* FA could inhibit the biosynthesis of long-chain PUFA with 20 or 22 carbon atoms and thus affect infant development is supported by studies demonstrating an inverse correlation between plasma *trans* FA and n-3 and n-6 long-chain PUFA in infants. However, no such relationship has been observed in human milk. Craig-Schmidt (117) concluded that the evidence supporting an unfavorable effect of *trans* FA on infant development is correlational and that the physiological implications of the reported relationships are largely unknown.

Larque *et al*. (118) also reviewed studies on the effects of dietary *trans* FA in early life. These authors added that multigenerational studies using animals have shown no correlation between birth weight or growth and dietary *trans* FA. Citing reports of inverse relationships between plasma *trans* FA, arachidonic acid, and DHA, Larque *et al*. (118) suggested that such results may indicate an inhibitory effect of *trans* FA on liver Δ6 FA desaturase activity. In contrast to blood and liver, the brain appears to be protected from *trans* FA accumulation in experimental animals, but no data have been reported for human infants.

Decsi *et al*. (119) evaluated previously reported inverse correlations between values of *trans* FA and long-chain PUFA in plasma lipids of full-term infants. In this study, the FA composition of venous cord blood lipids was determined in 42 healthy full-term infants. The investigators found significant inverse correlations between total *trans* FA and both arachidonic acid and DHA in phospholipids, cholesterol esters, and nonesterified FA, but not in TG. Because *trans* FA in the fetal circulation originate from the maternal diet, the authors suggested that maternal exposure to *trans* FA may inversely influence long-chain PUFA status in full-term infants at birth.

The Institute of Medicine report (29) recognized concerns that *trans* FA have been suggested to have adverse effects on growth and development through inhibition of the desaturation and elongation of linoleic and α-linolenic acids to arachidonic acid and DHA, respectively. However, considering available evidence, including experimental work showing that inhibition of the Δ6 desaturation of linoleic acid is not of concern with linoleic acid intakes above about 2% of energy, the IOM concluded that inhibition of EFA metabolism by *trans* FA is unlikely to be of concern for practical human diets.

A recent study by Friesen and Innis (120) indicated that the level of total *trans* FA in human milk samples in Canada decreased significantly from 7.1 g/100 g FA in 1998 to 4.6 g/100 g FA in early 2006. These results suggested a concomitant decrease in *trans* FA intake among lactating women and breastfed infants. This decrease in intake could be related in part to the introduction of *trans* fat labeling of retail foods in Canada in 2003 and also in part to recent efforts by edible oil manufacturers to reduce or eliminate *trans* FA from their products (to be discussed later in this paper). Innis (121) also has recommended the removal of *trans* FA from industrial sources from the diets of pregnant and lactating women and young children, while improving dietary intakes of n-3 FA.

In summary, it appears unlikely that current average dietary levels of *trans* FA in the United States and Europe will have unfavorable effects on growth and development, reproduction, or gross aspects of fetal development. Future studies should address the possible benefits to human growth, development, and health of current efforts by the food industry to reduce or eliminate *trans* FA from their products.

Trans FA in relation to type 2 diabetes. Salmeron *et al*. (122) suggested that an increase in PUFA intake and a decrease in *trans* FA intake would substantially reduce the risk of women developing type 2 diabetes. During a 14-yr follow-up of 84,204 women with no diabetes, cardiovascular disease, or cancer, the investigators documented 2,507 new cases of type 2 diabetes. Dietary information was assessed by food frequency questionnaires. Total fat intake, compared with equivalent energy intake from carbohydrates, was not associated with risk of type 2 diabetes. In contrast, PUFA intake was inversely associated and *trans* FA intake positively associated with risk. The authors estimated that replacing 2% of the energy from *trans* FA with PUFA would reduce the risk of type 2 diabetes by 40%.

Commenting on this study, Clandinin and Wilke (123) noted that the influence of dietary *trans* FA on insulin resistance has not been studied, and epidemiologic evidence relating *trans* FA intake to diabetes is lacking. There is no known functional or physiological relation to connect *trans* FA to disease mechanisms involved with type 2 diabetes. Clandinin and Wilke also

questioned the reliability of estimates of intake of *trans* FA from food frequency questionnaires.

An additional complication is that some processed foods containing *trans* FA also contain large amounts of refined carbohydrates (e.g., certain baked goods), which could exacerbate the insulin-resistant state in diabetes and/or contribute to increases in serum TG levels. This association of *trans* FA with simple and complex carbohydrates does not permit distinction about whether *trans* FA alone, *trans* FA plus carbohydrates, or carbohydrates alone in certain products would contribute to the risk of type 2 diabetes. Thus, the conclusions of Salmeron *et al*. (122) still represent a hypothesis to be tested.

A follow-up study by Hu *et al*. (124) looked at combined effects of dietary and lifestyle factors in relation to type 2 diabetes. Considering essentially the same subject population studied by Salmeron *et al*. (122), Hu *et al*. (124) documented 3,300 new cases of type 2 diabetes during 16 yr of follow-up. Overweight or obesity was the single most important predictor of diabetes. Lack of exercise, a poor diet, current smoking, and abstinence from alcohol use were all associated with increased risk of diabetes, even after adjusting for body mass index. Also, the combination of an appropriate diet, moderate amount of exercise, and abstinence from smoking, even in overweight and obese subjects, resulted in reduced risk of type 2 diabetes. A "poor diet" was described as being high in *trans* fat and glycemic load, low in cereal fiber, and having a low ratio of polyunsaturated to saturated fat. Quantitative levels of *trans* FA, sugars, cereal fiber, and polyunsaturated and saturated FA associated with the "poor diet" were not specified, and *trans* FA were not singled out as an individual risk factor.

A similar study by van Dam *et al*. (125) examined dietary fat and meat intake in relation to risk of type 2 diabetes in 42,504 male subjects initially free of diabetes, cardiovascular disease, and cancer. Diet was assessed by food frequency questionnaire. During 12 yr of follow-up, 1,321 new cases of type 2 diabetes were observed. Intakes of total fat and saturated fat were associated with a higher risk of type 2 diabetes. However, these associations disappeared after adjustment for body mass index. Also, intakes of oleic acid, *trans* FA, long-chain n-3 FA, and α-linolenic acid were not associated with diabetes risk after multivariate adjustment. Results of this study with men were not consistent with the Salmeron *et al*. study (122) reporting *trans* FA to be positively associated and PUFA negatively associated with risk of type 2 diabetes in women.

Trans FA in relation to macular degeneration. Age-related macular degeneration (AMD) is the leading cause of irreversible visual impairment and blindness in the United States and other developed countries. Two recent studies from the same institution that evaluated a possible connection between dietary *trans* FA and type 2 diabetes also considered a possible relationship between *trans* FA and the risk of AMD.

One of these studies, by Seddon *et al*. (126), evaluated the relationship between intake of total fat and of specific FA, including *trans* FA, and risk of AMD in a case-control study at five U.S. clinical ophthalmology centers. Case subjects included 349 individuals (aged 55–80 yr) with the advanced neovascular stage of AMD diagnosed within 1 yr of their enrollment into the study. Control subjects included 504 individuals without AMD but with other ocular diseases. Higher consumption of vegetable fat, monounsaturated FA, PUFA, or linoleic acid was associated with an elevated risk of AMD. In contrast, higher consumption of saturated or *trans* FA was not associated with higher risk of AMD.

The association between AMD and higher intake of vegetable, monounsaturated, and polyunsaturated fats and linoleic acid was suggested to be related to snack foods containing products that adversely affect the blood vessels of the choroids or retina. The authors felt that such foods might also increase oxidative damage in the macula, which is susceptible to oxidation because of high oxygen tension in the presence of light exposure. Thus, some individual dietary fats, but not necessarily total fat consumption, might increase or decrease the risk for AMD.

Cho *et al*. (127) assessed a possible association between total fat and specific types of fat and AMD. This was a prospective study that at baseline included 42,743 women and 29,746 men, aged 50 yr or older with no diagnosis of AMD. During the 12-yr follow-up period, 567 subjects were diagnosed with AMD. The pooled (women and men) multivariate relative risk for the highest compared with the lowest quintile of total fat intake was 1.54, a value considered statistically significant. Unexplained was why the fourth quintile for fat intake had a relative risk equal to that of the first quintile and lower than that of the second and third quintiles. *Trans* fat intake was not related to risk of AMD, whereas α-linolenic acid intake was positively associated with risk of AMD. DHA, on the other hand, showed a slight inverse relationship with AMD, and more than four servings of fish per week was associated with a 35% lower risk of AMD compared with three or fewer servings per month.

In summary, one study has reported an association between *trans* FA intake and type 2 diabetes, however, a follow-up study found no such association. In view of no known functional or physiological connection between *trans* FA and type 2 diabetes, the reported association requires further testing. In the case of AMD, neither of two studies reported an association between dietary *trans* FA and risk of developing the condition. Considering the difficulty of conducting meaningful studies on effects of dietary fat on specific human disorders, such as type 2 diabetes and macular degeneration, it is not surprising that no adverse effects were found in the few studies reported in these areas.

DIETARY RECOMMENDATIONS REGARDING SATURATED AND *TRANS* FA

Current dietary recommendations by health professional organizations within and outside the United States (29,128–133) address intake of cholesterol-raising saturated and *trans* FA. These organizations are consistent in their recommendations of an upper limit of intake of saturated FA of 10% of energy and reduced intake of *trans* FA. Recommendations from U.S. organizations are summarized in Table 4, and those from organiza-

TABLE 4
Dietary Recommendations for Saturated and *trans* FA: U.S. Organizations[a]

Organization	Saturated FA	*trans* FA
American Heart Association	<7% energy (population)	<1% energy (population)
Adult Treatment Panel III of the National Cholesterol Education Program	<7% energy (those at risk)	Keep intake low
Health and Human Services/US Department of Agriculture	<10% energy (population)	Low as possible
Institute of Medicine of the National Academy of Sciences	Low as possible	Low as possible

[a]Current dietary recommendations of U.S. health professional organizations for saturated and *trans* FA.

tions in Europe and Japan, in Table 5. The consistency of these recommendations provides the basis for food manufacturers in the United States and globally to consider ways to decrease or eliminate *trans* FA from their food products.

FOOD INDUSTRY EFFORTS TO REPLACE OR REDUCE TRANS FA

Food manufacturers are using or developing basically four technological options to reduce or eliminate *trans* FA in their products. These options include: (i) modification of the hydrogenation process; (ii) use of interesterification; (iii) use of fractions high in solids from natural oils; and (iv) use of trait-enhanced oils. Information on each of these topics was presented at a recent American Oil Chemists' Society symposium on *trans* fat (134). Some approaches may be used in combination with others. Discussion of each option follows.

Modification of the hydrogenation process. Certain food products, such as spreads, margarines, and shortenings, require oils with specific levels of solids at different temperatures to achieve desired functionality. Solids normally come from either *trans* FA (resulting from hydrogenation) or saturated FA. Modifying the conditions of hydrogenation (e.g., pressure, temperature, and catalyst) affects the FA composition of the resulting oil, including the amount of *trans* FA formed, and properties such as m.p. and solid fat content of the oil. It is possible to make equivalently performing low-*trans* fats by increasing the degree of hydrogenation, which reduces the level of *trans* FA but increases the level of saturated FA. This could increase the m.p. of the fat, which, in turn, might affect the sensory properties of fried foods. Such fats will differ analytically from fats hydrogenated to a lesser degree because saturates now contribute most of the solids. This is illustrated in Figure 6 indicating that with progressive hydrogenation (decreasing iodine

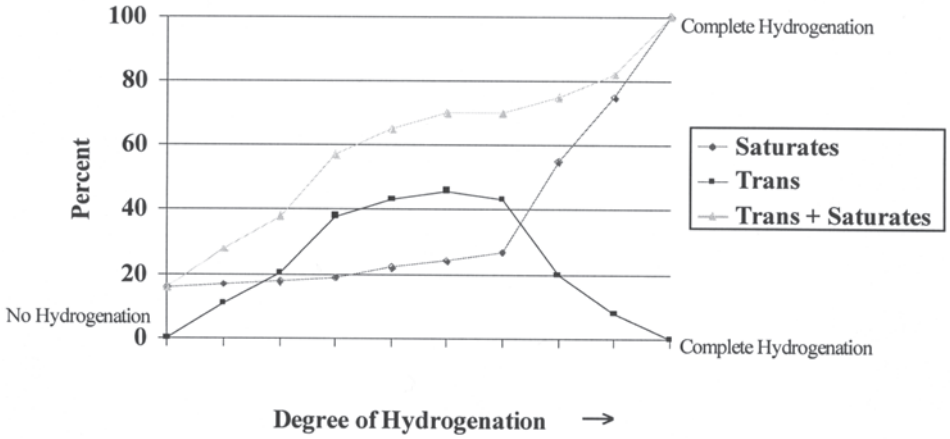

FIG. 6. Changes in percentages of *trans* and saturated FA with progressive hydrogenation of soybean oil. Progressive hydrogenation is indicated by decreasing iodine value. Corresponding levels of *trans* and saturated FA, expressed as percentage of total FA, are shown. The graph was provided by Bob Wainwright, Cargill, Inc.

value) of soybean oil, the content of *trans* FA increases to a maximum and then decreases essentially to zero. The corresponding level of saturated FA increases gradually until the content of *trans* FA is maximized and then increases rapidly.

Modification of the hydrogenation process can be used to prepare low-*trans* baking shortenings. The simple substitution of unhydrogenated (*trans*-free) fats for hydrogenated fats does not work well in baking applications. Some recipes for baked foods require a greater amount of saturated fat to replace a given amount of *trans* fat for the recipe to work (i.e., a one-to-one substitution of saturated fat for *trans* fat often does not produce foods of equivalent consumer acceptability).

Low- or zero-*trans* baking fats may have increased levels of stearic acid from the hydrogenation of α-linolenic, linoleic, and oleic acids, and also significant levels of palmitic acid for functionality. Palmitic acid may be provided by incorporating a high palmitic acid fat, such as cottonseed oil, into the shortening.

An increased level of stearic acid in a low- or zero-*trans* baking fat may offer nutritional benefits. Kelly *et al*. (135) reported that a high stearic acid diet reduced total, LDL-, and HDL-cholesterol levels in men compared with a baseline diet and also showed reduced factor VII coagulant activity and reduced mean platelet volume (both suggestive of decreased clotting tendency) compared with the baseline diet. In addition, an increased content of stearic acid in the serum FFA fraction has been associated with decreased risk of myocardial infarction (136).

Use of interesterification. The interesterification process involves the rearrangement (randomization) of the FA on the glycerol backbone of the fat (i.e., TG) in the presence of a chemical catalyst or an enzyme. Interesterification modifies the melting and crystallization behavior of the fat, thus producing fats with the desirable physical properties of *trans* fats but without *trans* FA. One current application of this process is in the production of *trans*-free or low-*trans* fats for margarine, spread, and shortening applications. Several human studies have shown no significant effects of interesterified fats on blood lipid parameters (137–140, summarized in 141).

In chemical interesterification, an unhydrogenated liquid vegetable oil (such as a salad oil) and a fully hydrogenated vegetable oil (called a "hardstock," which has a low iodine value and a low amount of *trans* FA) are mixed and heated. A typical blend may contain about 85% unhydrogenated oil and about 15% hardstock. Both components of the blend are essentially *trans*-free. A catalyst, commonly sodium methoxide, is added, and the interesterification process causes a random rearrangement of the FA on the glycerol backbone. It is important to note that in such blended fat products, the term "hydrogenated fat" or "partially hydrogenated oil" would appear on the ingredient statement, but the product would be very low in *trans* FA. Therefore, the listing of "hydrogenated fat" or "partially hydrogenated oil" on an ingredient statement does not always mean that the product contains a significant level of *trans* fat, as has been erroneously indicated by the popular press.

A recently modified interesterification process uses an enzyme instead of sodium methoxide to catalyze the reaction. The enzyme is a heat-stable, 1,3-specific lipase derived from a microorganism and immobilized on a granulated silica matrix. Because the lipase is specific for the 1- and 3-positions of the TG, its use results in a fat that is partially randomized rather than being completely randomized, as occurs with use of sodium methoxide. One advantage of enzymatic interesterification is that there are no waste or by-product issues, for example, no catalyst residues that could be released into the environment.

Table 6 compares the FA composition of a typical shortening fat prepared by partial hydrogenation with a newly developed product made by enzymatic interesterification. The interesterified fat is low in *trans* FA and has a lower oleic acid content and higher levels of stearic, linoleic, and α-linolenic acids compared with the partially hydrogenated fat. Although the FA

TABLE 6
FA Composition (percentages) of Shortenings Made by Partial Hydrogenation and by Enzymatic Interesterification[a]

FA (%)	Partial hydrogenation[b] (PHSBO, PHCSO)	Enzymatic interesterification[c] (SBO, FHSBO)
16:0	10.4	10.8
18:0	15.5	21.9
18:1 *cis* 9	37.5	21.9
18:2 *cis* 9,12	4.80	39.8
18:3 *cis* 9,12,15	0.30	5.6
Total *trans*	30.0	2.5–3.5 typical 5.0 max
Total saturates	25.9	32.7

[a]FA compositions and m.p. are shown for two shortening products, one made by conventional partial hydrogenation (using a blend of partially hydrogenated soybean oil [PHSBO] and partially hydrogenated cottonseed oil [PHCSO]) and one made by enzymatic interesterification (using a blend of unhydrogenated soybean oil [SBO] and fully hydrogenated soybean oil [FHSBO]). Data were provided by Tom Tiffany, Archer Daniels Midland Co. (Decatur, IL).
[b]m.p. (°F/°C): 117.5/47.5.
[c]m.p. (°F/°C): 110.0/43.3.

compositions of the two products differ from each other, the functional characteristics for shortening applications (e.g., m.p.) of the two products are very similar. The low level of *trans* FA (typically 2.5–3.5%, with a maximum of 5.0%) in this interesterified fat may have resulted in part from deodorization and/or incomplete hydrogenation of the component hydrogenated oil. Nevertheless, considering the normal 12-g serving size for shortening, the product made by interesterification would qualify for a declaration of 0.5 g of *trans* fat per serving according to the FDA's final labeling rule. If this shortening were incorporated into a baked product, depending on the amount of fat per serving, the product may be able to declare 0 g of *trans* fat per serving.

Use of fractions high in solids. Fractions high in solids derived from natural oils, namely coconut, palm, and palm kernel oils, are not new to the food industry and have been components of functional ingredients for years. Many commercially available fractions come from palm and palm kernel oils. They can be used successfully either as single fractions or in combination with other fractions to meet specific needs. Examples of fractions from palm oil that can be used in preparing *trans*-free or low-*trans* shortenings and margarines include palm olein, palm mid-fractions, and palm kernel stearin. Such fractions can be blended with liquid oils, such as soybean and canola oils, to create either no-*trans* shortenings and margarines or low-*trans*, low-saturates shortenings and margarines.

Fractions high in solids usually are prepared by reducing the temperature of an oil sample so that a more saturated fraction solidifies and a more unsaturated fraction remains liquid. The solid fraction is then physically separated from the liquid fraction by filtration or centrifugation. Liquid fractions, sometimes referred to as "olein fractions," are high in oleic acid and also are good sources of antioxidants, such as tocopherols and tocotrienols. Olein fractions frequently are used in Pacific Rim countries as salad oils and frying oils. Fractions with higher solids content may be incorporated into margarine or shortening fats.

Table 7 compares FA compositions of two no-*trans* shortenings and a no-*trans* margarine oil made with specific fractions from naturally solid vegetable oils such as palm or palm kernel oil. All of the products are *trans*-free, although there are differences in the levels of saturated monounsaturated, and polyunsaturated FA.

Use of trait-enhanced oils. Trait-enhanced oils generally fall into three categories: high-oleic acid oils, such as high-oleic sunflower and canola oils; mid-range oleic acid oils, such as mid-oleic sunflower and soybean oils; and low-linolenic acid oils, such as low-linolenic canola and soybean oils. (The term "low linolenic" commonly refers to an oil containing about 1–3% α-linolenic acid. Soybean oil typically contains about 7%, and canola oil, about 10% α-linolenic acid.) These types of oils are derived through traditional plant breeding or biotechnological methods. The high- and mid-range oleic acid oils are more stable oxidatively than traditional oils high in linoleic acid, such as soybean, corn, and sunflower oils. Low-linolenic acid oils have significantly reduced levels of oxidatively unstable α-linolenic acid. All of these trait-enhanced oils have good oxidative stability (i.e., a relatively high content of oleic acid

TABLE 7

18:3*c*9,12,15	10	4	<0.5	<0.5	<0.5	8	1

[a]Typical FA compositions of high-oleic canola oil, mid-oleic and high-oleic sunflower oils, and low-linolenic soybean oil are compared with their respective conventional oils. Data were provided by Bob Wainwright, Cargill, Inc. (Charlotte, NC).

and comparatively low levels of linoleic and α-linolenic acids), making them suitable for frying, spraying, beverages, and some bakery applications.

At present, the plant varieties that produce high-oleic and low-linolenic as well as some mid-oleic oils are not widely cultivated, and these oils are more expensive to produce than the corresponding polyunsaturated oils. Also, the high-oleic oils are liquid at room temperature and thus would not be particularly useful in spread and baking applications that require a relatively high solids content.

Table 8 shows typical FA compositions of several trait-enhanced oils. All have significant levels of oleic acid and comparatively lower levels of linoleic and α-linolenic acids. For salad oil and frying applications, these oils would not require hydrogenation and therefore would be *trans*-free.

The United Soybean Board (USB) has projected the future availability of low-linolenic soybean oil (having less than 3% α-linolenic acid) (142). Seed for low-linolenic soybeans has been developed by duPont (Wilmington, DE), Monsanto (St. Louis, MO), and Iowa State University (Ames, IA). For 2006, the USB expects 800,000 acres (320,000 hectares) to be planted, which likely would yield about 32 million bushels (870,000 metric tons) of soybeans and 320 million pounds (150,000 metric tons) of oil. By 2008, these totals are projected to be 4 million acres (1.6 million hectares), 160 million bushels (4.4 million metric tons) of soybeans, and 1.6 billion pounds (730,000 metric tons) of oil.

CURRENT STATUS OF USAGE OF ZERO- AND LOW-*TRANS* FATS

There is considerable interest in zero- and low-*trans* fats among food manufacturers, and current use of such products is increasing. For example, in frying applications, some restaurants and food service operations currently use unhydrogenated, *trans*-free oils. The use of such oils for frying will likely increase as greater quantities of trait-enhanced oils, such as high-oleic and mid-range-oleic oils, become available in the future. With regard to spreads and margarines, low-*trans* and *trans*-free products currently are marketed. Considering shortenings, in 2005 at least one *trans*-free product was being marketed. No safety or health issues are anticipated with the processes under consideration to reduce or eliminate *trans* FA from food products. Key challenges to manufacturers of zero- or low-*trans* fat products are to provide equivalent functionality at reasonable cost but without drastic increases in saturated FA content.

SUMMARY AND CONCLUSIONS

Dietary *trans* FA at sufficiently high levels have been found to increase LDL- and decrease HDL-cholesterol levels compared with diets high in *cis* monounsaturated or polyunsaturated FA. On the other hand, dietary *trans* FA have not been strongly related to cancer risk at specific sites or to other health conditions, including fetal growth and development, type 2 diabetes, and AMD. As a result of the effects of dietary *trans* FA on LDL- and HDL-cholesterol, most health professional groups have recommended reduced consumption of *trans* as well as saturated FA. Current efforts to replace or reduce *trans* FA in food products focus on: (i) modification of the hydrogenation process, (ii) use of interesterification, (iii) use of fractions high in solids from natural oils, and (iv) use of trait-enhanced oils.

ACKNOWLEDGMENTS

The author thanks the following individuals who provided information presented in this article: Frank Kincs (Bunge Foods Corp.), Tom Tiffany (Archer Daniels Midland Co.), Carl Heckel (Aarhus United USA Inc.), Bob Wainwright (Cargill Inc.), and Robert Reeves (Institute of Shortening and Edible Oils, Inc.). Appreciation is extended to Dr. James Deddens, Professor of Mathematics and Manager of the Statistical Consulting Laboratory at the University if Cincinnati, Cincinnati, OH, for assistance with statistical analyses. The author also is grateful to Dr. Ron Jandacek, Adjunct Professor at the University of Cincinnati, for reviewing the manuscript.

Effects of *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA Isomers on Liver and Adipose Tissue Fatty Acid Profile in Hamsters

A. Zabala, M.P. Portillo, M.T. Macarulla, V.M. Rodríguez, and A. Fernández-Quintela*

Department of Nutrition and Food Science, University of País Vasco, Paseo de la Universidad 7, 01006 Vitoria, Spain

ABSTRACT: The aim of the present study was to investigate the effect of *cis*-9,*trans*-11 and *trans*-10,*cis*-12 CLA on FA composition of TAG in epididymal adipose tissue and liver, and of hepatic phospholipids PL. Twenty-four Syrian Golden hamsters were randomly divided into three groups of eight animals each and fed semipurified atherogenic diets supplemented with either 0.5 g/100 g diet of linoleic acid or *cis*-9,*trans*-11 or *trans*-12,*cis*-9 CLA for 6 wk. Total lipids were extracted, and TAG and PL were separated by TLC. FA profile in lipid species from liver and adipose tissue, as well as in feces, was determined by GC. *Trans*-10,*cis*-12 CLA feeding significantly reduced linoleic and linolenic acids in TAG from both tissues, leading to reduced total PUFA content. Moreover, in the epididymal adipose tissue docosenoic and arachidonic acids were significantly increased. In liver PL, although no changes in individual FA were observed, total saturated FA (SFA) were decreased. No changes in TAG and PL FA profiles were induced by the *cis*-9,*trans*-11 CLA. TAG and PL incorporated *cis*-9,*trans*-11 more readily than *trans*-10,*cis*-12 CLA. This difference was not due to differential intestinal absorption, as shown by the analysis of feces. We concluded that only *trans*-10,*cis*-12 CLA induces changes in FA composition. Whereas increased PUFA content was observed in either liver or adipose tissue TAG, decreased SFA were found in liver PL. Incorporation of *cis*-9,*trans*-11 CLA in TAG is greater than that of *trans*-10,*cis*-12 CLA, but this is not due to differences in intestinal absorption.

Paper no. L9980 in *Lipids 41*, 993–1001 (November 2006).

CLA has been shown to modify TAG metabolism. The size of adipose tissue, the main store of fat in the body, is reduced after CLA feeding. Although this body-fat lowering effect has been clearly observed in different rodent species and pigs (1–6), important differences in terms of responsiveness to CLA have been observed among species. For example, in mice, the most responsive rodent, several authors have found a very strong reduction in fat accumulation (lipodistrophy) after CLA feeding (7–9). Body fat reductions in hamsters and rats are more moderate.

CLA influences TAG metabolism not only in adipose tissue but also in the liver, an organ that plays a very important role in the control of lipid homeostasis. These effects have been shown to be species-specific as well: in mice CLA produces strong liver fat accumulation, leading to steatosis (7,10–12); in contrast, no changes (13,14) or even decreases (1,15,16) can be observed in liver TAG in rats and hamsters.

Taking into account that in previous studies using the same experimental design as the present work quantitative changes brought about by CLA, namely a significant reduction in TAG accumulation either in adipose tissue or in liver (6,17–19), were observed, we were interested in assessing potential qualitative TAG changes. As a result, in this study the aim was to investigate the effect of dietary supplementation with the two main isomers of CLA, *cis*-9,*trans*-11 and *trans*-10,*cis*-12, on the FA profile of TAG in epididymal adipose tissue and liver in hamsters. Because the liver is a PL-rich organ, the influence on hepatic PL profile was also analyzed. In order to determine whether potential differences induced in FA profiles by both CLA isomers were due to different intestinal absorption rates, *cis*-9,*trans*-11 and *trans*-10,*cis*-12 isomers were quantified in feces.

EXPERIMENTAL PROCEDURES

Animals, diets, and experimental design. The experiment was conducted with 24 9-wk-old male Syrian Golden hamsters (105 ± 1 g) purchased from Harlan Ibérica (Barcelona, Spain), and took place following the institution's guide for the care and use of laboratory animals. The hamsters were individually housed in polycarbonate metabolic cages (Techniplast Gazzada, Gugguggiate, Italy) and placed in an air-conditioned room (22 ± 2°C) with a 12-h day-night rhythm. After a 6-d adaptation period, 24 hamsters were randomly divided into three groups of eight animals each and, over a period of 6 wk, fed semipurified atherogenic diets. CLA diets were enriched with 0.5 g/100 g diet of *cis*-9,*trans*-11 or *trans*-10,*cis*-12 CLA, respectively. Control diet was supplemented with sunflower oil used as a source of linoleic acid (Tables 1 and 2). This work is a part of a bigger study in which the effects of CLA isomers on serum and liver cholesterol were assessed. For this purpose, atherogenic feeding has been recognized as a useful dietary tool. The experimental diets were freshly prepared once a week, gassed with nitrogen and stored at 0–4°C to avoid rancidity. DL-Methionine and cholesterol were supplied by Sigma (St. Louis, MO); wheat starch and cellulose by Vencasser (Bilbao, Spain); CLA, as free FA, by Natural Lipids Ltd. (Hovdebygda, Norway); sucrose and sunflower oil (the source of linoleic acid provided as TAG) were obtained from local markets; and palm oil was a generous gift from Agra-Unilever (Leioa, Spain). Vitamin and mineral mixes were formulated according to AIN-93 guidelines (20) and supplied by ICN Pharmaceuticals (Costa Mesa, CA). According to the manufacturer, the compositions

TABLE 1
Composition of Experimental Diets

Ingredients (g/kg)	Linoleic acid	*cis*-9,*trans*-11 CLA	*trans*-10,*cis*-12 CLA
Casein (90 g/100 g)	200	200	200

Vitamin mix[a]	11	11	11
Choline chloride salt	4	4	4

[a]Formulated according to the American Institute of Nutrition (AIN-93; Ref. 20).

of the CLA isomer test substances were as follows: *cis*-9,*trans*-11 CLA (92.5% *cis*-9,*trans*-11 CLA, 0.8% *trans*-10,*cis*-12 CLA, and 3.4% other CLA isomers) and *trans*-10,*cis*-12 CLA (92.5% *trans*-10,*cis*-12 CLA, 3.4% *cis*-9,*trans*-11 CLA, and 3.3% other CLA isomers).

All animals had free access to food and water. Food intake and body weight were measured daily. Feces were collected daily during the last week and stored at –80°C. For chromatographic analysis, the seven samples from each animal were pooled.

At the end of the experimental period, animals were killed under anesthesia (diethyl ether) with cardiac puncture. Epididymal adipose tissue and liver were dissected, weighed, and immediately dropped in liquid nitrogen. Samples were stored at –80°C until analysis.

FA profiles. Frozen samples of 0.5–1 g of tissues (liver and epididymal adipose) or feces were weighed, kept at 0°C in an ice bath, and homogenized in trichloromethane:methanol 2:1 (vol/vol) using a Potter Heidolph RZR 1 homogenizer (Schwabach, Germany). Samples were allowed to stand at room temperature for 1 h. *n*-Nonadecanoic acid (19:0) and trinonadecanoin were added as internal standards at the beginning of this process. After drying under nitrogen, the sample was dissolved in 1 mL of trichloromethane.

TAG and PL were separated by TLC on precoated silica plates (DC-Platten Kiesegel 60 F254, Merck, Frankfurt, Germany) with trichloromethane:*n*-hexane:glacial ethanoic acid 65:35:1 (by vol). Lipid classes were visualized with rhodamine 0.05% in absolute ethanol. Bands were identified by using standards for TAG (triolein) and PL (lecithin) on the basis of their retention factor (R_f), scraped off, recovered in trichloromethane, and filtered through glass wool. The obtained sample was dried under nitrogen and dissolved in 1 mL trichloromethane for methylation.

Methylation of TAG and *PL.* Sodium methoxide (500 μL in 0.5 M methanol) (Sigma-Aldrich, Steinheim, Germany) was added to lipid extracts to prepare FAME. The mixture was heated at 50°C for 10 min, and the reaction was stopped with 100 μL of glacial ethanoic acid. Water (5 mL) was added, and the required esters were extracted twice with *n*-hexane (5 mL).

The hexane layer was dried over anhydrous sodium sulphate (Merck, Frankfurt, Germany) and filtered with a #1 Whatman filter paper. The solvent was removed under reduced pressure on a rotatory evaporator and dissolved in 500 µL of *n*-heptane containing 50 ppm of BHT as stabilizer, before the GC analysis.

Analysis by GC. Samples with FAME were transferred to GC vials and analyzed with a Hewlett Packard HP6890 gas chromatograph (Hewlett Packard, Palo Alto, CA) equipped with a FID, split/splitless injection port, an HP Chemstation software data system and an HP7673 autosampler (Hewlett Packard). The analytical column was a fused silica capillary SP-2380 column (100 m × 0.32 mm i.d., 0.20 µm film thickness) from Supelco (Bellafonte, PA). The oven temperature was initially programmed at 150°C (for 4 min) and raised to 220°C at a 4°C/min rate, then held for 25 min. Injection (1 µL) was run in split (40:1) mode. Helium was the carrier gas at constant flow (1 mL/min) and make-up gas for the FID. The injector was maintained at 200°C and detector at 250°C. FAME were identified by comparison of retention times with standards (Sigma, St. Louis, MO). Pure CLA isomers were purchased from Matreya (Matreya Inc., Pleasant GAP, PA).

Statistical analysis. Results are presented as means ± SEM. Statistical analysis was performed using SPSS 11.0 (SPSS Inc. Chicago, IL). Data were analyzed by one-way ANOVA followed by Newman-Keuls *post-hoc* test. Statistical significance was identified at the $P < 0.05$ level.

RESULTS

FA profile in liver. Table 3 shows the TAG FA profile. Total FA content in TAG was significantly reduced by *trans*-10,*cis*-12 CLA feeding but not by *cis*-9,*trans*-11 CLA. This CLA isomer did not induce changes in FA composition with the exception of its incorporation. In contrast, linoleic acid and linolenic acid were significantly reduced by *trans*-10,*cis*-12 CLA feeding, leading to reduced total PUFA content (53.5% lower than the linoleic group) (Fig. 1A). When the sums of saturated FA (SFA), monounsaturated FA (MUFA), and PUFA were expressed as the percentage of total FA quantified in TAG, a significant increase in SFA and a decrease in PUFA were observed in *trans*-10,*cis*-12 CLA–fed animals. With regard to *cis*-9,*trans*-11, a weaker but significant decrease in the percentage of PUFA was found (Fig. 1B). CLA feeding did not modify 16:0/16:1 n-9 ratio (7.95 ± 0.94 for LA group, 8.36 ± 1.76 for *cis*-9,*trans*-11 CLA group, and 9.16 ± 0.66 for *trans*-10,*cis*-12 CLA group; $P = 0.141$) nor 18:0/18:1 n-9 ratio (0.087 ± 0.010 for LA group, 0.086 ± 0.014 for *cis*-9,*trans*-11 CLA group, and 0.089 ± 0.006 for *trans*-10,*cis*-12 CLA group; $P = 0.878$). Incorporation of both CLA isomers into the liver TAG of CLA-exposed hamsters was evident.

The changes observed in TAG FA profile were not reflected in liver PL (Table 4). In this lipid species, no changes in total FA content were observed, and none of the FA was significantly modified by CLA isomers. Despite the lack of changes in individual FA, the sum of total SFA was significantly reduced by *trans*-10,*cis*-12 CLA (Fig. 2A). When the sums of SFA, MUFA, and PUFA were expressed as the percentage of total FA quantified in PL, no significant changes were found (Fig. 2B). The 16:0/16:1 n-9 and 18:0/18:1 n-9 ratios were not modified by CLA isomer feeding. Incorporation of both CLA isomers into the liver PL was markedly greater than that observed in hepatic TAG. The *cis*-9,*trans*-11 isomer was present in greater amount than *trans*-10,*cis*-12 CLA.

FA profile in epididymal adipose tissue. TAG FA profile is shown in Table 5. Total FA content in TAG was not modified. *Trans*-10,*cis*-12 CLA feeding significantly reduced linoleic acid and linolenic acid and increased docosenoic and arachi-

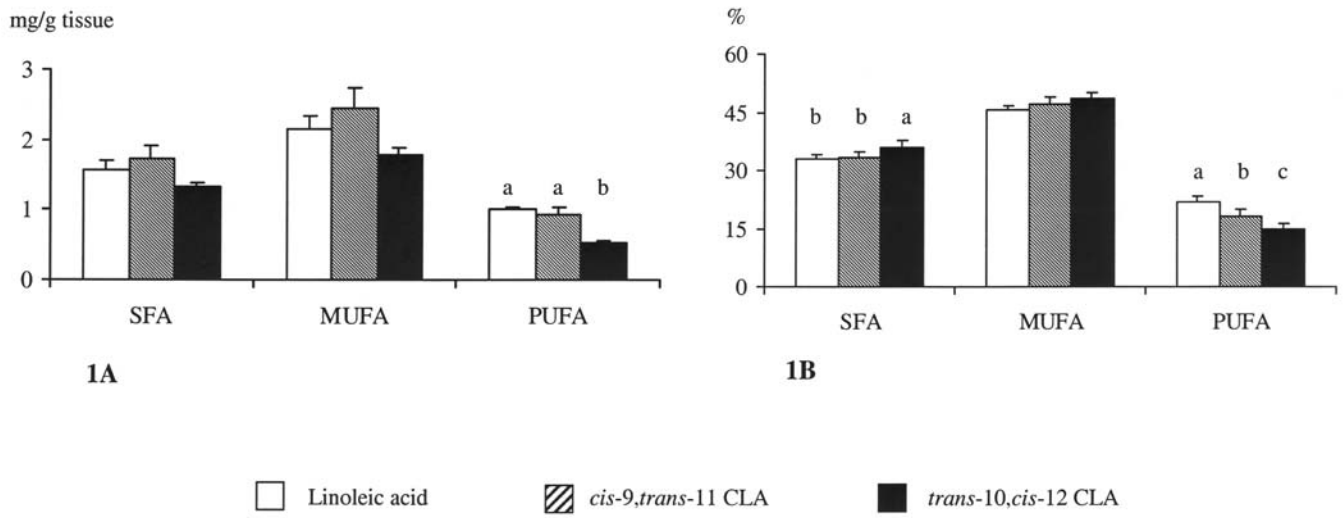

FIG. 1. Total SFA, MUFA, and PUFA in liver TAG of hamsters fed atherogenic diets supplemented with 0.5 g/100 g diet of linoleic acid, *cis*-9,*trans*-11 or *trans*-12,*cis*-9 CLA, respectively for 6 wk, expressed as mg/g tissue and as percentage of total FA. Values are means ($n = 8$) with their standard errors depicted by vertical bars. [a,b,c]Mean values with unlike superscript letters were significantly different ($P < 0.05$).

donic acids. No changes in FA profile were induced by the *cis*-9,*trans*-11. The sum of PUFA was significantly reduced in *trans*-10,*cis*-12 CLA–fed animals (Fig. 3A). Expressing SFA, MUFA, and PUFA as the percentage of total FA quantified in TAG, significant increases in SFA and MUFA, and a significant decrease in PUFA were observed after *trans*-10,*cis*-12 CLA feeding (Fig. 3B). As well as in liver TAG, CLA feeding did not modify 16:0/16:1 n-9 ratio (4.17 ± 0.49 for LA group, 4.73 ± 0.56 for *cis*-9,*trans*-11 CLA group, and 4.59 ± 0.61 for *trans*-10,*cis*-12 CLA group; $P = 0.194$) nor 18:0/18:1 n-9 ratio (0.058 ± 0.03 for LA group, 0.061 ± 0.004 for *cis*-9,*trans*-11 CLA group, and 0.063 ± 0.004 for *trans*-10,*cis*-12 CLA group; $P = 0.06$). Incorporation of both CLA isomers into the adipose tissue TAG was evident and sharply higher than in liver TAG. As in liver TAG and PL, the *cis*-9,*trans*-11 isomer was present in greater amount than the *trans*-10,*cis*-12.

CLA isomer content in feces. The amount of *cis*-9,*trans*-11 CLA in feces of hamsters fed the diet enriched with this isomer was 0.38 mg/g. That of *trans*-10,*cis*-12 CLA in animals fed the diet enriched with this isomer was 0.43 mg/g. Taking these values and daily food intake into account, the percentages of absorption were as follows: 99.5% for *cis*-9-*trans*-11 CLA and 98.3% for *trans*-10,*cis*-12 CLA. No significant differences were found among these values.

DISCUSSION

Changes in FA composition. Several studies have set out to analyze the effect of CLA feeding, either as a CLA mixture or as individual isomers, on FA composition in different lipid species, such as TAG, PL, and cholesterol esters, in various organs and tissues. These studies have been carried out using not only rodent species such as mouse (22–28), rat (29–33), and hamster (1), but also in pigs (34–37) and humans (39–42).

In all these studies FA composition was analyzed semiquantitatively: the content of each FA was expressed as a percentage of total FA. In the present work our objective was to analyze changes in FA profile induced by each of the two main isomers of CLA administered separately, by measuring quantitatively the amount of each FA in the selected lipid species, liver TAG, liver PL, and adipose tissue TAG.

Substitution of linoleic acid for *trans*-10,*cis*-12 CLA in the diet resulted in important changes in FA profile in TAG. In liver TAG, linoleic and linolenic acids were significantly decreased, leading to reduced total PUFA content. No changes in other FA

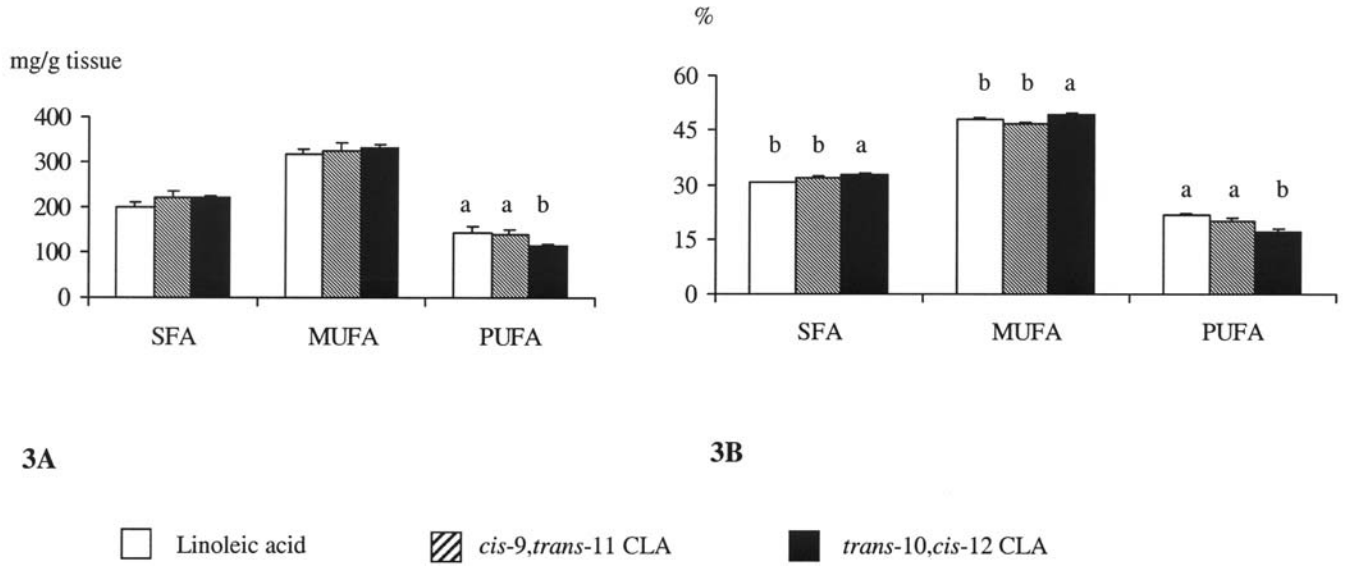

FIG. 3. Total SFA, MUFA, and PUFA in epididymal adipose tissue TAG of hamsters fed atherogenic diets supplemented with 0.5 g/100 g diet of linoleic acid, *cis*-9,*trans*-11 CLA, or *trans*-12,*cis*-9 CLA for 6 wk, expressed as mg/g tissue and as percentage of total FA. Values are means ($n = 8$) with their standard errors depicted by vertical bars. [a,b]Mean values with unlike superscript letters were significantly different ($P < 0.05$).

were observed. The same effect was found in epididymal adipose tissue TAG, but in this case a significant increase in docosenoic and arachidonic acids was also observed. The other CLA isomer, *cis*-9,*trans*-11, did not modify individual FA amounts either in liver TAG or in adipose tissue TAG.

Reductions in PUFA content, either in adipose tissue or in liver, have also been observed by other authors, although in these studies the amounts were expressed as percentages of total FA (23,25,38). With regard to arachidonic acid, several papers have shown a significant reduction of this FA in adipose tissue TAG from abdominal (29,37), perirenal (32), and retroperitoneal (27) anatomical locations in different animals species. In contrast, two studies performed in epididymal adipose tissue revealed a significant increase in arachidonic acid content (23,27). Our study, also carried out in the epididymal depot, is in good accord with these two works. Taking all these results into account, it could be hypothesized that the effects of CLA on TAG FA profile, or at least on arachidonic FA content, in adipose tissue depend on the anatomical location. Results concerning the effects of CLA on liver TAG arachidonic acid content are less consistent in the literature. Whereas Belury and Kempa-Steczko (22) reported a significant increase in mice by using 0.5% CLA and a significant decrease with higher doses, De Deckere *et al.* (1) did not find significant changes in hamsters fed *trans*-10,*cis*-12 CLA. Our results are in line with the latter study.

Some groups of researchers have reported a significant reduction in stearoyl-CoA desaturase (Δ9 desaturase) expression and/or activity induced by CLA (43–47). Moreover, significant increases in 16:0/16:1 n-9 and 18:0/18:1 n-9 ratios, two Δ9 desaturation indexes, have been found by some authors (29,30,34). In the present study, these two ratios were not modified in TAG in liver or in adipose tissue. These results suggest that CLA has no effect on this enzyme activity and agree with those observed by other authors (25,32,27,37). It seems that the effects of CLA on Δ9 desaturase are more evident when evaluating the activity or the expression of the enzyme than when the indirect indexes are calculated. Perhaps the ratios 16:0/16:1 n-9 and 18:0/18:1 n-9 are not as conclusive as believed. When the amount of 18:1 n-9 is high in the diet, as in the present experiment where oleic acid represents 28–30% of total FA in TAG (Table 2), and leads to significant accumulation of this FA in body lipids, small changes in the amount of this FA due to changes in Δ9 desaturase activity may not be evident.

Total FA content in liver TAG was significantly decreased in hamsters fed the *trans*-10,*cis*-12 CLA diet. This result is in good accord with the reduction in TAG content previously observed in hamsters fed the *trans*-10,*cis*-12 CLA isomer and measured by using a spectrophotometric method (19).

When total amounts of SFA, MUFA, and PUFA were expressed as percentages of total FA, SFA were increased in liver and adipose tissue TAG, MUFA were increased in adipose tissue TAG, and PUFA were reduced in liver and adipose tissue TAG by *trans*-10,*cis*-12 CLA feeding. When results are expressed in this way it is important to be careful not to give the wrong message. It should be pointed out that, despite the increased percentage of SFA, total amount of these FA was not actually enhanced. This important issue is seen only when a quantitative GC is used for FA profile analysis.

Liver PL were less sensitive than TAG to *trans*-10,*cis*-12 CLA feeding; no significant changes were observed in individual FA. By pooling FA according to their saturation index, important differences between liver TAG and liver PL were observed. Whereas TAG showed a decrease in PUFA, PL showed a decrease in SFA.

Incorporation of CLA isomers into tissues. The present results show that TAG incorporated *cis*-9,*trans*-11 more readily than *trans*-10,*cis*-12, the isomer responsible for body and liver fat reduction in hamsters (1,6,17–19). This pattern of accumulation was observed independently of the tissue analyzed (liver or adipose tissue). The selectivity in CLA isomer incorporation to TAG was in agreement with other studies in rodents (23,26,29,30,32).

The difference in CLA isomer accumulation was not due to differences in intestinal absorption because, taking into consideration CLA intake and fecal CLA excretion, similar percentages of absorption for both isomers were calculated. Thus, the results suggest a selective uptake of CLA isomers by tissues or a more efficient metabolism of *trans*-10,*cis*-12, leading to a reduced amount available to be stored. Martin *et al.* (48) found that the *trans*-10,*cis*-12 isomer was preferentially driven through the beta-oxidation pathway compared to the *cis*-9,*trans*-11 homologue. Moreover, Sébedio *et al.* (30) reported that the conversion of *trans*-10,*cis*-12 in long-chain metabolites is higher than that of *cis*-9,*trans*-11.

As expected, TAG deposition being largely greater in adipose tissue than in liver, dietary CLA isomers were incorporated into TAG mainly in adipose tissue and to a lesser extent in liver. Moreover, when the amount of CLA isomers was expressed as mg/g of TAG, the incorporation of both isomers was again greater in adipose tissue than in liver: 1.25 mg/g *cis*-9,*trans*-11 in liver TAG and 10.10 mg/g in adipose tissue TAG from hamsters fed this isomer, and 0.31 mg/g *trans*-10,*cis*-12 and 5.27 mg/g in adipose tissue TAG from hamsters fed this isomer.

With regard to liver PL, *cis*-9,*trans*-11 isomer was incorporated to a greater extent than *trans*-10,*cis*-12 isomer, similarly to that found in liver TAG. CLA isomer amounts in PL were greater than those in liver TAG. In the case of *cis*-9,*trans*-11 this difference was not due to a preferential incorporation into PL (1.56% in TAG and 1.57% in PL), but rather to the fact that PL content in a healthy liver is greater than TAG content. In contrast, in the case of *trans*-10,*cis*-12 isomer a more ready incorporation into PL (1.36%) than into TAG (0.40%) was observed.

It seems surprising to have found the *cis*-9,*trans*-11 isomer in *trans*-10,*cis*-12–fed hamsters and *vice versa*. A possible explanation is that the supplements, although highly enriched with one isomer, also contained about 6% of the other; the amounts of the of the minority CLA isomer found in tissue lipids probably arise from this small amount in the supplement.

In conclusion, this study shows that only *trans*-10,*cis*-12 CLA induces changes in FA composition. Whereas increased PUFA content was observed in either liver TAG or adipose tissue TAG, decreased SFA were found in liver PL. Incorporation of *cis*-9,*trans*-11 CLA in TAG is greater than that of the *trans*-10,*cis*-12 isomer, but this is not due to differences in intestinal absorption.

Institute of Aquaculture, University of Stirling, Stirling FK9 4LA, Scotland, United Kingdom

ABSTRACT: This study reports the cloning, functional characterization, tissue expression, and nutritional regulation of a Δ6 fatty acyl desaturase of Atlantic cod (*Gadus morhua*). PCR primers were designed based on the sequences of conserved motifs in available fish desaturases and used to isolate a cDNA fragment from cod liver, with full-length cDNA obtained by rapid amplification of cDNA ends. The cDNA for the putative desaturase was shown to comprise 1980 bp, including a 261-bp 5′-UTR, a 375-bp 3′-UTR, and an ORF of 1344 bp that specified a protein of 447 amino acids. The protein sequence included three histidine boxes, two transmembrane regions, and an N-terminal cytochrome b_5 domain containing the heme-binding motif HPGG, all characteristic of microsomal fatty acyl desaturases. The cDNA displayed Δ6 desaturase activity in a yeast expression system. Quantitative real-time PCR assay of gene expression in cod showed that the Δ6 desaturase gene was expressed highly in brain, to a slightly lesser extent in liver, kidney, intestine, red muscle, and gill, and at much lower levels in white muscle, spleen, and heart. The expression of the Δ6 desaturase gene did not appear to be under significant nutritional regulation, with levels in liver and intestine being barely altered in fish fed a vegetable oil blend, in comparison with levels in fish fed fish oil. This was reflected in enzyme activity, as hepatocytes or enterocytes showed very little highly unsaturated FA biosynthesis activity irrespective of diet. Further studies are required to determine why the Δ6 desaturase appears to be barely functional in cod under the conditions tested.

Paper no. L10093 in *Lipids 41*, 1003–1016 (November 2006).

Fish are the only major dietary source for humans of n-3 highly unsaturated FA (HUFA), EPA (20:5n-3), and DHA (22:6n-3) (1). With traditional fisheries declining, aquaculture supplies an increasing proportion of the fish in the human food basket (2). However, the current high use of fish oil (FO), derived from feed-grade marine fisheries, in aquaculture feeds is not sustainable, and will constrain growth of aquaculture activities (3,4). Vegetable oil (VO), a sustainable alternative to FO, can be rich in C_{18} PUFA such as linoleic (18:2n-6) and α-linolenic (18:3n-3) acids, but lack the n-3 HUFA abundant in FO (5). The extent to which fish can convert C_{18} PUFA to $C_{20/22}$ HUFA varies with species, and is associated with their capacity for fatty acyl desaturation and elongation (6). Marine fish are unable to produce EPA and DHA from 18:3n-3 at a physiologically significant rate (5) due to apparent deficiencies in one or more enzymes in the desaturation/elongation pathway (7,8). Thus, flesh FA compositions in marine fish fed VO are characterized by increased levels of C_{18} PUFA and decreased levels of n-3 HUFA, compromising their nutritional value to the human consumer (9,10).

Until depletion of the commercial stocks in the 1990s, Atlantic cod (*Gadus morhua* L.) was the most valued food fish obtained from the North Atlantic (11). In recent years significant progress has been made in the culture of cod and the life cycle has been closed, allowing production independent of wild fisheries (12). The large and highly developed market for cod, along with the high market price and the decreasing quotas set to preserve wild stocks, has greatly increased interest in cod culture in recent years (13–15). However, the establishment of large-scale, sustainable cod culture will require solutions to several nutritional issues including broodstock and larval nutrition and replacement of dietary FO with alternatives in on-growing diets (16–18).

Our overall aim is to determine what regulates HUFA biosynthesis in fish and how it can be optimized to enable fish to make effective use of dietary VO. Recently, fatty acyl desaturases, critical enzymes in the pathways for the biosynthesis of the long-chain $C_{20/22}$ HUFA from shorter-chain C_{18} PUFA, have been cloned from several teleosts (19,20). The cDNA for Δ6 and Δ5 desaturases have been cloned from Atlantic salmon (*Salmo salar* L.) (21,22) whereas, in contrast, only Δ6 desaturase cDNA have been cloned from marine fish (23,24). The expression levels of both Δ6 and Δ5 desaturases in salmon were shown to be upregulated in fish fed VO, in comparison with

Abbreviations: FO, fish oil; HUFA, highly unsaturated FA (carbon chain length ≥ C20 with ≥ 3 double bonds); ORF, open reading frame; Q-PCR, quantitative real-time polymerase chain reaction; RACE, rapid amplification of cDNA ends; $SCMM^{-uracil}$, Saccharomyces cerevisiae minimal medium minus uracil; UPM, universal primer mix; UTR, untranslated region; VO, vegetable oil.

levels in fish fed FO (25,26). The specific objectives of the study described here were to investigate FA desaturation and the regulation of the HUFA synthetic pathway in Atlantic cod. Thus, we describe the cDNA cloning, functional characterization, and tissue distribution of a fatty acyl desaturase of cod, and report the effects of nutrition on the expression of fatty acyl desaturase and elongase genes in cod fed diets containing either FO or a blend of VO.

MATERIALS AND METHODS

Cloning of putative fatty acyl desaturase from cod. Liver tissue was obtained from Atlantic cod fed for 3 mon with the VO diet described below. Total RNA was extracted from liver using TRIzol® reagent (Invitrogen Ltd., Paisley, UK). 3'-RACE cDNA was synthesized using MMLV reverse transcriptase (Promega, Madison, WI) primed by the oligonucleotide Not1polyT, 5'-GATAGCGCCGCGTTTTTTTTTTTTTTTV-3'. 5'-RACE-cDNA was synthesized using the SMART™ RACE cDNA amplification kit (Clontech, Mountain View, CA). Available fish desaturase sequences were aligned to enable the design of the degenerate forward primer, 5'-CARCAYCAYGCNAARCCNAA-3', and reverse primer, 5'-RAANARRTGYTCDATYTG-3'. These were used for PCR isolation of a cod desaturase cDNA fragment. PCR amplification was performed using Thermoprime plus DNA polymerase (ABgene, Surrey, UK) under the following touchdown PCR conditions: initial denaturation at 95°C for 1 min, 10 cycles of denaturation at 95°C for 15 s, annealing at 62°C for 30 s (–1.5°C /cycle), and extension at 72°C for 90 s, then 6 cycles of denaturation at 95°C for 15 s, annealing at 52°C for 30 s, and extension at 72°C for 90 s, followed by 24 cycles of denaturation at 95°C for 15 s, annealing at 51°C for 30 s, and extension at 72°C for 90 s. The PCR products were cloned into pBluescript KS II$^+$ vector (Stratagene, La Jolla, CA). The nucleotide sequences were determined by standard dye terminator chemistry using an Applied Biosystems ABI-377 DNA sequencer following the manufacturer's protocols (Applied Biosystems, Foster City, CA). Following isolation of a cDNA fragment flanked by the above primers, the specific forward primer 5'-GCCGATGAACATAGACCACG-3' was designed for 3' RACE PCR together with primer Not1PolyT under the following conditions: initial denaturation at 95°C for 1 min, 25 cycles of denaturation at 95°C for 20 s, annealing at 56°C for 30 s, and extension at 72°C for 2 min. The reverse primer, 5'-GGTGTTGGTGGTGATAGGG-CAT-3', was used in conjunction with forward universal primer mix (UPM), long and short, 5'-CTAATACGACTCACTATAG-GGCAAGCAGTGGTATCAACGCAGAGT-3' and 5'-CTAA-TACGACTCATATAGGGC-3', to perform 5' RACE PCR. Amplification involved an initial step at 95°C for 1 min, then 70°C for 3 min, and 5 cycles of denaturation at 95°C for 30 s, annealing at 60°C (–1°C/cycle) for 30 s, and extension at 72°C for 2 min, followed by 24 cycles of denaturation at 95°C for 30 s, annealing at 56°C for 30 s, and extension at 72°C for 2 min. Nucleotide sequences were determined as above, and the 3' and 5' RACE PCR fragment sequences were aligned to assemble the full nucleotide sequence of the cod putative desaturase cDNA using BioEdit version 5.0.6 (Tom Hall, Department of Microbiology, North Carolina State University, Raleigh, NC).

Heterologous expression of desaturase ORF in Saccharomyces cerevisiae. Expression primers were designed for PCR cloning of the cod putative desaturase cDNA ORF. The forward primer, 5'-CGGAATTCAAGCTTAAGATGGGAGGTGGAGGGCA-3', contained a *HindIII* site (underlined), and the reverse primer, 5'-GCTCTAGACTCGAGTCACTTATGGAGATAAGCATC-3', contained an *XhoI* site (underlined). PCR was performed using high-fidelity DNA polymerase (Roche Diagnostics Ltd., Lewes, East Sussex, UK), following the manufacturer's instructions. Amplification involved an initial denaturation step at 95°C for 2 min, followed by 30 cycles of denaturation at 95°C for 30 s, annealing at 58°C for 30 s, and extension at 72°C for 90 s, followed by a final extension at 72°C for 10 min. Following PCR, the DNA fragments were restricted and ligated into the similarly digested yeast expression vector pYES2 (Invitrogen Ltd., Paisley, UK). Ligation products were then used to transform Top10F' *E. coli* competent cells (Invitrogen Ltd.), which were screened for the presence of recombinants. Transformation of the yeast *S. cerevisiae* (strain InvSc1) with the recombinant plasmids was carried out using the S.c.EasyComp Transformation Kit (Invitrogen Ltd.). Selection of yeast containing the desaturase/pYES2 constructs was on *S. cerevisiae* minimal medium minus uracil (SCMM$^{-uracil}$). Culture of the recombinant yeast was carried out in SCMM$^{-uracil}$ broth as described previously (19), using galactose induction of gene expression. Each culture was supplemented with one of the following PUFA substrates: α-linolenic acid (18:3n-3), linoleic acid (18:2n-6), eicosatetraenoic acid (20:4n-3), dihomo-γ-linolenic acid (20:3n-6), docosapentaenoic acid (22:5n-3), or docosatetraenoic acid (22:4n-6). PUFA were added to the yeast cultures at concentrations of 0.5 mM (C_{18}), 0.75 mM (C_{20}), or 1 mM (C_{22}), as uptake efficiency decreases with increasing chain length. Yeast cells were harvested, washed, dried, and lipid extracted by homogenization in chloroform/methanol (2:1, vol/vol) containing 0.01% BHT as antioxidant, as described previously (19). FAME were prepared, extracted, purified by TLC, and analyzed by GC, all as described below. The proportion of substrate FA converted to the longer-chain FA product was calculated from the gas chromatograms as 100 × [product area/(product area + substrate area)]. Unequivocal confirmation of FA products was obtained by GC–MS of the picolinyl derivatives as described in detail previously (19).

Fish and diets. Atlantic cod were from a stock held at the Institute of Aquaculture (University of Stirling, Stirling, UK) and were fed a commercial fishmeal and oil-based diet prior to the trial. Fish with a mean body weight of 87 ± 5 g were stocked randomly (at 20 fish/tank) into two 1.5-m tanks of 400-L capacity supplied with recirculated seawater (37 ppt) at a constant temperature of 10°C at 400 L/h and were subjected to a photoperiod regime of 12 h light:12 h dark. Fish were fed at a rate of 1.5% biomass/d in two portions (9 am and 2 pm) for 3

mon before sampling. The diets were manufactured in-house, and differed only in the oil added to the basal mix (Table 1). In one diet, FO was the only added oil, and in the other diet FO was replaced by a VO blend containing rapeseed, linseed, and palm oils in a 2:2:1 ratio (Table 2). The diets were formulated to meet all the known nutritional requirements of marine fish (27). The experiment was conducted in accordance with British Home Office guidelines regarding research on experimental animals.

After 90 d, the fish weighed 258 ± 21 g, and there was no significant difference between weights of fish on different dietary treatments. Twelve fish per dietary treatment were sampled. Six were used for the preparation of hepatocytes from liver and preparation of enterocytes from pyloric ceca. Tissue samples were collected from the other six fish, with liver and cecal tissue collected from all six fish, and brain, heart, kidney, gill, spleen, adipose tissue, white muscle, and red muscle collected from three of these fish for RNA extraction and gene expression studies, and liver, ceca, and white muscle collected from four fish for lipid and FA analyses. All tissue samples were frozen immediately in liquid nitrogen and stored at –80°C prior to further analyses.

Cod tissue RNA extraction and quantitative real-time PCR (Q-PCR). Total RNA extraction was performed as described above. Five micrograms of total RNA was reverse transcribed into cDNA using M-MLV reverse transcriptase first-strand cDNA synthesis kit (Promega UK, Southampton, UK). Gene expression of the fatty acyl Δ6 desaturase and FA elongase (28) genes in tissues from cod fed the different diets was studied by Q-PCR. The PCR primers were designed according to the Δ6 desaturase (accession no. DQ054840), and published elongase (accession no. AY660881) cDNA sequences. For the Δ6 desaturase, the forward and reverse primers were 5'-CCCCAGACGTTTGTGTCAG-3' and 5'-CCTGGATTGTTGCTTTGGAT-3', respectively. For the elongase, the forward and reverse primers were 5'-TGATTTGTGTTCCAAATGGC-3' and

5'-CTCATGACGGGAACCTCAAT-3', respectively. PCR product sizes were 181 and 219 bp, respectively. Amplification of cDNA samples and DNA standards was carried out using SYBR Green PCR Kit (Qiagen, Crawley, West Sussex, UK) and the following conditions: 15 min denaturation at 95°C, 45 cycles of 15 s at 94°C, 15 s at 55°C, and 30 s at 72°C. This was followed by product melt to confirm a single PCR product. Thermal cycling and fluorescence detection were conducted in a Rotor-Gene 3000 system (Corbett Research, Cambridge, UK), with expression of target genes quantified and normalized as described previously (29).

Lipid extraction and FA analyses. Total lipids of livers, pyloric ceca, flesh (white muscle), and diet samples were extracted by homogenization in chloroform/methanol (2:1, vol/vol) containing 0.01% BHT as antioxidant (30). FAME were prepared from total lipid by acid-catalyzed transesterification using 2 mL of 1% H_2SO_4 in methanol plus 1 mL toluene (31), and FAME extracted and purified as described previously (32). FAME were separated and quantified by GLC (Fisons GC8600, Fisons Ltd., Crawley, UK) using a 30 m × 0.32 mm capillary column (CP wax 52CB; Chrompak Ltd., London, UK). Hydrogen was used as carrier gas, and temperature programming was from 50°C to 180°C at 40°C/min and then to 225°C at 2°C/min. Individual methyl esters were identified by comparison to known standards and by reference to published data (33).

Activity of the HUFA biosynthesis pathway in hepatocytes and enterocytes. Hepatocytes and enterocytes were prepared from livers and pyloric ceca by collagenase treatment of chopped tissue and sieving through 100-μm nylon gauze essentially as described in detail previously for salmonid and sea bass tissues (26,34). Approximately twice as much cod liver tissue was used for digestion due to the high fat content and consequently lower yield of cells (35). Viability, as assessed by trypan blue exclusion, was > 95% at isolation and decreased by less than 5% over the period of the incubation for both cell types. The enriched enterocyte preparation was predominantly enterocytes although some secretory cells were also present. One hundred microliters of the hepatocyte and enterocyte suspensions were retained for protein determination according to the method of Lowry *et al.* (36) following incubation with 0.4 mL of 0.25% (wt/vol) SDS/1 M NaOH for 45 min at 60°C.

Five milliliters of either hepatocyte or cecal enterocyte suspension were dispensed into 25-cm^2 tissue culture flasks and

incubated at 20°C for 2 h with 0.3 μCi (~1 μM) [1-^{14}C]18:3n-3, added as a BSA complex (37). After incubation, cells were harvested, washed, and lipid extracted as described previously (26), and total lipid transmethylated and FAME prepared as described above. The FAME were separated by argentation (silver nitrate) TLC (38), located on the plate by autoradiography for 14 d, and quantified by liquid scintillation after being scraped from the plates as described previously (39).

Materials. [1-^{14}C]18:3n-3 (50–55 mCi/mmol) was obtained from NEN (Perkin Elmer LAS Ltd., Beaconsfield, U.K.). Eicosatetraenoic (20:4n-3), docosapentaenoic (22:5n-3), and docosatetraenoic (22:4n-6) acids (all >98–99% pure) were purchased from Cayman Chemical Co. (Ann Arbor, MI). Linoleic (18:2n-6), α-linolenic (18:3n-3), and eicosatrienoic (20:3n-6) acids (all >99% pure), collagenase (type IV), FAF-BSA, BHT, and silver nitrate were obtained from Sigma-Aldrich Co. Ltd. (Poole, UK). TLC (20 × 20 cm × 0.25 mm) plates pre-coated with silica gel 60 (without fluorescent indicator) were purchased from Merck (Darmstadt, Germany). All solvents were HPLC grade and were from Fisher Scientific (Loughborough, UK).

RESULTS

Sequence analyses. The full length of the putative cod desaturase cDNA (mRNA), as determined by 5' and 3' RACE PCR, was shown to be 1980 bp, which included a 5'-UTR of 261 bp and a 3'-UTR of 375 bp. Sequencing revealed that the cDNA included an ORF of 1344 bp, which specified a protein of 447 amino acids (GenBank accession no. DQ054840). The protein sequence included all the characteristic features of microsomal fatty acyl desaturases, including two transmembrane regions, three histidine boxes, and an N-terminal cytochrome b_5 domain containing the heme-binding motif, HPGG (Fig. 1). Phylogenetic analysis comparing the cod desaturase sequence with desaturases from other fish species and human Δ5 and Δ6 desaturases clustered the cod most closely with tilapia, sea bream, and turbot, and more distantly from carp, zebrafish, and salmonids (Fig. 2). A pairwise comparison between fish and human desaturase sequences showed that the amino acid sequence predicted by the cod putative desaturase ORF showed greatest identity with that of gilthead sea bream Δ6 desaturase (82%), and 64% and 56% identity to the human Δ6 and Δ5 cDNA, respectively (Table 3).

Functional characterization. The FA composition of the yeast transformed with the vector alone showed the four main FA normally found in *S. cerevisiae*, namely 16:0, 16:1n-7, 18:0, and 18:1n-9, together with the exogenously derived FA (Fig. 3A and C). The most prominent additional peaks were observed in the profiles of transformed yeast grown in the presence of the Δ6 desaturase substrates, 18:2n-6 and 18:3n-3 (Fig. 3A–D). Based on GC retention time, and confirmed by GC-MS, the additional peaks associated with the presence of the cod desaturase cDNA were identified as 18:3n-6 (Fig. 3B) and 18:4n-3 (Fig. 3D), corresponding to the Δ6 desaturation products of 18:2n-6 and 18:3n-3, respectively. Approximately, 33.5% of 18:3n-3 was converted to 18:4n-3, and 17.5% of 18:2n-6 was converted to 18:3n-6 in yeast transformed with the cod desaturase. No additional peaks representing desaturated FA products were observed in the lipids of transformed *S. cerevisiae* incubated with 20:3n-6 or 20:4n-3 (Fig. 3E and F), indicating no Δ5 desaturase activity. Similarly, the cod desaturase cDNA did not express any Δ4 desaturase activity, as evidenced by the lack of additional peaks representing desaturated products of 22:5n-3 or 22:4n-6 (data not shown).

Fatty acyl desaturase and elongase gene expression in cod tissues. The fatty acyl Δ6 desaturase and PUFA elongase genes were expressed in all cod tissues examined. For the desaturase, the abundance of transcript was clearly greatest in brain, followed by liver, kidney, intestine, red muscle, and gill, and by much lower levels in white muscle, spleen, and heart (Fig. 4). The abundance of elongase transcript was very high in brain and gill, with lower levels in kidney, spleen, intestine, and heart, and a surprisingly low level of expression in liver.

Effect of diet on FA compositions of flesh, liver, and pyloric ceca. The FO diet contained around 25% total saturates, predominantly 16:0; approximately 46% total monoenes, with 26% as the long-chain monoenes 20:1 and 22:1; 3.7% n-6 PUFA, predominantly 18:2n-6; and almost 25% n-3 PUFA, with almost 20% as the n-3 HUFA 20:5n-3 and 22:6n-3 (Table 2). The VO diet provided slightly lower levels of total saturates and monoenes and a similar level of n-3 PUFA, but was characterized by increased proportions of 18:1n-9, 18:2n-6, and 18:3n-3, and decreased proportions of n-3 HUFA and long-chain monoenes. Therefore, the VO diet showed levels of 18:1n-9, 18:2n-6, and 18:3n-3 of around 26%, 10%, and 13%, respectively, whereas the combined level of 20:5n-3 and 22:6n-3 was reduced by half to 10% (Table 2).

The total lipid content of liver was greater than 50% of the wet weight, consistent with it being the major lipid storage organ in cod, whereas flesh had a low lipid content of 1%, and pyloric ceca contained around 3% total lipid (Table 4). Dietary VO had no significant effect on tissue lipid contents. The rank order of the major FA from total lipid of flesh from cod fed FO was 22:6n-3 > 16:0 > 20:5n-3 > 18:1n-9 > 20:1n-9 (Table 4). The changes in FA composition of the diets in response to replacement of FO with VO, described above, were reflected in the flesh FA compositions with increased proportions of 18:1n-9, 18:2n-6, and 18:3n-3, and decreased proportions of n-3 HUFA. Pyloric ceca showed a similar FA composition to flesh, with dietary VO having a very similar effect. However, consistent with the higher storage (neutral) lipid content, liver FA composition was characterized by higher levels of monounsaturated FA. Thus, the rank order of the major FA from total lipid of liver from fish fed FO was 18:1n-9 > 16:0 > 20:1n-9 > 22:6n-3 > 22:1 > 20:5n-3 > 16:1n-7 (Table 4). However, substitution of FO with VO resulted in similar changes to liver FA composition as in the other tissues, with increased proportions of 18:1n-9, 18:2n-6, and 18:3n-3, and decreased proportions of n-3 HUFA.

Effects of diet on the HUFA biosynthesis pathway in hepatocytes and enterocytes. Total activity of the HUFA biosynthe-

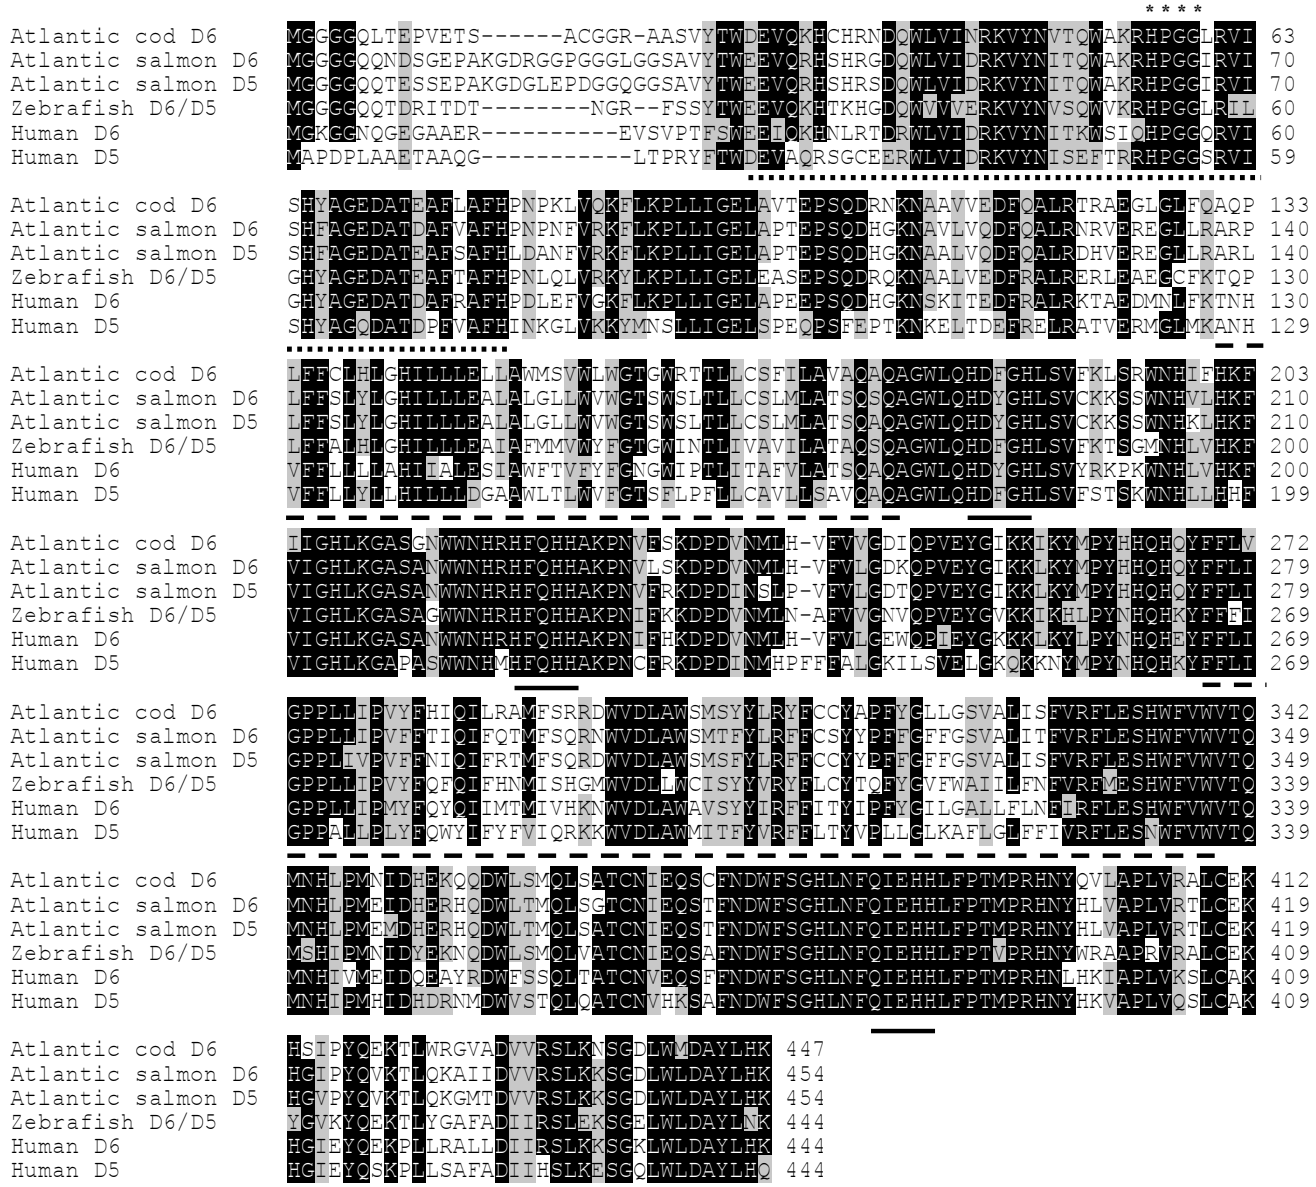

FIG. 1. Comparison of the deduced amino acid sequence of the Δ6 polyunsaturated fatty acyl desaturase from Atlantic cod with that of Δ6 and Δ5 desaturases from Atlantic salmon and human, and the Δ6/Δ5 bifunctional desaturase from zebrafish. Deduced amino acid sequences were aligned using ClustalX. Identical residues are shaded black and similar residues are shaded grey. Identity/similarity shading was based on the BLOSUM62 matrix, and the cutoff for shading was 75%. The cytochrome b_5–like domain is dot-underlined, the two transmembrane regions are dash-underlined, and the three histidine-rich domains are solid–underlined. The asterisks on the top mark the heme-binding motif, HPGG.

sis pathway as measured by the recovery of radioactivity in the summed desaturated products of [1-^{14}C]18:3n-3 was around 7-fold higher in enterocytes than in hepatocytes in cod (Fig. 5). In both cell types, the rate of synthesis of pathway products was unaffected by dietary treatment. The rate of the HUFA biosynthesis pathway in cod hepatocytes was between 40- and 120-fold lower than that observed in hepatocytes of Atlantic salmon smolts of similar size and assayed at the same time of year and fed similar diets (26) (Fig. 6). Similarly, the rate of the pathway in cod enterocytes was between 8- and 17-fold lower than that observed in salmon enterocytes. Furthermore, in contrast to the situation in cod, the rate of the HUFA biosynthesis pathway in salmon was significantly higher in both cell types from fish fed a VO blend compared with fish fed FO.

Effect of diet on expression of fatty acyl desaturase and elongase genes in liver and intestine. The effect of diet on the normalized expression of the Δ6 desaturase and PUFA elongase genes was determined in liver and intestine (pyloric ceca). The expression of both genes tended to be increased in terms of absolute copy number, but the data were characterized by a high degree of

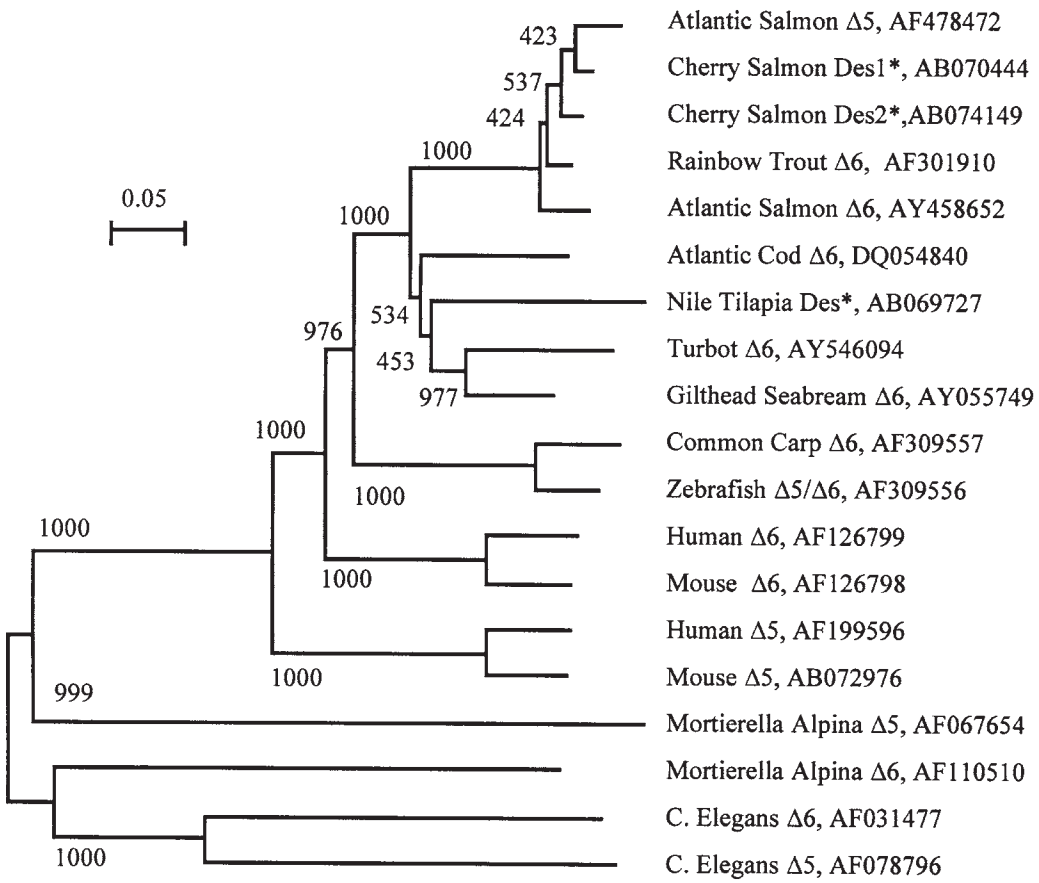

FIG. 2. Phylogenetic tree of cod Δ6 desaturase and desaturases from other fish species (Atlantic salmon, zebrafish, cherry salmon, rainbow trout, seabream, common carp, turbot, and tilapia), mammals (mouse and human), fungus (*Mortierella alpina*), and nematode (*Caenorhabditis elegans*). The tree was constructed using the neighbor-joining method (40) using *CLUSTALX* and *NJPLOT*. The horizontal branch length is proportional to amino acid substitution rate per site. The numbers represent the frequencies with which the tree topology presented here was replicated after 1000 bootstrap iterations. Sequences marked with an asterisk are not functionally characterized.

TABLE 3
Identity Matrix Showing the Results of a Pair-Wise Comparison Between the Amino Acid Sequences of Fish and Human Fatty Acyl Desaturases[a]

	Gilthead seabream Δ6	Turbot Δ6	Rainbow trout Δ6	Atlantic salmon Δ6	Atlantic salmon Δ5	Zebrafish Δ6/Δ5	Human Δ6	Human Δ5

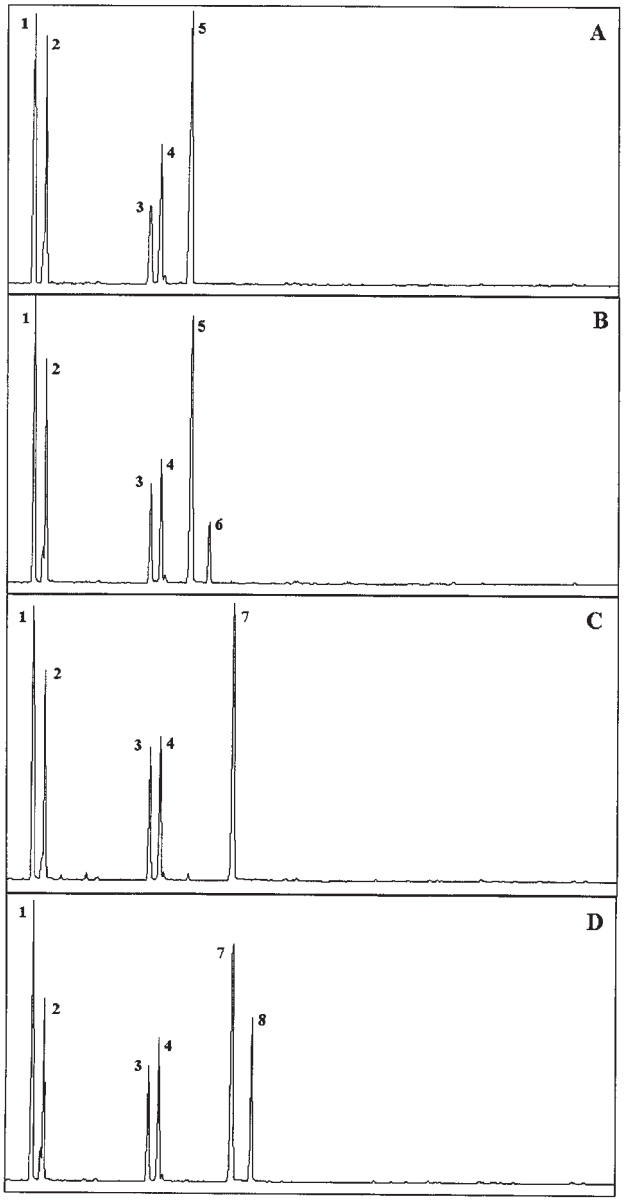
variation. Therefore, the only statistically significant effect of diet was increased expression of PUFA elongase in the liver (Fig. 7).

DISCUSSION

The study reported here revealed that Atlantic cod express a fatty acyl desaturase, and functional analysis in yeast confirmed the cod enzyme as a Δ6 desaturase. Comparing the protein sequence with sequences of a range of other desaturases of fish and human showed the cod Δ6 sequence to be more similar to the human Δ6 than to the human Δ5, but most similar to the Δ6 desaturases previously cloned from other marine fish, particularly gilthead sea bream (*Sparus aurata*) and turbot (*Psetta maximus*) (20,22). Phylogenetic analysis of the desaturase sequences reflected classical phylogeny, showing the cod (Paracanthopterygii; Gadiformes) branching from the Acanthopterygia (cichlids, perci-



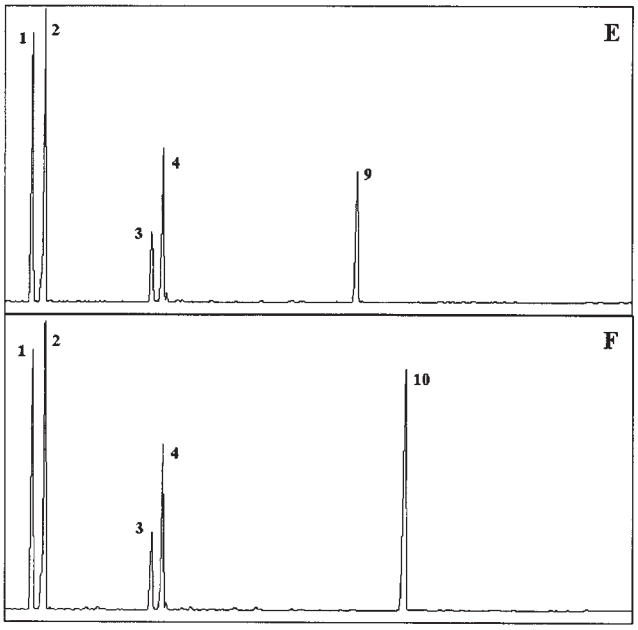


FIG. 3. Functional expression of the Atlantic cod putative fatty acyl desaturase in transgenic yeast (*Saccharomyces cerevisiae*). Panels A and C show the FA extracted from yeast transformed with pYES vector without insert and grown in the presence of 18:2n-6 and 18:3n-3. Panels B, D, E, and F show the FA compositions of yeast transformed with pYES vector containing the putative desaturase insert and grown in the presence of 18:2n-6, 18:3n-3, 20:3n-6, or 20:4n-3, respectively. The first four peaks in all panels are the main endogenous FA of *S. cerevisiae*, namely 16:0 (1), 16:1n-7 (2), 18:0 (3), and 18:1n-9 (with 18:1n-7 as shoulder) (4). Peak 5 in panels A and B and peak 7 in panels C and D are the exogenously added substrate FA, 18:2n-6 and 18:3n-3, respectively. Peaks 6 and 8 in panels B and D were identified as the resultant desaturated products, namely 18:4n-3 and 18:3n-6, respectively. Peaks 9 and 10 in panels E and F are the exogenously added substrate FA, 20:3n-6 and 20:4n-3, respectively. Vertical axis, FID response; horizontal axis, retention time.

formes, and pleuronectiformes) line, and further separated from both the carp and zebrafish (Ostariophysi; cyprinids), and salmonids (Salmoniformes; salmonidae) (42). Along with the cloning of Δ6 desaturase cDNA of sea bream and turbot, the work described has confirmed that marine fish have, and express, the gene required for the first step in the HUFA biosynthesis pathway, Δ6 desaturation, suggesting that any deficiencies in this pathway in marine fish would be at a further step such as chain elongation and/or Δ5 desaturation. This is consistent with biochemical data suggesting deficiencies in these steps in turbot and sea bream cell lines (7,8).

However, despite expressing an apparently active Δ6 desaturase, the activity of the HUFA biosynthesis pathway in both hepatocytes and enterocytes in cod was very low, and considerably lower than the activities measured in salmon hepatocytes and enterocytes (26,43). Indeed, the activities were so low that it was not possible to accurately quantify individual products, although in enterocytes, in which the activity was slightly higher, we were able to confirm that only Δ6 desaturated products (18:4n-3, 20:4n-3, and 22:4n-3) were observed on the autoradiographs. Furthermore, the majority product was 18:4, and so very little HUFA (defined as $\geq C_{20}$ and ≥ 3 double bonds) was actually produced, and neither EPA nor DHA were detected in cod. In contrast, functional expression in the yeast system had shown that the cod Δ6 had substantial enzymatic activity toward 18:3n-3. This perhaps highlights the known limitations of heterologous expression systems that use the endogenous yeast transcription system rather than the cod transcription machinery. It is also clear that it is essential that gene expression at the protein level should also be studied to confirm translation of the Δ6 desaturase gene in cod tissues. However, in the same yeast system, the salmon Δ6 gene gave over 60% conversion of 18:3n-3 (22), compared with 33% for the cod Δ6. Therefore, consistent with the salmon expressing higher HUFA synthesis activities, the salmon Δ6 was more active than the cod Δ6 in a comparative system, although this comparison is limited by the considerations mentioned above. Conversely, conversion of 18:2n-6 by the cod Δ6 exceeded that

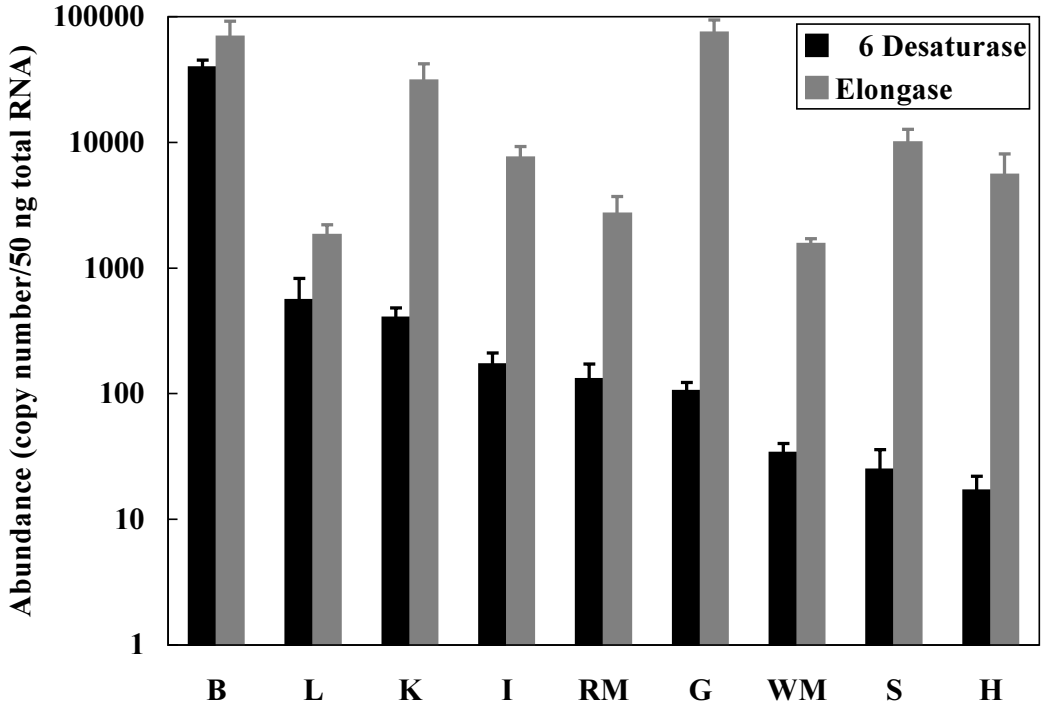

FIG. 4. Tissue distribution of fatty acyl Δ6 desaturase and PUFA elongase genes in Atlantic cod. Transcript (mRNA) copy number was determined by Q-PCR and normalized as described in the text. Results are expressed as means ± SEM (n = 4). L, liver; H, heart; G, gill; WM, white muscle; RM, red muscle; I, intestine; B, brain; A, adipose; S, spleen; K, kidney.

of the salmon Δ6 (18% *vs*. 14%) in the yeast expression system (22). This was interesting as it had previously been shown that the cod PUFA elongase was unique among the fish desaturase and elongase genes functionally characterized so far by being more active toward the n-6 substrate than the equivalent n-3 substrates (28). The reason for the cod genes being relatively more active toward n-6 substrates is unclear.

In addition to being considerably lower than in salmon, the rate of the HUFA biosynthesis pathway observed in cod was even lower than that observed in previous studies in other marine fish. The rate of desaturation of ^{14}C-18:3n-3 to all products in sea bass (*Dicentrarchus labrax*) was around 0.2 pmol.h^{-1}.mg protein^{-1} in hepatocytes and between 0.7 and 1.1 pmol.h^{-1}.mg protein^{-1} in cecal enterocytes, but this latter figure still represented only 2.1% of total radioactivity recovered, with 97.9% of total radioactivity recovered as the substrate [1-^{14}C]18:3n-3 (34). The activities in cod were around 10-fold lower at 0.02 and 0.15 pmol.h^{-1}.mg protein^{-1} in hepatocytes and enterocytes, respectively. It was perhaps noteworthy that the HUFA biosynthesis activities were higher in enterocytes than in hepatocytes in both sea bass and cod. This may be a real biological difference, as intestine is now acknowledged as a site of significant FA metabolism, at least in salmonids (44). However, it is possible that part of that difference may be due to the practical problems in isolating cells from such a lipid-rich tissue as cod liver. Despite using twice as much liver as ceca (in terms of wet weight), the cell yield of hepatocytes was very low and may have been a contributing factor. Problems of low yield from lipid-rich livers, and also of analyzing autoradiography data from very low activity samples (see above), were encountered in the previous study in sea bass (34).

Expression of the cod Δ6 desaturase was greatest in brain followed by liver, kidney, and intestine, whereas expression of the PUFA elongase was very high in brain and gill with a low level of expression in liver. In salmon, the expression of both Δ6 and Δ5 desaturases and the PUFA elongase were highest in intestine, liver, and brain (22). Mammalian Δ6 and Δ5 desaturases also show relatively high expression in liver and brain, as well as heart and kidney (45,46). A third desaturase gene in humans (FADS3) also shows highest expression in brain, heart, and liver (47). In contrast, intestine does not appear to be a site of high desaturase expression in mammals (48). In mouse, a PUFA elongase was expressed to the greatest extent in testis and liver followed by brain and kidney (49). In rat, two elongases were isolated: one, a PUFA elongase (rELO1), was expressed highly in lung and brain, whereas the other (rELO2), responsible for elongating saturated FA, was expressed only in liver (50). The tissue expression analysis in cod also showed that expression of PUFA elongase exceeded Δ6 desaturase expression. This was in contrast with the situation in salmon, where both Δ6 and Δ5 desaturase expression exceeded expression of PUFA elongase in all tissues (22). This may be a real biological difference between cod and salmon, but there may be other contributing factors. For example, in salmon, there are at least two other desaturase gene sequences in the genome (X. Zheng, unpublished data). The entire DNA gene sequences for

these two desaturases are not known, and the cDNA have not been isolated, and so the FA specificities, tissue distributions, and hence possible functions, if any, of these desaturases are not known. The function of the third (FADS3) desaturase gene in humans is also unknown at the present time (47).

Mammalian desaturase genes have been demonstrated to be subject to nutritional regulation. The expression of Δ6 desaturase in liver was increased in mice fed triolein (18:1n-9), an EFA-deficient diet, compared with mice fed corn oil, a diet rich in 18:2n-6 (45). Similarly, the expression of both Δ6 and Δ5 desaturases was 4-fold higher in rats fed a fat-free diet or a diet containing triolein compared with that in rats fed either safflower oil (18:2n-6) or menhaden oil (n-3 HUFA) (46). Similar results have been obtained in salmonids, with dietary linseed oil (rich in 18:3n-3) increasing the expression of liver Δ6 desaturase in rainbow trout, and of liver Δ5 desaturase and elongase in Atlantic salmon, compared with levels in fish fed FO (20,25). In recent studies, expression levels of both Δ6 and Δ5 desaturases were increased in liver of salmon fed a VO blend (rich in C_{18} PUFA) compared with levels in fish fed FO, but elongase expression was not increased (22,26). In the present study, the expression of Δ6 desaturase in cod liver and intestine was not significantly increased in fish fed VO compared with that in fish fed FO, although expression of the PUFA elongase was increased in liver by dietary VO. The expression of the genes was generally reflected in the activity of the HUFA biosynthesis pathway and in the FA compositions of the tissues, which showed no evidence of any Δ6 desaturase or PUFA elongase activity, with 18:4n-3 and 20:4n-3 levels not maintained, and 18:3n-6 levels only very low and 20:3n-6 not observed at all, in fish fed VO. Previously, increased desaturase expression was reflected in higher enzyme activities in both mice (45) and salmon (25,26). In the only other study on a marine fish, expression of Δ6 desaturase in sea bream liver was higher in fish fed a HUFA-free diet compared with that in fish fed a HUFA-rich diet, but activities were not measured in that study (23).

In conclusion, the study described here has demonstrated

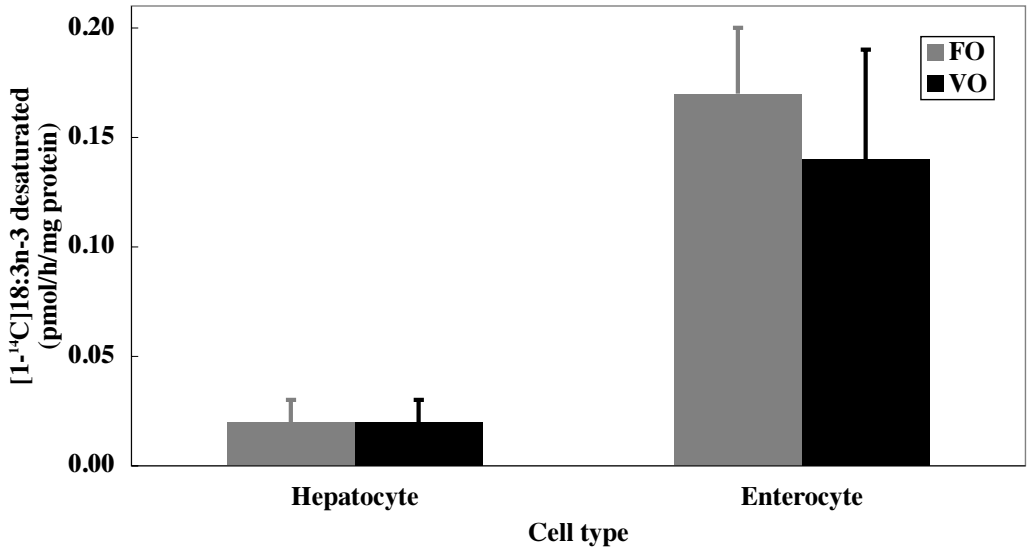

FIG. 5. Effect of diet on highly unsaturated fatty acid (HUFA) synthesis in hepatocytes and cecal enterocytes after feeding the experimental diets for 90 d. Results are means ± SD (n = 4), and represent the rate of conversion (pmol.h^{-1}.mg protein^{-1}) by desaturation/elongation of [1-^{14}C]18:3n-3 to all desaturated products. There was no significant effect of diet as determined by the student t-test (41).

that Atlantic cod express a fatty acyl desaturase gene, the product of which shows substantial Δ6 desaturase activity in a heterologous yeast expression system. The Δ6 desaturase was highly expressed in brain followed by liver, kidney, intestine, and all tissues examined. These data reinforce the impression that the poor ability of marine fish, such as cod, to synthesize HUFA is not due to lack of a Δ6 desaturase, but rather to deficiencies in other parts of the biosynthetic pathway. However, cod hepatocytes and enterocytes showed very little Δ6 desaturase or HUFA biosynthesis activity. The expression of the Δ6 desaturase and PUFA elongase genes did not appear to be under significant nutritional regulation, being generally similar

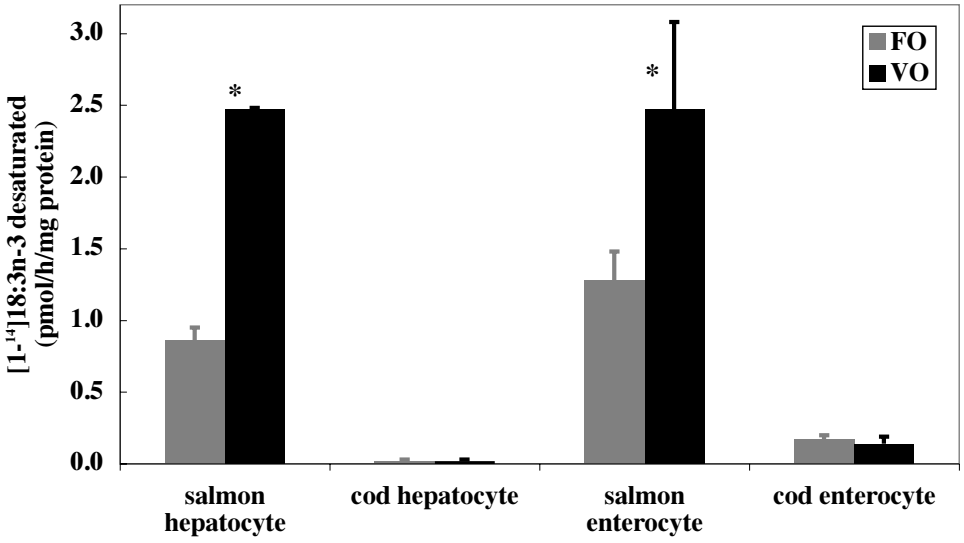

FIG. 6. Comparison of HUFA synthesis in Atlantic salmon and cod hepatocytes and enterocytes. Presentation of results is as described in the legend to Fig. 5. The salmon data were obtained in salmon smolts of similar size (220 g) to the cod in the present trial and assayed at the same time of year (July). The salmon were fed a similar FO and VO blend (26). An asterisk denotes a significant effect of diet as determined by the student t-test ($P < 0.05$) (41).

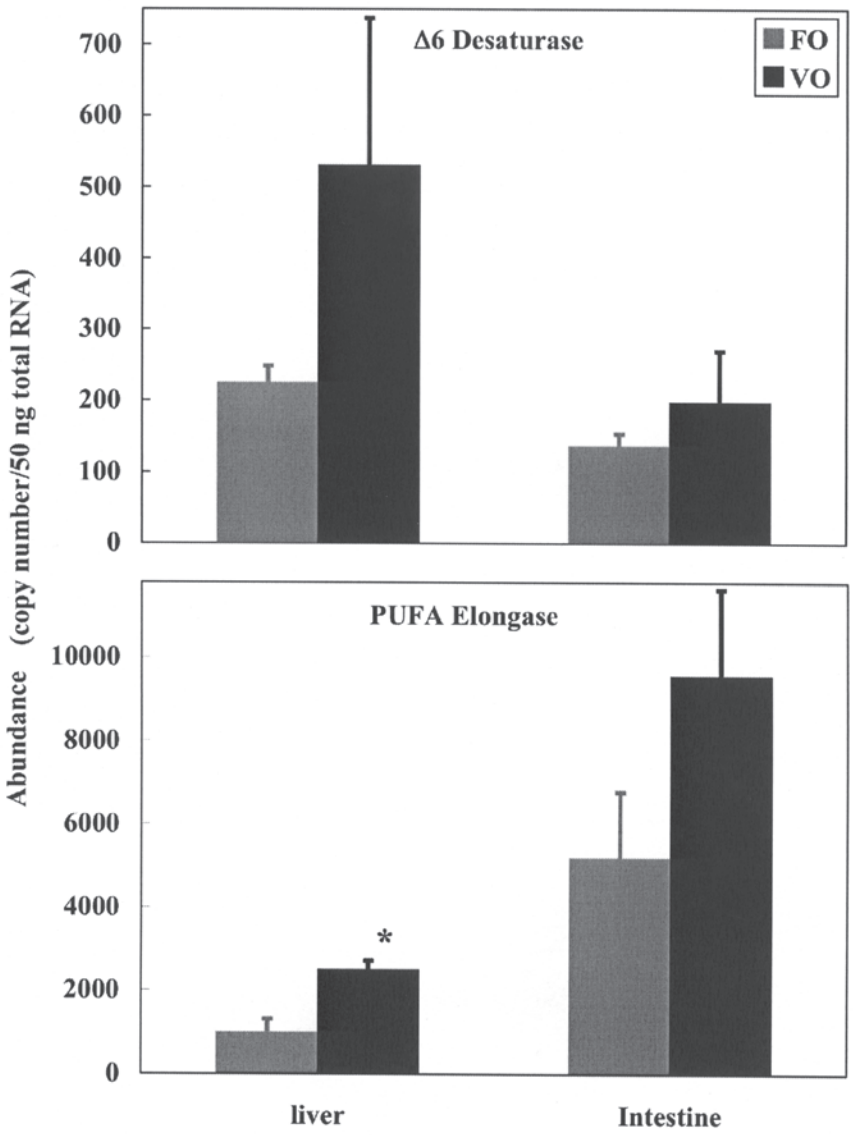

FIG. 7. Effect of dietary VOl on the expression of fatty acyl Δ6 desaturase and elongase genes in liver and intestine (pyloric ceca) from Atlantic cod. Transcript (mRNA) copy number was determined by Q-PCR and normalized as described in the text. Results are expressed as means ± SEM ($n = 4$). An asterisk denotes a significant effect of diet as determined by the student t-test ($P < 0.05$) (41).

in liver and intestine of fish fed the VO diet compared with fish fed the FO diet; this was reflected in unchanged enzyme activities in hepatocytes and enterocytes. Further studies are required to determine why the Δ6 desaturase appears to be barely functional in cod.

ABSTRACT: The scavenger receptor class B, type I (SR-BI) is an important player in regulation of mammalian lipid homeostasis. We therefore wanted to study this receptor in Atlantic salmon (*Salmo salar* L.), which requires a diet with particular high lipid content. We have for the first time cloned and characterized SR-BI from a salmonid fish. The predicted 494 amino acid protein contained two transmembrane domains, several putative N-glycosylation sites, and showed 72% sequence identity with the predicted homolog from zebrafish. SR-BI expression was analyzed by reverse transcription Real-Time PCR in several tissues, and a high relative expression in salmon midgut was detected, which may suggest that SR-BI has a role in uptake of lipids from the diet. We also expressed a construct of salmon *myc*-tagged SR-BI in salmon TO cells and HeLa cells, which gave a protein of approximately 80 kDa on reducing SDS-PAGE using an antibody against the *myc*-epitope. Immunofluorescence microscopy analyses of the salmon SR-BI protein in transiently transfected HeLa cells revealed staining in the cell periphery and in some intracellular membranes, but not in the nucleus, which indicated that the salmon protein may be a functional membrane protein. We also observed a high degree of co-localization using an anti-peptide SR-BI antiserum. We found that 20 μg mL^{-1} insulin up-regulated the SR-BI mRNA levels in primary cultures of salmon hepatocytes relative to untreated cells. Oleic acid, EPA, DHA, or dexamethasone did not affect the relative expression of SR-BI in this liver model system. In conclusion, the salmon SR-BI cDNA encoded a protein with several features common to those of mammalian species. SR-BI gene expression was high in the intestine, which leads us to propose that SR-BI may contribute to the uptake of lipids from the diet.

Paper no. L10090 in Lipids 71, 1017–1027 (November 2006)

The scavenger receptor class B, type I (SR-BI) (human homolog called CD36 and LIMPII analogous-1, CLA-1) has been characterized in a variety of mammals (1–2, reviewed in 3), non-mammalian vertebrates, and amphibians (4), and a similar receptor has even been discovered in the fruit fly (5). Mammalian SR-BI, which is a member of the CD36 receptor family, is a key player in cholesterol homeostasis (3) and was the first cell–surface, high-density lipoprotein (HDL)-receptor (6) to be molecularly well described. Glass *et al.* (7) discovered that there was a selective uptake of cholesteryl esters from HDL to rat liver, adrenals, and gonads, where there also is an abundant receptor expression closely regulated through trophic hormones. Transport of cholesterol from the liver to lipid-poor lipoprotein acceptors is also mediated through this HDL-receptor. The murine SR-BI is N-glycosylated and co-localized with caveolae (8). Two alternatively spliced transcripts of SR-BI, namely SR-BII (9) and SR-BIII (10), have been detected in mammals. They differ C-terminally, and it has been shown that at least the SR-BI and SR-BII isoforms possess various HDL-binding properties (11), while the function of SR-BIII detected in human atherosclerotic plaques has not been thoroughly studied. Mammalian SR-BI has broad ligand specificity. SR-BI is a receptor for native and modified lipoproteins (including low-density lipoprotein (LDL), oxidized LDL, acetylated LDL, HDL, oxidized HDL, very low-density lipoprotein (VLDL)), anionic phospholipids, maleylated bovine serum albumin (M-BSA), and advanced glycation end-products (AGE, as glycated BSA) (3). It has been shown that SR-BI is able to mediate phagocytosis of apoptotic cells through binding of phosphatidylserine residues on the cell surface (12). Recently, is has been shown that SR-BI also possesses other functions such as inducing ligand independent apoptosis in the absence of HDL (13) and transporting the lipophilic vitamin E across enterocytes (14). Additionally, Bietrix *et al.* (15) demonstrated a novel role of SR-BI in intestinal absorption of triacylglycesol (TAG) and cholesterol in mice.

Although various scavenger receptors have been studied in salmonids on a functional level (16-18), the SR-BI have, prior to this study, not been characterized in Atlantic salmon. Since this receptor is so important in mammalian lipid homeostasis, we wanted to clone and characterize this in Atlantic salmon, which is dependent on high-lipid diets for optimal growth (19). Hormones, fatty acids (FAs), and nutrients control the SR-BI expression levels in different tissues and species through com-

plex regulatory networks of transcription factors. Even though the SR-BI transcripts are quite well conserved through evolution, there is divergence between promoters in different species (3), and thus SR-BI's responsiveness to various ligands may be different—especially across vertebrate classes. Primary cultures of salmon hepatocytes are well suited as a model system for studies of lipid metabolism in salmon liver (20, 21). It would thus be interesting to study the expression of the receptor in a salmon primary hepatocyte culture by exposure to nutrients and hormones. Oleic acid (OA, 18:1n-9) and the n-3 (omega-3) polyunsaturated FA, (PUFAs) docosahexaenoic acid (DHA, 22:6n-3) and eicosapentaenoic acid (EPA, 20:5n-3), are abundant FAs in standard fish oil and fish/meal-based salmon feed. As in mammals, EPA, but not DHA, has a reducing effect on TAG secretion in salmon hepatocytes (21); however, the mechanisms for this have not been revealed. In hamsters, PUFAs in the diet resulted in up-regulation of hepatic SR-BI mRNA and protein *in vivo* (22), whereas insulin down-regulated hepatic SR-BI (23). Atlantic salmon hepatocytes were therefore incubated with these FAs in addition to insulin and the synthetic glucocorticoid dexamethasone. Dexamethasone has been shown to up-regulate SR-BI expression in primary rat hepatocytes (24). To our knowledge, no previous studies have examined the effects of glucocorticoid hormones on SR-BI mRNA expression in fish hepatocyte cultures. However, primary salmonid hepatocytes respond to glucocorticoids in terms of many other endpoints (reviewed in 25, 26). The fish liver seems to be a main target for the glucocorticoid cortisol, coping with the increased availability of FAs through oxidation and possibly resynthesis (25). Metabolic actions of insulin in fish have also been thoroughly characterized (reviewed in 27), and studies have confirmed that salmonid hepatocyte cultures respond both to bovine and salmonid insulin (26, 28). Plasma concentrations of FAs tend to decrease after insulin administration, but knowledge about the specific effects of insulin is scarce (27). However, the regulation of lipid metabolism by insulin does not seem to follow mammalian patterns.

By conducting this study we will be able to understand more about the expression and regulation of SR-BI in Atlantic salmon. Hence, such knowledge is an important contribution to the understanding of the mechanisms through which salmonids control and regulate the high lipid levels they are dependent on for optimal growth.

MATERIALS AND METHODS

Sampling, RNA isolation, and cDNA synthesis of tissues from Atlantic salmon. Tissue samples originated from VESO Vikan (Namsos, Norway). One hundred juvenile Atlantic salmon (average size 28.2 g) were kept in one tank at 12°C under controlled conditions. Samples were harvested from the gills, livers, spleens, head kidneys, hindguts (from immediately oral to anus), midguts (from immediately aboral to pylorus and pyloric caeca), and hearts of five fish and immediately stored in RNA*later*® (Ambion Inc, TX, USA) at –20°C until RNA extraction. Total RNA was isolated using the RNeasy® Mini Kit from Qiagen (MD, USA) according to the manufacturer's instructions. DNase digestion by TURBO DNA-*free*™ reagents from Ambion was performed according to the protocol to remove potential genomic DNA contamination. cDNA was made from 0.5 μg total RNA by using random hexamer primers and reverse transcription reagents from Applied Biosystems (ABI) (CA, USA).

Isolation of hepatocytes. Atlantic salmon of approximately 500 g were kept in seawater tanks at 9°C at NIVA's Research station, Drøbak, Norway. The fish were fed a commercial diet prior to isolation of hepatocytes. The fish were anesthetized with metacain, the abdominal cavity was exposed, and the vena porta cannulated. Livers were perfused following a two-step collagenase procedure developed by Seglen (29) and modified by Dannevig and Berg (30) to isolate hepatocytes. The hepatocytes were resuspended in L-15 medium containing 2% fetal bovine serum (FBS, Gibco, Scotland), 2 mM L-glutamine, and 0.1 mg mL^{-1} gentamycin (Cambrex Bio Science). Cell viability was assessed by staining with 0.4% Trypan blue. In average, more than 95% of the cells were viable. The protein content of the cell suspension was determined according to the method described in Lowry *et al.* (31). Approximately 8×10^6 cells (approx. 12 mg protein) were plated onto 25 cm^2 flasks and left to attach overnight at 12°C.

Hepatocyte culturing, incubation with ligands, sampling, and preparations for Real-Time PCR. Hepatocytes for gene-expression studies were thoroughly washed in serum-free L-15 medium. Each flask (except the controls) was incubated with 250 μM oleic acid (OA), DHA, EPA, and dexamethasone (Dex) or 20 μg mL^{-1} (3.3 μM) bovine pancreatic insulin (Ins) in a serum-free L-15 medium. FAs, insulin, and dexamethasone were purchased from Sigma (MO, USA). The FAs were added to the medium in the form of their potassium salts, bound to bovine-serum albumin (BSA). (The molar ratio between a FA and BSA was 2.5.) The controls were incubated with phosphate-buffered saline (PBS)/BSA (100 μM) only. There were six parallels for each treatment. After incubation for 48 h at 12°C, the cells were harvested and kept at –80°C until RNA extraction. Total RNA was isolated from hepatocytes, and cDNA was made as described above for the tissue samples from 2 μg total RNA. Analyses were duplicated in the reverse transcription step.

Production of a polyclonal antibody against salmonid SR-BI. Before cloning and sequencing full-length salmon SR-BI, we wanted to make a polyclonal AB against the protein based on a partial sequence from rainbow trout (*Oncorhynchus mykiss*). The partial SR-BI sequence from rainbow trout (GenBank accession no. DQ266043) obtained in our lab was translated and aligned with SR-BI amino acid (aa) sequences from other species. (See Table 2 in the Results section for GenBank accession numbers.) The peptide (FEPSMSVGNESDV) that was selected is situated in the extracellular loop of SR-BI and was coupled to keyhole limpet hemocyanin (KLH) carrier. Polyclonal antibody was produced by Eurogentec S.A. (Belgium) by immunization of two rabbits, followed by affinity purification against the peptide.

[a]Primers for RACE.
[b]Primers for cloning of SR-BI ORF; restriction sites in italics (EcoRI or HindIII), and start codon (ATG) underlined.
[c]Primers for quantitative Real-Time PCR.

Sequence information and primer design. Primers for random amplification of cDNA ends (RACE) and Real-Time PCR were designed by use of Primer3 (32) and PrimerExpress 2.0 (ABI), respectively (Table 1). Primers for subsequent steps in the cloning procedure were designed manually (Table 1).

Cloning of salmon SR-BI by RACE. Cultured hepatocytes were harvested, and total RNA was isolated and treated with DNase as described above for the tissue samples. SMART™ RACE cDNA amplification kit (BD Biosciences Clontech, CA, USA) and 1 μg total RNA were used to make 5'- and 3'-RACE-Ready cDNA. The RACE was performed using the gene-specific primer (GSP) 1 and GSP 2 (Table 1) for the 5' and 3' reactions, respectively, combined with the primers in the kit. A touchdown PCR was set up as follows: 5 cycles of 94°C 30 s, 72°C 3 min; 5 cycles of 94°C 30 s, 70°C 30 s, 72°C 3 min; and 25 cycles of 94°C 30 s, 68°C 30 s, 72°C 3 min. The 3' RACE was run for an additional 10 cycles of the latter parameters to obtain detectable products. PCR products were then TA subcloned into TOPO® Vectors (Invitrogen, CA, USA) and sequenced (GATC Biotech, Germany). After sequence analyses, new primers were designed in 5' untranslated region (UTR) and 3' UTR (Table 1), based on the obtained salmon sequence. Full-length cDNA was amplified using the 5' RACE cDNA as a template and Advantage 2 PCR reagents (BD Biosciences Clontech) in 50 μL volumes. The following PCR program was run: 94°C 1 min; 35 cycles of 94°C 30 s, 58°C 45 s, 68°C 2 min; and a final extension of 70°C 10 min. PCR products were subcloned and sequenced as described above.

Cloning of the SR-BI open reading frame (ORF) into an expression vector. A PCR with primers (Table 1) defining SR-BI ORF and including restriction sites was run at 95°C 2 min; 30 cycles of 95°C 30 s, 58°C 30 s, 68°C 2 min; and a final extension of 72°C 10 min. pcDNA™3.1/*myc*-His(-) A and the purified PCR product were double digested with EcoRI and HindIII restriction enzymes from New England Biolabs (NEB, MA, USA). The vector was treated with CIAP (Fermentas Inc, MD, USA), and a ligation was performed using T4 DNA ligase (Invitrogen) according to the manufacturer's instructions. Verification of correct insertion was done by sequencing. The construct is denoted pSR-BI-*myc*-His.

Transfection of human HeLa and salmon TO cells. HeLa cells were grown in Dulbecco-modified Eagle-Earle medium (D-MEM) (Gibco) containing 10% vol/vol FBS, 2 mM L-glutamine, 25 mM HEPES, 1 mM sodium pyruvate (Biochrom

AG, Germany), and penicillin-streptomycin (10,000 units of penicillin mL^{-1} and 10,000 µg of streptomycin mL^{-1}) (Gibco), at 37°C in a 5%-CO_2 incubator. The cells were plated at 5×10^5 cells in 21.5-cm^2 dishes with glass coverslips the day before transfection. They were transfected with 1 µg DNA (pSR-BI-*myc*-His) using FuGENE® 6 (Roche Applied Science, IN, USA) according to the manufacturer's instructions. The cells were then cultured for 48 h.

1.5 million salmon TO cells (head kidney cell line, passage 50) (33) were transfected using 5 µg DNA (pSR-BI-*myc*-His) and the Nucleofector™ technology from Amaxa Biosystems (MD, USA) and seeded in six-well culture dishes. The TO cells were cultured at 20°C in an L-15 medium containing 5% FBS, 2 mM L-glutamine, and 0.1 mg mL^{-1} gentamycin for 72 h.

Both cell lines were also transfected with pEGFP-N1 (Clontech Lab., CA, USA) as positive controls for transfection efficiency.

Immunofluorescence analysis. Transfected and untransfected HeLa cells on coverslips were washed in cold PBS and fixed with 4% paraformaldehyde in PBS (Electron Microscopy Sciences, PA, USA) for 20 min, then permeabilized with 0.1% Triton X-100 (Sigma) in PBS for 5 min, and washed with PBS. Unspecific staining was blocked by incubating the cells with 2% FBS in PBS for 30 min. The cells were incubated with one or both primary antibodies (ABs)—mouse anti-*myc* (kindly provided by Professor Harald Stenmark, Dept. of Biochemistry at the Norwegian Radium Hospital, Norway) diluted 1:50 in 2% FBS in PBS and anti-peptide SR-BI undiluted—for 60 min. After three washes in PBS, the cells were labeled for 60 min with secondary ABs conjugated to CY-2 and/or CY-3 (Jackson ImmunoResearch Laboratories Inc, PA, USA). The coverslips were washed three times in PBS and mounted in ProLong Gold (Molecular probes, OR, USA). Cells were then examined with a Nikon C-1 confocal mounted on a TE 2000E inverted microscope.

DNA and amino-acid sequence analysis. All nucleotide sequences obtained were assembled in ContigExpress in Vector NTI advance 9.1.0. (Invitrogen), and a consensus sequence was obtained. TBLASTX searches were performed to identify the protein. TMHMM 2.0 (34) was used to search for transmembrane domains and NetNGlyc 1.0 (35) was used to find potential N-glycosylation sites. Moreover, Simple Modular Architecture Tool (SMART) analyses (36) were performed to reveal other possible domains. The BLAST 2 SEQUENCES (bl2seq) program was used for pair-wise protein-protein sequence comparison (Blastp 2.2.14) (37). CLUSTALW (38) was used for multiple sequence analyses.

Quantitative Real-Time PCR analyses. Real-Time PCR was performed with the ABI Prism® 7000 system and gene-specific primers (Table 1). A 2× SYBR® Green PCR Mastermix (ABI), 0.4 µM of each primer, and the cDNA template (both from tissue samples and hepatocytes) were mixed in 25 µL volumes. Standard curves for each primer pair were calculated by serial dilution, and PCR efficiencies (E) were calculated according to the formula $E = 10^{(-1/slope)}$ (39). A two-step PCR was run for 40 cycles (15 s at 95°C, 1 minute at 60°C) with an initial incubation of 2 min at 50°C and 10 min at 95°C to activate the hot-start AmpliTaq Gold® DNA Polymerase. Specificity of the PCR products was verified by agarose-gel electrophoresis and amplicon sequencing.

Data analyses and statistics. Relative quantities of SR-BI transcription levels in the tissue samples were calculated by the $2^{-\Delta\Delta Ct}$ method (40), adjusted for PCR efficiency. Elongation factor 1 alpha (EF1A) was used as a reference gene to normalize data in these analyses (41). The mean values of all the tissues were related to the tissue sample with the lowest ΔCt value (hindgut).

Relative expression of SR-BI in hepatocytes was determined using the Relative Expression Software Tool (REST-384© – version 1) (42). A comparison of gene expression in hepatocytes cultured in normal conditions versus hepatocytes treated with different FAs and synthetic ligands were performed and normalized to the two reference genes 18S rRNA and EF1A (41). This analysis sets expression level (ratio between SR-BI and reference genes) in the untreated hepatocytes to 1 and the changes in the test groups (OA, EPA, DHA, Ins, and Dex) relative to this. Significant difference from expression in control hepatocytes was calculated by the Pair Wise Fixed Reallocation Randomization Test© (2000 randomizations) in the software. All samples were reverse transcribed and amplified in parallel, and mean values were used in REST, n = 6. Probability values (*P*) of less than 0.05 were considered significant.

Western blot analysis of transfected HeLa and TO cells. Transfected HeLa and TO cells were harvested in PBS, spun down, and resuspended in Laemmli sample buffer (containing β-mercaptoethanol) for SDS-PAGE (sodium dodecyl sulfate polyacrylamide gel electrophoresis) and subsequent Western analysis. Cell lysates were loaded and separated on a 10%-SDS polyacrylamide gel. Proteins were then electroblotted onto a methanol-activated Hybond™-P membrane (Amersham Biosciences). The membrane was pre-incubated in a blocking solution containing 5% skimmed milk in PBS/0.1% Tween 20, which was the basis for all subsequent dilutions of ABs. The blot was then incubated with a mouse anti-*myc* (1:200) primary AB, followed by goat anti-mouse HRP-IgG AB (1:5000) (Jackson ImmunoResearch Laboratories Inc) and chemiluminescent detection. A loading control was introduced by re-hybridizing the blot with a rabbit anti-actin (1:500) AB (Sigma, Product no. A2066) and a goat anti-rabbit HRP-IgG AB (1:10000) (Jackson ImmunoResearch Laboratories Inc).

RESULTS

Sequence analysis of salmon SR-BI cDNA. To obtain the salmon SR-BI cDNA, RACE was performed on salmon hepatocyte RNA using primers based on a partial sequence from rainbow trout. The resulting cDNA sequence of 1852 nucleotides (nt) contained a 280 nt 5' untranslated region (UTR), an open reading frame (ORF) of 1482 nt, and a 90 nt 3' UTR (Fig. 1; GenBank accession no. DQ914655). Translation of the ORF gave a putative protein of 494 aa. Further analyses of the

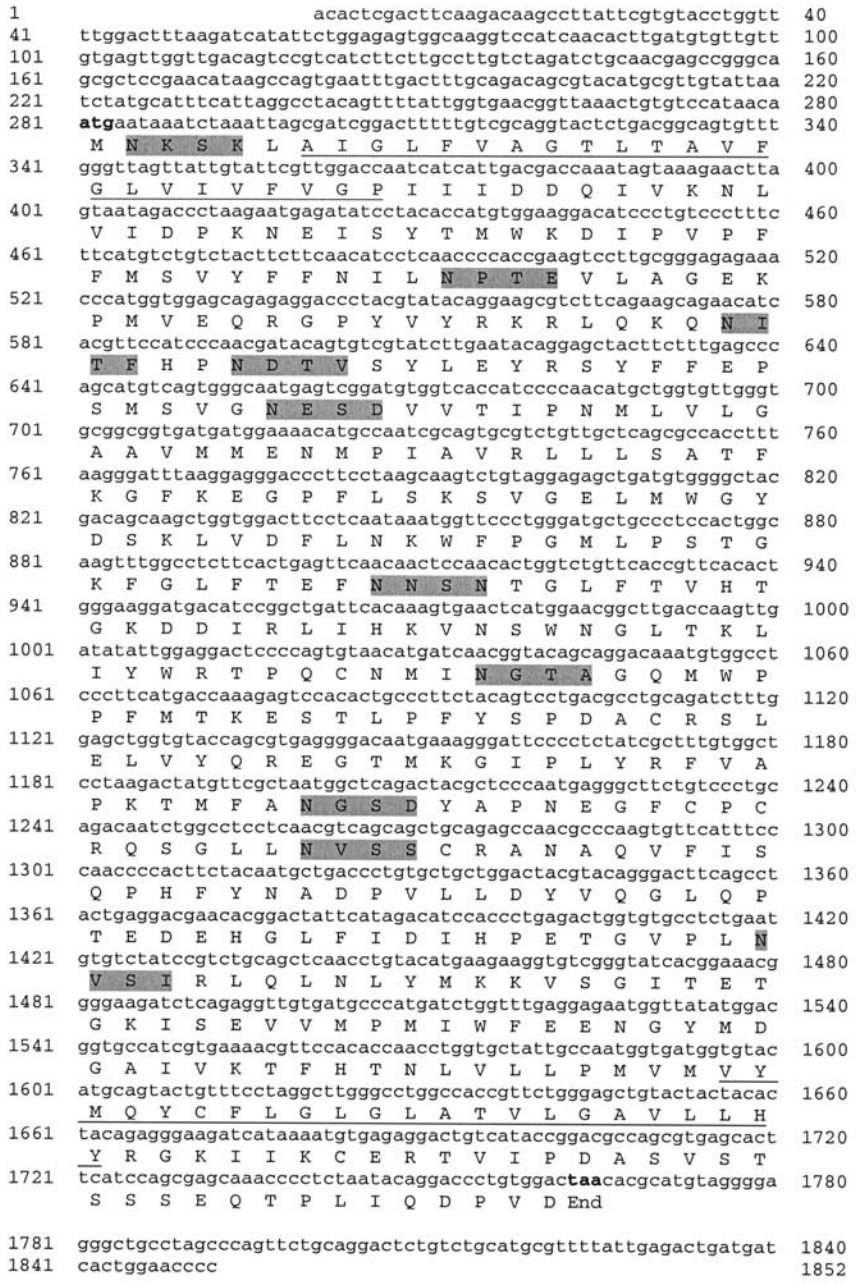

FIG. 1. Salmon SR-BI cDNA nucleotide sequence and its predicted amino acid sequence. Putative translation start codon (atg) and stop codon (taa) are indicated in bold. The positions of the N-terminal and C-terminal transmembrane domains are underlined, and the positions of the putative N-glycosylation sites are indicated with grey boxes. (GenBank accession no. DQ914655.)

predicted protein revealed two primary putative transmembrane alphahelical domains of 23 aa each (residues 7-29 and 439-461) and ten putative N-glycosylation sites (residues 2, 71, 99, 105, 126, 209, 252, 307, 327, and 380). A CD36 domain including aa 1 to 442 (E-value = 3.8e-180) was also discovered.

The deduced protein sequence shared overall similarity to SR-BI of other species (Fig. 2). All species contain the same phylogenetically conserved CXXS redox and GXXXG motifs. The leucine residues in a seven-heptad repeat-putative leucine zipper are not conserved between mammals and fish. Sequence identity obtained from BLAST 2 SEQUENCES analyses are shown in Table 2. Salmon SR-BI showed the highest identity to zebrafish (72%), and the lowest to mouse (54%), SR-BI.

Expression of SR-BI mRNA in salmon tissues. Relative expression of SR-BI mRNA in a selection of salmon tissues was investigated by reverse transcription Real-Time PCR and analyzed by the $2^{-\Delta\Delta Ct}$ method. Particular high expression was dis-

FIG. 2. Comparison of the predicted salmon SR-BI protein sequence with pig, cow, human, mouse, rat, and zebrafish SR-BI homologs. The sequences were aligned in CLUSTALW. "*" below alignment blocks denotes residue identities, ":" denotes conserved substitutions, and "." denotes semi-conserved substitutions. The 13 aa-peptide used for AB production is indicated in bold at residue 118-130, relative to the start of salmon SR-BI. The black box in the alignment denotes a conserved CXXS redox motif, and the grey box denotes a conserved GXXXG motif. Small black boxes below the alignment denote the leucine (L) residues in a seven-heptad repeat-putative leucine zipper proposed in mammals. Accession numbers are listed in Table 2.

covered in midgut (from immediately aboral to pylorus and pyloric caeca) (Fig. 3)—approximately 120-fold more than in the tissue with lowest expression, namely hindgut (from immediately oral to anus). Comparatively little mRNA was present in all other tissues investigated.

Transfection studies with the salmon pSR-BI-myc-His fusion construct. To further characterize the salmon SR-BI we constructed an expression vector with the putative ORF of salmon SR-BI in frame with a *myc*-His tag. We wanted to investigate the cellular localization in transiently transfected cells and hence used HeLa cells as a model system, as these cells are easy to work with and have high transfection efficiency (approximately 80–90%). Transfected HeLa cells were double labeled with the anti-peptide polyclonal SR-BI AB and an anti-

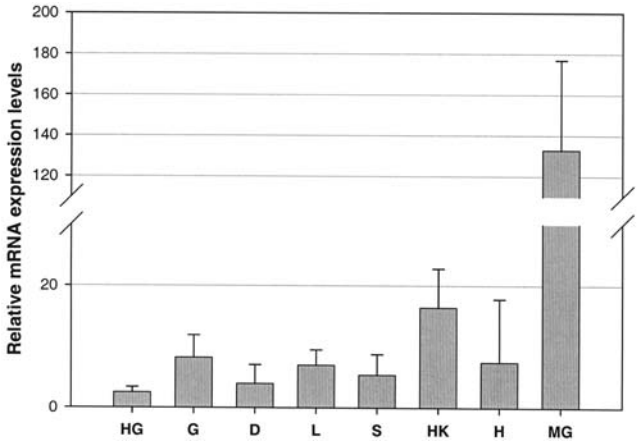

FIG. 3. Relative expression of SR-BI mRNA in salmon tissues; $2^{-\Delta\Delta Ct}$ analysis of the mRNA expression of SR-BI relative to mRNA levels of EF1A in eight salmon tissues. Data was normalized to the lowest relative expression (one HG sample). HG = hindgut (from immediately oral to anus), G = gills, D = dermis, L = liver, S = spleen, HK = head kidney, H = heart, and MG = midgut (from immediately aboral to pylorus and pyloric caeca). Data are means with standard deviation error bars. N = 5 for HG, G, D, L, and HK. N = 4 for S and MG.

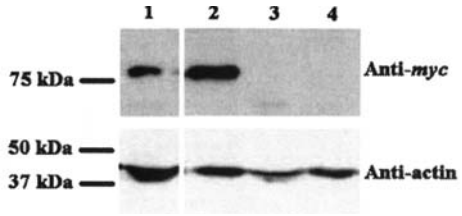

FIG. 5. Western blot analysis of the SR-BI-*myc*-His fusion protein in transiently transfected TO and HeLa cells detected with anti-*myc* AB. Transfected salmon TO (lane 1) and HeLa cells (lane 2) produce a protein of about 80 kDa. There were no bands in the untransfected controls for HeLa (lane 3) and TO (lane 4) cells. An anti-actin antibody was used as a loading control.

myc AB. Both antibodies stained the cell at the periphery and in the intracellular membranes, but not in the nucleus (Fig. 4).

Furthermore, to verify that the extent of glycosylation in salmon and human cells was comparable we transfected both HeLa cells and salmon TO cells with the pSR-BI-*myc*-His construct for Western analysis. A protein of about 80 kDa was detected for both cell types on a Western blot (reducing conditions) using an anti-*myc* AB (Fig. 5). We were not able to detect the fusion protein with the polyclonal AB made against salmonid SR-BI (data not shown).

Regulation of SR-BI gene expression in salmon hepatocytes. SR-BI expression in mammals is regulated in response to FAs and other ligands, and we investigated this in salmon-primary cultures of hepatocytes. We focused on some FAs relevant to salmon physiology (OA, EPA, and DHA), but also insulin and dexamethasone, which have been widely tested in mammalian assays. REST analyses of Real-Time PCR data showed that there was a 2-fold increase in the relative expression level of SR-BI in hepatocytes treated with 20 μg mL^{-1} insulin (Fig. 6).

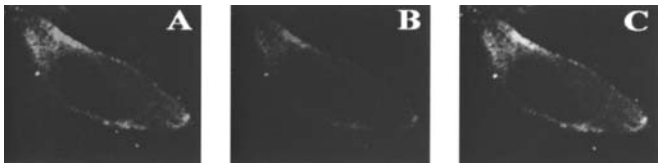

FIG. 4. HeLa cells transiently transfected with the pSR-BI-*myc*-His construct and visualized by confocal immunofluorescence microscopy. The cells were double-labeled with anti-peptide SR-BI/CY2-conjugated mouse anti-rabbit IgG (panel A) and anti-*myc*/CY3-conjugated rabbit anti-mouse IgG (panel B). An overlay is presented in panel C. No staining was detected with secondary ABs only (data not shown).

We did not detect any changes in the SR-BI expression level in hepatocytes treated with OA, EPA, DHA, or dexamethasone.

DISCUSSION

The coding region of SR-BI in salmon had 72% aa identity with zebrafish and between 54–58% aa identity with the SR-BI from other mammalian species. Transfection studies in both mammalian and salmon cells using a *myc*-tagged salmon SR-BI, gave an approximately 80 kDa protein by SDS-PAGE and immunodetection of the *myc*-epitope. In other species, the molecular weight of SR-BI varies slightly from 84–86 kDa in frog and gold fish (4) to 82 kDa in mammals (8). There are clearly domains in the receptor that are well conserved across vertebrate species (see Fig. 2), but there are also differences, partic-

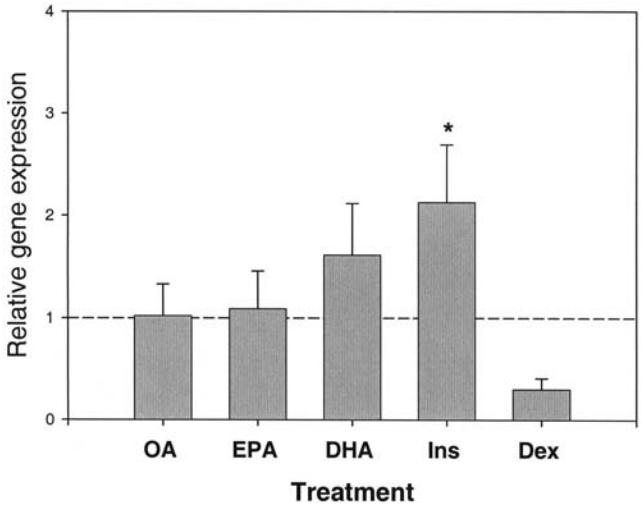

FIG. 6. Relative expression of salmon SR-BI mRNA in hepatocytes treated with OA, EPA, DHA, insulin (Ins), and dexamethasone (Dex). Dashed line denotes the ratio of SR-BI, and the two reference genes (18S rRNA and EF1A) in untreated hepatocytes (control set to 1). Significant difference from expression in control cells was calculated by the Pair Wise Fixed Reallocation Randomization Test© (2000 randomizations) in the REST©-384 software and is denoted with an asterisk (*), n = 6, $P < 0.05$.

ularly between mammals and fish in the N- and C-terminal regions.

One particularly interesting domain is the highly conserved CXXS redox motif that is present in all species investigated. In mammals, this motif has been suggested to be involved in a novel ligand-independent apoptotic pathway induced by SR-BI through activation of the caspase-8 pathway and regulated by endothelial nitric-oxide synthase (eNOS) and HDL (13). The authors hypothesized that SR-BI may play a pivotal role in the development of atherosclerosis when HDL levels are low and oxidative stress causes the relocation of eNOS away from caveolae. Furthermore, they proposed that SR-BI will contribute to the clearance of apoptotic cells to prevent further inflammatory damage to neighboring cells. It would be interesting to investigate whether the conserved CXXS motifs have similar functions in salmonids that have high levels of HDL (43) but at the same time have a high prevalence of coronary atherosclerotic lesions (reviewed in 44). However, the formation of atherosclerotic lesions in salmonids is probably caused by a combination of vascular injury, high growth rates, or stress associated with spawning migrations.

Another conserved motif near the C-terminal transmembrane domain is GXXXG, which is critical for proper delivery and metabolism of HDL-CE (45). The leucine residues in a seven-heptad repeat-putative leucine zipper in the same area (46) have been proposed to bind HDL via the amphipathic α-helical repeat units in apolipoprotein AI (47, 48). But most of these leucine residues are only semi-conserved in salmon and zebrafish. However, SR-BI is known to bind several ligands, and not much is known about the precise domains responsible for this interaction.

There are some conserved cysteine residues in the SR-BI across species, and thus these proteins have the potential to form extracellular disulfide bridges. There are also many potential N-glycosylation sites for the salmon protein as for mammalian SR-BI (8, 46). In summary, there are many structural similarities between salmon and mammalian SR-BI, and hence it is likely that SR-BI is also functionally conserved phylogenetically.

There was a 100% aa match in sequence between the partially deduced rainbow trout and Atlantic salmon SR-BI in the region that we chose for AB production. The polyclonal AB did not work in Western analyses, but we obtained good co-localization with the *myc*-epitope in transfected HeLa cells. This may suggest that our anti-SR-BI serum only recognizes the native form of the protein.

In this report we found a particularly high SR-BI mRNA expression in midgut. It is not known how closely SR-BI mRNA expression reflects SR-BI protein levels in fish (due to lack of good antibodies), but in mammalian tissues and cell systems mRNA and protein levels of SR-BI correlate well in several reports (6, 22, 49, 50). Atlantic salmon requires a high lipid content in the feed (19), and since the pyloric caeca and the proximal intestine are the main sites of fat digestion and absorption (51, 52) we propose that salmon SR-BI may be involved in lipid absorption in this part of the intestine. In mammals, on the other hand, it has been reported that the SR-BI has the highest expression in tissues with significant roles in cholesterol metabolism, namely the liver and steroidogenic tissues, but also, in lesser amounts, in tissues with critical functions in transport and lipid metabolism, including the heart and the intestine (6, 53). The receptor primarily has a function in selective uptake of CE from lipid-rich lipoproteins to the liver (reverse cholesterol transport) and secretion of excess cholesterol through the bile or efflux, and recycling of free cholesterol to lipoprotein acceptors. A recent study of mice over-expressing intestinal SR-BI has discovered a functional role *in vivo* for SR-BI in cholesterol and TAG intestinal absorption (15). Lately SR-BI has also been shown to be involved in vitamin E transport across mammalian enterocytes (14). Kiefer *et al.* (5) found that the *ninaD* gene encodes a class B scavenger receptor, which mediates uptake of dietary carotenoids, thus making them available for subsequent cell metabolism. However, there are only 26- and 27% aa identities between human and salmon SR-BI and the putative NinaD protein, respectively. In addition, the conserved CXXS and GXXXG motifs that are present in vertebrate SR-BI are not present in the NinaD protein. It would therefore be of interest in the future to further investigate the expression of SR-BI in salmon enterocytes and its potential role in the uptake of fat-soluble vitamins. Thus, evidently new functions of the SR-BI are currently discovered, and because of the highly variable physiology of mammals and lower vertebrates, particularly in terms of lipid plasma profiles and feed requirements, one can also suspect that salmon SR-BI has an important function in intestinal lipid absorption.

Salmon hepatocyte cultures have been used for two decades (54) as a model system to study various aspects of liver biology. Using primary cultures is generally advantageous compared to using cell lines, which have a tendency to become morphologically and biochemically changed over time. Treatment of salmon hepatocyte cultures with insulin gave a two-fold increase in expression levels of SR-BI (using two reference genes for normalization) relative to untreated cells. How gene transcription responds to external stimuli is largely determined by the promoter and other regulatory sequences surrounding the coding region. Promoters of the rat and human SR-BI genes have been characterized and include a number of essential elements to explain its regulation by cellular cholesterol levels and hormones (3). Even though the promoters of rat and man have many common elements, there are differences in numbers and placement, and some unique motifs exist in either one. We do not know if the salmon SR-BI promoters share the same regulatory elements as in rat and man, but promoters of other salmonid genes have shown that several common elements are conserved (55–57).

Metabolic responses to insulin occur at similar concentrations in salmonid hepatocyte culture to the expected range in hepatic portal insulin levels ($0.5 \times 10\text{-}9\text{–}15 \times 10^{-9}$ M) (27), and these cells have been shown to respond both to bovine and salmonid insulin (26, 28, 58). The stimulation of SR-BI mRNA expression we observed here occurred at a level above the physiological concentration of insulin. However, the interac-

tion between bovine insulin and the salmon insulin receptors may be weaker (reviewed in 59), and, therefore, higher concentrations may be required for activation of the receptor. Insulin has been shown to have an impact on lipid metabolism in mammalian hepatocyte cultures by influencing the secretion of several apolipoproteins (60-62). Hepatic SR-BI was reduced in hamsters after chronic infusions with insulin (23). In contrast, one study found that insulin increased the expression of SR-BI mRNA in rat theca-interstitial cells under both *in vivo* and *in vitro* conditions (63). Insulin has been shown to increase PPARγ2 expression in cultured mouse hepatocytes (64), and SR-BI expression increased in various cell types, including primary rat hepatocytes, in response to PPARγ agonists (65). However, we do not know anything about the underlying mechanisms for the increase in SR-BI expression in salmon hepatocytes observed here.

In the present study, there seemed to be a reduction in SR-BI mRNA levels for the hepatocytes treated with dexamethasone, but this was not significant, even though this synthetic glucocorticoid binds to the hepatic glucocorticoid receptor with high affinity in salmonids (25). Salmon hepatocytes were extremely sensitive (10^{-12} M and above) to dexamethasone in terms of inhibiting the response to growth hormone (26). In primary rat hepatocytes dexamethasone increased the expression of SR-BI and ABC transporter A1 (ABCA1), while it decreased the expression of both genes in a human hepatoma cell line (HepG2) (24). Effects of dexamethasone are both species and concentration dependent, and the range of dexamethasone we used here was much higher (250 μM) than in the studies mentioned above. Furthermore, we did not observe any regulation in SR-BI expression in response to either oleic acid or the PUFAs EPA and DHA, while in hamsters hepatic SR-BI mRNA and protein were enhanced in response to PUFAs (22).

In summary, there are many differences in regulation of SR-BI between species. So, even though the deduced salmon SR-BI protein had high similarity with SR-BI of other species and was expressed as a membrane protein in transfected cells, we cannot conclude that our clone is a functionally conserved HDL receptor. The high level of this transcript in the gut makes it tempting to propose that the SR-BI in salmon has an important function in the uptake of lipids from the intestine.

ACKNOWLEDGMENTS

The authors wish to thank Professor Harald Stenmark (Dept. of Biochemistry at the Norwegian Radium Hospital, Norway) for providing the anti-*myc* antibody. This work was carried out with support from The Research Council of Norway (153090/S40 and 135841/140).

Modification of Fillet Composition and Evidence of Differential Fatty Acid Turnover in Sunshine Bass *Morone chrysops* × *M. saxatilis* Following Change in Dietary Lipid Source

Ryan L. Lane, Jesse T. Trushenski, and Christopher C. Kohler*

Fisheries and Illinois Aquaculture Center and Department of Zoology, Southern Illinois University Carbondale, Carbondale, Illinois, USA

ABSTRACT: Marine oil-based finishing diets have been used to restore fillet FA profile in several "medium-fat" fleshed aquaculture species, and a simple dilution model describing FA turnover has been established to predict and tailor final fillet composition. We evaluated finishing diet efficacy and suitability of the dilution model to describe patterns of FA change in a lean-fleshed model, sunshine bass. Two practical diets (45% crude protein, 15% crude lipid) were formulated, respectively containing corn oil (CO) or menhaden oil (MO) as the primary lipid sources. Sunshine bass (age 1 [~14 mo], 347 ± 8.6 g, mean individual weight ± SEM) were stocked in a recirculating system and fed the diets according to different feeding regimens during the final 28 wk of the production cycle. Control groups were fed the CO or the MO feeds exclusively; whereas, the remaining treatment groups were transitioned from the CO diet to the MO diet at 4-, 8-, or 12-wk intervals. Upon completion of the feeding trial, fish were harvested, and production performance and fillet composition were assessed. Replacing MO with CO as the primary lipid source in sunshine bass diets yielded fillets with distinctly different FA profiles; however, finishing with a MO-based diet offered significant compensation for CO-associated reductions in fillet long-chain highly unsaturated FA (LC-HUFA). Although complete restoration was not observed, we achieved significant augmentation of endogenous n-3 FA within 4 wk of feeding the MO diet, and observed a significant increase in LC-HUFA and a beneficial shift in n-3:n-6 FA ratio after 8 weeks. Simple dilution accurately predicted tissue composition for most FA; however, deviations from the model were noted, suggesting selective retention of n-3, PUFA, and LC-HUFA and preferential catabolism of saturates. We conclude marine oil-based finishing diets can rapidly augment beneficial FA levels in sunshine bass fillets; however, simple dilution models do not fully describe selective FA metabolism observed for this lean-fleshed fish.

Abbreviations: CO, corn oil; FCR, food conversion ratio; HSI, hepatosomatic index; IP, intraperitoneal; LC-HUFA, long-chain highly unsaturated FA; MO, menhaden oil.

Marine oils derived from feed-grade, reduction fisheries often serve as the primary lipid constituents of aquaculture diets because of their high palatability to cultured animals, attractant properties, and historically widespread availability and competitive pricing. Unfortunately, exhaustive harvests and declining productivity of reduction fisheries (1) have caused marine oil prices to increase, along with pressure from conservationists to reduce use of marine animal-derived products (2). In addition to cost and availability issues, marine oils have recently been implicated as vectors of metals and various organic contaminants found in farm-raised fish (3), precipitating immense scrutiny of aquaculture from the scientific and lay communities. Although the validity of these concerns may be individually questioned (4,5), all professionals within fisheries and aquaculture recognize their cumulative impact and the limitations of capture fisheries in keeping pace with the growing demands of aquafeed production (5,6).

Sustainable expansion of aquaculture requires use of alternative lipid sources, but modified feed formulations may alter the final FA composition of cultured products and limit their nutritional value to human consumers. Marine oils contain substantial amounts of long-chain highly unsaturated FA (LC-HUFA, carbon chain length ≥20 and double bonds ≥3) that impart benefits beyond basic nutritive value (7,8) and have been shown to modulate a range of human health conditions (9,10,11,12). Tissue FA composition of fishes largely reflects the diet (13,14), and thus fillets of fish fed marine oil-based diets contain substantial amounts of bioactive LC-HUFA such as arachidonic (20:4n-6), eicosapentaenoic (20:5n-3), and docosahexaenoic (22:6n-3) acids. Conversely, oils derived from terrestrial plants do not contain these compounds, and reductions in LC-HUFA have been demonstrated following their incorporation in diets for sunshine bass *Morone chrysops* × *M. saxatilis* (15), rainbow trout *Oncorhynchus mykiss* (16), Atlantic salmon *Salmo salar* (17), gilthead seabream *Sparus aurata* (18), and red seabream *Pagrus auratus* (19). The functional nutritional value of these modified products is thereby reduced (20), linking alternative lipids with reductions in the nutritional benefit of consuming fillets from cultured fish.

To mitigate conflicting demands of sustainability and product value, aquaculture nutrition research groups have evaluated implementation of "finishing diets" at the end of the produc-

tion cycle to restore LC-HUFA content to fillets of several aquaculture species (6). Partial restoration of fillet LC-HUFA content was achieved using finishing diets in "medium-fat" species (approximately 2–8% lipid in fillet, fresh-weight basis [21]) such as turbot *Psetta maxima* (22) and Atlantic salmon (23–25). A simple dilution model (Fig. 1) has been used to describe FA turnover following dietary modification in these species (14,26–28), and has been suggested as a means of gauging feed management and finishing strategies to tailor final FA composition of cultured products. Although alternative lipid sources have been widely researched in many aquaculture species, finishing diets and FA turnover have not previously been evaluated using a lean-fleshed model (generally <2% [21]). Sunshine bass are interspecific hybrids of female white bass *Morone chrysops* and male striped bass *M. saxatilis* (reciprocal cross hybrid striped bass) and are widely cultured in freshwater systems for their mild-flavored, lean flesh. Accordingly, our objectives were to evaluate production performance and fillet composition of sunshine bass fed a low LC-HUFA content (plant-derived lipid) diet, tissue FA composition and turnover following implementation of a high-LC-HUFA content (marine-derived lipid) finishing diet, and the suitability of the established dilution model to describe patterns of FA change in this fish.

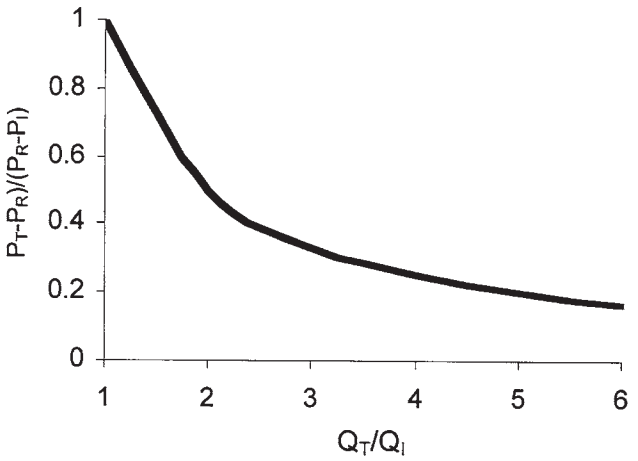

FIG. 1. Theoretical model of FA dilution within fish tissues following dietary change, where $(P_T - P_R)/(P_R - P_I)$ represents the ratio of relative change in fillet FA and Q_T/Q_I represents the relative change in total lipid (14).

EXPERIMENTAL PROCEDURES

Diet preparation and analyses. We formulated two isocaloric, isonitrogenous practical diets to contain 45% crude protein and 15% crude lipid (Table 1) and had them manufactured (extrusion processed, floating pellets) by a commercial aquafeed producer. Diets were formulated to meet all known nutritional requirements of growing sunshine bass (29) and differed only in lipid source. The formulations were designed to be generally characteristic of diets used in sunshine bass culture, but represent a plant-derived lipid "production diet" and a marine animal-derived lipid "finishing diet" to be evaluated during grow-out and at the end of the production cycle, respectively. The production diet utilized corn oil (CO) as the predominant lipid source, whereas the finishing diet contained menhaden (*Brevoortia* spp.) oil (MO), thus generating two distinct dietary FA profiles (Table 2). Although other plant-derived products such as canola and soybean oils possess greater 18-carbon n-3 FA content than corn oil, they do not provide LC-HUFA. We have previously observed the high levels of 18:3n-3 associated with these oils to complicate interpretation of fillet n-3 content with respect to the n-3 LC-HUFA of greatest functional nutritional value to human consumers (15). In this sense, corn oil serves as an excellent negative control with respect to n-3 FA content and was selected for its utility from a hypothesis-testing perspective. Proximate analyses of triplicate diet samples were conducted according to standard methods for analysis of animal feeds (30) for moisture (Official Method 930.15), crude protein (Official Method 954.01), and ash (Official Method 942.05). Crude lipid was determined gravimetrically according to the method of Folch *et al.* (31). Crude lipid samples were reserved for subsequent FA analysis (see section on FA analyses). Mean diet composition was confirmed as 9.6% moisture, 45.2% crude protein, 14.5% crude lipid, and 7.4% ash (dry matter, Table 1).

Experimental design and feeding trial. Before the study, feed-trained sunshine bass were obtained as fingerlings (Keo Fish Farms, Inc., Keo, AR, USA) and reared in-house to submarket size (age 1 [~14 months], 347 ± 8.6 g, mean individual weight ± SEM) on standard, commercial sunshine bass grow-out diets. The fish were then stocked into a water recirculation system consisting of 30 270-L tanks and associated mechanical and biological filtration units at six fish per tank.

The feeding trial (28-wk duration) consisted of five feeding regimen treatment groups using the CO diet, the MO diet, or temporal combinations of both diets (Fig. 2). To establish similar nutritional status and initial FA profiles, the fish were fed assigned diets for a 16-wk baseline period. After 16 wks, one fish was removed from each replicate tank, euthanized, and sampled to determine baseline FA profile. After collection of the baseline samples, the remaining 12 wk of the experimental period were divided into three 4-week intervals for finishing diet implementation. The positive control treatment was fed the MO diet and the negative control treatment was fed the CO diet for the duration of the 28-wk trial. Three interval treatment groups were initially fed the production diet, followed by implementation of the finishing diet at 4-, 8-, or 12-wk before harvest. The five treatments established over the 28-wk feeding trial—0 (CO control), 4, 8, 12, and 28 (MO control) wk of MO diet use—were each randomly assigned to six replicate tanks, with tanks serving as experimental units ($N = 6$). Fish were fed the appropriate diets every other day to apparent satiation, and any pellets remaining 1 h after feeding were removed and enumerated.

Temperature, dissolved oxygen (YSI Model 55 Oxygen Meter, Yellow Springs, OH, USA), and pH (WTW Model PH315i Handheld pH Meter, Weilheim, Germany) were mea-

TABLE 1
Formulation and Proximate Composition of Experimental Diets

	Dietary formulation	
	CO (production) diet	MO (finishing) diet
Ingredient[a]

[b]Includes FA with double bonds ≥2.
[c]Includes FA with carbon chain length ≥20 and double bonds ≥3.

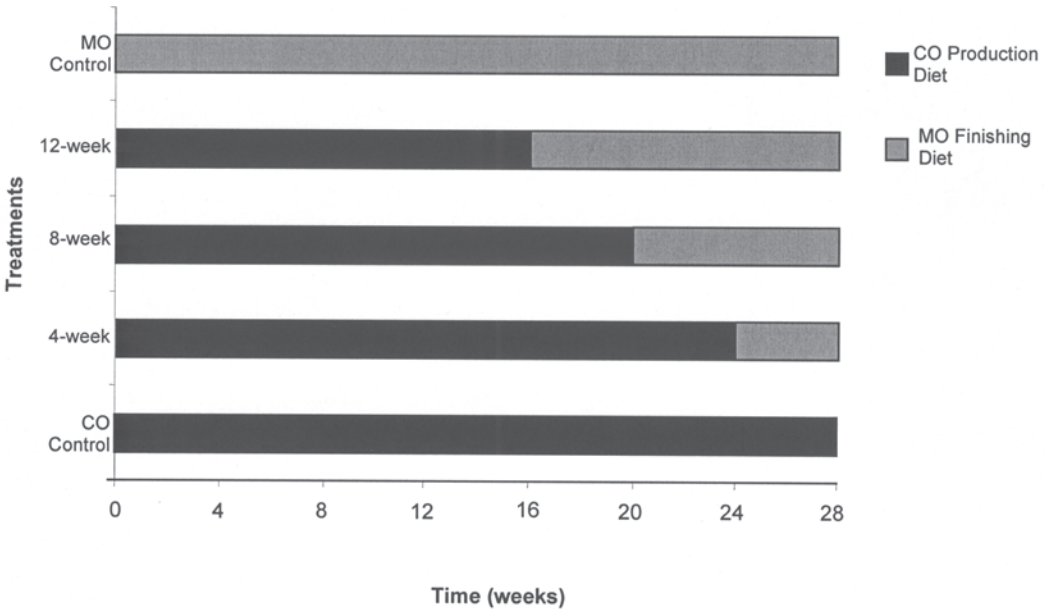

FIG. 2. Schematic representation of feeding regimen treatments with respect to timing of finishing diet implementation.

sured periodically and maintained at 24.0 ± 0.5ºC, 7.7 ± 0.2 mg L^{-1}, and 7.5 ± 0.3, respectively. Alkalinity (mg $CaCO_3$ L^{-1}), ammonia (mg NH_3-N L^{-1}), nitrite (mg NO_2-N L^{-1}), and nitrate (mg NO_3-N L^{-1}) were measured weekly (DR/2010 spectrophotometer and digital titrator, Hach Company, Loveland, CO, USA). All water quality parameters were maintained within ranges suitable for sunshine bass culture (32). All culture and husbandry methods, as well as euthanasia and sample collection procedures described below, were conducted under the direction and approval of the Southern Illinois University Institutional Animal Care and Use Committee, protocol No. 04-016.

Harvest, sample collection, and production performance. Fish were harvested from tanks, weighed, euthanized by single pithing, and immediately packed in ice before processing. Livers and intraperitoneal (IP) fat masses were dissected from the viscera to calculate hepatosomatic (HSI; liver weight/whole body weight*100) and liposomatic (IP fat weight/whole body weight*100) indices. Survival, percent weight gain ([average individual $weight_{final}$/average individual $weight_{initial}$]*100), and food conversion ratio (FCR; weight of food fed /weight gained) were calculated for each tank.

Fillets were harvested by one of four designated filleters, and dressout percentages were calculated as the ratio of the weight of skinless, boneless, J-cut fillets (without belly flap) to total weight of fish. One fillet from each fish was packaged in sterile, polyethylene bags (Whirl-pak®, Nasco, Fort Atkinson, WI, USA) and stored frozen (–80ºC) before proximate and FA analyses.

Proximate composition of fillet meat. Fillet samples were analyzed using standard methods (30) for meat products to determine percent moisture (Official Method 950.46), crude protein (Official Method 981.10), and ash (Official Method 920.153). Crude lipid content was determined using the method of Folch *et al.* (31). Crude lipid samples were reserved for subsequent FA analysis.

FA analyses. Crude lipid samples were subjected to acid-catalyzed transmethylation performed overnight at 50ºC as described previously by Christie (33). The resultant FAME were separated using a Shimadzu GC-17A gas chromatograph (Shimadzu Scientific Instruments**,** Kyoto, Japan) equipped with a flame ionization detector (FID) fitted with a permanently bonded polyethylene glycol, fused silica capillary column (Omegawax 250, 30 m × 0.25 mm i.d., 0.25 μm film). The injection volume was 1.0 μL, helium was the carrier gas (30 cm/s, 205ºC), and the injector temperature was 250°C. A split-less injection technique (100:1) was used, and the temperature program was as follows: 50°C held for 2 min, increased to 220°C at 4°C/min, and held at 220°C for 15 min. Individual FAME were identified by reference to external standards (Supelco 37 Component FAME Mix, PUFA-1, and PUFA-3; Supelco, Bellefonte, PA, USA). All solvents used were of HPLC grade and obtained from Sigma Diagnostics Inc. (St. Louis, MO, USA).

Evaluation of FA turnover and the dilution model. The dilution equation suggested as a generalized model of FA turnover in fishes (14,26–28) may be expressed as

$$P_T = P_R + (P_R - P_I)/(Q_T/Q_I)$$

where P_T is the percentage of a FA in a test fillet at time T following dietary change, P_I and P_R are the percentages of the same FA initially (before dietary change) and in a reference fillet (fed the initial diet throughout), and Q_I and Q_T represent total lipid (total FA) initially and at time T, respectively. To test the suitability of the dilution model for sunshine bass, we compared actual FA composition with the fillet composition predicted by the generalized dilution model using baseline and

harvest data from the MO control and 12-wk MO treatments. The model was previously shown to be relatively robust to using whole body masses as surrogate measures of Q_T and Q_I when total adiposity changed little over time (14). As the proximate composition of fillets did not differ among treatment groups or change considerably over the 12-wk finishing period, we substituted average baseline body mass (Q_B) and average mass at harvest (Q_H) for Q_I and Q_T, respectively.

Statistical analyses. Production performance, fillet proximate composition, and FA profile data were subjected to ANOVA within the GLM framework of the Statistical Analysis System, version 9.1 (SAS Institute, Cary, NC, USA) to determine if differences existed among feeding regimen treatment groups. Actual and predicted FA profiles of the 12-wk MO group were similarly analyzed using ANOVA to determine if observed FA abundance differed significantly from predicted levels. For all statistical analyses, individual tanks were used as experimental units, and variation among tanks within treatments was used as the experimental error to test for significance. Differences were considered significant at $P \leq 0.05$.

RESULTS

Feeding the CO diet during the baseline period significantly altered the FA profile of sunshine bass fillets, specifically reducing the level of n-3 and LC-HUFA in favor of n-6 and PUFA (double bonds ≥2), particularly 18:2n-6 (Table 3). After completion of the 16-wk baseline period, fillets of fish fed the CO diet (including CO control, 4-, 8-, and 12-week MO treatment groups) were significantly lower in 14:0, 16:0, 18:1n-7, 20:5n-3, and total saturates, and higher in 18:2n-6, total n-6, and total PUFA compared to fillets from fish that had been solely fed the MO diet (MO control group). Although some significant differences were observed among the CO fed treatment groups, that is, 16:1n-7, 22:5n-3, total n-3, total LC-HUFA, total bioactive LC-HUFA (20:4n-6, 20:5n-3, and 22:6n-3), and n-3:n-6 ratio; in general, these differences were numerically small and remained statistically distinct from the MO control group.

Implementation of the MO finishing diet during the final 12 wk of the experimental period significantly altered fillet FA composition, partially mitigating the effects of the CO diet on

fillet FA profile (Table 4). Although complete restoration (statistically equivalent to MO control group) was not observed, fillet 18:2n-6, 20:2n-6, 22:5n-3, total n-6, and total n-3 FA were significantly altered to reflect a MO-associated FA profile after a finishing period of 4 wk. After an 8-wk finishing period, significant restorative effects were observed for 14:0, 18:1n-7, 20:4n-6, 20:5n-3, 22:6n-3, total saturates, LC-HUFA, bioactive LC-HUFA, and n-3:n-6 FA ratio (Table 4). Fillet 16:1n-7 content also was observed to change following finishing diet implementation; however, significance was only noted after a finishing period of 12 wk.

Comparison of actual FA profile of fillets from the 12-wk MO group with the profile predicted by the model indicated simple dilution adequately described turnover for a majority of the dominant fillet FA; however, significant deviation from predicted values were noted (Fig. 3). Actual abundance greater than predicted values was observed for 20:2n-6, n-3, PUFA, LC-HUFA, and bioactive LC-HUFA, indicating selective retention of these FA classes. Conversely, saturates were less abundant than predicted by the model, indicating selective catabolism of these FA.

Equivalent production performance was observed among all treatment groups (Table 5). Survival (100 ± 0%, mean ± SEM), weight gain (206 ± 19%), food conversion ratio (1.7 ± 0.1), dressout (28 ± 0.4%), hepatosomatic (2.8 ± 0.1) and liposomatic (3.7 ± 0.5) indices were statistically equivalent among dietary groups and within acceptable ranges for sunshine bass production performance. Fillet moisture (75.3 ± 1.8%), crude protein (21.3 ± 1.2%), crude lipid (2.5 ± 0.5%), and ash (1.2 ± 0.1%) content were not affected by dietary treatment.

DISCUSSION

Replacing MO with CO as the primary lipid source in sunshine bass diet yielded fillets with distinctly different FA profiles (Table 3). However, finishing with a MO-based diet offered partial compensation for CO-associated reductions in beneficial fillet FA (Table 4). Use of the CO diet increased fillet n-6 and PUFA content at the expense of n-3 and LC-HUFA. These fillets were significantly lower in saturates and higher in PUFA, but this is primarily due to an approximately twofold increase in 18:2n-6 content. High levels of 18:2n-6 and reduced n-3 FA incorporation skewed the n-3:n-6 FA ratio heavily in favor of n-6 FA. This suboptimal ratio, coupled with markedly lower

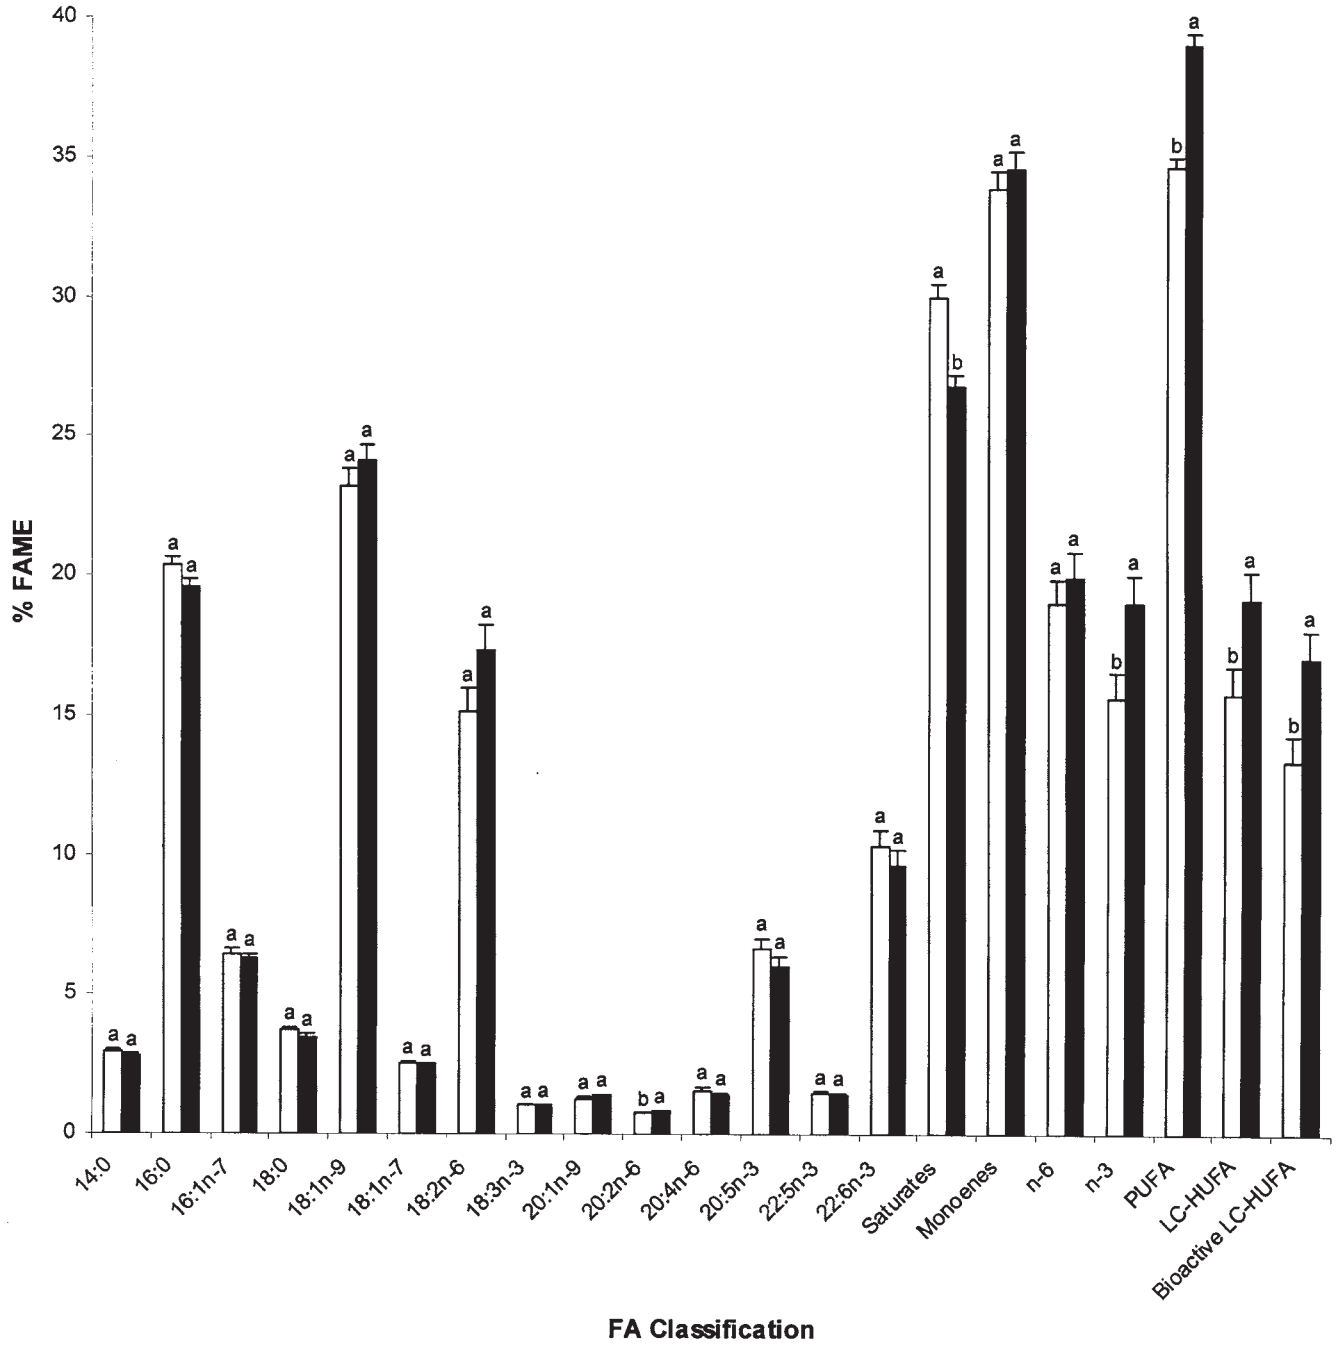

FIG. 3. Comparison of actual FA composition (relative mol%) of sunshine bass fillets (black bars) and predicted composition (white bars) based on the dilution model $P_{12} = P_R + (P_R - P_0)/(Q_H/Q_B)$ where P_0 and P_{12} are the percentages of a FA in the fillet before and after 12 wk of finishing diet implementation, P_R is the percentage of the FA in reference fillets from the MO control group, and Q_B and Q_H are the average body mass after completion of the baseline period and at harvest, respectively. Error bars represent ±SEM, and columns within FA classifications with common superscripts are not significantly different ($P \geq 0.05$).

levels of bioactive LC-HUFA, indicates these fillets would be of reduced functional nutritional value to human consumers. Implementation of the MO diet at the end of the production cycle had a restorative effect on fillet FA composition (Table 4), partially reversing the effects of using the CO diet. Significant restoration of endogenous n-3 FA was achieved within 4 wk of feeding the MO diet, and a significant increase in LC-HUFA and a beneficial shift in n-3:n-6 FA ratio was observed after 8 wk.

Finishing diets have been successfully used to augment MO-associated FA content of turbot (22) and Atlantic salmon (24,25) fed diets containing plant-derived lipids. Although the

negative effects of plant-derived lipid on fillet FA profile were partially reversed in these studies, the finishing period necessary to elicit significant compositional changes was longer (8–20 wk vs. 4–8 wk) for these species relative to our results. Moreover, many of these studies used diets containing in excess of 30% crude lipid, roughly twice the lipid content of the feeds we used to elicit similar composition changes.

Asymptotic dilution models suitably described FA turnover in Atlantic salmon (14,26), red seabream (27), and brown trout *Salmo trutta* (28), with rapid changes in fillet composition observed shortly after dietary modification giving way to diminishing effects over the growth period (Fig. 1). However, Jobling (14,26) cautioned the model, though apparently well-suited to medium-fat species, may not be appropriate for lean-fleshed fish. Structural phospholipids are dominant components of the lipid fraction in lean tissues, and it was suggested the relative unresponsiveness of the polar lipid fraction may cause FA turnover to deviate from the dilution model in these species (14,26). We found simple dilution accurately predicts tissue composition for most predominant FA, which are apparently deposited within muscle tissue with little-to-no specificity with respect to final tissue composition. However, deviations from the model were also noted, suggesting selective metabolism of certain FA classes (27). Specifically, we found total n-3 FA, PUFA, LC-HUFA, and especially bioactive LC-HUFA in greater than expected abundance, suggesting preferential retention of these FA; whereas actual levels of saturates were below predicted levels, suggesting preferential catabolism or deposition in other body compartments. Apparent processes of selective retention are further supported by differences in turnover rates observed for n-3, LC-HUFA, and bioactive LC-HUFA. Selective retention would imply faster turnover rates for FA selected for deposition compared to rates for other FA. Comparing the FA profiles of fillets from the CO control and the 4-wk MO treatments, the absolute percent change achieved after 4 wk of finishing diet use is consistently higher (mean 17%) for n-3, LC-HUFA, and bioactive LC-HUFA than other FA (mean 8%). Finally, it is important to note the preferentially retained FA classes were not those found in the greatest abundance in sunshine bass fillet polar fractions (namely 16:0, 18:1n-9, and 18:2n-6 [34]), and thus the selective processes we observed do not appear to be artifacts of greater total polar lipid. Accordingly, our results strongly suggest (1) n-3, PUFA, LC-HUFA, and bioactive LC-HUFA are selectively retained within sunshine bass muscle tissue; and (2) this process is functionally independent of changes in structural phospholipid elements during growth of muscle tissue.

Many fish species, including white bass *M. chrysops* (35), striped bass *M. saxatilis* (36), and their hybrids (37), have dietary requirements for 20:4n-6, 20:5n-3, and 22:6n-3 due to limited activity of appropriate enzymes to produce sufficient amounts of these bioactive LC-HUFA from 18-carbon precursors (38). Several groups have suggested limited endogenous and exogenous availability obliges moronids to conserve these FA (35,39–41). Our observation of bioactive LC-HUFA levels in excess of predicted values supports this hypothesis. The FA dilution model is adequate for estimating gross changes in fillet composition of fish species following dietary change; however, it does not appear to fully describe the pattern of FA turnover in lean-fleshed fish such as sunshine bass. Further experimentation carefully designed to address interspecific differences in biology, differences in gross dietary lipid content, and culture conditions is necessary to unequivocally define temporal patterns of FA change in fishes.

Nutritional and medical communities continue to recommend increasing human consumption of high-quality seafood to improve and maintain public health (42). With global seafood consumption at record highs and many food-grade

fisheries apparently static or in decline (1), aquaculture must assume a greater role in meeting seafood demand (43). Unfortunately, limited availability of high LC-HUFA-content feedstuffs places demands for increased quantity and quality of aquaculture products in juxtaposition. Partial or complete replacement of marine-derived lipid in aquafeeds reduces production costs, relieves harvest pressure on feed-grade fisheries, limits transfer and accumulation of contaminants, and reduces the environmental "footprint" of aquaculture. However, utilization of alternative lipids throughout the production cycle significantly alters fillet FA profile and reduces the functional nutritional value of cultured seafood products. By implementing finishing diets, aquaculturists may preserve or enhance the marketability of their products while decreasing production cost and dependence on finite resources. Although our results are promising, full realization of these goals will require the development of nutritional strategies to optimize fillet FA profile. Refining our understanding of FA turnover in fishes will provide the scientific foundation for successful application of these principles in aquaculture, and ultimately provide for optimal nutrition and management of aquatic livestock.

^{1}H and ^{13}C NMR Studies of Melon and Head Blubber of the Striped Dolphin (*Stenella coeruleoalba*)

P. Scano*, F. Cesare Marincola, E. Locci, and A. Lai

Dipartimento di Scienze Chimiche, Cittadella Universitaria di Monserrato, Monserrato, Italy

ABSTRACT: Intact portions of melon, the echolocation organ of the striped dolphin (*Stenella coeruleoalba*), and the corresponding raw oils were analyzed by means of one- and two dimensional ^{1}H and ^{13}C NMR techniques. For comparative purposes the tissue and the raw oil of head blubber were also examined. Complete assignments of the spectra were obtained. Furthermore, dynamics of the lipid components was investigated by means of ^{13}C NMR spin lattice relaxation time (T_1). Analysis of the data revealed that lipid molecules in the tissue compartments experience a liquid-like microenvironment and that T_1 values depend on the lipid composition and/or organization in the intact tissue framework. In particular, a dependence of the T_1 values on the wax esters content in melon intact tissues was found. A possible correlation between dynamic parameters and sound propagation properties has been hypothesized.

Paper no. L9981 in *Lipids 41*, 1039–1048 (November 2006).

It is well known that odontocetes echolocate by producing clicking sounds and then receiving and interpreting the resulting echo. The melon, the rounded region of the dolphin's forehead, is instrumental to echolocation; it has been hypothesized to act as an acoustic lens that focuses the sound waves, produced in the monkey lips/dorsal bursa (MLDB) complex, into a beam, which is projected forward, into the aqueous medium in front of the animal (1).

The melon of odontocetes contains very unusual lipid components, referred to as "acoustic fats," that differ from those of the blubber and other body fats (2,3). In the case of adult individuals of *Stenella coeruleoalba* (order Cetacea, suborder Odontoceti, family Delphinidae), morphological analysis has shown that the melon is mainly composed by an adipose tissue, with closely related voluminous cells, and a muscle component that progressively fades from the basal toward the upper sections (4). The lipid components belong to two main classes: triacylglycerols (TAG) and wax esters (WE), composed by high concentrations of iso-branched fatty acids and fatty alcohols, among which isovalerate (iso5:0) is the most abundant. The remaining fatty components are linear with chain of C10–C18 average length, and have a low degree of unsaturation (2–4). It has been demonstrated that the relative amounts of fatty molecules change greatly within the organ (5). Comparative studies on blubber fats have shown that they lack WE, exhibit a lower concentration of iso5:0, a higher unsaturation degree, and are composed of longer chain acids (C14–C22) (3,6).

Several investigations have suggested that the acoustic properties of the melon of odontocetes are due to its peculiar and heterogeneous lipid molecular composition and organization in the tissue framework (5,7–9). In this connection, areas with different lipid composition have been shown to exhibit different sound properties (5,7). Furthermore, several studies demonstrated that sound velocity in lipid mixtures from acoustic tissues of porpoises is influenced by changes in the ratio of WE to TAG (5,8), and that short and branched fatty acids have lower sound velocities compared to long- and straight-chain fatty acids (8,9). In particular, the *sn*-1,3 position of iso5:0 in TAG was suggested to be critical for modulating density and compressibility, which are properties correlated with sound transmission (6,7,10).

The above statements drive to the consequence that the molecular composition and organization *in situ* may hold clues to the acoustic properties of melon; therefore, studies on these acoustic fats should be performed on intact tissues. Nevertheless, most of the investigations of the acoustic tissues of odontocetes have been so far performed by using invasive techniques involving extraction and fractionation of the molecular components, thus destroying the structural organization of the tissues. NMR spectroscopy offers instead the opportunity of studying heterogeneous lipid mixtures, oils, and depot fats noninvasively and nondestructively (11–17), thus allowing investigations of composition and dynamics of the three-dimensional "packing" of lipids in intact tissues.

In a previous study we used the ^{13}C NMR technique to investigate intact tissue samples of melon of *Stenella coeruleoalba*, providing information on their lipid components at a qualitative and quantitative level (4). In the present work, we extend the use of the NMR spectroscopy to obtain a deeper insight into the lipid components both in intact tissues and in raw oil samples of melon of *Stenella coeruleoalba*. For comparative purposes also samples of tissue and raw oil of head blubber are examined. Compositional and structural details of the lipid matrix are obtained by performing ^{1}H and ^{13}C one-dimensional and two-dimensional heteronuclear single quantum correlation (HSQC) and heteronuclear multiple bond cor-

relation (HMBC) NMR experiments on the tissues and the corresponding raw oils. Furthermore, to gain an understanding of the dynamic properties of the lipid components in the intact tissue, where the three-dimensional arrangement is preserved, ^{13}C spin-lattice relaxation times (T_1) are measured in samples of melon and blubber tissues.

EXPERIMENTAL PROCEDURES

Samples preparation. Melon and head blubber tissue samples were kindly donated by the Department of Cytomorphology and the Department of Experimental Biology, University of Cagliari, Italy. They were dissected from three adult individuals of striped dolphins, *Stenella coeruleoalba*, found stranded and recently dead along the Mediterranean coasts. The melon and blubber were excised within 24 h from the finding of the stranded dolphins and divided in tissue specimens. For each individual, two samples of melon, obtained at different depths of the organ, were collected. Only one sample of head blubber was available. Samples were placed in 10-mm NMR tubes, rapidly frozen at –80°C, and stored before the NMR experiments. Since tissue samples are easily perishable they were examined only once.

The raw oils from samples of melon and of head blubber were obtained by mild pressing of the tissues. Compared to the melon, a larger amount of blubber tissue was needed to obtain an appreciable quantity of oil for NMR experiments.

NMR spectroscopy. ^1H and ^{13}C NMR spectra of intact portions of tissue were recorded on a Varian VXR 300 spectrometer (Palo Alto, CA) equipped with a 10-mm broadband probe at the resonance frequency of 299.93 and 75.42 MHz, respectively. The experiments were run at 25°C, unlocked and without rotation. ^1H spectra were acquired with a sweep width of 4 KHz, and 16 scans, 1-μs pulse width and 2-s delay. Quantitative ^{13}C spectra were acquired using the NOE suppressed, inverse gated proton decoupled technique (Waltz-16), with a 1-s acquisition time, a sweep width of 19 KHz; 500 scans were collected using a 90° pulse angle and a 35-s relaxation delay to allow all the carbon atoms to completely relax. Chemical shifts were externally referenced to tetramethylsilane (TMS; $\delta = 0.00$ ppm).

The raw oils dissolved in $CDCl_3$ (~50:50 vol/vol) were examined in 5-mm NMR tubes on a Varian UNITY INOVA 400 spectrometer at 25°C. The ^1H spectra were obtained at the frequency of 399.94 MHz, with a sweep width of 6 KHz and 16 scans. The ^{13}C spectra were acquired at the frequency of 100.56 MHz with a 2-s acquisition time, using a sweep width of 26 KHz; 500 scans were collected using a 90° pulse angle and a 30-s relaxation delay. Two dimensional ^1H-^{13}C HSQC and HMBC NMR experiments (18,19) were performed at 25°C with sweep widths of 3 KHz and 21.1 KHz in the proton and the carbon dimensions, respectively, 256 increments, 32 scans, and 2 K data points.

^{13}C spin-lattice relaxation times (T_1) were measured using the inversion-recovery (180-τ-90) pulse sequence (20), with τ values ranging from 0.01 to 30 s in 12 steps.

RESULTS AND DISCUSSION

^1H NMR spectra. Figure 1 shows the ^1H NMR spectra of one sample of intact tissue of melon and head blubber of *Stenella* (a and b, respectively) and those of the corresponding raw oils dissolved in $CDCl_3$ (a^1 and b^1). Despite the broadening of the tissue resonances, due to the semisolid nature of samples, the pattern of signals of each tissue is similar to that of the corresponding raw oil, except for the presence of the resonance at approximately 4.7 ppm attributed to water present in the tissue. Since the signal broadening of the tissue spectra makes the resonance assignments difficult, the identification of lipid components was made on the oil spectra according to the literature (11–13). Chemical shift assignments are reported in Table 1. The analysis of the ^1H NMR spectra evidences that all samples exhibit signals mainly from TAG, and, in the case of melon, also from WE. No molecular components such as those of connective and muscle tissues were detected, since their reduced molecular mobility broadens the signals beyond the detection threshold of the NMR spectrometer.

Comparison between the spectra in Figure $1a^1$ and b^1 shows that the oil of melon has a lower unsaturation degree (signals H-1, H-6, and H-12) than that of blubber, the latter being rich in HUFA (highly unsaturated fatty acids) (signals H-7 and H-13). Furthermore, NMR resonances assigned to iso-branched acyl groups in TAG or WE (signals H-9, H-11, H-15, H-17, H-19, and H-21) have lower intensities in blubber oil spectrum than in that of melon. Finally, signal H-5, assigned to the methylene alcoholic group in WE, and signal H-10, ascribed to isovalerate esterified in WE, are absent in the blubber oil spectrum, thus evidencing the lack of wax components.

^{13}C NMR spectra. The ^{13}C NMR spectra of melon and blubber intact tissues together with the corresponding diluted raw oils are shown in Figures 2 and 3, respectively. It is worth noting that the ^{13}C NMR spectra of both tissues exhibit a good resolution, showing general features similar to those of the corresponding oils.

In our previous study (4), chemical shift assignments of the ^{13}C NMR spectrum of the melon tissue were accurately performed only for alkyl carbons, since signals in the carboxyl and olefinic regions were markedly overlapped. In the present work, complete and detailed signal attributions for both melon and blubber spectra were obtained by comparing the tissue and the corresponding oil spectra and with the aid of the literature data (14–17). Furthermore, additional information were obtained by using the HSQC and HMBC NMR techniques. Chemical shift assignments of the ^{13}C spectra melon tissue and oil are reported in Table 2. As to the signals in the carboxyl region, the following detailed attributions were made: signal C-1 originates from waxes esterified with isovaleric acid; signal C-2 arises from acyl groups, other than isovalerate, in TAG *sn*-2 position; signal C-3 from isovalerate in TAG *sn*-1,3 positions. Moreover, in the olefinic region, signals C-5 and C-6, which are well separated in the oil spectrum, were attributed to the olefinic carbons of monounsaturated acyl groups in TAG or WE. The remaining olefinic resonances were assigned to

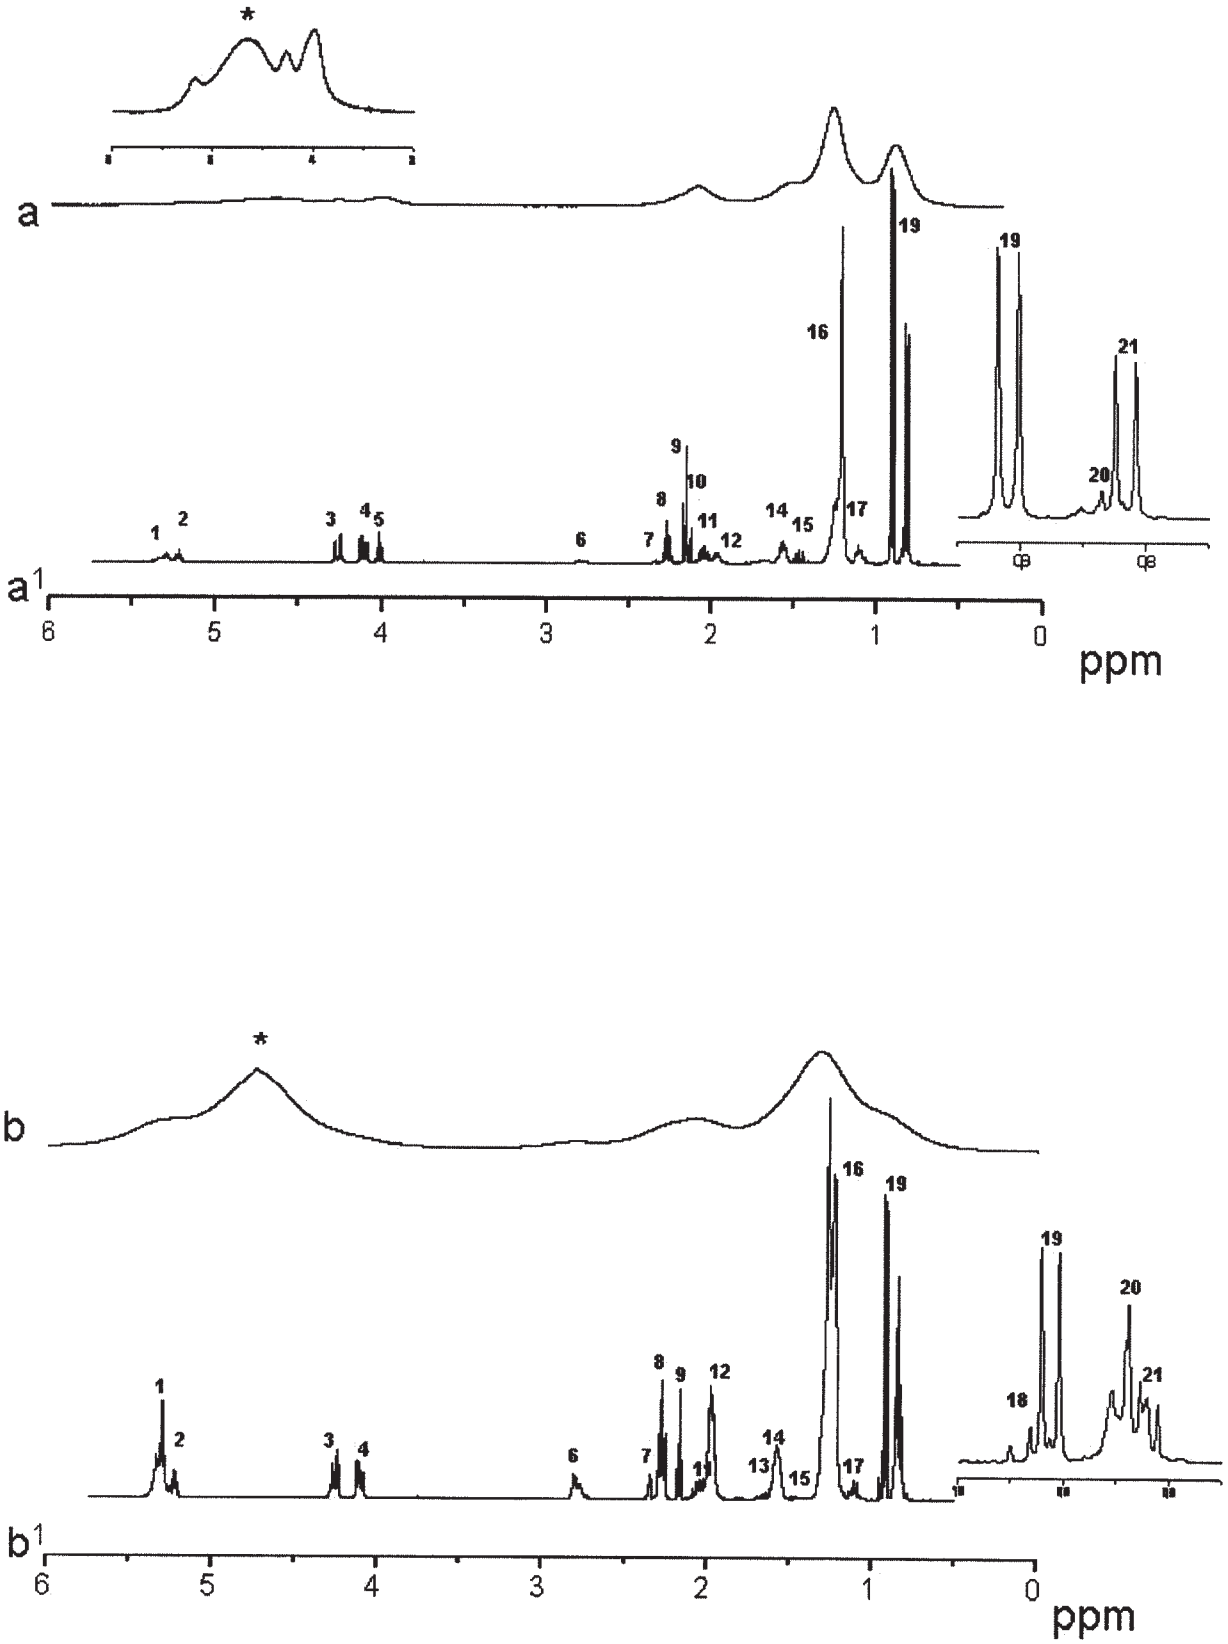

FIG. 1. ^{1}H NMR spectra of samples of intact tissue of melon (a) and head blubber (b) of *Stenella* and the corresponding oils in $CDCl_3$ (a^1 and b^1, respectively). Assignments of the numbered resonances are reported in Table 1. The asterisk indicates the water signal.

polyunsaturated acyl groups in TAG or WE, among which n-3.

Figures 4 and 5 show the ^1H-^{13}C HSQC and HMBC NMR spectra, respectively, of the melon raw oil. The HSQC experiment correlates protons with their directly attached carbons, whereas the HMBC allows correlations two or three bonds apart.

In Figure 4 cross-peaks between the oxygenated carbons (signals C-9, C-10, and C-11) and the directly attached protons (H-2, H-5, H-3, and H-4) in the respective glyceryl regions can be clearly seen, together with connections of the ^{13}C and ^1H signals of the methylene groups of isovalerate (C-12 and C-13, with H-9 and H-10), and methylene in ω3 position in iso-branched acyl groups (C-14 with H-17). A portion of the

[d]Not detected.
[e]The monounsaturated and the polyunsaturated fatty acids and alcohols contents were measured from a deconvolution procedure applied to the olefinic region and normalized to the area of the carbonyl signals.
[f]The contents of isovaleric, isobranched, and linear fatty acids and alcohols were measured from normalized areas of C-12 and C-13, C-14, C-28 signals in Figure 2a, and areas of C-22, C-23, C-36, and C-37 signals in Figure 3a.
[g]Present only as fatty acid.

HMBC spectrum is shown in Figure 5. Here, two bonds apart, correlations between the carbonyl carbons and the protons of the methylene groups of isovalerate and of the remaining acyl groups are observed (cross-peaks between C-1, C-2, C-3 and H-10, H-8, H-9, respectively). These results, together with the observed correlations between C-1, C-2, C-3 and H-5, H-2, H-3 and H-4 signals, respectively (not shown in Fig. 5), permitted to fully assign signals in the carbonyl region of the melon raw oil ^{13}C spectrum.

Chemical shift attributions of ^{13}C NMR spectra of intact blubber tissue and the corresponding oil are reported in Table 3. From the analysis of the HSQC and HMBC spectra (spectra not shown) the following attributions in the carbonyl region were made: C-1 and C-2 signals were ascribed to carboxyl carbons of acyl groups other than isovalerate and DHA, in the *sn*-1,3 and *sn*-2 positions of TAG, respectively, while C-3 corresponds to the carboxyl carbons of isovalerate and DHA in the *sn*-1,3 positions of TAG. Moreover, the intense C-6 and C-8 signals in the olefinic region originate from the olefinic carbons in Δ9 monounsaturated acyl groups, the remaining signals were attributed to PUFA, DHA, and EPA acyl groups in TAG. Interestingly, in the glyceryl region an additional signal (C-21) attributed to the methylene carbon of glycerol esterified with isovalerate appears besides the characteristic resonances of glycerol methine (C-19) and methylene carbons (C-20). It is worth noting that the *sn*-1,3 positions of isovalerate in TAG in both blubber and melon was previously observed in odontocete blubber and acoustic oils (10).

Information on the lipid composition of melon and blubber tissues was obtained by the analysis of the integrated areas in the corresponding ^{13}C NMR spectra. The relative percentages of the different classes of fatty components are reported in Table 4. As far as the melon samples are concerned, a high variability of all the lipid components is observed. Furthermore, by comparing data from melon and blubber tissues, significant differences occur; indeed, blubber does not contain WE and exhibits more unsaturated lipids and less isobranched acyl groups than the melon. These results are in good agreement with previous data obtained by methods that involved preliminary solvent extraction of lipids from the tissues (2,3,6,21).

^{13}C spin-lattice relaxation. Dynamics of lipid components in melon tissue, its undiluted oil, and blubber tissue of the same individual were investigated by measuring the ^{13}C spin-lattice relaxation times, T_1 (Table 5). It is worth reminding that the relaxation times of the ^{13}C nucleus are dominated by the dipolar interaction with the covalently attached protons and give specific information on the mobility of the molecular groups (20). Generally, taking into account the number of directly attached protons, larger T_1 values indicate a higher mobility.

In Table 5 it can be observed that T_1 values measured in melon tissue and in oil are very similar, even if differences occur for the carboxyl carbons in TAG and WE. These results indicate that the lipids arranged in the melon tissue and in the oil exhibit a similar dynamic behavior, thus suggesting that the lipid molecules in the tissutal framework experience an overall liquid-like microenvironment with no significant restriction in their segmental mobility.

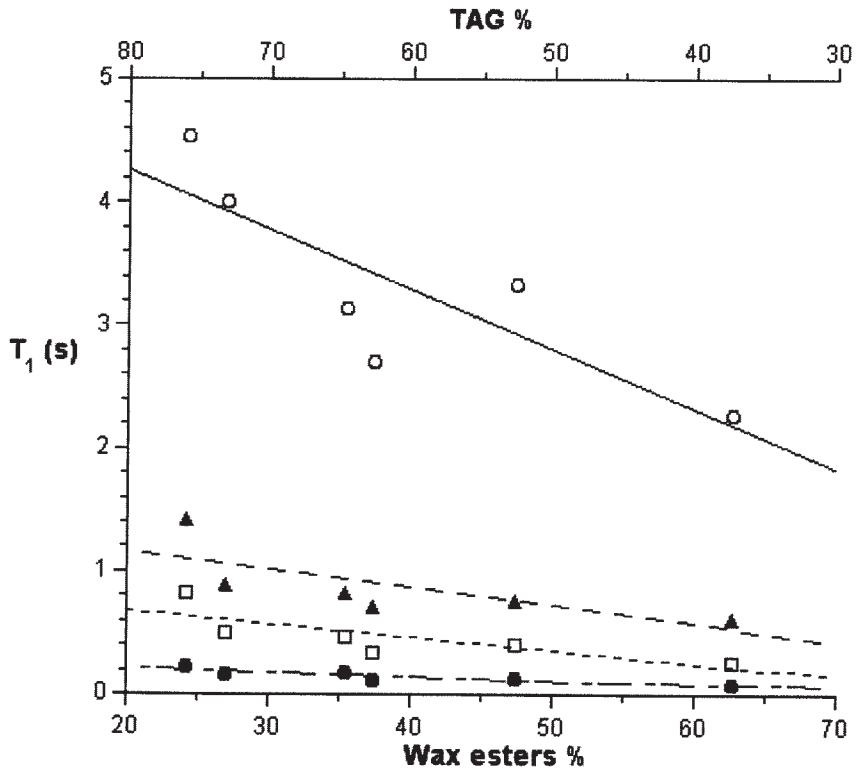

FIG. 6. ^{13}C NMR spin-lattice relaxation (T_1) vs. lipid composition for six samples of melon intact tissue of *Stenella*. The WE and TAG contents were obtained by the semiquantitative analysis of the ^{13}C NMR spectra. Symbols refer to signals in Figure 2: ○, signal 28 (-CH_3 in linear acyl groups); ▲, signal 14 (ω3 in isobranched f.a); □, signal 10 (-CH_2-OOC- in WE); ●, signal 11 (-CH_2-OOC- in TAG).

A comparison between the relaxation data of lipids in the melon and blubber tissues shows that a slight but systematic decrease of T_1 values occurs in the latter. This finding points to slower motions of fatty molecules in blubber than in melon tissue and may be ascribed to differences in the composition, although lipids experience a liquid-like environment also in blubber tissue.

To study the dependence of relaxation on the lipid composition in the tissutal framework, the ^{13}C spin-lattice relaxation times were measured in the six samples of melon intact tissue. In Figure 6 the T_1 values of selected well-resolved signals are reported as a function of WE and TAG relative contents. It can be seen that T_1 values decrease linearly as a function of the WE content increase, with a more pronounced slope for the -CH_3 functional groups. No linear dependence was observed for the other fatty components here examined. Therefore, in the light of these results it can be asserted that a more restricted mobility of lipids is induced by the increase of WE molecular components. Previous studies based on acoustic techniques demonstrated that also the sound properties of mixtures of lipids are influenced by the WE content, the increase of which appeared to decrease the ultrasonic velocity (7,8). The dependence of dynamics and sound properties of these acoustic lipids on the WE content suggests that this molecular component plays an important role in determining the heterogeneous three-dimensional map of lipid composition and sound velocity that makes the melon of odontocetes act as an acoustic lens.

In conclusion, this investigation demonstrates that NMR is a powerful tool for the study of composition and dynamics of the lipid matrices in intact tissues. Future works will be addressed to elucidate possible correlations between composition, dynamics, and acoustic properties in lipid matrices, thus contributing to shed light on the mechanism of the echolocation system in dolphins.

ABSTRACT: Enhanced intramuscular fat content (i.e., marbling) in beef is a desirable trait, which can result in increased product value. This study was undertaken with the aim of revealing biochemical factors associated with the marbling trait in beef cattle. Samples of *longissimus lumborum* (LL) and *pars costalis diaphragmatis* (PCD) were taken from a group of intact crossbred males and females at slaughter, lipids extracted, and the resulting FAME examined for relationships with marbling fat deposition. For LL, significant associations were found between degree of marbling and myristic (14:0, $r = 0.55$, $P < 0.01$), palmitic (16:0, $r = 0.80$, $P < 0.001$), stearic (18:0, $r = –0.58$, $P < 0.01$), and oleic (18:1c-9, $r = 0.79$, $P < 0.001$) acids. For PCD, significant relationships were found between marbling and palmitic ($r = 0.71$, $P < 0.001$) and oleic ($r = 0.74$, $P < 0.001$) acids. Microsomal fractions prepared from PCD muscle were assayed for diacylglycerol acyltransferase (DGAT), lysophosphatidic acid acyltransferase (LPAAT), and phosphatidic acid phosphatase-1 (PAP-1) activity, and the results examined for relationships with degree of intramuscular fat deposition. None of the enzyme activities from PCD displayed an association with marbling fat content, but DGAT specific activity showed significant positive associations with LPAAT ($r = 0.54$, $P < 0.01$), total PAP ($r = 0.66$, $P < 0.001$), and PAP-1 ($r = 0.63$, $P < 0.01$) specific activities. The results on FA compositions of whole muscle tissues provide insight into possible enzyme action associated with the production of specific FA. The increased proportion of oleic acid associated with enhanced lipid content of whole muscle is noteworthy given the known health benefits of this FA.

Paper no. L9916 in *Lipids 41*, 1049–1057 (November 2006).

The production of beef carcasses with high degrees of intramuscular fat deposition (i.e., marbling) is best achieved by the identification and selection of cattle with the genetic potential to efficiently deposit marbling fat, which contributes to beef flavor, texture, and quality grade (1). It is thought that selection for these animals might reduce the feeding period required to attain a high degree of marbling, while also having the effect of reducing fat accumulation in depots that impact the lean meat yield of the carcass. To achieve this goal, cow/calf producers require the information and tools to select herd sires and dams that will pass on the genetic predisposition for marbling to calves. Marbling is a heritable trait (2). Selection progress is most rapid when suitable herd animals can be identified at a relatively young age. The use of biochemical or genetic markers from samples of tissue greatly increases the rate of selection progress, especially if the marker(s) have predictive value early in the animal's life. The identification of suitable genetic or biochemical markers that can be applied in marker-assisted selection protocols will enable the beef industry to respond more efficiently and effectively to the market-driven demand for well-marbled beef.

Previous studies examining the possible relationship between marbling and the activity of fat-metabolizing enzymes and the FA composition of fat have been conducted using Japanese black hybrid cattle (3–5), which are known for their enhanced propensity to marble (6). These early studies used the readily accessible *pars costalis diaphragmatis* (PCD) (skirt muscle of diaphragm) as a source of enzymes rather than ribeye muscle (i.e., the *longissimus*), which was not accessible in a commercial abattoir situation until after extensive chilling of the carcass. Positive associations found previously in three separate studies (correlation coefficients, r, from 0.47 to 0.51, $P < 0.05$) between the fat content of the skirt muscle and ribeye suggested that the skirt muscle could serve as an appropriate source of stable enzyme activity (3–5). At least three biochemical properties associated with intramuscular fat content at maturity in Japanese black hybrid cattle have been identified (3–5). Two of these components are enzyme activities. Diacylglycerol acyltransferase (EC 2.3.1.20, DGAT) catalyzes the final step in the *sn*-glycerol-3-phosphate pathway leading to TAG, whereas hormone-sensitive lipase (EC 3.1.1.79, HSL) catalyzes the first step in the degradation of fat. DGAT activity

Abbreviations: DGAT, diacylglycerol acyltransferase; HIP, hexane/isopropanol; HSL, hormone-sensitive lipase; LL, *longissimus lumborum*; LPAAT, lysophosphatidic acid acyltransferase; NEM, *N*-ethylmaleimide; PAP, phosphatidic acid phosphatase; PAP-2, phosphate phosphohydrolase; PCD, *pars costalis diaphragmatis*; SM, *semimembranosus*; TEL, total extracted lipid.

from intramuscular fat tissue appeared to decrease with increasing whole muscle fat content (3) whereas HSL activity in whole muscle increased as the whole muscle fat content increased (5). HSL activity of whole skirt muscle is positively associated with the fat content of both skirt and ribeye muscle. Myristic acid (14:0), although a minor constituent of fat, displayed a positive association with whole muscle fat content for both the skirt muscle and ribeye from Japanese black hybrid cattle (4).

The current study focused on the evaluation of FA composition of *longissimus lumborum* (LL) and PCD muscles as it relates to fat content of the muscles. Activities of DGAT, lysophosphatidic acid acyltransferase (LPAAT), and phosphatidic acid phosphatase (PAP) from PCD microsomes, key enzymes associated with intramuscular fat formation in bovine muscle, were also determined and evaluated with respect to possible associations with PCD lipid content.

EXPERIMENTAL PROCEDURES

Maintenance of cattle. The cattle in this study were from the offspring (F_1) generation of the Canadian Beef Cattle Reference Herd, established at the University of Saskatchewan to study the genetic basis of live animal, carcass, and meat quality traits (7,8). The herd consisted of a parental generation composed of Angus, Belgian Blue, Charolais, Horned Hereford, Polled Hereford, Limousin, and Simmental breeds, which were used to develop an offspring generation of crossbred families. The F_1 animals thus represented a population of 17 different types of crossbred cattle, representing a wide range of genetic diversity that was ideally suited to the further study of biochemical markers for the marbling trait. The cattle in this study included intact males and females and were cared for according to guidelines set by the Canadian Council on Animal Care (9).

Animals from the F_1 generation of the herd were fed in a manner consistent with typical western Canadian beef production. Calves were weaned between 150 and 180 d of age and, after an initial period (272 ± 12 d) of background feeding, animals were placed on a finishing diet (89 ± 8 d) prior to slaughter. The initial diet, formulated for 11.8 megajoules (MJ) digestible energy per kilogram dry matter and 12.5% (all diet percentages w/w) crude protein, contained 41% barley silage, 33.5% brome hay, 15% barley grain, 8.8% canola meal, 0.5% tallow, 0.5% $CaCO_3$, 0.5% mineral supplement, 0.1% vitamin supplement, and 0.1% salt. The finishing diet, formulated for 14.9 MJ digestible energy (kg dry matter)$^{-1}$ and 12.5% crude protein, comprised 78.8% barley grain, 11% barley silage, 4.9% canola meal, 3.6% tallow, 0.9% $CaCO_3$, 0.4% salt, and 0.4% vitamin supplement.

Procurement and storage of samples. Animals were stunned by pneumatic captive bolt, exsanguinated, and dressed in a simulated commercial manner. Immediately following exsanguination a small cut was made in the hide of the animal, immediately posterior to the last rib, approximately 12 cm off the midline of the back. A sharpened cork borer (37 mm diameter) was inserted perpendicular to the hide, to a depth of approximately 8 cm. The muscle core was removed, and the subcutaneous fat was trimmed from the core prior to freezing in liquid nitrogen. Following removal of the LL core, the right *semimembranosus* (SM) muscle was accessed along the rear inside of the right leg, approximately 10 cm distal to the aitch bone. A cut was made through the hide, and through the overlying *gracillis* muscle. The core was then removed from the central portion of the SM, approximately one-third of the way down the length of the muscle from the proximal end with a 37-mm sharpened cork borer. The standardization of the location of the cores was confirmed following post-mortem dissection of the muscles.

Approximately 10 g of PCD muscle was sampled immediately following gutting, from the medial crus of the diaphragm at the level of the 10th thoracic vertebrae from within the abdominal cavity. All muscle samples were immediately frozen in liquid nitrogen and held frozen at –80°C until processed for lipid extraction and microsome preparation. After 24 h, the left sides of each carcass were fully evaluated for grade characteristics, including the assessment of American Meat Science Association (AMSA) marbling scores by an experienced meat quality biologist, who has over 20 yr of experience in carcass assessment and who is also a certified Canadian Beef Grading Agency grader. A photographic reference scale describing the various levels of marbling was used (Official USDA Marbling Photographs, National Livestock and Meat Board, Chicago, IL).

Lipid analysis. Following grading, samples of LL and SM muscles were collected from the left sides of all carcasses (n = 126). Following a week of vacuum-packaged storage at 2°C, muscle samples were ground three times [Butcher Boy Meat Grinder Model TCA22 with a 1/8-in. grind plate (Lasar Manufacturing Co., Los Angeles, CA)]. One hundred grams of the grind were weighed into stainless steel beakers and placed in a gravity convection drying oven (Model 1370FM; VWR Scientific, Mississauga, Ontario, Canada) at 105°C for 24 h. Beakers were removed from the oven, final masses recorded, and moisture losses calculated. The dried samples were pulverized to a fine grind and crude fat content determined by petroleum ether extraction (Tecator Soxtec System HT-1043; Tecator Ltd., Hoganas, Sweden).

A subset of 22 animals, representing the range of marbling from all available samples, was chosen for further FA and muscle enzyme activity analysis. These tissues were chosen solely on the basis of carcass marbling score and represented the following ranges: marbling score 100–290 (“devoid” and “practically devoid” of marbling), n = 5; marbling score 300–390 (“traces”), n = 3; marbling score 400–490 (“slight”), n = 4; marbling score 500–590 (“small”), n = 6; and marbling score 600–690 (“modest”), n = 4. Hexane/isopropanol (HIP) lipid extraction, methylation, and FA analysis by GC (4) were performed on PCD and LL muscles from this subset. Relative proportions, calculated as mol%, of all known FA were then statistically compared with measures of intramuscular fat (i.e., marbling score and lipid extraction data from both muscles) using the Pearson product-moment correlation method

(10) to identify FA exhibiting associations with the marbling trait.

Enzyme activity analysis. Microsomal fractions were prepared by differential centrifugation as described previously (3). Microsomes were prepared from the PCD muscle from the animals (n = 22, same subset as above). Microsomal protein content was determined using the Bio-Rad protein microassay (Hercules, CA) with BSA as the standard. All protein and enzyme assays were performed in triplicate. DGAT assays were performed as previously reported by Middleton *et al*. (3). PAP assays were conducted in the presence and absence of 0.5 mM *N*-ethylmaleimide (NEM) in order to distinguish between PAP-1 and PAP-2 activities (11,12). LPAAT assays were performed on microsomal fractions from the PCD muscle based on the assay published by Schlossman and Bell (13). As with the FAME analyses, enzyme specific activities were analyzed with respect to measures of intramuscular fat content for possible associations between enzyme activity and marbling fat deposition.

RESULTS AND DISCUSSION

While not necessarily conducive to the deposition of extensive amounts of intramuscular fat, the animals in this study were killed at a constant age because this allowed for a meaningful assessment of the variation in slaughter traits without having a measured trait as the factor that determined end point (e.g., through body weight or live ultrasound measurement). This strategy, as well as the inclusion of bulls (as opposed to steers) in the study, led to somewhat lower marbling scores in the experimental animals than those in typical North American commercial slaughters. The range in intramuscular fat deposition, as measured through both solvent extraction and marbling score, is shown in Figure 1.

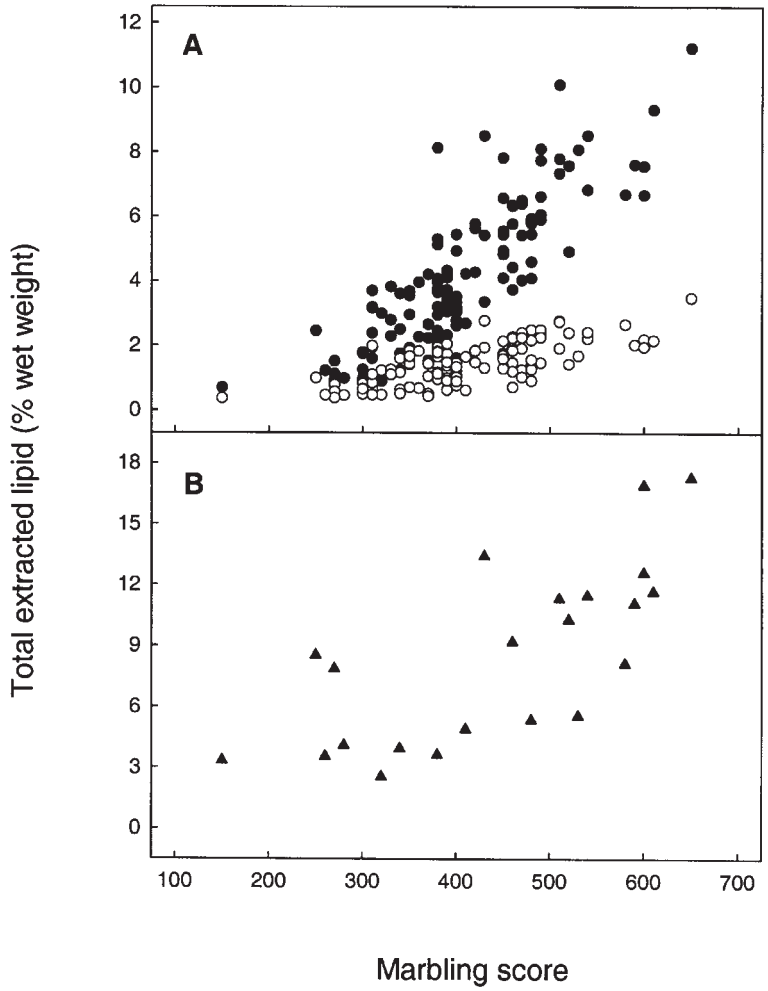

FIG. 1. Relationship between carcass marbling score and the amount of fat extracted from several bovine muscles. Panel A: Data from *longissimus lumborum* (●) and *semimembranosus* (○) muscles (n = 126). Panel B: Data from *pars costalis diaphragmatis* muscle (▲) from the subset of animals used for analyses of FA compositions and enzyme activities (n = 22). Pearson correlation coefficients (r) for the relationship between the lipid extract data and marbling score were 0.83 ($P < 0.0001$) for *longissimus lumborum,* 0.70 ($P < 0.0001$) for *semimembranosus,* and 0.73 ($P < 0.001$) for *pars costalis diaphragmatis.*

Association of total extracted fat with marbling score. Previous investigations of the relationships between muscle fat content and DGAT from PCD intramuscular adipose tissue (3), PCD FA composition (4), HSL activity from PCD muscle (5), and plasma leptin concentration (14) were conducted using Japanese black hybrid cattle (3–5,14). The current study has extended these investigations to examine cattle breeds that are more typically found in North American herds. Highly significant relationships between total fat content determined through Soxhlet extraction and the USDA marbling score were found for the two muscles studied from the F_1 herd (Fig. 1A). For LL and SM muscle, the association (r) between extracted lipid and marbling score was 0.83 ($P < 0.0001$) and 0.70 ($P < 0.0001$), respectively, and the relationship was stronger when lipid extraction data from the muscles were compared ($r = 0.87$, $P < 0.0001$). HIP extraction of lipid samples from PCD muscles of a subset ($n = 22$) of the F_1 herd also revealed highly significant associations between muscle lipid content and marbling score ($r = 0.73$, $P < 0.0001$; Fig. 1B) as well as between lipid content of this muscle and that of LL ($r = 0.83$, $P < 0.0001$) and SM ($r = 0.85$, $P < 0.0001$). Collectively, these results show that marbling score accurately reflects the amount of fat content in various bovine muscles and that intramuscular fat deposition is related among muscles that exhibit marbling. These results are supported by previous reports, both from our laboratory (4) and elsewhere (15).

Association of relative proportions of myristic, palmitic, and oleic acids with muscle lipid content. FA analysis of PCD and LL muscle was conducted using HIP lipid extracts prepared from muscle samples of a subset ($n = 22$) of the F_1 herd. The carcasses from the animals in this subset displayed a wide range in marbling score (i.e., from 150 to 650). Average values (±SE) for FA composition of total extracted lipid (TEL) from the two muscles from the subset of the F_1 herd are presented in Table 1. In general, the FA composition of the TEL of the two muscles was similar. The proportion of palmitic acid (16:0), however, was higher in LL than in PCD muscle and, conversely, stearic acid (18:0) in PCD was considerably greater than in LL muscle. These combined results implicate greater 16:0–18:0 elongase activity in the PCD. In contrast, analyses of the FA composition of TEL as a function of muscle lipid content or marbling score revealed a number of strong associations. Significant positive associations were found between the relative proportions of myristic (14:0; $r = 0.55$, $P = 0.0078$), palmitic ($r = 0.80$, $P < 0.0001$), and oleic (18:1 *cis*-9; $r = 0.79$, $P < 0.0001$) acids in relation to the TEL content of LL muscle, whereas a significant negative association ($r = –0.58$, $P = 0.0047$) was found for 18:0 for this muscle (Fig. 2). Positive associations were noted for 16:0 ($r = 0.71$, $P = 0.0002$) and 18:1 *cis*-9 ($r = 0.74$, $P = 0.0001$) in relation to TEL content of PCD muscle.

Kazala *et al.* (4) reported a significant positive association between the relative proportion of 14:0 and both total acyl lipid and TAG extracted from both PCD and *longissimus* muscle from Japanese black hybrid cattle. This association also has been noted by other groups (16,17). The fact that this relationship was detected in breeds more representative of North American beef production supports this trait as being present in the *Bos taurus* species as a whole, and not just specific to the Japanese black breed. The positive associations observed between 16:0 and TEL content of both muscles sampled in the present study were also detected in a previous study of Japan-

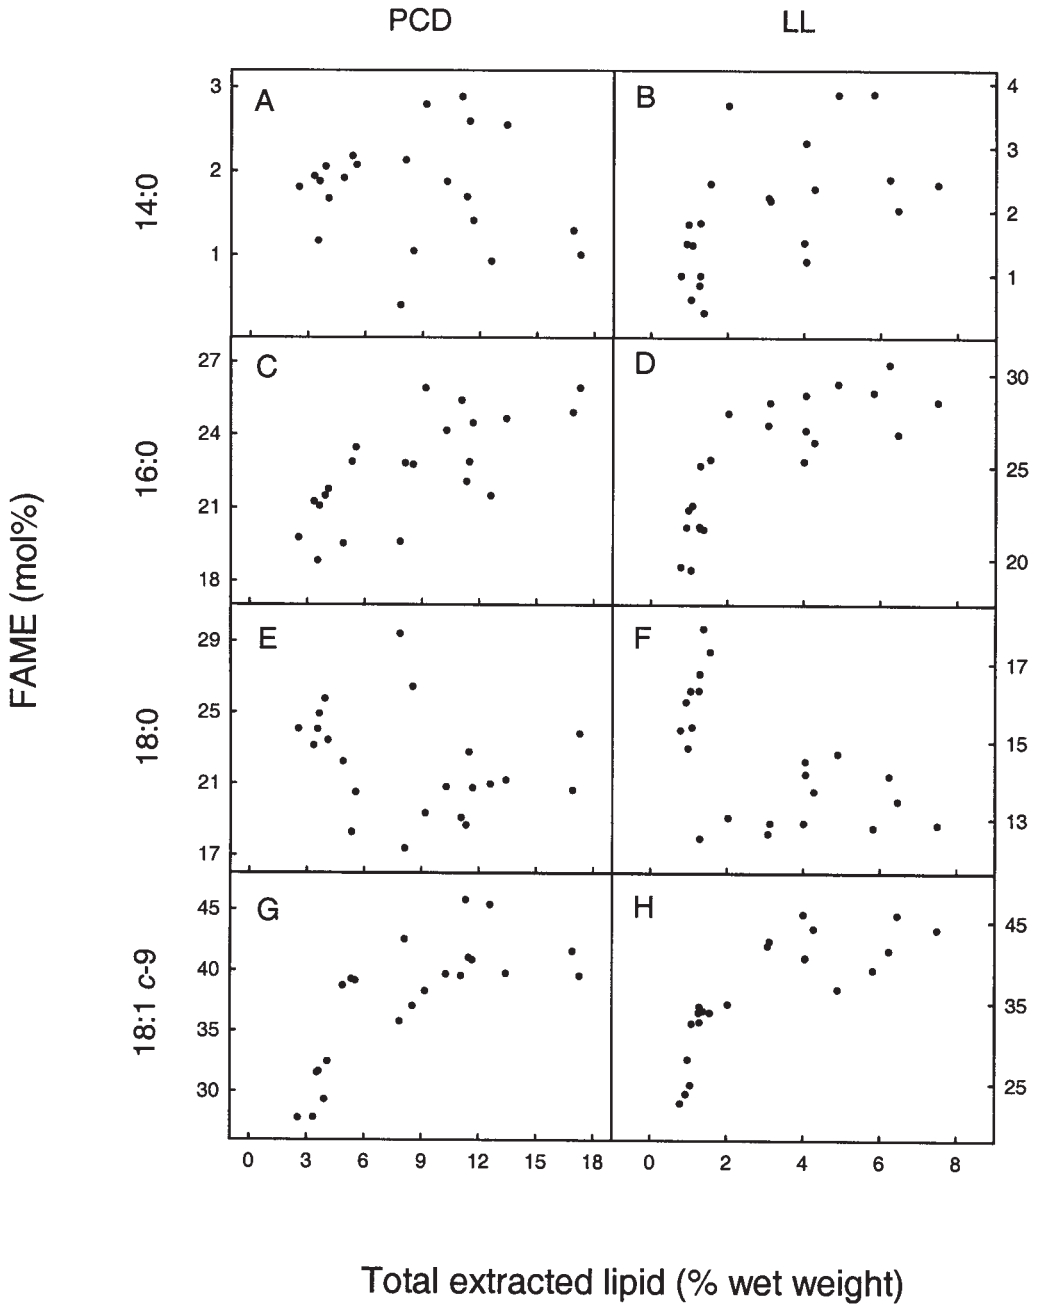

FIG. 2. Relationship between the amount of fat extracted from whole PCD (*pars costalis diaphragmatis*) and LL (*longissimus lumborum*) muscles and the relative content of several FAME in the extracted fat ($n = 22$). Correlation coefficients (r) for each panel and corresponding P values (in parentheses) are as follows: A, –0.12 (0.60); B, 0.55 (0.0078); C, 0.71 (0.0002); D, 0.80 (<0.0001); E, –0.29 (0.19); F, –0.58 (0.0047); G, 0.74 (0.0001); H, 0.79 (<0.0001).

ese black hybrid cattle (4). The association, however, was weaker ($r = 0.44$) for Japanese black hybrid cattle and only apparent in PCD muscle, not in *longissimus* muscle. It should be noted that, aside from breed differences between the present work and past studies involving Japanese black hybrid animals, the animals in previous studies (3–5) were slaughtered according to physical maturity measures (i.e., live weight and backfat thickness as determined through ultrasonography). Collectively, these differences would likely have a substantial effect on differences in intramuscular fat deposition, and this should be kept in mind when considering differences in the findings. Conversely, it can be argued that similar relationships found in both types of studies are likely to represent characteristics of the *Bos taurus* species, being present despite considerable differences in breed type and finishing regime.

In the present study, the correlations between relative proportions of both 14:0 and 16:0 and TEL content of LL muscle implicate the FA synthase complex as having a key role in gov-

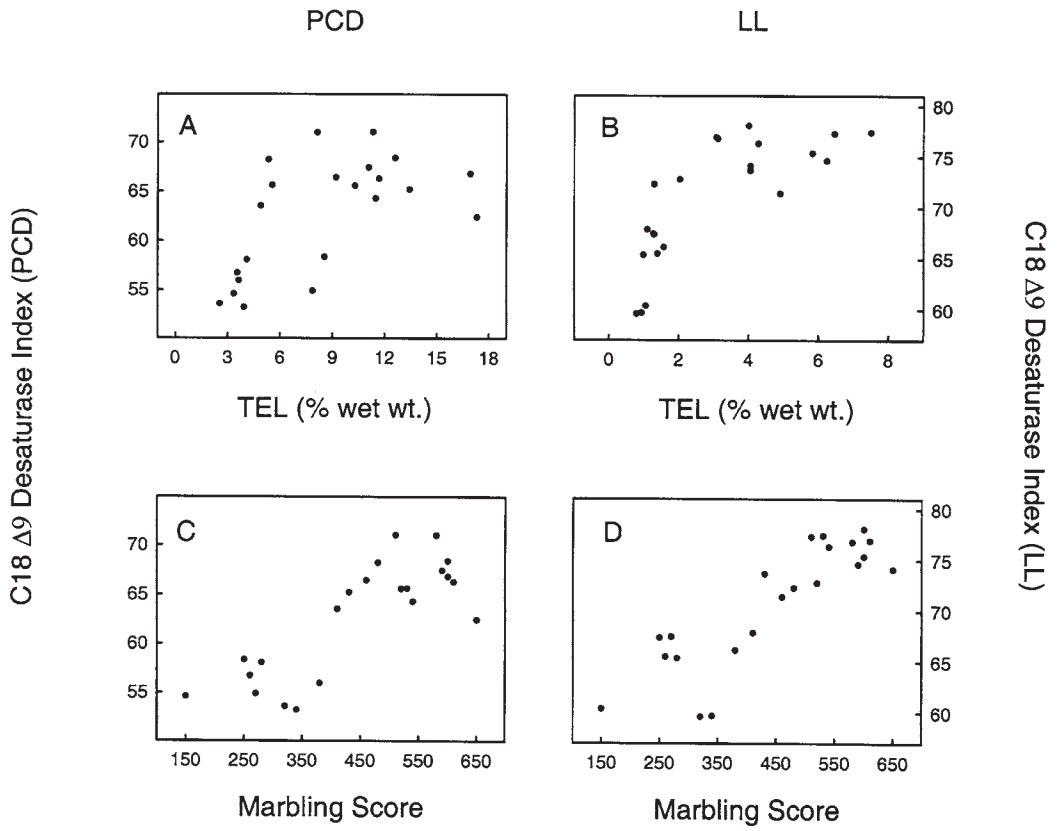

FIG. 3. Relationship between index of C18 Δ9 desaturase activity and two measures of muscle fat content. PCD, *pars costalis diaphragmatis*; LL, *longissimus lumborum*; TEL, total extracted lipid; C18 Δ9 desaturase index = [18:1 *cis*-9/(18:0 + 18:1 *cis*-9)]100. Correlation coefficients (*r*) for each panel and corresponding *P* values (in parentheses) are as follows: A, 0.60 (0.0034); B, 0.77 (<0.0001); C, 0.81 (<0.0001); D, 0.86 (<0.0001).

erning these associations. The typical end product of FA synthase action is 16:0, with 4- to 14-carbon products released in some mammalian tissues (18). The positive relationship presented for LL muscle suggests that the FA synthase complex may be somewhat more prone to 14:0 production in animals showing greater degrees of marbling. The increased proportions of 14:0 and 16:0 in TEL that occur with increased muscle fat content, however, might also be attributable to changes in acyltransferase selectivity. These enzymes are responsible for catalyzing the addition of fatty acyl moieties onto the glycerol backbone in the pathway leading to TAG (19,20). Factors such as substrate availability and/or possible allosteric modulation of one or more of these acyltransferases may have resulted in changes in selectivity such that 14:0 and 16:0 were more preferentially incorporated into TAG in animals with higher muscle fat content.

Of the FA examined, the proportion of 18:1 *cis*-9 in the TEL of both muscles showed the greatest increase as a function of muscle lipid content. Skelley *et al*. (17) reported a significant positive relationship between the relative content of 18:1 *cis*-9 in lipid extract of *longissimus* muscle and marbling score. Kazala *et al*. (4) reported a similar association between this FA and TEL content of PCD muscle from Japanese black hybrid cattle, although the relationship was not statistically significant ($0.05 < P < 0.1$). The relative increase of 18:1 *cis*-9 observed as TEL content increased might be due to increases in 18:0 Δ9 desaturase activity. The index of C18 desaturase activity as a function of TEL of PCD and LL muscle is shown in Figures 3A and 3B, respectively. The relationship between the index of C18 desaturation for each muscle in relation to marbling score at the grading site is depicted in Figures 3C and 3D. A highly significant positive association was found in each case. Thus, it might be useful to evaluate Δ9 stearoyl-CoA desaturase activity in relation to muscle lipid content. The selectivities of acyltransferases, which catalyze the transfer of fatty acyl moieties from the acyl-CoA pool onto glycerolipids, might also contribute to the increased proportion of 18:1 *cis*-9 in total acyl lipid of TEL as muscle lipid content increases.

Although the underlying reason(s) for the positive association between 18:1 *cis*-9 and the amount of marbling fat remain unclear, these results are relevant from a dietary and/or marketing perspective. Oleic acid, the predominant FA moiety in such "heart-healthy" vegetable oils as canola oil and olive oil, reduces both plasma total cholesterol and total LDL cholesterol in humans (21,22; reviewed in 23). Additionally, taste panel evaluations of tenderness, juiciness, and flavor of cooked *longissimus* report a more desirable flavor when increased amounts of 18:1 *cis*-9 are present (16); and similar trends be-

tween level of marbling, flavor intensity, and 18:1 *cis*-9 content were found in a more recent study by Camfield *et al*. (24) of crossbred feedlot steers, although their findings were statistically significant only between the extremes of finishing diet regimen and resulting marbling fat deposition. The results presented here show that as marbling fat content increases, so does the relative proportion of 18:1 *cis*-9 contained therein, resulting in better-tasting beef with the beneficial health effects associated with increased proportions of this FA.

Activities of lipogenic enzymes in muscle tissue samples. Analyses of enzyme activities involved in TAG assembly were conducted using microsomes prepared from PCD muscle of the same subset of animals used for FA analysis. Investigations of the relationship between enzyme activity and muscle lipid content in Japanese black hybrid cattle have been conducted using this muscle (3,5). Mean values for activities of three enzymes involved in TAG synthesis are shown in Table 2. Activities are shown on both a specific activity and activity per g fresh weight basis. In general, DGAT displayed the lowest activity of all three enzymes in the pathway. This is supported by a previous report, using the DGAT inhibitor 2-bromooctanoate on studies of rat hepatocytes, that showed that DGAT may have a rate-limiting role in the production of TAG (25).

Both total PAP activity and PAP activity specifically involved in glycerolipid synthesis (PAP-1) were measured. PAP-1 activity is responsible for generating the DAG required by DGAT to form TAG (19), whereas PAP-2, also referred to as phosphate phosphohydrolase and located in the plasma membrane, is involved in cellular signaling processes (26). Assays conducted in the presence of NEM resulted in the inhibition of PAP-2 activity involved in signal transduction, thereby allowing PAP-1 activity to be determined by subtraction of PAP-2 from total PAP activity (11). The relationships of the specific activities of the enzymes to each other are presented in Table 3. DGAT activity showed significant positive associations with LPAAT and both measures of PAP activity. The data suggest that the two acyltransferase activities were coordinated and that DGAT activity was coordinated with PAP-1 activity in the various samples of PCD muscle. None of these enzyme activities, however, was significantly associated with muscle fat content or marbling score (i.e., $P \geq 0.05$). In contrast, investigations of lipid synthesis in Japanese black hybrid cattle showed a significant negative association between microsomal DGAT specific activity of intramuscular fat and lipid content of the PCD (3). In that study, however, intramuscular fat was physically dissected from the surrounding muscle, and microsomal fractions were prepared from the muscle-free intramuscular fat. Also, the study used Japanese black hybrid cattle, which are not representative of the more typical Canadian breeds used in the present study. The generally lower degree of marbling in the present group of cattle, compared with Japanese black hybrid cattle, made it extremely difficult to dissect out sufficient amounts of intramuscular fat from the whole muscle for biochemical evaluation.

Summary and implications for the beef industry. The cattle used in the current study displayed a highly significant association between muscle fat content of LL and SM muscles and marbling score at the grading site. Significant positive associations between 14:0 or 16:0 FA moieties from bovine muscle lipid extracts (PCD and LL) and the amount of fat present in the same muscles implicate the activity of FA synthase and/or acyltransferase selectivity as having a role in determining the FA composition of marbling fat. The significant positive association between 18:1 *cis*-9 moieties from whole bovine muscle lipid extracts (PCD and LL) and the amount of muscle fat implicate the activity of Δ9 stearoyl-CoA desaturase and/or acyltransferase selectivity as having a role in determining the proportion of 18:1 *cis*-9 content in muscle fat. A reasonable starting point for investigating the possible involvement of specific acyltransferases contributing to the FA composition of bovine muscle fat would involve a study of the positional distribution of FA as a function of muscle lipid content. Thus, changes in acylation due to acyltransferase selectivity could be linked to specific positions on the glycerol backbone of TAG. None of the TAG bioassembly enzymes of the PCD muscle studied showed a significant association with marbling fat deposition. Microsomal DGAT and LPAAT activities, however, appeared to be coordinated in the various samples of PCD muscle.

The significant associations detected between 18:1 *cis*-9 from lipid extracts and extent of marbling should be verified in

more well-marbled carcasses (i.e., with more representation from modest, moderate, and abundant categories) and, if they hold, exploited with respect to marketing well-marbled beef. This particular monounsaturated FA is the major FA found in canola and olive oils and has been shown to help reduce plasma total cholesterol and total LDL cholesterol in humans. The results presented here show that as the amount of marbling fat increases, so does the relative proportion of this beneficial FA. The activities of TAG bioassembly enzymes should be examined over the development of beef cattle to better understand the relationship between these enzyme activities and marbling fat. Biochemical differences between animals with different propensities to marble might become apparent at earlier stages of development. Trends detected earlier in beef cattle development would be more useful from a marbling predictability standpoint.

ACKNOWLEDGMENTS

The authors thank the Canada-Alberta Beef Industry Development Fund (CABIDF) and the Canada Research Chairs program for supporting this research. As well, the authors are grateful to Dr. Ralph Cartar of the Department of Biological Sciences, University of Lethbridge, for his assistance with statistical methods and interpretation, and Tara Furukawa-Stoffer for her technical assistance in developing the LPAAT assays and performing the PAP assays.

Bovine Muscle n-3 Fatty Acid Content Is Increased with Flaxseed Feeding

S. L. Kronberg[a,*], G. Barceló-Coblijn[b], J. Shin[c], K. Lee[c], and E. J. Murphy[b,d]

[a]USDA, ARS, Northern Great Plains Research Laboratory, Mandan, North Dakota 58554, [c]Department of Animal Sciences and Interdisciplinary Ph.D. Program in Nutrition, The Ohio State University, Columbus, Ohio 43210, and Departments of [b]Pharmacology, Physiology and Therapeutics and [d]Chemistry, University of North Dakota, Grand Forks, North Dakota 58202-9037

ABSTRACT: We examined the ability of n-3 FA in flaxseed-supplemented rations to increase the n-3 FA content of bovine muscle. Two groups of animals were used in each of two separate trials: (i) Hereford steers supplemented (or not) with ground flaxseed (907 g/d) for 71 d, and (ii) Angus steers supplemented (or not) with ground flaxseed (454 g/d for 3 d followed by 907 g/d for 110 d). For the Hereford group, flaxseed-supplemented rations increased 18:3n-3 (4.0-fold), 20:5n-3 (1.4-fold), and 22:5n-3 (1.3-fold) mass as compared with the control, and increased total n-3 mass about 1.7-fold. When these data were expressed as mol%, the increase in 18:3n-3 was 3.3-fold and in 20:5n-3 was 1.3-fold in the phospholipid fraction, and 18:3n-3 was increased 4-fold in the neutral lipid fraction. For the Angus group, flaxseed ingestion increased masses and composition of n-3 FA similarly to that for the Herefords and doubled the total n-3 FA mass. The effect of cooking to a common degree of doneness on FA composition was determined using steaks from a third group of cattle, which were Angus steers. We demonstrated no adverse effects on FA composition by grilling steaks to an internal temperature of 64°C. Because n-3 FA may affect gene expression, we used quantitative real-time reverse transcriptase-polymerase chain reaction to quantify the effect of feeding flaxseed on heart-FA binding protein, peroxisome proliferator activated receptor γ (PPARγ) and α (PPARα) gene expression in the muscle tissue. PPARγ mRNA level was increased 2.7-fold in the flaxseed-fed Angus steers compared with the control. Thus, we demonstrate a significant increase in n-3 FA levels in bovine muscle from cattle fed rations supplemented with flaxseed and increased expression of genes that regulate lipid metabolism.

Paper no L9996 in *Lipids 41*, xxx–xxx (November 2006).

Most people on a Western diet consume much lower levels of n-3 FA than the recommended daily amounts and much higher levels of n-6 FA than is ideal for good health (1). Few of these people routinely eat the fish that are good sources of 20:5n-3 and 22:6n-3. Further, there is increasing concern about contaminants such as mercury and dioxins that may limit the healthfulness of high fish intake (2,3). In the United States, the average annual per capita fish intake is only 7.4 kg (4), with only some of this intake of species containing high levels of n-3 FA (5). On average, Americans eat four times as much beef as fish (mean annual per capita intake is 30 kg), and studies have shown that cattle consuming forages or feeds containing n-3 FA can produce meat with higher levels of n-3 FA and lower levels of n-6 FA (6–8).

Consequently, n-3 FA-enriched beef has the potential to help beef-eating Americans increase their n-3 FA intake. For example, a person who consumes 227 g (8 oz) of n-3-enhanced beef containing 155 mg of n-3 FA (18:3n-3, 20:5n-3, 22:5n-3, and 22:6n-3) per 100 g (8) could consume as much as 352 mg/d of total n-3 FA. For individuals who consume little or no fish with high n-3 levels, flaxseed-fed n-3-enriched beef consumed along with other n-3 sources could provide a diet with adequate n-3 intake (9). A diet with adequate n-3 intake, but essentially fish-free, could include flaxseed, walnuts, other 18:3n-3 sources in baked products and cereals, flaxseed oil in salad dressings, and perhaps eventually genetically modified plant sources of EPA and DHA, as well as n-3-enhanced dairy products (10–12), pork (13,14), lamb (15–17), chicken, and chicken eggs (18,19).

There is small but growing interest in North America in growing and fattening cattle on forage diets that are obtained primarily from grazing instead of the traditional feeding of high-grain diets to penned cattle. This interest relates to several beliefs including that meat from forage-consuming animals is healthier because of its composition and quantity of FA (8,20–22). However, because of the short growing season for the northern Great Plains of North America it is difficult to fatten yearling cattle to slaughter stage while grazing grass or grass-legume pastures. To overcome this problem, we grazed cattle on whole standing corn for the last 2–4 mon of their lives. Even after a killing frost and loss of nutritious corn leaves, cattle can still obtain enough energy by consuming the corn ears to fatten quickly. Unfortunately, corn grain has low levels of 18:3n-3 and high levels of 18:2n-6, so enrichment of beef with n-3 FA under this scenario will be impossible unless they also ingest a concentrated n-3 FA source such as flaxseed.

In light of these concerns, we conducted two field trials to determine whether the n-3 FA levels of muscle could be elevated in cattle finished on corn with supplemental flaxseed. Additionally, because there are mixed reports in the literature with respect to the effect of cooking on n-3 FA levels in beef (22–25), we evaluated the effect of cooking on n-3 FA levels contained in our n-3-enriched beef.

EXPERIMENTAL PROCEDURES

Feeding regimen for Hereford cattle for muscle enrichment. Eleven Hereford steers (castrated males) that were about 17 mon old with mean body weight of 510 kg (SD = 17 kg) at the beginning of the study were individually fed mixtures of grain each morning for 71 d while they grazed standing corn together in one group. Three and a half months prior to the commencement of the study, all steers grazed the same perennial grass. Six (controls) were fed mixtures of corn and field peas, and five (treatment) were initially fed mixtures of peas and ground flaxseed (907 g/d) and later mixtures of corn, peas, and ground flaxseed (corn was added to increase the energy intake of both groups as the weather cooled considerably). All animals were given 40 IU/d of Vitamin E and 29 g/d of calcium carbonate with the grain supplement. All animals had equal access to standing corn for grazing, and we balanced the supplements for available energy. The ground flaxseed was treated before feeding with the lignosulfonate process (26). At the end of the 71-d period, a biopsy was taken from the *longissimus dorsi* muscle of each animal between the 12th and 13th ribs. The muscle was immediately frozen and stored at –20°C until analysis.

Feeding regimen for Angus cattle for muscle enrichment. Twenty Angus steers that were about 16 mon old and had a mean body weight of 414 kg (SD = 39 kg) at the start of the study were used. Ten steers were supplemented with flaxseed and 10 control steers were not supplemented with anything. All of these cattle grazed grass pasture from early June to mid-July, then they grazed a mixture of oats and peas during the second half of July. During August they grazed stands of immature proso millet, and during September and October they grazed whole standing corn. For the first half of September, corn plants were immature and green, but began to die after a killing frost in mid-September. Through October the steers selected primarily the ears off the plants thus consuming mainly grain and cob. Ground flaxseed (nontreated) supplementation began on July 15 and continued through October. For the first 3 d of the trial, each steer was offered only 454 g/d of ground flaxseed to allow them to adjust to the new grain and then received 907 g/d for the remainder of the trial (107 d). Ground flaxseed was offered and consumed each morning while the steers were on the fields described above. While the cattle grazed the oat–pea and corn stands, a small amount (typically 45 to 65 g) of molasses powder was added to the flaxseed to increase its desirability. The steers were slaughtered at the end of the flaxseed supplementation period and cross-sectional pieces of *longissimus dorsi* and minor associated muscles (i.e., ribeye steaks) were collected from each carcass between the 12th and 13th ribs. To approximate the treatment of steaks prepared for human consumption, these steaks were stored in a cooler for 15 d at 4°C (i.e., "aged") then stored frozen until analysis.

Feeding regimen for Angus cattle for steak grilling trial. Ten Angus steers that were about 18 mon old and had a mean body weight of 351 kg (SD = 33 kg) at the beginning of the study were used. They were grazed together on grass pastures for 5 mon before flaxseed feeding began. They were fed a mixture of ground nontreated flaxseed and grain for 132 d before they were slaughtered. Ground flaxseed was fed at a rate of only 454 g/d for the first 22 d for an adjustment phase followed by 907 g/d for the final 110 d. The grain was a mixture of triticale, oats, peas, and corn, and the amount of feed was increased as the weather became colder and the cattle became more adapted to high grain diets. All animals were given 40 IU/d of Vitamin E and 29 g/d of calcium carbonate with the grain supplement. Grass hay was available to the cattle *ad libitum* during the 132-d feeding period. At the end of the feeding period steers were slaughtered; half of the carcasses had a quality grade of "Choice" and the other half were graded "Select" by standards of the U.S. Department of Agriculture. The carcasses were stored in a cooler for 12 d at 2°C (aged), then ribeye steaks that were about 2.5 cm thick were collected from each carcass between the 12th and 13th ribs, and these were stored at –20°C until analysis.

Meat preparation and cooking. Frozen ribeye steaks from the Angus cattle were slowly thawed in a refrigerator. Core samples were taken from the *longissimus dorsi* muscle of these steaks prior to grilling and flash-frozen in liquid nitrogen to minimize changes in tissue FA composition. Steaks were grilled on a gas barbecue to an internal temperature of about 64°C (considered "medium" in the United States and a popular degree of doneness for beef steaks) and another sample was cored from the cooked muscle for analysis and then flash-frozen in liquid nitrogen. Frozen tissue was pulverized under liquid nitrogen temperatures and extracted as described below.

Tissue lipid extraction. Tissue cores were taken from visibly lean portions of the frozen steaks and immersed in liquid nitrogen. These samples were then pulverized under liquid nitrogen temperatures into a fine homogeneous powder. Lipids from the tissue powder were extracted using a single-phase extraction with *n*-hexane/2-propanol (3:2 vol/vol) (27). After centrifugation at 1,000 × *g* to pellet debris, the lipid-containing liquid phase was removed and stored under a nitrogen atmosphere at –80°C until analysis.

Phospholipid and neutral lipid separation. Because beef muscle tissue contains considerable amounts of neutral lipids, primarily TAG, the neutral lipid and phospholipid fractions were separated by liquid column chromatography, using activated silicic acid as the stationary phase (Clarkson Chemical Company, Inc., Williamsport, PA). Neutral lipids, containing cholesterol, cholesteryl esters, TAG, and DAG, were eluted with 10 vol of chloroform/methanol (58:1 vol/vol) (28). Phospholipids were eluted with 10 vol of methanol. The eluents were stored at –80°C until analysis.

Phospholipid mass determination. Phospholipid mass was determined by assaying for lipid phosphorus content of phospholipid fraction separated by liquid column chromatography as described above (29). After drying down the solvent under a stream of nitrogen, 0.5 mL of water and 0.65 mL of perchloric acid (70%) were added and the tubes heated at 185°C for 1 h. Following digestion, the tubes were cooled to room temperature and 0.5 mL ascorbic acid (10%, wt/vol), 0.5 mL ammonium molybdate (2.5%, wt/vol), and 3.3 mL water were added

and mixed. Color was developed by boiling the mixture for 5 min and, after cooling, the absorbance at 797 nm was measured. Absorbance was converted to mass based on a standard curve.

Cholesterol mass determination. Cholesterol mass of the neutral lipid fraction was determined by an iron-binding assay (30). Briefly, the solvent was removed by evaporation using a stream of N_2 and the lipids were dissolved in 3 mL of ethanol. Then 3 mL of the working solution in concentrated sulfuric acid was added to the ethanol. The working solution was made up by q.s. 8 mL of stock solution containing 2.5% ferric chloride hexahydrate ($FeCl_3 \cdot 6H_2O$) in 85% phosphoric acid with concentrated sulfuric acid (H_2SO_4) were added. Color was developed by mixing, and the absorbance at 550 nm was measured. Absorbance was converted to mass based on a standard curve.

Transesterification. Phospholipids and neutral lipids were subjected to base-catalyzed transesterification, converting the acyl chains to FAME. To each fraction, 2 mL of 0.5 M KOH dissolved in anhydrous methanol was added and the samples were incubated at 35°C for 30 min (31). The reaction was quenched with methyl formate, and the FAME were extracted using 2 mL of *n*-hexane. The lower phase was re-extracted two more times with *n*-hexane, and these washes were combined with the original aliquot.

GLC. Individual FAME were separated by GLC by using an SP-2330 column (0.32 mm i.d. × 30 m length) and a Trace GLC (ThermoElectron, Austin, TX) equipped with dual autosamplers and dual FID. FAME were quantified using a standard curve from commercially purchased standards (Nu-Chek-Prep, Elysian, MN); 17:0 was the internal standard (32).

Total RNA isolation and real-time polymerase chain reaction (PCR). Pulverized tissues were shipped on dry ice to The Ohio State University for analysis of gene expression using quantitative real-time reverse transcriptase PCR (RT-PCR). Total RNA from tissue was isolated using Trizol (Invitrogen, Carlsbad, CA) following the manufacturer's instructions, and RNA quality was assessed by agarose gel electrophoresis. Reverse transcription was performed using 1 μg of RNA and M-MLV (Moloney murine leukemia virus RT (Invitrogen); RT condition was 65°C for 5 min, 37°C for 50 min, and 70°C for 15 min. Cyclophilin (CYC), peroxisome proliferator activated receptor gamma (PPARγ), PPARα, and heart-FA binding protein (H-FABP) were quantified by RT-SYBR green real-time PCR using AmpliTaq Gold polymerase (Applied Biosystems, Foster City, CA) and SYBR green as the detection dye. The forward and reverse primers were designed to be located on different exons separated by long introns to prevent the generation of noise signals from contaminated genomic DNA during the PCR reactions. The sequences of the primers used were described as follows: H-FABP-F (5´-CGT GCA GAA GTG GAA TGG ACAA-3´), H-FABP-R (5´-TCT GGT GGC GAG TCC AGG AGT-3´), PPARγ-F (5´-CTG TGA AGT TCA ACG CAC TGGA-3´), PPARγ-R (5´-GGT TCA GCT TGA GCT GCA GCT-3´), PPARα-F (5´-ATC ATG GAA AAG TTC GACT-3´), PPARα-R (5´-TTC TGT AGG TGG AGT TTG AGCA-3´), CYC-F (5´-GTG GTC ATC GGT CTC TTT GG -3´), and CYC-R (5´-CAC CGT AGA TGC TCT TAC CTC-3´). Conditions for real-time PCR were 95°C for 10 min and 40 cycles of 94°C for 15 s, 60°C for 1 min, 72°C for 30 s, and 82°C for 16 s. Real-time PCR was performed in duplicate in 25 μL reactions on the Stratagene MX3000P cycler. The relative level of target gene expression was determined using the comparative $\Delta\Delta C_T$ method for relative quantification with cyclophilin as an endogenous reference.

Statistical analysis Statistical analysis was done using Instat2 from GraphPad (San Diego, CA), using an unpaired, two-way Student's *t*-test, and values were considered significant if $P < 0.05$.

RESULTS

Flaxseed feeding increased muscle n-3 FA. The masses of individual FA in the total phospholipid fraction from Hereford muscle were measured (Table 1). Flaxseed feeding significantly increased the mass of 18:3n-3 (4.0-fold) and increased the elongation products of 18:3n-3, namely, 20:5n-3 (1.4-fold) and 22:5n-3 (1.3-fold). In addition, in the flax-fed group the mass of 18:0 was significantly increased (1.2-fold), as was that of 22:1n-9 (2-fold). There were no observed alterations in 18:2n-6 or 20:4n-6 mass between groups. There was a net increase (1.7-fold) in total n-3 FA in the flax-fed group, which resulted in an elevated n-3/n-6 ratio. Thus, the muscle of Hereford steers fed lignosulfonate-treated flaxseed had significantly elevated n-3 FA mass in the phospholipid fraction.

The FA composition (mol%) of the phospholipid fraction was determined using the data in Table 1, and we also measured the FA composition of the neutral lipid fraction (Table 2). Similar to phospholipids, neutral lipid 18:3n-3 content was significantly elevated (4-fold) by flax feeding. This resulted in a 3-fold increase in the total n-3 FA and an increase in the n-3/n-6 ratio. However, note that PUFA did not account for much of the total FA, rather the saturated and monounsaturated FA accounted for the majority of the FA in the neutral lipid fraction. Flaxseed feeding produced similar changes in neutral and phospholipid 18:3n-3 when expressed as mol%. These data indicate that although the 18:3n-3 content of the neutral lipid fraction was altered by flax feeding, the major source of n-3 FA in the muscle tissue was the phospholipid fraction, owing to the limited amount of long-chain n-3 FA in the neutral lipid fraction.

As in the case of the flax-fed Hereford steers, flaxseed supplementation of the Angus steers significantly increased the mass of 18:3n-3 (4.3-fold) as well as the masses of 20:5n-3 (2.0-fold) and 22:5n-3 (1.2-fold) but the mass of 20:4n-6 was unaltered (Table 3). In contrast to the flaxseed-fed Hereford steers, the mass of 18:0 was not increased by flaxseed intake in the Angus steers, but 18:2n-6 was increased slightly (1.2-fold). There was a net increase (2-fold) in total n-3 FA in the flax-fed Angus group, which resulted in an elevated n-3/n-6 ratio. With respect to FA composition (mol%) of Angus muscle (Table 4), the n-3 FA were elevated 4.3-fold (18:3), 2-fold (20:5), 1.2-fold

(22:5), and 1.3-fold (22:6) by flaxseed feeding, and 18:0 and 18:2n-6 were also elevated slightly (1.1- and 1.2-fold, respectively). Flaxseed intake decreased the FA 16:0 slightly, and reduced each of the FA 16:1, 18:1n-9, 22:4n-6, and 22:5n-6 about 40%.

Grilling did not decrease n-3 FA content. Because cooking meat may result in a reduction in the n-3 FA, we grilled the steaks from the Angus group on a gas barbecue to a often-used internal temperature of about 64°C. We observed no change in the FA composition of the neutral lipid or phospholipid fraction (Table 5). These data were expressed as mole composition (mol%) because loss of water during the cooking process would alter the FA mass per unit of tissue. We observed a net increase in the total phospholipid and cholesterol mass when normalized to wet weight (Table 6), demonstrating this point. However, the cholesterol-to-phospholipid ratio was unchanged, indicating no adverse changes in these parameters. Note that these data were not corrected for water loss, thus accounting for the changes observed. Thus, the n-3 FA composition of the neutral lipid and phospholipid fractions was not altered by grilling, demonstrating that the enrichment of the n-3 FA is preserved during this cooking process.

Flaxseed feeding increased bovine PPARγ mRNA expressions in muscle tissue. To investigate the effect of feeding flaxseed containing high levels of n-3 FA on H-FABP, PPARγ, and PPARα gene expression in the muscle tissues, quantitative real-time RT-PCR was done (Fig. 1). The PPARγ mRNA expression in the flaxseed-fed Angus steers was increased 2.7-fold compare with control Angus steers, indicating that the increased n-3 FA contents may up-regulate PPARγ in bovine muscle. However, there was no significant difference in the expression levels of H-FABP and PPARα gene between groups.

DISCUSSION

To meet the needs of American beef consumers for a healthier beef product, we examined the ability of two different flaxseed feeding regimens to produce an n-3 FA-enriched beef product. This is not without precedent, and others have demonstrated an enrichment of n-3 FA in cattle fed various forms of n-3 FA (6,8,33–35). In Charolais steers fed for 83 d with flaxseed oil (220 g/d) mixed with soybean and sunflower oils (these at 70 and 8% of the mixture, respectively) that were treated with a formaldehyde-protein treatment to protect PUFA from biohy-

[c]For abbreviations see Table 1.

drogenation (36), 18:3n-3 mass was 15.6 mg/100 g of tissue (35). The phospholipids values in the present study were comparable with these, as we observed an 18:3n-3 mass of 12 mg/100 g of tissue in the flax-fed Herefords and 13 mg/100 g of tissue in the flax-fed Angus. The mass of 20:5n-3 in the flax-fed Hereford group was similar to that observed by Scollan *et al*. (35), but the flax-fed Angus had a lower level (8.9 mg/100 g). The flax-fed Hereford steers had 39 and 50% higher 22:5n-3 and 22:6n-3 levels, respectively, than observed by Scollan *et al*. (35) in their Charolais steers, but the Angus steers had 10 and 7% lower levels of 22:5n-3 and 22:6n-3 levels than observed in their Charolais steers. Note that 220 g/d of flax oil is equivalent to 630 g/d of flaxseed, which is lower than the amounts used in our study. This suggests that the technique Scollan *et al*. used for protecting flaxseed oil from rumen biohydrogenation was at least partially effective.

In another trial, Scollan *et al*. (34) fed slightly cracked flaxseed to Charolais steers (771 g/d for an average of 120 d), and these animals had total masses of n-3 phospholipid FA (61 mg/100 g muscle) that were 36 and 110% greater than the masses for our Hereford and Angus cattle, respectively. However, neither our attempts to raise n-3 FA levels in beef with a plant source of n-3 FA (α-linolenic acid) nor those of Scollan *et al*. (34,35) or Choi *et al*. (33) have raised the mass of total n-3 FA in bovine muscle as high as those reported for cattle consuming only pasture forage in Australia (155 mg/100 g of rump muscle; 8). The Australian study found that rump and blade cuts of beef had higher total levels of n-3 FA than did strip loin cuts, which is an important finding in light of the fact that most studies related to n-3 enrichment of beef evaluate only loin muscles. A number of factors can cause variation in n-3 FA levels in beef including the particular muscle sampled (7), breed of cattle (33), length of time an n-3 FA source is consumed (6), amount of daily consumption (6), type of dietary source fed (34), and whether the source has some protection from biohydrogenation by rumen microbes (35,37). Several of these factors were different for each study, which may account for the study-to-study variation.

[a]All values represent mean ± SD (mg/100 g tissue) with *n* as indicated in the table. The asterisk (*) signifies statistical significance from control samples as determined using an unpaired, two-tailed Student's *t*-test, $P < 0.05$.
[b]For abbreviations see Table 1.

Although flaxseed is a good source of plant-based n-3 FA, others have fed cattle fish meal-based rations. In one of these studies, feeding fish meal to cattle for 112 d elevated 20:5n-3 and 22:6n-3 levels in bovine *longissimus* muscle considerably higher than seen by feeding flaxseed meal or oil alone (6). Others have observed somewhat higher 20:5n-3 and 22:6n-3 levels in bovine muscle when a combination of flaxseed and fish oil was fed (33). These results indicate that if higher 20:5n-3 and 22:6n-3 levels are desired in bovine muscle, sources of 20:5n-3 and 22:6n-3 may have to be fed rather than relying solely on synthesis *de novo* of 20:5n-3 and 22:6n-3 from 18:3n-3. Dietary 18:3n-3 is probably the direct precursor for the synthesis *de novo* of 20:5n-3, 22:5n-3, and 22:6n-3 (34,35), and our previous results in rats with 18:3n-3 feeding indicates tissue selectivity with regard to elongation and accretion of 18:3n-3-derived FA such as 20:5n-3, 22:5n-3, and 22:6n-3 (38). However, it is conceivable that greater elevations in muscle 20:5n-3, 22:5n-3, and 22:6n-3 content may occur either by increasing the conversion of 18:3n-3, by increasing the duration of 18:3n-3 feeding, or by using cattle selected for finishing on forage, such as seen in Australian beef (8).

In hogs, feeding flaxseed produces much different results compared with those for cattle. Feeding hogs crushed flaxseed (6% of the ration) for 60 d prior to slaughter increased the mass of 18:3n-3 and 20:5n-3 in phospholipids of pork *longissimus* muscle 3.8- and 2.8-fold, respectively (14). A higher ground flaxseed content (15% of ration) fed to pigs for 42 d had an even greater increase in phospholipid 18:3n-3 and 20:5n-3 mass of pork *longissimus* muscle: 11.7- and 3.2-fold, respectively (13). Clearly, in hogs it is much easier to enrich the muscle in 18:3n-3 and 20:5n-3 by including flaxseed in the rations than it is in cattle. Microbial fermentation of feedstuffs before the true stomach of cattle and the consequent low level of n-3 FA available to their muscle cells compared with no microbial fermentation of digesta before the stomach of pigs likely explains differential enrichment potential for swine vs. cattle. However, similar to the results in cattle, hogs have limited conversion of 18:3n-3 to longer-chain n-3 FA in muscle. Certainly in cattle, the major longer-chain n-3 FA is 22:5n-3, suggesting no biological need for the muscle to elongate 22:5n-3 to 22:6n-3, consistent with our observations here and in rats (38).

Cooking meat may decrease the PUFA content due to oxidation or loss in drippings. When comparing cooked to uncooked meat, one must take into account the water loss observed during cooking. Our approach was to express our data in mol%, thereby negating the need to account for water loss, as this parameter is independent of the mass of the starting material. Our results with grilled steaks are consistent with others

demonstrating that cooking of the *longissimus* muscle to a final internal temperature of 65°C does not alter the FA composition (25). However, another study showed a small increase in 18:3n-3 content in beef patties cooked to an internal temperature of 77°C, although this study did not examine longer-chain n-3 FA (24). In contrast, another study with *longissimus* muscle demonstrated that cooking to an internal temperature of 70°C resulted in substantial loss of 18:3n-3 and a loss of PUFA in general (23). This report is similar to a study with grilled rump steak cooked to "rare," "medium," or "well-done," where there were no changes in 18:3n-3 content but a decrease in 20:5n-3 and 22:6n-3 contents when the meat was cooked beyond "rare" (22). However, in the study of Sinclair et al. (22), the content of 22:5n-3 was reduced if the steaks were cooked at all, whereas in our study, we demonstrate no change in phospholipid FA composition. In addition, when the values are expressed as mass, there is a clear increase in n-3 FA content (data not shown) similar to that observed in total phospholipid mass (Table 6).

Dietary FA are well known regulators of gene expression (39–41), acting through a number of different transcriptional activators including the PPAR family. Both n-3 and n-6 FA are regulators of gene transcription (41), with 20:5n-3 and 22:6n-3 inducing gene expression through a PPARγ-mediated process (42). PPARγ activation is associated with reduced late-stage progression of type-2 diabetes (43,44), a well-known problem associated with feedlot cattle production. Because the PPAR family regulates expression of FA transport proteins (45) and because n-3 FA stimulate this PPAR-mediated process (42), we examined the impact of n-3-enriched diets on PPAR expression in muscle. In addition, we examined the impact of this dietary regimen on H-FABP (FABP3) expression, a protein associated with FA uptake in muscle (46). We found that PPARγ mRNA level was elevated 2.7-fold in the muscle from the flaxseed-fed cattle, whereas PPARα and FABP3 mRNA levels were unchanged. These results suggest that this feeding regimen may have potential downstream protection of cattle from complications associated with type-2 diabetes. In addition, it suggests a potential change in the PPARγ regulated gene-expression, known to have an impact on genes associated with lipid metabolism (40,41) and inflammation (42).

In summary, n-3 levels in the *longissimus* muscle from Hereford and Angus cattle were clearly enriched by feeding flaxseed. The n-3 FA mass was maintained during cooking, demonstrating that the enrichment was preserved during the cooking process. Overall, these results represent an important step in providing Americans an n-3 FA-enriched beef product. In addition, our n-3 feeding regimen increased expression of PPARg in muscle, suggesting long-term feeding may change gene expression for proteins involved in lipid metabolism.

[a]All values represent means ± SD (nmol/g wet weight), $n = 10$. The asterisk (*) signifies statistical significance from uncooked samples as determined using an unpaired, two-tailed Student's *t*-test, $P < 0.05$.
[b]Ribeye steaks were cooked to an internal temperature of 64.1 ± 0.4°C.
[c]Not corrected for water loss.
[d]The cholesterol/phospholipid ratio represents total nmol of cholesterol divided by the total nmol of phospholipid.

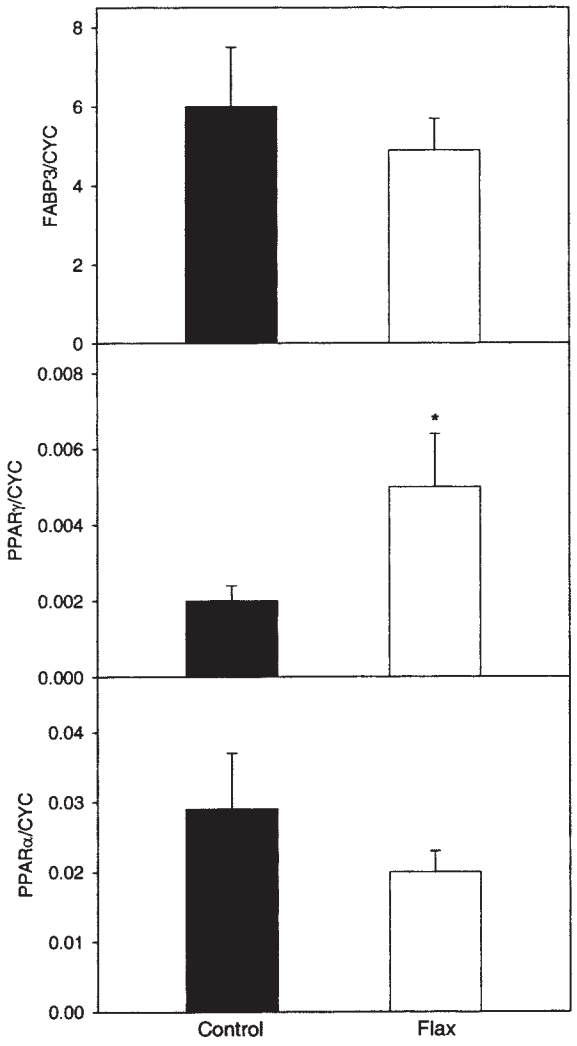

FIG. 1. The effect of flaxseed-feeding on the heart-FA binding protein (FAPB3), peroxisome proliferator activated receptor γ (PPARγ), and PPARα mRNA levels in *longissimus dorsi* muscle of Angus steers. Values represent means and SD, $n = 10$. The asterisk (*) indicates significance from control, $P < 0.05$. CYC, cyclophilin.

ACKNOWLEDGMENTS

We thank Clay Erickson, Charles Flakker, and Curtis Klein for assistance with cattle management and feeding, Blain Hopfauf for doing the biopsies, Travis Maddock for grading the Angus carcasses, Tom Winowiski and LignoTech USA (Rothschild, WI) for providing the material used to treat flaxseed with the lignosulfonate process, and Neil Effertz for helping procure the Angus cattle that provided steaks for the cooking trial. We also thank Dr. Carole Haselton for her technical assistance in the lipid analysis. This work was supported in part by 5P20R017699-02 to EJM and by the Healthy Beef Initiative.

Diacylglycerol Acyltransferase: A Key Mediator of Plant Triacylglycerol Synthesis

Shiu-Cheung Lung and Randall J. Weselake*

Department of Agricultural, Food and Nutritional Science, University of Alberta, Edmonton, Alberta T6G 2P5, Canada

ABSTRACT: Many plants deposit TAG in seeds and fruits as the major form of storage lipid. TAG production is of tremendous socioeconomic value in food, nutraceutical, and industrial applications, and thus numerous conventional and molecular genetic strategies have been explored in attempts to increase TAG content and modify the FA composition of plant seed oils. Much research has focused on the acyl-CoA–dependent reaction catalyzed by diacylglycerol acyltransferase (DGAT), which is an integral endoplasmic reticulum protein and has also been shown to be present in oil bodies and plastids. DGAT enzymes exhibit diverse biochemical properties among different plant species, many of which are summarized here. In addition to catalyzing a critical step in TAG biosynthesis, there is evidence that DGAT has roles in lipid metabolism associated with germination and leaf senescence. TAG can also be formed in plants via two different acyl-CoA–independent pathways, catalyzed by phospholipid:diacylglycerol acyltransferase and diacylglycerol transacylase. The current understanding of the terminal step in TAG formation in plants and the development of molecular genetic approaches aimed at altering TAG yield and FA composition of TAG are discussed.

Paper no. L10049 in *Lipids 41*, 1073–1088 (December 2006).

In a number of plants, TAG are the major storage lipids that constitute a highly reduced form of carbon and serve as an important energy reserve in seeds for subsequent germination and seedling development. These storage lipids are of great nutritional and nutraceutical value, and thus a common source of edible oils for human consumption. They are also becoming increasingly important raw materials in the petrochemical industry for the production of paints, detergents, lubricants, biofuels, and nylon precursors, as it is an undisputable fact that non-renewable crude oil reserves are rapidly being exhausted. Because of our heavy reliance on plant oils in the food and petrochemical industries, boosting the seed oil content and generating desirable FA in oilseed crops are of tremendous socioeconomic value. The implementation of molecular genetic strategies to achieve these goals necessitates a comprehensive understanding of TAG synthesis in plants.

Formation of storage lipids in plants involves *de novo* FA synthesis in the stroma of plastids and subsequent incorporation of the FA into glycerol backbone leading to TAG in the endoplasmic reticulum (ER). The present review sets out to evaluate the terminal step in TAG formation in plants. This committed step primarily involves the catalytic action of diacylglycerol acyltransferase (DGAT; EC 2.3.1.20), which acylates DAG to form TAG in an acyl-CoA–dependent manner. The subcellular localization, biochemical properties, molecular biology, and physiological roles of this enzyme are reviewed in the present article. Recently, acyl-CoA–independent reactions leading to TAG formation have also been described. Current understanding of the two involved enzymes, phospholipid:diacylglycerol acyltransferase (PDAT; EC 2.3.1.158) and diacylglycerol transacylase (DGTA), is also evaluated. This review begins with a brief description of storage lipid synthesis in plants.

STORAGE LIPID SYNTHESIS IN DEVELOPING SEEDS

A generalized scheme of TAG synthetic pathways in developing seeds is depicted in Figure 1. FA synthesis in plants has been extensively reviewed elsewhere (1,2). In plastids, FA are synthesized from acetyl-CoA in a three-step process: (a) irreversible carboxylation of acetyl-CoA by the action of acetyl-CoA carboxylase (EC 6.4.1.2) to form malonyl-CoA; (b) repeated condensation of malonyl-CoA with a growing acyl carrier protein (ACP)-bound acyl chain by the action of FA synthase complex, consecutively adding two carbon units to form 16:0-ACP; and (c) elongation and desaturation of 16:0-ACP to form 18:0-ACP and 18:1-ACP, respectively. The *de novo* synthesized FA enter the cytosolic pool in an esterified form known as acyl-CoA, which are synthesized by an ATP-dependent esterification of FA and CoA through the action of acyl-CoA synthetase (EC 6.2.1.3). In erucic acid–rich *Brassica* species, the acyl-CoA pool is further enriched with 22:1-CoA by the action of membrane-bound FA elongation (FAE) complex on the ER.

In the ER, the sequential incorporation of FA onto the glycerol backbone is commonly known as the Kennedy pathway (3). The pathway starts with the acyl-CoA–dependent acylation of *sn*-glycerol-3-phosphate to form lysophosphatidic acid through the action of *sn*-glycerol-3-phosphate acyltransferase (EC 2.3.1.15). The second acyl-CoA–dependent acylation is

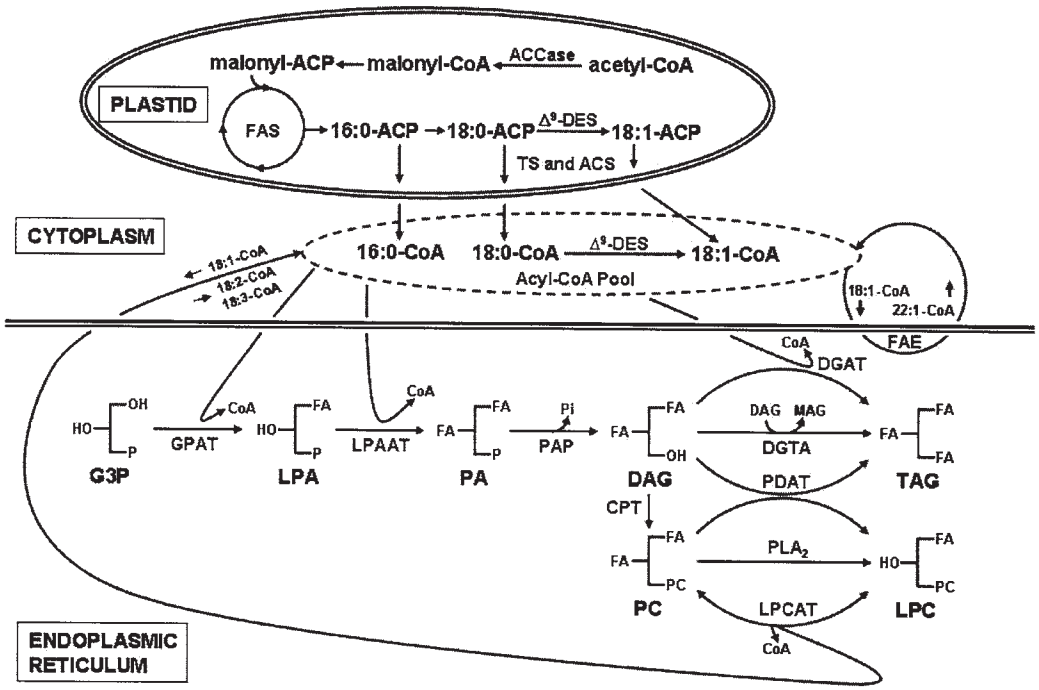

FIG. 1. Generalized scheme of FA and TAG synthesis in developing seeds of oleaginous plants. FA synthesis occurs in plastids. The *de novo* synthesized FA enter the cytosolic acyl-CoA pool, which fuels the assembly of TAG from *sn*-glycerol-3-phosphate (G3P) in the ER. PUFA are enriched in the acyl-CoA by the action of desaturase at the level of PC and lysophosphatidylcholine acyltransferase (LPCAT)-mediated acyl exchange. In *Brassica* species, erucic acid is produced by two-step elongation of oleoyl-CoA. Δ^9-DES, Δ^9-desaturase; ACCase, acetyl-CoA carboxylase; ACP, acyl carrier protein; ACS, acyl CoA synthetase; CPT, CDP-choline: 1,2-diacylglycerol cholinephosphotransferase; DGAT, diacylglycerol acyltransferase; DGTA, diacylglycerol transacylase; FAE, FA elongase; FAS, fatty acid synthase; GPAT, *sn*-glycerol-3-phosphate acyltransferase; LPA, lysophosphatidic acid; LPAAT, lysophosphatidic acid acyltransferase; LPC, lysophosphatidylcholine; PAP, phosphatidate phosphatase; PDAT, phospholipid:diacylglycerol acyltransferase; PLA_2, phospholipase A_2; TS, acyl-ACP thioesterase.

catalyzed by lysophosphatidic acid acyltransferase (EC 2.3.1.51), leading to the formation of PA, which is dephosphorylated through the action of phosphatidate phosphatase (EC 3.1.3.4) to form *sn*-1,2-DAG. The third acyl-CoA–dependent acylation catalyzed by DGAT leads to the production of TAG. DAG is situated at the branch point of the pathway between TAG and membrane phospholipid formation. Cytidine diphosphate (CDP)-choline:1,2-DAG cholinephosphotransferase (CPT; EC 2.7.8.2) catalyzes the transfer of a phosphocholine from CDP-choline into DAG and leads to the formation of PC and cytidine monophosphate.

PUFA are enriched in the acyl chains of DAG by the FA desaturation (FAD) pathways catalyzed by FAD2 and FAD3 desaturases that utilize PC as substrate (4) and the reverse reaction of CPT that channels PC back to DAG. The acyl moiety at the *sn*-2 position of PC may undergo acyl exchange with the acyl-CoA pool by the reversible reaction catalyzed by lysophosphatidylcholine acyltransferase (EC 2.3.1.23). Lysophosphatidylcholine can also be formed through hydrolysis of PC catalyzed by phospholipase A_2 (EC 3.1.1.4). Recent studies have indicated that TAG could also be formed in acyl-CoA–independent reactions using DAG and PC as the acyl donors (5,6). PDAT catalyzes the acyl transfer from PC to DAG leading to the formation of lysophosphatidylcholine and TAG, whereas DGTA catalyzes the transfer of an acyl moiety between two DAG molecules to form TAG and monoacylglycerol (MAG).

SUBCELLULAR LOCALIZATION OF DGAT

The subcellular localization of DGAT has been a subject of controversy for decades. Numerous earlier studies have demonstrated the presence of DGAT activity in oil bodies (7), which have been regarded as the principal site of TAG synthesis (8–15). Subsequently, other researchers, however, argued that DGAT is associated with the ER (16–19). By retaining the attachment of polysomes to the membrane fractions in the presence of Mg^{2+} during isolation, Cao and Huang (20) were able to localize the maize DGAT to the rough ER.

Although there is evidence for DGAT activity in both oil bodies and ER, the debate over how DGAT ends up in oil bodies can be related to investigations of the ontogeny of the oil bodies. The widely accepted theory is that oil bodies are continuous with and generated from the DGAT-harboring ER (21,22), leading to the persistence of DGAT in the membranes of oil bodies after budding (23). This theory has been supported

by electron microscopy observations in developing oilseeds that indicated that sphereosomes budded off from the terminal strands of ER and developed into oil bodies (20), and that oil bodies were frequently in proximity to the ER (24), implicating their *in vivo* association. Thus, the *de novo* biosynthesis of TAG in purified oil body fractions could be due to their contamination with membrane fractions (25). For instance, DGAT from oil bodies and membrane fractions have been found to share similar enzymic properties (11). The purified oil bodies from germinating soybean cotyledons also exhibited activities for ER markers, suggesting *in vivo* association of the two organelles (24).

On the other hand, some researchers have hypothesized that oil bodies are independent of the ER, exuded into the cytoplasm in the form of naked droplets and subsequently coated with oleosins and phospholipids (14,18,26–28). In this context, earlier studies with acyltransferases in crambe (*Crambe abyssinica*) seeds indicated the presence of enzymic activities in oil body, nuclear/plastid, and mitochondrial fractions with apparent absence of DGAT activity in microsomal fractions (29). The most critical cue that favors the second theory is the considerably higher DGAT activity in the oil body fractions of certain plant materials than in the microsomal fractions in terms of specific (9,11,13,15) and total (11) activity. Concomitantly, a recent investigation of DGAT in oil bodies purified from freshly excised maize developing embryos indicated that the enzyme activity in this organelle was too high to be completely ascribed to microsomal contamination and may have been underestimated in the absence of endogenous DAG for enzyme assays (30).

Nonetheless, Kamisaka and Nakahara (11) argued that the floating membrane-bound DGAT might be drawn into the lipid-rich oil body fraction due to a high enzyme-lipid affinity, leading to the high occurrence of artificial DGAT activity in this fraction. Lacey and Hills (17) clearly showed the heterogeneity of ER in developing seeds of *Brassica napus* L. with respect to lipid synthesis, from which they proposed another explanation that DGAT might concentrate in certain TAG-secreting ER regions separated from the bulk ER by their lower equilibrium density.

Despite the controversy regarding oil body ontogeny, the ER is believed to be the principal site of TAG synthesis in developing oilseeds (25). In fact, recent studies of DGAT have extensively utilized the microsomal fractions from developing seeds of many plants as well as the microspore-derived (MD) culture of *B. napus* (31). Recently, Shockey *et al.* (32) further localized two unrelated tung DGAT activities (type 1 and type 2) to non-overlapping, distinct subdomains of ER using immunofluorescence staining. The subcellular localization of both enzymes to the ER is attributable to the presence of ER retrieval motifs at C-termini, whereas the targeting of both enzymes to their respective ER subdomains requires additional protein sequences (32).

In addition to the subcellular localization of DGAT in oil bodies and the ER, this protein has also been found in the chloroplasts of spinach leaves (33) and soybean cell suspension cultures (34). Plastidial DGAT may account for the presence of a trace amount of TAG in chloroplast envelopes (33,35,36) and plastoglobuli (oil bodies in stroma) (33). The relatively low DGAT activity in the microsomal fractions from photoautotrophic cells (33,34) is in agreement with the suggestion that lipid assembly in chloroplasts is self-sufficient (37), although it is plausible that certain lipids are imported from the ER to the thylakoids and envelopes (38,39). Interestingly, TAG assembly from palmitic acid, exogenously applied to the upper surface of spinach leaves, was evident, confirming the activity of plastidial DGAT *in vivo* (40). Recently, immunochemical techniques were used to demonstrate that DGAT is localized to intact chloroplasts, purified thylakoids, and envelope membranes from *Arabidopsis* leaves, but it is absent from the stroma (41).

OPTIMIZATION OF *IN VITRO* DGAT ASSAYS

The role of exogenous DAG as an acyl acceptor varies with different assay systems. It has been reported that DGAT activity in maize microsomes was reduced by one-third in the absence of exogenous DAG (20). Concomitantly, supplementation of exogenous DAG enhanced DGAT activity in the particulate fractions from maturing safflower seeds (42,43) and microsomal and oil body fractions from palm mesocarp (15). Other researchers have reported, however, that the effect of exogenous DAG on *in vitro* DGAT activity was not substantial (17,30,35,44–48), presumably due to the adequate amount of DAG endogenously present in the enzyme preparations or produced during the course of incubation (20,23,48). The degree of enzyme dependency on exogenous DAG takes into account the endogenous DAG content, which varies with the plant species and the stage of seed development (43), as well as the accessibility of the exogenous DAG to the enzyme (49). The degree of dependence on endogenous DAG is probably also affected by the molecular species of DAG present. By dispersion of the exogenous DAG in a suitable detergent (e.g., Triton X-100), DGAT activity was found to be enhanced in association with an increasing amount of exogenous DAG (49). Valencia-Turcotte and Rodríguez-Sotres (30) also observed that the octanoyl-*N*-methylglucamide (MEGA-8)-solubilized DGAT was notably more active after the addition of emulsified DAG. Commonly used DAG substrates and assay concentrations of substrate are listed in Table 1.

[a]Added in a mixture.

Radiolabeled acyl-CoAs were routinely supplied as acyl donors in most *in vitro* assays of DGAT activity (Table 2). Hobbs and Hills (45) demonstrated that omission of acyl-CoA led to a 10-fold reduction in DGAT activity. Radiolabeled TAG product can be quantified following separation by TLC or using radio-HPLC (48,50). Radiolabeled DAG can be used only if the label is located on the glycerol moiety because FA-labeled DAG is subject to possible interference by acyl exchange reactions (31,51). Assays conducted using radiolabeled acyl-CoA, however, are not subject to interference by acyl-CoA–independent processes including the reactions catalyzed by DGTA and PDAT (52).

In an assay system, the reactants and enzymes can be dispersed by sonication (30,53) or detergents such as Tween-20, Triton X-100, and Zwitteronic detergent 3-08 (Table 3). Selecting a suitable detergent in an assay system takes into consideration the compromise between its solubilizing ability as well as its denaturing effect on the enzyme, both of which vary with different DGAT samples. For instance, Triton X-100 was routinely used in some studies (Table 3), and it was found to be inhibitory to the activity of other DGAT preparations (35,42,43), although Cao and Huang (20) later demonstrated that the inhibitory effect of Triton X-100 could be minimized by pretreatment of the enzyme preparation with the same detergent. Other detergents including sodium deoxycholate, sodium dodecyl sulfate, and sucrose monolaurate have been shown to abolish enzyme activity (20,42,49).

SUBSTRATE SPECIFICITY AND SELECTIVITY OF DGAT

It is possible that some DGAT can utilize acyl acceptors other than DAG such as sterols. A DGAT mutant in *Arabidopsis* has not been shown, however, to exhibit any abnormality in steryl ester proportion compared to the wildtype (54). Similarly, Bouvier-Navé *et al.* (23) have shown that overexpression of a DGAT-encoding cDNA from *Arabidopsis* (*AtDGAT1*) did not complement the knocked-out acyl-CoA:cholesterol acyltransferases (ACAT; EC 2.3.1.26) in a yeast double-mutant, which exhibited similar sterol profiles and ACAT activity, despite the relatively high homology between the encoding sequences of the two enzymes (55). It is interesting to note, however, that fungal (*Mortierella ramanniana*) (56) and mouse (57) DGAT can acylate MAG, whereas the latter also exhibited activity with wax monoesters, diesters, and retinyl esters (57).

Ichihara and Noda (43) reported that DGAT activity in the particulate fraction from maturing safflower seed utilized *sn*-1,2-DAG and *sn*-2,3-DAG, but was apparently inactive with *sn*-1,3-DAG. The acyl composition of DAG affects DGAT activity differently depending on the source of the enzyme. A relatively broad preference for molecular species of DAG has been observed in some studies (43,58). DAG species with very long chain FA were preferred in certain nasturtium (59) and rape varieties (60,61). DGAT-catalyzed TAG synthesis in spinach leaves was considerable with diolein, but hardly detectable with dipalmitin (35). Water-soluble DAG including *rac*-1,2-diacetylglycerol and *rac*-1,2-dibutyrylglycerol are poor substrates of DGAT from safflower seeds (43). Vogel and Browse (58) demonstrated that microsomal DGAT from *Cuphea* and castor bean exhibited high activity toward DAG containing unusual FA (e.g., lauric and ricinoleic acids) at both *sn*-1 and *sn*-2 positions. The investigation proposed that rapid conversion of unusual DAG species to TAG might be a mechanism of plants to restrict the entry of unusual FA into PC and other membrane phospholipids.

The abundance of medium-chain and hydroxyl FA in *Cuphea* seeds (62,63) and castor beans (63,64) has been attributed to the high selectivity of their respective DGAT for DAG species containing these FA. Although it has been suggested that the substrate specificity of DGAT might not be an important factor for determining the acyl composition of TAG (56), a precise conclusion on the preference of specific DGAT for specific DAG species certainly necessitates a survey of more DGAT from various sources, which has been hindered by the difficulties associated with removing endogenous DAG in the enzyme preparations (35,46). Sukumar and Sastry (65) removed the endogenous DAG in a microsomal preparation from developing groundnut seeds by high-salt (4 M KCl) extraction, dialysis, and precipitation.

It is generally believed that DGAT exhibits absolute specificity to acyl-CoA as the acyl donor, despite the limited evidence obtained from a fungal (*Mortierella ramanniana*) DGAT, which did not acylate with PC, DAG, or oleic acid (56). Inter-

For each sample, DGAT specificity is ranked in descending order of activity: 1, highest; 5, lowest; N: negligible.
[a]DGAT was obtained from leaves

estingly, Shine *et al.* (66) claimed that an enzyme preparation from avocado mesocarp microsomes could catalyze the incorporation of an acyl moiety from ACP thioesters into the *sn*-3 position of TAG. In contrast to the rather similar acyl composition in leaf tissues, tremendous variability in acyl composition and occurrence of unusual FA are mostly confined to oilseeds (8). Accordingly, the biochemical characterization of DGAT from developing seeds has mostly, if not exclusively, dealt with the acyl-CoA preference of the enzyme. Substrate preference of DGAT is studied with respect to specificity and selectivity determinations. The former is studied using a single acyl-CoA species at a time, whereas a mixture of acyl-CoA species is utilized in the measurement of the latter, which is generally regarded as a more realistic reflection of the *in vivo* situation (31). An equimolar mixture of different acyl-CoA species is commonly used in a selectivity study, which in certain cases has also been carried out with different ratios of thioesters (67). For a better assessment of the substrate preference of DGAT (68), complete assembly of TAG from exogenously applied *sn*-glycerol-3-phosphate has also been studied (60,68,69).

In some plant species, different acyl-CoA species can hardly be differentiated by DGAT (43,67), whereas other plant DGAT preferentially utilize certain acyl-CoA species (Tables 4 and 5). The acyl-CoA selectivity of DGAT depends on several factors, including acyl composition of the DAG pool (32,70), acyl-CoA concentration (48), and temperature (2,8,19,71,72). It has been reported that the incorporation of saturated FA into glycerolipids was preferred at higher temperature in a study over a range of 15–40°C using cacao microsomes (72). The temperature effect on acyl-CoA selectivity of DGAT has been attributed to the differential changes in substrate-enzyme affinity and solubility of the substrates (71).

In general, plant DGAT exhibit a broad acyl-CoA preference as revealed by the specificity (Table 4) and selectivity studies (Table 5). As a result, it is believed that the acyl composition of TAG in oilseeds is predominantly controlled by other factors such as availability of specific DAG and acyl-CoA pools to the enzymes (56). In some cases, however, the substrate preference of DGAT does play a decisive role in the specific channelling of certain FA into TAG molecules (16), exemplified by the selectivity of cocoa DGAT for stearoyl-CoA (68) and the strong preference of DGAT from certain rape varieties for erucoyl-CoA (9,48,73) and DAG species with very long-chain acyl moieties (60,61). It is noteworthy that the per-

sisting selectivity of DGAT from low–erucic acid *Brassica napus* varieties for erucoyl-CoA is consistent with the breeding efforts that modified the genes encoding enzymes that catalyzed FA elongation but not DGAT genes (71). Griffiths *et al.* (74) suggested that the strong selectivity of DGAT from common borage for γ-linolenic acid could potentially lead to the efficient removal of this FA from the acyl-CoA pool and thereby account for the rare occurrence of this FA at the *sn*-2 position of TAG, compared with the efficient DGAT-catalyzed incorporation of this FA at the *sn*-3 position.

In addition to advancing our knowledge of the factors that control the acyl composition of seed oils, the extensive studies of acyl-CoA preference of plant DGAT offer new insights into developing strategies for genetic engineering of seed oil composition. For instance, in an attempt to generate unusual FA in seed oils of certain species, one should take into account the compatibility of the DGAT in the host plants with the engineered unusual FA. In this context, activity of DGAT from *Cuphea* and maize toward erucic acid was negligible (71), whereas the incorporation of EPA (20:5*cis*$\Delta^{5,8,11,14,17}$) and DHA (22:6*cis*$\Delta^{4,7,10,13,16,19}$) into TAG via DGAT action is apparently feasible in developing flax seeds (47).

MODULATORS OF DGAT ACTIVITY

A better understanding of DGAT modulators may provide new opportunities to enhance TAG accumulation in oilseed plants. Currently known activators and inhibitors are summarized in Tables 6 and 7, respectively. A number of metabolites involved in the TAG biosynthetic pathway have been shown to enhance *B. napus* DGAT activity substantially (44,60,75). *sn*-Glycerol-3-phosphate may stimulate CPT activity and thereby facilitate the channelling of PC to DAG, which is an acyl acceptor in the DGAT-catalyzed reaction (60). Alternatively, exogenous PA has been shown to fuel the production of DAG via PA phosphatase, and thereby favor the DGAT-catalyzed reaction

(44,75). Adenosine triphosphate (ATP) and CoA, which are the important key metabolites in the synthesis of acyl-CoA, the acyl donor in the DGAT-catalyzed reaction, have been shown to exhibit a stimulatory effect on *B. napus* DGAT activity (44,75). Whether or not these metabolites act as allosteric effectors of DGAT *in planta*, however, remains to be investigated.

Among various stimulating proteins (Table 6), BSA has been used routinely in DGAT assays to increase the sensitivity of enzyme detection (Table 6) (46). In studies with MD embryos of *B. napus*, BSA increased DGAT activity in a concentration-dependent manner, with a maximum of 5-fold stimulation at a concentration of 3–4 mg BSA mL^{-1} (46). The BSA-stimulatory effect on DGAT may be related to the acyl-CoA binding ability of BSA, such as prevention of acyl-CoA micelle formation (detergent effect), protection of acyl-CoA from thioesterase activities, and/or the preference of DGAT for acyl-CoA in protein-bound form (15,46,76,77). These hypotheses are supported by another observation that a recombinant acyl-CoA binding protein increased the activity of *A. thaliana* DGAT1 expressed in insect cell culture by up to 70% (45). Interestingly, BSA was found to severely inhibit the activity of safflower DGAT (43).

In another study with the DGAT from MD embryos of *B. napus* (78), a similar stimulatory effect on DGAT has been observed in the presence of human acylation stimulating protein (ASP). Transformation of *B. napus* with the cDNA encoding ASP resulted in an apparent increase in seed size and lipid content per seed in some transgenic lines (78). As well, transformation of *B. napus* with cDNA encoding ASP or BSA resulted in some lines having changes in the FA composition of the seed oil (79). Thus, ASP or BSA appears to exert modulatory effects on DGAT activity *in vivo*. It is plausible that one or more certain small organic molecules act as DGAT modulator because the activity of microsomal DGAT from MD cultures of *B. napus* was shown to be enhanced by the addition of the cytosolic fraction that lost its stimulatory effect after ashing (44). A number of electrolytes have also been shown to activate or inhibit DGAT activity (Tables 6 and 7). Observed modulatory effects brought about by exposure of enzymes to electrolytes have been attributed to changes in enzyme conformation (46).

SOLUBILIZATION AND PARTIAL PURIFICATION OF DGAT

DGAT are highly hydrophobic, membrane-bound enzymes, and thus their solubilization necessitates the use of detergents, which are known to be enzyme denaturants and inhibitors of enzyme activity (80). Nonetheless, the successful development of a solubilization scheme facilitates not only the purification process but also the removal of endogenous DAG for selectivity assays (30).

Solubilization of DGAT has been reported for the enzyme from spinach leaves (35), germinating soybean (80), developing maize embryos (30), and MD cultures of *B. napus* (46,48,81). Solubilization of DGAT from spinach leaves with salt solution favorably yielded a 10- to 40-fold purification and a recovery of 20% enzyme activity (35). Kwanyuen and Wilson (80) reported that solubilization of microsomal DGAT from germinating soybean using ionic agents such as NaCl, KCl, sodium cholate, and deoxycholate at various concentrations resulted in significant inhibition or loss of enzyme activity. Treatment of the same membrane preparation with 9 mM 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate also reduced the activity drastically, but yielded the highest recovery of specific activity among all tested agents and produced a three-fold purification (80). In another study with microsomal DGAT from MD cultures of *B. napus* (48), ionic detergents similarly inhibited enzyme activity substantially, whereas a nonionic detergent, *n*-octyl β-D-glucopyranoside, was found to be the least inhibitory. Further studies on the effects of different nonionic detergents indicated that dispersion of the enzyme with MEGA-8 could ideally maintain the enzyme activity (81). Subsequently, the solubilization of the enzyme with MEGA-8 was optimized at a detergent (1% wt/vol) to protein ratio of 2:1, in the presence of 2 M NaCl (46). This solubilized enzyme was later used in photoaffinity labeling studies with the radiolabeled substrate analog [^{125}I]12-[(4-azidosalicyl)amino]dodecanoyl-CoA ([^{125}I]ASD-CoA), which identified a 39-kDa polypeptide in the solubilized fraction (82). The solubilization procedure for *B. napus* DGAT was reproduced using microsomal DGAT from developing maize embryos with high recovery of enzyme activity, although it was found to be ineffective in the removal of endogenous DAG (30). Valencia-Turcotte and Rodríguez-Sotres (30) proposed another method in which dried microsomal and oil body fractions were delipidated by repeated washing with benzene followed by solubilization with a solution of methanol/acetic acid/water (1:1:1, by vol) in preparation for molecular sieve chromatography using controlled-pore glass. The active fractions could subsequently be identified by assay with exogenous DAG, PC, and [^{14}C]oleoyl-CoA (30).

Partial purification of solubilized DGAT has been reported for a number of plant tissues, including germinating soybean seeds (80), developing safflower seeds (43), MD culture of *B. napus* (46,81), and spinach leaves (35). DGAT from germinating soybean cotyledon has been highly purified and the final enzyme fraction was believed to be homogenous (80), but reported later to contain oil body proteins (83). Characterization of this partially purified enzyme indicated the presence of three possible subunits (84). DGAT has been purified to apparent homogeneity from an oil body fraction of *Mortierella ramanniana* (56).

DGAT1

In 1998, there were two reports on the cloning of putative acyltransferase genes from mouse and human based on sequence homology to ACAT (85). Expression of the mouse cDNA in insect cells increased DGAT activity in the microsomes (85). The isolation of *DGAT1* cDNA from mouse was immediately followed by the identification of other *DGAT1* members from a number of plant species, including *Arabidopsis* (23,54,55,86), olive (87),

tobacco (23), oilseed rape (88), burning bush (89), castor bean (64), and tung (32). Cloning of the same *Arabidopsis* DGAT1 (*AtDGAT1*) cDNA has been reported in four independent studies (23,54,55,86). Although the *AtDGAT1* gene was obtained from expressed sequence tag (EST) or genomic clones through similarity searches of database in all three studies, Routaboul *et al.* (86) were capable of further confirming the gene identity by cloning of two mutated alleles (AS11 and ABX45) from the T-DNA insertion mutant collection by screening for wrinkled, incompletely filled seeds with reduced oil composition.

The identification of *AtDGAT1* assisted the subsequent cloning of *DGAT1* cDNAs from olive (87), tobacco (23), burning bush (89), and tung (32). The deduced amino acid sequences represented by two olive *DGAT1* cDNAs differ by 26 amino acids in the central part of the polypeptide (87), whereas a shorter oilseed rape DGAT-encoding cDNA, designated as *BnDGAT2*, is a truncated version of the *BnDGAT1* and encodes a protein lacking the hydrophilic N-terminal segment found in BnDGAT1 (88). Interestingly, the DGAT1 from burning bush exhibits both acetyl and long-chain acyltransferase activity and can probably switch between either specificity depending on *in vivo* conditions (89).

Alignment of the deduced amino acid sequences of DGAT1 from different plant species is presented in Figure 2A. In the phylogenetic tree, the plant and animal DGAT1 proteins apparently separate into two major clusters (Fig. 2B). The variants between different plant and animal DGAT1 proteins are primarily concentrated at the N-terminal segments (Fig. 2A), which might account for the differences in enzymic properties among DGAT1 from different plant sources. For instance, although the deduced amino acid sequence of DGAT1 from burning bush shares 91% similarity with the *Arabidopsis* counterpart (89), the unique acetyltransferase activity of burning bush DGAT can probably be ascribed to the greatly different N-terminal end. The divergence between DGAT and ACAT is also centered on the N-terminal parts of the proteins (23). In fact, it has been demonstrated that the N-terminal fragment of BnDGAT1 interacts with acyl-CoA exhibiting greater affinity for erucoyl-CoA than oleoyl-CoA (78,90). It is also noteworthy that the N-terminus of BnDGAT1 has been localized to the cytosolic side of the ER and shown to self-associate into tetramers (90). The N-terminus also appears to be important in the self-association of ACAT1 (91) and human DGAT1 (92).

In general, each DGAT1 protein consists of 9–10 putative transmembrane domains and a relatively hydrophilic N-terminal segment (Fig. 2A). Topological studies of tung DGAT1 suggested that both N- and C-termini of the protein are oriented toward the cytosolic side of ER membranes (32). Common functional domains predicted in several DGAT1 proteins include phosphorylation sites (55,64,88), leucine zippers (23,55,88), and DAG/phorbol-binding motif (54,87,88). An invariant proline residue is believed to participate in acyl-CoA binding (54). In addition, an inner membrane component signature of the binding-protein–dependent transport system is uniquely present in DGAT1 from castor bean (64), implicating potential interaction of the enzyme with acyl-CoA binding proteins.

DGAT2

In 2001, Lardizabal *et al.* (93) reported the cloning of two type 2 DGAT species from the oleaginous fungus *Mortierella ramanniana*. The deduced amino sequences of the two unrelated polypeptides of MrDGAT2 shared no homology with DGAT1. Cases *et al.* (94) used the *MrDGAT2* sequence for homology searches of EST libraries and successfully identified the DGAT2-related genes from mouse and human. From the studies with single and multiple gene disruptions, Sandager *et al.* (95) suggested that DGAT2 was the major TAG-synthesizing enzyme in yeast. Based on the amino acid sequence of a putative *DGAT2* homologue in *Arabidopsis* (92), a novel DGAT2 cDNA has recently been identified in tung (32). The encoded protein possesses two predicted transmembrane segments and both N- and C-termini are oriented toward the cytosolic side of ER (32).

Cases *et al.* (94) have developed assay conditions to differentiate DGAT1 and DGAT2 activity in microsomes from several mouse tissues including brain, heart, muscle, liver, and adipose tissue. A method for determining the relative contributions of DGAT1 and possible DGAT2 activity in plant microsomes, however, has not yet been developed. Thus, at this time, it is not possible to ascribe the effects of activators or inhibitors of plant DGAT activity to a specific DGAT isoform in assays conducted with microsomes. Some idea of the relative contributions of DGAT1 and DGAT2 to oil accumulation in plant tissues might be obtained using immunochemical methods with specific antibodies directed against each of the isoforms. Nykiforuk *et al.* (88) have raised monospecific polyclonal antibodies against synthetic peptides representing peptide segments within *B. napus* DGAT1.

NOVEL DGAT FAMILIES

A gene encoding a bifunctional enzyme (*AcDGAT*) exhibiting wax ester synthase and DGAT activity has been identified in *Acinetobacter calcoaceticus* and found to be unrelated to known wax synthases, DGAT1 and DGAT2 (96). The enzyme, however, was shown to share similarity to a large family of putative proteins in *Arabidopsis*, implying that the acyl-CoA–dependent synthesis of TAG in *Arabidopsis* may be accomplished by multiple enzymes (96). AcDGAT may also be a membrane-bound enzyme due to the presence of a predicted membrane-spanning region (96). However, a cytosolic DGAT was recently identified in developing peanut cotyledons and its full-length cDNA cloned (97). The deduced amino acid sequence of this novel DGAT shares 13% identity with the bifunctional AcDGAT and less than 10% identity with DGAT1 and two family members (97). The presence of orthologous genes in the genomes of other plant species implicates the possible existence of a cytosolic TAG synthetic pathway in plants that is not restricted to peanut (97).

THE ROLE OF DGAT IN TAG SYNTHESIS

The spatiotemporal expression of DGAT in plants has provided insight into the role of DGAT in regulating TAG biosynthesis.

A

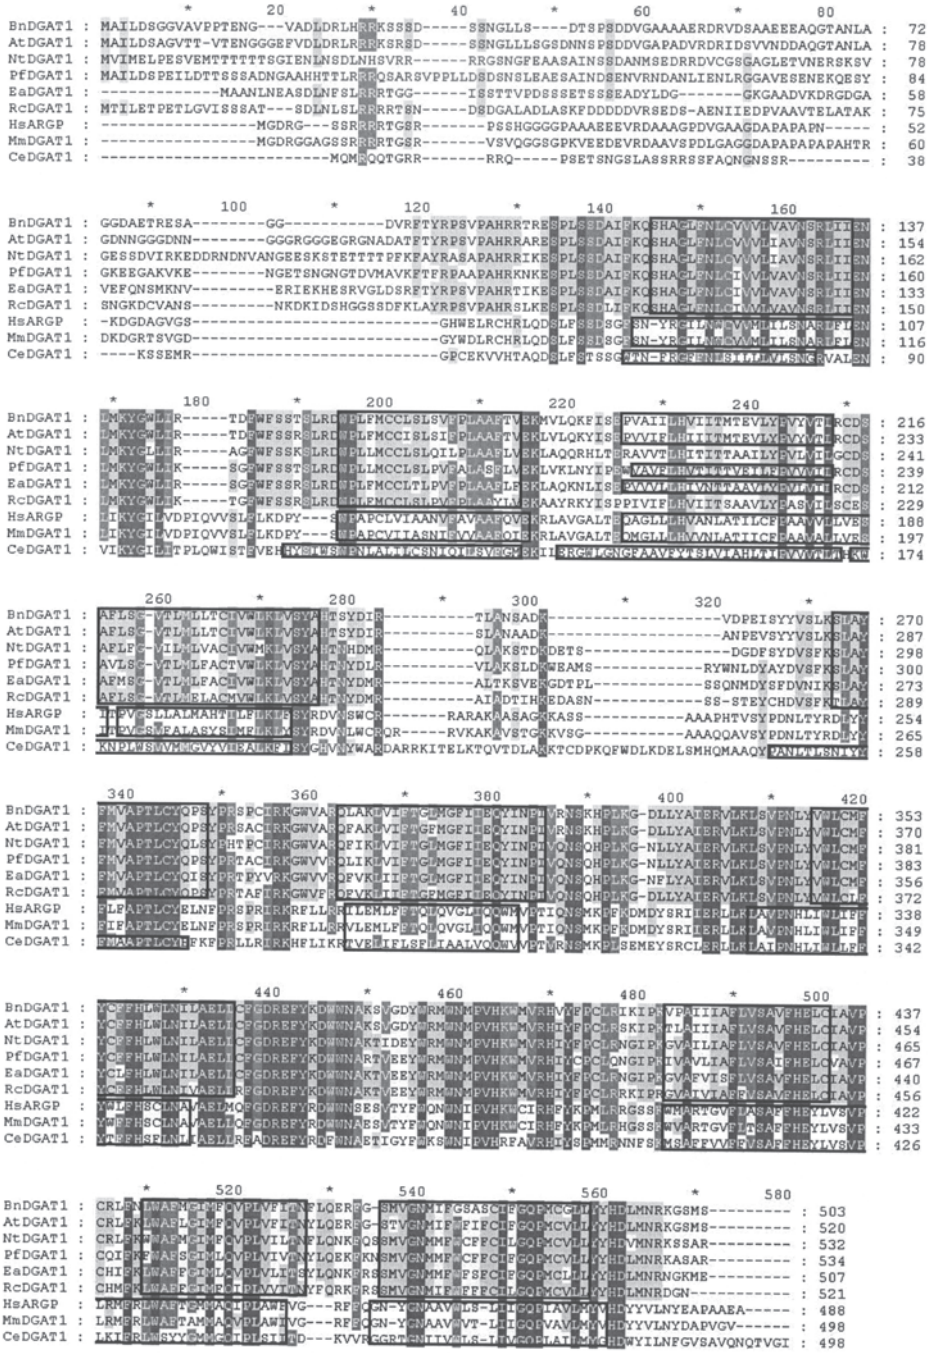

FIG. 2. Comparison of deduced amino acid sequences from different putative or demonstrated type-1 DGAT. (A) Amino acid sequence alignment. DGAT-1, diacylglycerol acyltransferase-1; ARGP, acyl-CoA:cholesterol acyltransferase-related gene product. Alignment was performed using ClustalX v1.83 formatted in Genedoc (Multiple Sequence Alignment Editor and Shading Utility v. 2.6). The residues blocked with a white foreground on a dark grey background are 100% conserved bases, residues with a white foreground on a grey background are 75% or more conserved bases, and residues aligned with a black foreground on a light grey background are 50–74% conserved bases. Putative transmembrane domains are boxed. GenBank accession numbers are shown in parentheses: *BnDGAT1*, *B. napus* (AF164434); *AtDGAT*, *A. thaliana* (AF051849); *NtDGAT*, *N. tabacum* (AF129003); *PfDGAT*, *P. frutescens* (beefsteak mint; AF298815); *EaDGAT*, *E. alatus* (winged euonymus; AY751297); *RcDGAT*, *Ricinus communis* (AY366496); *HsDGAT*, *H. sapiens* (L21934); *MmDGAT*, *M. musculus* (AF078752); *CeDGAT*, C. *elegans* (AF221132). (B) The phylogenetic tree was constructed by the neighbor joining method using the MEGA 3 program (129) with 1,000 bootstrap repetitions. The bootstrap values (%) are given at the respective nodes. (Continued)

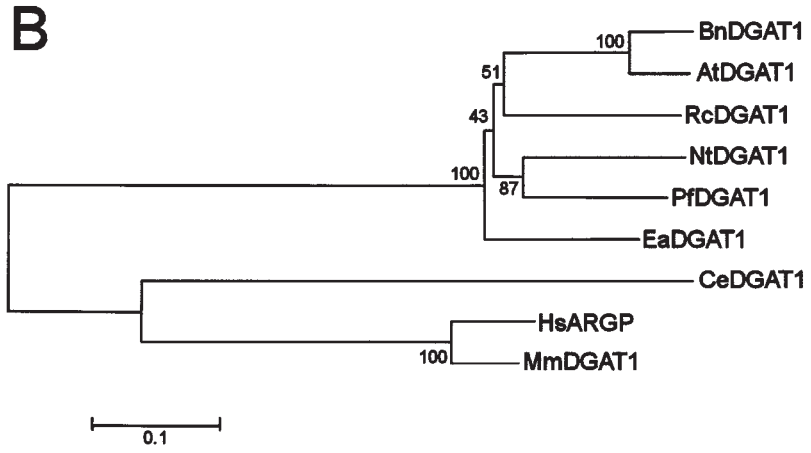

FIG. 2. (Continued)

Spatial expression of DGAT has been investigated primarily in *Arabidopsis* (41,54,55,98). In general, it has been shown that the *Arabidopsis* DGAT1 transcript and protein were at the highest concentration in oil-forming organs, specifically inflorescence and developing seeds (55,98), although considerable amounts of transcript and protein were also apparent in leaf (41,54,55), flower (41,54), root (41,54), and stem (41,98) tissues. A similar expression pattern for *DGAT1* was also observed in oilseed rape (55). Interestingly, a recent investigation on the spatiotemperal expression of tung DGAT1 and DGAT2 as well as their acyl-CoA selectivities suggested that the former type plays a constitutive role in TAG metabolism in several tissues whereas the latter type is more specific in production of TAG containing eleostearic acid in seeds (32).

Oilseed development is a three-stage process, which includes cell division, biosynthesis of storage materials, and desiccation. The temporal expression of *DGAT* in developing seeds is generally synchronized with TAG biosynthesis. For instance, *DGAT1* transcript was detectable during later stages of embryo development in olive when the expression of FA synthase dropped to an undetectable level (87). The expression of a DGAT1-β-glucuronidase (GUS) fusion protein was visualized to be most intense in maturing embryos and pollen of *Arabidopsis*, whereas the GUS activity was undetectable during early embryogenesis or in desiccating seeds (98). Earlier studies showed that high DGAT activity in developing seeds was parallel to the active phase of rapid lipid accumulation and subsequently reduced as the seed lipid content reached a plateau (47,65,73,99).

As DAG is located at the branch point between TAG and membrane phospholipid biosyntheses (Fig. 1), DGAT potentially plays a decisive role in regulating the formation of TAG in the glycerolipid synthesis pathway. Considering the putative protein kinase-targeting motif conserved between DGAT and other acyltransferases, it is believed that at least some of the regulation operates at the protein level (54,100). Some characteristic regulatory elements have also been recognized in the *AtDGAT1* gene and may be important in regulating the expression of the gene during seed maturation (23,98), although it has been suggested that DGAT activity in oilseed rape is not tightly regulated in relation to transcript (100,101). The regulatory role of DGAT is supported by multiple lines of evidence that have suggested that modulation of DGAT activity results in sizable effect on seed oil production. For instance, mutation of the *DGAT1* gene severely affects seed development in *Arabidopsis*, including the appearance of wrinkled and incompletely filled seeds (86), reduction in seed oil content (54,86,102) and increased DAG/TAG ratio (50), increased flow of elevated FA toward β-oxidation (102), and aberrant seedling growth (86). Whereas the effect of osmoticum on enhancing TAG formation has been noticed in several plant species (103–107), the induction of TAG accumulation in oilseed rape by sucrose has been correlated with the increase in DGAT activity (88,101,108, 109). Similarly, modulation of lipid accumulation in oilseed rape by light/dark treatments indicated that the activity of DGAT was the lowest among the four enzymes in the Kennedy pathway, and such modification of carbon flux resulted in changes in the DAG pool but not other intermediates (53). In other studies, the rate-limiting role of DGAT in TAG formation has also been proposed from the general observation of the lowest specific activity of DGAT compared with other Kennedy pathway enzymes (18) and the highest accumulation of DAG as a Kennedy pathway intermediate (110,111), although it should be noted that DAG accumulation can also be due to a shortage of acyl-CoA (112). Interestingly, it has also been suggested that the rate-limiting role of DGAT might also be important for the equilibration of DAG with the PC pools to achieve some degree of polyunsaturation of FA moieties at the level of PC (68,113). In this context, the most convincing observation is that methanesulfonate-induced mutation of *AtDGAT1* resulted in substantial increase in the proportion of PUFA (e.g., linoleic and α-linolenic acids) to monosaturated FA (e.g., oleic and erucic acids) in *Arabidopsis* (50).

Despite the remarkable effect of plant DGAT on TAG accumulation, the rate-limiting role of DGAT is not observed in all plant species, as exemplified by the independence of TAG production in lupin species from DGAT activity (114). As suggested by Bao and Ohlrogge (112), oil content is a quantitatively inherited trait and is, therefore, probably regulated by multiple steps involving a number of enzymes including FA synthases, elongases, and hydrolases. Nonetheless, overexpression of DGAT genes is a promising strategy to boost TAG yield. Whereas overexpression of *AtDGAT1* in tobacco leaves produced up to 7-fold increase in TAG content of leaf tissues (23), seed-specific expression of the same cDNA in *Arabidopsis* led to an overall increase of 11–28% in seed oil content (115).

THE ROLE OF DGAT IN SEED GERMINATION

As stored TAG in seeds is broken down actively to meet the high energy requirement for seedling development during germination, it was surprising to observe that the expression of *AtDGAT1* was up-regulated in germinating seeds and young seedlings (54). The DGAT expression in seedlings was later confirmed in transformation studies with a DGAT-GUS fusion construct (98). The increased sensitivity of *Arabidopsis* DGAT mutants to sugars and various stress conditions during germination and seedling development strongly suggests that DGAT also plays a post-embryonic role in plants (116). Although it has been known that germinating seedlings are capable of TAG synthesis (117), Lu *et al.* (98) proposed that DGAT might also play a role in sequestration of TAG-released FA and coordination of metabolism during seedling development in response to environmental cues.

Recently, He *et al.* (118) also proposed that TAG synthesis in early seedling development may be of relevance to heading off the osmotic effects of excessive sucrose, which is the major breakdown product of storage oil during germination. In their studies, lipid synthesis in germinating castor seed cotyledons was shown to correlate with *de novo* expression of *RcDGAT1,* and such process is probably regulated by proteolytic degradation (118).

THE ROLE OF DGAT IN LEAF METABOLISM

During protoplast isolation from *Arabidopsis* leaves, Browse *et al.* (119) reported that the mass of all major polar lipids decreased by 10–20% while the amount of neutral lipids including TAG increased by three-fold compared with the original leaf tissue, concomitant with the transfer of hexadecatrienoic acid (16:3), a characteristic acyl component of thylakoid monogalacyosyldiacylglycerol, to other lipid classes. From similar observations of acyl migration from polar lipids to neutral lipids in ozone-treated spinach leaves, Sakaki *et al.* (120,121) proposed that free FA were released from monogalacyosyldiacylglycerol by galactolipase, esterified to acyl-CoA by the catalytic action of acyl-CoA synthetase, and eventually acylated with *sn*-1,2-DAG to form TAG in a DGAT-catalyzed reaction. A recent study has shown that the expression of *DGAT1* was up-regulated during leaf senescence in *Arabidopsis* and the accumulated TAG was similarly enriched in hexadecatrienoic acid and linolenic acid (41). Although the significance of the sequestration of galactolipid FA in TAG remains unknown, some authors have suggested that it is a means to diminish the toxicity of free FA (120) or an intermediate step in the conversion of thylakoid FA to phloem-mobile sucrose in response to stresses (41). Similar results were obtained when leaf tissues were incubated in 0.5 M sorbitol solution (119), implying that such a conversion of polar lipids to neutral lipids may be a response to stresses.

ACYL-COA–INDEPENDENT PATHWAYS FOR TAG FORMATION

The *Arabidopsis* mutants (ABX45 and AS11) possess a mutated allele of *AtDGAT1*, which was proven to be single-copy gene by Southern blot analyses (54,86). The inactivation of *AtDGAT1* gene does not completely abolish the TAG-synthesizing capacity of the plants (54,86,98), suggesting the existence of other DGAT isoforms and/or non–DGAT-catalyzed reaction(s) that could lead to TAG formation in plants. Two enzyme activities (i.e., PDAT and DGTA) catalyzing acyl-CoA–independent synthesis of TAG have been described.

PDAT

PDAT is a transacylase that catalyzes the acyl-CoA–independent transfer of FA from phospholipid to *sn*-1,2-DAG to form TAG and lyso-phospholipid. The PDAT-encoding gene identified in yeast shares sequence homology to mammalian lecithin-cholesterol acyltransferase (EC 2.3.1.43), which catalyzes the acyl transfer from lecithin to cholesterol (6). The PDAT-catalyzed reaction has been shown to mediate the majority of TAG formation in yeast during exponential growth, whereas mutation of the four yeast DGAT-like genes has been shown to result in little or no effect on TAG synthesis (6). Concomitantly, a significant increase in TAG content in PDAT-overexpressing yeast cells was observed (122). Dahlqvist *et al.* (122) characterized PDAT in microsomal preparations from developing seeds of sunflower, castor bean, and *Crepis palaestina*, in addition to the cloning of the yeast PDAT-encoding gene. The specificity of PDAT from different plant sources toward acyl donors is species-dependent (122,123), such that the *C. palaestina* PDAT preferentially catalyzes the transfer of the vernoloyl groups (*cis*-12-epoxyoctadeca-*cis*-9-enoic acid) of phospholipids into TAG, whereas castor bean PDAT catalyzes the incorporation of both ricinoleoyl (HO-18:1) and vernoloyl groups (122). PDAT in oilseed plants may therefore play a critical role in removal of unusual FA from membrane phospholipids by the selective transfer of these FA into TAG (122). The substrate specificity of yeast PDAT depends on the head group of the acyl donor, the acyl group transferred, and the acyl chains of the acceptor DAG molecule (122). Recently, a PDAT-encoding cDNA that shares 28% amino acid identity to the yeast PDAT has been identified in *Arabidopsis* (124), suggest-

ing that PDAT activity is not limited to the unusual FA-producing oilseed plants. Gene identity was confirmed by overexpression in *Arabidopsis* and the protein was found to exhibit broad substrate specificity toward different phospholipids as acyl donor containing different acyl moieties ranging from C10 to C22 (124). Despite the 10-fold increase in PDAT activity of the transformants, no alteration in FA composition in either vegetative parts or in the oil accumulating seeds was observed, implying that PDAT might not be important for the control of lipid composition or redistribution of acyl groups between lipids in *Arabidopsis* (124). A recent study with a knockout mutant of *Arabidopsis* possessing a T-DNA insertion in the PDAT locus indicated no significant changes in FA content and composition in the mutant seeds (125). Although it is plausible that PDAT may not be major TAG contributor in plants, the specific physiological roles of PDAT remain to be elucidated.

DGTA

In 1993, Lehner and Kuksis (5) first reported the purification and characterization of a DGTA from rat intestinal microsomes. The purified enzyme did not catalyze the incorporation of radioactivity from [1-^{14}C]oleoyl-CoA into any acyl acceptors, but catalyzed a transacylation reaction in which the free hydroxyl group of a DAG molecule was acylated with a FA moiety from another DAG molecule, forming a MAG and a TAG molecule. The enzyme was found to utilize both *sn*-1,2-DAG and *sn*-2,3-DAG at similar rates but not *sn*-1,3-DAG or other neutral lipid esters (5). DGTA also appears to catalyze the acyl transfer from a TAG molecule to a MAG molecule to yield two DAG molecules in the reverse reaction, which may be important in further desaturation of acyl groups from TAG via the interconversion between DAG and PC (52). By manipulating the Mg^{2+}-dependent conversion of PA to DAG in microsomal membrane preparations from developing sunflower seeds, the flux of TAG formation from DAG in the presence of Mg^{2+} after EDTA treatment was found to be primarily independent of acyl-CoA, suggesting the more important role of DGTA and other acyl-CoA–independent pathways for TAG synthesis in this crop (126). Mancha and Stymne (127) observed a remodeling of *in situ*–synthesized TAG species in microsomal preparations from developing castor bean endosperm, such that ricinoleate in TAG was substituted by non-hydroxylated FA groups derived from polar lipids and mainly from PC, implicating the activity of DGTA. To date, however, no cDNA encoding DGTA has been isolated from any source. Recently, Stymne *et al.* (128) showed that yeast PDAT also displayed transacylase activity, which may have accounted for the observation on apparent DGTA activity in plants (52).

CONCLUSIONS AND FUTURE DIRECTIONS

In general, oilseed biotechnology sets out to accomplish two ultimate goals: (a) to increase oil accumulation in the seed and (b) to produce a desirable FA composition in the seed oil. A detailed understanding of the terminal step in TAG formation in plants will provide valuable knowledge for accomplishing these long-term goals. The physiological role of DGAT in regulating TAG accumulation in plants opens a new perspective on improving seed oil content by overexpression of DGAT-encoding cDNA in transgenic plants. Although the results from *AtDGAT1*-overexpressing tobacco and *Arabidopsis* have been promising, the feasibility of this approach for improving major oilseed crops remains to be investigated. The biochemical properties of DGAT vary among different plant species as well as a number of environmental conditions. cDNA encoding plant DGAT1 and DGAT2 have been functionally expressed in yeast. The recent discovery of a bifunctional DGAT/wax ester synthase gene from *Acinetobacter calcoaceticus* (96) and a novel cytosolic DGAT from developing DGAT cotyledons (97) may lead to the identification of orthologues of these novel DGAT from other species. The identification of all DGAT-encoding genes will also assist in investigation of the physiological role(s) of DGAT in plants through the use of multiple knockout mutants. In *Arabidopsis*, the increase in the proportion of PUFA to monounsaturated FA that resulted from methanesulfonate-induced mutation of *AtDGAT1* (50) implicates the importance of DGAT in influencing FA composition of the seed oil. Thus, site-directed mutagenesis of *DGAT1* might create enzyme variants with altered FA selectivity properties. In this context, the deduced amino acid sequence of the currently known plant DGAT implicates that the difference in enzymic properties among different plant DGAT may be primarily dependent on the variation in N-terminal regions of the proteins. Investigations of DGAT modulators could lead to other strategies for enhancing seed oil content. Whilst the enhancement of oil deposition associated with increased seed size in ASP-overexpressing oilseed rape is encouraging (79), a comprehensive study of potential interacting partners of DGAT within the oil-forming cell might lead to additional strategies for altering seed oil content.

ACKNOWLEDGMENTS

RJW is grateful to the Alberta Agricultural Research Institute, the Alberta Crop Industry Development Fund, the Flax Council of Canada, Genome Canada/Genome Prairie, the Natural Sciences and Engineering Research Council of Canada, and the Canada Research Chairs Program for supporting his research on TAG biosynthesis in oilseeds. SCL is supported by the Provost Doctoral Entrance Award from the University of Alberta. The authors also thank Dr. Salvatore Sparace and Chris Kazala for their critical evaluations of the manuscript.

Department of Biochemistry and Molecular Biology, Faculty of Sciences, University of Granada, 18071 Granada, Spain

ABSTACT: The cyclic fluctuations of HMG-CoA reductase activity and mRNA are reportedly related to feeding the cells in culture or to variations in food consumption by the animals over a 24-h cycle. In this work, we demonstrate cyclic increments in HMG-CoA reductase activity in smooth muscle cells (SMC) not associated with the culture feeding. Since reductase activity also shows a marked rise preceding the S phase, one of the major goals of the present work was to evaluate this dual role of reductase activity and mRNA fluctuations related to the cell cycle and to food intake in the SMC-C/SMC-Ch cultures derived from control-fed (SMC-C) and cholesterol-fed (SMC-Ch) chicks. The period and amplitude oscillations in HMG-CoA reductase activity varied depending on culture conditions: lipoprotein-deficient serum vs. FBS, young vs. senescent cells, or confluent vs. nonconfluent cultures. The HMG-CoA reductase mRNA concentration showed a marked rise after feeding not correlated to the fluctuation activity, suggesting posttranscriptional modulation. Reductase activity and mRNA were down-regulated in SMC-Ch. Since the nutritional culture conditions were the same in both cell lines, these findings indicate that consumption of a high-cholesterol diet by the animals prior to the establishment of the SMC cultures induced changes in the HMG-CoA reductase gene expression in aortic SMC.

Paper no. L9929 in *Lipids 41*, 1089–1099 (December 2006).

The enzyme HMG-CoA reductase (EC 1.1.1.34), from the endoplasmic reticulum, catalyzes the conversion of HMG-CoA to mevalonate, the rate-limiting step in cholesterol biosynthesis (1). The rate of cholesterol biosynthesis from different tissues was shown to have a diurnal rhythm many years ago (2–4). These rhythmic changes are associated with changes in HMG-CoA reductase activity (1,2,5,6). In rodent liver, diurnal variation of hepatic cholesterol synthesis is driven primarily by varying the steady-state mRNA levels for HMG-CoA reductase (6–11). The diurnal rhythm of HMG-CoA reductase from chick liver and intestine has also been observed in our laboratory. In this animal, both reductase activities were maximal during the light period, in agreement with chick feeding habits. However, chick liver and intestine reductase do not show diurnal rhythm at hatching (5) or during the first week of life, when the chick is still reabsorbing the yolk (12) and thereby developing a transient hypercholesterolemia, which becomes almost three times higher in cholesterol-fed chicks (13). Indeed, the rise in reductase activity is depressed in hypercholesterolemic chicks (13) and following cholesterol or mevalonate feeding in cell cultures (14). Moreover, the diurnal rhythm of mevalonate metabolism by sterol and nonsterol pathways and of mevalonate-activating enzymes has been demonstrated (15). The multivalent feedback regulation of HMG-CoA reductase involves cholesterol and one or more of the other products that are synthesized from mevalonate (16). Both cholesterol and mevalonate are required for the depression of reductase activity at the transcriptional, posttranscriptional, and posttranslational levels (17–20). The diurnal variation in activity is a good example of short-term physiological regulation of hepatic HMG-CoA reductase (1,2) and is due to changes in the state of phosphorylation of the enzyme; however it has been reported that the diurnal variation in hepatic HMG-CoA reductase is due to changes in enzyme protein levels rather than changes in the phosphorylation state of the enzyme (21). It has also been demonstrated *in vivo* that the short-term changes in enzyme activity are due to changes in the quantity of enzyme rather than to a modulation of the catalytic activity (22).

On the other hand, HMG-CoA reductase activity regulation participates in cell division (23–26), as reflected by a marked rise in HMG-CoA reductase activity just preceding the S phase of the cell cycle (25). However, parallel changes in HMG-CoA reductase activity have been observed in synchronized and unsynchronized cells (14). In fact, HMG-CoA reductase activity was low at the time of the medium change and increased 10- to 20-fold 5–10 h after medium change, returning to basal levels by 24 h in both synchronized and unsynchronized cells. Thus, other factors besides the cell cycle may also play a role. If the rise in HMG-CoA reductase activity is blocked by a competitive inhibitor such as compactin, the cells will not enter the S phase (23). The arrest in the cell cycle cannot be overcome by the addition of cholesterol, but rather by the addition of mevalonate (24,25). Studies in a rat embryo fibroblast cell line, synchronized by double thymidine (dThd) block and cultured in cholesterol-containing medium, have demonstrated cyclic variations of HMG-CoA reductase activity with two maxima in the S and G_2M phases (26). In this culture model, the cyclic varia-

tions of the enzyme activities appeared to be due more to increased synthesis at given times of the cycle than to periodic dephosphorylation.

Although it has been well established that the diurnal rhythm of hepatic HMG-CoA reductase is associated with variations in food consumption over a 24-h cycle in the whole animal (5,6,8,27,28), the marked change that the reductase activity shows in cell cultures is not so well established and cannot be explained by the contribution of nutrients. This fluctuation of reductase in cell cultures has been associated with feeding the cells or with the cell cycle and DNA replication. Early experiments (27) demonstrated a small increase of the reductase activity in cultured fibroblasts 19 h after changing to fresh media supplemented with FBS, whereas a large (fivefold) increase occurred in reductase activity after changing to fresh media supplemented with lipoprotein-deficient serum (LPDS). Moreover, early experiments (14) also demonstrated that HMG-CoA reductase activity increased in a murine macrophage-like cell line (J774) under normal culture conditions (in the presence of 10% FBS) and that this variation was associated with feeding the cells. These authors also demonstrated the increase of reductase activity in confluent and unsynchronized cultures, emphasizing that other exogenous factors besides the cell cycle could play a role. On the other hand, several investigators have observed that HMG-CoA reductase activity is high in rapidly dividing cells but declines as cells reach confluence (28,29). This view contrasts with the results reported previously (14) since these authors reported that reductase activity increased in confluent cells where no transient changes in DNA synthesis or in cell number were observed. Also, marked fluctuations during the various phases of the cell cycle have been reported in HMG-CoA reductase activity, in the G_1 phase when quiescent, growth-inhibited cells are stimulated by replenishment of growth factors or serum in synchronized cultures (29), increasing to twice that of the unsynchronized cells examined concomitantly.

Thus, the cyclic fluctuations of HMG-CoA reductase activity and mRNA levels are related to feeding the cells in culture or variations in food consumption over a 24-h cycle in the animals. Since HMG-CoA reductase activity also shows a marked rise just preceding the S phase of the cell cycle, one of the major objectives of the present work was to evaluate the variations in HMG-CoA reductase activity and mRNA concentration in an *in vivo/in vitro* model of arterial smooth muscle cell (SMC) cultures and to investigate the relationships between HMG-CoA reductase, food availability, and cell division. In our laboratory, we isolated SMC from cholesterol-fed chicks (SMC-Ch), which are very proliferative in culture compared with SMC isolated from control-fed chicks (SMC-C). Thus, DNA synthesis in the S phase was fourfold higher; moreover, after 20 d of culture, SMC-Ch cells increased their cholesterol content to double that of SMC-C, producing SMC-Ch cultures under conditions mimicking a very early atherosclerosis model at the SMC level (30). We have studied cholesterol synthesis and HMG-CoA mRNA concentrations in these cultures and showed great differences between SMC-C and SMC-Ch (31,32). In this study, we demonstrate the existence of cyclic fluctuations of HMG-CoA reductase activity in nonsynchronized SMC cultures that are not correlated to the cultured feeding or to the increase of mRNA, suggesting the existence of posttranscriptional modulation of the HMG-CoA reductase and of relationships between HMG-CoA reductase activity and cell division.

MATERIALS AND METHODS

Animals. Newly hatched White Leghorn male chickens (*Gallus domesticus*) were provided by a commercial hatchery and fed *ad libitum* in a chamber with a light cycle from 0900 to 2100 hours and controlled temperatures of 29–31°C. Two groups of chicks that were 10 d old were used. The control group was kept on a standard diet (Sanders A-00) whereas the treated, or diet-group, was fed on the same diet supplemented with 5% w/w powdered cholesterol (pure grade; Panreac Química, Spain) mixed homogeneously. The diet was started at hatching and kept on until the chicks were killed (10 d after). Water was available at all times. None of the chicks died a natural death during the treatment nor developed any illness.

SMC cultures. SMC were isolated from the aortic arch of the chicks as described before (33,34) with slight modifications (30) and cultured in DMEM containing D-glucose (4.5 g/L) and L-glutamate (584 g/L) and supplemented with 1% of antibiotic cocktail composed of penicillin (100 μg/mL) and amphotericin (0.25 μg/mL) (Sigma Chemical Co.) and 10% (vol/vol) of whole serum (FBS). When specified, delipidized serum (LPDS) was substituted for whole serum during the incubation period. Medium was buffered with bicarbonate, and cultures were kept at 37°C in a humidified atmosphere of 95% air and 5% CO_2. Medium was renewed every 48 h, and cells were passaged by trypsinization (0.05% trypsin–0.02% EDTA in PBS). All experiments were conducted using 3 or 4 passages (young cultures) or 13–15 passages (senescent cultures). Cells were seeded at approximately 2×10^4 cells per dish (60 mm) containing 4 mL fresh medium.

Cells were identified as vascular SMC by their "hill-and-valley" pattern of confluence (34) and by positive staining to smooth muscle actin and myosin (35). Cell number and viability were checked using the trypan blue exclusion test (Sigma). Cell viability was usually about 90%.

For culture, exponentially growing cells from three passages were synchronized by double-excess thymidine block (36). After 15 h in medium containing 2 mM thymidine, the cultures were washed two times with PBS saline solution and incubated again in normal medium for 8, 9, or 10 h. Synchronization was achieved by a second thymidine treatment for 15 h. At the end of this thymidine block, cells were carefully washed three times with 3 mL of PBS, and normal fresh medium was added. At all time points, cells were examined by light microscopy and monitored for viability by determining trypan blue exclusion. Cell viability was about 90%, and the senescent aspect of the cultures follows the normal evolution through 15 passages.

LPDS was prepared from the plasma of standard diet-fed

chickens, using a single spin gradient density ultracentrifugation according to Poumay and Ronveaux-Dupal (37).

Flow cytometry. Cell fixation was carried out as described previously (38). The cells were harvested and washed with PBS containing 10% FBS. Cell pellets were resuspended in 250 µL PBS, followed by 250 µL PBS containing 2% paraformaldehyde. After incubation for 15 min at 4°C, cells were washed, resuspended in 5 mL of ice-cold 70% ethanol, and refrigerated overnight at –20°C. Then, cells were processed for cellular DNA content and cell-cycle distribution of SMC populations. Fixed cells were resuspended in PBS containing 200 µg/mL ribonuclease and 5 µg/mL propidium iodide (PI) and then incubated for 30 min at room temperature. Cells were analyzed for red (PI, allowing DNA quantification) fluorescence using a dual laser flow cytometry FACS Vantage (Becton Dickinson Immunocytometry System, San José, CA.), with a Coherent Enterprise laser (160 mW, 488 nm and 60 mW, UV). The laser was regulated to 488 nm and 15 mW with the sample in the detector, FL_2-regulated to 495 nm (lineal), with a filter 585/42 BP. Five thousand cells were analyzed (300 cells/s); data were processed on the CellFiT (v. 2.01.2 Becton Dickinson).

Assay of HMG-CoA reductase activity in SMC cultures. HMG CoA reductase activity was measured essentially as described by Goldstein *et al*. (39) but adapted to SMC as described below. After three washings of a cell monolayer (1×10^6 cells) with PBS, cells were scraped with a rubber policeman, pelleted at $400 \times g$ then disrupted by incubation in buffer A (5 mM EDTA, 200 mM KCl, 5 mM DTT, 0.25% Brij 97, and 50 mM phosphate buffer pH 7.4) for 15 min at 37°C. After centrifugation at $10,000 \times g$ for 10 min, the protein concentration in the supernatant was determined according to Bradford (40), and about 60–100 µg of protein was used for assay of HMG-CoA reductase activity. The $10,000 \times g$ supernatant was preincubated for 5 min at 37°C in the presence of an NADPH-generating system in buffer B (12 mM DTT, 60 mM glucose-6-phosphate, 7.5 mM NADP, 20 µg/mL glucose-6-phosphate dehydrogenase, and 300 mM phosphate buffer pH 7.4), then incubated with 40 µM [3-^{14}C]HMG-CoA (specific activity: 5550 dpm/nmol) for 15 min in a final volume of 30 µL. The reaction was stopped by adding 5 µL of 5 M HCl and 20 µL of a solution containing 50 mg/mL of mevalonolactone, which acts as a marker for visualization on the TLC sheets.

Samples were then incubated for 30 min at 37°C to permit mevalonic acid to lactonize. The protein-free supernatant solution was chromatographed on a thin layer plate of silica gel G and developed in benzene/acetone (1:1, vol/vol). The plates were then placed in an iodine chamber and the mevalonolactone band (R_f 0.4–0.6) was scraped off and transferred to scintillation vials for measurement of radioactivity. Reductase activity was expressed as pmol of mevalonic acid synthesized/min/mg protein.

Data analysis. Data are expressed as mean ± SEM. Results were analyzed by Student's *t*-test.

Competitive reverse transcription-polymerase chain reaction (c-RT-PCR). Cloning was carried out in *Escherichia coli* strain JM101 (F traD36 proA+ proB+ lacI lacZΔM15/supE thi Δ(lac-proAB)) using the pGEM-T vector system I (Promega, Madison, WI). *Escherichia coli* was cultured in Luria–Bertani broth containing the appropriate antibiotic (ampicillin, 50 µg/mL). Oligonucleotide primers were synthesized with Gibco BRL (Barcelona, Spain) custom primers.

Total cytoplasmic RNA from both the SMC-C and SMC-Ch culture lines was isolated by the acid guanidinium isothiocyanate method as described elsewhere (41,42) with the slight modifications described previously (32).

The construction and sequencing of a chick HMG-CoA reductase cDNA (complementary DNA) fragment was carried out as described by Carazo *et al*. (32). This gave a fragment without primers (22 pb) of 199 pb, which was gel purified; both strands were sequenced by the chain-termination DNA sequencing method of Sanger *et al*. (43) using AmpliTaq, FS and deoxy nucleotide 5´-triphosphates (dNTP) (ABI Prism™ fluorescence labeled; PerkinElmer/Applied Biosystems Division, Foster City, CA) in a Dye Terminator Cycle Sequencing Ready Reaction (PerkinElmer/Applied Biosystems Division). The design and synthesis of chick HMG-CoA reductase homologous primers was carried out as described by Carazo *et al*. (32). To construct a chick HMG-CoA reductase mRNA standard (competitive template), we designed composite primers as described by Carazo *et al*. (32).

RT-PCR was carried out in a single reaction tube using Tth polymerase (GeneCraft GmbH, Münster, Germany), a thermostable DNA polymerase that shows RT activity, by using Mn^{2+} (44,45). All RT and PCR reactions took place in a DNA Thermal Cycler 480 (Techne, Princeton, NJ). The RT reaction was set up in 20 µL containing the appropriate amount of total cytoplasmic RNA; 10× RT buffer [670 mM Tris-HCl, pH 8.8, 166 mM $(NH_4)_2SO_4$, 0.1% Tween-20]; 1 mM $MnCl_2$; 0.25 mM dNTP; 1.25 pmol/µL downstream primer; and 0.12 units/µL of Tth polymerase and then incubated at 72°C for 30 min. Competitor DNA, as indicated above, was added before amplification. For the amplification reaction, 30 µL of a mix containing 5× PCR buffer [33.5 mM Tris-HCl, pH 8.8, 83 mM $(NH_4)_2SO_4$, 3.75 mM EGTA, 25% glycerol, 0.196 Tween-20], 1.5 mM $MgCl_2$, 0.2 mM dNTP, 0.5 pm/µL of both primers (upstream and downstream), and 0.05 units/µL Tth polymerase were added per reaction. Thirty cycles were routinely performed with 1 min denaturation at 95°C, 1 min annealing at 52°C, and 1 min per cycle of PCR at 72°C.

Separation and quantification of PCR products. PCR products were loaded directly onto a 2% agarose gel and electrophoresed at 5 V/cm for 1.5 or 2 h. DNA was visualized and photographed under UV light (320 nm) after ethidium bromide staining (45). The picture was digitized and analyzed using the QuantiScan Program (Biosoft, Milltown, NJ). This DNA quantification system is very sensitive and is able to detect nanogram amounts of DNA. Reactions containing the different masses of DNA were performed in triplicate. All the ethidium bromide colorimetric data included fall into the range where the DNA quantity ratio was linear. A plot of the log of the ratio of target to competitor product against the log of the competitor concentration should give a straight line with a slope of –1 (46).

Competitive RT-PCR analysis involves titrating the standard with a constant amount of sample SMC cytoplasmic RNA per reaction tube (25 ng from young cells and 50 ng from senescent cells). The amount of competitor used at which the ratio of target to competitor PCR products is equal to unity (log ratio = 0; the equivalence point) can be used to calculate the initial number of molecules in the target sequence.

RESULTS

Cell cycle analysis. We prepared unsynchronized SMC cultures of different passage numbers: early-passage cultures or young (3 or 4 passages) with exponentially growing cells or confluent cultures, late-passages cultures or senescent (13–15 passages), and synchronized cultures. Flow cytometry was used to analyze the cell cycle by cell DNA content in SMC-C cultures. Figure 1 shows the cell cycle of three passages of exponentially growing cells from unsynchronized cultures (50–60% of confluence) and the cell cycles of cultures with 100% confluency. Both in exponential growth and at confluency, the proportion of the cells in S phase was the same (almost 30%). Exponential growth SMC cultures show 50% of the cells in G_0/G_1 phase and 30% in G_2/M phase; however, at confluence in the SMC cultures the proportion of the cells in the G_0/G_1 phase is higher (70%) and in G_2/M phase is lower (10%) (Fig. 1).

Cell-synchrony experiments were performed by double excess dThd block after previous determination of the thymidine concentration range (0–4 mM) that was nontoxic for the cells. Figure 2 shows the cell cycle of three passages in exponentially growing SMC cultures synchronized by dTHd block at different times of incubation in normal medium between the first and the second 15-h dThd block. The cells were 80% blocked by thymidine at the G_0/G_1 phase with an interblockage period of 8–9 h (Fig. 2). When released from thymidine block, 20% of the cells entered the S phase, followed by less than 10% of the cells entering the G_2/M phase. Slight differences were found after 10 h of interblockage time. All experiments carried out with synchronized cultures were performed within 9 h of interblockage.

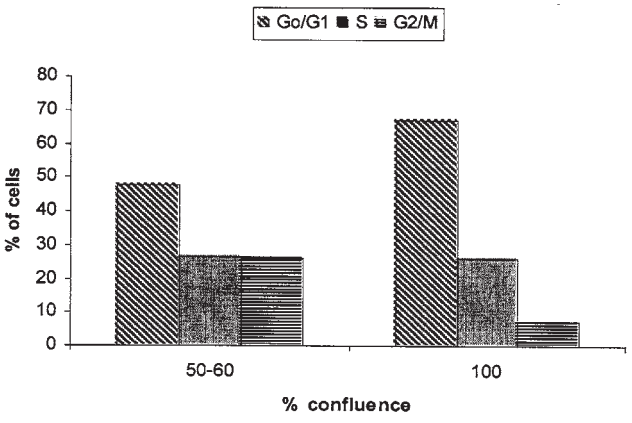

FIG. 1. Cell cycle of third passage smooth muscle cell–control fed (SMC-C) cultures at different confluence. Cells were fixed in ethanol and stained with propidium iodide prior to DNA content analysis by flow cytometry.

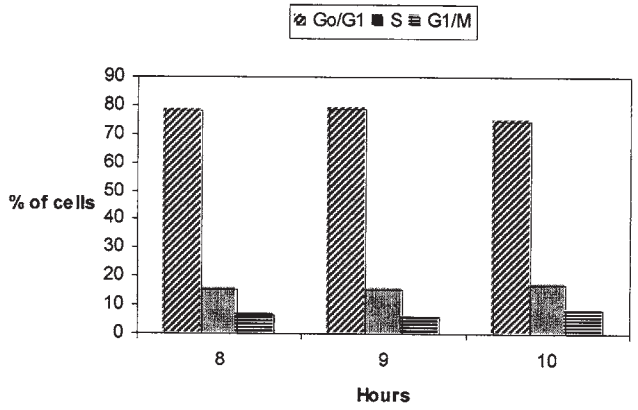

FIG. 2. Cell cycle of synchronized SMC-C cultures. Three passage cultures were grown in DMEM with 10% FBS and synchronized by the double double thymidine (dThd) block procedure with 8, 9, and 10 h of interblockage. Four hours after the second block was released, cells were fixed in ethanol and stained with propidium iodide prior to DNA content analysis by flow cytometry. For other abbreviation see Figure 1.

Effect of medium change on HMG-CoA reductase activity. Control SMC (SMC-C) cultures isolated from control chicks were prepared and at the third passage were assayed for HMG-CoA reductase activity. SMC-C shows cyclic fluctuations in HMG-CoA reductase activity although the period and amplitude of oscillations vary depending on culture conditions (LPDS or FBS, young or senescent, synchronized or unsynchronized). Figure 3 represents HMG-CoA reductase activity measured at different times during 72 h after the medium change (time zero) in synchronized cultures with FBS (A), unsynchronized cultures with FBS (B), unsynchronized cultures with LPDS (C), and 15 passages of unsynchronized cultures with FBS (D). Figure 3A shows the fluctuations of HMG-CoA reductase activity in synchronized cultures decreasing at the time of the medium change followed by a 50% increase in activity at 40 h and more than 50% at 72 h. Figure 3B shows that unsynchronized SMC-C cultures with FBS present a peak of HMG-CoA reductase activity after 5 h of the medium change (increasing around 30%). This first peak is followed by two more peaks at 32 and 64 h of around 30% of reductase activity. However, in the presence of LPDS (Fig. 3C), the absence of cholesterol produces a great induction of the reductase activity after 58 h of media change. HMG-CoA reductase activity measured in 15-passage cultures (Fig. 3D) shows the first peak 16 h after the medium change, followed by very low activity afterward that was minimal at 72 h.

Changes on HMG-CoA reductase activity in SMC-Ch and SMC-C cultures. SMC-C cultures and SMC cultures from cholesterol-fed chicks (SMC-Ch) at the third passage were assayed for HMG-CoA reductase activity. Table 1 shows HMG-CoA reductase activity measured at different times after the medium change for 12 h, reflecting first that the reductase activity was higher in SMC-C than in SMC-Ch at each time studied. Moreover, Table 1 shows the rise in reductase activity at the time of

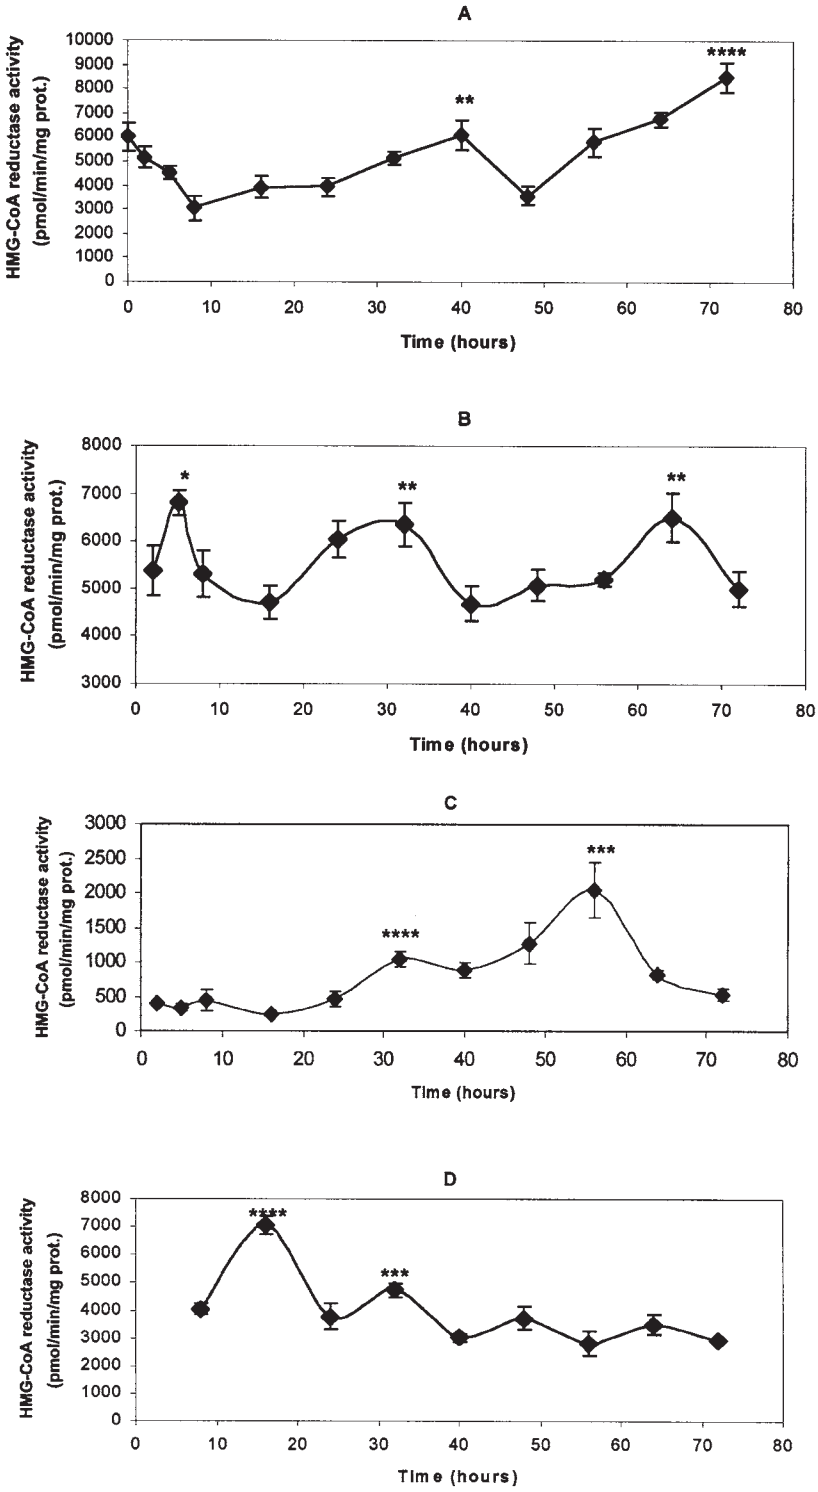

FIG. 3. Fluctuations in HMG-CoA reductase activity of three passages SMC-C synchronized cultures after media change (time 0) supplemented with FBS (A), unsynchronized SMC-C cultures supplemented with FBS (B), unsynchronized SMC-C cultures supplemented with lipoprotein-deficient serum (LPDS) (C), and 15 passages unsynchronized SMC-C cultures supplemented with FBS (D). At time zero, cultures that presented 50–60% confluence were washed with PBS and then fed fresh media. Cells were harvested at each time point, and the HMG-CoA reductase activity was determined. Results are mean ± SEM of 3 experiments. $*P \leq 0.05$, $**P \leq 0.01$, $***P \leq 0.001$, $****P \leq 0.0001$ vs. the previous lower value. For other abbreviation see Figure 1.

TABLE 1
HMG-CoA Reductase Activity in Aortic Smooth Muscle Cell (SMC) Cultures from Control Fed Chicks (C-SMC) and Cholesterol Fed Chicks[a] (Ch-SMC)

	HMG-CoA reductase activity ($pmol \cdot min^{-1} \cdot mg\ prot^{-1}$)	
Time (h)	SMC-C	SMC-Ch
2	9766.2 ± 689	6310.7 ± 520
6	7669.9 ± 888	5856.9 ± 528
12	8433.9 ± 1015	6943.4 ± 616

[a]At time zero, monolayers of three passage cultures that presented 60% confluence were washed with PBS and then fed fresh media. Cells were harvested and the reductase activity was measured at 2, 6, and 12 h after the media change. Results are mean ± SEM for 2 experiments with at least 5 values each for each experiment.

medium change not only in SMC-C but also in SMC-Ch cultures.

In senescent cultures (15 passages; Fig. 4), both SMC-C and SMC-Ch present lower reductase activity than in young cultures, and an activity peak only at 30 h after a change in medium, followed by return to basal values at 48 h. In experiments performed with LPDS, HMG-CoA reductase activity was induced 30 h after the medium change in SMC-C ($P \leq 0.05$) and 40 h after the medium change in SMC-Ch cultures ($P \leq 0.0001$) (Fig. 5).

HMG-CoA reductase gene expression in SMC-C and SMC-Ch cultures after medium change. To measure the HMG-CoA reductase gene expression in chick aorta SMC at several times after re-feeding cultures, the HMG-CoA mRNA of SMC-Ch and SMC-C of three passage cultures was measured by RT-PCR. The quantification of HMG-CoA reductase mRNA showed that the mRNA levels from young SMC-C cultures rose markedly after 16 h of medium change ($P \leq 0.0001$), returning to basal values by 56 h (Fig. 6). This rise in the number of HMG-CoA reductase mRNA molecules occurred also in young SMC-Ch cultures after a change of medium but registered far lower levels with smaller increases in reductase mRNA after 8 h of medium change in SMC-Ch ($P \leq 0.001$) (Fig. 6).

Under normal culture conditions, HMG-CoA reductase activity varied widely among experiments. To examine whether the cyclic fluctuation found in HMG-CoA reductase activity after medium change in SMC-C cultures occurred also in SMC-Ch, and to determine their possible correspondence with changes in mRNA concentration, we prepared three passage cultures isolated from cholesterol-fed chicks (SMC-Ch) and control-fed chicks (SMC-C). The reductase activity was measured after medium change (time zero) in SMC-C and SMC-Ch cultures at different times during 40 h. A parallel experiment was performed to measure the reductase mRNA concentration (Fig. 7). Although the magnitude of the fluctuations varied somewhat among SMC-C and SMC-Ch (Fig. 7A), increases of reductase activity fluctuated over the study period. The greatest change and the highest reductase activity occurred in SMC-C with cultures of three passages vs. SMC-Ch (Fig. 7A). Figure 7B shows a comparison in HMG-CoA reductase mRNA in both SMC-C and SMC-Ch cultures; the increases of reductase mRNA after medium change in SMC-Ch and SMC-C young cultures was similar to the results shown in Figure 6. SMC-C cultures showed a large rise after a change in medium, returning to basal values afterward. However, there was varia-

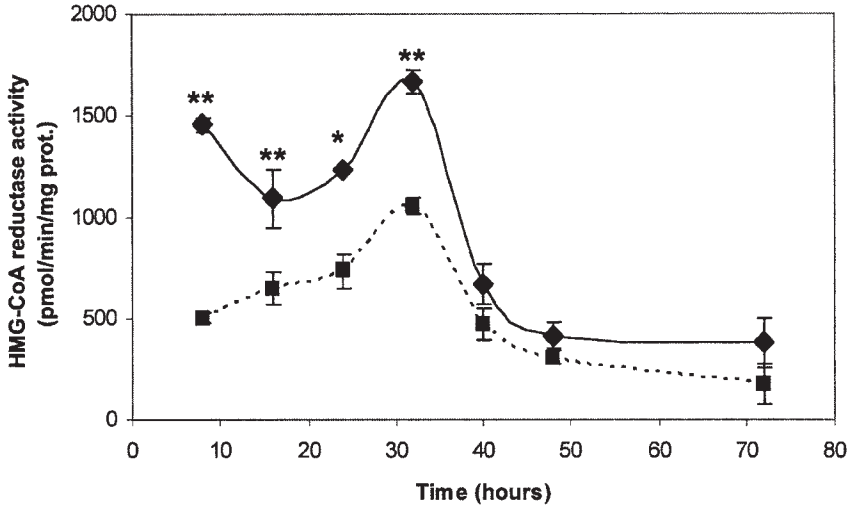

FIG. 4. Variations in HMG-CoA reductase activity of 15 passages SMC-C (◆) and smooth muscle cell–cholesterol-fed (SMC-Ch) (■) unsynchronized cultures after media change supplemented with FBS. At time-zero, cultures with 50–60% of confluence were washed with PBS and then fed with fresh media. Cells were harvested at each time point, and the HMG-CoA reductase activity was determined. Results are mean ± SEM for 3 experiments. *$P \leq 0.001$, **$P \leq 0.0001$ vs. SMC-Ch. For other abbreviation see Figure 1.

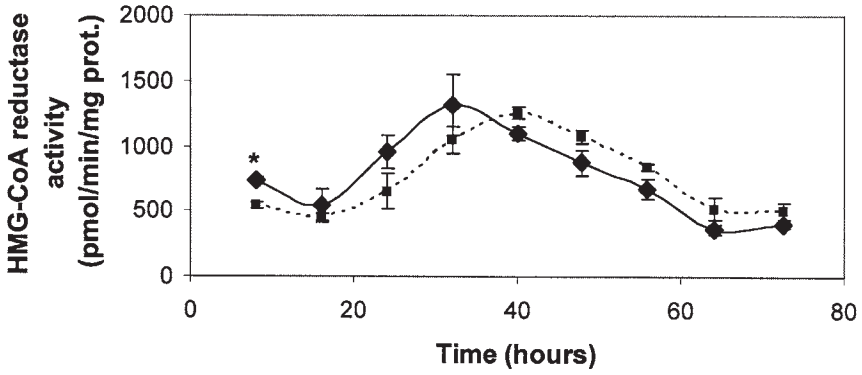

FIG. 5. Effect of media change supplemented with LPDS on HMG-CoA reductase activity of three passages SMC-C (◆) and SMC-Ch (■) unsynchronized cultures. At time zero, cultures with 50–60% confluence were washed with PBS and then fed fresh media with LPDS. Cells were harvested at each time point, and the HMG-CoA reductase activity was determined per mg protein (prot.). Results are mean ± SEM for three experiments. *$P \leq 0.001$ vs. values in SMC-Ch cells at the same time point. For abbreviations see Figures 1, 3, and 4.

tion in the time of rise of these mRNA concentrations with regard to Figure 6. Moreover, SMC-Ch presents the smallest changes and the lowest number of mRNA molecules (Fig. 6).

DISCUSSION

The primary purpose of the present study was to verify and extend the evidence for the dual role of reductase activity fluctuations related to the cell cycle and to food intake in the SMC-C/SMC-Ch cultures. We also wanted to determine specifically whether the alteration of steady-state levels of mRNA for HMG-CoA reductase could also account for cyclic fluctuations in cell cultures, as has been shown for diurnal variations in rat liver (6), or whether this cyclic fluctuation must be predominantly controlled by posttranscriptional regulation of HMG-CoA reductase activity, as it has been claimed previously (47).

The major finding of the present study is that HMG-CoA reductase activity in synchronized and unsynchronized cell cultures underwent marked fluctuations over a long period (72 h) after the change in medium. These fluctuations are not associated with feeding the cells as reported previously (14), since cultured cells were fed only at time zero. These results partially agree with the previous observation in synchronized cell cultures, with two peaks occurring 24 h prior to or at the time of the S phase (24), and also agree with the cyclic variations of reductase activity in dThd block synchronized cells with maximal activity in S or G_2/M phases (26). However, these findings contrast with those of Tavangar *et al*. (14), who stated that this variation in reductase activity is associated only with feeding the cells.

Since the culture does not suffer any re-passage, the growth of the cells is markedly different throughout the experiment.

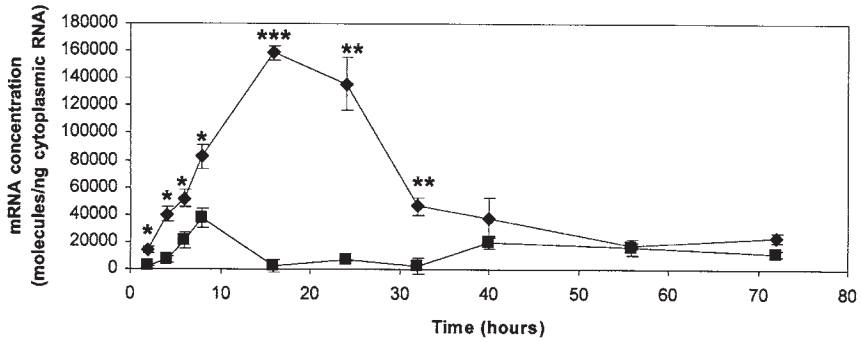

FIG. 6. Comparison of the effect of media change on HMG-CoA reductase mRNA in SMC-C (◆) and SMC-Ch (■) cultures. At time zero, three passage cultures that presented 50–60% confluence were washed with PBS and then fed fresh media. Cells were harvested at each time point, and the HMG-CoA reductase mRNA levels were quantifed by competitive reverse transcription polymerase chain reaction. Results are mean ± SEM for 3 experiments. *$P \leq 0.05$, **$P \leq 0.001$, ***$P \leq 0.0001$ vs. values in SMC-Ch cells at the same time point. For abbreviations see Figures 1 and 4.

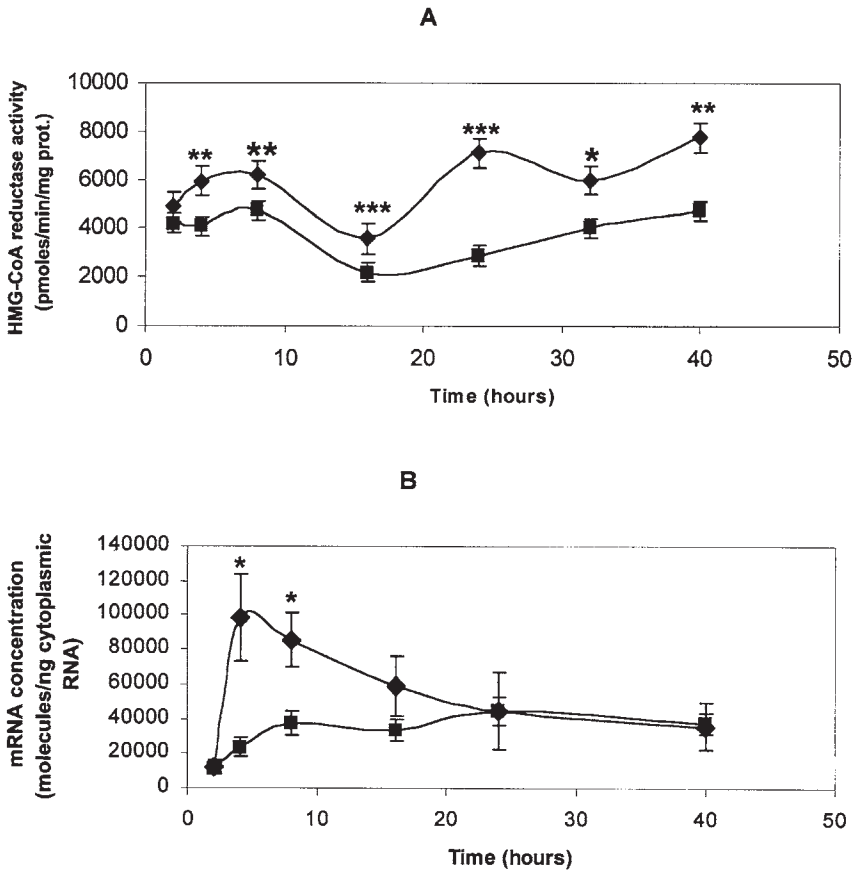

FIG. 7. Comparison of the effect of media change supplemented with FBS on HMG-CoA reductase (A) activity, and (B) mRNA in SMC-C (◆) and SMC-Ch (■) unsynchronized cultures. At time-zero, 3 passage cultures with 50–60% confluence were washed with PBS and then fed fresh media. Cells were harvested at each time point, and the HMG-CoA reductase activities and the HMG-CoA reductase mRNA levels were quantified. Results are mean ± SEM for 3 experiments. (A) $*P \leq 0.01$, $**P \leq 0.001$, $***P \leq 0.0001$; (B) $*P \leq 0.05$ vs. SMC-Ch. For abbreviations see Figures 1 and 4.

Initially the cultures were not confluent and the cells were in the logarithmic growth phase. At the end of the experiment, when confluence was reached, they were in the stationary growth phase. Peaks of reductase activity between 55 and 72 h after the change of medium, when the cultures reach confluence, could contrast with previous results of a decrease in reductase when cultures reach confluence (28,29) or a maximal activity in S or G_2/M phase. However, in SMC cultures the proportion of the cells in S phase was the same between cultures with 50–60% confluence and 100% confluence. In late-passage cultures (senescence), the HMG-CoA reductase activity was down-regulated and fluctuations were found, with activity peaking at 16 h after the medium change and returning to basal values afterward, as described previously (14). In addition, senescent cell cultures underwent apoptosis since they presented nuclear fragmentation (DNA leader) (results not shown). It could be speculated that the inhibition of HMG-CoA reductase in senescent cultures has the same effect of inhibitors of reductase (statins) that induce apoptosis in vascular SMC (48). In this regard, there is evidence of apoptosis in SMC from human atherosclerosis and in an experimental model (49,50). Thus, senescent cells could vary in the probable molecular mechanism that leads to the fluctuations in the reductase activity, with differences in behavior between senescent and young cells resulting from the metabolic change that cells in culture suffer with time. These alterations have been interpreted as an accelerated process of senescence due to the "proliferate stress" of the cells in culture (51), similar to the natural senescence of the cells within the animal. One important exception is transformed cells, such as the established cell line, which does not undergo senescence (36). Previous studies with confluent cultures of the established cell line (14) described only a peak after medium change; however, they measured reductase activity only during the first 24 h in confluent cultures.

The concentration of the reductase mRNA in SMC cultures showed a marked increase only after 16 h of exposure to fresh media in unsynchronized cell cultures. To confirm that cyclic fluctuations of the reductase activity are not correlated with

fluctuations of mRNA concentrations, these experiments were repeated by assaying reductase activity and concomitantly measuring the mRNA concentration. Although with wide variations in amplitude and periods of the cyclic activity among experiments, similar results were found in three additional experiments (not shown). We confirmed our observation of several peaks for reductase activity and one peak for mRNA concentration. The first peak of reductase activity could be explained by correlating feeding cells with the mRNA concentration rise, but the following fluctuations in reductase activity, which did not correlate with fluctuations in mRNA concentration, could not be explained by a contribution of exogenous nutrients and were strongly suggestive of a posttranscriptional modulation of the HMG-CoA reductase activity. The posttranscriptional modulation could be related to DNA synthesis, because the S phase of the cell cycle in confluent cultures was the same as in 50% confluence. The posttranscriptional modulation of reductase activity has previously been suggested (52) for feedback regulation of hepatic HMG-CoA reductase activity by dietary cholesterol.

Our results from the experiments with SMC-C vs. SMC-Ch also showed the effect of a high-cholesterol diet on the cyclic fluctuations of HMG-CoA reductase. In fact, we showed previously that SMC-Ch develops the characteristics of macrophage-like foam cells after 30 d in culture under the same culture conditions as the SMC-C (30). The SMC cultures used in these studies were young (three passages), and the SMC-C and SMC-Ch characteristics studied previously were identical even with respect to the intracellular cholesterol concentration that would become double in SMC-Ch after 20 d in culture, but it was identical during the first 14 d of culture (30). In the present study, we found a sharp decrease in HMG-CoA reductase activity and mRNA concentration in SMC-Ch vs. SMC-C in three-passages cultures, this not being dependent on the intracellular cholesterol concentration. These observations were repeated in experiments with senescent cultures except that, in the experiments with LPDS, the induction of reductase activity was similar in the two cultures.

These results suggest that the cholesterol diet induces change in HMG-CoA reductase gene expression in SMC cultures before the morphologic transformation of the SMC in the artery wall (53). SMC *in vivo* were shown to increase cholesterol biosynthesis significantly and decrease the intracellular cholesterol efflux associated with phenotype changes in SMC in culture (54,55). In this work, however, it should be noted that we are making a comparison with an SMC-C culture that underwent the same phenotype modulation by cultured conditions as the SMC-Ch. Thus, changes in HMG-CoA reductase activity and gene expression at transcriptional levels in SMC-Ch must be due to the cholesterol feeding of the chicks. These observations may be explained by the nutritional control by sterol regulatory element-binding proteins (SREBP), a family of transcription factors that bind to the sterol regulatory element (SRE) in the promoter of the HMG-CoA reductase gene. These transcription factors have been defined as key regulators of nutritional homeostasis and, in response to diet, SREBP gene regulation depends on changes in the levels of oxysterols, insulin/glucose, and PUFA (56).

Although the reductase activity and the mRNA concentration proved lower in SMC-Ch than in SMC-C, the fluctuations in the activity and the increase in reductase mRNA concentration after the medium change do not disappear in SMC-Ch. Even in senescent cultures, which present a high intracellular concentration of cholesterol in SMC-Ch (30), the reductase activity was not completely inhibited. Moreover, in cultures with LPDS induction the reductase activity underwent the same rise in SMC-C as in SMC-Ch after the change of the medium with FBS. These data agree with our results concerning the synthesis of cholesterol in the previously reported model of SMC-C/SMC-Ch cultures (31) and contrast with the general established decrease of HMG-CoA reductase activity and mRNA in hypercholesterolemic animals (57,58) or the depression of the diurnal rhythm after cholesterol-diet feeding (12–16). A possible explanation is that SRE function as conditional positive elements and are necessary for activated transcription in sterol-deprived cells but are not required for basal transcription that occurs in cholesterol-loaded cells (55). These differences of the reductase activity and the mRNA concentration between SMC-C and SMC-Ch are more important in young cultures than in senescent ones. Since in three-passage cultures the intracellular cholesterol in SMC-C and SMC-Ch was the same, other explanations must be considered regarding the transformation of the aortic SMC by cholesterol diet in the chick prior to cell harvest.

The failure to abolish the fluctuations of reductase activity in young SMC-C cultures could have a plausible explanation in the continued cell proliferation after confluence (30). The cell cycle of SMC-C in different confluence states of the cultures presents the same proportion of the cells in the S phase as when 100% confluence of the culture is reached. The mRNA concentration from young SMC-C cultures presents a peak only several hours after the medium change. However, it decreases to baseline when the cultures are confluent, so at transcriptional levels the HMG-CoA reductase regulation is affected by the degree of confluence of the culture and could be unrelated to S phase of the cell cycle.

In conclusion, in cultured aortic SMC, the HMG-CoA reductase activity shows fluctuations not associated with feeding the cells and that must be modulated at the posttranscriptional level. This fluctuation in activity changes with the culture conditions: young vs. senescent; synchronized vs. unsynchronized; LPDS vs. FBS; and confluent vs. nonconfluent. Moreover, a high-cholesterol diet in the animals before obtaining the SMC cultures induced changes in the HMG-CoA reductase gene expression. Thus, the mRNA concentration was down-regulated in SMC-Ch vs. SMC-C. Since the nutritional culture conditions, the intracellular cholesterol concentration, and the ultrastructural morphology were the same during the first days of culture, this change in reductase gene expression must have been induced by the cholesterol diet in the aortic SMC *in vivo*, probably at the SREBP gene-expression level. New studies would be necessary to demonstrate the implication of the SREBP's gene expression as well as if new protein synthesis is

required for the increase in the enzyme activity or if some peaks of activity correlate with other regulatory events. Changes in mRNA stability may also contribute to the changes observed in HMG-CoA reductase mRNA.

ABSTRACT: A protective association between breastfeeding and the development of bronchial asthma has been demonstrated. However, a mechanism remains unclear. FA present in human milk but rare in infant formula have been associated with marked immunological modulation as well as some indications of protection from asthma development. We examined the effect of *in vitro* manipulation of membrane phospholipid on the production of cytokines and prostaglandin (PG)E_2 by respiratory epithelial cells (A549) in response to stimulation by mast cell mediators of allergic disease [histamine, tumor necrosis factor (TNF)-α, interleukin (IL)-4 and IL-5]. DHA and CLA significantly decreased the production of IL-8 in response to stimulation by TNF-α [2907 ± 970 (DHA) and 6471 ± 1203 (CLA) vs. 12,287 ± 2309 (control) pg/mL; $P \leq 0.05$, mean ± SEM], whereas both EPA and DHA reduced histamine-stimulated RANTES (regulation on activation, T cell-expressed and -secreted) production [2314 ± 861 (EPA) and 877 ± 326 (DHA) vs. 8526 ± 1118 (control) pg/mL; $P \leq 0.03$]. PGE_2 released in response to histamine was decreased by n-3 [1305 ± 399 (α-linolenic acid), 406 ± 73 (EPA), and 265 ± 32 (DHA) vs. 9324 ± 3672 (control) pg/mL; $P \leq 0.05$] and increased by n-6 [18,843 ± 4439 (arachidonic acid) vs. 9324 ± 3672 (control) pg/mL; $P = 0.02$], with CLA producing a decrease of the same magnitude as DHA [553 ± 126 (CLA) vs. 9324 ± 3672 (control) pg/mL; $P = 0.03$]. This study demonstrates the potential for immunological manipulation of the respiratory epithelium by FA *in situ* during allergic responses and suggests that further investigation into FA intervention in infants *via* human milk or supplemented infant formula, to prevent the development of allergic disease, may be worthwhile.

Paper no. L9986 in *Lipids 41*,1101–1107 (December 2006).

Systematic reviews and meta-analyses of prospective studies examining the association between breastfeeding and the development of bronchial asthma found a lower incidence with exclusive breastfeeding during the first months of life (1,2). However, the mechanism by which breastfeeding may confer this benefit to the infant is unclear. Fat, at 4%, is second only to lactose among the nonaqueous constituents of human milk (3). Many of the PUFA present in human milk but absent from some infant formulas alter the production of cytokines and eicosanoids in peripheral blood in models of disease and inflammation, as well as demonstrate beneficial effects in diseases such as cancer, atherosclerosis, and rheumatoid arthritis (4). There have also been some indications of positive effects on asthma (5). These studies have examined asthma incidence in relation to dietary habits and found that diets high in the n-3 PUFA eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 22:6n-3), which are derived predominantly from fish, are associated with a lower prevalence of asthmatic disease.

Human milk has, until recently, been an infant's only source of preformed EPA and DHA. The amounts received by each breastfed infant are variable due largely to long-term maternal diet. However, other factors such as maternal atopy may also contribute to significant differences in the composition of PUFA in human milk (6,7). These differences may contribute to an explanation for discrepancy in studies examining the protective effects of breastfeeding on the development of allergic disease.

Allergic disease of the airways is driven by cytokines produced in response to allergen presentation by macrophages and dendritic cells to T lymphocytes. The predominant T lymphocyte present, T helper (Th)1 or Th2, determines the course that the processing of allergens will take (8,9). The source of the cytokines that drive the development of the Th2 lineage responsible for the development of allergic disease includes both epithelial cells and respiratory tissue mast cells. The production of inflammatory mediators such as prostaglandin (PG)E_2 by the airway epithelium and surrounding tissue leukocytes results in a pronounced cellular infiltrate of the airway epithelium and submucosa by lymphocytes, eosinophils, and mast cells (10). On activation in the airways, these cells produce additional mediators that can further exacerbate inflammation and enhance development of the Th2-driven response. Mast cells are one of the primary contributors to this *via* release of pre-formed histamine, tryptase, and chymase, as well as by producing cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-4, and IL-5. These mast cell products are responsible for increasing vascular permeability, Th2 lymphocyte development, and

eosinophil attraction leading to bronchoconstriction; and the up-regulation of a number of secondary inflammatory and chemotactic products including PGE_2, IL-1β, TNF-α, IL-8, and regulation on activation, normal T cell-expressed and -secreted (RANTES).

This study used a model developed in our laboratory (11,12) of *in vitro* FA manipulation in a respiratory cell line (A549) to examine the hypothesis that changes in membrane PUFA would significantly alter the production of inflammatory mediators in response to mediators of allergic disease. We examined the effect of manipulation of membrane phospholipid on the production of cytokines (IL-1β, TNF-α, IL-8, RANTES) and PGE_2 by respiratory epithelial cells in response to stimulation by mast cell mediators of allergic disease (histamine, TNF-α, IL-4, IL-5).

EXPERIMENTAL PROCEDURES

Mast cell mediator stimulation of A549 Cells. Human transformed alveolar respiratory epithelial cells (A549) at 2.5×10^5 cells/well were cultured in 24-well cell culture plates (Greiner Labortechnik GmbH, Frickenhowsen, Germany) in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 5% heat-inactivated FBS (JRH Biosciences, Lenexa, KS). At confluence (24 h), supernatants were removed and cells cultured for a further 24 h with or without the human recombinant cytokines IL-5 (20 ng/mL; Peprotech, Rocky Hill, NJ), IL-4 (20 ng/mL), or TNF-α (2 ng/mL; R&D Systems Inc., Minneapolis, MN) or 16 mM histamine (Sigma Chemical Company, St. Louis, MO) in serum-free DMEM in triplicate. At 24 h, each culture plate was subjected to a single freeze-thaw cycle to lyse the cells. Culture supernatants were then harvested, spun at ~2200 × *g* to pellet cell debris, and aliquoted before storing at –80°C until assay for cytokine or PG production.

Mast cell mediator stimulation of long-chain PUFA (LCPUFA)-supplemented cells. A549 cells were cultured as above in the presence or absence of 10 or 50 μg/mL α-linolenic acid (ALA; 18:3n-3), linoleic acid (LA; 18:2n-6), EPA, arachidonic acid (AA; 20:4n-6), DHA, CLA (Fig. 1) (Nu-Chek-Prep Inc., Elysian, MN), or oleic acid (OA; 18:1n-9) (ICN Pharmaceuticals Inc., Costa Mesa, CA) as FFA solubilized in 100% ethanol. These FA concentrations result in approximately 50% incorporation and maximal incorporation, as described previously (11,12). Briefly, incorporation of FFA was determined in separate triplicate experiments. Cellular lipids were extracted using the method described by Broekhuyse (13). The phospholipid fraction was separated *via* TLC, lipids were transesterified, and FAME were separated and quantified as described previously (11) using a Hewlett-Packard 6890 gas chromatograph fitted with a 50 m capillary column (0.33 mm i.d.) coated with BPX-70 (0.25 mm film thickness; SGE Pty Ltd., Victoria, Australia). The injector temperature was set at 250°C and the FID temperature at 300°C. The initial oven temperature was 140°C and was programmed to rise to 220°C at 5°C/min. Helium was used as the carrier gas at a velocity of 35 cm/s. FAME were identified based on the retention time of authentic lipid standards (Nu-Chek-Prep Inc.). At the commencement of this project, CLA was only available as a combined mixture of approximately five isomers (14). The use of this blend of CLA isomers, while preventing analysis of individual effects, most closely mimics the CLA component of human milk, which contains measurable quantities of all but the 11-*cis*,13-*trans* 18:2 CLA isomer, with 9-*cis*,11-*trans* 18:2 CLA constituting the largest fraction (15). The relative incorporation of each of these isomers is described by Figure 1. Correct identification of each isomer was confirmed using a Hewlett-Packard 6890 GC-Mass Spectrometer. At confluence cells were cultured with or without TNF-α or histamine (as above), with or without the appropriate FFA (10 and 50 μg/mL). At 24 h, cells were lysed and supernatants collected and stored as above.

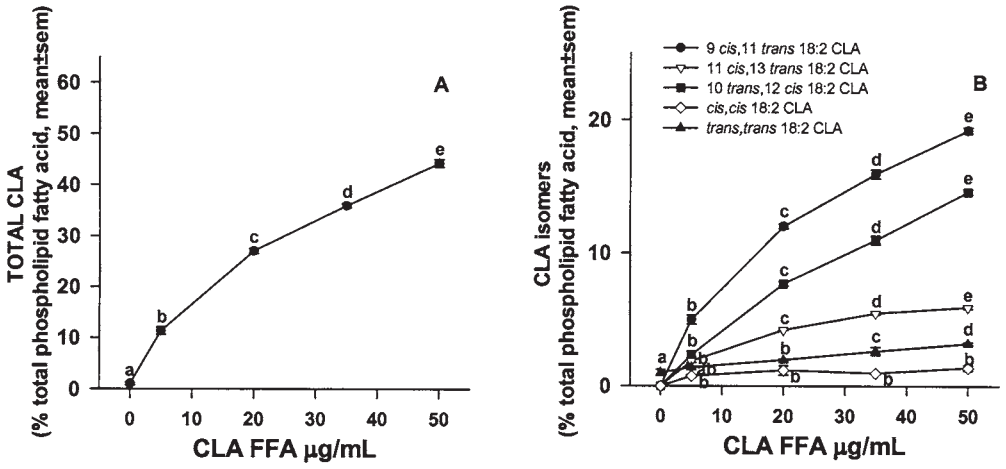

FIG 1. Cell membrane phospholipid CLA from respiratory epithelial cells incubated with a range of concentrations of CLA as FFA. Results from 3 or 4 experiments are expressed as a relative percentage of the total FA (mean ± SEM). Points with different superscripts indicate significant differences ($P < 0.05$). (A) Total incorporated CLA. (B) Individual amounts of each CLA isomer.

PG assay. Cell culture supernatants were assayed for PGE_2 by competitive enzyme immunoassay (EIA) (Prostaglandin E_2 EIA Kit—Monoclonal; Cayman Chemical Company, Ann Arbor, MI). The limit of detection for the EIA was 8 pg/mL. Samples were diluted at least 1:10 in the EIA buffer supplied as per the manufacturer's instructions.

Cytokine assays. Cell culture supernatants were assayed for IL-1β, TNF-α (Endogen, Rockford, IL), IL-8 (BD Pharmingen, San Diego, CA) and RANTES (R&D Systems) using double antibody sandwich ELISA as described previously (12). The limit of detection for each ELISA was 8, 10, 20, and 4 pg/mL, respectively. Samples were diluted 1:10 and 1:20 for the measurement of IL-8 and RANTES, respectively.

Statistical analysis. Data are presented as mean ± SEM. Differences between FA and mediator treatments were examined using Independent-Samples *T*-test or one-way ANOVA followed by LSD (least significant difference) *post-hoc* analysis. All analyses were performed using SPSS for Windows 10.0 (SPSS Inc., Chicago, IL).

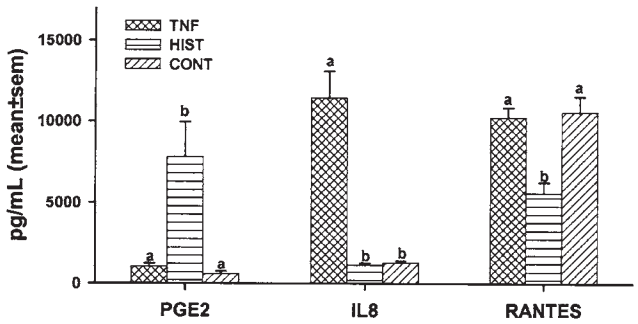

FIG. 2. Effect of incubation with mast cell mediators [tumor necrosis factor-α (TNF-α), 2 ng/mL; histamine (HIST), 16 mM; no stimulant control (CONT)] on prostaglandin $(PG)E_2$, interleukin (IL)-8, and RANTES (regulation on activation, T cell-expressed and -secreted) production by A549 cells after 24 h of culture. Results from 6 experiments are expressed as pg/mL (mean ± SEM). Points with different superscripts indicate significant differences ($P < 0.05$).

RESULTS

Production of cytokines and PGE_2 in response to stimulation with mast cell mediators. Incubation with TNF-α significantly increased the production of IL-8 by A549 cells above that of control, or no stimulant, levels (Fig. 2). Similarly, histamine significantly increased PGE_2 production while also eliciting a decrease in RANTES production when compared with control levels. There was no effect on the production of IL-8 by A549 cells in response to incubation with histamine. Similarly, there was no effect of TNF-α on the production of PGE_2 or RANTES. Stimulation of the cells with IL-4 and IL-5 did not elicit a significant increase in production of any of the mediators tested (data not shown). Although there was constitutive production of the inflammatory cytokine IL-1β (228 ± 79 pg/mL, mean ± SEM), there was little to no spontaneous production of TNF-α, thus resulting in a mean below the limit of detection for this assay (10 pg/mL). No difference was found in the production of either IL-1β or TNF-α between the control and those cells treated with cytokine or histamine (data not shown).

Effect of FA incorporation into the A549 cell membrane on constitutive PGE_2, IL-8, and RANTES production. The degree to which each of the FFA, excluding CLA, was incorporated into the A549 cells has been reported previously (11,12). As with all other FFA used in this project, each CLA isomer was readily incorporated dose-dependently into the cell membranes of the A549 respiratory epithelial cells. However, the incorporation of CLA continued to increase up to, and including, 50 μg/mL supplemental total CLA FFA. Each of the CLA isomers was incorporated proportionally to the content of the FFA mixture, resulting in a majority of 9-*cis*,11-*trans* CLA (~45%) and 10-*trans*,12-*cis* CLA (~35%) with the remaining isomers making up the final 20% of the total CLA increase. The incorporation of each of the FA—ALA, LA, OA, EPA, AA, DHA, and CLA—into the membranes of A549 cells at maximum incorporation (50 μg/mL FFA; 20–25% total phospholipids) (11,12) resulted in a significant decrease in the production of IL-8 when compared with approximately 50% maximum incorporation (10 μg/mL FFA) (Fig. 3B). A similar pattern was observed in the production of RANTES by A549 cells after incorporation of FFA at each concentration. However, this trend only attained statistical significance with EPA, AA, and DHA (Fig. 3C). In contrast, no significant difference in PGE_2 production between differing FFA concentrations (10 or 50 μg/mL) was found for each of the FA tested (Fig. 3A). Changes in cell membrane phospholipid resulted in significant differences in the production of each of the products examined. However, this effect was only attained at the higher FFA concentration of 50 μg/mL for the chemokines, IL-8, and RANTES, whereas the effects on PGE_2 were similar for both concentrations. Incorporation of AA resulted in a significant increase in PGE_2 production, which was also apparent at 50 μg/mL supplementation with its precursor FA LA, when compared with control (no FFA). The amount of PGE_2 produced by cells after incorporation of OA, ALA, EPA, DHA, and CLA was significantly lower than that of the cells incubated with AA at both concentrations but reached statistical significance compared with LA only at 50 μg/mL (Fig. 3A). There was no difference in the production of the chemokines IL-8 and RANTES in response to incorporation of FFA at 10 μg/mL. At 50 μg/mL supplemental FFA, the amount of both chemokines produced by cells having incorporated each of the n-3 PUFA ALA, EPA, and DHA, as well as CLA, was decreased from that of the control cells, in serum-free media. However, rather than resulting in an increased production as with PGE_2, the incorporation of the n-6 PUFA AA also manifested as a decrease in IL-8 and RANTES (Figs. 3B, 3C). The production of RANTES was similarly reduced in response to DHA incorporation when compared with production by cells incubated with all FFA treatments, with the exception of EPA (Fig. 3C).

Effect of FA incorporation into the A549 cell membrane on IL-8 production in response to stimulation with TNF-α. The n-

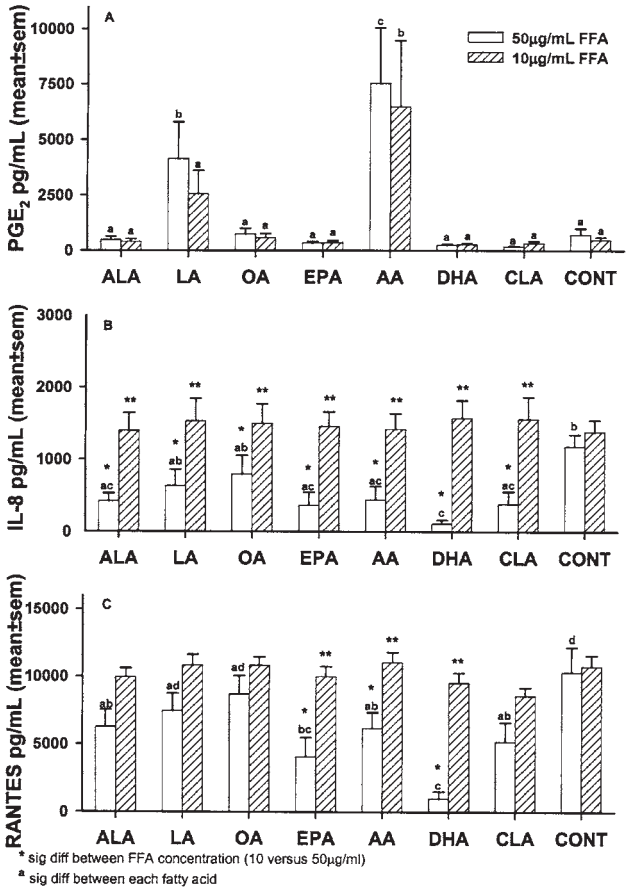

FIG. 3. Effect of incubation with PUFA [α-linolenic acid (ALA), linoleic acid (LA), oleic acid (OA), EPA, arachidonic acid (AA), DHA, CLA, no FFA (CONT)] at 10 µg/mL vs. 50 µg/mL on (A) PGE_2, (B) IL-8, and (C) RANTES production by nonstimulated A549 cells (human transformed alveolar epithelial cell line) after 24 h of culture. Control cells were incubated in serum-free medium containing equivalent ethanol to the 10 or 50 µg/mL FFA solutions, respectively. Results from 6 experiments are expressed as pg/mL (mean ± SEM). Points with different superscripts indicate significant differences ($P < 0.05$) between each FA. Asterisks (*) indicate significant differences between FFA concentrations (10 vs. 50 µg/mL). For other abbreviations see Figure 2.

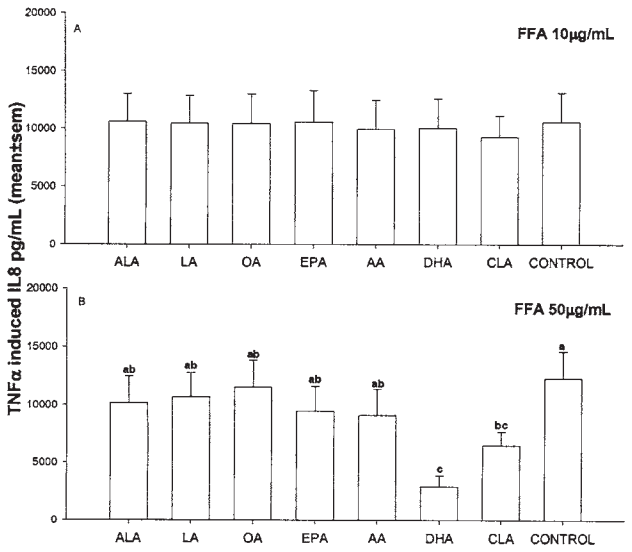

FIG. 4. Effect of incubation with PUFA (ALA, LA, OA, EPA, AA, DHA, CLA) at 10 and 50 µg/mL on IL-8 production by A549 cells after 24 h of culture with TNF-α (2 ng/mL). Control cells were incubated in the presence of TNF-α in serum-free medium containing equivalent ethanol to the 10 or 50 µg/mL FFA solutions, respectively. Results from 6 experiments are expressed as pg/mL (mean ± SEM). Points with different superscripts indicate significant differences ($P < 0.05$). For abbreviations see Figures 2 and 3.

3 FA, CLA, and AA were able to decrease the production of IL-8 by epithelial cells significantly. However, DHA and CLA only maintained this effect upon stimulation with TNF-α. At 50 µg/mL FFA supplementation, a significant difference in the TNF-α–stimulated production of IL-8 was observed between cells that had incorporated either DHA or CLA when compared with control cells incubated in the absence of FFA (Fig. 4B). No changes in TNF-α stimulated IL-8 production in response to FA incorporation at 10 µg/mL were apparent (Fig. 4A).

Effect of FA incorporation into the A549 cell membrane on PGE_2 and RANTES production in response to stimulation with histamine. PGE_2 production by cells that had incorporated exogenous FA and then were incubated with histamine demonstrated a distinct n-3-induced pattern at maximal FFA incorporation (50 µg/mL) that was only partially retained at half maximum incorporation (10 µg/mL) (Figs. 5A, 5B). At 50 µg/mL, incorporation of ALA was sufficient to reduce the production of PGE_2 significantly in response to histamine with further decreases with both EPA and DHA incorporation. Incorporation of CLA again mimicked the n-3 PUFA. In contrast, incorporation of the n-6 PUFA AA resulted in a significant increase in PGE_2 production at both 10 and 50 µg/mL supplemental FFA. Whereas PGE_2 production by LA-supplemented cells also increased when compared with all n-3 PUFA and CLA at 50 µg/mL, and DHA and CLA at 10 µg/mL, incorporation of LA did not significantly increase PGE_2 at either FFA concentration in comparison with control cells in the absence of FFA. The n-3 LCPUFA, CLA, and AA were all able to suppress the production of RANTES by A549 cells (Fig. 3C). However, EPA and DHA only maintained this effect when a mast cell mediator (histamine) was present (Fig. 5B). The effect of FA incorporation on histamine inhibition of RANTES production was only apparent at maximal FFA incorporation. Again there was an effect of n-3 LCPUFA composition with increasing EPA and DHA resulting in a decrease in RANTES production when compared with no FFA control cells. There was no effect of incorporation of any of the remaining FFA on the production of RANTES in response to incubation with histamine.

DISCUSSION

In this study, the incorporation of both n-3 and n-6 PUFA and CLA affected the production of PGE_2, IL-8, and RANTES by respiratory epithelial cells in response to exposure to products of stimulated mast cells, TNF-α and histamine.

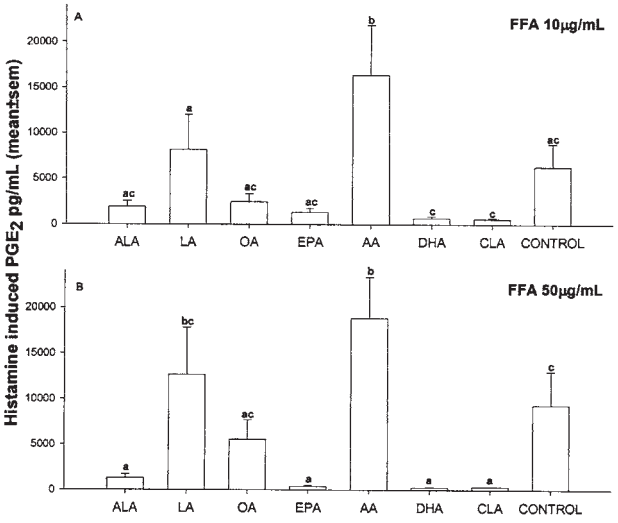

FIG. 5. Effect of incubation with PUFA (ALA, LA, OA, EPA, AA, DHA, CLA) at 10 and 50 μg/mL on PGE_2 production by A549 cells after 24 h of culture with histamine (16 mM). Control cells were incubated in the presence of histamine in serum-free medium containing equivalent ethanol to the 10 or 50 μg/mL FFA solutions, respectively. Results from 6 experiments are expressed as pg/mL (mean ± SEM). Points with different superscripts indicate significant differences ($P < 0.05$). For abbreviations see Figures 2 and 3.

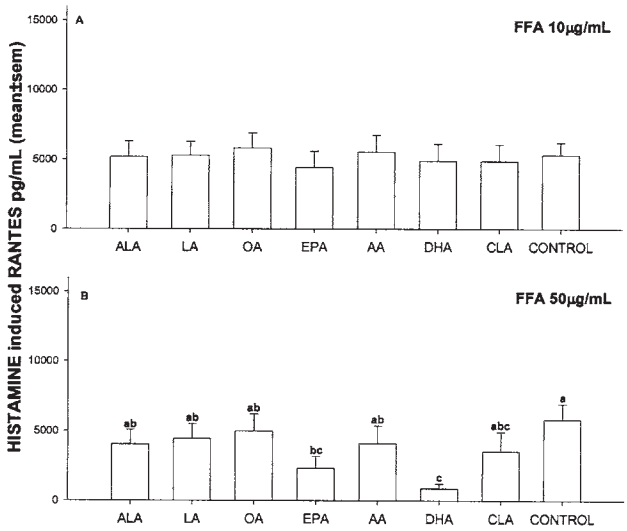

FIG. 6. Effect of incubation with PUFA (ALA, LA, OA, EPA, AA, DHA, CLA) at 10 and 50 μg/mL on RANTES production by A549 cells after 24 h of culture with histamine (16 mM). Control cells were incubated in the presence of histamine in serum-free medium containing equivalent ethanol to the 10 or 50 μg/mL FFA solutions, respectively. Results from 6 experiments are expressed as pg/mL (mean ± SEM). Points with different superscripts indicate significant differences ($P < 0.05$). For abbreviations see Figures 2 and 3.

Prostanoids such as PGE_2 play a pivotal role in the regulation of allergic airway disease through both pro- and anti-inflammatory actions. Although PGE_2 concentrations in tissues are generally low, they are rapidly increased in acute inflammation prior to the influx of leukocytes, which act to enhance prostanoid production further, usually *via* an up-regulation of cyclo-oxygenase (COX)-2 expression (16). During airway inflammation, PGE_2 acts *via* the prostanoid receptor, EP2 to stimulate smooth muscle cells resulting in vasodilation, and the EP3 receptor to induce mast cell degranulation, increasing vascular permeability. However, after the initial phase of inflammation, increasing PGE_2 levels produced by epithelium, as well as infiltrating macrophages, act to inhibit leukocyte activation and promote bronchodilation *via* the EP2 and EP4 receptors (17). PGE_2 regulation by decreasing n-6 to n-3 ratios, or by supplementation with CLA, may dampen the initial pro-inflammatory response in the allergic airway, thereby controlling the establishment of inflammation before the anti-inflammatory properties of increased PGE_2 levels come into play. Decreasing first phase PGE_2 concentrations would reduce vasodilation and vascular permeability, as well as mast cell degranulation. Alternatively or perhaps concurrently, changes in the relative amounts of eicosanoid products formed owing to the concentrations of precursor FA would result in substantial effects on the production of many cytokines. Lowering of the PGE_2 concentration owing to changes in the ratio of AA to EPA would result in decreases in the production of proinflammatory cytokines such as IL-1βb and TNF-α, as well as the Th1 cytokines IL-2 and IFN-γ (4). As IL-1β, TNF-α, and IFN-γ are all stimulants of epithelial production of chemokines (18,19), this decrease in production of stimulant cytokines would thereby reduce production of IL-8 and RANTES.

Chemotactic factors, such as IL-8 and RANTES, produced by the respiratory airways in response to degranulation of tissue mast cells during allergic airway disease, also play an important role in the progress of airway inflammation. Release of mast cell products in response to binding of either allergen-specific or, prior to sensitization, nonspecific IgE to the $\underline{F}_{C\varepsilon}RI$ (high-affinity IgE receptor), contributes not only to the development of chronic inflammation but also to the initiation of allergic sensitivity (20). By promoting the influx of large numbers of activated leukocytes into the airways, these chemotactic factors contribute to the increased concentrations of inflammatory eicosanoids and cytokines and to the development of structural airway changes. Increases in epithelial IL-8 production due to the presence of mast cell-derived TNF-α would result in elevated granulocyte (neutrophil, basophil, and eosinophil) numbers migrating to allergic airways. There, both TNF-α and IL-8 would activate the incoming granulocyte populations, resulting in the further release of chemotactic and inflammatory mediators (21). Conversely, the release of preformed granules containing histamine from airway mast cells may inhibit the production of RANTES by respiratory epithelium. RANTES is responsible for inducing the migration of mast cells, eosinophils, basophils, macrophages, and T lymphocytes into the airways, resulting in increases in PGE_2, allergic inflammation, bronchial hyperresponsiveness, and eosinophil activation, as well as additional release of histamine by mast cells and basophils (22–24). Therefore, decreases in

the production of both IL-8 and RANTES by enhanced tissue n-3 or CLA FA incorporation may substantially diminish cellular infiltration in the airways and the resultant inflammatory responses to allergens, thereby significantly reducing the progression of respiratory hyperresponsiveness to asthma.

Although FA effects on the production of PG such as PGE_2 by peripheral blood leukocytes are well documented (4), the literature contains few studies relating to FA affecting production of PG in the lung (25,26). Perhaps the most relevant studies have determined that rat pups from dams fed diets supplemented with fish oil throughout pregnancy and lactation have significantly depressed PGE_2 production in their lung tissue compared with those born to dams on control diets (27,28). These experiments confirm *in vivo* the potential application of FA supplementation on inflammatory mediator production in the lungs of infants during lactation.

A number of studies have found significantly lower EPA and DHA concentrations in the milks of nonatopic mothers whose infants develop atopy, resulting in lower plasma n-3 levels and higher n-6/n-3 ratios, indicating an n-3-mediated affect (29) and a link between the early infant diet and the development of allergic disease (30–35). However, dietary studies in children and adults have produced conflicting results, with those examining n-3 intake *via* consumption of fish demonstrating some small but positive effects on recurrent airway disease (airway hyperresponsiveness, wheeze, or asthma) (36) but with placebo-controlled supplementation studies showing mixed results especially on established asthmatic disease (37-40). These studies provide preliminary data that may encourage speculation for the requirement for FA intervention during infant development or over a longer term via human milk or supplemented infant formula, which also provides a source of CLA. High dietary intake of CLA and n-3 FA may be required during early immune maturation and first exposures to allergens in order to modulate the immune system and thereby prevent the development of allergic disease rather than to treat symptoms of established conditions.

ABSTRACT: This work was undertaken to study the impact of the source of n-3 FA on their incorporation in serum, on blood lipid composition, and on cellular activation. A clinical trial comprising 71 volunteers, divided into five groups, was performed. Three groups were given 400 g smoked salmon (n = 14), cooked salmon (n = 15), or cooked cod (n = 13) per week for 8 wk. A fourth group was given 15 mL/d of cod liver oil (CLO) (n = 15), and a fifth group served as control (n = 14) without supplementation. The serum content of EPA and DHA before and after intervention revealed a higher rise in EPA and DHA in the cooked salmon group (129% rise in EPA and 45% rise in DHA) as compared with CLO (106 and 25%, respectively) despite an intake of EPA and DHA in the CLO group of 3.0 g/d compared with 1.2 g/d in the cooked salmon group. No significant changes were observed in blood lipids, fibrinogen, fibrinolysis, or lipopolysaccharide (LPS)-induced tissue factor (TF) activity, tumor necrosis factor-α (TNFα), interleukin-8 (IL-8), leukotriene B_4 (LTB_4), and thromboxane B_2 ($T\times B_2$) in whole blood. EPA and DHA were negatively correlated with LPS-induced TNFα, IL-8, LTB_4, $T\times B_2$, and TF in whole blood. In conclusion, fish consumption is more effective in increasing serum EPA and DHA than supplementing the diet with fish oil. Since the n-3 FA are predominantly in TAG in fish as well as CLO, it is suggested that the larger uptake from fish than CLO is due to differences in physiochemical structure of the lipids.

Paper no. L9972 in *Lipids 41*, 1109–1114 (December 2006).

Seafood provides an excellent source of high biological-value proteins, peptides and amino acids, unsaturated EFA, vitamins, antioxidants, minerals, and trace metals, all with various beneficial effects on important physiological factors.

In the late 1970s the groundbreaking observation of a significantly reduced prevalence of cardiovascular disease (CVD) in Greenland Eskimos living on their traditional diet compared with Eskimos living in Denmark suggested that intake of long-chain n-3 PUFA from fish and marine mammals may protect against CVD (1). The biological effects of consuming fish-derived PUFA have been intensively explored (2–6). These studies have lent support to the notion that n-3 PUFA might affect several cellular processes known to be important in the development of coronary heart disease, stroke, etc. (7,8). Hence, there is evidence that PUFA protect against CVD and other conditions where cellular inflammatory processes are involved, even though the beneficial effects of fish-derived n-3 PUFA recently have been questioned in a meta-analysis (9). Most studies have used fish oils, but the natural source rich in these PUFA is fatty fish. Unfortunately, the doses administered in most studies exceed what is typically found in the diet (10). In contrast, considerable vascular benefits from modest fish consumption have been observed (11,12). It is well accepted that Western populations consuming little seafood have a high prevalence of CVD, in contrast to people in Japan and Greenland with higher intakes of seafood. Although it has been suggested that the bioavailability of PUFA might be better from fish compared with dietary supplements (13), these issues needs further investigation.

Based on the questions raised concerning the beneficial effects of fish oil-derived FA and the interesting observation of Visioli *et al*. (13), it is important to confirm and extend their study. Therefore, a study was undertaken to compare the effects of intake of four fish-derived sources of n-3 FA—three rich sources: raw fatty fish (smoked salmon), cooked fatty fish (salmon fillet), or fish oil (cod liver oil: CLO); and one poor source: fish low in n-3 FA (cod fillet)—on the uptake of n-3 FA in blood, lipid composition in blood, and functional properties of blood cells, as measured by the potential of lipopolysaccharide (LPS) to generate activation products in whole blood.

STUDY DESIGN AND EXPERIMENTAL PROCEDURES

Study design. Seventy-one healthy volunteers gave informed consent to the study, which had been approved by the regional Ethical Committee. The test subjects were divided into five groups, which were given, respectively, 400 g of smoked salmon (farmed *Salmo salar*) per week (14 subjects), 400 g salmon fillet per week (15 subjects), 400 g cod (*Gadus morhua*) fillet per week (13 subjects), or 15 mL CLO per day (15 sub-

Abbreviations: apoA, apolipoprotein A-1; apoB, apolipoprotein B; apoE, apolipoprotein E; CLO, cod liver oil; CVD, cardiovascular disease; EIA, enzyme immunoassay; HRP, horseradish peroxidase; IL-8, interleukin-8; LPS, lipopolysaccharide; LTB4, leukotriene B4; MPV, mean platelet volume; RBC, red blood cells; TF, tissue factor; TNFα, tumor necrosis factor α; TxB2, thromboxane B2.

jects). The raw cod and salmon fillets were prepared by the participants themselves, according to traditional Norwegian meal-preparation techniques.

Fourteen subjects were controls; they were asked not to change their diet during the study. All volunteers were told strictly to follow the same diet as prior to the study, except for the subjects in the three fish groups, who were asked to substitute regular diet items with their respective meal of fish.

Drawing of blood. Venous blood was drawn from the antecubital vein into a sterile plastic syringe (20 mL) using 19G sterile needles. Part of the blood volume was added to a plastic test tube containing heparin (10 U/mL blood) to be used for the LPS activation, some of the blood was collected in vacutainer tubes containing citrate (0.006 M Na_3citrate, 0.004 M citric acid final concentration), and 5 mL of the blood was added to a glass vacutainer containing 15% K_3EDTA (0.054 mL/4.5 mL) to be used for the cell counts. Blood was drawn after an overnight fast between 8:00 and 10:00 AM at the start of the study and at the end of the study after 8 wk intervention.

Isolation of plasma and serum. Plasma was isolated by centrifugation of blood collected in citrate at 1500 × *g* for 10 min at room temperature. The resulting top plasma layer was divided into five test tubes and frozen at –70°C until assay analysis. Serum was prepared by clotting whole blood in glass tubes for 1 h at 37°C, followed by the centrifugation at 1500 × *g* for 10 min at room temperature.

Lipids in serum. Serum was tested for total cholesterol (enzymatic colorimetric test, cholesterol esterase, and cholesterol oxidase), HDL-cholesterol (after precipitating chylomicrons, VLDL, and LDL with phosphotungstic acid and Mg^{2+}), TAG (enzymatic colorimetric test, lipoprotein lipase/oxidation/-peroxidase). The analyses were done in an Axon autoanalyzer (Technicon/Bayer). Apolipoprotein A-1 (apoA), apolipoprotein B (apoB), and apolipoprotein E (apoE) were determined in a Beckman Nephelometer Immunonephelometric method (Beckman Immage, Fullerton, CA), using reagents from Dako (Glostrup, Denmark).

FA in serum. Total FA in serum were determined after extraction by using a modified Folch method (chloroform/methanol/KCl aq., 8:4:3) and methylation (BF_3 in methanol) as described in previous studies (14,15). The FA were analyzed by capillary GLC using a Fisons Carlo Erba 8340 (Fisons Instruments, Beverly, MA) gas chromatograph with a 50 m × 0.25 mm Chrompack CP-Sil 88 CB capillary column (Varian Inc., Palo Alto, CA). The injector temperature was 240°C, and the oven was programmed as follows: 80°C (1 min); 20°C/min to 170°C (0 min); 3°C/min to 200°C (0 min); 5°C/min to 240°C (15 min). The temperature of the FID was 270°C. The signal was analyzed by Agilent's EZchrom software (Santa Clara, CA) and compared with mixtures of FA supplied by Supelco (Bellefonte, PA).

The individual FA in serum were calculated by use of 17:0 as an internal standard and expressed as mmol/L. The identification was based on retention times.

Lipids and FA in fish muscle. The fat content of fish samples was determined by AOCS method Ba 3-38 (16) using a Soxhlet extractor (Soxtec System HT6; Tecator, Höganäs, Sweden) and the FA composition of the samples was determined by using GC after direct acidic methylation of fish (17) and extraction of lipid samples using a modified Bligh and Dyer (18) method. Further analytical procedures are described in the previous paragraph.

LPS activation procedure. Five ng/mL LPS (E. coli 026:B6 LPS; Difco Laboratories, Detroit, MI) was added to each of four plastic test tubes. Fifty microliters of heparin (10 U/mL final concentration; Sigma, Oslo, Norway) was used as anticoagulant for 5.0 mL of drawn blood. The samples were then gently mixed, aliquoted into four test tubes, each containing 1.0 mL blood, and incubated at 37°C for 2 h under constant rotation at 200 rpm. The reaction was stopped using 100 μL of 2% EDTA, and samples were subjected to mononuclear cell isolation and blood plasma isolation.

Mononuclear cell isolation. One milliliter of 0.15 M NaCl was added to the blood samples, mixed well, carefully layered on top of Lymphoprep (Axis-Shield PoC AS, Oslo, Norway), and centrifuged at 420 × *g* (1500 rpm) for 15 min. The top layer was pipetted off and discarded, whereas the cell band was transferred to a new test tube containing 0.15 M NaCl and centrifuged at 1450 × *g* (2800 rpm) for 10 min. The liquid was removed and the resulting mononuclear cell pellet resuspended in 200 μL 0.15 M NaCl. All samples were then frozen at –20°C until quantification of tissue factor (TF) activity.

Quantification of TF activity. TF activity was measured from isolated monocytes and based on the ability of TF to accelerate Factor X activation mediated by Factor VIIa, using bovine Factor V and barium citrate eluate (containing Factor VII, Factor X, and Factor II) as described in previous studies (19).

Standard hematological parameters. Blood (5 mL) collected in EDTA was used for plasma isolation (4 mL), whereas 1 mL blood was transferred to a plastic test tube and allowed to stand undisturbed on the workbench for half an hour. Samples were then mixed well and cell counts were performed on a Sysmex K1000 automated hematology analyzer.

TNFα assay. TNFα was quantified using a human TNFα ELISA kit (CLB, Amsterdam, The Netherlands). The ELISA was based on a "sandwich-type" enzyme immunoassay using monoclonal antihuman TNFα antibody bound onto the polystyrene microtiter wells (to which the TNFα binds) and a second monoclonal TNFα antibody (biotinylated and to which the TNFα also binds). Horseradish peroxidase (HRP) conjugated streptavidin, which was bound to the biotinylated antibody, was used to react with a substrate, and the absorbance of the product was measured spectrophotometrically at 450 nm. Samples were diluted in a 1:20 ratio with dilution buffer. The assay sensitivity was 1–3 pg/mL.

Interleukin-8 (IL-8) assay. IL-8 quantification was obtained using a human IL-8 ELISA system (Amersham Pharmacia Biotech, Buckinghamshire, United Kingdom). The ELISA was based on a highly specific IL-8 monoclonal antibody bound to the wells of a microtiter plate and a second polyclonal IL-8 antibody that is conjugated to HRP. A substrate is added, and the

TABLE 1
Content of EPA and DHA in the Various Products Tested in This Study, and the Daily Intake of EPA and DHA

Product[a]	Product (g/wk)	EPA (g/wk)	DHA (g/wk)	EPA + DHA (g/d)
Smoked salmon	400	3.31	5.00	1.20
Salmon fillet	400	3.17	5.04	1.20
Cod fillet	400	0.06	0.15	0.03
CLO	105	9.66	11.25	3.00

[a]Intervention with smoked salmon (400 g/wk), cooked salmon fillet (400 g/wk), cooked cod fillet (400 g/wk), or cod liver oil (CLO) (15 mL/d).

product is measured spectrophotometrically at 450 nm. Blood plasma samples were diluted in a 1:100 ratio with dilution buffer. The assay sensitivity was 10 pg/mL (range 1.56–100 pg/well).

Leukotriene B_4 (LTB_4) and thromboxane B_2 (TxB_2) assays. LTB_4 and TxB_2 levels in plasma of LPS-stimulated blood were determined using enzyme immunoassay (EIA) systems (Amersham Pharmacia Biotech). The EIA were based on the competitive binding of LTB_4 (TxB_2) and LTB_4 (TxB_2)-peroxidase to a rabbit anti-LTB_4 (TxB_2) antibody. The LTB_4 (TxB_2)-peroxidase reacts with 3,3′,5,5′-tetramethylbenzidine substrate to form a product that is measured spectrophotometrically at 450 nm. Therefore, sample LTB_4 (TxB_2) is inversely proportional to the concentration of unlabeled LTB_4 (TxB_2). Samples were diluted to a 1:6 ratio (LTB_4) and to a 1:60 ratio (TxB_2), respectively, with the assay buffer. The assay sensitivity for LTB_4 was around 0.3 pg/well or 6.0 pg/mL (range 0.3–40 pg/well), and the sensitivity for TxB_2 was approximately 0.2 pg/well (range 0.5–64 pg/well).

Statistical analyses. All results are presented as mean ± SD. Univariate and multivariate analyses were performed to search for significant changes caused by the various interventions. Within-group changes during the intervention period were analyzed using Student's *t*-test or Wilcoxon nonparametric signed rank test. Simultaneous, multiple comparisons of the test groups against the control group were performed using one-way ANOVA followed by Dunnett's *t*-test. Correlations were calculated by means of the Spearman's rank correlation coefficient (r). P values less than 0.05 were considered significant.

RESULTS

FA composition in the supplemented products. Table 1 shows the composition of n-3 FA in the various products (smoked salmon, cooked salmon fillet, cooked cod fillet, and CLO) used in this study. It is noteworthy that intake of salmon fillet was associated with almost 3 times less intake of EPA and DHA as compared with the group drinking 15 mL/d CLO.

The content of n-3 FA in serum after intake of fish and fish oils. One of the major interests of this study was to explore whether the source of n-3 FA influences the rise in their serum concentration after 8 wk of fish diet or fish oil supplementation. Thus, when consumption of 400 g of fish (salmon, smoked salmon, or cod fillet) per week was compared with the dietary supplementation of 15 g per day of CLO, FA analyses of serum content of EPA and DHA revealed a relatively high rise in n-3 FA in the salmon groups (Table 2). Although the intake of EPA and DHA was 3.0 g/d in the CLO group, the rise in total amount of n-3 FA in this group was not that much larger in EPA and even less marked in DHA when compared with the salmon fillet groups where the intake of EPA and DHA was 1.2 g/d. The rises in EPA and DHA were significantly larger in the CLO group and in both salmon groups compared with the changes in the cod and control groups ($P < 0.05$).

White Blood Cells (WBC), Platelet Numbers, and Mean Platelet Volume (MPV) (mean values ± SD) Before and After 8 wk of Intervention[a]

Group	WBC (10^9/L) Before	WBC (10^9/L) After	Platelets (10^9/L) Before	Platelets (10^9/L) After	MPV (fL) Before	MPV (fL) After
Smoked salmon	5.90 ± 1.23	5.83 ± 1.46	250 ± 36	235 ± 33	9.63 ± 0.58	9.88 ± 0.58
Salmon fillet	6.03 ± 0.99	6.00 ± 1.24	255 ± 65	237 ± 47	9.74 ± 1.05	10.01 ± 1.15[b]
Cod fillet	6.37 ± 0.74	6.28 ± 1.82	257 ± 50	255 ± 55	9.37 ± 0.61	9.19 ± 0.48
CLO	6.24 ± 1.55	6.15 ± 1.49	260 ± 52	260 ± 52	9.61 ± 0.93	9.76 ± 1.09
Control	6.03 ± 2.24	6.58 ± 1.99	256 ± 71	252 ± 67	9.77 ± 0.96	9.65 ± 1.12

[a]Intervention with smoked salmon (400 g/wk), cooked salmon fillet (400 g/wk), cooked cod fillet (400 g/wk), or CLO (15 mL/d). The control group was not supplemented.
[b]Increase in MPV is higher in salmon fillet group as compared with the smoked salmon, cod fillet, CLO, and control groups ($P < 0.05$). For abbreviation see Table 1.

Changes in serum lipids. Intake of n-3 PUFA has been documented (7,8) to be associated with a reduction in TAG. In this study, however, only trends in TAG reductions were observed in all the groups except the control group, and no significant changes were observed in TAG, total cholesterol, or HDL-cholesterol (results not shown).

Changes in mean platelet volume (MPV) and cell counts. Among the blood cells, a significant increase in MPV was observed in the salmon fillet group as compared with MPV in the smoked salmon, cod fillet, and control groups (Table 3). MPV also tended to be increased in the smoked salmon fillet group and to a lesser degree in the CLO group (not significant). The rise in MPV was associated with a reduction in platelet count, but this was not significant. No significant changes were seen in any of the cell counts (white blood cells and platelets).

Changes in cellular activation products. No significant changes were observed in fibrinogen, tissue plasminogen activator, or plasminogen activator inhibitor-1 during the study (results not shown). LPS-stimulation of blood generates many activation products, which may be down-regulated by intake of n-3 FA. However, probably owing to the low number of subjects in each test group, there were no significant changes in these test parameters, although a trend was seen by the relatively small reduction of TNFα, LTB_4, and TxB_2 in all the groups excluding the cod fillet group (results not shown). Multivariate analyses revealed a negative correlation between changes in 20:5n-3, 20:6n-3, and changes in TNFα, IL-8, LTB_4, TxB_2, and TF ($P < 0.05$).

DISCUSSION

The major message of our study is that the apparent differences in sources of n-3 PUFA affect the content of EPA and DHA in serum lipids. After 8 wk on a diet consisting of n-3 FA-rich fish (smoked salmon or cooked salmon fillet) compared with supplementing the diet with CLO, the serum content of EPA and DHA was almost as high in the fish-eating groups as in the CLO group. The daily intake of EPA and DHA was almost 3 times less in the fish groups compared with the CLO group. Our results support the study by Visioli *et al*. (13), and revisited by Galli and Marangoni in 2006 (20), suggesting that a daily fish intake more effectively enhanced the plasma concentration of n-3 FA(s) as compared with intake of concentrated EPA and DHA ethyl esters in capsules. However, in the present study we show that consumption of as little as 2 meals per week including salmon (a total of 1.2 g EPA + DHA on average per day) is almost as effective as intake of 15 mL cod liver oil per day (a total of 3.0 g EPA + DHA per day) in raising the serum concentrations of EPA and DHA. This is experimental evidence that n-3 FA from fish are more effectively incorporated into serum lipids than when administered as a natural oil supplement. The administration of EPA as salmon fillet was nearly twice as effective compared with administration as CLO. Farmed salmon contains large amounts of TAG (93.2% of total lipid), and thus large amounts of EPA and DHA are bound to TAG whereas relatively small amounts of the FA are bound to phospholipids (21). In this regard, the distributions of EPA and DHA are similar in CLO, as they are all bound to TAG. Conceivably, the greater uptake of n-3 FA from fish as compared with CLO might be attributed to the more diluted emulsion of n-3 FA when consumed in the form of fish fillets as compared with the intake of a lipidic bolus of oil as CLO. This higher dilution together with their incorporation within the food item may favor the processes that are involved in fat digestion and absorption at the intestinal level. One may anticipate a higher surface of interaction between the food component and the intestinal wall together with a more favorable secretion of agents for the absorption of lipids.

A need of a nine times the amount (by wt) of DHA if served as capsules compared with to when served as salmon flesh was reported by Visioli *et al.* (13). An exaggerated incorporation of DHA from salmon is also seen in the present study, but it is not as pronounced as in the former work (13). This may reflect an enhanced effect when administered as TAG rather than as ethyl esters. DHA is predominantly esterified in the *sn-2* position whereas EPA is more randomly distributed in all three positions of TAG molecules (22). Since it has been reported that the absorption of EPA and DHA is higher when these FA are predominantly in the *sn*-2 position than when they are distributed randomly among the three positions of TAG molecule (23), this may at least partially account for the apparently greater incorporation of DHA from fish oil (CLO) as compared with the uptake from the concentrated EPA and DHA ethyl esters in capsules in the earlier work (13).The incorporation of

DHA is affected by the co-supplementation of EPA (23). A low ratio of EPA to DHA will probably favor the incorporation of DHA. In our study, this ratio was lower (0.9) than in the study by Visioli *et al*. (13), where the ratio was 1.4. In other words, EPA is more easily incorporated than DHA. When EPA/DHA is low, DHA incorporation is favored.

The incorporation of n-3 FA from cooked salmon fillets tended to be enhanced compared with the smoked salmon fillets (not significant). Differences in bioavailability that depend on food preparation methods and increased digestibility and bioavailability due to heat treatment are well documented (25).

It is well established that intake of EPA and DHA reduces serum levels of TAG. This is only observed as a trend in the present study and mainly in the salmon fillet and CLO groups, and surprisingly also in the cod fillet group.

In this study, intake of n-3 FA results in fewer but larger blood platelets; in particular, the intake of salmon results in larger MPV, but compared with the fish oil group the platelet number does not drop to the same extent. In a previous study we observed the following: Even if the whale oil contained less (than half of the) EPA and DHA compared with CLO, and the incorporation of these FA was lower in the group supplemented with whale oil compared with the group supplemented with CLO, the effect on or the increase in MPV was higher in the whale oil group than in the CLO group (26). This implies that the increased MPV is affected not only by a rise in n-3 FA but also by some unknown factors.

Intake of n-3 FA has been associated with reduction in cellular activation products of blood cells. In our model of LPS-stimulated whole blood, no significant reductions were found although TNFα, LTB_4, and TxB_2 tended to be lower after 8 wk in the salmon groups and CLO group. The failure to see significant reductions can be explained by the relatively strong agonist, LPS, used in our study, which may mask changes at the physiological level *in vivo*, i.e., activation reactions going on all the time. Larger numbers of subjects in each group would have been needed in this respect. Not surprisingly, multivariate analyses demonstrated that the changes in the inflammatory activation products showed a significant negative correlation to the changes in EPA + DHA.

Thermal processing of food produces both positive and negative effects, and the degree of heat-induced changes depends on the treatment applied (25). In fish processing, sarcoplasmic proteins, peptides, amino acids, and other water-soluble compounds are lost with drip (the fluid that is lost during handling), and cooking generally amplifies these losses (27). We failed to see any significant differences between the effects of cooked fish as compared with raw fish (smoked salmon). This may also be explained by the relative small groups in the present study and the lack of having a more strict diet regime for the test subjects.

It may be concluded that intake of fatty fish is more effective in increasing EPA and DHA than supplementation of diet with fish oils and is more likely to have beneficial effects on HDL-cholesterol and activation reactions of whole blood.

ACKNOWLEDGMENTS

This project has been financed with the aid of EXTRA funds from the Norwegian Foundation for Health and Rehabilitation in Norway and the Norwegian Research Council. The authors also want to thank Dr. Inger Solheim for her help with multivariate analysis of the data and Paul D. Johe for his skillful language advice.

ABSTRACT: The higher incidence of inflammatory diseases in Western countries might be related, in part, to a high consumption of saturated fatty acids and n-6 polyunsaturated fatty acids (PUFA) and an insufficient intake of n-3 fatty acids. The purpose of this study was to examine the effects of dietary n-3 fatty acids on innate and specific immune response and their anti-inflammatory action in models of contact and atopic dermatitis. Balb/C mice were fed for 3 wk either n-6 or n-3 PUFA-fortified diets. After inducing a contact or an atopic dermatitis, immunological parameters were analyzed to evaluate the anti-inflammatory potential of these n-3 PUFA. n-3 PUFA reduced innate and specific immune responses through inhibition of T_H1 and T_H2 responses, increase of immunomodulatory cytokines such as IL-10, and regulation of gene expression. The inhibition of both kinds of responses was confirmed by the anti-inflammatory effect observed in contact and atopic dermatitis. Reduction in weight, edema, thickness, leukocyte infiltration, and enhancement of antioxidant defenses in the inflamed ears of mice from both models along with the prevention of delayed-type hypersensitivity induced in atopic dermatitis proved n-3 PUFA efficacy. Our data suggest that dietary fish oil-derived n-3 fatty acids have immunomodulatory effects and could be useful in inflammatory disorders.

Paper no. L10060 in *Lipids 41*, 1115–1125 (December 2006).

The immune system is a complex set of interactive cells and molecules that has evolved to maintain the internal environment (1). Nutrition is one of the factors that regulate immune response and why a balanced and an adequate diet is required for optimal development and functioning of the immune system (2,3). Among different nutrients, lipids play a key role in immune function. Much of the interest in lipids has focused on polyunsaturated fatty acids (PUFA), especially those of the n-6 and n-3 families. The biological functions of these PUFA render them necessary for human well-being, especially because of their impact on nervous tissue development and immune function (4).

A possible explanation for the increase of arteriosclerosis, inflammatory, allergic, or autoimmune diseases, and cancer in Western countries may be related to the type of diets, plenty of saturated and *trans* fatty acids together with a high consumption of n-6 PUFA, and the absence of n-3 PUFA (5,6). The improvement reached with the Mediterranean diet, rich in oleic and n-3 fatty acids and scarce in saturated fats, confirms the relevant role of dietary lipids in human health, because of the low incidence of such pathologies (7). Experimental studies have provided evidence that incorporation of n-3 fatty acids into the diet also modifies inflammatory and immune reactions, making them potentially therapeutic for inflammatory and autoimmune response (8). In spite of the success in animal models (9–11), n-3 PUFA efficacy in humans is less conclusive (12,13).

Dietary fatty acids are able to modulate the immune system through several mechanisms that include alterations in lymphocyte proliferation, cytokine synthesis, phagocytic activity, or immune cell activities (14,15). Such modulation of immune functions may be produced as a consequence of several factors; but in general, the main event involved in this process is associated with changes in the cell membrane composition due to dietary fatty acid manipulation. However, phospholipid changes will depend on many factors such as the amount, type or time of dietary manipulation, and sex and species of animals (or humans) fed dietary lipids (16).

The main mechanism of action of n-3 PUFA is related to eicosanoids synthesis. When arachidonic acid (ARA) is substrate of cyclooxygenase (COX) or lipooxygenase (LOX) enzymes, eicosanoids with proinflammatory properties are produced, whereas EPA derived-compounds are less biologically potent. These intermediates, together with the competitive inhibition of ARA metabolism exerted by EPA, are the most important reasons to consider n-3 PUFA an anti-inflammatory compound (17). Other mechanisms of action are related to modulation of gene expression, involvement in signal transduction pathways, apoptosis or alterations of membrane fluidity, among others (4).

In this work we have analyzed the inflammatory response, innate and specific, in animal models of contact and allergic dermatitis after the consumption of an n-3 fortified diet in comparison with a common Western-like n-6 rich diet.

Abbreviations: ARA, arachidonic acid; Con A, concanavalin A; COX, cyclooxygenase; DNFB, 2,4-dinitro-1-fluorobenzene; DTH, delayed-type hypersensitivity; FO, fish oil; GSH, glutathione; LOX, lipooxygenase; LPS, lipopolysacharide; LXR, liver X receptor; M-CSF, macrophage-colony stimulating factor; MDA, malondialdehyde; MPO, mieloperoxidase; PGE_2, prostaglandin E_2; PPAR, peroxisome proliferator-activated receptor; SO, sunflower oil.

EXPERIMENTAL PROCEDURES

Reagents. The fish oil used in de study was Eupoly®-EPA from Puleva Biotech, SA (Granada, Spain). All chemicals were of the highest available grade and were purchased from Sigma Chemical (St. Louis, MO, USA) except those indicated in the text.

Animals and diets. Weaned male Balb/C mice (n = 10 per group) of 3 weeks of age were purchased from the Granada University breeding colony and housed in a temperature (22ºC) and light (12 h) controlled cycle. This study was carried out in accordance with the *Guide for the Care and Use of Laboratory Animals* (18), as promulgated by the National Institutes of Health, and it was approved by the Animal Research and Ethic Committee of the University of Granada (Spain). The global experiments were conducted three times with similar results.

Semisynthetic diets were prepared following the recommendations given by the American Academy of Veterinary for Animal Nutrition. Differences among the diets were only the source of fat included, which was 5% of the diet in all cases. Diets were composed of 19.1% crude protein, 5% crude oil, 5% crude fiber (in the form of α-cellulose), and 62.9% carbohydrates (which included 57.9% starch and 5% sucrose). Other components such as methionine and the mineral and vitamin mix represented 0.3% and 1%, respectively. After a methanol-toluene extraction, lipid profiles of the diets were obtained by gas chromatography coupled to flame ionization detection (FID) (Column SP2380 Supelco, 60 m × 25 mm) (9,19). In Table 1 diet lipid profiles are shown.

In each of the experimental models used in this work, animals were divided in two groups. One of the groups received a diet based on sunflower oil, rich in n-6 fatty acids (SO diet); the other group consumed a diet fortified with fish oil, rich in n-3 fatty acids (FO diet). Fish oil was supplemented at 15% of the fat content in the latter diet. Diets were consumed for 3 weeks and were conserved in argon atmosphere and at –80ºC. They were administrated daily to the mice to avoid PUFA oxidation.

During this period, weight, physical aspect, and behavior of the animals were evaluated. Animals were killed by intraperitoneal (IP) administration of sodium pentothal (50 mg/kg of body weight) and blood was collected by cardiac puncture in ethylenediamine-tetraacetic acid tubes. Blood was then centrifuged, 2,200 × g for 10 min at 4ºC, and plasma aliquots were collected and frozen at –80ºC.

Fatty acid contents in tissues. Total plasma, liver, and spleen fatty acid profile was determined as described (9,19). Livers and spleens were homogenized in distillated water (1:2) while plasma was directly used. After fat extraction lipid profile of tissues was determined in the same way as the lipid profile of diets.

Cell cultures. Spleens were removed from all mice and homogenized in complete culture medium, DMEM plus 10% FBS, plus 1% penicillin/streptomycin. After centrifugation (1,500 rpm, 5 min) erythrocytes were lysed with a lysing solution (NH_4Cl 1.7 mol/L, $KHCO_3$ 0.12 mol/L, ethylenediaminetetraacetic acid 9 mmol/L) for 15 min at 4°C. Resting cells were counted by using a hemacytometer and cultured to perform proliferation and stimulation assays in current culture medium (DMEM + 10% FBS). Cells were incubated at 37ºC in a humidified 5% CO_2 atmosphere (20).

Bone marrow-derived macrophages were obtained from the mice and cultured in DMEM that contained 20% FBS and 30% L cell-conditioned media as a source of macrophage-colony stimulating factor (M-CSF) (21). After 7 days of culture, a homogeneous population of adherent macrophages was obtained. To render cells quiescent, at 80% confluence macrophages were deprived of L cell-conditioned medium for 16–18 h before the distinct stimulus (22).

Proliferation assays. Spleen-derived lymphocytes were cultured in 24-well plates (2×10^6 cells/well) in 1 mL of medium and stimulated with concanavalin A (Con A) (5 μg/mL) or lipopolysaccharide (LPS) (50 μg/mL). Bone marrow-derived macrophages were cultured in 24-well plates (1×10^5 cells/well) in 1 mL of medium and stimulated with L cell. Cell proliferation was measured by [^{3}H]thymidine incorporation as previously described (23,24).

Analysis of cytokine production, PGE_2, and histamine. Spleen-derived lymphocytes were cultured in 6-well plates (5×10^6 cells/mL) in 5 mL of medium and incubated during 24 h in

the presence or absence of Con A (5 μg/mL) or LPS (50 μg/mL). The supernatants were collected after 48 h of incubation. Differentiated macrophages were cultured in 6-well plates (3×10^6 cells/well). After 12 h, adherent macrophages were stimulated with LPS (100 ng/mL). Supernatants were collected after 24 h. Concentrations of IgG_1, IgE, interleukin- (IL-) 2, IL-1β, IL-4, tumor necrosis factor alpha (TNFα), IL-12, IL-5, transforming growth factor beta (TGFβ), or interferon gamma (IFNγ) were determined by enzyme immunoassay (ELISA) according to the manufacturer's instructions (BETHYL, Montgomery, TX, USA, for immunoglobulins or CytoSets; BIOSOURCE, Camarillo, CA, USA, for cytokines) in plasma and supernatants from lymphocyte or macrophage cultures as indicated. Analysis of histamine (IBL Laboratories, Hamburg, Germany) and prostaglandin E_2 (PGE_2; Oxford Biomedical Research, Rochester Hills, MI, USA) levels in different samples were also determined by using the indicated commercial ELISA kits.

Analysis of gene expression by RT-PCR. Expression of IL-2, IFNγ, IL-10, IL-1β, IL-4, TNFα, peroxisome proliferator-activated receptor alpha (PPARα), PPARγ, LXRα, and LXRβ was analyzed. Total mRNA was isolated from tissue and cultured spleen cells by using Trizol Reagent (Invitrogen, Carlsbad, CA, USA) as described by the manufacturer. Reversed transcription was performed by using Reverse Transcriptase AMV (Roche, Indianapolis, IN, USA). First-strand cDNAs were either stored at –20ºC or used directly in the PCR step. PCR reactions (25 μL total volume) were carried out as previously reported (25). Murine oligonucleotides primers used in the PCR were purchased from MWG-Biotech AG (Ebersberg, Germany) and the nucleotide sequences are shown in Table 2.

Measurement of malondialdehyde. Malondialdehyde (MDA) plasma concentration was measured by separation with HPLC as previously described (26), which is based on the thiobarbituric acid reaction and reverse-phase separation with fluorescence detection.

Induction of contact and atopic dermatitis and ear analysis. The contact dermatitis was induced in the left ear of each mouse by application of 80 μL of a solution including 0.5% of 2,4-dinitro-1-fluorobenzene (DNFB) in a mixture of acetone/olive oil (4:1 by vol) 12 h before they were killed. The right ear received the solvent alone (27).

In another group of animals, to induce an atopic dermatitis, mice were sensitized with 25 μL of 0.5% DNFB solution applied to the shaved dorsal skin. Five days later, 10 μL of 0.2% DNFB (a nonirritant dose) was applied onto both sides of the left ear and the same amount of solvent alone on the right

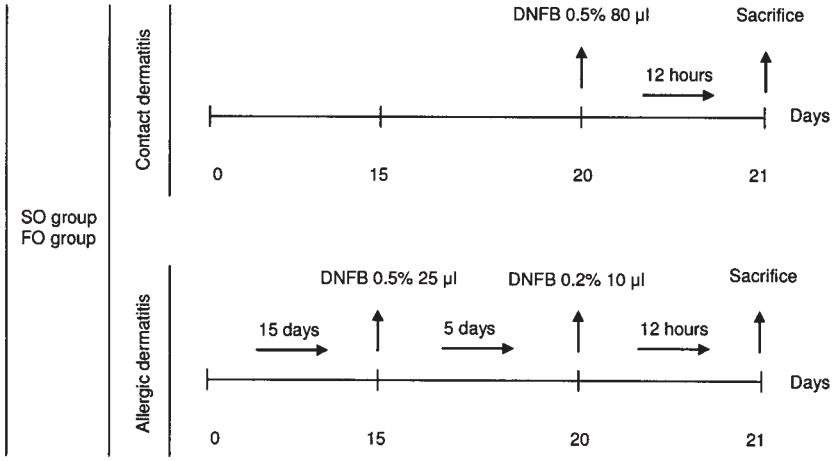

FIG. 1. Scheme of the animal models used.

ear (28). Figure 1 shows the designs of the two inflammatory models.

Both ears from animals of both studies were weighed. In the model of contact dermatitis, half of them were introduced in a heater for 24 h at 60ºC and afterward their dried weights and their consequent content of water were analyzed. In the model of atopic dermatitis, ear thickness was determined by a micrometer (Mitutoyo, Urdorf, Switzerland). The ears were homogenized in a 50 mmol/L solution of hexadecyltrimethyl-ammonium bromide to measure total glutathione (GSH), myeloperoxidase (MPO) activity, and cytokine levels. Such measurements were carried out following procedures described previouly (9,29).

Statistical analysis. All data are represented as mean ± SD values. Differences between means were tested for significance using one-way ANOVA. All statistical analyses were carried out with SPSS software (version 12.0; Chicago, IL, USA), with differences considered significant at $P < 0.05$.

RESULTS

Mice behavior and dietary intake of fatty acids. Animals were observed during the 3 wk the study lasted, and there were no significant differences in the average daily food intake between the two groups (4.0 ± 0.57 vs. 3.7 ± 0.91 g/day; SO vs. FO). Mice in the two groups grew normally, and there were no significant differences in weekly body weights (45.7 ± 29.9 vs. 52.5 ± 26.8 weight increment [%]; SO vs. FO, $P > 0.05$). No differences were observed between animals of the two experimental protocols (contact vs. allergic dermatitis) in spite of the initial abdominal DNFB dose at day 15 in the allergic model (data not shown). Moreover, no side effects such as occurrence of diarrhea or differences in either the aspect or the behavior were observed in the mice from the two groups.

The analysis of the diets confirmed the enrichment in n-3 fatty acids. Table 1 shows fatty acid compositions of the diets given. The approximate amounts of oleic acid, linoleic acid, EPA, and DHA ingested daily by mice fed the FO were 45 ± 8 mg, 87 ± 15.5 mg, 2.75 ± 0.5 mg, and 2.65 ± 0.5 mg, respectively, while SO-fed animals consumed 50.5 ± 7.1 mg, 102.5 ± 14.5 mg, and 0.5 ± 0.1 mg of oleic acid, linoleic acid, and EPA per day, respectively. Thus, the FO diet contained more than 10 times the amount of EPA and DHA n-3 fatty acids compared to the SO diet. This was the main difference between the diets since there were no important changes in other fatty acid profiles with the exception of n-6 PUFA content, which was slightly lower (45.5% vs. 39.3%; SO vs. FO). The increase in n-3 PUFA was compensated by a decrease in n-6 PUFA in the diet. Consequently, the n-3/n-6 PUFA ratio in the SO diet was clearly lower than that of the FO diet (0.01 vs. 0.08; SO vs. FO) (Table 1).

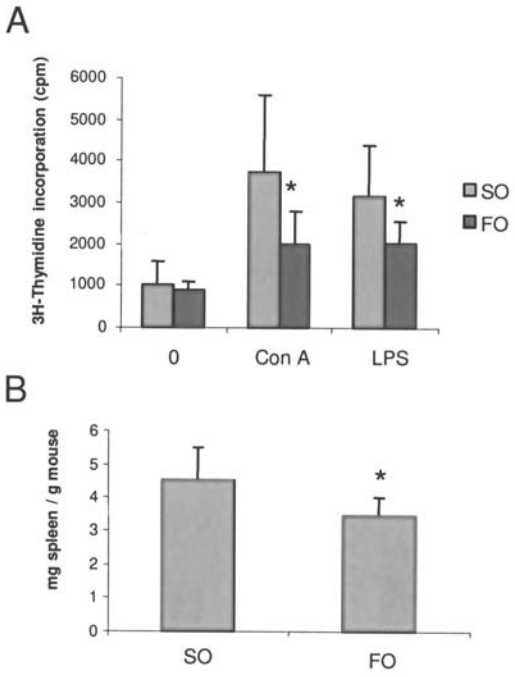

FIG. 2. FO diet decreases lymphocyte proliferation. (A) Spleen was removed from each mouse immediately after killing, erythrocytes were then lysed and spleen-derived lymphocytes from each mouse were cultured in the presence or absence of Con A (5 µg/mL) or LPS (50 µg/mL). [^{3}H]Thymidine (1 µCi/mL) was added and incubated for 48 h. Proliferation ratios were determined as [^{3}H]thymidine incorporation. Results are expressed as cpm ± SD ($n = 10$). (B) Milligrams (mg) of spleen per gram (g) of mouse body weight consuming SO or FO diets. Values are mean ± SD, $n = 10$. *Significant difference between SO and FO group ($P < 0.05$).

[a]$P < 0.05$ vs. SO group.
[b]$P = 0.06$ vs. SO group.

FO diet reduces both T_H1 and T_H2 response. After 3 wk of diet consumption, proliferative response to mitogens of splenocytes was assessed by [^{3}H]thymidine incorporation (Fig. 2A). B and T cells obtained from FO-fed mice exhibited a significantly lower level of proliferation compared to cells from the SO group ($P < 0.05$ in both cases). In concordance with these findings, a reduction in the size of the spleen (Fig. 1B) was appreciated in the FO group.

To determine whether alterations in mitogen-induced IL-2 production by T lymphocytes might be responsible for the suppressive effects of dietary EPA and DHA fatty acids on lymphocyte proliferation, IL-2 secretion in the culture supernatants was measured. In this sense, T cells from FO-fed mice secreted less IL-2 relative to SO-fed mice when T cells were stimulated with Con A (Table 3).

Besides IL-2 reduction, other T_H1 cytokines were also modulated by the consumption of fish oil. In this sense, the levels of IL-1β and IFNγ produced by stimulated splenocytes were significantly lower when mice consumed the FO diet in contrast to the SO diet (Table 3). In the same way, we found lower levels of IL-12 in supernatants from stimulated FO-derived splenocytes although the results did not reach statistical significance.

The effects of the dietary lipids on macrophage proliferation induced by M-CSF were also evaluated, but there were no significant differences between the two groups (81,073 ± 15,574 vs. 91,530 ± 15,724 cpm; SO vs. FO). In spite of the absence of effect at this level, lower concentrations of inflammatory cytokines were found in the supernatants of cultured LPS-stimulated macrophages from FO-fed mice in comparison to SO-fed mice. In this sense, we observed reduction in the secretion of IL-1β and TNFα (Table 3) but IL-12 levels remained unchanged.

T_H2 parameters were also studied in mice fed with both diets. A decrease in the levels of IL-4 in supernatants obtained from spleen-derived lymphocytes was observed (Table 3). In a similar way, IL-4 concentration was also significantly lower in plasma (Table 4). Other T_H2 parameters were analyzed to check the impact of PUFA n-3 above allergic response, finding a decrease in other mediators such as IL-5, IgE, IgG_1, and histamine in plasma of the animals consuming the FO diet (Table 4).

The increase in immunoregulatory cytokines by the FO diet may be involved in the reduction of both T_H1 and T_H2 responses. Looking for an explanation for the immunomodulatory effects of the fish oil n-3 fatty acids in both T_H1 and T_H2 response, we studied the production of the regulatory cytokines

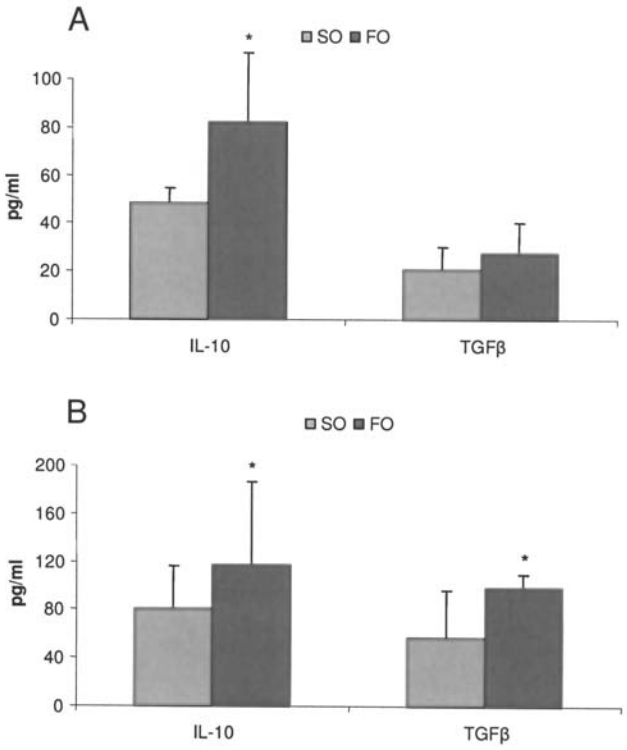

FIG. 3. n-3 fatty acids increase synthesis of immuneregulatory cytokines. (A) Spleen-derived lymphocytes from each mouse were cultured with or without Con A (5 μg/mL) as a T-cell stimulus. After 48 h in culture, supernatants were collected and IL-10 and TGFβ concentration was measured by ELISA. (B) Bone marrow-derived macrophages were cultured in the presence or absence of LPS (100 ng/mL). Production of IL-10 and TGFβ was measured. Results are expressed as mean ± SD (pg/mL). *Significant difference between SO and FO group ($P < 0.05$).

IL-10 and TGFβ, which are able to inhibit both responses in some circumstances. In this sense, levels of IL-10 in supernatants from stimulated T lymphocytes and LPS-stimulated macrophages were enhanced significantly in the FO group in contrast to the control (Fig. 3). Moreover, we also found higher amounts of IL-10 in serum of mice belonging to the FO group (24.58 ± 15.68 vs. 33.01 ± 10.5 pg/mL, SO vs. FO). Similarly, TGF-β production by both lymphocytes and macrophages was also increased in the FO group (Fig. 3).

Modulation of inflammatory eicosanoids and gene expression might be a mechanism of action of dietary n-3 PUFA. In vivo incorporation of dietary lipids was verified by liver, spleen, and total plasma lipids analysis (Table 5). In both tissues and plasma, fish oil significantly increased the content of EPA and DHA when compared to sunflower oil. There was more DHA than EPA in the analyzed samples, especially in the liver, despite that the content of EPA and DHA in the FO diet was similar. The increase in n-3 fatty acids in plasma and liver of FO-fed mice occurred without affecting the n-6 fatty acids, leading also to an increase in the n-3/n-6 ratio. However, in the spleen, the higher incorporation of EPA and DHA was associated with a decrease in n-6 PUFA, especially ARA, precursor of inflammatory eicosanoids.

These data suggest that the release of eicosanoid mediators from the immune cells might have been affected by the FO diet. To check this hypothesis, we analyzed the n-6 fatty acid-derived eicosanoid PGE_2 in splenocytes and in macrophage supernatants. The results obtained showed lower concentrations of this inflammatory mediator produced by lymphocytes of the FO-fed mice (4.1 ± 0.2 vs. 2.4 ± 0.9 ng/mL, SO vs. FO; $P < 0.05$) or produced by stimulated macrophages (8 ± 0.2 vs. 5 ± 0.6 ng/mL, SO vs. FO; $P < 0.05$).

Due to the different possibilities of action of fatty acids, it was decided to investigate other possible mechanisms involved in the immunomodulatory effects observed for fish oil-enriched diets.

Dietary fatty acids are known for their capacity for modulating gene expression. When we analyzed gene expression after n-3 PUFA consumption, we observed an increase of IL-10 expression in T lymphocytes (Fig. 4A). The decrease of inflammatory and allergic cytokines observed was also associated with a lower expression of the corresponding genes (Fig. 4A, B). Moreover, the expression of other proteins involved in immune response was altered. In this sense, the expression of nuclear factors such as LXRα, LXRβ, or PPARγ was increased by the FO diet, suggesting its anti-inflammatory action (Fig. 4C). However, PPARα expression was not affected by fish oil consumption.

Other mechanisms suggested were those related to the effects carried out by products of lipid peroxidation of n-3 PUFA. However, we found similar levels of MDA in serum from mice consuming SO or FO diets (1.3 ± 0.1 vs. 1.4 ± 0.3 μM, SO vs. FO), suggesting that an increase in lipid peroxidation is not responsible for the effects of the different diets.

Since macrophage and lymphocyte responses were affected by dietary fish oil, immune disorders mediated by these could be prevented by n-3 PUFA consumption. To check the capacity of n-3 fatty acid of suppressing these kinds of responses, we evaluated the FO diet in animal models of contact and allergic dermatitis in which innate or specific responses are involved, respectively (30).

Prevention of contact dermatitis by the supplementation with fish oil n-3 fatty acids. To confirm the results we checked

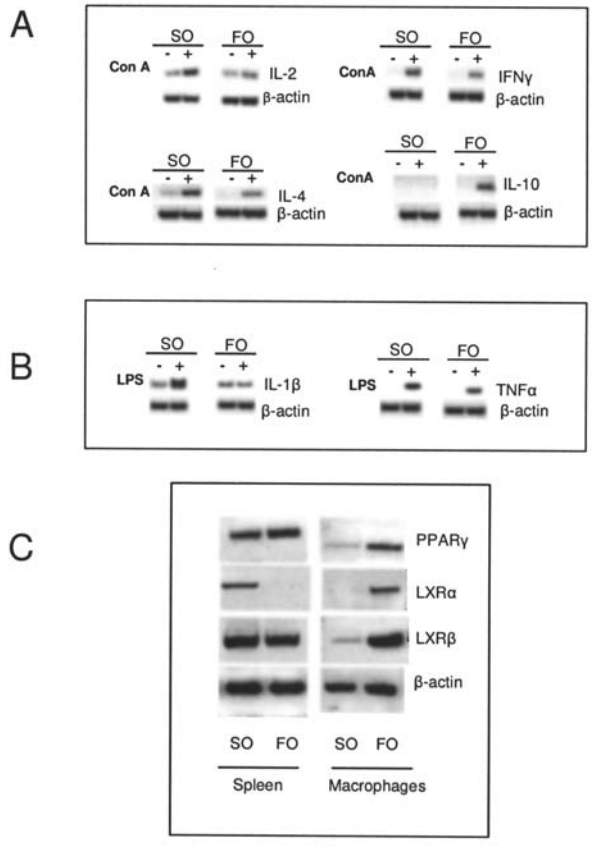

FIG. 4. FO diet alters expression of genes related to immune function. (A) Total mRNA from control and Con A-stimulated T lymphocytes was obtained and expression of IL-2, IFNγ, IL-4, and IL-10 was analyzed by reverse transcription (RT)-PCR. (B) mRNA from control and LPS-stimulated macrophages was extracted and the expression of TNFα and IL-1β was evaluated. (C) LXR·, LXRβ, and PPARγ expression in lymphocytes and macrophages was studied by RT-PCR. β-Actin was used as a control.

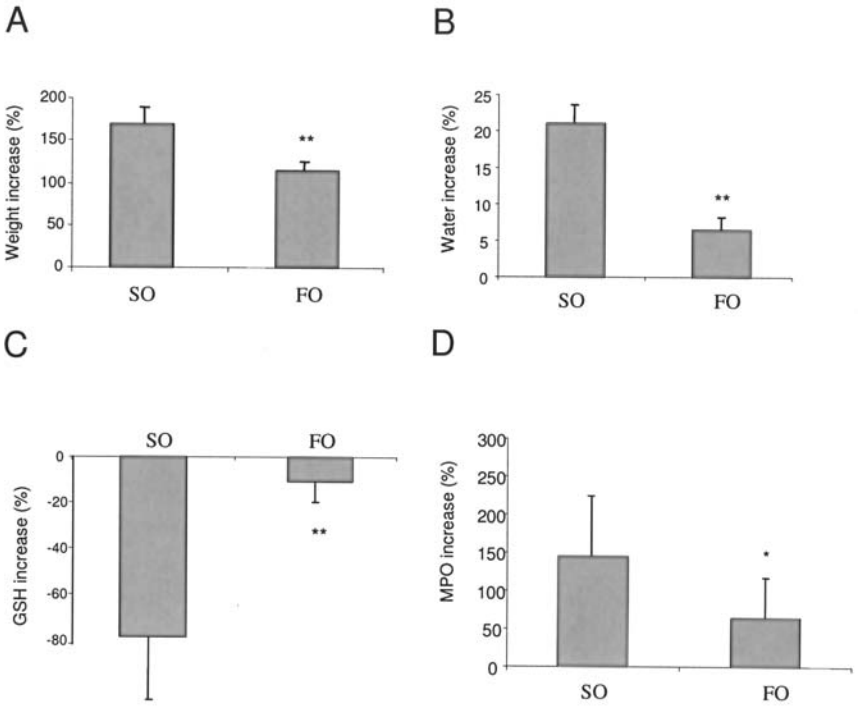

FIG. 5. FO diet improves contact dermatitis. (A) Percentage of weight increase of treated ears compared to healthy ones in mice consuming SO or FO diets. (B) Percentage of water increase of treated ears compared to healthy ones in mice consuming SO or FO diets. (C) Percentage of glutathione increase in treated ears compared to healthy ones in mice consuming SO or FO diets. (D) Increase of myeloperoxidase activity in treated ears compared to healthy ones expressed as percentage in mice consuming SO or FO diets. Results are expressed as mean ± SD ($n = 10$). **Significant difference between SO and FO groups ($P < 0.01$).

the effects of the diets in a murine model of ear contact dermatitis. Once the contact dermatitis was induced, ears were removed and weighed. As a consequence of the inflammatory process, ear weight increased in both groups; however, FO-fed mice showed a significantly weaker increase than SO-fed mice (Fig. 5A).

To determine the severity of the edema, the content of water in the ears from mice were measured. Differences between healthy and inflamed ears showed a higher increase of extravased liquids in ears from SO-fed mice in contrast to FO-fed mice (Fig. 5B). Moreover, the reduction of GSH in the inflamed ears in comparison to the healthy ones was lower in FO-fed mice, suggesting a protective role of the dietary n-3 fatty acids against oxidative stress during inflammation (Fig. 5C). Along with these results, we also observed a decrease in leukocyte infiltration measured as MPO activity in FO-fed mice, indicating that the FO diet improved the course of the inflammation (Fig. 5D). Finally, the lower local production of TNFα (99.8 ± 18.6% vs. 41.2 ± 7.3% of TNFα increase, SO vs. FO; $P < 0.05$) in the irritated ears of mice consuming FO diet confirmed the anti-inflammatory effects of n-3 fatty acids in this model of acute inflammation. Other cytokine concentrations were determined, but no changes were found (data not shown).

Prevention of atopic dermatitis by the supplementation with fish oil n-3 fatty acids. To better evaluate the lymphocyte involvement in the inflammatory response and the n-3 PUFA effects, we explored the anti-inflammatory actions of n-3 fatty acids on a second model of dermatitis that involves an allergic reaction and consists of two doses of DNFB (see experimental procedures section). After the first sensitization dose in the abdomen, we observed an absence of the delayed-type hypersensitivity (DTH) in animals consuming the FO diet (Fig. 6) in contrast to animals belonging to the SO group, in which the DTH appeared 3 days after the first challenge. The analysis of

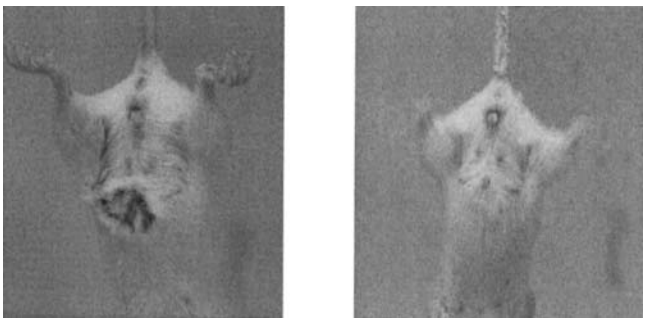

FIG. 6. Dietary fish oil prevents delayed-type contact dermatitis (DTH). (A) DTH occurred in mice belonging to the SO group after the first sensitization in the abdomen with DNFB (0.2%, 25 µL). (B) DTH was absent in mice belonging to the FO group.

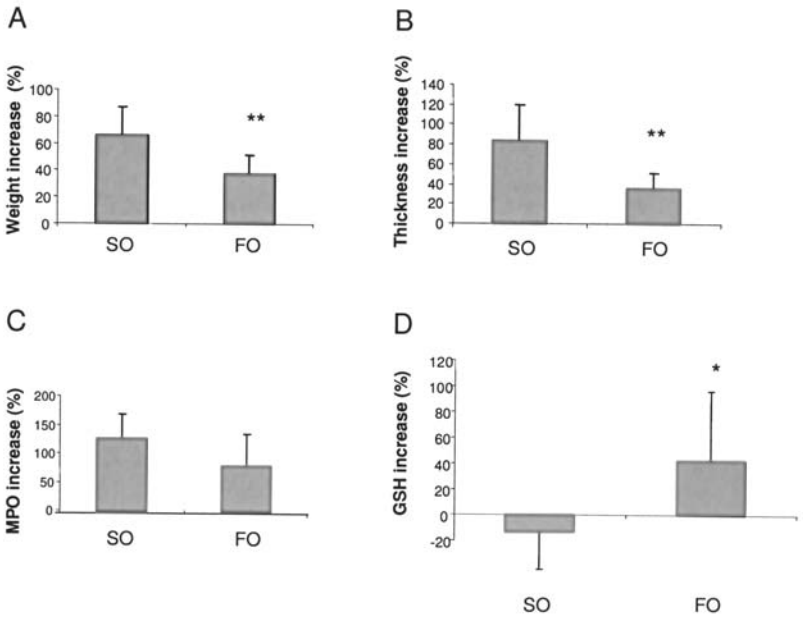

FIG. 7. FO diet improves allergic dermatitis. (A) Percentage of weight increase of treated ears compared to healthy ones in mice consuming SO or FO diets. (B) Percentage of thickness increase of treated ears compared to healthy ones in mice consuming SO or FO diets. (C) Percentage of glutathione increase in treated ears compared to healthy ones in mice consuming SO or FO diets. (D) Increase of myeloperoxidase activity in treated ears compared to healthy ones expressed as percentage in mice consuming SO or FO diets. Results are expressed as mean ± SD (n = 10). Significant difference between SO and FO groups (*$P < 0.05$, **$P < 0.01$).

the ears at the place of the second sensitization revealed an improvement of the inflammatory process induced. Reduction of ear swelling occurred after n-3 PUFA intake as was observed from the lower weight and thickness reached by irritated ears in mice from the FO group (Fig. 7A and B). GSH concentrations in damaged ears were not only restored but also increased (Fig. 7C); whereas, in the same way as in the model of contact dermatitis, MPO activity was decreased in ears of FO-fed animals (Fig. 7D). Local production of cytokines was also analyzed and only IL-4 levels were significantly decreased by dietary fish oil in irritated ears (153.1 ± 83.3 vs. 107.5 ± 26.2 pg/mL, SO vs. FO; $P < 0.05$).

DISCUSSION

A series of studies have demonstrated that EPA and DHA n-3 PUFA from fish oil have many biological effects, ranging from decreasing the levels of serum triacylglycerols (31) and reducing blood pressure (32) to inhibiting the growth of tumor cells (33), and modulating symptoms in patients with autoimmune and inflammatory diseases (34). The importance of n-3 essential fatty acids in the diet is consequently evident as well as the need to return to a more physiological n-6/n-3 ratio of about 4:1 rather than a ratio of 20–30:1 provided by current Western diets. Because of the relevant role of n-3 fatty acids, the scientific community is trying to explain their anti-inflammatory effect, to have scientific proofs that lead people to increase fish oil-derived n-3 fatty acids consumption. In this sense, it is essential to elucidate the mechanisms by which dietary fish oil suppress the immune response to maximize the potential therapeutic anti-inflammatory effects without compromising important antimicrobial or anti-tumor functions of the immune system.

The suppressed T- and B-lymphocyte proliferative response observed in FO-fed mice is consistent with the results of other investigations regarding fish oil (35,36). As IL-2 is a potent polyclonal autocrine and paracrine T-lymphocyte growth factor, the reduced IL-2 secretion by lymphocytes found in the FO-fed mice suggests that the suppressed lymphocyte proliferation observed was due, at least in part, to a reduction in IL-2, as has previously been shown (36).

As a result of the decrease in proliferation, other lymphocyte responses could also be affected. In this way, n-3 fatty acids not only were able to reduce IL-2 production, but also other T_H1 and T_H2 cytokines. In addition, the production of IL-1β and TNFα by macrophages was also decreased, indicating that diets supplemented with n-3 fatty acids have the capability to alter the whole cytokine profile. In spite of the strong effect of n-3 PUFA on inflammatory cytokines, they hardly modulated the secretion of the more characteristic T_H1 cytokine IL-12 by both macrophages and lymphocytes, suggesting that the inhibition of the inflammatory response does not imply a lower capacity of response to antigens. As this cytokine has important implications for host infectious disease resistance, the maintenance of its level at normal amounts suggests a correct function of the organism defenses. This is in contrast to considerations by other authors stating that n-3 fatty acids lead to an immunosuppressive status (37).

The decrease in cytokines exerted by these lipids could be related to the immunosuppressive effect regulated by IL-10 and TGFβ, which levels appear to be increased in macrophages and lymphocytes from the FO group. Despite that other groups showed the same increase of IL-10 after fish oil ingestion, none of these authors considered this immunoregulatory cytokine responsible for immune suppression (38). To confirm this hypothesis, research with IL-10–/– knockout mice would be necessary.

Although in this work we have not established the mechanism directly responsible for the observed cytokine modulation, several mechanisms could be proposed, namely eicosanoid modulation and gene expression modulation.

The reduction of eicosanoid production of series 2 and 4, such as PGE_2, by immune cells is indicative of the incorporation of n-3 fatty acids in membrane phospholipids. In fact, the results from this study demonstrate the significant increase of EPA and DHA in plasma, liver, and spleen (Table 5). Both fatty acids were incorporated in tissues substituting, in the case of spleen, ARA. This result might explain the lower levels of arachidonic-derived eicosanoids found. Although quantities of both fatty acids were similar in the diets, DHA is significantly enhanced, especially in liver samples, which indicates that, possibly, part of the EPA is converted into DHA by elongases and desaturases, important enzymes of lipid metabolism (3). The higher levels of DHA in tissues are logical, as DHA is the major form of restoration of n-3 PUFA in the organism (39). However, the reason immunoregulatory cytokines are increased by immune cells is not related to PGE_2, although other arachidonic-derived eicosanoid may be involved, since the lower levels of PGE_2, a potent inductor of IL-10, should lead to reduced concentrations of IL-10 (40).

Another potential mechanism that may explain the results described in this document is the capacity of n-3 PUFA to modulate gene expression, a mechanism by which these fatty acids could reduce inflammatory/T_H1 and T_H2 cytokines or increase T_H3 cytokines. The lower expression of several cytokines induced by fish oil consumption could be the consequence of a direct effect of the n-3 fatty acids on the implicated genes or an indirect effect exerted by IL-10, a cytokine capable of reducing the expression of inflammatory cytokines (41). In this sense, recent studies have demonstrated the capacity of certain PUFA to directly suppress Nuclear factor κB activation in immune cells through an ERK-mediated IL-10 mechanism, leading to an anti-inflammatory effect (42). In a similar way, higher expression of PPARγ and LXR in immune cells leads to a more potent anti-inflammatory effect as they mediate anti-inflammatory events (43). It is noteworthy that the observed PPARγ protective role in several diseases seems to be partly independent of IL-10 (44), a fact that indicates that the anti-inflammatory effect of n-3 PUFA may be due to the combination of the increase in IL-10 and the higher expression of PPARγ. In fact, EPA and DHA have been described to activate these nuclear receptors (45).

From the results obtained in healthy animals we could extrapolate the important role of dietary n-3 PUFA in both natural and acquired responses and, consequently, their potential therapeutic applications. To demonstrate their therapeutic role, we checked how a contact dermatitis, characterized by an innate response, mainly mediated by local macrophages and neutrophils, and an allergic dermatitis, with a specific lymphocyte response involved, could be improved by intake of diets enriched with fish oil.

The contact dermatitis induced resulted in an acute inflammation of the skin characterized by the two main features of the process, swelling (edema) and granulocyte infiltration, but does not seem long enough to induce a clear T_H1 or T_H2 response, which needs at least 24 h to develop. Although there are limitations in the use of this model for inflammatory reactions, it is one approach for studying the initial phase of inflammation (46) and could give some clues about the anti-inflammatory potential of n-3 PUFA. In this model, weight and water content of irritated ears was lower in FO-fed mice, suggesting that vasodilatation and edema had been less drastic. The weaker leukocyte infiltration could be explained by a lower MPO activity in the ears of these mice. The amelioration of this key step during inflammation, together with reduction of TNFα in the damaged ears by n-3 fatty acids, points to a critical role of these n-3 PUFA to attenuate the inflammatory process.

As a result of the irritation induced, a drastic decrease of antioxidant defenses took place, and GSH levels in the irritated ears were reduced. However, the reduction in GSH observed in inflamed ears from the FO-fed mice was less severe, possibly because of a lower breakdown of GSH or because of a better capacity to restore antioxidant defenses. Restoration of GSH after n-3 PUFA consumption in inflammation models correlates with effects observed in other studies (47). In fact, the possible antioxidant effect of n-3 PUFA has been already suggested (48), a fact that correlates with the similar plasma levels of MDA found in mice consuming, or not, the n-3 PUFA diet.

The model of allergic dermatitis, also called contact hypersensitivity, implies, however, complete T_H1 and T_H2 responses and allows a more exhaustive study of the n-3 fatty acids effects in inflammation. In addition, allergic response can also be studied since a type IV allergy takes place in this model (49).

Contact hypersensitivity is a T cell-mediated cellular immune response caused by repeated epicutaneous exposure against contact allergens, chemically reactive haptens that are able to bind directly to soluble or cell-associated proteins. This reaction is divided into two phases, sensitization and elicitation. In the first phase allergens are presented to naïve T cells, and in the second phase allergen-specific T cells are activated upon rechallenge with the same allergen, resulting in local inflammation (50). Both acute and T cell-mediated responses were prevented with the prophylactic administration of dietary n-3 PUFA.

In this sense, the results from our study demonstrate the capability of n-3 PUFA to suppress a specific immune response. On one hand, DTH after the first challenge was totally avoided in FO-fed mice, suggesting the n-3 PUFA-suppressive action on T lymphocytes and especially macrophages, the major type of cells involved. This effect attributed to n-3 PUFA has been

previously suggested by other groups (51). On the other hand, local inflammation was also ameliorated in the same way as in the previous model. Thus, leukocyte infiltration, ear swelling, and GSH content of the treated ears improved.

Such a model of inflammation mimics atopic dermatitis in humans and can curse as a T_H1 or a T_H2 response depending on the situation. The reduction of IL-4 concentration observed in ears suggests the capacity of n-3 PUFA to downregulate the T_H2 response induced, collaborating with the restoration of the damaged tissues. On the contrary, in the contact dermatitis model, inflammatory cytokines such as TNFα were decreased by fish oil; whereas in this model, the T_H1 local response is not so important in the elicitation phase. This fact, together with the prevention of DTH suggests an antiallergenic effect for n-3 PUFA. Other authors have already suggested an important role of n-3 PUFA in allergic sensitization and allergic pathologies (52), and how changes in Western diets have contributed to enhance incidence of these kinds of disorders (5). A more complete study of the systemic response should be carried out to clarify the role of n-3 PUFA during the different phases of the model.

In conclusion, we can attribute to fish oil-derived n-3 fatty acids an anti-inflammatory role with several possible therapeutic applications, especially in autoimmune and chronic inflammatory diseases. In an attempt to elucidate the mechanisms of action, immunoregulatory cytokines and special mediators such as nuclear receptors seem to be involved through their immunosuppressive actions. However, additional studies are required to further clarify the mechanisms of immunomodulation to optimize the potential beneficial effects of EPA and DHA.

[a]Nutraceuticals Research Group, School of Biomedical Sciences, Faculty of Health, University of Newcastle, Callaghan, NSW 2308, Australia, and [b]Department of Cardiology, John Hunter Hospital, New Lambton Heights, NSW 2299, Australia

ABSTRACT: Recent studies have demonstrated that long-chain n-3 PUFA (LCn-3PUFA) are beneficial in reducing the risk of cardiac arrhythmias. This study was conducted to determine the extent of incorporation of LCn-3PUFA into human atrium following supplementation with a fish oil concentrate high in LCn-3PUFA. Volunteers preparing for coronary bypass surgery were randomized either to the treatment group (n = 8), receiving 6 g/d of fish oil concentrate (4.4 g of LCn-3PUFA), or the placebo group (n = 9), receiving 6 g/d of olive oil for a minimum period of 6 wk. Blood samples were collected prior to commencement of treatment, and preoperatively before bypass surgery. Atrial biopsies were obtained during surgery. The plasma and atrium samples were analyzed by GC following trans-methylation to determine FA profile. Post-supplementation, the treatment group had significantly higher plasma levels of 20:5n-3, 22:5n-3, and 22:6n-3 than the placebo group. Analysis of the atrium total lipids revealed a significant increase in the proportion of 20:5n-3 following fish oil supplementation. There was no significant difference in the concentration of 22:5n-3 and 22:6n-3 in the atrium total lipids; however, an upward trend was observed in subjects receiving fish oil supplementation. In the phospholipid fraction of the atrium, both 20:5n-3 and 22:6n-3 increased, whereas 20:4n-6 levels decreased. This study demonstrates for the first time that short-term supplementation with fish oil concentrate results in significant incorporation of LCn-3PUFA with a concomitant depletion of the eicosanoid substrate (20:4n-6) in the human atrium.

Paper no. L10085 in *Lipids 41*, 1127–1132 (December 2006).

Observational, clinical, and experimental studies have demonstrated that long-chain n-3 PUFA (LCn-3PUFA) supplementation reduces the risk of heart diseases including cardiac arrhythmias (1,2). Several mechanisms by which LCn-3PUFA prevent cardiac arrhythmias have been proposed. Studies using experimental animals have shown that LCn-3PUFA supplementation prevents arrhythmias by increasing the ventricular fibrillation threshold (3,4) and by decreasing ventricular fibrillation (5,6). Calo *et al.* (7) demonstrated that short-term LCn-3PUFA administration in patients undergoing coronary artery bypass graft (CABG) substantially reduced the incidence of postoperative atrial fibrillation and was associated with a shorter hospital stay. Other human studies have confirmed anti-arrhythmic potential of LCn-3PUFA (7–9). In isolated cardiac myocytes, EPA, and DHA have been shown to reduce contraction (10,11) and ouabain-induced arrhythmias (12). Several mechanisms have been suggested to explain the anti-arrhythmic actions of LCn-3PUFA, and they have been extensively reviewed (13–15). Some of the mechanisms suggested include modification of membrane phospholipids, alterations in the type and amount of eicosanoids generated, and the effects of these modifications on intracellular calcium release and calcium channels via the second messenger operated signaling system.

Billman *et al.* (5) suggested that non-esterified LCn-3PUFA have a direct antiarrhythmic effect without prior incorporation of LCn-3PUFA into myocardial phospholipids. However, as arrhythmias occur suddenly it is impractical to infuse non-esterified LCn-3PUFA. Evidence suggests that the incorporation of LCn-3PUFA into myocyte membrane phospholipids is essential for anti-arrhythmic action, so that these FA are readily available for release as free acids to prevent arrhythmias following myocardial ischemia (15). Indeed, phospholipase activity has been shown to be increased following myocardial ischemia (16). Regardless of the mechanism by which LCn-3PUFA supplementation prevents cardiac arrhythmias, incorporation of LCn-3PUFA into the myocardium pools appears to be a prerequisite for their action (15). In the animal experiments very high doses of dietary LCn-3PUFA supplementation were used. It is not known if dietary supplementation of LCn-3PUFA practically achievable with fish oil capsules in humans will result in significant incorporation of these FA into cardiac membranes.

Therefore it was of interest to investigate whether LCn-3PUFA supplementation results in the enrichment of atrium with LCn-3PUFA. Patients scheduled to undergo coronary bypass surgery were supplemented with fish oil capsules prior to obtaining blood and atrium biopsies. It was assumed that LCn-3PUFA incorporation into the lipid fractions of atrium biopsies would reflect LCn-3PUFA enrichment of the ventricle tissue. Because mechanisms for anti-arrhythmic action of LCn-3PUFA may be mediated via changes in the FA composition of cardiac membrane phospholipids and/or amount and type of LCn-3PUFA in the non-esterified fraction (15), FA composition of atrium major lipid fractions was determined separately.

EXPERIMENTAL PROCEDURES

Subjects. Patients attending preoperative clinic for coronary artery bypass graft requiring a left internal mammary artery graft to left anterior descending artery were screened for the study. Patients were randomized 6 wk prior to the surgery to receive either a fish oil (Lube AS, Hadsund, Denmark) concentrate (six 1-g capsules, each containing approximately 676 mg of EPA and DHA, providing a total of approximately 4.4 g/d of LCn-3PUFA, $n = 9$) or a placebo (six 1-g olive oil capsules, $n = 8$).

The study protocol was approved by the Human Research Ethics Committee of the University of Newcastle and Hunter Area Research Ethics Health Committee, and the subjects gave informed consent prior to randomization. Characteristics of the patients involved in the trial are presented in Table 1. There was no significant difference in the mean age of the placebo and the treatment groups. All the patients except one in the placebo group were males. A large majority of the patients (with the exception of one in the fish oil group) were taking aspirin prior to the surgery. One participant in each of the placebo and the fish oil group was on ACE inhibitors, and nearly half of them in each group were taking statin drugs as a cholesterol-lowering therapy.

FA composition of the placebo and fish oil concentrate capsules is presented in Table 2. The fish oil concentrate contained 73.5% long-chain LCn-3PUFA in the form of 20:5n-3 (37.5%), 22:5n-3 (5.9%), and 22:6n-3 (30.1%). Six fish oil capsules, therefore, supplied about 4.3 g/d of LCn-3PUFA. The placebo oil was devoid of these FA and contained saturated (12.1%), monounsaturated (81.9%), and n-6PUFA (5.0%).

The supplements continued until the day prior to the surgery. Compliance was measured by the capsule count-back method and by LCn-3PUFA incorporation into plasma lipids. Baseline and preoperative blood samples were collected for measurement of cholesterol, triglyceride, LDL cholesterol, HDL cholesterol, and FA analysis. Atrium biopsies were obtained during the surgical procedure, frozen in liquid nitrogen, and stored at –80°C.

FA analysis. The FA composition of the plasma lipids was determined according to a modification of the method of Lepage and Roy (17). Briefly, 100 µL of plasma was mixed with 2 mL of methanol:toluene (4:1 vol/vol) containing 4 µg/mL of C21:0 as an internal standard, and 0.12 mg/L butylated hydroxytoluene as an antioxidant, in a glass culture tube, and vigorously mixed by vortex. This was followed by the slow addition of 200 µL of acetyl chloride while mixing by vortex. The tube was then sealed with a teflon-lined cap, and heated at 100°C for 60 min. The tubes were then rapidly cooled under running water. The reaction was halted by the addition of 5 mL of 6% K_2CO_3 solution, followed by vigorous mixing by vortex. The tubes were then centrifuged at $3,000 \times g$ for 10 min. at 4°C. Following centrifugation, the toluene supernatant containing the FAME was transferred to a glass vial and crimp sealed with a teflon-lined cap for subsequent analysis by GC.

FAME were quantified using a Hewlett Packard 6890 gas chromatograph equipped with a 30 m × 0.25 mm capillary column (DB-225, J&W Scientific, Folsom, CA) and a flame ionization detector (18). Chromatographic conditions were as follows: inlet temperature 250°C, inlet pressure 97.5 kP, split ratio 20:1, carrier gas as hydrogen (ultra-high purity) with a flow rate 1.6 mL/min. The chromatographic conditions were as follows; initial temperature of 170°C held for 2 min, ramped to 190°C at a rate of 10°C/min, held there for 1 min, ramped to 220°C at a rate of 3°C/min, and held at 220°C for 15 min. FAME were identified and quantified by comparison with authentic FAME standards (Nu-Chek-Prep, Elysian, MN)

Lipids from the atrium tissues were extracted by the methods described by Folch *et al.* (19). An aliquot of the total lipid extract was methylated and FA composition determined as described above. The remaining lipid extract from the atrial tissues was spotted on TLC plates, and the plates were developed in a solvent system comprising hexane:diethyl ether:acetic acid (85:15:1, by vol) for the separation of phospholipid, triglyceride, and non-esterified fractions (20). Lipid fractions were scraped off the plates and methylated, and FA composition was determined as detailed above.

Statistical analysis. The results are presented as mean ± SD.

Total n-6 PUFA	5.0	5.5
Total n-3 PUFA	0.6	73.6

[a]Three random placebo and fish oil concentrate capsules were analyzed, and the average ($n = 3$) values are presented in the table.

Prior to analysis, data were assessed for linearity and homoscedasticity assumptions using the Scatterplot option of the Statistical Package for Social Sciences (SPSS) version 14 for Windows. Data were also assessed for the assumption of normality. Change in plasma data over time between treatment groups was analyzed by repeated measures analysis using the MIXED Model procedure in the SAS program. Unpaired two-tailed student's t-test was used to test the difference between treatments at post-intervention (preoperative) for the atrium results. Values were considered to be significant if $P < 0.05$.

RESULTS

No side effects of fish oil supplementation were reported except one patient complaining of fishy eructation. Two of nine patients in the placebo and two of eight patients in the fish oil group experienced atrial fibrillations following CABG surgery (Table 1). Plasma cholesterol and LDL and HDL cholesterol contents were similar in both the placebo and the fish oil–supplemented groups at baseline as well as post-intervention. Plasma triglyceride levels were significantly reduced following fish oil supplementation for 6 wk, whereas the placebo supplementation made no difference (Table 3).

The FA composition of plasma lipids was similar in the placebo and the supplement groups at baseline. LCn-3PUFA (20:5n-3, 22:5n-3, and 22:6n-3) were all significantly higher in the plasma of volunteers supplemented with fish oil concentrate. There was no change in any of the saturated, monounsaturated, or n-6 PUFA in the fish oil–supplemented compared with the placebo group (Table 4). The changes in LCn-3PUFA, calculated by subtracting the baseline FA concentrations from post-intervention values, were significantly higher in the fish oil (20:5n-3, 22:5n-3, and 22:6n-3 being 55.5 ± 29.6, 10.4 ± 7.5, and 43.8 ± 23.76, respectively) compared with the placebo group (20:5n-3, 22:5n-3, and 22:6n-3 being 1.19 ± 9.19, 1.85 ± 3.51, and 1.82 ± 11.27, respectively). Fish oil supplementation for 6 wk resulted in a significantly higher incorporation of 20:5n-3 into the lipids of atrium biopsy samples (Table 5). In the phospholipid fraction of the atrium tissue, LCn-3PUFA (20:5n-3 and 22:6n-3) were elevated following 6 wk of fish oil supplementation. This increase in LCn-3PUFA was accompanied

TABLE 3
Effects of Fish Oil or Placebo Supplementation on Blood Lipids (mmol/L)

	Placebo		Fish oil	
	Baseline	Preoperative	Baseline	Preoperative

by a reduction in 20:4n-6 content of atrium phospholipid fraction (Table 6). In the non-esterified FA fraction, no differences were found in the LCn-3PUFA (20:5n-5, 22:5n-3, and 22:6n-3) content (Table 7). FA composition in the placebo and the triglyceride fraction was similar with the exception that 20:5n-3 content was significantly elevated in the fish oil–supplemented group (Table 8).

DISCUSSION

The main purpose of this study was to examine the incorporation of LCn-3PUFA into atrium tissue lipids of patients undergoing CABG surgery. Several studies in the literature have reported insertion of LCn-3PUFA into heart membranes and their subsequent effects on heart functions, including vulnerability of the heart to becoming arrhythmic, using animal models.

Values are the mean (%, wt/wt) ± SD. Values without a common superscript are significantly different, $P < 0.05$.

However, this is the first study to demonstrate the incorporation of dietary LCn-3PUFA into the human atrium. It is clearly evident from the results presented that 6-wk supplementation with 4.4 g/d of LCn-3PUFA results in significant enrichment of plasma and atrium lipids with these FA. It is a fair assumption to make that FA composition of atrium is reflective of myocardium tissue composition.

The phospholipid fraction of atrium lipids was particularly enriched with the major LCn-3PUFA such as 20:5n-3, 22:5n-3, and 22:6n-3. Incorporation of these FA into phospholipids is known to alter the physico-chemical property of the heart membrane and alter associated functions (21). The concomitant reduction in 20:4n-6 in the atrium phospholipids following fish oil supplementation is reflective of the preferential incorporation of LCn-3PUFA into heart membranes at the cost of n-6PUFA (22). It has been previously demonstrated that LCn-3PUFA inhibit desaturation and chain elongation of 18:2n-6 and inhibit synthesis of 20:4n-6 FA (23,24). A reduction in 20:4n-6 in the atrium tissue may result in the reduced synthesis of eicosanoids (thromboxane, prostaglandin, and leukotriene), which may further influence the heart functions as a result of fish oil supplementation (25).

This study established that 22:6n-3 is the most prevalent LCn-3PUFA in the human atrium and that the prevalence of 22:6n-3 is 7.5 times higher than that of 20:5n-3 in the atrium total lipids as well as in the phospholipid fraction of the placebo group. This is consistent with the FA data (22:6n-3 is greater than 7.5 times that of 20:5n-3) reported by Harris *et al.* (26). Sexton *et al.* (27) reported a 22:6n-3/20:5n-3 ratio of 6.0 in male and 8.5 in female human myocardium. It is evident from the results presented that the plasma FA composition is reflective of the 22:6n-3/20:5n-3 ratio (0.8) of the fish oil supplement. However, in the atrium tissue, more of 22:6n-3 than 20:5n-3 is incorporated in the atrium total lipids (22:6n-3/20:5n-3 ratio of 2.54) and phospholipids (22:6n-3/20:5n-3 of 2.78) despite fish oil supplements being higher in 20:5n-3 than 22:6n-3 content. Furthermore, it is apparent that LCn-3PUFA are enriched in phospholipids to at least twofold in comparison with those in atrial total lipids in both the placebo and the fish oil supplemented groups. Because there is only limited conversion of 20:5n-3 to 22:6n-3 in humans (28), it may be preferable to recommend 22:6n-3 enriched supplements in order to modulate cardiac membrane FA composition and, therefore, cardiac functions.

Several studies using animal models have demonstrated that dietary LCn-3PUFA prevents cardiac arrhythmias. The fibrillation threshold in animal models is significantly elevated following the feeding of a diet rich in LCn-3PUFA. It has been proposed that once the heart membranes are enriched with LCn-3PUFA, these will be preferentially released as non-esterified FA to inhibit arrhythmic events. A recent study has reported for the first time data, albeit preliminary, on acute antiarrhythmic effects of marine LCn-3PUFA in patients with implanted cardioverter defibrillators. Ventricular tachycardia was not induced in five of seven patients infused with LCn-3PUFA (29). Enrichment of the phospholipid fraction with LCn-3PUFA suggests that these FA are now readily available to be released as non-esterified acids should the arrhythmic events occur.

The incidence of atrium fibrillation was similar in the placebo and the fish oil–supplemented (2/9 and 2/8 respectively) group of patients following CABG surgery (data not shown). These results are in contrast with those of a recently published randomized controlled trial involving 160 patients that reported a 54.4% reduction in atrium fibrillations in patients supplemented with n-3PUFA for at least 5 d prior to CABG procedure compared with the control subjects (7). The sample size in the present study was too low to pick up any significant effects of fish oil supplementation on arrhythmic events. Indeed the dose of LCn-3PUFA supplemented in this study was nearly 2.5 times that used in the study by Calo *et al.* (7) and nearly 5 times that used in the GISSI Prevenzione study (8) that established prevention of ventricular fibrillation and sudden death post–myocardial infarction. Further long-term studies relating dose level, incorporation into cardiac membranes, and cardiac events are warranted to confirm the anti-arrhythmic effects of fish oils. Plasma lipid levels were similar prior to surgery in comparison with the baseline values. Although statistically insignificant, cholesterol levels tended to be lower at baseline compared with those prior to the surgery in both the placebo and the fish oil groups. It would appear that the plasma lipid lowering in a majority of the patients just prior to the surgery may be due to a combination of factors including better compliance with lipid-lowering drug (statin) therapy, better adherence to a lipid-lowering diet, and mental and physical preparation for the surgery. The fish oil–supplemented group exhibited significantly lower levels of triglyceride, which is consistent with the well-known triglyceride-lowering effects of marine LCn-3PUFA.

In summary, the results presented suggest that dietary supplementation with marine LCn-3PUFA for 6 wk increase LCn-3PUFA content of plasma and atrium lipids in humans. The timeframe for achieving the heart health benefits of LCn-3PUFA in humans remains to be investigated.

ACKNOWLEDGMENTS

The authors are grateful to all subjects who participated in the study, and to the nursing staff for their assistance. This trial was conducted without a dedicated fund source. Fish oil and the placebo capsules for the trial were supplied by Lube AS, Hadsund, Denmark. The company had no input into the analysis or interpretation of the results or the preparation of the manuscript. There is no other conflict of interest to declare.

Chlorinated Fatty Acids in Lipid Class Fractions from Cardiac and Skeletal Muscle of Chinook Salmon

Matthew D. King[a,c], Lorrie D. Rea[c], and John M. Kennish[a,b,*]

[a]Department of Chemistry and [b]Applied Science, Engineering, and Technology Laboratory, University of Alaska, Anchorage, Alaska 99508, and [c]Alaska Department of Fish and Game, Division of Wildlife Conservation, Fairbanks, Alaska 99701

ABSTRACT: Analysis of chlorinated fatty acids (CFA) in tissues can be difficult because of their low concentrations. This task becomes even more difficult when samples are from organisms living in remote locations with very little exposure to environmental contamination. Therefore, enrichment of CFA is necessary prior to analysis. In this study, CFA were enriched from fractionated lipid classes of cardiac and skeletal muscle of Chinook salmon (*Oncorhynchus tshawytscha*) to determine CFA distribution among lipid classes and tissue types and to demonstrate the sensitivity of this method to detect CFA at trace concentrations. The lipids extracted from cardiac and skeletal muscle of *O. tshawytscha* were separated into fractions containing TAG, FFA, and phospholipids. After transesterification, the FAME derivatives from each lipid class were analyzed by GC with a halogen-selective detector (XSD) to determine the concentrations of dichlorostearic acid and dichloropalmitic acid. Other chlorinated compounds detected by GC-XSD were analyzed by GC–MS. CFA were observed in all lipid classes in both cardiac and skeletal muscle tissues. However, the highest concentrations of CFA were found in the phospholipids of both tissue types, about 1–2 mg/g lipid. It was also shown that dichloropalmitic acid concentrated in cardiac phospholipids whereas dichlorostearic acid was found primarily in the phospholipids of skeletal tissue. CFA concentrations in TAG and FFA fractions were below 150 mg/g lipid. This study demonstrates a small-scale approach to the study of CFA at trace concentrations and their distribution among lipid classes.

Paper no. L10025 in *Lipids 41*, 1133–1140 (December 2006).

Chlorinated fatty acids (CFA) are found in almost all marine biota. However, the concentrations vary greatly depending on the environmental load of chlorine to which they are exposed. The increased chlorine load on the environment from anthropogenic sources such as effluents from pulp bleach mills and flour bleaching processes has lead to increased concentrations of extractable chlorinated organic compounds present in marine organisms (1). Chlorinated compounds such as PCBs, DDT, dioxins, and other persistent organic pollutants are widespread in the environment and have received considerable attention owing to their bioaccumulation in marine biota and their resulting physiological effects (2–6). However, these compounds constitute less than 5% of the total extractable chlorinated organic compounds (7–10). The majority of the remaining chlorine resides in chlorinated fatty acids (CFA) (7,8,11). The potential physiological impacts of CFA are not fully understood, but research has shown that high CFA concentrations affect reproduction and sperm motility, cause abnormal weight gain of certain organs of rats, and cause cell membrane disturbances (12–14).

The uptake and turnover of CFA are similar to those of other FA (15). CFA are incorporated into phospholipids and into cell membranes. The resulting effects are changes in membrane fluidity, interference with ion transport and membrane-bound enzymes, and ATP leakage through mitochondrial membranes brought about by the conformational change to the FA owing to the large radii of chlorine (12,13). Despite these physiological effects, CFA are not recognized by the tissues as xenobiotic and are not eliminated from the cell. Studies on the influence of CFA on the activation of cytochrome P450, the enzyme responsible for the removal of xenobiotics and toxic substances, have shown that CFA do not induce enzymatic detoxification in response to these compounds (12).

The limitation in the study of CFA is their relatively low concentrations compared with that of other FA. To compensate, enrichment of CFA must be performed before analysis of the samples can be successful. However, even with the enrichment, large sample volumes are needed to detect CFA at trace levels such as those found in marine organisms from remote areas. Improvements in enrichment methods allow for use of smaller sample volumes and therefore open new research opportunities by making available new sample sources.

This study is aimed at demonstrating the sensitivity to detect trace CFA concentrations, and at determining CFA distribution among lipid classes and tissue types using a solid-phase extraction (SPE)-based enrichment method. In this method, the removal of saturated FA is accomplished using SPE fractionation techniques as opposed to a urea complexation step most commonly used in CFA enrichment. The sufficient removal of saturated FA by SPE will eliminate the need for the use of urea, which is time consuming and can produce low recoveries of CFA. The expected outcome is a higher CFA concentration per total lipid in the final enriched fraction. This will allow for analysis of the CFA by halogen-sensitive detector (XSD) without losing sensitivity due to the selectivity of the instrument in the presence of nonhalogenated compounds. At higher XSD reactor temperatures, such as 1100°C used in this study, sensi-

tivity for chlorinated compounds is increased, but the advantage is lost without enrichment due to a decrease in selectivity of the XSD for the chlorinated compounds (16).

Chinook salmon (*Oncorhynchus tshawytscha*) tissue samples used in this study were obtained from the Kenai River, Alaska. This is an optimal tissue source for testing the sensitivity of this method because of the life cycle of *O. tshawytscha* and their resulting low levels of contaminants. Chinook salmon are an anadromous species, which spend the majority of their lives in the ocean, only returning to their natal freshwater to spawn. A tissue amount of 1 g was used from both cardiac and skeletal muscle tissues. The resulting FA from the different lipid classes applied to the enrichment procedure had masses ranging from 5 mg down to 200 mg total lipid. This study demonstrates the sensitivity of the improved methodology and the opportunity provided for the microscale analysis of CFA in muscle tissues.

MATERIALS AND METHODS

Chemicals. All reagents used in this study were of analytical grade. The following chemicals were used: chloroform (#049, >99.9%; Burdick & Jackson, Muskegon, MI), dichloromethane (#DX0837, >99.9%; EMD, Gibbstown, NJ), methanol (#VW4303, >99.8%; VWR, West Chester, PA), ethanol (#BDH1156, 89–91%; VWR), 2,2,4-trimethylpentane (#9335, >99.8%; J.T. Baker, Phillipsburg, NJ), *n*-hexane (#442437, >95%; Aldrich, Milwaukee, WI), ammonium hydroxide (#AX1303, 28.0–30.0%; EMD), sodium sulfate (#SX0760, >99.0%; EMD), potassium chloride (#P3911, 99.0–100.5%; Sigma Chemical, St. Louis, MO), silver nitrate (#2179, >99.7%; J.T. Baker), 2,6-di-*tert*-butyl-4-methylphenol (BHT; #B1378, >99.0%; Sigma), ethyl ether (#106, >99.9%; Burdick & Jackson), sodium acetate (J.T. Baker 3460, 99.0-101.0%), sulfuric acid (SX1247, 95.5–96.5%; EMD), acetic acid (#9507, >99.7%; J.T. Baker), hydromatrix drying agent (Varian, Palo Alto, CA), helium (>99.9999%; Air Liquide America, Houston, TX), hydrogen (#9200, >99.9995%; Airgas, Anchorage, AK). Glassware was washed and solvent-rinsed before use. FA and TAG standards were purchased from Nu-Chek-Prep, Inc. (Elysian, MN). CFA standards dichloropalmitic acid and dichlorostearic acid were prepared from palmitoleic acid and oleic acid, respectively (17).

Preparation of standards. CFA standards were synthesized in an ionic liquid. The liquid was prepared by combining equimolar amounts of 1-butyl-3-methylimidazolium chloride and aluminum chloride (10 and 7.6 g, respectively) in an inert nitrogen atmosphere. Each specific unsaturated FA, such as methyl oleate (1 g), was added with stirring, and chlorine gas was supplied to the mixture for 30 min. After stirring the reaction mixture for another 30 min, the product was extracted with *n*-hexane and the solvent stripped with a stream of nitrogen (17).

Tissue samples. Cardiac and skeletal muscle tissues from *O. tshawytscha* were collected during May and June of 2005 from sport-caught fish from the Kenai River, Alaska, and from the Alaska Department of Fish & Game Kenai River King Salmon netting project. The fish were removed from the Kenai River between the Soldotna Bridge at river-mile 20 and Warren Ames Bridge at river-mile 6.0. No sources of industrial contamination influence the water quality of the river. Upon removing the fish from the water, the entire heart and skeletal muscle samples were immediately extracted and stored on ice until leaving the field, after which they were vacuum-sealed and stored at –20°C.

Sample preparation. Samples were removed to room temperature and thawed. Entire hearts and several grams of skeletal muscle from each fish were minced separately using a stainless steel knife. The mass of each sample was determined gravimetrically. The samples were then placed in a stainless steel blender and diluted 1:1 (by wt) with saline solution and further homogenized. From the tissue homogenates, 2-g samples, representing 1 g tissue before dilution, were weighed on an analytical balance (model AT201; Mettler, Columbus, OH), and the exact masses recorded. Approximately 1 g of hydromatrix drying agent (Varian) was mixed with each sample portion. The mixture was transferred to 11-mL stainless steel cells containing two cellulose filters (Dionex, Sunnyvale, CA) for extraction by accelerated solvent extraction (ASE) system (ASE 200; Dionex). Additional hydromatrix was added to fill each cell.

Lipid extraction. Lipids were extracted by ASE using a method modified by Dodds *et al.* (18). The ASE was operated at 100°C and 2000 psig (13.8 MPa) for two 5-min static extraction cycles using a chloroform/methanol (65:35, vol/vol) solvent system. Chloroform was prepared with BHT at a concentration of 100 mg/L to prevent oxidation of samples.

To sample collection vials, about 30 mL 0.7% NaCl solution was added to remove any proteins present in extract and to partition the methanol from the chloroform phase containing the extracted lipids. Vials were vortexed and allowed to separate for about 30 min until complete phase separation occurred. The aqueous layer was then removed and discarded. The remaining extract was dried by pouring through a sintered funnel containing anhydrous sodium sulfate into TurboVap (Zymark, Hopkinton, MA) evaporation vessels. Vials and funnels were thoroughly rinsed several times with chloroform to ensure quantitative transfer of lipid content.

Extracts were dried under nitrogen using a TurboVap II solvent evaporation system at a water bath temperature of 35°C. Lipid residues in each tube were immediately redissolved in *n*-hexane and quantitatively transferred to preweighed vials. Solvent was removed under a gentle stream of nitrogen, and exact masses were determined gravimetrically to 0.01 mg. Lipids were quickly dissolved in hexane/chloroform/methanol (95:3:2, by vol) for a concentration of 20 mg/150 μL for lipid class fractionation.

Lipid class fractionation. Lipids were separated into FFA, nonpolar and polar lipid fractions using a solid-phase extraction (SPE) procedure modified from Ruiz *et al*. (19). A Visiprep vacuum manifold (Supelco, Bellefonte, PA) was set up with 500 mg aminopropyl SPE minicolumns (Supelclean LC-NH_2 SPE Tubes, 3 mL, 50 mg loading capacity; Supelco,

No. 57014). SPE columns were conditioned with 5 mL *n*-hexane at a flow rate of 1–2 mL/min. Flow was stopped when the solvent level reached the solid phase. The column was loaded with 150 mL lipid extract containing 20 mg total lipid. The flow rate was adjusted to 0.5–1 mL/min, and fractions were collected in separate vials. Fraction 1 (TAG), containing nonpolar TAG, was eluted with 5 mL chloroform. Fraction 2, containing FFA, was eluted with 5 mL diethyl ether/acetic acid (98:2, by vol). The polar lipids of fraction 3 (PL) were eluted with 2.5 mL methanol/chloroform (6:1, vol/vol) followed by 2.5 mL 0.05 M sodium acetate in methanol/chloroform (6:1, vol/vol). FFA and PL were washed with 3 mL H_2O to remove acetic acid from FFA and to remove sodium acetate and methanol from PL. The organic phases were transferred to new vials and dried over anhydrous sodium sulfate. Fractions were transferred to round-bottomed reaction tubes and evaporated to dryness under a gentle stream of nitrogen.

Transmethylation. Each lipid fraction was subjected to an acid-catalyzed transesterification to produce FAME derivatives (20). All recovered lipids from each fraction were dissolved in 2 mL 1% sulfuric acid (by vol) in methanol. Tubes were placed on heating blocks at 70°C overnight (at least 12 h). Samples were removed from heat and cooled to room temperature. To each, 1 mL hexane and 2 mL H_2O were added. Tubes were vortexed and centrifuged at 1315 × *g* (BD-Clay Adams 0131, Franklin Lakes, NJ) for 3 min.

The hexane phase was removed to a new vial. An additional 1 mL of hexane was added to the aqueous phase in each reaction tube and then vortexed and centrifuged as before. The hexane phase was removed, and the two hexane phases were combined and dried over anhydrous sodium sulfate. Dried solutions were decanted to new vials and evaporated under a gentle stream of nitrogen. Masses of remaining FAME were determined gravimetrically. FAME were immediately dissolved in hexane for 200 µL SPE sample loading at concentrations listed in Table 1.

Chlorinated FAME isolation by SPE. CFA were isolated from saturated and monounsaturated FAME using an SPE method modified from Åkesson-Nilsson *et al*. (21). The vacuum manifold and LC-NH_2 SPE column were used as described previously. After the columns had been conditioned with hexane, 200 µL of the FAME solution was applied. In this separation, two fractions were collected. The first fraction (f1), which contains primarily saturated and monounsaturated FAME, was eluted with *n*-hexane. The second fraction (f2), containing CFA, was eluted with hexane/diethyl ether/dichloromethane (89:1:10, by vol). FAME from f2 were evaporated to dryness under nitrogen, then dissolved in 1 mL 2,2,4-trimethylpentane. The f1 fractions were evaporated under nitrogen and redissolved in 1mL *n*-hexane for GC analysis. Excess FAME from transesterifaction not used in SPE separation were prepared in *n*-hexane for GC analysis of total lipid content.

Removal of polyunsaturated FAME. Enrichment of CFA by the removal of polyunsaturated FAME was performed using a method modified from Mu *et al*. (22). To each f2 sample in 2,2,4-trimethylpentane, approximately 1 mL 1.5 M $AgNO_3$ in ethanol/H_2O (1:1, vol/vol) was added and mixed thoroughly to remove PUFA. The phase containing uncomplexed FAME and CFA was decanted to a new vial. The $AgNO_3$ phase was washed with an additional 1 mL 2,2,4-trimethylpentane, which was removed and combined with the first extraction and dried over anhydrous sodium sulfate. To the $AgNO_3$ phase, 1 mL H_2O was added and polyunsaturated FAME were extracted with 1 mL *n*-hexane three times. The hexane phases were combined and dried over sodium sulfate. All samples were transferred to new vials and evaporated under nitrogen. They were then redissolved in *n*-hexane for GC analysis.

TABLE 1
FAME Recovered from Each Lipid Class[a] and Applied to SPE Isolation of CFA[b]

Lipid fraction-tissue type[c]	FAME (mg)	FAME applied to SPE (mg)
TAG-C	3.67–5.92	3
TAG-S	11.11–13.07	5
FFA-C	5.31–6.52	5
FFA-S	2.16–3.54	2
FFA-S (sample 6)[d]	2.02	1
PL-C (sample 1)[d]	0.96	0.75
PL-C	1.12–1.68	1
PL-S	0.25–1.19	0.200

[a]Quantity of FAME received from each lipid class separated from 20 mg total lipid.
[b]Amount of FAME per 200 µL of *n*-hexane applied to solid-phase extraction (SPE) of chlorinated fatty acids (CFA).
[c]C, cardiac muscle; S, skeletal muscle; PL, polar lipid.
[d]Amount of FAME applied to SPE for these samples varies from other samples of same lipid class and tissue type.

GC. The FAME were analyzed for dichloropalmitic and dichlorostearic acids and other chlorinated compounds using a Varian CP-3800 gas chromatograph equipped with an XSD detector (#5360; OI Analytical, College Station, TX). The samples were injected using a splitless injection for 1 min onto a fused-silica capillary column (DB23, 60 m × 0.25 mm i.d.; film thickness, 0.25 mm; J&W Scientific, Folsom, CA). Helium was used as a carrier gas at a flow rate of 1 mL/min with a pressure pulse of 25 psi for 0.5 min. The injector temperature was set at 300°C. The column temperature was raised from 125 to 250°C at 3°C/min and held at 250°C for 20 min. The XSD reactor temperature was set at 1100°C. Purified air was used as the reaction gas at a flow of 12–20 mL/min.

MS. GC–MS was used to calculate recoveries and to identify unknown compounds. The Varian GC and DB23 column were connected to a Varian Saturn 2200 ion trap mass spectrometer, and the same GC conditions and temperature program as above were used for GC–MS analysis. For electron impact ionization (EI), the electron energy was 70eV with a source temperature of 120°C. Ammonia was used as the reagent gas for positive-ion chemical ionization (PICI).

RESULTS AND DISCUSSION

The XSD chromatograms indicated that halogenated compounds were present in all lipid classes of both types of muscle tissue (Table 2). Dichloropalmitic acid ($C_{16}Cl_2$) was found in high concentrations in both skeletal and cardiac muscle tissue,

TABLE 2
CFA Concentrations[a] Following Enrichment in All Lipid Classes of Cardiac and Skeletal Muscle from *Onchorhynchus tshawytscha*

	Total CFA (μg/g lipid)	$C_{16}Cl_2$ (μg/g)	$C_{18}Cl_2$ (μg/g)	Unknown (μg/g)
Cardiac muscle				
Phospholipids	1187	1098	0	88.7
FFA	144	35.1	15.8	93.4
TAG	55.4	8.4	10.4	36.6
Skeletal muscle				
Phospholipids	2197	855	634	708
FFA	15.2	0	0	15.2
TAG	131	0	0	131

[a]Concentration were quantified by GC–halogen-selective detector (XSD) using dichloropalmitic ($C_{16}Cl_2$) and dichlorostearic ($C_{18}Cl_2$) acid methyl ester external standards. Unknown CFA were calculated using the calibration for dichloropalmitic acid methyl ester. For abbreviation see Table 1.

whereas dichlorostearic acid ($C_{18}Cl_2$) was found mainly in skeletal muscle phospholipids (Fig. 1). Other chlorinated compounds were found in all fractions; however, the most diverse group was found in the nonpolar TAG fractions (Fig. 2). The predominant unknown chlorinated compound was tentatively identified as dichloromyristic acid ($C_{14}Cl_2$) based on retention time and GC–MS analysis (Fig. 3). The retention time of dichloromyristic acid was calculated by extrapolation from the plot of $C_{16}Cl_2$ and $C_{18}Cl_2$ retention times given the linear elution of homologs.

The intensity of *m/z* of 69, 74, and 87, are consistent with the mass spectrum of myristic acid methyl ester. 5,6-Dichloromyristic acid has been previously identified as a major constituent in marine biota (11). Other peaks, which could not be identified by GC–MS owing to low concentrations and coelution with other FAME, were possibly chlorohydroxy FA or chlorinated sulfones. These compounds also have been previously identified in some marine biota (23). Statistical analysis by one-way ANOVA ($P = 0.05$) showed no significant difference between CFA concentrations in cardiac and skeletal muscle, or between CFA concentrations in corresponding lipid classes from these tissues. However, there are significant differences in CFA species between the two compounds. $C_{16}Cl_2$ was found at higher concentrations in cardiac tissue, whereas $C_{18}Cl_2$ was found at detectable levels only in skeletal muscle. This differential uptake and incorporation of CFA species may be correlated with the aforementioned physiological effects attributed to CFA.

In the phospholipid fractions of both tissue types, co-elution of two isomers of dichlorostearic and dichloropalmitic acids was evident on the chromatograms (Fig. 4). The second of the two peaks to elute is possibly a dimethyl acetal derivative resulting from the transmethylation of the vinyl-ether bound FA present in phospholipids (24). Because of the resolution and similar mass spectra of FAME and FA dimethyl acetals, the identification of these compounds could not be confirmed. In the cardiac muscle phospholipids, roughly 20–35% of the $C_{16}Cl_2$ was in the suspected dimethyl acetal conformation. A very small amount of dichlorostearic dimethyl acetal was present in any fraction. To confirm identification of these compounds in future experiments, the phospholipid fractions could be further separated into constituent molecular species using an SPE method prior to transmethylation and CFA enrichment (25). This could result in the separation of the methyl ester and dimethyl acetal derivatives since ether-bound FA are primarily found in ethanolamine phospholipids (26). However, this separation of phospholipid species would require a larger sample size than used in this study owing to the small PL content of the samples. This separation may also result in the inability to detect small CFA concentrations otherwise detectable in a total phospholipid fraction.

The extraction by ASE yielded about 30 mg lipid per g of cardiac tissue, and an average of about 60 mg lipid per g skeletal muscle. This coincides with previous findings of roughly

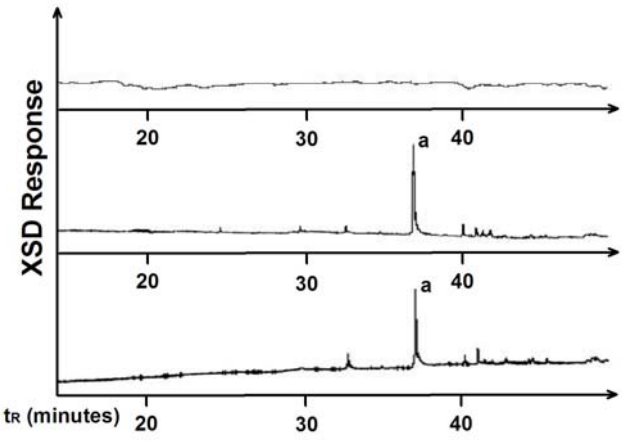

FIG. 1. Halogen-selective detector (XSD) chromatograms of samples before chlorinated FA (CFA) enrichment and after enrichment. Samples were from phospholipid fractions of cardiac and skeletal muscle of chinook salmon. Top chromatogram is of a sample containing FAME from cardiac phospholipids before the enrichment procedure. The sample was run at a concentration of 1 mg total lipid/mL. At this concentration, CFA were not at detectable levels. Middle and bottom chromatograms are after CFA enrichment. The middle is from cardiac muscle and the bottom from skeletal muscle. (a) Dichloropalmitic acid methyl ester.

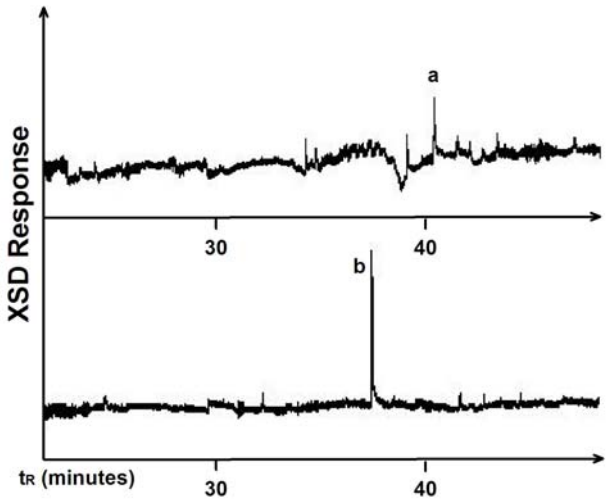

FIG. 2. XSD chromatograms of CFA enriched from TAG fractions of cardiac and skeletal muscle. Top chromatogram is from cardiac muscle, bottom is from skeletal muscle. (a) Dichlorostearic acid methyl ester, (b) dichloropalmitic acid methyl ester. For abbreviations see Figure 1.

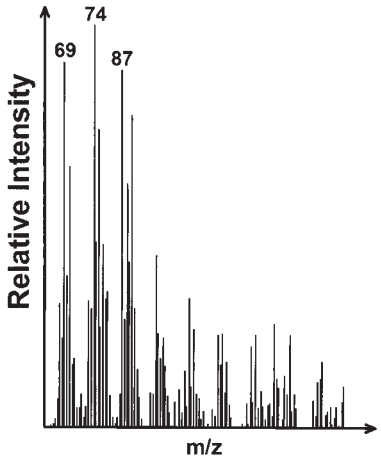

FIG. 3. EI mass spectrum of dichloromyristic acid methyl ester from skeletal muscle TAG. Peaks at *m/z* of 69, 74, and 87 are characteristic of a saturated FA.

6–7% lipid content in skeletal muscle of *O. tshawytscha*. The percent recovery of total FA for the extraction and transesterification was determined using a trinonadecanoic acid (19:0) surrogate standard, which was spiked in the tissue samples at a concentration of 50 μg/mL prior to lipid extraction. After extraction, lipid class fractionation, and transesterification, 19:0 was measured and a recovery was calculated of 76% (±2.9%). This surrogate recovery is within the expected range given the previously reported recoveries of the individual methods used. The losses can be attributed to the combination of an 80–90% recovery of lipids by ASE, high recoveries by SPE lipid fractionation, and the additional loss of phosphoserine, phosphocholine, phosphoethanolamine, and other phospholipid derivatives during the transesterification process, which constitute about one-third of the mass of phospholipids (27).

To measure percent recoveries of FAME for the enrichment of CFA, quantities of the following were measured: myristic acid (14:0), palmitic acid (16:0), stearic acid (18:0), oleic acid (18:1n-9), EPA (20:5n-3), and DHA (22:6n-3). These compounds were chosen because previous studies found them to be the primary FA in salmon (Fig. 5). This combination of saturated, monounsaturated, and polyunsaturated FAME is sufficient to demonstrate the effectiveness of the CFA enrichment method. SPE isolation of CFA was used to remove 14:0, 16:0, 18:0, and 18:1n-9, among other trace saturated FA and short-chain unsaturated FA. Silver ion complexation was used to remove unsaturated FA, primarily 20:5n-3 and 22:6n-3, found in salmon tissue.

The recoveries of 14:0, 16:0, and 18:0 from the SPE enrichment were within 20% of the initial quantities of lipid applied to the SPE column for the FFA and the cardiac TAG fractions (Table 3). The recovery of 18:1n-9 was lower in these fractions, between 64 and 85%. Recoveries for these FAME in skeletal muscle TAG were from 127 to 149%. These high recoveries may be attributed to incomplete elution of the surrogate in the first fraction of this SPE separation procedure. This would increase the apparent concentration of these target compounds in this fraction. The SPE method described by Åkesson-Nilsson (21) did not use 19:0 in the development of this method. The levels of FAME from the phospholipid fractions of cardiac muscle were highly variable, from 12 to 82%, whereas there was no recovery for saturated FAME in the skeletal muscle phospholipids. The reason for the variability in the cardiac phospholipids is that FAME were at low concentrations owing to the small initial lipid mass (0.75–1.00 mg total lipid) applied to the SPE column. The resulting recoveries were near detection limits for some of these compounds. Detection limits of the GC–MS method used for calculating these recoveries were between 4 and 13 μg/mL. The lack of recovery of saturated FAME in the skeletal tissue was also due to the low initial lipid

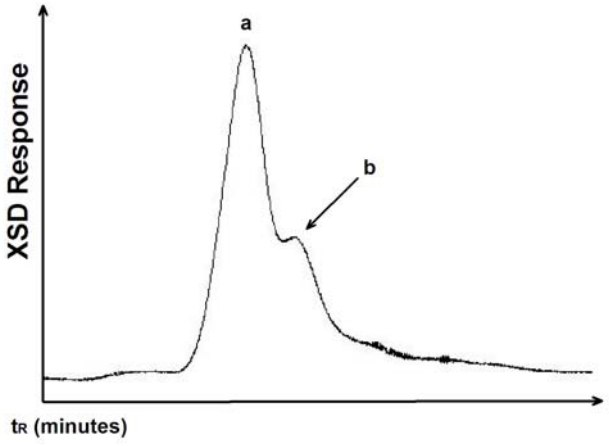

FIG. 4. XSD chromatogram of dichloropalmitic acid isomers. (a) Dichloropalmitic acid methyl ester, (b) tentatively identified dichloropalmitic dimethyl acetal. For abbreviation see Figure 1.

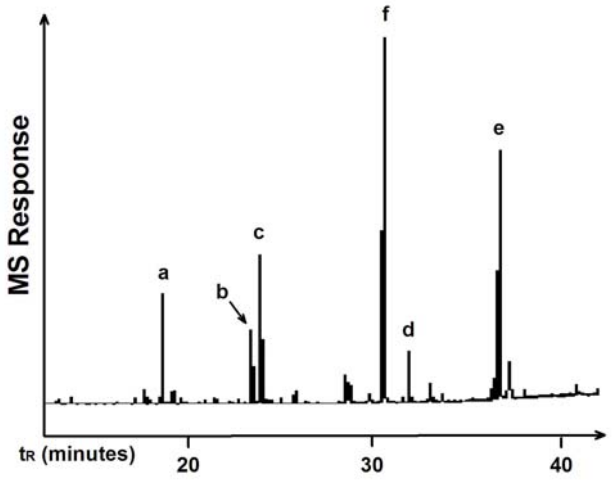

FIG. 5. Content of total FAME content liberated from unfractionated lipids of salmon muscle tissue. (a) Palmitic acid methyl ester, (b) stearic acid methyl ester, (c) oleic acid methyl ester, (d) EPA methyl ester, (e) DHA methyl ester, (f) internal standard.

mass (200 μg total lipid). Any amounts of saturated FA recovered were below the limits of detection.

The recoveries of polyunsaturated FAME from the silver ion complexation were low for all lipid fractions except for 22:6n-3 in the skeletal TAG and 20:5n-3 in skeletal phospholipids. The rest showed between 39 and 77% recoveries. This was to be expected as a large portion of polyunsaturated FAME is not eluted in the two fractions during the SPE enrichment procedure (21). The unsaturated FAME have a greater dipole interaction with the NH_2 column and require a more polar solvent than the hexane/diethyl ether/dichloromethane (89:1:10, by vol) solvent mixture used to elute the CFA. The high recovery of 22:6n-3 in the skeletal TAG may be have the same cause as the high recoveries of other FAME in this lipid class. The high recovery of 20:5n-3 in the skeletal PL is likely a result of low FAME concentrations, i.e., near the limits of detection.

TABLE 3
Percent Recoveries and SD of Primary FAME in All Salmon Lipid Classes for CFA Enrichment Following Transesterification[a]

	Cardiac muscle		Skeletal muscle	
	% Recovery[b]	SD	% Recovery[b]	SD
TAG FAME				
14:0	79.3	17.8	144.8	21.2

[a]Samples were analyzed in triplicate.
[b]Recoveries for saturated and monounsaturated FA were calculated using data from SPE fractions. Polyunsaturated FA recoveries were calculated from silver ion complexation recoveries. For abbreviations see Table 1.

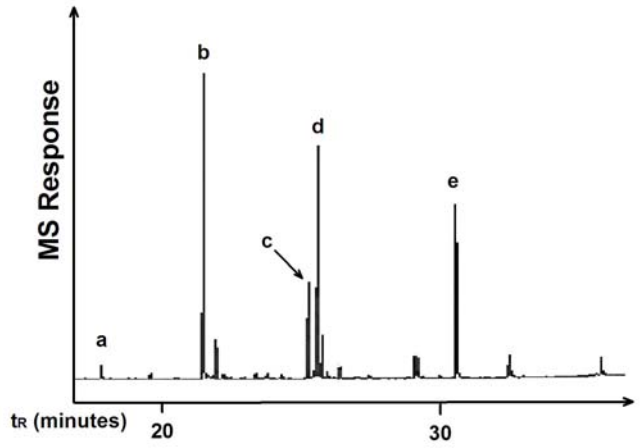

FIG. 7. Chromatogram of first fraction from solid-phase extraction enrichment of CFA in cardiac TAG. (a) Myristic acid methyl ester, (b) palmitic acid methyl ester, (c) stearic acid methyl ester, (d) oleic acid methyl ester, (e) internal standard. For abbreviation see Figure 1.

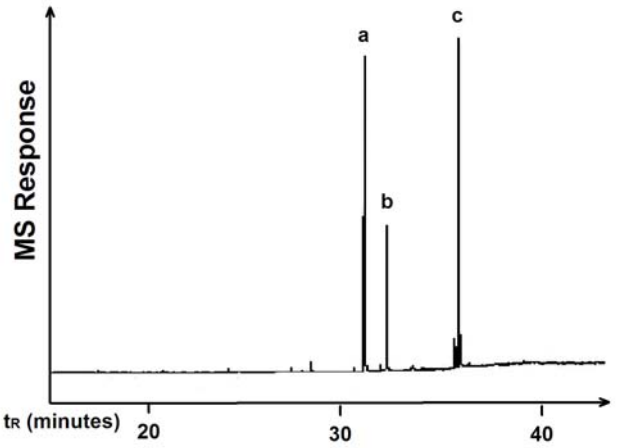

FIG. 8. GC–MS chromatogram of FAME recovered from silver ion complexation procedure on cardiac tissue TAG. (a) Internal standard, (b) EPA methyl ester, (c) DHA methyl ester.

After enrichment, GC analysis of the fractions containing the CFA did not indicate any significant quantities of nonchlorinated FAME (Fig. 6). As seen in Figure 6, the only quantifiable peak was that of the internal standard. All recoveries of nonchlorinated FAME in the enriched fractions were below detection limits for GC–MS.

None of the f1 fractions from the SPE procedure, containing primarily saturated FAME, showed significant levels of long-chain polyunsaturated FAME (Fig. 7). Any observed peaks were below limits of detection. Likewise, chromatograms from the silver ion complexation procedure did not indicate the presence of saturated or monounsaturated FAME (Fig. 8). This agrees with previous studies showing that saturated FAME will not complex with Ag, and that CFA, which act as saturated FAME in nature, also will not form Ag complexes (10).

XSD analysis of f1 fractions and the FAME recovered from the silver ion complexes showed that no CFA were present in these solutions. This demonstrates an accurate separation of CFA, saturated FAME, and unsaturated FAME by this method. The removal of the predominant saturated FAME by SPE, namely, 14:0, 16:0, and 18:0, eliminates the need for the removal of these compounds by urea complexation, a procedure that is time consuming and yields a lower recovery than the SPE method. With the removal of most of the dominant FA species present in these tissues, the final CFA fraction can be concentrated for CFA enrichment.

The method for the enrichment of CFA used in this experiment allows for the detection of CFA at trace concentrations. The combination of this CFA enrichment and XSD detection limits near 100 pg Cl allows detection of CFA in tissue samples at concentrations less than 80 ng/g. This makes this method ideal for measuring CFA levels in organisms living in non-chlorine-loaded habitats, such as *O. tshawytscha* that spend that majority of their life in the open ocean. The sensitivity of this method also allows for the use of sample sizes of less than 1 g, depending on the lipid class or compound of interest. The 1 g sample mass used in this experiment was sufficient for all CFA analyses except on the skeletal muscle PL fractions. The reason this sample size was not large enough for this fraction is that the proportion of phospholipids is small compared with that of TAG (the major fat storage molecule) in the skeletal muscle of salmon. Of the 20 mg total lipid used for the lipid class fractionation, only about 0.5 mg FAME were recovered from the PL fraction. Despite the inability to verify the method from FAME recoveries for this lipid class owing to concentrations below GC–MS detection limits, high concentrations of CFA were detected by XSD after the enrichment procedure.

The XSD chromatograms in Figure 1 demonstrate the need for enrichment of CFA for analysis at trace concentrations. The top chromatogram shows total FAME before the enrichment procedure. CFA are not detectable because of their low concentrations with respect to nonchlorinated FAME. The total FAME content before enrichment prevents samples from being concentrated down to volumes necessary for CFA detection because of the resulting overloading of sample on the GC column and the reduction of XSD selectivity for CFA. As shown in the bottom two chromatograms of Figure 1, CFA enriched through this procedure can be concentrated to adequate levels for XSD detection.

In future experiments it may be beneficial to use Ag-impregnated LC-NH_2 SPE columns, a method described by Christie (20) that eliminates the separate silver ion complexation step. This would decrease the chances of CFA loss during solution transfers between the SPE and silver ion complexation procedures.

The differential uptake and incorporation of primary CFA species between both lipid classes and tissue types are subjects that need further investigation. The specific accumulation of dichloropalmitic acid in cardiac tissue and the similar accumulation of dichlorostearic acid in skeletal muscle may be directly

linked to the development of physiological defects. Although not obvious in *O. tshawytscha* given the life cycle of this fish, the physical condition of organisms exposed to high levels of chlorine in their environment may be adversely affected. However, there has been limited research focused on the distribution of CFA among lipid classes and among different tissue types.

Thus, the sequential method of CFA enrichment described in this experiment using SPE separation techniques appears to be a sensitive method for the isolation and analysis of trace levels of CFA. This small-scale approach to the analysis of CFA in biological tissues could make it possible for the development of less-invasive sample collection procedures to be used on live organisms given the small sample size requirements. This study also demonstrates the persistence of CFA in marine biota as well as their concentration in skeletal and cardiac muscle phospholipids.

ACKNOWLEDGMENTS

This research was supported by financial assistance from the Alaska Department of Fish & Game, Division of Wildlife Conservation, and from the University of Alaska Anchorage, Department of Chemistry. Technical support and preparation of FAME standards by Ben Applegate are appreciated.

ABSTRACT: Flaxseed derivatives, including both oil and flax lignan, modify progression of renal injury in animal models, including Han:SPRD-*cy* polycystic kidney disease (PKD). Gender is a significant factor in the rates of progression of many forms of human renal disease, but the role of gender in the response to nutrition intervention in renal disease is unexplored. In this study, male and female Han:SPRD-*cy* rats or normal littermates were fed either corn oil (CO) or flax oil (FO) diets, with or without 20 mg/kg of the diet flax lignan secoisolariciresinol dyglycoside (SDG). Renal injury was assessed morphometrically and biochemically. Renal and hepatic PUFA composition was assessed by GC and renal PGE_2 release by ELISA. FO preserved body weight in PKD males, with no effect in females. SDG reduced weight in both normal and PKD females. FO reduced proteinuria in both male and female PKD. FO reduced cystic change and renal inflammation in PKD males but reduced cystic change, fibrosis, renal inflammation, tissue lipid peroxides, and epithelial proliferation in PKD females. SDG reduced renal inflammation in all animals and lipid peroxides in PKD females. A strong interaction between SDG and FO was observed in renal FA composition of female kidneys only, suggesting increased conversion of C_{18} PUFA to C_{20} PUFA. FO reduced renal release of PGE_2 in both genders. Gender influences the effects of flaxseed derivatives in Han:SPRD-*cy* rats. Gender-based responses to environmental factors, such as dietary lipid sources and micronutrients, may contribute to gender-based differences in disease progression rates.

Paper no. L10062 in *Lipids 41*, 1141–1149 (December 2006).

Although diet as a strategy to slow the progression of renal disease has yet to make a major impact in clinical medicine, it remains a potent strategy in experimental renal disease. Despite a paucity of encouraging human results, and, indeed, a lack of clinical trials of sufficient duration and rigor to explore effects on the early phases of kidney disease, patient interest in diet and other nonpharmacologic strategies to slow renal disease continues to grow (1). The interest of the medical community in nutrition as a prevention strategy in renal disease progression, on the other hand, seems to be waning. The annual international Prevention in Renal Failure conferences organized through the University of Toronto have not included a section on nutrition for the last 5 years.

Flaxseed has been demonstrated to have possible benefits in the reduction of inflammation in rheumatic disease, reduction of atherosclerosis and modification of growth of hormone-dependent tumors (2–6). A possible mechanism for health benefits of flaxseed includes enrichment with the PUFA α-linolenic acid (ALA). Such enrichment has been associated with reduction in pro-inflammatory prostanoids or cytokines in circulating mononuclear cells (7), particularly tumor necrosis factor α and interleukin-1β (8). Flaxseed is also the richest natural source of lignans, present in the husk of the seed as the ester secoisolariciresinol diglycoside (SDG), which is hydrolyzed in the intestinal lumen to enterodiol and enterolactone (9). SDG or its hydrolyzed products may influence health or disease through estrogenic pathways, an antioxidant effect, or through antagonism of platelet activating factor (10). SDG is, however, lipophobic, and refined flax oil (FO) contains only negligible amounts of SDG, making it possible to separate the contribution of the oil and the lignan experimentally. In addition, recent studies have suggested that flaxseed meal, which is enriched in flax protein but contains little oil or lignans, ameliorates experimental diabetic nephropathy (11). We have demonstrated that partial dietary substitution of ground flaxseed, pure FO, and the addition of SDG can modify histologic markers of renal injury early in the course of disease in the male Han:SPRD-*cy* rat (12–14). This complements previous studies that showed benefits of flaxseed or FO in the rat 5/6 nephrectomy model (15) and murine or human lupus erythematosus (16,17).

The role of gender as a factor that influences progression of renal disease, particularly polycystic kidney disease (PKD), has been the subject of growing interest. Both Gabow *et al.*, in a population in which the PKD genotype was not known (18), and Magistroni *et al.* in a cohort of patients identified at PKD2 demonstrated longer renal survival in female patients (19), although Yium *et al.* did not reproduce these findings in black PKD patients (20). These findings are tempered somewhat by the finding of Kausz *et al.* who reports that women in the United States tend to start dialysis at lower level of residual renal function than men (21). Exploration for the biological

Abbreviations: ARA, arachidonic acid; ALA, α-linolenic acid; CO, corn oil; FO, flax oil; LNA, linoleic acid; ox-LDL, oxidized low density lipoprotein; PCNA, proliferating cell nuclear antigen; PKD, polycystic kidney disease; SDG, secoisolariciresinol dyglycoside.

basis of gender differences has identified potential estrogen-sensitive pathways in inflammatory, vascular, and mesangial responses to renal injury (22–26).

Current research on gender as a determinant of progression of renal injury is yet to consider the possibility that gender exerts a modulating effect on environmental influences such as diet on the progression of renal disease. Major studies of dietary intervention in renal disease, such as the Modification of Diet in Renal Disease Study (27), already challenged by issues of compliance and difficulty in controlling for specific nutrient effects, have not considered or lacked power to consider potential interactions between gender and diet, or alternatively, like the Nurses' Health Study (28), were single-gender in nature. The Han:SPRD-*cy* rat also shows marked sexual dimorphism in an autosomal dominant form of PKD, with much slower progression of histologic and functional renal injury in female animals (29). Castration of male animals slows the progression of the disease, and treatment of female animals with testosterone accelerates the rate of disease progression, although not to same rate as seen in non-castrated male animals (30). Prior interventional studies in this model, including our own, have focused on the more seriously affected male animals, exploiting the ability to both observe and modify a chronic disease course in a relatively short period of time (12–14). We therefore undertook the studies described in this report to test the hypotheses that benefits that we have previously observed of FO and SDG would be additive, and that the response to these dietary interventions would be influenced by animal gender in the Han:SPRD-*cy* rat.

EXPERIMENTAL PROCEDURES

Animals. All animal procedures and care were examined by the University of Manitoba Committee on Animal Use, and were within the guidelines of the Canadian Council on Animal Care. Surviving offspring of known Han:SPRD-*cy* heterozygotes from our own breeding colony were randomly assigned to groups fed FO or corn oil (CO) with or without 20 mg/kg diet supplementation with SDG *ad libitum* at weaning at 3 wk of age. Animals were killed after 12 wk on the diet, and kidney, liver, and serum were collected for analysis. Fasting 6-h urine was collected for protein excretion using metabolic cages on the day prior to tissue harvest. Diets were based on the AIN 93 formula using casein as the protein source (20% by weight) supplemented with 0.3% methionine, corn starch (52% by weight), and dextrose (13% by weight) as the carbohydrate sources and 7% CO or 7% FO (Omega Nutrition, Vancouver). SDG was a kind gift of Dr. Neil Westcott, Agriculture Canada, Saskatoon SK, Canada. The FA analysis of this diet has been previously reported (14). The animals were fed *ad libitum*, as our prior studies have not found differences in intake related to disease status in animals in the earlier stages of disease progression (12–14,31,32).

Histology and immunohistochemistry. Tissue from the left kidney was processed using our previously described methods (13,31) for histologic and immunohistochemical analysis. These studies included hematoxylin and eosin, aniline blue staining for fibrosis, and macrophages (MAB1435, Chemicon International, Temecula, CA). Oxidized LDL (ox-LDL) staining was used as a marker of oxidant injury (33), using a polyclonal antibody (AB3230, Chemicon, Temecula, CA). Animals were classified as affected by one of two experienced observers (NBC, MRO), blinded to dietary intervention on the basis of the characteristic cystic and inflammatory pathology of this disease.

Image analysis. Image analysis procedures were performed with a system consisting of a Spot Junior CCD camera mounted on an Olympus BX60 microscope. The captured images from random stage movement through the sections were subsequently analyzed using Image Pro version 4.5 Package (Media Cybernetics, Silver Spring, MD). The observer was blinded to dietary treatment, although disease status is obvious upon microscopic examination. Raw analysis data were processed as previously described (13,31) to give objective measures of cystic change, fibrosis, interstitial macrophage infiltration, and extent of ox-LDL staining. Measurements of fibrosis and cellular markers were corrected to solid tissue areas of sections so that the presence of empty cystic areas on the section did not lead to an underestimate of these parameters.

Chemistry. Biochemical measurements were performed by an observer blinded to disease status and dietary intervention (E.N.). Serum and urine creatinine, and serum cholesterol, were determined by spectrophotometric methods using Sigma kits (Sigma Chemical Co., St Louis, MO). Urine protein was measured by the brilliant Coomassie Blue method of Bradford.

Gas chromatography. Lipids were extracted for GC analysis using a modified Folch extraction procedure, as we have previously described (13,31,34). Prior to analysis, samples were redissolved in 1 mL of dry toluene, mixed with 2.0 mL of 0.5 M sodium methoxide and heated to 50°C for 10 min, then mixed with 0.1 mL of glacial acetic acid, 5 mL of distilled H_2O, and 5 mL of hexane. After vortexing, the mixture was centrifuged at 2500*g* for 10 min, and the hexane fraction was removed. Fresh hexane was added to the remaining solution and the previous steps repeated. The hexane fractions were dried under anhydrous sodium sulfate and evaporated under nitrogen, and the lipid esters were redissolved in 1 mL hexane. GC was performed on a Varian Chrompack 3800 instrument, using a Zebron ZB Wax 30-m column (Phenomenex, Torrance, CA). Total n-6:n-3 ratio was calculated from the sum of proportions of linoleic acid (LNA, 18:2 *c*9,*c*12), γ-linolenic acid (GLA), 20:3 n-6 and arachidonic acid (ARA), divided by the sum of α-linolenic acid (ALA), 20:3 n-3, EPA, and DHA. The ratio of ARA:LNA was calculated as a measure of Δ-6 desaturase activity.

PGE_2 measurement. Approximately 250 mg of kidney was snap frozen in liquid nitrogen immediately upon removal from the animal and subsequently lyophilized. The lyophilized tissue was later reconstituted in 10 mL of Hanks balanced salt solution. The homogenate was incubated at 37°C for 1 h, at which point indomethacin was added and the solution vortexed to stop synthesis (35). After centrifugation, the supernatant was stored

at –80°C until duplicate analysis of PGE_2 using an ELISA (R&D Systems, Minneapolis, MN). To minimize the interference of the Hanks balanced salt solution with the alkaline phosphatase enzyme (according to manufacturer's specifications), standards were reconstituted using this solution as opposed to the buffer provided with the kit. This kit does have cross reactivity with PGE_1 (70%) and PGE_3 (16.3%). As prostanoid production of the 2 series has previously been shown to be very predominant in the kidney, even when diets are enriched with other prostanoid series precursors (36), PGE_2 would represent the major molecule detected by a system that recognizes both PGE_1 and PGE_2.

Statistical analysis. Data was analyzed using a general linear model ANOVA using the Minitab 13 software package. Disease effects on physical and biochemical parameters were analyzed in a model using disease *vs.* normal, FO *vs.* CO, and SDG *vs.* no SDG as variables. Analysis included detection of potential interaction between variables. *Post hoc* comparisons were performed using the Tukey-Kramer method within the same software package. The relationship of renal prostaglandin release to disease state, gender, histologic variables, and FA content was explored with logistic regression using the same software package.

RESULTS

A total of 76 male animals, including 28 without PKD and 48 with PKD, and 79 female animals, including 29 without PKD and 50 with PKD ,were included in the study. The distribution between diet and disease groups is shown in Table 1 for males and Table 2 for females. Animal weights were higher in male animals, as expected, and significantly reduced by PKD, although FO conferred significant protection against this weight loss ($P = 0.012$) (Table 1). In female animals, however, disease was not associated with weight reduction, but SDG produced a small but significant reduction in weight in both normal and PKD animals that was not observed in male animals. Kidney weight was significantly increased by PKD ($P < 0.001$) in both genders, and uninfluenced by dietary therapy (Tables 1 and 2). In male animals, there was a small but significant increase in serum creatinine associated with SDG therapy in normal animals ($P = 0.014$), but a small but just significant decrease in serum creatinine in animals with PKD ($P = 0.05$). In female animals, FO was associated with a small statistically, but not clinically, significant decrease in serum creatinine. (Tables 1 and 2). Protein/creatinine ratio was significantly increased by the presence of PKD in males only, although FO was associated with significant reduction of this ratio in PKD animals of both gender ($P < 0.05$).

Male PKD animals demonstrated significant reductions in cystic change ($P = 0.036$) and macrophage infiltration ($P = 0.001$) in response to FO, as we have described previously, and reduction in macrophages in response to SDG ($P < 0.001$), with no effect of SDG detected on fibrosis, epithelial proliferation, or ox-LDL detection (Figs. 1 and 2). In female PKD animals, however, FO was associated with significant reduction in cyst area ($P = 0.001$), fibrosis ($P = 0.031$), ox-LDL ($P = 0.026$), macrophages ($P < 0.05$), and epithelial proliferation ($P = 0.028$), with SDG associated with reduced ox-LDL detection ($P = 0.011$) and reduced macrophage infiltration ($P = 0.017$) (Figs. 1 and 2).

PGE_2 release was increased by the presence of PKD only in male animals ($P = 0.001$), and reduced by FO in all but normal female animals (male normal $P = 0.003$, male PKD $P < 0.001$, female PKD $P < 0.001$) (Fig. 3). Gender was not significantly related to PGE_2 release in the regression analysis. Macrophage count ($r^2 = 0.082$, $P = 0.004$) and renal arachidonic acid (ARA) ($r^2 = 0.145$, $P < 0.001$) were positively related to PGE_2 release, and renal tissue EPA ($r^2 = 0.30$, $P < 0.001$) was negatively related to PGE_2 release.

In male animals, FO was generally associated with decrease in renal n-6 PUFA and increase in renal n-3 PUFA, as expected (Table 3). Significant interaction between the pres-

ence of PKD and oil was observed, with *post hoc* analysis confirming that the presence of PKD was associated with a reduction in LNA ($P = 0.042$) and increase in ARA ($P = 0.031$ and ARA:LNA ratio, implying increased Δ6-desaturase activity. FO diet was associated with a reduction in ARA:LNA ratio, implying a reduction in Δ6-desaturase activity. SDG had no effect on renal PUFA content in males. Female animals showed a similar profile of FO effects to the males (Table 4), but SDG feeding was associated with reduction in renal content of LNA and ALA, which demonstrated a significant interaction that *post hoc* analysis attributed to an apparent increase in ARA and EPA, respectively, implying increased Δ6-desaturase activity, that was greater in CO-fed animals.

Both male and female rats demonstrated the expected effects of FO on hepatic PUFA content as described in our previous studies (14), so detailed data are not presented. Interestingly, in contrast to renal tissue, SDG was associated with higher hepatic ARA content as seen in male animals only ($P = 0.02$). Neither SDG nor disease state influenced hepatic FA content in female animals, nor was there interaction between dietary components or between diet and disease. The lack of difference in hepatic PUFA content suggests that the observed differences in renal content are not due to unrecognized differences in intake.

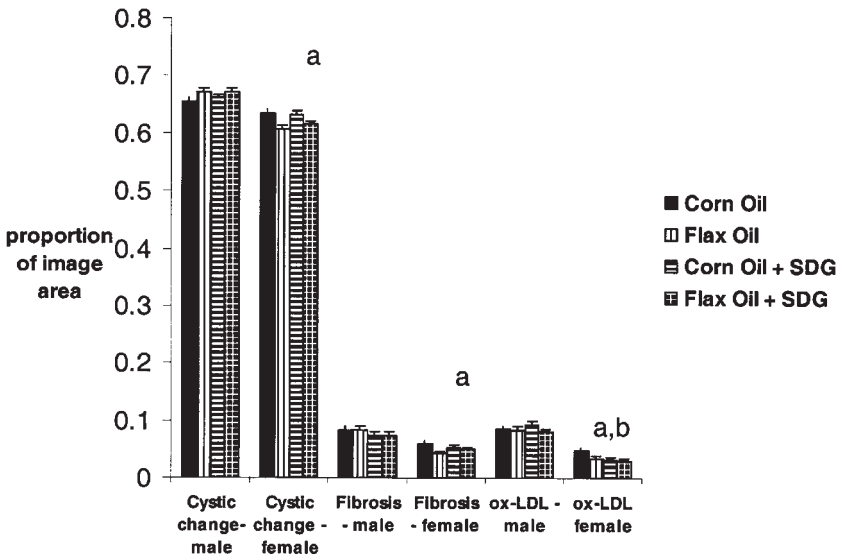

FIG. 1. Morphometric assessment of cystic change, renal fibrosis, and ox-LDL staining of renal tissue of male and female animals with PKD. Results are expressed as an average fraction of section area demonstrating staining or cystic change as applicable. Fibrosis and ox-LDL are corrected to non-cystic area. a, significant effect of dietary oil within the gender group ($P < 0.05$); b, significant effect of SDG within gender group. Bars represent SEM.

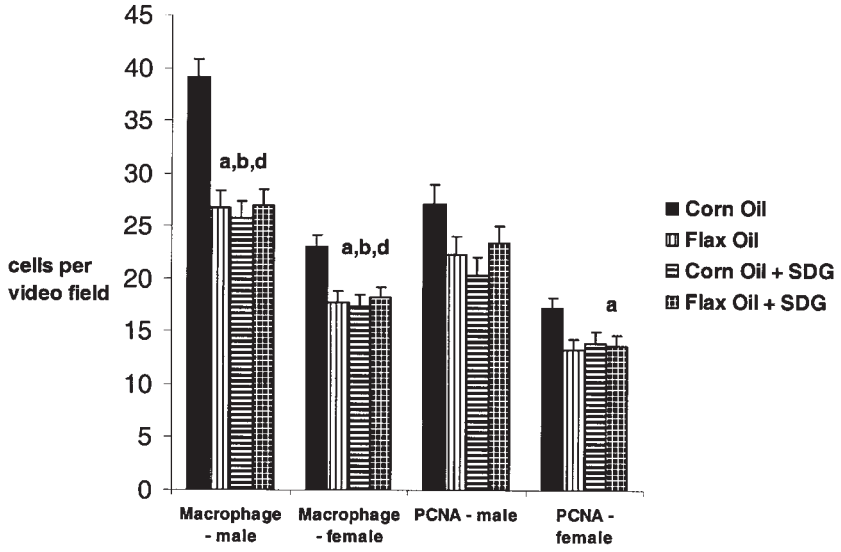

FIG. 2. Morphometric assessment of macrophage infiltration as a marker of inflammation and PCNA as a marker of proliferation. Results are expressed as the average number of positive staining cells per high-power video field, corrected to non-cystic tissue area. a, significant effect of dietary oil within the gender group ($P < 0.05$); b, significant effect of SDG within gender group ($P < 0.05$); d, significant interaction detected with SDG having a greater effect in post hoc testing in the presence of CO. Bars represent SEM.

DISCUSSION

Our results generally confirm the benefit of flax derivatives demonstrated in our earlier studies. The relative differences in beneficial effect between male and female animals could arise from either a direct relationship between gender and the biological consequences of feeding flax derivatives, or from a relationship between the feeding intervention and the stage of disease progression at a specified age, which clearly differs between genders in this model.

In the context of the Han:SPRD-*cy* rat, gender-dependent effects might include deleterious effects of androgens, or benefi-

cial effects of estrogens, either naturally occurring or in the form of derivatives of SDG. Nagao *et al.* have recently shown that male Han:SPRD-*cy* rats demonstrate significantly increased renal androgen receptor (AR) expression, which is reduced by castration and restored by exogenous androgen administration (37). They also examined the phospho-extracellular signal–regulated kinase 1/2 (P-ERK) pathways that have been linked to up-regulated cell proliferation in the Han:SPRD-*cy* rat model and found evidence of a relationship between AR expression and P-ERK that suggested that P-ERK was abnormally regulated with or without androgens but androgens had an additive role. Interestingly, although our earlier studies in younger male animals did demonstrate an effect of both FO and SDG on renal epithelial cell proliferation as detected by PCNA, the older male animals in this study demonstrated no dietary effect of either FO or SDG on proliferation, whereas FO reduced proliferation in females to an extent comparable to that seen in younger males (14). As the proliferative pathway seems to be predominant mediator of androgen effect, it seems unlikely that the gender differences observed here arise from androgen antagonism. This would also be in accord with the findings of Cowley *et al.* who confirmed the earlier findings of Zeier *et al.* that castration slowed histologic disease progression in males, and that the rate of progression was restored by testosterone administration (30,38). Testosterone administration to ovarectomized or sham operated female animals, however, in the later study accelerated the rate of disease progression, but not to the degree normally seen in males. The inference is that gender influences disease progression through both sex steroid–dependent and nondependent effects. Our results suggested that baseline renal PGE_2 production was

higher in female animals, an effect previously observed in SHR rats by Sullivan *et al.* (39). In those studies, the authors reported increased PGE metabolite excretion and renal expression of PGE synthase in females, and increases in response to orchidectomy in male animals. The levels of metabolite excretion and PGE synthase activity observed in males after orchidectomy, however, remained lower than both ovarectomized and intact females. Yang *et al.* have reported that female gender is protective against hypertension and renal injury in cyclooxygenase 2–deficient mice, although this effect was only specific to one genetic background (40). PGE_2 is know to act through four G-protein coupled receptors, and evidence is accumulating that the different and sometimes contradictory effects of PGE_2 in the kidney, such as vasodilatation and salt excretion *vs.* vasoconstriction and activation of the renin-angiotensin system, may be mediated interactions with different receptors (41). The EP4 receptor in particular has been linked to interactions that are relevant to the pathogenesis of renal injury in this model. Vukicevic *et al.* reported reduced glomerular and tubulo-interstitial injury in nephrotoxic renal injury in rats treated with a selective EP4 receptor agonist (42). The distribution and expression of these receptors in the kidney are incompletely characterized, and the possibility of gender influence on that effect remains to be explored

There are a number of estrogen-mediated pathways that may have a moderating influence on renal injury, which may be relevant to SDG effects. Estrogen downregulates the key inflammatory cytokine, monocyte chemoattractant protein 1 (MCP-1) (43,44). In a prior study, we have demonstrated upregulation of MCP-1 in the Han:SPRD-*cy* rat (45), with a reduction in MCP-1 RNA expression in association with severe dietary protein restriction. Krepinsky *et al.* have shown that estrogen inhibits strain-activated MAP-kinase expression in mesangial cells, and posit that this may reduce maladaptive glomerular responses to renal injury (46). Estrogen-progesterone combination therapy reduces expression of endothelin-1 and renal injury in the DOCA-salt hypertension rat model (24). An estrogen receptor–mediated role in cystic disease has been the subject of speculation in the pathogenesis of acquired cystic disease of the kidney, an entity seen in the failed kidneys of patients who are supported for many years on dialysis, which also demonstrates male preponderance. Concolino *et al.* have suggested that the decreased androgen/estrogen ratio of uremia results in greater epithelial stimulation in males as the male tissues are less adapted to the high-estrogen environment, but this is yet to be supported by experimental data in human or animal models (47). Other beneficial effects ascribed to estrogen include antioxidant effects, favorable shift in the collagen synthesis/degradation balance, and suppression of pro-inflammatory or proliferative cytokines (48). In this study, it is interesting to note that SDG had more histologic effect in the female animals, where both a change in inflammation and tissue ox-LDL content was detected whereas only the anti-inflammatory effect was seen in the males. It is possible that the direct antioxidant effect of SDG alone was not sufficient to produce a detectable effect in the males, whereas the combination of the direct effect of SDG and the indirect effect of estrogenic metabolites in the females resulted in a detectable difference. It is also of interest the SDG treatment significantly interacted with FO diet with respect to renal PUFA composition in females, but not in males. This effect was specific to renal tissue, whereas the composition of hepatic tissue was consistent with expectations created by the nature of the dietary lipid source. The implication is that SDG has effects on renal lipid composition that are gender-specific and may relate to the level of expression of renal estrogen receptors and the availability of estrogenic ligands.

Another explanation of our findings is that the maximal benefit of flax-based interventions occurs only in the early course of histologic renal injury. Our prior studies of flaxseed, FO, and SDG all involved feeding male animals from weaning until 9 or 11 wk of age (13,31,32), whereas this study fed until 15 wk, when disease is more advanced, which is reflected in the higher cyst scores in this study. By analogy based on morphometric scoring of cystic change in our different studies, which we have done as early as 2 and 4 wk of age, the disease in the female animals is probably at a level comparable to male animals less than half their age. The range and magnitude of effect we saw in the female animals is certainly comparable to our results in younger males, whereas our results in the older males in this study were considerably less impressive.

Gender did not influence the impact of FO on renal prostanoids release, an outcome that also was not influenced by SDG. The other outcome that was clearly unrelated to gender was the reduction of proteinuria, considered a marker of glomerular injury, by FO. This benefit of n-3 PUFA enrichment has been described in both rodent and human studies, and may be a direct effect of the modification of prostanoid synthesis (15,16,49,50). The significance of this and other effects of histologic improvements in renal injury needs to be studied in longer-term, and therefore unfortunately more expensive, survival studies.

Our study has a number of implications for research and application of dietary modification of renal disease. Our findings continue to add weight to the concept that whole-of-life dietary pattern may be more important in the relationship of diet to renal injury than dietary changes late in the course of disease, thus supporting the general findings of most human studies. More importantly, our studies reinforce that there may be a biologic basis to consider gender as not only a variable in the natural history of illness, but also in the biology of therapeutic strategies.

ACKNOWLEDGMENTS

This work was supported by operating grants from the Manitoba Health Research Council and the Flax Council of Canada. The research facilities in which this research was conducted are supported by the Manitoba Institute of Child Health (a division of the Children's Hospital Foundation of Manitoba, Inc.). Dr. Hope Weiler was a recipient of a New Investigator Award of the Canadian Institutes of Health Research during the time that this research was conducted.
