

## New Publishing Arrangement Between AOCs and Springer

Eric J. Murphy

Published online: 13 January 2007  
© AOCs 2007

Dear *Lipids* readers,

This issue marks a major new direction for *Lipids* as AOCs embarks on a joint publishing arrangement with Springer, who is the second largest STM journals publisher in the world. Under the terms of this agreement, AOCs will maintain ownership and content control over *Lipids*, while Springer becomes responsible for production and lends significant marketing resources to promote our journal. At Springer, all marketing activities are tailored to directly reach the various target audiences including readers and authors, libraries and subscription agents. Springer's online platform SpringerLink currently serves 600 international consortia, comprising over 35,000 institutions, thereby enormously boosting the visibility of *Lipids*.

This new arrangement will result in significant upgrades to the electronic delivery of the content of *Lipids*. Springer's Online First capability will ensure speedy availability of articles ahead of your print subscription. Springer will also make the entire legacy content of *Lipids* available back to volume 1, issue #1 in 1966. We will also be implementing the use of the Manuscript Central peer review system, enabling more thorough and rapid communication among the editors of *Lipids* while enhancing the submissions process for contributing authors.

While we embrace modern electronic delivery systems for the content of *Lipids*, we remain dedicated to the science. As such, the *Lipids* editorial team will retain full authority over subject matter, peer review, and final acceptance–revision–rejection status of each submitted

manuscript. We will continue to welcome your submissions via the internet, so please go to <http://www.mc.manuscriptcentral.com/lipids> to submit your latest work.

On behalf of the American Oil Chemists' Society and *Lipids*, I salute this publishing arrangement with Springer. I fully expect that we will continue to fulfill *Lipids*' mandate by offering papers of the highest quality for the lipids research community. While I will maintain the broad emphasis of the Journal, by publishing papers on biochemistry, clinical nutrition, and metabolism, we will have an increasing emphasis on publishing novel methods for use in addressing questions involving lipids. The new invited thematic reviews will add substantially to the Journal, as leading experts will author timely reviews on a particular topic over three to four issues. The first topic is plant lipid biochemistry; future topics will include fatty acid binding proteins, acyl-CoA synthetases, and fatty acid desaturases. Combined, this new arrangement will make *Lipids* a stronger journal and one with a bright future.

Thank you for your interest in *Lipids*. On behalf of our editorial team, we look forward to continuing to provide you with a journal dedicated to publishing quality papers with a broad emphasis in lipid biochemistry.

Sincerely,

Eric J. Murphy  
Editor-in-Chief

## Recent Advances in Sterol Research

Presented at the 97th AOCs Annual Meeting and Expo in St. Louis, MO, USA,  
May 2006

Edward J. Parish · Robert A. Moreau ·  
Thomas J. Bach · W. David Nes · John R. Williams

Published online: 20 January 2007

The AOCs has been a regular host to sterol symposia since 1970. The history of this symposium series has been published [Weete JD, Parish EJ, Nes WD (2000) *Lipids* 35:241]. These symposia have focused on current research in the areas of sterol structure, biosynthesis, chemistry, regulation, and function.

The 2006 Sterol Symposium, "Recent advances in sterol research," was held at the AOCs Annual Meeting in Saint Louis, MO, USA. During the symposium, the third G.J. Schroepfer Jr. Award for steroid research was presented. The Award was established to honor the memory of Dr. George J. Schroepfer Jr., a prominent steroid biochemist and chemist who made major and lasting contributions to the steroid field. Much of his research dealt with the biosynthesis of cholesterol and its regulation. In addition, he maintained a strong organic synthesis program to support

his biochemical studies. A biography describing many of Dr. Schroepfer's contributions can be found in this journal [Wilson WK (2000) *Lipids* 35:242]. Dr. Schroepfer was scheduled to be the keynote speaker at the sterol symposium in Orlando, Florida, in 1999, but he unfortunately passed away on December 11, 1998.

The first two recipients of the Schroepfer Award were Professor Geoffrey F. Gibbons (2002) and Professor Jan B. Sjöval (2004). The third recipient of the G.J. Schroepfer Jr. Award, which was presented on May 2, 2006, was Professor Ingemar Björkhem of the Department of Laboratory Medicine, from the Karolinska Institutet in Stockholm, Sweden. Professor Björkhem has made major contributions to the steroid field, and we were pleased when we learned that he was chosen to receive this prestigious award. Professor Björkhem is well known for research on the metabolism of sterols and oxysterols.

As in past symposia, we are indebted to our corporate partners who helped make the symposium a success: Avanti Polar Lipids, Forbes Medi-Tech, Pfizer, and Seraloids, Inc. We appreciate their contribution and look forward to their continued support of our symposium series.

This symposium was sponsored by the Biotechnology Division of the AOCs. Speakers at the 2006 Sterol Symposium represented an international group of senior and junior scientists. We express here our appreciation to each of them for their cooperation during the planning process and for their participation in the symposium. By all accounts, the event was a success. We are looking forward to the next sterol symposium, which will be held at the 99th Annual Meeting and Expo of the American Oil Chemists' Society, May 18–21, 2008, in Seattle, Washington.

# Rediscovery of Cerebrosterol

Ingemar Björkhem

Received: 15 June 2006 / Accepted: 27 July 2006 / Published online: 23 January 2007  
© AOCs 2007

**Abstract** 24S-hydroxycholesterol was identified more than half a century ago and was initially given the name “cerebrosterol” due to the fact that it was abundant in the brain. A decade ago, we showed that the most important mechanism by which cholesterol is eliminated from the mammalian brain involves a hydroxylation into cerebrosterol followed by diffusion of this steroid over the blood–brain barrier. Using an  $^{18}\text{O}_2$  inhalation technique, we showed that about two-thirds of the cholesterol synthesis in rat brain is balanced by conversion into cerebrosterol. The hydroxylase responsible for the reaction was found to be dependent upon NADPH and oxygen, consistent with involvement of a species of cytochrome, P-450. The gene coding for the cytochrome P-450 responsible for the reaction was later cloned by the group of David Russell in Dallas and the enzyme was found to be located to neuronal cells in the brain. Recent studies by us and others on this new pathway for elimination of cholesterol from the brain have given new insights into the mechanisms by which cholesterol homeostasis is maintained in this organ. In addition, these studies have resulted in new diagnostic and prognostic tools in connection with neurological and neurodegenerative diseases. An overview of the studies is presented here and the possibility is discussed

that the cholesterol 24S-hydroxylase in the brain may be a new drug target in connection with neurodegenerative diseases.

## Introduction

I am deeply honoured to be the third recipient of the Schroepfer award.

I never met George Schroepfer in person, but I am very familiar with his work. He was one of the pioneers in the field of research on oxysterols, which is my major research interest at present. In addition to this, I have a personal link to George Schroepfer. My tutor, the late Professor Henry Danielsson, was a very good friend of George and often mentioned him. Both Henry and George had been working in the laboratory of Konrad Bloch.

I have learnt that the two previous recipients of the Schroepfer award have given broad overviews. Jan Sjövall, who received the award 2 years ago, described his 50 years with bile acids in health and disease [1]. I will be more selective and focus on a topic that I have been working on only during the last decade. However, given the interest of George Schroepfer in oxysterols, I think that the topic is appropriate.

## Oxysterols: General Properties

Oxysterols are defined as oxygenated derivatives of cholesterol (or precursors to cholesterol) that may be formed by autoxidation or by the action of specific monooxygenases (for details, see the classical very extensive review by Schroepfer [2]). Oxysterols may

also be formed secondary to enzymatic or nonenzymatic lipid peroxidation. Most oxysterols are short-lived compounds which are rapidly oxidized to bile acids and eliminated from the body. The rapid degradation of these compounds, in particular side-chain oxidized oxysterols, is facilitated by their physical properties which allow them to pass lipophilic membranes orders of magnitude faster than cholesterol itself [3, 4].

An important feature of oxysterols is that they are present in trace amounts only in biological systems, and always in the presence of a great excess of cholesterol (most often this excess is in the range  $10^4$ – $10^6$ ). In some specific biological systems, as in the brain and in lipid-loaded macrophages, the excess of cholesterol may be somewhat lower than  $10^3$ . Exposing cultured cells to pure oxysterols at micromolar concentrations in the absence of cholesterol may be regarded as highly unphysiological. While such experiments may give some information concerning whether or not the system is sensitive to sterols, it is not possible to draw conclusions concerning the biological role of oxysterols under *in vivo* conditions.

Oxysterols have been ascribed important functions in connection with atherosclerosis, apoptosis, necrosis, inflammation, immunosuppression, development of gallstones (for a review, see [5]).

However, most of the evidence for this is still indirect and there is a clear discrepancy between the documented effects of the oxysterols under *in vitro* conditions and the studies demonstrating direct physiological effects *in vivo*.

The most obvious role of oxysterols is that they are precursor to bile acids. Another well established role is that they represent a transport form of cholesterol, allowing an elimination over biological membranes that is not dependent on specific transport proteins. To what extent oxysterols are of regulatory importance under *in vivo* conditions is still controversial. It is well documented that side-chain oxidized oxysterols are efficient ligands and activators of the nuclear receptors LXR $\alpha$  and LXR $\beta$  [6]. A knockout of these receptors leads to specific effects on cholesterol homeostasis. According to current concepts, oxysterols are the physiological activators of the above receptors, but this has not been established with certainty [5, 7].

### Cerebrosterol

More than half a century ago an oxysterol was isolated from horse and human brain by two Italian researchers, Ercoli and Ruggieri, that was given the name “cerebrosterol”. In 1953, they established the identity of this

oxysterol to be 24-hydroxycholesterol [8] (Fig. 1). The concentration of this oxysterol in the brain was found to be about 0.1–0.3% of that of cholesterol. About 20 years later, Leland L Smith and collaborators performed detailed studies on the occurrence of this compound in the brain and showed that it is only one of the two epimers of 24-hydroxycholesterol (24S) which is present (for a review, see [9]). This group also showed that 24S-hydroxycholesterol most probably originates from brain cholesterol. Homogenates and microsomal fractions from rat brain were thus shown to convert tritiated cholesterol into 24-hydroxycholesterol at a rate of about 0.01% per hour [10]. The extremely low degree of conversion prevented further characterization of the enzyme involved.

In retrospect it is interesting to note that Smith et al. draw the conclusion from their studies that “Our data on the levels of 24-hydroxycholesterol in several brain regions suggest that any physiological function of the trace steroid must be a generalized one, which is important to all major regions” [9].

In later work, 24S-hydroxycholesterol was found to be also present in adrenals, in the circulation, and as a sulphate in human meconium and infant faeces [11].

### A Surprising Discovery

As part of the general interest in oxysterols in our laboratory, accurate methods were developed for assay of oxysterols in plasma based on isotope dilution-mass spectrometry [12, 13]. 24S-hydroxycholesterol was found to be one of the major oxysterols in human circulation, ranging from 50–100 ng/ml. Using an  $^{18}\text{O}_2$ -inhalation technique to study oxygenation of cholesterol in the rat, we were able to show that most of the 24S-hydroxycholesterol present in the circulation is formed *in vivo*, most probably in an enzymatic reaction [14]. In view of this, it was considered to be of interest to have this oxysterol included in the panel of oxysterols that we measured.

A number of studies were performed in order to evaluate the possibility that oxysterols in the circulation may be used as biomarkers in different clinical conditions expected to have consequences for cholesterol homeostasis. We observed that some patients with atherosclerosis had increased levels of 27-hydroxycholesterol [15] and that patients with increased bile acid biosynthesis had increased levels of 7-hydroxycholesterol [16]. Up to 1995, only very small changes were seen in the levels of circulating 24S-hydroxycholesterol in any of all the different patients that we studied. Patients treated with the drug ketoconazole had

**Fig. 1** Structure of 24S-hydroxycholesterol

moderately increased levels of 24S-hydroxycholesterol, most probably due to a drug interference with its metabolism.

In 1995, a visiting scientist in my laboratory, Dr Dieter Lutjohann, analyzed plasma from a 14-year-old girl with sitosterolemia [17]. He found a level of 235 ng/ml of 24S-hydroxycholesterol—a level about three-fold the upper limit of the normal range that we had defined for adults. The younger sister of the patient had an even higher level, whereas the parents had normal plasma levels. It was not possible to couple this finding to sitosterolemia and so the obvious explanation was that infants have higher levels than adults. Analyses of a great number of plasma samples from subjects of different ages confirmed that this was the case (Fig. 2).

We considered the possibility that the increased levels of 24S-hydroxycholesterol in childhood were due

**Fig. 2** Age-dependent variations in plasma levels of 24S-hydroxycholesterol (modified from [18])

to effects of, e.g., growth hormone, or due to dietary factors (e.g., milk), but these possibilities were easily excluded. We then speculated that the high levels in infancy could be due to increased turnover of cholesterol in the brain of infants in relation to adults. The major fraction of cholesterol in the central nervous system is present in myelin, and it is known that the major portion of myelination occurs in the human brain during the first years of life.

Such a hypothesis must however be based on the assumption that the cerebrosterol present in human circulation originates from the brain.

### Demonstration that the Cerebrosterol Present in Human Circulation Originates from the Brain

We first confirmed the previous finding [8, 9] that the brain contains high levels of 24S-hydroxycholesterol. The level of 24S-hydroxycholesterol was found to vary between 4 and 15 ng/mg (wet weight) in different areas of the human brain. In contrast, the levels in all other organs, except the adrenals, was less than 0.2 ng/mg. In the adrenals, the level was about 3 ng/mg. When related to cholesterol levels, the ratio between 24S-hydroxycholesterol and cholesterol was found to vary between 0.7 and 2 ng/ $\mu$ g in the brain, but was only about 0.05 ng/ $\mu$ g in the circulation. It is evident that there is a marked concentration gradient between the brain and the circulation, consistent with the possibility of a flux of cerebrosterol in this direction. In accordance with a flux driven by the concentration gradient, the ratio between 24S-hydroxycholesterol and cholesterol in cerebrospinal fluid was between the corresponding ratio in the brain and in the circulation (about 0.3 ng/ $\mu$ g).

In order to measure the flux of 24S-hydroxycholesterol from the human brain into the circulation, we collaborated with two clinical physiologists who inserted catheters into the jugular vein, the hepatic vein, and the brachial artery of healthy volunteers. Almost all of the subjects had higher levels of 24S-hydroxycholesterol in the internal jugular vein than in the artery [18, 19], and this difference was highly significant from a statistical point of view. From the arteriovenous difference and an estimation of the blood flow through the brain, the net efflux of 24S-hydroxycholesterol was estimated to be about 6 mg/24 h. Most of the subjects had higher levels 24S-hydroxycholesterol in the artery than in the hepatic vein, and it was estimated that there was a net uptake of this oxysterol in the liver corresponding to about 7 mg/24 h. Since the secretion by the brain and the uptake in liver were found to be about

the same, the data are consistent with the possibility that most of the 24S-hydroxycholesterol present in human circulation originates from the brain (Fig. 3).

### Studies on Formation of 24S-Hydroxycholesterol in Rat Brain In vivo and In vitro

By exposing rats to  $^{18}\text{O}_2$  in the inhalation atmosphere, we had previously shown that 24S-hydroxycholesterol is formed by a monooxygenase that incorporates one of the two oxygen atoms in molecular oxygen in the product [14]. This technique was now used to measure the rate of incorporation of  $^{18}\text{O}$  in 24S-hydroxycho-

lesterol in the brain of rats exposed for some hours to  $^{18}\text{O}_2$  [20]. From the results obtained, it could be calculated that the rate of conversion of brain cholesterol into the oxysterol corresponded to about 0.02% of the total endogenous pool of cholesterol per hour. It was shown that there was also an incorporation of  $^{18}\text{O}$  in the 24S-hydroxycholesterol present in the circulation, although this incorporation was lower than that in the brain. This is consistent with a flux of the oxysterol from the brain into the circulation.

It was considered to be of interest to also measure the rate of synthesis of cholesterol in the brain of the above rats. We had previously demonstrated that it is possible to also use the  $^{18}\text{O}_2$ -technique for such measurements [21]. Thus the synthesis of cholesterol also requires a mixed function oxidation (the squalene oxidase step). As a consequence,  $^{18}\text{O}$  is incorporated in the  $3\beta$ -position under conditions when the de novo synthesis of cholesterol occurs in  $^{18}\text{O}_2$ -atmosphere. With use of this technique we could show that the rate of synthesis of cholesterol in the brain of a rat exposed to  $^{18}\text{O}_2$  corresponds to about 0.03% of the pool per hour. This means that the de novo synthesis of cholesterol in rat brain is balanced to about two-thirds by a metabolism into 24S-hydroxycholesterol.

Attempts were then made to set up a reliable in vitro assay for conversion of cholesterol into 24S-hydroxycholesterol in brain homogenates. In our hands, the assay described by Smith et al. [10], measuring the rate of conversion of added labeled cholesterol, was not reproducible, mainly due to the extremely low degree of conversion (about 0.01% of the pool per hour). A better assay was obtained by measuring the amount of endogenous 24S-hydroxycholesterol in the homogenate by isotope dilution-mass spectrometry before and after incubation. The best and most reliable assay was obtained by carrying out the incubation in  $^{18}\text{O}_2$  and measuring the incorporation of  $^{18}\text{O}$  in the 24S-hydroxycholesterol after the incubation [20]. By this technique, we could confirm the previous finding by Smith that the enzyme was located in the endoplasmic reticulum. We could also show that the reaction was dependent upon NADPH and oxygen. The rate of conversion was found to be comparable with the rate of conversion that we had found in vivo.

**Fig. 3** Flux of 24S-hydroxycholesterol from the brain to the circulation and liver (modified from [19])

### Attempts to Purify the Cholesterol 24-Hydroxylase and the Cloning of the Gene Coding for the Enzyme by the Group of David Russell

Several attempts were made in our laboratory to purify the microsomal cholesterol 24-hydroxylase from rat

and rabbit brain. It appeared most likely that the enzyme was a species of cytochrome P-450 and so some of the methods previously used for purification of such enzymes were tested. Unfortunately, all these attempts failed, and only a very modest degree of purification was obtained. Removal of the lipids from the membrane fractions by different methods almost invariably resulted in an irreversible loss of most of the enzymatic activity.

Meanwhile, my previous PhD student Erik Lund, working as a post-doctoral student in David Russell's laboratory in Dallas, cloned a new species of cytochrome P-450 from mouse liver by expression cloning [22]. This species of cytochrome, containing 500 amino acids, was expressed and found to be able to catalyze 24S-hydroxylation of cholesterol. Antibodies towards the enzyme were prepared, and it was confirmed that the enzyme was present almost exclusively in the brain in humans. The neuronal cells expressing the enzyme included pyramidal cells of the cortex and hippocampus, granule cells of the dentate gyrus and Purkinje cells of the cerebellum. The expression of the gene was low during the first year of life, but was then about constant during the rest of the life.

The new species of cytochrome P-450 was given the name CYP46.

The very successful work in the laboratory of David Russell not only confirmed and expanded our work, but also provided the necessary molecular tools for a further elucidation of the role of 24-hydroxylation of cholesterol in the brain. More recently, Drs Lund, Russell and collaborators developed a mouse model with a disruption of the gene coding for CYP46 [23]. The mice had no obvious biochemical phenotype, but had a reduction of cholesterol synthesis by about 40% in the brain. In accordance with our previous findings in the rat, the disruption of the gene resulted in a reduction of the flux of steroids from the mouse brain by about two-third [23].

### Characterization of the Cholesterol 24S-Hydroxylase (CYP46)

Due to the low enzymatic activity of the cholesterol 24S-hydroxylase in brain microsomes, it was difficult to characterize the enzyme in detail with such preparations. The cloning of the gene coding for the CYP46 protein by Lund et al. allowed a more detailed characterization by use of transfected mammalian cells and partially purified recombinant CYP46A1 protein. In collaboration with the group of Dr Irina Pikuleva at Galveston, it was shown that the enzyme was able to

further metabolize 24S-hydroxycholesterol into 24,25- and 24,27-dihydroxycholesterols [24]. C27-steroids other than cholesterol could undergo side-chain hydroxylation. Furthermore, the enzyme could introduce a hydroxyl group in the steroid nucleus of progesterone and testosterone and metabolize some xenobiotics. The physiological importance of the latter hydroxylations is, however, difficult to evaluate at the present state of knowledge. In spite of several attempts, we have only found trace amounts of the steroids 24,25- and 24,27-dihydroxycholesterols in the brain or cerebrospinal fluid.

### Studies on the Regulation of the Cholesterol 24S-Hydroxylase

In view of the obvious importance of the cholesterol 24S-hydroxylase for cholesterol homeostasis in the brain, we made a structural and functional characterization of the promoter of the human CYP46 gene [25]. No canonical TATA or CAAT boxes were found in the promoter region. Moreover, this region had a high GC content, a feature often found in genes considered to have a largely housekeeping function. A broad spectrum of different potential modulators using a variety of promoter constructs did not result in a significant transcriptional regulation, although oxidative stress caused a significant increase in transcriptional activity. The possibility of a substrate-dependent transcriptional regulation was explored in vivo in a sterol deficient model (*Dhcr24* null) [26] in which almost all cholesterol had been replaced with desmosterol, which is not a substrate for CYP46A. Compared to heterozygous littermates there was no statistically significant difference in the mRNA levels of the enzyme. However, during the first 2 weeks of life in the wild-type mouse, a significant increase of the mRNA levels was found, in parallel with an increase in 24S-hydroxycholesterol level and a reduction of cholesterol synthesis.

The most significant transcriptional effect on the gene was thus the induction of the enzyme during the neonatal stage. Attempts to define the factor(s) behind this induction have failed thus far, and we were able to exclude the possibility that growth hormone is involved in this effect.

The apparent resistance to regulation of the cholesterol 24S-hydroxylase at a transcriptional level is in marked contrast to the regulation of the rate-limiting enzyme for elimination of cholesterol from the liver, the cholesterol 7 $\alpha$ -hydroxylase (CYP7A1). The latter is subject to a highly sophisticated transcriptional

regulation by the flux of bile acids and cholesterol through the liver, and by a great number of dietary and hormonal factors [27]. It may be concluded that it is the synthesis rather than the metabolism of cholesterol that is regulated in the mammalian brain.

### Why is There a Need for Conversion of Cholesterol into 24S-Hydroxycholesterol by the Brain?

The rate of cholesterol synthesis in the brain of mammals is very low [19], and there appears to be a highly efficient reutilization of this compound. At the present state of knowledge, the most important role of the cholesterol 24S-hydroxylase system appears to be a compensation for the rate of de novo synthesis of cholesterol. Pfrieger has suggested a mechanism by which 24S-hydroxycholesterol may be involved in an interplay between neuronal and glial cells [28] (Fig. 4). Neuronal cells appear to have a low rate of synthesis of cholesterol in relation to glial cells, and there may be a flux of cholesterol in apoE bound form from the glial cells to the neuronal cells. This flux may in part be regulated by the cholesterol transporter ABCA1, which is under control of the nuclear receptor LXR [28]. 24S-hydroxycholesterol is an efficient activator of this receptor, and an increased flux of 24S-hydroxycholesterol from the neuronal cells to the glial cells would thus be expected to cause an increased flux of cholesterol to the neuronal cells. In accordance with a stimulatory effect of 24S-hydroxycholesterol on the efflux of cholesterol from glial cells, it was recently shown that 24S-hydroxycholesterol seems to have a direct effect on the production of apoE in glial cells [29].

The autoregulatory mechanism suggested by Pfrieger is conceptually attractive and is consistent with most experimental data. There is, however, a need for further testing of the hypothesis in other systems than those used thus far. A complicating factor in such studies is the extremely low rate of synthesis of 24S-hydroxycholesterol, and to our knowledge no cell culture experiments have been described at this point in time with a measurable reproducible production of 24S-hydroxycholesterol.

### Metabolism of 24S-Hydroxycholesterol

In view of the fact that a hydroxyl group is introduced in the 24-position during the normal conversion of cholesterol into bile acids, a conversion of 24-hydroxycholesterol into bile acids would be expected. In the major pathway for formation of bile acids, the first and rate-limiting step is the introduction of a hydroxyl group in the 7 $\alpha$ -position by the cytochrome P-450 enzyme CYP7A. In collaboration with the group of Dr Kjell Wikvall we could demonstrate that reconstituted human CYP7A has activity towards 24S-hydroxycholesterol [30]. In contrast, the cytochrome P-450 CYP7B, which is able to introduce a hydroxyl group in other side-chain oxidized C27-steroids like 25- and 27-hydroxycholesterol, had no such activity. The group of Dr David Russell cloned and characterized a novel species of cytochrome P-450 denoted CYP39 [31]. This enzyme was found to have a high 7 $\alpha$ -hydroxylase activity towards 24S-hydroxycholesterol. However, the relative importance of CYP39 and CYP7A in the metabolism of 24S-hydroxycholesterol is not known.

**Fig. 4** Regulatory effects of 24S-hydroxycholesterol on the flux of cholesterol from a glial cell to a neuronal cell (cf. [28, 29])

In a study on the metabolism of 24*S*-hydroxycholesterol in humans, we prepared tritium labeled 24*S*-hydroxycholesterol and incubated it with human primary hepatocytes, administered it to human volunteers and quantitated free and conjugated 24*S*-hydroxycholesterol and its neutral metabolites in ileocecal fluid from patients with ileal fistulae [32]. 24*S*-hydroxycholesterol, as well as the 24*R*-hydroxylated analog, were converted into the normal bile acids by human hepatocytes at a rate about 40% of that of the normal intermediate in bile acid synthesis, 7 $\alpha$ -hydroxycholesterol. There was also a conversion of the oxysterol into conjugates of the corresponding 27-hydroxylated derivative. The rate of the latter conversion was similar to that of the rate of conversion into bile acids. When administered to a human volunteer, labeled 24*S*-hydroxycholesterol was converted into bile acids at a rate about half that of simultaneously administered 7 $\alpha$ -hydroxycholesterol. Free, sulfated and glucuronidated 24*S*-hydroxycholesterol, as well as 27-hydroxylated 24*S*-hydroxycholesterol, were identified in ileocecal fluid. The excretion of these steroids was about 3.5 mg/24 h, amounting to about half of the production of 24*S*-hydroxycholesterol from the brain.

It was concluded from the above studies that 24*S*-hydroxycholesterol is a less efficient precursor to bile acids and that about half of it is conjugated and eliminated in bile as such or as a conjugate of a 27-hydroxylated metabolite [32]. The less efficient metabolism of 24*S*-hydroxycholesterol may explain the surprisingly high levels of this oxysterol in the circulation.

### **What is the Explanation for the High Levels of 24*S*-Hydroxycholesterol in the Circulation of Infants? Which Factors Other than Age are of Importance for the Levels?**

Our first hypothesis was that the high levels of 24*S*-hydroxycholesterol in infants are due to a higher rate of turnover of cholesterol in a developing brain. The high levels are apparently not related to the level of CYP46 in the brain, as reported by Lund and collaborators [22]. Measurement of 24*S*-hydroxycholesterol in the brain and circulation of experimental animals gave no information about the reason for the high levels in human infants. In this situation we measured the concentration of 24*S*-hydroxycholesterol in plasma of chondrodystrophic dwarfs [33]. The concentrations were increased in these subjects to a level similar to that seen in infants. The most likely explanation is that the levels of 24-hydroxycholesterol in the circulation

are dependent upon a balance between the secretion capacity of the brain and the metabolic capacity of the liver. Newborns have a size of the brain that is about three-fold that of the liver, whereas the size of the two organs is about the same in adults. In old age, the size of the liver is reduced to a greater extent than is the size of the brain. In accordance with this, there is a slight but significant increase in the plasma level of 24*S*-hydroxycholesterol after the age of 65. As expected from the relation between the size of the liver and the body surface, there is an inverse relationship between surface area and plasma 24*S*-hydroxycholesterol.

Since 24*S*-hydroxycholesterol is transported in plasma by the same lipoproteins as cholesterol, hypercholesterolemia would be expected to affect the circulating levels of this oxysterol. In accordance with this, there is a relationship between levels of cholesterol and levels of 24*S*-hydroxycholesterol [19, 33]. Reducing cholesterol levels by treatment with a statin causes a slight increase in the ratio between 24*S*-hydroxycholesterol and cholesterol in the circulation (unpublished observation).

In spite of the fact that the cholesterol level may affect the level of 24*S*-hydroxycholesterol in the circulation, this level is remarkably stable under most conditions. Thus, there is no diurnal variation and, with the exception of some efficient inhibitors of cytochrome P-450 enzymes (ketoconazol and itraconazol), there are surprisingly small effects of drugs on the levels. Except for very advanced stages of liver cirrhosis, liver diseases also appear to have little or no effect on the levels in the circulation.

### **24*S*-Hydroxycholesterol as a Marker for Neurological and Neurodegenerative Diseases**

Given the fact that almost all 24*S*-hydroxycholesterol present in human circulation is of cerebral origin, and the fact that hepatic metabolism appears to be constant during most conditions in adult life, we tested the possibility that 24*S*-hydroxycholesterol may be used as a surrogate marker for brain cholesterol homeostasis. We first tested the most drastic clinical situation possible, that of a brain-dead patient with little or no circulation in the brain [34]. As expected, the levels of 24*S*-hydroxycholesterol were low, and in accordance with our previous finding that the half-life of the oxysterol in the circulation is about 12 h, patients who had been brain-dead for about this period of time had a reduction in the concentration of 24*S*-hydroxycholesterol of about 50%. Patients with advanced Alzhei-

mer's disease were found to have significantly reduced plasma levels of the oxysterol, in accordance with the demonstration by Lund et al. that almost all of the enzyme is present in neuronal cells. A complicating factor in the interpretation, however, is that we could demonstrate some abnormal expression of the CYP46 enzyme in glial cells in the brain of patients with Alzheimer's disease [35], a finding that was recently confirmed by another group [36].

Patients with brain tumors and some severe CNS infections also have reduced levels of 24S-hydroxycholesterol. A few patients with multiple sclerosis in an active stage were found to have increased levels of 24S-hydroxycholesterol in the circulation. However, in the chronic situation, most patients have reduced plasma levels of the oxysterol [37].

From the low levels of 24S-hydroxycholesterol in the cerebrospinal fluid, it can be calculated that less than 1% of the oxysterol is excreted from the brain by this route. Surprisingly, this minor fraction appears to reflect neuronal damage and rate of neuronal loss rather than the total number of metabolically active neuronal cells [38]. Thus, patients with neurodegenerative disorders were found to have increased levels of 24S-hydroxycholesterol in cerebrospinal fluid, in parallel with decreased levels in the circulation. The changes in the cerebrospinal fluid were thus much more marked than those in the circulation. The diagnostic potential of the level of 24-hydroxycholesterol in cerebrospinal fluid is under investigation at present in our laboratory and in the laboratory of Dr Dieter Lutjohann. Levels of the tau protein, phosphorylated tau, and  $\beta$ -amyloid in cerebrospinal fluid are routinely used as biomarkers for neurodegenerative diseases and dementia. We recently showed that the level of 24S-hydroxycholesterol in cerebrospinal fluid appears to have about the same diagnostic sensitivity as these markers in connection with Alzheimer's disease and may be the most sensitive marker in early stages [39].

### Cholesterol 24S-Hydroxylase as a Potential Drug Target

We recently measured the levels of 24S-hydroxycholesterol and 27-hydroxycholesterol in brain materials from patients who had died from Alzheimer's disease and in the corresponding materials from control subjects [40]. The levels of 24S-hydroxycholesterol were decreased in most brain areas, whereas the levels of 27-hydroxycholesterol were increased. Interestingly, similar changes were observed in the brain of mice

with a mutation in the gene coding for Amyloid Precursor Protein (APP) (the Swedish mutation). The ratio between 24S-hydroxycholesterol and 27-hydroxycholesterol was markedly reduced in all the brain areas of both the AD patients and the transgenic mice.

The reduced levels of 24S-hydroxycholesterol may be due to the neuronal degeneration. We have shown that most of the 27-hydroxycholesterol present in the brain originates from the circulation [41, 42] and the increased levels may be due to increased flux over the blood–brain barrier. Another possibility is reduced metabolism.

According to a recent work by Brown et al. [36], 24S-hydroxycholesterol is an efficient inhibitor of the formation of  $\beta$ -amyloid under in vitro conditions. 27-hydroxycholesterol had a much lower capacity to inhibit the reaction. If the oxysterols are important for the generation of  $\beta$ -amyloid also under in vivo conditions, the reduced levels of 24S-hydroxycholesterol may accelerate the progress of the disease, and the increased levels of 27-hydroxycholesterol may not be able to compensate for this [43].

According to current concepts, cholesterol-rich membranes are more likely to lead to a primary cleavage of APP by  $\beta$ -secretase with subsequent generation of  $\beta$ -amyloid than membranes with a low concentration of cholesterol (for a review, see [44]). Theoretically, upregulation of the cholesterol 24S-hydroxylase may prevent formation of  $\beta$ -amyloid by two separate mechanisms: reduction of cholesterol in neuronal membranes and a direct inhibitory effect by the 24S-hydroxycholesterol [43]. On the other hand, high levels of 24S-hydroxycholesterol may have neurotoxic effects [45]. The possibility must be considered that pharmacological effects on the cholesterol 24S-hydroxylase may be utilized as a new therapeutic strategy in connection with neurodegenerating diseases. Such an approach would, however, require development of specific modulators of the enzyme activity which are able to cross the blood–brain barrier.

**Acknowledgments** The author is grateful to the previous PhD students (and, in some cases, later post doctoral students) in his laboratory working on different parts of the project: Karl Bodin, Olof Breuer, Ewa Ellis, Maura Heverin, Valerio Leoni, Erik Lund, Dieter Lutjohann, and Steve Meaney. In addition, he is grateful for the fruitful collaboration with his colleagues, Leonel Bretillon, Ulf Diczfalusy, Curt Einarsson, Elena Feinstein, Maria Norlin, Yoshihiko Ohyama, Irina Pikuleva, Lars-Olof Wahlund, John Wahren, Kjell Wikvall, Åke Wennmalm, Bengt Winblad, and Jan Sjövall. **Abstract** Sterol biosynthesis inhibitors (SBIs), discovered in the late 1960s and subsequently used commercially to treat ergosterol-dependent fungal diseases, represent a unique drug class targeted at an enzyme in a biosynthetic pathway. To date, few drugs have been commercialized as enzyme inhibitors; yet, prescription of SBIs has emerged as the gold standard for some cases of non-life-threatening antifungal chemotherapy and in crop protection. SBIs are not designed for their structural resemblance to the sterol molecule; they nonetheless can engender a curative effect by interfering with sterol production and homeostasis in the pathogenic organism. The increased use of SBIs in recent years, particularly the azole antifungals, has resulted in the development of resistance to those drugs, necessitating additional work to further our understanding of antifungal resistance and to explore opportunities to develop new enzyme inhibitors and uncover new enzyme targets that can regulate carbon flux in the post-lanosterol/cycloartenol pathway. This article reports general considerations for enzyme mechanism and active-site probes using inhibitors of the C-methylation reaction, including a potential new class of antifungal/antiparasitic agents of phytosterol synthesis tailored as mechanism-based inactivators. These steroid-based compounds prepared with different sterol side chain functionalities are designed to reversibly or irreversibly impair the sterol methyltransferase, an enzyme expressed in pathogenic microbes and plants but not in the human host. The salient aspects of these and related

topics directed toward the enzyme recognition of sterol structure, and the inhibitory properties and catalytic competence of a series of specifically modified substrate analogs that affect sterol methyltransferase action are discussed.

Primarily due to their impact upon plant and human health, the similarities and differences in sterol content between microbes of eukaryotic origin and more advanced systems, the functions of the various sterols and biosynthetic intermediates, as well as the characterization of the enzymatic reactions involved have all received substantial investigation. An important goal of most of these studies is to provide basic information about sterol biochemistry from which drugs, herbicides, etc., can be developed to exploit a fundamental difference in sterol homeostasis (involving the type and amount of cellular sterol) between the pathogenic microbe and its host, whether human or plant. Excellent reviews that cover the topic of sterol biosynthesis inhibitors are available [1–4]; the last time this subject was reviewed in the journal *Lipids* was in 1986 by the Strasbourg group, who made seminal contributions to the field [5].

## Ergosterol Homeostasis

The major sterol of microbes, ergosterol accumulates in the cell at ca. 20–100 fg/cell; this contrasts with the sterols of advanced plant and animal systems, sitosterol and cholesterol respectively, that occur at ca. 3,000 fg/cell [6] (Fig. 1). Ergosterol and sitosterol are regarded as phytosterols (sterols that contain a 24-alkyl

**Fig. 1** Representative zoosterol and phytosterols (24-alkyl sterols). The structure of ergosterol is boxed to show different domains of the nucleus and a side chain of functional significance; arrows indicate structural features of key importance

group in the sterol side chain), whereas cholesterol is regarded as a zoosterol (sterols that lack a 24-alkyl group in the sterol side chain) [6]. The physiological importance of ergosterol to fungal–plant/human interactions provide a biochemical paradigm that ergosterol-dependent diseases can be cured or eradicated through the disruption of ergosterol homeostasis. The key element of this paradigm is that *de novo* sterol synthesis and the structural features of ergosterol are important to fungal growth and that loss of the native ergosterol structure, such as through blockage of the addition of the C24-methyl group to the intermediate structure, will harm cell physiology.

The first evidence that disruption of ergosterol homeostasis can lead to impaired fungal growth was the study by Nes and coworkers, who in the 1970s cultured yeast anaerobically to generate sterol auxotrophy. By supplementing the culture medium with different sterols, they established the functional significance of the structural features of yeast ergosterol and demonstrated that lanosterol and other intermediates were harmful to cell proliferation and morphology [7, 8]. From a functional perspective, the structural features can be divided into the ring and side chain requirements (cf. the ergosterol structure in Fig. 1). For the ring, the 3 $\beta$ -OH group is obligatory for growth, whereas the presence of C4 and C14 methyl groups in the nucleus did not allow growth. There appeared to be little advantage in the presence of double bonds compared to the fully saturated B-ring sterol. In the side chain, the 24 $\beta$ -methyl group was obligatory for growth, but better growth still was observed with the natural side chain containing a 24 $\beta$ -methyl group and  $\Delta^{22}$ -double bond. By comparing the growth response to sterols with opposite configurations at C20 and C24, only sterols with the natural configuration at C20R- and C24 $\beta$ -methyl groups supported growth. This work

highlighted, for the first time, the importance of sterol specificity that can manifest itself in ergosterol-dependent diseases, and permitted a rational manipulation of ergosterol homeostasis that will lead to cell death. The importance of ergosterol to other microbial systems and sitosterol to plants in growth has been reported and confirms the original observations. In further work on this issue, several groups were able to show that sterol played a dual function in microbial physiology [1, 6, 7, 9–11]: the first as a bulk membrane component and the second as a “sparking” compound to signal cell proliferation; this second function uses orders of magnitude less sterol than that required in the membrane. Clearly, if those features that are essential for growth could be exploited as antifungal targets, then it should be possible to obtain an effective inhibitor for therapeutic purposes and for crop protection.

The study of ergosterol biosynthesis in fungi and protozoa became of particular interest after it was discovered that specifically acting compounds, the “azoles” [4], a diverse group of compounds including the imidazoles, triazoles, pyrimidines and pyridines, interfere quite precisely in fungal metabolism, mainly in one or three steps of the lanosterol–ergosterol pathway [viz., with the Erg11p, Erg24p and Erg2p]. The mechanism of action by which many of the azoles interrupt ergosterol synthesis is based on their ability to bind to the 14 $\alpha$ -demethylase enzyme [CYP51, Erg11p] with greater affinity in fungal cells than to the 14 $\alpha$ -demethylase in animal cells. A common structural feature of these compounds that promote enzyme inhibition is an unsubstituted imidazole ring or triazole ring, bound via the N-3 atom of the heterocycle to a carbon atom in the remainder of the molecule.

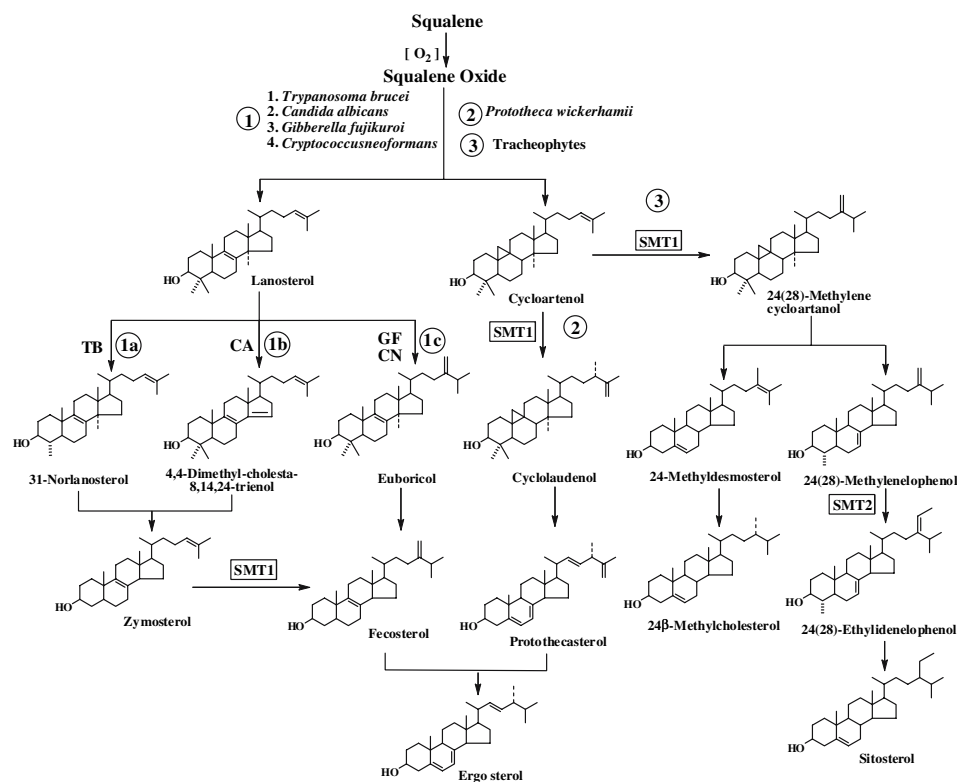

From a compound intervention standpoint, impaired activity that disrupts carbon flux would be

expected when substrates are produced on which the enzymes fail to catalyze; consequently, these substrates should become deleterious to the cell because they are present in abnormally high concentration and contain structural features harmful to membrane structure and function. This proposal has been confirmed in studies which show that impaired Erg11p activity can lead to an accumulation of lanosterol and 24(28)-methylene lanosterol in inhibitor-treated cells, causing these cells to die [4]. A related set of experiments has been performed with anaerobic yeast and a no-growth result occurred when cells were supplemented with lanosterol, consistent with the observations of the inhibitor-treated fungi. Although the activity of the 14 $\alpha$ -demethylase enzyme can be interrupted by azole treatment, thereby generating lanosterol in vivo, it is not necessarily the presence of the 14 $\alpha$ -methyl group [C32] on the back face of the sterol molecule that prevents proper sterol–lipid interactions in the lipid leaflet; rather it is more likely the presence of the C4-geminal methyl group on the sterol molecule that can perturb the hydrogen bonding ability of the C3-hydroxyl group in the membrane [12]. Removal of the C14-methyl group is necessary to allow for the introduction of the  $\Delta^5$ -bond in the nucleus, which can also have functional significance [10].

## Ergosterol Biosynthesis

In the early stages of formation, the synthetic pathway to fungal ergosterol uses an isoprenoid pathway to squalene oxide similar to the one involved in cholesterol formation (viz, the acetate–mevalonate pathway); thereafter the pathway can diverge into routes that are phylogenetically distinct based on whether the organism will synthesize lanosterol (animals and fungi) or cycloartenol (plants) (Fig. 2) [12, 13]. In most fungi and many protozoa, the following key transformations from lanosterol to ergosterol take place in the order: (1) methylation at C24; (2) demethylation at C4 followed by demethylation at C14; (3) double bond transformations in the nucleus from  $\Delta^8$  to  $\Delta^5$ , and (4) double bond transformations in the side chain at C24(28) and C22(23). The yeast *Saccharomyces cerevisiae* is an important exception; methylation at C24 occurs after C4-demethylation. In *Prototheca wickerhamii* there is an additional enzyme system not present in fungi that is involved in catalyzing the opening of the 9 $\beta$ ,19-cyclopropane ring in the cycloartenol structure characteristic of a plant pathway to ergosterol. Higher plants can also synthesize 24 $\beta$ -methyl sterols similar in structure to ergosterol but these are obtained through a different route (Path 3 in Fig. 2). They can also produce 24-ethyl sterols where the 24-ethyl group is stereochemically

**Fig. 2** Proposed general pathway for the biosynthesis of  $\Delta^5$ -phytosterols from the first tetracyclic sterol formed by the cyclization of squalene oxide, lanosterol or cycloartenol

opposite to the C24-methyl group in fungal sterol ergosterol (Path 3 in Fig. 2).

### Phytosterol Diversity

It has become increasingly evident that considerable variability can exist during the post-squalene stages of ergosterol (phytosterol) synthesis among microbes, and this may partially explain the different responses to sterol biosynthesis inhibitors in pathogenic organisms. In some cases, the organism's sterol content and/or composition and hence its synthetic pathway can undergo a marked change as a function of host–parasite interactions or from morphological switching of the single cell to the hyphal phase of growth. In order for these changes to occur in the sterol synthetic pathway, the relevant enzymes that compose the pathway must undergo a change in activity and/or transcript level accompanied by a change in protein level. In the parasite *Trypanosoma brucei*, which causes sleeping sickness, the protozoan form cultured on a lipid-deficient medium contains significant levels of 24-methyl sterols, whereas the main sterol is cholesterol in the bloodstream form; there are no detectable 24-methyl sterols in these cells [14]. Presumably, the cholesterol is absorbed from the host, causing the set of ergosterol enzymes in the parasite to be down-regulated. In a similar fashion, the opportunistic pathogen *Pneumocystis carinii*, isolated from its animal host, contains 31 sterols but no ergosterol; the main sterol cholesterol is also absorbed from the animal host [15].

In the phytopathogen *Gibberella fujikuroi*, 38 different sterols have been identified at different stages of development with multiple 24 $\beta$ -methyl sterol end-products produced, including ergosterol during mycelial growth [16]. In the fungal-like pathogen *P. wickerhamii*, the microbe can synthesize ergosterol by a cycloartenol-based pathway [13], whereas in the zygomycetous fungus *Mortierella alpina* [17], the major sterol synthesized by the mycelia is cholesta-5,24-dienol (desmosterol), with minor amounts of 24-alkyl sterols, suggesting that desmosterol is the membrane insert and the 24-alkyl sterol(s) is the “sparking” compound. In *M. alpina*, as reported for *P. carinii*, no ergosterol can be detected in the organism.

Several microbes have been found to utilize an unconventional phytosterol synthetic pathway that includes the ability to use a mevalonate-independent route to squalene [18, 19]. In the case of unconventional phytosterol side chain construction, multiple 24-alkyl sterol products are formed by sterol methyltransferase (SMT) catalysis in *T. brucei* [20], rather than a single

product as found in *S. cerevisiae* [21]. Other examples of unconventional phytosterol C-methylation pathways include formation of the  $\Delta^{25(27)}$ -olefins with a 24 $\beta$ -methyl group in *P. wickerhamii* [22] and in *T. brucei*, the formation of a 24-dimethyl group in trypanosomoid phytosterols [20], the formation of multiple C24-alkylated sterol side chains in *P. caranii* (analogous to the product outcome that has recently been found to be catalyzed by plant SMTs [23]), and the synthesis of the 24 $\beta$ -methyl group in 22,23-dihydrobrassicasterol in *G. fujikuroi* by a route distinct from the route to ergosterol [24].

A distinguishing feature of phytosterols is the SMT-catalyzed introduction of the 24-alkyl group. This class of catalyst can be appealing targets for the design of inhibitors to inhibit microbe growth, since they lie on a pathway that is essential to phytosterol formation and are absent from the sterol pathway in animals. SMTs are unique since they not only catalyze the C-methylation reaction stereospecifically and with a high degree of substrate specificity, but they can also provide a critical slow step that is used to regulate carbon flux in post-squalene pathway transformations [6]. Interestingly, when the SMT is blocked in certain pathogens it will promote the accumulation of lanosterol or cycloartenol analogous to the situation inazole-treated fungal cells [1–6]. Having identified the SMT as a biochemical target, we can now address what is known about its C-methylation reaction, enzymatic properties and tests involving substrate analogs, concluding with future directions that incorporate recent findings about reversible and irreversible inhibitors affecting SMT action and their potential use in medicine and agriculture.

### SMT: Steric–Electric Plug Model of Binding and Catalysis

The crucial C-methylation reactions that generate the parent phytosterol side chain skeletons are catalyzed by enzymes collectively known as sterol methyltransferases [25]. These enzymes bind a  $\Delta^{24}$ -sterol acceptor molecule and a methyl donor AdoMet cofactor to produce a 24-methylated (ethylated) sterol product and AdoHcy. The SMTs can be divided into two families based on their genetics and substrate preference for a sterol with a side chain structure of  $\Delta^{24(25)}$ -(SMT1) or  $\Delta^{24(28)}$ -(SMT2) [26]. However, largely based on our recent work which showed that SMT isoforms from different sources exhibit a high degree of substrate specificity for either zymosterol, cycloartenol, lanosterol and 24(28)-methylene lophenol, there has been a refinement of the

Enzyme Commission's (E.C.) classification of the reactions they catalyze [21]. By also considering the genetics and substrate specificity, the SMTs can be classed as follows; SMT1 zymosterol 24-methyltransferase (E.C. 2.1.1.41); SMT1 cycloartenol 24-methyltransferase (E.C. 2.1.1.142); (no E.C. number assigned for a lanosterol-binding SMT) and SMT2 24-methylene lophenol C-methyltransferase (E.C. 2.1.1.143). Therefore, in the E.C. classification of enzymes, SMT activity can be classified according to the catalytic mechanism of their active site into one of four mechanistic sets that involve the generation of a C-methyl- $\Delta^{24(28)}$ - and  $\Delta^{25(27)}$ -,  $\Delta^{23(24)}$ - and  $\Delta^{24(25)}$ -olefin. Although, as we will show below, SMT1 or SMT2 may be characterized by one of these catalytic mechanisms, this characteristic is not yet used in the E.C. nomenclature.

Since 1978, a series of investigations carried out using intact organisms and recombinant SMT by several research groups has greatly added to the present understanding of C-methyl transfer reactions catalyzed by SMT. In one case, the results support a nonstop (concerted) mechanism for the first  $C_1$ -transfer that produces a single product with a 24-methyl  $\Delta^{24(28)}$ -olefin, whereas the second series of studies provides the first evidence for a step-wise ionic mechanism for the second  $C_1$ -transfer, which generates multiple product sets such as those with a mixture of 24-methyl (or ethyl)  $\Delta^{24(28)}$ - and  $\Delta^{25(27)}$ -olefins. The stereochemical features on the path to the second  $C_1$ -transfer reaction were the same as those noted in the first  $C_1$ -transfer reaction [25]. Thus, the enzymatic transfer of a methyl group of AdoMet to a  $\Delta^{24(28)}$ -olefin acceptor sterol occurs on the *Si*-face of the original substrate double bond such that the C25 configuration obtained during the first  $C_1$ -transfer reaction is retained during the second  $C_1$ -transfer reaction. Based on the above considerations, related work with plant, fungal and protozoan SMT isoforms with unique sterol specificity, the results from other relevant biogenetic studies, and the conclusions drawn from model reactions [27], a general scheme for the first and second  $C_1$ -transfer methylation reactions has been proposed (Fig. 3) and embodied in the "steric–electric plug" model of sterol/AdoMet binding and catalysis [28] (Fig. 4).

This stereochemical model predicts the structural features of the sterol molecule needed to generate a productive Michaelis–Menten complex that includes a free  $3\beta$ -OH group, a planar tetracyclic nucleus, a side chain that orients to the "right" ( $C_{20R}$ -configuration) in a pseudocyclic conformation, and a double bond located at position C24. A related, central prediction of the model is that the ProE-26 of the  $\Delta^{24}$ -substrate derived from C2-MVA becomes the ProS-C26 of the

24-methyl(ene) product as a consequence of an  $S_N2$  type mechanism that involves  $\beta$ -face nucleophilic attack by the  $\pi$ -electrons of the  $\Delta^{24}$ -bond on the *S*-methyl group of AdoMet coupled to a stereospecific 1,2-hydride shift of H24 to C25 on the *Re*-face of the original substrate double bond (Fig. 4).

### C-Methylation Reaction Progress

The observed regiochemistry and stereochemistry of any particular sterol C-methylation reaction depends upon the precise amino acid contacts resulting in the active center with specific nucleophilic groups on the sterol acceptor. One approach to designing potent inhibitors of the SMT that can disrupt these interactions is to unmask the probable structure of the transition state of the chemical reaction catalyzed by the enzyme. Kinetic constants involved with catalytic efficiency,  $k_{cat}$  and  $k_{cat}/K_m$ , are measures of the stabilization of the catalytic transition state of the enzyme, where the  $K_d$ ,  $K_i$  and  $K_m$  values are measures of substrate/inhibitor binding affinity [29]; the term "transition state stabilization" is often used in the literature to refer to specific electrostatic interactions that are strengthened in the transition state. In the case of the yeast SMT-catalyzed reaction, one can envisage the involvement of a transient interaction in the activated complex between the C24 and C25 cationic intermediate(s) and the active site of the enzyme. Electrostatic interactions that occur in the SMT active site between enzyme and substrate can be disrupted by transition state analogs, such as 24(*R,S*)25-epiminocholest-8-enol, that possess a positively charged functional group at physiological pH. In our research laboratory we recently determined (for the first time for any enzyme that acts on sterol) the relevant kinetic constants to establish a free-energy diagram for an SMT enzyme-catalyzed reaction [6, 30]. As demonstrated schematically in Fig. 5, the reaction coordinate proceeds energetically uphill, from the binding interactions of the ground state (associating sterol and AdoMet) to the interactions of the activated complex (which involve stabilizing the making and breaking of chemical bonds associated with the methylation–deprotonation reaction, product formation, and then the release of the products from the enzyme)[6, 30].

In work carried out by the Strasbourg group [5], it was found that the high-energy intermediate [carbocation (**2** in Fig. 4)] generated at C25 during the methylation–deprotonation reaction could be replaced by a positively charged nitrogen atom (e.g., protonated form) introduced at C25 to mimic the structure of the

**Fig. 3** Proposed mechanism for the biosynthesis of phytosterols that generates successive mono and double C24-alkylation in the side chain from a  $\Delta^{24}$ -acceptor molecule. Deuterium-labeled

sterol side chains were studied to reveal the mechanism (adapted from [23, 32])

**Fig. 4** Steric–electric plug model of the sterol methyltransferase binding and catalysis of sterol and S-adenosyl-L-methionine (AdoMet). SMT sterol methyltransferase enzyme; *E* enzyme; *S* substrate or acceptor molecule; *P* C24-methylated product; *B* unidentified enzymic base; S-adenosyl-L-homocysteine (AdoHcy) (adapted from Parker and Nes in [28])

putative “charged” intermediate formed during catalysis. If the transition state stabilization is equated to the binding energy, a stable analog that mimics the structure of the transition state should bind to an enzyme more tightly than the native substrate, i.e., it should bind with a strength at least three orders of magnitude higher than that of the best substrate for the enzyme [5]. In support of this view, utilizing the yeast SMT we found that the  $K_m$  for zymosterol is 30  $\mu\text{M}$ , whereas a transition state analog and potent noncompetitive inhibitor of the C-methylation reaction, 24(*R,S*),25-epiminocholest-8-enol, generated a  $K_i$  value of 3 nM [31]. From the  $K_i/K_m$  values for the isostere cholest-8-enol and its “charged” counterpart 24(*R,S*),25-epiminocholest-8-enol [30], we calculate a  $\Delta(\Delta G)$  of 5.6 kcal/mol; this amount of binding energy reflects the contribution of electrostatic association to the total energy of formation of the inhibitor–enzyme complex in wild-type enzyme. In related work using a

plant SMT, Rahier et al. [5] reported a similar value for the  $K_m$  of cycloartenol and  $K_i$  values for 25-azacycloartenol in the micromolar and nanomolar range, respectively, as well as a value of 5.1 kcal/mol when comparing a similar set of inhibitors. However, the mechanistic work fails to show whether SMT actually lowers the activation energy for the making and breaking of bonds in the activated complex, or whether it simply forces the selection of a single reaction channel through the precise control of substrate conformation and the positions of counter ions that affect product outcome.

### SMT1 and SMT2 Isoforms

Over the past several years there have been remarkable advances in the study of SMT enzymes, because it has been possible to generate recombinant species of

**Fig. 5** A hypothetical free energy profile for the sterol methyltransferase-catalyzed activity representing the C-methylation reaction that proceeds through the formation of a high-energy chemical intermediate (activated complex) by way of a C24-

methyl C25-cationic [or that of a C24(25)-bridged carbenium ion] intermediate. Compounds 1–4 assayed with the enzyme and the experimental values provided in the energy diagram are taken from [6, 30]

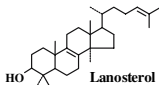

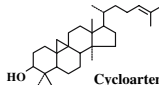

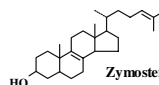

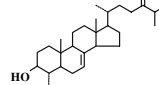

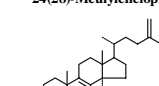

the native enzyme. Until now, the type and number of SMTs involved in catalyzing the product diversity observed in nature were not known. These enzymes had remained incompletely characterized until recently because of their low concentration in tissues, their membrane-bound nature and their lack of stability during purification efforts. Using cloned enzyme, it is now known that the pure SMT has unique properties that contribute to sterol specificity, kinetic and reaction properties, and to slow turnover, which serves to control carbon flux under physiological conditions. The cloned SMT from plant, fungi and protozoa possesses a pH that ranges from 6 to 8 with an optimum pH of 7.5, it is tetrameric with four identical subunits, and it has theoretical pI values that range from 5.4 to 7.5. The predicted molecular masses of the monomeric SMTs range from 38 to 43 kDa. The amino acid sequences deduced are reasonably similar to each other (21–78% identity), with 130–197 amino acids conserved in the primary structure [10, 21, 25, 27].

Fungi and protozoa have the genetics to express a single SMT (SMT1), whereas plants have a genome for SMT families and can express up to three SMT isoforms—one of the SMT1 type (C<sub>1</sub>-methylation activity) and two of the SMT2-type (C<sub>2</sub>-methylation activity) [21]; the different SMT activities possess different substrate properties and can produce various C24-methylated products. Both SMT1 and SMT2 from plants are currently known to be capable of performing either of the C<sub>1</sub>-transfer methylation activities, whereas the yeast SMT1 only performs the first C<sub>1</sub>-transfer methylation activity. The protozoa SMT1

can perform two C<sub>1</sub>-methyl transfers, but the doubly C24-alkylated product is different from that formed in plants [21]. There appear to be at least five sterol molecules that can serve as optimal substrate for the SMT, as shown in Fig. 6. In the case of fungi and protozoa, either lanosterol, 24(28)-methylene lanosterol (euboricol) or zymosterol are the preferred substrates of the enzyme. In the case of plants, cycloartenol or 24(28)-methylene lophenol are the preferred substrates for the enzyme. Equilibrium dialysis and time-dependent inhibition experiments indicate that the enzyme characteristically contains one active center with subsites for sterol and AdoMet. The turnover numbers for SMT1 and SMT2 are similarly slow, about 0.01 s<sup>-1</sup>, and the K<sub>m</sub> values for the optimal substrates for these enzymes are about the same, around 30 μM [20, 25, 27].

Biosynthetic pathways often involve enzymes that catalyze reversible bond formation, as determined for the Δ<sup>8</sup>- to Δ<sup>7</sup>-sterol isomerase. Alternatively, the plant SMT was found to act in an irreversible manner, with AdoMet binding predominantly in the forward direction. The enzyme activity responds to allostery; in soybean, the SMT1 is subject to down-regulation by the final product (K<sub>i</sub> of 65 μM), sitosterol (it is ergosterol in the case of yeast SMT1), but not by either cholesterol or ergosterol, and to up-regulation by physiological concentrations of ATP (400 μM) [25]. The position of SMT1 in, for instance, the soybean phytosterol pathway (in the first step), the relatively irreversible nature of the binding isotherm involving the cosubstrates, and the allosteric nature of the

**Fig. 6** Functional characteristics of the sterol methyltransferase in relation to sequence relatedness. SMT1 and SMT2 are distinguished by substrate specificity toward the  $\Delta^{24(25)}$ - and  $\Delta^{24(28)}$ -olefin side chain structure. The gene families are grouped into five distinct subfamilies based on sequence relatedness and substrate preference, as indicated in the figure (adapted from Nes et al. in [6, 21, 25])

SMT Classification	Substrate	Primary Catalytic Activity	Gene Family (Example)
SMT1	 Lanosterol	C <sub>1</sub> -transfer to 24,25-double bond	SMTc-fungal (Gibberella) (Cryptococcus)
SMT1	 Cycloartenol	C <sub>1</sub> -transfer to 24,25-double bond	SMTa-plant (Glycine)
SMT1	 Zymosterol	C <sub>1</sub> -transfer to 24,25-double bond	SMTb-fungal (Saccharomyces) SMTe-protzoan (Trypanosoma)
SMT2	 24(28)-Methylenlophenol	C <sub>1</sub> -transfer to 24(28)-double bond	
SMT2	 24(28)-Methylenlanosterol	C <sub>1</sub> -transfer to 24(28)-double bond	SMTc-fungal (Pneumocystis) (Glycine)

enzyme, together with the fact the SMT gives rise to the product diversity are all consistent with the SMT acting as the rate-limiting enzyme of phytosterol synthesis.

In cases where there is credible steady-state kinetic data for enzyme-catalyzed bisubstrate reactions, the yeast SMT1 is shown to proceed by a different reaction pathway than the one that operates for the plant SMT1 [23, 31]. In both cases, the cosubstrates, sterol and AdoMet, are bound to the enzyme at the same time at some point during the course of the reaction, forming a ternary complex. The possibility of the intervention of an X-group bound intermediate was eliminated experimentally; rather, for yeast a concerted addition–elimination C-methylation reaction was demonstrated kinetically [25]. In the yeast SMT1 case, a random ordered *bi bi* mechanism operates, where either substrate can bind first to the enzyme, and either product can leave first. For the plant SMT1, it was found that the AdoMet binds first to the SMT. Interestingly, the plant SMT1 can catalyze the second C<sub>1</sub>-transfer reaction in a mechanistically different way to the first C<sub>1</sub>-transfer, using a *bi ter* reaction to catalyze the  $\Delta^{24(28)}$ -substrate [32].

### SMT Sequence Relatedness

Over the past ten years, SMTs have been cloned, sequenced and purified from each of the major phylogenetic groups, including plant, fungi and protozoa.

Including the four families which represent enzymes of the SMT1 and SMT2 isoforms, sequences of another 60 SMTs are now available. Of the 383 amino acids in the *S. cerevisiae* SMT, 78 residues were completely conserved (21%) in those that we studied, including the SMT1-types *Glycine max*, *Cryptococcus neoformans*, and *Trypanosoma brucie* and the SMT2-type *Arabidopsis thaliana*. Overall, yeast SMT contains a distinct number of aromatic amino acids that are completely conserved (16 out of 47 with 34% identity), and two notable conserved regions of about ten amino acids each, referred to as Regions 1 and 3. In the yeast SMT, Region 1, which is highly hydrophobic with about 50% aromatic residues, spans Tyr81 to Phe91, and Region 3 spans Tyr192 to Pro201. Regions 1 and 3 are found only in the SMT, suggesting that they might have functional importance with respect to sterol biosynthesis. A third region that also contains ten amino acids, referred to as Region 2, spans Leu124 to Pro133. This signature motif is present in other AdoMet-dependent methyl transferases, where it is known to be part of the AdoMet binding site and therefore likely functions in the SMT structure in a similar fashion.

The possibility that several of the electron-rich aromatic residues with  $\pi$ -systems of indoles and phenyl groups might be part of the active center that directs the folding of the sterol side chain close to the AdoMet and contributes negative point charges that allow ion pairs to form, which could stabilize the developing cationic center(s) on the methylating substrate, was considered [25, 27]. The high degree of sequence

conservation in Regions 1–3 led us to perform leucine screening by site-directed mutagenesis of the aromatic residues in these regions [29–31]. We discovered that none of the conserved aromatic residues were essential to activity, but in the case of the *S. cerevisiae* SMT Tyr81 (Region 1) and Tyr192 (Region 3), substitution with a related aromatic amino acid can lead to altered substrate specificity, product formation and differential control of the first versus the second C<sub>1</sub>-transfer reaction, consistent with the hypothesis that aromatic amino acid residues at the active site play a crucial role in the C-methylation reactions. On the other hand, loss of activity was associated specifically with His-90 and Glu-195.

Chemical and photoaffinity labeling studies provided direct proof that Regions 1 and 3 are part of the sterol binding subsite and Region 2 is part of the AdoMet binding subsite. Supporting data, using site-directed mutagenesis, revealed that the aromatic amino acids of Regions 1 and 3 play a functional role in catalysis by managing reaction channeling that contributes to product diversity, whereas the histidine-90 residue in Region 1 and the glutamic acid-195 residue in Region 3 may act as the deprotonating agent and counter ion, respectively. According to Kyte–Doolittle hydrophathy plot analysis, the SMTs are moderately hydrophilic proteins without apparent membrane-spanning domains [25]. Thus, microsomal SMTs appear to associate weakly with membranes; this may explain the ease of solubilization from wild-type sources under mild conditions and their association with lipid droplets upon cell disruption.

### Substrate Analogs and Topological Considerations

Substrate, transition state and dead-end analogs tested with SMTs have long been useful for mapping the substrate specificity of the active site with regard to stereochemistry, three-dimensional shape, charge significance of functional groups or for determining the binding order of substrates and the molecular parameters of inhibition. In addition, we recently found that tight-binding SMT inhibitors can be used in an experimental strategy to determine the active enzyme concentration in wild-type cultured cells. The substrate specificity of SMT has been explored with a variety of analogs of zymosterol, cycloartenol and lanosterol. In a manner reminiscent of the forces involved in binding sterol to phospholipids in the membrane, the affinity of SMT for its substrates depends on polar interactions with the C3-hydroxyl group and C-24 double bond and nonpolar interactions with the nucleus and side chain.

The molecule must be flat and the sterol side chain oriented to the “right-handed” conformation for optimal catalysis. The most extensive investigations of analogs used to test a specific region of the SMT1 and SMT2 were performed in this laboratory using compounds that differed in a single structural modification associated with a specific domain of the putative native substrate, referred to as Domain A, B, C or D (cf. Fig. 1), as summarized in Structures 1–5. The SMT1 can accept either a 4-demethyl sterol, such as zymosterol, or a 4,4-dimethyl sterol, such as cycloartenol, depending on the source of the enzyme (fungus or plant, respectively).

### Structure–Activity Studies: Substrates

When using  $V_{\max}/K_m$  determinations as the measure of catalytic competence for substrates assayed with the SMT, the SMT1 from a fungus and plant was found to recognize the stereochemistry, bulk and polarity at C3 (and at C4) [25]. Structure 1 shows substrates with modifications in Domain A. The yeast SMT1 prefers compound 2 with a 3 $\beta$ -hydroxyl group that is unhindered by a neighboring methyl group [3] at C4. It also accepts compounds 4 and 6 in which the 3-OH group has been replaced with a related oxygen-containing group. Alternatively, the plant SMT1 prefers a substrate that possesses the 3 $\beta$ -hydroxyl group with C4 substituted by a geminal methyl group, compound 10. The plant SMT1 will also accept compounds 13 and 15, but not the related methyl ether (compound 14), which is the case for the yeast SMT1. The results imply that the active sites of these SMT1 enzymes differ with respect to specific contact amino acids that are involved in hydrogen bonding to Domain A of the sterol molecule. The plant SMT2, which is not as extensively studied as the SMT1 isoforms because it is difficult to generate test sterols with a  $\Delta^7$ -nucleus, has been shown to prefer C4-monomethyl sterols with a 3 $\beta$ -hydroxyl group (e.g., compounds 17 vs. 18) [32].

In Structure 2, modifications of the sterol nucleus that refer to Domain B are explored. Sterols with a  $\Delta^{8(9)}$ ,  $\Delta^7$  or  $\Delta^5$  nucleus (monoene or diene) are good substrates for the plant or fungal enzyme, with  $\Delta^{8(9)}$ -sterols being the optimal substrates. Alternatively, sterols with a  $\Delta^{8(14)}$ -nucleus are poor substrates. Dredging models reveal that  $\Delta^{8(9)}$ -sterols are flatter than the other sterols tested with the SMT. An unexpected finding was that the yeast SMT1 utilized both of the 14 $\alpha$ -methyl sterols tested (compounds 25 and 26), converting them to C24(28)-methylene product (as judged by HPCL radiocounting against appropriate reference

## Structure 1

specimens and GC–MS). Earlier speculations [5] that  $9\beta,19$ -cyclopropane plant sterols are bent in shape, that they produce  $24\alpha$ -methyl sterols as a direct consequence of C-methylation, but that they cannot be converted to a  $24\beta$ -methyl sterol product because of their three-dimensional shape (Fig. 7), indicated that the ring structures in these substrates were similar [33]. Since plant sterols that contain a  $9\beta,19$ -cyclopropane ring structure have been found to be “flat” in solution and the solid state [39], the enzymatic results obtained with the two substrates (compounds **25** and **26**) are consistent with one another. In a second set of activity assays using plant SMT1 from soybean and sunflower [23, 34], we discovered that by assaying the structural isomers with a  $\Delta^{24}$ -bond and a  $9\beta,19$ -cyclopropane group,  $\Delta^9-\Delta^8-\Delta^7$  (compounds **27** to **30** and **32**) or no double bond in the nucleus (compound **31**), the optimal substrate for the SMT contained a  $9\beta,19$ -cyclopropyl group whereas the corresponding saturated sterol (lanostanol) that can flex somewhat into various physiological conformations failed to bind productively, suggesting that double bond character is important for locking the nucleus into a preferred conformation for binding. Further modification of the ring by changing the structure of the A/B ring system from flat to bent (compound **34**) or inverting the centers at C13, C14 and C17 to rearrange the methyl groups in C/D ring

junctions and the stereochemistry of the 17(20) bond (compound **33**) eliminated productive binding of the substrate. These results are keeping with the proposal that the substrate must possess a specific flat shape to be catalyzed by the SMT [25].

In Structure 3, the structure and stereochemistry at C20 were tested using SMTs from *S. cerevisiae* and *P. wickerhamii* [22, 35]. First, compounds **35** and **37** (which place the sterol side chain into the “right-handed” conformation) were converted to methylated product, whereas compounds **36** and **38** (which orient the sterol side chain into a “left-handed” conformation) were not accepted as substrates. These results suggest that the natural  $20R$  configuration in the sterol side chain is crucial to SMT-catalyzed reactions. The SMT enzyme can also catalyze a reaction with the planar  $\Delta^{20(22)E}, 24$ -dienol substrate (compound **39**), which proves that tetrahedral character at C20 is not essential for sterol binding to the SMT.

In Structure 4, the sterol side chain structure has been modified in terms of double bond position, double bond character, length and heteroatom substitution [22, 35, 36]. The presence of a  $\Delta^{24}$ -bond is crucial to catalysis. However, as found by studying the binding abilities of the substrate cholest-8-enol (compound **48**,  $K_d$  of 10  $\mu\text{M}$ ), it binds somewhat less effectively than zymosterol (cholesta-8,24-dienol; compound **40**,  $K_d$  of

### Structure 2

4  $\mu$ M) and it can impair catalytic activity since it has a  $K_i$  of ca. 100  $\mu$ M, suggesting that sterol can compete in the active site with native substrate. Activity is lost when the double bond in the side chain is moved to the

### Structure 3

$\Delta^{22}$ - (compound **41**) or  $\Delta^{25}$ - (compound **42**) position, but the  $\Delta^{24(25)}$ -sterol can undergo methylation to product (compound **44**) [20]. Steric hindrance produced by the addition of a methyl group at C24 (compounds **44** and **51**) can prevent methylation of the  $\Delta^{24}$ -substrate [33]. However, compounds **44** and **51** can both inhibit the yeast SMT, suggesting that the yeast SMT active site has limited freedom to accept added bulk to the side chain. Moving the substrate double bond from  $\Delta^{24(25)}$ - to generate a  $\Delta^{24(28)}$ -acceptor prevents the substrate from undergoing methylation by the wild-type yeast SMT, but in the case of the native SMT1 from plants, the  $\Delta^{24(28)}$ -acceptor is recognized in the second  $C_1$ -transfer reaction; both of the methylation activities can occur at the same active center in plant SMT1 and SMT2 isoforms, suggesting distinct subsites for binding the  $\Delta^{24(25)}$ - and  $\Delta^{24(28)}$ -olefins. Conjugated double bonds in the side chain at C22 and C24 or at C24 and C26 are not harmful to activity. Upon testing compound **45** with a truncated side chain, a requirement for the terminal branch in the side chain becomes apparent. Upon testing a homolog, compound **46**, a modest lengthening of the chain by one carbon was found to be tolerated by the SMT. The latter observation is worth noting, since in the case of the methylene cyclopropane (compound **47** [37]) the

**Fig. 7** Alternative C-methylation reaction pathways that form  $24\alpha$ -methyl and  $24\beta$ -methyl sterols from substrates of possible distinct conformations: flat (lanosterol) or bent (cycloartenol);

work by the Nes research group discovered that the plant pathway illustrated does not operate in nature (adapted from Nes [25])

## Structure 4

substrate was methylated on the cyclopropane bridge-head C26 rather at C24, which is typical of all other  $\Delta^{24}$ -acceptor sterols. The  $\Delta^{24}$ -acceptor sterols catalyzed by the SMT were incorporated into the methylated sterol product regiospecifically; the methylene cyclopropane gave rise to a diene with double bonds at  $\Delta^{23}$  and  $\Delta^{25}$ , whereas all other  $\Delta^{24}$ -acceptors produced a  $\Delta^{24(28)}$ -olefin product.

The question of whether the 24,25-double bond in the sterol side chain could be replaced with an analog containing a fixed-locus nitrogen atom to mimic the developing olefin nucleophile of zymosterol by heteroatomic substitution of C24 or C25 has been examined with SMT from yeast, soybean and sunflower. Neither the azirdine-containing compound **54** nor its cyclopropane-containing surrogate (compound **52**) nor the 25-aza-containing side chain (compound **53**) were methylated by SMT, consistent with kinetic data that showed they were reversible inhibitors [35, 39].

The first studies directed at defining the structural parameters necessary for substrate recognition and subsequent initiation of the C-methylation reaction catalyzed by different SMT isoforms were confirmed and extended by examining the natures and magnitudes of inhibition (measured via experimentally determined  $K_i/K_m$  values) of a series of structurally related substrate analogs with nitrogen or sulfur introduced into the nucleus and/or side chain [35–40]. Using those nitrogen-containing analogs, which differ in a single structural feature but are otherwise similar to the natural substrate, and assuming that the recognition of an analog and natural substrate arises from a common set of enzyme interactions, it has been possible to identify and evaluate at least four critical structural elements of recognition involving the same

four domains reported before for the sterol structure. The principal determinant during binding appears to be associated with Domain A and the C3-hydroxyl group, since removal of the C3-hydroxyl group in the analog by replacement with hydrogen or by making a derivative of the C3-acetate alone is capable of non-competitively inhibiting the SMT at concentrations at least an order of magnitude lower than the inhibitor with the C3-hydroxyl group. The order of effectiveness of 25-azasteroids at inhibiting yeast SMT is 25-azazy-mosterol > 25-azalanosterol, and for plant SMT it is 25-azacycloartenol > 25-azacholesterol or 25-azalanosterol, consistent with the recognition of the sterol nucleus by the fungal and plant SMT1.

The stereochemistries at C20 and Domain C are also considered to be a major contributor to enzyme–substrate interactions for SMT isoforms. Consistent with earlier observations obtained using stereochemically varied substrates that show that the enzyme prefers 20*R*-sterols with the 20 $\beta$ -hydrogen atom (Structure 3), testing the diastereoisomeric pair of C20*R* and C20*S*-22-azacholesterols with side chain 20 $\alpha$ - or 20 $\beta$ -hydrogens, respectively (thereby placing the sterol side chain in a “left-handed” or “right-handed” conformation), revealed that the analog with the natural C20-configuration was a relatively potent noncompetitive inhibitor of SMT ( $K_i$  250 nM), whereas the analog with the unnatural C20 configuration was a weak competitive inhibitor of SMT ( $K_i$  1.2  $\mu$ M). The change in kinetic pattern suggests that the two inhibitors bind to different subsites in the active center of the enzyme.

The  $\Delta^{24}$ -bond associated with Domain D appears to be recognized electronically and specific to the natural side chain length, with a stringency paralleling that for the binding of the hydrophobic portion of the substrate

side chain. This follows from the observations that transition state analogs with a C25-nitrogen (in the salt form) inhibit the reaction three orders of magnitude more than the  $K_m$  for the natural substrate, as compared to the related inhibitor with an oxygen function (compound **64**) which failed to inhibit the reaction, and the 25-azasteroid with the terminal branch of the side chain was eliminated from the structure, producing a  $K_i/K_m$  value that was an order magnitude less than that of the corresponding natural 25-azasteroid.

### Structure–Activity Studies: Inhibitors

Structure 5 shows a set of inhibitors where modifications have been made to the structure and the location of the nitrogen atom along the lateral side chain. The “charged” aziridine compound **54** is more potent against the yeast SMT than any of the other inhibitors of similar structure for which compound **54** has been tested. The 24(28)-ethyl-containing aziridine, compound **55**, is less effective against the SMT than the 24(25)-aziridine inhibitor due to the added steric bulk at C24, which interferes with tight binding of the compound in the active site of the yeast SMT. The structure of the nitrogen—modified from a secondary amine (compound **54**) to a primary amine (e.g., compound **62**) to a tertiary amine (e.g., compound **61**)—had a significant effect on the inhibitor potency; the primary and tertiary amines were less potent by about an order magnitude than the secondary amine. Restricting rotation of the side chain by including a  $\Delta^{22}$ -bond (compound **60**) or by modifying the terminal branching in the side chain (e.g., compounds **61** and **63**) affected the binding such that these compounds were about an order magnitude less potent than the best inhibitor tested with the yeast SMT 24,(*R,S*),25-epiminocholest-8-enol. These results are consistent with the substrate preference for a  $\Delta^{24}$ -sterol and a distinct C-methylation mechanism performed by the yeast SMT; in this case,

the high-energy intermediate involves a bridged 24,25-carbenium ion, and the mechanism is short-lived and nonstop. On the other hand, in cases where the ionic C-methylation mechanism is rather long-lived and occurs step-wise to allow for a reversible hydride shift of H24 to C25, the C24,25-aziridine-containing inhibitor is less potent against the plant SMT than the 25-aza-containing compounds (e.g., compound **56**). When the C25-sulfur derivatives are prepared in the salt form [5, 35], they act in a similar fashion to C25-azasteroids and inhibit the SMT with equal effectiveness. The results described here provide strong suggestive evidence for the intermediacy of the predicted cationic species which the sulfonium and ammonium analogs were intended to mimic, and thus for the electrophilic nature and course of this reaction type.

The nitrogen atom can be moved toward the distal or proximal end of the sterol side chain, and the inhibitor will continue to bind quite well to the SMT. Inhibitors that contain a nitrogen function around C24–C25 usually impair catalysis between 1 and 50 nM. However, as the nitrogen atom is moved closer to C20, the inhibitor becomes less potent. When the inhibitor potency rises from the low nanomolar range to the low micromolar range, we observed that the kinetic pattern of inhibition changes from a noncompetitive-type to a competitive-type inhibition with respect to zymosterol. In a similar fashion the steroidal alkaloids solanidine and solasodine, which have the sterol side chain cyclized into a fifth ring and contain a nitrogen atom at about the equivalent of the C22–C23 position in the open extended side chain of cholesterol (Fig. 8), also generate a competitive-type kinetic pattern and will inhibit the enzyme in the low micromolar range [22, 36, 39]. The different  $K_i$  values and kinetic patterns of the various inhibitors tested with the SMT indicate that they possess different modes of binding in the active center.

It appeared possible that “charged” nitrogen-containing compounds (synthetically prepared or natural

### Structure 5

products) might serve as inhibitors of SMT until it was appreciated that these compounds lack specificity in terms of inhibiting enzymes of sterol biosynthesis, particularly during cholesterol synthesis [41–44]. For instance, the animal  $\Delta^{24}$ -reductase enzyme operates in a mechanistically similar way to the C-methylation reaction, so high-energy intermediate analogs with side chains shown in Structure 5 that inhibit SMT action should, and indeed have been found to, inhibit the animal  $\Delta^{24}$ -reductase. For instance, testing triparinol (a structural mimic of the natural products berberine and palmatine that inhibit SMT [45]) which, like 24(*R,S*),25-epiminolanosterol, can inhibit both the SMT and  $\Delta^{24}$ -reductase enzyme (Fig. 9) [33, 42], as an antihypercholesterolemic agent led to a range of side effects of sufficient severity to require withdrawal of the drug from the market [46]. The steroidal alkaloids from *Veratrum* (e.g., verazine) and *Solanum* steroidal alkaloids (e.g., solasodine) have good antifungal properties with  $IC_{50}$  values in the range 35–50  $\mu$ M [22, 47–49]. However, they can induce teratogenic effects in cows, causing malformations during embryonic development [50]. A further lack of specificity of these inhibitors is indicated by 25-azacholesterol binding to the human  $\Delta^8$ - to  $\Delta^7$ -isomerase with a  $K_i$  of 21  $\mu$ M [43], which might interrupt carbon flux in humans.

### Mechanism-Based Inhibition of SMT Catalysis

A final series of analogs related to the native  $\Delta^{24}$ -sterol acceptor molecule have been prepared for use

as possible mechanism-based inactivators to probe the topography of the active site, to serve as leader compounds for a new generation of antifungal/anti-parasitic agents, and for use as compounds to quantify active SMT concentrations in microbes and tissues. Figures 10 and 11 show hypothetical mechanisms for the inactivation of SMT by sterols with side chain modifications (including heteroatomic substitution with fluorine and sulfur or chemical alteration with novel olefin combinations to render them more electron-withdrawing), thereby allowing for the production of a unique reactive intermediate capable of trapping an enzyme nucleophile. Each of the side chain structures shown in Figs. 10 and 11 were prepared with a cycloartenol, lanosterol, desmosterol or zymosterol nucleus and the relevant inhibitor was tested with SMT from plant, fungus or protozoan [20, 32, 38, 40, 51–53, Song Z, Nes WD, unpublished data]. Our hypothesis is that mechanism-based inactivation of SMT requires ternary complex formation of the inhibitor followed by substrate methylation that undergoes rearrangement or delocalization to place a positive charge in a region of the active site that does not normally encounter electrophilic species. One or more of the resulting allylic cation species generated in the activated complex can serve as substrate to react with an active site base or nearby nucleophilic amino acid side chain, generating a covalent adduct with the enzyme. Alternatively, as in the case of the sulfur derivative (A, Fig. 11), the methylated intermediate may serve as a methyl donor to methylate an amino acid in the active site.

**Fig. 8** Representative natural products with a nitrogen in the structure that are found to inhibit fungal growth and to inhibit the sterol methyltransferase

**Fig. 9** Postulated similarity between the C-24 alkylation and reduction of the sterol side chain  $\Delta^{24}$ -bond and inhibition by a hypothetical transition state analog of the reaction mechanism; the substrate mimic 24(*R,S*),25-epiminolanosterol and the related compound triparanol with structural features that can mimic the hydrophobic part of the sterol nucleus and a charged nitrogen at the tail portion of the molecule that can mimic the protonated nitrogen group in the tail portion of the 24(*R,S*),25-epiminolanosterol side chain

**Fig. 10** Two possible mechanisms for the conversion of 26,27-dehydrozymosterol (DHZ) to methylated product and potential modes of inactivation by DHZ; of the two alternatives, only Path 2 is catalyzed by the SMT (adapted from Nes et al. in [38, 51])

As shown in Fig. 10, two possible mechanisms for the inactivation of yeast SMT by activity assay with 26,27-dehydrozymosterol can be envisioned. In Path 1, the analog is expected to bind normally to the SMT and undergo C-methylation at C24, as with the natural substrate zymosterol. The resulting high-energy intermediate containing a cyclopropyl cation should undergo facile electrocyclic rearrangement to the more stable allylic cation, in which a positive charge is generated at C26. Presumably, the C26 cation can be placed in the immediate vicinity of the enzymic base involved with the normal C28-deprotonation step, which generates fecosterol [cholesta-8,24(28)-dienol]. Since the allylic

cation cannot be discharged directly by deprotonation, and it is presumably shielded from capture by water, alkylation of the SMT can proceed to inactivate the enzyme. The mechanism illustrated in Path 2 involves the nucleophilic attack of a methyl group from AdoMet on the C26 methylene cyclopropane, leading to a cyclopropyl cation followed by ring opening and ring expansion. In this case, an alternative set of high-energy intermediates can be predicted, including (1) the secondary carbonium ion at C24, which can eliminate a proton directly from C23 to produce a  $\Delta^{23(24)}$ -bond, or the positive charge can be eliminated through covalent attachment with an enzyme base, or (2) during the

**Fig. 11** Proposed modes of inactivation of the SMT by substrate analogs designed to be mechanism-based inactivators

initial rearrangement a second high-energy intermediate is formed with C26 methylated by AdoMet and C27 generating a cation, which can then interact with a base from the enzyme. Ring strain and the rich  $\pi$ -electron density associated with the overlapping  $sp^2$  system make the cyclopropanoid susceptible to C-methylation from AdoMet and nucleophilic rupture, leading to selectivity with respect to the direction of bond cleavage shown in Path 2. Recent studies performed using wild-type and a Tyr81Trp mutant of the yeast SMT indicate that the mechanism-based inactivation process for 26,27-dehydrozymosterol-treated SMT follows Path 2 in Fig. 11 [30, 38]. The wild-type yeast SMT does not appear to produce significant amounts of the C25(26)-methyl, C25-OH product. However, by using the Tyr81Trp yeast SMT mutant it has been possible to show that the alternate high-energy intermediate that leads to the C25(26)-methyl, C25-OH product together with the other high-energy intermediate that leads to the C25(27)–C24-OH product will associate with Regions 3 and 1, respectively, to covalently modify the enzyme [30]. The methylene cyclopropane-containing substrate analog has been attached to the zymosterol and cycloartenol nucleus and the resulting mechanism-based inactivator tested with SMT1 and SMT2 from fungi, plant and protozoa. The SMT from each group was shown to catalyze the inhibitor to a similar methylated product. In addition, the SMT1 from soybean, yeast and *Trypanosoma* was strongly inactivated, with  $k_{\text{inact}}$  values of 0.3, 1.5 and 0.3  $\text{min}^{-1}$  observed,

respectively [20, 38, 51], whereas the SMT2 from *Arabidopsis* was inactivated ( $k_{\text{inact}}$  of 0.60  $\text{min}^{-1}$ ), and the yeast-like *Prototheca* SMT1 was not inactivated by the inhibitor [51, 52]. The variation in the recognition of the inhibitor by the yeast and yeast-like SMTs suggests that subtle differences exist in the topographies of the active sites of these enzymes. The results reported here provide, for the first time, a route towards active site labeling involving a substrate mimic that is complementary to the previously described use of 24-sulfur-containing sterols [35, 40, 54]; it is mechanistically relevant that the location of the cations generated during the catalysis of 26,27-dehydrozymosterol become spatially distributed in a segment of inhibitor that is different from the region on the natural substrate that forms a C25 cation during catalysis. Thus, this class of inhibitor should not necessarily be harmful to a  $\Delta^{24}$ -reductase reaction (and hence, we discovered the long sought after differential specificity in enzyme mechanism that can be used in the design of second-generation mechanism-based inhibitors containing multiple sites in the sterol molecule modified either via heteroatomic substitution or with another site developed to inhibit additional enzyme targets in sterol synthesis, which can serve as dual action drugs). Finally, the generation of a covalent adduct using 26,27-dehydrozymosterol is entirely consistent with the postulated carbonium ion mechanism for the C<sub>1</sub>-(wild-type yeast SMT) and C<sub>2</sub>-transfer activities (Tyr81Phe yeast SMT mutant).

The inhibitory properties of a set of rationally designed analogs were tested recently with plant and yeast SMTs [40, 51–53, Song Z, Nes WD, unpublished data]. As shown in Fig. 11, two inhibitors were constructed with side chains of heteroatomic substitution at C24 (**A** and **B**), and two inhibitors were constructed with side chains of multiple olefin character involving a  $\Delta^{24}$ -bond conjugated to a double or triple bond attached to a C26 appendage (**C** and **D**). In each case, the test compound inhibited one or more SMTs. The inhibitors exhibited an irreversible-type and time-dependent inactivation kinetic pattern against the SMTs tested. For the soybean SMT, the sulfur and fluorine-derivatives generated  $k_{\text{inact}}$  values of 0.3 and 0.1  $\text{min}^{-1}$ , respectively, and the 24,26-diene compound and 24,26-triple bond-containing compounds generated  $k_{\text{inact}}$  values of 0.2 and 0.1  $\text{min}^{-1}$ , respectively. Marked specificity toward these inhibitors was observed between the fungal and plant SMTs. For instance, the inhibitor with the 24,26-dienol side chain attached to either the zymosterol or the cycloartenol nucleus to ensure optimal binding generated a  $k_{\text{inact}}$  value of 0.2  $\text{min}^{-1}$  for soybean SMT and 0.3  $\text{min}^{-1}$  for *P. wickerhamii* SMT, whereas no detectable enzyme inactivation was observed following the assay of the 24,26-dienol-containing inhibitor with the yeast SMT, although in the latter case the inhibitor was turned over to 24-methylated product, as determined by MS and NMR characterization. These results suggest that the SMT-active sites of the different enzymes are subtly different. The proposed mechanism for inhibiting the sulfur derivative is different from that of the other analogs; the sulfur derivative is considered to undergo methylation and then serve as a substrate to methylate the enzyme active site (**A**, Fig. 11) [53]. Alternatively, the other inhibitors are considered to form an adduct with the enzyme during catalysis (**B**, **C** and **D**, Fig. 11). The results indicate that, as with assays using the other substrate and transition state analogs, interactions between the enzyme and the  $\Delta^{24}$ -bond in the sterol side chain appear to be the major binding forces that affect product formation, and this therefore provides a key site in the sterol structure for chemical modification in rational drug design.

An exciting new analytical method of quantifying proteins crucial to phytosterol synthesis has emerged from our work, which uses the knowledge that the mechanism-based inhibitors bind to the SMT in stoichiometric fashion. Thus, it has become possible to use these inhibitors, especially sterols constructed with the methylene cyclopropane-containing side chain, to determine the concentration of *active* SMT in organisms/tissues and to use this information to establish the

turnover number ( $k_{\text{cat}}$  values) for a specific enzyme system in an intact system. In *S. cerevisiae* cultured to the onset of growth arrest, the active SMT concentration was measured at 0.7 fg/cell, which contrasts with the total SMT concentration measured from the same preparations by Western blotting at ca. 5.0 fg/cell, and the cellular ergosterol content, determined to be 40 fg/cell by GC–MS (Song Z, Nes WD, unpublished data). In separate work, the turnover numbers of the yeast and soybean SMTs from microsome preparations of wild-type material were found to be in excellent agreement with that shown for the corresponding pure enzyme, at ca. 0.01  $\text{s}^{-1}$  (Song Z, Nes WD, unpublished data).

## Summary

The past few years have seen major advances in the design and testing of SBIs. The first generation of SBIs that target ergosterol-dependent diseases are a defined class of highly effective antifungal agents, whose common structural features are the presence of a nitrogen atom in the molecule and a greasy nature, possessing limited volume to fit the active site. The structures and mechanisms of action of those drugs are unrelated to the class of lead compounds under review here, many of which contain a nitrogen atom in the steroid frame; however, several of the azasteroids tested so far, which show good specific activities in the low nanomolar range in vivo and in vitro toward the SMT, are not suitable for commercial use because cholesterol synthesis can be affected in animals, causing side effects. In order to avoid the biological and mechanistic concerns related to azasteroid-treatment of enzymes of the cholesterol pathway, a second generation of sterol biosynthesis inhibitors—mechanism-based inactivators of SMT—are being developed as new alternatives for plant protection and for use as therapeutics. Moreover, these compounds could potentially be used in biochemical diagnostics to quantify active enzyme isoforms, since they can be prepared for specific enzymes of the phytosterol pathway and they can be used to probe the uniformity and differences in active site topography amongst SMTs of different origins. With the arsenal of sterol analogs available to us now, we can begin to address the many challenging mechanistic and evolutionary questions about sterol enzymes that still remain:

- What are the substrate–enzyme interactions involved in the initiation and termination of C-methylation?

- How is the active center organized to recognize acceptor molecule and inhibitor?
- Is there a critical amino acid in the active center that can be targeted for blockage via ligand binding to provide a species-specific drug?
- How and in what way has nature modified structural motifs in the SMT during the evolution of this class of catalyst to make them more or less susceptible to a mechanism-based inactivator?

Studies in progress in this and other research laboratories around the world will provide rationales to develop new lead inhibitors of SMT action.

**Abstract** Oxygenated derivatives of cholesterol and lanosterol, known as oxysterols, have consistently displayed significant activity as inhibitors of 3-hydroxy-3-methylglutaryl (HMG) CoA reductase, a key regulatory enzyme in sterol biosynthesis. We have developed the chemical syntheses of ring C oxysterols for evaluation as inhibitors of sterol biosynthesis. A key intermediate in the chemical synthesis was 3 $\beta$ -benzoyloxy-9 $\alpha$ , 1 $\alpha$ -epoxy-5 $\alpha$ -cholest-7-ene (**1**), whose structure was confirmed by X-ray crystallographic analysis and is presented herein.

## Introduction

As a class of compounds, oxysterols can be defined as sterols bearing a second oxygen function, in addition to that at carbon-3, and having an iso-octyl or modified

iso-octyl side chain. These compounds have demonstrated a variety of biological properties, including cytotoxicity, atherogenicity, carcinogenicity, mutagenicity, hypocholesterolemia, and effects on specific enzymes [1–3]. Widely distributed in nature, they have been found in animal tissues and food stuffs [1] and have been isolated from drugs used in folk medicines for the treatment of cancer [4–6]. A number of oxygenated derivatives of cholesterol and sterol intermediates in cholesterol biosynthesis in animal cell culture. The specific inhibition of cholesterol biosynthesis in mammalian cells by oxygenated derivatives of cholesterol and lanosterol has been shown in many cases to decrease cellular levels of HMG-CoA reductase, a key regulatory enzyme in sterol biosynthesis [7–12]. These observations suggest a regulatory mechanism which, by analogy to steroid hormone receptors and bacterial introduction-repression systems, requires a binding protein to recognize oxysterols and mediate subsequent cellular events. Evidence for the existence of a specific cytosolic receptor protein for oxysterols has been presented. After the activities of a number of sterol were evaluated, a good correlation was found between the actions of certain oxysterols on HMG-CoA reductase in L cells and their affinity for an oxysterol binding protein [11, 13, 14]. This oxysterol model for the regulation of cholesterol biosynthesis proposes that oxygenated derivatives of cholesterol or lanosterol are produced in cells as signal molecules that feedback and regulate enzymes of the cholesterol biosynthetic pathway [15–18].

The ring C oxysterols 5 $\alpha$ , 8 $\beta$ -cholest-7-ene-3 $\beta$ , 11 $\alpha$ -diol (**3**) and 3 $\beta$ -hydroxy-5 $\alpha$ -cholest-9-(11)-en-12-one (**8** and their 3-keto derivatives) were previously known to be effective inhibitors of HMG-CoA reductase [11, 19].

Lanosterol derivatives possessing a  $9\alpha$ -hydroxyl group were found to be less effective as inhibitors [19].  $3\beta$ -Hydroxy- $5\alpha$ -cholest-8-en-11-one (**12**), while demonstrating poor reductase inhibition, was found to be an effective inhibitor of tumor-cell growth and was shown to produce significant, but not sustained, hypocholesterolemic activity in laboratory animals [11, 20, 21].

Scheme 1 shows the chemical synthesis of the  $3\beta,11\alpha$ -diol **3** and its corresponding 3-keto derivative **4** [19]. Diol **3** was obtained from the hydroboration–oxidation of 7,9(11)-diene **2**. The diene intermediate **2** was prepared from 7-dehydrocholesterol [19]. Scheme 2 shows the chemical synthesis of  $3\beta$ -hydroxy-12-ketone **8** and its corresponding 3-keto and  $3\alpha$ -hydroxy derivatives **7** and **8**, respectively [19]. These 12-keto sterols were prepared from cholesterol [5]. The ring C oxysterols shown in Schemes 1 and 2 were found to be significant inhibitors of sterol synthesis and reduction of levels of HMG-CoA reductase activity in L cells [19]. Their inhibitory activity is shown in Fig. 1 [19].

In our continuing study, we have sought to prepare oxysterols and observe their activity as potential inhibitors as HMG-CoA reductase and sterol biosynthesis. Oxysterols in ring C have not been studied to the same degree as those found on the side chain and other regions of the steroid nucleus [11, 18]. Since the C ring of steroids is associated with biochemical pathways essential for mammalian growth and development it appeared to be worthwhile to study the effects of oxysterols of ring C further and observe their inhibitory activity on HMG-CoA reductase and their effects as hypocholesterolemic agents.

We have made additional examples of ring C oxysterols in our continuing studies of the hypocholesterolemic effects of 7-keto and 11-keto sterols [21]. The chemical synthesis of the key intermediate  $3\beta$ -benzoyloxy- $9\alpha,11\alpha$ -epoxy- $5\alpha$ -cholest-7-ene (**1**) and the corresponding 7-keto (**10**) and 11-keto (**12**) sterols derived from it are shown in Scheme 3 [21]. The key  $9\alpha,11\alpha$ -epoxide **1** was prepared from the corresponding 7,9(11)-diene **9**. The diene **9** was prepared from 7-dehydrocholesterol [21].

**Scheme 1** Synthesis of  $11\alpha$ -hydroxy- $\Delta^7$ -sterols and their derivatives (19)

**Scheme 2** Synthesis of  $11\alpha$ -hydroxy- $\Delta^7$ -sterols and their derivatives (19)

**Scheme 3** Chemical synthesis of ketosterols derived from 3β-benzoyloxy-9α,11α-epoxy-5α-cholest-7-ene (**1**) (R = C<sub>8</sub>H<sub>17</sub>)

In this present study, we were particularly interested in determining the absolute conformation of the epoxide in 3β-benzoyloxy-9α,11α-epoxy-5α-cholest-7-ene (**1**). Other steroids/epoxides in the C and O rings of steroids had been found to be in the α (down) configuration when they were obtained by peroxyacid oxidation of the corresponding alkene double bond (e.g. 3β-benzoyloxy-14α,15α-epoxy-5α-cholest-7-ene) [22, 23]. Based upon purely historical grounds, this was presumed to be an α-epoxide, although typical spectroscopic and chemical data were unable to confirm this. Since this epoxide is a sensible precursor for synthesis of additional ring C oxysterols and other related compounds, we initiated an X-ray crystallographic study of epoxide **1** to determine the configuration of the epoxy group as well as the orientation of the ancillary alkane (C<sub>8</sub>H<sub>17</sub>) side chain.

## Results and Discussion

Several cholesterol oxidation products and other oxidized sterol intermediates in cholesterol biosynthesis have been found to be potent inhibitors of sterol biosynthesis in various animal cells. The specific inhibition of cholesterol biosynthesis in mammalian cells by

**Fig. 1** Molecular structures of the two crystallographically independent molecules (**a** and **b**) present in the unit cell of 3β-benzoyloxy-9α,11α-epoxy-5α-cholest-7-ene (**1**) and their numbering scheme. The thermal ellipsoids are scaled to 50% probability

cholesterol oxidation products is thought to be an inhibition of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase activity, the key enzyme in cholesterol biosynthesis. These oxidation products appear to perturb cholesterol and fatty-acid homeostasis and contribute profoundly to the initiation of various diseases.

The three-dimensional structure of steroids plays a primary role in governing their interactions and activities. X-ray crystallographic studies provide the most reliable and precise data concerning molecular structure. By combining solid-state data with physical chemical data on structures in solution, a reasonable picture of the dynamic properties of steroids can be constructed. This information when combined with biochemical, pharmacological, and physiological data, give a better insight into the molecular mechanisms of biosynthesis, metabolism, membrane transport, receptor binding, and nuclear interaction [24].

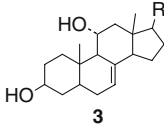

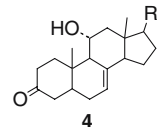

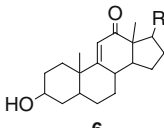

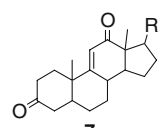

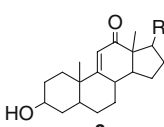

The three-dimensional structural details of hormones, drugs, and antibiotics determined by X-ray crystallographic techniques provide essential information on the global minimum-energy conformations of these molecules or local minimum-energy conformations that are very near the global minimum. X-ray data can be employed to define the most stable conformations of molecules, aid in the interpretation of solution spectra, and unambiguously assign the conformation of key intermediates allowing useful insight into the structure of further derivatives.

Indeed, **1** was confirmed to be an  $\alpha$ -epoxide with a C(9)-O(3)-C(11) angle of  $61.3^\circ$  which is consistent with other  $\alpha$ -epoxides [25]. As expected,  $\beta$ -epoxide conformation is disfavored due to the steric hindrance arising from the C(18) and C(19) angular methyl groups on the steroid nucleus. There are no unusually long contacts (e.g. hydrogen bonds) between the molecules in the unit cell and all bond lengths and angles are consistent with other structurally characterized oxysterols [25]. There are two independent molecules present in the unit cell that are nearly super-imposable with the only significant deviation being a  $67.9^\circ$  twist occurring at C25 (C125), C26 (C126) and C27 (C127) of the dimethylhexyl unit, which may be attributed to packing forces within the crystal.

## Methods and Materials

A small white oblique hexagonal prism was mounted on the end of a glass fiber. The unit cell was determined by centering 25 reflections in the  $2\theta$  range  $17$ – $28^\circ$ . Data were collected using the  $2\theta$ – $\theta$  scan

## Conclusions

In summary, we have developed the chemical syntheses of ring C oxysterols utilizing 3β-benzoyloxy-9α,11α-epoxy-5α-cholest-7-ene (**1**). Since this epoxide has the potential to be a key intermediate for the chemical synthesis of additional ring C oxysterols and other related compounds, it was necessary to unambiguously assign the absolute configuration. The results of a single-crystal X-ray diffraction study of **1** is described.

biguously assign the absolute configuration. The results of a single-crystal X-ray diffraction study of **1** is described.

# Phytosterols, Cholesterol Absorption and Healthy Diets

Richard E. Ostlund Jr

Received: 31 July 2006 / Accepted: 23 November 2006 / Published online: 9 January 2007  
© AOCs 2007

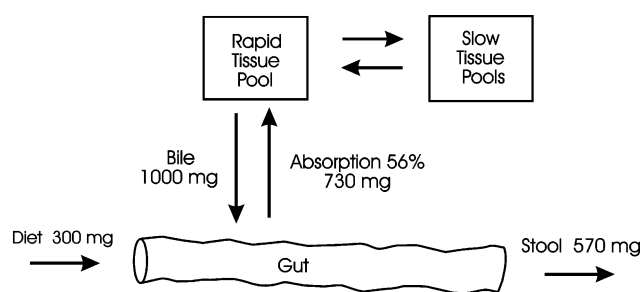

**Abstract** The purpose of this review is to outline the emerging role of dietary phytosterols in human health. Dietary saturated fat, cholesterol and fiber are currently emphasized in the reduction of low-density lipoprotein cholesterol levels. However, other dietary components such as phytosterols may have equivalent or even larger effects on circulating cholesterol and need further study with respect to the potential for coronary heart disease risk reduction. Phytosterol effects were not considered in classic fat-exchange clinical trials and may account for some of the differences attributed to the food fats studied. Phytosterols reduce cholesterol absorption while being poorly absorbed themselves and the effects can be studied in human subjects in single-meal tests using stable isotopic tracers. Because phytosterols are insoluble and biologically inactive when purified, careful attention needs to be given to ensuring that commercial supplement products are rendered bioavailable by dissolution in fat or by emulsification. Recent work shows that phytosterols in natural food matrices are also bioactive. The retention of phytosterols during food manufacturing and the use of foods with high phytosterol content may constitute an alternative to the use of supplements.

## Introduction

There is a scientific consensus that reduction of low-density lipoprotein (LDL) cholesterol is important for coronary risk reduction and specific recommendations for cholesterol monitoring and treatment in the general population have been made by the United States National Cholesterol Education Program [1]. Lifestyle variables, including diet and dietary supplements, are an important part of this initiative. A better understanding of how dietary sterols may relate to LDL cholesterol can be gleaned from Fig. 1, which sketches the framework of whole body cholesterol metabolism [2]. Dietary cholesterol intake is variable but is often less than 300 mg/day and currently 200 mg/day is recommended. Biliary cholesterol is larger and is the principal component of intestinal cholesterol. Approximately 25% of the plasma cholesterol production rate is due to absorbed dietary cholesterol while 75% is accounted for by endogenously synthesized cholesterol [3]. However, dietary cholesterol appears to be quite important because it and endogenous cholesterol biosynthesis are inversely correlated, suggesting that they are coregulated [4]. In contrast to other nutrients, for which gastrointestinal absorption is nearly quantitative, cholesterol absorption averages only 56% (Fig. 2) and is variable between individuals [5]. However, when measured repeatedly in the same individual under standardized conditions, percentage cholesterol absorption is highly reproducible [6]. This indicates that there may be substantial inter-individual differences in susceptibility to dietary sterols. Since the principal route for cholesterol elimination is excretion in the stool, the efficiency of cholesterol absorption is a critical determinant of cholesterol catabolism and

**Fig. 2** Distribution of percent cholesterol absorption in normal subjects. Taken from [5]

unabsorbed dietary and biliary cholesterol are the largest terminal components of what is often termed reverse cholesterol transport [2, 7, 8]. This model underscores the potential importance of increasing cholesterol catabolism and complements the pharmaceutical emphasis on reducing cholesterol biosynthesis with statin drugs.

### Types of Phytosterols

Phytosterols are structurally similar to cholesterol but have slight modifications of the aliphatic side chain [9, 10]. The principal molecular forms are sitosterol, campesterol and stigmasterol, and these may be esterified in the 3-position with fatty acids or ferulic acid. Since it is difficult to separate all the phytosterols in pure form in the amounts needed for clinical studies, there is relatively little information about the biological effects of

individual phytosterols and they are usually given as mixtures in clinical trials. Phytosterols are often categorized into classes consisting of  $\Delta^5$ -sterols and 5- $\alpha$ -reduced stanols, which appear to be equally effective in reducing LDL cholesterol [11]. Phytosterol glycosides are present in substantial quantities in many foods [12], but they are not cleaved efficiently by pancreatic enzymes *in vitro* so that their bioactivity has been questioned [13]. More work is needed to clarify the effectiveness of carefully purified and characterized phytosterols and their conjugates.

### Mechanism of Action

Phytosterols are thought to act primarily in the intestinal lumen. As cholesterol analogs they compete for cholesterol in absorptive micelles resulting in reduced solubility of cholesterol [14–16]. The affinity of plant sterols for micelles is greater than that of cholesterol [17]. In important human physiological studies the inclusion of phytosterols in a test meal resulted in the reduction of absorbable micellar cholesterol in duodenal aspirates [18]. An intraluminal site of action fits well with the small net systemic absorption of phytosterols, which varies by chemical structure.  $\Delta^5$ -Sterols such as campesterol and sitosterol have absorptions of 1.9 and 0.5% whereas stanols such as sitostanol have values as little as 0.04% [19]. A recent report of rapid and presumably transient absorption of phytosterols in an animal model [20] needs to be followed up since the low absorption figures cited above would not include those undergoing enterohepatic recycling with preferential biliary excretion. Although phytosterols have been proposed to have intracellular actions in enterocytes [21, 22], recent work has failed to show effects of phytosterols on cellular cholesterol transport proteins and the question of cell-based mechanisms remains open [23].

The reduction in cholesterol absorption by phytosterols is incomplete, with 30–40% decreases in absorption efficiency being reported even with high phytosterol doses [24, 25]. The prescription drug ezetimibe reduces cholesterol absorption by only 54% in humans [26]. These data open the possibility that there may be more than one pathway for cholesterol absorption and also suggest that more-effective methods of blocking cholesterol absorption need to be sought.

Phytosterols have a primary mechanism of action in the intestine, but these effects are mirrored in changes to circulating LDL cholesterol. Reduced delivery of absorbed cholesterol to the liver resulted in increased tissue LDL receptor expression as measured in

peripheral blood mononuclear cells [27]. In some subjects the production rate of LDL was decreased [28]. Further evidence of relative cholesterol deficiency after phytosterol treatment is the measured increase in whole body cholesterol biosynthesis of 38–53% [29]. This also demonstrates the rationale for using phytosterols with statin drugs.

### Phytosterol Supplements

Phytosterols, which are inherently hydrophobic and tend to form stable crystals, must be solubilized or formulated in order to become bioavailable [24]. Figure 3 demonstrates that dried unesterified sitostanol has very little immediate solubility in artificial bile salt micelles and even after many days the results are similar. But sitostanol emulsified with lecithin or other agents dissolves in the micelles in minutes. When unesterified sitostanol was administered to humans in pure crystalline form there was no significant effect on cholesterol absorption even at a dose of 1 g, but after formulation with lecithin cholesterol absorption was reduced by 37% [24].

Sitostanol/lecithin complexes reduced cholesterol absorption by 32–38% when administered to patients in test meals in nonfat beverages or egg whites and resulted in a 14.3% reduction in LDL cholesterol when taken for several weeks [30]. Other emulsifiers are also effective. Unesterified mixed phytosterols combined with sucrose ester and dispersed in milk reduced cholesterol absorption by 32% [31]. Food matrices themselves may be used as emulsifiers as demonstrated by direct addition of mixed unesterified phytosterols to orange juice at elevated temperature and pressure to

**Fig. 3** Solubility of dried sitostanol in artificial bile. Sitostanol was dried in either the absence (*open circles*) or presence (*closed circles*) of lecithin and then artificial bile was added for the time indicated. Taken from [24]

form a non-sedimenting product that reduced LDL cholesterol by 12.4% [32]. Since cholesterol needs to be in micellar form to be absorbed [33], it is likely that preparing phytosterols in micellar form would improve activity.

A common method of formulation is solubilization in fatty foods such as oils and margarines. In order to reduce the amount of fat needed the phytosterols are usually esterified with long-chain fatty acids to increase their solubility in food oils [34]. An analysis of cholesterol-lowering clinical trials showed a dose–response relationship with phytosterol dose and a maximum effect of about 10% lowering of LDL cholesterol at a dose of 2 g/day [10, 11]. The United States National Cholesterol Education program has recommended a dose of 2 g/day as a lifestyle change for reduction of LDL cholesterol and this is the level of effectiveness that can be expected from a properly formulated material. However, the consumer may not receive acceptable products because the United States Food and Drug Administration allows health claims for phytosterol supplements without requiring any demonstration of bioactivity.

Recent work has also focused on preparation of bioactive tablet or capsule formulations. Lecithin/stanol tablets reduced LDL cholesterol by 10.4% [35] and when added to statin drug treatment resulted in a further reduction of 9.1% in LDL cholesterol [36].

### Phytosterols Naturally Present in Foods

The quantity of phytosterols in natural diets is variable and values of 167–437 mg/day have been found in different populations [37–39]. Vegetable oils, breads and nuts have relatively large amounts while most fruits and vegetables have relatively little [40]. Whether or not food phytosterols would be important in achieving control of LDL cholesterol in communities is the subject of ongoing research, but existing work shows that cholesterol absorption can be significantly affected by the diet. The bioactivity of corn oil phytosterols was demonstrated by including corn oil containing 270 mg phytosterols in single-meal cholesterol absorption tests that also included labeled cholesterol [41]. Chemically purifying the corn oil triglycerides to remove phytosterols resulted in a 38% increase in cholesterol absorption and this was reduced to normal after adding the phytosterols back to purified oil. Corn oil containing as little as 150 mg phytosterols administered in a single meal had a statistically significant effect on reducing cholesterol absorption efficiency, suggesting that low levels might be more effective than previously thought. Similar results were obtained from

a study of the endogenous phytosterols of wheat germ. Cholesterol absorption was measured by including labeled cholesterol in a wheat germ muffin which contained 328 mg phytosterols [42]. Three single-meal tests were performed in the same individuals using either untreated wheat germ, selectively phytosterol-extracted wheat germ, or extracted wheat germ to which the phytosterols had been returned. Cholesterol absorption increased 42.8% when extracted wheat germ was used, and this was reduced to the original value when phytosterols were added back. These results show that phytosterols in low amounts in common foods can reduce cholesterol absorption (Fig. 4).

Many clinical trials have been performed to study the effect of food fats on serum LDL cholesterol levels. However, the phytosterol content of food oils, which is very high for vegetable oils and nil in animal fats [43], has been a confounding covariate which has not been adequately addressed in the literature [44]. For example, diets using polyunsaturated or monounsaturated fat often also contain increased amounts of phytosterols that might affect LDL cholesterol levels. Further complicating interpretation of diet studies is the lack of

**Fig. 4** Effect of endogenous wheat germ phytosterols on cholesterol absorption. Percent cholesterol absorption was measured in 10 subjects in random order on three occasions using single-meal tests consisting of a wheat germ muffin and labeled cholesterol. The wheat germ used was either the original untreated material, wheat germ from which phytosterols had been selectively extracted, or extracted wheat germ reconstituted with the original phytosterols. Plasma tracer enrichment of cholesterol reflects cholesterol absorption. *Asterisk* denotes  $P < 0.01$  with respect to the original wheat germ. Taken from [42]

complete food database reference data on the phytosterol content of foods, which makes estimation of phytosterol content difficult.

## Conclusions

Phytosterols are recognized as an important component of healthy diets and diets designed to reduce hypercholesterolemia. The United States National Cholesterol Education Program recommends dietary phytosterol supplementation of 2 g/day as a lifestyle modification for cholesterol reduction, and this will lower LDL cholesterol by approximately 10%. Phytosterols are inactive as supplied in pure form and must be solubilized or emulsified to achieve biological activity. The principal mechanism of action appears to be competition for absorbable cholesterol in the intestine, resulting in reduced cholesterol absorption. Potentially more important than supplements are natural dietary phytosterols, which may be bioactive in their natural food matrices. Work is needed to add information about phytosterol content to existing food databases and to extend the evidence that feeding phytosterol-rich foods improves LDL cholesterol.

**Acknowledgments** This work was supported by NIH grant R01-50420. Dr. Ostlund and Washington University have an interest in Lifeline Technologies, Inc., a company providing emulsified phytosterols.

**Abstract** Sterols, which are biosynthesized via the cytoplasmic mevalonate (MVA) pathway, are important structural components of the plasma membrane and precursors of steroid hormones in both vertebrates and plants. Ergosterol and cholesterol are the major sterols in yeast and vertebrates, respectively. In contrast, plants produce a wide variety of phytosterols, which have various functions in plant development. Although the general biosynthetic pathway to plant sterols has been defined, the details of the biochemical, physiological, and developmental functions of genes involved in the biosynthetic network and their regulation are not well understood. Molecular genetic analyses are an effective approach to use when studying these fascinating problems. Since three enzymes, 3-hydroxy-3-methylglutaryl CoA reductase, farnesyl diphosphate synthase, and lanosterol synthase, have been functionally characterized in planta, we reviewed recent progress on these enzymes. *Arabidopsis* T-DNA and transposon insertion mutants are now widely available. The use of molecular genetics, molecular biology, and bioorganic chemical approaches on these mutants, as well as inhibitors of the MVA pathway, should help us to understand plant sterol biosynthesis comprehensively.

**Keywords** Sterol · *Arabidopsis* · HMG-CoA reductase · Farnesyl diphosphate synthase · Oxidosqualene cyclase · Lanosterol · Cycloartenol · Phytosterol · Gene knockout · Isoprenoid

## Abbreviations

AACT	Acetoacetyl-CoA thiolase
CAS	Cycloartenol synthase
DMAPP	Dimethylallyl diphosphate
ER	Endoplasmic reticulum
FPS	Farnesyl diphosphate synthase
HMGR	3-Hydroxy-3-methylglutaryl-CoA reductase
HMGS	3-Hydroxy-3-methylglutaryl-CoA synthase
IPI	Isopentenyl diphosphate isomerase
IPP	Isopentenyl diphosphate
LAS	Lanosterol synthase
MVD	Mevalonate diphosphate decarboxylase
MEP	2-C-methyl-D-erythritol-4-phosphate
MK	Mevalonate kinase
MVA	Mevalonate
OSC	Oxidosqualene cyclase
PMK	Phosphomevalonate kinase
SQE	Squalene epoxidase
SQS	Squalene synthase

## Introduction

The occurrence of a wide variety of phytosterols demonstrates the diversity of plant species. To produce this variety of phytosterols, plants have evolved a steroid biosynthetic pathway that differs from that of vertebrates. All isoprenoids, including phytosterols, are biosynthesized from two common C5 isoprene units: isopentenyl diphosphate (IPP) and its isomer, dimethylallyl diphosphate (DMAPP). Unlike vertebrates, plants synthesize IPP and DMAPP via two

pathways: the cytosolic mevalonate (MVA) and plastidial 2-C-methyl-D-erythritol-4-phosphate (MEP) pathways. Although metabolites flow between them [1–3], the MVA pathway is the main route to the production of steroidal backbones [4, 5]. As shown in Fig. 1, steroidal backbones are biosynthesized in 11 steps from acetyl-CoA: (a) the conversion of acetyl-CoA into acetoacetyl-CoA catalyzed by acetoacetyl-CoA thiolase (AACT); (b) the conversion of acetoacetyl-CoA into 3-hydroxy-3-methylglutaryl-CoA by 3-hydroxy-3-methylglutaryl-CoA synthase (HMGS); (c) the conversion of 3-hydroxy-3-methylglutaryl-CoA into MVA by 3-hydroxy-3-methylglutaryl-CoA reductase (HMGR); (d) the conversion of MVA into phosphomevalonate by mevalonate kinase (MK); (e) the conversion of phosphomevalonate into diphosphomevalonate by phosphomevalonate kinase (PMK); (f) the conversion of diphosphomevalonate into IPP by mevalonate diphosphate decarboxylase (MVD); (g) the isomerization of IPP to DMAPP by IPP isomerase (IPI); (h) the condensation of DMAPP with IPP to form farnesyl diphosphate by farnesyl diphosphate synthase (FPS); (i) the tail-to-tail condensation of two farnesyl diphosphate molecules to form squalene by squalene synthase (SQS); (j) the oxidation of squalene to 2,3-oxidosqualene by squalene epoxidase (SQE); and (k) the cyclization of 2,3-oxidosqualene into cycloartenol or lanosterol by cycloartenol synthase (CAS) or lanosterol synthase (LAS), respectively. Although the plant sterol biosynthetic route is similar to that in vertebrates, plant sterol biosynthesis has characteristic features. The 12 kinds of enzyme that

catalyze these steps are encoded by 24 genes in *Arabidopsis*; plants often have multiple genes in some steps, such as AACT, HMGR, MVD, IPI, FPS, SQS, and SQE (Fig. 1). This is a major difference between plant and vertebrate sterol biosynthesis, as mammals generally have only a single gene for each enzymatic step. The presence of multiple genes implies that these genes possess different biochemical or physiological functions. As summarized in Table 1, however, the functions of many of the genes in these 11 steps have been analyzed in vitro only or by expression in bacteria or yeast, while no functional analyses have been conducted in planta. Only three steps, those encoding HMGR, FPS, and LAS, have been analyzed for function in planta. In this review, we highlight recent progress in these genes using molecular genetic studies.

### 3-Hydroxy-3-Methylglutaryl-CoA Reductase (HMGR)

The plant HMGR gene was first isolated from *Arabidopsis* by two research groups. Learned and Fink [6] isolated it via expression cloning in a yeast mutant deficient in HMGR, and Caelles et al. [7] did so using classical hybridization methods. Upon isolation of the first plant HMGR gene (*Arabidopsis HMGI*), orthologous genes from a large variety of plant species were subsequently isolated. Expression analyses of these genes in the 1990s revealed features of the plant HMGRs that distinguish them from their mammalian counterparts. The protein structure of plant HMGR is

**Fig. 1** The putative pathway of sterol biosynthesis in *Arabidopsis thaliana*. Arrows indicate 12 reactions corresponding to 11 steps from acetyl-CoA to cycloartenol or lanosterol. Abbreviations for the enzymes that catalyze these reactions are shown under each arrow. The numbers correspond to the numbers annotated to each gene, which encode these biosynthetic enzymes in Table 1

somewhat different from that of vertebrate HMGR. Although both plant and vertebrate HMGR are localized to the endoplasmic reticulum (ER), vertebrate HMGR possesses eight transmembrane domains, while plant HMGR possesses only two. Vertebrate HMGR is degraded through proteasomes after their transmembrane domains are ubiquitinated in response to high cholesterol levels. The mechanisms of plant HMGR homeostasis may differ from those of vertebrate HMGR.

First, plant HMGR genes constitute a multigene family [cf., two genes in *Arabidopsis* (*HMG1*, *HMG2*) [8], three in potato [9], and four in tomato [10], whereas HMGR is encoded by a single gene in mammals [11]. Second, plant HMGR genes are differentially regulated, which might lead to the biosynthesis of different types of isoprenoids; *HMG1* is expressed throughout the plant [8], whereas *HMG2* expression is restricted to meristematic and floral tissues, based on a tobacco heterologous expression system [12]. Choi and Bostock [13] reported that in potato, wounding and pathogens induce different antimicrobial isoprenoids (steroid glycoalkaloids and sesquiterpenoids, respectively), followed by the induction of different HMGR genes.

Despite these intensive studies, the role of each HMGR gene in plant development and metabolic

regulation of isoprenoid biosynthesis is unclear, as molecular genetics analyses of plant HMGRs have not been performed. Suzuki et al. [14] isolated *Arabidopsis* T-DNA insertion knockout mutants of *HMG1* and *HMG2*. *hmg1* mutant shows dwarfism, early senescence, and male sterility, which are consistent with its ubiquitous expression throughout the plant and a role as a housekeeping gene [8]. Brassinosteroids (BRs) and cytokinins (CKs) are isoprenoid-type phytohormones, which promote cell elongation and inhibit senescence, respectively. The dwarf and early senescence phenotype of *hmg1* is reminiscent of BR and CK deficiency in *hmg1*. However, *hmg1* did not show photomorphogenesis in the dark, the characteristic phenotype in BR-deficient mutants, indicating that *hmg1* is not a BR-deficient mutant [14]. Moreover, levels of CKs were not lower in *hmg1*, suggesting that CKs are not involved in the early senescence of *hmg1* [14]. Instead, these pleiotropic phenotypes were rescued by feeding the mutants with squalene, the precursor of sterols and triterpenoids. Indeed, levels of both sterols and triterpenoids were reduced in *hmg1* [14] (K. Ohya and T. Muranaka, unpublished data). Based on these results, it is clear that *HMG1*, which is shown to be responsible for the biosynthesis of sterols and triterpenoids, is important for plant development from vegetative through to reproductive stages.

What then is the function of *HMG2*? Based on the restriction of *HMG2* expression to meristematic and floral tissues, it was proposed that *HMG2* is important for cell division [12]. Under normal growth conditions, however, the *hmg2* mutant shows no obvious phenotype, suggesting that *HMG1* can compensate for the *HMG2* deficiency [14]. *HMGR2* seems to be a functional HMGR, as *hmg2* is more sensitive than the wild type to an HMGR inhibitor [14] and loss of both *HMG1* and *HMG2* is lethal (N. Nagata and T. Muranaka, unpublished data). *HMG2* might be involved in the production of specific isoprenoids in response to environmental stimuli such as light, drought, or pathogen attack. Metabolomic studies [15] on *HMG2*-overexpressing plants may be used to detect previously unknown isoprenoids. *HMG1* encodes two HMGR isoforms, *HMGR1S* and *HMGR1L* [16]. The subcellular localization of *HMGR1S* protein, a major isoform derived from *HMG1*, was recently analyzed in detail [17]. In contrast, the characteristics of *HMGR1L* and *HMGR2* have not been thoroughly investigated. Comparison of the subcellular localizations of these three proteins should prove interesting.

In vertebrates, HMGR is highly regulated on the transcriptional, post-transcriptional, and post-translational levels. The vertebrate HMGR gene contains an octameric *cis* sequence called the sterol regulatory element (SRE-1); sterol regulatory element binding proteins (SREBPs) are located in the ER but are cleaved in response to high cholesterol to produce active forms that migrate to the nucleus and regulate the expression of sterol regulatory genes such as HMGR [18]. SRE-1 and SREBP do not exist in plants, however, suggesting that the regulation of HMGR differs between the vertebrate and plant kingdoms.

Another approach to identifying the regulatory mechanism of HMGR is to isolate mutants that are resistant to the HMGR inhibitor, mevinolin (MEV). Rodríguez-Concepción et al. [19] screened for *Arabidopsis* MEV-resistant mutants based on leaf development. One of their MEV-resistant mutants, *rim1*, is a new allele of *phyB* (phytochrome B photoreceptor). The MEV-resistant phenotype of *rim1* resulted from the up-regulation of HMGR gene expression and thus increased enzymatic activity. The mutant is also resistant to fosmidomycin, which is an inhibitor of the MEP pathway. We are currently identifying and characterizing other mutants resistant to HMGR inhibitors based on a root elongation phenotype (K. Kobayashi and T. Muranaka, unpublished data), which will provide further insights into the unique HMGR regulation mechanism in plants.

## Farnesyl Diphosphate Synthase (FPS)

Farnesyl diphosphate (FPP) is formed by the sequential head-to-tail condensation of DMAPP and two molecules of IPP. The metabolic flow from IPP is slightly different between plants and vertebrates. In vertebrates, IPP is mainly metabolized to dolichols, ubiquinone, farnesylated proteins, and steroids via FPP but not isopentenyl adenine (tRNA). In plants, IPP is provided by both the cytosolic MVA and plastidic MEP pathways [20]. Plant IPP is metabolized to tRNA and CKs without going through FPP, but it is metabolized to dolichols, ubiquinone, farnesylated proteins, sesquiterpenes, and steroids via FPP. FPS is the great branching point in plants. Like HMGR, FPS is encoded by a multigene family in higher plants. Two genes, *FPS1* and *FPS2* [21, 22], encode three FPS isoforms, *FPS1S*, *FPS1L*, and *FPS2* [23], in *Arabidopsis*. *FPS1S* and *FPS1L* are both encoded by *FPS1*; *FPS1L* has an N-terminal extension of 41 amino acid residues with respect to *FPS1S* and is targeted to mitochondria [23]. *FPS1* was cloned by expression cloning in a yeast mutant deficient in FPS, *erg20*. The cDNA corresponding to *FPS2* was isolated using RT-PCR and its function was determined by complementation using *erg20*. The protein structure and molecular size of plant FPS are similar to those of vertebrate and yeast FPS.

The expression profiles of these two genes have been examined by Northern hybridization [22] and histochemical analyses using  $\beta$ -glucuronidase [24]. *FPS1S* is widely expressed in all plant tissues throughout development, suggesting a role for *FPS1S* in the synthesis of isoprenoids that are necessary for basic plant cell functions. In contrast, *FPS2* expression is restricted to specific organs at particular stages of development. The highest expression of *FPS2* has been observed in flowers, especially in pollen grains from the early stages of flower development. These results support a role for *FPS2* in the synthesis of specific isoprenoids with specialized functions. The expression profiles of *FPS1S* and *FPS2* are similar to those of *HMG1* and *HMG2*, suggesting that the physiological functions of *HMG1* and *FPS1S*, and of *HMG2* and *FPS2*, may be similar. If so, metabolites that are biosynthesized via HMGR1 and *FPS1* may be different from those produced via HMGR2 and *FPS2*.

When transgenic *Arabidopsis* plants overexpressing *FPS1S* were generated and characterized to investigate the physiological functions of *FPS1*, overexpression of *FPS1S* led to early senescence and reduced CK levels [25]. HMGR activity was not affected in this transgenic line. The CK zeatin, a phytohormone with strong antisenesescence activity, was biosynthe-

sized from IPP but not via FPP. These results indicate that reduced CK levels resulting from the overexpression of *FPS1S* may lead to early senescence. The details of CK biosynthesis were reported in 2004. While *trans*-zeatin, a bioactive form of CK, was predominantly biosynthesized via the MEP pathway, *cis*-zeatin, an inactive form, was biosynthesized via the MVA pathway [26].

In a subsequent paper examining *FPS1S* overexpression, Ferrer's group proposed a new hypothesis. As the activity of HMGR was not affected by *FPS1S* overexpression, the ratio of HMGR to FPS activity was drastically reduced in the transgenic plants. Because HMGR activity decreases with leaf age, the early senescence caused by *FPS1S* overexpression may be due to an imbalance between HMGR and FPS levels [27]. The authors demonstrated that the early senescence phenotype in the *FPS1S*-overexpressing *Arabidopsis* was rescued by co-overexpression of *HMG1*. *FPS1S* overexpression did not result in the overaccumulation of sterols, indicating that *FPS1S* is not limiting for sterol biosynthesis. It will be interesting to clarify which metabolites are affected by the imbalance of HMGR and FPS. Since the expression profiles of *FPS1S* and *FPS2* are different, suggesting different roles for *FPS1S* and *FPS2*, it will be important to examine knockout or knockdown mutants of these genes.

### Cycloartenol Synthase (CAS) and Lanosterol Synthase (LAS)

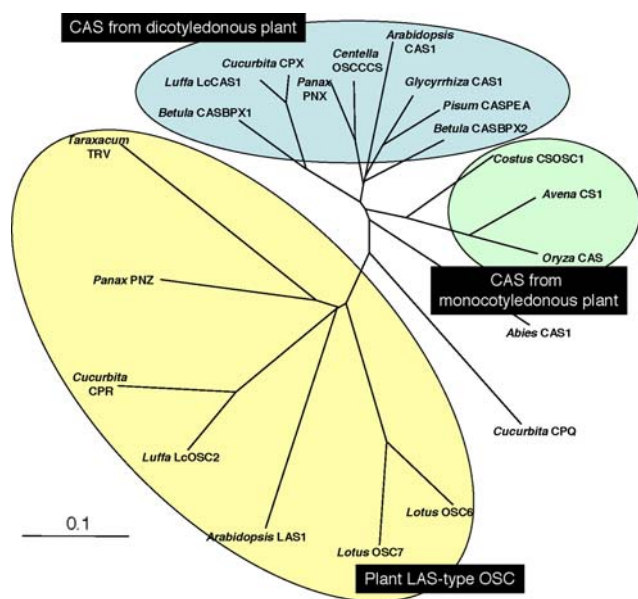

Sterols are 6,6,6,5-tetracyclic triterpene alcohols, which are formed by the cyclization of 2,3-oxidosqualene. This cyclization, which is catalyzed by oxidosqualene cyclases (OSCs), is one of the most complicated and fascinating reactions found in nature. While OSCs in vertebrates [28] and fungi [29] convert 2,3-oxidosqualene only to lanosterol, a sterol precursor, OSCs in plants convert 2,3-oxidosqualene to cycloartenol [30] and some other cyclic triterpenes [31]. Since plant triterpenes have diverse structures with more than 100 different carbon skeletons, plants have several genes encoding OSCs, including nine genes in rice and 13 genes in *Arabidopsis* [32]. Two of the 13 *Arabidopsis* OSCs are steroidal backbone synthases and others are nonsteroidal triterpenoid synthases [33].

For several decades, cycloartenol was thought to possibly replace lanosterol as the first cyclic triterpene during phytosterol biosynthesis [34]. The first cloned CAS gene was isolated from *Arabidopsis* in 1993 using a chromatographic screen of a heterologous expression

system [35]. This was the second OSC gene to be cloned, following the LAS gene from *Candida albicans* [36]. Following the cloning of *CAS1* from *Arabidopsis*, many cycloartenol synthase genes were isolated from dicotyledonous plants, such as *CASPEA* from *Pisum sativum* [37], *PNX* from *Panax ginseng* [38], *LcCAS1* from *Luffa cylindrical* [39], *GgCAS1* from *Glycyrrhiza glabra* [40], *CASBPX1* and *CASBPX2* from *Betula platyphylla* [41], *CPX* from *Cucurbita pepo* [42], and *OSCCCS* from *Centella asiatica*. Also isolated were *CSI* from *Avena strigosa* [43] and *CSOSCI* from *Costus speciosus* [44], both monocotyledonous plants, and *CAS1* from the gymnosperm *Abies magnifica*.

Despite the consensus that cycloartenol is the plant sterol precursor and the identification of CAS genes from many plant species, lanosterol has also been identified in some plants [45–47]. Since plants lack the ability to convert cycloartenol to lanosterol [48], lanosterol must be synthesized directly from oxidosqualene. In other words, LAS must be present in the plant kingdom. Very recently three laboratories independently identified LAS genes, including *LAS1* (also called as *LSS*) from *Arabidopsis* [49, 50], *PNZ* from *P. ginseng* [50], and *OSC7* from *Lotus japonica* [51]. *Arabidopsis* At3g45130 (*LAS1*) was previously postulated to be a CAS, based on its 77% similarity in amino acid sequence to *CAS1*. *LAS1* has been shown to complement LAS-deficient yeast [49, 50] and to function as a LAS in plant cells [50]. *LAS1* is the first plant OSC whose function has been verified in planta. *CAS1* mutant analyses demonstrated that Tyr410, His477, and Ile481 are important for CAS product specificity [52–55]. With just two amino acid substitutions, the CAS activity of *CAS1* (His477Asn and Ile481Val) is converted to LAS activity [56]. It is interesting to note that the amino acid residues of *LAS1*, *PNZ*, and *OSC7*, which correspond to His477 and Ile481 of *CAS1*, are Asn and Val, respectively. This is consistent with *LAS1*, *PNZ*, and *OSC7* having LAS rather than CAS activity.

Phylogenetic analyses showed that *LAS1*, *PNZ*, and *OSC7* belong to a branch that is most closely related to but distinct from the plant CAS branch (Fig. 2) [33, 42, 50, 57]. The plant LAS-type and CAS branches are different from other plant triterpenoid synthase branches. It has been proposed that other plant triterpenoid synthases, such as lupeol synthase and  $\beta$ -amyrin synthase, evolved in that order from ancestral CAS [41, 42]. Although CAS and LAS cyclize 2,3-oxidosqualene through chair–boat–chair conformations, other triterpenoid synthases cyclize 2,3-oxidosqualene through chair–chair–chair conformations. The differences in the primary structures of plant OSCs may reflect dif-

**Fig. 2** The phylogenetic tree of LAS1 homologous plant OSCs. The distance of each clone was calculated using the program CLUSTAL W. The indicated scale represents 0.1 amino acid substitution per site

ferences in their reaction mechanisms. Some other plant OSCs, such as TRV from *Taraxacum officinale*, CPR from *C. pepo*, LcOSC2 from *L. cylindrical*, and OSC6 from *L. japonica* belong to the plant LAS-type branch [49, 50, 57]. However, no LAS activity for these four OSCs has been identified [50, 51]. It may be worth noting that a conserved Asn residue is found in TRV (residue 451), CPR (residue 452), LcOSC2 (residue 453), and OSC6 (residue 454). The corresponding residue is a conserved Asp in other CAS and LAS enzymes (including plant, human, and yeast LAS), but is a conserved Asn in other triterpenoids synthases. TRV, CPR, LcOSC2, and OSC6 may thus represent intermediates in the evolution of plant LAS to other triterpenoid synthases.

Plant CAS and LAS genes have been cloned from many plant species, and their activities have been characterized in heterologous expression systems. Yet few biological functions of these genes have been determined. Only *Arabidopsis LAS1* has been characterized in planta. What determines whether 2,3-oxidosqualene is cyclized to cycloartenol, lanosterol, or other triterpenoids? What are the physiological and developmental functions of plant CAS and LAS? How are the expression patterns of the plant CAS and LAS regulated? All of these questions remain to be answered. Mutant analyses of *Arabidopsis cas1* suggested that the *cas1* homozygous mutant is lethal (M. Suzuki and T. Muranaka, unpublished data). This suggests

that the metabolites derived from cycloartenol are not necessarily the same as those derived from lanosterol. Whether sterol biosynthesis via lanosterol occurs in plants also remains to be determined.

In this review, we highlighted recent in planta molecular genetic studies of HMGR, FPS, and LAS. These three enzymes catalyze extremely important steps: HMGR is generally considered to be a regulatory enzyme in sterol biosynthesis, FPS acts at the important branching point in isoprenoid biosynthesis, and the presence of LAS shows the two routes of steroidal backbone synthesis in plants. However, previous research progress is insufficient for a comprehensive understanding of plant sterol biosynthesis. Important steps are highly regulated by multiple genes other than HMGR, FPS, and LAS. For example, seven genes encode SQE (Table 1; Fig. 1). Why does *Arabidopsis* need so many SQE genes? What are the differences between the biochemical and physiological functions of the SQE genes? Much research is needed to answer these questions. T-DNA and transposon insertion mutants of *Arabidopsis* are now widely available from several public services [67–69]. Studies of these mutants and inhibitors of the MVA pathway, using molecular genetics, molecular biology, and bioorganic chemistry, should help us to more fully understand the pathways of plant sterol biosynthesis.

**Acknowledgments** We thank Kiyoshi Ohyama (RIKEN) and Hubert Schaller (CNRS) for valuable discussions, and Robert Moreau (USDA) and Thomas Bach (CNRS) for the opportunity to review this topic. # Formation of Triterpenoids throughout *Olea europaea* Fruit Ontogeny

Naim Stiti · Saïda Triki · Marie-Andrée Hartmann

Received: 5 October 2006 / Accepted: 30 November 2006 / Published online: 12 January 2007  
© AOCS 2007

**Abstract** Drupes were handpicked from olive (*Olea europaea* L.) trees, cv chemlali, at 13 distinct stages of fruit development, referred to as weeks after flowering (WAF), and analyzed for their free and esterified sterols and triterpenoids content. These two classes of compounds are synthesized via the acetate/mevalonate pathway and share common precursors up to oxidosqualene (OS). Cyclization of OS in either cycloartenol or  $\beta$ -amyirin constitutes a branch point between primary (sterol pathway) and secondary (triterpenoid pathway) metabolisms. At the onset of fruit development, i.e., between 12 and 18 WAF, drupes were found to contain high amounts of  $\alpha$ - and  $\beta$ -amyirins as well as more-oxygenated compounds such as triterpenic diols (erythrodiol and uvaol) and acids (oleanolic, ursolic and maslinic acids). Concomitantly, sterol precursors were barely detectable. From 21 WAF, when the olive fruit reached its final size and began to turn from green to purple,  $\alpha$ - and  $\beta$ -amyirins were no longer present, while 4,4-dimethyl- and 4 $\alpha$ -methylsterols started to be formed, indicating a redirection of the carbon flux from the triterpenoid pathway towards the sterol pathway. Between 21 and 30 WAF, sterol end products, mainly

represented by sitosterol, progressively accumulated and triterpenic diols were replaced by triterpenic acids, essentially maslinic acid. Interestingly, the developing olive fruit was found to accumulate significant amounts of parkeol as an ester conjugate. Whatever the stage of development, triterpenoids represent the major triterpenic compounds of the olive fruit.

**Keywords** *Olea europaea* · Olive fruit development · Triterpene synthases · Non-steroidal triterpenoids · Oleanane triterpenoids · Sterols · Ester conjugates

## Abbreviations

$\beta$ AS	$\beta$ -Amyrin synthase
CAS	Cycloartenol synthase
HPTA	Hydroxy pentacyclic triterpenic acid
OS	Oxidosqualene
RRT	Relative retention time
TAG	Triacylglycerol
WAF	Week after flowering

## Introduction

Besides sterols, higher plants produce a vast array of non-steroidal triterpenoids. Over 100 different carbon skeletons are known and further oxidative modifications and glycosylations generate even more diversity [1–3]. Despite the increasing interest in the wide range of biological properties of plant triterpenoids and their derivatives for human health [4–7], their roles and functions *in planta* still remain poorly understood. Sterols and non-steroidal triterpenoids are synthesized via the cytoplasmic acetate/mevalonate pathway and

Part of this work was presented at the 97th Annual Meeting of the AOCS in Saint Louis, Missouri, April 30–May 3, 2006.

share common biosynthetic precursors up to (3*S*)-2,3-oxidosqualene (OS) [8, 9]. Then, OS serves as a substrate for various OS cyclases, also called triterpene synthases. Cycloartenol synthase (CAS, EC 5.4.99.8) cyclizes OS folded in the pre-chair-boat-chair conformation via the protosteryl cation into cycloartenol, the first cyclic precursor of the sterol pathway, whereas non-steroidal triterpenoids are assumed to be formed from OS folded in the all-pre-chair conformation (see Scheme 1). As an example,  $\beta$ -amyrin synthase ( $\beta$ AS, EC 5.4.99) catalyzes the cyclization of OS into  $\beta$ -amyrin (olean-12-en-3 $\beta$ -ol), one of the most commonly occurring triterpenes. By generating four or five rings and several asymmetric centers in a single step, the OS cyclization reaction is thought to proceed through a series of rigidly held carbocationic intermediates [10]. As shown in Scheme 1, the proton-initiated cyclization first produces the tetracyclic dammarenyl C-20 cation, and the subsequent rearrangement leads to the pentacyclic oleanyl cation via the baccharenyl and lupenyl cationic intermediates. Finally, a series of 1,2-hydride shifts, with elimination of the 12-*pro-S* or 12-*pro-R* proton gives  $\beta$ - or  $\alpha$ -amyrin, respectively. Up to now, several triterpene synthase complementary deoxyribonucleic acids (cDNAs) have been cloned from plant sources and their enzyme functions identified by het-

erologous expression in yeast [11–14]. These studies have shown that most of these triterpene synthases, like other terpene synthases, are able to simultaneously form a vast array of products (up to 10) from OS [15]. They are called multifunctional and each product might result from the stabilization of a specific carbocationic intermediate [12]. Non-steroidal triterpenes are then metabolized into more-oxygenated compounds, which serve as substrates for synthesis of triterpenic saponins [16]. As the cyclization of OS to sterols and non-steroidal triterpenoids represents a branch point between primary and secondary metabolisms, triterpene synthases are attractive tools for investigating physiological roles of non-steroidal triterpenoids.

The aim of the present study is to shed more light on the biosynthetic relationships between sterol and triterpenoid pathways in *Olea europaea* L. throughout fruit development. The olive tree leaf and olive oil have been known for a long time to contain a variety of sterols and triterpenoids, including erythrodiol, oleanic acid and maslinic acid, which are oxygenated derivatives of  $\beta$ -amyrin [17–19]. However, very little attention has been paid so far to sterol and triterpenoid metabolism in developing drupes, mainly because of the low content of these compounds (around 1%)

**Scheme 1** Postulated biosynthetic pathway of non-steroidal triterpenoids in *Olea europaea* fruit. CCC and CBC refer to the all-pre-chair and pre-chair-boat-chair conformations of OS, leading to non-steroidal triterpenes and sterols, respectively. The

postulated carbocationic intermediates are represented in *brackets*. The width of the arrows reflects the relative proportions of the carbon flux between the different families of products

compared to triacylglycerols (TAGs) and the long maturation period of the olive fruit (6–7 months).

Batches of drupes were collected from olive trees belonging to the prominent Tunisian cultivar, Chemlali, at various stages of ripening, referred to as weeks after flowering (WAF), and analyzed for their content of free and esterified sterols and triterpenoids. The present results provide evidence for a complex regulation process of the carbon flux between sterol and triterpenoid pathways taking place at the OS cyclization step, a process also controlled by the acylation of intermediates and end products.

## Materials and Methods

### Plant Material

Batches of olives were handpicked from olive (*Olea europaea* L.) trees, cv Chemlali, at 13 distinct stages of development, referred to as WAF. Olive fruit were stored at  $-80\text{ }^{\circ}\text{C}$  until use. Fruit from two consecutive harvests (2003–2004) were analyzed, but data presented here correspond to only one set of analyses.

### Isolation of Total Lipids

After lyophilization, olives from each batch (between 1.4 and 2.7 g of dry weight) were ground in liquid nitrogen, and then homogenized with an ultra-turrax in the presence of dichloromethane/methanol (2:1 by volume). Total lipids were extracted twice by heating under reflux at  $65\text{ }^{\circ}\text{C}$ , for 2 h. The combined organic phases were filtrated and evaporated under reduced pressure. Analyses were performed on the third of each extract.

### Sterol Analysis

Free sterols and esterified sterols were isolated as previously described [20]. Briefly, total lipids were applied to 60 F<sub>254</sub> (Merck, Darmstadt, Germany) silica gel thin-layer chromatography (TLC) plates developed with dichloromethane (two runs). The bands corresponding to squalene and sterol esters ( $R_f$  0.95), to 4,4-dimethyl- ( $R_f$  0.4), 4 $\alpha$ -methyl- ( $R_f$  0.35) and sterols ( $R_f$  0.25) were scraped off and compounds eluted from silica with dichloromethane.

Squalene was separated from sterol esters by TLC with cyclohexane/toluene (19:1 by volume) as the developing solvent. Squalene ( $R_f$  0.4) was directly analyzed by gas chromatography (GC) whereas sterol

esters ( $R_f$  0.2) were hydrolyzed by heating at  $90\text{ }^{\circ}\text{C}$  for 1 h with 6% (wt/vol) KOH in methanol (2.5 mL). After addition of water (1 vol), sterols were extracted three times with hexane (3 vol) and separated into 4,4-dimethyl-, 4 $\alpha$ -methyl- and 4-desmethylsterols as described above.

Free sterols and sterols released from ester conjugates were acetylated with acetic anhydride/pyridine (2:1 by volume). Acetate derivatives were then purified and analyzed by GC using a Varian GC, model 8300, equipped with a flame ionization detector (FID) and a DB-1 capillary column (25 m  $\times$  0.32 mm i.d., 0.25  $\mu\text{m}$  thickness, J&W scientific), with H<sub>2</sub> as the carrier gas (2 mL/min). The temperature program included a fast rise from 60 to  $230\text{ }^{\circ}\text{C}$  ( $30\text{ }^{\circ}\text{C min}^{-1}$ ), a slow rise from 230 to  $280\text{ }^{\circ}\text{C}$  ( $2\text{ }^{\circ}\text{C min}^{-1}$ ), and a plateau at  $280\text{ }^{\circ}\text{C}$  for 10 min. Free cholesterol was used as an internal standard. The standard deviation (SD) for quantitative determinations was  $\pm 5\%$ . Sterol acetates were identified by gas-chromatography mass-spectrometry (GC-MS) analyses performed on an Agilent gas chromatograph equipped with an on-column injector and a DB-5 (J&W Scientific) capillary column (30 m  $\times$  0.25 mm, i.d.) and interfaced to a 5973 MSD using electron impact at 70 eV. Spectra were compared to those of authentic samples or our own reference sterols or to literature data [21].

### Triterpenoid Analysis

Free and esterified triterpenoids were isolated from the total lipid extract by TLC with dichloromethane as the solvent (two runs). Under these conditions, triterpenic diols ( $R_f$  0.1) were separated from free tetra- and pentacyclic triterpenes ( $R_f$  0.4) and esterified triterpenes ( $R_f$  0.95). Identification of lupenone ( $R_f$  0.6) and 3-*epi*-lupeol (3 $\alpha$ -lupeol) ( $R_f$  0.5) required the preliminary hydrolysis of TAGs.

Tetra- and pentacyclic triterpenes as well as triterpenic diols were acetylated, purified by TLC and identified by GC and GC-MS under similar conditions as sterol acetates, using free cholesterol as an internal standard. For triterpenic diacetates, the final temperature at  $280\text{ }^{\circ}\text{C}$  was held for 25 min instead of 10 min. Standards were prepared from commercially available uvaol (Sigma), erythrodiol and betulin (Extrasynthese).

Hydroxy pentacyclic triterpenic acids (HPTAs) were isolated according to the method of Pérez-Camino and Cert [22] with some modifications. Briefly, total lipids were firstly dissolved in tetrahydrofuran (THF), and then loaded on a bonded aminopropyl phase solid-phase extraction (SPE) cartridge, which

had been pretreated successively with methanol (3 mL), acetone (3 mL) and hexane (4 mL). The column was washed with hexane/dichloromethane (90:10 by volume), to eliminate hydrocarbons, waxes and TAGs, then with hexane/ethyl acetate (40:60 by volume), to discard alcohols, sterols, and diacylglycerols. Finally, HPTAs and free fatty acids were eluted from the cartridge with diethyl ether/acetic acid (98:2 by volume). The solvent was evaporated until dryness and the residue was treated with ethereal diazomethane, at 0 °C for 1 h. After removing the methylation reagent with a nitrogen flow, the corresponding methylesters were acetylated and purified by TLC (mono-acetoxymethylesters,  $R_f$  0.65; diacetoxymethylesters,  $R_f$  0.4). A standard of oleanolic acid methylester was run under the same conditions. Acetate derivatives of methyl esters were analyzed by GC under similar conditions as triterpene diacetates, but with oleanolic methylester as internal standard and a slightly different temperature program (from 60 to 240 °C, at 40 °C min<sup>-1</sup>, then from 240 to 300 °C at 2 °C min<sup>-1</sup> and a plateau at 300 °C for 25 min). Non-steroidal triterpenoids were identified by their relative retention time (RRT) in GC on DB-1 or DB-5 columns and by GC-MS. Spectra were compared to those of available authentic samples (acetate derivatives of oleanolic, ursolic and betulinic methyl esters prepared from the corresponding free acids provided by Sigma, Aldrich and Extrasynthese, respectively) or to literature data [23, 24].

#### Chemical Synthesis of 3-*epi*-lupeol

Lupenone (Extrasynthese, 10 mg) was dissolved in absolute ethanol and stirred in the presence of an excess of NaBH<sub>4</sub> for 2–3 h at room temperature. The reaction was stopped with addition of 3N HCl to eliminate NaBH<sub>4</sub>, and the mixture extracted with hexane. After TLC with dichloromethane as the solvent (two runs), 3-*epi*-lupeol ( $R_f$  0.5) was separated from lupeol ( $R_f$  0.4). The yield of the reaction was about 25%.

## Results and Discussion

Drupes (i.e. the whole fruit comprising the epicarp, the fleshy mesocarp and the endocarp or pit containing the seed) were harvested from *Olea europaea* L. trees, cv Chemlali, at 13 distinct stages of fruit growth and development corresponding to 12, 13, 15, 16, 18, 21, 23, 25, 27, 29, 30, 32 and 33 WAF. At the time of harvesting, the lignification of the olive endocarp had ended. Between 12 and 18 WAF, drupes were green

and progressively increased in size and fresh weight, but in the case of this cultivar, these changes were of limited amplitude compared to other olive varieties. At the end of this period, the final fruit size was almost fixed and from 21 WAF, epidermal color began to change, coinciding with the start of the synthesis of anthocyanins and loss of chlorophylls [25]. The olive fruit gradually turned from green to black. Complete maturity was observed after 29 WAF. The 33 WAF stage referred to an over-mature stage.

Drupes from the different batches were analyzed for their content of free and esterified sterols and triterpenoids, but only data obtained for olive fruit harvested at 12, 18, 21 and 30 WAF are presented here.

### The Olive Fruit Contains a Vast Array of Triterpenoids and Sterols

#### *Non-steroidal Compounds (Table 1)*

Most OS cyclase products co-migrate on TLC plates, including cycloartenol, 24-methylene cycloartanol and various tetra- and pentacyclic triterpenes. The resolution of such complex mixtures into individual compounds was not trivial, even by GC. Since most compounds were present in very low amounts, the use of <sup>1</sup>H NMR was excluded. All the compounds were identified as acetate derivatives by their RRT in GC and MS fragmentation pattern in GC-MS as described in the experimental section. Among the compounds found in the olive fruit (Tables 1, 2), at least 12 non-steroidal triterpenes and 4,4-dimethylsterols had the same molecular weight (MW) of 468 (acetate derivative) and, for many of them, very similar mass spectrometry (MS) fragmentation patterns. Besides 3 $\beta$ -OH triterpenes, we could also identify more-polar compounds with additional hydroxyl or carboxylic groups, corresponding to pentacyclic diols and mono- or di-HPTAs.

The different triterpenoids identified in the olive fruit are listed in Table 1 and their structures shown in Scheme 1. They include 18 pentacyclic triterpenoids arising from four different carbon skeletons: oleanane ( $\beta$ -amyirin,  $\beta$ -amyrone, 28-nor- $\beta$ -amyirin,  $\delta$ -amyirin, erythrodiol, oleanolic acid and maslinic acid), ursane ( $\alpha$ -amyirin, 28-nor- $\alpha$ -amyirin, uvaol, ursolic acid), lupane (lupeol, lupenone, 3-*epi*-lupeol, 3-*epi*-betulin and 3-*epi*-betulinic acid) and taraxane (taraxerol, D-fridoolean-14-ene-3 $\beta$ ,28-diol). Oleanane triterpenoids were largely predominant. We also found butyrospermol and traces of bacchar-12,21-dien-3 $\beta$ -ol, two tetracyclic triterpenes with euphane and baccharane carbon skeletons, respectively.

**Table 1** Triterpenoids of the Chemlali olive fruit: GC-MS analysis

Compound	MS (% relative abundance of molecular and characteristic fragment ions): experimental or literature data <sup>a</sup>
<b>Euphane group</b>	
Butyrospermol ( <i>5α</i> -eupha-7,24(25)-dien-3β-ol)	MS: <i>m/z</i> 468 [M <sup>+</sup> ] (22), 453 (100), 393 (68), 355 (18), 301 (7), 271 (8), 255 (10), 241 (12), 189 (20), 109 (38), 95 (41), 69 (79)
<b>Taraxane group</b>

Taraxer-14-ene-3β,28-diol (D-friedoolean-14-ene-3β,28-diol)	(23)
<b>Oleanane group</b>	
β-Amyrin ( <i>5α</i> -olean-12-en-3β-ol)	(14)
β-Amyrone	MS: <i>m/z</i> 424 [M <sup>+</sup> ] (13), 409 (15), 406 (8), 355 (10), 218 (100), 207 (20), 203 (43), 189 (17), 163 (22)
28-Nor-β-amyrin (28-nor-5α-olean-12-en-3β-ol)	MS: <i>m/z</i> 454 [M <sup>+</sup> ] (3), 439 (2), 394 (2), 379 (2), 204 (100), 189 (39), 175 (17)
δ-Amyrin ( <i>5α</i> -olean-13(18)-en-3β-ol)	MS: <i>m/z</i> 468 [M <sup>+</sup> ] (35), 453 (17), 408 (3), 393 (8), 218 (43), 206 (43), 205 (100), 204 (37), 189 (78), 109 (78)
Erythrodiol ( <i>5α</i> -olean-12-ene-3β,28-diol)	(23)
Oleanolic acid (3β-hydroxy-5α-olean-12-en-28-oic acid)	MS: <i>m/z</i> 512 [M <sup>+</sup> ] (2.5), 453 (4), 452 (10), 262 (54), 249 (7), 203 (100), 189 (27), 175 (8), 133 (14)
Maslinic acid (2α,3β-dihydroxy-5α-olean-12-en-28-oic acid)	MS: <i>m/z</i> 570 [M <sup>+</sup> ] (3), 511 (6), 510 (9), 450 (8), 435 (11), 262 (50), 249 (10), 203 (100), 189 (28), 173 (13), 133(18)
<b>Lupane group</b>	
Lupeol ( <i>5α</i> -lup-20(29)-en-3β-ol)	(24)
Lupenone	MS: <i>m/z</i> 424 [M <sup>+</sup> ] (49), 409 (20), 382 (5), 369 (7), 342 (7), 314 (37), 245 (15), 232 (18), 218 (15), 205 (83), 189 (47), 175 (9), 149 (28), 109 (48), 69 (100)
3- <i>epi</i> -lupeol ( <i>5α</i> -lup-20(29)-en-3α-ol)	MS: <i>m/z</i> 468 [M <sup>+</sup> ] (23), 453 (3), 408 (9), 393 (4), 249 (10), 229 (8), 218 (17), 205 (20), 204 (23), 203 (18), 191 (43), 189 (100), 175 (22), 161 (25), 135 (40), 133 (20)
3- <i>epi</i> -betulin ( <i>5α</i> -lup-20(29)-ene-3β,28-diol)	MS: <i>m/z</i> 526 [M <sup>+</sup> ] (3), 466 (65), 453 (12), 451 (8), 423 (22), 406 (7), 393 (7), 391 (7), 249 (7), 213 (22), 203 (45), 189 (100), 187 (58), 175 (27)
3- <i>epi</i> -betulinic acid (3α-hydroxy-lup-20(29)-en-28-oic acid)	MS: <i>m/z</i> 512 [M <sup>+</sup> ] (2), 453 (13), 452 (30), 437 (7), 262 (34), 249 (17), 203 (39), 189 (100), 175 (21), 173 (24), 161 (33), 133 (31), 131 (18)
<b>Ursane group</b>	
α-Amyrin ( <i>5α</i> -urs-12-en-3β-ol)	(14)
28-Nor-α-amyrin (28-nor-urs-12-en-3β-ol)	MS: <i>m/z</i> 454 [M <sup>+</sup> ] (9), 439 (3), 394 (3), 379 (2), 207 (40), 204 (100), 189 (27), 175 (26)
Uvaol ( <i>5α</i> -urs-12-ene-3β,28-diol)	(19)
Ursolic acid (3β-hydroxyurs-12-en-28-oic acid)	MS: <i>m/z</i> 512 [M <sup>+</sup> ] (2), 497 (1), 453 (3), 452 (7), 437 (2.5), 393 (2), 262 (100), 249 (19), 233 (6), 215 (4), 203 (82), 189 (29), 133 (53), 119 (21)
<b>Baccharane group</b>	
Bacchar-12,21-dien-3β-ol	MS: <i>m/z</i> 468 [M <sup>+</sup> ] (3), 453 (3), 408 (2.5), 393 (5), 249 (7), 218 (100), 203 (38), 189 (23), 133 (87)

<sup>a</sup> Recorded MS correspond to either the monoacetate derivative of triterpenes or the diacetate derivative of triterpene diols or the mono or diacetate derivative of HPTA methylesters

To our knowledge, the occurrence of 3-*epi*-lupeol, with a 3α-hydroxyl group, and its oxygenated derivatives (3-*epi*-betulin and 3-*epi*-betulinic acid) in the *Olea europaea* fruit had not been reported yet. It should be pointed out that MS of 3-*epi*-acetate derivatives exhibit fragmentation patterns very similar to those of 3β-OH acetates, but both epimers of each pair have different RRTs in GC. As an example, the RRTs of 3α- and 3β-lupenyl acetates in a DB-5 column are 1.285 and 1.333, respectively, corresponding to a separation factor of 1.03, a result consistent with data reported for the

corresponding trimethylsilyl (TMS) derivatives [26]. Because of its lower polarity compared to β-lupeol, we initially missed 3-*epi*-lupeol. To check the presence of this compound in the olive fruit, we chemically synthesized a standard of 3-*epi*-lupeol by NaBH<sub>4</sub> reduction of an authentic sample of lupenone, as described in the experimental section. The 3-*epi*-epimer was found to co-migrate with TAGs. Evidence for the presence of 3-*epi*-lupeol and lupenone in the olive fruit was obtained after preliminary elimination of these very abundant compounds by alkaline hydrolysis.

**Table 2** Sterols of the Chemlali olive fruit: GC-MS analysis

$\Delta^{5,24}$ -Stigmastadienol	MS: <i>m/z</i> 454 [M <sup>+</sup> ], 394 (28), 379 (13), 315 (18), 296 (100), 281 (37), 253 (45), 213 (22)

<sup>a</sup> All the compounds have been identified by GC-MS, but only MS data, which have not been published before, are given here. Recorded MS spectra correspond to acetate derivatives

It is known that (3*S*)-2,3-OS is the precursor of both 3 $\alpha$ - and 3 $\beta$ -hydroxytriterpenes and that 3 $\alpha$ -epimers are biosynthesized from their 3 $\beta$ -isomers through reduction of the 3-oxo compounds [27]. The oxidation reaction can operate on the 3 $\beta$ -OH of a triterpene, a triterpenic diol or a triterpenic acid. Thus, the co-occurrence of lupeol, lupenone and 3-*epi*-lupeol as well as the absence of betulin, betulinic acid and the corresponding ketones, betulinone and betulinonic acid, strongly suggest that the change in the 3-OH group configuration takes place only at the level of lupeol in the olive fruit. No 3-*epi*-derivatives of  $\alpha$ - and  $\beta$ -amyrins have been detected.

#### Compounds of the Sterol Pathway (Table 2)

Free sterols and sterols released from ester conjugates were analyzed as described in [Materials and Methods](#).

They were identified as acetate derivatives by both their RRT in GC and their MS fragmentation by GC-MS analysis. The olive fruit was found to contain all the usual intermediates of the sterol pathway, from squalene up to sterol end products (Table 2). Sitosterol is by far the predominant sterol (95%), followed by 24-methylcholesterol, stigmasterol and isofucosterol ( $\Delta^5$ -avenasterol) (1–3%). We also detected other sterols such as brassicasterol, 24-methylenecholesterol,  $\Delta^{5,24}$ -stigmastadienol,  $\Delta^7$ -avenasterol and cholesterol. The classic sterol precursors, 4,4-dimethylsterols (cycloartenol and 24-methylenecycloartanol) and 4 $\alpha$ -methylsterols (obtusifoliol, cycloeucalenol, 24-methylene- and 24-ethylidenelophenol) were present, but also more unusual sterols such as (24*S*)-24-ethylcholesta-5,25-dien-3 $\beta$ -ol (clerosterol) and sterols with a double bond at C-23 ( $\Delta^{5,23}$ -stigmastadienol and 24-ethyl-*E*-23-dehydrolophenol) or C-11 (lanosta-9(11),24-dien-3 $\beta$ -ol or

parkeol). The acetate derivatives of cycloartenol and parkeol have very similar RRTs in DB-1 and DB-5 GC columns, but they can be easily discriminated by their MS fragmentation patterns [28]. Interestingly, parkeol was found only as an ester. Traces of a compound, which might be 24-methylene-lanost-9(11)-en-3 $\beta$ -ol, were detected.

All the compounds of the sterol pathway were also found as ester conjugates.

Thus, at least 20 compounds belonging to the sterol pathway have been identified in the olive fruit. Our results are consistent with previous reports about the sterol composition of olive oil [19, 29–31], especially that of the Chemlali cultivar [32].

### Changes in the Free Triterpenoid and Sterol Content Throughout Fruit Growth and Development

#### Total Lipids

Figure 1 shows the changes in total lipids during the whole period of olive fruit development. The olive mesocarp tissue begins to form large amounts of lipids from about 17 WAF until the end of the fruit ripening process. TAGs are by far the major compounds, accounting for 98–99% of total lipids. They progressively accumulate as lipid droplets, which progressively fuse to give a single large oil droplet [33].

#### Non-steroidal Triterpenoids

At the beginning of fruit ontogeny (i.e. between 12 and 18 WAF), the olive fruit was found to contain significant amounts of  $\alpha$ - and  $\beta$ -amyryns, in about a 3:2 ratio, as well as several more-oxygenated compounds with additional hydroxymethyl or carboxylic groups (Table 3; Scheme 1). The presence of a high content of

**Fig. 1** Changes in total lipids during olive fruit development

squalene was also observed (700  $\mu$ g/g dry wt at 13 WAF, data not shown), an unsurprising result since squalene is the direct precursor of OS needed for the synthesis of  $\alpha$ - and  $\beta$ -amyryns. Through several oxidation steps, the C-28 methyl group of  $\alpha$ - and  $\beta$ -amyryns might be sequentially converted into a hydroxymethyl, to give uvaol and erythrodiol, and then into a carboxylic group, to give ursolic and oleanolic acids (Scheme 1). The enzymes responsible for these oxidation reactions have not been characterized yet, but are likely to be cytochrome P-450 monooxygenases. Similar stepwise oxidations have been reported for the conversion of *ent*-kaurene into *ent*-kaurenic acid [34] or abietadienol into abietic acid [35], two series of reactions of diterpenoid metabolism, catalyzed by a unique multifunctional P-450 enzyme. If that holds true, this pathway does involve the intermediate formation of the aldehydes, 3 $\beta$ -hydroxy-5 $\alpha$ -urs-12-en-28-al and 3 $\beta$ -hydroxy-5 $\alpha$ -olean-12-en-28-al. The presence of these relatively unstable compounds in the olive fruit has not been verified. However, the triterpene fraction of the young olive fruit was found to contain significant amounts of 28-nor- $\alpha$ -amyryn (6%) and 28-nor- $\beta$ -amyryn (17%) (Table 3). These two compounds, which have no carbon at C-17, might arise from the decarbonylation *in planta* of both aforementioned aldehydes. Indeed, it has been reported that ursaldehyde can be partially converted to 28-nor- $\alpha$ -amyryn, when exposed to diffuse sunlight [36]. Both 28-nor- $\alpha$ - and 28-nor- $\beta$ -amyryns have also been identified in the leaves of *Nerium oleander* [37] and the resin of *Pistacia lentiscus* [38], among the whole series of ursane and oleanane triterpenoids, from  $\alpha$ - and  $\beta$ -amyryns to HPTAs via pentacyclic triterpene diols and aldehydes. In that context, it may be emphasized that uvaol and erythrodiol as well as ursolic and oleanolic acids have been found in the waxy epiderm of the olive fruit [39]. Thus, the complete sequence of oxidation reactions from triterpenes to pentacyclic acids via triterpenic diols and aldehydes might take place in the green epicarp of the fruit, which is directly exposed to the intense summer sunlight.

Between 12 and 18 WAF, maslinic acid, which differs from oleanolic acid by an additional hydroxyl group at the C-2 position, was also formed (Table 3). Its later accumulation suggests that the introduction of this additional hydroxyl group occurs after the oxidation of the C-28 methyl group and might involve a different P-450 enzyme.

Interestingly, taken together, these data indicate that, although  $\alpha$ -amyryn was present in excess compared to  $\beta$ -amyryn, oleanane compounds as a whole were produced in higher amounts than ursane com-

Numbers in brackets correspond to relative weight percentages of each class of compounds; the SDs for quantitative determinations are  $\pm 5\%$

pounds. Erythrodiol accounted indeed for about 60% of triterpenic dialcohols and oleanic and maslinic acids, for 98–99% of mono- and di-HPTAs (Table 3). Thus, the metabolic fate of  $\alpha$ -amyrin in the olive fruit remains to be elucidated.

Besides  $\alpha$ - and  $\beta$ -amyryns and the corresponding 28-nor compounds, no other tetra- or pentacyclic triterpenes were detected in the young olive fruit. However, the fractions of pentacyclic diols and acids were found to contain lupane derivatives, identified as 3-*epi*-betulin and 3-*epi*-betulinic acid, and a taraxane derivative, D-fridoolean-14-ene-3 $\beta$ ,28-diol. These compounds are likely to be formed through oxidation steps similar to those described above in the case of ursane and oleanane triterpenoids.

Between 21 and 30 WAF, a dramatic decrease in the content of  $\alpha$ - and  $\beta$ -amyryns and their derivatives was observed. Only  $\beta$ -amyrin remained detectable, with traces of taraxerol. During the same period, triterpenic diols were converted into mono- and di-HPTAs. Consequently, maslinic acid became the major triterpenoid (60% of total triterpenoids) and mono- and di-HPTAs together represented as much as 2.25 mg/g dry wt. At 30 WAF, a significant decrease in the content of all HPTAs was observed (Table 3), indicating that these compounds might be further metabolized, maybe into triterpenic saponins [16].

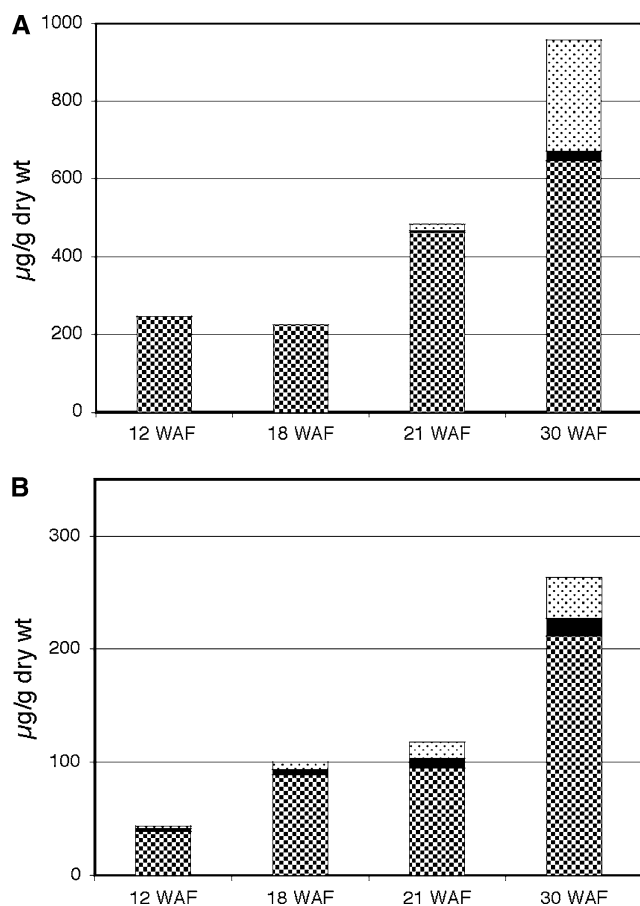

### Sterols

As described before, the very young olive fruit (between 12 and 18 WAF) was found to contain high

amounts of squalene, but the other usual sterol precursors such as 4,4-dimethyl- and 4 $\alpha$ -methylsterols were barely detectable. Sterol end products were present as a mixture in which sitosterol was largely predominant (95 wt% of total sterols), but the total free sterol content (about 220  $\mu\text{g g}^{-1}$  dry wt) was found not to change and even slightly decrease during this period, indicating that no significant sterol biosynthesis was occurring in the green olive fruit. The pre-existing  $\Delta^5$ -sterols in the young fruit arose from the floral ovary tissue as well as one of the two ovules, which gave the mesocarp and the seed after fertilization, respectively.

From 21 WAF, dramatic changes were observed in the sterol pathway. Early biosynthetic intermediates, i.e., 4,4-dimethyl- (cycloartenol and 24-methylene cycloartanol) and 4 $\alpha$ -methylsterols (cycloeucalenol, obtusifoliol, 24-methylene- and 24-ethylidene lophenol) as well as late precursors (isofucosterol) of the sterol pathway began to be detectable whereas a progressive increase in sterol end products was observed. Throughout the fruit ripening process, sterols continued to accumulate, with sitosterol remaining the major compound and no change in the relative proportions of the various sterols. At 33 WAF, the free sterol content of the olive fruit amounted to 720  $\mu\text{g g}^{-1}$  dry wt, corresponding to a three-fold total increase. At this stage, a significant increase in the content of some precursors, especially 24-methylene cycloartanol and 24-ethylidene lophenol, was observed, indicating a slowing down of the metabolic flux through the sterol pathway (Fig. 2a).

Taken together, these data indicate that a preferential channeling of available OS molecules towards

**Fig. 2** Changes in free (a) and esterified (b) sterols at four distinct stages of olive fruit development. (Medium shade square) sterols, (filled square) 4 $\alpha$ -methylsterols, (light shade square) 4,4-dimethylsterols

the triterpenoid pathway occurs in the very young olive fruit at the expense of the biosynthesis of housekeeping sterols, a situation which is reminiscent of that prevalent in pea (*Pisum sativum* L.) plantlets, where  $\beta$ -amyirin is actively produced just after germination and before sterol synthesis [40]. From 21 WAF,  $\alpha$ - and  $\beta$ -amyirins were no longer detected whereas sterol biosynthetic precursors began to appear (Fig. 3), clearly indicating a redirection of the carbon flux from the triterpenoid pathway towards the sterol pathway and the synthesis of membranes. Between 18 and 30 WAF, the total amount of free sterols was fivefold increased whereas mono- and di-HPTAs, mainly represented by maslinic acid, accumulated at the expense of non-steroidal triterpenes and diols (Table 3).

Thus, a complex regulation takes place at the level of OS cyclization. Studies of differential expression patterns of  $\beta$ AS and cycloartenol synthase at different stages of fruit development, which are currently in progress, should allow us to better understand the

**Fig. 3** A redirection of the carbon flux from the triterpenoid pathway (free  $\alpha$ - and  $\beta$ -amyirins) towards the sterol pathway (free cycloartenol and 24-methylenecycloartenol) occurs between 18 and 21 WAF. (light-shaded square)  $\alpha$ -amyirin, (filled square)  $\beta$ -amyirin, (medium-shaded square) 24-methylene cycloartenol, (opensquare) cycloartenol

mechanisms underlying the sequential production of both sets of triterpenic compounds.

#### Changes in Esterified Sterols and Triterpenoids throughout Fruit Growth and Development

##### Triterpenoids

The young olive fruit (i.e. between 12 and 18 WAF) was found to contain only very low amounts of acylated non-steroidal triterpenes (Table 4), representing less than 2% of the corresponding free forms. This result indicates an almost complete metabolization of newly synthesized  $\alpha$ - and  $\beta$ -amyirin molecules into triterpenic diols and acids. Besides  $\alpha$ - and  $\beta$ -amyirins, esters of taraxerol,  $\delta$ -amyirin and lupeol were detected as traces.

From 21 WAF, when amyirins were not formed any longer, esterified triterpenes progressively accumulated (Table 4) and their content became higher than that of free non-steroidal triterpenes (Table 3). Concomitantly, a change in the profile of triterpenes could

**Table 4** Changes in esterified triterpenes throughout olive fruit development

Stage of development	12WAF		18WAF		21WAF		30WAF	
	$\mu\text{g/g}$ dry wt	%	$\mu\text{g/g}$ dry wt	%	$\mu\text{g/g}$ dry wt	%	$\mu\text{g/g}$ dry wt	%

Butyrospermol	n.d.	–	n.d.	–	24	61	21	60
$\alpha$ -Amyrin	tr	5	tr	6	tr	–	tr	–
Lupeol	2	27	3	37	tr	–	tr	–
Total amount	7		9		39		35	

be noticed, mainly consisting in the appearance of a new compound, identified as butyrospermol, which represented up to 60% of total esterified triterpenes. Traces of esterified baccharadienol were detected only at late stages of ripening. As shown in Scheme 1, butyrospermol, baccharadienol as well as  $\delta$ -amyrin are likely to result from stabilization of carbocationic intermediates located on the route to  $\alpha$ -amyrin.

#### Sterols (Fig. 2b)

Between 12 and 18 WAF, the olive fruit was found to contain significant amounts of esterified sterols, with sitosterol being the major compound. The fraction of sterol esters contains the same compounds as free sterols, but in different proportions. For instance, an increase in the relative amounts of 24-methylcholesterol (2.5% vs. 0.4%) and stigmasterol (7–8% vs. 1.5%) was observed (data not shown). Only traces of 4,4-dimethyl- and 4 $\alpha$ -methylsterols were detected. Interestingly, despite the absence of sterol biosynthesis (Fig. 2a), a twofold increase in the total amount of sterol esters was observed (Fig. 2b), which occurred at the expense of sterol end products initially present in the fruit, indicating the presence of a functional sterol acyltransferase in the green olive. After the onset of free sterol biosynthesis, which takes place at around 21 WAF, sterol esters continue to accumulate, particularly between 27 and 30 WAF (Fig. 2b), with a total amount representing a sevenfold increase during the whole period of fruit development. All the usual sterol biosynthetic precursors (4,4-dimethyl- and 4 $\alpha$ -methylsterols) as well as end products were present as ester conjugates, but other compounds such as 24-ethyl-*E*-23-dehydrolophenol, 24-methyl- and 24-ethyl lophenol could also be detected. At the end of the ripening process, a specific accumulation of 24-methylene cycloartanol and 24-ethylidene lophenol was observed, in agreement with previous data about olive oil [29]. An interesting observation was the appearance of a new compound in the fraction of 4,4-dimethylsterols, which

has been identified to parkeol. This compound, which had been previously detected in olive oil [19], was formed concomitantly to cycloartenol, as shown in Fig. 4 and represented more than 50% of the total esterified 4,4-dimethylsterols.

A phospholipid:sterol acyltransferase (PSAT) involved in the acylation of free sterols has recently been identified in *Arabidopsis* [41]. This enzyme was shown to be able to acylate various sterols as well as sterol intermediates but not lupeol or  $\beta$ -amyrin [41], suggesting that a distinct enzyme would be involved in the acylation of non-steroidal triterpenes. During the period of active sterol biosynthesis, the physiological function of such a sterol acyltransferase might be to regulate the pool of free sterols as well as the amount of sterol biosynthetic intermediates in membranes [41]. In contrast, the role of sterol acylation at earlier stages of fruit development is less clear.

During the whole period of the olive fruit development, free sterols remained predominant compared to sterol esters (Fig. 2a, b).

Sterol esters, which are not membrane components, have been reported to be present with TAG in the core

**Fig. 4** Changes in products arising from OS cyclization via the protosteryl cation throughout olive fruit development (dot) esterified parkeol, (dotted line) free and esterified (cycloartenol and 24-methylene cycloartanol)

of oil bodies [42], but the olive fruit contains oil droplets rather than proper lipid bodies [43]. Olive oil, which is comprised of 98–99% TAGs, is formed in the mesocarp of the developing fruit. TAG synthesis was found to begin between 16 and 17 WAF (Fig. 1), i.e. before sterol biosynthesis, and to depend on light [44]. The whole process involves the contribution of photoassimilates imported from adjacent leaves as well as those generated as the products of the photosynthesis taking place in the fruit itself [44]. Sterol esters thus appear to be formed concomitantly to TAGs and might therefore directly participate in oil droplet formation.

### Origin of the Structural Diversity of Triterpenoids in Olive Fruit

The present data provide evidence for the occurrence of a vast array of non-steroidal triterpenoids in the olive fruit, which might arise from the different carbocationic intermediates generated en route to  $\alpha$ -amyrin biosynthesis (Scheme 1). The question is now to elucidate whether the olive fruit contains one or several triterpenes synthases. In the young fruit,  $\alpha$ -amyrin is actively produced together with  $\beta$ -amyrin in a 3:2 ratio and these two pentacyclic triterpenes are by far the major products. As no monofunctional  $\alpha$ -amyrin synthase has been identified so far, one can postulate that in the olive fruit,  $\alpha$ - and  $\beta$ -amyrins could be formed by a mixed amyrin synthase similar to that of *Pisum sativum* [12]. Besides  $\alpha$ - and  $\beta$ -amyrins, the pea enzyme would be able to generate six other products including butyrospermol, lupeol and  $\delta$ -amyrin, which have been also identified in the olive fruit (Table 1). In this case, the amyrin synthase of the olive fruit would not belong to the family of monofunctional  $\beta$ AS [12, 45–48]. In addition to this mixed amyrin synthase, the olive fruit might contain a lupeol synthase, similar to that identified in olive leaves, catalyzing the formation of only lupeol [49]. The occurrence of other monofunctional lupeol synthases has been reported [46, 48–51], but it should be pointed out that lupeol can be also formed by multifunctional triterpene synthases [11, 13, 14]. These two classes of lupeol synthases are phylogenetically distinct [49].

An interesting point concerns the biosynthetic origin of parkeol in the olive fruit. In contrast to pentacyclic triterpenes, parkeol arises from the protosteryl C-20 cation, which is formed by cyclization of OS folded in the pre-chair-boat-chair conformation (Scheme 1). This cation undergoes a series of 1,2-methyl and hydride shifts with proton elimination to yield either cycloartenol (C-19 deprotonation), lanosterol (C-6

deprotonation), parkeol (C-11 deprotonation) or cucurbitadienol, the precursor of cucurbitacins [2].

The presence of parkeol has been reported in sea cucumbers [52, 53] and a few plants such as *Butyrospermum parkei* [54, 55] or *Neolitsea aciculata* [56]. Parkeol is not incorporated into sterols [57]. Some plants contain 24-alkyl- $\Delta^{9(11)}$ -sterols [58], which maybe result from metabolization of parkeol, but the question of whether or not parkeol is a by-product of sterol metabolism remains to be solved. No natural parkeol synthase has been cloned so far. It has been shown that wild-type *Arabidopsis* CAS, expressed in a yeast mutant, is able to produce 1% parkeol, but not lanosterol (<0.1%) [28]. Moreover, the possibility to generate an enzyme that makes parkeol as its major product from either CAS [28, 59, 60] or lanosterol synthase [61, 62] has been reported. As an example, the work by Segura et al. [60] has emphasized the critical role played by His477, which is strictly conserved in all CAS. The *Ath* H477Q mutant was shown indeed to form up to 73% parkeol. The natural occurrence of a nondiscriminating OS cyclase in the bacterium *Gemmata obscuriglobus*, producing both lanosterol and parkeol [63], has to be mentioned. Interestingly, in this organism, both lanosterol and parkeol are present exclusively as esters.

Parkeol seems not to be formed in young olive drupes. It appeared only from 21 WAF, concomitantly with cycloartenol (Fig. 4). Cycloartenol was rapidly converted into 24-methylenecycloartanol, which was then converted into ester. The fact that cycloartenol and parkeol were simultaneously formed during olive fruit ripening suggests the possible involvement of a single protein for production of both compounds. In this case, the olive fruit CAS would have evolved differently from other plant CAS. The fact that parkeol occurs in the olive fruit only as an ester conjugate suggests that it is not metabolized further on and is acylated immediately after release from the OS cyclase by a sterol acyltransferase similar to PSAT or by another sterol acyltransferase. Whether or not parkeol is a primary or secondary metabolite remains to be elucidated.

### Concluding Remarks

The present report represents the first detailed investigation into the triterpenoid composition of *Olea europaea* olive fruit and its changes occurring throughout the ripening process. Evidence is given for the presence of at least 23 sterols and 20 tetra- and pentacyclic non-steroidal triterpenoids. We have shown that the triterpenoid content of the olive fruit is closely dependent

on the stage of development and that a regulation process takes place at the OS cyclization step. Further work is now needed to investigate more deeply the non-steroidal triterpenoid biosynthetic pathway. Certainly, the rising interest in the valuable biological properties for human health of triterpenic acids, including maslinic acid (e.g., [64]), constitutes a strong motivation.

**Acknowledgment** We thank Prof. Z. Mighri (Faculté des Sciences, Monastir, Tunisia) for providing us with an authentic sample of maslinic acid and Dr. Pierrette Bouvier-Navé (IBMP, Strasbourg, France) for critical analysis of the work.

**Abstract** *ERG2* and *ERG24* are yeast sterol biosynthetic genes which are targets of morpholine antifungal compounds. *ERG2* and *ERG24* encode the C-8 sterol isomerase and the C-14 reductase, respectively. *ERG2* is regarded as a non-essential gene but the viability of *ERG24* depends on genetic background, type of medium, and  $\text{CaCl}_2$  concentration. We demonstrate that *erg2* and *erg24* mutants are viable in the deletion consortium background but are lethal when combined in the same haploid strain. The *erg2erg24* double mutant can be suppressed by mutations in the sphingolipid gene *ELO3* but not *ELO2*. Suppression occurs on rich medium but not on synthetic complete medium. We also demonstrate that the suppressed *elo3erg2erg24* does not have a sterol composition markedly different from that of *erg24*. Further genetic analysis indicates that *erg24* combined with mutations in *erg6* or *erg28* is synthetically lethal but when combined with mutations in *erg3* is weakly viable. These results suggest that novel sterol intermediates probably contribute to the synthetic lethality observed in this investigation.

## Abbreviations

CSM	Synthetic complete media
GC	Gas chromatography
PCR	Polymerase chain reaction
YPAD	Yeast extract, peptone, adenine, dextrose

## Introduction

Synthesis of lanosterol is the first step in yeast sterol biosynthesis. The yeast *ERG24* gene encodes the C-14 reductase required to complete C-14 demethylation of lanosterol. This gene has been cloned and disrupted by several investigators who demonstrated that the C-14 reductase enzyme is essential for viability [1, 2]. Originally, *erg24* mutants were found to be lethal in wild-type genetic backgrounds but viable in genetic backgrounds containing mutations in *elo2/fen1* [1, 2]. Mutations in the *ELO2/FEN1* [3] gene result in resistance to the morpholine fenpropimorph [1, 2]. The morpholines inhibit both the C-8 isomerase and the C-14 reductase encoded by *ERG2* and *ERG24*, respectively [4, 5] possibly indicating a common target site on the two enzymes or an uncharacterized protein–protein interaction between them. Resistance to fenpropimorph because of a mutation in *FEN1* results in tolerance to accumulation of the sterol intermediate, ergosta-8,14-dienol, however. Lorenz and Parks [1] were able to construct a deletion mutation in the *ERG24* gene that was viable only in a *fen1* background. Similarly, Ladeveze et al. [6] also demonstrated that *ERG24* mutants were viable in a *fen1* background. Subsequent work by Baudry et al. [7] demonstrated

that *erg24* mutants were also suppressed by mutations in *elo3/sur4*. *ELO2/FEN1* and *ELO3/SUR4* encode enzymes that are involved in sphingolipid synthesis and are components of a fatty acid elongation system that elongates  $C_{16}/C_{18}$  to  $C_{24}/C_{26}$  [3]. Further analysis indicated that *erg24* mutants could be grown in some genetic backgrounds (wildtype for *ELO2* and *ELO3*) on synthetic complete or rich medium containing  $Ca^{2+}$  or  $Mg^{+2}$  [8, 9]. Thus replacement of ergosterol by ergosta-8,14-dienol is not lethal in itself but requires an adequate amount of these ions. Although both the C-8 isomerase and C-14 reductase enzymatic reactions are sensitive to morpholine antifungals, overexpression of the non-essential gene *ERG2* does not lead to fenpropimorph resistance whereas overexpression of the essential gene *ERG24* does [10]. Whereas *erg2* mutants have been generally isolated as non-essential in different genetic backgrounds, a single *erg2* mutant isolate in an FL100 wildtype genetic background was shown to be lethal but suppressible by mutations in either the *ELO2* or *ELO3* gene [3, 11].

We have previously demonstrated that *ERG24* is an essential gene in a wildtype Y294 genetic background [10] but the *erg24* mutant strain produced by the deletion consortium project using the S288C wildtype genetic background clearly indicates that viable *erg24* mutants can occur in genetic backgrounds not containing the *ELO2* or *ELO3* mutations. In this study we demonstrate the different synthetic lethal interactions that can occur with an *erg24* strain derived from the deletion consortium genetic (S288C) background.

## Materials and Methods

### Strains, Media, and Growth Conditions

Yeast strains used in this study are derived from W303; SCY325 strain (*MAT $\alpha$* , *ade2-1*, *his3-11,15*, *leu2-3,112*, *trp1-1*, *ura3-1*) and SCY328 (*MAT $\alpha$* , *ade2-1*, *his3-11,15*, *leu2-3,112*, *trp1-1*, *ura3-1*) are wildtype laboratory strains and were used to generate all ergosterol mutant strains other than *erg24*. The *erg24* strain was obtained from the deletion consortium [12] and the construction of other ergosterol deletion strains *erg2*, *erg3*, *erg4*, *erg5*, *erg6*, and *erg28* were as reported previously [13]. The deletion mutant strains *elo2* and *elo3* were generated by homologous recombination with PCR products [14] from plasmid-containing selectable marker genes [15] and from oligonucleotides containing gene-specific sequences. The *elo2* and *elo3* strains derived in the W303 background were isolated as *elo2::TRP1* and *elo3::TRP1* disruptions using the

forward and reverse primers (*ELO2* fwd: 5'-ATG AATTCACCTCGTTACTCAATATGCTGCTCCGTT GTTCGAGCGTTATCCCCAACTTCATTGGCGG GTGTCCGGGGCTGGC-3' and *ELO2* rev: 5'-TAGG AACGTTTTTCAAGTCAACGTTAACATACTCA TTAACCTTTGCGGGAACACCGCCGTTTGCCG ATTTCCGGCCTATTG-3' for *elo2::TRP1* and *ELO3* fwd: 5'-AGCTTACTTCTAGTTTATTTATTCGG CTTTTTCCGTTTGTGTTACGAAACATAAACAG TCGGCGGGTGTCCGGGGCTGGC-3' and *ELO3* rev: 5'-TAAGCAGCAGCAGCCTGAGTACCATAACA AGTACCCTTGTTTGGTAAAATACCGTCCAAG TTGCCGATTTCGGCCTATTG-3' for *elo3::TRP1*). Verification of the deletion was performed by PCR analysis using checking primers. Gene-specific oligonucleotides were obtained from Invitrogen. Disruptions containing the kanamycin (G418) resistance marker were obtained from deletion consortium or isolated as segregants from different crosses. Yeast strains were grown in either YPAD (1% yeast extract, 2% bacto-peptone, 2% glucose, and 0.012% adenine sulfate) or in synthetic complete media (CSM) containing 0.67% yeast nitrogen base (Difco) supplemented with appropriate amino acids and 2% glucose. Additional uracil (0.004%), leucine (0.02%), histidine (0.004%), and tryptophan (0.01%) were added when required. CSM lacking specific nutrients was used for selection of different marker genes. Ergosterol, when used, was added to autoclaved media at 20  $\mu\text{g mL}^{-1}$  to rescue synthetically lethal double mutant strains. For anaerobic growth, anaerobic jars containing the GasPaks system (BBL Microbiology System) were used. Sporulation media have been described previously [14]. All solid media for growth of yeast contained 2% Bacto Agar (Difco).

### Genetic Methods

Mating, sporulation, and genetic dissections to obtain double and triple mutants were as described previously [14]. Crosses and asci dissections of the four-spore meiotic products were performed on YPAD solid media supplemented with 20  $\mu\text{g mL}^{-1}$  ergosterol in 1:1 (v/v) Tween 80–ethanol solution and grown anaerobically. Briefly, diploids grown on YPAD medium were transferred to a 1% potassium acetate medium to induce sporulation. After a 1-h treatment with glucylase (Perkin–Elmer Life science), the four spored-asci were dissected under a microscope using a micromanipulator. All meiotic segregants were analyzed by replica plating on YPAD and CSM plates with and without ergosterol for synthetic lethal screening and the genotype confirmed by genetic markers.

## Sterol Analysis

Sterols were isolated as described previously [16]. Briefly, cells were grown for 20–24 h in YPAD liquid or solid media containing 20  $\mu\text{g mL}^{-1}$  cholesterol. Cells were pelleted, washed twice with Igepal (1%), and twice with distilled water, saponified with alcoholic KOH, and extracted in *n*-heptane. Sterols were first analyzed by gas chromatography (GC) with a Hewlett–Packard HP5890 series II chromatograph equipped with HP Chemstation software. The DB-5 capillary column (15 m  $\times$  0.25 mm  $\times$  0.25  $\mu\text{m}$  film thickness) with nitrogen as carrier gas (30 cm s<sup>-1</sup>) was programmed from 195 to 300 °C (3 min at 195 °C then increased at 5.5° min<sup>-1</sup> to 300 °C and held for 10 min). All injections were made in splitless mode with an inlet temperature of 280 °C. To identify novel sterols, gas chromatography–mass spectrometry (GC–MS) analysis was also performed, using an HP5890 GC coupled to a HP5972 mass-selective detector. GC separations were performed on a fused silica column (DB-5 15 m  $\times$  0.32 mm  $\times$  0.25  $\mu\text{m}$  film thickness), programmed from 40 to 300 °C (40 °C for 1 min, 30° min<sup>-1</sup> to 300 °C then held for 4 min). Helium was the carrier gas with a linear velocity of 50 cm s<sup>-1</sup> in the splitless mode. Mass spectra were generated in electron-impact mode with an electron energy of 70 eV and an ion-source temperature of 150 °C. The instrument was programmed to scan between 40 and 700 amu at 1-s intervals.

## Results

### Synthetic Lethality of *erg2erg24*

The observation that both *erg2* and *erg24* mutants could be suppressed by *elo2* or *elo3* mutations and the further observation that *erg24* was lethal in some genetic backgrounds but not in others led us to ask whether the *erg2erg24* double mutant strain was viable. The *erg2erg24* double mutant was obtained by mating viable *erg2* and *erg24* haploid strains to produce diploid heterozygotes; diploids were sporulated, and the four-spored asci were dissected on rich medium containing ergosterol (or cholesterol) and grown anaerobically. From a total of 100 tetrads, 83 *erg2erg24* double mutants were obtained, all of which could grow anaerobically with sterol supplement but failed to grow aerobically without sterol supplement (Table 1). In Fig. 1, wildtype, *erg2*, *erg24*, and *erg2erg24* strains were plated on both aerobic YPAD rich medium and synthetic complete medium (CSM). On YPAD medium,

*erg24* strains grew but growth was diminished at lower inocula; on YPAD medium, *erg2erg24* growth was completely absent. On CSM medium, however, both *erg2* and *erg24* strains grew normally but growth of the *erg2erg24* strain was minimal, indicating that it is not synthetically lethal on this medium. In the presence of ergosterol (which requires anaerobic growth conditions for sterol uptake) all four strains grew equally well. On YPAD or CSM media supplemented with 10 or 20 mmol L<sup>-1</sup> CaCl<sub>2</sub>, the growth responses were the same as without calcium. Results with 20 mmol L<sup>-1</sup> CaCl<sub>2</sub> (not shown) were exactly the same as with 10 mmol L<sup>-1</sup> CaCl<sub>2</sub> (Fig. 1).

### Suppression of *erg2erg24*

Mutations in *ELO2* and *ELO3* are known suppressors of *erg2* or *erg24* mutants [6, 7]. We generated *elo2erg2erg24* and *elo3erg2erg24* triple mutant strains to determine whether either or both suppressed the lethality of the *erg2erg24* strain. Figure 2 shows that only *elo3* suppressed *erg2erg24* lethality on YPAD medium as indicated by growth on this medium without ergosterol. On CSM medium, however, neither *elo2* nor *elo3* was found to be an efficient suppressor, because there was only small residual growth on this medium without ergosterol. Again, CaCl<sub>2</sub> supplementation in YPAD or CSM media did not rescue the synthetic lethality of *erg2erg24*.

### Sterol Analysis of *erg2erg24* and *erg2erg24elo3*

We proceeded to determine the sterol composition of each of these strains to assess whether a sterol composition difference could be attributable to the suppressed *erg2erg24elo3* strain. Table 2 indicates the sterol composition of the wildtype, *elo3*, *erg2*, *erg24*, *erg2erg24*, *erg2elo3*, *erg24elo3*, and the suppressed *erg2erg24elo3*

**Table 1** Genetic analysis to determine synthetic lethality of *erg24* double mutants in YPAD medium

Mating	Tetrads dissected	Viable double mutants <sup>a</sup>	Inviolate double mutants <sup>a</sup>
<i>erg2</i> $\times$ <i>erg24</i>	100	0	83
<i>erg3</i> $\times$ <i>erg24</i>	20	17 <sup>b</sup>	0
<i>erg4</i> $\times$ <i>erg24</i>	14	14	0
<i>erg5</i> $\times$ <i>erg24</i>	22	18 <sup>b</sup>	0
<i>erg6</i> $\times$ <i>erg24</i>	13	0	13
<i>erg28</i> $\times$ <i>erg24</i>	21	0	16

<sup>a</sup> Double mutants are *erg24* in combination with *erg2*, *erg3*, *erg4*, *erg5*, *erg6*, or *erg28*

<sup>b</sup> Poorly viable

**Fig. 1** Synthetic lethality of the *erg2erg24* double mutant strain. Cells were serially diluted and  $10^5$ – $10^2$  cells were sequentially spotted on to YPAD (upper panels) or CSM (lower panels) media with or without ergosterol or with  $10 \text{ mmol L}^{-1} \text{ CaCl}_2$ , to compare the phenotype of strains. The strains tested were wildtype, *erg2*, *erg24*, and *erg2erg24*. Plates containing ergosterol were incubated anaerobically, and those without ergosterol were incubated aerobically, both for 3 days at  $30^\circ \text{C}$ . The *erg2erg24* double mutant strain was able to grow only in presence of ergosterol

**Fig. 2** The mutation *elo3* but not the mutation *elo2* suppresses the *erg2erg24* double mutant. The growth response of strains *elo2*, *erg2erg24elo2*, *elo3*, and *erg2erg24elo3* was compared by spotting serial dilutions of  $10^5$ – $10^2$  cells of each strain on to YPAD (upper panels) or CSM (lower panels) media with or without ergosterol or with  $10 \text{ mmol L}^{-1} \text{ CaCl}_2$ . Plates containing

ergosterol were incubated anaerobically, and those without ergosterol were incubated aerobically, both for 3 days at  $30^\circ \text{C}$ . The *erg2erg24elo3* triple mutant strain was able to grow on YPAD but not on CSM media without ergosterol or with  $10 \text{ mmol L}^{-1} \text{ CaCl}_2$ . The *erg2erg24elo2* triple mutant strain was unable to grow on YPAD and grew very poorly on CSM media

strains grown in YPAD media under aerobic conditions. Identification of sterols was based on molecular ions and key fragment ions, and on comparison of standard sterol spectra and relative retention times (Table 3). The *erg2erg24* strain was grown anaerobically in the presence of cholesterol. There was essentially no difference between sterol profiles of the wildtype and *elo3* strains. The *erg2erg24* strain accumulated ergosta-8,14-diene sterols and squalene,

lanosterol, and the cholesterol provided in the growth medium. Sterol profiles from *erg24* and *erg2erg24elo3* strains were also similar in that 94 and 99% of the sterols accumulated in these two strains were ergosta-8,14 or cholesta-8,14 sterols, respectively, suggesting that the major effect of *elo3* suppression did not involve alteration of sterols. *erg2elo3* and *erg24elo3* usually reflected the sterol compositions of *erg2* and *erg24*, respectively.

### Synthetic Lethality of *erg24* in Combination with Other Ergosterol Biosynthetic Mutants

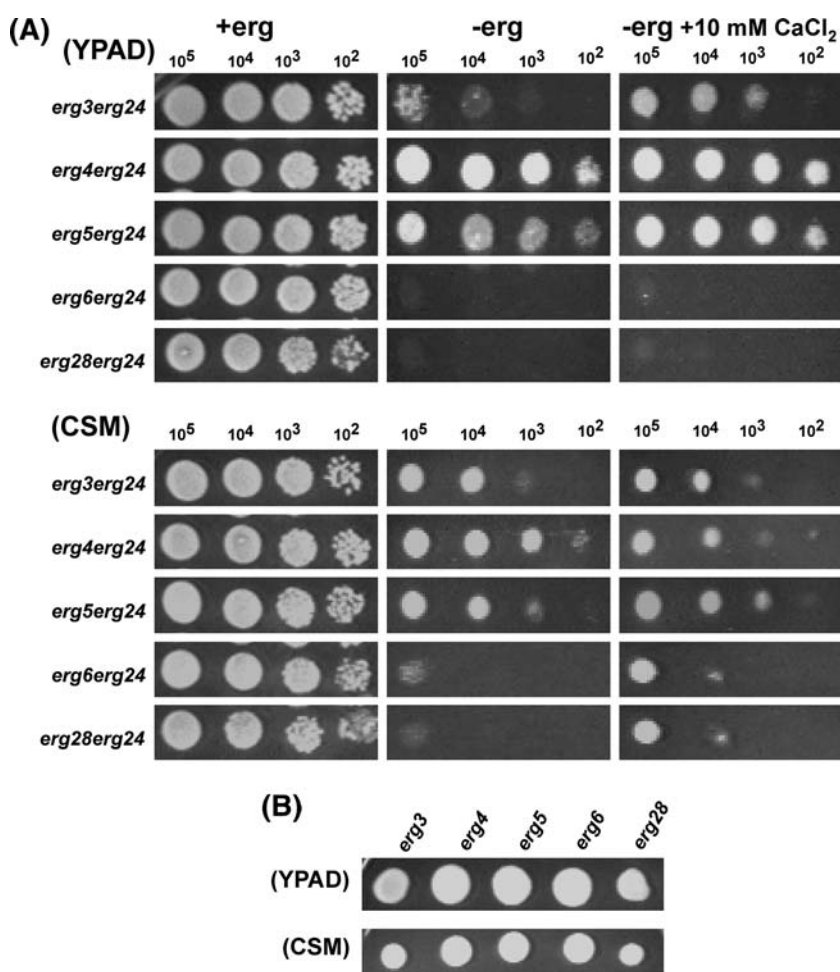

It was of interest to ascertain whether other ergosterol mutations, for example *erg3*, *erg4*, *erg5*, *erg6*, and *erg28*, would be synthetically lethal in combination with the *erg24* mutation. *ERG3* encodes the C-5 desaturase, *ERG4* encodes the C-24 reductase, *ERG5* encodes the C-22 desaturase, and *ERG6* encodes the C-24 trans-methylase; mutations in these genes are viable (Fig. 3b). *ERG28* encodes a scaffold protein required for complete C-4 demethylation and it, also, is non-essential for growth. We crossed all single mutants with the *erg24* strain to generate the haploid double mutants. All tetrads were dissected and grown anaerobically with ergosterol and then grown aerobically without ergosterol to assess viability (Fig. 3). Genetic analysis (Table 1) and spot-plating (Fig. 3) on YPAD medium demonstrated that the double mutants *erg4erg24* and *erg5erg24* were viable but the double mutants *erg6erg24* and *erg28erg24* were not. The *erg3erg24* double mutants

were only weakly viable, however. Addition of  $\text{CaCl}_2$  had a growth-enhancing effect on *erg5erg24* on YPAD medium but not on CSM medium; on CSM medium,  $\text{CaCl}_2$  also had a growth-enhancing effect on *erg6erg24* and *erg28erg24*. Finally, *elo3* failed to suppress *erg6erg24* or *erg28erg24* on YPAD or CSM media (data not shown). The observation that *elo3* did not suppress *erg6erg24* is expected, because Eisenkolb et al. [17] demonstrated that the double mutant *elo3erg6* is synthetically lethal.

### Discussion

The genes in the latter part of the yeast ergosterol pathway, *ERG6*, *ERG2*, *ERG3*, *ERG4*, and *ERG5*, are regarded as non-essential because the sterols produced by mutations of these genes function nearly as well as ergosterol and meet the biophysical and biochemical requirements of a sterol molecule. Mutations in *ERG24*, however, are lethal in some

**Fig. 3** An *erg24* mutation is synthetically lethal with *erg6* or *erg28* but not with *erg3*, *erg4*, or *erg5*. **A** Growth of the *erg24* mutant in combination with additional mutations in the ergosterol biosynthetic pathway—*erg3*, *erg4*, *erg5*, *erg6*, and *erg28*. Cells from the double mutants were serially spotted on to YPAD (*upper panels*) or CSM (*lower panels*) media with or without ergosterol or with 10 mmol L<sup>-1</sup> CaCl<sub>2</sub>. Plates containing ergosterol were incubated anaerobically, and those without ergosterol were incubated aerobically, both for 3 days at 30 °C. The *erg6erg24* and *erg28erg24* mutant strains did not grow on YPAD medium without ergosterol; the *erg3erg24* and *erg5erg24* mutant strains grew poorly; and the *erg4erg24* mutant strain grew well. All strains grew poorly or very poorly on CSM medium without ergosterol or with 10 mmol L<sup>-1</sup> CaCl<sub>2</sub>. **B** *erg3*, *erg4*, *erg5*, *erg6*, and *erg28* single mutant strains were viable on both YPAD and CSM media without ergosterol

genetic backgrounds but not others. The results presented here extend initial observations that the viability of *erg24* depends on factors such as type of medium, metal ion concentrations, and strain background. Studies by Parks and coworkers [8, 9] indicated that *erg24* could not grow on a rich medium (YPAD) but could grow on a synthetic complete medium, because of greater abundance of  $\text{Ca}^{2+}$  in the latter. Addition of  $\text{Ca}^{2+}$  to rich medium restored growth. Our studies confirm some of these findings but differ in that the deletion consortium *erg24* strain is viable on YPAD medium but growth is not enhanced by addition of  $\text{Ca}^{2+}$  (Fig. 1). Growth is enhanced on CSM medium, however. The combination of *erg2* and *erg24*, however, resulted in lethality on YPAD medium that was not rescued by  $\text{Ca}^{2+}$  supplementation. Growth of the *erg2erg24* strain was marginal on synthetic complete medium. Suppression of this lethality was achieved by introducing a third mutation, *elo3*. The *elo3* mutation has previously been found to individually suppress lethal isolates of *erg2* and *erg24*. Whereas *elo3* was able to restore growth of the *erg2erg24* strain on YPAD medium, however, it failed to restore growth on CSM medium (Fig. 2). Surprisingly *elo2* failed to suppress the lethality of *erg2erg24* on any medium, even media containing  $\text{Ca}^{2+}$  supplementation.

We next asked whether other ergosterol mutants were lethal in combination with *erg24* and the results indicated that *erg6erg24* and *erg28erg24* were also inviable on rich YPAD medium and this lack of growth was not suppressed by  $\text{Ca}^{2+}$  supplementation. The double mutant *erg3erg24* grew poorly and only *erg4erg24* and, to a lesser extent, *erg5erg24* was clearly growing on YPAD. On synthetic complete medium, however, we observed slightly better growth in the presence of  $\text{Ca}^{2+}$  (Fig. 3). All double mutants grew at least to some extent in synthetic complete medium if  $\text{Ca}^{2+}$  was added to the medium.

Crowley et al. [9] demonstrated that the concentration of  $\text{Ca}^{2+}$  was greater in a synthetic complete medium than on rich YPD medium and that increased  $\text{Ca}^{2+}$  resulted in resistance to fenpropimorph, suggesting that  $\text{Ca}^{2+}$  enhances membrane integrity in strains in which ergosterol is replaced by ergosta-8,14 sterol intermediates. It is not obvious why *erg2erg24* mutants are more compromised than *erg24* alone, because *erg24* mutants are epistatic to *erg2* and thus accumulate only C-8 sterols. Thus, in an *erg24* strain there is no evidence of Erg2p activity, because all accumulated sterols are C-8-sterols. Further work will reveal whether there is a regulatory sterol defect that must be taken into consideration. In considering the

synthetic lethality of *erg6erg24* and *erg28erg24* strains, however, each individual mutation should contribute to an altered sterol profile and thus may help explain why the double mutants in these cases are lethal.

**Abstract** Steroidal saponins are complex compounds that have a steroid attached to a carbohydrate moiety. They are natural surfactants and detergents and exhibit a number of biological effects. Steroidal saponins have shown membrane-permeabilizing, hypocholesterolemic, immunostimulant, and anticancer properties. They have also been found to affect the growth, food intake and reproductive capabilities of animals. Furthermore, they have been shown to act as antiviral and antifungal agents. They have been isolated from many plants and some animals, especially sea cucumbers and starfish. Fish belonging to the species *Pardachirus pavoninus* excrete a mixture of six steroidal *N*-acetylglucosaminides, pavoninins 1–6, with shark-repelling properties. We report syntheses of the C-15 $\alpha$  pavoninin-4 by both direct synthesis from diosgenin and by remote functionalization. A general solution for the glycosylation of hindered alcohols was developed using glycosyl fluorides as good glycosyl donors. The syntheses of two C-16 $\beta$  structural analogs of OSW-1 are described.

## Introduction

Steroidal saponins constitute a structurally and biologically diverse class of glycoconjugates, which have been isolated from a wide variety of both plant and animal species [1–3]. They consist of a hydrophobic aglycone (sapogenin) to which a sugar moiety is attached, usually containing a glucose, galactose, *N*-acetylglucosamine, glucuronic acid, xylose, rhamnose or methylpentose. The oligosaccharide is normally attached at the C-3 position but many are now known that have it attached at C-6, 7, 15, 16, 24, and 26. In this review we will survey some of the biological properties of saponins and report methods for the synthesis of 15 $\alpha$  and 16 $\beta$  steroidal saponins.

Steroidal saponins are natural surfactants, or detergents. They have been isolated from a great number of terrestrial plants, such as alliums, asparagus, aubergine, capsicum peppers, oats, tomato seeds, yams, and ginseng [2]. They are most abundant in the desert plants *Yucca* and *Quillaja*. They are common in plants used as herbs or for their health-promoting properties.

Steroidal saponins are uncommon animal constituents. In the animal kingdom they are almost ubiquitous in sea cucumbers and starfish, while found only rarely in alcyonarians, gorgonians, sponges, and as shark-repelling compounds in fish. The shark-repelling pavoninins 1–6 (**1–5**) were isolated from fish belonging to the species *Pardachirus pavoninus* [4, 5]. The steroidal saponin OSW-1 (**6**) was isolated from the bulbs of the plant *Ornithogalum saundersiae*, and has been proven to be a highly potent anticancer agent [6, 7] (Fig. 1). Despite their different origins, they are both derivatives of cholesterol with additional hydroxyl functionalities on the B or D rings and a functionalized side chain. Pavoninins have the monosaccharide *N*-acetylglucosamine attached at the B ring C-7 $\alpha$  or D ring C-15 $\alpha$  hydroxyl group, and OSW-1 (**6**) has a disaccharide attached to the D-ring C-16 $\beta$  hydroxyl group. Due to their structural similarity to anticancer agents, it is believed that pavoninins could also have other important pharmacological properties beyond their shark-repelling properties.

The effects of saponins in plants are not well understood. Many saponins are known to inhibit mold, to be antimicrobial, and to protect plants against insect

attack. Some can be considered to be part of a plant's defense system. This defensive property appears to carry over into animals, as some fish, such as the species *Pardachirus*, use saponins as defensive compounds in order to repel sharks [4, 5].

A broad range of biological effects have been ascribed to saponins: membrane-permeabilizing, hypocholesterolemic, immunostimulant, and anticancer properties [2]. They have also been found to affect growth and food intake in animals [8]. Furthermore, they have been shown to act as antiviral and antifungal agents.

Saponins have long been known to form pores in membranes, and this has resulted in their use in physiological research. There are a wide variety of saponin structures, as both the sapogenin and the sugar can be varied, and the site(s) and stereochemistry of conjugation on the sapogenin and the sugar can also be varied. This variation in saponin structure can lead to different biological mechanisms. For example, some steroidal saponins with a single monosaccharide were found to have strong hemolytic activity, whereas those with two sugars showed less activity [9]. However, this is not always the case and in some cases di- and triglycosides have been shown to have higher hemolytic activity [10].

**Fig. 1** Shark repellent pavoninins 1–6 (**1–5**) and the anticancer agent OSW-1, **6**

The exact details of the interactions between saponins and membranes needs more elucidation so that the molecular mechanisms involved can be better understood. It has been found that some saponins affect the permeability of the intestinal mucosa cells and thereby affect the uptake of nutrients through the intestinal membrane. The permeability of the brush border is apparently increased by sublethal levels of saponins and this has important implications for the uptake of macromolecules, such as allergens, whose passage through the epithelium is normally somewhat restricted [11].

Saponins from different sources have produced lower cholesterol levels in a variety of animals, including human subjects [12]. When saponin-rich foods are consumed, such as soybean, lucerne, and chickpeas, large mixed micelles are formed by the interaction of saponins with bile acids, which leads to their increased excretion [13]. Saponins also reduce the more harmful LDL-cholesterol selectively in the sera of rats, gerbils and human subjects [14].

The immune system is stimulated by saponins. *Quillaja* saponins have been reported to increase immune-cell proliferation in vitro, and to boost antibody production without producing any reagenic antibodies [15]. The mechanisms of the immune-stimulating actions of saponins are not clearly understood. Saponins reportedly induce the production of cytokines such as interleukins and interferons that might mediate their immunostimulant effects.

Saponins have been shown to inhibit the growth of cancer cells in vitro by unknown mechanisms. Saponin-induced apoptosis is primarily caused by stimulating the cytochrome *c*–caspase 9–caspase 3 pathway in the human cancer and other cell lines [16]. The tumor specificity of the cytotoxic action seems to be influenced by the structure of the sugar portion of the saponins after the hydrophobic aglycone core allowed saponins to traverse the mitochondrial membrane.

Saponins affect animal growth and feed intake. In ruminants and other domestic animals, dietary saponins have been found to improve growth, feed efficiency, and health [17]. Saponins are considered to have detrimental effects on protozoa through their binding with sterols on the protozoal surface [18]. Dietary saponins were often suspected of having a role in causing ruminant bloat, but clear experimental proof for this is lacking in the literature. Saponins damage the respiratory epithelia of some fish and are thus highly toxic [19]. However, fish belonging to the species *Pardachirus* excrete saponins that are ichthyotoxic and repel sharks and thus act as defensive compounds. Growth in common carp was significantly higher than control only when there was a continuous dietary

supply of saponins. Soybean saponins did not affect the growth of chicks when added at five times the concentration in a normal soybean-supplemented diet. Similarly in mice and rats, no effect on the growth response was observed on a soybean-supplemented diet. Dietary saponins depressed growth feed consumption in gerbils and egg production in poultry [20].

Saponins cause a reduction in protein digestibility, probably through the formation of sparingly soluble saponin–protein complexes [21]. The digestibility of bovine serum albumin–soyasaponin complex was much lower than that of free bovine serum albumin, indicating that complexing with saponins had an obstructing effect. Since a large number of foods and feed materials contain both saponins and proteins, the nature of the interactions between them would influence the nutritive value of the diet.

Due to the difficulty in isolating and purifying saponins, there is often very little pure material available. Since an understanding of the effects of these compounds will require significant amounts of the pure substances, methods for the isolation and preparation of target saponins need to be developed. Furthermore, the development of new synthetic methods frees the researcher from needing to use only naturally available saponins. Hopefully structure–activity relationships will lead researchers to design and synthesize new saponins in order to potentiate their desired biological activity. We apply these ideas to a study of the shark-repelling steroidal saponins called pavoninins.

Among the pavoninin family of steroidal saponins, the synthesis of pavoninin-1 (**1a**) [22], and the aglycone of pavoninin-1 (**1a**) and -2 (**1b**), have been reported [23]. Recently, we reported the syntheses of the aglycone of 26-*O*-deacetyl pavoninin-5 (**2b**) [24, 25], of pavoninin-4 (**3**) [26], and the aglycone of pavoninin-4 by remote functionalization [27]. The isolation and synthesis of shark-repelling saponins have recently been reviewed [28]. In this paper, we review our efforts in developing a good method for glycosylation of the hindered C-15 $\alpha$  and C-16 $\beta$  hydroxyl groups in a steroid, as well as the synthesis of the shark repellent pavoninin-4 (**3**). The synthesis of the structural analogs **32b** and **37** of the anticancer agent OSW-1 (**6**) are also reported.

## Results and Discussion

### Synthesis of the C-15 $\alpha$ Hydroxylated Steroid **14**

The synthesis of pavoninin-4 (**3**) presents three major problems: the presence of an *N*-acetylglucosamine moiety attached to a C-15 $\alpha$  hydroxylated cholesterol

and a C-26 acetate in the presence of three secondary and one primary alcohol. The synthesis of the C-15 $\alpha$  hydroxylated steroid **14** started from commercially available diosgenin **7**. Reduction of **7** using zinc and hydrochloric acid afforded (25*R*)-5-ene-cholesta-3 $\beta$ ,16 $\beta$ ,26-triol (**8**), which when subjected to a catalytic hydrogenation yielded the saturated (25*R*)-5 $\alpha$ -cholesta-3 $\beta$ ,16 $\beta$ ,26-triol (**9**). Subsequent Mitsunobu reaction [29] on the triol **9** afforded the 3 $\alpha$ ,26-dibenzoate **10** in 85% yield, and achieved several transformations. The C-3 and C-26 hydroxyl groups of triol **10** were chemoselectively protected, and at the same time the C-3 hydroxyl stereochemistry was inverted from  $\beta$  to  $\alpha$ , all in one step. We have reported a successful six-step method for transposing the C-16 $\beta$  hydroxyl in **8** to the 15 $\alpha$  position in our synthesis of the aglycone of 26-*O*-deacetyl pavoninin-5 [24, 25]. Oxidation of the C-16 alcohol afforded the ketone, which was converted to its silyl ether, and epoxidization followed by rearrangement yielded the 15 $\alpha$ -hydroxy-16-ketone. Protection of the C-15 $\alpha$  alcohol as its silyl ether followed by reduction of the ketone and chemoselective deoxygenation

of the C-16 alcohols using the Barton deoxygenation reaction afforded the 15 $\alpha$  alcohol [24, 25].

A very efficient four-step method for this transposition was developed via allylic oxidation and subsequent stereospecific reduction in our synthesis of (25*R*)-5 $\alpha$ -cholesta-3 $\beta$ ,15 $\alpha$ ,26-triol [30]. Using Kim's method [31], namely NaI in DMF, regiospecific dehydration of the hindered C-16 $\beta$  hydroxyl was achieved via a bis-protected 16-mesylate, to yield the disubstituted C-16 olefin, **11**, in 96% yield. Allylic oxidation at C-15 using chromium trioxide and 3,5-dimethylpyrazole yielded the 16-en-15-one, **12**. Stereospecific Luche reduction [32] proceeded quantitatively from the unexpected  $\beta$ -face to yield the 15 $\alpha$  allylic alcohol, **13**. The saturated alcohol **14** was prepared by catalytic hydrogenation. Comparison of the spectra of **14** with its 3 $\beta$  epimer (25*R*)-5 $\alpha$ -cholesta-3 $\beta$ ,15 $\alpha$ ,26-triol, whose structure has been determined by X-ray analysis [30], proved the  $\alpha$ -configuration of the C-15 hydroxyl group. Using this synthetic method, the C-15 $\alpha$  hydroxylated intermediate **14** was successfully achieved through an eight-step synthesis in a 41% overall yield from diosgenin, **7** (Scheme 1).

**Scheme 1** Synthesis of the C-15 $\alpha$  hydroxylated steroid **14**

## Synthesis of the Aglycone of Pavoninin-4 **24**, Using Remote Functionalization

The aglycone of pavoninin-4 (**24**) can be also be synthesized from diosgenin **7** via (25*R*)-26-hydroxycholesterol (**15**) [33], using Breslow's remote functionalization [34] strategy, as shown in Scheme 2.

Triol **8** was chemoselectively protected as the hydroxy diester **8a**, as described in Scheme 2. Mesylation of the C-16 alcohol **8a** afforded a C-16 mesylate, which upon reduction with LAH yielded the diol **15** and effected deoxygenation at C-16. The unsaturated diol **15** was catalytically reduced to afford the saturated diol **16**. Chemoselective protection of the primary C-26 hydroxyl by 3-pivaloyl-1,3-thiazolidine **17** and sodium hydride [35] gave the 3β,26-diol 26-pivaloate **18** in 80% yield. The required 3α stereochemistry for pavoninin-4 (**3**) was introduced by treatment of the 3β alcohol **18** under Mitsunobu conditions with the known acid **19** [36] to yield the

inverted ester **20** in 85% yield. Photolysis of **20** using a 450-W medium-pressure Hanovia lamp with a Pyrex filter and subsequent hydrolysis of the C-3 and C-26 esters with potassium hydroxide under refluxing conditions gave the intermediate 3α,26-diol. Since this was difficult to separate, the diol was converted into a mixture of the unreacted saturated (25*R*)-5α-cholestan-3α,26-diol 3α,26-diacetate (**21**) and the desired (25*R*)-5α-cholest-14-ene-3α,26-diol 3α,26-diacetate (**22**) in a 2:3 ratio in 65% combined yield. Subsequent hydroboration and oxidation [37] on the above unsaturated and saturated mixture of **21** and **22**, accompanied by a simultaneous hydrolysis of bis-protected acetyl groups at C-3 and C-26 hydroxyl afforded the easy separation of the more polar (25*R*)-5α-cholestan-3α,15α,26-triol (**23**). Finally, selective acetylation of the primary C-26 hydroxyl by Otera's transesterification strategy [38], using vinyl acetate with distannoxane as a catalyst, afforded the aglycone of pavoninin-4 (**24**) in 80% yield.

**Scheme 2** Synthesis of the aglycone of the pavoninin-4 (**24**) by remote functionalization

### The First Attempt at the Glycosylation Reaction

With both methods in place for making the C-15 $\alpha$  hydroxyl intermediate, we turned our attention to the glycosylation reaction on the steroid. We first tried to attach the *N*-acetylglucosamine to a C-16 $\beta$  hydroxyl steroid by using the commercially available 2-acetamido-2-deoxy- $\alpha$ -D-glucopyranosyl chloride 3,4,6-triacetate (**26**). Unfortunately, there was no reaction when using silver triflate as an activator [39]. So we tested the reaction conditions on 5-androsten-3 $\beta$ -ol-17-one (DHEA, **25**) as a model study. The result showed a successful glycosylation of DHEA that yielded the saponin **27** in 44% yield in a 2:1 ratio of  $\beta$ : $\alpha$  isomers (Scheme 3).

Many other activators have also been tried on this reaction. For example, iodine combined with DDQ [40], CdCO<sub>3</sub> [41], and thermal conditions as reported by Nishizawa et al. [42]. However, all these attempts failed, probably because the C-16 $\beta$  hydroxyl is so hindered by the steroid side chain that its reactivity is reduced in the glycosylation reaction. Therefore, we turned our attention to other glycosyl donors.

Because 2,3,4,6-*tetra-O*-acetyl-2-deoxy-D-glucopyranosyl fluoride (**29**) is commercially available, we decided to do another model study on the glycosylation

reaction using the glycosyl fluoride as a glycosyl donor. Following the procedure described by Mukaiyama et al. [43], we attempted to glycosylate the C-16 $\beta$  hydroxyl steroid (25*R*)-3 $\beta$ ,26-bis[(*tert*-butyldimethylsilyl)oxy]-cholest-5-en-16 $\beta$ -ol (**28**). However, the glycosylation reaction proceeded unexpectedly to yield (25*R*)-3 $\beta$ [(*tert*-butyldimethylsilyl)-oxy]-cholest-5-en-16 $\beta$ ,26-di-acetate (**30**) as an only product when glucosyl fluoride (**29**) was used as a glycosyl donor and AgClO<sub>4</sub>·SnCl<sub>2</sub> was used as an activator (Scheme 4). This result may be rationalized as a selective deprotection of the C-26 silyl protection group of **28** under the acidic glycosylation conditions, followed by an acetyl transfer between the resulting diol and the acetylated glucosyl fluoride **29**, due to catalyzation by the Lewis acid, SnCl<sub>2</sub>. Normally, the acetyl transfer can be avoided by using a less labile protection group [3]. Therefore, we tried the reaction by simply replacing the C-3 and C-26 bis-silyloxy groups with pivaloates (**31**). Under the same conditions, the glycosylation reaction went smoothly to afford the steroidal saponin **32** in 70% yield with a single  $\beta$  configuration based on proton NMR analysis of **32a**. When **32a** was treated with sodium methoxide in refluxing methanol, the C-16 $\beta$  analog of pavoninin-4, **32b**, was prepared in 90% yield (Scheme 5). Consequently, **32b** is also a structural analog of the OSW-1 [6], because

**Scheme 3** Glycosylation of DHEA using glycosyl chloride as a glycosyl donor

**Scheme 4** An unsuccessful glycosylation of the C-16 $\beta$  hydroxyl steroid, **3**

**Scheme 5** Synthesis of a C-16 $\beta$  analog of pavoninin-4 and OSW-1, **32b**

both are steroidal saponins with a sugar attachment on the same C-16 $\beta$  position of a steroid.

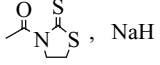

#### A Model Study on Selective Acetylation Reaction: Synthesis of a C-16 $\beta$ Analog of OSW-1 **32b** and **37**

Encouraged by the successful glycosylation of the hindered C-16 $\beta$  hydroxyl group, we turned our attention to selective acetylation at C-26 acetate of pavoninin-4 (**3**). In fact, five of the six pavoninins have an acetate group on the side chain at C-26 (see Fig. 1). The plan to introduce the C-26 acetate during a later stage of the synthesis would not work if the sugar alcohols were protected as acetates. Therefore, the benzyl group was used as a protecting group, since they could easily be removed by catalytic hydrogenation. We found that the benzyl-protected sugar fluoride, 2,3,4,6-tetra-*O*-benzyl-2-deoxy-D-glucopyranosyl fluoride (**33**) was commercially available, so we decided to pursue another model study on the chemoselective acetylation strategy (Scheme 6).

Under the same conditions, glycosylation of the hindered C-16 $\beta$  hydroxyl steroid **28** proceeded successfully to yield the saponin **34** in 70% yield, using the tetrabenzylated glucopyranosyl fluoride (**33**) as a donor. Subsequently, the C-3 and C-26 bis-silyl protection groups were removed with TBAF to afford a C-3 and C-26 diol **35**, which was then subjected to selective acetylation under three different conditions, as shown in Table 1.

Stork et al. achieved a selective acetylation of a primary alcohol in the presence of second alcohols by using 1.2 equiv. each of acetic anhydride and pyridine at  $-7^\circ\text{C}$ , in the total synthesis of prostaglandin  $F_{2\alpha}$  [44].

**Table 1** Selective acetylation of the saponin 3 $\beta$ ,26-diol **35**

Experiment	Condition	Yield (%)	Ratio (36a:36b)	Reference
1	Ac <sub>2</sub> O, pyr, 0–10 °C	N/A	N/A	Stork et al. [44]
2	 , NaH	50	~1:2	Yamada et al. [35]
3	Vinyl acetate, Bu <sub>8</sub> Sn <sub>4</sub> Cl <sub>4</sub> O <sub>2</sub>	80	~1:3	Otera et al. [38]

However, we found that the yield of chemoselective C-26 acetate **36** was poor when these conditions were used on the diol **35**, even after the reaction time was increased to three days. Therefore, Yamada's condition [35] for the highly selective acylation of di- and polyhydroxyl compounds by 3-acylthiazolidine-2-thiones was chosen as an alternative way to achieve the chemoselective acetylation of the C-3 and C-26 diol **35**. Results showed that two easily separated products **36a** and **36b** were prepared in 15% and 35% yields, respectively, which correspond to the selective acylation of C-3 and C-26 hydroxyls. This represents a considerable improvement over the yield obtained using Stork's conditions.

Otera used 1,3-dichlorodistannoxane as a catalyst for a highly selective acylation of alcohols [38]. When 1,3-dichlorodistannoxane was reacted with vinyl acetate in the presence of the diol **35**, the acetate group was transferred from the vinyl acetate to the C-3 (**36a**) or C-26 (**36b**) alcohol. The yield of the desired product

**Scheme 6** Synthesis of the C-16 $\beta$  analog of OSW-1 (**37**)

**36b** was dramatically increased to 60%. Furthermore, the ratio of **36b**:**36a** was increased from 2:1 to 3:1 with an 80% combined yield (Table 1).

Finally, deprotection of benzyl groups on the sugar alcohols was achieved by LiDBB reduction [45], yielding **37**, the second C-16 $\beta$  analog of pavoninin-4 and OSW-1 in 85% yield (see Scheme 6).

#### Synthesis of 2-Acetamido-3,4,6-Tribenzyl-2-Deoxy-D-Glucopyranosyl Fluoride (**39**)

From the results of model studies on the glycosylation of the hindered alcohols and chemoselective acetylation, we have learned that the best sugar fluoride for the synthesis of pavoninin-4 should be a benzyl-protected *N*-acetyl sugar fluoride; that is, 2-acetamido-3,4,6-tribenzyl-2-deoxy-D-glucopyranosyl fluoride (**39**). Since this sugar product is not commercially available, we turned our attention to the synthesis of the desired glycosyl fluoride **39** (Scheme 7).

We first attempted to convert the 2-acetamido-3,4,6-triacetyl-2-deoxy-D-glucopyranosyl chloride (**26**) directly into a fluoride, 2-acetamido-3,4,6-triacetyl-2-deoxy-D-glucopyranosyl fluoride (**38**), by reaction of **26** with silver fluoride in dry acetonitrile [46]. The result showed a successful conversion and the expected fluoride **38** was prepared in 50% yield (Scheme 8). However, the following steps for replacing the acetate protecting groups with benzyl to synthesize **39** were difficult to achieve in high yield, probably due to the instability of the fluoride under the hydrolysis reaction conditions [46].

**Scheme 7** An unsuccessful synthesis of the glycosyl fluoride (**39**)

**Scheme 8** Synthesis of 2-acetamido-3,4,6-tribenzyl-2-deoxy-D-glucopyranosyl fluoride (**39**)

Alternatively, another commercially available sugar source, *N*-acetyl-D-glucosamine (**40**), was a readily available starting material. In four steps, **40** was converted into 2-acetamido-3,4,6-tribenzyl-2-deoxy-D-glucopyranose (**43**) in 38% yield [47]. Reaction of **43** with DAST afforded the 2-acetamido-3,4,6-tribenzyl-2-deoxy-D-glucopyranosyl fluoride **39** [48] as outlined in Scheme 8.

#### Synthesis of the Shark Repellent Pavoninin-4

Through the use of the fluoride **39**, glycosylation of the C-15 $\alpha$  hydroxyl intermediate **14**, with  $\text{AgClO}_4\text{-SnCl}_2$  used as an activator [43], proceeded very successfully to yield the saponin **44** in 72% yield plus 15% of recovered starting material. Exclusive formation of the  $\beta$ -glycoside may be explained by the intramolecular cyclization of the neighboring C-2 $\alpha$  acetamide function at the C-1 $\alpha$  position, directing the C-15 alcohol to attack  $\beta$  via an  $\text{S}_{\text{N}}2$  reaction to yield the  $\beta$ -glycoside **44**. Hydrolysis of C-3 and C-26 benzoyl-protecting groups using potassium hydroxide in methanol gave the expected C-3 and C-26 diol **45**. The C-26 acetate was selectively and efficiently introduced by Otera's transesterification using vinyl acetate under dioxane catalysis [35] to afford **46** in 80% yield. Deprotection of the benzyl ethers using catalytic hydrogenation afforded pavoninin-4 (**3**) (Scheme 9). The spectroscopic data for the synthetic pavoninin-4 were identical to those reported for the natural product [5].

## Conclusions

In summary, a broad range of biological effects have been ascribed to steroidal saponins: membrane-permeabilizing, hypocholesterolemic, immunostimulant, and anticancer properties. They have also been found to affect growth and food intake in animals and to act as antiviral and antifungal agents. Methods for the synthesis of C-15 $\alpha$  hydroxylated cholesterol were developed and applied to the synthesis of pavoninin-4 (**3**) starting from diosgenin **7**. The intermediate pavoninin-4 aglycone **24** was made by two routes: carbonyl reduction of an intermediate conjugated enone, and by remote functionalization. A general solution for glycosylation of hindered alcohols was explored using glycosyl fluorides as good glycosyl donors for the synthesis of steroidal saponins. A highly efficient method for the chemoselective acetylation of the C-26 primary alcohol of the cholesterol skeleton in the presence of *N*-acetylglucosamine is also reported. The syntheses of **32b** and **37**, structural analogs of OSW-1, are also described.

# The Liebermann–Burchard Reaction: Sulfonation, Desaturation, and Rearrangement of Cholesterol in Acid

Quanbo Xiong · William K. Wilson · Jihai Pang

Received: 30 October 2006 / Accepted: 11 December 2006 / Published online: 18 January 2007  
© AOCS 2007

**Abstract** In the Liebermann–Burchard (LB) colorimetric assay, treatment of cholesterol with sulfuric acid, acetic anhydride, and acetic acid elicits a blue color. We studied the reactivity of cholesterol under LB conditions and provide definitive NMR characterization for approximately 20 products, whose structure and distribution suggest the following mechanistic picture. The major reaction pathways do not involve cholestadienes, i-steroids, or cholesterol dimers, as proposed previously. Instead, cholesterol and its acetate and sulfate derivatives undergo sulfonation at a variety of positions, often with skeletal rearrangements. Elimination of an  $\text{SO}_3\text{H}$  group as  $\text{H}_2\text{SO}_3$  generates a new double bond. Repetition of this desaturation process leads to polyenes and ultimately to aromatic steroids. Linearly conjugated polyene cations can appear blue but form too slowly to account for the LB color response, whose chemical origin remains unidentified. Nevertheless, the classical polyene cation model is not excluded for Salkowski conditions (sulfuric acid), which immediately generate consider-

able amounts of cholesta-3,5-diene. Some rearrangements of cholesterol in  $\text{H}_2\text{SO}_4$  resemble the diagenesis pathways of sterols and may furnish useful lipid biomarkers for characterizing geological systems.

## Introduction

Numerous colorimetric tests have been devised for the identification and quantitation of steroids [1]. Perhaps the foremost of these methods is the Liebermann–Burchard (LB) reaction, which was the leading assay for serum cholesterol in clinical laboratories during most of the twentieth century [2–4] and is still recommended by the USA Food and Drug Administration as a standard against which new methods are compared [5]. The LB reaction was first described in 1885 by Liebermann [6] and was later investigated extensively by Burchard [7]. Burchard developed the reaction into a quantitative test for cholesterol and used this assay to confirm the widespread presence of sterols in animal and plant tissues. The LB reaction has been studied for many other sterols; the color response varies markedly

depending on the double bond system [8], other functional groups, and the presence of a nonpolar side chain [9] (Fig. 1).

The mechanism that generates the LB color response has intrigued chemists for over 100 years, and much work was carried out even before the structure of sterols was established [10]. During the past 50 years, the color response has been attributed to polyene cations formed under LB conditions. Following Watanabe's [11] 1959 proposal of a tetraene dimer complexed with acid, Brieskorn and Hofmann [9] suggested the formation of a  $\Delta 4,6,8(14),15,17(20)$  steroid complex from cholesterol by a series of sulfonations with  $\text{SO}_3$ , coupled with elimination of  $\text{SO}_2$ . Key mechanistic analyses in 1974 [12, 13] supported and refined the polyene cation hypothesis, but extensive kinetic measurements failed to correlate  $\text{SO}_2$  evolution from the LB reaction with the color response. These and other mechanistic studies were summarized by Zuman [14] in 1991 in a comprehensive review covering the LB reaction and similar colorimetric assays.

A major weakness of the mechanistic work has been the lack of knowledge about the LB reaction pathways. Very few LB products have been characterized beyond UV and combustion analyses, and no polar intermediates have been reported apart from steryl sulfates and perchlorates. Investigators variously postulate cholesterol dimers [11, 15], cholestadienes [9, 12, 13], or epicholesterol derivatives [9] as pivotal intermediates without any evidence of their quantitative importance. As a result, the behavior of cholesterol in strongly acidic solution is still poorly understood.

We have now investigated the LB reaction with modern chromatographic and spectral methods. In situ NMR analysis and experiments with  $^{14}\text{C}$ -labeled cholesterol were used to trace the increasing levels of polar products as the reaction progresses. Preparative high-performance liquid chromatography (HPLC) and thin-layer chromatography (TLC) led to the isolation of numerous reaction products, whose structures were

determined by 2D NMR in conjunction with quantum-mechanical NMR calculations. The results indicated that cholesterol is rapidly converted to acetate and sulfate derivatives, which are slowly desaturated via sulfonic acids, eventually rearranging to aromatic steroids. These new insights into the behavior of cholesterol under LB conditions are discussed with regard to the chemical origin of the color response.

## Experimental Procedures

### Materials

Solvents and reagents were chromatography or reagent grade; chloroform was amylene-stabilized from bottles less than 6 months old unless otherwise specified. Deuterated reagents (acetic acid, acetic anhydride, and sulfuric acid) were obtained from Aldrich (Milwaukee, WI, USA). Commercial cholesterol (**1**) was purified via the dibromide and then recrystallized from methanol to remove oxysterol contaminants. [ $4\text{-}^{14}\text{C}$ ]Cholesterol was obtained from Amersham, and its purity was confirmed by radio-TLC (ethyl acetate/hexanes 2:7). A cholesteryl sulfate standard was purchased from Steraloids (Newport, RI, USA).

### LB Reaction

The LB color reagent was prepared freshly, as described by Abell et al. [16], by adding concentrated  $\text{H}_2\text{SO}_4$  to acetic anhydride at  $0\text{ }^\circ\text{C}$ , stirring for 10 min, adding acetic acid, and warming to room temperature. The proportion of  $\text{H}_2\text{SO}_4$ , acetic anhydride, and acetic acid is specified for each experiment, varying from the classic 1:20:10 (v/v) ratio to 8:20:10. Whereas the LB reagent is usually added directly to a dry residue in clinical protocols [16], we followed Burchard [7] in adding the reagent to a solution of cholesterol in chloroform; this facilitated in situ NMR studies and mixing in low-temperature experiments without qualitatively altering the color response.

### Spectral Methods

$^1\text{H}$  NMR and  $^{13}\text{C}$  NMR spectra of steroids were acquired at  $25\text{ }^\circ\text{C}$  in relatively dilute solution (1–20 mM) with Bruker AMX and Avance 500-MHz spectrometers. Proton spectra were referenced to tetramethylsilane;  $^{13}\text{C}$  spectra were referenced to  $\text{CDCl}_3$  at 77.0 ppm or  $\text{CD}_3\text{OD}$  at 49.0 ppm. Chemical shift reproducibility was about  $\pm 0.001$  ppm for  $^1\text{H}$  (except for protons near functional groups in  $\text{CD}_3\text{OD}$  solution)

and about  $\pm 0.03$  ppm for  $^{13}\text{C}$ . Mass spectra were obtained by direct probe using a ZAB-HF spectrometer with electron-impact ionization (70 eV) or fast-atom bombardment (FAB) in a matrix of glycerol or 3-nitrobenzyl alcohol (NBA). Higher-resolution mass spectra were acquired by infusing methanol solutions into a Waters (Micromass) Q-TOF Ultima with positive (ES+) or negative (ES-) electrospray ionization. Spectrophotometric analysis of LB reactions was done in 1.4- or 3.5-mL quartz cuvettes (10-mm path length) using a Shimadzu 1601 spectrophotometer. Radioactivity was measured with a Packard model 1500 liquid scintillation analyzer using ScintiVerse or toluene/2,5-diphenyloxazole.

### Quantum-Mechanical NMR Calculations

NMR shieldings were calculated with Gaussian 03 [17] by the gauge independent atomic orbital method at the B3P91/6-311G(d,p)//B3LYP/6-31G(d) level. The shieldings were converted to chemical shifts using empirical adjustments (L.-W. Guo, W. K. Wilson, and C. H. L. Shackleton, unpublished results). The structures of **10–20** were confirmed by comparing the observed  $^1\text{H}$  and  $^{13}\text{C}$  NMR chemical shifts with predicted shieldings, as described previously [18]. The agreement was generally within 0.1 ppm for  $^1\text{H}$  and within 1 ppm for  $^{13}\text{C}$ , except for systematic deviations affecting nuclei influenced by sulfonate groups. Sulfonates were modeled as sulfonic acids to compensate for hydrogen bonding; the model did not include solvation. The predicted shieldings greatly facilitated signal assignments, spectral interpretation, and positioning of sulfonate groups.

## Results

### Preliminary Studies of the LB Reaction

We initially explored many variations of the LB reaction. Under nearly all conditions, the reaction progressed from colorless, to pale blue, blue, bluish green, and green. A modified LB reagent with a 4:20:10 ratio (elevated amount of  $\text{H}_2\text{SO}_4$ ) increased the absorbance and was used in some studies. LB reactions with ethanol-stabilized chloroform were more sluggish than reactions with amylene-stabilized chloroform, producing the same sequence of colors but with lower absorbance. Omitting both acetic acid and anhydride, i.e., Salkowski conditions [19, 20], produced a red color, but other variations of LB conditions had no qualitative effect on color formation. Intermediate

stages of the LB reaction could be preserved for kinetic and NMR studies by maintaining the temperature below  $-20^\circ\text{C}$ . Substituting dichloromethane for chloroform reduced the reaction viscosity at low temperatures without affecting the color response. Quenching was explored by dropwise addition of cold 24% NaOH, ethanol, methanol, or pyridine, the last three reactions requiring subsequent neutralization with aqueous NaOH. Even nucleophilic quenching reagents generated only modest amounts of adducts with the nucleophile. The aim of quenching was to obtain stable products that reveal the structure of intermediates. Nevertheless, some workup conditions may have resulted in ester hydrolysis or further sulfonation.

### Studies of LB Reaction Products with $[4-^{14}\text{C}]$ Cholesterol

Reaction of  $[4-^{14}\text{C}]$ cholesterol (25 mg; 500,000 dpm) in chloroform (15 mL) with LB reagent (2.5 mL, 1:20:10 ratio) at room temperature produced a bluish-green color after 30 min. The mixture was immediately chilled to  $-70^\circ\text{C}$  and quenched by dropwise addition of cold 24% NaOH (10 mL). Scintillation counting of the resulting aqueous and organic layers and the precipitate indicated a 70:22:8 distribution of radioactivity. Chilling the aqueous layer to  $-20^\circ\text{C}$  produced more precipitate, corresponding to almost half the aqueous-layer radioactivity. A duplicate experiment gave similar results. With a more concentrated solution of cholesterol (250 mg) in chloroform (15 mL) and LB reagent (2.5 mL, 4:20:10 ratio), the distribution of the  $^{14}\text{C}$  label was 3:33:64 (aqueous layer, organic layer, precipitate). The precipitate was predominantly cholesteryl sulfate (see later). These results indicate that most of the cholesterol is converted to highly polar products that are insoluble in chloroform.

### Sterols Produced by LB Reaction A

To a solution of cholesterol (250 mg) in chloroform (25 mL; stabilized with 0.75% ethanol) was added LB reagent (1:20:10 ratio, 10 mL). The solution gradually turned blue and, before any appearance of green color, the reaction was quenched with 24% aqueous NaOH (3 mL) followed by water (20 mL). The precipitate that formed between the chloroform and the aqueous layers was identified as cholesteryl sulfate (**2**, 81 mg, above 99% purity). Evaporation of the chloroform layer gave a residue (201 mg) comprising cholesteryl acetate (**3**), with traces of *i*-steroids (3 $\alpha$ ,5 $\alpha$ -cyclocholestanes) and other sterols. This residue was subjected

**Fig. 2** Products from Liebermann–Burchard (LB) reactions quenched at the blue stage. The initial major products **2** and **3** are subsequently converted to polar steroids

to repeated column chromatography and TLC (silica gel; ethyl acetate/hexane 1:5, 1:8, and 1:40); the products in order of increasing polarity were the Δ<sup>6</sup> i-steroid **4** (0.2 mg), **3** (130 mg), 6β-acetoxy i-steroid **5** (1 mg), 6β-ethoxy i-steroid **6** (1 mg), cholesteryl ethyl ether (**8**; 1 mg), and 6β-hydroxy i-steroid **7** (0.5 mg). These compounds, which were identified by NMR, are shown in Fig. 2.

NMR data: **2** (CD<sub>3</sub>OD, δ<sub>H</sub>) 0.718 (s), 0.877 (d, 6.6 Hz), 0.881 (d, 6.6 Hz), 0.943 (d, 6.6 Hz), 1.031 (s), 2.341 (dddd, 13.4, 11.7, 3.4, 2.8, 2.1 Hz), 2.530 (ddd, 13.4, 5.0, 2.4 Hz), 4.129 (tt, 11.5, 4.7 Hz), 5.385 (dt, 5.4, 2.1 Hz); **4** (CDCl<sub>3</sub>, δ<sub>H</sub>) 0.435 (dd, 8.0, 5.0 Hz), 0.718 (s), 0.863 (d, 6.6 Hz), 0.867 (d, 6.6 Hz), 0.897 (s), 0.903 (d, 6.6 Hz), 5.185 (dd, 9.8, 2.6 Hz), 5.522 (dd, 9.8, 1.9 Hz); **5** (CDCl<sub>3</sub>, δ<sub>H</sub>) 0.413 (dd, 8.3, 5.3 Hz), 0.499 (dd, 5.1, 3.8 Hz), 0.726 (s), 0.863 (d, 6.6 Hz), 0.867 (d, 6.6 Hz), 0.912 (d, 6.6 Hz), 1.009 (s), 2.048 (s), 4.508 (t, 3.0 Hz); **6** (CDCl<sub>3</sub>, δ<sub>H</sub>) 0.377 (dd, 8.3, 5.3 Hz), 0.616 (dd, 5.0, 3.7 Hz), 0.720 (s), 0.863 (d, 6.6 Hz), 0.868 (d, 6.6 Hz), 0.910 (d, 6.6 Hz), 1.013 (s), 1.148 (t, 7.0 Hz), 2.863 (t, 2.9 Hz), 3.377 (dq, 9.5, 7.0 Hz), 3.600 (dq, 9.5, 7.0 Hz); **7** (CDCl<sub>3</sub>, δ<sub>H</sub>) 0.291 (ddd, 8.1, 4.8, 0.8), 0.523 (dd, 4.8, 3.8 Hz), 0.721 (s), 0.863 (d, 6.6 Hz), 0.867 (d, 6.6 Hz),

0.912 (d, 6.6 Hz), 1.057 (s), 1.999 (dt, 12.7, 3.5 Hz), 3.261 (t, 3.0 Hz); **8** (CDCl<sub>3</sub>, δ<sub>H</sub>) 0.677 (s), 0.863 (d, 6.6 Hz), 0.867 (d, 6.6 Hz), 0.914 (d, 6.6 Hz), 1.002 (s), 1.200 (t, 7.0 Hz), 3.155 (tt, 11.3, 4.4 Hz), 3.52 (dq, 9.2, 7.0 Hz), 3.53 (dq, 9.2, 7.0 Hz), 5.345 (dt, 5.2, 2.1 Hz).

Similar LB reactions, carried out and quenched under a variety of mild conditions, also generated mainly **2** and **3**, often with traces of i-steroids, sultone **10** (see later), and Δ<sup>3,5</sup> diene **9**. NMR of **9**: (CDCl<sub>3</sub>, δ<sub>H</sub>) 0.704 (s), 0.864 (d, 6.6 Hz), 0.869 (d, 6.6 Hz), 0.921 (d, 6.6 Hz), 0.953 (s), 5.388 (br dd, 5, 2 Hz), 5.588 (br dd, 10, 5 Hz), 5.926 (dd, 9.8, 2.7 Hz). No other hydrophobic sterols were observed in LB reactions, apart from **11** and artifactual products like cholesteryl chloride [δ<sub>H</sub> 0.675 (s), 1.027 (s), 3.766 (tt), 5.370 (dt)] and esters of 7-hydroxycholesterol [e.g., δ<sub>H</sub> 0.689 (s), 1.055 (s), 5.606 (t, 2 Hz)].

### Sterols Produced by LB Reaction B

To a solution of cholesterol (2 g) in chloroform (40 mL) was added LB reagent (4:20:10 ratio, 20 mL). After 30 min at room temperature, the bluish-green solution was chilled and quenched with ethanol (60 mL) at −78 °C. The resulting yellowish-green mixture was evaporated in vacuo at 40 °C until there was no odor of acetic acid. Water (15 mL) and 24% aqueous NaOH (2–3 mL) were added to adjust the pH to 8. This solution was extracted with chloroform (2 × 20 mL); no precipitate was observed. The organic phase was evaporated to a brown residue (0.37 g); <sup>1</sup>H NMR indicated a complex mixture comprising mainly **1**, **3**, **10**, and **11**, with traces of i-steroids but no **9** or backbone rearrangement products [21]; reversed-phase chromatography (C<sub>18</sub> column, elution with 70–100% methanol in water) gave sultone **10** and (after further purification by C<sub>8</sub> HPLC) the phenanthrene derivative **11**, which were characterized by NMR (Tables 1, 2).

The aqueous phase was evaporated in vacuo to a solid, suspended in methanol (40 mL) with sonication, and centrifuged at 3,000 rpm for 10 min. The methanolic supernatant was evaporated to a residue (5.3 g), which was chromatographed on a 200-g C<sub>18</sub> column (50–100% methanol in water) to give, in order of elution, **15**, **18**, **12**, **17**, **19**, **20**, **13**, **14**, and **16**. Compounds **12–14** crystallized as colorless needles, but most other sterols were eluted as mixtures that were further purified by HPLC or TLC on C<sub>18</sub> media. Apart from **2**, the polar sterols comprised a multiplicity of minor products. In addition to compounds **12–20** (roughly 5–10 mg each), at least ten unidentified polar sterols were noted, together with a larger number of less abundant products.

### Structure Elucidation of Compounds **10–20** by NMR and Mass Spectrometry

Because of the extensive rearrangements and/or presence of sulfonate groups, the structures of **10–20** were

not readily established by comparisons with NMR spectra of known compounds. Each of these steroids was analyzed by heteronuclear single quantum coherence, heteronuclear multiple bond correlation, correlation spectroscopy with F1 decoupling, and

Chemical shifts were measured at 25 °C in  $\text{CDCl}_3$  (**10**, **11**) or in  $\text{CD}_3\text{OD}$  (**12**–**20**). Ethoxy signals for **15**:  $\delta$  15.89, 63.36

<sup>a</sup> Assignments that may be interchanged

distortionless enhanced polarization transfer experiments. Signal assignments were aided by quantum-mechanical NMR shielding predictions. These results, together with chemical shift comparisons, established the carbon skeleton and double-bond positions. The presence of  $-\text{SO}_3\text{Na}$  and  $-\text{OSO}_3\text{Na}$  substituents was established by mass spectrometry, and their location was inferred from NMR shielding patterns. In aromatic systems,  $-\text{SO}_3\text{Na}$  substitution deshields the *ipso* carbon by 10–20 ppm, and resonance-related carbons (e.g., *ortho* and *para*) are deshielded by a few parts per million. In aliphatic systems, the *ipso* carbon is strongly deshielded (by approximately 30–40 ppm), and nearby carbons are modestly deshielded. The exact position of sulfonate substitution in ring A could not be deduced for **18**, and the stereochemistry at C17 and C20 was not established for **11** (a single stereoisomer).

Mass spectral analyses were consistent with the structures shown in Fig. 3: **10** ( $\text{C}_{27}\text{H}_{44}\text{O}_3\text{S}$ ), electron impact  $m/z$  448 (97,  $\text{M}^+$ ), 433 (22), 384 (46), 366 (48), 335 (100), 253 (52), 159 (91); FAB (NBA) 449 (43,  $\text{M} + 1$ ), 367 (100,  $\text{M} - \text{HSO}_3$ ); **12** ( $\text{C}_{27}\text{H}_{44}\text{O}_7\text{Na}_2\text{S}_2$ ), ES+ 613.216 ( $\text{M} + \text{Na}$ ), ES- 567.229 ( $\text{M} - \text{Na}$ ); **13** ( $\text{C}_{27}\text{H}_{45}\text{O}_4\text{NaS}$ ), ES+ 511.285 ( $\text{M} + \text{Na}$ ), ES- 465.292 ( $\text{M} - \text{Na}$ ); **14** ( $\text{C}_{29}\text{H}_{47}\text{O}_5\text{NaS}$ ), ES+ 553.294 ( $\text{M} + \text{Na}$ ), ES- 507.291 ( $\text{M} - \text{Na}$ ); **15** ( $\text{C}_{29}\text{H}_{48}\text{O}_7\text{Na}_2\text{S}_2$ ), FAB (glycerol) 641 (30,  $\text{M} + \text{Na}$ ), 537 (100,  $\text{M} - \text{HSO}_3$ ); **16** ( $\text{C}_{27}\text{H}_{43}\text{O}_3\text{NaS}$ ), FAB (NBA) 493 (100,  $\text{M} + \text{Na}$ ); **17**

( $\text{C}_{27}\text{H}_{41}\text{O}_4\text{NaS}$ ), FAB (NBA) 507 (100,  $\text{M} + \text{Na}$ ); **18** ( $\text{C}_{27}\text{H}_{38}\text{O}_6\text{Na}_2\text{S}_2$ ), FAB (glycerol) 591 ( $\text{M} + \text{Na}$ ); **19** ( $\text{C}_{27}\text{H}_{35}\text{O}_3\text{NaS}$ ), FAB (NBA) 485 (100,  $\text{M} + \text{Na}$ ).

#### Reactivity of Cholesterol Under Salkowski Conditions

To cholesterol (1 mg) in  $\text{CDCl}_3$  (0.6 mL) in an NMR tube was added  $\text{D}_2\text{SO}_4$  (1  $\mu\text{L}$ ). The tube was inverted several times (the solution becoming pale pink), placed in the magnet, and maintained at 15 °C for 2 h while  $^{25}\text{H}$  NMR spectra were measured at 2–10-min intervals. NMR analysis indicated rapid formation of  $\Delta 3,5$  diene **9**. The ratio of  $\Delta 5$ ,  $\Delta 3,5$ , and other olefins was 74:25:1 after 4 min and 70:24:6 after 15 min, with little change thereafter. In contrast, cholesterol in LB reactions mainly underwent acetylation and sulfation, with little or no  $\Delta 3,5$  diene formation. Under both LB and Salkowski conditions, NMR showed no aromatic signals until later stages of the reaction, well after the blue or red color had fully developed.

Another Salkowski reaction was performed by adding  $\text{H}_2\text{SO}_4$  (512  $\mu\text{L}$ ) to a solution of cholesterol (1 g) in chloroform (50 mL). The mixture was shaken until a dark red color persisted, followed by chilling to  $-78$  °C and quenching with ethanol (25 mL;  $-78$  °C). To the resulting colorless solution was added 24% aqueous  $\text{NaOH}$  (10 mL). The precipitate contained **2**;

**Fig. 3** Products from a LB reaction quenched at the bluish-green stage (reaction B) and worked up under conditions permitting further reaction. The position of the sulfonate groups in **18** was not determined, but 2,4 or 3,4 substitution appeared likely

the organic phase was separated by preparative TLC (developed with CHCl<sub>3</sub>) into cholesterol (main component) and two backbone-rearrangement products

that were characterized by NMR: **21** (CDCl<sub>3</sub>,  $\delta_{\text{H}}$ ) 0.833 (d, 6.6 Hz), 0.838 (d, 6.6 Hz), 0.897 (s), 0.949 (d, 6.6 Hz), 1.080 (s), 4.093 (quintet, 2.9 Hz); **22** (CDCl<sub>3</sub>,  $\delta_{\text{H}}$ ) 0.851 (d, 6.6 Hz), 0.857 (d, 6.6 Hz), 0.897 (s), 0.903 (d, 6.6 Hz), 1.080 (s), 4.093 (quintet, 2.9 Hz). These products were identified, except for C10 stereochemistry, from NMR data reported for the 3-deoxy analogs [21]. The 10 $\alpha$ -H stereochemistry was assigned as shown in Fig. 4 on the basis of the H3 shieldings (matching calculated values much better for the 10 $\alpha$ -H than the 10 $\beta$ -H structure) and H3 coupling constants (indicating an axial  $\beta$ -hydroxy group and thus an AB-*trans* ring junction).

## Discussion

We have investigated the fate of cholesterol under strongly acidic conditions, with the ultimate goal of elucidating the origin of the color response in the LB reaction. The isolated products shown in Figs. 2 and 3 indicate the operation of several reaction pathways, summarized in Fig. 5. The LB mixture of sulfuric acid, acetic acid, and acetic anhydride in chloroform rapidly converts cholesterol to its acetate and sulfate derivatives, accompanied by small amounts of *i*-steroids, cholesta-3,5-diene, and other unsaturated species. The predominant  $\Delta^5$  species are then slowly converted to monounsaturated, diunsaturated, and polyunsaturated sulfonic acids. The polyene species gradually rearrange to aromatic steroids that are likely devoid of blue/green color, even as cations. We argue that none of these mainstream unsaturated species are responsible for the LB color response and that its chemical origin remains unknown.

The nature of the color-generating species in the LB reaction has received much attention. A neutral polyunsaturated steroid would not be colored, as judged by UV spectra of conjugated tetraenes [22], although only five C=C bonds are needed to generate the blue color of azulene. More likely candidates are linearly conjugated polyene cations; linear tetraenylic and pentaenylic cations (from a pentaene and hexaene) absorb in

**Fig. 4** Structures for backbone rearrangement products formed under Salkowski conditions

**Fig. 5** Major and minor pathways occurring in the LB reaction. The initial  $\Delta^5$  species **1–3** are slowly sulfonated and desaturated (oxidized) to form polyene sulfonic acids and aromatic steroids, as exemplified by **10–20**. The blue color appears at the nascent stage of polyene formation

the vicinity of 550 and 620 nm [23], respectively, whereas a tetraenylic cation containing a benzene ring absorbs at only 389 nm [24].

Desaturation of cholesterol to a polyene involves sulfuric acid, which is present in the reagents for the LB, Salkowski, and Zak colorimetric assays. The ability of concentrated  $\text{H}_2\text{SO}_4$  or  $\text{ClSO}_3\text{H}$  to convert sterols to polyunsaturated sulfonic acids with evolution of  $\text{SO}_2$  has long been known [25]. Brieskorn and Hofmann [9] noted that the dehydrating effects of the LB reagent would convert some  $\text{H}_2\text{SO}_4$  to  $\text{SO}_3$ , and their observation of  $\text{SO}_2$  evolution during the LB reaction confirmed the role of  $\text{H}_2\text{SO}_4$  in the desaturation of cholesterol.

Our characterization of numerous sulfonic acids from the LB reaction provides the first detailed insights into how the desaturation of cholesterol proceeds. Possible mechanisms for the conversion of  $\Delta^5$  species **1–3** to sulfonic acid derivatives are suggested in Fig. 6a. The modest concentration of  $\text{SO}_3$  and the unfavorable activation energy for attack of an isolated  $\text{C}=\text{C}$  on  $\text{SO}_3$  are consistent with the sluggishness of the LB color response. Moisture or alcohol (from ethanol-stabilized chloroform) would reduce the  $\text{SO}_3$  concentration and further retard the reaction, as is observed.

Our NMR analysis of hydrophobic sterol intermediates (Fig. 2) indicates that  $\Delta^5$  species are the major substrates in the LB reaction, as shown in Fig. 5. In contrast, Salkowski conditions produce substantial

**Fig. 6** Suggested mechanisms for **A** the sulfonation of  $\Delta^5$  sterols and **B** oxidative elimination of  $\text{H}_2\text{SO}_3$  to give an olefin. Compounds **2** and **12** were isolated as sodium salts but are shown here as the sulfonic acids (**2a** and **12a**) that would exist in the LB reaction. For simplicity, the oxidative elimination in **B** is shown as a cyclic process, although the new O–H bond formation would normally proceed through an intervening solvent molecule

amounts of cholesta-3,5-diene (**9**), which would more readily attack  $\text{SO}_3$ , since an allylic cation would be formed. This is consistent with the rapid Salkowski color response. The Zak reaction (1:1.5  $\text{H}_2\text{SO}_4/\text{AcOH}$  with  $\text{Fe}^{3+}$ ) may similarly benefit from the absence of acetic anhydride, which favors 3-acetate formation over dehydration to **9**.

Cholesterol dimers have been proposed as the initial species in colorimetric reactions [11, 15]. As pointed

out by others [9, 12–14], the selectivity of the LB reaction (Fig. 1), the UV behavior, and the reaction kinetics (first order in cholesterol) indicate this to be a very minor pathway. We did not detect any sterol dimers in our analyses.

Our results raise serious doubts about the prevailing hypothesis that the LB color response is derived from linearly conjugated polyene cations. Our first concern with this hypothesis is the lack of intermediate colors in the LB reaction. Whereas the Zak reaction proceeds through distinct UV absorbance maxima separated by well-defined isosbestic points [13], our time-course UV analysis of the LB reaction (partially shown in Fig. 3 in [8]) and those of Burke et al. [12] indicated no intermediate species that absorb in the 300–500-nm range. Yellow and red colors are absent in the LB reaction, whereas sequentially yellow, red, blue, and green colors would be observed if double bonds are added one at a time to generate a polyene. Secondly, our NMR analysis showed only traces of sulfonic acids and polyenes at the stage of blue color. Thus, the formation of hexaunsaturated steroids seems too slow to account for the blue color response, even if the LB reagent is sufficiently acidic to protonate a linearly conjugated hexaene effectively. Finally, previous studies [12, 13] correlated the consumption of the oxidant ( $\text{Fe}^{3+}$  or  $\text{SO}_3$ ) with the color response in the Zak reaction but not the LB reaction. Taken together, these findings indicate that the LB color response does not stem from linearly conjugated polyene cations, although this mechanism may apply to the Zak reaction.

Some conceivable alternatives to the polyene cation model include charge-transfer complexes, phenol/quinone systems (e.g., a polycyclic analog of phenol red), and azulene systems (Fig. 7). Although these proposals are speculative and no such structures have been isolated, some of these systems contain structural features of **10–20** and might produce the observed color at trace levels. It is notable that the LB reaction produces a blue or green color, whereas the Zak and Salkowski assays are red.

Despite our advances in elucidating the mechanistic pathways of the LB reaction, the story is far from complete. We have not studied the elimination of  $\text{H}_2\text{SO}_3$  from sulfonic acids to generate olefins (Fig. 6b). This critical step appears to be slow under LB conditions, thus perhaps accounting for the paucity of polyunsaturated hydrocarbons and the predominance of sulfonic acid intermediates. Many more polar intermediates remain to be characterized and quantified; a comprehensive analysis would permit ranking the many sulfonation and rearrangement pathways in order of importance.

**Fig. 7** Polyunsaturated structures that produce intense color at low concentrations. Steroidal polyenes with some of these structural features might conceivably be responsible for the color response in the LB reaction

In summary, we have established the structures of many novel products of the LB reaction. In the presence of colorimetric reagents, cholesterol can variously undergo acetylation, i-steroid formation, backbone rearrangement, dimerization, sulfonation, oxidation/desaturation, and aromatization. Different kinetics among these pathways results in the different color responses observed for the LB, Zak, and Salkowski reactions. Although we have not identified the elusive color-producing species, our mechanistic insights and advances in methodology lay a sound foundation for future work. A resurrection of colorimetric assays is unlikely in clinical laboratories, but rapid and simple steroid assays continue to draw interest [26]. Some of the rearrangements observed for the LB and Salkowski reactions are similar to degradation pathways inferred from studies of sterol diagenesis under various geological conditions [27–29]. Modification of the LB reaction may provide conditions for accelerated ageing of sterols to produce lipid biomarkers that mimic specific geological processes. The behavior of sterols under acidic conditions is a fundamental, enduring topic of research, with many potential applications.

**Acknowledgements** This work was supported in part by startup funding from Texas Southern University for Q.X. We thank Alekha Kistic for supplying purified cholesterol. Quantum-mechanical calculations were carried out in part on the Rice Terascale Cluster funded by the NSF (EIA-0216467), Intel, and Hewlett-Packard and on the Rice Cray XD1 Research Cluster funded by the NSF (CNS-0421109) in partnership with AMD and Cray.

**Abstract** Naturally occurring vitamin E, comprised of four forms each of tocopherols and tocotrienols, are synthesized solely by photosynthetic organisms and function primarily as antioxidants. These different forms vary in their biological availability and in their physiological and chemical activities. Tocopherols and tocotrienols play important roles in the oxidative stability of vegetable oils and in the nutritional quality of crop plants for human and livestock diets. The isolation of genes for nearly all the steps in tocopherol and tocotrienol biosynthesis has facilitated efforts to alter metabolic flux through these pathways in plant cells. Herein we review the recent work done in the field, focusing on branch points and metabolic engineering to enhance and alter vitamin E content and composition in oilseed crops.

**Keywords** Vitamin E · Tocopherols · Tocotrienols · Tocochromanols · Vitamin E biosynthesis · Oilseed · Soybean · Antioxidants · Metabolic engineering

## Abbreviations

DXP	1-Deoxy-D-xyulose-5-phosphate
GGDP	Geranylgeranyldiphosphate
GGR	Geranylgeranyl reductase
HGA	Homogentisate
HGGT	Homogentisate geranylgeranyl transferase

HPP	<i>p</i> -Hydroxyphenylpyruvate
HPPD	Hydroxyphenylpyruvate dioxygenase
HPT	Homogentisate phytyltransferase
PDP	Phytyldiphosphate
PK	Phytol kinase
PMP	Phytylmonophosphate
PrBQMT	2-Methyl-6-prenylbenzoquinol methyltransferase
PrDP	Prenyldiphosphate
SDP	Solanesyldiphosphate
TC	Tocopherol/tocotrienol cyclase
TMT	Tocopherol/tocotrienol methyltransferase

## Introduction

Tocopherols and tocotrienols comprise the vitamin E family of antioxidants and are synthesized by plants and other photosynthetic organisms. These molecules consist of a chromanol head group linked to an isoprenoid-derived hydrophobic tail. The aliphatic tail of tocopherols is fully saturated, while the side-chain of tocotrienols contains three *trans* double bonds (Fig. 1). Four different forms of tocopherols and tocotrienols occur in nature and differ by the numbers and positions of methyl groups on the aromatic portion of the chromanol head group (Fig. 1). The  $\alpha$  form of tocotrienols and tocopherols has three methyl groups, the  $\beta$  and  $\gamma$  forms have two methyl groups, and the  $\delta$  form has one methyl group on the aromatic ring. In the case of the  $\beta$  and  $\gamma$  forms, the methyl groups are at positions 5 and 8 or 7 and 8, respectively, of the chromanol head group. The  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$  forms of tocopherols and

**Fig. 1** Naturally occurring vitamin E molecules (or tocochromanols) have one of eight forms, varying in the saturation of the prenyl group and methylation pattern on the chromanol ring.

Tocopherols contain fully saturated tails, while tocotrienol tails contain three *trans* double bonds. The hydrophilic head group has one, two, or three methyl groups. The hydrophobicity of the tail is greater than the hydrophilicity of the head group, thus vitamin E molecules are extracted with other lipids. Differences in methylation patterns are denoted by circles

tocotrienols are often referred to collectively as “tocochromanols.”

Tocopherols occur widely in plants, but the form of tocopherol often differs in the leaves and seeds of the same species.  $\alpha$ -Tocopherol is typically the primary form of tocopherols in leaves of plants and in photosynthetic prokaryotes such as *Synechocystis*. Seeds of different plant species, however, can be enriched in any of the four forms of tocopherol (Fig. 2). Soybean seeds, for example, contain primarily  $\gamma$ -tocopherol and lesser amounts of  $\delta$ - and  $\alpha$ -tocopherol. The occurrence of tocotrienols is more limited in plants. Tocotrienols are the principal tocochromanol of the seed endosperm of monocots, including important cereal grains such as wheat, rice, and barley (Fig. 2). Tocotrienols are also the major tocochromanol class in seeds of some dicots, including species of the Apiaceae (or Umbelliferae) family (e.g., coriander, celery) [1, 32]. Given their lipid soluble nature, tocopherols and tocotrienols are readily extracted as components of vegetable oils during the commercial processing of oilseeds. Soybean oil and palm oil, for example, are major commercial sources of tocopherols and tocotrienols, respectively.

Tocochromanols are potent lipid soluble antioxidants that protect plant cells against oxidative stresses. Tocopherols, for example, contribute to the maintenance of photosynthesis by mitigating photooxidative damage to photosystem II through the quenching of singlet oxygen [19]. In addition, seeds from *Arabidopsis* mutants that lack tocopherol display reduced storage life and accumulate increased amounts of compounds derived from the oxidation of stored oils [45]. The growth of these mutants at low temperatures is also reduced, suggesting that tocopherols contribute

to the cold-adaptation of plants [31]. It is likely that tocotrienols are also important for reducing oxidative stresses in plants, but the physiological role of these compounds in plants has yet to be established.

Tocopherols and tocotrienols are classified as vitamin E based on their ability to prevent the resorption of rat fetuses maintained on defined diets, the classical measure of “vitamin E activity.” In this assay,  $\alpha$ -tocopherol displays the greatest efficacy of the eight natural tocochromanols because of its ability to be more readily absorbed and retained by cells of the body [24]. As such,  $\alpha$ -tocopherol is considered to have the highest nutritional value of the different forms of tocopherols and tocotrienols, and has thus received the greatest attention for the vitamin E biofortification of crop plants. By comparison,  $\alpha$ -tocotrienol has about one-third of the vitamin E activity displayed by  $\alpha$ -tocopherol, while  $\gamma$ -tocopherol has only about one-tenth of the vitamin E activity of  $\alpha$ -tocopherol [24]. Regardless, all forms of tocochromanols are able to reduce free-radical damage to membrane lipids, and in model membrane studies, tocotrienols are better antioxidants than tocopherols [57, 48]. In addition, diverse health-promoting properties have been attributed to the various forms of tocochromanols. For example, low levels of  $\gamma$ -tocopherol, but not  $\alpha$ -tocopherol, in serum correlate with the incidence of coronary heart disease [34]. Likewise, tocotrienols have physiological properties that are distinct from those of  $\alpha$ -tocopherol. Tocotrienols inhibit cholesterol synthesis [39], and  $\gamma$ -tocotrienol is the most active inhibitor in studies with human hepatoma HepG2 cells [36]. Tocotrienols also reduce the *in vitro* growth of breast cancer cells [33], and  $\alpha$ -tocotrienol provides the

**Fig. 2** C18-reverse phase HPLC analysis of tocopherols in extracts from soybean seeds (**a**), sunflower seeds (**b**), rice seeds (**c**), and coconut endosperm (**d**). Tocopherols were detected in crude lipid extracts by fluorescence (292 nm excitation/330 nm emission). C18-reverse phase HPLC columns are typically unable to resolve  $\beta$  and  $\gamma$  forms of tocotrienols and tocopherols. These molecules can be resolved by normal phase (e.g., silica) HPLC columns. In the soybean seed extract (**a**), the  $\beta/\gamma$  tocopherol peak is composed almost entirely of  $\gamma$ -tocopherol, and in the rice seed extract (**c**), the  $\beta/\gamma$  tocotrienol peak is composed almost entirely of  $\gamma$ -tocotrienol

greatest protection against oxidative damage to neuronal cells of any of the tocopherols [35].

From a commercial standpoint, the oxidative stability that tocopherols confer to vegetable oils is perhaps their most important functional property. This property is especially valuable for reducing fatty acid oxidation and the formation of off-flavor compounds such as hexanals in foods fried or processed using vegetable oils [65, 67]. Of the different forms of tocopherol,  $\delta$ - and  $\gamma$ -tocopherols are the most effective at reducing the oxidative breakdown of vegetable oils in frying applications [65, 66]. In addition,  $\delta$ - and  $\gamma$ -tocotrienols have a slightly greater ability than the corresponding tocopherols to reduce the formation of fatty acid oxidation products during the frying of foods [66]. As interest in the use of vegetable oils as high-temperature lubricants grows [12], the ability to

genetically enhance the tocopherol content of oilseeds, particularly the  $\delta$  and  $\gamma$  forms, to improve oxidative stability will likely become increasingly important. Recent efforts to engineer oilseeds to produce long-chain  $\omega$ -3 polyunsaturated fatty acids (e.g., eicosapentaenoic acid), which are prone to oxidation, will also likely benefit from genetic enhancement of tocopherol content [11]. In addition to their contributions to the oxidative stability of vegetable oils, tocopherols are used commercially in cosmetics and sunscreens, and have potential value as livestock feed supplements to improve the quality and shelf-life of meats [30, 68].

Tocopherols are synthesized in plastids of plants from precursors that derive from the shikimate and methylerythritol phosphate pathways. The biosynthetic pathway for tocopherols and many of the associated enzymes were determined in the 1980s. Research during the past 8 years has uncovered nearly all of the genes that are required for the synthesis and modification of tocopherols and tocotrienols. This review summarizes recent advances in our understanding of the biochemistry and genetics of tocopherol and tocotrienol biosynthesis in plants and describes how this research has been applied for the biotechnological enhancement of the vitamin E content and composition of oilseed crops.

### Vitamin E Biosynthetic Enzymes

Vitamin E biosynthetic enzymes are found in chloroplasts [3, 21, 52, 55, 66] and chromoplasts [2], thus, presumably all plastids. Total vitamin E content increases during senescence [42], during chloroplast to chromoplast transition [2], and during seed development [15]. Although many of the enzymatic steps have been characterized for over 20 years [52], recent genetic work in dissecting the pathway has been facilitated by the availability of *Arabidopsis* mutants and the use of transgenic plants. Table 1 shows many of the available plant mutants and cloned genes. The generally accepted pathway for vitamin E biosynthesis is shown in Fig. 3 and major steps are summarized in Table 2. Only two steps are required to make a tocopherol: the prenylation of homogentisate (HGA) and a subsequent cyclization step. In this case, the vitamin E will be either  $\delta$ -tocopherol or  $\delta$ -tocotrienol. Additional methylation steps produce  $\alpha$ ,  $\beta$ , and  $\gamma$  forms of vitamin E.

Two substrates are required for vitamin E biosynthesis: HGA and a  $C_{20}$  prenyldiphosphate (PrDP). HGA supplies the aromatic ring of the chromanol head

group and is derived from tyrosine via the shikimate pathway. Tyrosine is deaminated to *p*-hydroxyphenylpyruvate (HPP), which in turn is oxygenated to HGA. HGA is also used in plastoquinone synthesis. The second required substrate is a prenyldiphosphate (PrDP), either phytyldiphosphate (PDP) or geranylgeranyldiphosphate (GGDP). These prenyl groups are supplied by the 1-deoxy-D-xyulose-5-phosphate (DXP) pathway, reviewed by Lichtenthaler [29]. GGDP can be used directly in tocotrienol synthesis or reduced to PDP for tocopherol biosynthesis. The proposed route for phytol synthesis has recently been revised [23, 61]. In the revised path, GGDP is incorporated into chlorophyll where the geranylgeranyl moiety is reduced to a phytyl moiety. Free phytol is released during chlorophyll breakdown [22]. One fate of this phytol may be phosphorylation and incorporation into tocopherols [23, 54, 61]. In addition to the two required substrates HGA and PrDP, tocopherols are mono-, di-, or trimethylated. The methyl donor is S-adenosyl-methionine [53]. The methylation pattern affects the bioavailability of the vitamin E as well as the antioxidant capabilities [24].

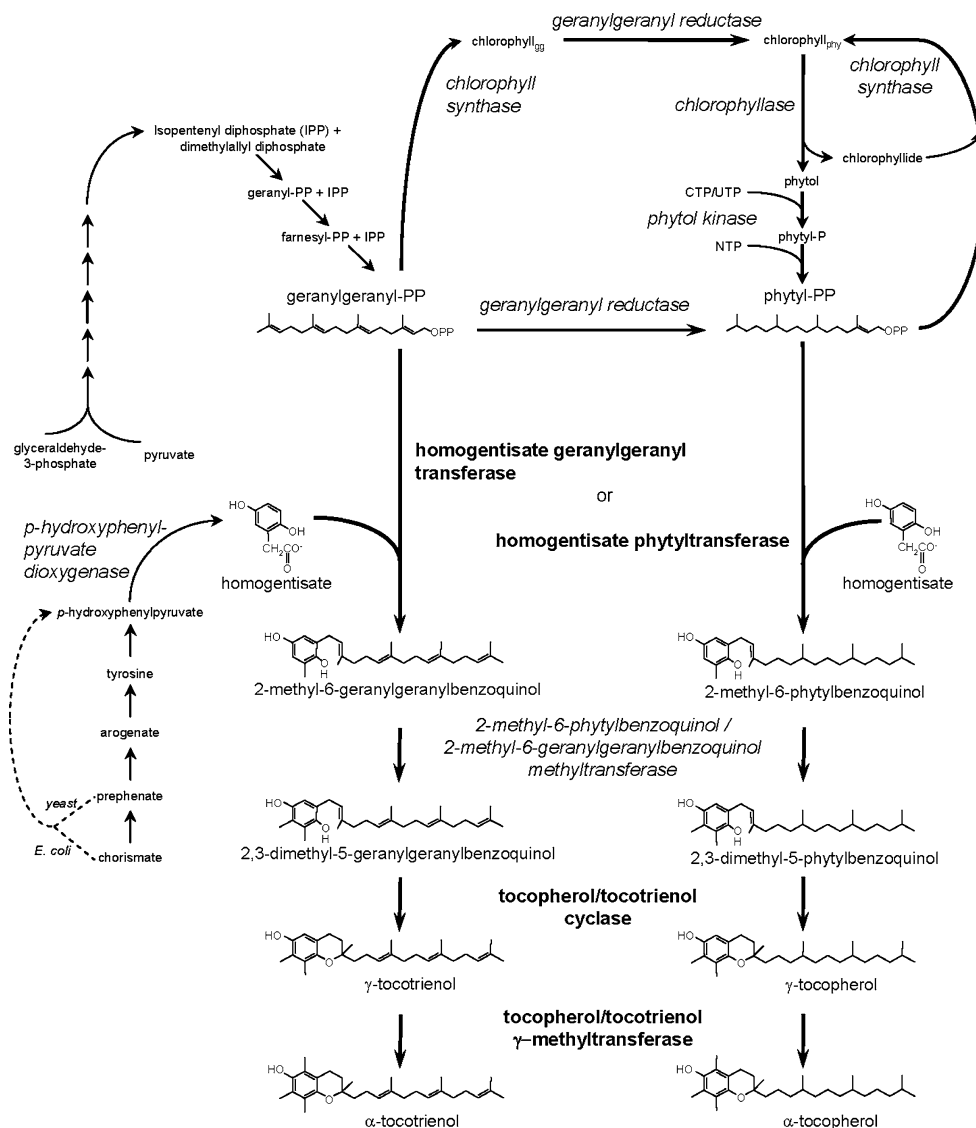

#### Homogentisate Prenyltransferases

The first step of vitamin E biosynthesis is the transfer of a prenyl group to HGA. This transfer, a condensation and decarboxylation [52], occurs via either homogentisate

phytyltransferase (HPT) or homogentisate geranylgeranyl transferase (HGGT). The substrate specificity of the prenyltransferase determines whether the final tocopherol will be a tocopherol or a tocotrienol. Tocopherols, with a phytyl tail, are more common in most plant tissues than tocotrienols, with a geranylgeranyl tail. Prenyltransferase activity was reported by Soll et al. [53] in 1980, working with spinach chloroplasts. To date, homogentisate prenyltransferase genes for vitamin E have been cloned from *Synechocystis* [7, 46, 47], *Arabidopsis* [7, 46], and the monocots barley, wheat, and rice [5]. The prenyltransferases are part of the ubiA prenyltransferase family and are predicted to be integral membrane proteins. Activity has been localized to the inner membranes of both chloroplasts [55] and chromoplasts [2] using cell fractionation methods.

The *Arabidopsis* HPT has been expressed in *E. coli*, where it has a strong substrate preference for PDP over GGDP [7, 43]. It shows no activity towards solanesyldiphosphate (SDP) [7, 43], a prenyltransferase activity required for phyloquinone biosynthesis. The *Synechocystis* enzyme has also been expressed in *E. coli* [7] and insect Sf-9 cells using a baculovirus system [46]. The *Synechocystis* HPT has activity for both PDP and GGDP, although in vitro GGDP activity is less than 20% of in vitro PDP activity [7]. No reports of HGGT expression have been made, and attempts to express the enzyme in *E. coli* have been unsuccessful [5]. However, HGGT is presumed to have

**Fig. 3** Biosynthesis of vitamin E occurs in plastids. The substrates, HGA and either GGDP (for tocotrienols) or PDP (for tocopherols) come from the shikimate and the deoxy-D-xylulose phosphate pathways, respectively. Enzymes in *bold* are specific to the synthesis of tocochromanols. Enzymes denoted in *italics*, while vital for vitamin E biosynthesis, are also used in other pathways. Neither methyltransferase step is required for tocochromanol synthesis. The figure shows the production of vitamin E molecules with  $\alpha$ - and  $\gamma$ -head groups.  $\delta$ -Head groups are produced when both methyltransferase steps are bypassed.  $\beta$ -Tocochromanols result when the first methylation step is omitted, but the second methylation step is included. The production of HPP varies. The pathway for plant synthesis is shown with *solid arrows*. Shunts, shown with *dashed lines*, have been used to manipulate vitamin E production in plants. In *E. coli* HPP is produced directly from chorismate by a bifunctional enzyme. In yeast, a prephenate dehydrogenase produces HPP

higher activity with GGDP than with PDP (as indicated in Fig. 3), based on the ability of the barley, wheat, and rice enzymes to confer tocotrienol biosynthetic ability to plant cells upon transgenic expression [5]. An additional prenyltransferase (referred to in Table 1 as “homogentisate prenyldiphosphate transferase”) has recently been identified [43, 65]. The recombinant enzyme expressed in *E. coli* shows strongest activity toward SDP, with minor activity for GGDP and PDP [43], however, the *in vivo* function of this prenyltransferase is not yet clear.

HPTs and HGGTs have been transgenically expressed in plants. Overexpression of HPT increases tocopherol content of *Arabidopsis* leaves [8], and antisense suppression of HPT expression in *Arabidopsis* seeds reduces levels up to ten-fold compared to seeds from non-transformed plants [46]. Expression of the barley HGGT in *Arabidopsis* leaves shifts toco-

chromanol biosynthesis toward the production of tocotrienols rather than tocopherols and increases total tocochromanol content [5]. This result clearly indicates that homogentisate prenyltransferases alone can dictate whether tocopherols or tocotrienols are produced by plant cells. In addition, the enhanced levels of tocochromanols that accompany HPT or HGGT overexpression suggest that homogentisate prenyltransferases can assert flux control through the vitamin E biosynthetic pathway. As such, these enzymes have been major targets for biotechnological efforts to fortify the tocochromanol content of oilseeds, as described below.

#### 2-Methyl-6-Prenylbenzoquinol Methyltransferase

In order to have  $\gamma$ - or  $\alpha$ -tocochromanols, the number 3 position on the benzoquinol ring must be methylated.

**Table 2** Summary of enzymes and major reactants found in vitamin E biosynthesis

Enzyme	Substrate(s)	Product(s)
<i>p</i> -Hydroxyphenylpyruvate dioxigenase (HPPD)	<i>p</i> -Hydroxyphenylpyruvate (HPP)	Homogentisate (HGA)
Geranylgeranyl reductase (GGR)	Geranylgeranyldiphosphate (GGDP)	Phytyldiphosphate (PDP)
Homogentisate phytyltransferase (HPT)	Chlorophyll <sub>geranylgeranyl</sub> HGA + PDP	Chlorophyll <sub>phytyl</sub> 2-Methyl-6-phytylbenzoquinol
Homogentisate geranylgeranyl transferase (HGGT)	HGA + GGDP (minor) HGA + GGDP	2-Methyl-6-geranylgeranyl-benzoquinol 2-Methyl-6-geranylgeranyl-benzoquinol
Prenylbenzoquinol methyltransferase (PrBQMT)	HGA + PDP (minor)	2-Methyl-6-phytylbenzoquinol
Tocopherol/tocotrienol cyclase (TC)	2-Methyl-6-phytylbenzoquinol 2-Methyl-6-geranylgeranyl-benzoquinol 2,3-Dimethyl-5-phytyl-benzoquinol 2,3-Dimethyl-5-geranylgeranyl-benzoquinol	2,3-Dimethyl-5-phytyl-benzoquinol 2,3-Dimethyl-5-geranylgeranyl-benzoquinol $\delta$ -Tocopherol $\delta$ -Tocotrienol $\gamma$ -Tocopherol $\gamma$ -Tocotrienol
Tocopherol/tocotrienol methyltransferase (TMT)	$\delta$ -Tocopherol $\delta$ -Tocotrienol $\gamma$ -Tocopherol $\gamma$ -Tocotrienol	$\beta$ -Tocopherol $\beta$ -Tocotrienol $\alpha$ -Tocopherol $\alpha$ -Tocotrienol
Phytol kinase (PK)	Phytol + CTP or UTP	Phytylmonophosphate (PMP)
Phytylmonophosphate kinase	PMP + NTP	PDP

This methylation step is omitted when  $\beta$ - and  $\delta$ -tocochromanols are produced. Methyltransferase activity was identified in 1980 [53] and a gene for 2-methyl-6-phytylbenzoquinol methyltransferase (PrBQMT) was cloned from *Synechocystis* in 2002 [51]. Since the production of  $\gamma$ - and  $\alpha$ -tocotrienols can be accomplished with the addition of the HGGT gene alone, PrBQMT appears to methylate either tocopherols or tocotrienols [5]. The enzyme has been localized to the chloroplast inner membrane [55] and the *Arabidopsis* gene has a putative transit peptide [6]. The *Synechocystis* gene was cloned via homology to the *Arabidopsis*  $\gamma$ -tocopherol methyltransferase (TMT) gene. The *Arabidopsis* PrBQMT gene has only 18% amino acid sequence identity to the *Synechocystis* gene [6], and was identified by forward genetics using screens for altered tocopherol composition [6, 62]. The *Arabidopsis* and cyanobacterial genes have been expressed in *E. coli*. In this system, the transferase activity does not appear to depend on the prenyl tail; both phytylbenzoquinols and solanesylbenzoquinols are used [6, 51, 62]. Although Soll and Schultz [53] reported methyltransferase activity with  $\beta$ -tocopherol, recent work has not duplicated that activity, activity assayed from *E. coli* expression experiments shows no activity toward  $\beta$ - and  $\delta$ -tocopherols [6, 51], thus, if the 3 position is to be methylated for either  $\gamma$ - or  $\alpha$ -tocochromanols, it appears that this methylation must happen before the cyclization. The main effect of overexpression of PrBQMT is to alter the composition, but not the total content of vitamin E. For example, overexpression in soybean seeds converts the pools of  $\delta$ - and  $\beta$ -tocopherols to  $\gamma$ - and

$\alpha$ -tocopherols but does not affect the total tocopherol content [62].

#### Tocopherol/Tocotrienol Cyclase

Tocopherol/tocotrienol cyclase (TC) is the second enzyme required for vitamin E biosynthesis (Fig. 3). It forms the chromanol head group from a benzoquinol intermediate. The product is either  $\gamma$ -tocochromanol or  $\delta$ -tocochromanol, depending on the methylation status of the chromanol head group. Unlike the other enzymes in the vitamin E pathway, TC has been localized to plastoglobules in chloroplasts [3, 64], but not to the inner membrane [52]. Since both  $\delta$ - and  $\gamma$ -tocochromanols are found in plants it is presumed that TC cyclizes both mono- and di-methylated prenylbenzoquinols. Cyclase genes from *Arabidopsis* [38, 44], potato [21], and maize [44] as well as cyanobacteria [56] have been cloned and expressed in *E. coli*. The activity shows little, if any, preference for phytylated substrates over geranylgeranylated substrates [21, 38]. Thus, TC produces both  $\gamma$ - and  $\delta$ -tocopherols and  $\gamma$ - and  $\delta$ -tocotrienols.

Although the cyclase gene was first identified as a vitamin E biosynthetic gene in 2002 [38], the *Arabidopsis* VTE1 gene is homologous to a maize gene *SXD1*. The maize mutant, *sxd1*, is deficient in sucrose transport [37]. Although further work has established that the maize gene complements the *Synechocystis* slr1737 knockout mutant [44] and affects tocopherol production in potato and *Arabidopsis* as well as maize and *Synechocystis* [21, 44], the *Arabidopsis* mutants do

not share the maize phenotype [38]. The link between vitamin E and sucrose transport is still under investigation.

When TC is constitutively overexpressed in *Arabidopsis*, the total leaf tocopherol content increases seven-fold, suggesting that TC, as well as the prenyltransferases, may play a role in flux control through the pathway [25].

#### Tocopherol/Tocotrienol Methyltransferase

Tocopherol/tocotrienol methyltransferase (TMT) catalyzes the final step in synthesis of  $\alpha$ - or  $\beta$ -tocochromanols: the methylation of the number 5 carbon on the chromanol ring (Fig. 3). This enzyme is often referred to as  $\gamma$ -tocopherol methyltransferase, but it also has activity with  $\delta$ -tocopherol,  $\delta$ -tocotrienol, and  $\gamma$ -tocotrienol. This methyltransferase activity was identified in 1980 and localized to the inner membrane of spinach chloroplasts [53], and the enzyme was purified from pepper chromoplasts [10]. The TMT gene was isolated from *Synechocystis* using homology to previously identified genes involved in vitamin E biosynthesis and looking for candidate genes on the same operon [50]. The *Arabidopsis* gene was then cloned via homology to the newly identified *Synechocystis* TMT [50]. *E. coli*-expressed *Arabidopsis* TMT methylates both  $\gamma$ - and  $\delta$ -tocopherol but has almost a three-fold preference for  $\gamma$ -tocopherol [50]. Overexpression of *Arabidopsis* TMT also converts nearly the entire content of  $\gamma$ -tocopherol in *Arabidopsis* seeds to  $\alpha$ -tocopherol [50]. Because most dicot seeds are enriched in  $\gamma$ -tocopherol, this result provides clear evidence that TMT activity is limiting for  $\alpha$ -tocopherol synthesis in dicot seeds, including major oilseeds such as canola and soybean.

#### Phytol Kinase and Phytylmonophosphate Kinase

While a phytol kinase (PK) activity had been reported in early work [54], conventional pathways had no source for PDP other than direct reduction of GGDP by geranylgeranyl reductase (GGR). However, recent work has demonstrated that a pathway from phytol to PDP exists [23] and a gene encoding PK has been identified and cloned [61]. Two separate kinase activities are required to synthesize PDP from phytol [23]. Free phytol increases during senescence as the phytyl moiety from chlorophyll is released by chlorophyllase [22]. Phytol from chlorophyll is phosphorylated by CTP or UTP [61, 23]. Using an *Arabidopsis* mutant with only 20% of wild type levels of total tocopherol Valentin et al. [61] cloned *VTE5*, which, when expressed in *E. coli*, phosphorylates free phytol. The

*Arabidopsis* phytol kinase gene contains a putative transit peptide and is predicted to be an integral membrane protein. A separate kinase activity phosphorylates phytylmonophosphate (PMP) to PDP using any of the four nucleotide triphosphates [23]. However, the gene that codes for PMP kinase activity has not yet been reported. Thus, phytol from chlorophyll breakdown can be used in tocopherol synthesis via direct phosphorylation of phytol and phytylmonophosphate.

#### Substrate Supply: Homogentisate and Prenyldiphosphates

The HGA used in tocochromanol biosynthesis is derived from HPP via a decarboxylation by hydroxyphenylpyruvate dioxygenase (HPPD) [17]. HPP, in turn, is derived from tyrosine via the shikimate pathway. HPP is synthesized differently in plants, bacteria, and yeast. In plants, chorismate, the end product of the shikimate pathway, is isomerized to prephenate. An aminotransferase creates aroenate from prephenate, and the aroenate is dehydrogenated to tyrosine. This aroenate-to-tyrosine step is subject to strong feedback regulation by tyrosine [9]. In *E. coli* and yeast, bifunctional enzymes bypass some or all of these steps. In *E. coli*, the precursor for tyrosine is chorismate [20], and in yeast the precursor is prephenate [41].

Overexpression of HPPD by itself has a negligible or only modest effect on increasing total tocopherol content in leaves and seeds of tobacco and *Arabidopsis* [14, 41]. Unlike the rest of the enzymes involved in vitamin E biosynthesis, HPPD is a cytosolic enzyme [17]. However, redirecting HPPD to plastids by addition of a transit peptide does not enhance tocopherol content over levels achieved by cytosolic expression [16]. In spite of this, feeding experiments in soybean suspension cultures indicate that HGA may limit vitamin E production, since addition of exogenous HGA doubles tocochromanol levels [26]. Thus, while the supply of HGA may be limiting, overexpression of HPPD alone does not result in large increases of tocochromanol content.

The prenyldiphosphate is supplied by the DXP pathway (also called the methylerythritol phosphate pathway), reviewed in [29]. Products of the DXP pathway are used in carotenoid, phyloquinone, terpenoid, and gibberellin biosyntheses as well as vitamin E biosynthesis [13]. Increased flux through the DXP pathway can increase vitamin E content. When 1-deoxy-D-xylulose-5-phosphate synthase, the gene for the first step in the DXP path, is overexpressed,

vitamin E content increases 1.5- to 2-fold [13]. Conversely, in deoxy-D-xylulose-5-phosphate synthase antisense plants, vitamin E content slightly decreases [13]. Additionally, competition for isoprenoid substrates between the vitamin E and other pathways can also decrease tocopherol content. For example, transgenic expression of a bacterial phytoene synthase, which uses GGDP as its substrate, results in a 50-fold increase in carotenoid levels in canola seeds, but the tocopherol content of these seeds is reduced by two-fold [49].

Four five-carbon isoprenoid moieties are required for the synthesis of the prenyldiphosphate moiety of tocochromanols. GGDP can be used directly in tocotrienol synthesis or reduced to PDP for tocopherol biosynthesis. Two paths for PDP synthesis have been proposed. In one, GGR reduces GGDP directly, and this PDP is available for incorporation into tocopherols [27, 55]. However, new evidence posits a second path for phytol synthesis through chlorophyll [23, 61]. In this pathway, GGDP is incorporated into chlorophyll, then reduced to phtylated chlorophyll. During chlorophyll breakdown, free phytol is released. This free phytol is then phosphorylated, creating PDP for incorporation into tocopherols. Kinase activity has been discovered as discussed above [23, 54, 61]. It is likely that both routes are used *in vivo*, since the phytol kinase mutant still has tocopherol [61], and many seeds that produce tocopherols lack detectable chlorophyll to support flux through the second pathway.

### Tocotrienol Biosynthesis

Tocotrienols occur principally in the endosperm of monocot seeds, and for the most part, tocotrienol biosynthesis differs little from tocopherol synthesis. The isolation of HGGT genes from barley, rice, and wheat provide a biochemical and genetic explanation for the occurrence of tocotrienols in monocot seeds [5]. The monocot HGGT identified to date share only 40–50% amino acid sequence identity with HPT, and the expression of the HGGT gene in barley was shown to be seed-specific, consistent with the location of tocotrienol accumulation in this plant [5]. Transgenic expression of the barley HGGT in tobacco callus and *Arabidopsis* leaves, which normally produce only tocopherols, results in the production of tocotrienols [5]. This result demonstrates that HGGT expression alone is sufficient to confer tocotrienol biosynthetic ability to plant cells. Seeds from some dicot species such as those of the Apiaceae family are also enriched in tocotrienols [1, 32]. Based on the monocot example, the simplest biosynthetic route that can account for tocotrienols in

these seeds is the activity of a yet to be identified HGGT-like enzyme.

The other enzymes of tocopherol biosynthesis have activity for both phtylated and geranylgeranylated compounds (Fig. 3). The *Arabidopsis* TC has about equal activity towards both forms of benzoquinols [38]. When tobacco callus is transformed with barley HGGT, all four forms of tocotrienols are detected [5], hence methyltransferase can use geranylgeranyl-derived substrates to produce different methylated forms of tocotrienols. However, it remains to be determined if variant forms of TC, PrBQMT, and TMT have evolved for the more efficient synthesis of tocotrienols in the endosperm of monocot seeds.

### HGGT-Independent Tocotrienol Synthesis

Several recent experiments in transgenic plants have uncovered an alternative route for tocotrienol synthesis. In these experiments, HGA synthesis is strongly upregulated by co-expression of HPPD with a yeast or bacterial enzyme that produces the HPP substrate for HPPD directly from the shikimate pathway. The yeast enzyme used in these studies was the prephenate dehydrogenase [41], and the bacterial enzyme used was the bifunctional chorismate mutase/prephenate dehydrogenase (encoded by the *tyrA* gene) [20, 26]. HPP is typically synthesized in two steps from tyrosine in plants (Fig. 3). The yeast and bacterial enzymes, however, shunt flux upstream of tyrosine (from prephenate or chorismate) toward the synthesis of HPP. This effectively bypasses steps in tyrosine synthesis that are normally negatively regulated by pool sizes of this amino acid [9, 20]. Through this strategy, high levels of tocotrienols were produced in tobacco leaves [20, 41], *Synechocystis* [26], and canola and soybean seeds [26], which normally accumulate only trace amounts of tocotrienols. In studies with soybean, HGA is increased to amounts high enough to alter the color of seeds [26]. Based on our current knowledge of vitamin E biosynthesis, it is unclear how greatly enhanced production of HGA results in tocotrienol synthesis. The *Arabidopsis* HPT, for example, displays relatively low activity with GGDP, the isoprenoid substrate for tocotrienol synthesis [7, 43]. Regardless, the production of tocotrienols, rather than tocopherols, through this alternative route suggests that available GGDP pools must greatly exceed those of PDP for tocochromanol synthesis. Although this transgenic method for production of tocotrienols is biochemically intriguing, it remains to be determined if this metabolic route normally contributes to tocotrienol synthesis in non-engineered plant cells.

## Genetic Enhancement of Vitamin E Composition and Content in Oilseeds

### Improvement of Tocochromanol Composition

The identification of vitamin E biosynthetic genes has facilitated biotechnological efforts to improve the nutritional value and antioxidant content of crop plants. One focus of this research has involved increasing the expression of methyltransferase genes to convert tocopherol in leaves or seeds into the more nutritious  $\alpha$  form. This approach has been of particular interest for the nutritional enhancement of seed oils from dicotyledonous grain crops (e.g., soybean and canola), which are typically enriched in  $\gamma$ -tocopherol. The ability to genetically convert the bulk of the tocopherol in plant organs from the  $\gamma$  to  $\alpha$  form was first demonstrated using the model plant *Arabidopsis thaliana* [50]. In this study, the tocopherol composition of *A. thaliana* seeds was shifted from 97%  $\gamma$ -tocopherol to 95%  $\alpha$ -tocopherol by genetic transformation with a cDNA for the *A. thaliana* TMT under control of a strong seed-specific promoter. Given that  $\alpha$ -tocopherol has ten-times greater vitamin E activity than  $\gamma$ -tocopherol, the net effect is an approximately nine-fold increase in the vitamin E activity of *Arabidopsis* seeds. Notably, this alteration in tocopherol composition is not accompanied by an increase in total tocochromanol content. The ability to increase relative amounts of  $\alpha$ -tocopherol by increased expression of TMT has subsequently been shown in seeds of crop plants including soybean [26, 59, 62] and *Brassica juncea* [69].

Soybean seeds offer an additional challenge for the generation of high levels of  $\alpha$ -tocopherol. The tocopherols of soybean seeds are composed of approximately 20%  $\delta$ -tocopherol and 65%  $\gamma$ -tocopherol. This is in contrast to the tocopherols of *A. thaliana* seeds, which are almost exclusively in the  $\gamma$  form. The conversion of  $\delta$ -tocopherol to  $\alpha$ -tocopherol requires two sequential enzymatic steps: (a) PrBQMT to convert  $\delta$ -tocopherol to  $\gamma$ -tocopherol and (b) TMT to convert the resulting  $\gamma$ -tocopherol to  $\alpha$ -tocopherol. Consistent with this, seed-specific co-expression of PrBQMT and TMT transgenes in soybean yields seeds with >90%  $\alpha$ -tocopherol [62]. In this study, enhanced expression of only PrBQMT results in seeds that contain exclusively the  $\gamma$  and  $\alpha$  forms of tocopherol, with a ratio of 80%  $\gamma$ -tocopherol and 20%  $\alpha$ -tocopherol. Increased expression of TMT alone yields seeds with approximately 75%  $\alpha$ -tocopherol and 25%  $\beta$ -tocopherol. These results demonstrate the utility of altering flux through PrBQMT and TMT to generate novel tocochromanol compositions.

Given that  $\delta$ - and  $\gamma$ -tocopherol confer greater oxidative stability to frying oils than  $\alpha$ -tocopherol [65, 66], it can be envisioned that suppression of methyltransferase expression may be of commercial value for generating improved vegetable oils for food processing and high-temperature lubricant applications. This is of particular significance with regard to sunflower. The tocopherols in seeds of this crop are composed of >90%  $\alpha$ -tocopherol. By mutational breeding, sunflower varieties have been generated with seeds that contain exclusively  $\delta$ - and  $\gamma$ -tocopherol [18, 58]. This composition was achieved by crossing lines with lesions in genes for PrBQMT and TMT [18, 58].

### Enhancement of Tocochromanol Content

A second focus of biotechnological efforts for vitamin E enhancement has been the production of increased total amounts of tocochromanols in seeds of crop species. As described in the “Introduction”, increasing the content of tocochromanols in seeds may be useful for enhancing the antioxidant capacity of vegetable oils. This, in turn, may improve the oxidative stability of vegetable oils in frying and other food processing applications and in high-temperature lubricants. This research to date has been successful in generating seeds with increased amounts of tocotrienols, but less successful in the enhancement of tocopherol levels in seeds. Attempts to increase the tocopherol content of seeds by use of a single transgene have centered on (a) increasing flux in the tocopherol biosynthetic pathway by overexpression of HPT or TC or (b) by increasing the supply of the HGA head group by overexpression of cDNAs for HPPD. Based on results obtained from overexpression studies in leaves, HPT and TC would appear to be logical targets for the enhancement of tocopherol levels in seeds. For example, overexpression of HPT and TC in leaves of *A. thaliana* results in a four- and seven-fold increase, respectively, in tocopherol content [7, 38]. However, expression of these enzymes using transgenes containing strong seed-specific promoters yields only modest increases (less than 1.5-fold) in the tocopherol content of seeds of *A. thaliana* [46], *B. napus* [28, 40], and soybean [26]. Similar results were also obtained with the overexpression of HPPD in seeds of these plants [26, 40, 60]. Only by co-expressing cDNAs for HPT, TC, and HPPD have increases in tocopherol content in the range 2- to 2.5-fold been achieved in *B. napus* seeds [40], which is the largest enhancement of tocopherol levels reported to date in an oilseed.

In contrast to the relatively small increases in tocopherol content attained by overexpression of HPT,

TC, or HPPD, seed-specific expression of an HGGT transgene resulted in up to a six-fold enhancement of the tocochromanol content of corn seeds, largely in the form of tocotrienols [5]. This is currently the largest increase in tocochromanol content in an engineered seed obtained by expression of only one transgene. A possible explanation for the success of this approach compared to HPT overexpression is that GGDP pools that support tocotrienol synthesis may greatly exceed those of PDP that are available for tocopherol synthesis.

The largest increase in total tocochromanol content achieved to date in genetically enhanced seeds was reported by Karunanandaa et al. [26]. In this study, co-expression of transgenes for HPPD, GGR, HPT, and a bacterial bifunctional chorismate mutase/prephenate dehydrogenase (encoded by the *tyrA* gene) increases total tocochromanol content in soybean seeds 10- to 15-fold. Although the goal of this experiment was to enhance tocopherol levels, the increase in tocochromanol content was largely due to the production of tocotrienols. In the highest tocochromanol-producing seeds, tocotrienols account for over 90% of the tocochromanols. Notably, tocotrienols are only trace components of the tocochromanols of non-engineered soybean seeds. The production of tocotrienols in vast preference to tocopherols in these seeds (in the apparent absence of HGGT) is also consistent with the existence of GGDP pools that greatly exceed those of PDP in seed plastids. Presumably under the metabolic conditions created in these seeds, HPT is able to use GGDP as a substrate despite its relatively low in vitro activity with this substrate [43].

The inability to engineer large increases in the tocopherol content of oilseeds points to a lack of understanding of the biosynthesis of PDP in seed plastids. The studies by Karunanandaa et al. [26] suggest that the availability of PDP limits the amounts of tocopherol synthesized. As described above, recent evidence points to a route of PDP synthesis involving the modification of geranylgeranyl-chlorophyll by the activity of GGR (Fig. 3) [61]. Developing metabolic engineering strategies to increase flux through this pathway may be necessary for increasing PDP pool sizes in plastids to support high levels of flux toward the synthesis of tocopherols rather than tocotrienols.

In conclusion, the isolation of genes for PrBQMT and TMT has facilitated biotechnological efforts to improve the nutritional value of vegetable oils. By increasing the expression of genes for one or both of these enzymes, it has been possible to shift the tocopherol content of oilseeds from the  $\delta$ ,  $\beta$ , and  $\gamma$  forms to the  $\alpha$  form, which has the highest vitamin E

activity of any of the naturally occurring tocochromanols. Efforts to engineer increased total tocopherol content in oilseeds, however, have met with only modest success. This appears to be due to the inability to generate enhanced pool sizes of the PDP substrate, because of gaps in our understanding of its synthesis from GGDP in seeds. The genetic enhancement of total tocotrienol content by expression of HGGT or by strong upregulation of HGA synthesis has proven to be a more successful strategy for generating seeds with increased amounts of vitamin E antioxidants. Through these approaches, corn and soybean seeds with 6- to 10-fold increases in total tocochromanol content have been produced. The availability of tocotrienol-enriched corn and soybean seeds should allow for functionality testing of the extracted oil to evaluate its performance in food processing, lubricants, and other commercial applications.

**Abstract** The objective of the study was to evaluate potential benefits of docosahexaenoic acid (DHA) rich fish oil supplementation as an adjunct to statin therapy for hyperlipidaemia. A total of 45 hyperlipidaemic patients on stable statin therapy with persistent elevation of plasma triglycerides (averaging 2.2 mmol/L) were randomised to take 4 g/day ( $n = 15$ ) or 8 g/day ( $n = 15$ ) of tuna oil or olive oil (placebo,  $n = 15$ ) for 6 months. Plasma lipids, blood pressure and arterial compliance were assessed initially and after 3 and 6 months in 40 subjects who completed the trial. Plasma triglycerides were reduced 27% by 8 g/day DHA-rich fish oil ( $P < 0.05$ ) but not by 4 g/day when compared with the placebo and this reduction was achieved by 3 months and was sustained at 6 months. Even though total cholesterol was already well controlled by the statin treatment (mean initial level 4.5 mmol/L), there was a further dose-dependent reduction with fish oil supplementation ( $r = -0.344$ ,  $P < 0.05$ ). The extent of total cholesterol reduction correlated ( $r = -0.44$ ) with the initial total cholesterol

levels ( $P < 0.005$ ). In the subset with initial plasma cholesterol above 3.8 mmol/L, plasma very low density lipoprotein (VLDL), intermediate-density lipoprotein (IDL) and low-density lipoprotein (LDL) were isolated and assayed for cholesterol and apolipoprotein B (apoB) at the commencement of the trial and at 3 months of intervention. Fish oil tended to lower cholesterol and apoB in VLDL and raise both in LDL. There were no changes in IDL cholesterol, IDL apoB and high-density lipoprotein cholesterol. The results demonstrate that DHA-rich fish oil supplementation (2.16 g DHA/day) can improve plasma lipids in a dose-dependent manner in patients taking statins and these changes were achieved by 3 months. Fish oil in addition to statin therapy may be preferable to drug combinations for the treatment of combined hyperlipidaemia.

## Introduction

Patients suffering from hyperlipidaemia with high plasma triglycerides, high low-density lipoprotein cholesterol (LDL-C) or low high-density lipoprotein cholesterol (HDL-C) are at increased risk of developing coronary heart disease (CHD) [1]. Patients newly diagnosed with hypercholesterolaemia are advised to adopt a cholesterol-lowering diet, e.g. National Cholesterol Education Program [2], in which replacement of saturated fat by polyunsaturated or monounsaturated fat results in lowering of plasma total and LDL-C. In cases where dietary management alone proves inadequate, hypocholesterolaemic drugs, primarily statins are prescribed. Statins inhibit cholesterol synthesis in the liver, subsequently reducing plasma total cholesterol and LDL-C levels, and have proven effective in counteracting CHD [3].

The potential benefit of triglyceride management is less clear, although lowering plasma triglyceride tends to improve HDL-C [4]. Omega-3 polyunsaturated fatty acids (PUFA) supplementation is now recognised as effective in lowering triglyceride, and fish oil extracts (e.g. Omacor) are indicated for hypertriglyceridaemia (American Heart Association guidelines). Both eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are effective at lowering plasma triglycerides [5, 6]. The extent of reduction correlates with initial plasma triglyceride levels and is usually accompanied by a modest rise in HDL-C and possibly transient elevation of LDL-C.

Omega-3 PUFA supplementation is also recommended for use in combined or mixed hyperlipidaemia, i.e. where both triglyceride and LDL-C are unacceptably high. This condition, estimated to occur in 60% of hypercholesterolaemic patients [7], is often treated with a combination of statin and fibrate drugs, the latter lowering plasma triglyceride. However, there are significant adverse effects associated with this drug combination [8], warranting further evaluation of the omega-3 PUFA supplementation as an alternative. Contacos et al. [9] demonstrated complementarity of the LDL-C lowering effect of pravachol and the triglyceride lowering effect of MaxEPA in subjects with combined hyperlipidaemia. Subsequent studies have also shown benefits of combining fish oil supplementation with statin treatment in combined hyperlipidaemic subjects [10–12].

Since then, newer statins with the ability to lower both LDL-C and triglyceride have been introduced [13, 14]. Nevertheless, a high proportion of statin-treated patients still have persistent hypertriglyceridaemia. Fish oil supplementation is indicated in hypertriglyceridaemia and in combined hyperlipidaemia as an adjunct to 3-hydroxy-3-methylglutarylcoenzyme A reductase inhibitors (statins) at daily doses of 3–4 g. To date, only EPA-rich fish oil has been evaluated in statin-treated subjects with combined hyperlipidaemia. Therefore, the purpose of the present study was to see whether such patients would derive further benefit from coadministration of a lower dose of fish oil, using, in this case, a DHA-rich fish oil supplement and to determine the duration of such achieved changes in plasma lipids.

Experimental Procedure

## Experimental Procedure

### Study Subjects and Study Design

Potential study subjects were recruited via the media (radio, newspaper and e-mail advertisements) in Wollongong, Australia. Entry criteria included subjects on stable statin treatment for hypercholesterolaemia (i.e. already taking statin drug for at least 3 months and expecting to continue on the same dosage during the study period) who had persistent hypertriglyceridaemia (greater than 1.6 mmol/L). Subjects were screened for fasting plasma triglyceride levels in fingerprick blood samples using a portable Accutrend instrument [15]. This study was approved by the University of Wollongong Human Ethics Research Committee and the subjects gave written informed consent.

Forty-five subjects who met the entry criteria were blocked for age, sex and entry plasma triglyceride levels and then randomly assigned to one of three treatments: DHA-rich tuna oil (HiDHA, Clover Corporation; 7% EPA, 27% DHA; 4 g/day, providing 1.08 g/day DHA) or DHA-rich tuna oil (8 g/day, providing 2.16 g/day DHA), or the olive oil group (placebo, half on 4 g/day and half on 8 g/day). DHA-rich tuna oil capsules comprise 27% saturated fats, 24.5% monounsaturated fats, 6% omega-6 polyunsaturated fats and 37.5% omega-3 polyunsaturated fats, of which 7% is EPA and 27% is DHA. The olive oil capsules comprise 14% saturated fats, 76% monounsaturated fats and 10% omega-6 polyunsaturated fats. The placebo group was matched to the fish oil group for dosage (4 and 8 g/day), but this difference in quantity is trivial compared to the dietary intake of monounsaturated fat. The subjects maintained their statin treatment throughout the study and consumed the capsules containing olive oil or DHA-rich tuna oil for 6 months. They attended the clinic on two consecutive days prior to the commencement of the trial and after 3 and 6 months of intervention to provide a fasted blood

sample and for the assessments of height (first clinic visit only), weight, arterial compliance and blood pressure.

### Plasma Lipids

Fasted blood samples were collected by venepuncture after an overnight fast in potassium EDTA tubes. Plasma was obtained after centrifugation at 3,000 rpm, 4 °C for 15 min. Plasma high-density lipoprotein (HDL) was isolated after precipitation with the dextran sulphate/magnesium chloride method [16]. Plasma total cholesterol, HDL-C and triglyceride were assessed by using the standard commercially available kits (from Roche Diagnostics) and an autoanalyser (Cobas Mira Plus). Plasma LDL-C was calculated by using the Friedewald calculation [17].

### Plasma Lipoproteins

In those subjects with plasma total cholesterol greater than 3.8 mmol/L, very low density lipoprotein (VLDL), intermediate-density lipoprotein (IDL) and low-density lipoprotein (LDL) were isolated from plasma. All lipoproteins were isolated using a 70Ti rotor at 35,000 rpm at 15 °C with polyallomer quick-seal centrifuge tubes (no. 342413, Beckman) in an L8 70 ultracentrifuge (Beckman).

Sequential ultracentrifugation was used to isolate VLDL, IDL and LDL from plasma. Briefly, 10 mL of plasma was overlaid with a 2 mL solution of  $d = 1.006$  g/mL per tube and subjected to ultracentrifugation for 16 h. VLDL particles were removed by tube slicing (approximately 2 mL), the remaining sample ( $d > 1.006$  g/mL) was adjusted to  $d = 1.019$  g/mL by the addition of  $d = 1.478$  g/mL solution, each tube was overlaid with 2 mL of  $d = 1.019$  g/mL solution and subjected to ultracentrifugation for 18 h. IDL was recovered by tube slicing (approximately 2 mL) and the remaining sample ( $d > 1.019$  g/mL) was adjusted to  $d = 1.063$  g/mL by the addition of  $d = 1.478$  g/mL solution, each tube was overlaid with 2 mL of  $d = 1.063$  g/mL solution and subjected to ultracentrifugation for 18 h. LDL was recovered by tube slicing (approximately 2 mL). VLDL, IDL and LDL were analysed for cholesterol and apolipoprotein B using standard commercially available kits.

### Arterial Compliance and Blood Pressure

Arterial compliance was assessed using a CR-2000 cardiovascular profiler instrument (Hypertension Diagnostic, Eagan, MN, USA), a noninvasive method

approved by the US Food and Drug Administration. It provides separate estimates of compliance in proximal or large arteries (C1, reflecting arterial capacitance) and in distal or small arteries (C2, reflecting resistance). These estimates correlate with aging and vascular disease (atherosclerosis), respectively. Three replicate assessments were taken at 5-min intervals whilst the patient was supine. Blood pressure (systolic, diastolic and mean arterial pressure) was assessed with the patient supine in the clinic while arterial compliance was measured using the cardiovascular profiler instrument.

### Statistical Analysis

Plasma triglyceride was the only variable that was not normally distributed; hence, data analysis was performed on the log transformation of plasma triglycerides. Other variables did not require transformation prior to data analysis. One-way analysis of variance (ANOVA) was used to determine the differences between the three groups (placebo, 4-g and 8-g dose). Multivariate correlation analysis was used to determine the correlation between the initial plasma total cholesterol levels and the change in plasma total cholesterol from 0 to 6 months. Repeated-measures ANOVA (Statistica for Windows, release 5.1) was used to compare the change of total cholesterol (after 3 and 6 months) from the baseline. Changes were considered significant when  $P < 0.05$ . All values are reported as the mean  $\pm$  the standard error of the mean.

### Results

Baseline characteristics of the 45 subjects enrolled in the study are shown in Table 1. The three groups were well matched for age, sex, body mass index and fasting plasma triglyceride levels and no significant differences between the groups were observed.

Forty subjects completed the 6-month trial (19 were taking simvastatin, 13 atorvastatin, 4 pravastatin, 2 cerivastatin and 2 fluvastatin). Table 2 and Fig. 1 show the effects of DHA-rich fish oil on plasma lipids in statin-treated subjects. The 8-g/day dosage of fish oil (providing 2.16 g/day DHA) was necessary to see a significant change (27% reduction) in plasma triglyceride levels as the 4-g/day dosage of fish oil (providing 1.08 g/day DHA) did not reach significance (Fig. 1). Although plasma total cholesterol levels were already well controlled by the statin therapy (average of 4.5 mmol/L), there was a trend toward a further reduction with the 8-g/day dosage of fish oil and a

<sup>a</sup> One-way analysis of variance between the three groups, *P* < 0.05

significant correlation between dosage of fish oil and extent of cholesterol reduction ( $r = -0.344$ ,  $P < 0.05$ ). HDL-C and LDL-C were unaffected by fish oil supplementation in this statin-treated population. These changes in plasma total cholesterol and triglycerides were achieved by 3 months and were sustained at 6 months of intervention.

The reduction of plasma total cholesterol correlated with initial cholesterol levels ( $r = -0.44$ ,  $P < 0.05$ ). Given that there is a significant influence of initial cholesterol levels, the effects of treatment were reevaluated after excluding those subjects with low plasma total cholesterol (below 3.8 mmol/L) at the baseline after 3 months' intervention, as the 6-month data showed no further reduction in plasma lipids. This subset (ten subjects per group) showed a greater response to fish oil with marginal significance (13% reduction of total cholesterol with the 8 g/day dosage,

**Fig. 1** Changes in plasma lipids after 3 and 6 months for all subjects. $P = 0.05$ , Fig. 2). In this subset VLDL, IDL and LDL were isolated and, although not significant, fish oil tended to lower plasma total cholesterol and apolipoprotein B in VLDL and raise both in LDL (Fig. 3).

There were no changes in blood pressure or in the indices of proximal (C1) or distal (C2) arterial compliance (results not shown) after DHA-rich fish oil treatment.

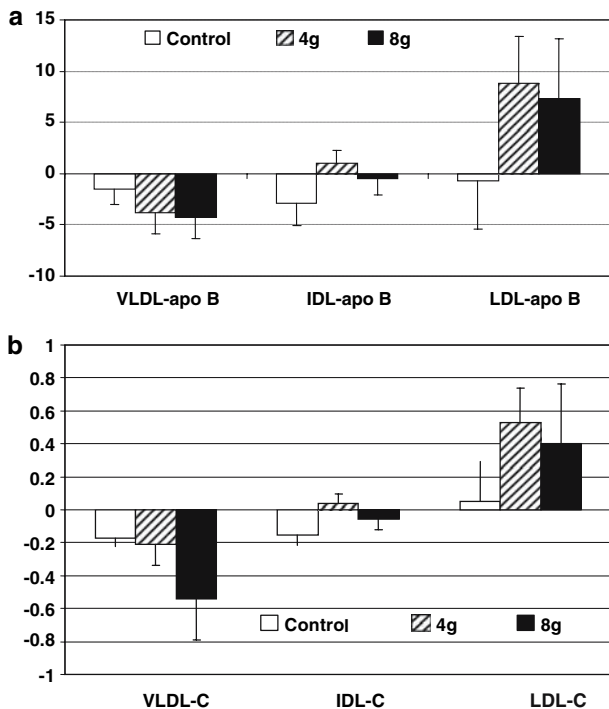

## Discussion

This study shows that, when administered as an adjunct to statin therapy in hypercholesterolaemic patients with persistent hypertriglyceridaemia, a tuna fish oil supplement yielding 2.16 g/day DHA can reduce plasma triglycerides by 27%, which is reflected in a reduction of VLDL. This reduction in plasma triglyceride levels were achieved by 3 months and was sustained to 6 months. There was a trend toward lowering plasma total cholesterol, which again is reflected in lowering circulating VLDL particles.

Drug combinations are usually prescribed for combined hyperlipidaemia. One such option is fibrate therapy in combination with a statin. Trials have tested this combination therapy with expected outcomes such as 50 [18] or 38% [19] reductions in plasma triglycerides. Despite the effectiveness of fibrates lowering plasma triglyceride levels, there have been reports of adverse side effects of the fibrates, such as liver and

**Fig. 2** Changes in total cholesterol, high-density lipoprotein cholesterol and plasma triglycerides after 3 months of fish oil treatment in those subjects (ten per treatment group) with initial total cholesterol above 3.8 mmol/L. Control group (white bars  $n = 10$ ), 4 g DHA-rich fish oil/day group (hatched bars  $n = 10$ ), 8 g DHA-rich fish oil/day group (black bars  $n = 10$ ). The number sign indicates marginal significance compared with the control and the 4-g dose,  $P = 0.05$ . The asterisk indicates significantly different from the control,  $P < 0.05$

**Fig. 3** In the subset of subjects with plasma total cholesterol above 3.8 mmol/L (ten subjects per group) very low density lipoprotein (VLDL), intermediate-density lipoprotein (IDL) and low-density lipoprotein (LDL) were isolated. **a** The change in VLDL, IDL and LDL apolipoprotein B (apoB) levels from 0 to 3 months of intervention with the control group (white bars  $n = 10$ ), 4 g DHA-rich fish oil/day group (hatched bars  $n = 10$ ), 8 g DHA-rich fish oil/day group (black bars  $n = 10$ ). **b** The change in VLDL, IDL and LDL cholesterol levels (VLDL-C, IDL-C, LDL-C) from 0 to 3 months of intervention with the control group (white bars  $n = 10$ ), 4 g DHA-rich fish oil/day group (hatched bars  $n = 10$ ), 8 g DHA-rich fish oil/day group (black bars  $n = 10$ )

muscle toxicity [20, 21]. In particular, combined treatment of cerivastatin and gemfibrozil has been poorly tolerated and together with increased incidence of rhabdomyolysis led to the withdrawal of cerivastatin from the market [22]. Another option for treatment of statin-treated subjects with persistent hypertriglyceridaemia is niacin therapy in combination with a statin, where plasma triglyceride can be reduced by 40% [23]. However, there have been reported cases of hepatic toxicity [24], myopathy [25] and rhabdomyolysis [26] in patients primarily taking the sustained-release and twice-daily form of niacin [8].

An alternative approach to combined therapy for people with hyperlipidaemia is fish oil supplementation in combination with statin treatment. Contacos et al. [9] first demonstrated the potential of fish oil (3 g EPA/day) to substitute for fibrates as an adjunct to pravastatin therapy for mixed hyperlipidaemia. They found complementary effects of the oil and the statin on plasma triglycerides (27–30% reduction) and LDL-C (13–24% reduction), respectively. Despite its subsequent recommendation to general practitioners in the *National Heart Foundation Guide to Plasma Lipids for Doctors* (1997), this promising combination is hardly used, probably because of inadequate information on dose requirements, efficacy and availability.

In further examining the cardiovascular benefits of fish oil–statin treatment combinations, a preliminary observation was made that administration of EPA-rich fish oil not only reduced plasma triglycerides (by 36%), but also appeared to potentiate the hypocholesterolaemic effect of the statin [27], an effect that is not normally seen with fish oil supplementation alone. In the present study we have shown that an 8-g/day dosage of DHA-rich fish oil, when given as an adjunct to statin therapy, not only reduced plasma triglyceride levels but also potentially enhanced the cholesterol-lowering effect of the statin, especially in people with plasma total cholesterol levels greater than 3.8 mmol/L (Fig. 2). This cholesterol-lowering effect was primarily due to reduction in VLDL cholesterol (VLDL-C). These positive effects on plasma triglyceride and total cholesterol appeared to be dose-dependent and are achieved by 3 months' intervention with no further reduction at 6 months. The dose-dependent effect is consistent with studies conducted in statin-treated subjects using EPA-rich fish oil. Nordoy et al. [10] found a significant reduction of total cholesterol as well as plasma triglycerides in hyperlipidaemic patients when fish oil (3.3 g omega-3 PUFA/day, Omacor) was combined with simvastatin (20 mg/day) for 5 weeks. These effects were not seen in a subsequent study with a lower dose of fish oil (1.7 g/day), although a more

potent statin was being used [28]. Durrington et al. [11] reported reductions of 20–30% in plasma triglyceride, 30–40% in VLDL and 10% in total cholesterol following supplementation with 3.4 g long-chain omega-3 PUFA per day for 6 months.

People with combined hyperlipidaemia exhibit other dyslipidaemias, including an increased number of small, lipid-dense LDL particles that are highly susceptible to oxidation [10]. People with hypertriglyceridaemia have increased small, dense LDL particles [29], which are more atherogenic than normal-sized LDL particles [30]. Nordoy et al. [28] demonstrated a shift from small, dense LDL particles to larger, less dense LDL particles in combined hyperlipidaemics who were treated with atorvastatin and omega-3 PUFA, suggesting that supplementation with omega-3 PUFA may reduce cardiovascular risk by reducing the number of small, dense LDL particles. A limitation of this study was that LDL particle sizes were not measured, but certainly fish oil supplementation certainly did not result in significant increases of LDL-C levels.

Despite the apparent therapeutic benefits of omega-3 PUFA and other hypolipidemic nutrients, there have been few attempts to evaluate their role as adjunct therapy. Take the case of plant sterols. There are only four randomised clinical trials that test the hypocholesterolaemic potential of combining plant sterols with statins as a primary outcome measure [31–34]. These trials with plant sterol/stanol doses of 2–3 g/day for 4–8 weeks resulted in a 7–11% reduction of LDL-C over and above statin therapy [35]. The use of such nutrient combinations to reduce drug requirements may have avoided fatal adverse outcomes with cerivastatin, particularly if substituted for fibrate cotherapy. Despite the ability of plant sterols/stanols to further lower total cholesterol and LDL-C, they do not effectively reduce plasma triglycerides or improve HDL-C. Thus, combination therapy with omega-3 PUFA supplementation may be more suitable for people with combined hyperlipidaemia. Furthermore, statin therapy alone results in unfavourable changes in plasma fatty acids in that the arachidonic acid to EPA ratio and the arachidonic acid to DHA ratio are increased [36]. Although combination therapy of statins with omega-3 PUFA may result in a more favourable fatty acid profile, this awaits confirmation [36].

Apart from their cholesterol-lowering efficacy, statins may contribute to CHD risk reduction through proendothelial, antiplatelet and other mechanisms [37]. However, there are some disadvantages of statin use and risks at high doses. Initially in Australia around 30% of people prescribed statins lapsed within the first 6 months of therapy owing to a number of factors

including minor and major adverse reactions, indicating there are significant problems associated with statin treatment [33]. The most common adverse reactions to monotherapy are musculoskeletal (approximately 1–7% of reported cases) as well as constipation, indigestion, stomach pain, skin rashes and flatulence [38].

In summary, it appears from our study that a DHA intake of 2.16 g/day is effective in lowering plasma triglyceride levels in statin-treated patients with persistent hypertriglyceridaemia and this reduction is achieved by 3 months and is sustained at 6 months. Moreover, omega-3 PUFA supplementation may also reduce plasma total cholesterol (primarily VLDL-C reduction), especially if the plasma total cholesterol is greater than 3.8 mmol/L. These effects are dependent on the initial cholesterol levels and the omega-3 PUFA dose and are achieved within 3 months.

In conclusion, omega-3 PUFA supplementation as DHA-rich fish oil has the potential to further improve cardiovascular disease risk and potentially reduce medication in hyperlipidaemic patients taking statins. Taking omega-3 PUFA together with a statin may be preferable to combinations of drugs currently prescribed for mixed hyperlipidaemia as there are fewer side effects associated with omega-3 PUFA supplementation.

**Acknowledgements** The authors would like to acknowledge the study volunteers for their participation in the trial and Professor Dennis Calvert for the medical supervision of subject enrolment. The supply of placebo and DHA-rich fish oil capsules from Clover Corporation is gratefully acknowledged.

**Abstract** Within the visual system, docosahexaenoic acid (DHA, 22:6n-3) is an important structural component for retinal photoreceptors and cortical gray matter. There is a marked decrease in neural DHA accumulation in the face of DHA deficiency. DHA is accumulated at an accelerated rate during pregnancy, especially in the third trimester. However, pregnant women in the US and Canada have dietary DHA intakes that are significantly below the optimal level. The main objective of this study was to determine whether a DHA-functional food during pregnancy would benefit infant visual acuity at four and six months of age measured behaviorally using the acuity card procedure (ACP). In a randomized, longitudinal, double-blinded, and placebo-controlled trial, 30 pregnant women received either the DHA-functional food ( $n = 16$ ) or the placebo ( $n = 14$ ). There were significant main effects for visual acuity at four months of age ( $P = 0.018$ ). The mean acuity scores were  $3.8 \pm 1.1$  cycles/degree in the DHA group versus  $3.2 \pm 0.7$  cycles/degree in the

placebo group. At six months there were no group differences. Based on our results, we conclude that DHA supplemented during pregnancy plays a role in the maturation of the visual system.

**Keywords** Visual acuity · Infant visual development · Docosahexaenoic acid · Pregnancy · Functional food

## Introduction

The visual system comprises a complex signaling system involving the retina, thalamus and primary visual cortex. In addition, multiple other cortical regions are involved in the cognitive integration of visual information. Previous studies focused on the impact of long-chain polyunsaturated fatty acids (LCPUFA) on infant visual development have assessed two main aspects of the visual system: retinal development using electroretinogram (ERG), and visual processing at the level of the primary visual cortex. Cortical measures of resolution include sweep visual evoked potential (VEP) and behavioral assessments like the acuity card procedure (ACP). Of the resolution (grating) acuity measures, VEP measures cortical response directly and has less variability [1]. However, behavioral acuity measures provide a different measure of what an infant actually perceives, and normative data are well established for this procedure [1, 2]. Behavioral acuity measured with ACP is dependent on different brain regions controlling eye movements, attention, and other processes involved in generating the behavioral response [1].

Compared to other cells of the body, retinal photoreceptors have the highest docosahexaenoic acid

(DHA, 22:6 *n*-3) content. The gray matter in the visual cortex and multiple other cortical regions also have high levels of DHA. In an animal model, a diet deficient in LCPUFA during pregnancy impeded accumulation of DHA in these tissues [3]. A 50% reduction of DHA in retinal tissue and a 25% reduction in cerebral cortex DHA was reported for the offspring of rhesus monkeys fed a diet deficient in  $\alpha$ -linolenic acid (ALA, 18:3 *n*-3) during pregnancy compared to controls [3]. Deficient animals also had lower visual acuity using behavioral measures and a prolonged recovery time of the dark-adapted ERG after a saturating flash.

In full-term infants, improved visual function related to the provision of *n*-3 fatty acids during the postnatal period has been repeatedly reported based on the application of methods of visual acuity assessment [4–9]. There are no reports of improved infant visual acuity assessed using the ACP related to maternal dietary DHA intake. Malcolm et al. [10, 11] used VEP and ERG to assess visual acuity and retinal function after maternal DHA supplementation. In these studies, no significant treatment effect was reported for ERG in the first postnatal week [8] or VEP at 2.5 or 6.5 months of age [7].

Pregnant women in the US and Canada have DHA intakes well below the 300 mg/day recommended by the National Institutes of Health Workshop on the Essentiality of and Recommended Dietary Intakes for Omega-6 and Omega-3 Fatty Acids [12–17]. As the developing fetus has an extremely limited capacity to derive DHA from the 18-carbon precursor, the fetus is clearly at risk of a relative deficiency of DHA.

In the current study, we hypothesized that infants of mothers who consumed the DHA-functional food during pregnancy would have better visual acuity when assessed with ACP at four and six months of age compared to infants of mothers consuming a placebo.

## Methods

### Study Design

In a randomized, longitudinal, double-blinded, and placebo-controlled trial, 30 pregnant women 18–35 years of age and <20 weeks gestation were recruited. The cohort used to assess visual acuity was derived from a larger study (unpublished data) focused on the impact of maternal DHA supplementation on infant sleep patterning in the first two postnatal days. Ten ACP assessments were lost initially due to a delay in implementing the ACP. Once implemented, 50% of the infants of women originally recruited were assessed

for vision. Colored marbles representing each study group were selected at random for group assignments by an individual who did not work directly on the project. All other personnel involved with the project were blinded to group assignments. The placebo bars were packaged in exactly the same manner as the intervention bars, making detection of group assignments impossible for investigators or participants. Study groups received: (1) the DHA-containing cereal-based bars, *n* = 16 (300 mg DHA as low EPA fish oil: EPA:DHA, 1:8, per 92 kcal bar) or (2) the cereal-based placebo bars containing corn oil, *n* = 14. Within each group, women consumed three, five or seven bars weekly from 24 weeks of pregnancy to delivery. The consumption of an average of five bars per week provided 214 mg DHA/day via the functional food. The cereal-based bars did not differ in energy, carbohydrate, protein or total fat content (Table 1).

The initial blood draw and 24-h recall were collected at 20–22 weeks gestation prior to starting the intervention at 24 weeks. Women were instructed to consume bars beginning at 24 weeks gestation and continue until delivery. Bars were delivered to women once monthly. Women were given logs to record bar intakes and these were collected monthly. Four times throughout the pregnancy the women were interviewed using 24-h dietary recalls by a trained researcher. All maternal dietary data were evaluated using the Nutrition Data System for Research (NDS, 2005). Infant medical history and diet histories of infants' intakes were obtained at four and six months of age from the mother or primary caregiver. Visual assessments were conducted only on healthy infants and appointments were rescheduled if infants became ill prior to their scheduled appointments. Care was also taken to schedule appointments during the time of day that the infant was most alert/active.

### Subjects

Subject recruitment was conducted in accordance with IRB guidelines at Hartford Hospital and the

**Table 1** Nutritional content of the cereal-based bars used for the intervention and placebo groups

Nutrient per 23 g bar	Intervention	Placebo

Protein (g)	1.3	1.3
Energy (kcal)	92	92

University of Connecticut. Women with a history of drug/alcohol addiction, smoking, hypertension, hyperlipidemia, renal disease, liver disease, diabetes or psychiatric disorder were excluded from study participation.

### Infant Visual Acuity Testing

Visual acuity assessments were conducted at four and six months of age by an individual trained in the ACP using Teller acuity cards [18, 19]. These rectangular cards each contain a square patch of black and white stripes; the cards are arranged from high to low stripe width or grating. One black and white stripe is referred to as one cycle and the frequency of the stripes is given in cycles per centimeter. The spatial frequency doubles stepwise every other card, and this increase in spatial frequency is referred to as an octave. Cards were presented to infants on a stage starting with 0.32 cycles/cm for the four-month assessment and 0.64 cycles/cm for the six-month assessment. Infants were seated 38 cm from the test stage at four months and 55 cm at six months of age. The distances from the stage based upon infant age were set according to the standard ACP procedure. Both groups were tested at identical distances from the stage at four and then at six months. A light meter was used to ensure that the lighting was consistent and adequate for all infants (minimum level of 10 candelas/m<sup>2</sup>).

The test administrator stood on the opposite side of the stage and observed the infants through a peephole in the cards. As the cards were presented to the infants, the tester was unaware of the location of the striped patch on the rectangular card, i.e., left or right. The high visual contrast of the black and white striped square provides a great deal of visual interest for young infants, causing them to look toward the grating pattern if it can be seen by the infant. The observer watched the infant's response to the card and made an assessment regarding whether the striped patch was located on the right or left side of the card based upon the infant's behavioral response. Cards were presented to infants from low to high visual frequency in 0.5 octave steps, and an assessment was made with each step as to whether the infant was able to see the stripes reliably. The observer repeated the presentation of each card; after the first presentation the card was typically flipped so that the stripes were on the opposite side (i.e., left versus right). If the infant could see the stripes, the observer expected the infant to look to the opposite side on alternate trials. The observer presented each card a sufficient number of times to

reliably answer the question, "Can the infant see the stripes?" (answer: yes or no). The card with the finest grating that the infant could see was defined as the threshold.

A single individual who was trained and validated in the procedure performed all visual assessments. All ACP assessments were completed at Hartford Hospital, ensuring that controlled conditions were used, e.g., lighting, sound, distance. Lastly, acuity scores in cycles/degree were converted to octaves, log (base 2), for all statistical analyses as a standard procedure associated with the ACP [18].

Previous studies of infants with diets supplemented with DHA demonstrated that significant differences between mean acuities were  $\geq 0.40$  octaves [20]. Because in the current study we were assessing dietary intake of pregnant mothers, rather than infants, we anticipated greater group differences (0.50 octaves). Using  $\alpha = 0.05$  and power = 0.80, the calculated sample size was 16 subjects per group.

### Statistical Analyses

All statistical analyses were conducted using the Statistical Analysis System (SAS) software [21]. The PROC GLM procedure was used for group comparisons of the log-transformed acuity scores. Analyses of baseline characteristics included the Student's *t*-test for numeric and chi-square for categorical variables. The Proc Mixed procedure was used to evaluate changes over time between four and six-month assessments.

### Results

Overall, groups were well randomized, as most group characteristics were similar between groups (Table 2). Total weight gain during pregnancy, infant gender and APGAR score at 5 min were significantly different between groups.

Information regarding maternal ethnicity and risk of depression was collected via a review of medical records, and there were no differences between groups. Incidence of venereal disease during pregnancy was low in both groups and there were no differences between groups.

The mean dietary DHA intake was not significantly different between groups, and the mean average DHA intake for our entire cohort was 80 mg/day. Thus, subjects in the intervention group received an average of 294 mg DHA/day with intervention and dietary intakes combined.

**Table 2** Visual acuity group characteristics of the DHA versus placebo groups

	DHA ( <i>n</i> = 16) <sup>a</sup>	Placebo ( <i>n</i> = 14)	<i>P</i> value
Maternal age (years) mean ± SD	23.9 ± 4.3	24.7 ± 4.8	0.643
Maternal education (years) mean ± SD	12.8 ± 2.2	12.2 ± 1.5	0.401
Parity mean ± SD	1.5 ± 0.8	1.8 ± 0.8	0.343
WIC participation	14	14	0.171
Single	13	10	0.775
Married	3	3	0.775
Pre-pregnancy BMI (kg/m <sup>2</sup> ) mean ± SD	25.4 ± 4.9 ( <i>n</i> = 15)	28.5 ± 6.1 ( <i>n</i> = 12)	0.151
Total pregnancy weight gain (kg) mean ± SD	17.3 ± 6.8	12.0 ± 5.2 ( <i>n</i> = 13)	0.027
Gestational age (weeks) mean ± SD	39.6 ± 1.3	39.3 ± 1.3	0.506

APGAR 1 min mean ± SD	8.0 ± 1.8	8.4 ± 1.2	0.247
APGAR 5 min mean ± SD	9.0 ± 0.0	8.8 ± 0.7	0.053

<sup>a</sup> Number of subjects used for comparison unless otherwise specified

Mode of infant feeding was categorized as: formula with DHA; formula containing no DHA; breast milk only; combination breast milk and formula no DHA; breastfed for 1–2 months, then changed to formula containing no DHA; breastfed for 2–4 months, then changed to formula containing no DHA. There were no differences between study groups for infant feeding type.

Groups were not different for timing of the ACP assessment at the four or six-month time points (133.2 ± 16.3 days, DHA intervention versus 126.7 ± 6.0 days, placebo at four months; 187.9 ± 7.5 days, DHA intervention versus 190.9 ± 9.6 days, placebo at six months of age). Mean visual acuity scores at four and six months of age for the DHA group compared to the placebo group are presented in Table 3.

The same regression model was used to evaluate infant visual acuity by group at four and six months. The main fixed factor was group (intervention, placebo). Independent and potentially confounding variables for the model were: infant gender, weight gain during pregnancy, APGAR score at 5 min, maternal hematocrit, participation in the WIC program and infant feeding type. Of these independent variables, infant gender and maternal weight gain were not

significant within the model (with significant group differences) and were therefore excluded. There was a significant group difference in visual acuity at four months of age after adjusting for potential confounding variables (*P* = 0.018). Using the same model, there was no significant group difference at six months of age.

There was an increase in ACP score over time for both groups between four and six months (*P* ≤ 0.0001); however, change over time was not significantly different between the DHA and placebo groups.

## Discussion

Our findings demonstrate that infants of mothers who consumed the DHA-functional food during pregnancy had higher ACP visual acuity scores at four months of age compared to controls. In principle, higher acuity scores indicate that the infant is able to resolve a finer grating and therefore demonstrate more mature sensory visual processing. Our finding suggests that the infants of mothers who consumed the DHA food during pregnancy had better visual development at four months than infants of women consuming the placebo, regardless of what the infants were fed post-natally. Group differences were not significant at six months of age.

Visual acuity improved from four to six months for both the DHA and placebo groups. An improvement in visual acuity from the four to the six-month time point was expected, as this is the pattern seen in normative ACP data [2]. These data can be interpreted from the standpoint that infants of mothers who consumed DHA during pregnancy had accelerated development of the visual system that occurred some time prior to four months of age, when we assessed it.

**Table 3** Visual acuity scores for DHA intervention and placebo groups at four and six months of age

	DHA	Placebo
Four-month mean acuity score	3.7 ± 1.3 cycles/degree ( <i>n</i> = 16)	3.2 ± 1.3 cycles/degree ( <i>n</i> = 14)
Six-month mean acuity score	5.9 ± 1.2 cycles/degree ( <i>n</i> = 15)	5.4 ± 1.3 cycles/degree ( <i>n</i> = 11)

Values are expressed as antilogs of the means of the original log transformed scores in mean ± SD

Although ACP has inherent subjectivity not associated with ERG and VEP, it provides an opportunity to evaluate the behavioral responses that require more integrated processing associated with the visual stimulus. As far as we know, this is the first report of the impact of DHA supplementation during pregnancy on infant visual acuity assessed with ACP.

Dietary DHA deficiency during pregnancy reduces the DHA content of photoreceptor membranes of the retina and induces subnormal visual acuity in offspring of nonhuman primates compared to controls [3]. In the absence of DHA, retinal tissue accumulated higher levels of *n*-6 derived docosapentaenoic acid (DPA, 22:5*n*-6), altering membrane characteristics [22]. Such changes in membrane properties interfere with cellular signaling pathways, leading to deficits in function. More specifically, impairment in the G protein-coupled receptor (GPCR) signal transduction was demonstrated in association with DHA deficiency in retinal rod outer segment membranes isolated from rats [22].

Alteration in GPCR signal transduction in the rat model provides a plausible mechanism for our findings of better visual acuity in those infants whose mothers consumed DHA during pregnancy. GPCR signal transduction also has been suggested as a likely basis for alterations in cortical processes related to suboptimal DHA status [23]. Like ACP, VEP is considered a functional measure, but it is a measure that is specific to the primary visual cortex. The ACP elicits a behavioral response, which requires integrative cortical processing. Future work should focus on evaluating (1) the maternal DHA status and the ability of infants to integrate visual stimuli, as in face and object recognition, and (2) the relationship of acuity assessed during infancy to vision at a later age, as well as to cognitive processes [24].

**Acknowledgments** We are grateful to so many who were instrumental in making this project a success: the staff at Hartford Hospital (Women's Ambulatory Health Services) especially, Brunella Ibarrola, Griselle Corcino, Lynn Deasy and Dr. John Greene who appreciated the importance of this work and supported us in establishing subject recruitment and follow-up procedures and provided us with an examination room to conduct our assessments; E. Eugenie Hartmann who provided us with the training and background necessary to establish reliability for the ACP procedures, interpreted results, and who kindly reviewed our manuscript; University of Connecticut graduate students Amber Courville, Charlotte DeMare, Melissa Keplinger, and Elizabeth McArthur, who worked collaboratively in recruitment and follow-up activities. A special thanks to the families from the greater Hartford area who took time from their busy lives to commit to participation in this longitudinal project. Supported in part by USDA IFAFS, Nestec, Ltd., the Hatch Act, the National Fisheries Institute and the American Dietetic Association Foundation.

**Abstract** The experiment was designed to study the effects of butters differing in conjugated linoleic acid (CLA) and *trans* 18:1 contents on lipoproteins associated with the risk of atherogenesis. New Zealand White male rabbits (9.6 weeks; 2.1 kg) were assigned for 6 or 12 weeks to three diets ( $n = 6$  per diet) made of conventional pellets with 0.2% cholesterol and with 12% fat provided from a butter poor in *trans*-10 and *trans*-11 18:1 and in CLA (standard group), or rich in *trans*-10 18:1 (*trans*-10 18:1 group) or rich in *trans*-11 18:1 and in *cis*-9,*trans*-11 CLA (*trans*-11 18:1/CLA group). Blood samples were collected at the end of dietary treatments. Lipoproteins were separated by gradient-density ultracentrifugation. Lipid classes were determined enzymatically and apolipoproteins A-I and B by radial immunodiffusion. Mainly in the 12-week rabbits, higher plasma triglycerides and apolipoprotein B levels shown in the standard and *trans*-10 18:1 groups compared with those in the

*trans*-11 18:1/CLA group are associated with higher plasma levels of very low density lipoproteins (VLDL) and low density lipoproteins (LDL) also shown in these two groups. In the 12-week rabbits, a shift towards denser LDL, considered as more atherogenic, was shown only in the *trans*-10 18:1 group. In these animals, the VLDL + LDL to HDL ratio was 1.7–2.3 times higher in the *trans*-10 18:1 group than in the other groups ( $P = 0.076$ ). These results suggest a rather neutral effect of *trans*-11 18:1/CLA butter towards the risk of atherogenesis, whereas *trans*-10 18:1 butter would tend to be detrimental.

## Introduction

Atherosclerosis and its consequences are the main causes of mortality in industrialized countries, the incidence being related to increasing cholesterol and saturated fatty acid intake. The other factors linking saturated fatty acid and cholesterol intake with coronary heart disease (CHD) are thrombosis and insulin resistance [41]. Milk is often considered to be detrimental towards atherosclerosis because milk fat is rich in saturated fatty acid (especially C12, C14 and C16), and provides low but variable levels of cholesterol and *trans* monounsaturated fatty acids. However, different European prospective studies indicate that there is no evidence that milk [30] or milk fat [41] consumption is associated with CHD. Among different hypotheses, conjugated linoleic acid (CLA), which is sometimes abundant in milk fat, is reported to be potentially antiatherogenic owing to both its hypolipidemic [20] and its antioxidative properties [31].

CLA represents a group of positional and geometric isomers of linoleic acid (*cis*-9,*cis*-12 18:2). It is produced by ruminant animals, to a low degree, by biohydrogenation and *trans* isomerization of dietary polyunsaturated fatty acids (PUFA) by bacteria in the rumen and, to a high degree, by desaturation of *trans*-11 18:1 (vaccenic acid, VA, another intermediate in the ruminal PUFA biohydrogenation process) catalyzed by the stearoylcoenzyme A desaturase in the extrahepatic tissues [2]. Ruminant CLA, dominated by ruminic acid (*cis*-9,*trans*-11 CLA isomer), is preferentially incorporated into triglycerides of fat tissues and milk [12]. The composition and the level of CLA isomers in ruminant products are influenced by animal husbandry factors, mainly by feeding conditions [7, 9]. Products of ruminants represent the major dietary source of CLA for humans, ranging from 150 to 200 mg CLA per day [33].

Associated with CLA in ruminant products, *trans*-18:1 represent a mixture of positional isomers generally dominated by VA in meat or milk from animals offered conventional diets. However, *trans*-10 18:1 (putatively produced by the hydrogenation of *trans*-10,*cis*-12 CLA in the rumen, and/or from oleic acid isomerization [29], is low in traditional feeding systems, but was shown to be increased in milk fat of cows given corn silage-based or concentrate-rich diets supple-

mented with plant oils, especially linoleic-rich oils (sunflower or soybean oil), which tend to decrease milk fat content [4, 8]. For example, with the diet proposed by Bauman et al. [3] to increase CLA, there was an increase in milk *trans*-10 18:1 after 3 weeks, up to 7% of total fatty acids [34], despite the fact that this diet (460 g forage, 160 g hay and 310 g corn silage on a dry matter basis) was not a “high-concentrate diet”. This could contribute to increasing the mean percentage of *trans*-10 18:1 in commercial bulk milk, if farmers used this type of diet, in order to decrease milk saturated fatty acids, to increase milk CLA or to decrease milk fat content (especially in Europe with the milk fat quota regulation systems).

Generally, *trans* fatty acid intake is associated with CHD risk factors, but this link is still controversial [23]. Many studies in humans have shown a positive correlation between total *trans* fatty acid intake and myocardial infarction [32], but some others suggested that their potential for atherogenicity varies with the type of *trans* fatty acids consumed [5]. Indeed, *trans* fatty acids are provided in human foods not only by ruminant fat products (dominated by the *trans*-11 18:1 form) but, above all, by partially hydrogenated vegetable oils (margarines or shortenings) having high levels of several *trans* isomers of 18:1 ( $\Delta$ 6/8,  $\Delta$ 9,  $\Delta$ 10,  $\Delta$ 11,  $\Delta$ 12 and  $\Delta$ 13/14) [15].

To evaluate the specific impact of natural (milk) CLA and *trans*-18:1 on the risk of atherogenesis, three butters were prepared from cow milk fats that differed in their CLA (ruminic acid) and either *trans*-11 or *trans*-10 18:1 contents [35]. These butters, mixed in a conventional rabbit diet supplemented with 0.2% cholesterol, were given for 6 or 12 weeks to New Zealand White rabbits (a validated model for the study of lipoproteins–atherosclerosis interactions [10]) to compare the effects of butter fat containing either *cis*-9,*trans*-11 CLA associated with *trans*-11 18:1 or *trans*-10 18:1 on the blood lipids and lipoprotein profile, indicators of the risk of atherogenesis.

## Experimental Procedure

### Animals and Diets

All experimental procedures were approved by the Local Animal Ethics Committee of the Institut National de la Recherche Agronomique (INRA), in accordance with the French recommendations for the use of experimental animals (guidelines 18 April 1988). The experiment was performed in the experimental

unit of INRA Theix Research Center in France (approval number 06–02630; authorization number for animal experimentation 63 20). Thirty-six male New Zealand White rabbits (age  $9.6 \pm 0.5$  weeks, body weight  $2.1 \pm 0.1$  kg, Elevage Scientifique des Dombes, Chatillon sur Chalaronne, France) were divided according to diet into three groups of 12 animals on the age and body-weight basis. In the same experiment, the animals were given one of three diets either for 6 weeks ( $n = 6$  per treatment) or for 12 weeks ( $n = 6$  per treatment) to ensure a mean body weight gain of 20–25 g/day. The animals were housed in individual stainless steel cages in a temperature-controlled room (18°C) maintained on a 12-h light–dark cycle and were allowed free access to water. Food intake was measured daily and body weight was recorded every week. All rabbits were killed at the end of the experiment (6 or 12 weeks) after a food deprivation of 17 h.

The three experimental diets given to the rabbits (Tables 1, 2) were prepared and pelletized by the INRA (Station de Recherches Cunicoles, Toulouse, France). The butters having different fatty acid composition were prepared from milk from cows given rations varying in the composition of ingredients leading to modifications of the milk fatty acid composition (especially *trans* isomers of 18:1 and CLA contents) as described earlier [35]. They were incorporated into conventional pellets for rabbits (around 12% diet dry matter) which were supplemented with cholesterol (0.2% diet dry matter) (Table 1). The fatty acid composition of the three experimental diets (Table 3) was determined in total lipids extracted by chloroform/methanol (2:1, vol/vol) and then by hexane/ethanol/HCl (25:10:10, vol/vol/vol) [21] by gas–liquid chromatography using a PR 2100 chromatograph (Perichrom Society, Sault-les-Charreaux, France) equipped with a CP Sil 88 glass capillary column (length 100 m; inner diameter 0.25 mm) under conditions described earlier [37].

## Blood Samples

At the end of the two experiments and just before the morning meal, blood samples (50 mL) were collected by cardiac puncture into tubes containing Na<sub>2</sub>-EDTA, NaN<sub>3</sub> and merthiolate (final concentrations 3 mM, 0.1 and 0.01 g/L, respectively). Plasma was prepared by centrifugation of blood samples at 2,700g for 15 min at

15°C. Three 500- $\mu$ L fractions of plasma were stored at -20°C until analysis of lipid fractions and apolipoproteins B and A-I, and one fraction of 20 mL was treated immediately for lipoprotein fractionation.

### Lipoprotein Isolation

To determine the density distribution and the chemical composition of lipoprotein subfractions, plasma lipoproteins were separated by ultracentrifugation according to a three-step sequence in a Centrikon T-2060 ultracentrifuge equipped with a TST 41–14 swinging-bucket rotor (Kontron Analysis Division). First, chylomicrons ( $d < 0.950$  g/mL) were isolated by ultracentrifugal flotation at 103,000g for 46 min at 15°C. Second, very low density lipoproteins (VLDL,  $d < 1.006$  g/mL) were removed from plasma by ultracentrifugal flotation at 205,000g for 16 h at 15°C. Third, the lipoprotein fractions of  $d > 1.006$  g/mL were separated by ultracentrifugation in a discontinuous density gradient in saline solution for 46 h at 205,000g and at 15°C into 22 successive subfractions corresponding to a density from 1.018 to 1.180 g/mL according the procedure described earlier [1]. VLDL (including chylomicrons) were defined as lipoproteins of  $d < 1.018$  g/mL, low-density lipoproteins (LDL) (including intermediate-density lipoproteins, IDL, of  $d = 1.018$ – $1.026$  g/mL) as lipoproteins of  $d = 1.018$ – $1.060$  g/mL, light high-density lipoproteins (HDL) as lipoproteins of  $d = 1.060$ – $1.091$  g/mL, and heavy HDL as lipoproteins of  $d = 1.091$ – $1.180$  g/mL. Lipoprotein fractions were dialyzed at 4°C for 7 h against a buffer containing 0.02 M  $\text{NH}_4\text{HCO}_3$ , 1.5 mM  $\text{NaN}_3$  and 1 mM  $\text{Na}_2\text{-EDTA}$  pH 8.6 in a Gibco BRL microdialysis system (Bethesda Research Laboratories, Rockville, MD, USA) supplied with membranes with cutoff at 12–14 kDa.

### Chemical Analysis

The enzymatic methods used for the determination of lipid classes in plasma and in lipoprotein subfractions have been described previously [22]. Briefly, free cholesterol (FC) was measured by using the properties of the cholesterol oxidase and of the peroxidase. Total cholesterol (TC) was measured by using the reagent kit Cholesterol RTU (BioMérieux, Marcy l'Etoile, France). Cholesteryl ester (CE) content was calculated using the relationship  $\text{CE} = (\text{TC} - \text{FC}) \times 1.68$ . The triacylglycerol (TG) content was estimated from the total glycerol value by the enzymatic method using the reagent kit PAP 150 (reference 61236) supplied by BioMérieux (Marcy l'Etoile, France). Phospholipids (PL) were determined by the method of Trinder using

the BioDirect Phospholipids Kit (Bio Direct, La Villeneuve, France). Plasma nonesterified fatty acids (NEFA) were determined by the enzymatic method using the kit NEFA C WAKO (WAKO Oxoid, Dardilly, France). Protein concentration was determined in lipoprotein subfractions by the colorimetric method of the bicinchoninic acid protein assay reagent (Pierce, Rockford, USA).

### Immunological Analysis

Apolipoprotein A-I and apolipoprotein B in plasma and in lipoprotein subfractions were determined by radial immunodiffusion using polyclonal sheep antisera to rabbit apolipoprotein A-I (purified from HDL) and to rabbit apolipoprotein B (purified from LDL). The diameters of the precipitation rings were proportional to the logarithm of the antigen concentration given by a standard range (rabbit apolipoprotein A-I or apolipoprotein B).

### Statistical Analysis

All data were treated by analysis of variance using the general linear model procedure of SAS [36]. Treatment differences were considered significant at  $P < 0.10$ . Values of the body weight of animals, determined every week, were used in repeated measurements. When the effect of diet was considered to be statistically significant ( $P < 0.10$ ), treatment of means was compared between the kinetic points using a Student's  $t$  test of SAS [21].

## Results

### Diets and Animal Performance

Experimental diets given to rabbits differed in their content of saturated fatty acids (29% higher in the standard diet than in the two other diets) and more especially in their contents of *trans*-10 18:1 (11.8% in the *trans*-10 18:1 diet vs. 0.4 and 2.2% in the standard and *trans*-11 18:1/CLA diets, respectively), *trans*-11 18:1 (7.0 % in the *trans*-11 18:1/CLA diet vs. 1.1 and 1.8% in the standard and *trans*-10 18:1 diets, respectively) and *cis*-9,*trans*-11 CLA (2.6% in the *trans*-11 18:1/CLA diet vs. 0.5 and 0.8% in the standard and *trans*-10 18:1 diets, respectively) (Table 3). All rabbits in both experiments survived during the entire experiment, except for one animal from the standard group in 6-week rabbits which died owing to an accident

during blood sampling. The three diets were generally well accepted during the experiments. No significant differences in food intake were observed between diets, except for the rabbits fed the *trans*-10 18:1 diet in the last week of the experiment (12 weeks), the food intake of which was significantly lower than that in the two other groups (Fig. 1a, b). Rabbits given the three experimental diets for 6 weeks had similar variations of their body weight (Fig. 1a) and daily body weight gain (Table 4). On the other hand, rabbits fed the standard diet for 12 weeks had significantly higher ( $P < 0.05$ ) body weight (6% higher, Fig. 1b) and daily weight gain (15% higher, Table 5) than the rabbits fed the *trans*-10 18:1 or *trans*-11 18:1/CLA diets, the differences in the body weight generally being significant from 4 up to 12 weeks (Fig. 1b).

### Plasma Lipids and Apolipoproteins

In the 6-week rabbits, the plasma TC content of rabbits given the *trans*-10 18:1 diet was 2.4 and 1.8 times higher than that of rabbits given the standard and *trans*-11 18:1/CLA diets, respectively (Table 5). Plasma NEFA was higher in the *trans*-11 18:1/CLA group than in the standard group (+72%) and in the *trans*-10 18:1 group (+122%). Plasma apolipoprotein B, specifically

associated with non-HDL, was 2.0 and 1.8 times higher in the *trans*-10 18:1 group than in the standard and *trans*-11 18:1/CLA groups, respectively (Table 5).

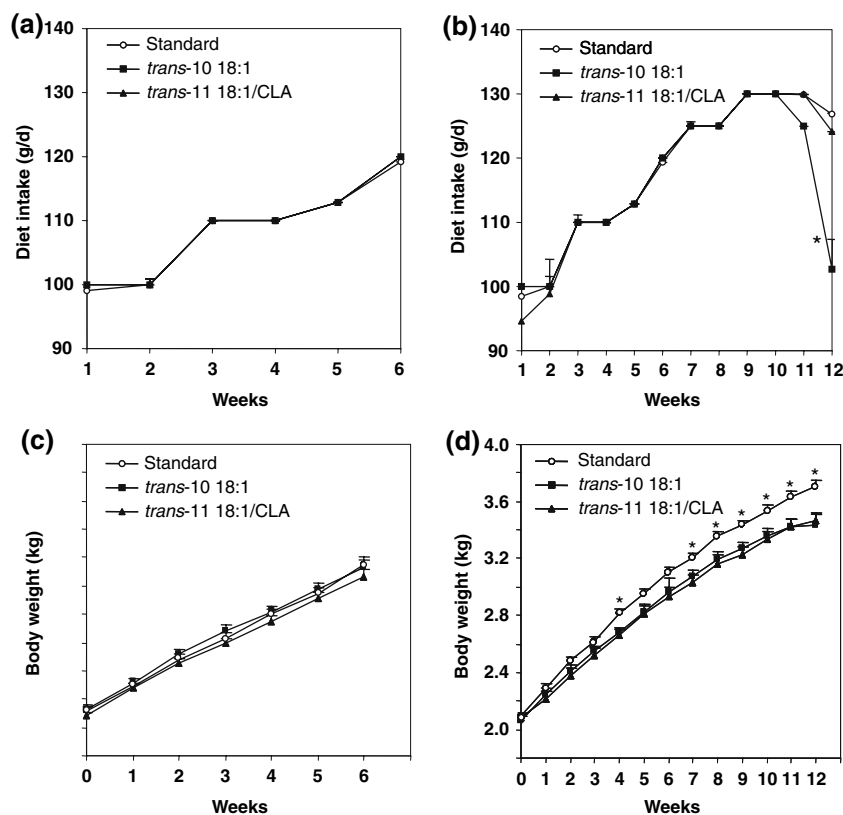

In the 12-week rabbits, plasma TC, PL and apolipoprotein B were generally lower in the *trans*-11 18:1/CLA group than in the standard group and the *trans*-10 18:1 group (Table 5). Plasma NEFA were higher in the *trans*-10 18:1 (+125%) and *trans*-11 18:1/CLA groups (+110%) than in the standard group. Plasma apolipoprotein A-I was lower in the *trans*-10 18:1 and *trans*-11 18:1/CLA groups than in the standard group (Table 5).

### Density Distribution of Plasma Lipoproteins

Lipoprotein classes were separated into 22 subfractions by isopycnic density gradient ultracentrifugation according to their hydrated density (Fig. 2). Lipid classes and apolipoprotein B and A-I contents of each individual subfraction were determined to characterize lipoprotein chemical composition and plasma concentration (Table 6).

In both experiments, plasma VLDL (including chylomicrons) ( $d < 1.018$  g/mL), the most abundant lipoproteins (with LDL) of plasma New Zealand White rabbits (26.0–45.9% of lipoproteins of  $d < 1.180$  g/mL; 160–584 mg/dL), was 1.4–3.7 times ( $P < 0.05$ ) and

**Fig. 1** Variations with time of the diet intake (a, b) and the body weight (c, d) (expressed as mean  $\pm$  the standard error) of New Zealand White rabbits given a diet with 0.2% cholesterol and with 12% fat provided from a standard butter ( $n = 5$ ), a *trans*-10 18:1 butter ( $n = 6$ ) or a *trans*-11 18:1/conjugated linoleic acid (CLA) butter ( $n = 6$ ) for 6 weeks (a, c) or 12 weeks (b, d). The asterisks indicate the mean body weight values of rabbits fed the *trans*-10 18:1 diet or the *trans*-11 18:1/CLA diet significantly different from those of rabbits given the standard diet ( $P < 0.05$ )

**Table 4** Mean body weight gain (g/day) of New Zealand White rabbits given a diet with 0.2% cholesterol and with 12% fat provided from a standard butter ( $n = 5$ ), a *trans*-10 18:1 butter ( $n = 6$ ) or a *trans*-11 18:1/CLA butter ( $n = 6$ ) for 6 or 12 weeks

	Standard	<i>trans</i> -10 18:1	<i>trans</i> -11 18:1/CLA	SEM	Diet effect
6 weeks	24.6	24.0	23.5	1.0	NS
12 weeks	19.2 <sup>a</sup>	16.4 <sup>b</sup>	16.2 <sup>b</sup>	0.6	0.006

Different *superscript letters* indicate significant differences between diets,  $P < 0.05$

SEM standard error of the mean, NS not significant

2.2–2.6 times ( $P < 0.05$ ) higher in the *trans*-10 18:1 group than in the standard and *trans*-11 18:1/CLA groups, respectively (Table 6, Fig. 2).

A similar trend was observed for total LDL (including IDL) particles ( $d = 1.018$ – $1.060$  g/mL), the other major rabbit lipoproteins (30–44% of total lipoproteins of  $d < 1.180$  g/mL; 159–512 mg/dL) (Table 6). In both 6-week and 12-week rabbits, plasma LDL concentration tended to be 1.8–2.6 times higher in animals given the *trans*-10 18:1 diet than the standard and *trans*-11 18:1/CLA diets, respectively ( $P = 0.086$ ) (Table 6). Total LDL was the lowest in the 12-week rabbits, especially in the *trans*-11 18:1/CLA group. The density profile of LDL subfractions was similar in the three groups in the 6-week rabbits, ranging from subfractions 2–10 (highest concentration in subfractions 6 and 7,  $d = 1.026$ – $1.035$  g/mL) (Fig. 2a, c). However, in the 12-week rabbits, a shift towards denser (putatively atherogenic) LDL particles (higher concentration in subfractions 8–12,  $d = 1.035$ – $1.068$  g/mL) was clearly observed in the *trans*-10 18:1 group, whereas a shift towards less dense (putatively nonatherogenic) LDL particles (higher values in subfractions 5 and 6,  $d = 1.023$ – $1.030$  g/mL) was noted in both the standard and the *trans*-11 18:1/CLA groups (Fig. 2b, d).

The total HDL (127–182 mg/dL) represented only 13–27% of total lipoproteins of  $d < 1.180$  g/mL in plasma of rabbits fed the three experimental diets (Table 6). They were dominated by heavy HDL

( $d = 1.091$ – $1.180$  g/mL) (64–72% of total HDL) compared with light HDL ( $d = 1.060$ – $1.091$  g/mL). The density profile of HDL subfractions (subfractions 11–22) was similar in plasma of 6-week rabbits given the three diets (Fig. 2a, e) and 12-week rabbits (Fig. 2b, f), with a maximal concentration for subfraction 17 ( $d = 1.108$ – $1.119$  g/mL). The mean concentrations of light and heavy HDL were generally not significantly influenced by the time of the experiments nor by the dietary treatments, except for the heavy HDL particularly in 6-week rabbits in which it was 1.3 times higher in the *trans*-10 18:1 group than in the *trans*-11 18:1/CLA group ( $P = 0.028$ ) (Table 6).

The ratio VLDL + LDL to HDL, an index of atherogenicity, tended to be modulated by the dietary treatments. It tended to be 2.3 and 1.7 higher in the *trans*-10 18:1 group than in the standard and the *trans*-11 18:1/CLA groups ( $P = 0.076$ ) (Table 6).

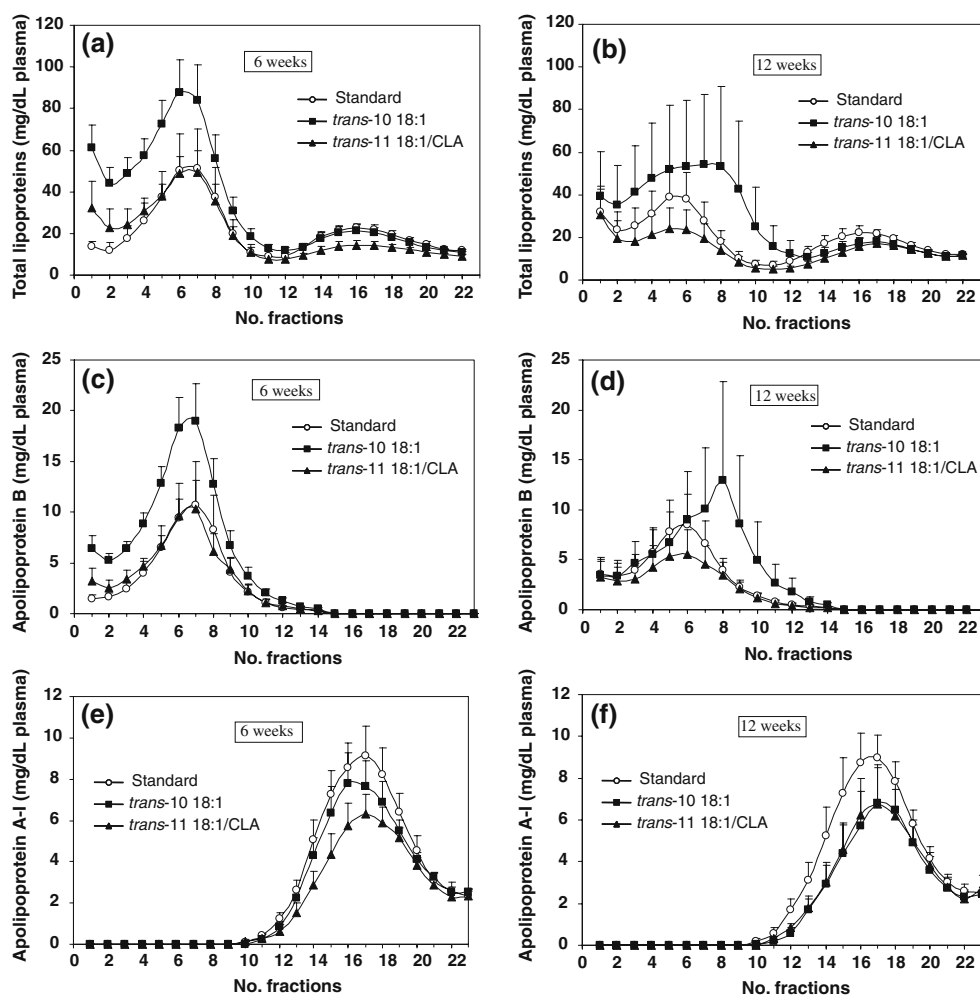

#### Chemical Composition of Plasma Lipoproteins

Analysis of lipid classes and total protein contents of the different lipoprotein classes showed more marked differences in the chemical composition of lipoprotein particles with the time of the experiments than with the dietary treatments (Table 6). Thus, the lipid core of VLDL and of LDL particles was, in the 12-week rabbits compared with the 6-week rabbits, 23–36% ( $P < 0.02$ ) and 8–32% ( $P < 0.04$ ) lower in the CE content in part to the benefit of TG. Similarly to TG, FC markedly increased (2.5–8.8 times) in VLDL particles in the 12-week rabbits compared with that in the 6-week rabbits ( $P = 0.004$ ). In the case of HDL particles, the same variations depending on the duration of the experiments were observed for lipids such as CEs (19–48% lower,  $P < 0.02$ ) and TG (11–82% higher,  $P < 0.01$ ). Finally, as for lipids, the protein content of LDL and HDL particles mainly varied with the duration of the experiments. Thus, the comparison of values determined for the 12-week rabbits with those determined for the 6-week rabbits showed a marked

increase for proteins in LDL (9–43.3% higher,  $P = 0.004$ ) and in light HDL (13–24% higher,  $P = 0.008$ ) and, to a lower extent, in heavy HDL (6–8% higher,  $P = 0.009$ ) (Table 6).

## Discussion

This study using the experimental hypercholesterolemic rabbit model showed that feeding butter enriched in *cis*-9, *trans*-11 CLA and *trans*-11 18:1 (VA) did not modify the susceptibility of animals to atherosclerosis, whereas feeding butter enriched in *trans*-10 18:1 tended to modify plasma lipids and lipoproteins in a way which could increase the risk of atherosclerosis.

### The New Zealand White Rabbit, a Pertinent Model for Experimental Atherosclerosis

Among different animal species, including rat, mouse, hamster, pig and nonhuman primate, used as experimental models for the study of lipoprotein metabolism

related to atherosclerosis, rabbit has been frequently used because of size and easy handling but, above all, because of the high sensitivity of the response to dietary cholesterol [10]. Most strains of rabbits rapidly develop elevated hypercholesterolemia leading to atherosclerosis with deep lesions of blood vessels (aorta, coronary and cerebral arteries). This can be the consequence of gene mutations, such as in Watanabe heritable hyperlipidic line and St. Thomas' Hospital strains, or of the high sensitivity to dietary manipulations (fatty acid composition, cholesterol level) (New Zealand White strain [10]). Unlike rat, hamster or pig, rabbit shares with human a lipoprotein profile dominated by LDL particles and an abundant and active CE transfer protein (CETP) in plasma, conditions that naturally predispose rabbit to atherosclerosis.

cholesterol-fed New Zealand White rabbits confirmed general data obtained with CLA supplements to cholesterol-fed animals, i.e., hamsters (butter CLA [24]), rats (beef CLA or mixed synthetic CLA [28]) and New Zealand White rabbits (mixed synthetic CLA [18, 19]). However, as in our 12-week rabbits, experiments of

long duration can reduce growth performance in cholesterol-fed New Zealand White rabbits (13 weeks, mixed synthetic CLA [18]), but had no negative effects in cholesterol-fed hamsters (12 weeks, *cis*-9,*trans*-11 CLA [40]). Indeed, concerning their growth performance, New Zealand White rabbits appeared to be

more sensitive than other animals to dietary CLA since a decreasing weight gain was reported in these animals given from 0.1 to 1% of mixed synthetic CLA [18], whereas no such variations were noted in rats given 0.5–1.5% of mixed synthetic CLA [39].

In our study, the higher level of CLA (dominated by *cis-9,trans-11* CLA, ruminic acid) in the experimental *trans-11* 18:1/CLA butter is associated with the higher level of VA (*trans-11* 18:1), this latter fatty acid being known to be converted into *cis-9,trans-11* CLA by  $\Delta 9$  desaturation in the mammary gland or in extrahepatic tissues [2]. Therefore, such a decrease of the growth performance noted in the New Zealand White rabbits of the *trans-11* 18:1/CLA group could also be the result of the presence of the large amount of VA in the diet since a decrease was reported in the growth performance in rats given a diet enriched with a mixture of *trans* 18:1 isomers [13] and in mice given a diet enriched with VA [25]. However, a lower growth performance was not observed in cholesterol-fed hamsters given a butter enriched with VA compared with those given a standard butter [24], the lack of an effect probably being explained by the relatively short duration (4 weeks) of the experiment as also observed in our 6-week experiment, or by animal species differences (hamster/rabbit).

It is likely that the (generally moderate) reduction of growth performance following *trans* fatty acid consumption, which affected food intake as well as feed efficiency, was independent of the position of the *trans* double bond in the aliphatic chain of 18:1. Indeed, the same negative effect was noted in our experiment with New Zealand White rabbits given *trans-10* 18:1 or *trans-11* 18:1 and in rats given a mixture of 18:1 *trans* isomers [13].

#### Dietary CLA or *trans* Fatty Acids and Plasma Lipids and Lipoproteins

The lack of an additional effect of the butter rich in *trans-11* 18:1 and in *cis-9,trans-11* CLA given to our cholesterol-fed New Zealand White rabbits, to increase cardiovascular risk factors, is in agreement with recent data reporting the effects of butters enriched in *cis-9,trans-11* CLA on the lipoprotein profile in the hyperlipidemic hamster [40] or the effects of butters enriched in *trans-11* 18:1 and *cis-9,trans-11* CLA on the lipoprotein profile in the cholesterol-fed hamster [24]. Indeed, when expressing the data as the ratio VLDL + LDL to HDL, an index of atherogenicity, our rabbits given this butter tended, especially for the long-duration experiment (12 weeks), to have an improved profile of lipoproteins (in relation to health).

This butter being enriched in *trans-11* 18:1 and *cis-9,trans-11* CLA specifically to the detriment of three saturated fatty acids (C12, C14 and C16), it could be hypothesized that the favorable effect on the lipoprotein profile observed mainly resulted from a lower intake of these saturated fatty acids that were shown in some studies to be proatherogenic fatty acids [17]. However, Valeille et al. [40] provided direct evidence that adding *cis-9,trans-11* CLA in a high-fat diet reduced the early signs of atherosclerosis (lower LDL/HDL and aortic cholesterol loading) in hamster in comparison to the nonsupplemented animals given the same high-fat diet. Therefore, we can hypothesize that *trans-11* 18:1, which is the precursor of *cis-9,trans-11* CLA by  $\Delta 9$  desaturation [2], would also participate in the nonbeneficial or beneficial effects observed after feeding butter rich in *trans-11* 18:1 and *cis-9,trans-11* CLA as recently suggested [24].

Antiatherogenic properties attributed to *trans-11* 18:1 and *cis-9,trans-11* CLA are believed to be mainly the result of modifications of the LDL metabolism. First, it was reported that the decrease in plasma LDL cholesterol was consistent with a decrease in hepatic apolipoprotein B secretion [16], and a higher sequestration of cholesterol by the liver in a dose-dependent manner [38]. Additionally, it is well documented that *cis-9,trans-11* CLA can improve the protection of LDL from oxidation by favoring paraoxonase activity and by downregulation of inflammatory-related genes (TNF  $\alpha$ , IL-1 $\beta$ , cyclooxygenase 2) [40]. In contrast, the fact that *trans-11* 18:1 and *cis-9,trans-11* CLA decreased also plasma light and heavy HDL contents (not previously reported in the literature) in our hypercholesterolemic New Zealand White rabbits minimized the lowering effect of these fatty acids on plasma VLDL and LDL and therefore the protection towards atherosclerosis.

Our study using the hypercholesterolemic rabbit shows, for the first time, a trend for a specific detrimental effect of *trans-10* 18:1 on plasma lipoprotein metabolism leading to hyperlipidemia associated with higher plasma levels of LDL particles, which could be atherogenic. The metabolic effects of *trans-10* 18:1 on plasma lipoproteins related to atherosclerosis have not been previously studied, but have always been associated (only 17–19% of total *trans* 18:1 as *trans-10* 18:1, compared with 80% in the present study) with other *trans* 18:1 isomers in partially hydrogenated vegetable oils (margarines, spreads) [15], namely, in  $\Delta 6-8$  (23–26%),  $\Delta 9$  (17–18%),  $\Delta 11$  (16–17%) and  $\Delta 12$  (23–25%) positions [13, 24].

Generally, in numerous human studies, partially hydrogenated vegetable oils (PHVO) providing *trans* fatty acids at 4% of energy intake increased LDL

cholesterol, and at 5–6% of energy intake decreased HDL cholesterol when compared with dietary lipid sources very poor or deprived in *trans* 18:1 [15]. Such proatherogenic effects of *trans* fatty acids (produced by catalytic hydrogenation of plant oils) reported in humans were not confirmed in animal models such as rat [6, 11, 13] or hamster [40]. In these species, *trans* fatty acids from PHVO lowered plasma TC and LDL cholesterol and had less or no effect on HDL metabolism when compared with the effects of diets rich in *cis* 18:1 or in saturated fatty acids [11], in oleate or in stearate [13], in *trans*-11 18:1 and in *cis*-9,*trans*-11 CLA [24] or of diets poor in *trans* fatty acids and in CLA [24]. Indeed, such opposite effects of *trans* fatty acids on lipoprotein metabolism between humans and rats/hamsters could be explained by differences in the metabolism of apolipoprotein B lipoproteins (especially LDL) linked to the activity of CETP as previously proposed [11]. These authors suggested that the regulation of lipoprotein metabolism by dietary *trans* fatty acids can be masked in animal species exhibiting a very low plasma CETP activity (i.e., rat, mouse, hamster or pig) compared with that in humans [14]. However, the CETP activity, which results in a greater rate of transfer of CEs (and triglycerides) from HDL to other lipoproteins, was shown to be very high in rabbit (1.9 times higher than in human) [14]. Such similarities in lipoprotein metabolism in relation to CETP activity in rabbits compared with humans would explain, at least in part, the trend towards similar effects on LDL and HDL of *trans*-10 18:1 butter in our experiment and in PHVO present in human food items. Compared with previous data on *trans*-9 18:1 considered to be neutral in hamsters [42] and *trans*-11 18:1 proposed to be beneficial for atherosclerosis [24], we provide original data showing a trend towards a detrimental effect of *trans*-10 18:1 on atherosclerosis risk factors in New Zealand White rabbits, an animal model sharing important lipoprotein specificities with humans (predominance of plasma LDL, high plasma CETP activity). As reported for humans consuming diets enriched with soy bean oil based margarines [27], we observed a net shift of LDL particles towards small, dense LDL (which are known to be more atherogenic in humans) in the present rabbits given the *trans*-10 18:1 butter when compared with those given standard or *trans*-11 18:1/CLA-rich butters.

Indeed, since *trans*-10 18:1 and, possibly, other *trans* isomers mainly present in PHVO (i.e., *trans*-6–8 or *trans*-12 18:1) would favor atherosclerosis, different strategies to eliminate or greatly reduce *trans* 18:1 are being investigated by the food industry [15]. They are based on modifications of the hydrogenation treat-

ment, use of the interesterification process and selection of trait-enhanced oils. Similarly, in the case of ruminant milk products, attention must be paid in order to avoid the uncontrolled development of “new” feeding strategies that promote an increase of *trans*-10 18:1 production in the rumen and its secretion in milk, especially association of cereal-rich diets with plant oils [8, 26], initially proposed to increase the energy supplying producing animals and to increase PUFA (especially n-3 PUFA) in products.

**Acknowledgements** The authors wish to gratefully acknowledge Marinett Brunel and Anne-Sophie Bage for skillful technical assistance and Daniel Thomas and Philippe Gaydier for the excellent maintenance and care of the animals. The study was supported in part by the AQS CLA Program with financial aid from the French Research and Technology Ministry.

**Abstract** Conjugated linoleic acids (CLAs) consist of a series of positional and geometrical isomers of linoleic acid. CLA have been reported to beneficially affect cardiovascular risk factors in animal models. In order to assess the role of individual CLA isomers on lipoprotein cholesterol concentration, 30 hamsters were fed for 12 weeks an hyperlipidic diet containing pure *cis*-9,*trans*-11 CLA (*c9,t11*) or pure *trans*-10, *cis*-12 CLA (*t10,c12*) isomers given alone or as a mixture. Plasma total cholesterol, LDL and HDL cholesterol

concentrations were significantly lower in the *c9,t11* CLA isomer fed hamsters relative to the Control group, with the most substantially effect on LDL cholesterol (–56%;  $P < 0.05$ ). Plasma triacylglycerol concentrations did not differ significantly regarding those two groups. Plasma cholesterol parameters showed a tendency to decrease in the *t10,c12* CLA isomer and CLA mixture fed hamsters compared with the Control group, but differences were not significant. For the first time, the atherogenic fraction of small dense LDL was investigated. Plasma small dense LDL cholesterol concentration was lower in the *c9,t11* CLA relative to Control, while the *t10,c12* and CLA mixture groups showed only a non significant tendency to decrease. Taken together, these data indicate that feeding rumenic acid (*c9,t11* CLA) may beneficially affect lipoprotein profile in hamster fed a cholesterol- and lipid-enriched semi-purified diet, when *t10,c12* CLA isomer or CLA mixture would be less active.

### Abbreviations

CAD	Coronary artery disease
CLA	Conjugated linoleic acid
EDTA	Ethylenediaminetetracetic acid
HDL	High-density lipoprotein
HDL-C	High-density lipoprotein cholesterol
LDL	Low-density lipoprotein
LDL-C	Low-density lipoprotein cholesterol
SdLDL	Small dense low-density lipoprotein
TC	Total cholesterol
TAG	Triacylglycerol(s)

## Introduction

Conjugated linoleic acids (CLAs) refer to a group of positional and geometrical isomers of linoleic acid in which the double bonds are conjugated [1]. Some CLA isomers are naturally present in foods (especially in ruminant milk fat and dairy products as well as in ruminant meat), with rumenic acid (*c9,t11* 18:2) as the predominant isomer [2]. Chemical synthesis from linoleic acid leads to the formation of a complex mixture made of different isomers [3]. The older CLA preparations generally contained all four positional isomers from 8,10 to 11,13, while most of the current commercial preparations contain mainly both *c9,t11* and *t9,c12* CLA isomers [4]. Most experimental studies on health effects of dietary CLAs have used such synthetic mixtures.

Several beneficial effects of CLAs have been suggested from results of animal studies and include: carcinogenesis inhibition [5, 6], growth modulation [7] and body composition [8], prevention and treatment of type II diabetes [9], improved bone density [10] and reduced wasting in response to immune stimulation [11].

Synthetic mixtures of CLAs have also been suggested to decrease low-density lipoprotein cholesterol (LDL-C) and to reduce fatty streak formation in some (but not all) animal models [12–14]. Dietary intake may affect not only LDL-C and high-density lipoprotein cholesterol (HDL-C) levels but also low-density lipoprotein (LDL) size and the importance of the atherogenic small dense LDL (sdLDL) fraction [15]. However the effect of CLA supplementation on lipoprotein profile remains equivocal in man, especially regarding the specific effect of individual CLA isomers [16, 17]. Of interest, while mice and rats have a very low cholesteryl ester transfer (CETP) activity and therefore little if any cholesterol exchange between lipoproteins, hamsters show some CETP activity and a lipoprotein profile (with higher LDL-C levels and a fraction of sdLDL) more comparable to that in man.

In the present study, we prospectively analyzed the serum lipoprotein profile (including the different LDL subfractions) of hamsters fed a hypercholesterolemic diet with or without pure CLA isomers (*c9,t11* or *t10,c12*), or an equimolar mixture of both isomers.

## Materials and Methods

### Material

Pure *cis-9,trans-11* CLA (*c9,t11* 89.9%, *t10,c12* 2.8%, *c,c* isomers 0.8%, and *t,t* isomers 1.1%) and *trans-*

*10,cis-12*-CLA (*t10,c12* 96.5%, *c9,t11* 0.5%, *c10,c12* 1.25%, and *t,t* isomers 0.9%) isomers were commercially supplied as free fatty acids by Natural Lipids (Hovdebygda, Norway). Cholesterol and oleic acid were purchased from Sigma-Aldrich (Saint Quentin Fallavier, France). Triacylglycerol GPO-PAP and Cholesterol CHOD-PAP assay kits were purchased from Roche Diagnostics GmbH (Mannheim, Germany).

### Animals and Protocol

Forty golden Syrian male hamsters (Harlan, Gannat, France),  $82.5 \pm 0.67$  g body weight, 6–7 weeks old, were randomly allotted to four groups of ten animals. All hamsters were individually housed in stainless steel cages in an animal house maintained at  $26 \pm 1$  °C, with a 7:00 a.m.–5:00 p.m. light:dark cycle and free access to tap water. All animals were fed ad libitum a hypercholesterolemic diet consisting of 10% coconut oil, 1% safflower oil and 0.12% cholesterol (w:w), blended in a semi-purified diet containing wheat starch (342 g/kg DM), sucrose (246 g/kg DM), casein (219 g/kg DM), cellulose (33 g/kg DM), mineral mix (47 g/kg DM), and vitamin mix (14 g/kg DM). Supplementation of oleic acid as a control, *c9,t11* CLA (rumenic acid), *t10,c12* CLA, or a 50:50 (w:w) mixture of *c9,t11* CLA and *t10,c12* CLA, was added and accounted for 1% (by weight) of the hypercholesterolemic diet. Animal groups were designated as “control”, “*c9,t11* CLA”, “*t10,c12* CLA” and “CLA mixture” group, respectively. Body weight of the animals was monitored on a weekly basis throughout the study.

At the end of the 12-week experimental period, the hamsters were fasted overnight and anesthetized with isoflurane breathing. Blood sample was obtained from the *vena cava inferior* and collected on EDTA. Plasma was separated by centrifugation for 10 min at  $1,860 \times g$  at room temperature, frozen in liquid nitrogen and maintained at  $-80$  °C until analyzed within 2 months.

### Plasma Lipids and Lipoproteins Analyses

Plasma triacylglycerol (TAG) and total cholesterol (TC) concentrations were measured enzymatically in plasma and lipoprotein subclasses using Triacylglycerol GPO-PAP and Cholesterol CHOD-PAP assay kits.

Plasma lipoproteins were isolated by sequential ultracentrifugation at 4 °C using a Beckman TL-100 ultracentrifuge (Beckman Instruments Inc., Fullerton, CA, USA) equipped with a fixed angle rotor (TLA-100.2, Beckman Instruments Inc.) [18]. The LDL fraction was separated at density ranges between 1.019

and 1.063 g/mL and HDL at a density >1.063 g/mL. Subsequent separation of LDL subpopulations was performed by isopycnic ultracentrifugation [19] of the fraction ( $d = 1.019$ – $1.063$  g/mL) previously isolated. In brief, the LDL fraction was adjusted to  $d = 1.040$  g/mL (by dilution with water) and layered between potassium bromide solutions (containing EDTA and sodium azide 0.01%) of different densities [ $d = 1.019$  (1 mL), 1.025 (3 mL), 1.040 (3 mL LDL fraction), 1.054 (3.5 mL) and 1.085 g/mL (1 mL)] and then centrifuged for 40 h (40,000 rpm; 4 °C) in a Beckman XL-100K Ultracentrifuge using a swinging bucket rotor (SW41Ti, Beckman Instruments Inc.). A high density KBr solution (1.29 g/mL) was then injected through the bottom of the tube (2232 Microperpex S Peristaltic Pump, LKB, Bromma, Sweden) and 25 subfractions (450  $\mu$ l each) of increasing densities were recovered from the top of the tube. Density and cholesterol content were measured in each collected subfraction. LDL density profile was obtained by plotting cholesterol content versus density. The sdLDL fraction was considered as the sum of subfractions collected between 1.040 and 1.063 g/mL.

#### Aortic Fatty Streak

After blood collection, the aorta was perfused with 10% buffered formalin solution (pH 7.0). After a few minutes, the flow of fixative solution was slowed and fixation allowed for additional 30 min. The heart and the thoracic aorta were removed and immersed into fixative solution overnight. To study aortic fatty streak formation, a piece of aorta (between the heart and including the aortic arch) was cut and cleaned with phosphate buffer saline pH 7.4, and then rinsed with isopropanol. The aortic tissue was placed in a vial containing 5% Oil Red O stain in 70% isopropanol for 10 min. Then the aortic piece was rinsed consecutively with isopropanol and distilled water, and placed in a vial containing 1% toluidine blue in distilled water for a few seconds. Finally, the tissue was rinsed with distilled water. The arch was dissected vertically in two, then opened longitudinally, mounted on a glass slide, and observed under microscope at appropriate magnification. Samples were blind to examiners.

#### Statistics

Data were analyzed by one-way ANOVA with Statgraphics Plus, Version 5.1. When appropriate, pair wise comparisons of means were made by using Bonferroni test and the significance level set at  $P \leq 0.05$ .

#### Results

Body weight prior to and after the treatment period did not significantly differ between the four groups of hamsters (Table 1). However, body weight gain tended to be slightly higher ( $P < 0.1$ ) for the  $c9,t11$  CLA group as well for the control group than for the CLA mixture and the  $t10,c12$  CLA fed animals.

Plasma TAG concentrations tended to be higher in hamsters fed  $c9,t11$  CLA as well as for the  $t10,c12$  CLA fed animals compared to the control group (+11 and +22%, respectively), but these differences were not significant (Table 2). In contrast, plasma TAG concentration was significantly higher in hamsters fed the CLA mixture relative to the control group (+79%) ( $P < 0.05$ ).

Plasma TC and HDL-C concentrations were significantly lower (–35 and –40%, respectively;  $P < 0.05$ ) in the  $c9,t11$  CLA fed hamsters relative to control group (Table 2). No significant differences in the TC/HDL-C ratio were observed between the groups. In contrast, there were no significant differences for plasma TC and HDL-C concentrations between hamsters fed  $t10,c12$  CLA or those fed the CLA mixture, and the control group.

Plasma LDL-C concentration was significantly lower in the  $c9,t11$  CLA fed group relative to the control group (–56%;  $P < 0.05$ ) and tended to be lower for this  $c9,t11$  CLA group than for the CLA mixture and  $t10,c12$  CLA fed animals, but these differences were not significant (Table 2). No significant differences for LDL-C concentration were found between the groups fed the  $t10,c12$  CLA or the CLA mixture, and the control group.

The small dense LDL (sdLDL) subfraction was particularly high after dietary manipulation in the animal model used in the present study: the hamsters fed a cholesterol- and lipid-enriched semi-purified diet had significantly ( $P < 0.01$ ) higher sdLDL cholesterol concentrations compared to hamsters fed usual rodent

<sup>a</sup> See experimental part... Groups were initially constituted by *n* = 10 hamsters, but due to too small plasma volumes available for some animals, final “*n*” were reduced for plasma parameter analysis. Values are mean ± SEM

Values in a column not sharing a superscript are significantly different (*P* < 0.05; Bonferroni test)

chow diet (data not shown). This increased fraction of sdLDL cholesterol was not associated with high cholesterol or high triacylglycerol levels when compared to a group of normocholesterolemic animals fed regular diet (data not shown). Plasma sdLDL cholesterol concentrations were significantly lower in the hamsters fed *c*9,*t*11 CLA relative to control group (−75%; *P* < 0.05) and tended to be lower compared to the groups fed the *t*10,*c*12 CLA and the CLA mixture (−50 and −66%, respectively), but these differences were not significant (Table 2). The concentration of cholesterol in the sdLDL did not differ significantly between the group fed the CLA mixture and the control group. There was a substantial interindividual variability in plasma cholesterol concentrations within each animal group.

Histological studies under microscope after Oil Red O staining did not show any fatty streak formation in aortas of hamsters from any group.

## Discussion

Male Golden Syrian hamsters have been extensively used in studies involving lipoprotein metabolism. They are considered as a useful model for studying nutritional modulation of cholesterol and lipoprotein metabolism [20–24]. In the present study, four groups of hamsters were fed different diets in order to investigate the effects of CLA isomers on cholesterol concentration in total plasma and in atherogenic lipoproteins.

Plasma total cholesterol concentrations of about 3–5 mM/L are generally reported in normolipidic hamsters with 50–70% of this cholesterol carried out in the HDL fraction [22, 25–27]. On the other hand, when hamsters are fed a diet rich in cholesterol and lipids, total plasma cholesterol concentrations may increase fourfold within a month, with an inversion in HDL to LDL cholesterol ratios [24]. Hypercholesterolemic hamsters generally present plasma total cholesterol concentrations ranging from 6 to 20 mM/L, with

20–40% of this cholesterol in the HDL fraction [22, 27–29].

In our study, hamsters from the control group showed only slight differences in plasma lipids and lipoproteins when compared to animals fed a regular chow-based diet: plasma TC, LDL-C, and HDL-C concentrations were comparable between both groups. However, hamsters fed the cholesterol- and lipid-enriched diet had significantly (*P* < 0.01) higher sdLDL cholesterol concentrations than hamsters fed regular chow-based diet (0.09 mM/L). In man, such sdLDL particles are considered to be particularly atherogenic [15, 30]; the plasma lipoprotein profile accompanying a predominance of sdLDL particles is associated with a two- to threefold increased risk of coronary artery disease [31]. Despite these elevated sdLDL cholesterol concentrations, there was in our model no evidence of aortic atherosclerosis in the hamsters fed the cholesterol- and lipid-enriched semi-purified diet. In addition, the cholesteryl ester content in the liver remained rather low (3–4 mg lipids/g liver). Both the type of diet and the hamster strain may account for these unexpected findings. Some studies have suggested that semi-purified diets, as those used in the present studies are not as atherogenic in hamsters as non-purified diets [13, 14, 32]. On the other hand, different hamster strains were reported to have different responses to an atherogenic diet [27, 33, 34]. Considerable variations in plasma cholesterol concentrations were observed between animals from any given group; such interindividual variability was also reported in other studies of experimental atherosclerosis in hamster [24].

The effect of CLA on plasma cholesterol level is somewhat controversial (Table 3). Previous studies [12–14] have shown a reduction of cholesterol concentrations in animals fed a CLA mixture compared with controls in an atherogenic hamster model [12–14]; however no difference of plasma cholesterol lowering was observed between supplementation with a CLA mixture and linoleic acid. Other authors also reported that dietary CLA did not produce any significant differences in serum TC or HDL-C concentration in

C57BL/6 mice fed an atherogenic diet but increased HDL-C:TC ratio [35]. In another study, de Deckere et al. [25] showed that the CLA mixture could lower cholesterol concentrations in proatherogenic lipoproteins and that the active compound would be the *t10,c12* CLA isomer. On the contrary, Valeille et al. [36] showed the beneficial effect of rumenic acid (*c9,t11* CLA) on the cholesterolemia of hamsters fed a cholesterol- and lipid-enriched diet.

In the present study, hamsters fed rumenic acid (*c9,t11* CLA) showed lower plasma LDL and sdLDL cholesterol compared with the other groups. HDL-C was also reduced in animal fed *c9,t11* CLA, so TC:HDL-C ratio was not significantly increased in this group. In contrast, we did not observe any significant difference in plasma cholesterol concentrations between hamsters fed the CLA mixture or *t10,c12* CLA, and the control group. These results are not in agreement with those reported by de Deckere et al. [26], but the experimental conditions and design markedly differed between both studies with respects to hamster strain, duration, atherogenic diet, and amounts of added CLA isomers. However, our data are in good agreement with those obtained by Valeille et al. [36]

showing rumenic acid to improve plasma lipoprotein profile in hamsters. Both current findings and results of Valeille et al. [36] are based on much more purified CLA isomers than mixtures used in previous studies, this could explain why they are more consistent. It is increasingly evident the different CLA isomers have different biological and pathologic effects, and it is not surprising since they exhibited different physical and chemical properties [4].

In conclusion, the present results indicate that rumenic acid, a natural CLA isomer, fed at 1% of a cholesterol- and lipid-enriched semi-purified diet, may significantly decrease plasma total cholesterol but also HDL, LDL and sdLDL cholesterol concentrations. The strong decrease of sdLDL cholesterol suggests rumenic acid to have a greater potential than the other CLA isomers for reducing lipoprotein atherogenicity in hamsters. As far as we know, it is the first time that such a decrease in sdLDL cholesterol concentrations is reported related to rumenic acid consumption by hamsters. It would be of interest to investigate the specific effect of both CLA isomer on lipoprotein parameters, especially sdLDL, in using a hamster model developing aortic fatty streak.

**Table 3** Comparative effects of CLA on lipoprotein parameters in different hamster strains

**Abstract** Apolipoprotein (apoB) plays a fundamental role in the transport and metabolism of plasma triacylglycerols (TAGs) and cholesterol. Several apoB polymorphic sites have been studied for their potential use as markers for coronary heart disease in the population. In view of the importance of apoB in postprandial metabolism, our objective was to determine whether the presence of the -516C/T polymorphism in the *APOB* gene promoter could influence postprandial lipoprotein metabolism in healthy subjects. Forty-seven volunteers who were homozygous for the E3 allele at the *APOE* gene were selected (30 homozygous for the common genotype (C/C) and 17 heterozygotes for the -516T allele (C/T). They were given a fat-rich meal containing 1 g fat and 7 mg cholesterol per kg body weight and vitamin A 60,000 IU/m<sup>2</sup> body surface. Fat accounted for 60% of calories, and protein and carbohydrates for 15 and 25% of energy, respectively. Blood samples were taken at time 0, every 1 h until 6 h, and every 2.5 h until 11 h. Total cholesterol and TAGs in plasma, and cholesterol, TAGs and retinyl palmitate in triacylglycerol-rich lipoproteins (large and small triacylglycerol-rich lipoproteins) were determined by ultracentrifugation.

Individuals carrying the C/T genotype presented greater postprandial concentrations of TAGs in small triacylglycerol-rich lipoproteins than did carriers of the C/C genotype ( $P = 0.022$ ). Moreover, C/T individuals presented higher concentrations of plasma TAGs during the postprandial period than did C/C subjects ( $P = 0.039$ ). No other statistically significant genotype-related differences for other parameters were observed. These results suggest that the presence of the genotype C/T is associated with a higher postprandial response. Thus, the allele variability in the -516C/T polymorphism in the *APOB* gene promoter may partly explain the interindividual differences in postprandial lipemic response in healthy subjects.

**Keywords** *APOB* polymorphism · Nutrigenetics · Postprandial lipemia · Triacylglycerol-rich lipoproteins

### Abbreviations

apoB	Apolipoprotein B
BMI	Body mass index
CHO	Carbohydrate
CHD	Coronary heart disease
LDL	Low-density lipoprotein
MUFA	Monounsaturated fatty acid
SFA	Saturated fatty acid
TAGs	Triacylglycerol
TRL	Triacylglycerol-rich lipoproteins

### Introduction

The postprandial state constitutes the normal metabolic situation of human beings throughout the day in

developed societies, as the clearance of triacylglycerol (TAG)-rich lipoproteins (TRL) of intestinal or hepatic origin last for a period of 6–8 h. Determination of the postprandial response is a complex process, which makes it all the more challenging to assess the cardiovascular risk associated with postprandial lipemia than during fasting conditions. Previous studies have suggested that postprandial small TRL may predict the onset of coronary heart disease (CHD), and evidence supporting an association between postprandial lipemia and atherosclerosis has been provided by clinical trials [1–6]. Individual variability in the postprandial lipemic response is usually greater than that observed in the fasting state, and appears to be modulated by environmental and genetic factors [7, 8]. This concept is supported by studies showing that certain polymorphisms at candidate gene loci are associated with variability in postprandial clearance of lipoprotein [9].

Apolipoprotein (apoB) plays a fundamental role in the transport and metabolism of plasma TAG and cholesterol and it is synthesized primarily in hepatocytes and enterocytes. The human *APOB* gene is located on chromosome 2 and several *APOB* polymorphic sites have been studied for their potential use as markers for CHD in the population [10]. Moreover, some of them have been investigated for the inter-individual variability observed during postprandial lipemia (XbaI polymorphism, I/D polymorphism within the apoB signal peptide) [11–13]. Previously, a common functional polymorphism of the *APOB* promoter was described by van't Hooft et al. [14] involving a C to T change located at 516 base pairs upstream from the transcription start site. This polymorphism was found to induce significant increase in the transcription rate of the *APOB* gene and, consequently, in circulating levels of low-density lipoprotein (LDL) cholesterol. These findings are consistent with the fact that the *APOB* gene promoter plays a major role in cholesterol homeostasis [15]. Furthermore, we have demonstrated that healthy males carriers of the -516T allele, have a significant increase in insulin resistance after the consumption of diets with different fat content, but the difference is more pronounced after an SFA-enriched diet than following MUFA and CHO-rich diets [16].

In view of the insulin sensitivity of postprandial metabolism, it would be interesting to find out whether the presence of this polymorphism in the *APOB* gene could modulate postprandial lipemia, in the same way as it has already been observed in other genotypes.

## Material and Methods

### Subjects of the Study

Forty-seven healthy men were recruited from among 97 students at the University of Cordoba. The 47 subjects had a mean age ( $\pm$ SD) of  $23 \pm 4.12$  years. Of these, 30 were homozygotes for the -516C allele (C/C) and 17 heterozygotes for the -516T allele (C/T). The distribution of genotypes was as expected from the Hardy–Weinberg equilibrium. Informed consent was obtained from all participants. All the subjects were selected to have the *APOE* 3/3 genotype to avoid the potential confounder from the presence of the other common *APOE* alleles on postprandial lipemia [17]. All subjects underwent a comprehensive medical history, physical examination, and clinical chemistry analysis before inclusion in the study, and they did not show evidence of any chronic disease (hepatic, renal, thyroid, or cardiac dysfunction). None of the subjects were obese, nor did they perform unusually high levels of physical activity (e.g., sports training). In addition, none of the subjects had a family history of premature coronary artery disease or had taken medications or vitamin supplements in the 6 months prior to the study. Subjects were encouraged to maintain their regular physical activity and lifestyle and were asked to record in a diary any event that could affect the outcome of the study, such as stress, change in smoking habits and alcohol consumption in the week before the fat loading test. Previous to the fat loading test, the volunteers consumed a saturated fatty acid diet period as a baseline regimen, as this Western-style diet is frequently consumed by Western countries, including most areas of Spain. All studies were carried out in the Research Unit at the Reina Sofia University Hospital, and the experimental protocol was approved by the Hospital's Human Investigation Review Committee.

### Vitamin A and Fat Loading Test

After a 12-h fast, subjects were given a fatty meal enriched with 60,000 units of vitamin A per  $m^2$  of body surface area. The amount of fat given was 1 g of fat and 7 mg of cholesterol/kg of body weight. The meal contained 65% of energy as fat, 15% protein and 25% carbohydrates and was eaten in 20 min. We calculated the amount of each ingredient fed as a function of individual weight, so that although all the subjects consumed the same types of food, the quantities involved were different. The foods were bread, whole milk, eggs and butter. After the meal, the subjects had

no energy intake for 11 h, but were allowed to drink water. Blood samples were drawn before the meal, every hour until the sixth hour and then every 2 h and 30 min until the eleventh hour.

### Lipoprotein Separations

Blood was collected in tubes containing EDTA to give a final concentration of 0.1% EDTA. Plasma was separated from red cells by centrifugation at 1,500 g for 15 min at 4 °C. The chylomicron fraction of TRL (large TRL) was isolated from 4 mL of plasma obtained from EDTA tubes. Plasma was put in the bottom of a 13.4 mL polyallomer ultracentrifuge tube (UltraClear, Beckman Instruments, Palo Alto, CA, USA) and overlaid with a preservative solution consisting of NaCl (0.15 mol/L), sodium azide (0.05 g/L), chloramphenicol (0.05 g/L), gentamicin sulfate (40 mg/L) and EDTA (1 mmol/L), (pH 7.4,  $d < 1.006$  kg/L). Ultracentrifugation was performed in a type TY65 rotor (Beckman Instruments, Fullerton, CA, USA) at 36,200 $\times$ g and 4 °C for 30 min. Chylomicrons contained in the top layer were removed by aspiration, placed directly into individual vials and stored at –80 °C until assay for retinyl palmitate, biochemical determinations, apoB-48 and apoB-100. The infranatant fluid was centrifuged at a density of 1.019 kg/L and overlaid with the same preservative cocktail. The ultracentrifugation was performed for 24 h at 183,000 g in the same rotor. The nonchylomicron fraction (also referred to as small TRL) was removed from the top of the tube by aspiration, placed directly into individual vials and stored at –80 °C until assay for retinyl palmitate, biochemical determinations, apoB-48 and apoB-100. All operations were done under subdued light in order to prevent the degradation of retinyl palmitate (RP).

### Lipid Analysis

Cholesterol and TAGs in plasma and lipoprotein fractions were assayed by enzymatic procedures [18, 19]. Apo A-I and apo B were determined by turbidimetry [20]. HDL cholesterol (HDL-C) was measured by analyzing the supernatant obtained following precipitation of a plasma aliquot with dextran sulphate-Mg<sup>2+</sup>, as described by Warnick et al. [21]. The LDL cholesterol (LDL-C) was obtained as the difference between the cholesterol from the bottom part of the tube after ultracentrifugation at a density of 1.019 kg/L.

### Retinyl Palmitate Assay

The RP content of large and small TRL fractions was assayed using a method previously described [22]. Briefly, different volumes of the various fractions (100  $\mu$ L for chylomicrons and 100–500  $\mu$ L for remnant) were placed in 13  $\times$  100 mm glass tubes. The total volume in each tube was adjusted, as necessary, to 500  $\mu$ L using normal saline. Retinyl acetate (40 ng in 200  $\mu$ L of mobile phase buffer) was added to each tube as internal standard. Five hundred milliliter of methanol was added followed by the addition of 500  $\mu$ L of the mobile phase buffer for a total volume of 1.7 mL. The mobile phase buffer was prepared fresh on a daily basis by combining 90 mL of hexane, 15 mL *n*-butyl chloride, 5 mL acetonitrile, and 0.01 mL acetic acid (82:13:5 by volume with 0.01 mL of acetic acid). The tubes were thoroughly mixed after each step. The final mixture was centrifuged at 350 g for 15 min (room temperature) and the upper layer was carefully removed by aspiration and was injected into a high-performance liquid chromatography (HPLC) system. The autoinjector was programmed to deliver 100  $\mu$ L per injection and a new sample every 10 min in a custom prepackaged silica column SupelcoSil LC-SI (5 mm, 25 cm  $\times$  mm ID) provided by Supelco Inc. The flow was maintained at a constant rate of 2 mL/min and the peaks were detected at 330 nm. The peak of RP and retinyl acetate were identified by comparing its retention time with a purified standard (Sigma, St Louis, MO, USA) and the RP concentration in each sample was expressed as the ratio of the area under the RP peak to the area under the retinyl acetate peak [23]. All operations were performed in subdued light.

### Determination of ApoB-48 and ApoB-100

ApoB-48 and apoB-100 were determined by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) as described by Karpe et al. [24]. In brief, samples containing isolated lipoprotein fractions were delipidated in a methanol/diethyl ether solvent system and the protein pellet was dissolved in 100–500  $\mu$ L of 0.15 mol/L sodium phosphate, 12.5% glycerol, 2% SDS, 5% mercaptoethanol, and 0.001% bromophenol blue (pH 6.8), at room temperature for 30 min followed by denaturation at 80 °C for 10 min. Electrophoresis was performed with a vertical Hoefer Mighty Small II electrophoresis apparatus connected to an EPS 400/500 (Pharmacia) power supply on 3–20% gradient polyacrylamide gels. The upper and lower electrophoresis buffers contained 25 mmol/L

Tris, 192 mmol/L Glycine, and 0.2% SDS adjusted to pH 8.5. ApoB-100 derived from LDL was used as a reference protein and for standard-curve dilutions. A dilution curve ranging from 0.10 to 2 mg of apo B-100 was applied to four of the gel lanes. Electrophoresis was run at 60 V for the first 20 min and then at 100 V for 2 h. Gels were fixed in 12% trichloroacetic acid for at least 30 min and stained in 0.2% Coomassie G-250/40% methanol:10% acetic acid for at least 4 h. Destaining was done in 12% methanol:7% acetic acid with four changes of destaining solution for 24 h. Gels were scanned with a videodensitometer scanner (TDI, Madrid, Spain) connected to a personal computer for integration of the signals. Background intensity was calculated after scanning an empty lane. The coefficient of variation for the SDS-PAGE was 7.3% for apo B-48 and 5.1% for apo B-100.

#### DNA Amplification and Genotyping

DNA extraction was performed by standard procedures. Genotyping for the -516C/T polymorphism was carried out using the restriction enzyme Ear I (Biolabs, New England, Inc.) as described previously [14].

#### Statistical Analysis

Several variables were calculated in order to characterize the postprandial responses of plasma TAGs, large TRL and small TRL to the test meal. The area under the curve (AUC) is defined as the area between the plasma concentration versus time curve and a line drawn parallel to the horizontal axis through the 0 h concentration. This area was calculated by a computer program using the trapezoidal rule. Other variables were the normalized peak concentration above baseline and the peak time, which was the average of the time of peak concentration and the time to the second greatest concentration. Data were tested for statistical significance between genotypes, and between genotypes and time by analysis of variance for repeated measures and the Kruskal–Wallis test. In this analysis, we studied the statistical effects of the genotype alone, independent of the time in the postprandial study, the effect of time alone or of changes in the variable after ingestion of fatty food over the entire lipemic period, and the effect of the interaction of both factors, genotype and time, indicative of the magnitude of the postprandial response in each group of individuals with a different genotype. When statistical significance was found, the Tukey's post-hoc comparison test was used to identify group differences. A probability value less than 0.05 was considered significant.

All data presented in text and tables are expressed as means  $\pm$  SDs. SPSS 11.0 was used for the statistical comparisons.

#### Results

The basal characteristics by genotype are shown in Table 1. No differences for any of the variables examined were observed at baseline between genotype groups.

The postprandial response of plasma TAGs and TAGs in different lipoprotein fractions were analyzed. A significant effect of time in plasma for all variables measured except large TRL-RP was observed, with respect to baseline levels, indicating an increase of these parameters in the different groups of subjects during the postprandial period.

Individuals carrying the C/T genotype displayed greater postprandial concentrations of small-TRL TAGs than did carriers of the C/C genotype ( $P = 0.022$ ) (Fig. 1). C/T individuals also presented higher concentrations of plasma TAGs during the postprandial period than C/C subjects ( $P = 0.039$ ) (Fig. 1). No other statistically significant genotype-related differences for other parameters were observed.

The area under the postprandial curve in study participants according to the APOB -516C/T polymorphism was analyzed and no significant differences were observed between genotypes (Table 2).

#### Discussion

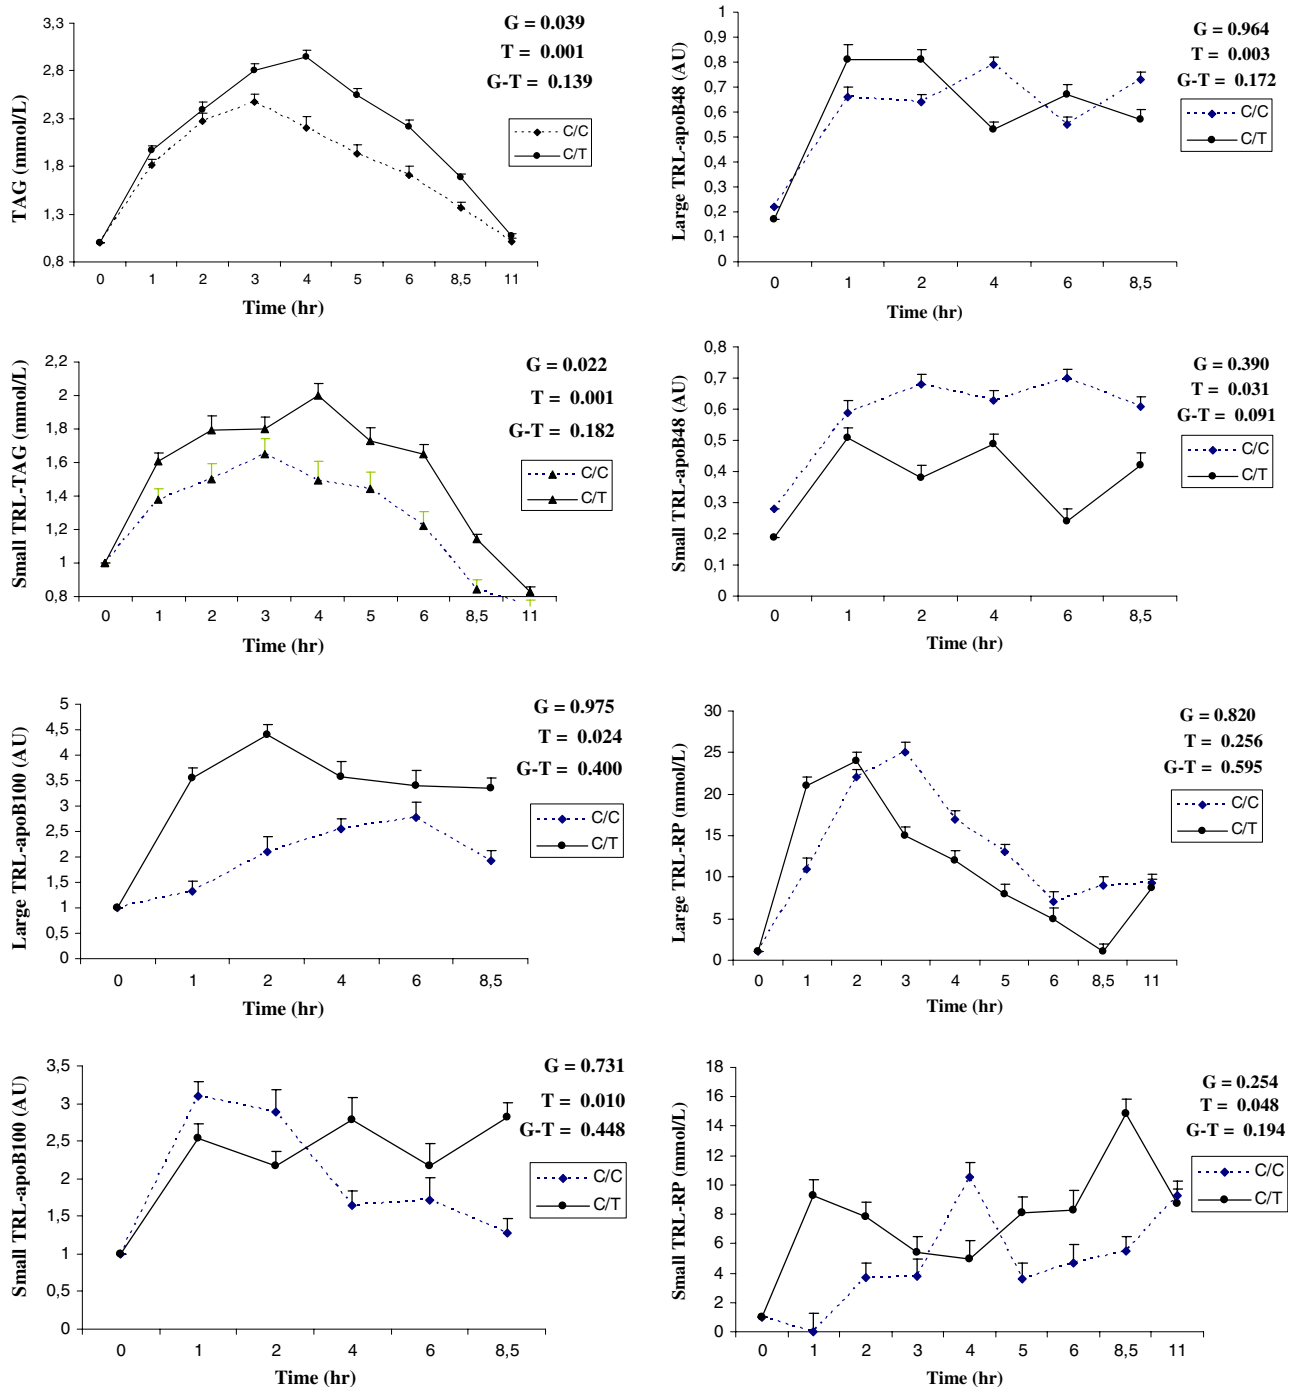

Our findings show that healthy male carriers of the T allele at the -516C/T polymorphism in the APOB gene

**Table 1** Baseline characteristics according to the -516C/T polymorphism in the ApoB gene promoter

	Genotype		<i>P</i>
	C/C [n = 30]	C/T [n = 17]	
Age (year)	23.40 $\pm$ 4.10	22.60 $\pm$ 3.98	0.504

promoter have a greater postprandial response of TAGs in small TRL as compared with C/C individuals.

A growing body of experimental and clinical evidence suggests that TRL, and in particular small TRL, contribute to atherogenesis and consequently to cardiovascular disease progression and that high levels of

small TRL of both hepatic and intestinal origin are associated with the progression of coronary atherosclerosis [25, 26]. A study by Phillips et al. found that neither LDL-C nor TG fasting levels correlate highly with lesion progression or clinical events [26]. Small TRL-TG concentrations in plasma reflect postprandial

metabolism, and these did correlate with both lesion progression and cardiac events. Thus, smaller, partially catabolized TRL are believed to be more atherogenic or thrombogenic than larger, newly secreted TRLs, which makes our results of particular interest.

ApoB is required for the assembly secretion of chylomicrons in the intestine and very low-density lipoproteins (VLDL) in the liver, and it also acts as the ligand for LDL recognition by LDL receptors. Several studies have demonstrated an association between the C/T genotype and elevated plasma levels of LDL-C [27]. However, the influence of this polymorphism on postprandial lipemic response remains unknown. Our study is to our knowledge the first to examine the association between the -516C/T polymorphism in the APOB gene promoter and postprandial lipemic response in healthy subjects. We have observed a delayed postprandial clearance of TAGs in small TRL in subjects with the less common C/T genotype than in C/C individuals. A limitation of our study is that it includes a relatively small number of subjects. However, because the magnitude of postprandial lipemia is subject to considerable individual variability and is affected by several genetic factors [28, 29], our study sample was limited to healthy men with the Apo E3/E3 genotype, in order to avoid the variable postprandial lipid response of other apoE isoforms or gender [30].

Two mechanisms might explain the change observed in the catabolism of TRL in subjects with the -516C/T polymorphism. We have previously demonstrated that carriers of the -516T allele also have a significant increase in insulin resistance [16]. These data are in accordance with previous evidence demonstrating that small TRL concentrations are significantly higher in insulin-resistant healthy individuals with normal glucose tolerance [31]. In this context, a positive relation

between insulin resistance and altered postprandial lipemia has repeatedly been reported [32, 33]. Consequently, insulin resistance increases the hepatic synthesis of lipid substrates. These effects potentially increase the plasma concentrations of small TRL and increase competition for hepatic uptake between small TRL and VLDL remnants [34]. Nevertheless, postprandial lipemia is not a uniform abnormality and its pathophysiology has not yet been fully clarified; it is possible that the response to dietary fat is a multifactorial phenomenon. Previous studies suggest that the relationship between plasma insulin and TRL levels is partly influenced by other polymorphisms in the APOB gene (i.e., apoB XbaI polymorphism [11]). Furthermore, in our study C/T subjects showed a higher postprandial response of plasma TAGs than did carriers of the C/C genotype. In this context, subjects who display an increase in plasma TAGs concentrations have smaller and denser LDL particles and an enhanced degree of postprandial lipemia [35]. Previous data also suggest that individuals carrying the C/T genotype present significant increases in the transcription rate of the APOB gene and, consequently, in circulating levels of LDL cholesterol, a delayed postprandial clearance of TAGs in small TRL, and an increase in insulin resistance. On the other hand, the presence of this polymorphism is independently associated with the presence of carotid atherosclerotic disease [36]. Although these results are preliminary, the fact that our study was carried out on healthy individuals in a controlled interventional trial could be the key to a better understanding the effect of this polymorphism on postprandial lipoprotein metabolism.

Furthermore, because all the study subjects were young and healthy, it is possible that the effects on postprandial lipemia response observed in these individuals will be magnified as the subjects become older or obese, as has previously been shown with other polymorphisms (LPL HindIII polymorphism) [37].

In conclusion, allele variability in the -516C/T polymorphism in the APOB gene promoter could partly explain the interindividual differences in the postprandial lipemic response in healthy subjects.

**Abstract** Exogenous and endogenous cholesterol oxidation products (COPs) perturb various metabolic processes, and thereby they may induce various homeostasis-related disorders. Here, we observed that procyanidin-rich dietary apple polyphenol (APP) from unripe apples alleviates the perturbation of lipid metabolism by decreasing the exogenous COP levels in rats. Dietary COPs may be the greatest source of COPs found in the human body. Rats (4 weeks of age) were fed AIN-purified diets containing 0.3% COPs supplemented with 0.5 or 2.5% APP for 3 weeks. Dietary APP alleviated the growth inhibition action of the exogenous COPs. The modulations of the liver lipid profile by COPs remained unchanged. However, serum total cholesterol, high-density lipoprotein cholesterol, and triglyceride levels increased following the intake of

dietary APP. Further, dietary APP inhibited the increase in lipid peroxide levels in the liver and serum by COPs. The activity of hepatic  $\Delta 6$  desaturase was lowered by dietary APP in a dose-dependent manner, although exogenous COPs generally increased the activity of this enzyme. In keeping with this observation,  $\Delta 6$  desaturation indices in the phospholipids and cholesteryl esters of the liver and serum lipids were lower in the APP-fed groups than those in the control group. Dietary APP also promoted the excretion of exogenous COPs, cholesterol, and acidic steroids in feces. Therefore, the inhibition of intestinal absorption of COPs may partly contribute to the alleviation of the perturbation of lipid metabolism and lipid peroxidation levels. Thus, APP may be an important removal agent of exogenous toxic material such as COPs contained in processed or fast foods.

## Introduction

Cholest-5-en-3 $\beta$ -ol (cholesterol) in common foods is readily oxidized by exposure to oxygen, high temperature, irradiation with UV rays, and reaction with free radicals during processing or storage. Substantial amounts of cholesterol oxidation products (COPs) have been detected in a variety of processed foods [1] and fast foods [2, 3]. The major COPs were produced through the cholesterol oxidation process, as shown in Fig. 1. Previously, we observed that in rats approximately 30% of the major exogenous COPs are absorbed into the lymph from the intestine [4]. In addition, high levels of COPs were detected in the rat liver and sera following their oral administration at high doses (between 0.2 and 0.5%) [5–7]. COPs are produced in the human body by the attack of free radicals; however, dietary COPs may be the greatest

source of COPs found in the human body because of eating many processed foods containing high levels [1–3] of COPs from animals.

Many *in vitro* studies have shown that COPs exhibit specific deleterious effects such as cytotoxicity, mutagenicity, carcinogenicity, atherogenicity, inhibition of sterol biosynthesis, and modulation of immune function [8]. In previous studies, we observed that dietary COPs specifically disturbed growth, cholesterol metabolism, linoleic acid desaturation, and age-related changes in lipid metabolism [5, 6]. Thus, exogenous COPs appear to exert biologically deleterious effects on lipid metabolism. However, the regulation of COP-induced deleterious effects has not yet been explored. Recently, we observed that soybean protein partly alleviated some of the deleterious effects of exogenous COPs, including the promotion of hepatic linoleic acid desaturation and modulation of lipid parameters [9]. Dietary soybean protein exerted a modulatory effect via the inhibition of intestinal absorption of COPs and regulation of lipid metabolism.

Some reports indicated that dietary polyphenols exert a hypocholesterolemic action [10] and regulatory function on lipid metabolism [11]. The bioavailability of each polyphenol has not yet been completely

**Fig. 1** Common cholesterol oxidation pathways in foods

defined; however, they may not necessarily be absorbed at high levels as intact molecules from the intestine. Moreover, some reports found that tea catechins inhibit the intestinal absorption of sterols [12, 13]. These observations appear to be associated with the inhibition of the micellar solubility of sterols in the intestine. Therefore, it is possible that dietary polyphenols influence the intestinal absorption of exogenous COPs.

Leth and Jusrensen [14] evaluated that we consume approximately 28 mg polyphenols per day from various plant foods and beverages. The total polyphenol level in a typical fruit serving of 200 g is 50–500 mg [15]. Moreover, we consume tea and onions, etc.; therefore, our daily intake level of polyphenols may be much higher than 28 mg. Among fruits, apples have more than 200 mg polyphenols [15]. Compared with ripe apples, unripe apples contain a significantly higher level of procyanidins [16]; however, except for their antioxidative function, the nutritional function of these procyanidins has not yet been elucidated. Procyanidins in unripe apples consist of oligomeric (–)-epicatechins of 2–14 mer, and they comprise over 60% of total polyphenols [16]. Among procyanidins, low and intermediate molecular weight compounds are soluble in water, alcohol, and acetone [15]. Some of these compounds may be absorbed from the intestine, and their metabolites may influence lipid metabolism. In contrast, high molecular weight compounds are insoluble in the same solvents [15]. The bioavailability of these compounds may be low; however, they interfere with the micellar solubility of lipids. Therefore, the soluble fractions of apple polyphenol (APP), such as 2–4 mers of (–)-epicatechin, may alleviate various disturbances in lipid metabolism that are induced by COPs during metabolic processes. Moreover, the insoluble fractions, such as those over 5 mer of (–)-epicatechin, may inhibit the intestinal absorption of COPs. Since we usually consume many processed foods and fast foods in the modern diet, in the present study, we examined the effect of procyanidin-rich APP (approximately 64% procyanidins of 2–14 mer) on the perturbation of lipid metabolism induced by exogenous COPs in rats. Additionally, we aimed to evaluate the nutritional functions of procyanidin-rich APP as a preventive agent against toxic components in processed foods.

## Experimental Procedures

### Chemicals

[1-<sup>14</sup>C]Linoleic acid ( $\text{CH}_3(\text{CH}_2)_4\text{CH}=\text{CHCH}_2\text{CH}=\text{CH}(\text{CH}_2)_7^{14}\text{CO}_2\text{H}$ , 51 mCi/mmol) was purchased from

New England Nuclear (Boston, MA, USA), and it was purified by thin-layer chromatography prior to use [5]. Solvents and chemicals of reagent grade or better quality were purchased from Nacalai Tesque Co. (Kyoto, Japan) and Kanto Chemical Co. (Tokyo, Japan).

### Animals and Diet

Male Sprague–Dawley rats (3 weeks old, CLEA Japan, Co., Tokyo, Japan) were housed individually in a room with controlled temperature (20–23 °C) and light (0800–2000). After the rats had acclimatized for 1 week, they were divided into groups of seven and fed diets containing either 0.5 or 2.5% APP (99% purity, product of Fundamental Research Laboratory, Asahi Breweries) and 0.3% COPs. APP contained the following by weight percentage: (–)-epicatechin, 6.1; (+)-catechin, 1.1; phloridzin, 1.1; phloridzin xyloglucoside, 2.7; chlorogenic acid, 4.8; *p*-coumaroylquinic acid, 1.5; procyanidins (2 mer), 11.1; procyanidins (3 mer), 12.3; procyanidins (4 mer), 8.7; procyanidins (5 mer), 5.9; procyanidins (6 mer), 4.9; and procyanidins (above 7 mer), 39.8. The composition of added COPs is described in the section “Preparation of the Oxidized Cholesterol Mixture.” The diets were prepared according to the formula recommended by the American Institute of Nutrition [17]. They contained the following constituents by weight percentage: casein (Wako Pure Chemicals Co.), 20; safflower oil (Rinoru Oil Co.), 10; mineral mixture (AIN-76 mixture, Oriental Yeast Co.), 3.5; vitamin mixture (AIN-76 mixture, Oriental Yeast Co.), 1.0; choline bitartrate, 0.2; DL-methionine, 0.3; cellulose, 5.0; corn starch, 15; and sucrose to 100. COPs and APP were added at the expense of sucrose. COPs were added in the diet after emulsifying them into safflower oil. The experimental diet was prepared weekly, packed in a pouch containing an oxygen absorbent, and stored at 4 °C to prevent the autooxidation of lipids. The amount of diet given to the control and 0.5% APP diet-fed groups was the same as that consumed by the 2.5% APP-fed group because the high level of APP caused a significant reduction in food intake. After 3 weeks, the rats were decapitated; their liver was immediately excised and microsome was prepared at 4 °C. The plasma was separated by centrifugation after allowing the blood to clot at room temperature. These samples were maintained at –80 °C until analyses. In order to avoid oxidation, nitrogen gas was diffused through the samples. In order to analyze the fecal neutral and acidic steroids, feces were collected for 2 days, beginning 10 days prior to killing, and these were then lyophi-

lized. The Hirosaki University Animal Policy approved this animal study, and the rats were maintained according to the guidelines of Hirosaki University for the care and use of laboratory animals.

#### Preparation of the Oxidized Cholesterol Mixture

A COP-rich fraction was prepared from pure cholesterol (99.9%) by using the method described in a previous report [5]. The major COPs were identified by gas–liquid chromatography (GLC, Shimadzu GC-14B, Shimadzu Co., Kyoto, Japan) with a flame ionization detector (FID) and a C-R6A integrator after trimethylsilyl derivatization of the prepared fraction. The GLC conditions were as follows: a fused-silica capillary ULBON HR-1 column (0.25 mm × 50 m, Shimwa Chemical Industries, Kyoto, Japan) with a liquid-phase thickness of 0.25 μm; oven temperature, 270 °C; injector temperature, 300 °C; flow rate of helium, 0.7 mL/min; split ratio 1:10. This mixture contained the following by weight percentage: cholesterol, 6.8; cholest-5-en-3β,7α-diol (7α-hydroxycholesterol), 9.9; cholest-5-en-3β,7β-diol (7β-hydroxycholesterol) and 5,6β-epoxy-5β-cholestan-3β-ol (5β-epoxycholesterol), 13.3; 5,6α-epoxy-5α-cholestan-3β-ol (5α-epoxycholesterol), 4.4; 5α-cholestan-3β,5,6β-triol (cholestanetriol), 3.7; 3β-hydroxycholest-5-en-7-one (7-ketocholesterol), 10.2; cholest-5-en-3β,25-diol (25-hydroxycholesterol), 1.3; and identified oxysterols, 45. Unidentified oxysterols comprised more than ten unknown peaks. These may originate from slightly cleaved sterols, although we do not have an exact explanation.

#### Enzyme Activity

The activity of Δ6 desaturase in liver microsomes was measured by Sevansson's method [18]. The microsomal protein concentration was determined by the method of Lowry et al. [19].

#### Superoxide Dismutase Activity of Red Blood Cells

The activity of superoxide dismutase (SOD) in red blood cells was measured by the nitrite method according to the report of Oyanagui [20].

#### Lipid Peroxide Level

Liver and serum lipoperoxides were measured by the method of Yagi [21] and Ohokawa et al. [22], as thiobarbituric acid reactive substances (TBARS) are markers of lipid peroxide.

#### Lipid Analysis

Liver and serum lipids were extracted by the method of Folch et al. [23], and the concentrations of triglyceride, cholesterol, high-density lipoprotein (HDL) cholesterol, and phospholipids were measured as described previously [24]. The fatty acid compositions of liver phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were analyzed by GLC (Shimadzu GC-8A) by using a FID and a Silar 10C column (2 mm × 3 m) [25].

#### Analysis of Fecal Steroids

Further, the levels of fecal acidic steroids were analyzed by GLC (Shimadzu GC-8A) with a FID by using a AN-600 column (2 mm × 3 m) using 23-nordeoxycholic acid (Steraloids, Wilton, NH, USA) as an internal standard [26]. The concentration of the sterols in the serum, liver, and feces were measured by GLC (Shimadzu GC-14B) by using a FID with a ULBON HR-1 column (0.25 mm × 50 m, 0.25 μm, Shinwa Chemical Industries) according to the condition described above. 5α-Cholestan (Sigma Chemical Co., St Louis, MO, USA) was used as an internal standard, and measurements were carried out after converting the sterol to a trimethylsilyl ester derivative [27].

#### Prostaglandin Analysis

For measurement of the aortic production of prostacyclin (PGI<sub>2</sub>), the thoracic aorta (approximately 25 mg) was incubated in Krebs–Henseleit bicarbonate buffer (pH 7.4) at 25 °C for 30 min, and the concentration of 6-ketoprostaglandin F<sub>1α</sub> (6-keto-PGF<sub>1α</sub>) in the medium was measured using a Shimadzu LC 10ADVP high-performance liquid chromatography (HPLC) system [28]. HPLC analysis of 6-keto-PGF<sub>1α</sub> was performed using a reversed-phase HPLC column (250 × 4.6 mm) at 195 nm by using a UV–vis detector. The contents of the column were eluted with acetonitrile/0.1% phosphoric acid (33:67 by volume) at a flow rate of 1 mL/min.

#### Identification of Major COPs

GLC–mass spectrometry was also performed to identify the major COPs according to a previous method [27]. The analysis was performed by using a Shimadzu GCMS-QP5050A mass spectrometer with a Shimadzu GC-17 gas chromatograph. The GLC–mass spectrometry conditions were as follows: a fused silica capillary ULBON HR-1 column (0.25 mm × 50 m) with a liquid-phase thickness of 0.25 μm; oven temperature,

270 °C; injector temperature, 300 °C; flow rate of helium, 0.7 mL/min; split ratio 1:50; make-up gas (helium), 40.1 mL/min. The mass spectra were measured within a mass range of  $m/z$  50–600. The scan speed was one scan per second. The ionization energy was 70 eV.

#### Effect of APP on Micellar Solubility of Cholesterol In Vitro

A mixed-micellar solution containing 6.6 mM sodium taurocholate, 0.6 mM egg yolk PC, 0.2 mg/mL COPs, 132 mM NaCl, and 15 mM sodium phosphate at pH 7.4 was prepared by sonication and kept at 37 °C for 24 h according to the method of Ikeda et al. [12]. A 100- $\mu$ L solution of various concentrations of APP (0.5, 1, and 2 mg/mL) was added to the 5-mL micellar solution. The mixed solution was incubated for 1 h at 37 °C after the addition of APP, and centrifuged at 1,000g for 10 min. The supernatant was filtered using a 220-nm Millex-GV filter (Japan Millipore, Tokyo). The COPs in each filtrate were identified by GLC as described above. The level of bile acid in the micelles was measured using a commercial kit (Enzabile-2, Daiichi Kagaku, Tokyo, Japan).

#### Statistical Analysis

Data were analyzed by Duncan's [29] new multiple range test to determine the exact nature of the difference ( $P < 0.05$ ) among the groups.

## Results

### Growth and Liver Weight

Compared with the control group, groups receiving dietary APP showed an increase in weight in a dose-dependent manner despite the pair-feeding protocol (Table 1). The relative liver weight was not influenced by dietary APP.

**Table 1** Effect of dietary apple polyphenol (APP) on growth in rats given cholesterol oxidation products (COPs)

Group	Initial body weight (g)	Weight gain (g/21 days)	Food intake (g/day)	Liver weight (g/100 g body weight)
Control	82 ± 1	119 ± 3 <sup>b</sup>	14.9 ± 0.1	4.58 ± 0.11
0.5% APP	82 ± 1	121 ± 39 <sup>bc</sup>	14.9 ± 0.2	4.57 ± 0.12
2.5% APP	82 ± 1	131 ± 4 <sup>c</sup>	14.9 ± 0.4	4.79 ± 0.30

Data are the mean ± the standard error (SE) of seven rats. Means with different letters in rows are significantly different ( $P < 0.05$ )

### TBARS Values of Serum and Liver

Table 2 shows the levels of serum and liver lipoperoxides that were measured as TBARS. A significant dose-dependent reduction in serum and liver TBARS values was observed in the groups receiving dietary APP when compared with the control group.

### SOD Activity of Red Blood Cells

The SOD activity of red blood cells was significantly lower in the APP-fed groups than in the control group (control group 574.5 ± 124.3 NU/mg protein, APP-0.5 group 254.9 ± 70.7 NU/mg protein, APP-2.5 group 284.0 ± 65.5 NU/mg protein).

### $\Delta 6$ Desaturase Activity of Liver Microsomes

The APP-fed groups showed lower hepatic  $\Delta 6$  desaturase activity than the control group (control group 1,138.1 ± 94.9 pmol/min/mg protein, AP-0.5 group 731.9 ± 142.8 pmol/min/mg protein, AP-2.5 group 496.1 ± 165.5 pmol/min/mg protein). In particular, this enzyme activity was significantly lower in the APP-2.5 group than in the control group.

### Concentration of Liver and Serum Lipids

Serum total cholesterol level was not changed by dietary APP; however, the HDL-cholesterol level was increased in a dose-dependent manner (Table 3). Further, dietary APP increased the serum triglyceride level in a dose-dependent manner. The liver total cholesterol level was not influenced by dietary APP. In contrast, the liver triglyceride level in the APP-fed groups was lower than that in the control group, particularly in the APP-2.5 group (Table 4). The liver phospholipid level in the APP-fed groups was lower than that in the control group; however, the serum phospholipid levels remained the same.

#### Δ6 Desaturation Index of Liver and Serum Lipids

The levels of linoleic acids (18:2n-6) in liver and serum lipids were higher in APP-fed rats than in the control group rats. In contrast to these observations, the levels of arachidonic acids (20:4n-6) in the liver and serum were lower in the APP-fed groups than that in the control group. These changes that were induced by

dietary APP occurred in a dose-dependent manner. In keeping with these results, the ratio of Δ6 desaturation indices (20:3n-6 + 20:4n-6)/18:2n-6 in liver PC and PE were lower in the APP-fed group than in the control group. This reduction occurred in a dose-dependent manner. Similar observations were made in the case of serum PC and CE (Table 5).

#### Level of PGI<sub>2</sub>

The aortic production of PGI<sub>2</sub> was significantly decreased by dietary APP (control group 9.90 ± 0.66 nmol/aorta mg, AP-0.5 group 7.56 ± 0.71 nmol/aorta mg, AP-2.5 group 5.95 ± 0.55 nmol/aorta mg).

#### Excretion of Acidic Steroids in Feces

The APP-fed group tended to show higher excretion of acidic steroids in the feces (Fig. 2) than the control group. Reflecting these observations, the total level of excreted acidic steroids in feces was significantly higher in the APP-fed rats than that in rats fed with a diet free of APP (control group 3.20 ± 0.35 mg/day, APP-0.5 group 3.55 ± 0.51 mg/day, APP-2.5 group 5.09 ± 0.35 mg/day).

#### The Levels of Major Oxidized Cholesterols in Tissues and Excreted Feces

Major COPs, including 7β-hydroxycholesterol, 25-hydroxycholesterol, 5α-epoxycholesterol, 5β-epoxycholesterol, cholestanetriol, and 7-ketocholesterol, were

**Fig. 2** Effect of dietary apple polyphenol on excretion of fecal acidic steroids in rats given cholesterol oxidation products. Data are the mean ± the standard error of seven rats in each group. Means with different letters are significantly different at ( $P < 0.05$ ). APP apple polyphenol, litho lithocholic acid, deoxy deoxycholic acid, cheno chenodeoxycholic acid, hyo hydoxycholic acid, urso ursodeoxycholic acid, cholic cholic acid, α-muri α-muricholic acid, β-muri β-muricholic acid

detected in the serum and liver, irrespective of the consumption of APP (Table 6). The APP-fed group had lower accumulation of these COPs in the serum and liver than the control group. In contrast, the level of each COP in the feces tended to be significantly higher in the APP-fed groups than in the control group. Therefore, the levels of the major COPs that were excreted in the feces significantly increased in a dose-dependent manner.

**Effects of APP on Micellar Solubility of COPs and Bile Acids**

The addition of APP to a mixed-micellar solution containing COPs decreased the micellar solubility of COPs in a dose-dependent manner (Fig. 3). Further, the addition of APP reduces the levels of bile acid in micelles in a dose-dependent manner.

**Discussion**

We consume various levels of COPs in daily food, especially processed food [1] and fast foods [2, 3] in our

modern diet. Compared with fatty acid oxidation products, these COPs are more easily absorbed from the intestine [30, 31]. Subsequently, they disturb lipid metabolism through their toxic effect [5, 7–9]. Thus, exogenous COPs from processed foods are hazardous to human health. However, no counterplan for this hazardous problem has been considered until now. We examined the preventive functions of dietary APP, which is an oligomeric (–)-epicatechin-rich polyphenol, on the perturbation of lipid metabolism by exogenous COPs. This was done because dietary APP may inhibit the intestinal absorption of COPs and their metabolites and regulates the disturbance of lipid metabolism by COPs without the various side effects caused by medicines.

Exogenous COPs generally inhibit growth and food intake [6, 32]; however, dietary APP appears to alleviate the growth inhibition induced by exogenous COPs. Recently, we observed that hepatic function including glutamate oxaloacetate transaminase (control  $41.5 \pm 1.9$  IU/L, APP-0.5  $25.5 \pm 1.6$  IU/L, APP-1.0  $18.4 \pm 1.7$  IU/L) and glutamate pyruvate transaminase (control  $20.1 \pm 0.9$  IU/L, APP-0.5  $10.6 \pm 0.8$  IU/L, APP-1.0  $7.7 \pm 0.8$  IU/L) was also alleviated by the consumption of APP in rats fed with 0.5% COP (unpublished data). Thus, dietary APP may alleviate the impairment of growth and hepatic function induced by exogenous COPs.

Exogenous COPs increase tissue lipoperoxide levels and disturb the biological antioxidative system [5, 7–9]. We observed that dietary APP decreased lipoperoxide levels (as TBARS values) in the liver and sera of rats that were fed COPs in this experiment. Moreover, the SOD activity of blood cells was higher in the control group than in the APP-fed groups. Dietary COPs may induce SOD activity because they elevated the TBARS value [7]. However, the metabolites from APP, particularly low molecular weight procyanidins, including 2–4 mers of (–)-epicatechin, may have antioxidative effect. Moreover, high molecular weight procyanidins such as greater than 4 mer in APP inhibited the absorption of COPs as described below. Therefore, SOD activity may not be induced in APP-fed groups. However, we observed that dietary APP prevented the exhaustion of tocopherols and SOD in rats fed a normal diet without COPs (unpublished data). We need to perform more experiments to explain this conflict. Analysis of the hydroperoxide levels of each lipid class or other more specific markers of lipid oxidation such as  $F_2$  isoprostanes is needed in future studies to more precisely evaluate the antioxidative effects of dietary APP.

We previously observed that exogenous COPs promoted the desaturation of linoleic acid through the

increase of  $\Delta 6$  desaturase activity [5, 7–9]. This promotive activity of the enzyme by COPs may be associated with the modulation of microsomal membrane fluidity [33, 34]. Moreover, the modulation of the messenger RNA (mRNA) level of  $\Delta 6$  desaturase may contribute to these modulations. The promotion of linoleic acid desaturation may cause an imbalance in the eicosanoid level because eicosanoids are metabolites of arachidonic acid. In fact, dietary COPs increase the production of  $PGI_2$  in the aorta. It has been reported that COPs influence arachidonic acid release from cell membrane phospholipids and cyclooxygenase activity in vitro [35, 36]. The imbalance in the eicosanoid level is associated with various homeostasis-related disturbances concerning lipid metabolism. Therefore, dietary APP may play an important role as a regulatory food factor in the perturbation of linoleic acid desaturation. Further study is needed to elucidate the relationship between dietary APP and the modulation of cyclooxygenase or lipoxygenase activities by exogenous COPs.

COPs generally perturb cholesterol biosynthesis; this reduces the cholesterol level in the liver and serum. In this study, dietary APP did not influence the liver cholesterol level. The metabolites from APP and COPs may inhibit hepatic 3-hydroxy-3-methylglutarylcoenzyme A (HMG-CoA) reductase; therefore, this may have been responsible for the unchanged liver cholesterol level in this experiment. In fact, we observed that dietary APP decreased the activity of hepatic HMG-CoA reductase in rats fed a cholesterol-free diet (polyphenol-free diet  $162.2 \pm 31.3$  pmol/min/mg protein, APP monomer diet  $122.7 \pm 18.1$  pmol/min/mg protein, APP oligomer fraction diet  $61.7 \pm 8.2$  pmol/min/mg protein, unpublished data). Further, the serum total cholesterol level was also the same in each group; however, the HDL cholesterol level increased in a dose-dependent manner. Therefore, the ratio of HDL cholesterol to total cholesterol significantly increased (control  $60.4 \pm 6.7\%$ , APP-0.5  $73.6 \pm 5.0\%$ , APP-1.0  $86.5 \pm 4.3\%$ ) and the atherosclerosis index [(total cholesterol–HDL cholesterol)/HDL cholesterol] significantly decreased owing to consumption of APP (control  $0.68 \pm 0.21$ , APP-0.5  $0.38 \pm 0.09$ , APP-1.0  $0.32 \pm 0.06$ ). Dietary APP increased the HDL cholesterol level in the rats fed a cholesterol-free diet (APP-free diet  $28.4 \pm 2.1$  mg/dL, APP-0.1 diet  $39.0 \pm 2.6$  mg/dL, APP-0.5 diet  $40.3 \pm 2.6$  mg/dL, unpublished data). The same observations were made in diabetic rats fed cocoa extract containing procyanidins [37]. Heat-epimerized tea catechins also increased the HDL cholesterol level in rats [38]. Dietary APP may increase the HDL cholesterol level through an increase of lecithin cholesterol acyl trans-

ferase, although we do not have exact explanation now. More study is needed to explain this mechanism. Thus, dietary APP may alleviate the modulation of the lipid profile by exogenous COPs, and therefore it may inhibit the induction of atherosclerosis by exogenous COPs.

In previous studies, we found that exogenous COPs inhibit hepatic cholesterol  $7\alpha$ -hydroxylase activity [5, 7–9]; however, dietary APP alleviated this inhibition effect in a dose-dependent manner. In fact, the total fecal acidic steroid level was significantly increased by dietary APP in a dose-dependent manner. We observed that dietary APP tended to increase the CYP7 mRNA in the liver and cholesterol  $7\alpha$ -hydroxylase activity [39]. Thus, the APP metabolite may modulate the perturbation of cholesterol catabolism by exogenous COPs.

Dietary APP also modulated the levels of serum and liver COPs in a diet containing 0.3% COPs. Major COPs in the serum and liver decreased in a dose-dependent manner when APP was consumed. In contrast to these observations, dietary APP increased the levels of the major COPs in the feces. These results refer to the inhibition of exogenous COPs from the intestine by dietary APP. Several studies have shown that tea catechins such as (–)-epigallocatechin gallate, which has gallate esters, decrease cholesterol absorption in the intestine [12]. Our *in vitro* study also demonstrated the possible mechanism by which COPs solubilized in mixed bile salt micelles are eliminated from the micelles by the addition of APP. In general, low and intermediate molecular weight polyphenolic compounds, such as hydrolysable tannins and procyanidins, can solubilize in water, alcohol, and acetone [15]. However, high molecular weight procyanidins remain insoluble in the same solvents. Some reports found that oligomeric procyanidins such as 2 mer, which have comparatively low molecular weight and are soluble in water and alcohol, were detected in the plasma [40]. Shoji et al. [41] observed that dietary procyanidins ranging from 2 mer to 5 mer were absorbed and detected in the plasma when rats were given apple condensed tannin. Our APP consists of 11.1% of 2 mer, 12.3% of 3 mer, 8.7% of 4 mer, 5.9% of 5 mer, 4.9% of 6 mer, 39.8% of greater than 7 mer, and 17.3% of other low molecular weight polyphenolic compounds. Therefore, the high molecular weight procyanidins in the added APP may form insoluble coprecipitates with COPs in a mixed-micellar solution similar to the relationship between (–)-epigallocatechin and cholesterol reported by Ikeda et al. [12]. Moreover, the addition of APP changed the concentration of bile acid in the micelles. This effect may be attributed

to the water-soluble complex of APP, particularly with low molecular weight polyphenolic compounds including procyanidins and bile acid. This complex may disrupt the micelles and then induce the precipitation of COPs in the intestinal lumen. The same observation was revealed in the case of water-soluble dietary fibers [42, 43]. Thus, dietary APP, especially high molecular weight procyanidins such as greater than 4 mer, may inhibit the intestinal absorption of hazardous COPs by disruption of the micelles and promote the excretion of procyanidins in feces. Recently, hypocholesterolemic function by dietary phytosterol such as  $\beta$ -sitosterol also has been investigated [44].  $\beta$ -Sitosterol also inhibited the absorption of dietary COPs; therefore, the combination of APP and  $\beta$ -sitosterol in the diet may be effective in the inhibition of absorption of hazardous materials such as COPs from the intestine.

Thus, dietary APP appears to alleviate the toxic action and perturbation of lipid metabolism by exogenous COPs. Two mechanisms may contribute to these alleviative functions. Firstly, high molecular weight procyanidins interfere with the intestinal absorption of exogenous COPs. Secondly, the metabolites from low molecular weight procyanidins such as procyanidins ranging from 2 mer to 4 mer and other monomeric polyphenols regulate the perturbation of lipid metabolism. In particular, the former may play an important role in our observed alleviatory effects against the hazardous effect of exogenous COPs. Rats were fed diets with high levels of COPs; however, this level may be not necessarily be at the physiological concentration. Dietary COP levels in the human diet have not yet been estimated, although we eat high levels of COPs in processed foods. Therefore, we must estimate the COP levels in the modern diet. In future, more animal feeding studies in which the subjects are fed with comparatively low levels of COPs are required. However, we can infer that procyanidin-rich diets and supplements or beverages containing high levels of APP containing high levels of procyanidins may be useful in inhibiting the absorption of hazardous COPs in diets such as those involving processed or fast foods. Thus, it will be possible to maintain a healthy condition while consuming a modern diet.

**Abstract** To elucidate the transepithelial transport characteristics of lipophilic compounds, the cellular uptake of tocopherol and tocotrienol isomers were investigated in Caco2 cell monolayer models. These vitamin E isomers formed mixed micelles consisting of bile salts, lysophospholipids, free fatty acid, and 2-monoacylglycerols, then the micelles were supplied to Caco2 cells. The initial accumulation of tocotrienol isomers in Caco2 cells was larger than those of corresponding tocopherol isomers. There was little difference among the cellular accumulations of four tocopherol isomers. These findings suggested that the difference between the molecular structures of the C16 hydrocarbon chain tail in tocopherol and tocotrienol was strongly responsible for the rapid epithelial transport into the Caco2 cells membranes rather than the difference in the molecular structures of their chromanol head groups. Furthermore, the secretion of  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol from Caco2 cells was investigated using Caco2 cells plated on a transwell. The time courses of their secretions from Caco2 cells showed that the initial secretion rate of  $\gamma$ -tocotrienol was also larger than that of  $\alpha$ -tocopherol. To investigate the intestinal uptake of  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol in vivo, the mice were fed single doses of  $\alpha$ -tocopherol or  $\gamma$ -tocotrienol with triolein. The  $\gamma$ -tocotrienol responded faster in plasma than  $\alpha$ -tocopherol,

although the maximal level of  $\gamma$ -tocotrienol was lower than that of  $\alpha$ -tocopherol. This suggested that the intestinal uptake properties of administered  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol would characterize their plasma level transitions in mice.

### Introduction

Vitamin E is known as a lipolytic antioxidant and is therefore important for people to take, whether through foods or supplements [1]. Vitamin E deficiency leads to severe degenerative diseases such as ataxia, infertility, and Duchine-like muscle degeneration [2]. Oxidative stress is a source of pathological problems [3, 4]. Vitamin E is a generic descriptor for all tocopherol and tocotrienol derivatives. Each tocopherol consists of a phytyl tail with three chiral centers in an R-configuration and a chromanol ring ( $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -) varying in the number and position of methyl groups on them. On the other hand, tocotrienol possesses an isoprenoid side chain [5]. Among these eight vitamin E derivatives,  $\alpha$ -tocopherol is known as the most abundant and the most powerful active form of vitamin E in vivo. Its high level of biological activity is supposed to be correlated with its strong affinity for  $\alpha$ -tocopherol transfer protein ( $\alpha$ -TTP) [6].

In addition to its lipophilic antioxidant activity, vitamin E was recently found to possess beneficial functions in human health that are independent of its antioxidant/radical scavenging abilities. These are called beyond-antioxidant functions. The roles of

vitamin E derivatives except  $\alpha$ -tocopherol have therefore received renewed attention [7, 8]. In particular, tocotrienol has exhibited widely varying degrees of biological effectiveness [9–11]. For example,  $\alpha$ -tocotrienol and  $\gamma$ -tocotrienol were more effective than  $\alpha$ -tocopherol in preventing glutamate-induced neuronal cell death by regulating signal transduction processes [12]. It has been pointed out that the superiority of these tocotrienol functions over those of  $\alpha$ -tocopherol against various cultured cell membranes would be responsible for the efficient transfer of tocotrienol into these cells [12–14].

Now more information on the absorption properties of dietary vitamin E derivatives by epithelial cells of the intestine is required to further understand their variations in biological actions. Since vitamin E is a lipophilic compound, it must be dissolved in mixed micelles before intestinal uptake [15]. Although the uptake by intestinal epithelial cells is a rate-limiting step throughout the entire process of dietary lipolytic component metabolism, the detailed absorption processes of vitamin E in mixed micelles have not been fully revealed. Previous reports suggested a simple diffusion mechanism for the cellular uptake of emulsified vitamin E by intestinal cells [16, 17]. Moreover, no transporter proteins for vitamin E absorption have been identified in intestinal cells so far.

In this study, we investigate the intestinal absorption properties of tocopherol and tocotrienol in the model system of Caco2 cells derived from human colonic carcinoma. In the previous studies, the serum concentration changes of the rat fed  $\alpha$ -tocopherol or  $\alpha$ -tocotrienol were traced [18]. In the other case,  $\alpha$ -tocotrienol and  $\gamma$ -tocotrienol were used for their uptake experiments by rats [19]. We here evaluate the plasmatic change of  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol in mice fed each with oil in order to clarify the *in vivo* effect of the difference in molecular structure between them upon their intestinal uptake.

## Materials and Methods

### Materials

Several acylglycerols and free fatty acids were purchased from Funakoshi Co. (Tokyo, Japan). The micelle mixture components—lysophosphatidylcholine (1-palmitoyl-*sn*-glycero-3-phosphocholine) (LysoPC) and taurodeoxycholic acid sodium salt (Tau) were obtained from Sigma Chemical (St. Louis, MO, USA). Tocopherol and tocotrienol isomers were obtained from Merck (Darmstadt, Germany) and American River (Boston,

USA).  $\gamma$ -Tocotrienol was kindly supplied by Eisai Co. Ltd. (Tokyo, Japan). Other chemicals and solvents of analytical grade were purchased from Wako Pure Chemical (Osaka, Japan) and Kanto Chemical (Tokyo, Japan).

### Cell Culture

Caco2 cells (American Type Culture Collection, Rockville, MD, USA) were maintained in 10-cm dishes (Corning Glass Works, Corning, NY, USA) containing Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum, 4 mmol/L L-glutamine, 40,000 U/L penicillin, 40 mg/L streptomycin, and 1% non-essential amino acids. The cells were kept at 37 °C in a humidified atmosphere of 95% air and 5% CO<sub>2</sub>. The growth medium was replenished every 2 or 3 days. Cells were reseeded when the cell monolayers became semiconfluent. For the experiments, cells at passages 25–50 were seeded in 12-well plates at  $1.2 \times 10^5$  cells per well and grown under the same conditions as those described above. For experiments on tocopherol and tocotrienol secretion from Caco2 cells, cells were seeded in 6-transwell filter chambers (polycarbonate membrane, 0.4  $\mu$ m pore size, Costar, Cambridge, MA, USA) at  $1.0 \times 10^6$  cells per well. The experiments were performed at 20–22 days post-seeding.

### Preparation of Mixed Micelles

Tocopherols and tocotrienols were delivered as mixed micelles prepared by modified versions of previously described procedures [20]. Briefly, appropriate volumes of stock solutions of the components of mixed micelle, bile salts, lysophospholipid, lipid metabolites and tocopherols, were transferred to glass tubes, and the organic solvent was removed under a stream of argon. The residue was dissolved in serum-free DMEM to eliminate amphiphilic activity of serum, because lipolytic compound were dissolved into the mixed micelle *in vivo*. The medium was sonicated using a micro-equipped Astrason ultrasonic processor model W-380 (Heat-System Ultrasonics, Inc., Farmingdale, NY, USA) until a predefined particle size distribution was achieved. The final concentration of each component in the medium was as follows: 2 mmol/L Tau, 0.2 mmol/L LysoPC, 0.1 mmol/L 2-monoacylglycerol, and 0.1 mmol/L free fatty acids. The resultant solutions were optically clear. The weight-averaged particle sizes of the mixed micelles were determined from quasi-elastic light-scattering measurements (NICOMP model 380 ZLS; Particle Sizing Systems, Santa Barbara, CA,

USA). The particle diameters of the mixed micelles ranged from 20–100 nm.

#### Incubation of Caco2 Cells with Micellar Lipids and Vitamin E Isomers

The differentiated monolayers of Caco2 cells in a 12-well plate or on a 6-transwell plate were washed twice with 1.0 mL serum-free DMEM. For the epithelial absorption experiments, 2 mL of the medium containing mixed micelles of lipid metabolites and vitamin E isomers was supplied to each well, and the Caco2 cells were incubated for 2 h. For the epithelial secretion experiments, 2 mL of the same medium was poured into each apical side of the transwell, and 2.5 mL serum-free medium was added to the basolateral one, followed by incubation for the defined periods.

#### Extraction of Vitamin E Isomers from Caco2 Cells and Medium

After the Caco2 cells on the wells were incubated for the indicated time, the medium was removed and the cells were washed twice with 1.0 mL PBS containing 4 mmol/L Tau to remove surface-bonded lipolytic compounds, followed by two additional washings with 1.0 mL PBS. The washed cells were harvested in 1 mL PBS and collected by centrifugation at 1,000×g for 5 min at 4 °C. The supernatants were discarded, and the cell pellets were homogenized with a microtube in 1.0 mL PBS. An aliquot of each cell homogenate was taken to determine the protein content according to the method of Lowry et al. [21]. Total lipolytic fractions containing Tocopherol and Tocotrienol from Caco2 cells were extracted by the method of Folch et al. [22]. Briefly, 0.75 mL chloroform/methanol (2:1, v/v) was added to the cell homogenate (0.25 mL) and mixed with the solution in a vortex shaker (NSD-12, Nissinrika Ltd., Tokyo, Japan) for 5 min following centrifugation at 1,000×g for 2 min. The resultant lower layer of chloroform was withdrawn and transferred to another tube. The upper layer was similarly extracted with 0.75 mL chloroform/methanol (2:1, v/v). The chloroform layer was combined with the initial extract. The combined extract was dried under a stream of argon gas.

#### HPLC Analysis of Vitamin E Isomers

Tocopherol and tocotrienol in the extracts from the Caco2 cells and medium were quantified with an HPLC system consisting of an EYELA Model PLC-5D (Tokyo Rika Kikai Co. Ltd., Tokyo, Japan), a JASCO Model FP-821 spectrofluorometer (Tokyo, Japan), an

AS-8020 autosampler (Tosoh, Tokyo, Japan), and a Chromatopack C-RIA integrator (Shimadzu, Kyoto, Japan). Vitamin E isomers were separated on a TSK gel ODS-80Tm column (Tosoh), 4.6 × 150 mm. Ethanol/acetonitrile (50:50, v/v) was used as a mobile phase for the analysis. An isocratic analysis was performed at a flow rate of 0.8 mL/min. Vitamin E isomers were monitored with a fluorescent detector (excitation at 295 nm and emission at 325 nm). They were quantified from their peak areas by use of the standard curves of reference compounds.

#### Animal Breeding and Vitamin E Administration

Animal breeding and experiments were entrusted to Sunplanet Co., Ltd. (Gifu, Japan). Male SicSD mice (6-weeks-old) obtained from Japan SLC Co. Ltd., (Shizuoka, Japan) were housed at 23 ± 2 °C on a 12 h light/dark cycle. The animals had free access to tap water and a commercially available diet (MF, Oriental Yeast Co. Ltd., Tokyo, Japan). The mice were handled according to the guidelines for experimental animals of Sunplanet Co. Ltd., Gifu, Japan.

After 7 days of feeding, the mice were divided into two groups ( $\alpha$ -tocopherol and  $\gamma$ -tocotrienol) according to the method of Statlight #11 (Yukmus Co. Ltd.). Fasting was not conducted before  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol administration. Each group was fed  $\alpha$ -tocopherol (10 mg) or  $\gamma$ -tocotrienol (10 mg) diluted with 50 mg triolein. Mice in the zero-time control ( $n = 6$ ) and in two groups ( $n = 6$ /time point) at 2, 4, 6, 8, and 24 h after feeding were anesthetized with diethyl ether. Blood was collected from the caudal vena cava with a heparinized syringe. Plasma was immediately separated by centrifugation at 1,000×g for 15 min at 4 °C and then was immediately stored at –80 °C until analyzed.

#### Extraction from Plasma

$\alpha$ -Tocopherol and  $\gamma$ -tocotrienol were extracted from the plasma according to the procedures of Satomura et al. [23] with slight modifications. Briefly, the plasma (0.4 mL) was diluted to 0.8 mL with ice-cold deionized water, and 2.4 mL of chloroform/methanol (1:2, vol/vol) containing 0.2 pmol PMC (2,2,5,7,8-pentamethyl-6-hydroxy-chroman) as an internal standard for HPLC analysis was added and mixed vigorously using a vortex mixer. Then 1.2 mL of hexane was mixed with the solution. The resultant upper layer of hexane/chloroform was withdrawn. The extraction procedure was repeated for the lower layer one more time. The combined extract was evaporated until dry under a

stream of argon gas. The determination of  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol in the plasma extracts was conducted by fluorometric HPLC as described above.

### Statistical Analysis

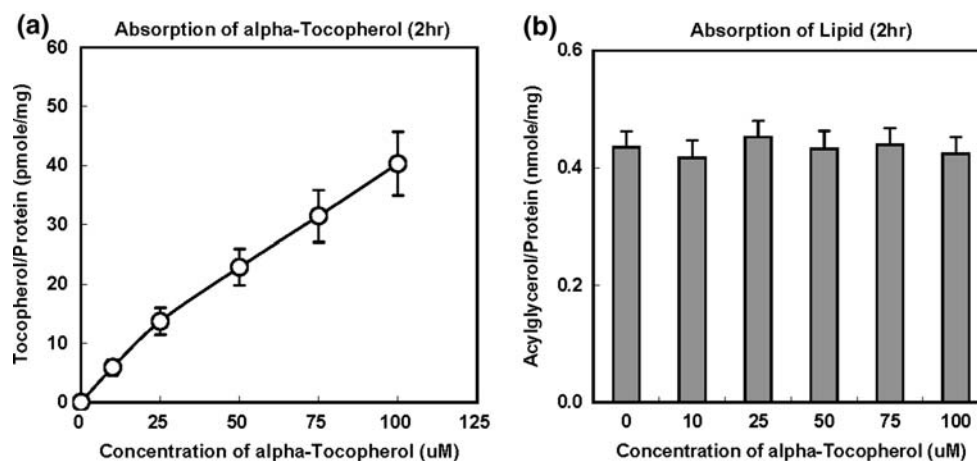

The data represent means  $\pm$ SD. Statistical analysis was made by one-way ANOVA and Dunnett's or Scheffe's F-test to identify significant differences between the groups.

## Results

### Effect of $\alpha$ -Tocopherol Concentration in the Mixed Micelles on its Absorption by Caco2 Cells

In vivo, lipophilic compounds such as a vitamin E are solubilized in mixed micelles before the intestinal uptake [15]. In this experiment, each vitamin E isomer formed mixed micelles with lipid metabolites, bile salts, and lysophospholipid, and the micelles were supplied to Caco2 cells monocultured in the wells to find the appropriate experimental condition of the absorption by Caco2 cells. The concentration of  $\alpha$ -tocopherol in the mixed micelles was varied from 0–100  $\mu$ M. After 2 h incubation with the mixed micelles, the cellular  $\alpha$ -tocopherol concentration was measured. As shown in Fig. 1a, the absorption of  $\alpha$ -tocopherol increased depending on its concentration in the mixed micelles. Based on this result, the concentration of  $\alpha$ -tocopherol in the mixed micelles was set at 50  $\mu$ M. In the examined concentration range of  $\alpha$ -tocopherol, no effect was detected on the absorption of lipid metabolites, as shown in Fig. 1b. This suggested that the transfer mechanism of lipid metabolites (oleic acid and 2-monoolein) to Caco2 cells from the mixed micelles was completely independent from that of  $\alpha$ -tocopherol.

**Fig. 1** The accumulation amount of the cellular  $\alpha$ -tocopherol (**a**) and acylglycerol (**b**) in the Caco2 cells incubated with various concentration of  $\alpha$ -tocopherol in the mixed micelles for 2 h. The mixed micelle was composed of 2-monoacylglycerols (0.1 mmol/L), oleic acid (0.1 mmol/L), bile salt (2.0 mmol/L) and lysophosphatidylcholine (0.2 mmol/L) in addition to  $\alpha$ -tocopherol (0, 20, 40, 60, 80, 100 mmol/L)

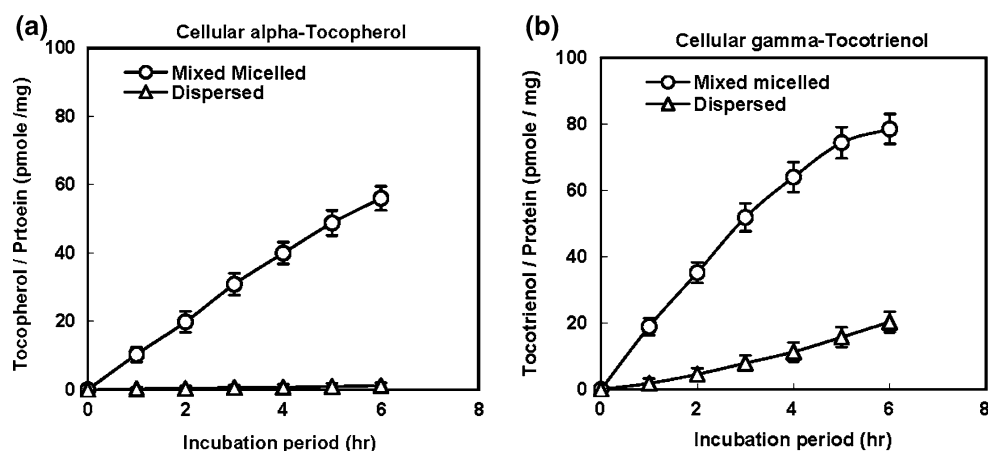

### Time Courses of the Absorption of $\alpha$ -Tocopherol and $\gamma$ -Tocotrienol by Caco2 Cells

To elucidate the comparative intake of  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol by Caco2 cells, the time courses of their cellular concentrations were monitored. In the cases of  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol contained in the mixed micelles, the cellular concentration of  $\gamma$ -tocotrienol increased more rapidly than that of  $\alpha$ -tocopherol (Fig. 2a, b). For example, the cellular concentrations of  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol after 4 h incubation with each of the mixed micelles were 40.0  $\mu$ g/mg and 64.0  $\mu$ g/mg, respectively. The significant difference in the initial cellular accumulation between  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol was more conspicuous in the case of Caco2 cells supplied by the dispersed  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol than by the mixed-micellar ones (Fig. 2a, b). When the dispersed  $\alpha$ -tocopherol was supplied to the Caco2 cells, no increase was found in the cellular  $\alpha$ -tocopherol concentration, which meant that  $\alpha$ -tocopherol dispersed in the medium could scarcely transfer to the Caco2 cells (Fig. 2a). On the other hand, the cellular concentration of  $\gamma$ -tocotrienol increased gradually depending on the incubation period, when Caco2 cells were incubated with the dispersed  $\gamma$ -tocotrienol in the medium (Fig. 2b). This indicated that Caco2 cells could absorb not only the mixed-micellar  $\gamma$ -tocotrienol but also the dispersed one. However, the transfer rate of the dispersed  $\gamma$ -tocotrienol was considerably lower than that of the micellar one.

### Comparison of Absorption of Tocopherols and Tocotrienol Isomers by Caco2 Cells

Four tocopherol and tocotrienol isomers formed mixed micelles and were incubated with Caco2 cells to compare their initial absorption by Caco2 cells. After 2, 4 and 6 h incubation of mixed micelles, the cellular

**Fig. 2** Time course of accumulation of  $\alpha$ -tocopherol (a) and  $\gamma$ -tocotrienol (b) in Caco2 cells. The cells were incubated with mixed-micelled  $\alpha$ -tocopherol ((open circle) in a), with mixed-micelled  $\gamma$ -tocotrienol ((open circle) in b), with the dispersed  $\alpha$ -tocopherol ((open triangle) in a) and with the dispersed  $\gamma$ -tocotrienol ((open triangle) in b)

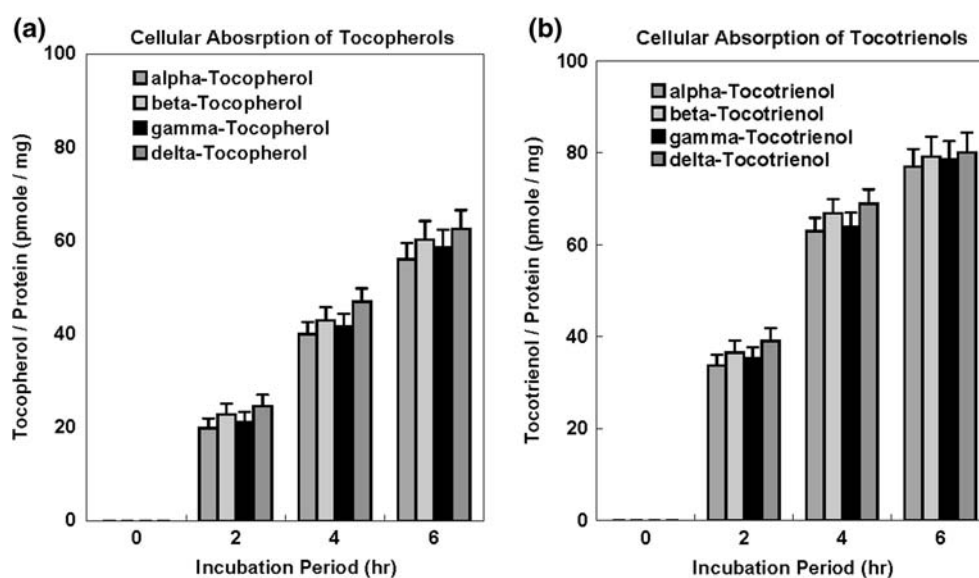

concentrations of these isomers were measured. As shown in Fig. 3a, there was a little difference in the incipient cellular concentrations among the four tocopherol isomers. Such tendency was also found among four tocotrienol isomers (Fig. 3b). Meanwhile, the cellular concentration of each tocotrienol isomer at each incubation period was significantly larger than those of the corresponding tocopherol isomers. This suggested that the molecular structure of C16 hydrocarbon chain tail, but not that of the chromanol ring of vitamin E isomers, was responsible for their initial transfer from mixed micelles to Caco2 cells.

#### Time Course of the Secretion of $\alpha$ -Tocopherol and $\gamma$ -Tocotrienol from Caco2 Cells

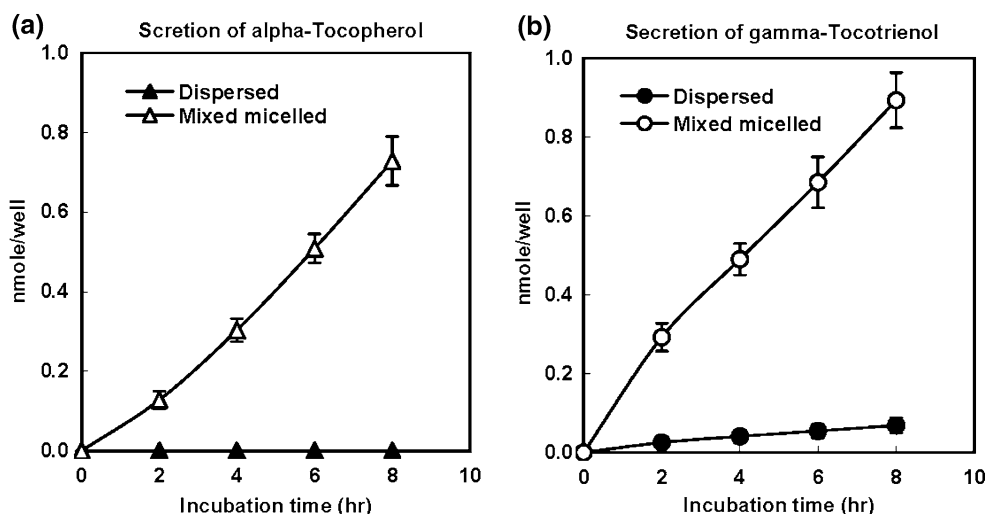

To characterize the secretion of vitamin E isomers from Caco2 cells, the cell monolayer fixed on a polycarbonated transmembrane was used.  $\alpha$ -Tocopherol

and  $\gamma$ -tocotrienol secreted into basolateral medium were measured at definite times after the mixed micelles were added in the apical medium. Both  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol started to be secreted from Caco2 cells after 2 h incubation with the mixed micelles, as shown in Fig. 4. The secretion of  $\gamma$ -tocotrienol was quantitatively larger than that of  $\alpha$ -tocopherol in this initial period of secretion. Especially, the ratio of  $\gamma$ -tocotrienol to  $\alpha$ -tocopherol values secreted from Caco2 cells were 2.29-fold and 1.62-fold at 2 and 4 h after incubation, respectively (Fig. 4). In the absorption experiments using Caco2 cells described above,  $\gamma$ -Tocotrienol in the mixed micelles transferred into Caco2 cells more rapidly than  $\alpha$ -tocopherol. Such absorption of  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol by Caco2 cells would characterize each secretion from Caco2 cells into the basolateral medium. This indicated that the  $\gamma$ -tocotrienol transferred throughout the membrane of Caco2 cells faster than  $\alpha$ -tocopherol did.

**Fig. 3** The accumulation amount of the tocopherol and tocotrienol isomers in the Caco2 cells. The cells were incubated with mixed-micelled each isomer for 0, 2, 4 and 6 h

**Fig. 4** Time course of secretion of  $\alpha$ -tocopherol (a) and  $\gamma$ -tocotrienol (b) from Caco<sub>2</sub> cells to the basolateral medium. The cells were incubated with mixed-micelled  $\alpha$ -tocopherol ((open triangle) in a), with mixed-micelled  $\gamma$ -tocotrienol ((open circle) in b), with the dispersed  $\alpha$ -tocopherol ((filled triangle) in a) and with the dispersed  $\gamma$ -tocotrienol ((filled circle) in b)

When the Caco<sub>2</sub> cells were incubated with the dispersed  $\alpha$ -tocopherol instead of the micellar one, no  $\alpha$ -tocopherol was detected in the basolateral medium in the examined period (Fig. 4a). On the other hand, some  $\gamma$ -tocotrienol secretion from Caco<sub>2</sub> cells was detected, depending on the incubation period with the dispersed  $\gamma$ -tocotrienol (Fig. 4b). A quantitative comparison of the secreted  $\gamma$ -tocotrienol from Caco<sub>2</sub> cells supplied by the dispersed  $\gamma$ -tocotrienol with that supplied by the micellar one suggested that the solubilization of  $\gamma$ -tocotrienol into the mixed micelles was significant for its efficient transfer throughout the Caco<sub>2</sub> cells.

#### The Plasma Response of $\alpha$ -Tocopherol and $\gamma$ -Tocotrienol in Mice

To study the intestinal uptake of  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol in mice administrated by them, their concentrations in plasma were monitored at 0, 1, 2, 4, 6, 8, and 24 h after oral administration (Fig. 5). Only  $\alpha$ -Tocopherol was detected in the plasma of mice in both groups at 0 h ( $20.5 \pm 0.5$  nM, data not shown), because no nutritional restraint was conducted in the mouse food prior to this experiment. During the initial 1–2 h after the administration, the increase of  $\gamma$ -tocotrienol level in plasma was abrupt, whereas the  $\alpha$ -tocopherol level in the plasma gradually increased with some lag time. The  $\alpha$ -tocopherol level in plasma was optimum ( $31.3 \pm 1.6$  nM) at 6–8 h after administration. On the other hand, the  $\gamma$ -tocotrienol level reached a maximum of  $7.96 \pm 0.89$  nM at 2–4 h, which suggested that the increase rate of the  $\gamma$ -tocotrienol level in plasma was larger than that of  $\alpha$ -tocopherol. The  $\gamma$ -tocotrienol level peaked at 6 h after administration and then immediately decreased. Thus, the faster response of the  $\gamma$ -tocotrienol

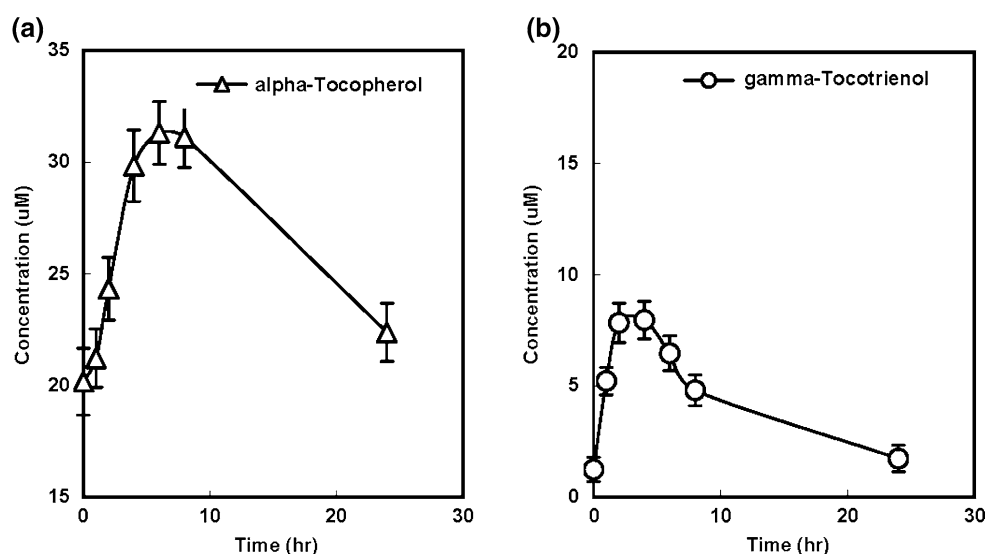

level in rat plasma compared to that of  $\alpha$ -tocopherol would reflect the rapid intestinal uptake of  $\gamma$ -tocotrienol.

#### Discussion

In the digestion processes, lipophilic compounds released from the food matrix are dispersed in lipid emulsion followed by solubilization into the mixed micelles containing bile salts. The mixed micelles move across the unstirred water layer adjacent to the cells of intestinal mucosa [15, 24]. The intestinal cellular uptake of tocopherol and tocotrienol isomers is thought to be mediated by a simple diffusion mechanism [16, 17]. Mixed micelle formation in the intestinal lumen plays an important role in the absorption not only of digested lipid but also of other lipophilic compounds.

In a previous study, the uptake and metabolism of isotope-labeled  $\alpha$ -tocopherol were compared with those of isotope-labeled  $\gamma$ -tocopherol using rats [18]. They concluded that the uptake of both tocopherols in rat was similar although there was a difference between the concentrations of them. Furthermore,  $\alpha$ -tocopherol and  $\alpha$ -tocotrienol concentrations of the plasma in the rats fed them were investigated and they found no difference between the uptake rates [19]. So, in the present study, the intestinal uptake of  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol was compared. The most significant finding in this study was that  $\gamma$ -tocotrienol was more readily transferred to the intestinal cell membrane than  $\alpha$ -tocopherol in the Caco<sub>2</sub> cell model or in the rat administration experiments. This result is in accordance with the previous finding that tocotrienol isomers were more readily incorporated into various kinds of culture cells than tocopherol isomers [12, 14, 25–28]. Those studies concluded that the inter-membrane

**Fig. 5** Time course of concentrations of  $\alpha$ -tocopherol (a) and  $\gamma$ -tocotrienol (b) in the serum of the mice administered with these isomers

mobility of  $\gamma$ -tocotrienol was greater than that of tocopherol isomers [27]. The present study is the first to demonstrate the superior trans-membrane movement of tocotrienol isomers to tocopherol ones in Caco2 cells, human colonic carcinoma cells. In particular, these cells absorbed  $\gamma$ -tocotrienol dispersed in the medium but did not absorb dispersed  $\alpha$ -tocopherol isomers (Fig. 4). Even when tocopherol and tocotrienol isomers formed mixed micelles by bile salt and lysophospholipid, the transfer rate of tocotrienol isomers into Caco2 cells from the mixed micelles was faster than those of Tocopherol isomers (Fig. 4). On the other hand, there was no difference in the transfer rates of tocopherol isomers through the Caco2 cell membrane. This result was in good accordance with previous findings that the tocopherol isomers were taken up in equal amounts by epithelial cells in an unspecified process [29]. Tocopherol has a phytyl chain in its molecule, whereas tocotrienol possesses an isoprenoid chain with three double bonds at positions 3', 7', and 11'. A previous study suggested that the difference in the 16 carbonate chain between tocopherol and tocotrienol contributed to the larger inter-membrane mobility of tocotrienol compared with those of tocopherol isomers [27]. The results of the present study are supported by this previous explanation in the case of Caco2 cells.

Tocopherol and tocotrienol isomers are transported in chylomicrons from the intestine and subsequently in remnants to the liver. There, only  $\alpha$ -tocopherol is preferentially carried stereo-selectively by the cytosolic protein  $\alpha$ -tocopherol transfer protein ( $\alpha$ -TTP) to a very low-density lipoprotein, and then they are released into the circulation [32, 33]. These facts were confirmed by isotope-labeling studies [6, 30–32]. In fact, previous

studies reported that the  $\alpha$ -TTP binding affinity of  $\gamma$ -tocotrienol was about one-eighth of that of  $\alpha$ -tocopherol [6]. Tocotrienols are transported nonspecifically like other lipophilic compounds and the are dominantly found in a high-density lipoprotein fraction [15, 33, 34]. In the animal experiment in the present study, mice were administered an excessively large amount of non-isotope-labeled  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol (10 mg per mouse), so that the time-dependent changes in their serum concentration could be successfully traced. The absolute serum concentration of  $\gamma$ -tocotrienol (from 1.24 to 7.96  $\mu\text{g}/\text{mL}$ ) in recipient mice was smaller than that of  $\alpha$ -tocopherol (from 20.1 to 31.3  $\mu\text{g}/\text{mL}$ ) as shown in Fig. 5. This comes from the difference in binding affinity  $\alpha$ -TTP between  $\alpha$ -tocopherol and  $\gamma$ -tocotrienol and in their circulation pathway in vivo between VLDL and HLD transports. However,  $\gamma$ -tocotrienol appeared in the mouse serum more rapidly than  $\alpha$ -tocopherol and increased at a faster rate. From the results of the present study, it was concluded that the epithelial transfer rates of  $\gamma$ -tocotrienol and  $\alpha$ -tocopherol in the absorption step in the intestine would reflect their serum circulation characteristics. On the other hand,  $\gamma$ -tocotrienol was cleared more rapidly from the plasma of mice than was the case with  $\alpha$ -tocopherol. That fact is probably due to the low affinity of tocotrienol to  $\alpha$ -TTP.

Because  $\alpha$ -TTP binds preferentially to  $\alpha$ -tocopherol compared to other tocopherol and tocotrienol isomers, the biological effectiveness of  $\alpha$ -tocopherol has been dominant [30, 32]. However, various bioactivities, beyond antioxidant functions, of tocopherol and tocotrienol isomers, have recently been reported [35, 36]. Several biological activities of tocotrienol isomers were reported to be more effective than those of tocopherol

isomers [12, 26–28]. Further information about the digestive behaviors of tocopherol and tocotrienol isomers will be needed in the near future so that their advanced use can be considered.

**Abstract** In addition to being a very good antioxidant,  $\gamma$ -tocopherol is also an excellent electrophile trap. This is a study of the reactivity of  $\gamma$ -tocopherol with hypochlorous acid/hypochlorite, a potential biological foe that is both an oxidant and an electrophile. Aqueous sodium hypochlorite (1.72 mmol; pH 7.4) was stirred with  $\gamma$ -tocopherol (0.12 mmol) in hexane for 2 min at room temperature. The following products were isolated:  $\gamma$ -tocopheryl quinone (0.6%), tocopherol (10%), 3-chloro- $\gamma$ -tocopheryl quinone (14%), an ether dimer of 3-chloro- $\gamma$ -tocopheryl quinone (0.4%), two isomers of 5-(5- $\gamma$ -tocopheryl)- $\gamma$ -tocopherol (3 and 2% respectively), 5-chloro- $\gamma$ -tocopherol (14%) and two chlorinated dimers (14 and 24% respectively) which were identified as diastereomers of (3*R*,10*R*)-11a-chloro-2,3,9,10-tetrahydro-3,5,6,10,12,13-hexamethyl-3,10-bis[(4*R*,8*R*)-4,8,12-trimethyltridecyl]-1*H*-pyrano(3,2*a*)-8*H*-pyrano(3,2*g*)-dibenzofuran-14(7*aH*)(14*aH*)-one. The chlorinated dimers, 5-chloro- $\gamma$ -tocopherol, 3-chloro- $\gamma$ -tocopheryl quinone and its ether dimer are new compounds.

**Keywords**  $\gamma$ -Tocopherol · Hypochlorous acid · Oxidation · Antioxidants · Electrophiles · Chlorinated dimers

## Introduction

Although  $\alpha$ -tocopherol is the most widely available form of vitamin E, and the form found in pharmaceutical preparations, probably the most common form in Western diets is  $\gamma$ -tocopherol (**1**, Fig. 1), because of the widespread use of soybean in many food products. Compound **1** is an excellent antioxidant, although slightly inferior to  $\alpha$ -tocopherol. However, **1** has another string to its bow in that it is an excellent scavenger of electrophiles due to the lack of substitution at the 5-position. Thus **1** has been shown to react rapidly with nitrite and nitric oxide to produce 5-nitro- $\gamma$ -tocopherol in high yield [1].

Another electrophile (and oxidant) that **1** may encounter is hypochlorous acid (HOCl), the major and most powerful oxidant produced by the myeloperoxidase of neutrophils [2]. HOCl has been shown to react rapidly with 2,2,7,8-tetramethyl-6-chromanol, the model compound of  $\gamma$ -tocopherol, to form a dichloropyrano-benzenedione [3].

This study was undertaken to determine whether **1** reacted in the same way as its model compound with HOCl.

## Experimental Procedures

### Instrumental

Ultraviolet spectra were determined on a Varian (Palo Alto, CA, USA) Cary IE spectrophotometer.  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were recorded on a Bruker (Karlsruhe, Germany) AM-500 or a DMX-600 FT-NMR spectrometer and were taken in  $\text{CDCl}_3$  and are

**Fig. 1**  $\gamma$ -Tocopherol

reported in parts per million downfield from tetramethylsilane used as internal standard. Heteronuclear single quantum correlation (HSQC) and heteronuclear multiple bond correlation (HMBC) techniques were used to assign correlations between  $^1\text{H}$  and  $^{13}\text{C}$  signals. Relative configuration was determined using nuclear Overhauser enhancement spectroscopy (NOESY).

Electron-impact mass spectra were determined on a Finnigan Polaris Q Ion-Trap mass spectrometer (Thermo Electron Corporation, Waltham, MA, USA), and ionisation was achieved with a 70 eV electron beam.

## Materials

*RRR*- $\gamma$ -Tocopherol and *RRR*- $\alpha$ -tocopheryl quinone (both from Acros Organics, Morris Plains, NJ, USA), sodium hypochlorite (NaOCl; 12.5% solution) and *n*-hexane (Spectrosol) (both from Asia Pacific Speciality Chemicals, NSW, Australia), and silica gel 60 GF254 (Merck, Darmstadt, Germany) were commercially available.

## Oxidation Reaction

In a typical reaction, **1** (50 mg, 0.12 mmol) was dissolved in hexane (3 mL) and stirred with NaOCl (128 mg, 1.72 mmol) in water (3 mL, adjusted to pH 7.4 with HCl) for 2 min at room temperature. The hexane layer was washed with water until neutral, dried ( $\text{Na}_2\text{SO}_4$ ), and the solvent removed in vacuo. The residue was chromatographed on thin layers of silica gel using light petroleum/ethyl acetate (19:1, v/v) as eluting solvent. Ten bands were observed with  $R_f$  values from 0.01 to 0.85. As all products were oily and complete removal of solvent from them could not be guaranteed, their yields were calculated using known molar extinction coefficients in ethanol, which were as follows (in units of  $\text{LM}^{-1}\text{cm}^{-1}$ ): for  $\gamma$ -tocopheryl quinone (**3**) at 262 nm, 19,000 (assumed similar to  $\alpha$ -tocopheryl quinone) [4], for tocored (**8**) at 281 nm (270 nm in hexane [5]) (6,500) [6], for 2,2,7,8-tetramethylchroman-5,6-dione, the model compound of **8**, at 467 nm (438 nm in hexane [5]), 1,200 [7], for 5-( $\gamma$ -tocopheryl)- $\gamma$ -tocopherol (**10**) ( $R_f$  0.48) at 300 nm 10,300

[6], and for its isomer (**5**) ( $R_f$  0.69) at 300 nm 10,500 [6]. The extinction coefficient of **1** at 298 nm, 3,802 [8], was also used to estimate 5-chloro- $\gamma$ -tocopherol (**4**) and the two chlorodimers, (**13** and **14**; bands 9 and 10). Both **8** and 3-chloro- $\gamma$ -tocopheryl quinone (**7**) have the same  $R_f$  values and are very difficult to separate, and both compounds absorb strongly at 270 nm. However, **8** can be estimated from its second, lower intensity, peak at 436 nm by using the molar extinction coefficient of 2,2,7,8-tetramethylchroman-5,6-dione at 467 nm (438 nm in hexane [5]), 1,200 [7]. From this amount and the known extinction coefficient of **8** at 281 nm (270 nm in hexane) (6,500) [6], the contribution of **8** to the total absorption at 270 nm can be calculated. The residual absorption is due to **7** and can be estimated using the extinction coefficient of **3**.

Compound **11** is believed to be an ether dimer of **7** and therefore an extinction coefficient of 38,000 for a molecular weight of 914 was used for it.

The yields thus calculated for all compounds are clearly approximate as most of the measurements were made in hexane solution rather than ethanol.

Band 1 ( $R_f$  0.01), which was not identified, had UV  $\lambda_{\text{max}}$  (in hexane) of 257 nm.

Band 2 ( $R_f$  0.03; pale yellow; 0.3 mg; 0.6%) was not completely pure but was identified as **3** ( $\gamma$ -tocopheryl quinone) on the basis of its spectral data: UV  $\lambda_{\text{max}}$  (in hexane) 257, 263 nm.  $^1\text{H}$  NMR  $\delta$  ( $\text{CDCl}_3$ ) 0.83–0.88, m, 12H,  $4 \times -\text{CH}_3$ ; 1.25, s, 3H,  $-\text{CH}_3$ ; 1.00–1.67, m, 23H,  $10 \times -\text{CH}_2 + 3 \times -\text{CH}$ ; 2.02, s, 3H,  $-\text{C}=\text{C}-\text{CH}_3$ ; 2.03, s, 3H,  $-\text{C}=\text{C}-\text{CH}_3$ ; 2.50, m, 2H, 2-(1'- $\text{CH}_2$ -); 6.54, s, 1H,  $-\text{C}=\text{C}-\text{H}$ .

Band 3 ( $R_f$  0.07; red) was identified as a mixture of **7** and **8**.

Compound **7** (3-chloro- $\gamma$ -tocopheryl quinone) (7.6 mg; 14%) had UV  $\lambda_{\text{max}}$  (in methanol) of 264 (sh) and 272 nm.  $^1\text{H}$  NMR  $\delta$  ( $\text{CDCl}_3$ ) 0.83–0.88, m, 12H,  $4 \times -\text{CH}_3$ ; 1.25, s, 3H,  $-\text{CH}_3$ ; 1.00–1.67, m, 23H,  $10 \times -\text{CH}_2 + 3 \times -\text{CH}$ ; 2.06, s, 3H,  $-\text{C}=\text{C}-\text{CH}_3$ ; 2.09, s, 3H,  $-\text{C}=\text{C}-\text{CH}_3$ ; 2.72, m, 2H, 2-(1'- $\text{CH}_2$ -). MS (ei)  $m/z$  (relative intensity) 452 (36), 451 (33), 450 (89), 244 (5), 243 (15), 242 (17), 241 (30), 227 (19), 225 (49), 200 (17), 199 (28), 198 (41), 187 (37), 186 (31), 185 (100), 184 (45).

Compound **8** (tocored) (5 mg; 10%) had UV  $\lambda_{\text{max}}$  (in hexane) of 268 and 436 nm.  $^1\text{H}$  NMR  $\delta$  ( $\text{CDCl}_3$ ) 0.83–0.88, m, 12H,  $4 \times -\text{CH}_3$ ; 1.00–1.67, m, 21H,  $9 \times -\text{CH}_2 + 3 \times -\text{CH}$ ; 1.32, s, 3H,  $-\text{CH}_3$ ; 1.74, m, 2H, 3- $\text{CH}_2$ ; 1.95, s, 3H,  $-\text{C}=\text{C}-\text{CH}_3$ ; 2.03, s, 3H,  $-\text{C}=\text{C}-\text{CH}_3$ ; 2.42, m, 2H, 4- $\text{CH}_2$ .

Band 4 ( $R_f$  0.24; colorless), was identified as **1**. It had UV  $\lambda_{\text{max}}$  (in hexane) of 294, 300 nm.  $^1\text{H}$  NMR  $\delta$  ( $\text{CDCl}_3$ ) 0.83–0.89, m, 12H,  $4 \times -\text{CH}_3$ ; 1.00–1.40, m,

19H, 8 × -CH<sub>2</sub> + 3 × -CH; 1.25, s, 3H, -CH<sub>3</sub>; 1.52, m, 2H, 1'-CH<sub>2</sub>; 1.71, m, 1H, (3-CH); 1.78, m, 1H, (3-CH); 2.12, s, 3H, Ar-CH<sub>3</sub>; 2.14, s, 3H, Ar-CH<sub>3</sub>; 2.68, m, 2H, 4-CH<sub>2</sub>; 4.23, s, 1H, -OH, 6.38, s, 1H, =C-H.

Band 5 (*R<sub>f</sub>* 0.42; 0.2 mg; 0.4%; colorless), was identified tentatively as **11**. It had UV λ<sub>max</sub> (in hexane) of 265 (sh) and 273 nm. <sup>1</sup>H NMR δ (CDCl<sub>3</sub>) 0.83–0.88, m, -CH<sub>3</sub>; 1.11, s, -CH<sub>3</sub>; 1.00–1.67, m, -CH<sub>2</sub> + -CH; 2.06, s, -C=C-CH<sub>3</sub>; 2.09, s, -C=C-CH<sub>3</sub>; 2.72, m, -(1'-CH<sub>2</sub>). MS (ei) *m/z* (relative intensity) 452 (14), 450 (33), 283 (17), 281 (54), 265 (19), 241 (7), 229 (26), 227 (50), 225 (74), 213 (16), 211 (67), 209 (100), 187 (12), 186 (10), 185 (35), 184 (15).

Band 6 (*R<sub>f</sub>* 0.48; colorless; 1.6 mg; 3%), was identified as **10** (5-(5-γ-tocopheryl)-γ-tocopherol) with “R” configuration. $\alpha$ -Tocopheryl quinone has the following mass spectrum (ei;  $m/z$  (relative intensity) 446 ( $\text{M}^+$ )(12), 431 (8), 430 (13), 429 (16), 428 (17), 221 (64), 205 (19), 204 (18), 203 (100), 180 (51), 179 (69), 178 (58), 165 (75), 164 (25).

## Results and Discussion

The method of ionisation used in the mass spectrometer proved a problem. Electrospray ionisation (ESI-MS) and atmospheric pressure chemical ionisation (APCI-MS) were attempted before settling on electron impact (EI-MS). Both ESI-MS and APCI-MS tended

to produce dimerisation in the source and unreliable results as a consequence.

The product with the lowest  $R_f$  (0.03) was **3**. It constituted only 0.6% of the total products and was the only product identified that was not substituted at the original position 5 of the aromatic ring of **1**. This gives some indication of the reactivity of position 5 of **1**.

Compound **7** (14% of the products), which had the same  $R_f$  as **8** and was very difficult to separate from **8**, does not seem to have been reported previously. Although **7** was clearly a quinone from its UV and  $^1\text{H}$  NMR spectra, and had a side-chain hydroxyl group, judging by its very low  $R_f$ , it did not give a molecular ion (mw 466) in the EI mass spectrum. However, the molecular weight of **7** is confirmed by a major chlorine-containing fragment of mw 241 which corresponds to the loss of the 4,8,12-trimethyltridecyl side chain from **7** (Scheme 1). This fragment is directly analogous to the 221 fragment of  $\alpha$ -tocopheryl quinone, whose EI mass spectrum is recorded above at the end of “[Experimental procedures](#)” for reference. Loss of ketene from the 241 fragment of **7** gives the cluster of ions at 198, 199, 200 (Scheme 1), which has its analogy in  $\alpha$ -tocopheryl quinone where the loss of ketene from the 221 fragment gives the cluster at 178, 179, 180. It appears that a major fragmentation pathway of **7** involves

**Scheme 1** Electron impact fragmentation pathways for **7** (3-chloro- $\gamma$ -tocopheryl quinone)

recyclisation in the source of the mass spectrometer to form **4** (mw 450) which then fragments to give major daughter peaks at 225 (loss of a 4,8,12-trimethyltridecyl group) and 184, 185 (loss of 2,6,10,14-tetramethyl-1-pentadecene) (Scheme 1). It seems that recyclisation of  $\alpha$ -tocopheryl quinone (mw 446) to form  $\alpha$ -tocopherol (mw 430) also occurs in the source of the mass spectrometer, but that this is a less prominent pathway than in **7**. Fragmentation of  $\alpha$ -tocopherol produces the fragment 205 corresponding to the 225 fragment of **7**. Loss of 2,6,10,14-tetramethyl-1-pentadecene from  $\alpha$ -tocopherol produces the cluster of ions at 164, 165, which corresponds to the 184, 185 ions from **7** (Scheme 1).

Compound **7** was obviously formed by the oxidation of **4** (14% of the products), which also does not seem to have been reported previously. The  $^1\text{H}$  NMR spectrum of **4** is very similar to that of 5-bromo-2,2,7,8-tetramethyl-6-chromanol [9]. It is interesting to note the deshielding effect of chlorine on the phenolic hydroxyl group of **4** (5.19 ppm) compared with that of **1** (4.23 ppm). The phenolic hydroxyl (5.04 ppm) of 5-bromo-2,2,7,8-tetramethyl-6-chromanol is also deshielded significantly compared to that of 2,2,7,8-tetramethyl-6-chromanol (4.24 ppm) [10].

Compound **8** is the best-known oxidation product of **1** but, in this reaction **8** only accounted for 10% of the products.

**Scheme 2** Electron impact fragmentation pathways for **11** (the ether dimer of (3-chloro- $\gamma$ -tocopheryl quinone)

The isomers **5** and **10** have been reported [6, 11, 12] and are clearly the precursors of **13** and **14** in this reaction. It seems likely that **5**, with the “S” configuration [12], is the immediate precursor. It is remarkable that these isomers are so easy to separate by TLC on silica gel. The lower  $R_f$  (0.48) isomer **10**, when kept in an NMR tube in the refrigerator, changed slowly into the higher  $R_f$  (0.69) isomer **5**, while **5** was unchanged.

Compound **11** (band 5), a minor product, is believed to be an ether dimer of compound **7**. However the structure of **11** is speculative since the fragments in the EI mass spectrum are much smaller than the putative molecular weight of 914 (Scheme 2). However, the UV and  $^1\text{H}$  NMR spectra of **11** are virtually identical to those of **7**, suggesting that they are closely related quinones. However the  $R_f$  of **7** is 0.07, whereas that of **11** is 0.42, suggesting that **11** does not have an hydroxyl group. The mass spectra of **7** and **11** have several fragments in common and some of which are different. Both **7** and **11** have fragments at 450, 225 and 184, 185. In addition **7** has a cluster of ions at 198, 199, 200 not shared by **11**, while **11** has major fragments at 281 and 209 not shared by **7**. Schemes 1 and 2 attempt to explain how the differences in fragmentation arise.

Additional evidence for the ether dimer structure of **11** comes from its  $^1\text{H}$  NMR spectrum. The only difference between the  $^1\text{H}$  NMR spectra of **7** and **11** is the chemical shift of their 3' methyl protons, 1.25 and 1.11 ppm respectively. Molecular models show that, as the two halves of **11** rotate around the central ether bond, the 3' methyl groups are either very close to each other or to the first methylene group in the phytyl side chain on the other half of the molecule. The very close proximity of the methyl groups to each other or to a neighbouring methylene would result in strong shielding and therefore a shift to higher field.

Compounds **13** and **14**, which make up 38% of the products, have not been reported previously and their spectra are very similar in all respects. Table 1 shows that the chemical shifts of both protons and carbons near the dibenzofuranone centre of the pentacyclic nucleus are almost identical. The differences appear on the periphery, i.e. positions 1 (protons and carbons), 2 (carbons), 8 (protons), 9 (protons and carbons), 15 (protons and carbons) and 18 (protons and carbons).

Although **13** and **14** each have nine chiral carbon atoms, and thus  $2^9$  possible isomers, the side chains, together with their points of attachment to the pentacyclic nucleus, account for six chiral carbons and do not alter from isomer to isomer, and therefore the number of isomers simplifies down to eight, determined by positions 7a, 11a and 14a. The eight possible isomers are listed in Table 2.

**Table 2** Possible stereoisomers of **13** and **14**

Isomer number	Carbon positions		
	7a	11a	14a
1	S	R	R
2	R	S	S
3	R	R	S
4	S	S	R
5	R	R	R
6	S	S	S
7	R	S	R
8	S	R	S

Configurations at positions 3 and 10 of the nucleus and 4' and 8' in each  $\text{C}_{16}\text{H}_{33}$  side chain are all “R”

NOE spectroscopy (NOESY) allows one to eliminate four of these isomers. The proton on carbon 14a lies in a central position in the molecule, midway between the two peripheral pyran rings. The C14a proton has NOE correlations with both C1 protons and both C8 protons in **13** and **14**. This means that the only possible isomers are 1–4. Isomers 5–8 are excluded because the C1 and C8 protons in these isomers are further from the C14a protons than they are in isomers 1–4, and, in addition, the C14a protons in isomers 5–8 lie on the opposite surface of the ring system from the protons on C8.

One may eliminate two more isomers by using the chemical shift of the C18 methyl protons. Isomers 1 and 2 are diastereomers but, if one considers only positions 7a, 11a and 14a, may be thought of as pseudo-enantiomers. One may eliminate isomer 1 because its C18 methyl group would be expected to have a similar chemical shift to that of the C15 methyl, whereas, in isomer 2, the C18 methyl would be deshielded by the ethylenic double bond of the enone system. A similar argument applies to isomers 3 and 4. Isomer 4 may be eliminated because its C18 methyl group would be expected to have a similar chemical shift to that of the C15 methyl, whereas in isomer 3 the C18 methyl would be deshielded by the chlorine on C11a. The ability of chlorine to deshield may be seen in the chemical shift

of the phenolic hydrogen of compound **4** (5.19 ppm) compared to that of compound **1** (4.23 ppm).

Molecular models suggest that **13** (Band 9;  $R_f$  0.80) is isomer 2. The reason for this is the chemical shifts of the C1a protons, which are close to the C14 carbonyl. In **13**, the C1a proton is at 3.06 ppm, whereas in **14** it is at 3.00 ppm. Molecular models of isomer 2 show that the C1a proton is significantly closer to the carbonyl, and hence more deshielded, than in isomer 3.

Scheme 3 shows how the products may be formed. The actual oxidising species is unknown but, since HOCl,  $\text{Cl}_2\text{O}$  and  $\text{Cl}_2$  are in equilibrium, it may be a mixture of all three [13]. At pH 7, HOCl is about 50% ionised ( $\text{p}K_a$  7.5), so each of the above chlorine species

would be present to some extent in the hexane layer. Whichever chlorine species is involved, it is almost certainly a two-electron oxidant and may be thought of as being equivalent to  $\text{Cl}^+$ , which it will be termed for the purposes of this discussion. It is acknowledged that  $\text{Cl}^+$  itself is not the actual species [13]. In the formation of **4**,  $\text{Cl}^+$  behaves as an electrophile. In the case of **7**,  $\text{Cl}^+$  is both an electrophile and an oxidant. In all other cases  $\text{Cl}^+$  behaves as an oxidant.

The key intermediate from which all other products derive is the oxonium ion **2** (see Scheme 3). Addition of water to **2** at position 8a produces **3**, while the addition of water at position 5 gives rise to the catechol **6**, which is then oxidised further to **8**. Compound **2** can

**Scheme 3** Products of the reaction of **1** ( $\gamma$ -tocopherol) with hypochlorous acid

also behave as an electrophile in an attack by another molecule of **1**, producing the two isomers **5** and **10**. Oxidation of **5** produces the chromanol-oxonium species **9** which then cyclises to form **12**. Compound **12** can react with hydrogen chloride to form the diastereomers **13** and **14**. Alternatively, **9** may react with HCl before cyclisation occurs.

The formation of **3**, **7** and **8** all require water. The fact that these three compounds made up less than 25% of the total products suggests that most of the reactions occurred within the hexane layer rather than at the hexane–water interface. Another reason for thinking this is that oxonium species such as **2** react very readily with water to the extent that the quinone of  $\alpha$ -tocopherol is its major oxidation product when water is present [14]. If the formation of **13** and **14** occurs within the hexane layer, it is likely that the source of chlorine in them is hydrogen chloride rather than chloride ion.

It was noted previously that 2,2,7,8-tetramethyl-6-chromanol, the model compound of **1**, reacted rapidly with HOCl to form a dichloro-pyrano-benzenedione [3]. There was no trace of the equivalent derivative of **1** in the present reactions. The reason for this may be related to the polarity of **1** and its model compound. Since the model compound lacks the phytyl side chain of tocopherol, it is considerably smaller and more polar than **1**. Thus a higher concentration of it at the water interface would be expected, leading to greater formation of 3-chloro-2-(3-hydroxy-3-methylbutyl)-5,6-dimethyl-1,4-benzoquinone (CIBQ), the model compound of **7** and the immediate precursor of the dichloro-pyrano-benzenedione. In addition, the side chain of CIBQ is much shorter, and presumably more flexible, than that of **7**, making it much easier to cyclise.

**Acknowledgments** Thanks are due to Dr. K. Fisher for running the mass spectra, to Mrs. H. Stender for the NMR spectra, and to Dr. J. Brophy for helpful discussions.

# Engineering Oilseed Plants for a Sustainable, Land-Based Source of Long Chain Polyunsaturated Fatty Acids

Howard G. Damude · Anthony J. Kinney

Received: 22 December 2006 / Accepted: 7 February 2007 / Published online: 14 March 2007  
© AOCS 2007

**Abstract** Numerous clinical studies have demonstrated the cardiovascular and mental health benefits of including very long chain omega-3 polyunsaturated fatty acids, namely eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) in the human diet. Certain fish oils can be a rich source of omega-3 long chain polyunsaturated fatty acids although processed marine oils are generally undesirable as food ingredients because of the associated objectionable flavors and contaminants that are difficult and cost-prohibitive to remove. Oilseed plants rich in omega-3 fatty acids, such as flax and walnut oils, contain only the 18-carbon omega-3 polyunsaturated fatty acid alpha-linolenic acid, which is poorly converted by the human body to EPA and DHA. It is now possible to engineer common omega-6 rich oilseeds such as soybean and canola to produce EPA and DHA and this has been the focus of a number of academic and industrial research groups. Recent advances and future prospects in the production of EPA and DHA in oilseed crops are discussed here.

## Abbreviations

LCPUFA	Long chain polyunsaturated fatty acids
DHA	Docosahexaenoic acid
EPA	Eicosapentaenoic acid
ARA	Arachidonic acid
COX-2	Cyclooxygenase-2
LNA	Linoleic acid

ALA	Alpha-linolenic acid
GLA	Gamma-linolenic acid
STA	Stearidonic acid
DGLA	Dihomo-gamma-linolenic acid
ETA	Eicosatetraenoic acid
EDA	Eicosadienoic acid
ERA	Eicosatrienoic acid
DPA	Docosapentaenoic acid
CoA	Coenzyme A
PtdCho	Phosphatidylcholine
LPAAT	Lysophosphatidic acid acyltransferase
SCA	Sciadonic acid
JUN	Juniperonic acid
PKS	Polyketide synthase

## Manipulating the Fatty Acid Content of the Human Diet

The main sources of oils and fats in the human diet are oilseed crop plants, mostly soy, canola (oilseed rape), palm, peanut and sunflower. Many of the oils from these crops are rich in 18-carbon omega-6 fatty acids. It has been demonstrated that excess consumption of omega-6 fatty acids leads to the depletion of omega-3 fatty acids in human body tissues, with numerous negative health consequences [1]. Hydrogenated or partially hydrogenated vegetable oils also contribute to the sensory characteristics of numerous processed food products. Edible vegetable oils are hydrogenated to improve shelf-life, maintain the flavor and provide the expected mouth-feel and consistency of oil-containing foods [2]. Hydrogenation leads to the formation of *trans* unsaturated fatty acids, which provide the

e-mail: Anthony.Kinney@USA.dupont.com

necessary solid-fat functionality for certain food applications. However, the negative health consequences of *trans* unsaturated fatty acid consumption on human health has become better understood in recent years [3].

The first successful attempts of genetically manipulating the fatty acid profile of omega-6 oilseed crops were focused on the redirection of fatty acid biosynthesis in the developing seed, either by blocking specific steps, such as fatty acid desaturation [4], or introducing single enzyme activities to redirect fatty acid synthesis to new end products that provided the required functionality [5]. By these means it was possible to improve the oxidative stability and provide a solid fat functionality in vegetable oils without the need for hydrogenation and the consequent formation of *trans* fatty acids [6, 7].

With advances in gene expression technology it is now possible to consider more complex manipulations of plant cell lipid metabolism, such as the introduction of entire metabolic pathways. Thus it is theoretically possible, for example, to transfer a metabolic pathway for EPA or DHA synthesis from a marine organism to an oilseed crop plant. This would provide an abundant, clean, sustainable and relatively inexpensive source of omega-3 long chain polyunsaturated fatty acids for the human diet. Here we discuss metabolic engineering efforts to achieve this goal.

### Long Chain Polyunsaturated Fatty Acids Human Health

Long chain polyunsaturated fatty acids (LCPUFA) are important components of cell membrane phospholipids in humans. Docosahexaenoic acid (DHA, 22:6 [4, 7, 10, 13, 16, 19]), for example, is an important component of mammalian retinal and brain membranes and has been shown to play a role in the cognitive development of infants as well as the mental health of adults [8, 9, 10]. Numerous studies [11–14] have shown cardiovascular health benefits arising from the consumption of eicosapentaenoic acid (EPA, 20:5 [5, 8, 11, 14, 17]). LCPUFA are also precursors to the eicosanoid family of metabolites which include prostaglandins, leukotrienes, thromboxanes [15, 16]. These molecules regulate certain key metabolic functions in the human body, such as inflammatory responses and the induction of blood clotting as well as the regulation of blood pressure [17]. Eicosanoids derived from omega-6 LCPUFA, such as arachidonic acid (ARA, 20:4 [5, 8, 11, 14]), are generally pro-inflammatory while those derived from omega-3 LCPUFA, such as eicosapentaenoic acid, are anti-inflammatory [12, 16, 18].

The first step in eicosanoid biosynthesis from LCPUFA is catalyzed by the cyclooxygenase-2 (COX-2) enzyme [16], which can utilize either ARA or EPA as a substrate.

Thus, in addition to the anti-inflammatory action of omega-3-derived eicosanoids themselves, the anti-inflammatory action of EPA can be attributed to its competitive inhibition of ARA for COX-2 [18]. Thus an optimal balance of omega-3 and omega-6 LCPUFA must be achieved to maintain a healthy state.

Direct inhibition of COX-2 activity is the mechanistic basis of a whole class of non-steroidal, anti-inflammatory pharmaceuticals used in the treatment of arthritis and similar conditions. However, while EPA and DHA are beneficial to cardiovascular health, preventing their conversion to eicosanoids by anti-arthritis pharmaceuticals can result in various negative cardiovascular side effects. Indeed negative cardiovascular side effects have been attributed to the use of some COX-2 selective inhibitors in some individuals [19]. It is apparent, therefore, that achieving a balanced dietary intake of omega-6 and omega-3 fatty acids is the most preferred means of preventing negative inflammation responses and of maintaining cardiovascular health for large segments of the population.

Eicosapentaenoic acid and ARA can be synthesized in the human body from the essential dietary fatty acids linoleic acid (LNA, 18:2 [9, 12]) or alpha-linolenic acid (ALA, 18:3 [9, 12, 15]), respectively [20]. The conversion of LNA and ALA to ARA and EPA is relatively inefficient and EPA, DHA and ARA can also be obtained more efficiently directly from the diet, mainly from the consumption of fish and fish-oil [16, 20]. In Western societies, the dietary ratio of omega-6 to omega-3 fatty acids has shifted heavily toward omega-6 fatty acids over the past 60 years [21]. This shift is the result of an overall decrease in the consumption of fish and fish oils, which contain high levels of omega-3 LCPUFA, as well as a large increase in the consumption of omega-6-containing foods, such as common vegetable oils or grain-fed meat and poultry [21]. By some estimate the current omega-6 to omega-3 intake in the human diet is as much as 30-fold too high [21, 23]. This has led to a general imbalance of ARA and EPA in the blood stream with numerous possible negative consequences [21]. Thus consumption of foods rich in omega-3 LCPUFA may help to correct this imbalance by shifting the omega-6 to omega-3 fatty acid ratio to more optimal levels in the human body.

An increasing demand for fish and fish oils high in omega-3 LCPUFA is putting an even greater stress on an already overexploited resource [24]. In addition, the cost associated with removing objectionable odors and flavors, as well as contaminants such as mercury and PCBs, generally limits the use of fish oils as food ingredients [25, 26]. Microalgal-derived omega-3 oils produced through fermentation are free from the contaminants found in fish oils but their high cost restricts their use to infant formula and medical foods and generally prohibit their inclusion in common food products.

A potentially cost-effective and sustainable alternative would be to engineer a biosynthetic pathway for omega-3 LCPUFA-production into a land-based host, such as a commercial oilseed crop. Since most cold water marine fish oils have very low levels of omega-6 fatty acids (2–5%) and a combined omega-3 LCPUFA content of 10–25% (EPA + DHA), this composition provides a suitable commercial target for omega-3 LCPUFA in plants.

### Engineering omega-3 LCPUFA into Plants: Polyketide Biosynthetic Pathways

Although many cold-water fish are capable of synthesizing LCPUFA from LNA and ALA, the typically high content of EPA and DHA found in their body oils can only be attained through their dietary intake of LCPUFA [27]. For large marine carnivores, such as tuna and salmon, substantial amounts of LCPUFA are obtained by eating smaller fish, such as Menhaden. For the small fish the main sources of LCPUFA are marine microorganisms such as diatoms, golden-brown algae, green algae, blue-green algae, microbial fungi and dinoflagellates, all of which are rich in LCPUFA synthesized *de novo* by one of two classes of biochemical pathway. These two classes are the anaerobic polyketide synthase pathways [28] and the aerobic fatty acid desaturation/elongation pathways [29].

Polyketides are a very broad group of secondary metabolites that are usually defined by their method of synthesis; that is, the iterative addition of carbon to a growing acyl-ACP chain catalyzed by a single enzyme complex known as a polyketide synthase (PKS). These PKS complexes catalyze reactions analogous to those of fatty acid metabolism [30]. But whereas aerobic fatty acid synthesis is the result of over 30 distinct enzyme activities, a PKS synthase consists of a single, multidomain enzyme with subunits encoded by only three or four open reading frames in the genome of the polyketide-producing organism [30]. While most PKS products, such as aflatoxins and antibiotics, are highly derivatized and cyclized acyl chains some marine organisms use PKS-type complexes to synthesize EPA or DHA. In general, the species of LCPUFA produced by these organisms is specific to the particular polyketide synthase they contain [28]. In some cases, a single organism may contain both PKS and fatty acid synthase pathways for EPA or DHA synthesis. For example, a complete PKS type DHA-synthase has been cloned and characterized from a number of Thraustochytrid species, as have various fatty acid synthase-type enzymes involved in EPA and DHA synthesis [31, 32].

Genes encoding the three subunits of a *Schizochytrium* PKS that catalyzes the synthesis of DHA from malonyl-CoA have been expressed in yeast. When co-expressed

with a phosphopantetheinyl transferase (PPT) from *Nostoc*, essential for activating the ACP domains of the DHA-synthase PKS, the yeast are able to produce small amounts (2.5%) of DHA [33]. Presumably, the ultimate intent is to transfer the *Schizochytrium* PKS and *Nostoc* PPT genes into an oilseed plant with the goal of producing DHA in the seed oil, although there are no published reports to date of the success or otherwise of this approach.

### Engineering omega-3 LCPUFA into Plants: Fatty Acid Biosynthetic Pathways

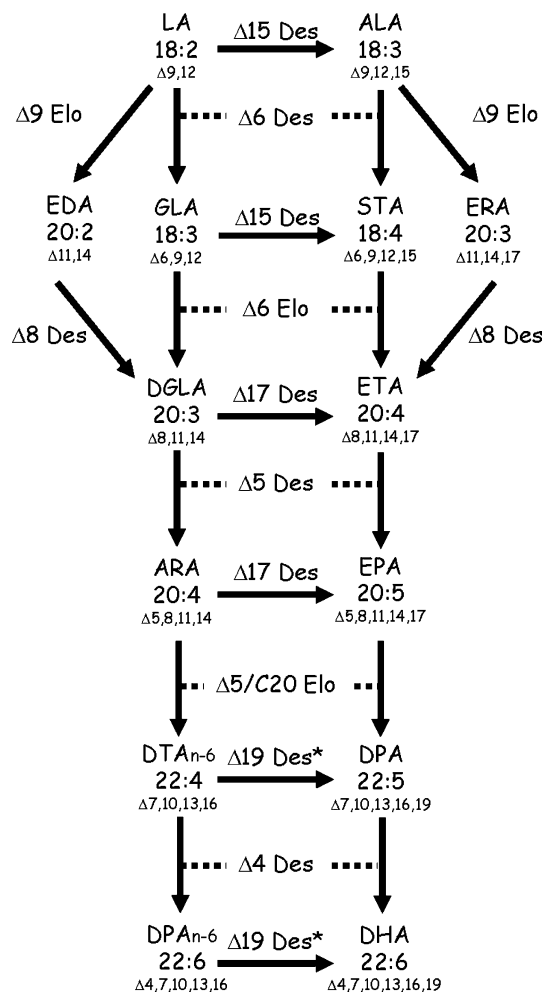

In contrast to PKS synthases, the pathways of aerobic ARA, EPA and DHA synthesis use a series of individual desaturase and elongase activities to catalyze the conversion of LNA and ALA to LCPUFA [34]. For ARA and EPA synthesis this requires the addition of two carbons and two double-bonds to LNA and ALA respectively. ARA can be converted to EPA by the action of a third (omega-3) desaturase [35].

Two converging ARA/EPA pathways have been identified in LCPUFA-producing organisms (Fig. 1); in both pathway types LNA and ALA are the metabolic precursors. In the first pathway type, LNA and ALA are first desaturated to gamma-linolenic acid (GLA, 18:3 [6, 9, 12]) and stearidonic acid (STA, 18:4 [6, 9, 12, 15]), respectively, by a delta-6 fatty acid desaturase. These fatty acids are then elongated to 20-carbons by a microsomal fatty acid elongation complex [28]. This elongation is initiated by a delta-6 specific beta-ketoacyl-CoA synthase enzyme (delta-6 elongase). The 20-carbon ketoacyl-CoA is then reduced, dehydrated and reduced again by the elongation complex to yield dihomo-gamma-linolenic acid (DGLA, 20:3 [8, 11, 14]) or eicosatetraenoic acid [ETA, 20:4 [8, 11, 14, 17]]. These fatty acids are then desaturated to ARA and EPA respectively by a delta-5 desaturase.

In the second pathway type, LNA and ALA are first elongated by a delta-9-specific elongase to eicosadienoic acid (EDA, 20:2 [11, 14]) and eicosatrienoic acid (ERA, 20:3 [11, 14, 17]), followed by delta-8 desaturation to DGLA and ETA, respectively. As in the first pathway, these fatty acids are then desaturated to ARA and EPA, respectively by a delta-5 desaturase.

Independent of the aerobic pathway utilized, some organisms have the added capability of efficiently converting omega-6 fatty acids to omega-3 fatty acids by the action of an omega-3 fatty acid desaturase [35–39]. This desaturation can occur on either 18-carbon or 20-carbon fatty acids.

In most organisms, conversion of EPA to DHA occurs by delta-5/C20 elongation of EPA to docosapentaenoic acid (DPA, 20:5 [7, 10, 13, 16, 19]) followed by delta-4

**Fig. 1** Aerobic LCPUFA biosynthetic pathways in marine microbes. The delta-6 pathway is shown with a delta-6 desaturase ( $\Delta 6$  Des) and delta-6 elongase ( $\Delta 6$  Elo) and the delta-9 pathway is shown with a delta-9 elongase ( $\Delta 9$  Elo) and a delta-8 desaturase ( $\Delta 8$  Des). Both pathways utilize a delta-5 desaturase ( $\Delta 5$  Des). All pathway enzymes utilize both omega-3 and omega-6 fatty acid substrates and this is indicated with a dotted line. Conversion of 18 carbon or 22 carbon omega-6 fatty acids to omega-3 fatty acids is catalyzed by the delta-15 desaturase ( $\Delta 15$  Des), delta-17 desaturase ( $\Delta 17$  Des) and possibly by a hypothetical delta-19 desaturase ( $\Delta 19$  Des\*), respectively. Elongation of ARA or EPA is catalyzed the  $\Delta 5/C20$  elongase ( $\Delta 5/C20$  Elo) and further delta-4 desaturation by the delta-4 desaturase ( $\Delta 4$  Des)

desaturation to DHA [29]. In humans and some other mammals, DHA synthesis is considerably more complex, involving two further elongations, a desaturation and beta-oxidation in a separate cellular compartment [34].

Among the first published descriptions of expression of a fatty acid-type LCPUFA pathway in plants was a report describing the constitutive expression of a delta-9 elongase pathway using genes from the microalgae *Isochrysis galbana* and *Euglena gracilis* and the microbial fungus *Mortierella alpina* in the model plant *Arabidopsis* [40]. Individual pathway genes (delta-9 elongase, delta-8

desaturase, delta-5 desaturase) were each linked to a Ca35S promoter and resulting EPA contents as high as 3.0% and ARA contents up to 6.6% were produced in *Arabidopsis* leaves. The ratio of omega-3 to omega-6 ratio fatty acids (2.2:1) was slightly lower in the transgenic plants than that for wild-type *Arabidopsis* leaves (3.5:1), but the new ratio was still in the range commonly found in fish oils [22]. A number of pathway intermediates and pathway by-products not commonly found in fish oils were also observed. These results were a significant proof-of-concept for expressing LCPUFA pathways in plants; however, *Arabidopsis* leaves could not be an economic production platform for these lipids.

In another report, published around the same time as the *Arabidopsis* study, Abbadi et al. [41] demonstrated very minor accumulation (less than 2%) of ARA and EPA in tobacco and flax seeds expressing a microbial delta-6 type pathway with genes from the diatom *Phaeodactylum tricornutum* and the fungus *Physcomitrella patens*. As in the *Arabidopsis* study there was substantial accumulation of pathway intermediates, mostly GLA and STA.

Thus, 18-carbon fatty acid elongation appeared to be limiting in the delta-6 pathway experiments (elongation was estimated to be around 10% in both tobacco and flax) but not in the delta-9 pathway experiments (where elongation in *Arabidopsis* was estimated to be about 36%). Poor elongation of delta-6 fatty acids was attributed to the low pool of the delta-6 acyl-CoA (GLA-CoA, STA-CoA) which are the main substrates for the delta-6 elongase. The low delta-6 acyl-CoA pools were probably the result of poor acyl-exchange of these lipids from the phospholipid substrates of the delta-6 desaturase to the acyl-CoA substrates for elongation. The pools of LNA-CoA and ALA-CoA for delta-9 elongation were presumably not limiting in the *Arabidopsis* study since these acyl species are the major fatty acids found in *Arabidopsis* leaf lipids. In a later study [42] the abundance of EPA in *Brassica juncea* expressing a delta-6 pathway was increased to as high as 15% partly by including a gene encoding a lysophosphatidyl acyltransferase from *Thraustochytrium* sp. This acyltransferase presumably increased the exchange of delta-6 acyl groups for acyl-phospholipids to acyl-CoAs for elongation.

However, a third report from 2004, describing commercially-significant amounts of LCPUFA in plant seeds reported good delta-6 elongation and a high abundance of EPA without the use of additional acyltransferases [43]. In this study, a delta-6 desaturase-type pathway from *M. alpina* was expressed in the agronomically-important oil-seed crop soybean, under control of strong, seed-specific promoters. In addition to the delta-6 pathway-genes (delta-6 desaturase, delta-6 elongase, delta-5 desaturase), the omega-6 ratio was increased from 0.2:1 (the normal soybean ratio) to 1.5:1 (a ratio close to that of many fish oils)

by concomitant expression of an *Arabidopsis* Fad 3 gene [44] and a *Saprolegnia diclina* delta-17 desaturase [39, 45].

The soybean study was the result of extensive characterization of multiple seed specific promoters and LCPUFA biosynthetic genes from different microbial sources, as well as optimization of promoter-gene cassette combinations and orientations in soy. Using this approach soybean seeds with an EPA content as high as 19.5% were produced with virtually no ARA. The low ARA content was attributed to the use of the *S. diclina* delta-17 desaturase. Additionally, the DHA precursor, DPA was found in high EPA lines at an abundance of about 4%, a result of the additional activity of the *M. alpina* delta-6 elongase towards the delta-5 fatty acid EPA. This same elongase had virtually no delta-5 EPA-elongating activity when expressed in yeast [46].

As in the other plant studies, pathway intermediates and by-products were present (35% in total). Unlike the flax and tobacco studies however, fatty acid elongation was not limiting in soybean. The total 20-carbon fatty acid content was as high as 40.2% representing 56% elongation of 18-carbon substrates.

In a more recent study, in which a similar set of LCPUFA biosynthetic genes for the same source were expressed (but without the omega-3 desaturases since the intent was to produce ARA), a very low abundance of total LCPUFA was observed (2.1%) in soy embryos [47]. The authors conclude that, as demonstrated in the soybean work of Kinney et al. [43], the careful combination of specific genes with individual promoters, gene cassette design and the screening of numerous events is crucial to obtaining the correct balance and a significant abundance of the desired LCPUFA in plants. Similar conclusions around the need for unique seed-specific promoters and pathway flux optimization were reached by Robert et al. [48] who expressed genes from a species of zebrafish (*Danio rerio*) and *Caenorhabditis elegans* in *Arabidopsis* seeds and observed a total LCPUFA content (ARA + EPA + DHA) of only 4.2%.

The flux to omega-3 fatty acids has since been further improved in soybean embryos [49] by the use of a novel, bifunctional delta-12/delta-15 desaturase from *Fusarium moniliforme* [39] in place of the *Arabidopsis* omega-3 desaturase. In the best events, the overall omega-3 fatty acid content was as high as 57% of total fatty acids. The *Fusarium* delta-15 desaturase was shown to be very active in soybean and when expressed alone, lead to ALA contents as high as 72%. It also had broad substrate specificity for numerous omega-6 fatty acids including LNA > GLA > DGLA > ARA [38], which further increases its usefulness in an LCPUFA pathway. Further LCPUFA pathway flux optimization and reduction in non-target fatty acids has since been achieved by further selection of the

types of desaturases and elongases used, codon optimization of microbial genes for plants and engineering optimal enzyme specificities (Damude and Kinney, unpublished data).

## Replacing Fish Oils with Transgenic Plant Oils

In the soybean study above, Kinney et al. [43] reported a relative abundance of DHA in soybean somatic embryo oil of up to 3.3%, which was the first demonstration of DHA in an oilseed plant. Soy somatic embryos are equivalent to the zygotic embryos of seeds [50]. This was achieved by the addition of a delta-5 elongase from *Pavlova* sp. [45] and a delta-4 desaturase from *Schizochytrium aggregatum* [51] in addition to the EPA biosynthetic pathway genes described above. The delta-4 desaturase used was highly active in plants with, in some cases, close to 100% conversion of DPA to DHA. In two other studies [42, 48], DHA was produced in a relative abundance of 0.5–1.5%. These are important milestones since all fish oils contain a mixture of EPA and DHA and thus the realization of a plant-based fish oil substitute appears to be on the horizon. Nevertheless, key challenges remain in obtaining a plant-based oil that is substantially similar to other commercially available fish oils. The first target will be to produce an EPA plus DHA plant oil with DHA comprising at least 10% of the total fatty acids, close to that of some marine oils. Although the highest abundance of DHA reported so far is less than 4%, current technology will allow for this abundance to be increased around threefold while maintaining an EPA abundance in the 10–15% range and this will provide an effective marine oils substitute. It will also be important to keep omega-6 fatty acids, pathway intermediates and pathway by-products to a minimum. It is now understood that by achieving the correct balance of relative gene expression and optimum metabolic flux through the engineered pathway it is possible to meet these criteria in commercial oilseed plants. Of course, once a seed oil having the desired target fatty acid composition has been achieved, there remains the key regulatory and agronomic challenges that face all new transgenic crop plants. However, the promising use of plant seed oils modified by biotechnology to produce n-3 long chain fatty acids will provide a readily available source of these important fatty acids in the future, overcoming the problems associated with obtaining n-3 LCPUFA from declining ocean fish supplies.

**Abstract** Diacylglycerol lipase (EC 3.1.1.3) was purified from bovine brain microsomes using multiple column chromatographic techniques. The purified enzyme migrates as a single band on SDS-PAGE and has an apparent molecular weight of 27 kDa. Substrate specificity experiments using mixed molecular species of 1,2-diacyl-*sn*-glycerols indicate that low concentrations of  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  have no direct effect on enzymic activity and 1,2-diacyl-*sn*-glycerols are the preferred substrate over 1,3-diacyl-*sn*-glycerols. The enzyme hydrolyzes stearate in preference to palmitate from the *sn*-1 position of 1,2-diacyl-*sn*-glycerols. 1-*O*-Alkyl-2-acyl-*sn*-glycerols are not a substrate for the purified enzyme. The native enzyme had a  $V_{\max}$  value of 616 nmol/min mg protein. Phosphorylation by cAMP-dependent protein kinase resulted in a three-fold increase in catalytic throughput ( $V_{\max} = 1,900$  nmol/min mg protein). The substrate specificity and catalytic properties of the bovine brain diacylglycerol lipase suggest that diacylglycerol lipase may regulate protein kinase C activity and 2-arachidonoyl-*sn*-glycerol levels by rapidly altering the intracellular concentration of diacylglycerols.

**Keywords** Diacylglycerols · 2-arachidonoyl-*sn*-glycerol · Lipase · Brain · Phosphorylation · Protein kinase A · Protein kinase C

## Abbreviations

DAG	Diacylglycerols
PKC	Protein kinase C
PKA	cAMP-dependent protein kinase
PLC	Phospholipase C
PLD	Phospholipase D
CB-1	Cannabinoid receptor 1
2-AG	2-Arachidonoyl- <i>sn</i> -glycerol
PtdIns(4,5)P <sub>2</sub>	Phosphatidylinositol-4,5-bisphosphate
Ins(1,4,5)P <sub>3</sub>	Inositol-1,4,5-trisphosphate
thioester substrate	<i>rac</i> -1,2- <i>S</i> , <i>O</i> -didecanoyl-1-mercapto-2,3-propanediol
physiologic substrate	1-Stearoyl-2-arachidonoyl- <i>sn</i> -glycerol

## Introduction

The phospholipid-derived second messenger, 1,2-diacyl-*sn*-glycerol, is an important bioactive molecule that plays a central role in the biosynthesis of phospholipids [1], is a physiological activator of protein kinase C [2], and is the precursor for the cannabinoid receptor (CB-1) agonist, 2-arachidonoyl-*sn*-glycerol [3–5]. Following cell stimulation, 1,2-diacyl-*sn*-glycerols are produced by mechanisms that involve either the G-protein-linked phospholipase C (PLC)  $\beta$ 1 and  $\beta$ 2 or the tyrosine kinase-linked PLC  $\gamma$ 1 and  $\gamma$ 2 (Fig. 3). These PLC isoforms preferentially hydrolyze phosphatidylinositol-

4,5-bisphosphate (PtdIns(4,5)P<sub>2</sub>) producing 1,2-diacyl-*sn*-glycerols and inositol-1,4,5-trisphosphate [6]. An increase in the concentration of intracellular Ca<sup>2+</sup> can also activate PLC through voltage-dependent or receptor-mediated mechanisms. Further, sustained thyrotropin-releasing hormone stimulation in rat pituitary cells results in a biphasic release of intracellular 1,2-diacyl-*sn*-glycerols [7]. Following the transient hydrolysis of PtdIns(4,5)P<sub>2</sub> by PLC, sustained release is brought about by a Ca<sup>2+</sup>-independent mechanism that involves activation of both protein kinase C and phospholipase D (PLD)-mediated pathways in which PLD hydrolyzes phosphatidylcholine to choline and phosphatidic acid [7, 8]. Sustained levels of 1,2-diacyl-*sn*-glycerols are required for long-term responses such as cell growth and differentiation and are initiated by growth factors and phorbol esters [9].

Increased levels of 1,2-diacyl-*sn*-glycerols activate protein kinase C by binding to its C1 domain. This increases its affinity for the cellular membrane and removes the pseudo-substrate inhibition caused by the N-terminal of the protein kinase C polypeptide chain [10, 11]. The biological functions of protein kinase C are broad. The recurring themes attributed to its function include: receptor desensitization, modulation of membrane restructuring events, regulation of transcription, mediation of immune response, regulation of cell growth, and influencing learning and memory [10]. The product of the diacylglycerol lipase-catalyzed reaction, 2-arachidonoyl-*sn*-glycerol, also functions as an endogenous CB-1 receptor agonist [12, 13]. The endocannabinoid, 2-arachidonoyl-*sn*-glycerol, modulates intracellular Ca<sup>2+</sup> and results in the attenuation of voltage-gated Ca<sup>2+</sup> influx in differentiated NG108-15 cells [14, 15] and the transient release of intracellular Ca<sup>2+</sup> in non-differentiated NG108-15 cultures [12]. High frequency stimulation of hippocampal slices also increases brain 2-arachidonoyl-*sn*-glycerol levels fourfold and is dependent on neuronal depolarization and external Ca<sup>2+</sup> [16]. The coupling of calcium influx, diacylglycerol lipase activity, and 2-arachidonoyl-*sn*-glycerol is necessary and sufficient in controlling axonal growth and guidance in response to FGF receptor activation [17]. Unfortunately, the mechanism that couples the hydrolysis of 1,2-diacyl-*sn*-glycerols and the formation of 2-arachidonoyl-*sn*-glycerol to the calcium response is poorly understood.

To investigate the possibility that the activity of diacylglycerol lipase in the brain is regulated by phosphorylation and to investigate its function in the metabolism of 1,2-diacyl-*sn*-glycerols, we measured the substrate specificity and catalytic properties of the native (non-phosphorylated) and phosphorylated brain

microsomal enzyme. We report here that the  $V_{\max}$  values of bovine brain diacylglycerol lipase are increased threefold following phosphorylation by cAMP-dependent protein kinase, and that diacylglycerol lipase hydrolyzes stearate from the *sn*-1 position of 1,2-diacyl-*sn*-glycerols. Substrate specificity assays with the native enzyme show that microsomal diacylglycerol lipase shows a preference for 1,2-diacyl-*sn*-glycerols having arachidonic or linoleic acid esterified at the *sn*-2 position. These results suggest that native and phosphorylated diacylglycerol lipase can regulate both protein kinase C and CB-1 receptor activation by modulating the intracellular levels of 1,2-diacyl-*sn*-glycerols and 2-arachidonoyl-*sn*-glycerol. The data also suggest that protein phosphorylation tightly regulates brain diacylglycerol lipase activity, and that the metabolism of 1,2-diacyl-*sn*-glycerols following receptor-mediated cell stimulation may play an active role in organizing signaling responses following the initial stimulus.

## Materials and Methods

### Protein Purification

Bovine brain diacylglycerol lipase was purified to homogeneity using multiple column chromatographic procedures [18, 19]. Protein concentrations were determined with a dye-binding assay [20] using bovine serum albumin as standard. The purified protein was divided into aliquots and stored in 50 mM 3-(*N*-morpholino) propane sulfonic acid (MOPS) buffer, pH 7.4, containing 50% glycerol at –80 °C. Assays were performed on freshly thawed aliquots of enzyme. All chemicals used were of reagent grade and purchased from the Sigma Chemical Company (St Louis, MO) unless noted otherwise. The physiologic substrate, 1-stearoyl-2-arachidonoyl-*sn*-glycerol, was purchased from Matreya Inc. (Pleasant Gap, PA) and *rac*-1,2-*S,O*-didecanoyl-1-mercapto-2,3-propanediol (thioester substrate) was made as described previously [21].

### Substrate Preparation

Mixed molecular species of diacylglycerol were prepared from bovine brain phospholipid. Briefly, bovine brain phospholipid (200 mg), stored in *n*-hexane/2-propanol (3:2, by vol) was concentrated to zero under a steady-stream of N<sub>2</sub> at 45 °C and sonicated into solution in 50 mM MOPS buffer (pH 7.4) containing 5.0 mM CaCl<sub>2</sub>, 0.1% Triton X-100, and 0.25% essentially fatty acid free bovine serum albumin. The lipid suspension was incubated at room temperature in the

presence of 10,000 units phospholipase C (*Bacillus cereus*, Boehringer, Ridgefield, CT) to produce mixed molecular species of diacylglycerols. The reaction was stopped with the addition of 3.75 vol of chloroform/methanol (1:2, by vol) and extracted with the addition of 1.25 vol H<sub>2</sub>O. The lower phase containing the lipid was collected and purified with standards on TLC (silica gel G, Analtech) using heptane/isopropyl ether/acetic acid (60:40:4, by vol) [22]. Bands corresponding to 1,2-diacyl-*sn*-glycerols were extracted from the silica gel with *n*-hexane/2-propanol (3:2, by vol) and stored at -80 °C. The 1,3-diacyl-*sn*-glycerol isomers were produced by incubating 1,2-diacyl-*sn*-glycerols in methanol/H<sub>2</sub>O (1:1, by vol) for 24 h at 37 °C, and purified by TLC as outlined above. The diacylglycerol substrate isomers were re-purified using the above separation immediately prior to assay. Kinetic experiments were performed using a physiologic substrate, 1-stearoyl-2-arachidonoyl-*sn*-glycerol purchased from Matreya Inc. (Pleasant Gap, PA) or using a thioester substrate, *rac*-1,2-*S*,*O*-didecanoyl-1-mercapto-2,3-propanediol, prepared as described [21]. Substrate suspensions of known amounts of mixed molecular species of 1,2- or 1,3-diacyl-*sn*-glycerols, 1-stearoyl-2-arachidonoyl-*sn*-glycerol, or *rac*-1,2-*S*,*O*-didecanoyl-1-mercapto-2,3-propanediol were prepared via sonication of substrates in an assay buffer containing 6 mg lysophosphatidylcholine (Sigma).

#### Diacylglycerol Lipase Assay

Assays using mixed molecular species of diacylglycerol were performed at 37 °C in 50 mM MOPS buffer (pH 7.4) containing 0.25% essentially fatty acid free bovine serum albumin (BSA). Phosphorylated diacylglycerol lipase assays were preformed, using enzyme preparations that were pre-incubated at 37 °C for 10 min in 50 mM MOPS buffer pH 7.4 containing 0.25% BSA, 25 units of catalytic subunit of cAMP-dependent protein kinase (Promega, Madison, WI), 20 mM MgCl<sub>2</sub>, and 0.2 mM ATP. Parallel assays of “native” diacylglycerol lipase using both the physiologic substrate and the thioester substrate were performed, using those conditions outlined for the phosphorylated diacylglycerol lipase in the absence of the catalytic subunit of cAMP-dependent protein kinase. All diacylglycerol lipase assays (12.5 µg protein per assay), having a total volume of 0.5 ml, were initiated with the addition of suspensions containing known final amounts of substrate (18.75–300 µmol for kinetic analysis or 150 µmol for molecular species analysis) to the diacylglycerol lipase preparations. The reactions were stopped with the addition of 3.75 vol (2 ml) chloroform/methanol

(1:2, by vol) and samples were extracted as outlined above. The non-hydrolyzed diacylglycerols and non-esterified fatty acids released following incubation were isolated via TLC as outlined above then quantified by GLC. The molecular species preferences was determined using a subtraction assay in which the initial substrate and the substrate remaining following incubation were converted to their dinitrobenzoyl derivatives then isolated using silica Gel G developed with a solvent system of petroleum ether/ethyl ether/acetic acid (90:10:1, by vol) followed by second elution with toluene [23]. The 1,2-diacyl-*sn*-glycerols, 1,3-diacyl-*sn*-glycerols, and 1-*O*-alkyl-2-acylglycerols were extracted off the silica using hexane:2-propanol (3:2, by vol) and stored at -20 °C prior to analysis.

#### Molecular Species Determination

Molecular species analyses of the dinitrobenzoyl derivatives were isolated by HPLC on a Nucleosil C18 column (Phenomenex, Torrance, CA) using an isocratic elution of acetonitrile/2-propanol (80:20, by vol) as described in [23]. Fractions absorbing light at 254 nm were collected, methylated, and quantified by gas liquid chromatography.

#### Gas Liquid Chromatography (GLC)

Esterified fatty acids were converted to their methyl ester derivatives in 0.5 M methanolic KOH at 37 °C for 30 min and extracted in *n*-hexane. Non-esterified fatty acids were methylated in toluene/methanol (1:1, by vol) + 2% H<sub>2</sub>SO<sub>4</sub> at 60 °C for 2 h and extracted in petroleum ether following the addition of 0.5 vol H<sub>2</sub>O. Fatty acid methyl esters were quantified with a GLC (Shimadzu GLC-14A, Kyoto, Japan) equipped with a SP-2330 capillary column (0.32 mm ID × 30 m length, Supelco, Bellefonte, PA) and a flame ionization detector. Column temperature was maintained at 185 °C with nitrogen as the carrier gas at a pressure of 0.5 kg/cm<sup>2</sup>. Detector and injector temperatures were maintained at 220 °C. Known standards (NuChek Prep, Elysian, MN) were used to establish relative retention times and relative correction factors. The detector response was linear within the sample concentration range for all fatty acids of varying chain lengths and degree of saturation with correlation coefficients of 0.990 or greater.

#### Calculations

Reaction rates were determined by calculating the rate of hydrolysis of 1,2-diacyl-*sn*-glycerols, 1,3-diacyl-*sn*-

glycerols, or 1-*O*-alkyl-2-acyl-*sn*-glycerols or the formation of 2-arachidonoyl-*sn*-glycerol as a function of time compared to enzyme control blanks. One-way Analysis of Variance (ANOVA) with a Tukey-Kramer multiple comparison test (Instat<sup>®</sup> Ver. 3.05, GraphPad, San Diego, CA) was used to compare the hydrolysis rates of the enzyme towards different molecular species (Table 2), statistical significance was taken as  $p \leq 0.05$ . Data are presented as mean  $\pm$  SD.

## Results

### Molecular Species Specificity

Substrate specificity of native diacylglycerol lipase using mixed molecular species of 1,2-diacyl-*sn*-glycerols or 1,3-diacyl-*sn*-glycerols showed that diacylglycerol lipase cleaves primarily 1,2-diacyl-*sn*-glycerols (Fig. 1). Only trace amounts of the 1,3-diacyl-*sn*-glycerols or 1-*O*-alkyl-2-acyl-*sn*-glycerols were hydrolyzed. Due to the inability to separate 1-*O*-alkyl-2-acyl-*sn*-glycerols from 1,2-diacyl-*sn*-glycerols prior to their conversion to a dinitrobenzoyl derivative, the percent hydrolyzed was determined following the assay by measuring the amount of dinitrobenzoyl derivatives remaining of each species. In these experiments 1-*O*-alkyl-2-acyl-*sn*-glycerols composed approximately 7% of the total substrate being approximately 10.5  $\mu$ mol per assay and resulted in approximately 0.26 nmol hydrolyzed during

**Fig. 1** Specificity of diacylglycerol lipase toward different isomers of diacylglycerols. Bars represent the percent of substrate hydrolyzed by diacylglycerol lipase over a 4 min incubation period at 37 °C (values represent mean  $\pm$  SD,  $n = 5$ ). The inset represents reaction coordinates of free acid release during incubations performed using 1,2-diacyl-*sn*-glycerols, 1,3-diacyl-*sn*-glycerols, and 1-*O*-alkyl-2-acyl-*sn*-glycerols as substrate (values represent mean  $\pm$  SD,  $n = 5$ )

the 4.0 min incubation period. Substrate competition between the 1,2-diacyl-*sn*-glycerol and 1-*O*-alkyl-2-acyl-*sn*-glycerol molecular species was not determined. The rate of hydrolysis of 1-stearoyl-2-arachidonoyl-*sn*-glycerol or the substrate specificity of diacylglycerol lipase using the mixed molecular species assay was not affected following the addition of 25  $\mu$ M CaCl<sub>2</sub> or 25  $\mu$ M MgCl<sub>2</sub>.

### Fatty Acid Specificity

The reaction time course (Fig. 1, inset) shows the enzyme hydrolyzes stearate 35 times more readily than palmitate despite a 4.3-fold differential in the concentration ratio of these fatty acids in the substrate used (Table 1). These data were confirmed by directly quantifying the free fatty acid released following experiments using 150  $\mu$ mol of mixed molecular species of 1,2-diacyl-*sn*-glycerols. The release of palmitate was found in these assays; however the levels were near the detection limits of the gas chromatograph. Assays performed for 10 and 20 min resulted in the depletion of stearate-containing molecular species, but did not produce significant increases in the level of hydrolyzed palmitate nor a significant loss of palmitate-containing molecular species. Experiments were performed in which the 1,2-diacyl-*sn*-glycerols were depleted of stearate-containing molecular species by pre-incubating the substrate with diacylglycerol lipase then re-assaying the 18:0-depleted 1,2-diacyl-*sn*-glycerols. These experiments showed palmitate is hydrolyzed, but at a very slow rate compared to stearate (data not shown). Therefore, it was concluded that native diac-

**Table 1** Molecular species profile of the 1,2-diacyl-*sn*-glycerols purified from bovine brain phospholipid

Molecular species	nmol	mol %
16:0/22:6	46.2 $\pm$ 0.5	7.8
16:0/22:4	12.7 $\pm$ 0.3	2.1
16:0/20:5	17.3 $\pm$ 0.2	2.9
16:0/20:4	4.4 $\pm$ 0.3	0.7
16:0/18:1	30.6 $\pm$ 0.8	5.2
18:0/22:6	137.8 $\pm$ 0.2	23.3
18:0/22:5	60.9 $\pm$ 1.9	10.3
18:0/22:4	40.6 $\pm$ 0.3	6.9
18:0/20:4	96.7 $\pm$ 1.2	16.4
18:0/20:3	4.9 $\pm$ 0.6	0.8
18:0/18:2	12.0 $\pm$ 1.8	2.0
18:0/18:1	108.6 $\pm$ 0.04	18.4
18:0/18:0	18.1 $\pm$ 0.2	3.1
Total	590.61	99.9

Values are the mean  $\pm$  SD and represent the concentration (nmol) and mole percentage of individual species of 1,2-diacyl-*sn*-glycerols in aliquots of the mixed molecular species substrate ( $n = 6$ )

ylglycerol lipase does hydrolyze palmitate from 1,2-diacyl-*sn*-glycerols. Statistical analysis of the rates at which the different molecular species were hydrolyzed showed diacylglycerol lipase maintains a preference in the rate of hydrolysis of certain molecular species. This preference was 18:0/20:4 = 18:0/18:1 = 18:0/22:6 > 18:0/22:5 > 18:0/22:4 (Table 2).

### Enzyme Kinetics

The native enzyme displayed linear kinetic characteristics when incubated with varying concentrations between 300 and 18.75  $\mu\text{mol}$  of 1-stearoyl-2-arachidonoyl-*sn*-glycerol. The  $V_{\text{max}}$  values of native diacylglycerol lipase using 1-stearoyl-2-arachidonoyl-*sn*-glycerol or didecanoyl-1-thioglycerol were 616 and 120 nmol/min mg protein, respectively (Table 3). Experiments in which synthetic didecanoyl-1-thioglycerol was used, the decrease in the  $V_{\text{max}}$  of diacylglycerol lipase towards the thioester substrate suggests that the acyl chain length and degree of saturation of the fatty acids in the substrate may alter substrate presentation and catalysis. Phosphorylation of native diacylglycerol lipase by cAMP-dependent protein kinase increased the  $V_{\text{max}}$  of diacylglycerol lipase to 1,900 nmol/min mg protein, representing a threefold increase when compared to the native enzyme (Fig. 2).

**Table 2** Specificity of diacylglycerol lipase toward mixed molecular species of 1,2-diacyl-*sn*-glycerols

Molecular species	mol %	Activity (nmol/min)	SP activity (nmol/min/mg)

SP activity specific activity

### Discussion

It was found that bovine brain microsomal diacylglycerol lipase maintains a high level of substrate specificity in that the enzyme preferentially hydrolyzes stearate over palmitate from the *sn*-1 position of 1,2-diacyl-*sn*-glycerols. These experiments also demonstrated that  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ , at low concentrations, had no effect on the catalytic properties of the enzyme and that phosphorylation of native diacylglycerol lipase by cAMP-dependent protein kinase increased its  $V_{\text{max}}$  threefold. The presence of an actively regulated diacylglycerol lipase in the brain may serve several important functions in that it may regulate protein kinase C by modulating the intracellular levels of 1,2-diacyl-*sn*-glycerols as well as stimulate the cannabinoid receptor system by producing the CB-1 receptor ligand, 2-arachidonoyl-*sn*-glycerol.

The characterization and solubilization of membrane-bound diacylglycerol lipase using a thioester substrate has been reported. These studies show that the purified microsomal diacylglycerol lipase maintains a  $V_{\text{max}}$  of 182 nmol/min/mg protein [19]. Results found in these studies are similar to those found with the native microsomal diacylglycerol lipase using the thioester substrate (Table 3). The differing characteristics of the native diacylglycerol lipase toward the physiologic substrate suggest that the presence of an ester bond or the acyl-chain length of the esterified fatty acids influence the rate of hydrolysis of the substrate by the enzyme. Interestingly, assays using mixed molecular species show that the enzyme hydrolyzes palmitate esterified at the *sn*-1 position of the diacylglycerol molecule at a much slower rate compared to stearate. These results suggest that the acyl-chain length of the fatty acid found at the *sn*-1 position may influence the catalytic capacity. Therefore it is likely that the fivefold increase in the  $V_{\text{max}}$  of native diacylglycerol lipase toward the physiologic substrate is in part due to the presence of the ester bond and increased acyl chain length found at the *sn*-1 position of the native substrate.

**Table 3** Catalytic values for different substrates and different activation of diacylglycerol lipase

Substrate	Enzyme	$K_m$ ( $\mu\text{M}$ )	$V_{\text{max}}$ (nmol/min/mg protein)
1,2-Didecanoyl-1-thioglycerol	Non-phosphorylated (native)	38	120
1-Stearoyl-2-arachidonoyl - <i>sn</i> -glycerol	Non-phosphorylated (native)	63	616
1-Stearoyl-2-arachidonoyl - <i>sn</i> -glycerol	Phosphorylated	55	1,900

Values represent mean catalytic constants of non-phosphorylated (native) and phosphorylated enzyme when incubated with either 1,2-didecanoyl-1-thioglycerol or 1-stearoyl-2-arachidonoyl-*sn*-glycerol ( $n = 3$ ) experimental measures per concentration analyzed (18.75, 37.5, 75, 150, and 300  $\mu\text{mol}$ )

**Fig. 2** Plot of the velocity dependency as a function of substrate concentration of native (non-phosphorylated) and phosphorylated diacylglycerol lipase. (Open circles and closed circles represent assays performed on native enzyme using the thioester substrate, didecanoyl-1-thioglycerol or the physiologic substrate, 1-stearoyl-2-arachidonoyl-*sn*-glycerol, respectively). The plot showing closed triangles represent assays performed on phosphorylated enzyme preparations using 1-stearoyl-2-arachidonoyl-*sn*-glycerol. Values represent the mean  $\pm$  SD ( $n = 3$ )

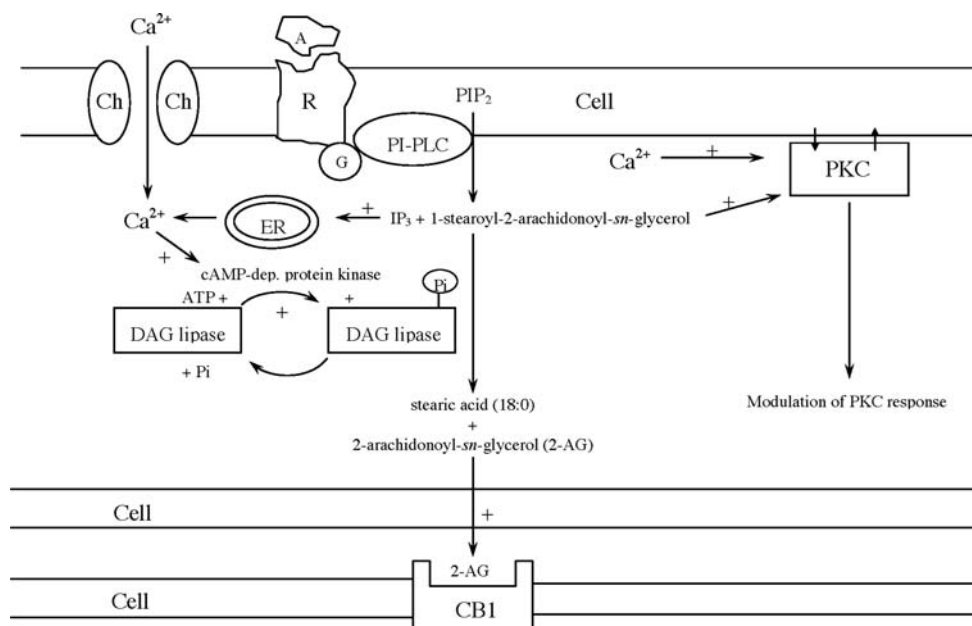

High calcium, magnesium, and manganese ions markedly stimulate the enzymic activity of the solubilized microsomal diacylglycerol lipase using the thioester substrate [19]. Diacylglycerol lipase activity in human platelet microsomes and the  $\alpha$  and  $\beta$  isoforms cloned from brain are also stimulated by  $\text{Ca}^{2+}$  ions [24–26]. However, we found that 25  $\mu\text{M}$  calcium or magnesium did not alter the enzymic activity of diacylglycerol lipase in assay using the physiologic substrate 1-stearoyl-2-arachidonoyl-*sn*-glycerol. These results suggest that the stimulation of diacylglycerol lipase by high concentrations of these ions in the presence of the thioester substrate may be due to the interaction with the thioester substrate rather than direct interactions with the protein molecule. The concentration-dependent stimulation by the non-ionic detergent Triton X-100 of the partially purified enzyme [18] supports the premise that the interfacial binding of the enzyme to the lipid bilayer is a crucial aspect of diacylglycerol lipase activity. The change in the bilayer organization of membrane lipids by calcium ions [27, 28] supports our previous assumption that the interaction of calcium ions with the thioester substrate reorganizes the aggregated structure of *rac*-1,2-*S,O*-didecanoyl-1-mercapto-2,3-propanediol [19]. Therefore, comparing the results from assays performed using the artificial and physiologic substrates suggests that the effect of increasing the concentration of positive ions on diacylglycerol lipase activity is probably due to contact of

the ions with the thioester substrate rather than a direct interaction with the protein.

As the cellular concentration of the biologically active 1,2-diacyl-*sn*-glycerols can modulate the activity of protein kinase C and is the precursor for the endocannabinoid, 2-arachidonoyl-*sn*-glycerol [27, 28], the amount of diacylglycerols in brain must be tightly regulated. Because the basal level of 2-arachidonoyl-*sn*-glycerol in brain is much lower than the binding affinity of anandamide with the CB1 receptor [29], a rapid equilibrium between formation and breakdown of this molecule is necessary to explain its action as a brain CB<sub>1</sub> receptor ligand [26, 30]. Several lines of evidence suggest that  $\text{Ca}^{2+}$ -dependent phosphorylation may act as a regulatory component in this system. The first is that treatment of neuron-enriched spinal cord cultures with NMDA and glutamate results in a dose- and time-dependent stimulation of diacylglycerol lipase activity [31, 32]. Further, diacylglycerol lipase activity and 2-arachidonoyl-*sn*-glycerol is necessary and sufficient in controlling axonal growth and guidance in response to FGF receptor activation [17]. Moreover, ATP increases the rate of 2-arachidonoyl-*sn*-glycerol formation in mouse astrocytes by a factor of 60, which is dependent on calcium and greater than any stimulus-induced increase in endocannabinoid production reported in brain to date [33]. Diacylglycerol lipase present in chicken adipose tissue is activated by cAMP-dependent protein kinase, which increases the catalytic capacity of the enzyme 1,000-fold [34, 35]. Therefore, the substrate specificity of the brain microsomal diacylglycerol lipase coupled to the positive regulatory effect of phosphorylation outlined above suggests that 2-arachidonoyl-*sn*-glycerol formation in brain is likely a result of activation of diacylglycerol lipases.

Two diacylglycerol lipase isoforms,  $\alpha$  and  $\beta$ , have been cloned when the sequence of a *Penicillium* diacylglycerol lipase is “blasted” against the human genome [26]. These isoforms have a molecular weight of 120 and 70 kDa, respectively, and thus do not correspond to the 27 kDa enzymatic activity studied here. Analyses of these isoforms show that they share similar substrate specificities with regard to the hydrolysis of fatty acid esterified to the *sn*-1 position of the diacylglycerol molecule, show a marked dependence on  $\text{Ca}^{2+}$  ions for activity, and demonstrate well-defined expression patterns during development. Thus, while it is at this point unclear, further studies are needed to determine whether the enzyme activity outlined in this manuscript represents a new diacylglycerol isoform or proteolytic cleavage of one of the cloned isoforms. Future studies to clone this enzyme and to produce

**Fig. 3** General schematic representing the hypothetical contribution that diacylglycerol lipase has following receptor-mediated signaling. Diacylglycerol lipase is phosphorylated by cAMP-dependent protein kinase (protein kinase A), but not protein kinase C.  $Ca^{2+}$  calcium, *Ch* calcium channel, *A* agonist, *R* receptor, + activation, *G* G-protein, *CB* cannabinoid receptor, *PI-PLC* phosphoinositide-specific phospholipase C, *PIP<sub>2</sub>* phosphatidylinositol-4,5-bisphosphate, *PKC* protein kinase C, *ER* endoplasmic reticulum *IP<sub>3</sub>* inositol-1,4,5-trisphosphate, *P<sub>i</sub>* phosphate, *DAG* diacylglycerols

antibodies against it will aid in determining the physiologic role this enzyme has in the brain.

Further, the common assumption that receptor-mediated activation of phospholipase C results in the release of arachidonic acid due to diacylglycerol lipase activation is not completely correct. Our results and others [26] support the idea that diacylglycerol lipase is not involved directly in the release of arachidonic acid from the *sn*-2 position of the diacylglycerol molecule (Fig. 3). The endocannabinoid, 2-arachidonoyl-*sn*-glycerol, is the primary product of the diacylglycerol lipase-mediated reaction. The majority of esterified arachidonic acid is located at the *sn*-2 position of the diacylglycerol moiety (Table 1) and the activation of the diacylglycerol lipase is able to release fatty acid only from the *sn*-1 position thereby forming primarily stearic acid and 2-arachidonoyl-*sn*-glycerol. Although several investigators have shown a relationship between ionomycin-induced activation of PLC and the subsequent release of arachidonic acid [36, 37], which can be inhibited with the diacylglycerol lipase inhibitor RHC 80267, our data suggest that this is more likely the result of subsequent hydrolysis by a monoacylglycerol lipase or possible overlapping PLA<sub>2</sub> activity. Therefore the more likely product of the diacylglycerol lipase reaction is the biologically active endocannabinoid, 2-arachidonoyl-*sn*-glycerol, followed by degradation by monoacylglycerol lipase [38]. Activation of diacylglycerol lipase by phosphorylation with cAMP-dependent protein kinase suggests that diacylglycerol lipase can be recruited by  $Ca^{2+}$ -dependent protein kinases to modulate cellular levels of 1,2-diacylglycerols.

Diacylglycerols derived from inositol glycerophospholipids are more effective in stimulating protein kinase C isoforms than the diacylglycerols derived from the hydrolysis of choline glycerophospholipids [2, 39].

In summary, these data support the premise that brain diacylglycerol lipase plays a role in regulating the intracellular levels of 1,2-diacyl-*sn*-glycerols. The diacylglycerol lipase activity can be modulated by phosphorylation by cAMP-dependent protein kinase. The microsomal diacylglycerol lipase in its phosphorylated form can produce the CB-1 receptor agonist, 2-arachidonoyl-*sn*-glycerol, at rates higher than previously appreciated. Therefore, the modulation of diacylglycerol lipase activity by phosphorylation can greatly influence its catalytic properties making it a more potent modulator of both protein kinase C and the cannabinoid receptor system in the brain.

**Abstract** We examined the in vivo contribution of insulin, T090137 (T09), agonist of liver X receptor (LXR), fenofibrate, agonist of peroxisome proliferator activated receptor (PPAR- $\alpha$ ) and sterol regulatory element binding protein-1c (SREBP-1c) on the unsaturated fatty acid synthesis controlled by  $\Delta 6$  and  $\Delta 5$  desaturases, compared with the effects on stearoyl-coenzyme A desaturase-1. When possible they were checked at three levels: messenger RNA (mRNA), desaturase protein and enzymatic activity. In control rats, only fenofibrate increased the insulinemia that was maintained by the simultaneous administration of T09, but this increase has no specific effect on desaturase activity. T09 enhanced SREBP-1 in control animals and the mRNAs and activity of the three desaturases in control and type-1 diabetic rats, demonstrating a LXR/SREBP-1-mediated activation independent of insulin. However, simultaneous administration of insulin and T09 to diabetic rats led to a several-fold increase of the mRNAs of the desaturases, suggesting a strong synergic effect between insulin and LXR/retinoic X receptor (RXR). Moreover, this demonstrates the existence of an interaction between unsaturated fatty acids and cholesterol metabolism performed by the insulin/SREBP-1c system and LXR/RXR. PPAR- $\alpha$  also increased the expression and activity of the three desaturases independently of the insulinemia since it was

equivalently evoked in streptozotocin diabetic rats. Besides, PPAR- $\alpha$  increased the palmitoylcoenzyme A elongase, evidencing a dual regulation in the fatty acid biosynthesis at the level of desaturases and elongases. The simultaneous administration of fenofibrate and T09 did not show additive effects on the mRNA expression and activity of the desaturases. Therefore, the results indicate a necessary sophisticated interaction of all these factors to produce the physiological effects.

**Keywords**  $\Delta 9$ ,  $\Delta 6$  and  $\Delta 5$  desaturases · Diabetes mellitus type 1 · Sterol regulatory element binding protein-1c · T091317 · Liver X receptor · Fenofibrate · Peroxisome proliferator activated receptor  $\alpha$

## Introduction

Unsaturated fatty acids, either essential or nonessential, play a relevant role in animal metabolism and physiology, and as lipid components they determine

the structure and properties of membranes. Polyunsaturated fatty acids accomplish very important physiological functions when converted to eicosanoids and docosanoids, and they are important brain components. They are agonists in the expression of several nuclear receptors that activate or deactivate enzymes and proteins, modulating cellular signaling involved in human health and diseases.

Unsaturated fatty acids are provided by the diet, but the endogenous biosynthesis is another important way they are provided. It provides palmitoleic and oleic acids by  $\Delta 9$  desaturation of coenzyme A (CoA) thioesters of palmitic and stearic acids, respectively, whereas successive  $\Delta 6$  and  $\Delta 5$  desaturations evoked by the front-end  $\Delta 6$  and  $\Delta 5$  desaturases and elongation reactions of the CoA thioesters of the essential acids linoleic acid and  $\alpha$ -linolenic acid are necessary to biosynthesize the highly polyunsaturated acids of the n-6 and n-3 families.

These enzymes are expressed mainly in liver, which is the major site of polyunsaturated fatty acid biosynthesis and provision to other tissues.

The desaturating enzymes modulate the unsaturated fatty acid biosynthesis, and their activity is regulated by diet components, hormones and other factors as well as by competition among the different acids [1]. However, we have demonstrated that many hormones, like corticoids, testosterone and 17- $\beta$ -estradiol, upregulate  $\Delta 9$  desaturase and downregulate  $\Delta 6$  and  $\Delta 5$  desaturases. In the case of experimental diabetes mellitus type 1, unlike diabetes type 2 characterized by insulin deficiency, they have been known since the 1960s to depress the biosynthesis of unsaturated fatty acids of the n-6, n-3 and n-9 families. This was evoked by decreasing the gene expression of the corresponding messenger RNAs (mRNAs) and enzymatic activities of  $\Delta 9$ ,  $\Delta 6$  and  $\Delta 5$  desaturases [2–6] and that activity was recovered by insulin administration. Moreover, Waters and Ntambi [7] and Rimoldi et al. [8] have demonstrated that the insulin-dependent recovered expression of stearoyl-CoA desaturase-1 (SCD-1) (current name of one of the  $\Delta 9$  desaturases) and  $\Delta 6$  desaturase mRNAs is not a direct effect of insulin, but it is evoked by the previous biosynthesis of one or more proteins.

Since the studies by Shimomura et al. [9] and Matsuzaka et al. [10] and other authors, this protein has been considered to be mainly represented by the transcription factor sterol receptor element binding protein-1c (SREBP-1c) since insulin induces the transcription of the *srebp-1c* gene into the precursor SREBP-1c, which after a hydrolytic step is converted to the nuclear active form nSREBP-1c, which then

reaches the nucleus and activates the expression of the three desaturases.

In addition, peroxisome proliferator activated receptor  $\alpha$  (PPAR- $\alpha$ ) (NR1-C1), which together with PPAR- $\beta$ /PPAR- $\delta$  (NR1C2) and PPAR- $\gamma$ 1 and PPAR- $\gamma$ 2 (NR1C3) belongs to the nuclear receptor superfamily, is activated by xenobiotic agonists like fenofibrate and endogenous ligands like unsaturated fatty acids in general. Although the active PPAR- $\alpha$  is characterized by its catabolic effect on lipid metabolism, it has also been shown to enhance the activity of the fatty acid desaturases [11]. However, the effects are only evoked after heterodimerization with the retinoic X receptor (RXR).

*srebp-1c*, according to Repa et al. [12], is also a target gene of the nuclear liver X receptors (LXR) LXR- $\alpha$  (NR1-H3) and LXR- $\beta$  (NR1-H2), which are activated by oxysterol and are considered as intracellular cholesterol sensors. Also, LXR- $\alpha$ , the predominant liver isoform, and RXR- $\alpha$  form a heterodimer and the SREBP-1c gene promoter revealed a RXR/LXR-DNA binding site that is essential for this regulation.

Moreover, polyunsaturated fatty acids suppress SREBP-1c promoter activity, and according to Yoshikawa et al. [13], this effect is evoked by inhibition of LXR binding to LXR response elements. To complete this picture, Chen et al. [14] have demonstrated a central role for LXR in insulin-mediated activation of SREBP-1c transcription and stimulation of fatty acid synthesis in liver. Therefore, LXR activates genes involved in the catabolism of cholesterol to bile acids, but it indirectly enhances lipogenic enzymes by LXR-mediated induction of SREBP-1c.

This information mainly gathered through in vitro experiments led us to investigate the in vivo interactions among LXR, PPAR- $\alpha$ , SREBP-1c and insulin specifically in the modulation of hepatic  $\Delta 6$  and  $\Delta 5$  desaturases at three levels, the mRNA abundance, the amount of enzyme protein and the microsomal enzymatic activities, as well as the correlated fatty acid compositions, comparing them with the effects evoked on SCD-1.

The activation of LXR was achieved by administration of the exogenous agonist T091317 (T09) [15] and the activation of PPAR- $\alpha$  by fenofibrate. Both agonists were chosen because they are widely used in the activation of the aforementioned nuclear receptors. They were administered to streptozotocin diabetic and control rats. To assess the effect of these drugs on the nuclear receptors, peroxisomal acyl-CoA oxidase activity as well as SREBP-1 and nSREBP-1 were tested. In addition to the measurement of the desaturases, the effect on hepatic palmitoyl-CoA elongase was also investigated.

## Experimental Procedure

### Materials

[1-<sup>14</sup>C]Stearic acid (58 mCi/mmol), 98% radiochemically pure, [1-<sup>14</sup>C] $\alpha$ -linolenic acid (53 mCi/mmol), 97% radiochemically pure, and [1-<sup>14</sup>C]eicosa-8,11,14-trienoic acid (52 mCi/mmol), 97% radiochemically pure, were purchased from Amersham Biosciences (Little Chalfont, UK), PerkinElmer (Boston, MA, USA) and New England Nuclear (Boston, MA, USA), respectively. Unlabeled free fatty acids were provided by Doosan Serdary Research Laboratories (Toronto, Canada).

Cofactors used for enzymatic analysis and fenofibrate were obtained from Sigma Chemical Co. (St. Louis, MO, USA). Analytical grade solvents were purchased from Carlo Erba (Milan, Italy).

Rat complementary DNAs of SCD-1,  $\Delta 6$  desaturase and  $\Delta 5$  desaturase were kind gifts from Juris Ozols (Department of Biochemistry, University of Connecticut, Central Health, Farmington, CT, USA), Tsunehiro Aki (Department of Molecular Biotechnology, Hiroshima, Japan), and Reza Zolfaghari and Catharine Ross (Department of Nutritional Sciences, The Pennsylvania State University, University Park, PA, USA), respectively. Restriction enzymes and other molecular biology reagents were obtained from Promega (Madison, WI, USA). LXR agonist T09 was a kind gift from Amgen (South San Francisco, CA, USA).

### Animal Treatment

Male Wistar rats from our animal room, weighing 170–200 g, were used. Animal care followed international rules for experimentation with animals. They were fed on a complete commercial diet, containing 5.5% of lipids (Cargill, Buenos Aires, Argentina) and water ad libitum. The fatty acid composition of the food was 22.5 wt% 16:0, 1.1 wt% 16:1, 13.7 wt% 18:0, 25.9 wt% 18:1n-9, 2.5 wt% 18:1n-7, 30.7 wt% 18:2n-6 and 3.4 wt% 18:3n-3.

Diabetes type 1 was induced in nonfasted rats by intravenous injection of streptozotocin (70 mg/kg body weight) dissolved in 10 mM citrate buffer, pH 4.5, while control rats received only the vehicle. A week later, streptozotocin-treated rats were fasted for 12 h, and glycemia was determined by a commercial enzymatic method (Wiener Lab Test, Rosario, Argentina). Only animals with glycemia above 300 mg/dl were considered diabetic.

The rats were then separated into four control groups, three of which received the following by oral

gavage: first group, 10 mg/kg weight/day T09 for 6 days; second group, 100 mg/kg weight/day fenofibrate for 9 days; third group, same doses of both drugs, fenofibrate for 9 days and T09 for the last 6 days.

The streptozotocin diabetic rats were separated into four groups, of which three received the following by oral gavage, where appropriate: first group, T09 for 6 days as before; the second group was injected with 5 U/kg weight/day glargine insulin for 6 days; the third group received simultaneously the insulin and T09 treatment for 6 days.

After the periods indicated, the animals were fasted overnight and killed by decapitation without anesthesia, at the same time, in the morning to avoid circadian rhythm effects.

### Blood Parameters

Glycemia, insulinemia [16] and cholesterolemia (by a commercial enzymatic method, Wiener Lab Test, Rosario, Argentina) were measured.

### Liver Organelle Fractionation

After killing the animals, livers were excised and homogenized in a solution (1:3 wt/vol) composed of 0.25 M sucrose, 0.15 M KCl, 9.1 mM EDTA, 1.41 mM *N*-acetyl cysteine, 5 mM MgCl<sub>2</sub> and 62 mM phosphate buffer (pH 7.4). Samples were centrifuged at 10,000g for 30 min and postmitochondrial supernatant was used for fatty acyl-CoA oxidase assay. Microsomes were separately by differential ultracentrifugation at 100,000g (Beckman Ultracentrifuge) as usual. Protein concentration was measured according to the procedure of Lowry et al. [17].

### Lipid Analysis

Lipids were extracted from liver homogenate and microsomes according to the procedure of Folch et al. [18]. The samples were esterified with F<sub>3</sub>B at 64°C for 3 h.

The fatty acid composition of microsome total lipids was determined by gas-liquid chromatography of their methyl esters. They were injected into an Omega Wax 250 (Supelco, Bellefonte, PA, USA) capillary column of 39 m, 0.25-mm inner diameter and 0.25  $\mu$ m film. The temperature was programmed to obtain a linear increase of 3 °C/min from 175 to 230 °C. The chromatogram peaks were identified by comparison of their retention times with those of authentic standards.

## Enzymatic Activity Assays

Acyl-CoA oxidase was assayed in the liver postmitochondrial supernatant by measuring palmitoyl-CoA dependent  $\text{H}_2\text{O}_2$  production according to the spectrophotometric method of Small et al. [19].

The SCD-1 activity was estimated in hepatic microsomes using as a substrate  $30 \mu\text{M}$  [ $1\text{-}^{14}\text{C}$ ]stearic acid, the  $\Delta 6$  desaturation using  $40 \mu\text{M}$  [ $1\text{-}^{14}\text{C}$ ] $\alpha$ -linolenic acid and the  $\Delta 5$  desaturation using  $40 \mu\text{M}$  [ $1\text{-}^{14}\text{C}$ ]eicosa-8,11,14-trienoic acid. The acids were incubated with 2.5 mg of microsomal protein in a final volume of 1.5 ml at  $36^\circ\text{C}$  for 15 min. The reaction mixture consisted of 0.25 M sucrose, 0.15 M KCl, 1.41 mM *N*-acetyl-L-cysteine, 40 mM NaF, 60  $\mu\text{M}$  CoA (sodium salt), 1.3 mM ATP, 0.87 mM NADH, 5 mM  $\text{MgCl}_2$  and 40 mM potassium phosphate buffer (pH 7.4). After incubation, free fatty acids were dissolved in methanol/water/acetic acid (85:15:0.2 by volume), and fractionated by reversed-phase high-performance liquid chromatography on an Econosil C18, 10-mm particle size, reversed-phase column (250 mm  $\times$  4.6 mm) (Alltech Associates, Deerfield, IL, USA), coupled to a guard column (10.4 mm filled with pellicular C18). The mobile phase consisted of methanol/water/acetic acid (90:10:0.2 by vol) at a flow rate of 1 ml/min. The Merck–Hitachi (Darmstadt, Germany) L-6200 solvent delivery system was used. The eluate from the column was monitored by a UV spectrometer at 205 nm for fatty acid identification on the basis of retention times. The effluent was mixed with Ultima Flo-M scintillation cocktail (Packard Instruments, Downers Grove, IL, USA) at a 1:3 ratio, and the radioactivity was measured by passing the mixture through an online Radiomatic Instruments (Tampa, FL, USA) Flo-One- $\beta$  radioactivity detector fitted with a 0.5-ml cell.

The assay for the microsomal chain elongation of palmitoyl-CoA was performed by measuring the incorporation of [ $2\text{-}^{14}\text{C}$ ]malonyl-CoA into palmitoyl-CoA [20].

## Measurement of mRNA of Desaturases

Total liver RNA of different animals tested was isolated with a Wizard RNA isolation system (Promega, Madison, WI, USA) according to the manufacturer's instructions. Twenty micrograms of total RNA was size-fractionated on a 1% agarose/formaldehyde gel and then transferred to a Zeta-Probe nylon membrane (Bio-Rad, Richmond, CA, USA). SCD-1,  $\Delta 6$  desaturase and  $\Delta 5$  desaturase, and  $\beta$ -actin probes were prepared by incorporating [ $^{32}\text{P}$ ]deoxycytidine 5'-triphosphate by random prime labeling. Northern blot hybridization

analyses were performed as described by Sambrook et al. [21]. The radioactive signals for mRNAs of SCD-1,  $\Delta 6$  desaturase and  $\Delta 5$  desaturase were quantified using a Phosphorimager apparatus (Molecular Dynamics, Sunnyvale, CA, USA). They were normalized to mRNA for  $\beta$ -actin with all the mRNAs probed on the same gel. Northern blot analyses were performed using an unpaired *t* test.

## Western Blot Analysis

Following the method performed by D'Andrea et al. [22], a polyclonal anti-rat  $\Delta 6$  desaturase antibody was produced. The 131 N-terminal amino acid section of the enzyme was selected for the construction of the glutathione *S*-transferase/ $\Delta 6$  desaturase fusion protein, using PCR amplification with the forward primer 5'-CAGTGGATCCATGGGGGAAGGGAGGTA-3' and the reverse primer 5'-CTGCTCGAGTCACAGGTGGTTGGTTTTGAAAAGG-3'. The purified bacterial expressed fusion protein was used as an immunogen on rabbits.

Total microsomal protein samples (70  $\mu\text{g}$  per lane) were analyzed by sodium dodecyl sulfate polyacrylamide gel electrophoresis and blotted onto Hybond-ECL nitrocellulose membrane (Amersham Biosciences, Little Chalfont, UK). The membrane was probed with the anti- $\Delta 6$  serum obtained (1:33,000 dilution) and then with horseradish peroxidase conjugated anti-rabbit (Sigma) (1:5,000 dilution), using PBS-T buffer [11.5 g anhydrous disodium hydrogen orthophosphate, 2.96 g sodium dihydrogen orthophosphate, 5.84 g sodium chloride per liter, pH 7.5, with 0.1% (v/v) Tween 20], containing 5 and 1% nonfat dried milk, for saturation and incubation with antibodies, respectively. Washes were carried out using PBS-T buffer. Finally, peroxidase activity was revealed using Pierce ECL Western blotting substrate (Pierce, Rockford, IL, USA) and quantified using Kodak Digital Science software (Kodak, Rochester, NY, USA).

For SREBP-1 measurements, cytoplasmic and nuclear protein extracts were obtained using NE-PER nuclear and cytoplasmic extraction reagents (Pierce Biotechnology, Rockford, IL, USA). They were subjected to Western blot analysis as indicated above, except that anti-SREBP-1 antibody, K-10 (Santa Cruz Biotechnology, Santa Cruz, CA, USA), was used as the primary antibody (1:200 dilution).

## Statistical Methods

Data are expressed as means  $\pm$  standard deviation. Statistically significant differences among groups were

assessed by analysis of variance (Instat version 2.0, Graph Pad Software, San Diego, CA, USA). The Tukey–Kramer multiple-comparison test was used. Statistical significance was defined as  $P < 0.05$ .

## Results

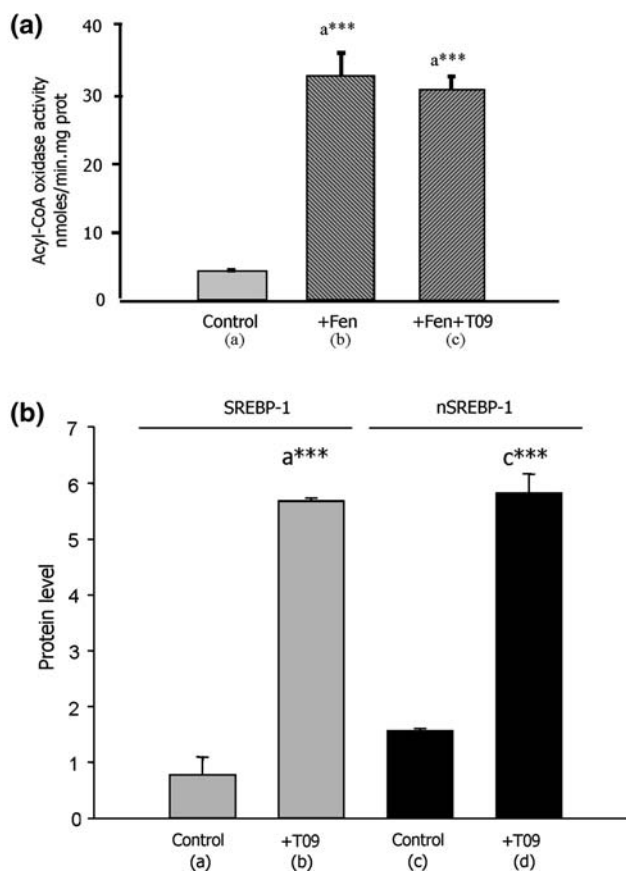

### Effects of Fenofibrate and T09 on Acyl-CoA Oxidase and SREBP-1

To confirm that the administration of fenofibrate activated PPAR- $\alpha$ , we measured, as usual, the effect evoked on its specific hepatic target enzyme, the extramitochondrial acyl-CoA oxidase. Figure 1 shows clearly that fenofibrate evoked an eightfold increase of the enzyme activity, and that the addition of T09, a specific agonist of LXR, did not modify that increase. On the other hand, the activating effect of T09 administration on the LXR response was assessed by the induced expression of the LXR target gene *srebp-1* [15]. Figure 1b confirms that in our experimental conditions the administration of T09 to nondiabetic rats enhanced LXR activity as evidenced by a 7.3-fold increase of the hepatic 125-kD SREBP-1 precursor and a 3.8-fold increase of the nuclear active 68-kD n-SREBP-1. SREBP-2 was not measured because it is encoded by a different gene to that of SREBP-1, and it preferentially activates cholesterol synthesis [14].

### Effects of T09 and Fenofibrate on Insulinemia and Cholesterolemia

Both in control rats, in which the level of insulin is normal, and in diabetic animals with undetectable insulinemia, T09 administration in the doses tested did not modify significantly glycemia, cholesterolemia or the corresponding insulinemia after 6 days of treatment (data not shown). On the other hand, fenofibrate administration to control animals for 9 days significantly increased insulinemia from  $1.32 \pm 0.61$  to  $2.36 \pm 0.13$  ng/ml ( $P < 0.05$ ), confirming our previously published data [11], while it did not alter glycemia and cholesterolemia (data not shown). The simultaneous administration for the last 6 days of 10 mg/kg weight/day of T09 to the fenofibrate-treated control animals did not alter glycemia, while insulinemia increased ( $3.13 \pm 0.47$  ng/ml) ( $P < 0.001$ ).

Fenofibrate enhancement of the circulating insulin level in normal rats is attributed to increased expression and activity of PPAR- $\alpha$  in view of the fact that using the test usually employed by other authors we found an increase of the target enzyme acyl-CoA oxidase (Fig. 1).

**Fig. 1** Assessment of the efficacy of fenofibrate and T0901317 (T09) in vivo activation of peroxisome proliferator activated receptor  $\alpha$  (PPAR- $\alpha$ ) and sterol regulatory element binding protein-1 (SREBP-1). **a** Effect of fenofibrate and T09 on extramitochondrial acylcoenzyme A oxidase activity in nondiabetic rats. Results expressed in nanomoles per minute per milligram of protein are the mean of four animals  $\pm$  the standard deviation (SD). **b** Effect of T09 on SREBP-1 precursor and nuclear active nSREBP-1 forms. Cytoplasmic and nuclear protein extracts were obtained using NE-PER nuclear and cytoplasmic extraction reagents and were subjected to Western blot analyses. Results expressed in arbitrary units are the mean of four animals  $\pm$  SD. Statistical differences were analyzed by analysis of variance (ANOVA).  $P < 0.001$

On the other hand, the addition of T09 to the control rats treated with fenofibrate evoked a specific depression of cholesterolemia from  $53.3 \pm 6.6$  mg/100 ml for the control rats,  $46.5 \pm 14.3$  mg/100 ml for control rats treated with T09 and  $60.9 \pm 6.6$  mg/100 ml for control rats treated with fenofibrate, to only  $25.7 \pm 5.7$  mg/100 ml ( $P < 0.001$ ) for control animals treated with fenofibrate and T09. In consequence, these results suggest an apparent interaction between PPAR- $\alpha$  and LXR in cholesterol-trafficking modulation.

Diabetic animals showed, as usual, significant increases of glycemia, no change of cholesterolemia and nearly undetectable insulinemia. T09 administration

did not significantly modify the levels of the aforementioned parameters as found in the diabetic animals and insulin increased insulinemia to about 0.20 mg/ml and normalized glycemia (data not shown).

#### Activating Effect of T09 and Fenofibrate on Fatty Acid Desaturase mRNA Levels

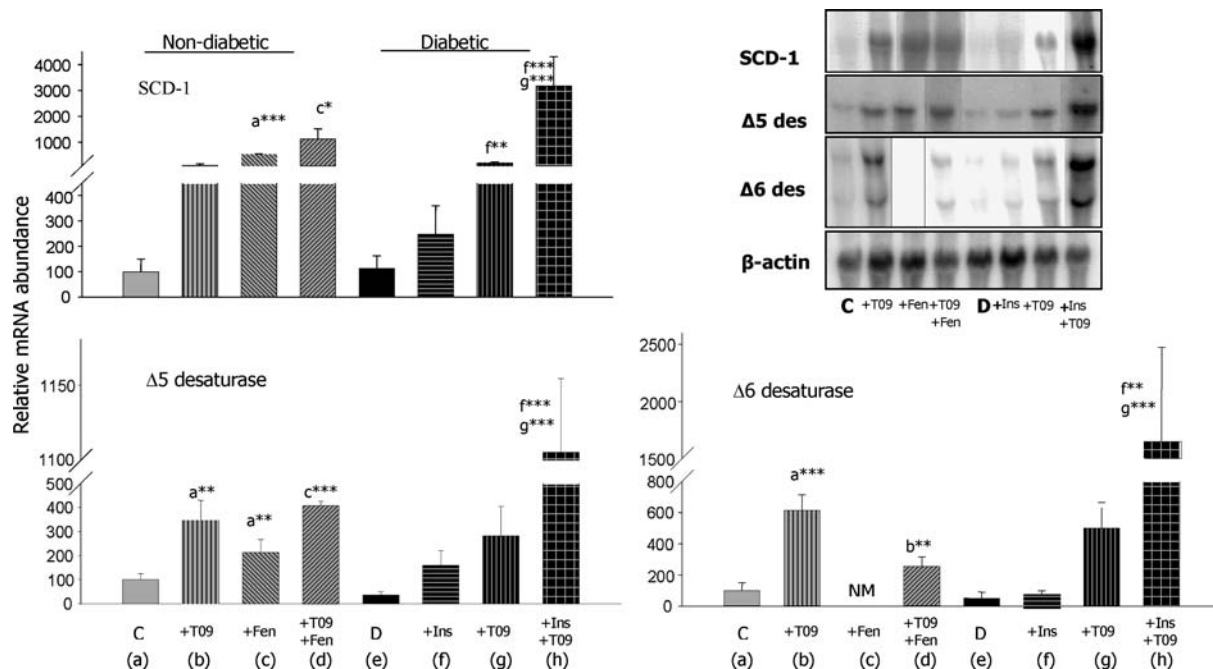

The effect of T09 and fenofibrate on control rats and that of T09 and insulin on the mRNAs levels of  $\Delta 6$  and  $\Delta 5$  desaturases and SCD-1 in diabetic animals are described in Fig. 2. It shows that not only the transcriptions of SCD-1 mRNA are modified but also that the mRNAs of  $\Delta 6$  and  $\Delta 5$  desaturases follow in general a similar pattern of changes.

Specifically Fig. 2 shows clearly that both in control and in diabetic rat livers, the mRNAs of SCD-1 and  $\Delta 6$  and  $\Delta 5$  desaturases were enhanced by the administration of LXR specific agonist T09, demonstrating that LXR activation evokes a similar insulin-independent increase of the three mRNAs. Therefore, these results support again, as found by Shulz et al. [15] and others, that LXR activates the *scd-1* liver expression, but now we add that this nuclear receptor also activates mRNA expression of  $\Delta 6$  and  $\Delta 5$  desaturases and the corresponding polyunsaturated fatty acid biosynthesis. Since

we found that LXR- $\alpha$  agonist T09 not only enhanced the expression of the three desaturases, but also the hepatic cytosolic SREBP-1 precursor (125-kD spot) and its nuclear active form nSREBP-1 (68-kD spot) (Fig. 1), our results are also consistent with a SREBP-1c mediated LXR- $\alpha$ /RXR- $\alpha$  dependent desaturase activation in which the secreted insulin through activation of SREBP cleaving activating protein (SCAP) [23] would cleave SREBP-1c to its nuclear active form.

Moreover, a large increase of the mRNA levels of  $\Delta 5$  and  $\Delta 6$  desaturases and SCD-1 was evoked by the T09 administration to the diabetic animals simultaneously treated with insulin (Fig. 2). This indicates an extraordinary hyperactivation of the expression of these enzyme mRNAs owing to a cooperative effect of LXR- $\alpha$  and insulin. Although LXR- $\alpha$  activates the expression of the mRNA of the three enzymes, both in normal rats having a normal insulin cycle secretion and in diabetic animals with undetectable insulinemia, only when LXR- $\alpha$  along with insulin were administered to the diabetic rats was the unexpectedly high synergic effect evoked. This effect could be explained by a SREBP-1c confluent stimulation.

In control rats, the administration of fenofibrate, a PPAR- $\alpha$  agonist, evoked an increase of  $\Delta 5$  desaturase and SCD-1 mRNAs (Fig. 2). A similar effect on  $\Delta 6$

**Fig. 2** Effects of T09 and fenofibrate (*Fen*) on control rats (*C*) and T09 and insulin (*Ins*) on diabetic rats (*D*) on the messenger RNAs (*mRNAs*) of stearoylcoenzyme A desaturase-1 (*SCD-1*), and  $\Delta 5$  and  $\Delta 6$  desaturases. Hepatic mRNA signals of desaturases as described in the text were quantified using a Phosphorimager apparatus and normalized to mRNA of  $\beta$ -actin. They are

expressed in arbitrary units referred to control rats (100) as the mean of four animals  $\pm$  SD. Statistical differences were analyzed by ANOVA in nondiabetic and diabetic animals, respectively. Different superscript letters indicate differences between this value and that in the group indicated by that letter. \*\*\* $P < 0.001$ ; \*\* $P < 0.01$ . ND not determined

desaturase mRNA, though not measured here, has been found by Montanaro and Brenner in an independent experiment (personal communication). In addition, Montanaro et al. [11] found an enhancement of  $\Delta 5$  desaturase and SCD-1 mRNAs not only in nondiabetic but also in diabetic rat livers after forced feeding with fenofibrate for 9 days; therefore, they demonstrate that PPAR- $\alpha$  activation evoked an increase of the mRNAs of the three desaturases that is not related to the presence of insulin.

The simultaneous administration of T09 and fenofibrate to control rats also evoked an increase of mRNAs  $\Delta 6$  desaturase,  $\Delta 5$  desaturase and SCD-1. However, whereas the increases of  $\Delta 5$  desaturase and SCD-1 were on the same order as for those rats administered T09 alone, the enhancement of  $\Delta 6$  desaturase mRNA was smaller. Anyhow, this demonstrated the absence of an additive stimulating effect between LXR- $\alpha$ /RXR- $\alpha$  and PPAR- $\alpha$ /RXR- $\alpha$  in the transcription of mRNA of desaturases.

#### Activating Effect of T09 and Fenofibrate on Fatty Acid Desaturase Enzymatic Activities

Figure 3 displays the individual and combined effects of T09 and fenofibrate, as well as those induced by insulin, T09 and their combination on the three liver desaturase activities in control and diabetic rats, respectively.

In control rats the results show rather similar effects of T09 and fenofibrate on the SCD-1,  $\Delta 5$  desaturase and  $\Delta 6$  desaturase activities. On the other hand, they correlate fairly well with those changes evoked by the same factors on the mRNA expression of SCD-1,  $\Delta 5$  desaturase and  $\Delta 6$  desaturase in the same group of rats.

As in the case of these mRNAs, the three desaturating enzymes were activated by T09 both in control animals and in diabetic rats, confirming that LXR- $\alpha$  activation may evoke an insulin-independent increase of activities of hepatic SCD-1,  $\Delta 6$  desaturase and  $\Delta 5$  desaturase.

However, since the activations of SCD-1,  $\Delta 5$  desaturase and  $\Delta 6$  desaturase enzymes evoked in diabetic rats by T09 or T09 plus insulin as shown in Fig. 3 were quantitatively equivalent and no up-shooting was found by treatment with T09 plus insulin, we may deduce that the overexpression of the desaturase mRNAs did not produce enzyme-equivalent proteins synthesis and folding since this was not correlated by similar increases of the enzymatic activities.

The changes evoked by T09, fenofibrate and fenofibrate plus T09 treatment on the translation of the  $\Delta 6$  desaturase in the control nondiabetic rats were also

**Fig. 3** Enzymatic activities of hepatic SCD-1 and  $\Delta 6$  and  $\Delta 5$  desaturases in nondiabetic and diabetic rats after T09 and fenofibrate treatment in vivo. Activities were measured as described in “Experimental Procedures” and are expressed in nanomoles per minute per milligram of protein and are the mean of four animals  $\pm$  SD. Statistical differences were analyzed by ANOVA as described in the legend to Fig. 2. \*\*\* $P < 0.001$ ; \*\* $P < 0.01$ ; \* $P < 0.05$ . NM not measurable, ND not determined

monitored by measuring the amount of  $\Delta 6$  desaturase protein by immunoblotting (Fig. 4). Data show that T09, fenofibrate and T09 plus fenofibrate increased the amount of  $\Delta 6$  desaturase protein in control animals in correspondence to what happened with the mRNAs and with the enzymatic activity. In consequence, they

support the idea that the increased desaturase activity in these animals was due to an increase of the amount of enzyme and that PPAR- $\alpha$  competes with LXR- $\alpha$  in the activation of  $\Delta 6$  desaturase.

#### Effect of T09 and Fenofibrate on Fatty Acid Elongation

Fatty acid elongation is another reaction that modifies the fatty acid composition of animal lipids by converting palmitoyl-CoA to stearoyl-CoA and also the polyunsaturated fatty acids of 18 carbons to long-chain polyunsaturated acids of 20, 22 and 24 carbons.

Figure 5 shows that whereas T09 administered alone to control rats only evoked a statistically nonsignificant increase of the microsomal hepatic palmitoyl-CoA elongase, fenofibrate alone or fenofibrate plus T09 increased fivefold and eightfold, respectively, the activity of the enzyme.

In the diabetic rats the elongase activity was low, but neither insulin nor T09 administration increased significantly the palmitoyl-CoA conversion to stearoyl-CoA: however, the simultaneous administration of T09 and insulin to diabetic rats increased around tenfold

**Fig. 4** Western blot analysis of  $\Delta 6$  desaturase of nondiabetic rats (C) treated with T09 and fenofibrate (Fen). A polyclonal anti-rat  $\Delta 6$  desaturase antibody was produced and total microsomal protein samples (70  $\mu$ g per lane) were analyzed by sodium dodecyl sulfate polyacrylamide gel electrophoresis, blotted on a Hybond-ECL nitrocellulose membrane, and the 45-kD spots were quantified as described in “Experimental Procedures.” Results expressed in arbitrary units referred to nondiabetic rats (100) are the mean of three animals  $\pm$  SD. Statistical differences were analyzed by ANOVA. \*\* $P < 0.01$

the activity of the reaction, showing again a synergic effect. Therefore, these results suggest that both LXR plus PPAR- $\alpha$  and LXR plus insulin evoke an important cooperative effect that upregulates palmitoyl-CoA elongase.

#### Effect of T09 and Fenofibrate on Microsomal Liver Lipid Fatty Acid Composition

Changes in the microsomal liver lipid fatty acid composition are monitored and widely used to detect the effect of changes in the food fatty acid composition as well as alterations evoked in the endogenous biosynthesis of fatty acids that may modify the biological status of an animal.

Table 1 shows the changes evoked by the aforementioned metabolic agents in microsomal fatty acid composition after only 9 days of treatment. Throughout this short period of time, the fatty acid composition of microsomal liver lipids was in general poorly modified by the different factors tested. However, early changes evoked by PPAR- $\alpha$  could be detected.

In control rats, though T09 increased the activity of all the desaturating enzymes, it did not evoke significant changes in the percentage of the acids, but on the other hand fenofibrate, which also modified the activity of the desaturases, not only doubled the percentages of palmitoleic acid and oleic acid and increased arachidonic acid, but decreased by half the proportion of the biologically important docosahexaenoic acid (22:6n-3)

**Fig. 5** Effect of T09, fenofibrate and insulin in vivo on hepatic palmitoylcoenzyme A elongase activity of nondiabetic and diabetic rats. Results expressed in nanomoles per minute per milligram of protein are the mean of four animals  $\pm$  SD. Experimental conditions, abbreviations and statistical differences analyzed by ANOVA are as described in the legend to Fig. 2. \*\*\* $P < 0.001$

and of the other n-3 polyunsaturated acids of 20 and 22 carbons. Also, it enhanced palmitic acid and depressed stearic acid.

The addition of T09 to fenofibrate did not much alter the effect of fenofibrate alone, and a similar increase of the percentages of palmitoleic acid and oleic acid, an equivalent depression of 22:6n-3 as well as the other changes were found. Therefore, it seems that in normal rats PPAR- $\alpha$ /RXR- $\alpha$  activation through the fenofibrate treatment was more effective than LXR- $\alpha$ /RXR- $\alpha$  activation through the T09 administration to evoke earlier changes in the fatty acid composition of liver lipids.

On the other hand, during the short period of diabetes tested, the only important change found was the increase of 22:6n-3, and insulin injection did not modify it significantly. This delayed action of diabetes and insulin agrees with their recognized time-dependent effect in the alteration of the fatty acid composition of different animal tissues [24]. T09 administration to diabetic animals did not modify the fatty acid composition, and the increase of 22:6n-3 was maintained. Besides, insulin and T09 when simultaneously administered to diabetic rats promoted a very significant increase of the monoenoic acids, palmitoleic and oleic, but not of other acids. Therefore, SCD-1 showed a stronger and more effective response than that of  $\Delta 5$  and  $\Delta 6$  desaturases to these combined effectors.

## Discussion

Since Burr and Burr demonstrated the essentiality of linoleic and  $\alpha$ -linolenic acids, it has been gradually shown that their biological effects are mainly produced through their conversion to the high polyunsaturated acids of 20 and 22 carbons of the n-6 and n-3 families and their derivatives, respectively. This conversion is mainly modulated by the  $\Delta 6$  and  $\Delta 5$  desaturases [1] that, therefore, play a key role in maintaining the healthy status of individuals. Their activity is altered in several diseases and it has been studied in depth in diabetes, in relation to inflammatory effects, oxidative stress, cholesterol metabolism, atherogenesis and, in general, cardiovascular diseases. However we have proved [1, 25] that the two main types of diabetes, type 1, evoked by insulin deficiency, and type 2, which shows normoglycemia or hyperglycemia, modify the activity of SCD-1 and  $\Delta 6$  and  $\Delta 5$  desaturases in opposite directions. In diabetes type 1, the three desaturases are downregulated, whereas in diabetes type 2, they are generally upregulated.

The downregulation evoked by diabetes type 1 is corrected by insulin, but we showed in the present

study that SREBP-1c, LXR and PPAR- $\alpha$  are also involved in this reactivation.

Firstly, we found that in control rats in which the cycle of blood insulin follows its normal rhythm of synthesis and degradation fenofibrate evoked an increase of insulinemia that exceeded the normal values. This effect was undoubtedly due to an activation of the PPAR- $\alpha$ /RXR heterodimer as usually tested by the enhancement of the peroxisomal specific target enzyme acyl-CoA oxidase; however, this hyperinsulinemia did not decrease the glycemia normal values, suggesting poor efficiency or the presence of compensatory metabolic effects.

The increasing fenofibrate effect on insulinemia in normal rats has already been shown and discussed in our previous publication [11] where it was found not to be evoked in insulin-treated diabetic rats. Therefore, the results suggest that PPAR- $\alpha$  stimulates pancreas insulin secretion and not decreased insulin degradation. However, while it is known [26] that PPARs are expressed in pancreatic  $\beta$  cells and many authors conclude that PPAR- $\alpha$  modulates insulin secretion of islets [27–29], there is no consensus on the mechanisms of action. In that respect, Tordzman et al. [30] have found by incubation of INS-1 cells, a rat insulinoma cell line, with clofibric acid for 48 h that this PPAR- $\alpha$  agonist decreased basal and glucose-stimulated insulin secretion. This effect would be evoked through a PPAR- $\alpha$  stimulated fatty acid oxidation that impairs  $\beta$ -cell function. However, Ravnskjaer et al. [29] proved that the expression of PPAR- $\alpha$ /RXR- $\alpha$  indeed potentiates glucose-stimulated insulin secretion in rat islets and INS-1E cells without affecting the mitochondrial membrane potential.

T09, which activates LXR- $\alpha$ , when administered to normal rats has no effect on insulinemia and glycemia, and it did not modify the hyperinsulinemia induced by fenofibrate, showing there was no interaction.

Notwithstanding this, Anderson et al. [31] and Ide et al. [32] found overlapping transcriptional programs regulated by PPAR- $\alpha$ , RXR and LXR- $\alpha$  in rodent liver and cross-talk between PPAR- $\alpha$  and LXR- $\alpha$  in nutritional regulation of fatty acid metabolism. These results suggested to the authors that LXR- $\alpha$  ligands evoked a reduction in the PPAR- $\alpha$ /RXR formation by competition of new LXR- $\alpha$  with PPAR- $\alpha$  for RXR in heterodimer formation, and therefore they decreased PPAR- $\alpha$ /RXR- $\alpha$  effects. This expected result, however, could not be detected in our experiment when administering T09 to these animals with increased fenofibrate-dependent insulinemia, suggesting an apparent lack of interaction in the case of pancreas insulin secretion.

The ineffectiveness of T09 to depress the normoglycemia in nondiabetic rats agrees with the results of Cao et al. [33] that showed that 1–100 mg/kg weight per day dosages of T09 were unable to evoke hypoglycemia. However, while we found that 10 mg/kg weight of T09 did not decrease hyperglycemia in our diabetic type 1 rats, they found significant decreases in hyperglycemia in obese insulin-resistant female Zucker (*fa/fa*) rats with doses from 3.0 to 30 mg/kg weight. That decrease was attributed by the authors to an increased insulin sensitivity and reduced gluconeogenesis derived from a depressed phosphoenolpyruvate carboxykinase. This apparent discrepancy might be due to the model of the diabetic animal studied. We used streptozotocin, insulin-deficient diabetic type 1 rats, whereas they used insulin-resistant diabetic type 2 animals [25].

However, the stimulation of LXR- $\alpha$  by T09 required the corresponding stimulation of PPAR- $\alpha$  by fenofibrate to depress the cholesterolemia that was decreased neither by LXR- $\alpha$  nor by PPAR- $\alpha$  separately. This cooperative effect between the two nuclear receptors on the depression of blood cholesterol level is due to the modulation of integrating factors of the PPAR/LXR cholesterol oxidation and efflux pathways [31, 34–36]. This suggests the convergence of the homeostatic mechanisms for cholesterol and fatty acid metabolism. In this respect, we demonstrated some time ago [37] an interaction of cholesterol with unsaturated fatty acid biosynthesis. It was shown that 1% of cholesterol in the diet for 21 days progressively activated hepatic SCD-1 mRNA transcription and activity, but it depressed enzymatic activity of  $\Delta 6$  and  $\Delta 5$  desaturases, modifying correlatively the fatty acid composition of liver lipids.

The present study of the effect of the mentioned nuclear receptors on liver fatty acid desaturase modulation showed, in the first place (Figs. 2, 3), that T09 administration by increasing LXR- $\alpha$  expression enhanced mRNA expression of hepatic SCD-1 and  $\Delta 6$  and  $\Delta 5$  desaturases as well as the activities of the same enzymes not only in control but also in diabetic rats with undetectable insulinemia.

The fact that LXR- $\alpha$  activation enhances the activity of SCD-1 has been already demonstrated in different ways in the last years by several authors [15, 38, 39], but in addition we prove here that LXR also activates  $\Delta 6$  and  $\Delta 5$  desaturases.

Moreover, Fig. 2 demonstrates a marked interaction between LXR- $\alpha$  and insulin in the modulation of the expression of fatty acid desaturases. In the first place, as indicated, LXR- $\alpha$  does not require the absolute assistance of insulin to evoke an enhancement of the desaturase expression, in view of the fact that in both normal and diabetic rats T09 administration increased

the mRNA expression of  $\Delta 6$  and  $\Delta 5$  desaturases and SCD-1 (Fig. 2). However, what is really remarkable, indicating an important insulin–LXR- $\alpha$  interaction, is that the activation of the LXR- $\alpha$  receptor not only increased per se the mRNA expression of  $\Delta 6$  and  $\Delta 5$  desaturases and SCD-1 in diabetic rats, but also the injection of insulin into the diabetic animals treated with T09 increased the expression strongly.

LXR- $\alpha$  not only enhanced the activity of the desaturases but also both SREBP-1 and nSREBP-1, and since Chen et al. [14] have already demonstrated the central role for LXR- $\alpha$  in the insulin activation of SREBP-1c transcription, and SREBP-1c per se has a pivotal role in expression and activity of desaturases [9, 10], the results obtained are easily explained by a collaborative effect of LXR- $\alpha$  and insulin in SREBP-1c activation that evokes the hyperexpression of the desaturases. The contribution of LXR- $\alpha$ /RXR- $\alpha$  is evoked through the induction of SREBP-1c gene expression as well as by an additional contribution of insulin through SCAP-dependent cleavage of the precursor SREBP-1c to the mature nuclear form nSREBP-1c [23].

This hyperexpression of the desaturase mRNAs by the joint action of LXR- $\alpha$  and insulin on the diabetic rats was, however, not correlated by a quantitatively similar increase of the desaturase enzymatic activities (Fig. 3), and therefore was not quantitatively transmitted to the ribosomal synthesis of desaturases.

PPAR- $\alpha$  activation by fibrates evokes also an increase of mRNAs and enzymatic activities of SCD-1 and  $\Delta 5$  and  $\Delta 6$  desaturases in control and diabetic rats as proved in this experiment and by Montanaro et al. [11]. In addition, Tang et al. [40] demonstrated that in rats, another PPAR- $\alpha$  activator, WY 14643, enhanced the transcription of hepatic  $\Delta 6$  desaturase by more than 500%. Moreover, they found that an imperfect direct repeat DR-1 element located at –385/–373 of the human  $\Delta 6$  desaturase gene possesses the ability to bind the heterodimer PPAR- $\alpha$ /RXR- $\alpha$  and subsequently to function as a PPAR- $\alpha$ -RE. The activation of  $\Delta 6$  desaturase mRNA expression by agonists of PPAR- $\alpha$  was also demonstrated by Matsuzaka et al. [10] and He et al. [41]. This fact that PPAR- $\alpha$  activation through fenofibrate administration activates both normal and diabetic rat [11] expression and activity of the desaturases demonstrates that the fenofibrate-dependent desaturase increase found in normal rats was not due to insulin in spite of the fact that insulinemia was enhanced by fenofibrate, but it was due to the genuine action of insulin-independent PPAR- $\alpha$ .

The simultaneous administration of T09 to fenofibrate-treated control rats did not further enhance significantly the activation of mRNA expression and

enzymatic activities of  $\Delta 5$  and  $\Delta 6$  desaturases and SCD-1 (Figs. 2, 3), and even the presence of fenofibrate reduced the enhancement of  $\Delta 6$  desaturase mRNA evoked by T09. Besides, Fig. 4 depicts a fenofibrate- and T09-dependent enhancement of the  $\Delta 6$  desaturase protein that follows a parallel pattern to the mRNA changes, but not the enzymatic activity. Therefore, we did not detect the existence, in control rats, of an additive effect of LXR- $\alpha$  and PPAR- $\alpha$  effects leading to an activation of unsaturated fatty acid biosynthesis through desaturase regulation.

The elongation of fatty acyl-CoAs is now considered another putative step in the control of polyunsaturated fatty acid biosynthesis [42]. PPAR- $\alpha$  as shown in Fig. 5 activates palmitoyl-CoA elongase in control rats and a simultaneous activation of LXR- $\alpha$  evokes a synergic effect. In that respect, according to Inagaki et al. [43] from two elongase genes identified in rats, rELO1 and rELO2, the rELO1 gene, a homologue of human ELOVL5, was shown to elongate monosaturated and polyunsaturated fatty acids of 16–20 carbons; however, its expression was little modified by fasting or rat re-feeding. On the other hand, the rELO2 gene expression in hepatocytes, which is responsible for palmitic acid elongation, was activated by fasting and refeeding cycles of the rats [42, 43]. Besides, a similar long chain fatty acid elongase that elongates saturated and monounsaturated acids was found to be activated in mouse liver by nSREBP-1c overexpression and T09 administration [44]. Therefore, a cross-talk exists between LXR- $\alpha$  and PPAR- $\alpha$  and LXR- $\alpha$  and insulin in elongase regulation. The mechanism and consequences of this activation are an interesting field for further investigation.

The translation of insulin, PPAR- $\alpha$ , LXR and SREBP activation of desaturase mRNA expression to the desaturases and their effects on liver fatty acid composition after a short treatment are depicted in Table 1. During this short period of time, the depressing effect of diabetes on the desaturase enzymatic activity was not found to be transferred to a statistically significant reduction of the unsaturated fatty acids. However, the activation of LXR- $\alpha$  by T09 and the simultaneous insulin administration to the diabetic rats, which evoked the highest desaturase expression, enhanced specifically palmitoleic and oleic acids synthesized by SCD-1, but not the  $\Delta 6$  and  $\Delta 5$  desaturase-dependent polyunsaturated acids. Therefore, that result is probably the consequence of a strong effect of LXR- $\alpha$  and insulin interaction on a SREBP-1c dependent activation specific for the SCD-1 desaturase reaction since it could not be detected after T09 administration to control and diabetic rats.

PPAR- $\alpha$ , in contrast, enhanced palmitic acid and depressed the amount of stearic acid, as already shown by Montanaro et al. [11], though it activated palmitoyl-CoA elongase (Fig. 5) and increased palmitoleic and oleic acids in correlation with an increase of SCD-1 activity (Fig. 3) [11, 45]. The increase of palmitic acid evoked by fenofibrate administration is difficult to understand, as attributed to an increased synthesis as already discussed by Montanaro et al. [11], in view of the antidyslipidemic, catabolic effect generally attributed to PPAR- $\alpha$  that would lead, as pointed out by Desvergne and Wahli [46], to the simultaneous activation of both anabolic and catabolic effects producing a futile cycle. However, in spite of the fact that the PPAR- $\alpha$  mediated activation of the malic enzyme gene generating the NADPH required for fatty acid synthesis might lead to lipid increases, on the other hand the coordinate genetic activation of acyl-CoA synthase, carnitine palmitoyl transferase I, medium-chain acyl-CoA dehydrogenase and liver fatty acid binding protein would evoke an increase of mitochondrial fatty acid oxidation [46], and we consider that the increase

of palmitic acid in liver phospholipids does not necessarily indicate an enhanced fatty acid biosynthesis antagonistic to the catabolic effect. We suggest that a possible PPAR- $\alpha$  dependent activation of a specific acyl-CoA synthase in coordination with an acyl-CoA transferase could lead to a diversion of palmitic acid to interesterify membrane phospholipids without antagonizing the catabolic pathway.

PPAR- $\alpha$  activation depressed the highly polyunsaturated acids of the n-3 family, 20:5n-3, 22:5n-3 and 22:6n-3, as usually observed in some treatments in spite of the increase of desaturase activity [1, 11]; therefore, it would depress the anti-inflammatory, antioxidant and anti-atherogenic effects attributed to these acids as well as the beneficial effects in brain cognitive behavioral development and glucose uptake.

## Conclusions

As summarized in Fig. 6, we have been able to demonstrate the contribution of LXR- $\alpha$ , insulin, SREBP-1c and

**Fig. 6** LXR- $\alpha$ , PPAR- $\alpha$ , SREBP-1c and insulin interactions on modulation of liver fatty acid desaturases and unsaturated fatty acid biosynthesis

PPAR- $\alpha$  in vivo interaction in the sophisticated modulation of SCD-1 and  $\Delta 6$  and  $\Delta 5$  hepatic desaturases. Briefly, LXR- $\alpha$  activation increases Srebp-1c expression. Also insulin increases srebp-1c expression in addition to SREBP-1c hydrolysis to the nuclear active form. These increases enhance the mRNAs of SCD-1 and also of the  $\Delta 6$  and  $\Delta 5$  desaturases. LXR- $\alpha$  and insulin interact evoking a large cooperative enhancement of mRNAs of the desaturases. PPAR- $\alpha$  also activates the expression of the desaturases, but independently of the contribution of SREBP-1c and insulin. LXR- $\alpha$  and PPAR- $\alpha$  interact through the coparticipation of RXR- $\alpha$  in the formation of the corresponding heterodimers LXR- $\alpha$ /RXR- $\alpha$  and PPAR- $\alpha$ /RXR- $\alpha$  in the activation of mRNAs of the desaturases and the enzymatic activities reach levels not higher than those evoked by LXR- $\alpha$ . However, the level of expression and the enzymatic activities reached require some time to concomitantly modify the fatty acid composition of tissue lipids. Therefore, the biosynthesis of unsaturated fatty acids is modulated in vivo by the interplay of all these factors that may modify the specific effects of insulin and are very important in human physiology. They must be considered for an appropriate treatment of diabetes and cardiovascular diseases.

Anyhow, it is necessary to remark that in normal and even abnormal physiological conditions, in vivo, the real modulators of these factors are the unsaturated fatty acids and derivatives which also control their own biosynthesis and are supplied in foods [47]. The structure of the unsaturated fatty acids determines also their activity [48, 49], and they compete in their own biosynthesis and even evoke retroinhibitions as demonstrated a long time ago [50].

**Acknowledgements** This research is published in honor of the coauthor María S. González who passed away in October 2006. The gifts of T0901317 from Amgen and the SCD-1,  $\Delta 6$  desaturase and  $\Delta 5$  desaturase complementary DNA from J. Ozols, T. Aki and R. Zolfaghari and C. Ross, respectively, are greatly acknowledged. This work was partially supported by grant PIP 5724 from CONICET, Argentina.

**Abstract** We studied lipid metabolism and the anti-oxidant defense system in plasma and liver of rats fed diets supplemented with  $L^{\omega}$ -nitro-L-arginine methyl ester (L-NAME), isosorbide dinitrate (DIS), L-arginine (Arg), or the associations of these drugs. Liver hydroperoxide and thiobarbituric-acid-reactive substance (TBARS) levels were decreased by Arg and increased by L-NAME or DIS treatments. Oxidized glutathione and conjugated dienes were increased by DIS. Nitrate + nitrite levels and serum calcium ( $[\text{Ca}^{++}]$ ) were incremented by Arg or DIS and reduced by L-NAME. Superoxide dismutase and catalase activities decreased under Arg treatment, while L-NAME or DIS caused stimulation. Liver high-density lipoprotein (HDL) cholesterol was increased by DIS or NAME (alone or associated with Arg). Free fatty acids and neutral and polar lipids were increased by Arg, L-NAME, and DIS. However, predominating phospholipid synthesis increased the neutral/polar ratio. Decreased levels of nitric oxide (NO) (low  $[\text{Ca}^{++}]$ ) was directly associated with increased fatty acid synthetase, decreased phospholipase  $A_2$ , carnitine-palmitoyl transferase, and fatty acid desaturase activities. Raised NO (high  $[\text{Ca}^{++}]$ ) inversely correlated with increased phospholipase- $A_2$  and acyl-coenzyme A (CoA) synthetase and decreased fatty acid synthetase and  $\beta$ -oxidation rate. Arg or DIS produced changes that were

partially reverted by association with L-NAME. Based on these observations, prolonged therapeutical approaches using drugs that modify NO availability should be carefully considered.

**Keywords** Oxidative stress · Calcium · Lipid metabolism · Rat liver · Nitric oxide

## List of Abbreviations

NO	Nitric oxide
$[\text{Ca}^{2+}]$	Calcium concentration
$[\text{NOx}]$	Nitrite plus nitrate concentration
Arg	L-arginine
CAT	Catalase
DIS	Isosorbide dinitrate
FAS	Fatty acid synthetase
GSHPx	Glutathione peroxidase
GSHRd	Glutathione reductase
GSHTTr	Glutathione transferase
LLC	Low-level chemiluminescence
L-NAME	$L^{\omega}$ -nitro-L-arginine methyl ester
NL	Neutral lipids
PL	Polar lipids (phospholipids)
PL- $A_2$	Phospholipase $A_2$
ROOHs	Lipid hydroperoxides
SOD	Superoxide dismutase

## Introduction

The central role of nitric oxide (NO) as a messenger molecule is well documented in various biochemical processes such as immune function [1, 2], inflammation [3–6], apoptosis and necrosis [7–10], neurotransmission

[11, 12], mitochondrial respiration [13, 14], and endothelial function [10, 15–19], among others. It has also been reported that NO production is involved in the regulation of carbohydrate metabolism [20, 21] and inhibition of the Krebs cycle [22]. Lipid metabolism is strongly influenced by antioxidant status, although the mechanism involved remains unknown. Previous works demonstrated that deficiency of ascorbate [23, 24],  $\alpha$ -tocopherol [25], and the oligoelements involved in the antioxidant system, such as selenium [26] or copper [27], were able to induce rapid and significant hyperlipidemia with a concomitant increase in liver very-low-density lipoprotein (VLDL) secretion [28]. A key study by Khedara et al [29] proved that serum concentration of nitrate negatively correlated with those of plasma triacylglycerides and total cholesterol. These authors concluded that lower NO levels in rats led to hyperlipidemia and that elevation in serum triacylglycerides might be due—at least in part—to reduced fatty acid (FA) oxidation [29, 30]. Taking into account that reduced NO production is one factor leading to hyperlipidemia and increased atherosclerotic risk [15–17, 29], we decided to further explore whether oxidative stress would affect lipid metabolism by either increasing or decreasing NO levels. Various enzymes of the antioxidant defense system and lipid metabolism, together with concentration of the major water- and lipid-soluble antioxidants, were also correlated with lipid composition in plasma and tissues of rats fed diets supplemented with  $L^{\omega}$ -nitro- $L$ -arginine methyl ester ( $L$ -NAME), isosorbide dinitrate (DIS)—usually employed as an antihypertensive drug in humans—and  $L$ -arginine (Arg) alone or in combination with other drugs. Considering the central role of lipid metabolism and antioxidant defense system in the pathogenesis of atherosclerotic lesions [6, 9, 15–17, 19, 31, 32], we investigated the mechanism by which changes in NO production might affect biochemical pathways involved in FA and complex lipid metabolisms.

## Materials and Methods

### Chemicals

The following chemicals were purchased from Sigma Chem. Co. (Buenos Aires, Argentina):  $L$ -NAME, Arg, standards for high-performance liquid chromatography (HPLC) (retinol, oxidized and reduced glutathione,  $\beta$ -carotene,  $\alpha$ - and  $\beta$ -tocopherols, FA methyl esters, glutathione, and ascorbate); snake venom (*Crotalus atrox* western diamondback rattlesnake); nicotinamide adenine dinucleotide (NAD)<sup>+</sup>, hydrogenated NAD

[NADH(H)], hydrogenated NAD phosphate [NADPH(H)], thiobarbituric acid; coenzyme A (CoA, lithium salt),  $N$ -ethylmaleimide, deferoxamine mesylate, organic and inorganic components for buffer preparations, triphenylphosphine; xylenol orange, tetraethoxypropane; sodium deoxycholate (grade II); delipidated serum albumin bovine serum albumin (BSA); fraction V from bovine); and butylated hydroxytoluene. DIS was purchased as Isordil from John Wyeth Lab. (Buenos Aires, Argentina). Sodium nitrite and nitrate were from Merck (Darmstadt, Germany). All solvents were HPLC grade and were provided by Carlo Erba, Milano, Italy. Silicagel G-60 plates for thin-layer chromatography (TLC) were provided by Fluka-Riedel-de Häen (Darmstadt, Germany). Lipid standards for TLC identification of neutral and polar lipids were from Serdary Research Laboratories (London, Ontario, Canada). Unlabeled FAs were provided by Nu-Chek Prep. (Elysian, MN, USA). Labeled [ $1\text{-}^{14}\text{C}$ ]FA (palmitic, linoleic,  $\alpha$ -linolenic, and eicosa-8,11,14-trienoic) (98–99% pure, 50–60 mCi/mmol) were obtained from Amersham Biosciences (Buckinghamshire, UK). All acids were stored in benzene under nitrogen atmosphere at  $-20\text{ }^{\circ}\text{C}$ . Concentrations and purities were routinely checked by both gas liquid chromatography (GLC) and liquid-scintillation counting. Other chemicals used were reagent grade from local commercial sources.

### Animal Treatment

Female Wistar rats from Comisión Nacional de Energía Atómica (Buenos Aires, Argentina) weighing  $170 \pm 10\text{ g}$  were bred and maintained on a control diet (Cargill type “C”, Rosario, Argentina) throughout gestation and lactation. Dams were housed in plastic cages (one animal per cage) in a vivarium kept at  $22 \pm 1\text{ }^{\circ}\text{C}$  with a 12-h light/dark cycle and relative humidity  $60 \pm 10\%$ . After weaning, 36 male pups (weighing  $46 \pm 4\text{ g/animal}$ ) were randomly divided into six groups of six animals fed ad libitum a balanced diet (group C) prepared in our laboratory as described in a previous paper [33]. Other groups were supplemented with Arg (40 g/kg) $L$ -NAME (200 mg/kg), DIS (10 mg/kg), or a combination of Arg +  $L$ -NAME or DIS +  $L$ -NAME. During the ad libitum feeding period (35 days), body weight, water consumption, and food intake were determined every day. Blood samples (100–150  $\mu\text{l}$ ) were collected from the tail vein once a week to determine plasma calcium and nitrite + nitrate ([NOx]) levels. Animals were sacrificed on day 35 after feeding. To avoid individual differences among animals that might result from an ad libitum feeding, on day 34,

all rats were fasted for 24 h, re-fed with the corresponding diet for 2 h, and then killed by rapid decapitation without prior anesthesia 12 h after the re-feeding period. All diet components used were purchased from Carlo Erba (Milano, Italy) or Mallinckrodt (New York, USA). Animal maintenance and handling were in accordance with the National Institutes of Health (NIH) Guide for the Care and Use of Laboratory Animals [34].

#### Sample Collection and Subcellular Fraction Preparation

Liver, heart, kidneys, lungs, and brain from all experimental groups were rapidly excised and immediately placed in an ice-cold homogenizing medium [35]. The homogenates were processed individually at 1°C. Microsomal suspensions and cytosols (soluble fractions) were separated by differential centrifugation at 110,000 g, as described previously [35]. Microsomal pellets were resuspended in cold homogenizing solution up to a final protein concentration of 30 mg/ml. Mitochondrial suspensions from liver homogenates were obtained as described by Kler et al. [36]. Blood was also collected after killing the rats by decapitation. Samples were individually dispensed into heparinized tubes and fractionated by centrifugation at 500 g (10 min). Plasmas were immediately processed for calcium determination following the method described elsewhere [37, 38] using the procedure of Tomlinson and Dhalla [39]. Nitrite plus nitrate levels were measured according to Verdon et al. [40]. Lipid analysis was performed as described above. Erythrocyte ghosts were prepared by hypotonic lysis according to the procedure of Dodge et al. [41] modified by Berlin et al. [42].

#### Oxidative Stress Biomarkers

Thiobarbituric-acid-reactive substance (TBARS) were measured by the fluorometric method of Yagi [43]. Organo peroxides were determined with the FOX version II assay for lipid hydroperoxides (ROOHs) (FOX2) according to Nourooz-Zadeh et al. [44]. Contents of oxidized glutathione (GSSG) were determined following the HPLC method of Asensi et al. [45], while reduced glutathione (GSH) was measured following the glutathione-S-transferase assay described by Brigelius et al. [46]. Samples for GSSG analyses were obtained in the presence of *N*-ethylmaleimide and deproteinized using trichloroacetic acid (15% final concentration) [45].  $\alpha$ - and  $\beta$ -tocopherols, lycopene, and  $\beta$ -carotene were determined by HPLC according to Butris and Diplock [47] as modified by Bagnati et al.

[48]. Ascorbate was determined in deferoxamine mesylate-treated samples by the method of Benzie et al. [49]. Catalase activity (CAT) was measured according to Aebi [50]. Cytosolic (Cu,Zn) and mitochondrial (Mn) superoxide dismutase (SOD) activities were assayed as described by Flohé and Ötting [51]. Glutathione peroxidase (GSHPx), glutathione transferase (GSHTTr), and glutathione reductase (GSHRd) were assayed according to Wheeler et al. [52], Habig et al. [53], and Carlberg et al. [54], respectively. Light emission by chemiluminescence from lipid peroxidation assays was measured following the procedure of Wright et al. [55] with some modification. Liver microsomal suspensions obtained from control Wistar rats (2 ml; 0.5 mg protein/ml) in 0.1 M TRIS-HCl buffer (pH 7.40) and 0.15 M KCl were incubated in glass vials at 25 °C with a solution containing 100  $\mu$ M Fe<sup>2+</sup> and 100  $\mu$ M sodium ascorbate to initiate nonenzymatic lipid peroxidation. Low-level light emission was continuously monitored in the dark over a 130-min period and recorded as constant photocurrent method (cpm) using a liquid scintillation counter (1214 Rackbeta Scintillation Counter, Turku, Finland) in the out-of-coincidence mode. At zero time, membrane preparations were supplemented with 0.5 mg cytosolic proteins from the different experimental groups. Other vials lacking ascorbate, Fe<sup>2+</sup>, or both were run as control assays in the same conditions. The sum of total chemiluminescence (areas under each curve) was used to calculate percent change in respect to the assay with no cytosol addition (reference curve).

#### Lipid Analysis and Enzyme Activities of Lipid Metabolism

Total lipids were extracted by the method of Folch et al. [56]. Phospholipid and neutral lipid fractions were separated from the Folch extracts by the microcolumn chromatography method described elsewhere [57] and/or TLC [58, 59]. GLC of fatty acid methyl esters (FAMES) was performed as indicated in our previous paper [60], except that in this case, we used a capillary column mounted on a Hewlett Packard HP 6890 Series GC System Plus (Avondale, PA, USA) equipped with a terminal computer integrator. The FAMES were identified by comparison of their relative retention times with authentic standards, and mass distribution was calculated electronically by quantification of the peak areas. Cholesterol content was enzymatically measured according to Allain et al. [61]. High-density lipoprotein (HDL) cholesterol was determined using a commercial kit (Wiener Lab. Rosario, Argentina). Total and neutral lipids were

estimated gravimetrically after evaporation of an aliquot of the corresponding lipid extract (Folch or silicic acid subfraction, respectively) up to constant weight [62]. Phospholipids were also measured as phosphorus content [63] after mineralization of an aliquot from the silicic acid partition. Phospholipase A<sub>2</sub> (PL-A<sub>2</sub>) activity was determined with [<sup>14</sup>C]phenylcyclohexene ([<sup>14</sup>C]PC) (24.0 mCi/mmol, 99% pure) as substrate according to the method of Hirata et al. [64] with the modifications described in our previous paper [65]. To determine FA desaturase activities in microsomal suspensions, each FA used as substrate [[1-<sup>14</sup>C] 16:0, [1-<sup>14</sup>C] 18:2 (n-6),  $\alpha$ -18:3 (n-3), or [1-<sup>14</sup>C] 20:3 (n-6)] was diluted to a specific activity of 0.20–0.25  $\mu$ Ci/mol with the respective pure unlabeled FA. In order to compare results, enzymatic assays were conducted at saturated substrate concentrations. Analyses were done as described in previous papers [65, 66]. Acyl-CoA synthetase assays were performed on cytosol fractions obtained as supernatants of 110,000 g, according to the method of Tanaka et al. [67] modified as described in our previous paper [38]. FA synthetase activity was assayed according to Horning et al. [68]. Carnitine-palmitoyl transferase activity was measured following the method of Bieber and Fiol [69], while the rate of  $\beta$ -oxidation was determined as the production of acid-soluble metabolites derived from [1-<sup>14</sup>C]palmitate in hepatic microsomal suspensions as described by Kler et al. [36]. Ketone bodies (acetoacetate plus 3-hydroxybutyrate) were measured according to Laun et al. [70] by an enzymatic assay using 3-hydroxybutyrate dehydrogenase. Free fatty acids (FFAs) were determined as described in the paper of Duncombe and Rising [71].

#### Other Methodologies

Calcium content was determined after sample mineralization by atomic absorption in a Shimadzu Atomic Absorption Spectrophotometer AA-630-12 (Shimadzu Corp., Kyoto, Japan) or calcium-sensitive electrode model 93-20 (Orion Res. Inc., Cambridge, MA, USA) as described elsewhere [37–39]. Protein content was determined by the micromethod of Bradford [72] with crystalline BSA as standard.

#### Graphic Software and Statistical Treatment of Data

All values represent the mean of six individual determinations (assayed in duplicate)  $\pm$ 1 standard error of the mean (SEM). Data were analyzed by either the Student's *t* test or by analysis of variance (ANOVA), with the aid of Systat (version 8.0 for Windows) from

SPSS Science (Chicago, IL, USA). Results were also plotted and analyzed using Sigma Scientific Graphing Software (version 8.0) from Sigma Chem. Co. (St. Louis, MO, USA) and/or GB-STAT Professional Statistics Program (version 4.0) from Dynamic Microsystems Inc. (Silver Springs, NV, USA).

## Results

### Animal Model

We found that the addition of L-NAME, Arg, or a combination of these drugs to the standard diet produced no significant differences in final body weight or water consumption among the experimental groups (data not shown). From day 15 to the end of the experiment, DIS or DIS + L-NAME groups showed a 16% increase and a 19% decrease (mean values compared to control group, not statistically significant) in the water and diet consumption, respectively, either expressed as milliliter water/body weight, milliliter water/rat, or grams food/body weight, grams food/rat.

### Oxidative Stress Biomarkers

Figure 1 shows the plasma [NO<sub>x</sub>] during the feeding period. Inclusion of DIS in the diet composition produced a rapid and sustained increase in [NO<sub>x</sub>] concentration detected 5 days after treatment. Values were maintained at this level up to the end of the experimental period. The effect of DIS was not significantly modified by association with L-NAME. Arg caused an increase in [NO<sub>x</sub>] levels 10 days after treatment, reaching a maximum (three-fold in respect to control values) on day 15. Then it tended to decline slightly. L-NAME decreased the [NO<sub>x</sub>] concentration from day 5 up to the end of the experimental period. However, when Arg was associated with L-NAME, [NO<sub>x</sub>] values were restored to control values after 10–15 days of the combined treatment. Levels of [NO<sub>x</sub>] in soluble (cytosolic) fractions from different tissues of control and treated rats are shown in Table 1. Arg-treated rats exhibited increased [NO<sub>x</sub>] concentrations in liver, heart, and lungs. Association with L-NAME completely abolished these increments. Supplementation with L-NAME alone caused a significant reduction of [NO<sub>x</sub>] levels in all tissues studied, but this effect did not impair the important increment produced by DIS treatment in all soluble fractions analyzed. As a measurement of the oxidant capacity of cytosol fractions obtained from the different experimental groups, we

**Fig. 1** Nitrate + nitrite [NO<sub>x</sub>] concentration was determined in plasma samples obtained from the rats' tail vein every 5 days during the entire feeding period. Determination was based on reduction of nitrate to nitrite followed by Griess reaction (see "Materials and Methods"). Data are mean  $\pm$  1 standard error of the mean (SEM) (pmoles/mg protein) of duplicate or triplicate

measurements from six independent animals. \*Significantly different with respect to the corresponding control value ( $P < 0.01$ )

tested the increase or decrease in low-level chemiluminescence (LLC) induced by Fe/ascorbate in vitro (Fig. 2). The curve indicated as "P" (without cytosol addition) showed the importance of endogenous components as antioxidants, as total CCL (area under the curve) increased 123% with respect to that obtained after the addition of control cytosol considered as the reference curve. Cytosols from DIS- or DIS + L-NAME-treated rats increased LLC by 250% and 259%, respectively, whereas cytosol from L-NAME-treated rats produced a 32% increase. Supplementation with Arg or Arg + L-NAME decreased LLC by -64% and -26%, respectively, with respect to the ref-

erence curve. "M" and "R" curves demonstrated that there was no spontaneous LLC—at least in a detectable extension—without induction by ascorbate or Fe/ascorbate.

Plasma from the Arg group showed increased values of TBARS, tocopherols, GSH, ascorbate, and carotene + glutathione, whereas retinol contents were decreased (Table 2) in comparison with the control group. L-NAME-treated rats showed increased levels of TBARS and ROOHs with respect to the control group. Ascorbate was also decreased in DIS- and DIS + L-NAME-treated rats and increased in Arg-supplemented animals. The combination of Arg +

**Fig. 2** Low-level chemiluminescence [constant photocurrent method (cpm)  $10^3$ , mean of six determinations] induced by Fe/ascorbate in vitro at 25°C in control liver microsomes as a function of time. Control microsomes were incubated in a buffer solution (pH: 7.40) supplemented with cytosol fractions (0.5 mg protein/ml) obtained from liver of rats fed different experimental diets. Nonenzymatic peroxidation of lipids was induced by addition of Fe/ascorbate at zero time. Curve “P” represents data obtained in the presence of liver cytosol fraction from

nonsupplemented diet. *Control* corresponds to no cytosol addition. *M* and *R* are curves obtained without addition of cytosol and lacking Fe or ascorbate, respectively. Cytosol from L-arginine (Arg)- (filled diamond); Arg + L-nitro-L-arginine methyl ester (L-NAME)- (square with dot); L-NAME- (filled square); P- (filled circle); DIS + L-NAME- (circle with dot); and DIS- (open circle) treated animals. Standard errors of the mean (SEM) were omitted for simplicity, and they were between 5% and 8% of each mean value

L-NAME restored all values to control levels with the exception of GSH. Ratios of GSH/GSSG for Arg, L-NAME, and Arg + L-NAME groups were not modified with respect to control group. DIS or DIS + L-NAME treatments produced similar alterations in all biomarkers assayed. ROOHs and TBARS were increased, lipid soluble antioxidants were dramatically reduced, and ascorbate was decreased by  $27\% \pm 3\%$  with respect to the control group. The ratios of GSH/GSSG in DIS and DIS + L-NAME groups were decreased by 51% and 84%, respectively, compared with the control group. In DIS-treated rats, conjugated dienes also showed a marked increase with respect to other groups.

Table 3 shows the activities of some enzymes of the antioxidant defense system in plasma and erythrocytes from six experimental groups. Erythrocyte SOD and CAT activities were decreased by Arg treatment and increased by L-NAME supplementation. Glutathione-related enzymes were not significantly altered in either plasma or erythrocyte lysates from these experimental groups. Combined supplementation with Arg + L-NAME restored the activities of both enzymes to control values. DIS- or DIS + L-NAME-treated rats showed an important increase in SOD and GSHPx activities from plasma and erythrocytes, whereas CAT activity in erythrocytes was reduced by 41–45% with

respect to the control group. Characteristic stress biomarkers in liver from treated rats are shown in Table 4. The pattern of alterations was similar to that observed in plasma (Table 2). Livers from the Arg group exhibited decreased contents of tocopherols and increased amounts of  $\beta$ -carotene + glutathione. Arg caused a reduction in ROOHs and TBARS, whereas L-NAME supplementation produced an increment in both biomarkers with an elevation in diene conjugate concentration. In the Arg group, tocopherols were significantly decreased. The addition of L-NAME to the Arg diet neutralized all these alterations. However, L-NAME was ineffective in restoring the modifications caused by DIS, such as the elevation in ROOHs, TBARS, and diene conjugate levels and the concomitant decreased in tocopherol and ascorbate contents. The ratio GSH/GSSG decreased in DIS-treated rats compared with control rats.

Table 5 shows enzyme activities of the antioxidant defense system in liver of treated rats. SOD activity was measured using selective inhibitors for Mn-, Cu, and Zn-dependent isoforms [sodium cyanide and sodium dodecyl sulfate (SDS)]. Arg decreased both SOD isoforms and, as a consequence, total SOD activity. CAT was also diminished compared with controls. Glutathione-related enzymes were not significantly

Biomarkers were determined according to the methods described in "Materials and Methods." Results were calculated in different ways and are expressed as the mean  $\pm$  1 standard error of the mean (SEM) of six independent determinations assayed in duplicate or triplicate

C control, Arg L-arginine, L-NAME L $\omega$ -nitro-L-arginine methyl ester, DIS isosorbide dinitrate

\*Significantly different with respect to the corresponding control value ( $P < 0.01$ )

modified. L-NAME supplementation produced increased total SOD activity at the expense of the cytosolic isoform, with no changes in the other enzymes assayed. Modifications observed for Arg or L-NAME were abolished by combination of these two drugs. DIS and DIS + L-NAME groups showed significant increments in SOD isoforms, GSHPx, and GSHPd activities with concomitant reduction of CAT activity.

#### Lipid Metabolism Parameters

Enzymatically determined total cholesterol and HDL cholesterol in plasma and liver microsomal suspensions are shown in Table 6. Total cholesterol was increased by supplementation with Arg, L-NAME, DIS, or

DIS + L-NAME. HDL cholesterol was reduced by DIS treatment either alone or in combination with L-NAME. As a result, the ratio HDL/total cholesterol was decreased in the Arg-, L-NAME-, DIS-, and DIS + L-NAME-treated groups. In liver microsomes only DIS supplementation produced a significant increase in cholesterol content that could not be reverted by simultaneous supplementation with L-NAME.

Supplements that modified NO levels also affected the absolute and relative amounts of neutral (NL) and polar (PL) lipids in liver microsomes and plasmas (Table 7). Liver NL and PL were increased by Arg, L-NAME, DIS, or DIS + L-NAME. The ratio NL/PL was decreased in the L-NAME-supplemented group. The same experimental groups exhibited elevated

levels of NL and PL in plasma. The ratio NL/PL decreased significantly in Arg, L-NAME, DIS, and DIS + L-NAME groups.

Table 8 shows modifications in FFA and ketone bodies in plasma from treated rats. Increased production of NO by Arg, DIS, or DIS + L-NAME supplementation increased FFA concentration. Ketone bodies were elevated in DIS and DIS + L-NAME groups.

Some key enzymes of long-chain FA metabolism were measured under different experimental conditions (Table 9). Particulate PL-A<sub>2</sub> activity was diminished by the addition of L-NAME to control diet and elevated by DIS or DIS + L-NAME supplementation. Transport of FA into mitochondria was decreased by Arg, L-NAME, DIS, or DIS + L-NAME treatments. The rate of FA oxidation was also decreased in the same experimental groups. L-NAME supplementation increased acyl-CoA synthetase activity and decreased all FA desaturase activities measured. Groups treated with either DIS or DIS + L-NAME showed decreased activity of the fatty acid synthase (FAS) complex. We also analyzed the composition of fatty acyl chains in NL and PL from plasma and liver subfractions under the different experimental conditions. Figure 3 shows a typical fatty acyl pattern expressed in terms of FA ratios corresponding to PL in liver microsomal fractions. Similar modifications were observed in total lipids from plasma and liver homogenates and in NL from liver (data not shown). Monoenoic/saturated FA ratio was decreased in all experimental groups except the Arg-supplemented one with respect to control animals (which was taken as 0% change). The ratio of linoleic/arachidonic FA was significantly increased

only in the L-NAME group, whereas the docosahaenoic/docosapentaenoic ratio was elevated in all experimental groups.

#### Calcium Levels in Liver and Plasma from Treated Rats

Atomic absorption measurements of [Ca<sup>2+</sup>] in liver postmitochondrial supernatants and microsomal suspensions are shown in Table 10. Arg supplementation increased the concentration of calcium, whereas L-NAME produced a significant reduction. Combination of these supplements had no effect. DIS or DIS + L-NAME groups exhibited increased contents of [Ca<sup>2+</sup>]. Similar results were obtained in crude homogenates (data not shown). In liver microsomes, Arg, DIS, or DIS + L-NAME treatments elevated calcium levels, whereas L-NAME alone caused depletion. Total (free + linked to proteins) circulating [Ca<sup>2+</sup>] was not modified by any treatment (Table 10).

## Discussion

### Calcium Concentration and Oxidative Stress Biomarkers

It is well known that NO can both promote and inhibit lipid peroxidation [31]. By itself, it acts as an efficient scavenger of lipid peroxy radicals induced by a variety of oxidants, thus preventing the accumulation of oxidative chain propagators [73, 74]. However, in the presence of superoxide, NO forms peroxynitrite, which is a powerful oxidant capable of initiating lipid peroxidation and destroying water and lipid-soluble antioxidants and even deactivating antioxidant enzymes [74, 75]. We demonstrated that feeding rats with L-NAME decreased [NOx] levels in both plasma and homogenates from several tissues. Previous experimental data proved that more than 90% of [NOx] is derived from nitric oxide synthase (NOS) activity and that the contribution of the diet to [NOx] level is negligible [75]. Considering that the mean life of [NOx] in biological fluids is very short, the anion level indicates recent status in the activity of NOS isoforms [75]. We also observed how the level of [NOx] was increased after Arg supplementation in a more physiological way than that produced under the administration of pharmacological doses of DIS. This is very important, as supplementation with Arg reduces atherosclerotic risk, decreases platelet aggregation, and inhibits monocyte adhesion to endothelial cells [76–79], all of which are promising effects with therapeutic

**Table 8** Free fatty acids (FFA) and ketone bodies (KB) in plasma from treated rats

implications [80–83]. Considering the dual behavior of NO as a pro- and an antioxidant [31, 84], it is not surprising that inhibition of NO with L-NAME is currently considered a neuroprotective strategy without undesirable side effects [82, 83]. However, our study also demonstrated that alterations in NO levels may induce dangerous modifications in other components

of the antioxidant defense system and in calcium concentration.

Although NO was first discovered as a mediator of vascular smooth relaxation, where it leads to a decrease in intracellular  $[Ca^{2+}]$  [85], other investigations carried out in several tissues demonstrated that treatments with NO and/or NO donors elicit increases in

[Ca<sup>2+</sup>] [86]. This effect persists even in the absence of extracellular calcium and is dependent on ryanodine-sensitive calcium-release channels [86]. NO and peroxynitrite are responsible for [Ca<sup>2+</sup>] increase in the cytosolic compartment of various cell types [86–93]. Other reports suggested that peroxynitrite levels and, in general, NO availability determine calcium handling, especially from mitochondrial and endoplasmic reticulum stores [90, 91, 93]. Moreover, Berkels et al. [94] demonstrated a close correlation between NO and [Ca<sup>2+</sup>] by simultaneous detection using fluorometric probes. We found that there was a direct relationship between NO availability and [Ca<sup>2+</sup>] in liver homogenates, postmitochondrial supernatants, and microsomal suspensions. Perhaps this effect was produced through alterations in superoxide and/or peroxynitrite concentrations as suggested in previous reports [86, 88, 90, 93]. We observed unaltered total [Ca<sup>2+</sup>] in plasma. This may not be surprising and could be attributed to a compensatory mechanism that involves large calcium bone stores.

Modification in water- and lipid-soluble antioxidant levels may be an adaptive response to compensating peroxynitrite formation. It seems that there is an optimal concentration of NO that maintains antioxidant concentrations and GSH/GSSG ratio within the physiological range. Other authors suggested that there may be a relationship between NO availability and glutathione content [95, 96]. We also think that elevated NO may stimulate enzymes that synthesize glutathione, perhaps through a stimulatory effect of oxidative stress on  $\gamma$ -glutamyl-cysteinyl synthase

activity as previously reported for the central nervous system [96]. Changes described for antioxidant contents were reflected in the ability of cytosol fractions for quenching the low-level chemiluminescence signal derived from Fe/ascorbate-induced lipid peroxidation. It is feasible to speculate that such an in vitro effect may correlate with similar actions displayed in vivo.

ROOHs and TBARS are usually used as indicators of lipid peroxidation. A slight increase in NO production exerted a protective effect in liver homogenates but not in plasma. Decreasing or significantly increasing NO generation led to an opposite effect that was more evident in liver homogenates and plasma. These changes agree with previously discussed pro- and antioxidant actions of NO [31, 72–75, 84].

SOD is one of the key enzymes for controlling excessive superoxide production in both cellular compartments (mitochondrial matrix and cytosol) through activity of their specific isoforms. Hydrogen peroxide generated by these isoenzymes is further reduced to water by GSH peroxidase and by catalase. Thus, the content of GSH and SOD are both considered the predominant antioxidant defense, at least in liver [52]. The relative importance of CAT as a scavenger of peroxide depends—in consequence—on the availability of GSH, and conversely, levels of GSH are affected by the specific activity of CAT. SOD and CAT are inducible by oxidative stress and incremented NO levels [52]. GSHRd is also incremented by elevation of the GSSG/GSH ratio. We found that SOD isoforms were elevated in both plasma erythrocytes and liver homogenates by high levels of NO. On the contrary, SOD activities decreased in liver homogenates and erythrocytes under a mild increment of NO. This phenomenon may be the consequence of a minor superoxide production due to the antioxidant effect of NO and, as discussed before, may involve therapeutic implications for NO donors [74–83]. Thus, when L-NAME suppressed NO production, the oxidative status derived from this event significantly increased SOD activity. Oscillations in the activities of SOD isoforms were also in accordance with changes in the GSH/GSSG ratio. There was an inverse correlation between this ratio and the SOD activity that was more evident in DIS-treated animals. Results obtained may be analyzed in different ways, and multiple comparisons can be performed. However, if we focus the impact evoked by dietary supplements on liver biomarkers, some key conclusions can be obtained. The ratios [(GSHRd/GSHPx) × 10<sup>2</sup>], [CAT/SOD) × 10<sup>2</sup>], and [(GSHPx/SOD) × 10<sup>2</sup>] reflect the effort of the antioxidant defense system in maintaining the GSH/GSSG ratio between physiological values, neutralizing peroxide

overproduction, and reducing the formation of superoxide, respectively. Under excessive NO generation, the first ratio was increased significantly, as the stimulation of GSHRd observed in the DIS groups was insufficient to compensate for the level of SOD activity. Similarly, when NO levels were more physiological, CAT/SOD ratio was maintained at a mean value of 3.10. However, under excessive NO production, this ratio dropped to 0.90 because stimulation of CAT was unable to compensate for the SOD increase.

#### Lipid Metabolism and NO Availability

Diets that modified NO availability produced a major impact on lipid metabolism at both systemic and liver levels. Our findings concerning the changes in cholesterol content were in agreement with those previously reported by Khedara et al. [29, 30]. These authors suggested a relationship between cholesterol and the concentration of plasma nitrates. In addition, we found that the increase in plasma total cholesterol produced by either increased or decreased NO production was accompanied by elevated cholesterol levels in liver microsomes under DIS supplementation (not reverted by L-NAME). Interestingly, HDL cholesterol decreased in DIS groups and, as a result, a significant reduction in HDL/total cholesterol ratio was observed in experimental groups in which NO was decreased or increased by dietary manipulation. It is important to note that this finding was also observed under Arg or L-NAME treatment; both are currently used in human therapeutic approaches [74–83]. Our results suggest that careful consideration should be taken in prolonged administration of Arg or L-NAME in order to consider their real impact on one factors leading to hyperlipidemia and increased atherosclerotic risk. Hyperlipidemia induced by dietary manipulation was not mediated by renal dysfunction, as previous papers demonstrated that kidney size, serum creatinine, and albumin were not modified by prolonged administration of Arg or L-NAME [29, 30]. This study further demonstrated an important decrease in the NL/PL ratio especially observed in plasma under both NO depletion and increment of NO production. In these two conditions, alterations of the NL/PL ratio were the consequence of significant increments of both types of glycerolipids, with a predominant increase in PL concentration. These results showed for the first time that NO availability can simultaneously modify neutral and polar glycerolipid content in plasma and liver microsomes. Thus, in addition to the effects exerted on cholesterol metabolism, defective or excessive formation of NO should be considered a key point in

atherosclerotic patients receiving drugs that directly (or indirectly) modify NOS activity. The underlying mechanism that justifies these modifications is an issue that remains to be elucidated. Our study demonstrated that increased or decreased NO levels in plasma and tissues correlated with increased contents of plasma FFA and, in the case of NO overproduction, with a concomitant elevation of plasma ketone bodies. Misbalance in NO production established an oxidative stress condition that led to impairment of FA oxidation. In agreement with this, we found significant decreases in carnitine-palmitoyl transferase activity and acetate formation as an indicator of  $\beta$ -oxidation rate.

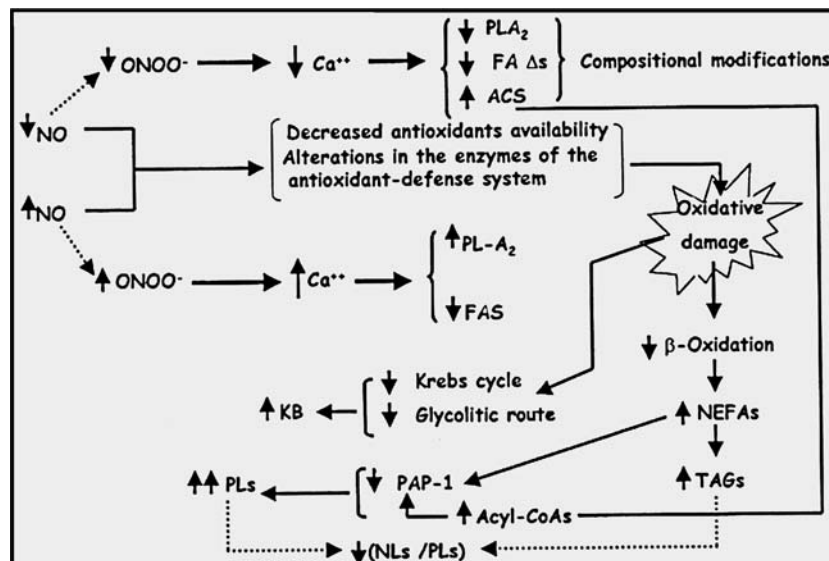

Interestingly, FA desaturase activities were inhibited in the L-NAME-treated rats in which availability of NO was depressed. This finding may be justified by our previous report concerning the general inhibitory effect exerted by deprivation of  $[Ca^{2+}]$  on FA desaturase enzymes [37]. Only L-NAME-treated animals underwent a constant low level of NO and exhibited diminished  $[Ca^{2+}]$  in liver homogenates and microsomal suspensions. In the same experimental group, acylation of FFAs was stimulated by calcium deprivation in accordance with our previous findings [38]. PL- $A_2$  is another key enzyme for glycerolipid metabolism. We found a direct correlation between NO levels,  $[Ca^{2+}]$ , and PL- $A_2$  activity. In the group in which  $[Ca^{2+}]$  was decreased, PL- $A_2$  was inhibited, and conversely, increased NO levels and  $[Ca^{2+}]$  stimulated PL- $A_2$  activity. This question is crucially important from the physiological point of view, as liberation of polyunsaturated fatty acids (PUFAs) (especially arachidonate) from PL stores plays a key role under different pathological conditions associated with modifications in local or systemic NO concentrations [97, 98]. We observed that the lipogenic enzyme FAS was inhibited when NO was generated in excess. Previous studies from other laboratories demonstrated that this enzyme was unaffected under discrete modifications of NO or administration of NO inhibitors [29]. However, DIS-treated animals showed a significant reduction of FAS activity, probably exerted via elevation of peroxynitrite and  $[Ca^{2+}]$  [99], and/or the strong accumulation of FFAs observed in these animals [100]. In addition, Mohr et al. [20] demonstrated that excessive NO formation inhibits glyceraldehydes-3-phosphate dehydrogenase. This fact may lead to depletion of the glycolytic route that in conjunction with the inhibitory effect exerted by NO on the Krebs cycle [22, 101] and mitochondrial respiration [13, 14, 102, 103] produced a general failure in availability of precursors and energy for FA synthesis.

All these modifications in lipid metabolism were reflected on the fatty acyl pattern of liver and plasma lipids. Alterations observed are difficult to analyze, as they depend on at least three factors: precursor desaturation–elongation rate, antioxidant influence, and selective  $\beta$ -oxidation (catabolism) and/or peroxidation (oxidative damage). In brief, we think that monoenoic/saturated FA ratio was diminished in the L-NAME group as a consequence of the inhibition of  $\Delta 9$  desaturase activity (via decrease in NO and  $[Ca^{2+}]$  availability) [37]. In DIS-treated rats, a less important decrease in this ratio may be attributed to a relative accumulation of saturated FA, perhaps due to a minor  $\beta$ -oxidation rate (the extension of which exceeded that of FAS inhibition). Decreased activities of  $\Delta 6$  and  $\Delta 5$  FA desaturases may account for the elevated linoleic/arachidonic FA ratio observed in L-NAME-treated animals. Biosynthesis of 22:6 (n-3) is carried out in mitochondria and depends critically on carnitine and  $\alpha$ -tocopherol levels [104]. In fact, this ratio was employed as an indicator of  $\alpha$ -tocopherol deficiency in mitochondria [105]. We found that there was a direct correlation between vitamin E levels and nmoles of 22:6 (n-3) per mg protein. However, the amount of 22:5 (n-3) also decreased at different proportions among the experimental groups, resulting in the ratios observed. Decrease of 22:5 (n-3) by peroxidation was intense in DIS-treated animals (data not shown). However, they exhibited minor values in the 22:6 (n-3)/22:5 (n-6)

ratios. This may be the consequence of the extensive drop in the amount of docosahexaenoic acid, which correlates with the important deficiency of  $\alpha$ -tocopherol in these experimental groups. Alterations in the ratio of PUFAs acylated to glycerolipids in general and to PL in particular should be considered of physiological relevance from at least two points of view: modifications in physicochemical properties of biomembranes (and indirectly most of their functions) as well as misbalance in the production of eicosenoids derived from the n-6 family (proinflammatory and proaggregating factors) and n-3 homologs (antiaggregating and anti-inflammatory) [106].

## Conclusions

Figure 4 depicts a general view of our findings. Oxidative damage can occur due to either increased or decreased NO levels through alterations in the antioxidant defense system (antioxidant depletion and/or modifications of antioxidant enzymes). Key enzymes in the lipid metabolism were also modified in a calcium- and NO-dependent way. A failure in the main producing energy routes was the consequence of changes in NO and in the oxidative-stress-derived condition. Decreased  $\beta$ -oxidation of FA was accompanied by increased production of ketone bodies and FFA concentration that may be channeled, at least in part, to

**Fig. 4** General scheme showing the main changes evoked by oxidative stress due to increased or decreased nitric oxide (NO) levels. Alterations in the antioxidant defense system and in the activities of enzymes are also shown in relation to calcium concentration ( $[Ca^{++}]$ ) and NO. ACS acyl-CoA-synthetase; FA

$\Delta s$  fatty acid desaturases, FA(s) fatty acid(s), FAS fatty acid synthetase, KB Krebs cycle, NEFAs nonesterified fatty acids, NLs neutral lipids, ONOO<sup>-</sup> peroxynitrite, PAP-1 phosphatidate-phosphohydrolase-1, PL-A<sub>2</sub> phospholipase A<sub>2</sub>, PLs polar lipids (phospholipids), TAGs triacylglycerides

glycerolipid biosynthesis. Accumulation of FFA and increased acylation of CoA inhibited phosphatidate-phosphohydrolase-1 activity [107]. Such a condition resulted in more availability of phosphatidate to be transformed into glycerophospholipids. Increased PL biosynthesis overcomes that of NL and, as a result, LN/PL ratio decreased. This metabolic situation should be considered in detail when modifications of NO levels are implemented in an attempt to ameliorate the consequences of graft rejection, immune disorders, septic shock, and cardiovascular and neurological pathologies [78–85], among others [108].

**Abstract** Miltefosine (hexadecylphosphocholine, HePC) is the first effective oral agent for the treatment of visceral leishmaniasis. The characteristics of HePC incorporation into the human intestinal epithelial cell line Caco-2 were investigated in order to understand its oral absorption mechanism. The results provide evidence for the involvement of a carrier-mediated mechanism, since the association of HePC at the apical pole of Caco-2 cells was (1) saturable as a function of time with a rapid initial incorporation over 5 min followed by a more gradual increase; (2) saturable as a function of concentration over the range studied (2–200  $\mu\text{M}$ ) with a saturable component which followed Michaelis–Menten kinetics (apparent  $K_m$  15.7  $\mu\text{mol/L}$ ,  $V_{max}$  39.2 nmol/mg protein/h) and a nonspecific diffusion component; (3) partially inhibited by low temperature and ATP depletion, indicating the temperature and energy-dependence of the uptake process. Moreover, we demonstrated, by an albumin back-extraction method, that HePC is internalized via translocation from the outer to the inner leaflet of the plasma membrane and that HePC may preferentially diffuse through intact raft microdomains. In conclusion, our results

suggest that incorporation of HePC at the apical membrane of Caco-2 cells may occur through a passive diffusion followed by a translocation in the inner membrane leaflet through an active carrier-mediated mechanism.

### Introduction

Miltefosine [hexadecylphosphocholine (HePC)], an alkylphosphocholine belonging to the antitumor ether lipids (AELs), is the first effective oral agent against *Leishmania donovani*, the parasite responsible for visceral leishmaniasis (VL), with a 98% cure rate of VL patients [1] with a dose of 2.5 mg/kg daily for 28 days [2]. This drug is considered as a breakthrough in antileishmanial treatment because of its high efficacy, its low toxicity and its high oral bioavailability which is a major advantage over currently employed antileishmanial drugs that require parenteral administration. Although the remarkable activity of HePC after oral administration has been demonstrated, little is known so far about HePC uptake by the intestinal epithelium. This question is all the more relevant since a previous *in vivo* study on the distribution of alkyl analogs of lysophosphatidylcholine in mice demonstrated a very remarkable depot effect at the sites of administration, especially after oral dosing where more than 80% of the drug remained in the gastro-intestinal tract 5 h after administration [3]. In this context, it was of particular interest to investigate the mechanism of

HePC uptake by the intestinal epithelial cells in depth in order to elucidate the reason for this sequestration.

The intracellular distribution and metabolism of radiolabeled HePC was determined in MDCK cells [4], and found to be similar to that of other AELs which showed a high affinity for the plasma membrane and appeared to accumulate in the phospholipid bilayers of cellular membranes [5, 6], but not in the cytosolic fraction. Although the primary target of AELs is thought to be the plasma membrane, the mechanism of the cytotoxic action of AELs remains unknown. It has been demonstrated that after incorporation in the plasma membrane, they influence physical properties such as permeability [7] and fluidity [6, 8], inhibit normal phospholipid metabolism [9] and affect several membrane proteins including protein kinase C [10] and phospholipase C [11].

The mechanism of HePC accumulation within the enterocyte plasma membrane could be either passive diffusion or a specific and saturable process. Kelley et al. [12] proposed passive diffusion as the possible uptake mechanism of another ether lipid, edelfosine (ET-18-OCH<sub>3</sub>), by leukaemia cells, whereas other authors [13] suggested that internalization of ether lipids occurred through an endocytotic mechanism. On the other hand, there is strong evidence for the involvement of an active or carrier-mediated mechanism in the uptake of HePC into various membranes. Indeed, the transporters ligand-effect modulator 3 protein (Lem3p) [14] and LdMT (*L. donovani* putative Miltefosine Transporter) [15, 16] have recently been found to be required for the inward translocation of HePC into *Saccharomyces cerevisiae* yeast cells and *L. donovani* parasites, respectively.

The aim of this study was to investigate the mechanism(s) of HePC uptake by the human intestinal epithelial cells. The human colon carcinoma cell line Caco-2 was used as a suitable in vitro model system for studying intestinal uptake [17]. The objectives of this study were (1) to demonstrate whether the HePC association with these cells involved an active or passive mechanism and (2) to characterize the cellular accumulation by studying the kinetics of the cellular uptake and binding.

## Materials and Methods

### Materials

[<sup>3</sup>HC<sup>9</sup>-<sup>3</sup>HC<sup>10</sup>]HePC was synthesized as described previously [18, 19]. Its purity was monitored by  $\beta$ -imaging and was found to be 96%. Working solutions

were prepared with isotopic dilution and the specific activity was fixed at 50  $\mu$ Ci/mmol. HePC was obtained from Cayman Chemical Company (Ann Arbor, MI, USA). Solutions of HePC (10 mM) were freshly made in water or in Krebs modified buffer immediately before each experiment. Dulbecco's modified Eagle's medium (DMEM), phosphate-buffered saline (PBS), fetal bovine serum (FBS), non-essential amino acids solution (NEAA 10 mM, 100X), penicillin-streptomycin solution (10,000 units/ml penicillin and 10 mg/ml streptomycin), trypsin-EDTA solution (0.05% trypsin, 0.53 mM EDTA) were obtained from Invitrogen-Life Technologies. Transwell<sup>®</sup>-clear polyester membranes 12-well (1 cm<sup>2</sup> surface area, 0.4  $\mu$ m pore size) and 12-well cluster trays were purchased from the Costar Corning Corporation (NY, USA). The Cytotoxicity Detection Kit (LDH) was from Roche Diagnostics (Meylan, France). Ultima Gold<sup>™</sup> liquid scintillation was from Perkin Elmer Life Science Products (Boston, USA). All others chemical products were from Sigma-Aldrich (St Louis, MO, USA).

### Cell Culture

Caco-2 cells (passages 45–65) were cultured in DMEM supplemented with 20% FBS, 1% non-essential amino acids, 1% L-glutamine, and 1% penicillin–streptomycin mixture. Cells were kept at 37 °C in 5% CO<sub>2</sub> and 95% humidity. Every week, cells were trypsinized and seeded at  $5 \times 10^4$  cells per insert onto 12-well Transwells<sup>®</sup> or at  $5 \times 10^4$  cells per well in simple 12-well trays. Cells were then grown in the plates for a minimum of 14 days and used for experimentation between days 14 and 21. The medium was changed daily. The quality of the monolayers grown on the polyester membrane was assessed by measuring the transepithelial electrical resistance (TEER) using a EVOM Epithelial Tissue Voltohmmeter (World Precision Instrument, Sarasota, FL, USA). Monolayers that displayed a TEER of 200–300  $\Omega$  cm<sup>2</sup> were used in the experiments. For all the experimental conditions used, cell viability and plasma membrane integrity were checked using the MTT colorimetric assay [20] and the LDH release assay [21], respectively, as previously described [22].

### Cellular Accumulation Experiments

The incubation medium consisted of Krebs modified buffer: 5.4 mM KCl, 2.8 mM CaCl<sub>2</sub>, 1 mM MgSO<sub>4</sub>, 0.3 mM NaH<sub>2</sub>PO<sub>4</sub>, 137 mM NaCl, 0.3 mM KH<sub>2</sub>PO<sub>4</sub>, 10 mM glucose, and 10 mM HEPES/Tris (pH 7.4) or 10 mM MES/Tris (pH 6.0). For cellular incorporation studies from the apical side, Caco-2 cells were grown

on 12-well dishes for 14 days. Before experiments, the culture medium was removed and cells were washed three times with substrate-free incubation medium consisting of Krebs modified buffer pH 6.0. The compounds to be tested were dissolved in the same buffer. For cellular incorporation studies from the basolateral side, cells were grown on permeable supports (Transwell®) for 18 days. The pH of the incubation medium was adjusted to 6.0 in the apical compartment and 7.4 in the basolateral compartment. The culture medium in the apical and basolateral compartments was removed by aspiration, and monolayers were washed three times with substrate-free incubation medium at 37 °C, 30 min before the beginning of the experiment. At time 0, buffer containing [<sup>3</sup>H]HePC was added to the apical (0.5 ml) or basolateral (1.5 ml) compartment of the insert. At the end of the incubation period, the medium was immediately collected; the cells were washed three times with ice-cold Krebs modified buffer, solubilized with Triton-X100 at 1% and the amount of radiolabeled compound within Caco-2 cell monolayers was determined by counting the samples in a Beckman LS 6000TA liquid scintillation counter.

Unless otherwise indicated, 20 μM HePC was used for cellular accumulation studies, and incubations were carried out at 37 °C for 1 h in Krebs modified buffer. When the effect of endocytosis and metabolic inhibitors on HePC accumulation was investigated, cells were preincubated with Krebs modified buffer pH 6.0 containing the inhibitor for 30 min at 37 °C prior to the uptake study. When the influence of cholesterol on HePC accumulation was investigated, Caco-2 cells were incubated for 48 h in 20% FBS DMEM medium containing 25 μg/ml of cholesterol. This treatment has already been used to obtain cells with a high cell cholesterol concentration [23]. Cholesterol was dissolved in ethanol and added to the culture medium. The medium used for control incubation received the same amount of ethanol, at a concentration not exceeding 0.3% in the final incubation medium.

### Cellular Fractionation

The cell fractionation method used was adapted from previously described methods for different cell lines [24, 25]. Caco-2 cells, grown on 12-well dishes, were incubated for 1 h with [<sup>3</sup>H]HePC (20 μM, 0.1 μCi per well). At the end of the incubation period, cell monolayers were washed three times with ice-cold Krebs modified buffer and were then incubated 15 min at 4 °C with digitonin 0.01% in Krebs modi-

fied buffer for selective permeabilization of the plasma membrane. Cells in suspension were centrifuged 1 min at 16,000g. The supernatant, corresponding to the cytosolic fraction, was collected. The cell pellet was washed three times by resuspension in Krebs modified buffer and centrifugation (5 min, 500g). The pellet was then resuspended in Krebs modified buffer supplemented with 1% Triton X100 and incubated for 10 min at 4 °C to solubilize the cell membranes. The suspension was then centrifuged at 16,000g for 5 min at 4 °C and the resulting supernatant containing the cell membranes was referred as the Triton-soluble fraction. The pellet, containing the nucleus and cytoskeleton, was washed, solubilized in Chaps solution and referred as the Triton-insoluble fraction. The amount of radiolabeled compound in each fraction was determined by liquid scintillation counting.

Cytosolic lactate dehydrogenase (LDH), a stable cytoplasmic enzyme, was used as a cytosolic marker and the LDH activity was determined in each fraction. As described previously [26], a correct permeabilization protocol should result in than 80% of recovery of LDH in the cytosolic fraction. The amounts of LDH in the Triton-soluble and Triton-insoluble fractions were negligible, and 85.4 ± 3.2% of total cellular LDH were found, as expected, in the cytosolic fraction. The 100% value for LDH was determined by the addition of Triton 1% to control cells.

### Energy Depletion

To investigate whether the HePC incorporation was energy-dependent, the total intracellular ATP level was reduced using a method previously described [27]. Both the oxidative phosphorylation and the glycolytic pathways were blocked, by omitting glucose from the transport medium and supplementing it with sodium azide (NaN<sub>3</sub>, 10 mM), sodium fluoride (NaF, 2 mM) and 2-deoxyglucose (2-DG, 50 mM). After 30 min incubation at 37 °C, medium was removed, [<sup>3</sup>H]HePC (20 μM, 0.5 μCi per well) in Krebs modified buffer pH 6.0 was added and the cellular association was determined as described above.

### Evaluation of HePC Translocation Across the Cell Membrane

The assay for translocation was performed by using a method previously described for lysophosphatidylcholine [28]. This procedure is reported to remove the drug located in the outer leaflet of the plasma membrane. Briefly, after incubation with [<sup>3</sup>H]HePC,

back-extraction of HePC was performed by washing the cells three times with Krebs modified buffer with or without 1% (w/v) fatty acid-free bovine serum albumin (BSA). Radioactivity counted after saline washes alone was considered to represent the total HePC in both leaflets of the bilayer, while that measured after albumin washes was considered to represent HePC which was inaccessible due to translocation to the inner leaflet of the lipid bilayer of the intact cells. The difference between these two values represented HePC remaining in the outer leaflet.

#### Kinetics Analysis of HePC Incorporation

To estimate the kinetic parameters of the saturable cellular accumulation by Caco-2 cell monolayers, [ $^3\text{H}$ ]HePC accumulation across the apical membrane was determined after a 1-h incubation by adding increasing concentrations of unlabeled HePC (2–200  $\mu\text{M}$ ) to the apical compartment at 4 and 37  $^{\circ}\text{C}$  for binding and uptake measurements, respectively. Michaelis–Menten plots were constructed to calculate the kinetic parameters (the apparent Michaelis–Menten constant  $K_m$  and the maximal velocity  $V_{\text{max}}$ ) of HePC uptake in Caco-2 cells using a nonlinear least-square regression analysis by Prism 4 (GraphPad Software).

#### Determination of Protein Content

The amount of HePC incorporated was expressed as the amount of cell-associated HePC relative to the protein content. Therefore, for total protein extraction, Caco-2 cells pellets were homogenized at 4 $^{\circ}\text{C}$  in lysis buffer (Tris 10 mM, EDTA 5 mM, NaCl 126 mM, Triton 1% and SDS 0.1%) supplemented with 100  $\mu\text{mol/l}$  aprotinin, leupeptin and pepstatin. The homogenates were centrifuged at 12,000g for 20 min at 4  $^{\circ}\text{C}$ , the supernatants collected and proteins were quantified using the Bio-Rad Protein Assay Kit with BSA as reference (Bio-Rad Laboratories, Hercules, CA, USA).

#### Statistics

All experiments were conducted at least in triplicate and results are expressed as mean  $\pm$  standard deviation (SD). Statistical analysis was performed using one-way analysis of variance (ANOVA) with a Mann-Whitney non-parametric post-test for double comparisons or a Student's  $t$  test (GraphPad InStat, San Diego, CA, USA). Statistical significance was accepted as  $P < 0.05$ .

## Results

### Effect of pH, Localization and Albumin on HePC Incorporation

The effect of pH on 20  $\mu\text{M}$  [ $^3\text{H}$ ]HePC incorporation from the apical and from the basolateral side of Caco-2 cell monolayers was investigated. The pH on the apical side was changed from 6.0 to 7.4, while the basolateral pH was fixed at pH 7.4, corresponding to the physiological serosal pH of cells. Figure 1 showed that, at a concentration of 20  $\mu\text{M}$ , the change in apical pH did not significantly affect drug uptake, indicating that the HePC uptake process by Caco-2 cells was independent of the proton gradient. It should be noted that HePC is a zwitterion over the pH range studied.

In order to study the polarity of HePC uptake in the intestinal cell, the total amount of HePC incorporated into the Caco-2 monolayer was determined after incubation with HePC in the apical or basolateral medium (Fig. 1). The results show that the total amount of HePC associated with the cells after a 3-h incubation was almost twofold lower after incubation on the basolateral side ( $3.36 \pm 0.16$  nmol/monolayer) than on the apical side ( $5.66 \pm 0.09$  nmol/monolayer) of the Caco-2 cell monolayer ( $P < 0.01$ ). It is unlikely that the presence of the polyester membrane is

**Fig. 1** Effect of pH and albumin on cellular accumulation of HePC from the apical (AP) and the basolateral (BL) side of Caco-2 cells. AP pH 6.0 and BL pH 7.4 (white bar); AP pH 7.4 and BL pH 7.4 (grey bar); AP pH 6.0 and BL pH 7.4 with albumin in the BL compartment (black bar); AP pH 6.0 and BL pH 7.4 with albumin in the AP compartment (cross-hatched bar). Cells were incubated with [ $^3\text{H}$ ]HePC (20  $\mu\text{M}$ , 0.5  $\mu\text{Ci}$  per well) either at the apical or the basolateral membrane surfaces for 3 h. All measurements are expressed as mean  $\pm$  SD of three determinations with three different monolayers ( $n = 9$ ). \*\* $P < 0.01$ , \*\*\* $P < 0.001$

responsible for the lower basolateral uptake of such a small molecule as HePC (MW 408), since the filter pore size was 0.4  $\mu\text{m}$  and since the transport of HePC in the apical-to-basolateral and in the basolateral-to-apical directions was similar [29].

Furthermore, the influence of adding human serum albumin to the apical or basolateral compartment was studied. As shown in Fig. 1, albumin in the basolateral compartment had no effect on HePC cellular accumulation on the apical membrane surface, but strongly inhibited its cellular accumulation when the drug was loaded basolaterally ( $0.31 \pm 0.06$  vs.  $3.36 \pm 0.16$  nmol/monolayer,  $P < 0.001$ ). The apical uptake of HePC was also markedly reduced when human serum albumin was added to the AP compartment compared to the apical uptake under albumin-free conditions.

#### Time-course of Incorporation of HePC at the Apical Cell Surface

The apical incorporation of 20  $\mu\text{M}$  [ $^3\text{H}$ ]HePC by the Caco-2 cells was determined as a function of time over a 5-h period (Fig. 2). A profile with an extremely rapid initial linear accumulation over the first 5 min followed by a more gradual increase was observed. The initial incorporation rate, measured as the slope of the regression analysis during the linear phase, was 0.78 nmol/mg protein/min. This extremely rapid initial

**Fig. 2** Time course of apical uptake of HePC by Caco-2 cell monolayers at 37 °C. Cells were incubated with incubation buffer containing [ $^3\text{H}$ ]HePC (20  $\mu\text{M}$ , 0.1  $\mu\text{Ci}$  per well) for 5 h. At various time intervals, the cellular accumulation was determined as described in the [Materials and Methods](#) section. All measurements were expressed as mean  $\pm$  SD ( $n = 12$ ). The equation of the linear regression analysis for the first 5 min was  $y = 3.8541x$ ,  $R^2 = 0.988$ . All measurements are expressed as mean  $\pm$  SD ( $n = 9$ )

incorporation suggested that association of the drug with the cell membrane was almost instantaneous. The accumulation of HePC was saturable and reached a plateau level of  $32.4 \pm 0.9$  nmol/mg protein after approximately 180 min, which persisted until at least 300 min. This slower increase in radioactivity could represent subsequent accumulation of HePC in cell membranes. The 1-h time point was used for all subsequent experiments to study both the concentration-dependence and the effect of various modulators on the apical association of HePC.

#### Subcellular Distribution of HePC

A previous study has shown that the accumulation of HePC within Caco-2 cells was very high compared with its transport across the monolayer, with more than 55% of the drug incorporated or sequestered within the cells after a 3-h incubation on the apical side [29].

The subcellular distribution of HePC in Caco-2 cells was investigated after a 1-h incubation (Table 1). The results show that more than 85% of the HePC incorporated into the cell was located in the membrane fraction whereas only 15% was located within the cytosol. No drug was found in the nucleus, in accordance with the observation that HePC does not interfere with DNA [30].

Taking into account our results and previous studies demonstrating that the cell plasma membrane is the main localization and site of action of HePC [5, 6], it is reasonable to assume that the majority of the HePC accumulated during our experiments was located within the plasma membrane.

#### Concentration-Dependence and Kinetics of HePC Incorporation at the Apical Surface

Cellular accumulation of HePC as a function of concentration was studied at 4 °C, a condition under which carrier-mediated processes are almost completely blocked and only nonspecific binding can take place. As shown in Fig. 3, this nonspecific binding of HePC was nonsaturable, since association of HePC with Caco-2 cells remained linear with respect to concentration in the range tested (2–200  $\mu\text{M}$ ). These results suggested that cell surface binding was not receptor-mediated (no extracellular membrane protein specific for HePC) and was more likely to occur by nonspecific insertion into the outer leaflet of the plasma membrane phospholipid bilayer.

At 37 °C, cellular accumulation of HePC was found to include a saturable component: the relationship between HePC accumulation rate and concentration

**Table 1** Subcellular distribution of HePC

Fraction	HePC (% <sup>a</sup> ) <sup>b</sup>
Cytosol	15.5 ± 1.9
Membranes	83.7 ± 3.4
Nucleus and cytoskeleton	0.8 ± 0.3

<sup>a</sup> Values are expressed as a percentage of total HePC accumulation in the cells

<sup>b</sup> Values are expressed as mean values ± SD of three separate experiments ( $n = 9$ )

**Fig. 3** Concentration-dependence of apical binding and uptake of HePC in Caco-2 cell monolayers. Cells were incubated apically for 1 h with increasing concentrations of HePC from 2 to 200  $\mu\text{M}$ , keeping the concentration of [ $^3\text{H}$ ]HePC constant at 12.5 nM (0.1  $\mu\text{Ci/ml}$  per well) and adding unlabeled HePC to obtain the desired concentrations. The cumulative accumulation curve (filled square) with both saturable and nonsaturable components was obtained at 37 °C, the nonsaturable (nonspecific) component (open square) was obtained at 4 °C. This component was subtracted from total uptake to calculate the saturable component (filled triangle) (specific uptake) which was used in kinetic analysis. *Inset* Eadie-Hofstee plots of HePC uptake after correction for nonsaturable component ( $B/F$  vs.  $B$ ;  $B$  is the rate of HePC bound to cells and  $F$  is the rate of free HePC). Each value represents the mean  $\pm$  SD of three separate experiments ( $n = 9$ )

was non-linear, indicating that a process other than simple diffusion occurred. The cellular accumulation of HePC due to the saturable component was determined by subtracting incorporation by the nonsaturable component (4 °C) from the total accumulation (37 °C) at each HePC concentration examined. The result indicated that apical HePC cellular accumulation into Caco-2 cells could be explained by a Michaelis–Menten-like expression rather than by simple diffusion alone. The kinetic parameters of the saturable component were determined after one hour of uptake

and were found to be 15.7  $\mu\text{mol/L}$  and 39.2 nmol/mg protein/h for the apparent  $K_m$  and  $V_{max}$ , respectively. The value of the diffusion constant for the nonsaturable component  $K_D$ , calculated as the slope of the binding line at 4 °C, was  $0.51 \pm 0.02$  ml/mg protein/h.

### Translocation of HePC within the Cell Membrane

To examine the involvement of a carrier-mediated process in HePC incorporation into Caco-2 cells further, we investigated how HePC was internalized. The translocation of the drug from the outer to the inner membrane leaflet was evaluated by an albumin back-extraction method described previously for lysophosphatidylcholine [28]. HePC, because of its phospholipid-like structure (single long alkyl chain), easily inserts into the outer leaflet of the plasma membrane lipid bilayer. The strong binding of HePC to albumin was used to remove accessible HePC from the outer monolayer of the membrane, and therefore determine the fraction of the drug translocated into the inner face of the bilayer and into the cell. The translocated fraction of HePC into Caco-2 cells was determined after 1-min and 1-h incubation at 37 °C and compared to the total membrane accumulation observed at 37 °C or 4 °C (Fig. 4). The fact that some HePC remained associated with the membrane after albumin washing demonstrated that HePC was translocated across the cell membrane. Moreover, initially (at 1 min), most of the HePC associated with Caco-2 cells could be back-extracted by albumin, demonstrating that a high proportion of the drug remained in the outer leaflet of the plasma membrane. In contrast, after a 1-h incubation, almost 75% of HePC accumulated at 37 °C remained cell-associated after back-extraction, indicating that the majority of the drug was translocated or internalized and therefore situated within the cells or in the inner layer of the plasma membrane. This result demonstrated an increase in internalization and retention over the time and suggested translocation of the drug from the outer to the inner bilayer of the plasma membrane.

These results were then compared with cellular accumulation at 4 °C, when carrier-mediated transport was inhibited. The initial cellular amount of HePC, measured at 1 min, was not significantly decreased at 4 °C compared with 37 °C, further demonstrating that at 1 min the major part of HePC cellular accumulation occurred in the outer leaflet of the plasma membrane. On the other hand, after 1 h, incubation at 4 °C led to a decrease in cellular accumulation of HePC to less than 60% of control. Given that transmembrane transport mechanisms are far more sensitive to low temperature than cell surface binding, these data support our

**Fig. 4** Assessment of internal and external HePC. [ $^3\text{H}$ ]HePC (20  $\mu\text{M}$ , 0.1  $\mu\text{Ci}$  per well) apical uptake by Caco-2 cells was determined after 1 min or 1 h incubation with saline washes at 37°C (black bar) or 4 °C (white bar), and with albumin washes at 37 °C (grey bar). Resistance to BSA back-extraction indicates movement of HePC from the outer membrane leaflet to another cellular location. Uptake at 37 °C without BSA back-extraction after a 1-h incubation was used as control. All measurements are expressed as mean  $\pm$  SD of three independent experiments with three monolayers ( $n = 9$ ). Values are expressed as a percentage of the control. \*\* $P < 0.01$

conclusion that a subsequent cellular incorporation through internalization occurred at 37 °C after 1 h.

#### Effect of Endocytosis and Metabolic Inhibitors on HePC Incorporation

To characterize the putative carrier responsible for HePC translocation in Caco-2 cells we examined the proportion of uptake that could be attributed to receptor-mediated endocytosis. We therefore used various endocytosis inhibitors such as colchicine, which disrupts microtubules, monensin, which acts by increasing endosomal pH, and cytochalasin B, which is an inhibitor of actin polymerization [31]. The extent of HePC uptake after these various treatments is given in Table 2. These treatments did not affect the amount of HePC associated with cells, suggesting that HePC internalization in Caco-2 cells did not occur via endocytosis but possibly by transbilayer movement.

In addition, the effect of ATP depletion was investigated. Therefore, cells were incubated with metabolic inhibitors, sodium fluoride, sodium azide and 2-deoxyglucose, a treatment that induces a rapid drop in the cellular ATP level by blocking both glycolysis and oxidative phosphorylation [27, 32]. This treatment did not totally abolish the accumulation of [ $^3\text{H}$ ]HePC into Caco-2 cells but inhibited it by almost 30%, demon-

strating that this process depended partially on cellular energy.

#### Effect of Cholesterol on HePC Incorporation

We investigated the influence of cholesterol on HePC incorporation in three different ways. Firstly, we used methyl- $\beta$ -cyclodextrin (Me- $\beta$ -CD) to remove cholesterol from cell plasma membrane and therefore disrupt the microdomain structures of the plasma membrane known as “rafts”, secondly, we pre-incubated Caco-2 cells for 48 h in 20% FBS DMEM medium containing 25  $\mu\text{g}/\text{ml}$  of cholesterol, in order to obtain Caco-2 cells with a high cell cholesterol concentration and, thirdly, we added cholesterol to HePC in the incubation medium. The results are depicted in Fig. 5. Pretreatment with Me- $\beta$ -CD led to a 30% inhibition of HePC internalization, demonstrating that cholesterol, and therefore the integrity of lipid rafts in the apical plasma membrane of enterocytes, seemed crucial for the incorporation process. This result is a further indication for the involvement of specialized membrane structures in HePC incorporation. Enrichment of Caco-2 cell membranes with cholesterol did not significantly affect the amount of HePC associated with the cells, whereas the presence of 25  $\mu\text{g}/\text{ml}$  of cholesterol and HePC together in the incubation medium led to a large decrease in HePC incorporation to approximately 30% of the control value.

#### Discussion

The aim of this study was to elucidate the mechanism of HePC incorporation by human enterocytes after the oral administration of this antileishmanial agent. We therefore used the human-derived intestinal epithelial cell line Caco-2 as a validated in vitro intestinal model system [17].

In this study, we showed that the membrane accumulation of HePC was higher when the drug was presented apically. This difference between total accumulation from apical and basolateral membranes cannot be ascribed to membrane surface area because it has been demonstrated that the relative apical and basolateral membrane surface areas of the Caco-2 cells was 1:3 [33], but might be the result of differences in the plasma membrane composition since it is known that apical and basal membranes of Caco-2 cells differ in lipid and protein composition. Furthermore, the lipid composition [34] and the cholesterol content [35] have been shown to influence the incorporation of AELs into the plasma membrane. This result should be

**Table 2** Effects of endocytosis and metabolic inhibitors on HePC incorporation into Caco-2 cells

correlated with previous data demonstrating that the effect of HePC on paracellular permeability was asymmetrical and much more pronounced when HePC was applied to the apical than when it was added to the basolateral side of Caco-2 cell monolayers [22]. Interestingly, these results are in accord with studies on the polarity of free fatty acid uptake in the enterocyte: the total uptake of palmitate was found to be 2-fold higher at the apical plasma membrane than at the basolateral one [33]. Thus, higher apical incorporation is likely to

**Fig. 5** Effect of cholesterol status on HePC association with Caco-2 cells. *White bar* control cells. *Cross-hatched bar* cells were pre-incubated for 30 min with Me- $\beta$ -CD 10 mM to remove cholesterol from the plasma membrane. *Grey bar* (pre-exposure): cells were pre-incubated for 48 h with cholesterol (25  $\mu\text{g}/\text{ml}$ ) to enhance its content in the plasma membrane. *Black bar* (co-exposure): cholesterol (25  $\mu\text{g}/\text{ml}$ ) was added to [<sup>3</sup>H]HePC during the experiment. [<sup>3</sup>H]HePC (20  $\mu\text{M}$ , 0.1  $\mu\text{Ci}$  per well) was added to all groups and the amount of association with the cells was determined after 1 h incubation at 37 °C. All measurements are expressed as mean  $\pm$  SD ( $n = 12$ ). Values are expressed as a percentage of the control. \*\*\* $P < 0.001$  versus control

reflect specific HePC internalization mechanisms in the enterocyte.

The cellular accumulation at 37 °C from the basolateral side of Caco-2 monolayers was linear as a function of HePC concentration added to the basolateral compartment (data not shown), whereas it showed a saturable profile at the apical side, further arguing for a specific mechanism at the apical membrane of the enterocyte. Indeed, the cellular accumulation from the apical side included two components: one temperature-independent, with characteristics of nonspecific binding; and the other, saturable and temperature-dependent, with characteristics suggestive of specific internalization. The saturable component predominated for HePC concentrations below 50  $\mu\text{M}$ ; its kinetic constants were calculated to be  $V_{\text{max}}$ , 39.2 nmol/mg protein/h and  $K_m$ , 15.7  $\mu\text{mol}/\text{L}$ . This saturable process suggests that HePC incorporation into the enterocyte may occur in part by a protein-mediated pathway or a facilitated diffusion membrane transport process. This result could appear to be in contradiction with prior studies which have reported a nonsaturable uptake of edelfosine by two human leukemia cell lines, HL60 and K562 [36, 37]. However, the concentrations of the ether lipid that were used were extremely low (0–35 nM) and the uptake of this molecule could therefore appear to be nonsaturable in the concentration range used in these studies. It should be noted that the saturation of the incorporation process observed in our study occurs at concentrations which could easily be attained during therapy. The clinical dose of 100 mg/day administered orally [38] would lead to concentrations of 0.1–1 mg/ml in the intestine assuming that the fluid volume is 100–1,000 ml, which is about tenfold higher than the concentrations used in this study. In conclusion, the cellular incorporation of HePC occurs by both saturable and nonsaturable processes, suggesting that a carrier-mediated pathway coexists with the passive diffusion mechanism. HePC is a phospholipid analogue and it is interesting to note that our results are in accordance with the uptake process of micellar fatty acids by Caco-2 cells, which also include a dual mechanism by both saturable and nonsaturable diffusion processes [39, 40].

These results concerning association of HePC with Caco-2 cells have to be considered in conjunction with our previous study of the transepithelial transport of the drug in the same cell line [29]. Transport across the Caco-2 cell monolayer was found to occur, at least in part, by a passive paracellular mechanism. However, transport of HePC across the epithelial was found to be quantitatively much lower than the amount of drug accumulated within the cells. Release of labeled HePC

from the cells was slow and incomplete, even under sink conditions [29]. Therefore, in the in-vivo setting, these different mechanisms will co-exist. A part of the drug will be absorbed rapidly by the paracellular route, while another part will be accumulated within the enterocyte cell membranes. This cell-associated drug would be absorbed more slowly, giving rise to the delayed  $T_{\max}$  of about 48 h observed in mice [3]. It is difficult to predict from in-vitro experiments how much of the absorption will be by the paracellular route and how much by the slower transcellular pathway, since this will depend on the local HePC concentration. Given the affinity of HePC for albumin, binding to plasma proteins in the intestinal capillaries certainly plays an important role.

The cellular accumulation of HePC by Caco-2 cells was found to be partially inhibited by energy depletion and low temperature, suggesting the involvement, at least in part, of an energy-requiring component for HePC incorporation at the apical membrane of Caco-2 cells. These results are in agreement with previous studies on HePC uptake in various tumor cell lines [41], by MDCK cells [4], and for other AELs [42].

HePC incorporation into Caco-2 cells was found not to involve receptor-mediated endocytosis, since it was unaffected by inhibitors of this process. However, we cannot totally rule out the hypothesis of a caveolae-mediated endocytosis, although it has been demonstrated that Caco-2 cells do not express caveolin-1 and have very few caveolae [43]. In the literature, some investigators argue that endocytosis is a major pathway by which AELs are taken up [13, 42, 44], whereas others reach the opposite conclusion [12, 45, 46]. We cannot directly compare our results with studies arguing for the involvement of endocytosis because of differences in the drug used, in the incubation conditions and in the cell lines. The different cell types used may have dissimilar pathways of intracellular lipid trafficking or different membrane composition, leading to an alteration of the predominant pathway of AELs translocation. Moreover, it has been observed that the sensitivity of HePC uptake to compounds like chloroquine, monensin, cytochalasin B or colchicine was cell-line-dependent [47]. However, our results are consistent with a more recent study, which demonstrated that ether lipids are not internalized by endocytosis [14] and with the current understanding that the endocytotic uptake mechanism normally handles high-molecular-weight molecules, whereas ether lipids are much smaller molecules.

We also showed that HePC entry into Caco-2 cell plasma membrane was restricted by the presence of human serum albumin in the medium and that washing

with albumin removed a significant amount of HePC from cells. These results show that albumin plays an important role in HePC incorporation. As reported before, AELs bind to serum proteins [10, 12, 48] and a decrease edelfosine uptake by HL-60 cells [42], K562 cells [36] and *Trypanosoma cruzi* [49], caused by albumin, has already been observed. This binding to serum proteins, and especially albumin, would decrease the amount of HePC able to interact with the cells by lowering the concentration of free HePC in the medium. Taken together, these results suggest that HePC must be free in solution to be inserted in the plasma membrane of the cells and that the direct transfer from albumin to the plasma membrane is limited. HePC is a phospholipid analogue and our results can be correlated with previous studies using lipids and fatty acids, where similar competitive effects have been demonstrated with BSA-bound lipids [50]. Here we provide information that HePC behaves in the same way as fatty acid aggregates where albumin controls the lipid monomer concentration and therefore cell association.

We showed that removal of cholesterol from the cell plasma membrane using methyl- $\beta$ -cyclodextrin (Me- $\beta$ -CD) significantly decreased the capacity for HePC incorporation. This result could be explained by three hypotheses. Firstly, the incorporation of HePC might be correlated with the amount of cholesterol present in the plasma membrane, since HePC possesses a high affinity for the cholesterol molecule and forms a stable complex [51]. The reduction of HePC accumulation observed when cholesterol was present at high levels in the medium is in accordance with this hypothesis and with the formation of mixed aggregates between HePC and cholesterol. However, when the Caco-2 cell membranes were enriched in cholesterol, HePC accumulation was not enhanced. One can assume that the membrane rigidification induced by the enhancement of cholesterol content - since it is well established that cholesterol decreases the permeability of the lipid bilayer in membrane models—could inhibit HePC incorporation in the phospholipid bilayer and therefore counterbalance the affinity of HePC for cholesterol. The second hypothesis is that HePC may preferentially localize in rafts microdomains. Indeed, treatment by Me- $\beta$ -CD has been reported to disrupt these membrane domains, suggesting that intact rafts are required for the association of HePC to Caco-2 cell membranes, as demonstrated for the uptake of edelfosine by S49 cells [52]. Thirdly, the cholesterol content could affect the putative transporter activity. Finally, we have demonstrated, by albumin back-extraction of HePC and by low temperature treatment, that HePC is

translocated by Caco-2 cells from the outer to the inner leaflet of the plasma membrane bilayer.

Taken together, our results strongly suggested that HePC incorporation consists of passive absorption into the plasma membrane followed by translocation to the inner membrane leaflet by an active and saturable transport mechanism. The nonsaturable association may therefore represent the drug in the outer layer of the plasma membrane and the saturable component the drug which moves to inner membrane of the plasma membrane bilayer. The intriguing question is obviously the mechanism by which the translocation process occurs. Our results indicated that a protein-mediated translocation (“translocase activity”) is involved rather than a “spontaneous” flip-flop. Aminophospholipids and their fluorescent analogues are known to be actively translocated across cellular membranes, mediated by a specific translocase (“flippase”) [53]. In this respect, it is interesting to note that an HePC translocation process has been identified in *L. donovani* parasites [16] and the protein responsible has recently been cloned [15]. This novel P-type ATPase, belonging to the aminophospholipid translocase subfamily and called LdMT (*L. donovani* putative Miltefosine Transporter), was shown to be responsible for the inward translocation of HePC in the parasites [16]. LdMT has 47% homology with the human ATPase II and shares all the P-type ATPase consensus sequences and the APT subfamily-specific motifs from the mammalian homologues [15]. It is conceivable that this kind of transporter could take up HePC in the intestinal epithelium, as in vitro studies have suggested the presence of an aminophospholipid translocase in the plasma membrane of Caco-2 cells [54].

In summary, the present study indicates the involvement of a carrier-mediated process handling HePC at the apical membrane of Caco-2 cells. This conclusion is based on a number of observations that may be summarized as follows: (1) the accumulation of HePC was composed of both saturable and nonsaturable (specific and nonspecific) processes, (2) the saturable component followed Michaelis–Menten kinetics (15.7  $\mu\text{mol/l}$  and 39.2 nmol/mg protein/h for  $K_m$  and  $V_{max}$ , respectively), (3) cellular ATP depletion by treating cells with inhibitors of oxidative phosphorylation and the glycolytic pathway reduced the accumulation significantly, indicating the energy-dependence of this process, (4) reduction of the incubation temperature from 37 to 4 °C decreased the HePC accumulation. These observations fulfill the criteria for a carrier-mediated mechanism and provide good circumstantial evidence for the participation of a membrane protein, i.e., a carrier protein, responsible for the inward translocation of HePC in the

plasma membrane, after the nonspecific insertion of HePC into the outer leaflet of the plasma membrane. The fact that inhibitors of energy-dependent mechanisms only partially abolished the HePC accumulation may indicate that this carrier protein has a limited capacity to transport HePC compared with the amount of drug that can be incorporated into the outer leaflet of the membrane by passive diffusion. In parallel with this specific saturable mechanism, some HePC sequestered in the plasma membrane may enter intracellular membranes by the normal membrane recycling processes of the cell, as suggested by Fleer et al. [41]. Work remains to be done to determine the molecular mechanism of HePC uptake in intestinal epithelial cells, including localization of the saturable component and isolation of the protein, if any, that is involved.

# Lymphatic Absorption and Deposition of Various Plant Sterols in Stroke-Prone Spontaneously Hypertensive Rats, a Strain Having a Mutation in ATP binding cassette transporter G5

**Abstract** ATP binding cassette transporter G5 (ABCG5) and ATP binding cassette transporter G8 (ABCG8) have been suggested to transport absorbed plant sterols and cholesterol from enterocytes to the intestinal lumen and from hepatocytes to bile. It has been thought that mutations of *ABCG5* or *ABCG8* cause the deposition of plant sterols in the body. In the present study, lymphatic absorption of various plant sterols and their deposition in various tissues was investigated in stroke-prone spontaneously hypertensive rats (SHRSP), having a mutation in *Abcg5* and depositing plant sterols in the body. The order of

lymphatic 24-h recovery of plant sterols was as follows: campesterol > sitosterol > brassicasterol > stigmasterol = sitostanol. When SHRSP were fed a diet containing one of the plant sterols, the depositions of campesterol and sitosterol were comparatively higher than those of brassicasterol, stigmasterol and sitostanol. Highly positive correlations were obtained between lymphatic recovery of plant sterols and their levels in plasma, liver, adipose tissue and heart. The tendency of differential absorption of plant sterols to the lymph in SHRSP was similar to that in normal Wistar rats previously reported by us (Hamada et al. *Lipids* 41:551–556, 2006). These observations suggest that differential absorption of various plant sterols is kept in SHRSP in spite of a mutation in *Abcg5*.

## Introduction

Plant sterols contained in plant foods and vegetable oils are less absorbable than cholesterol [1]. It is also

known that each plant sterol has a different absorption rate in humans [2, 3] and experimental animals [4–6]. In our study using Wistar rats, lymphatic 24-h recovery of campesterol given to the stomach was the highest among the plant sterols examined. Lymphatic recoveries of brassicasterol and sitosterol were intermediate and those of stigmasterol and sitostanol were extremely low [7]. The mechanisms of differential absorption of plant sterols are not well understood. Recently, various mutations in ATP binding cassette transporter G5 (*ABCG5*) and ATP binding cassette transporter G8 (*ABCG8*) have been found in sitosterolemic patients whose absorption and deposition of plant sterols are higher than those of normal subjects [8, 9]. *ABCG5* and *ABCG8* are mainly expressed in the intestine and the liver and form a heterodimer. They are thought to excrete sterols from intestinal epithelial cells to the intestinal lumen and from hepatocytes to bile [8–10]. Igel et al. [11] showed that plant sterols were once incorporated into the intestinal cell and then they were secreted to the intestinal lumen. They suggested that the secretion of plant sterols by *ABCG5* and *ABCG8* could be an important determinant for intestinal absorption of sterols. This means that *ABCG5* and *ABCG8* determine differential absorption of plant sterols.

In contrast, we suggested that solubility in and affinity for the bile salt micelle of plant sterols are important determinants for their intestinal absorption in rats [7]. We think that differential incorporation of plant sterols into the intestinal cell determines differential absorption of various plant sterols. Yu et al. [12] reported that differential absorption of cholesterol, campesterol and sitosterol was observed in *ABCG5*-/*ABCG8*-deficient mice. Observations by Yu et al. [12] and us [7] suggest that differential absorption of plant sterols is independent of the function of *ABCG5* and *ABCG8*.

It has been reported that stroke-prone spontaneously hypertensive rats (SHRSP) deposit plant sterols, in particular campesterol and sitosterol, in the body [13–15]. We showed that lymphatic absorption of radiolabeled sitosterol was higher and biliary excretions of campesterol and sitosterol were lower in SHRSP than in Wistar King-A rats [13]. Scoggan et al. [16] and Yu et al. [17] revealed that SHRSP have a mutation in *Abcg5*; therefore, it is thought that malfunction of *ABCG5*/*ABCG8* induces increased absorption and deposition of plant sterols in SHRSP [16, 17]. Because dietary plant sterols were rich in campesterol and sitosterol in the feeding study of SHRSP [13–15], it is not known whether plant sterols

other than campesterol and sitosterol can be absorbed in SHRSP.

In the present study, to reveal the relationship between differential absorption of plant sterols and the function of *ABCG5*/*ABCG8*, lymphatic absorption and deposition of various plant sterols were compared in SHRSP. There is a possibility that when a plant sterol mixture is given to rats, each plant sterol inhibits intestinal absorption of other plant sterols. Therefore, one of the purified plant sterols was given to rats in the present study.

## Experimental Procedure

### Materials

Brassicasterol (purity 93.5%), campesterol (94.4%), stigmasterol (97.7%) and sitosterol (98.6%) were kindly provided by Tama Biochemical Co. (Tokyo, Japan). Sitostanol (95.9%) and triolein were purchased from Sigma (Tokyo, Japan). Sodium taurocholate (purity better than 97%) was purchased from Nacalai Tesque (Kyoto, Japan).

### Lymphatic Absorption of Plant Sterols in SHRSP

Seven-week-old male SHRSP (SHRSP/Sea, inbred, SPF) ( $n = 35$ ) were obtained from Seac Yoshitomi, Fukuoka, Japan. The rat strain obtained from Seac Yoshitomi was proved to have a mutation in *Abcg5* by Scoggan et al. [16] and Yu et al. [17]. Rats were fed an AIN-93G purified diet [18] containing 10% lard for 5 weeks ad libitum. Since rat chow diets contain considerable amounts of plant sterols, SHRSP obtained from the breeder had already deposited plant sterols in the body. To reduce plant sterol levels in the body as low as possible, lard was used as the sole dietary fat, because the plant sterol content in lard is extremely low (sterol content in weight percent: cholesterol, 0.05%; campesterol, 0.0011%; sitosterol, 0.0013%). These rats were subjected to surgery. The average body weight at surgery was 273 g. After anesthetizing the animals with sodium pentobarbital given intraperitoneally (50 mg/kg body weight), the left thoracic lymphatic duct cephalad to the cisterna chili was cannulated as described previously [19]. A second indwelling catheter was placed in the stomach for administration of the test emulsion. After surgery, the animals were placed in restraining cages and intragastrically given a solution containing 139 mM glucose and 85 mM NaCl at a rate of 3.4 ml/h by an

infusion pump (Shinkoseiki, Fukuoka, Japan) continuously until the end of the experiment. The same solution was given as drinking water. The next morning, animals with a constant lymph flow rate were divided into five groups ( $n = 6-7$  rats per group) and used for sterol absorption study. Lipid emulsions composed of 67 mg sodium taurocholate, 17 mg fatty acid free bovine serum albumin (Serologicals, Kankakee, IL, USA), 67 mg triolein and 16.7 mg of highly purified plant sterol in 1 ml were prepared by sonication and administered into the stomach via the stomach tube at 1 ml per 100-g body weight. In this study, five types of highly purified plant sterols, brassicasterol, campesterol, stigmasterol, sitosterol and sitostanol, were used for preparing test emulsions. The chemical structures of the plant sterols and cholesterol are shown in Fig. 1. Lymph was collected on ice-chilled tubes containing EDTA and aliquots were subjected to sterol analysis. Because trace amounts of plant sterols were detected in lymph before the infusion of a test emulsion, the amounts of plant sterols in lymph before administration were used as the baseline. All animal studies were carried out under the guidelines for animal experiments of the Faculty of Agriculture, Graduate School of Kyushu University, and Law 105 and Notification 6 of the government of Japan.

**Fig. 1** Chemical structures of the plant sterols and cholesterol

## Feeding Study of Plant Sterols in SHRSP

Four-week-old male SHRSP ( $n = 30$ ) were fed an AIN-93G purified diet containing 10% lard for 4 weeks. After that, 8-week-old SHRSP were separated into five groups ( $n = 6$  rats per group) and these rats were fed a purified diet containing 10% lard and 0.5% of one of the plant sterols for 10 days more. Five types of highly purified plant sterols, brassicasterol, campesterol, stigmasterol, sitosterol and sitostanol, were used. At the termination of the feeding period, the rats were fasted for 7 h and blood was withdrawn from the abdominal aorta under diethyl ether anesthesia. Liver, adipose tissue, heart and adrenals were excised and frozen at  $-40^{\circ}\text{C}$  until sterol analysis.

## Sterol Analysis

Lipids in plasma, liver, adipose tissue, heart, adrenals and lymph were extracted and purified by the method of Folch et al. [20]. After saponification of total lipids, unsaponifiable matter collected was derivatized to trimethylsilyl ethers and was quantified by gas-liquid chromatography using a SPELCO SPB-1<sup>TM</sup> column ( $0.25\text{ mm} \times 60\text{ m}$ ,  $0.25\text{-}\mu\text{m}$  film thickness, Sigma-Aldrich, Tokyo, Japan) and  $5\alpha$ -cholestane (Sigma) as an internal standard. Free and esterified sterols in total lipids were separated by thin-layer chromatography (hexane/diethyl ether/acetic acid, 83:16:1, by volume, as the developing solvent) and subjected to sterol analysis.

## Statistics

All data are expressed as the mean  $\pm$  the standard error. The Tukey–Kramer test was used and  $P < 0.05$  was considered significant.

## Results

### Lymphatic Recovery of Plant Sterols in SHRSP

As shown in Fig. 2 and Table 1, campesterol had the highest and stigmasterol and sitostanol the lowest lymphatic 24-h recovery among the five types of plant sterols. The lymphatic recoveries of brassicasterol and sitosterol were intermediate. The order of the absorption rates of each plant sterol was campesterol > sitosterol > brassicasterol > stigmasterol = sitostanol. The esterification ratio of campesterol in lymph was the highest and that of stigmasterol was the lowest among the five types of plant sterols. The order of esterification of each plant sterol was

**Fig. 2** Lymphatic recovery of plant sterols in stroke-prone spontaneously hypertensive rats (SHRSP). Thoracic duct cannulated SHRSP were administered 1 ml/100 g body weight of a lipid emulsion containing 67 mg/ml triolein, 17 mg/ml fatty acid free bovine serum albumin, 6.7 mg/ml plant sterol and 67 mg/ml sodium taurocholate. Lymph was collected for 24 h. *Open circles* brassicasterol, *filled circles* campesterol, *open squares* stigmasterol, *filled squares* sitosterol, *triangle* sitostanol. Different letters show significant differences among plant sterols at  $P < 0.05$  in the Tukey–Kramer test

campesterol > brassicasterol > sitosterol = sitostanol > stigmasterol.

#### Plasma Sterol Levels in SHRSP

All of the dietary plant sterols fed to SHRSP were detected in plasma. The plasma level of campesterol was the highest and that of stigmasterol was the lowest

among the five types of plant sterols. The order of the plasma levels of each plant sterol was campesterol > sitosterol > sitostanol > brassicasterol > stigmasterol. The esterification ratio of sitostanol in plasma was the highest and the esterification ratios of brassicasterol and stigmasterol were the lowest among the five types of plant sterols. The order of esterification of each plant sterol was sitostanol > sitosterol > campesterol > brassicasterol = stigmasterol. There were no significant differences in plasma cholesterol levels among the groups. The percentages of cholesterol ester ranged from 70 to 75% (Table 2).

#### Sterol Levels of Various Tissues in SHRSP

All of dietary plant sterols fed to SHRSP were deposited in all of the tissues examined. On the basis of tissue weight, plant sterol levels in adrenals were the highest and those of adipose tissue were the lowest. In the liver, campesterol had the highest deposition and stigmasterol and sitostanol had the lowest deposition among the five types of plant sterols. The order was campesterol > sitosterol > brassicasterol > stigmasterol = sitostanol. The same tendency was obtained in adipose tissue and heart. In adrenals, the deposition of brassicasterol was higher than that of sitosterol and the order was campesterol > brassicasterol > sitosterol > stigmasterol > sitostanol (Table 2). The order of the cholesterol levels in liver was stigmasterol > sitostanol > campesterol > brassicasterol > sitosterol. The percentages of cholesterol ester in liver ranged from 15 to 45%. The orders of the cholesterol levels in adipose tissue and heart were similar, sitostanol > brassicasterol = stigmasterol > sitosterol > campesterol. The order of the cholesterol levels in adrenals was brassicasterol = sitostanol > stigmasterol > campesterol > sitosterol (Table 2).

#### Correlation Between Lymphatic Recovery and Plant Sterol Levels in SHRSP

As shown in Fig. 3, there was highly positive correlation between lymphatic recovery of plant sterols and

Data are the mean ± SE of six rats per group. Different *superscript letters* show significant differences among plant sterols at  $P < 0.05$  in the Tukey–Kramer test. The percentage of total sterol is the amount of the respective plant sterol to the sum of the plant sterols and cholesterol

**Fig. 3** Correlation between lymphatic recovery of plant sterols and their levels in liver in SHRSP. *Open circle* brassicasterol, *filled circle* campesterol, *open square* stigmasterol, *filled square* sitosterol, *triangle* sitostanol. When the data for campesterol were omitted, the correlation coefficient between lymphatic recovery of plant sterols and their levels in liver was  $r = 0.84$  ( $P = 0.16$ )

the sterol levels in liver ( $r = 0.99$ ,  $P < 0.01$ ). The levels of plant sterols in plasma ( $r = 0.95$ ,  $P < 0.05$ ), adipose tissue ( $r = 0.99$ ,  $P < 0.01$ ) and heart ( $r = 0.99$ ,  $P < 0.01$ ) were also significantly correlated to the

lymphatic recovery, whereas those of adrenals were not significantly correlated ( $r = 0.86$ ,  $P = 0.06$ ). Since it was thought that correlations between lymphatic recovery of plant sterols and their levels in plasma and various tissues were biased by the data for campesterol, we also calculated correlation coefficients when the data for campesterol were omitted. The correlation coefficients were  $r = 0.69$  ( $P = 0.31$ ) in plasma,  $r = 0.84$  ( $P = 0.16$ ) in liver,  $r = 0.93$  ( $P = 0.07$ ) in adipose tissue,  $r = 0.91$  ( $P = 0.08$ ) in heart and  $r = 0.55$  ( $P = 0.45$ ) in adrenals, respectively.

## Discussion

The present study clearly showed that lymphatic recoveries and deposition in the body of various plant sterols were remarkably different from each other in SHRSP. Lymphatic recovery of campesterol was the highest and was 27 times higher than that of sitostanol, the least absorbable sterol. Lymphatic recovery of stigmasterol was also extremely low and comparable to that of sitostanol. Brassicasterol and sitosterol were about 4–5 times more absorbable than stigmasterol and sitostanol. We observed the same tendency of

differential absorption rates of plant sterols in Wistar rats, which have no mutation in *Abcg5* [7]; therefore, we can conclude that a mutation in *Abcg5* of SHRSP does not largely influence the differential absorption of the various plant sterols examined.

Our previous study showed that both the micellar solubility of plant sterols and their affinity for the bile salt micelle are important determinants for their intestinal absorption in Wistar rats [7]. The affinity of plant sterols for the bile salt micelle was assessed as sterol transfer from the bile salt micelle to triolein [7, 21]. If a sterol has a high affinity for the bile salt micelle, its transfer to the oil becomes low. Highly positive correlation ( $r = 0.88$ ,  $P < 0.05$ ) was observed between the lymphatic recovery of plant sterols and the multiplication product of their micellar solubility and the transfer rate [7]. In the present study, differential absorption of plant sterols in SHRSP was similar to that in normal Wistar rats. We calculated the correlation coefficient between the lymphatic recovery of plant sterols in SHRSP and the multiplication product of their micellar solubility and the transfer rate obtained in our previous study [7]. Again, highly positive correlation ( $r = 0.88$ ,  $P < 0.05$ ) was observed. The correlation coefficient between the lymphatic recovery rates of various plant sterols in SHRSP in the present study and in Wistar rats obtained in our previous study [7] was  $r = 0.995$ ,  $P < 0.001$ . The results strongly suggest that even in SHRSP, micellar solubility of plant sterols and their affinity for the bile salt micelle are important determinants for their differential absorption in the intestine. Yu et al. [12] reported that in *ABCG5*-/*ABCG8*-deficient mice, campesterol was more absorbable than sitosterol and suggested that differential absorption of plant sterols is largely independent of *ABCG5* and *ABCG8*. Our results support their observation.

Although Igel et al. [11] proposed that plant sterols are unselectively incorporated into the intestinal mucosal cells, we propose in the present study that less absorbable sterols are incorporated less into the intestinal mucosal cell. We think that the ability of secretion of various plant sterols from the intestinal cell to the intestinal lumen in SHRSP must be lowered at the same rate as in normal rats, because the pattern of differential absorption of plant sterols was similar between SHRSP and Wistar rats.

Altmann et al. [22] and Davis et al. [23] reported that Niemann-Pick C1 like 1 protein (NPC1L1) is involved in intestinal uptake of cholesterol and plant sterols. NPC1L1 contributes to about half of the intestinal absorption of cholesterol and plant sterols, because about half of the sterols are absorbed in

NPC1L1-deficient mice compared with wild-type mice [22, 23]. In addition, Yu et al. [24] showed that the administration of ezetimibe, a potential inhibitor of NPC1L1, to normal mice reduced the intestinal absorption of campesterol and sitosterol roughly to a half. The results suggest the possibility that NPC1L1 participates in differential incorporation of plant sterols into the intestinal cell. To clarify the role of NPC1L1 on differential absorption of plant sterols, intestinal absorption of various plant sterols should be measured in normal rats given ezetimibe or in NPC1L1-deficient mice.

Sterols are incorporated into enterocytes as their unesterified form and then they are subjected to esterification by microsomal acylcoenzyme A:cholesterol acyltransferase (ACAT) [25]. This process appears to be important for intestinal sterol absorption because esterification of absorbed sterols within the enterocyte promotes simple diffusion of unesterified sterols by maintaining their concentration gradient between the intestinal lumen and the intestinal cell [25]. In our previous study, about 80–90% of absorbed cholesterol was esterified in lymph, whereas the amount of sitosterol esterified was around 10% in rats [21]. Low absorbability of sitosterol is in part explained by less esterification by ACAT [26]. In the present study, although campesterol, the most absorbable plant sterol, showed the highest esterification rate among the plant sterols examined, the lymphatic absorption of the other plant sterols does not necessarily follow their esterification rates. For example, the esterification of sitostanol in lymph was almost the same as that of sitosterol (nearly 16%), whereas the absorbability of sitostanol (0.17%) was one fifth of that of sitosterol (0.83%). In addition, although the esterification of brassicasterol (28%) was about twice as high as that of sitosterol (16%), the absorbability of brassicasterol (0.64%) was almost comparable to that of sitosterol (0.83%) (Table 1). Therefore, there is no positive correlation between esterification rate and lymphatic recovery of less absorbable plant sterols, i.e., brassicasterol, stigmasterol, sitosterol and sitostanol. The results suggest that esterification of less absorbable plant sterols is not a determinant for their intestinal absorption.

In the present study, the percentages of the plant sterol esters in the liver were lower than those in plasma as shown in Table 2 and those in lymph as shown in Table 1. It is thought that absorbed plant sterols are partly esterified and incorporated into chylomicrons in the intestinal cell, secreted to lymph and then transported to the bloodstream. Chylomicrons are transformed to chylomicron remnants in the

bloodstream and are then incorporated into the liver. Since it is thought that plant sterol esters contained in chylomicrons and chylomicron remnants are not hydrolyzed in the bloodstream, plant sterol esters in chylomicrons are incorporated into the liver. There are some possibilities for the causes of the low esterification rates of plant sterols in the liver. One possibility is that plant sterol esters in chylomicron remnants are hydrolyzed in the liver and plant sterols are utilized as membrane components and substrates for bile acid synthesis, at least in SHRSP. There is a possibility that plant sterols incorporated into the cell membrane widely influence membrane functions. When SHRSP were fed a high plant sterol diet, stroke was induced at an early stage and their life span was shortened [14, 15]. Ratnayake et al. [15] suggested that plant sterols made the cell membrane more rigid in SHRSP and shortened the life span of SHRSP. It is also known that plant sterols are minor substrates for bile acid synthesis in rats [4, 27]. Another possibility is that plant sterol esters are preferentially secreted to plasma as very low density lipoproteins, and therefore the levels of plant sterol esters in plasma were higher than those in liver. The plant sterol esters are thought to be transported to extrahepatic tissues. It has been suggested that some plant sterols are utilized as substrates for steroid hormone synthesis [28, 29]. Since studies on the influence of plant sterols deposited in the body are scarce, SHRSP may be an appropriate model for those studies.

As we previously observed [13], the depositions of campesterol and sitosterol in SHRSP having a mutation in *Abcg5* were estimated to be higher than those in normal rats, because campesterol and sitosterol constituted 38 and 20% of total sterols in the plasma and 30 and 14% in the liver, respectively (Table 2). In contrast, the depositions of brassicasterol, stigmasterol and sitostanol were comparatively lower than those of campesterol and sitosterol. In the present study, significant positive correlations were observed between lymphatic recoveries of five types of plant sterols and their depositions in tissues examined, except for adrenals. It is thought that the positive correlations observed are biased by a high level of campesterol. Therefore, we calculated the correlations without the data for campesterol. Relatively high positive correlations were also found between lymphatic recoveries of plant sterols and their levels in liver, adipose tissue and heart even when the data for campesterol were omitted. These results suggest that intestinal absorption rates of plant sterols may be an important determinant for their deposition in the body.

Our results showed that deposition of brassicasterol in adrenals was relatively higher than that in other tissues and organs. The causes of the specific deposition of brassicasterol in adrenals cannot be explained at present. It is also not clear if the deposition is specific in SHRSP. Since it has been reported that the side chain of campesterol and sitosterol is cleaved by adrenal side chain cleavage enzyme and transformed into pregnenolone [28], brassicasterol may also be a substrate for steroid hormone. Yang et al. [30] suggested the possibility for the inhibition of cholesterol synthesis by specific plant sterols, campesterol, stigmasterol and brassicasterol, in the adrenal glands of *ABCG5*-/*ABCG8*-deficient mice; therefore, the deposition of brassicasterol in adrenals might influence steroid hormone synthesis. Further investigation is necessary to clarify the safety and functions of plant sterols accumulated in the body.

**Abstract** Alteration of lipid constituents of cellular membranes has been proposed as a possible mechanism for cancer promotion by fumonisin B<sub>1</sub> (FB<sub>1</sub>). To further investigate this hypothesis a dietary dosage which initiates and promotes liver cancer (250 mg FB<sub>1</sub>/kg) was fed to male Fischer rats for 21 days and the lipid composition of plasma, microsomal, mitochondrial and nuclear subcellular fractions determined. The effect of FB<sub>1</sub> on the cholesterol, phosphatidylcholine (PC) and phosphatidylethanolamine (PE), as well as sphingomyelin (SM) and the phospholipids-associated fatty acid (FA) profiles, were unique for each subcellular membrane fraction. PE was significantly increased in the microsomal, mitochondrial and plasma membrane fractions, whereas cholesterol was increased in both the microsomal and nuclear fraction. In

addition SM was decreased and increased in the mitochondrial and nuclear fractions, respectively. The decreased PC/PE and polyunsaturated/saturated (P/S) FA ratio in the different membrane fractions suggest a more rigid membrane structure. The decreased levels in polyunsaturated fatty acids in PC together with a pronounced increase in C18:1 $\omega$ 9 and C18:2 $\omega$ 6 were indicative of an impaired delta-6 desaturase. The increased  $\omega$ 6/ $\omega$ 3 ratio and decreased C20:4 $\omega$ 6 PC/PE ratio due to an increase in C20:4 $\omega$ 6 in PE relatively to PC in the different subcellular fractions suggests a shift towards prostanoid synthesis of the E2 series. Changes in the PE and C20:4 $\omega$ 6 parameters in the plasma membrane could alter key growth regulatory and/or other cell receptors in lipid rafts known to be altered by FB<sub>1</sub>. An interactive role between C20:4 $\omega$ 6 and ceramide in the mitochondria, is suggested to regulate the balance between proliferation and apoptosis in altered initiated hepatocytes resulting in their selective outgrowth during cancer promotion effected by FB<sub>1</sub>.

### Introduction

The structure, function and integrity of biological membranes are governed by the lipid composition of its bilayer [1–3]. Membranes show an asymmetric bilayer of aminophospholipids, such as phosphatidylethanolamine (PE) and phosphatidylserine located in the inner leaflet, whereas phosphatidylcholine (PC)

and the sphingolipid, sphingomyelin (SM), are located in the outer leaflet [4, 5]. The membrane structure and dynamics are important in maintaining cellular function that regulates signalling pathways related to cellular homeostasis [6, 7]. The role of cellular membranes during carcinogenesis has become more prominent and forms a part of subtle changes underlying epigenetic events [8, 9]. Isolated membrane fractions from tumour cells demonstrated alterations in their composition, structure and organization and thus in their functional properties [10, 11].

Fumonisin B<sub>1</sub> (FB<sub>1</sub>), a natural occurring mycotoxin with cancer promoting properties produced by the fungus *Fusarium verticillioides* in maize [12]. FB<sub>1</sub> causes several diseases in animals and is associated with a high incidence of human oesophageal and liver cancer in certain geographical areas in the world [13, 14], and the development of neural tube defects [15]. FB<sub>1</sub> is hepatotoxic and hepatocarcinogenic [16, 17] when chronically fed to rats and effects both cancer initiation and promotion properties in a short-term rat liver carcinogenesis model [18, 19]. This model provides an excellent opportunity to study the mechanisms associated with cancer induction by this “apparent” non-genotoxic compound as it lacks genotoxicity in the *Salmonella* mutagen and DNA repair assays [20–22]. However, FB<sub>1</sub> induces oxidative damage [23] and exhibited clastogenic properties [24], suggesting that the compound could either directly or indirectly, induce DNA damage. Short-term studies utilizing a cancer initiating/promoting model in rat liver indicated that FB<sub>1</sub> closely mimics the characteristics of other genotoxic carcinogens with respect to initiation [18]. With respect to cancer promotion, evidence supports a hypothesis that FB<sub>1</sub> effects a growth differential, during which initiated hepatocytes proliferate in an environment where the growth of normal cells is inhibited [25]. This became evident as FB<sub>1</sub> inhibits the epidermal growth factor (EGF) stimulatory response in primary hepatocytes in vitro [26] and hepatocyte regeneration following partial hepatectomy in vivo [18] suggesting that FB<sub>1</sub> induces a growth differential similar to most cancer promoters [27, 28].

The disruption of lipid metabolism and the subsequent affect on membrane integrity and function has been proposed as a possible mechanism for cancer promotion by fumonisin B<sub>1</sub> [25, 29, 30]. The present study described the effect of FB<sub>1</sub> on the lipid profiles of different rat hepatic subcellular membrane fractions including the microsomes, mitochondria, plasma membrane and the nuclei. The possible role of these changes during cancer promotion of FB<sub>1</sub> in rat liver is critically evaluated.

## Materials and Methods

### Chemicals and Reagents

Fumonisin B<sub>1</sub> was extracted and purified (>90%) according to the method described by Cawood et al. [31]. Fatty acid (FA) analytical standards (C14:0 to C24:1), used for calibration and identification, were obtained from Sigma Chemical Company (St Louis, MO, USA). All the chemical solvents were of analytical grade and glass distilled prior to use.

### Animals and Diets

Male Fischer rats (150 g body weight) were fed a modified AIN-76 diet after weaning [18] and housed individually in a controlled environment (23–25 °C) with a 12 h light/dark cycle with free access to feed and drinking water. FB<sub>1</sub> was dissolved in methanol prior to application on a subsample (200 g) of the AIN-76A diet and dried overnight. The subsample was mixed with the standard diet to obtain a concentration of 250 mg FB<sub>1</sub>/kg, a dose that both initiates [18] and promotes [19] cancer in rat liver. The diet was stored under nitrogen at 4 °C. A control diet was prepared in the same way using an equal volume of methanol. The control and FB<sub>1</sub>-containing diets were fed to the rats over a 21-day period. Following the feeding regimen, animals were sacrificed under sagatal anaesthesia after which the livers were harvested and stored in saline at –80 °C.

### Preparation of Membrane Subcellular Fractions

Membrane subcellular fractions were isolated at 4 °C according to the method of Bartoli et al. [32] and Loten and Redshaw-Loten [33] with modifications. In short, the livers were homogenized in a buffer containing 250 mM sucrose, 10 mM Tris–HCl, 1 mM EDTA (pH 7.4) and centrifuged at 1,500g for 10 min. Both the supernatant (S1) and the pellet (P1) were retained for further isolation of the different subcellular membrane fractions. The supernatant (S1) was centrifuged at 18,000g for 10 min to obtain the mitochondrial subcellular pellet (P2) whilst the microsomal fraction remained in the supernatant (S2). The microsomal subfractions were subsequently collected from the S2 fraction by ultra centrifugation at 105,000g for 60 min. The mitochondrial and microsomal subcellular fractions were suspended in 10 mM Tris–HCl buffer (pH 7.4) and centrifuged at 18,000g for 10 min and 105,000g for 30 min, respectively. All the subcellular fractions were stored at –80 °C until analysed.

Liver nuclear and plasma membrane subcellular fractions were prepared by fractionating the pellet (P1) on a self-forming Percoll (Sigma Chemical Co., St Louis, MO, USA) gradient by centrifugation at 35,000g for 20 min. By retaining the top layer and applying another Percoll gradient (45,000g for 30 min), the subsequent top and bottom layers, respectively, yielded the plasma membrane and nuclear fractions. The collected fractions were centrifuged in 10 mM Tris–HCl buffer and stored at  $-80^{\circ}\text{C}$  prior to analysis. The protein concentration of the different fractions was determined according to the method of Kaushal and Barnes [34].

### Lipid Analyses

The different subcellular membrane fractions were subjected to detailed lipid analysis; these included PC, PE, SM, total cholesterol and FA profiles of PC and PE. In short, the different subcellular fractions (1–2 mg protein/ml) were extracted with chloroform/methanol (2:1, v/v) containing 0.01% butylated hydroxytoluene as anti-oxidant [35, 36] and stored under nitrogen until analysed.

The sample extracts were analysed for cholesterol and subsequently for phospholipids by thin layer chromatography on  $20 \times 20$  silica plates [37] using chloroform–methanol–petroleum ether–acetic acid–boric acid (40:20:30:10:1.8, v/v/v/v/w) as developing solvent. Plates were developed for 90 min at room temperature followed by drying under  $\text{N}_2$  gas for 30 min, and the respective phospholipid concentrations and FA content determined.

### Phospholipids and Cholesterol

The phospholipid concentrations were quantified colourimetrically with malachite green dye [38] following digestion in saturated perchloric acid at  $170^{\circ}\text{C}$  for approximately 1 h. Total cholesterol was determined on aliquots of the original lipid extract by an enzymatic iodide method [39] with cholesterinoxidase and cholesterinesterase (Boehringer Mannheim, South Africa).

### Fatty Acids

The PC and PE fractions were transmethylated with 2.5 ml methanol:18 M sulphuric acid (95:5, v/v) at  $70^{\circ}\text{C}$  for 2 h as described by Tichelaar et al. [40]. The resultant FA methyl esters (FAME) were analysed on a Varian 3700 Gas Chromatograph equipped with 30 m fused silica megabore DB-225 columns of

0.53 mm internal diameter (J & W Scientific, Cat. No. 25-2232). The individual FAME were identified by comparison of the retention times with those of a standard mixture of free FA C14:0 to C24:1 and quantified with an internal standard (C17:0) as  $\mu\text{g}$  FA/mg protein.

### Statistical Analyses

For comparisons to test whether two independent diet groups with normal distributions had the same mean, the *t*-test was used. The pooled method was used if variances were equal, and the Satterthwaite method for unequal variances. Otherwise the non-parametric Wilcoxon Rank Sum test was used to compare the two independent diet groups with numerical observations that were not normally distributed.

## Results

### Cholesterol and Phospholipid Content

The  $\text{FB}_1$  treatment significantly increased the cholesterol content in the microsomal ( $P = 0.0001$ ) and nuclear ( $P = 0.05$ ) subcellular fractions, while no significant differences were observed in the mitochondrial and plasma membrane subcellular fractions. The phospholipid, PC was significantly increased in the microsomal ( $P = 0.003$ ) and decreased in the mitochondrial ( $P = 0.026$ ) fractions, respectively. PE was significantly increased in the microsomal ( $P = 0.0001$ ), mitochondrial ( $P = 0.026$ ), plasma membrane ( $P = 0.048$ ) fractions. The SM content was significantly decreased and increased in the mitochondrial ( $P = 0.013$ ), and nuclear ( $P = 0.01$ ) fractions, respectively, in the  $\text{FB}_1$ -treated rats (Table 1).

### Membrane Lipid Parameters

No significant change in the cholesterol/phospholipid (PC + PE) ratio was observed in any of the fractions of the  $\text{FB}_1$ -treated rats (data not shown). In contrast, a significant decrease in the PC/PE ratio was observed in the microsomal ( $P = 0.005$ ), mitochondrial ( $P = 0.005$ ) subcellular fractions of the  $\text{FB}_1$ -treated rats, mainly due to an increase in the phospholipid, PE (Table 1).

The polyunsaturated/saturated (P/S) FA ratio was significantly decreased in PC of the microsomal ( $P = 0.039$ ); mitochondria ( $P = 0.024$ ) and plasma membrane ( $P = 0.015$ ) fraction. In PE, the P/S ratio was only decreased in mitochondrial ( $P = 0.035$ ) and plasma membrane ( $P = 0.001$ ) fractions.

**Table 1** The effect of FB<sub>1</sub> treatment on the lipid and FA parameters of different membrane subcellular fractions from rat liver

Values are means  $\pm$  STD of five determinations. Values in bold, differ significantly (*P* < 0.05) from the corresponding control subcellular fraction (actual *P* values are indicated in brackets)

Quantitatively ( $\mu\text{g FA}/\text{mg protein}$ ), the total PUFA ( $\omega 3$  and  $\omega 6$  PUFA) levels in PC decreased significantly in the mitochondria ( $P = 0.0001$ ); plasma membrane ( $P = 0.05$ ) and nuclear ( $P = 0.04$ ) fraction. In the microsomal fraction the total polyunsaturated fatty acid (PUFA) increased significantly ( $P = 0.001$ ) only in PE. Qualitatively, PUFA (expressed as the % of the total FA) decreased significantly in PC of the microsomal ( $P = 0.001$ ), mitochondrial ( $P = 0.0001$ ) and plasma membrane ( $P = 0.002$ ) subcellular fractions. In PE, PUFA was significantly decreased only the mitochondrial ( $P = 0.012$ ) and plasma membrane ( $P = 0.001$ ) subcellular fractions due to  $\text{FB}_1$  treatment.

The  $\omega 6/\omega 3$  PUFA ratios of the treated rats was significantly increased in the PC fraction of the plasma membrane ( $P = 0.01$ ) and marginally in the nuclei ( $P = 0.08$ ). The 20:4 $\omega 6$  PC/PE ratio was significantly reduced, quantitatively in the microsomal ( $P = 0.005$ ); mitochondrial ( $P = 0.008$ ) and marginally in the plasma membrane ( $P = 0.066$ ) fractions. Qualitatively, the 20:4 $\omega 6$  PC/PE ratio qualitative decreased significantly in the microsomal ( $P = 0.005$ ), mitochondria ( $P = 0.008$ ), plasma membrane ( $P = 0.02$ ) and only

marginally ( $P = 0.09$ ) in the nuclear fraction as a result of the  $\text{FB}_1$  treatment.

### Fatty Acids

Fatty acid profiles of the PE and PC phospholipids fractions of the different subcellular fractions are summarized in Tables 2, 3, 4 and 5. Data from the different subcellular fractions is expressed quantitatively ( $\mu\text{g}/\text{mg protein}$ ) and qualitatively as a percentage (%) of total FA content.

### Saturated Fatty Acid (C16:0 and C18:0)

The  $\text{FB}_1$  treatment significantly increased C16:0 ( $P = 0.023$ ) in the PC phospholipid fraction in the microsomes. The total saturated fatty acid (SFA) content of PE ( $P = 0.002$ ) increased significantly mainly due the increase in both C16:0 ( $P = 0.005$ ) and C18:0 ( $P = 0.002$ ). In the mitochondria, the SFA levels were decreased in PC ( $P = 0.005$ ) due to a significant decrease in C18:0 ( $P = 0.001$ ). In PE, the SFA levels were significantly increased ( $P = 0.001$ ) due to a sig-

Values are means ± STD of five determinations. Values in bold, differ significantly (*P* < 0.05) from the corresponding control subcellular fraction (actual *P* values are indicated in brackets). Percentage (%) = % of total FA

nificant increase in both C16:0 (*P* = 0.0001) and C18:0 (*P* = 0.046). Similar patterns were also noticed in the plasma membrane PE and PC fractions although differences were not significant. In the nuclear subcellular fraction no effects were observed.

Qualitatively total SFA in the microsomal fraction of the treated rats were not altered despite a significant decrease and increase of the percentage C16:0 in the PC (*P* = 0.033) and PE (*P* = 0.015) fractions, respectively. In the mitochondrial fraction, the percentage total SFA was marginally increased (*P* = 0.056) due to a marginal increase in C16:0, whereas in the plasma membranes it was significantly increased (*P* = 0.02) in the PE fraction. In the nuclei, C16:0 (*P* = 0.061) and the total SFA marginally (*P* = 0.065) increased in PC.

#### Monounsaturated Fatty Acid (C16:1 and C18:1)

The total monounsaturated fatty acid (MUFA) content of PC and PE was significantly elevated in the microsomal fraction (*P* = 0.0001) due to an increase in C16:1 (*P* = 0.008) and C18:1 (*P* = 0.0001) in PC and C18:1

(*P* = 0.0001) in PE. In the mitochondria, the total MUFA was increased in PC (*P* = 0.032) and PE (*P* = 0.015) due to an increase in C18:1 in PC (*P* = 0.033) and PE (*P* = 0.019) fractions. Only a marginally (*P* = 0.066) decrease of C16:1 was noticed in the nuclear PC. Except for a marginal (*P* = 0.08) increase in C18:1 in PE, no changes was noticed in the plasma membrane in the nuclear fraction.

In the PC fractions, the qualitative levels of the MUFA was significantly increased in the microsomal (*P* = 0.0003), mitochondrial (*P* = 0.0005) and plasma membrane (*P* = 0.0005) subcellular fractions due to an increase in C18 (*P* < 0.001 to *P* < 0.0001). In the plasma membrane fraction C16:1 (*P* = 0.037) was increased in PC. In the PE fraction C18:1 was marginally (*P* = 0.096) increased only in the plasma membrane fraction.

#### Polyunsaturated Fatty Acid

ω6 PUFA: (C18:2, C18:3, C20:3, C20:4, C22:4 and C22:5): In the microsomal subcellular fraction C18:2

Values are means  $\pm$  STD of five determinations. Values in bold, differ significantly (*P* < 0.05) from the corresponding control subcellular fraction in controls (actual *P* values are indicated in brackets). Percentage (%) = % of total FA

was significantly increased (*P* = 0.0004) in the PC fraction. The total  $\omega$ 6 PUFA content in the PE fraction was significantly (*P* = 0.001) increased due to a significant increase in the levels of C18:2 (*P* = 0.0001), C20:4 (*P* = 0.002), C22:4 (*P* = 0.0001) and C22:5 (*P* = 0.002).

In the mitochondria, the total  $\omega$ 6 PUFA content was significantly reduced in PC (*P* = 0.0001) due to a decrease in C20:4 (*P* = 0.0001), C22:4 (*P* = 0.0001) and C22:5 (*P* = 0.004) despite the fact that C18:2 (*P* = 0.014) increased. Except for a significant increase in C18:2 (*P* = 0.022), no other changes were noticed with respect to the PE fraction. In the plasma membrane PC, the total  $\omega$ 6 PUFA content was marginally (*P* = 0.05) decreased due to a decrease in C20:4 (*P* = 0.02), C22:4 (*P* = 0.02) and C22:5 (*P* = 0.003). In the nuclei, the total  $\omega$ 6 FA was decreased significantly in PC (*P* = 0.044) due to a decrease in C20:4 (*P* = 0.022). In PE, C22:4 (*P* = 0.001) increased significantly. Due to the low levels of C18:3 and C20:3 it was not included in Table 4 however; they were included in determining the total PUFA values.

Qualitatively the total  $\omega$ 6 PUFA decreased significantly (*P* < 0.005) in PC in the microsomal, mitochondrial and plasma membrane fractions due to a significant (*P* < 0.05) decrease in the long-chain  $\omega$ 6 PUFA (C20:4; C22:4 and C22:5), in spite of significant increases in C18:2 in the microsomes (*P* = 0.0003), mitochondria (*P* = 0.0002) and plasma membrane (*P* = 0.0002) fractions. In the nuclei the total  $\omega$ 6 PUFA only decreased marginally (*P* = 0.089) due to a marginal (*P* = 0.054) and significant (*P* = 0.011) decrease in C20:4 and C22:5, respectively, while C22:4 significantly (*P* = 0.003) increased. The total  $\omega$ 6 PUFA in the PE fraction was decreased significantly in the mitochondrial (*P* = 0.02) and plasma membrane (*P* = 0.014) fractions due to a decrease in the level of C20:4 (*P* = 0.041) and C22:4 (*P* = 0.003), respectively. C18:2 was significantly increased in both the microsomal fraction (*P* = 0.033) as well as the mitochondrial fraction (*P* = 0.022) and marginally in the plasma membrane (*P* = 0.056). In the nuclear fraction, only C22:4 (*P* = 0.002) was increased.

$\omega$ 3 PUFA: (C22:5, C22:6): The total  $\omega$ 3 FA in PC significantly decreased quantitatively in the mitochondrial ( $P = 0.0001$ ) and plasma membrane ( $P = 0.012$ ) due to a decrease in both C22:5 and C22:6 ( $P < 0.05$ ). In the microsomes, only C22:5 was significantly ( $P = 0.019$ ) decreased while in the nuclear fraction, the total  $\omega$ 3 FA decreased significantly ( $P = 0.041$ ) due to a decrease ( $P = 0.046$ ) in C22:6. In the microsomal PE the total  $\omega$ 3 FA ( $P = 0.006$ ) significantly increased due to an increase in C22:5 ( $P = 0.033$ ) and C22:6 ( $P = 0.01$ ).

Qualitatively the total  $\omega$ 3 PUFA decreased significantly in PC in the microsomal ( $P = 0.014$ ), mitochondria ( $P = 0.027$ ) and plasma membrane ( $P = 0.002$ ) fractions. This is due to a significant decrease in both C22:5 and C22:6 in the microsomal (C22:5,  $P = 0.004$ ; C22:6,  $P = 0.018$ ), mitochondria (C22:6,  $P = 0.038$ ) and plasma membrane (C22:5,  $P = 0.032$ ; C22:6,  $P = 0.005$ ) fractions. The total  $\omega$ 3 FA in the PE fraction, was marginally decreased ( $P = 0.051$ ) in the plasma membrane subcellular fraction due to a decrease in C22:5 ( $P = 0.012$ ). No changes were observed in PE for any of the other subcellular fractions.

## Discussion

FB<sub>1</sub> disrupts sphingolipid, phospholipids, FA and cholesterol metabolism in the liver and kidneys of different animal species. The disruption of the critical balance between proliferation and apoptosis by these different lipid parameters has been associated with cancer promotion by FB<sub>1</sub> in the liver and kidney of rats [25, 41]. However, it is unclear how changes in the lipid components of the different subcellular membrane fractions could create a growth differential in the liver that selectively stimulate the outgrowth of initiated cells. The current model and FB<sub>1</sub>-dose used promotes cancer in the liver [19] while a similar dose over a period of 5 weeks induces hepatocellular carcinoma in Fischer 344 rats [17].

Alterations to lipid components in the liver are associated with changes in membrane fluidity reflected by changes in the cholesterol/phospholipid (PC + PE) ratio, PC/PE and P/S ratios [42–44]. In the present study, the PC/PE ratio fluidity indicator, decreased significantly in the microsomal and mitochondrial subcellular fractions, mainly due to a significant increase in PE. The P/S ratio was decreased in PC from the microsomal, mitochondrial and plasma membrane subcellular membrane fractions and in PE in the mitochondrial and plasma membrane subcellular frac-

tions due to a significant decrease and increase in the qualitative levels of PUFA and SFA, respectively. Changes in these lipid parameters, which differ depending on the subcellular fraction, are likely to alter membrane fluidity. A reduction in the PC/PE and P/S ratios is associated with a more rigid membrane structure [42, 43], which could adversely affect many critical biological processes occurring at the membrane. Although the cholesterol/phospholipid (PC + PE) ratio was not altered significantly in the present study, the cholesterol was increased in the microsomal and nuclear membrane fraction, which will further increase the rigidity of the membrane structure as it stabilizes the fatty acyl groups [45].

Regarding the maintenance of cellular homeostasis, the organization of lipids and proteins into specialized clusters or microdomains on the outer leaflet in the plasma membrane is of importance. These microdomains, including lipid rafts and caveolae, are enriched with SM, cholesterol, C20:4 $\omega$ 6-containing plasmalogen ethanolamine and glycolipids serve as platforms for vesicular trafficking and the initiation and regulation of cell signalling processes [46, 47]. Many different growth factor receptors, including the endothelin, EGF, insulin receptor, insulin-like growth factor, platelet-derived growth factor, tumour necrosis factor (TNF) and folic acid receptor are lodged in lipid rafts/caveolae [48–51]. Lipid rafts/caveolae-associated signalling events affected by FB<sub>1</sub>, include the inhibition of folate receptor-mediated vitamin uptake [52], increased expression of TNF- $\alpha$ , TNF receptor-1, TNF-related apoptosis-induced ligand [53] and the inhibition of the EGF-induced mitogenic response [25]. The effect of FB<sub>1</sub> on these signalling processes has been related to the disruption of membrane integrity involving alterations in the sphingolipid [52, 53], cholesterol, phospholipid and FA metabolism [54]. Although, the plasma membrane concentrations of SM and cholesterol were not altered, the P/S ratio and PUFA were significantly reduced suggesting, as discussed above, a more rigid membrane structure, likely to affect membrane receptor and enzyme responses. The  $\omega$ 6/ $\omega$ 3 ratio was also increased due to a decrease in  $\omega$ 3 PUFA in PC which will impact on the prostaglandin synthesis by directing prostanoids synthesis more towards the E2-series associated with sustained cell proliferation [55]. In this regard the C20:4 $\omega$ 6 PC/PE ratio was significantly decreased, possibly due to the FB<sub>1</sub>-induced increase in the concentration of PE and the decrease in C20:4 $\omega$ 6 in PC. The increased level of C20:4 $\omega$ 6 in PE relative to PC has been implied as an important growth stimulus in hepatocyte nodules [44]. Changes in the content of C20:4 $\omega$ 6-enriched ethanolamine plasmalogens could

also be important during raft-mediated receptor responses and should be further investigated.

Changes to the major lipid parameters in the microsomal membrane fraction are similar to that reported previously [14]. Altered lipid parameters are known to impact on the activity of membrane enzymes relating to the synthesis of proteins, lipids and sterols [56]. The activity of cytochrome P450 isozymes [57], ceramide synthase [58], and the delta-6 desaturase [14] has been reported to be inhibited by FB<sub>1</sub>. Although FB<sub>1</sub> increased the level of cholesterol in the rat liver microsomal membrane fraction [14] the effect on 3-hydroxy-3-methylglutaryl coenzyme A reductase, the rate-limiting enzyme in endogenous cholesterol biosynthesis, has not been elucidated. The level of SM was not altered in the microsomal membrane fraction, which is in agreement with a previous report [24].

In the mitochondrial subcellular fraction, the PC/PE ratio was significantly reduced due to a decrease and increase in PC and PE, respectively. Disruption of the typical asymmetric lipid distribution of cell membranes could impact negatively on important physiological processes such as the induction of apoptosis [59]. In addition to the changes in PC and PE, SM was also reduced, presumably due to the disruption of the de novo sphingolipid biosynthesis by FB<sub>1</sub>. In this regard the presence of both ceramide synthase and ceramide has been observed in the mitochondrial membrane fraction [60, 61]. Ceramide regulates the generation of reactive oxygen species and the activation of mitochondrial apoptosis via several mechanisms, including glutathione peroxidase depletion and increased lipid peroxidation [62]. One of these mechanisms involves the down regulation of Bcl-2, an anti-apoptotic protein, which leads to the opening of the mitochondrial permeability transition pores (PTP) and apoptosis. Resistance to mitochondrial PTP opening is responsible for the promotion of initiated cells and an important event in the 2-acetylaminofluorene-induced hepatocarcinogenesis [63]. A moderate increase in lipid peroxidation was noticed in rat liver mitochondria after a dietary exposure of 250 mg FB<sub>1</sub>/kg [22], which could be related to the disruption of ceramide synthase.

It is unclear whether the depletion of ceramide in the mitochondria of altered hepatocytes is related to the cancer promoting properties of FB<sub>1</sub>. However, it was suggested that FB<sub>1</sub>-induced apoptosis may be due to the inhibition of ceramide synthase resulting in the depletion of ceramide and other complex sphingolipids and the accumulation of sphinganine and sphingosine [41, 64]. Cells sensitive to the proliferative effects of decreased ceramide and increased sphingosine 1-phosphate may have a selective growth advantage.

Although the liver is not normally a proliferative organ, it seems likely that the disruption of lipid and sphingolipid metabolism in the mitochondria by FB<sub>1</sub> could result in the impairment of apoptosis in the altered hepatocytes. The differential effect of FB<sub>1</sub> on mitochondrial oxidative damage in normal and initiated hepatocytes, therefore, could play an important role in their altered growth pattern. It has been postulated that, depending on the cell type, the disruptive effect of FB<sub>1</sub> on the sphingolipid metabolism, i.e. a decrease in ceramide and increased sphingosine 1-phosphate, will either favour proliferation or induce cell death [41, 65]. A recent study indicated that sphingosine accumulates in FB<sub>1</sub>-induced hepatocyte nodules suggesting it may be involved in the enhanced growth characteristics of these lesions via the formation of sphingosine 1-phosphate [66].

Lipid metabolism in the nuclear membrane fraction is considered to play an important role in signalling events that occur in this cellular compartment [67]. The effect of FB<sub>1</sub> on nuclear-associated membrane enzymes regarding lipid metabolism has not been established. In the present study the nuclear membrane fraction behaved very similarly to the microsomes regarding the increase in cholesterol with the exception that SM also increased. The presence of an SM cycle has been established in the rat liver nuclei [67], however the increase in SM in the nuclei due to FB<sub>1</sub> is unknown. As it was reported that similar levels of cholesterol and SM occur in the rat liver nuclei [67], the increase in SM could result from the corresponding increase in cholesterol. This increase and decrease of SM in the nuclei and mitochondria, respectively, could also explain why the level of SM was not affected by FB<sub>1</sub>-exposure when analysing whole liver [29]. The decrease in both  $\omega$ 3 and  $\omega$ 6 PUFA in the PC fraction could be due to an increase in lipid peroxidation in rat liver nuclei [23]. FB<sub>1</sub>-induced peroxidation of the membrane lipids was reported to induce oxidative DNA damage in isolated liver nuclei [68].

When considering the FA parameters, the observed changes differ for each subcellular membrane fraction as a result of the FB<sub>1</sub> exposure. Apart from the relative increase and decrease in SFA and PUFA, respectively, the total MUFA were moderately to significantly increased in PC and PE in the different subcellular fractions, except for the nuclear fraction. Of interest is the increase in C18:1 $\omega$ 9, the most abundant MUFA in membranes [69], which is associated with the modulation of the function of membrane-bound proteins in normal cells [1]. In addition, the increased in MUFA, specifically C18:1 $\omega$ 9 and C18:2 $\omega$ 6 is associated with the disruption of the delta-6 desaturase enzyme known to

be inhibited by  $FB_1$  [30]. The resultant increase in MUFA could also be due to an increase in delta-9 desaturase as observed in tumour growth in mouse mammary carcinoma cells [70], hepatoma cells [71], human leukemia and lymphoma cells [72]. The growth of mammary carcinogenesis in vitro was blocked by the addition of an inhibitor of delta-9 desaturase [73]. It is not known at present whether  $FB_1$  affects the activity of delta-9 desaturase. As C18:1 $\omega$ 9 is suggested to exhibit anti-oxidative properties [74] the accumulation thereof is likely to protect against the increased lipid peroxidation induced by  $FB_1$  in rat liver and subcellular fractions [74, 75]. The significant reduction in PUFA in most of the subcellular fractions indicated that apart from the inhibition of the delta-6 desaturase, the  $FB_1$ -induced lipid peroxidation also impacted on the status of the long chained FA such as C22:5 $\omega$ 6 and C20:6 $\omega$ 3. The increase lipid peroxidation and the resultant lipid breakdown products, especially in the nuclei, could be important in the cancer initiating properties of  $FB_1$  and in determining the extent of necrotic and/or apoptotic cell death.

Arachidonic acid (C20:4 $\omega$ 6) has been associated with the growth regulatory effects of  $FB_1$  in primary hepatocytes and cancer cells [24, 76]. It was hypothesized that the increase of C20:4 $\omega$ 6 in the PE phospholipids fraction together with the decrease of long-chain PUFA and associated low levels of lipid peroxidation are early events in the neoplastic transformation of hepatic nodules [44]. In the present study the C20:4 $\omega$ 6 PC/PE ratio was decreased in all the subcellular membrane fractions, due to an increased level of C20:4 $\omega$ 6 in PE. The importance of C20:4 $\omega$ 6 is further highlighted by the dual effect it has on cell proliferation or apoptosis via the formation of prostanoids or ceramide, respectively [77–79]. Recently a member of the phospholipase  $A_2$  ( $PLA_2$ ) enzyme-family, the type VI calcium-dependent  $iPLA_2$ , involved in C20:4 $\omega$ 6-generation and associated with C20:4 $\omega$ 6-induced apoptosis, was detected in close proximity of cyclooxygenase-2 (COX-2) in the mitochondria [80]. It has also been shown that  $FB_1$  stimulates cytoplasmic  $PLA_2$  activity, resulting in an increase in C20:4 $\omega$ 6 and its metabolites [81]. The suppression of apoptosis seems to be related to the conversion of C20:4 $\omega$ 6 to prostanoids by two isoforms of the enzyme COX, shown to be overexpressed in numerous human neoplasms [82]. In this regard the elevated expression of these COX isoform enzymes could be responsible for reduced availability for ceramide generation via the sphingomyelinase pathway [79]. The current study indicated that SM synthesis is also impaired by  $FB_1$  in the mitochondria through the inhibition of ceramide synthase.

The interaction between COX-2,  $PLA_2$  and ceramide synthase play a determining role in the regulation of apoptosis and cell proliferation during  $FB_1$  exposure. Therefore, the differential regulation of C20:4 $\omega$ 6 and ceramide levels in normal and altered hepatocytes are likely to be important determinants in the selective stimulation of preneoplastic lesion in the liver by  $FB_1$ .

**Acknowledgments** The authors wish to thank the Nutritional Intervention Research Unit for the use of their laboratory and gas-chromatography equipment. With thanks also to Johanna van Wyk for conducting the gas-chromatography analysis as well as Amelia Damons and John Moketary for washing and cleaning all the glassware. This project was funded by the Medical Research Council of South Africa and the National Research Foundation. Grant no FA2005032200026.

**Abstract** Castor seed triacylglycerols (TAGs) contain 90% ricinoleate (12-hydroxy-oleate) which has numerous industrial applications. Due to the presence of the toxin ricin and potent allergenic 2S albumins in the seed, it is desirable to produce ricinoleate from temperate oilseeds. To identify regulatory genes or genes for enzymes that may up-regulate multiple activities or entire pathways leading to the ricinoleate and TAG synthesis, we have analyzed expression profiles of 12 castor genes involved in fatty acid and TAG synthesis using quantitative reverse transcription-polymerase chain reaction technology. A collection of castor seeds with well-defined developmental stages and morphologies was used to determine the levels of mRNA, ricinoleate and TAG. The synthesis of ricinoleate and TAG occurred when seeds progressed to stages of cellular endosperm development. Concomitantly, most of the genes increased their expression levels, but showed various temporal expression patterns and different maximum inductions ranging from 4- to 43,000-fold. Clustering analysis of the expression data indicated five gene groups with

distinct temporal patterns. We identified genes involved in fatty acid biosynthesis and transport that fell into two related clusters with moderate flat-rise or concave-rise patterns, and others that were highly expressed during seed development that displayed either linear-rise or bell-shaped patterns. Castor diacylglycerol acyltransferase 1 was the only gene having a higher expression level in leaf and a declining pattern during cellular endosperm development. The relationships among gene expression, cellular endosperm development and ricinoleate/TAG accumulation are discussed.

## Introduction

The castor plant (*Ricinus communis*) is a perennial shrub mainly cultivated in tropical and subtropical areas of India, China and Brazil as an oilseed crop. Its seeds accumulate 60% oil in the form of triacylglycerol (TAG) that serves as a major energy reserve for seed germination and seedling growth. Castor oil is unique in that 90% of its fatty acid content is ricinoleate, 12-hydroxyoleic acid. The hydroxy group imparts unique chemical and physical properties that make castor oil a vital industrial raw material for numerous products such as cosmetics, paints, coatings, plastics and anti-fungal products [1]. Castor oil is also used as an additive to prevent fuels and lubricants used in aircraft engines from freezing at extremely low temperatures [1], and its replacement for sulfur-based lubricity components in petroleum diesel helps to reduce sulfur emissions [2].

One of the problems associated with castor seeds is that they contain the toxin ricin and hyper-allergenic 2S albumins that are detrimental to growers and processors. Therefore it is highly desirable to develop a safe source for castor oil production. In the past decade scientists have sought to identify key genes responsible for the ricinoleate synthesis in order to develop temperate oilseeds to produce ricinoleate. A castor gene (FAH) for the hydroxylase which is directly responsible for synthesis of ricinoleate was successfully isolated [3], but transgenic expression of the FAH in the model oilseed *Arabidopsis* produced only 17% ricinoleate [4], which was too low to be useful. There are many examples of transgenic production of other unusual fatty acids by over-expression of a key gene in oilseeds. With the exception of lauric acid and gamma-linolenic acid, the amount of desired fatty acids in the transgenic oilseed has been considerably lower than in the wild species from which the transgene was obtained [5]. These results suggest that expressing a single key gene required for unusual fatty acid biosynthesis in transgenic plants is insufficient to produce a large amount of unusual fatty acids in seed.

Current efforts on metabolic engineering of new oilseeds have been shifted towards searching for additional genes [6] or general transcription factors [7] that may up-regulate multiple activities or entire pathways leading to oil biosynthesis. Therefore, knowledge of the expression of multiple genes and

their regulation during castor oil biosynthesis is needed to further understand the regulatory mechanisms controlling castor oil metabolism. In general, castor oil biosynthesis mostly follows the common biosynthetic pathways for fatty acid in the plastid as well as TAG in the endoplasmic reticulum (ER), although there is a modification step for ricinoleate formation in the latter pathway [8]. In this paper, we survey the available castor sequences in National Center for Biotechnology Information (<http://www.ncbi.nlm.gov>) to identify 12 genes that participate in different steps of the pathways leading to fatty acid and TAG synthesis. We characterize the expression profiles of these genes in developing castor seeds during the time-course of seed development and ricinoleate/TAG accumulation. Additionally, a leaf sample is included as vegetative control and for comparative studies. To further compare the temporal expression patterns among the genes, we perform a clustering analysis that reveals five groups with distinct temporal patterns. Our results provide not only the initial information on promoter activity for each gene, but also a first glimpse of the global patterns of gene expression and regulation, which are critical to metabolic engineering of transgenic oilseeds for safe castor oil production.

## Experimental Procedures

### Plant Material

Castor (*R. communis* L.) seeds, PI215769, were obtained from the USDA-Germplasm Resources Information Network, Southern Regional Plant Introduction Station (Griffin, GA). Plants were germinated and grown in a greenhouse at temperatures between 28 °C (day) and 18 °C (night), with supplemental metal halide lighting to provide a 15-h day length (1,000–1,250  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ). Mature female flowers were individually pollinated and tagged, and the tagging dates were recorded as 0 day after pollination (0 DAP). Capsules were harvested at 7-day intervals from 12 to 61 DAP. Dissected seeds were frozen immediately in liquid nitrogen and stored at –80 °C. Leaf tissue was collected from a fully expanded young leaf in a mature castor plant.

### Isolation of Total RNA and Reverse Transcription

Total RNA was extracted using TRIzol Reagent (Invitrogen, Carlsbad, CA). RNA pellets were dissolved in DEPC-treated water, quantified by absorbance at 260 nm and checked for quality by ethidium bromide

gel electrophoresis. The total RNA samples were first treated with DNase I, and then reverse transcribed to first-strand cDNA using an Oligo(dT) primer and SUPERSRIPT III (Invitrogen, Carlsbad, CA). Finished cDNA products contained 50 ng/ $\mu$ L reverse transcribed total RNA, and were stored at  $-80^{\circ}\text{C}$ .

#### Primer Design and Standard Curve Construction

Putative primers were designed according to the SYBR Green Design criteria incorporated in the Beacon Designer 4.0 software (Premier Biosoft International Palo Alto, CA). To ensure maximum specificity and efficiency during quantitative PCR, putative primer pairs were further tested for linearity of response by constructing standard curves on five or six serial ten-fold dilutions. The templates used for the standard curve analysis were mixed cDNAs from 12 to 54 DAP samples with a starting concentration of 2.5 ng/ $\mu$ L. A standard reaction mixture (25  $\mu$ L) contained 10  $\mu$ L cDNA template, 1x iQ SYBR Green I Supermix (Bio-Rad, Hercules, CA) and 300 nM forward and reverse

primers. The Bio-Rad iCycler iQ-system was used for all amplifications. The PCR protocol consisted of an initial denaturing step of  $95^{\circ}\text{C}$  for 3 min, followed by 40 repeats of  $95^{\circ}\text{C}$  for 10 s and  $55^{\circ}\text{C}$  for 30 s. A melt-curve protocol immediately followed the amplification with heating to  $95^{\circ}\text{C}$  for 1 min and annealing at  $50^{\circ}\text{C}$  for 1 min, followed by 80 repeats of heating for 10 s, starting at  $50^{\circ}\text{C}$  with  $0.5^{\circ}\text{C}$  increments. The Bio-Rad iQ iCycler System software produced standard curves by plotting the  $\log_{10}$  of the starting quantity against the threshold cycle ( $C_T$ ). Correlation coefficients were determined from the standard regression formulas. Standard curves showing correlation coefficients of 0.99 or higher and PCR efficiencies between 90 and 110% were accepted. For each primer set, at least three independent standard curves were analyzed, and the average number was used in data analysis. PCR product specificity was confirmed by melting-curve analysis and by electrophoresis on 4% agarose gel to ensure that PCR reactions were free of primer dimers and non-specific amplicons. Information on optimized primer pairs is listed in Table 1.

## Quantitative RT-PCR Data Analysis

The method of Pfaffl [9] was applied to calculate comparative expression levels between samples. The castor actin gene (a house-keeping gene, [10]) was used as internal reference to normalize the relative amount of mRNAs for all samples. For each selected gene, triplicate sets of PCR reaction samples including the actin controls, and duplicate negative controls (reaction samples without cDNA templates), were prepared and run in a 96-well plate. The SYBR fluorescence was analyzed by iQ iCycler software and the  $C_T$  value for each sample was reported. The average  $C_T$  from 26 DAP measurements were calibrated as 100, 1,000 or  $10^5$  copy numbers, and the relative copy numbers of a gene were averaged over triplicates. The PCR experiments were repeated for each plate to ensure that similar results could be obtained.

## Data Clustering Analysis and Visualization

To partition the lipid genes into distinct groups such that genes assigned to the same cluster should have similar expression patterns, the quantitative expression data of each gene at various developmental stages were first normalized to the genes maximum expression (set at 100%) and then subjected to gene expression clustering analysis using the *k*-mean clustering method [11] provided within the software Expression Analyzer and DisplayER (EXPANDER, [12]). The *k*-mean clustering numbers, 4, 5 and 6 were tested (data not shown) and the clustering into five groups was selected because it gave the best scores for clustering quality. To view the expression patterns of clusters by a graph, the option of mean patterns with error bars operated by the EXPANDER was chosen that allows each cluster to be displayed in a separate panel with error bars representing standard deviations.

## Chemicals

Ricinoleic acid methyl ester and cyclohexane were obtained from Sigma–Aldrich (St. Louis, MO). Nonadecanoic acid methyl ester and GLC-68 FAME standard mixture were obtained from Nu-Chek Prep, Inc. (Elysian, MN). Heptadecanoic acid methyl ester and anhydrous acetyl chloride were purchased from Alltech (Deerfield, IL) and butylated hydroxytoluene (BHT) was obtained from Spectrum Chemical MFG Corp. (Gardena, CA). Anhydrous sodium sulfate was purchased from J.T. Baker Inc. (Philipsburg, NJ). 2-Propanol, methanol, hexane and toluene were obtained from Fisher Scientific (Fair Lawn, NJ).

Sodium chloride and potassium bicarbonate were obtained from Mallinckrodt Laboratory Chemicals (Philipsburg, NJ). Ethanol was purchased from AAPER Alcohol and Chemical Co. (Shelbyville, KY). The water used was double distilled, and all chemicals and solvents used were of reagent grade.

## Lipid Extraction, Seed Dry Weight and Water Content Measurement

Castor seeds were peeled and thoroughly homogenized using a mortar and a pestle. Seed samples were weighed (seed fresh weight) into Eppendorf tubes and dried under vacuum centrifugation over night. The dried samples were weighed and the water content was calculated. Triplicate samples were prepared by accurately weighing 0.01 g of dried seed sample into 10 mL glass tubes. The lipids were extracted using 2 mL of hexane/2-propanol (8:2) containing  $50 \mu\text{g mL}^{-1}$  of BHT. Internal standard (nonadecanoic acid methyl ester) was added and the extraction took place at  $55^\circ\text{C}$  for 30 min with shaking every 10 min. The extracts were filtered and dried over sodium sulfate, and the solvent was evaporated under nitrogen. The lipid weight was determined gravimetrically. After addition of 0.5 mL toluene, the lipids were methylated for 1 h at  $80^\circ\text{C}$  using methanolic hydrogen chloride (3%), as described by Christie [13]. The resulting FAMES were dissolved in 10 mL of cyclohexane (0.01% BHT) for GC analysis. The non-lipid dry weight was obtained by subtracting the lipid and water weight from the seed fresh weight.

## GC Analysis

Quantitative analysis was carried out by GC-FID using a Hewlett Packard 6890 GC system with split injection connected to a 7673 automatic liquid sampler, Agilent Technologies (Palo Alto, CA). Separation was achieved on a DB-WAX column (20 m  $\times$  0.12 mm i.d., 0.18  $\mu\text{m}$  film thickness) purchased from J & W Scientific, Agilent Technologies. The injector and detector temperatures were 250 and  $280^\circ\text{C}$ , respectively. The column temperature program was  $100^\circ\text{C}$  for 1 min,  $5^\circ\text{C min}^{-1}$  to  $250^\circ\text{C}$ , and hold 1 min. Standard solutions of a mixture of FAMES including methyl ricinoleate at three different concentrations in the range of  $40\text{--}400 \mu\text{g mL}^{-1}$  for methyl ricinoleate and  $5\text{--}150 \mu\text{g mL}^{-1}$  for the other FAMES were used for generating standard calibration curves.  $50 \mu\text{L}$  of methyl heptadecanoate ( $1 \text{ mg mL}^{-1}$ ) was added as internal standard to each 1-mL aliquot of standard sample. One microlitre injections were used, and

duplicate determinations were applied. Identification of peak components was achieved on a Hewlett Packard 5890 GC system connected to a 5970A mass selective detector, Agilent Technologies. Split injection was applied, and the same type of column and temperature program as described above was used. Comparison to mass spectra of known FAMES was used for identification of each peak. In addition, double-bond locations for the unsaturated fatty acids were determined by interpreting spectra from picolinyl derivatives of free fatty acids (FFAs), employing the methodology described by Christie [13].

## Results and Discussion

### Changes in Water, Lipid and Ricinoleate Content During Seed Development

A mature castor seed contains a mass of endosperm that synthesizes and stores oil and protein as major reserves [14]. We have previously characterized the morphological changes of developing castor seeds and established a time-course for assessing endosperm development [15]. Castor endosperm development has a nuclear endosperm development pattern that starts with a free-nuclear stage and then progresses into cellularization and maturation. The whole course takes about 54 DAP. At 61 DAP and after, seeds are completely mature and begin desiccation [15]. During the first 19 DAP, castor seeds grew rapidly to full size ([15], Fig. 1d), and consisted mostly of water at 90% of seed fresh weight and small amounts of lipid at about 5% (Fig. 1a). The endosperm stayed at free-nuclear stage and did not enter cellular endosperm development (Fig. 1d). Between 26 and 40 DAP, the endosperm underwent cellularization, expanding and eventually filling the most of the seed at 40 DAP ([15], Fig. 1d). Then the cellular endosperm continued maturation up to 54 DAP without showing visible changes [15]. During the course of cellular endosperm development (26–54 DAP), the seeds gradually lost water and gained storage lipid to a maximum level of 60% at 54 DAP (Fig. 1a) and maintained the same high level thereafter.

To examine the ricinoleate content, total fatty acid represented by FAME and ricinoleate was measured in seeds at various developmental stages. As shown in Fig. 1b, the ricinoleate and total FAME showed accumulation patterns parallel to each other, and the increase of the FAME was attributed predominantly to the increase of ricinoleate. At early stages (12 and 19 DAP) in free-nuclear endospermic seeds, the

**Fig. 1** Changes in water, lipid and ricinoleate content during seed development. Each data point represents the mean ( $\pm$ SD) of three measurements and at least 20 seeds. **d** transverse cross section of developing castor seeds. Cellular endosperm is shown in opaque color. DAP days after pollination

ricinoleate was not detectable (Fig. 1c). However by 26 DAP when 30% of seed's volume filled with cellular endosperm (Fig. 1d), the ricinoleate accumulated immediately to 9.2% of seed dry weight (Fig. 1b) and accounted for 77% of fatty acid content (Fig. 1c). During the remaining stages of cellular endosperm development, the ricinoleate kept increasing and reached plateaus of 55% of seed dry weight at 54 DAP and 90% of total FAMES at 40 DAP (Fig. 1b, c). Besides ricinoleate, there were about seven minor fatty acids detected in seeds at all stages of the development, all of them accumulated at low background levels in a total amount of 2.8–6.5% of dry seed weight (data not shown). These fatty acids were probably components of structural lipids for maintaining the cell membrane and seed coat, in addition to being minor components of the oil. By using the same sets of developing seeds, similar results were observed by measuring changes in lipid classes, including acylglycerols, FFAs, phosphatidylcholine (PC) and phosphatidylethanolamine (PE) [16]. Before 19 DAP, there were considerable amounts of PC and PE present in seed lipid, and the acylglycerols contain less than 7% TAG. After 26 DAP, the relative amount of PC and PE dropped to negligible levels, and the fatty acids were almost exclusively in acylglycerols of which 77–89% was TAG [16]. It is known that ricinoleate accumulates almost exclusively as storage TAGs rather than as membrane lipids in castor seeds [8], therefore, the appearance of ricinoleate indicates the initiation of storage TAG synthesis. Taken together, the FAMES measured in seeds before 19 DAP (Fig. 1b) would represent mostly fatty acids from membrane lipids, whereas, after 26 DAP, the FAME are mostly of TAG origin. As shown in Fig. 1, ricinoleate and TAG synthesis started at 26 DAP, coinciding with the beginning of endosperm cellularization. Our previous studies in castor showed increased expression of ricin [17] and 2S albumins [15] genes that also started at 26 DAP. These results all suggest that the time between 19 and 26 DAP is a critical switchover stage for synthesizing both oil and storage proteins in castor. Moreover, these results also demonstrate that our series of developing seeds allows us to identify the initial timing and temporal pattern of different biochemical and cellular activities during seed development and to draw accurate comparisons between experiments.

#### Selection of Lipid Genes and Optimized PCR Primers

In order to find the lipid genes for castor oil biosynthesis, we searched the Genbank nucleotide database

(<http://www.ncbi.nlm.gov>) by using compound queries each consisting of *R. communis* and the nomenclature of genes involved in synthesis of fatty acid and TAG from a comprehensive lipid gene catalog [18], which lists 600 genes representing 210 cellular activities involved in various aspects of acyl lipid metabolic pathways including fatty acid and TAG biosynthesis from plant kingdom. We noticed that all hits were for cDNA clones from developing castor seeds, indicating their functional expression during seed lipid biosynthesis. In some cases, more than one accession exists because of multiple partial sequences submitted by different laboratories. We examined the candidate genes by multiple sequence alignment and selected the most complete sequence to represent the gene. The search also found a partial sequence (GenBank ID T15158) containing an enoyl-reductase domain of Type I fatty acid synthase (FAS). This sequence is tentatively designated as FASI-like gene in Table 1.

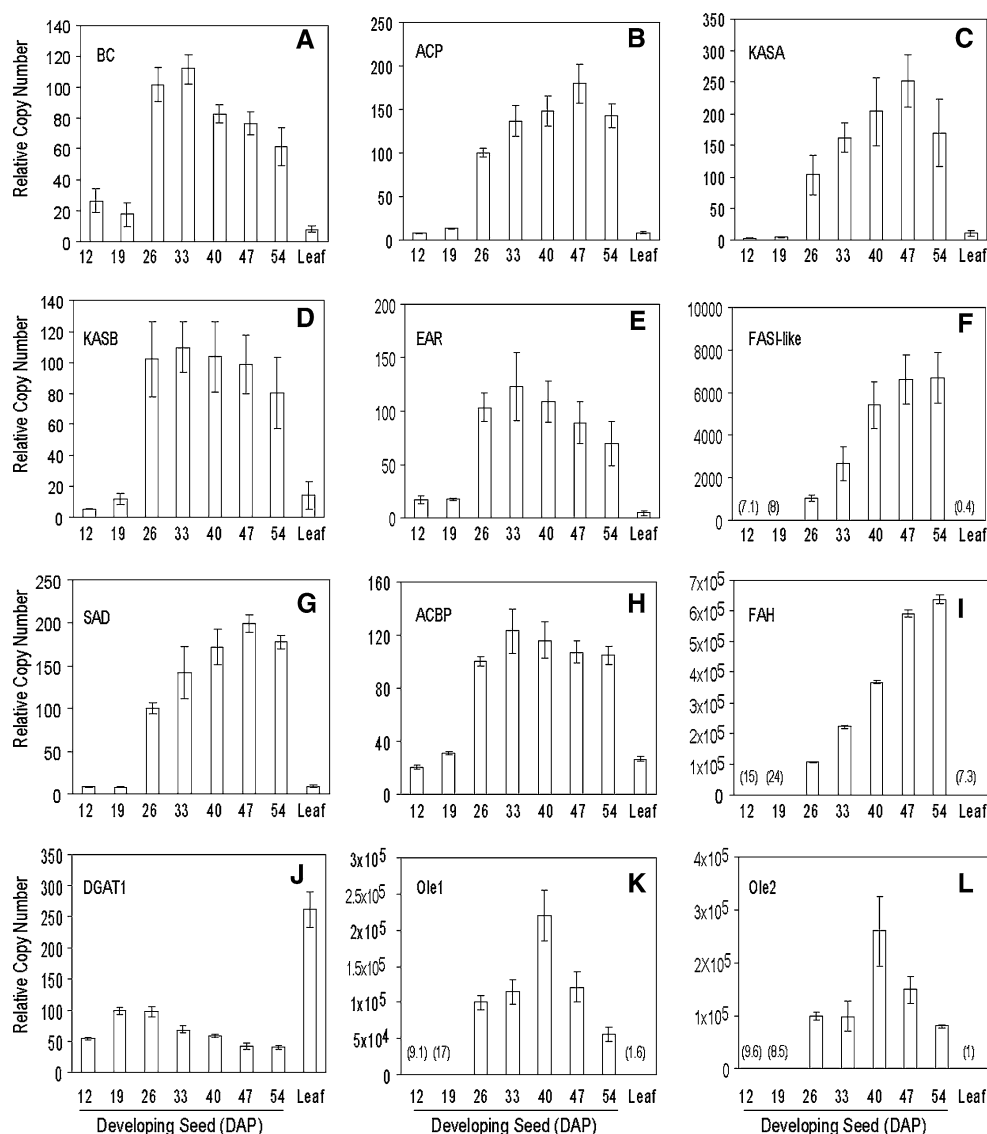

Quantitative PCR is one of the most sensitive and quantitative methods for measuring mRNA levels [19]. We optimized all assay conditions (“[Experimental Procedures](#)”), and the primer sets and PCR efficiencies are listed in Table 1. In addition, PCR products were designed to have similar sizes between 100 and 230 bp (Table 1). These optimized conditions allow simultaneous analysis of multiple genes on a 96-well plate and permit accurate comparison of relative copy numbers among genes.

#### General Expression Profiles of Lipid Genes and Lipid Gene Clusters

Using the quantitative RT-PCR technology, we examined the steady state mRNA levels of lipid genes in seed samples from various developmental stages. For convenience, these mRNA levels are referred to as ‘expression’ in this article. Expression profiles of the lipid genes are shown in Fig. 2. With the exception of the diacylglycerol acyltransferase 1 (DGAT1), we detected low background expression for the majority of lipid genes in leaf tissue and in young seeds at 12 and 19 DAP when endosperm was at the free-nuclear stage. When the seeds progressed to cellular endosperm development (26–54 DAP), the expression of the majority of lipid genes was induced to higher levels, displaying various temporal patterns; the maximum induction also varied dramatically, ranging from 4- to 43,000-fold (Fig. 2, Table 2). The results revealed that a major transcriptional activation of lipid gene expression occurred at the onset of cellular endosperm development, coinciding with the beginning of the storage TAG accumulation (Fig. 1b). It indicates a

**Fig. 2** Expression of lipid genes in developing seeds and leaf. Abbreviated names for the genes are described in Table 1. Each data point represents the mean  $\pm$  SD of three replicates. DAP days after pollination. Values in parentheses indicate relative copy number

primary role of gene transcription in regulating castor oil biosynthesis.

To examine relationships among the temporal expression patterns of the lipid genes, we performed clustering analysis (“[Experimental Procedures](#)”), which classified the lipid genes into five groups based on their pattern similarities. As expected, the DGAT1 itself formed a cluster showing a specific declining pattern (cluster 1 in Fig. 3a). The majority of the lipid genes showed various up-regulated patterns during seed development including flat-rise (cluster 2), concave-rise (cluster 3), bell-shaped (cluster 4) and linear-rise (cluster 5). The clusters are summarized in Fig. 3 and Table 2, together with their gene members and normalized mean pattern description, the changes in expression (maximum ratio) for each gene as well as

the maximum ratio between the developing seed and mature leaf.

#### Expression Profiles of the Lipid Genes Involved in Fatty Acid Biosynthesis

According to our current knowledge of castor seed TAG synthesis, oleic acid is synthesized in the plastid and then exported to cytoplasm following the standard fatty acid biosynthesis pathway [20]. Oleic acid is activated to oleoyl-CoA in the cytoplasm and imported into ER with help of acyl-CoA binding protein (ACBP) for TAG synthesis [20]. We have examined seven castor lipid genes involved in oleic acid biosynthesis and transport and found they belong to either cluster 2 or cluster 3. Cluster 2 has a flat-rise pattern

**Table 2** Summary of transcript profiles of lipid genes

Temporal pattern during seed development	Gene <sup>a</sup>	Maximum ratio of expression	
		Seed/seed <sup>b</sup>	Seed/leaf <sup>c</sup>
Cluster 1, decline	DGAT1	2.4	0.4
Cluster 2, flat rise	BC	4	12
	KASB	21	7.8
	EAR	7	28
	ACBP	6	4.7
Cluster 3, concave rise	ACP	22	20
	KASA	70	22
	SAD	23	23
Cluster 4, bell-shaped	Ole1	24,172	140,400
	Ole2	27,150	252,230
Cluster 5, linear rise	FASI-like	940	18,288
	FAH	43,083	86,990

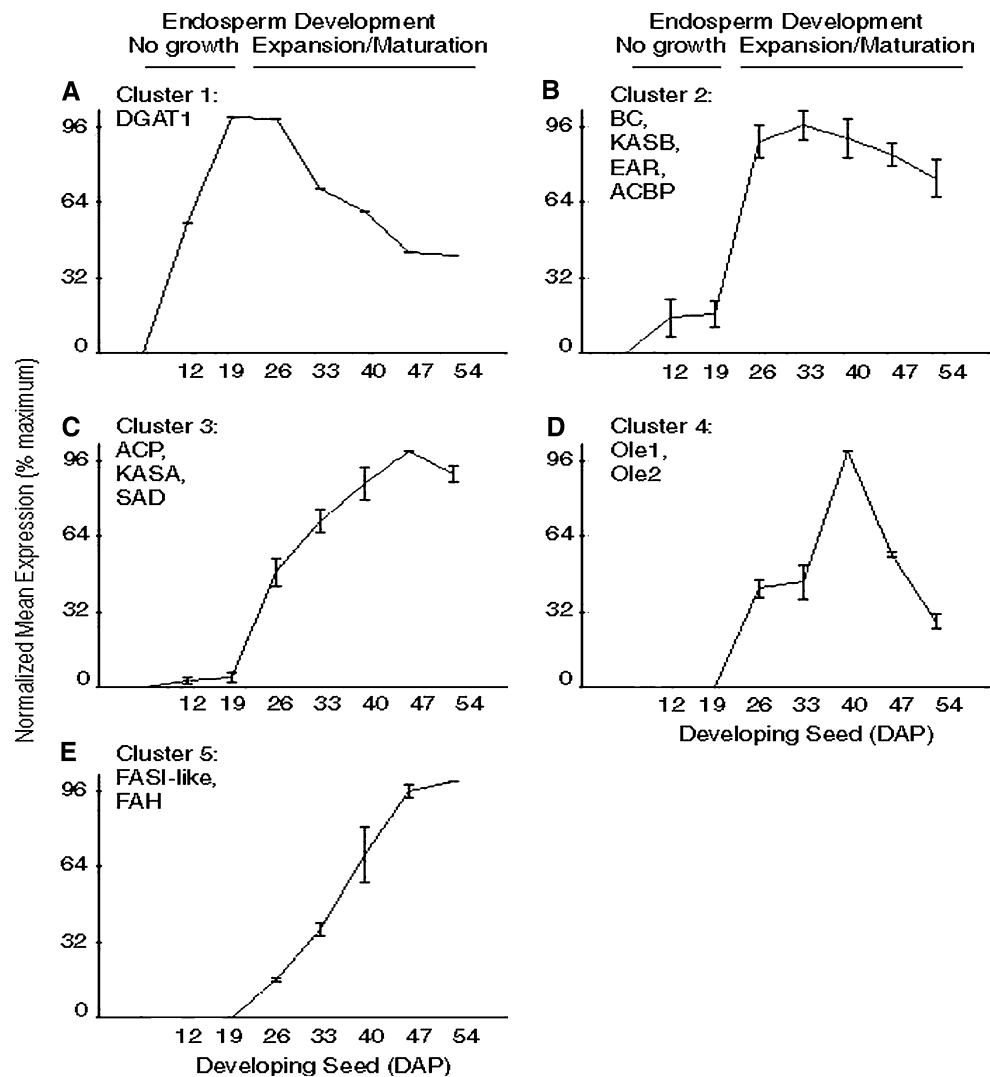

<sup>a</sup> The gene short names are described in the Table 1

<sup>b</sup> Ratio of the maximum to the minimum expression in seed

<sup>c</sup> Ratio of the maximum expression in seed to the expression in leaf

(Fig. 3b) with four members: acetyl-CoA carboxylase biotin carboxylase subunit (BC), 50 kDa  $\beta$ -ketoacyl-ACP synthase (KASB), enoyl-ACP reductase (EAR), and ACBP; while cluster 3 (Fig. 3c) includes three genes, acyl carrier protein (ACP), 46 kDa  $\beta$ -ketoacyl-ACP synthase (KASA), and stearoyl-acyl-carrier protein desaturase (SAD), all with a concave-rise pattern. Further comparisons among gene clusters reveal that cluster 2 and 3 share certain expression characteristics. First, the maximum induction ratios between seed and leaf in cluster 2 and 3 (4.7 to 28-fold) are much smaller than those in cluster 4 and 5 (18,288 to 252,230-fold). Second, during the time-course of seed development, cluster 2 and 3 have moderate maximum induction ratios (4 to 70-fold) compared to cluster 4 and 5 (940 to 43,083-fold). Third, the temporal patterns of cluster 2 and 3 are less dynamic than those of cluster 4 and 5; cluster 2 has a simple flat-rise, whereas cluster 3 has a quick rise that reaches its half-maximum at the

**Fig. 3** Expression patterns of lipid gene clusters during seed development. Abbreviated names are described in the Table 1. Each cluster is represented by the mean expression pattern over all the genes assigned to it. Error bars denote  $\pm$ SD. DAP days after pollination

beginning of cellular endosperm development, and increases slowly (<2 fold) during the rest of the seed development. As a consequence of these features, the levels of induction among clusters 2 and 3 at the onset of cellular endosperm development (26–33 DAP) are similar, ranging between 4 to 21 and 11 to 35 fold, respectively. These shared characteristics between clusters 2 and 3 suggest that common regulatory factors might be present to up-regulate the expression of these lipid genes in plastid. Moreover, the appearance of overall moderate expression and related patterns shared by clusters 2 and 3 would also suggest their house-keeping functions in cellular endosperm tissue. There is evidence that fatty acid biosynthesis is a house-keeping function and it undergoes coordinated regulation through gene expression to provide constant demands of fatty acids for membrane lipid biosynthesis, in addition to its involvement in storage TAG assembly. For instance, biochemical data show that individual enzymes required for fatty acid biosynthesis in the plastid may be retained as a functional unit, or a house-keeping metabolon [21]. Genes encoding components of the plastidic acetyl-CoA carboxylase in *Arabidopsis* [22] and the FAS in *Brassica* [23] are expressed at constant molar ratios both in different tissues of mature plants and throughout seed development. Furthermore, the microarray analysis of more than 100 *Arabidopsis* lipid genes demonstrates that 60% of them do not change in expression during the time-course of seed development, including some core enzymes of FAS, such as  $\beta$ -ketoacyl-ACP synthaseIII and isoforms of ACP [24]. In castor seed, cluster 2 and 3 may represent house-keeping genes and their boosted expressions obviously associated with the increasing demand of the oleic acid for TAG biosynthesis during cellular endosperm development. It is possible that cluster 2 and 3 genes also contribute to castor membrane lipid biosynthesis, because we have also observed low expression of cluster 2 and 3 in non-storage tissues such as leaf and young seeds at 12 and 19 DAP (Fig. 2). The low expression of cluster 2 and 3 in the vegetative tissues would correlate with the low demand for fatty acid in membrane lipid synthesis. Similar results were reported for the castor SAD gene expression using Northern blot analysis, showing highest expression in developing seed, moderate to low expression in leaf and low expression in root [25]. So probably there are two different mechanisms existing in castor to regulate the expression of genes involved in fatty acid biosynthesis, one at low levels for membrane function and the other at higher levels for reserve synthesis. Without castor whole genome information, other alternatives also exist, for example, isoforms of

cluster 2 and 3 may contribute to fatty acid biosynthesis in different tissues or at different developmental stages.

#### Expression Profiles of Castor Oleosin Genes

The clustering analysis groups two oleosin genes into cluster 4 showing a bell-shaped pattern (Fig. 3d). Oleosins are oil body-associated proteins that cover and stabilize oil bodies during TAG accumulation [26]. In most plants oleosins are encoded by multi-gene families and some of them are co-expressed [26]. We have observed that castor oleosin1 and oleosin2 genes were co-expressed during seed development with maximum induction ratios of 24,172 and 27,150-fold, respectively (Fig. 2k, l; Table 2). The oleosin proteins have been shown to accumulate in equal amounts [27] or different amounts with the oleosin1 at a higher level [10]. The difference in relative protein level between oleosin1 and oleosin2 could be due to genotype discrepancy among castor cultivars and/or post-transcriptional regulation involvement in oleosin protein accumulation. However our time-course data showed peaks at 40 DAP, a time point when cellular endosperm reached its full expansion (Fig. 1d). The peak expression of oleosins is probably driven by the demand for newly synthesized oil bodies resulting from the growing ER membranes during cellular endosperm expansion.

#### Expression Profiles of Castor FAH and FASI-Like Genes

The FAH and FASI-like genes are grouped into cluster 5 and display a linear rise pattern during seed development (Fig. 3e). As the enzyme responsible for ricinoleate biosynthesis, the FAH hydroxylates the *sn*-2 oleoyl chain of oleoyl PC to form *sn*-2 ricinoleate-PC [8]. The expression of the FAH gene was reported to be high in seed and very low in leaf [3]. Our data on the FAH gene expression is consistent with the previous report, but with new quantitative and detailed temporal expression profiles. In leaf and young seeds at free-nuclear endosperm stages (12 and 19 DAP), FAH is expressed at negligible levels (Fig. 2i). FAH is expressed at a high level when seeds progress into cellular endosperm development and storage TAG/ricinoleate biosynthesis during 26–54 DAP (Fig. 1b), showing an immediate 5,000-fold induction at the beginning (26 DAP, Fig. 2i) and continuous sharp increases during the rest of the stages. As a consequence, the FAH expression showed a linear-rise pattern and a maximum induction of 43,083-fold at the

end of the seed development (54 DAP, Fig. 2i; Table 2). These results would indicate that the FAH gene is transcriptionally expressed at similar high rates throughout the cellular endosperm development and, at the same time, the FAH transcripts are probably also very stable in cellular endosperm, resulting in its high accumulation. Furthermore, such high accumulation of the FAH gene transcript would suggest transcriptional regulation is the mechanism for maintaining high ricinoleate synthesis to fulfill the growing demand of TAG synthesis in developing cellular endosperm.

The function of the FASI-like gene remains unknown due to its incomplete sequence information. When searching the Genbank protein database with the truncate FASI-like protein sequence as a query, it retrieved a plant sequence encoding phenylpropenal double-bond reductase from *Pinus taeda* (Genbank accession: DQ829775.1) among five top hits (alignment score from 60 to 62). Although this enzyme is involved in phenylpropanoid metabolism for plant defense [28], it also shows sequence similarity to enzymes involved in plant lipid metabolism [28]: the enoyl acyl carrier protein reductase (Genbank accession: CAC41367) from *Brassica napus* and the 2-alkenal reductase (Genbank accession: At5g16970) from *Arabidopsis*. The castor FASI-like gene was highly expressed during seed development and oil synthesis, showing a maximum induction of 940-fold and a similar linear-rise pattern as that of FAH (Fig. 3e; Table 2). The results reveal intriguing information on the FASI-like gene, which should lead to future investigations on its enzymatic and cellular function during castor seed development.

#### Expression Profile of Castor DGAT1

Diacylglycerol acyltransferase catalyzes the final step in TAG synthesis that acylates diacylglycerol (DAG) with acyl-CoA to form TAG [29]. Castor DGAT1 has been shown to preferentially incorporate ricinoleate into diricinolein to form triricinolein [30]. Among the lipid genes examined, the DGAT1 is the only member in cluster 1 displaying a declining pattern. During seed development, the DGAT1 mRNA accumulated to highest level at early stages (19–26 DAP, Fig. 2j) and then decreased to lower levels over time (33–54 DAP), showing a maximum of 2.4-fold reduction from 26 to 54 DAP. The temporal pattern of DGAT1 (Fig. 3a) is in agreement with previous Northern data [16] and quantitative RT-PCR data [31]. However the DGAT1 protein level and enzymatic activity during seed development increased at 26 DAP, reached a maximum at 40 DAP, and both protein and activity were at

least 50% maximum level from 26 to 54 DAP [16], consistent with the pattern of TAG synthesis (Fig. 1a). The shifted pattern of DGAT1 protein/activity in comparison to its mRNAs was interpreted as post-transcriptional regulation contributing in part to the mechanism of TAG synthesis [16]. Since we observed the onset of cellular endosperm development that also started at 26 DAP (Fig. 1d), it is possible that the cellular endosperm plays a role in regulating the DGAT1 protein/activity by providing a micro-environment for its cellular function. The DGAT1-involved TAG synthesis takes place mainly in developing seed and pollen as storage reserves [29], but it also occurs in various vegetative tissues of *Arabidopsis*, such as root, stem, senescing leaf, flower and silique [32, 33]. We found that the DGAT1 mRNA in leaf tissue was higher than that in developing seeds (Fig. 2j; Table 2). Also, in cotyledons and true leaves of germinating castor seedlings, the DGAT1 mRNA, protein and enzyme activity were found to be expressed and temporally associated with increased levels of newly synthesized TAG [34]. These results suggest that DGAT1 may also play a regulatory role in balancing DAG and acyl-CoA molecules in membrane lipid metabolism to maintain membrane function in vegetative tissue. Besides DGAT1, there are at least other two independent reactions contributing to the final step of TAG synthesis in castor. A castor DGAT2 gene which has little amino sequence homology to DGAT1 but can also use diricinolein as acceptor and ricinoleoyl-CoA as the donor in TAG synthesis has been identified recently ([31], our unpublished data). Studies show that the DGAT2 displays a bell-shaped temporal pattern during seed development and is more highly expressed in seeds than in leaves ([31], our unpublished data). A castor enzyme, phospholipid:diacylglycerol acyltransferase (PDAT), has also been shown to contribute to TAG synthesis by acyl-CoA-independent acylation using ricinoleoyl-PC as acyl donors and ricinoleoyl-DAG as acceptors [35]. More independent gene families, such as bifunctional wax ester synthase/DGAT [36] and cytosolic DGAT [37] have been identified to catalyze the formation of TAG. It is possible that these gene families also participate in the final step in TAG synthesis in castor. Taken together, the final step in TAG synthesis in castor and other oilseeds is complicated and the question remains as to which of these genes and at what developmental stage do they play more or less important roles in TAG synthesis.

Overall, our series of seed studies, including endosperm development, storage TAG accumulation and gene expression, are all in parallel with the same

time-course, which provides integrative information for understanding their relationships during castor seed development. It is evident that synthesis of TAG requires coordinated regulation controlled by seed developmental programs at multiple levels, such as endosperm cellularization, gene transcription and post-transcriptional regulation. Obviously, gene transcription exerts a primary control in castor oil biosynthesis. The clustering analysis on temporal expression of lipid genes reveals five distinct patterns, indicative of different transcriptional regulatory mechanisms among these lipid genes. Our results of analysis of gene expression represent snapshots of a global transcriptional activities taking place during castor seed development and oil biosynthesis.

**Abstract** Since ceramides (CERs) play roles in signal transduction and cell regulation, CERs of human hair might be responsible for apoptosis during keratinization, in addition to their structural barrier and water-holding functions. Although, we previously developed a method for comprehensive profiling of the CERs in hair, that method was too insensitive to quantitatively characterize the CERs in a small amount of hair samples. The aim of this study was to develop a novel method for the highly sensitive determination of the diverse CERs. The method developed is negative ion electrospray ionization mass spectrometry (ESI-MS) coupled to reversed-phase high-performance liquid chromatography (RP-HPLC) using methanol containing 10 mM ammonium acetate as a mobile phase. By this method, 48 peaks derived from 73 kinds of CERs were simultaneously determined in selected ion monitoring measurement using one calibration line of the standard *N*-palmitoyl dihydrospingosine, based on extremely small differences in the molar responses among different species of CERs, followed by the calculation of the actual levels using corrections for  $^{13}\text{C}$  and  $^2\text{H}$  effects. This method had extremely high sensitivity as indicated in the limit of quantification being in the femtomolar range. Other quantitative validation data, such as reproducibility, linearity and recoveries, were all sufficient. The quantitative levels of CERs

determined by RP-HPLC–ESI-MS were comparable with those determined by thin-layer chromatography. This method was successfully applied to the characterization of levels of CERs in only 1-mm pieces derived from a single hair fiber and revealed the presence of interindividual and intraindividual variations of the CER composition. This RP-HPLC–ESI-MS method can be a powerful tool for future research on physicochemical and physiological roles of CERs in hair.

## Introduction

Ceramides (CERs) play roles in signal transduction and cell regulation [1–4] in addition to physicochemical roles as a barrier against cell permeability and as a matrix for the association of membrane proteins. Human cells/tissues predominantly include CERs consisting of even carbon atom containing non-hydroxy fatty acids and C<sub>18</sub> sphingosine moieties together with low levels of CERs consisting of even carbon atom containing  $\alpha$ -hydroxy fatty acids and C<sub>18</sub> sphingosine moieties [5–8]. In the human stratum corneum, there are diverse CERs with sphingosine, dihydrosphingosine, phytosphingosine and 6-hydroxysphingosine moieties [9, 10]. Those CERs and CER-related lipids may be involved not only with physicochemical roles in determining the barrier and water-holding functions in the intercellular spaces among the horny cells [11, 12], but also with physiological roles of differentiated keratinocytes where apoptosis occurs [13]. On the other hand, human hair also contains CERs which are predominantly composed of non-hydroxy or  $\alpha$ -hydroxy fatty acids and C<sub>18</sub> dihydrosphingosine moieties [14, 15]. We have hypothesized that CERs in hair might be responsible for apoptosis during keratinization, which proceeds from living hair matrix cells to dead cuticular or cortical cells, in addition to their contributions to the barrier function and the water-holding property of hair. To investigate this hypothesis, it was essential to have a method for the analysis of CERs.

While many conventional methods, such as gas chromatography–mass spectrometry (MS) [15], thin-layer chromatography (TLC) [16], diacylglycerol (DAG) kinase assay [17], liquid chromatography (LC)–evaporative light-scattering detection [18] and LC–UV detection using a derivatizing technique [19], have been used to determine CERs, Mano et al. [20], Gu et al. [21] and Couch et al. [22] reported MS using electrospray ionization (ESI) or atmospheric pressure chemical ionization (APCI) to be a valuable tool in the analysis of mixed CERs in 1997. Since the methods based on ESI-MS or APCI-MS were far superior to the

conventional methods in terms of sensitivity and selectivity, since after their articles, many methods using LC–MS and tandem MS (MS/MS) for the analysis of CERs have been developed. Among them, some methods have been applied to the determination of CERs in practically mixed samples including lipid extracts of human cells/tissues [5, 6, 23–30]. However, those methods could not be used for the determination of diverse CERs in hair because the analytes targeted by them were sphingosine-containing CERs and not the dihydrosphingosine-containing CERs that are predominantly present in hair. Therefore, we designed a new method to comprehensively profile diverse kinds of CERs, using reversed-phase high-performance liquid chromatography (RP-HPLC) coupled to APCI-MS [31]. We used this technique and found that there are at least 73 kinds of CERs, including isobaric and isomeric ones, in hair, which led to our interest in the biosynthesis of that diversity of CERs in hair matrix cells. However, this RP-HPLC–APCI-MS method was too insensitive to quantitatively characterize the CERs in a small amount of hair samples growing in a single hair follicle.

The aim of this study was to develop a method for the highly sensitive determination of diverse CERs in hair using LC–MS. We found that different deprotonated ions of monoisotopic molecules for standard CERs can be detected with extremely small differences in their molar responses when methanol containing ammonium acetate as the mobile phase in RP-HPLC combined with negative ion ESI-MS was used. Herein, we describe the successfully developed method using RP-HPLC–ESI-MS and its application to the analysis of the diverse CERs in hair samples collected from different subjects and among different 1-mm pieces derived from a single hair fiber. The application revealed that the high sensitivity of this method enables the characterization of the diverse CERs in only 1-mm pieces derived from a single hair fiber and that there are interindividual and intraindividual variations of CER composition, which demonstrates the applicability of this RP-HPLC–ESI-MS method for future research on physicochemical and physiological roles of CERs in hair.

## Experimental Procedure

### Nomenclature

CERs are termed according to previous reports [31, 32]. Briefly, non-hydroxy fatty acid,  $\alpha$ -hydroxy

fatty acid, dihydrosphingosine and sphingosine moieties are designated as N, A, DS and S, respectively. On the basis of this terminology, for example, a CER with a non-hydroxy fatty acid and dihydrosphingosine moieties is expressed as NDS. The number of fatty acid carbons and unsaturation (if present) is expressed following the letters N or A, while the number of sphingoid carbons is expressed following the letters DS or S, as shown in N24:1DS18 for a CER consisting of nervonic acid and C<sub>18</sub> dihydrosphingosine moieties.

## Chemicals

Methanol and chloroform, of infinity pure grade from Wako Pure Chemicals Industries (Tokyo, Japan), and *n*-hexane, of HPLC grade from Kanto Reagents (Tokyo, Japan), were used to prepare crude hair lipids. Methanol, of HPLC grade from Kanto Reagents (Tokyo, Japan), was used to prepare the mobile phase for RP-HPLC–ESI-MS. Ultrapure water prepared using a Milli-Q purification system (Millipore, Bedford, MA, USA) was used in all procedures. All other chemicals were of the highest analytical grade commercially available. Standard CERs, such as N-16:0 sphinganine (N16DS18), N-18:0 sphinganine (N18DS18), N-24:0 sphinganine (N24DS18), N24:1 sphinganine (N24:1DS18), CER C<sub>14:0</sub> (N14S18), CER C<sub>16:0</sub> (N16S18), CER C<sub>18:0</sub> (N18S18), CER C<sub>20:0</sub> (N20S18), CER C<sub>24:0</sub> (N24S18) and CER C<sub>24:1</sub> (N24:1S18) (purity above 98%) were from Avanti Polar Lipids (Alabaster, AL, USA). Other standard CERs, such as A16DS18, A24DS18, A16S18 and A24S18, were synthesized in the laboratory, with a slight modification of a method of Ramjit et al. [33]. Briefly, for the synthesis of A16DS18, 0.70 mmol C<sub>18</sub> dihydrosphingosine, 1.20 mmol 2-acetoxy palmitic acid, 1.30 mmol *N*-[3-(dimethylamino)propyl]-*N'*-ethylcarbodiimide hydrochloride and 1.30 mmol 1*H*-1,2,3-benzotriazol-1-ol hydrate were dissolved in chloroform and then were stirred at room temperature for 24 h under a nitrogen atmosphere. The resulting mixture was subjected to liquid–liquid extraction (700 ml chloroform and 700 ml 5% sodium hydrogen carbonate aqueous solution) and the separated organic phase was evaporated to dryness. About 40 ml of tetrahydrofuran/methanol (1:3, by volume) and potassium carbonate (0.415 g, 3.0 mmol) were added to the residue, which was then stirred at room temperature for 2 h. The solvent was evaporated again, followed by purification with silica gel column chromatography. The analysis by <sup>1</sup>H-NMR and <sup>13</sup>C NMR confirmed the structure of A16DS18 and the purity was determined as better than 98% by LC–UV

detection. The other CERs (A24DS18, A16S18 and A24S18) were synthesized and their purities were examined (better than 98%), similarly to the aforementioned CERs. Each standard solution was prepared as a molar solution using its average molecular weight (e.g., for N16DS18, not the monoisotopic mass 539.5 but rather the average mass 539.9 was used). Thus, individual standard stock solutions (1 mM each) were prepared by dissolving accurate amounts of the standard CERs in chloroform/methanol (1:9, by volume) and were stored at –4°C. Individual or mixed working standard solutions were obtained by further dilution of the stock solutions with methanol just prior to use.

## Hair Fibers and Preparation

Scalp hair fibers were collected from seven Japanese volunteers (designated as Hair-A for a 15-year-old female, Hair-F1 for a 10-year-old female, Hair-F2 for a 42-year-old female, Hair-F3 for a 76-year-old female, Hair-M1 for a 9-year-old male, Hair-M2 for a 25-year-old male and Hair-M3 for an 86-year-old male). None of these hair samples had been exposed to any chemical reactions, such as hair coloring or permanent waving. First of all, qualitative analyses of CERs in these hair samples were performed according to our previously reported RPLC–APCI-MS and RPLC–ESI-MS/MS methods [31]. Since the results showed that all the hair samples contained 73 kinds of CERs corresponding to our previous results [31], we did the quantitative analyses using full-length fibers from the proximal root end to the distal tip of Hair-A and five hair fibers of 2-cm-length each just from the root end (approximately 1 mg each in weight) of Hair-F1, Hair-F2, Hair-F3, Hair -M1, Hair-M2 and Hair-M3. These fibers were washed with plain shampoo for 1 min and rinsed with water for 10 min, which was repeated twice. The fibers were washed with *n*-hexane for approximately 1 min to remove contaminating CERs on the surface, which might come from the stratum corneum of the scalp, and their weights were measured accurately with an ultra-micro-balance (UTM2, Mettler Toledo, Tokyo, Japan) after drying at room temperature for more than 24 h. In a separate experiment, 1-mm pieces were cut with a knife from a single hair fiber (approximately 7 cm in length from the root end, Hair-M1). Thus, pieces (approximately 10 µg each in weight) of the hair fiber at 1–2, 13–14, 25–26, 37–38, 49–50 and 61–62 mm from the root end were obtained. The pieces were subjected to lipid extraction without any washing after their weights had been measured using the UTM2 instrument. The

preparative procedures were performed according to our previous reports [31, 34]. Briefly, the fibers were immersed successively into chloroform/methanol (2:1, 1:1, 1:2, by volume), followed by chloroform/methanol/water (18:9:1 by volume) each for 24 h at room temperature. The extracts were combined and dried using a nitrogen stream. The residues were then dissolved in methanol.

### MS Analysis

An Agilent 1100 series LC/MSD SL (single quadrupole) system equipped with an ESI or APCI source, ChemStation software, a 1100 well plate autosampler (Agilent Technologies, Palo Alto, CA, USA) and an L-column ODS separation column (2.1-mm inner diameter  $\times$  150 mm, Chemicals Evaluation and Research Institute, Tokyo, Japan) was used. In the case of flow-injection MS analysis, the column was uncoupled from the system. In this system, a 1100 binary pump was operated at a flow rate of 0.2 ml/min. The injection volume was 5  $\mu$ l each of standard solutions and extracted crude hair lipid solutions. The column temperature was maintained at 40°C. ESI measurements in the mass spectrometer were performed with the following settings: polarity, negative and positive; heater temperature of nitrogen gas, 350°C; flow of heated dry nitrogen gas, 8.0 l/min; nebulizer gas pressure, 30 psi; capillary voltage, -3,000 V for negative setting and 3,000 V for positive setting; fragmenter voltage (one of the parameters used in this mass spectrometer, which is the same as “cone voltage” used in others), 250 V. In contrast, APCI measurements were performed with the following settings: vaporizer temperature, 300°C; flow of heated dry nitrogen gas, 5.0 l/min; nebulizer gas pressure, 40 psi; corona current, 4.0  $\mu$ A; the other settings were the same as for ESI. These parameters were optimized in preliminary tests to get the highest abundance of the molecule-related ions for standard N16DS18. The selected ion monitoring (SIM) measurement in negative ion ESI was performed using unit mass resolution mode. To simultaneously detect 73 kinds of CERs in hair, 33 deprotonated ions of the monoisotopic molecules were used as follows (dwell time 36 ms each):  $m/z$  510.5 for N14DS18; 524.5 for N15DS18; 526.5 for A14DS18; 536.5 for N16:1DS18 and N16S18; 538.5 for N16DS18 (+N18DS16\*); 552.5 for A16S18 and N17DS18<sup>\$</sup> (+N18DS17\* + N16DS19\*); 554.5 for A16DS18; 564.5 for N18:1DS18 and N18S18; 566.6 for N18DS18; 568.5 for A17DS18; 580.6 for N19DS18<sup>\$</sup> (+N18DS19\*); 582.6 for A18DS18; 592.6 for N20S18; 594.6 for N20DS18 (+N18DS20\*); 608.6 for N21DS18<sup>\$</sup> (+N20DS19\*); 620.6 for N22:1DS18 and

N22S18; 622.6 for N22DS18 (+N20DS20\*); 634.6 for N23:1DS18; 636.6 for N23DS18<sup>\$</sup> (+N22DS19\*<sup>\$</sup>); 646.6 for N24:1S18; 648.6 for N24:1DS18 and N24S18; 650.6 for N24DS18 (+N22DS20\*); 662.7 for N25:1DS18<sup>\$</sup> (+N24:1DS19\*); 664.7 for A24:1DS18, A24S18 and N25DS18<sup>\$</sup> (+N24DS19\*<sup>\$</sup> + N23DS20\*); 666.6 for A24DS18 (+A22DS20\*); 674.7 for N26:1S18; 676.7 for N26:1DS18 (+N24:1DS20\*) and N26S18; 678.7 for N26DS18 (+N24DS20\*); 690.7 for N27:1DS18 (+N26:1DS19\*); 692.7 for N27DS18<sup>\$</sup> (+N26DS19\*<sup>\$</sup> + N25DS20\*<sup>\$</sup>); 704.7 for N28:1DS18 (+N26:1DS20\*); 706.7 for N28DS18 (+N26DS20\*); 732.7 for N30:1DS18 (+N28:1DS20\*). The asterisks and dollar signs indicate isobaric and isomeric CERs, respectively.

### Determination of CERs in Hair

Prior to the determination of the CERs, 1, 2.5, 5, 10, 25, 50, 100 and 250 fmol each of standard N16DS18 was injected into the RP-HPLC-ESI-MS system and then the calibration line was generated by plotting molar quantities corresponding to the monoisotopic molecule of standard N16DS18 (0.68, 1.7, 3.4, 6.8, 17, 34, 68 and 170 fmol) versus the peak areas obtained. Using the calibration line, we converted each peak area of the CER(s) in the SIM chromatogram to the levels of its (their) monoisotopic molecule(s). The levels were then converted to their actual levels by correction for <sup>13</sup>C and <sup>2</sup>H effects. To calculate isotopologue abundances of each CER, we used Microsoft Excel 2000 (Microsoft Corporation, Troy, NY, USA), based on the fundamental principles for obtaining mass spectral isotopic distributions previously reported by Yerger [35]. Every hair lipid sample was analyzed in triplicate. The means  $\pm$  the standard deviations of the levels are expressed as weights of lipids to that of hair fibers (micrograms per gram of hair). Recovery studies were performed by spiking the extracted crude hair lipids with 10 fmol of standard CERs. The levels of the CERs determined in spiked hair lipid were compared with those in nonspiked hair lipids.

### TLC Analysis

Hair lipid extracts (0.21 g) were obtained from approximately 10 g of Hair-A, following extraction with chloroform, methanol and water, as described already. The extracts were purified with silica gel column chromatography. The extracts dissolved in chloroform were injected onto the column, which had been previously equilibrated with chloroform, followed by the successive elution of 300 ml each of chloroform/methanol, 100:0, 99:1, 98:2, 96:4, 94:6, 92:8, 90:10, 85:15

and 80:20 (by volume). Comparison of  $R_f$  values of spots of the fractions with those of authentic N16DS18 and A16DS18 in the TLC analysis revealed that fractions of 98:2 and 96:4 included NDSs/NSs and ADSs/ASs, respectively. Their levels were determined using the standard N16DS18 by the TLC analysis, and their levels were compared with summed levels of individual CERs determined by RP-HPLC–ESI-MS. This TLC analysis was based on a slight modification of a previously reported method [15]. Briefly, high-performance TLC plates (silica gel 60, 20 cm × 10 cm, Merck) were used for the separation. After aliquots of concentrated fractions had been applied on the plate, it was developed with chloroform/methanol/acetic acid (190:9:1 by volume) twice. After drying, the plate was sprayed with 10% copper sulfate and 8% phosphoric acid solution and was charred by heating at 180°C for 5 min. Spots corresponding to NDSs/NSs and ADSs/ASs were densitometrically determined using a TLC Scanner 3 photodensitometer (Camag, Muttenz, Switzerland) and using the calibrated line of N16DS18.

## Results

### Optimization of Analytical Conditions

On the basis of our previous results [31], deprotonated ions  $[M - H]^-$  of monoisotopic molecules for standard NDSs and NSs were targeted in the SIM measurement of negative ion APCI and ESI, while protonated ions  $[M+H]^+$ , of monoisotopic molecules for standard NDSs and protonated ions with loss of 1 mol water  $[M + H - H_2O]^+$ , of monoisotopic molecules for standard NSs were selected in positive ion APCI and ESI. When equivalent numbers of moles of ten standard NDSs and NSs were subjected to flow-injection MS using methanol as a carrier, the intensities of the ions detected for the NDSs and NSs gradually decreased with increases in the chain lengths of fatty acid moieties in both negative ion and positive ion APCI, whereas the intensities were drastically decreased in both negative ion and positive ion ESI. Thus, as represented in Fig. 1a, the intensity of  $[M - H]^-$  for N24S18 was approximately 20% of that for N14S18 under conditions with negative ion ESI-MS. To improve the difference in intensities among the ten standard NDSs and NSs, effects of addition of acids or salts to methanol under conditions of different ionizations on the intensities of molecularly related ions derived from equivalent molar quantities of the ten NDSs and NSs were tested. Thus, we examined all combinations of addition of acids (formic acid or

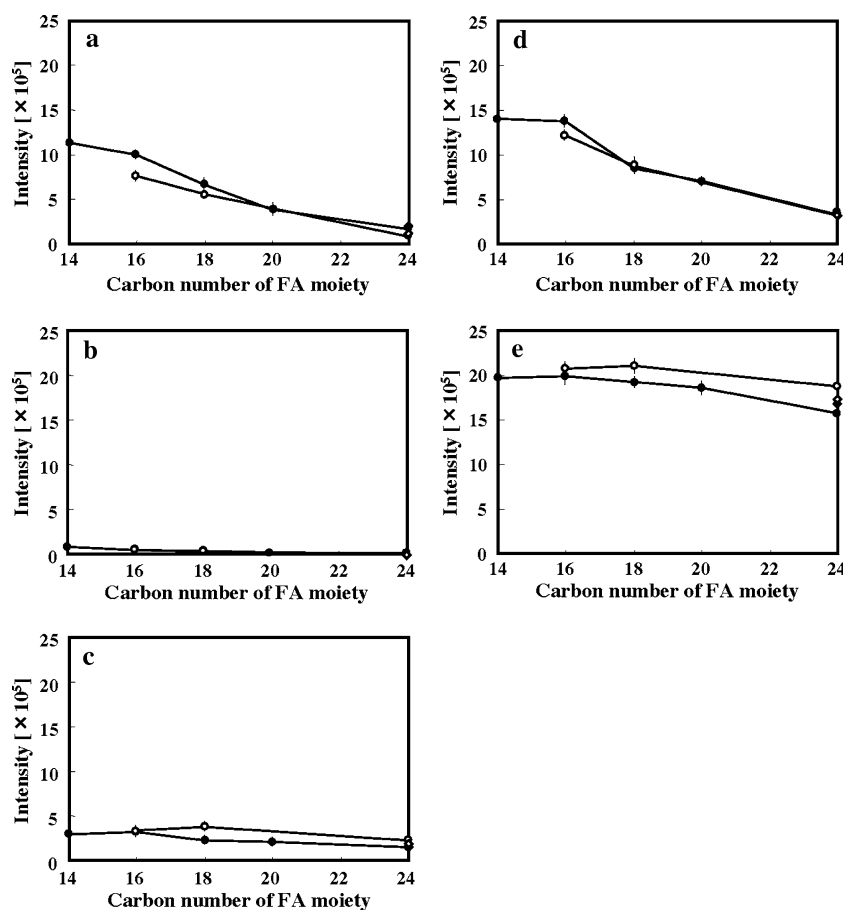

acetic acid) or salts (ammonium formate or ammonium acetate) and different ionization modes (negative ion ESI-MS, positive ion ESI-MS, negative ion APCI-MS or positive ion APCI-MS). Since we planned to couple MS with RP-HPLC using an octadecyl silica gel column after optimization of the MS conditions, acidic or neutral conditions but not basic ones were examined. It is known that silica gel is extremely unstable under basic conditions.

Of all the combinations tested, the addition of 50 mM ammonium acetate upon negative ion ESI-MS showed the highest mean of the intensities of the ten standard NDSs and NSs and the smallest difference in the intensities. This implies that the combination of ammonium acetate and negative ion ESI-MS provides the average highest sensitivity and the smallest difference in molar responses for the NDSs and NSs tested. The experimental data from negative ion ESI-MS are depicted in Fig. 1. In the case of the addition of 50 mM formic acid to methanol, the intensities for all the NDSs and NSs tested decreased to approximately 10% of those using methanol with no additives (Fig. 1a, b). When methanol containing 50 mM ammonium formate was used, the intensities of the NDSs and NSs with shorter chain lengths in the fatty acid moieties decreased to 30–40% of those using no additives, while the differences in the intensities tended to be rather small (Fig. 1a, c). Methanol containing 50 mM acetic acid yielded increased intensities up to 120–210% of those using no additives, while it hardly improved differences in the intensities (Fig. 1a, d). On the other hand, when 50 mM ammonium acetate was added to methanol, the differences in the intensities among the NDSs and NSs tested became the smallest (Fig. 1a, e). On the basis of those results, we selected the combination of negative ion ESI-MS and methanol containing ammonium acetate. Further, when the optimal concentration of ammonium acetate was examined in the range 1–200 mM, the maximal mean of the intensities for the ten standard NDSs and NSs was observed at a concentration of 1 mM, while the minimal difference in the intensities was observed at 10 mM. Since the mean was not improved much from 1 to 10 mM while the difference was greatly improved, 10 mM ammonium acetate was selected.

### Determination of CERs Using RP-HPLC–ESI-MS

Negative ion ESI-MS combined with RP-HPLC using a mobile phase of methanol containing 10 mM ammonium acetate and a stationary phase of L-column ODS was examined to develop a method for the highly sensitive determination of the diverse CERs. Figure 2

**Fig. 1** Effects of addition of acid or salt to the carrier on the intensities of deprotonated ion derived from 50 pmol each of standard NDSs and NSs in flow-injection mass spectrometry (MS) analysis with negative ion electrospray ionization (ESI). Carrier **a** methanol (no additives), **b** methanol containing 50 mM formic acid, **c** methanol containing 50 mM ammonium formate, **d** methanol containing 50 mM acetic acid, **e** methanol containing 50 mM ammonium acetate. *Open circles* NDS with saturated fatty acid moiety, *filled circles* NS with saturated fatty acid moiety, *open diamonds* N24:1DS18, *filled diamonds* N24:1S18. shows RP-HPLC–ESI-MS multi-SIM chromatograms of ten standard NDSs and NSs (dwell time 120 ms each). All monoisotopic molecules for the NDSs and NSs were detected as separate and distinct peaks in the chromatograms. There were five small peaks in the

**Fig. 2** Reversed-phase high-performance liquid chromatography (RP-HPLC)–ESI-MS multiple selected ion monitoring (SIM) chromatograms of ten standard NDSs and NSs (250 fmol each, including all isotopic molecules)

$m/z$  538.5, 566.6, 648.6 and 650.6 SIM chromatograms in Fig. 2. Among the five, two small peaks were included in the  $m/z$  650.6 SIM chromatogram. The small peak that occurred in the  $m/z$  538.5 SIM chromatogram had identical retention times to those of the monoisotopic molecules of N16S18 that were eluted in the  $m/z$  536.5 SIM chromatogram. Therefore, the small peak was identified as an  $M + 2$  isotopologue of N16S18. Isotopic ions, such as  $M + 1$  and  $M + 2$  isotopologues, occurs naturally owing to the existence of  $^{13}\text{C}$  and  $^2\text{H}$ . Similarly, the small peaks in the  $m/z$  566.6 and 648.6 SIM chromatograms were identified as  $M + 2$  isotopologues of N18S18 and N24:1S18, respectively. As for the two small peaks in the  $m/z$  650.6 SIM chromatogram, the peaks having shorter and longer retention times were identified as  $M + 2$  isotopologues of N24:1DS18 and N24S18, respectively. The least hydrophobic CER of all those tested, N14S18, was eluted at approximately 6 min, while the most hydrophobic CER, N24DS18, was eluted at approximately 24 min. This indicates that isocratic elution with methanol containing 10 mM ammonium acetate may allow the appearance of N30:1DS18 or N28DS18 (one of the most hydrophobic CERs in hair) within a single

run, although it is slightly more time-consuming compared with the gradient elution system [31].

It is well known that MS can accurately provide isotopologue ratios of lipid molecules [25, 36–39]. By use of this property, individual lipid molecules are quantitatively determined even if more than two isotopologues derived from different lipid molecules have the same  $m/z$ . Therefore, under these RP-HPLC–ESI-MS conditions using unit mass resolution mode, it was validated whether monoisotopic molecules of targeted NDSs and NSs could be quantitatively detected. As representative standards, N16DS18 and N24DS18 were used in this experiment. The relative intensities of peak areas of four isotopologue ions ( $[M - H]$ ,  $[M + 1 - H]$ ,  $[M + 2 - H]$  and  $[M + 3 - H]$ ) for N16DS18 were obtained by simultaneously performing SIM on the four isotopologue ions and then comparing the peak areas in their SIM chromatograms. The same SIM measurement was performed for N24DS18. Those measured relative intensities were compared with theoretically calculated relative intensities, based on the isotopologue ratios of  $^{13}\text{C}$  and  $^2\text{H}$ . As a result, the measured relative intensities under the RP-HPLC–ESI-MS conditions were almost in agreement with the theoretical ones (Table 3). This implies that monoisotopic ions can be quantitatively detected even in the unit mass resolution mode of this RP-HPLC–ESI-MS method and that quantitative values of monoisotopic molecules for the CERs can be theoretically converted to their actual level, by correction for  $^{13}\text{C}$  and  $^2\text{H}$  effects. For example, if the level of the monoisotopic molecule for N16DS18 is obtained as 1.00  $\mu\text{g/g}$  hair, the actual level can be calculated as 1.47  $\mu\text{g/g}$  hair, because the monoisotopic molecule accounts for 67.9% of the total molar quantities for N16DS18.

#### Determination of 73 Kinds of CERs in Human Hair

There are 73 kinds of CERs, including many isobaric and isomeric ones, in hair, and these are divided into 33 molecular weights [31]. Therefore, to simultaneously detect the 73 kinds of CERs, multi-SIM measurement with 33 ions in this RP-HPLC–ESI-MS analysis was performed (dwell time 36 ms each). Prior to use of this method, crude hair lipids extracted from Hair-A were subjected to RPLC–APCI-MS and RPLC–ESI-MS/MS [31] and it was confirmed that Hair-A contains the 73 kinds of CERs. A set of multi-SIM chromatograms of the 73 kinds of CERs in hair (approximately 1 mg, Hair-A) is shown in Fig. 3, in which no peaks chromatographically interfere with the 48 peaks corresponding to the 73 kinds of CERs. The

identities of the 48 peaks were also confirmed using RP-HPLC–ESI-MS/MS [31] under identical RP-HPLC conditions, and were in complete agreement with the 73 kinds of CERs. The reproducibility (percentage coefficient of variation, % CV,  $n = 6$ ), limit of detection (LOD, signal-to-noise ratio of 3), limit of quantification (LOQ, signal-to-noise ratio of 10) and calibration lines for 13 standard CERs were obtained under conditions of simultaneous SIM of the 33 ions (Tables 1, 2). The % CVs of the peak areas of six consecutive analyses of 100 fmol were in the range 2.1–4.6%. The LOD and LOQ for 5  $\mu\text{l}$  of the standard solutions were in the ranges 0.14–0.40 and 0.46–1.37 fmol, respectively. As for their calibration lines, all determination correlations were greater than 0.9987 in the range between 1 and 250 fmol. There seemed to be a definite trend toward slightly larger slopes for the CERs with non-hydroxy fatty acid moieties than for those with  $\alpha$ -hydroxy fatty acid ones and with longer chain lengths in fatty acid ones. However, the % CV of the slopes of the 13 calibration lines corresponding to the 13 monoisotopic molecules was calculated to be 3.9%, implying there are extremely small differences in molar responses of monoisotopic ions among the 13 different CERs.

Recoveries were estimated by comparison of the determined levels of 13 standard CERs in spiked crude hair lipids with those in nonspiked hair lipids, using only one calibration line produced by the standard N16DS18 (Table 2). The average recoveries were in the range between 97.0 and 108.2% with the % CV being 1.9–5.1%. This demonstrated that our RP-HPLC–ESI-MS method using only one standard calibration line produced by the standard N16DS18 provides precise and accurate levels of the 13 CERs in hair, because of extremely small differences in molar responses of monoisotopic molecules between N16DS18 and the other CERs. Further, quantitative values obtained by RP-HPLC–ESI-MS were compared with those obtained by TLC. When fractions containing NDSs/NSs and ADSs/ASs obtained from hair lipid extracts of Hair-A were subjected to RP-HPLC–ESI-MS, the total levels of NDSs/NSs and ADSs/ASs were determined to be 352 and 47  $\mu\text{g/g}$  hair, respectively, where each of the 48 peaks corresponding to the 73 kinds of CERs was determined using a calibration line of the standard N16DS18 and the peaks were then summed up. In contrast, the TLC analysis showed 372 and 56  $\mu\text{g/g}$  hair as NDSs/NSs and ADSs/ASs, respectively. These results indicate that quantitative levels measured by RP-HPLC–ESI-MS are comparable with those determined by TLC.

The asterisks and dollar signs indicate isobaric and isomeric ceramide molecules, respectively

## Applications

Similar to Hair-A, prior to the quantification, it was confirmed that Hair-F1, Hair-F2, Hair-F3, Hair-M1, Hair-M2 and Hair-M3 contain the 73 kinds of CERs by RPLC-APCI-MS and RPLC-ESI-MS/MS [31]. Table 3 shows the levels of CERs in different hair samples obtained from three females and from three males ( $n = 3$ , analysis in triplicate for each). In all the hair samples tested, 48 peaks corresponding to the 73 kinds of CERs were commonly observed. The following characteristics of the levels of CERs were observed among the subjects tested: (1) the levels of A16DS18 were greater in the hair samples derived from the males tested (Hair-M1, Hair-M2 and Hair-M3), while the levels of N22DS18 (+N20DS20), N23DS18 (+N22DS19), N24DS18 (+N22DS20) and A24DS were greater in those derived from the females tested (Hair-F1, Hair-F2 and Hair-F3); (2) the hair samples collected from the youngest female and the youngest male tested (Hair-F1 and Hair-M1) contained greater levels

of sphingosine-containing CERs (NSs and ASs), as seen in the levels of N16S18, A16S18, N22S18, A24S18 and N26S18; (3) there were other variations, such as the hair samples from two of the females tested (Hair-F1 and Hair-F3) had extremely high levels of N18DS18 and N20DS18 (+N18DS20).

In a separate experiment, the possibility to detect and determine the CERs using very small sample amounts of hair was examined. A set of the multi-SIM chromatograms of CERs in 1-mm pieces (approximately 10  $\mu\text{g}$  in weight) derived from a single hair fiber (Hair-M1) is shown in Fig. 4. Of the 48 peaks to be detected, 46 peaks of CERs were observed. No peaks originating from N16:1DS18 and N19DS18 were detected, probably owing to their extremely low level in this hair specimen, i.e., Hair-M1 (Table 3). Next, the levels of the CERs in six different pieces of 1-mm length (approximately 10  $\mu\text{g}$  each in weight) prepared from the fiber are listed in Table 4 ( $n = 1$ , analysis in triplicate for each). The six 1-mm pieces at intervals of 11 mm from the root end were analyzed. Since hair fibers generally grow approximately

**Table 1** Comparison of measured relative intensity of four isotopologue ions derived from 250 fmol each of standard N16DS18 and N24DS18 in selected ion monitoring (SIM) measurement of reversed-phase high-performance liquid chromatography–electrospray ionization mass spectrometry (RP-HPLC–ESI-MS) with theoretically calculated relative intensity based on  $^{13}\text{C}$  and  $^2\text{H}$  effects

Ceramide	Relative intensity <sup>a</sup>

<sup>b</sup> [M – H] = 538.5, [M + 1 – H] = 539.5, [M + 2 – H] = 540.5, [M + 3 – H] = 541.5

<sup>c</sup> [M – H] = 650.6, [M + 1 – H] = 651.6, [M + 2 – H] = 652.6, [M + 3 – H] = 653.6

12 mm/month [40], these pieces roughly correspond to monitoring 2.5 days of biosynthesis of CERs in a hair follicle at intervals of 1 month over 5 months. The levels

of the CERs tended to gradually decrease with the distance from the root end, as represented in A16DS18 and N24DS18 (+N22DS20). However, the levels of sphingosine-containing CERs (NSs and ASs), such as N16S18, A16S18, N18S18, N20S18, N22S18, A24S18, N26:1S18 and N26S18, were higher in the 49–50-mm piece than the root region (1–2 mm), while the levels of nervonic acid containing CERs, such as N24:1S18, N24:1DS18, A24:1DS18 and N26:1DS18 (+N24:1Ds20), were higher in the 25–26-, 49–50- and 61–62-mm pieces than in other regions (Table 4).

## Discussion

The aim of this study was to develop a method for the highly sensitive determination of the diverse CERs in hair. First, we found that a combination of methanol containing ammonium acetate and negative ion ESI-MS greatly improves molar sensitivity and differences in molar responses of monoisotopic molecules among different kinds of CERs, consisting of NDSs and NSs. When finally optimized RP-HPLC–ESI-MS with methanol containing 10 mM ammonium acetate as a mobile phase was applied to 13 standard CERs, including NDSs, NSs, ADSs and ASs, we observed definite differences in the molar responses of the

monoisotopic molecules, i.e., the CERs with longer chain lengths and/or a hydroxyl group in the fatty acid moieties had slightly greater molar responses than those with shorter chains and/or no hydroxyl group.

However, the % CV of the slopes of the calibration lines among the 13 standard CERs was as low as 3.9%, which was comparable with 2.1–4.6% as the % CV of the peak areas in six consecutive injection analyses.

**Fig. 4** Detection of ceramides in a 1-mm piece derived from a single hair fiber at 1–2 mm from the proximal root end using RP-HPLC–ESI-MS. For the explanation of the peaks, see the legend to Fig. 3

This suggested that the extremely small differences in the molar responses of monoisotopic molecules among the 13 CERs may make it possible to determine any monoisotopic molecules of CERs in hair using only one calibration line generated by a monoisotopic molecule of a given standard CER. In this study, we selected N16DS18 for a calibration line, since N16DS18 is one of the predominant species in hair and other researchers can readily get it from suppliers if they want to use this method. The actual levels of the targeted CERs can be theoretically converted, because correction for  $^{13}\text{C}$  and  $^2\text{H}$  effects is available in this RP-HPLC–ESI-MS method using the unit mass resolution mode. This validity is corroborated by the fact that the recoveries of the crude hair lipids spiked with 13 standard CERs were close to 100% (97.0–108.2%) even when only standard N16DS18 was used for the determination.

From the % CVs of the slopes and the peak areas for the 13 standard CERs, the systematic error is theoretically estimated to be  $\pm 12.1\%$  [ $2\sigma = 2 \times (3.9^2 + 4.6^2)^{1/2}$ ] of the values determined. This theoretical error allows discrimination among the determined levels of CERs if their differences are more than 12%. We could not directly validate the quantitative recovery values for other CERs that are not available as standards but that are present in hair, because we had none of them as substantial materials. Also, we could not validate the

apparent quantitative values for peaks consisting of more than two kinds of isobaric CERs, which account for 21 of all 48 peaks. However, currently, we consider that the values determined for nonvalidated CERs would be roughly estimated within  $\pm 12\%$  as well as the 13 standard CERs, because of the experimental data that the summed quantitative levels of CERs by RP-HPLC–ESI-MS were comparable with those determined by TLC. Although an internal standard is generally used in MS analysis to determine targeted analytes, which enables one to normalize the absolute ion intensities that may be altered owing to ion suppression, we did not adopt an internal standard in our method. That was because, firstly, our method has been already normalized based on a characteristic that a molar response of the monoisotopic ion of N16DS18 is nearly equivalent to those of other CERs. Thus, in our method, monoisotopic ions derived from diverse CERs are determined using a calibration line of standard N16DS18 monoisotopic ion, produced just prior to the analysis. Secondly, since the recoveries of crude hair lipids spiked with standard CERs were nearly 100% (97.0–108.2%) and their % CV was less than 5.1% in three replicates, it is thought that there is no ion suppression in the analysis of CERs in crude hair lipids.

Here, we discuss how to use the newly developed RP-HPLC–ESI-MS. When RP-HPLC–ESI-MS is used for the determination of diverse CERs in hair, hair

samples that were previously subjected to RP-HPLC–APCI-MS and RP-HPLC–ESI-MS/MS for qualitative analyses [31] must be analyzed, as shown in our applications. Therefore, it should be noted that the presence of other kinds of CERs in a certain hair sample cannot be excluded when no qualitative analysis using RP-HPLC–APCI-MS and RP-HPLC–ESI-MS/MS is conducted owing to too small amounts of the hair samples collected. When other researchers want to use this method, especially in the case of mass spectrometers other than ours [Agilent 1100 series LC/MSD SL (single quadrupole) system], validation data must be acquired under ESI-MS conditions that seem to be equivalent to those described in the

“**Experimental Procedure.**” The most important point is that calibration lines of monoisotopic molecules derived from commercially available standard CERs (N16DS18, N18DS18, N24DS18, N24:1DS18, N16S18, N18S18, N20S18, N24S18 and N24:1S18) have nearly equivalent slopes to each other (roughly within 5.0% in CV), as represented in Table 2. On the basis of the validation data proving nearly equivalent molar responses in the standard CERs, other researchers can use this method. When the slopes are not equivalent to each other, ESI-MS conditions must be examined. In that case, first of all, the in-source collision energy, which greatly affects the transmission and the fragmentation of the targeted ions (“fragmenter

voltage” in our instrument or “cone voltage” in others), should be changed. That is because, in our experience, the intensities of different kinds of CERs greatly depend on in-source collision energies, while Xan [25] described effects of different collision energies on relative intensities among different molecular species of CERs despite neutral loss analyses in ESI-MS/MS being employed. If molar responses in the standard CERs are not improved, other parameters affecting ESI efficiencies, such as the flow of heated dry nitrogen gas, nebulizer gas pressure, dry gas temperature and capillary voltages, should be examined further.

Ammonium acetate as an additive to the mobile phase is generally used in RP-HPLC–ESI-MS analysis. Our method is not the first to use ammonium acetate for the analysis of CERs in RP-HPLC–ESI-MS, because Vietzke et al. [41, 42] already reported such a RP-HPLC–ESI-MS method. However, they used that method only to identify a few kinds of NSs and they did not examine the possibility to use it for the determination of diverse CERs, including NDSs, ASs and ADSs, whereas our method can be used to determine diverse kinds of CERs present in hair. Therefore, we can say that our RP-HPLC–ESI-MS method using the mobile phase of methanol containing ammonium acetate is quite different from the previous one [41, 42]. On the other hand, some methods to determine CERs using RP-HPLC–ESI-MS have been reported [26, 27, 30], while a method using RP-HPLC–thermospray MS has been described [28]. However, in those methods, quantitative targets were restricted to CERs available as standard materials and even the highest sensitivity was not sufficient, such as subpicomolar ranges of the LOD [26, 27]. Among the methods previously reported for the analysis of CERs, those close in performance to our RP-HPLC–ESI-MS method were reported by Han [25] and by Pettus et al. [29]. The method using direct MS/MS and neutral loss ion scan reported by Han [25] is superior to others because it can simultaneously determine NSs and ASs. Although the author described the applicability of that method to the analysis of NDSs and ADSs, this applicability is his speculation because there is no experimental evidence for the quantification of NDSs and ADSs. Therefore, we thought that method is for the quantitative analysis of only NSs and ASs but not NDSs and ADSs. As for the sensitivity, the LOD is approximately 10 fmol (consumed) as a standard CER. Another method using normal-phase HPLC–APCI-MS for NDSs and NSs reported by Pettus et al. [29] achieved the simultaneous determination of NDSs and NSs, but that method does not include ADSs and ASs as targets and

has low sensitivity and low linearity. Therefore, both methods are insufficient for the highly sensitive determination of diverse CERs, including NSs, NDSs, ASs and ADSs. In contrast, our method can achieve the comprehensive determination of the diverse CERs with extremely low LOD, such as in the subfemtomolar range at a signal-to-noise ratio of 3.

There are squalene, wax esters, triglycerides, free fatty acids, cholesterol, 18-methyleicosanoic acid and cholesterol sulfate within human hair fibers, in addition to CERs [34]. In the method developed in this study, it is obvious that these lipids do not interfere with the detection of CERs, because they are extremely different from CERs in terms of molecular weight and polarities. However, there is a possibility that DAGs produced by the hydrolysis of triglycerides may overlap with CERs in this method. For example, the molecular weights of palmitoyl-oleoyl DAG (16-18:1DAG) and N20DS18 are 594.6 and 595.6, respectively, whereas those of oleoyl-stearoyl DAG (18:1-18DAG) and N22DS18 are 622.6 and 623.6, respectively. Therefore, if 16-18:1DAG and 18:1-18DAG are predominantly detected as deprotonated ions  $[M - H]^-$  in negative ion ESI-MS, their isotopic ions  $[M+1 - H]^-$  would interfere with the monoisotopic ions  $[M - H]^-$  of N20DS18 and N22DS18 in their SIM chromatograms. When standard DAGs were subjected to this RP-HPLC–ESI-MS method, those DAGs yielded prominent acetate-adduct ions  $[M + CH_3COO]^-$  but no deprotonated ions  $[M - H]^-$  (data not shown). This may be due to an effect of ammonium acetate in the mobile phase used in this method. An examination of detected mass numbers of all possible DAGs with various constitutional fatty acids and 73 kinds of CERs present in hair led to the conclusion that the monoisotopic ions  $[M + CH_3COO]^-$  of DAGs and their isotopic ions, such as  $[M + 1 + CH_3COO]^-$  and  $[M + 2 + CH_3COO]^-$ , do not at all interfere with monoisotopic ions derived from the 73 kinds of CERs in hair. This indicates that the interference in the detection of CERs with other lipids, including DAGs, can be ignored and that the newly developed RP-HPLC–ESI-MS technique is specific for CERs in crude hair lipids.

Our previous report [31] showed that hair has 73 kinds of CERs and is unique in terms of the higher levels of NDSs and ADSs, compared with other human cells/tissues and human stratum corneum, which contain low levels of them [5–10]. In this study, the 73 kinds of CERs were qualified and then quantified in all hair samples collected from six subjects. Although it was roughly known that hair contains higher levels of NDSs/ADSs and lower levels of NSs/ASs [14, 15, 31], this RP-HPLC–ESI-MS analysis revealed quantitative

levels not only of predominant kinds but also of less abundant ones for the first time. The levels of CERs varied among the hair samples collected from three females and from three males. This interindividual variation in the CER composition suggests that there might be differences between females and males, or younger and older subjects, as described in “Results.” However, it should be noted that such differences in the levels of CERs between females and males, or between younger and older subjects, must be investigated further. On the other hand, the application to the analysis of CERs in 1-mm pieces of a single hair fiber demonstrates the high sensitivity of this RP-HPLC–ESI-MS method. The quantitative data of CERs show a tendency for gradual decreases in the levels of CERs in the direction from the root end to the tip. This is reasonable because of the interpretation of gradual loss by weathering effects during daily life activities [34, 43]. However, the levels of sphingosine-containing or nervonic acid containing CERs are obviously higher in regions more distant from the root end, which demonstrates the presence of intraindividual variation in the CER composition. Such variations might be related to the physicochemical properties or physiological phenomena of hair.

The de novo pathways for CERs are as follows [7]: (1) production of 3-ketosphinganine from palmitoyl-coenzyme A and L-serine by serine palmitoyltransferase; (2) production of dihydrosphingosine from 3-ketosphinganine by 3-ketosphinganine reductase; (3) production of NDS from dihydrosphingosine and fatty acylcoenzyme A by CER synthase; (4) production of NS from NDS by desaturase; (5) production of AS from NS by hydroxylase. Of all the hair samples tested, the levels of NDSs and ADSs are much higher than those of NSs and ASs. This fact suggests a lower activity of process 4 in hair matrix cells and a pathway for the production of ADSs directly from processes 3–5. Also, variation in the levels of sphingosine-containing CERs among different subjects and in different regions of a single hair fiber suggests that there might be differences in the activities of desaturase in process 4 in hair matrix cells among different individuals and among different periods during hair growth even in a single hair follicle. The fluctuation of NSs is of special interest because they might play a role in apoptosis of hair matrix cells [1, 2, 44, 45], related to the differentiation into cuticular or cortical cells.

Finally, we discuss the advantage of the newly developed method. There are two advantages: the applicability of the determination of CERs in small amounts of hair samples and the comprehensive property covering unusual CERs of humans [31]. As for the

first advantage, one can observe the CER composition even in the hair root region of a single hair follicle by use of this method. An individual hair fiber differs from others in terms of diameter, structure and physicochemical properties that might cause different regulation of hair growth even if they grow on the same scalp. The signal-to-noise ratio of the multi-SIM chromatograms in the 1-mm pieces of hair, as shown in Fig. 4, indicates that this method can be used for pieces shorter than 1 mm if minor species are ignored. According to the speed of hair growth [36], the analysis of CERs in each 400- $\mu$ m piece of hair corresponds to monitoring 1-day's production of CERs in hair matrix cells. Therefore, the first advantage may contribute to future research on hair science. As for the second advantage, this method can be used for the quantitative determination of unusual CER molecules of humans, such as odd-number CERs having odd carbons in sphingoid moieties and isomeric combinations assumed to have a branched acyl chain [31]. They are minor components but interest us in terms of their biosynthesis. The second advantage may contribute to future research on the physiology of CER metabolism of humans.

**Acknowledgements** We would like to express our cordial gratitude to Katsumi Kita of the Kao Corporation for his discussions and encouragement of this study. Our sincere thanks also go to Manabu Watanabe, Yoshiya Sugai and Yoshinori Nishizawa of the Kao Corporation for technical support in the synthesis of standard CERs.

**Abstract** A novel phosphonium salt methodology was utilized for the first time to synthesize 1,3-, and 1,2-diphosphatidylglycerol. Optically active 1,2-di-*O*-acyl-*sn*-glyceryl phosphate was coupled with unprotected glycerol in the presence of pyridiniumbromide perbromide and triethylamine to yield, after final removal of phosphate protecting group, the title compounds. The 1,2-diphosphatidylglycerol (1,2-isomer of cardiolipin) may be a member of a new class of phospholipids for industrial applications similar to other phosphocholines.

## Introduction

The most general methods used for the chemical synthesis of cardiolipin (CL) involve phosphatidic acid (PA) and phosphatidylglycerol (PG). Selective phosphorylation of the primary alcohol group of PG with PA, either by a semi-synthetic (by enzymes) method [1] or by condensation of PG or 2-*O*-protected glycerols with PA in the presence of 2,4,6-triisopropylbenzenesulfonyl chloride [2–5], will result in protected cardiolipin. Other synthetic approaches describe the use of phosphorylating agents such as cyclic enediol pyrophosphates [6–8], silver salts of PA [9, 10], phosphorus oxychloride [11], and 2-chlorophenyl phosphorodi-(1,2,4-triazolide) [12]. As part of our ongoing research towards the synthesis of cardiolipin and its analogues, we have developed and reported convenient alternative methodologies [13–15] based on phosphoramidite chemistry [16, 17]. However, all these methods utilize 2-*O*-protected glycerols along with the phosphorylation or condensation reagents. The synthesis of 2-*O*-protected glycerols in turn involves three additional steps starting from glycerol and

restrictions on the choice of protecting groups. We report herein a concise total synthesis of cardiolipin starting from unprotected glycerol via the phosphonium salt methodology [18, 19]. The versatility of this method was exemplified by the use of unprotected glycerol and completed in three steps (Structure 1). This method gives both 1,3-diphosphatidylglycerol (cardiolipin) and 1,2-diphosphatidylglycerol (1,2-isomer of cardiolipin). The synthetic method of 1,2-diphosphatidylglycerol is also developed (Structure 2) (Fig. 1).

## Experimental Section

Melting points were determined at atmospheric pressure and were uncorrected.  $^1\text{H}$ ,  $^{31}\text{P}$  NMR spectra were recorded using Varian Inova (500 MHz) NMR spectrometer at 500, 125 and 100 MHz, respectively.  $^1\text{H}$  chemical shifts are in ppm from internal tetramethylsilane. For  $^{31}\text{P}$  the external standard was 85%  $\text{H}_3\text{PO}_4$  calibrated to 0 ppm. Mass spectral analyses [electron spray ionization (ESI)] were carried out on Triple

**Fig. 1** Chemical structures of 1,3-diphosphatidylglycerol (1,3-cardiolipin, **1**) and 1,2-diphosphatidylglycerol (1,2-cardiolipin, **2**)

Quadruple LC/MS/MS mass spectrometer API 4000 (Applied Biosystems). Infrared (IR) spectra were recorded on a Nicolet Nexus 470 FT-IR spectrophotometer. Samples were prepared by attenuated total reflectance (ATR) method. Thin layer chromatography (TLC) was carried out on Merck silica gel 60 F<sub>254</sub> plates (250  $\mu\text{m}$ ) and developed with the appropriate solvents. The TLC spots were visualized with either UV light or by heating plates stained with a solution of phosphomolybdic acid (5% ethanolic solution) or spraying with molybdenum blue (Sigma Chemical Co., St. Louis, MO, USA). Flash column chromatography was carried out on silica gel (230–400 mesh). All chemicals were purchased from Aldrich Chemical Co. (Milwaukee, WI, USA). All of the extracts were dried over anhydrous Na<sub>2</sub>SO<sub>4</sub>. Anhydrous dichloromethane (CH<sub>2</sub>Cl<sub>2</sub>) and tetrahydrofuran (THF) were used without further drying.

1,3-Bis [(1,2-Myristoyl-*sn*-Glycero-3)-Phosphoryl] Glycerol Dibenzyl Ester [5] and 1,2-Di [(1,2-Myristoyl-*sn*-Glycero-3)-Phosphoryl] Glycerol Dibenzyl Ester [6]

To a solution of 1,2-dimyristoyl-*sn*-glycerol **3** (7.35 g, 14.35 mmol) and 1*H*-tetrazole (8.4 mL of 0.45 M sol. in acetonitrile, 17.2 mmol) in 150 mL anhydrous CH<sub>2</sub>Cl<sub>2</sub>, dibenzyl diisopropyl phosphoramidite (5.45 g, 15.79 mmol) was added and stirred at room temperature for 1 h. The contents were diluted with 200 mL of CH<sub>2</sub>Cl<sub>2</sub> and then washed with 5% aqueous NaHCO<sub>3</sub> (2  $\times$  50 mL), brine (2  $\times$  50 mL), dried over Na<sub>2</sub>SO<sub>4</sub>, concentrated in vacuo and the oily residue **4** (10.84 g) was dried in a desiccator for 8 h and used as such in the next reaction.

A solution of the above phosphite **4**, glycerol (10.84 g, 14.35 mmol), pyridine (8.75 mL, 108.4 mmol) and Et<sub>3</sub>N (9.4 mL, 71.7 mmol) in CH<sub>2</sub>Cl<sub>2</sub> (150 mL) was cooled to  $-40^\circ\text{C}$  and pyridinium tribromide (6.88 g, 21.52 mmol) was added. The mixture was stirred at the same temperature for 1 h and gradually allowed to attain room temperature over a period of 2 h and treated with water (30 mL). The contents were diluted with EtOAc (250 mL) and the organic layer

was washed successively with aqueous 5% NaHCO<sub>3</sub> (2  $\times$  50 mL), water (50 mL) and brine (50 mL), dried (Na<sub>2</sub>SO<sub>4</sub>) and concentrated. The residue was purified on SiO<sub>2</sub> (8% acetone in CH<sub>2</sub>Cl<sub>2</sub>) to give 1.8 g (80%) of **5** as a colorless syrup as the major product. A minor product **6** (900 mg) was also obtained. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 500 MHz) **5**:  $\delta$  0.88 (*t*, *J* = 7.0 Hz, 12H), 1.22–1.34 (*m*, 80H), 1.54–1.63 (*m*, 8H), 2.24–2.31 (*m*, 8H), 3.86–4.19 (*m*, 11H), 4.25–4.31 (*m*, 2H), 4.60–4.64 (*m*, 2H), 5.02–5.11 (*m*, 4H), 5.14–5.21 (*m*, 2H), 7.31–7.39 (*m*, 10H). **6**:  $\delta$  0.88 (*t*, *J* = 7.0 Hz, 12H), 1.22–1.34 (*m*, 80H), 1.54–1.62 (*m*, 8H), 2.23–2.31 (*m*, 8H), 4.02–4.31 (*m*, 12H), 4.60–4.64 (*m*, 1H), 5.02–5.11 (*m*, 4H), 5.14–5.21 (*m*, 2H), 7.31–7.39 (*m*, 10H).

1,3-Bis [(1,2-Dimyristoyl-*sn*-Glycero-3)-Phosphoryl] Glycerol Diammonium Salt [1]

A solution of protected cardiolipin [5] (1.5 g, 1.05 mmol) in tetrahydrofuran (30 mL) was hydrogenated at 50 psi over 10% Pd/C (350 mg) for 10 h. The catalyst was filtered off over a celite bed, treated with 5 mL of 30% ammonia solution and concentrated. The residue was dissolved in CHCl<sub>3</sub>, filtered through a 0.25  $\mu\text{m}$  filter and precipitated with acetone to give tetramyristoyl cardiolipin **1** (1.21 g, 90%) as a white solid. TLC (SiO<sub>2</sub>) CHCl<sub>3</sub>/MeOH/NH<sub>4</sub>OH (6.5:2.5:0.5) *R<sub>f</sub>* ~ 0.30. ### 3-*O*-Benzyl-1,2-Di[(1,2-*O*-Dimyristoyl-*sn*-Glycerol-3)Phosphoryl]Glycerol Dimethyl Ester [8]

To a solution of 1,2-*O*-dimyristoyl-*sn*-glycerol [3] (4.95 g, 9.66 mmol) and dry *N,N*-diisopropylethylamine (1.85 mL, 10.63 mmol) in anhydrous dichloromethane (80 mL) was added dropwise *N,N*-diisopropylmethylphosphonamidic chloride (2.06 mL, 10.63 mmol) at room temperature over a period of 30 min. After addition, the reaction solution was stirred at room temperature for 2 h and then 1*H*-tetrazole (25.76 mL, 11.59 mmol, 0.45 M sol. in acetonitrile) was added. To this reaction mixture, a solution of 3-*O*-benzylglycerol **7** (703 mg, 3.86 mmol) in  $\text{CH}_2\text{Cl}_2$  (20 mL) was added dropwise. The reaction mixture was stirred at room temperature for 3 h. The reaction mixture was then cooled to  $-40$  °C, and a solution of *tert*-butylhydroperoxide (2.9 mL, 14.49 mmol) was added such that the temperature of the reaction mixture was kept below 0 °C. The mixture was warmed to 25 °C before it was transferred to a separatory funnel and washed with 5%  $\text{Na}_2\text{S}_2\text{O}_3$  ( $2 \times 40$  mL), 5%  $\text{NaHCO}_3$  ( $2 \times 50$  mL), cold 1 N HCl ( $2 \times 20$  mL), Water and brine. The organic phase was dried over anhydrous  $\text{Na}_2\text{SO}_4$  and concentrated in vacuo to yield an oily residue. The residue was purified by flash chromatography on silica gel and eluted with hexane/ethyl acetate (2:1–3:2, vol/vol) to afford **8** as a colorless oil. Yield 4.19 g (85%). TLC (hexane/EtOAc 1:1, vol/vol),  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500 MHz)  $\delta$  0.88 (*t*,  $J = 7$  Hz, 12H), 1.23–1.33 (*br s*, 80H), 1.59 (*m*, 8H), 2.28–2.34 (*m*, 8H), 3.66–3.71 (*d*,  $J = 5$  Hz, 2H), 3.73–3.80 (*dt*,  $J = 11.3, 3.0$  Hz, 6H), 3.84–3.89 (*m*, 1H), 4.12–4.37 (*m*, 10H), 4.55 (*br s*, 2H), 5.20–5.27 (*m*, 2H), 7.26–7.34 (*m*, 5H).

### 3-*O*-Benzyl-1,2-Di[(1,2-*O*-Dimyristoyl-*sn*-Glycerol-3)Phosphoryl]Glycerol Diammonium Salt [9]

To a stirred solution of **8** (2.45 g, 1.81 mmol) in 2-butanone (20 mL) was added sodium iodide (811 mg, 5.42 mmol), and the reaction mixture was refluxed at

90 °C for 3 h. The solvent was removed in vacuo and the resulting disodium salt was dissolved in cold  $\text{CHCl}_3$  (80 mL), MeOH (150 mL), and 0.1 N HCl (75 mL), and stirred at room temperature for 30 min. After addition of water (80 mL) and  $\text{CHCl}_3$  (80 mL), the  $\text{CHCl}_3$  layer was isolated and washed with  $\text{H}_2\text{O}$  (50 mL). The organic layer was neutralized with 10 mL of 10%  $\text{NH}_4\text{OH}$ . The organic layer was separated and concentrated to give a residue which was further purified by flash chromatography on silica gel and eluted with  $\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$  (7.0:2.0:0.5) to afford **9** as a white solid. Yield 1.92 g (72%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500 MHz)  $\delta$  0.88 (*t*,  $J = 6.9$  Hz, 12H), 1.25–1.34 (*br s*, 80H), 1.56 (*br s*, 8H), 2.23–2.68 (*m*, 8H), 3.58 (*m*, 2H), 3.94 (*br s*, 6H), 4.07–4.16 (*m*, 3H), 4.28–4.36 (*dd*,  $J = 2$  Hz), 4.52 (*br s*, 2H), 5.22 (*m*, 2H), 7.24–7.30 (*m*, 5H), 9.26 (*br*, 8H,  $\text{NH}_4$ ).

### 1,2-Di [(1,2-Dimyristoyl-*sn*-Glycerol-3)-Phosphoryl]Glycerol Diammonium Salt [2]

Compound **9** (1.75 g, 1.28 mmol) was dissolved in tetrahydrofuran (50 mL) and 10% Pd/C (600 mg) was added. The solution was hydrogenated using a Parr hydrogenator at a pressure of 50 psi for 4 h. After filtration on celite to remove the catalyst, the solution was evaporated to dryness. The residue was dissolved in chloroform (10 mL) and precipitated using acetone (65 mL). The mixture was stored in a freezer overnight, and the white solid was filtered and washed with a small amount of cold acetone. After drying in a vacuum desiccator over phosphorus pentoxide overnight, 1,2-di [(1,2-dimyristoyl-*sn*-glycerol-3)-phosphoryl] glycerol diammonium salt [2] was obtained. Yield 1.3 g (85%). TLC ( $\text{SiO}_2$ )  $\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$  (6.5:2.5:0.5)  $R_f \sim 0.23$ ; Mp 184–185 °C,  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500 MHz):  $\delta$  0.88 (*t*,  $J = 7.0$  Hz, 12H), 1.22–1.34 (*bs*, 80H), 1.52–1.63 (*m*, 8H), 2.25–2.33 (*m*, 8H), 2.92 (*bs*, 1H), 3.59–3.69 (*m*, 2H), 3.86–3.98 (*m*, 6H), 4.12–4.18 (*m*, 2H), 4.28–4.39 (*m*, 3H), 5.16–5.23 (*m*, 2H), 7.43 (*br s*, 8H).  $^{31}\text{P}$  NMR ( $\text{CDCl}_3$ , 161 MHz, 85%  $\text{H}_3\text{PO}_4$  as external standard)  $\delta$  0.34, 0.68; ESI-MS (negative),  $m/z$  1,240.21 ( $\text{M}-2\text{NH}_4^+ + \text{H}^+$ ), 1,011.9 ( $\text{M}-2\text{NH}_4^+ - \text{RCOO}^-$ ), 619.6 ( $\text{M}-2\text{NH}_4^+$ ) $^2$ .

### HPLC Method

Compounds **1** and **2** were analyzed at a concentration of 1 mg/mL on a prepacked DIOL cartridge column (ASTEC, 5  $\mu\text{m}$  particle size, 25 cm  $\times$  4.6 mm i.d.) using Agilent 1100 Series HPLC systems (Agilent Technology, Palo Alto, CA, USA). The column temperature was set at 40 °C and 50  $\mu\text{L}$  of sample was

injected into the HPLC for analysis and the sample temperature of the autosampler was maintained at 20 °C. The detection was done using evaporative light scattering detector (ELS1000, Polymer Laboratories Inc. Amherst, MA, USA). For the detector settings, nebulization occurred at 80–82 °C, evaporation temperature at 110 °C and the nitrogen flow was maintained at 1 mL/min. An isocratic mobile phase (MeOH:CHCl<sub>3</sub>, 9:1) was used at the flow rate of 0.8 mL/min.

## Results and Discussion

The new method presented here involves the treatment of unprotected glycerol with 1,2-diacyl-*sn*-glyceryl phosphite in the presence of pyridiniumbromide perbromide (PBP) and triethylamine in dichloromethane to afford a phosphoric triester. Removal of the phosphate protecting group will furnish the 1,3-diphosphatidylglycerol (cardiolipin). Accordingly, treatment of unprotected glycerol with dibenzyl 1,2-dimyristoyl-*sn*-glyceryl phosphate [4] prepared by a 1*H*-tetrazole mediated reaction of 1,2-dimyristoyl-*sn*-glycerol [3] with dibenzyl *N,N*-diisopropyl phosphoramidite in the presence of PBP and triethylamine afforded benzyl protected 1,3-diphosphatidylglycerol [5] along with the 1,2-phosphorylated product [6] (ratio of 6:1) in 75% yield (Structure 1). Both of these products were separated by silica gel chromatography and the structures were confirmed by NMR spectroscopy. The phosphates were individually subjected to hydrogenolysis with 10% Pd/C at 50 psi in tetrahydrofuran at room temperature to obtain tetramyristoyl cardiolipin [1] and 1,2-isomer of cardiolipin [2],

respectively, which were immediately converted to ammonium salt with the addition of ammonia. Alternatively, the crude phosphate mixture was subjected to hydrogenolysis and the products were separated at the final stage. The products (1 and 2) are easily separable on silica gel by flash chromatography with dichloromethane/methanol/ammonia (80:20:1) as eluent.

The identity and structure of 1,2-phosphorylated product 2 was further confirmed by an independent synthesis of the same (Structure 2). The synthesis of 2 was initiated by treating methyl *N,N*-diisopropylchlorophosphoramidite with 1,2-dimyristoyl-*sn*-glycerol [3] and 3-*O*-benzylglycerol [7] followed by in situ oxidation yielding the protected phosphate derivative [8]. The methyl group was deprotected by refluxing with sodium iodide (NaI) in 2-butanone to afford 9 and the debenzylation was accomplished by catalytic dehydrogenation yielding the 1,2-derivative 2 (1,2-isomer of cardiolipin) with a 76% yield (Structure 2). The products 1 and 2 were soluble in chloroform and showed clear <sup>1</sup>H NMR signals. The structures were characterized by NMR (<sup>1</sup>H, <sup>31</sup>P), IR and ESI-MS. Compound 2 is essentially a mixture of *sn*-1,2- and *sn*-2,3 isomers. Further purification of these regioisomers by chiral HPLC and with derivatization might be useful for the further synthesis of specific isomers of interesting compounds having biological importance.

Compound 1 and 2 were analyzed by HPLC on ASTEC diol column using an isocratic mobile phase (MeOH:CHCl<sub>3</sub>, 9:1) The detection was done using an evaporative light scattering detector. 1,3 Cardiolipin and 1,2-cardiolipin were well separated having retention times 3.42 and 3.28, respectively (Fig. 2). Both the cardiolipin were also injected together to observe the specification of the compounds, the peaks are found to

**Fig. 2** HPLC chromatograms **a** 1,3-diphosphatidylglycerol (1,3-cardiolipin), **b** 1,2-diphosphatidylglycerol (1,2-cardiolipin), **c** mixture of 1,3- and 1,2-diphosphatidylglycerol

be very close to each other indicative of two different compounds with similar structure as shown in Fig. 1.

In conclusion, the route used to make cardiolipin derivatives outlined here offers several advantages over other strategies used. The synthesis begins with readily available, 1,2-diacyl-*sn*-glycerols and dibenzyl phosphoramidites. Installation of the polar head group has been made easy by phosphate chemistry instead of cyclic enediol pyrophosphates and relatively labile PA. The present study has been aimed at the development of the 1,2-isomer of cardiolipin and also at a cost effective synthesis of 1,3-phosphatidylglycerol by reacting unprotected glycerol with 1,2-diacyl-*sn*-glyceryl phosphite. 1,2-Diphosphatidylglycerol may be a member of a new class of phospholipids for industrial applications similar to other natural or synthetic phosphocholines. Further, this method can be carried out on a gram scale with various types of metal ions and fatty acid chain lengths.

**Abstract** Dietary calcium modulation of adiposity is mediated, in part, by suppression of calcitriol, while the additional effect of dairy products is mediated by additional components; these include the high concentration of leucine, a key factor in the regulation of muscle protein turnover. We investigated the effect of leucine, calcitriol and calcium on energy metabolism in murine adipocytes and muscle cells and on energy partitioning between adipocytes and skeletal muscle. Leucine induced a marked increase in fatty acid oxidation in C2C12 muscle cells ( $P < 0.001$ ) and decreased FAS expression by 66% ( $P < 0.001$ ) in 3T3-L1 adipocytes. Calcitriol decreased muscle cell fatty acid oxidation by 37% ( $P < 0.001$ ) and increased adipocyte FAS gene expression by threefold ( $P < 0.05$ ); these effects were partially reversed by either leucine or calcium channel antagonism with nifedipine. Co-culture of muscle cells with adipocytes or incubation with 48-h adipocyte conditioned medium decreased muscle fatty acid oxidation by 62% ( $P < 0.001$ ), but treating adipocytes with leucine and/or nifedipine attenuated this effect. Leucine, nifedipine and calcitriol also modulated adiponectin production and thereby exerted additional indirect effects on fatty acid oxidation in C2C12 myotubes. Adiponectin increased IL-15 and IL-6 release by myotubes and partially reversed the inhibitory effects of calcitriol. Comparable effects of leucine, calcitriol and adiponectin were found in myotubes treated with conditioned medium derived

from adipocytes or co-cultured with adipocytes. These data suggest that leucine and nifedipine promote energy partitioning from adipocytes to muscle cells, resulting in decreased energy storage in adipocytes and increasing fatty acid utilization in muscle.

## Introduction

Adipose tissue has previously been perceived predominantly as a fuel reservoir that provides skeletal muscle and other organs with non-esterified fatty acids (NEFA) when exogenous nutrients are insufficient for their energy needs. Accordingly, many previous studies have focused on the development and metabolism of adipose tissue with the final aim of understanding the control of body fat stores. However, adipose tissue is now recognized as an active endocrine organ which synthesizes and secretes a variety of biological molecules, including adiponectin, leptin, tumor necrosis factor alpha (TNF $\alpha$ ), interleukins-6 (IL-6) and interleukins-15 (IL-15) [1–4]. The more recent recognition that skeletal muscle may also assume a similar role in response to various metabolic stimuli suggests a potential interaction between skeletal muscle and adipose tissue [5–6].

Previous data from this laboratory demonstrate that dietary calcium exerts an anti-obesity effect by inhibiting calcitriol secretion [7–10]. We have shown that calcitriol mediates increases in intracellular calcium ( $[Ca^{2+}]_i$ ) in adipocytes via the 1, 25(OH) $_2$ -D $_3$ -membrane associated rapid response steroid hormone

(1, 25D<sub>3</sub>-MARRS) binding protein and stimulates lipogenesis and inhibits lipolysis via a calcium dependent mechanism [11–15]. We have also shown a dose responsive inhibition of uncoupling protein 2 (UCP2) expression by calcitriol in human adipocytes mediated by the nuclear vitamin D receptor (nVDR) [16]. Moreover, we have shown that suppression of circulating calcitriol levels by increasing dietary calcium suppresses adipocyte [Ca<sup>2+</sup>]<sub>i</sub>, increases UCP2 expression, promotes adipocyte apoptosis in white adipose tissue and reduces metabolic efficiency and adiposity in a mouse model of obesity [7–9], suggesting that dietary strategies designed to suppress circulating calcitriol levels may reduce adiposity.

In support of this concept, dietary calcium suppressed fat gain on eucaloric diets and accelerated fat loss on hypocaloric diets in both animals and humans [7–9]. Notably, providing calcium in the form of dairy, which also provides branch chain amino acids (BCAAs), exerted a greater effect on adiposity and protected muscle mass during energy restriction and increased muscle mass on eucaloric diets [17–18], suggesting that dietary calcium provided with BCAAs may regulate energy partitioning in a tissue selective manner and regulate energy metabolism by modulating endocrine function of both adipose tissue and skeletal muscle, favoring elevated energy expenditure in adipose tissue and promoting protein synthesis in skeletal muscle. However, the effect of BCAAs, specifically leucine, in regulating this process is unclear. Accordingly, the objective of the present study was to determine the role and mechanism of calcium, calcitriol and leucine in regulating cross-talk between adipose tissue and skeletal muscle, and in thereby modulating adiposity.

## Material and Methods

### Cell Culture

C2C12 and 3T3-L1 preadipocytes (American Type Culture Collection) were incubated at a density of 8,000 cells/cm<sup>2</sup> (10 cm<sup>2</sup> dish) and grown in Dulbecco's modified eagle's medium (DMEM) containing 10% fetal bovine serum (FBS), and antibiotics (adipocyte medium) at 37 °C in 5% CO<sub>2</sub>. Confluent 3T3-L1 preadipocytes were induced to differentiate with a standard differentiation medium consisting of DMEM (1:1, vol/vol) medium supplemented with 1% FBS, 1 μM dexamethasone, 3-isobutyl-1-methylxanthine (IBMX) (0.5 mM) and antibiotics (1% penicillin–streptomycin). Preadipocytes were maintained in this

differentiation medium for 3 days and subsequently cultured in adipocyte medium. Cultures were re-fed every 2–3 days to allow 90% cells to reach fully differentiation before conducting chemical treatment. For differentiation of C2C12 cells, cells were grown to 100% confluence, changed into differentiation medium (dexamethasone with 2% horse serum and 1% penicillin–streptomycin), and fed with fresh differentiation medium every day until myotubes were fully formed (3 days).

### Co-culture of Adipocyte and C2C12

Cells were co-cultured by using transwell inserts with a 0.4 μm porous membrane (Corning) to separate adipocytes and C2C12 muscle cells as described previously [19]. Each cell type was grown independently in the transwell plates. Following cell differentiation and growth to confluence, inserts containing adipocytes were transferred to myotube plates, and inserts containing myotubes were transferred to adipocyte plates. After incubation for 48 hours, the cells in the lower well were harvested for further analysis.

### Treatment of Cells

Calcitriol, leucine, nifedipine or/and adiponectin were freshly diluted in medium before treatment. Cells were incubated in serum free medium overnight and then washed with fresh medium, re-fed with medium containing the different treatments (2.5 mM leucine and/or 5 μM nifedipine with or without 10 nM calcitriol or 70 ng/ml adiponectin) and incubated at 37 °C in 5% CO<sub>2</sub> for 48 h before analysis. In some experiments, the supernatants of differentiated 3T3-L1 adipocytes were used to replace the medium of C2C12 myotubes. Cell viability was measured via trypan blue exclusion. At the end of the incubation, culture supernatants were collected and stored at –20 °C until assayed.

### Fat Oxidation

Muscle cell fat oxidation was measured as described previously [20], with minor modification. Briefly, C2C12 cell monolayers were rinsed twice with phosphate-buffered saline (PBS) and incubated in substrate mixture containing 22 μM unlabeled palmitate plus 5 μCi [<sup>3</sup>H]palmitate in Hank's basic salt solution containing 0.5 mg/ml BSA for 2 h. Negative controls were prepared by treating the monolayer with methanol for 30 s to abolish cellular metabolism. The reaction medium was then collected from cell monolayer and treated with 0.2 ml 10% trichloroacetic acid. The

protein precipitate was removed by centrifugation while supernatants were treated with 6 N NaOH and then applied to a poly-prep chromatography column with 1 ml Dowex-1. The  $^3\text{H}_2\text{O}$  passed through the column and the following 1 ml of water wash was collected and radioactivity was measured with a liquid scintillation counter.

To determine total cellular protein of cultures used for fatty acid oxidation assays, cell monolayers were harvested after removal of the reaction mixture and subjected to protein measurement using Bradford protein assay reagents.

#### Total RNA Extraction

A total cellular RNA isolation kit (Ambion, Austin, TX) was used to extract total RNA from cells according to manufacturer's instruction. The concentration and purity of the isolated RNA were measured spectrophotometrically ( $A_{280}/A_{260}$  between 1.9 and 2.1) and the integrity of RNA sample were analyzed via BioAnalyzer (Agilent 2100, Agilent Technologies).

#### Quantitative Real Time PCR

Adipocyte and muscle 18s, fatty acid synthase (FAS), peroxisome proliferator-activated receptor gamma (PPAR gamma) and mitochondrial uncoupling protein 3 (UCP3) were quantitatively measured using an ABI 7300 Real-Time PCR System (Applied Biosystems, Branchburg, NJ) with a TaqMan 1000 Core Reagent Kit (Applied Biosystems, Branchburg, NJ). The primers and probe sets were obtained from Applied Biosystems TaqMan® Assays-on-Demand™ Gene Expression primers and probe set collection according to manufacturer's instruction. Pooled adipocyte total RNA were serial-diluted in the range of 1.5625–25 ng and used to establish a standard curve; total RNAs for unknown samples were also diluted in this range. Reactions of quantitative RT-PCR for standards and unknown samples were also performed according to the instructions of ABI 7300 Real-Time PCR System and TaqMan Real Time PCR Core Kit. The mRNA quantitation for each sample were further normalized using the corresponding 18s quantitation.

#### Measurement of Secretion of Cytokines in Culture Supernatants

Concentrations of adiponectin, IL-15 and IL-6 in cell culture supernatants were determined by enzyme-linked immunosorbent assay (ELISA). ELISA kits were purchased from Assay Designs (Ann Arbor, MI)

and experiments were performed according to the manufacturer's instructions.

#### Statistical Analysis

All data were expressed as mean  $\pm$  SEM. Data from studies were evaluated by one-way or two-way ANOVA, and significantly different group means ( $P < 0.05$ ) were then separated by the least significant difference test using SPSS (SPSS Inc, Chicago, IL).

#### Results

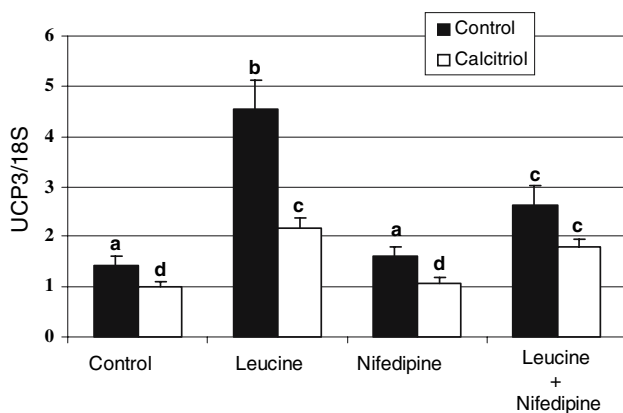

Both leucine and nifedipine stimulated fatty acid oxidation in C2C12 muscle cells and this effect was attenuated by calcitriol ( $P < 0.001$ ) (Fig. 1a). Adiponectin markedly increased fatty acid oxidation in C2C12 myotubes and restored fatty acid oxidation suppressed by calcitriol in the presence of leucine (Fig. 1a). Comparable effects of leucine, calcitriol and adiponectin were found in myotubes co-cultured with adipocytes (Fig. 1b); however, the presence of adipocytes markedly suppressed fatty acid oxidation. This effect is attributable to secreted factor(s), as a comparable suppression resulted from exposure of the myotubes to adipocyte conditioned medium (Fig. 1c).

Consistent with this, the expression of UCP3 in C2C12 cells was significantly upregulated by leucine, and calcitriol partially inhibited this effect ( $P < 0.001$ ) (Fig. 2). However, nifedipine did not significantly affect UCP3 expression, indicating that leucine and calcitriol regulate UCP3 expression in a  $\text{Ca}^{2+}$ -independent manner. This is consistent with our previous data which demonstrates that calcitriol regulates uncoupling protein expression via the nVDR and is independent of  $\text{Ca}^{2+}$  signalling [16].

Leucine and calcitriol exerted complementary regulation on adipocytes. Leucine inhibited FAS ( $P < 0.001$ ) (Fig. 3a) and PPAR gamma ( $P < 0.001$ ) (Fig. 3b) expression in differentiated 3T3-L1 adipocytes while calcitriol stimulated both FAS and PPAR gamma expression and attenuated the effect of leucine on FAS expression and nifedipine exerted the opposite effect.

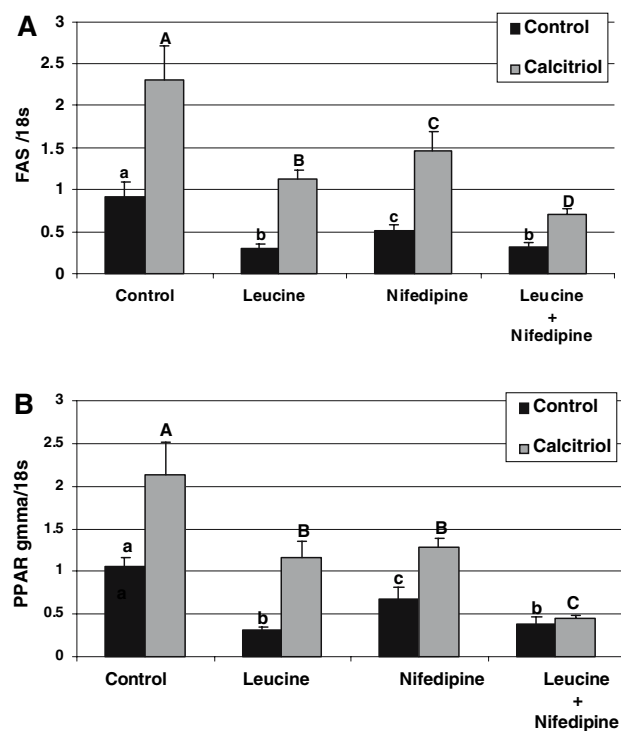

Our data also demonstrate that leucine, calcium and calcitriol regulate cytokine release from adipocytes and skeletal muscle and suggest that they may play a role in modulating their effect on energy metabolism. Leucine and nifedipine markedly increased adiponectin production in adipocytes while calcitriol exerted the opposite effect (Fig. 4). Adiponectin significantly enhanced IL-15 release in muscle cells compared to

**Fig. 1** The effect of leucine, nifedipine, adiponectin and calcitriol on fatty acid oxidation in C2C12 muscle cells. Fatty acid oxidation was determined by palmitate oxidation. C2C12 myotubes were treated with or without leucine (2.5 mM), nifedipine (10  $\mu$ M), adiponectin (70 ng/ml) or/and calcitriol (10 nM) for 48 h in basal medium (a), co-cultured with adipocytes (b) or in conditioned medium derived from 48-h incubation with adipocytes (c). Total cell numbers of cultures used for oxidation assays were evaluated by the DNA content. Values are presented as mean  $\pm$  SEM,  $n = 6$ . Means with different letter differ with  $P < 0.05$

**Fig. 2** The effect of leucine, nifedipine and calcitriol on UCP3 to 18s expression ratio in C2C12 muscle cells. C2C12 myotubes were treated with or without leucine (2.5 mM), nifedipine (10  $\mu$ M), or/and calcitriol (10 nM) for 48 h. Values are presented as mean  $\pm$  SEM,  $n = 6$ . Means with different letter differ with  $P < 0.05$

basal medium and this effect was attenuated by addition of calcitriol (Fig. 5a). Leucine appeared to exert no additional effect on IL-15 release in basal medium with or without adiponectin while nifedipine alone promoted IL-15 release but adiponectin exerted no addition effect. Adiponectin also increased IL-15 release in muscle cells treated with both leucine and nifedipine and this effect was not attenuated by addition of calcitriol, indicating the effect of calcitriol is mediated, at least in part by calcium signaling. Comparable effects were found in myotubes co-cultured with adipocytes (Fig. 5b) or treated with conditioned medium derived from differentiated adipocytes (Fig. 5c).

**Fig. 3** The effect of leucine, nifedipine and calcitriol on FAS to 18s expression ratio (a) and PPAR gamma to 18s expression ratio (b) in 3T3-L1 adipocytes. Adipocytes were treated with or without leucine (2.5 mM), nifedipine (10  $\mu$ M), or/and calcitriol (10 nM) for 48 h. Values are presented as mean  $\pm$  SEM,  $n = 6$ . Means with different letter differ with  $P < 0.05$

Similar observations were found in IL-6 production in muscle cells, with nifedipine stimulating IL-6 production, although leucine exhibited no effect (Fig. 6a).

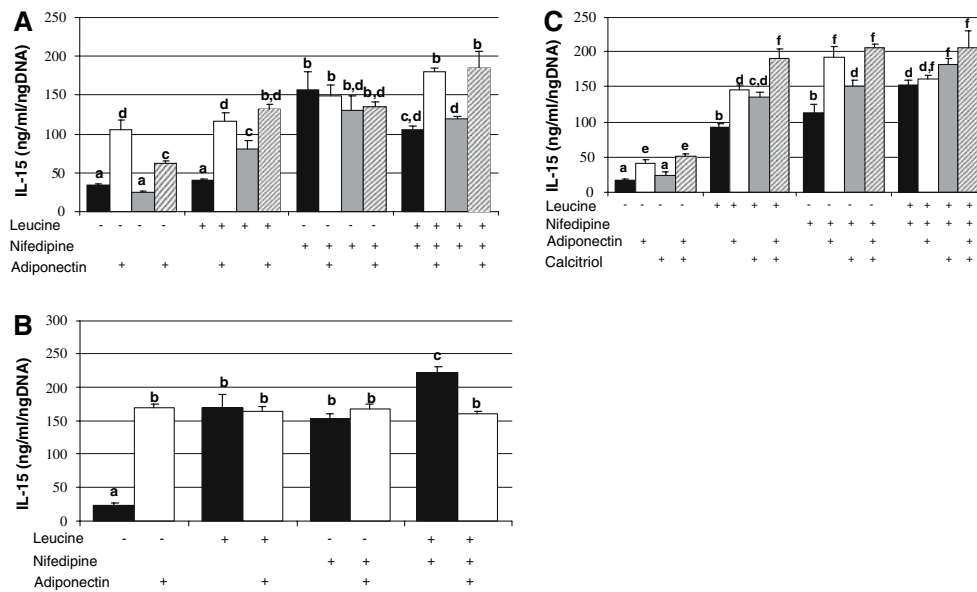

**Fig. 4** The effect of leucine, nifedipine and calcitriol on adiponectin production in 3T3-L1 adipocytes. Adiponectin was determined by ELISA as described in “Materials and methods” section. Adipocytes were treated with or without leucine (2.5 mM), nifedipine (10  $\mu$ M), or/and calcitriol (10 nM) for 48 h. Total cell numbers of cultures used for adiponectin production were evaluated by the DNA content. Values are presented as mean  $\pm$  SEM,  $n = 6$ . Means with different letter differ with  $P < 0.05$

Adiponectin increased IL-6 production and this effect was enhanced by nifedipine but not leucine. Although calcitriol exerted no significant effect on IL-6 production, it attenuated the effect of adiponectin on IL-6 production. Comparable effects were found in muscle cells co-cultured with adipocytes (Fig. 6b) or treated with conditioned medium derived from differentiated adipocytes (Fig. 6c).

## Discussion

The present data demonstrate independent roles of leucine and calcium antagonism in regulating energy partitioning between adipocytes and muscle cells, with both favoring fatty acid oxidation and UCP3 expression in C2C12 muscle cells. Calcitriol, a steroid hormone which has been shown to stimulate calcium influx via 1, 25D<sub>3</sub>-MARRS, suppressed fatty acid oxidation and attenuated the effects of leucine and nifedipine. Consequently, we hypothesize that this increase in muscle fat oxidation is coupled with decreased fat storage and increased fat catabolism in adipocytes. Consistent with this concept, we found that leucine inhibited FAS and PPAR gamma expression in differentiated 3T3-L1 adipocytes while calcitriol stimulated the expression of both genes and attenuated the effect of leucine on FAS expression, while nifedipine exerted the opposite effect. In addition, muscle cells treated with conditioned medium derived from adipocytes or co-cultured with adipocytes exhibited suppressed fatty acid oxidation, indicating that one or more factors derived from adipocytes regulate skeletal muscle energy metabolism. Indeed, leucine, nifedipine and calcitriol also modulate adiponectin production, with leucine and nifedipine increasing adiponectin production while calcitriol exerted the opposite effect. Consequently, we further evaluated the role of

**Fig. 5** The effect of leucine, nifedipine, adiponectin and calcitriol on IL-15 production in C2C12 muscle cells. IL-15 production was determined by ELISA and C2C12 myotubes were treated with or without leucine (2.5 mM), nifedipine (10  $\mu$ M), adiponectin (70 ng/ml) or/and calcitriol (10 nM) for 48 h in basal

medium (a), co-cultured with adipocytes (b) or in conditioned medium derived from 48-h incubation with adipocytes (c). Total cell numbers of cultures used for oxidation assays were evaluated by the DNA content. Values are presented as mean  $\pm$  SEM,  $n = 6$ . Means with different letter differ with  $P < 0.05$

**Fig. 6** The effect of leucine, nifedipine, adiponectin and calcitriol on IL-6 production in C2C12 muscle cells. IL-6 production was determined by ELISA and C2C12 myotubes were treated with or without leucine (2.5 mM), nifedipine (10  $\mu$ M), adiponectin (70 ng/ml) or/and calcitriol (10 nM) for 48 h in basal

medium (a), co-cultured with adipocytes (b) or in conditioned medium derived from 48-h incubation with adipocytes (c). adiponectin in mediating the response to leucine, nifedipine and calcitriol. Adiponectin promoted fatty acid oxidation, consistent with previously reported data [21], and enhanced leucine and nifedipine stimulated fatty acid oxidation in muscle cells. This effect was accompanied by up-regulation of IL-15 and IL-6 production in muscle, both of which have been shown to stimulate fatty acid oxidation [22–24].

Adipose tissue excess is an important pathogenic mechanism underlying the obesity-associated metabolic syndrome [25–27]. However, weight loss through energy control is associated with the loss of lean body mass, contributing to decreased energy expenditure [28–29]. This decrease in energy expenditure is of sufficient magnitude to contribute to the very high recidivism following successful weight reduction. Thus, strategies to reduce body fat while also maintaining lean body mass may contribute to successful long-term management of obesity and associated disorders. Previous data demonstrate a role of calcium in regulating adipose tissue lipid metabolism and a role of BCAAs in maintenance of lean mass [18]. However, the effect of calcium and BCAAs in regulation of adipose-muscle cross-talk in modulating energy partitioning had not been evaluated. Data from this study suggest that both leucine and cellular calcium antagonism promote energy partitioning from adipocytes to muscle cells, resulting in decreased energy storage in adipocytes and increasing fatty acid utilization in muscle; moreover,

these effects appear to be partially attributable to modulation of cytokine production.

We have previously demonstrated that high calcium diets inhibit weight and fat gain in both mice and humans on obesigenic diets and accelerate weight and fat loss during energy restriction [17–18]. A key mechanism underlying this anti-obesity effect is suppression of calcitriol, which modulates intracellular  $\text{Ca}^{2+}$  signaling and mitochondrial uncoupling in adipocytes and consequently results in reduced adiposity and oxidative stress [10–16]. Notably, dairy sources of calcium exert a markedly greater effect on adiposity in both mice and humans [7–9, 30–31]. Moreover, unlike supplementary or fortified sources of calcium, utilization of intact dairy products as a calcium source resulted in a modest increase in muscle mass in the absence of energy restriction and substantially reduced the loss of lean mass which otherwise accompanies hypocaloric diets, while supplementary calcium was without effect on lean mass in either mice or humans. Accordingly, dairy appears to cause a significant change in energy partitioning between adipose tissue and muscle, resulting in reduced energy storage in adipose tissue and increased fat oxidation and energy utilization (presumably for protein synthesis) in skeletal muscle. Provision of BCAAs to skeletal mimics the effect of a complete mixture of amino acids in promoting protein synthesis both in vivo and in vitro [32–33]. For example, incubation of rat diaphragm with BCAAs results in similar

stimulation of protein synthesis to that found with a complete mixture of amino acids [34]. Similarly, perfusion of rat skeletal muscle with BCAAs produces a comparable stimulation of protein synthesis to that found with perfusion of a complete mixture of amino acids [35]. Conversely, perfusion with an amino acid mixture without BCAAs has no effect on protein synthesis. Of the BCAAs, leucine appears to be primarily responsible for this anabolic effect via both mammalian target of rapamycin (mTOR)-dependent and mTOR-independent signaling [36–39]. Leucine inhibits protein degradation in muscle and infusion of leucine in human subjects results in decreased plasma levels of other amino acids [40], indicating that leucine favors protein synthesis by either reducing protein breakdown or increasing amino acid disposal for protein synthesis. Recent data suggest that the effect of leucine in regulation of protein synthesis appears not to be limited to muscle and may regulate protein metabolism in adipose tissue as well [41–42].

Energy partitioning between adipose tissue and skeletal muscle has been previously demonstrated. Animals lacking myostatin exhibit markedly increased skeletal muscle mass and reduced body fat accumulation [43–44]. Comparable results can be achieved by blocking myostatin signaling via c-ski gene overexpression [45]. Moreover, stimulation of beta-adrenergic receptors produces a dramatic increase in skeletal muscle mass and a corresponding reduction body fat content [46–47]. These data suggest an important connection between adipose tissue and skeletal muscle, and *in vitro* evidence from the present study demonstrated that leucine, nifedipine and calcitriol regulate energy metabolism in both adipocytes and muscle cells. These data are consistent with previous *in vivo* observations that dairy increase fat loss but protect lean muscle mass [17]. However, whether leucine and calcium regulate energy partitioning between adipose tissue and skeletal muscle instead of modulating each tissue is yet unclear.

Adipocyte and skeletal muscle derived cytokines may play a key role in the adipocyte-muscle cross-talk in regulating energy partitioning. For example, TNF $\alpha$ , which is expressed and produced by adipocytes and increases in obesity, has been shown to induce muscle wasting via multiple mechanisms [48–50]. On the other hand, leptin and adiponectin, which are also synthesized and secreted by adipose tissue, alter lipid partitioning in skeletal muscle by increasing fat oxidation and decreasing fatty acid incorporation into triacylglycerols [21]. Moreover, adipocytes and muscle both produce IL-6 and *in vitro* studies suggest that IL-6 may stimulate adipocyte fatty acid release and muscle fatty

acid oxidation [22–23], although its *in vivo* effect remains unclear. Notably, IL-15, a cytokine highly expressed in skeletal muscle, decreases fat deposition in adipose tissue but increases skeletal muscle fiber growth [51–52]. Thus, a reciprocal regulation between adipose tissue and skeletal muscle may exist and may control adiposity by regulating the synthesis of fat and protein in adipose tissue and skeletal muscle respectively. Data from this study demonstrate that muscle cells cultured alone exhibit markedly higher fatty acid oxidation than those cultured in conditioned medium derived from adipocytes or co-cultured with adipocytes, suggesting that adipocyte-derived factor(s) participate in the regulation of muscle energy metabolism. In addition, leucine, nifedipine and calcitriol regulate adiponectin production in adipocytes and IL-15 and IL-6 in muscle cells. Administration of adiponectin at a comparable level to that derived from adipocytes stimulated significant increases in fatty acid oxidation and IL-15 and IL-6 production in muscle cells, indicating that adiponectin may play a key role in the metabolic connection between adipose tissue and skeletal muscle. However, the role of additional adipokines is not yet clear.

In conclusion, the present study demonstrates a role for leucine, calcium and calcitriol in the modulation of adipocyte-muscle cross talk in an *in vitro* system. We found leucine and nifedipine to suppress fat anabolism in adipocytes while they promote fatty acid oxidation in muscle cells. Calcitriol, which is increased by low-calcium diets, exerted the opposite effect. These results suggest a potential role of dietary calcium in modulation of energy partitioning between adipose tissue skeletal muscle and that leucine exerts an additional effect on this system.

**Abstract** In adipocytes, short and long term stimulation of  $\beta$  adrenergic receptors ( $\beta$ AR) induces the desensitization to catecholamines, leading to a decrease in the intracellular accumulation of cAMP, but the roles played by this in lipolysis is not clear. In this study, we assessed the catecholamine-induced desensitization of lipolysis and compared this in adipocytes isolated from visceral and subcutaneous fat tissues of rats. When adipocytes were pretreated with isoproterenol (ISO), the norepinephrine (NE)-induced lipolysis was significantly reduced dose- and time-dependently. A similar reduction of the lipolytic response was also found in NE-, dobutamine-, terbutaline- or BRL37344-induced lipolysis. The ISO- and each  $\beta$ AR agonist-induced lipolysis in the visceral fat was not only higher than in the subcutaneous fat, but also markedly reduced by ISO- or NE-pretreatment. These results showed that short-term treatment of three subtypes of  $\beta$ AR by each agonist induces a rapid reduction in the lipolytic response to  $\beta$ AR stimulation. This suggests some common mechanism for the rapid desensitization of  $\beta$ AR-agonist-induced lipolysis, in contrast with previous reports on the characteristics of  $\beta$ AR subtypes. In addition, the regional difference of adipose tissue not only in inducing lipolysis but also in rapid desensitization was also apparent.

**Keywords** Rapid desensitization ·  $\beta$  adrenergic receptors · Isolated adipocytes · Lipolysis · Visceral fat · Subcutaneous fat

### Abbreviations

$\beta$ AR	$\beta$ adrenergic receptor
$\beta$ ARK	$\beta$ AR kinase
Gs	Stimulatory G protein
HSL	Hormone sensitive lipase
ISO	Isoproterenol
NE	Norepinephrine
PKA	Protein kinase A

### Introduction

The lipolytic reaction in adipocytes is mainly explained by the intracellular signaling mechanism using cAMP as a second messenger. That is, adrenaline and noradrenaline stimulate  $\beta$  adrenergic receptors ( $\beta$ AR) on the adipocyte cell surface and sequentially induce the activation of stimulatory G protein (Gs), increase cAMP due to the activation of adenylate cyclase, activate cAMP-dependent protein kinase A (PKA) and activate hormone-sensitive lipase (HSL), resulting in the hydrolysis of triglycerides in intracellular lipid droplets. There are at least three subtypes of  $\beta$ AR involved in lipolysis,  $\beta$ 1,  $\beta$ 2 and  $\beta$ 3, although their expression levels and functions are still controversial.

In addition to the acute Gs-mediated activation mechanism described above, the presence of inhibitory mechanisms that modify the activating reaction have also been known for  $\beta$ ARs. One is the attenuation of the response to short-term stimulation, that is, “acute desensitization”,

and the other is the down regulation of the  $\beta$ AR expression level by long-term stimulation of  $\beta$ ARs, that is, “chronic desensitization” [1–5]. In the former, the stimulated  $\beta$ ARs transmit intracellular activation signals, and at the same time, activate a negative regulatory mechanism. The following multistep inactivation mechanism has been proposed [6]. (1) The structure of the receptors is changed due to phosphorylation by PKA and  $\beta$ AR kinase ( $\beta$ ARK), and the affinity to G protein is decreased, resulting in dissociation. (2) Next,  $\beta$  arrestin binds to the phosphorylated receptors. (3) Finally, the receptors are incorporated into cells (internalization), and the number of agonist binding sites on the cell surface is reduced. In accordance with this mechanism, a marked reduction of the rise in the intracellular cAMP concentration in response to second stimulation after the first adrenaline stimulation has been reported in adipocytes [7, 8]. However, many problems remain unsolved, particularly whether the desensitization seen in the intracellular signal transduction system of adipocytes is correlated with any attenuated response in lipolysis. Also, the difference in desensitization among the three receptor subtypes has not been fully elucidated.

Adipocytes in different deposits of adipose tissue show similar lipolytic reactions, but their sensitivity to catecholamines or  $\beta$ AR agonists vary among regions, such as visceral and subcutaneous fat [9, 10]. However, no regional differences in desensitization have ever been investigated.

In this study, we investigated the rapid desensitization phenomenon of  $\beta$ AR-stimulated lipolysis in isolated adipocytes, by monitoring glycerol release, a final product and a direct index of lipolysis, rather than by monitoring cAMP formation. First, we confirmed the  $\beta$ AR stimulation-induced desensitization in lipolysis. Next, we investigated the receptor subtype lipolytic response to rapid desensitization. Different lipolytic responses between the visceral and subcutaneous fats were also examined with regard to the characteristics of the desensitization phenomenon.

## Experimental Procedures

### Preparation of Isolated Adipocytes

Isolated adipocytes were prepared from the epididymal and abdominal-inguinal subcutaneous fat pads of three male Wistar rats aged 9 weeks and weighing about 200–220 g, according to the method reported by Rodbell [11]. Briefly, the excised adipose tissue was cut into small pieces using ophthalmologic scissors, suspended and washed with Hank's buffer containing a 2% bovine serum albumin fraction (Sigma, MO, USA), and digested with collagenase (1 mg mL<sup>-1</sup>, Type I, Worthington Biochemical, NJ, USA) in the presence of 1 mg mL<sup>-1</sup> glucose for about 60 min at

37 °C. The digested tissue was filtered through a nylon mesh, and floating cells were collected and gently rinsed three times with Hank's buffer, and suspended in the same buffer.

### Pretreatment and Stimulation of Isolated Adipocytes

The isolated adipocyte suspension was pre-incubated with various concentrations of norepinephrine (NE) or isoproterenol (ISO, non-selective  $\beta$ AR agonist) in Hank's buffer at 37 °C for 0–30 min. The pretreated cells were gently rinsed three times with Hank's buffer, resuspended to approximately 10<sup>5</sup> cell mL<sup>-1</sup> and stimulated with NE, dobutamine ( $\beta$ 1AR agonist), terbutaline ( $\beta$ 2AR agonist) or BRL37344 ( $\beta$ 3AR agonist) at 37 °C for 2 h. The glycerol released into the buffer after stimulation was measured using the enzyme method [12]. Briefly, the buffer after stimulation was mixed with glycerol detecting solution and absorbance at 480 nm was measured. The composition of the glycerol detecting solution was 2.7 mM *p*-chlorophenyl, 0.04% Triton X-100, 2 mM magnesium sulfate, 2 mM ATP, 0.05 mM 4-amino antipiline, 1 mM EDTA, 0.5 U glycerokinase, 4 U glycerol-3-phosphate oxidase and 2 U peroxidase. Quantified glycerol concentration was normalized by number of isolated adipocytes and this was calculated using a hematocytometer. The data were statistically analyzed by ANOVA followed by Bonferoni method for multiple comparisons between pairs. All determined data are presented as the mean  $\pm$  SEM of triplicate incubation tubes for each condition. Each experiment was repeated three times with similar results.

## Results

### Time-Dependent Changes in NE-Induced Lipolysis

Time-dependent glycerol release was examined after the addition of 0.3 or 3  $\mu$ M NE in adipocytes isolated from the rat epididymal fat pad. As shown in Fig. 1, while the amounts of glycerol released were mostly stable without NE, they markedly increased with NE. The increase in the glycerol release was not linear with incubation time. The speed was higher when the incubation time was short, and moderated as the incubation time was prolonged according to stimulation time, showing that the amount of glycerol release per unit time decreased with time (Fig. 2). In adipocytes from subcutaneous fat, level of lipolysis were approximately 55% of that in the epididymal adipocytes (data for only one dose was shown in Fig. 1), and the releasing speed was gradually reduced, but the reduction was more moderate than with the epididymal adipocytes (Fig. 2).

**Fig. 1** Glycerol release from isolated adipocytes after stimulation with NE. Adipocytes were stimulated with or without NE (0.3  $\mu$ M, 3  $\mu$ M) for 0–120 min. Epididymal adipocytes are shown by a *solid line*, and subcutaneous adipocytes with a *dashed line* (only one dose was shown). Each value represents the mean  $\pm$  SEM of three incubation tubes for each condition. \* $P < 0.05$ , compared with the value of the control

This phenomenon indicates that NE stimulation rapidly activates the signaling pathway to lipolysis, and that some inhibition mechanism subsequently reduces it; that is, the NE-induced desensitization of lipolysis. And amplitude of the inhibition is possibly different between the adipocytes from the visceral fat and the subcutaneous fat.

**Fig. 2** Glycerol releasing speed of isolated adipocytes after stimulation with NE. Adipocytes were stimulated with 3  $\mu$ M NE for 0–120 min. Epididymal adipocytes were shown by *black bars*, and subcutaneous adipocytes by *white bars*. Each value represents the mean  $\pm$  SEM of released glycerol per minutes from three incubation tubes for each condition. \* $P < 0.05$ , compared with the value of the epididymal adipocytes

### Effects of NE Pretreatment on NE-Induced Lipolysis

The lipolysis induced by NE was evaluated in adipocytes pretreated with 3  $\mu$ M NE for 0 (control), 10 and 30 min. As shown in Fig. 3, in the control epididymal adipocytes without pretreatment, the NE concentration-dependently induced lipolysis, showing a maximum response at 10  $\mu$ M. In the NE pretreated cells, the maximum response decreased as the time of pretreatment was increased, being 56% of that of the control in cells pretreated for 30 min. In the subcutaneous adipocytes, the lipolytic response to NE in the control cells was approximately 40% lower than that in the control epididymal adipocytes. The pretreatment with NE also reduced the response. Reduction rates, which are the values of released glycerol for pretreated cells relative to the control cells, were lower with statistically significance in the subcutaneous adipocytes than those in the epididymal adipocytes.

Thus, the pretreatment of adipocytes with NE reduces the lipolytic response to NE stimulation, indicating a rapid desensitization. This desensitization is more evident in adipocytes from the epididymal fat pad than subcutaneous adipocytes.

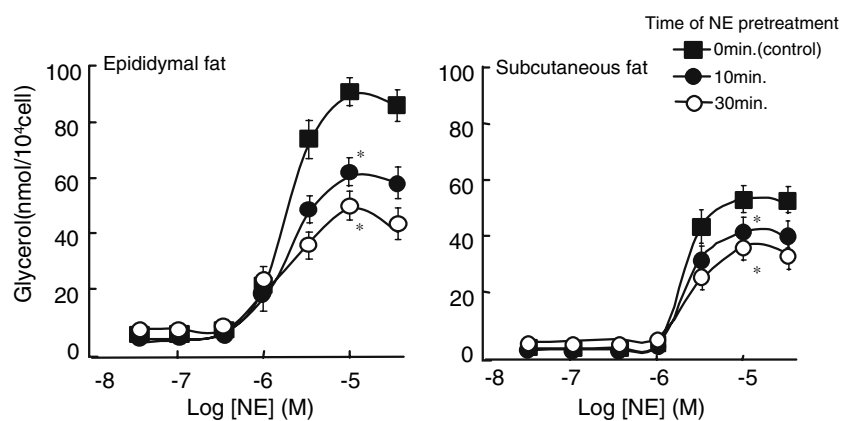

### Effects of $\beta$ AR Agonist Pretreatment on NE-Induced Lipolysis

The lipolytic response to NE was also investigated in adipocytes pretreated with a non-selective  $\beta$ AR agonist, ISO. In the same way as NE, ISO sufficiently induced lipolysis in adipocytes from both epididymal and subcutaneous fat (Fig. 4), showing maximum responses at 1  $\mu$ M, but to a lesser extent in adipocytes from subcutaneous fat (about 60% of that from the epididymal cells). When the cells were pretreated with 1  $\mu$ M ISO for 5–30 min (Fig. 5), the NE-induced lipolysis was reduced in a time-dependent manner. A significant reduction was observed after 10- and 30-min pretreatment of adipocytes from the epididymal and the subcutaneous fat, respectively. Reduction rates were significantly higher in the epididymal than the subcutaneous adipocytes.

The effects of 30-min pretreatment with varying concentrations of ISO were similarly evaluated. As shown in Fig. 6, the NE-induced lipolysis was reduced more in adipocytes pretreated with higher concentrations of ISO. At 100  $\mu$ M ISO-pretreatment, the maximum response was about 48 and 72% that of the controls in adipocytes from the visceral and subcutaneous fat, respectively. Their reduction rates were different with statistically significance.

Thus, transient treatment with ISO, as with NE, results in the desensitization of the lipolytic response to NE, more markedly or sensitive in the epididymal than in the subcutaneous fat.

**Fig. 3** Effect of NE pretreatment on NE-induced lipolysis in adipocytes from epididymal fat and subcutaneous fat. Adipocytes were pretreated with NE (3  $\mu$ M) for 0–30 min, washed, and stimulated again with varying concentrations of NE. Each value

represents the mean  $\pm$  SEM of three incubation tubes for each condition. \* $P < 0.05$ , compared with the value of the control at the maximum effecting dose of NE treatment

**Fig. 4** ISO-induced lipolysis in adipocytes. Adipocytes from the epididymal fat (filled circles) and subcutaneous fat (open circles) were stimulated with varying concentrations of ISO for 30 min. Each value represents the mean  $\pm$  SEM of three incubation tubes for each condition. \* $P < 0.05$ , compared with the value of the epididymal adipocytes at 1  $\mu$ M ISO

#### Lipolytic Response to Agonists for Individual $\beta$ ARs

Since all of the  $\beta$ AR subtypes,  $\beta_1$ ,  $\beta_2$  and  $\beta_3$ , are considered to be involved in the stimulation of lipolysis, the lipolytic response to the stimulation of each subtype was examined in adipocytes pretreated with 10 nM–100  $\mu$ M ISO for 30 min. As shown in Figs. 7, 8 and 9, dobutamine ( $\beta_1$ AR agonist), terbutaline ( $\beta_2$ AR agonist) and BRL37344 ( $\beta_3$ AR agonist) markedly stimulated lipolysis in the control untreated cells, and the maximum responses were at 10  $\mu$ M, 100  $\mu$ M and 300 nM, respectively, in adipocytes from the epididymal fat. In the subcutaneous adipocytes,

the responses were about 45, 55 and 60%, respectively, of those in the epididymal adipocytes.

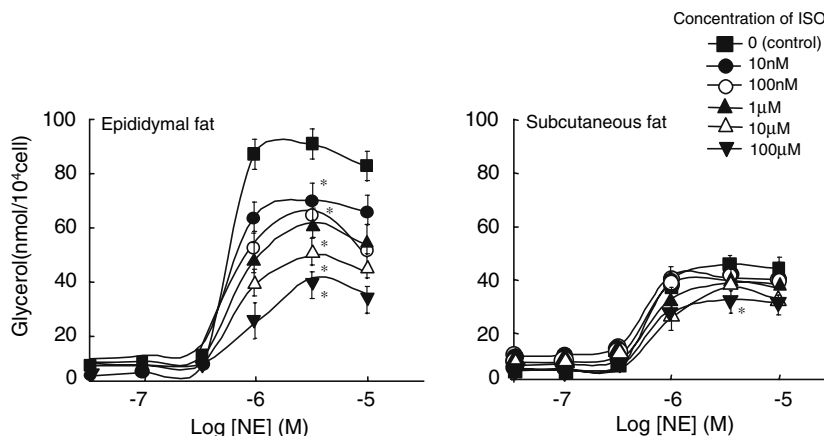

When the cells were pretreated with ISO, the lipolytic response was reduced in an ISO concentration-dependent manner. In adipocytes from the epididymal fat, pretreatment with 100  $\mu$ M ISO reduced the responses to dobutamine, terbutaline and BRL37344 to about 10, 15 and 20% of the controls, respectively. In adipocytes from the subcutaneous fat, the pretreatment with ISO also reduced each lipolytic response, but the degrees of reduction were significantly smaller and the effective dose was higher than in the epididymal fat.

Thus, ISO-pretreatment induced reduction of  $\beta_1$ ,  $\beta_2$  and  $\beta_3$ AR agonist-induced lipolysis in similar manner, and the reduction was more marked in adipocytes from epididymal fat than from subcutaneous fat.

#### Discussion

Although there have been many reports of the acute and chronic desensitization of  $\beta$ AR-mediated responses [3–8], rapid desensitization in adipocytes has been focused on at the  $\beta$ AR level or coupled with adenylate-cyclase activity, which does not always parallel the final lipolytic reaction. In this study, we characterized the rapid desensitization in isolated adipocytes using lipolysis as an index. Our results showed  $\beta$ AR agonist-induced lipolysis was reduced after short-term pretreatment with NE or ISO. The degree of desensitization was dependent on the time and concentration of pretreatment with ISO. These results seem consistent with the previous reports that the  $\beta$ AR agonist-induced activation of adenylate cyclase was reduced by short-term (45–60 min) pretreatment with ISO in human adipocytes, and also in adipocyte membrane fractions.

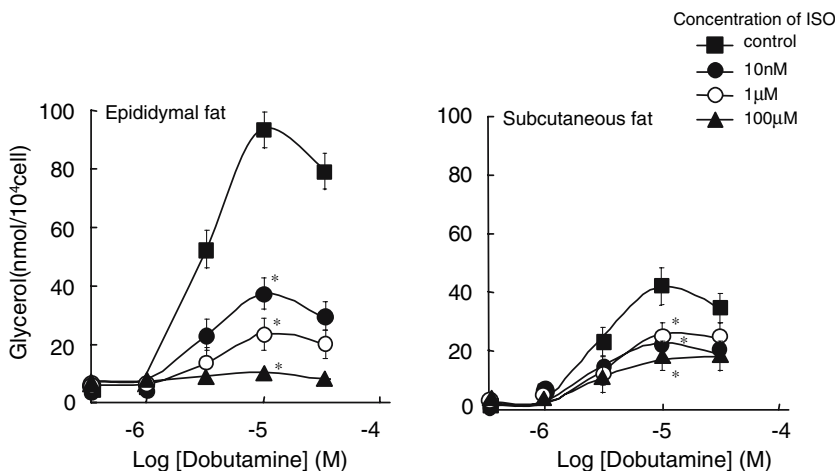

**Fig. 5** NE-induced lipolysis in ISO-pretreated adipocytes: effects of pretreatment time. Adipocytes were pretreated with ISO (1  $\mu$ M) for 0–30 min, washed, and stimulated with varying concentrations of NE for 2 h. Each value represents the mean  $\pm$  SEM of three incubation tubes for each condition. \* $P < 0.05$ , compared with the value of the control at the maximum effecting dose of NE treatment

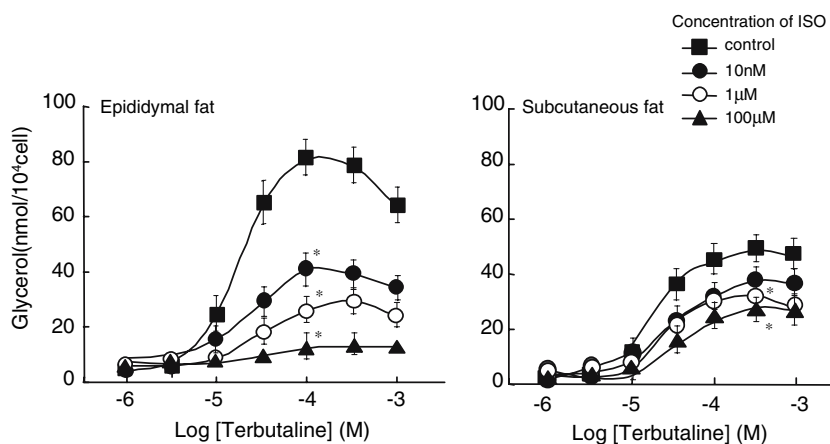

**Fig. 6** NE-induced lipolysis in ISO-pretreated adipocytes: Effects of ISO concentration. Adipocytes were pretreated with varying concentrations of ISO for 30 min, washed, and stimulated again with varying concentrations of NE for 2 h. Each value represents the mean  $\pm$  SEM

of three incubation tubes for each condition. \* $P < 0.05$ , compared with the value of the control at the maximum effecting dose of NE treatment. In the subcutaneous fat, statistically significance was shown in 10 and 100  $\mu$ M ISO- pretreated cells

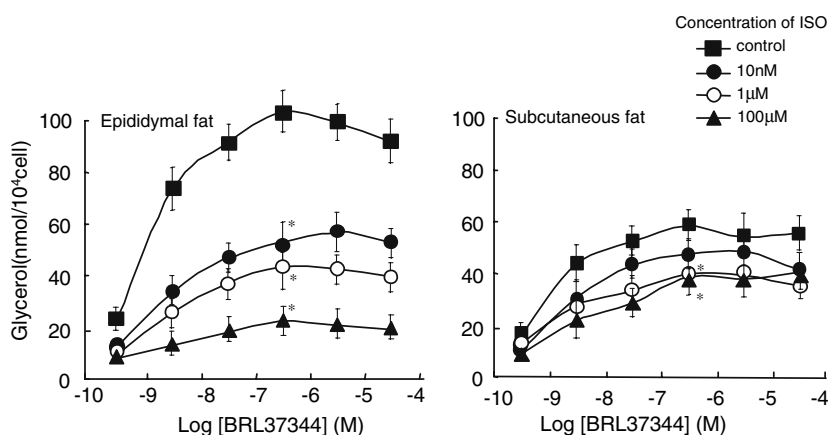

**Fig. 7** Effect of ISO pretreatment on  $\beta$ 1AR agonist-induced lipolysis. There are at least three  $\beta$ AR subtypes,  $\beta$ 1,  $\beta$ 2 and  $\beta$ 3ARs, in adipocytes, all of which are known to be involved in the activation of lipolysis. Regarding the desensitization of individual  $\beta$ AR subtypes, it has been shown that rapid desensitization scarcely occurs in  $\beta$ 3AR compared to the other two subtypes. It is mainly considered that the weak desensitization of  $\beta$ 3AR is due to the structural characteristics of  $\beta$ 3AR [2, 7, 8], which lacks 3 of 11 PKA- and  $\beta$ ARK-phosphorylation sites present in  $\beta$ 1 and  $\beta$ 2ARs [13]. In contrast to these previous reports, our results showed rapid reduction of the lipolytic response to stimulation of the three subtypes, and some desensitization mechanism common to all of the subtypes. There may be, for example, common unidentified phosphorylation sites, co-factors, or mechanisms inhibiting lipolysis at levels downstream of the receptors, such as the activation of phosphodiesterase and perilipin. Further studies are needed, especially regarding the signal transduction cascade involved with this desensitization phenomenon.

The present study also revealed the regional differences in  $\beta$ AR agonist-induced lipolysis and desensitization between adipocytes from the epididymal and subcutaneous fats. This rapid desensitization has never been considered with regard to the differences between fat deposits. As many have previously reported, the lipolytic response to  $\beta$ AR stimulation was higher in the epididymal than in the subcutaneous adipocytes. The low lipolytic response in the subcutaneous fat may be due to the lower expression of  $\beta$ AR or the higher expression of  $\alpha$ 2 adrenergic receptors. However, any other differences, including the intracellular signal transduction and enzyme activity, have not appeared in detail [9, 14–20]. We expected that adipocytes from the subcutaneous fat may be desensitized more easily than the visceral fat, and thereby show a lower lipolytic response during a 2-h stimulation by  $\beta$ AR agonists. However, this is unlikely because the NE or  $\beta$ AR agonist-induced lipolysis in the visceral adipocytes was more strongly reduced by ISO pretreatment than it was in subcutaneous adipocytes. The visceral

fat around the digestive organs or cardiovascular system organs must rapidly and strongly respond to lipolytic hormones and neurotransmitters, but may be easily desensitized by these stimuli. This is the first finding about the regional differences of adipose desensitization.

The findings of the present study were obtained using rat adipocytes *in vitro*. There have been some reports suggesting similar desensitization *in vivo*. Marion-Latard et al. [21] reported that 60 min exercise stimulation desensitized the glycerol-releasing response to NE in adipose tissues in humans.

As for chronic desensitization *in vivo*, Ikezu et al. [22] reported that  $\beta$ 3AR agonist-induced lipolysis was less in adipocytes isolated from rats with burn injuries, while the expression levels of lipolysis-related protein, such as PKA and HSL, were not affected. In contrast, the up-regulation of  $\beta$ 3AR by chronic  $\beta$ AR stimulation has been reported [23–25], and it is considered that cAMP-response-element promotes the translation of the  $\beta$ 3AR gene.

In human adipocytes, the expression of  $\beta$ 3AR is rare and its physiological function has been controversial [13, 14]. Recently, it has been revealed that the coupling of  $\beta$ 3AR binding to the lipolytic reaction is weaker than the other  $\beta$ ARs, but it clearly shows active lipolysis *in vivo* or with the *in situ* microdialysis technique [26].

In conclusion, we demonstrated that short-term treatment of  $\beta$ AR agonists induce rapid reduction in the lipolytic response to  $\beta$ AR stimulation, regardless of the different  $\beta$ AR subtypes, and showed the regional differences not only in the lipolytic response, but also in the sensitivity of desensitization between the visceral and subcutaneous fat. The difference of metabolic character between these two types of adipocytes must be related to their physiological role of each fat deposit. Elucidation of the mechanisms of such rapid, as well as chronic, desensitization is important for a better understanding of the mechanism regulating fat and energy metabolism in adipose tissues. Moreover, it would be helpful for the development of  $\beta$ AR agonists and/or antagonists that are more effective and selective to adipocytes.

**Abstract** The process of interesterification results in changes in triacylglycerol (TAG) structure and is used to increase the melting point of dietary fats. The acute health effects of this process on palmitic acid-rich fats are uncertain with regard to postprandial lipemia, insulin and factor VII activated (FVIIa) concentrations. Two randomized crossover trials in healthy male subjects compared the effects of meals containing 50 g fat [interesterified palm oil (IPO) versus native palm oil (NPO);  $n = 20$ , and IPO versus high-oleic sunflower oil (HOS);  $n = 18$ ], on postprandial changes in lipids, glucose, insulin, chylomicron composition and FVIIa. Compared with NPO, IPO decreased postprandial TAG and insulin concentrations. Both NPO and IPO increased FVIIa concentrations postprandially; mean increases at 6 h were 21 and 19%, respectively. Compared with HOS, IPO decreased postprandial TAG (47% lower incremental area under the curve) and reduced the postprandial increase in FVIIa concentration by 64% at 6 h; no significant differences in hepatic and total lipase activities or insulin concen-

trations were noted. All three test meals increased postprandial leukocyte counts (average 26% at 6 h). The fatty acid composition of the chylomicron TAG was similar to the test fats following all test meals. It is concluded that interesterification of palm oil does not result in adverse changes in postprandial lipids, insulin or FVIIa compared to high oleate and native palm oils.

### Introduction

The positional composition of palmitic acid-rich triacylglycerol (TAG) varies between fats and oils and is believed to affect lipid metabolism. Fats from plant origin, such as cocoa butter and palm oil, generally have palmitic acid distributed in the outer positions of the TAG molecule (the *sn*-1 and *sn*-3 positions) whilst in

fats of animal origin, such as lard and human breast milk, palmitic acid is commonly found in the middle (*sn*-2) position. Random interesterification of vegetable fats, which is a technique being widely adopted by the food industry, results in the generation of TAG with a higher proportion of palmitic acid in the *sn*-2 position and a fat with a higher melting point.

Evidence from animal and human infant studies suggests that palmitic acid is better absorbed when found in the *sn*-2 position compared with the *sn*-1 and -3 positions [1], a phenomena that has been utilized by food manufacturers who have developed a fat with a high proportion of palmitic acid esterified to the *sn*-2 position of the TAG to produce a vegetable equivalent to human breast milk fat. It has also been claimed that palmitic acid in the *sn*-2 position of the TAG renders that TAG more atherogenic in animal models than when in the *sn*-1 or *sn*-3 positions [2]. The reason behind this is unclear as chronic studies in humans have not found an effect of positional composition of palmitic acid on cholesterol concentrations [3, 4].

A comparison of palmitic acid in the *sn*-2 position of TAG compared with the *sn*-1 or *sn*-3 positions, demonstrates superior absorption, a faster rate of chylomicron transport into lymph [5] and a slower chylomicron clearance rate [6, 7], suggesting a more pronounced and prolonged postprandial lipemia. However, this is not supported by a study comparing palm oil and Betapol<sup>TM</sup> [8] and one comparing meals rich in the TAG species 1, 3-oleyl, 2-palmityl glycerol and 1, 2-oleyl, 3-palmityl glycerol [9]. Furthermore, a small study in female subjects [10] reported a reduced postprandial lipemia following 50 g interesterified palm oil (IPO) compared with native palm oil (NPO).

Previous work indicates that compared with oleic acid-rich TAG, the postprandial increase in factor VII activated (FVIIa) concentrations is less marked following palmitic acid-rich TAG [11–13], and none have examined the effects of interesterification of palmitic acid-rich TAG on postprandial FVIIa concentrations. The present study tests the hypothesis that TAG structure of palmitic acid-rich TAG determines the extent to which plasma TAG and FVIIa increases postprandially. Palm oil was chosen as it has a unique TAG structure with almost all of the palmitic acid being present in the *sn*-1 and *sn*-3 position of the TAG as 1, 3-palmityl, 2-oleyl, and is the world's most important vegetable oil (accounting for over 30% of the total world production of oils and fats). The first study compares the postprandial response to NPO versus IPO. A subsequent study compares IPO versus high oleic sunflower oil (HOS).

## Experimental Procedures

### Subjects

Male subjects aged 18–60 years were recruited from among staff and students of King's College London. The subjects were healthy and exclusion criteria included history of cardiovascular disease, diabetes, body mass index <20 or >35 kg/m<sup>2</sup>, plasma cholesterol >7.8 mmol/l, plasma TAG >3 mmol/l, current use of antihypertensive or lipid lowering medication, and a self reported intake of alcohol of greater than 28 U/week (1 U = 10 mL ethanol). Fasting plasma lipoprotein lipid concentrations, body weight, blood pressure, blood cell count and liver function were confirmed to be within the prescribed limits prior to entry into the study. Habitual nutrient intake was assessed from a 3-day food intake diary and nutrients were estimated using the Microdiet programme (Downlee Systems Limited, UK). Twenty-one subjects were recruited for the first study and 18 subjects for the follow-up study, subject details are shown in Table 1. The characteristics of the subjects were broadly similar between both studies except that the subjects in the follow-up study were slightly heavier. One subject withdrew from the first study due to time constraints. Dietary intakes were close to recommended dietary guidelines for the UK [14].

### Study Design

A randomized crossover study design was used. Each subject received two experimental meals with at least 1 week between meals, such that treatment sequences were balanced. The day preceding each postprandial test, subjects were given advice to avoid consuming foods high in fat and were provided with a standardized low fat dinner (containing <10 g fat) to consume as their evening meal. To control for physical activity levels, subjects were asked to refrain from strenuous exercise, including cycling and sporting activities, and from the use of alcohol on the day before and on the day of the test meal. Subjects fasted overnight from 22:00 h and the following morning a cannula was inserted into the forearm (antecubital vein) of each subject between 08:00 and 10:00 h and fasting venous blood samples were obtained. The test meal was consumed within 15 min. Further venous blood samples were obtained at 15 min, 30 min, 1 h, 90 min, 2 h, 3 h, 4 h, 5 h and 6 h. In the follow-up study, an intravenous injection of heparin (100 IU heparin/kg body weight; Monoparin, CP Pharmaceuticals Ltd., UK) was given following the 6 h sample, and further blood samples

were collected 5 and 15 min later. During the postprandial period, subjects refrained from the consumption of any food or drink except water, which they were asked to consume at regular intervals throughout, and following the 3 h blood sample when subjects received a standardized lunch (1.7 MJ) consisting of fresh fruit and a low fat yogurt (less than 1 g fat), which was given to make the procedure tolerable to the subjects. This has previously been shown not to interfere with the measurement of postprandial lipemia or the postprandial increase in FVIIa [12, 15]. The study protocol was reviewed and approved by King's College Research Ethics Committee, and all participants gave written informed consent.

#### Formulation of the Test Meals

The test fats consisted of NPO, IPO (ADM-Pura, Kent, UK) and HOS (Anglia Oils Ltd., Hull, UK). Differential scanning calorimetry (DSC) showed a major melting peak at 39 °C for the NPO and a broad melting endotherm for the IPO between 30 and 52 °C with two mean peak melting temperatures of 43 and 48 °C. All of the HOS was melted at approximately -8 °C. The proportion of unmelted fat determined by pulsed low-resolution nuclear magnetic resonance analysis (NMR) at body temperature (37 °C) of the NPO, IPO and HOS was 3.6, 15.2 and 0%, respectively. The fatty acid and positional composition and physical characteristics were determined, shown in Table 2.

The test meals consisted of two muffins (each containing 25 g test fat) and a milkshake and were formulated to provide 3.57 MJ (853 kcal), 50 g fat, 15 g protein and 89 g carbohydrate. The milkshake

consisted of 220 mL skimmed milk and 15 g Nesquick milkshake mix (Nestlé Ltd., Switzerland). The two muffins contained 50 g test fat, 28 g baking flour, 10 g cornflour, 28 g sugar, 38 mL skimmed milk, 4 g pasteurized egg white, 4 g vanilla essence, and 2 g baking powder. In the first study, the test fats consisted of NPO and IPO, and in the follow-up study they consisted of IPO and HOS. For each study, the muffins were made in a single batch, and stored at -20 °C. Before serving, muffins were defrosted and heated in a microwave to warm.

#### Collection and Handling of Blood Samples

Venous blood samples were collected from a cannula into a syringe and dispensed into vacutainers (Beckton Dickenson, UK). Blood samples were processed within 30 min of blood collection. Blood for lipid analysis (plasma fatty acid and TAG concentrations and chylomicron composition) was collected into 6 mL EDTA containing vacutainers and plasma was separated by centrifugation at 1,500g for 15 min at 4 °C. Blood for lipoprotein analysis (total and HDL cholesterol) was collected into 2 mL vacutainers containing no anti coagulant, centrifuged at 1,500g for 15 min at 4 °C. Blood for full blood counts was collected into 2 mL EDTA vacutainers for analysis on the same day. For FVIIa, blood was collected into 4.5 mL vacutainers containing 38 g/l trisodium citrate solution and centrifuged at 1,500g for 15 min at 18 °C. Blood for glucose analysis was collected into 4 mL fluoride oxalate tubes, and blood for insulin analysis was collected into 2 mL lithium heparin tubes, both were centrifuged at 1,500g for 15 min at 4 °C. Samples for lipid analysis were

collected at hourly intervals. Samples for lipoprotein analysis (2 mL no anti coagulant), full blood counts (2 mL EDTA) and FVIIa (4.5 mL Na Cit) were collected at 3 and 6 h postprandially. The chylomicron-rich fraction ( $S_f > 400$ ) was separated by ultracentrifugation from the EDTA plasma samples [16] at 2, 3, 4 and 5 h. Samples for glucose (4 mL fluoride oxalate) and insulin (2 mL lithium heparin) were collected at 15, 30, 60, 90 and 120 min postprandially. In the follow-up study, blood for lipoprotein lipase (LPL) and hepatic lipase (HL) activity was collected into 6 mL lithium heparin vacutainers 5 and 15 min following the heparin injection and centrifuged at 1,500g for 15 min at 4 °C.

### Analytical Methods

Melting characteristics of the test fats were determined by DSC using a Mettler-Toledo DSC 820 unit (Mettler-Toledo Ltd., Leicester, UK). The solid fat content profiles were measured by NMR using a QP<sup>20+</sup> pulsed NMR (Oxford instruments Ltd., Oxfordshire, UK) at five temperatures (32, 37, 42, 47 and 52 °C). A standard pre-conditioning procedure for fats showing polymorphisms was followed; samples were melted at 80 °C and kept at 60 °C for 5 min followed by storage in a water-bath at 26 °C for 40 h, prior to analysis samples were equilibrated for 90 min at 0 °C and at each measurement temperature for 60 min.

Plasma total, HDL cholesterol and TAG were determined by enzymatic assays [15]. Plasma insulin was measured by a solid-phase, two-site chemiluminescent immunometric assay on a DPC IMMULITE (Diagnostic products corporation, Caernarfon, UK). Plasma glucose was analyzed using the full enzymatic colorimetric procedure (GOD-PAP) using an automated instrument (Boehringer Hitachi 704 EC, Boehringer Mannheim, Lewes, UK). Plasma FVIIa was measured using a one-stage clotting assay as previously

described [17]. Plasma concentrations of palmitic, stearic, oleic and linoleic acid were determined by gas-liquid chromatography (GLC) using pentadecanoic acid (C15:0) as an internal standard [18] on a BP75 column (25 m × 220 μm × 0.25 μm SGE) on an Agilent 6890 (Agilent Technologies, Cheshire, UK). For determination of chylomicron TAG composition, lipids were extracted from the chylomicrons and the TAG fraction isolated by thin layer chromatography (TLC) and analyzed by GLC as described elsewhere [19]. The composition of the fatty acids in the *sn*-2 position of the test fats and the chylomicron TAG fraction were determined by specific enzymatic hydrolysis [16] followed by separation of the 2-monoacylglycerol by TLC and analysis of their fatty acid methyl esters by GLC.

LPL and HL activity were determined using an adaptation of the continuous fluorimetric lipase test (CONFLOULIP<sup>TM</sup>, Progen Biotechnik, Heidelberg, Germany) on a Cobas Fara II with a fluorescence measurement capability, fitted with a 400 nm emission filter, and a thermostatically controlled cuvette holder (37 °C). Two CONFLOULIP<sup>TM</sup> kits were used; the 'Total lipase test kit' and the 'Hepatic lipase select test kit'. The modification from the kit method was to use high and low salt concentration buffers both with a pH of 7.4. At low salt concentrations LPL and HL are active and total lipase activity is measured, at high salt concentrations LPL activity is inhibited so that only HL is active. LPL was then calculated by subtracting HL from total lipase activity.

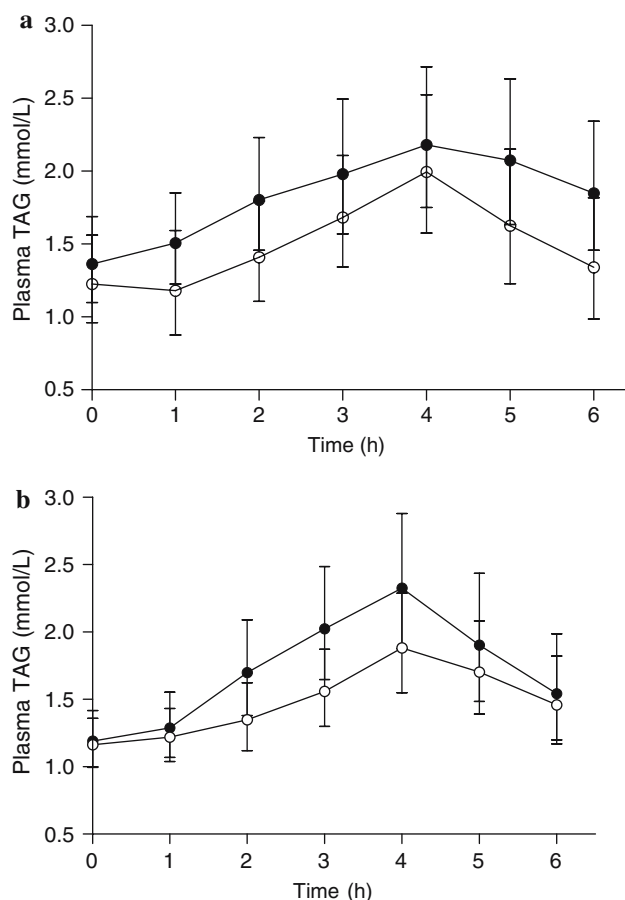

### Statistical Analysis

Data that was not normally distributed was log transformed prior to analysis. Incremental area under the curves (iAUC) were calculated using GraphPad Prism (version 3.0) using the trapezoid rule. Statistical analysis of the data was carried out using repeated

measures analysis of variance (ANOVA) using SPSS PC version 10. Comparisons with fasting values were made using Dunnett's multiple comparison test.

## Results

Twenty subjects completed the first study and 18 subjects completed the follow-up study. Postprandial plasma TAG concentrations following IPO and NPO are shown in Fig. 1a. The incremental area under the curve (iAUC) was not significantly different between test fats [geometric mean with 95% CI; NPO; 138 (89, 214), IPO; 96 (64, 146),  $P = 0.075$ ]. However, the pattern of response differed (ANOVA; diet  $\times$  time interaction  $P = 0.002$ ), with the increase in plasma TAG concentrations being significantly greater at 1, 2, 5 and 6 h following the NPO compared with the IPO. The maximum increase occurred at 4 h for the NPO and IPO [geometric mean with 95% CI; 60% (38, 86) and 63% (43, 85) respectively, NS]. The postprandial increases in plasma palmitic and oleic acid concentrations (measured as iAUC) were not significantly different following IPO and NPO: geometric mean with 95% CI; 191.0 (145.2, 251.4) versus 235.6 (172.9, 320.9) for palmitic acid and 160.7 (117.7, 219.4) versus 208.4 (142.5, 304.6) for oleic acid. However, there was a significant diet  $\times$  time interaction for oleic and palmitic acid ( $P < 0.001$  for both), with the IPO showing a sharp rise and decline in concentrations compared with NPO, which remained significantly elevated above interesterified values at 6 h ( $P < 0.05$ ), similar to the plasma TAG response. There was no change in the proportion of fatty acids in the chylomicrons over time (ANOVA of diet  $\times$  time interaction; NS) consequently mean 2–6 h values are shown in Table 3. The proportion of palmitic, stearic, oleic and linoleic acid in the chylomicron TAG largely reflected those in the test fats, and was not significantly different between test fats except for oleic acid which was significantly lower in the chylomicron TAG ( $P = 0.005$ ) following the IPO compared with the NPO (mean  $\pm$  SD;  $40.9 \pm 1.4$  vs.  $42.3 \pm 1.3$  wt %, respectively). The distribution of fatty acids in the *sn*-2 position of the chylomicron TAG did not change with time (ANOVA of diet  $\times$  time interaction; NS) and broadly reflected that of the test fats, except for palmitic acid, which was higher in the *sn*-2 position of the chylomicrons compared to corresponding test fats. Furthermore, there was a significantly ( $P < 0.001$ ) higher proportion of palmitic acid in the *sn*-2 position in the chylomicrons following the IPO compared to NPO (mean  $\pm$  SD:  $44.6 \pm 1.5$  vs.  $23.6 \pm 1.9$  wt %, respectively).

**Fig. 1** **a** Plasma triacylglycerol (TAG) concentrations following 50 g native palm oil (closed symbols) and interesterified palm oil (open symbols). Geometric mean with 95% CI,  $n = 20$ . Data was analyzed by ANOVA on deviations from fasting values: significant diet  $\times$  time interaction  $P = 0.002$ , diet effect  $P = 0.023$  and time effect  $P < 0.001$ . **b** Plasma triacylglycerol (TAG) concentrations following 50 g high oleic sunflower oil (closed symbols) and interesterified palm oil (open symbols). Geometric mean with 95% CI,  $n = 18$ . Data was analyzed by ANOVA on deviations from fasting values: significant diet  $\times$  time interaction  $P = 0.006$  and time effect  $P < 0.001$

In the follow-up study, plasma TAG concentrations increased to a lesser extent following the IPO compared with the HOS (Fig. 1b). Repeated measures ANOVA showed a significant diet  $\times$  time interaction for TAG concentrations ( $P = 0.003$ ) and for deviations of TAG from fasting ( $P = 0.006$ ). The incremental area under the curve for plasma TAG was significantly lower ( $P = 0.004$ ) following the IPO meal compared with the HOS meal (geometric mean with 95% CI): 120 (175, 192) versus 225 (159, 319), respectively. Peak 4 h increases in plasma TAG concentrations were 62% for IPO in the follow-up study compared with 63% in the first study, showing good reproducibility in postprandial responses between studies. Concentrations of plasma palmitic and oleic acid were significantly

different between test fats (diet × time interaction; *P* < 0.001 for both), with large increments from fasting values in palmitic acid [peak increase at 4 h of 40% (95% CI 26, 56)] following the IPO and a larger increase in oleic acid [peak increase at 4 h of 126% (95% CI 94, 165)] following the HOS. The proportion of fatty acids in the chylomicron TAG reflected that in the corresponding test fats and was significantly different between test meals, with a higher proportion of palmitic acid and lower proportion oleic acid (*P* < 0.001 for both) following the IPO compared with the HOS (mean ± SD: 43.5 ± 2.4 vs. 8.5 ± 1.9 for palmitic acid and 41.7 ± 2.9 vs. 79.4 ± 3.2 for oleic acid, respectively). There were no significant differences following the IPO compared with the HOS in post-heparin total lipase, LPL and HL activity (Table 4).

No differences were observed in postprandial serum cholesterol (total, HDL and LDL cholesterol) and glucose concentrations between the test fats in both studies. Following the IPO and NPO there was a significant diet × time interaction for insulin concentrations (*P* = 0.004) and for the deviations of insulin from fasting (*P* = 0.049) (Fig. 2a), with greater increases (difference in log transformed values) at 30, 90 and 120 min (*P* < 0.05 for all) following the NPO compared with the IPO, although the iAUC were not significantly different (*P* = 0.072). In the follow-up study, postprandial changes in insulin concentrations were not different between HOS and IPO (Fig. 2b).

**Table 4** Plasma post-heparin total lipase (TL), lipoprotein lipase (LPL) and hepatic lipase (HL) activity following test meals

	Interesterified palm oil	High oleic sunflower oil
TL	22.9 ± 7.0	24.2 ± 7.4

No differences between fats

FVIIa concentrations increased postprandially but the increase was not significantly different between the IPO and NPO (Fig. 3a). However, the increase in FVIIa was significantly lower following the IPO at 6 h (*P* = 0.006) compared with the HOS (Fig. 3b). White blood cell (WBC) counts did not differ postprandially between the test fats [for both IPO vs. NPO (Fig. 4a) and IPO vs. HOS (Fig. 4b)], but there was a significant time effect for WBC (*P* < 0.001) and neutrophils (*P* < 0.001), which increased at 3 and 6 h postprandially. No other significant differences were noted.

## Discussion

This study aimed to investigate whether the interesterification of a palmitic acid-rich fat resulted in adverse effects on postprandial lipemia, insulin and FVIIa concentrations. Previous work has suggested that palmitic acid-rich fats may increase insulin secretion [20] and delay the clearance of postprandial TAG [21] compared with unsaturated fats. However, not all studies have concurred with these findings [22] and some studies have not been able to demonstrate any significant difference between palm oil and an oleic acid rich oil [12, 15]. Both the present study, which was conducted in men, and a study in young women [10] indicate a blunted increase in plasma TAG following IPO versus NPO. The postprandial increase was also markedly lower following IPO compared with HOS (a 47% lower iAUC for plasma TAG).

Several possible explanations can be advanced for the lower postprandial rise in plasma TAG following the IPO, including differences in the rate of absorption, lipolysis and/or clearance. However, there were no differences in HL and LPL activities following the test fats, in agreement with a study by Tholstrup et al. [21], suggesting that differences in rates of chylomicron clearance or TAG lipolysis are unlikely to account for the differences observed. Furthermore, analysis of the

**Fig. 2** **a** Increase in plasma insulin concentrations from fasting following native palm oil (closed symbols) and interesterified palm oil (open symbols). Mean difference in log-transformed values with 95% CI,  $n = 20$ . chylomicron TAG in plasma following the test meals revealed that the fatty acid composition and the proportion of palmitic acid in the *sn-2* position was broadly similar to the dietary fats, and as expected, the proportion of palmitic acid in the *sn-2* position of the chylomicron was greater following the IPO compared with the NPO. This would imply that there were unlikely to be differences in the extent of absorption of the different dietary fats, and this is supported by studies that have reported palmitic acid to be well digested in humans when in the outer positions [23, 24], randomly distributed on all three positions of the glycerol [25], or as tri-palmitin [26]. An alternative explanation may be that the IPO, which contains a higher proportion of solid fat at 37 °C compared with

**Fig. 3** **a** Postprandial changes in plasma factor VII activated (FVIIa) concentrations following the native (hatched bars) and interesterified (open bars) palm oil, mean difference in log-transformed values with 95% CI,  $n = 20$ . <sup>1</sup>Significant increase from fasting values,  $P < 0.05$  (paired  $t$  test). No differences between fats. **b** Postprandial changes in plasma factor VII activated (FVIIa) concentrations following the high oleic sunflower oil (hatched bars) and interesterified palm oil (open bars), mean difference in log-transformed values with 95% CI,  $n = 18$ . <sup>1</sup>Significant increase from fasting values,  $P < 0.05$  (paired  $t$  test). <sup>2</sup>Significantly different from interesterified palm oil,  $P = 0.006$  (paired  $t$  test). the NPO and HOS (IPO; 15%, NPO; 4% and HOS; 0%), may be emulsified less readily due to its high melting point [27], resulting in a slower increase in plasma TAG.

Saturated fatty acids are believed to have an adverse effect on plasma insulin concentrations and it has been reported that palm oil acutely increases plasma insulin concentrations to a greater extent compared to unsaturated fats [20]. A novel finding in the present study was that the IPO resulted in a lower increase in plasma insulin compared with NPO, mainly as a consequence of a lower initial rise in plasma insulin concentrations. As this occurs well before the increases in plasma TAG, it is likely that this effect is mediated by gut

**Fig. 4** **a** Mean white blood cell counts (WBC  $\times 10^9/l$ ) following test meals containing native (closed symbols) and interesterified (open symbols) palm oil (with SEM;  $n = 20$ ). Data was analyzed by ANOVA; time effect  $P < 0.001$ , no effect of diet. **b** Mean white blood cell counts (WBC  $\times 10^9/l$ ) following test meals containing interesterified palm oil (open symbols) and high oleic sunflower oil (closed symbols) palm oil (with SEM;  $n = 18$ ). Data was analyzed by ANOVA; time effect  $P < 0.001$ , no effect of diet

hormones, whose release has previously been shown to be acutely influenced by dietary fat intake [28, 29]. Indeed, the NPO may be hydrolyzed more rapidly than the IPO, resulting in a rapid increase in the secretion of the gut hormone gastric inhibitory polypeptide and subsequent increase in insulin. This finding, taken together with the observation that there were no differences in the insulin response following IPO and HOS, suggests that interesterification may attenuate the postprandial rise in insulin observed following palm oil. This observation requires confirmation and further research on the mechanisms involved is warranted.

It is now well established that there is substantial increase in FVIIa concentrations 3–6 h following a meal high in fat [12, 15]. Both types of palm oil increased FVIIa but the increase in FVIIa was less marked for the IPO compared with HOS oil. The mechanism for the postprandial activation of FVII is uncertain but is believed to be associated with the process of lipolysis and lipid transfer reactions that occur in the postprandial period that generate a charged surface that activate FVII. It has been suggested that this might be a consequence of activation of the ABC-A1 transporter protein, which may be stimulated by unsaturated fatty acids, resulting in the expression of charged phospholipids on the outer surface of WBC and platelets [30]. In the present study, there was a substantial postprandial increase in WBC counts following all three test meals, probably a consequence of increased lymph output associated with chylomicron secretion, regardless of their ability to

increase FVIIa. The mechanism responsible for the postprandial activation of FVII requires further investigation.

In conclusion, the results of the present study indicate that interesterification of palm oil does not result in adverse changes in postprandial lipemia, insulin or factor VII activation compared with NPO or HOS.

**Acknowledgments** We thank ADM-Pura and Anglia Oils for providing and processing the test fats. We also thank David Howarth for the coagulation assays, Peter Lumb for the lipase assays, Roy Sherwood for the insulin and lipoprotein assays and Robbie Gray for technical help. Thomas A.B. Sanders and Sarah E.E. Berry conceived and devised the study and contributed to the analysis and writing of the manuscript. George J. Miller supervised the FVIIa analysis, Rebecca Woodward and Christabelle Yeoh organized and conducted the follow-up study. Sarah Berry was the recipient of King's College London Research Studentship Award and the project was institutionally funded. The authors have no financial or commercial interest in any company or organization sponsoring the research.

**Abstract** Plant sources of omega-3 fatty acids (FA) are needed that can materially raise tissue levels of long-chain omega-3 FA [i.e., eicosapentaenoic acid (EPA; 20:5n-3) and docosahexaenoic acid (DHA; 20:6n-3)]. Stearidonic acid (SDA; 18:4n-3) is the delta-6 desaturase product of alpha-linolenic acid (ALA; 18:3n-3), and when fed to humans, increases red blood cell (RBC) content of EPA to a greater extent than does ALA. This study was undertaken to determine the dose-dependence and time course of the increase in the EPA and DHA content of the heart and RBC in dogs. Adult male Beagles were fed 21, 64, or 193 mg/kg of SDA in their food daily for up to 12 weeks. Positive and negative controls were given EPA (43 mg/kg) or high oleic acid sunflower oil, respectively. The baseline EPA content of RBC was  $0.38 \pm 0.03\%$  which increased ( $P < 0.01$ ) in a dose-dependent manner, with the high dose of SDA and EPA achieving levels of  $1.33 \pm 0.26$  and  $1.55 \pm 0.28\%$ , respectively. In the heart, the content of EPA rose from  $0.06 \pm 0.01$  to  $1.24 \pm 0.22\%$  in the EPA group and to  $0.81 \pm 0.32\%$  in the high SDA group (both  $P < 0.01$ ). In both tissues, DHA did not change. Compared

to dietary EPA, SDA was 20–23% as efficient in raising tissue EPA levels. In conclusion, SDA supplementation increased the EPA content of RBC and heart and may have utility as a plant-based source of omega-3 FA.

### Introduction

Omega-3 fatty acids, specifically eicosapentaenoic acid (EPA, 20:5) and docosahexaenoic acid (DHA, 22:6), have well-known cardioprotective properties. These include a decreasing risk of arrhythmias [1], inhibition of platelet aggregation [2], a reduction in serum triglyceride levels [3], and diminishing inflammatory responses [4]. The primary source of EPA and DHA is fish, especially oily fish such as sardines, salmon, mackerel and tuna. The American Heart Association has recommended that all adults eat at least two, preferably oily, fish meals per week, and that patients

with coronary heart disease (CHD) ingest about 1 g of EPA and DHA per day [5].

As concerns grow about the long-term sustainability of fish as the sole source of omega-3 fatty acids [6], interest has turned to the potentially infinite supply of plant-based forms of omega-3 fatty acids, notably alpha-linolenic acid (ALA) which is found in high concentration in flax seed oil, and at lower concentrations in canola and soybean oils. While epidemiological data suggest there may be a relationship between intake of ALA and reduced risk for heart disease, clinical evidence supporting a cause-and-effect relationship of ALA and reduce risk of heart disease is lacking [7–9]. In addition, ALA is poorly converted to EPA in humans and generates virtually no DHA [10]. The rate-limiting step in the conversion of ALA to EPA is the delta-6-desaturase, the enzyme that converts ALA to stearidonic acid (SDA). Previous work in animals and humans has shown that SDA is converted to EPA more efficiently than ALA [11], and increases the EPA content of human immune cells [12, 13], and RBC and plasma phospholipids [14]. The extent to which SDA will enrich heart cells (i.e., those cells in which the protective effects of omega-3 FA appear to reside) with EPA and DHA is unknown. In humans, supplementation with fish oil increases EPA and DHA in RBC and heart to the same extent [15].

The main purpose of this study was to determine the extent to which SDA feeding will increase EPA and DHA in RBC and heart in dogs. ALA is known to be converted to long-chain omega-3 FA in this species [16], and it is a model in which EPA and DHA (infused intravenously) have been shown to reduce risk for cardiac arrhythmias [17]. We also determined whether SDA per se accumulates in tissues, and we compared the relative efficiency with which various intakes of SDA are converted into EPA in vivo.

## Materials and Methods

### Animals and Diets

Eighty adult male, purpose-bred Beagle dogs (Ridgland Farms, Mt. Horeb, WI, USA) weighing 8–19 kg (17–33 months old) were housed individually at WIL Research Laboratories, LLC (Ashland, OH, USA). Animals were maintained in accordance with the Guide for the Care and Use of Laboratory Animals. The study was reviewed and approved by the Institutional Animal Care and Use Committee. Water was available ad libitum and the light cycle was 12 h on/off. One week prior to the initiation of the study, dogs were acclimated to the feeding procedure. Each morning after an overnight fast, dogs were offered one can (154 g) of Pet Pride Gourmet Beef flavor, to which about

13 mg of alpha-tocopherol acetate (Ameri-Pac, St. Joseph, MO, USA) and control oil (high oleic acid sunflower oil, SFO; ACH Food Companies Inc., USA) were added by dropper or syringe, respectively. For the next 2–4 h, 250 g of dry dog food pellets (Harlan Teklad 25% Lab Dog Diet #8653) was provided ad libitum. The former contained, by weight, 13.5% fat of with the following fatty acid composition: 25% palmitate, 6% palmitoleate, 11% stearate, 41% oleate, 13% linoleic, 2.5% arachidonate, and all others less than 1%. The latter contained, by weight, 10% fat and 1.4% linoleic acid. The volume of control oil added to each dog's food was based on his body weight and matched the volume of omega-3 test oil that would subsequently be added to his food. Control and omega-3 test oils were quantitatively ( $\pm 0.1$  ml) added to the canned food daily via calibrated syringe. The dogs readily and consistently consumed the entire portion of canned food, thus assuring complete consumption of the test oils. This regimen was followed throughout the entire study.

After 1 week of acclimation, 5 dogs were randomly set aside to serve as baseline controls (see below) and the remaining 75 dogs were randomized into five groups of 15 dogs each: low SDA (21.4 mg/kg), mid SDA (64.2 mg/kg), high SDA (192.9 mg/kg), EPA (42.9 mg/kg), and control SFO. The randomization was performed to achieve similar average and range of body weights across the five groups. The doses were chosen to provide the body-weight-based human equivalent of SDA (1.5, 4.5 and 13.5 g, low to high) or 3 g EPA, assuming an average human body weight of 70 kg. Dogs in the SDA and EPA groups also were given SFO so that all dogs received the same amount of added oil.

The test materials, SDA ethyl ester (76.7% purity) and EPA ethyl ester (90.6% purity) were purchased from KD Pharma (Bexbach GmbH, Germany.) These oils were maintained in small aliquots at  $-80^{\circ}\text{C}$ . They were thawed and stored refrigerated and under nitrogen prior to administration. No aliquot was used two days past its thawing. The SFO control oil was stored at room temperature. Individual food consumption was recorded daily and body weights were recorded weekly. Detailed physical examinations were conducted weekly, and animals were observed twice daily for mortality and morbidity.

Prior to the initiation of dosing, fasting blood samples were drawn from five dogs randomly selected to serve as baseline controls. These dogs were then euthanized and samples of heart muscle (right ventricle) were obtained for fatty acid analysis. At weeks 2, 4, 8 and 12, blood samples were collected from all surviving dogs, and at weeks 4, 8 and 12, five dogs per treatment group were euthanized to obtain tissue samples. Heart tissue samples were rapidly frozen in liquid nitrogen and stored at  $-70^{\circ}\text{C}$  until analyzed.

## Tissue and Cell Preparation/Lipid Extraction

RBC were separated from the plasma by centrifugation at  $1,500\times g$  for 20 min at  $4\text{ }^{\circ}\text{C}$ . Plasma and RBC were collected after discarding the buffy coat, and stored at  $-70\text{ }^{\circ}\text{C}$  until use. Packed RBC were thawed and  $50\text{ }\mu\text{l}$  were dried at  $45\text{ }^{\circ}\text{C}$  under nitrogen. Thereafter the samples were directly methylated by the addition of 0.5 ml boron trifluoride methanol (Sigma, St. Louis, MO, USA) and then heated at  $100\text{ }^{\circ}\text{C}$  for 10 min. This generated fatty acid methyl esters (FAME) from the glycerophospholipids in the RBC membranes [18]. After cooling, 1 ml water and 1 ml hexane containing 50 mg/l butylated hydroxytoluene (BHT, an antioxidant, Sigma) were added. Following manual-shaking for 30 s, the samples were centrifuged for 3 min at  $1,500\times g$  at room temperature. The hexane layer was collected, the solvent was evaporated  $45\text{ }^{\circ}\text{C}$  under nitrogen and the FAME thus generated were reconstituted with  $50\text{ }\mu\text{l}$  hexane and analyzed by flame ionization gas chromatography (GC).

Heart samples were first lyophilized (Savant Speed-Vac Plus) overnight. They were subsequently pulverized between two ground glass slides, returned to their test tubes in 1 ml saline and sonicated (4710 Ultrasonic homogenizer, Cole-Parmer, Chicago, IL, USA) for 10–15 s. Methanol and methylene chloride (both containing 50 mg/l BHT) were added, the samples were briefly agitated and centrifuged at  $1,500\times g$  for 10 min at  $4\text{ }^{\circ}\text{C}$ . The aqueous layer was discarded and the organic phase was dried under nitrogen in a  $45\text{ }^{\circ}\text{C}$  water bath. The samples were methylated and processed as described above for RBC.

## Gas Chromatography

The GC (GC-14A, Shimadzu, Columbia, MD, USA) was fitted with a fused silica capillary column (SP-2560, 100 m length, 0.25 mm internal diameter, 0.25  $\mu\text{m}$  film thickness) obtained from Supelco (Bellefonte, PA, USA). Hydrogen was used as the carrier gas and nitrogen as the make-up gas. The split ratio was 1:25, and the purge was set at 15–20 ml/min. The following temperature program was used: initial temperature,  $140\text{ }^{\circ}\text{C}$  held for 5 min; ramp to  $240\text{ }^{\circ}\text{C}$  at  $6.5\text{ }^{\circ}\text{C}/\text{min}$  and hold for 37 min. FAME are reported as percent of total and were identified by comparison with known standards.

## Statistical Analysis

Heart data were derived from independent samples within each treatment group and time point, and were analyzed using a general linear cell-means model, allowing for heterogeneity of variances. RBC data contained repeated measurements over time for surviving animals, and so were

analyzed using a general linear repeated measures model accounting for temporal within-animal correlations as well as heterogeneous variances. Analyses were conducted using SAS v9.1 (SAS Institute, Inc., Cary, NC, USA). Differences were considered significant when  $P < 0.01$  unless otherwise noted.

## Results

All animals survived to the scheduled necropsies. There were no test article-related clinical findings or effects on body weight or food consumption. SDA was undetectable (i.e., was less than 0.05% of total FA) in all of the tissues examined (data not shown).

### EPA

There was a dose- and time-dependent increase in the EPA content of RBC following SDA or EPA administration (Table 1, Fig. 1). By 12 weeks of treatment, the EPA had increased from  $0.38 \pm 0.03\%$  at baseline to  $1.55 \pm 0.28\%$  in the EPA group (308% increase) and to  $1.33 \pm 0.26\%$  in the high SDA group (249% increase) (Fig. 2). Both of these increases were significant ( $P < 0.007$ ), and values in the high SDA and EPA groups did not differ from each other. The low dose SDA maintained baseline RBC EPA levels, while the EPA levels in the SFO control group declined by 57% at 12 weeks. The mid and high SDA and EPA treatments significantly increased RBC EPA at all time points versus baseline. There was a significant dose–response relationship across treatment groups at each time point ( $P < 0.001$ ). In the heart, the content of EPA rose from  $0.06 \pm 0.02\%$  at baseline to  $1.24 \pm 0.22\%$  in the EPA group and to  $0.81 \pm 0.32\%$  in the high SDA group (Fig. 2). Again, both of the changes were significant ( $P < 0.001$ ), but unlike the RBC, heart EPA was higher after EPA than after high SDA ( $P = 0.004$ ). The mid- and high SDA and EPA treatments significantly increased the EPA content of the heart by 4 weeks, and it remained significantly elevated at all time points. Low dose SDA and the SFO control maintained baseline EPA levels. The correlation between RBC and heart EPA at the end of the experiment was 0.85 ( $P < 0.001$ ).

### DPA

The SFO control oil caused a decrease in RBC DPA, from  $0.29 \pm 0.05\%$  at baseline to  $0.10 \pm 0.02\%$  at week 12 ( $P < 0.01$ ). On the other hand, EPA produced an increase in RBC DPA which was evident at week 2 ( $0.51 \pm 0.11\%$ ,  $P < 0.01$ ) and persisted through week 12. Across all time points, high dose SDA did not significantly raise RBC DPA

**Fig. 1** Effect on tissue EPA content (percent of total FA) of three doses of SDA (21.4, 64.2 and 192.9 mg/kg, respectively) versus EPA (42.9 mg/kg) and sunflower oil (control) in dogs. Values derive from five animals at each time point and each dose. Variances and significant differences are given in Table 1

**Fig. 2** Effects of high dose SDA and EPA (vs. baseline) on individual omega-3 FA in RBC and heart tissue after 12 weeks of treatment. *a* different from baseline,  $P < 0.01$ ; *b* different from high SDA,  $P < 0.01$

(although at 4 weeks values were statistically higher than at baseline). At week 12, heart DPA was increased over baseline only with EPA feeding, and was significantly

higher than that observed with high dose SDA as well (Fig. 2). In RBC, DPA increased above baseline only in the EPA feeding group (Table 2, Fig. 2).

## DHA

The baseline DHA level in RBC was  $0.10 \pm 0.05$ . At week 12, DHA in heart was significantly increased only in the high dose SDA group ( $P < 0.01$ ; Fig. 2). Nevertheless, averaging across all time points and treatment groups, DHA levels were not affected in this study (Table 3).

## Relative Efficiency of Deposition of EPA in RBC and Heart by SDA versus EPA

Based on the data in Table 1, an estimate of the relative efficiency of deposition of EPA by SDA versus EPA can be made for each tissue (Table 4). For this analysis, RBC or heart EPA values from all available time points were included. For RBC EPA there were 45 data points from each treatment group: 5 at week 12, 10 at week 8, and 15 each at weeks 2 and 4. For the heart EPA, there were 15 points from each group: 5 each at weeks 4, 8 and 12. For each tissue, the overall percent increase in EPA (relative to baseline levels shown in Table 1) was first determined. The percent increase per gram of omega-3 FA (human equivalent) fed was calculated, and then the efficiency (with respect to EPA's ability to raise tissue EPA content) was determined for each SDA treatment group (Table 4). For example, RBC EPA at baseline was 0.38% of total fatty acids. For the EPA group, the mean RBC EPA level (averaging data from weeks 2–12) was 1.46%, which is an increase of 284%. The EPA dose fed to the dogs was equivalent to 3 g of EPA in a 70-kg human. Therefore, the incorporation efficiency (per gram of omega-3 FA fed) was

$284\%/3 \text{ g}$ , or  $95\%/g$ . Setting the  $95\%/g$  rate pure EPA as maximal (i.e., 100%) efficiency, then the  $20\%/g$  incorporation into RBC seen in the low SDA group was 22% of that observed with pure EPA ( $20\%/95\%$ ). This analysis revealed that the efficiency of deposition of EPA derived from SDA ranged from 15 to 27% in the heart and 20–26% in RBC. Averaging across doses within a tissue, the efficiency of deposition of EPA after SDA consumption was approximately 20–23% that of deposition of EPA after consumption of EPA.

## Discussion

Increased levels of EPA and DHA in RBC have been associated with a marked reduction in risk for sudden cardiac death both prospectively and cross-sectionally [19, 20], and RBC EPA and DHA content is highly correlated with that of the human heart [16]. Hence, if SDA feeding can materially raise RBC and heart EPA and DHA content, it may have clinical import.

Increasing RBC levels of EPA and DHA can readily be achieved by consuming fish [21] or fish oil [22], but many Americans do not consume adequate quantities of fish, and it seems unlikely that fish availability, affordability and consumption will increase markedly in the future. Thus, alternative, readily available dietary sources of omega-3 fatty acids are needed. While soybean, canola and flax seed oils contain the omega-3 fatty acid ALA, it has not been established that ALA favorably affects heart health, although substantial epidemiological support for this

hypothesis exists [23–25]. In addition, the basis for any health benefit from ALA is unclear since its conversion to EPA via the rate-limiting enzymatic step, delta-6-desaturase, is highly inefficient [11]. Estimates of the fraction of ALA converted to EPA by humans range from 0.2% [10] to 7% [26]. Some of this inefficiency is also likely due to the high intake of linoleic acid which competes with ALA for the delta-6-desaturase.

A recent clinical study by Wilkinson et al. assessed the effects of feeding high doses of ALA-rich flax seed oil on RBC EPA and DHA content [27]. After 12 weeks of consuming 15 g/day ALA or 1.5 g/day EPA from fish oil, RBC EPA content increased by 153 or 124%, respectively. On a per-g of omega-3 FA-fed basis, EPA raised RBC EPA content by 82%/g and ALA, by 10%/g. Hence, ALA was 12% as efficient as EPA in raising RBC EPA levels in this study. This value is similar to that observed by James et al. [14] who gave humans an average of 1.125 g ALA, SDA or EPA for 6 weeks. Compared to EPA feeding, which raised RBC EPA by 192%/g omega-3 fed, SDA raised it by 44%/g and ALA, 13%/g. Therefore, in this study ALA was only 7% as efficient as EPA in raising RBC EPA levels.

Since SDA is the delta-6-desaturase product of ALA, its conversion to EPA should be more efficient. In the study by James et al. [14], the human efficiency of deposition of EPA from SDA into RBC was 23% of that seen for EPA itself. In our study in dogs we found the same, but since we did not include an ALA treatment group, the relative efficiency of ALA versus SDA in this species could not be evaluated. However, from the data of James et al., it can be estimated that EPA formed from SDA is deposited in tissues at about three times the rate at which it is from ALA (23 vs. 7%). Further studies are needed to confirm this estimate.

Both low- and mid-SDA treatment prevented the loss of DPA in RBC caused by the SFO control, but only EPA was effective in raising RBC and heart DPA levels. The role of DPA in myocardial metabolism and in cardiovascular disease risk remains unclear.

Neither SDA nor EPA feeding increased the DHA content of the heart. However, DHA content of RBC was slightly but significantly raised by high dose SDA but not by EPA. Nevertheless, the minimal impact of DHA precursors on tissue DHA reported by many investigators was generally confirmed here [10, 14, 28, 29].

The time course of incorporation of EPA differed somewhat in the RBC versus heart tissue following SDA feeding. In RBC stable levels were apparently achieved in about 8 weeks, whereas in heart tissue, there was a plateau between 4 and 8 weeks with a further increase at 12 weeks. This is similar to what has been observed with DHA in rat RBC and heart [30]. In the same study, EPA appeared to stabilize in the heart at 7 days but not until 6 weeks in RBC.

In this model, the degree of EPA deposition after omega-3 FA feeding was similar in RBC and the heart, with tissue EPA values reaching about 1.5% of total FA in both cases. In humans, similar percent increases in omega-3 fatty acid incorporation were observed in the human heart and RBC after 6 months of fish oil supplementation [15]. In contrast to EPA, there are marked differences in DHA in dog RBC and heart tissue, and as a consequence, the ratio of EPA to DHA differs in these two tissues. Dogs are known to have much lower levels of DHA in RBC than do rabbits, rats or humans [31, 32], and their heart DHA level is only one-third the level seen in guinea pigs (0.1 vs. 0.3%) [33]. Although baseline omega-3 FA levels are very low in this species, Beagles (like guinea pigs [33]) respond to fish oil feeding with robust increases in RBC EPA and DHA [34].

Although SDA increases tissue EPA levels, it is not clear that higher heart EPA alone affords cardiovascular benefit. When EPA and DHA are fed together (as in fish oils), cardiovascular events are reduced [35], and at high intakes (e.g., 3–4 g/day), serum triglycerides are lowered [3]. EPA alone has also been reported to lower serum TG [36] and remnant lipoproteins [37], to inhibit platelet aggregation [38–41] and to reduce in LDL peroxidation [37]. In vitro, EPA can block the toxic effects of ouabain in isolated rat cardiomyocytes [42, 43]. Similar benefits of EPA were observed using beta-adrenergic agonists [44] and acylcarnitine [45] to induce fibrillation. There is evidence that EPA acts on cardiac sodium, calcium and potassium channels, ultimately preventing calcium overload and prolonging the inactivated state of the channels [45–47].

The Japan EPA Lipid Intervention Study (JELIS) provided strong evidence for cardioprotective effects of EPA alone [results summarized in 48]. In this trial, over 18,000 hypercholesterolemic patients, all taking low-dose statins, were randomized to 1.8 g of EPA ethyl esters or usual care and followed for major adverse cardiac events for

4.5 years. There was a 19% reduction in risk observed in the EPA group ( $P = 0.01$ ). Complicating the interpretation (and extrapolation of these results to the US context) was the high background intake of EPA and DHA in the Japanese population [49]. Median intakes are approximately 1 g/day in this population compared to the 100–150 mg/day typical of the US population [50]. Nevertheless, the results of the JELIS trial indicate that increasing already high tissue levels of omega-3 FA with additional EPA confers additional protection against cardiovascular disease.

The western diet contains very little SDA, but there are natural sources, notably fish oils, which contains 1–2% SDA [51]. At present there are no commercially-viable plant sources for SDA. SDA is found in echium oil at about 12% [52], and feeding echium oil led to an increase in the EPA content of peripheral blood mononuclear cell phospholipids [12, 13]. Consumption of 15 g echium oil for 4 weeks decreased serum triacylglycerol concentrations by 21–30% and significantly increased EPA and DPA, but not DHA, in plasma and neutrophils in hypertriglyceridemic humans [52]. This suggests that echium oil possesses hypotriglyceridemic properties similar to those of fish oil whereas ALA does not [8]. However, echium oil is very limited in abundance compared to canola or soybean oil, and is not approved for consumption in the US. Other sources of SDA are also limited, and include evening primrose, borage and black currant seed oils. However, genetically enhanced soybeans can produce oils with about 20% SDA [51]. If suitable for commercialization and acceptable to consumers, SDA-enriched soybean oil could provide a substantial amount of omega-3 fatty acids in the human diet. Whether this would translate into health benefits remains to be seen.

**Abstract** Transfer of fatty acids from mother to fetus during pregnancy is a requirement for optimal fetal growth. We report a longitudinal study of full maternal erythrocyte fatty acid profile assessed at each trimester of pregnancy [mean 12.5 (range 8–14), 26.1 (24–28) and 35.5 (33–38) weeks' gestation] and in the post partum period [18.1 (12–26) weeks]. The study recruited healthy women ( $n = 47$ ) from routine antenatal clinics at the Princess Royal Maternity Unit, Glasgow, Scotland. There were increases in 16:1 $n$ 7 (22%,  $p = 0.0005$ ), 24:1 $n$ 9 (13%,  $p = 0.0032$ ), 22:5 $n$ 6 (25%,  $p = 0.0003$ ), 18:3 $n$ 3 (41%,  $p = 0.0007$ ) and 22:6 $n$ 3 (20%,  $p = 0.0005$ ) concentrations during pregnancy. The greatest increases took place between gestations at sampling of 12.5 and 26.1 weeks. The change in 16:1 $n$ 7 concentration between gestations at sampling of 12.5 and 35.3 weeks was negatively associated with maternal booking body mass index ( $r = -0.40$ ,  $p = 0.006$ ). The change in 22:6 $n$ 3 concentration was correlated with the change in 24:1 $n$ 9 ( $r = 0.70$ ,  $p < 0.001$ ). In samples taken four months post partum, 14:0 concentration was lower (29%,  $p = 0.0002$ ) and 24:0 concentration (15%,  $p = 0.0009$ ) and  $n6/n3$  ratio (11%,  $p = 0.0019$ ) were higher than at a gestation at sampling of 12.5 weeks. In conclu-

sion, several fatty acids are specifically mobilised during pregnancy. The correlation between maternal 22:6 $n$ 3 and 24:1 $n$ 9 suggests that mobilisation of these fatty acids may be coordinated. The inverse relationship between 16:1 $n$ 7 and maternal central obesity warrants further investigation.

**Keywords** Fatty acid · Pregnancy · Obesity

## Abbreviations

12:0	Lauric acid
14:0	Myristic acid
16:0	Palmitic acid
18:0	Stearic acid
20:0	Arachidic acid
22:0	Behenic acid
24:0	Lignoceric acid
16:1 $n$ 7	Palmitoleic acid
18:1 $n$ 9	Oleic acid
20:1 $n$ 9	Eicosenoic acid
22:1 $n$ 9	Erucic acid
24:1 $n$ 9	Nervonic acid
18:2 $n$ 6	Linoleic acid
18:3 $n$ 6	Gamma-linolenic acid
20:3 $n$ 6	Dihomo-gamma-linolenic acid
20:4 $n$ 6	Arachidonic acid
22:4 $n$ 6	Adrenic acid
22:5 $n$ 6	Docosapentaenoic acid
18:3 $n$ 3	Alpha-linolenic acid
20:5 $n$ 3	Eicosapentaenoic acid
22:5 $n$ 3	Docosapentaenoic acid
22:6 $n$ 3	Docosahexaenoic acid
$n9$	Omega-9 monounsaturated fatty acids
$n7$	Omega-7 monounsaturated fatty acids
$n6$	Omega-6 polyunsaturated fatty acids
$n3$	Omega-3 polyunsaturated fatty acids

LC	Long chain
MUFA	Monounsaturated fatty acids
FA	Fatty acids
C20-22	Fatty acids with carbon chain lengths of 20–22 carbons
SCD	Stearyl CoA desaturase
WHR	Waist:hip ratio
BMI	Body mass index
DEPCAT	Deprivation score, which is a measure of socioeconomic status
PUFA	Polyunsaturated fatty acids
SAFA	Saturated fatty acids

## Introduction

Fatty acids are important constituents of cell membranes and are therefore essential for tissue formation (reviewed in [1]). The long chain polyunsaturated fatty acids (LCPUFA) commonly found in membranes, especially in the brain, are derived via elongation and desaturation from the essential fatty acids 18:2*n*6 (linoleic acid) and 18:3*n*3 (alpha-linolenic acid) (reviewed in [2]). In pregnancy, the fetus is reliant on placental transfer of fatty acids from the mother to support growth [2, 3]. The mother must therefore mobilise key fatty acids and make them available for accretion by the fetus [2]. Maternal LCPUFA status during pregnancy is critical to determining essential fatty acid status in the newborn [2, 4].

Al et al. have assessed the fatty acid statuses of mothers longitudinally throughout pregnancy by analysing plasma phospholipid fatty acid content [5]. Focussing mainly on the essential fatty acids and their long chain derivatives, they observed that the percentage of 18:2*n*6 did not change during pregnancy, whereas the percentage of 20:4*n*6 (arachidonic acid) decreased [5]. The maternal plasma phospholipid 22:6*n*3 (docosahexaenoic acid) percentage rose until 18 weeks and thereafter declined during pregnancy concomitant with an increase in umbilical plasma phospholipid 22:6*n*3 content [5]. These observations were consistent across populations selected from five different countries despite the variation in maternal essential fatty acid status between countries [6]. Similar changes in total plasma fatty acid compositions were observed longitudinally in pregnancy by Montgomery et al. [7]. It has been suggested [4, 8] that, in the populations studied and under their prevailing dietary conditions, the decline in plasma 22:6*n*3 in late gestation indicates that the mother may be unable to meet the fetal demand for essential long chain polyunsaturated fatty acids.

While plasma phospholipid fatty acid status has been used to indicate fatty acid mobilisation, these fatty acids

will be derived mainly from plasma lipoproteins, and their measurement is open to confounding by maternal fasting status. Erythrocyte fatty acid composition is most likely to represent an integrative measure of the fatty acid status over the preceding three months (the half life of an erythrocyte is 120 days), although new evidence indicates that erythrocyte fatty acid composition may reflect more recent changes in at least some plasma fatty acid concentrations [9]. It has been suggested that erythrocytes may act as a potential storage vehicle for 20:4*n*6 and 22:6*n*3 [10]. Montgomery [7] observed similar changes in erythrocyte fatty acids during pregnancy to those seen for plasma fatty acids. In a cross-sectional study, Ashby et al. [11] observed a second trimester increase in the erythrocyte content of the essential fatty acids 22:6*n*3, 20:5*n*3 (eicosapentaenoic acid), 20:4*n*6 and 18:2*n*6, followed by a decline in the third trimester in the absence of any significant changes in plasma fatty acids. Maternal plasma and erythrocyte 22:6*n*3 and 22:5*n*6 (docosapentaenoic acid) declined between 24 weeks' gestation and three months post partum in African-American women, while 20:5*n*3 and 20:4*n*6 increased over the same period [12].

Most longitudinal studies of changes in maternal fatty acid status in pregnancy have focused primarily on the LCPUFA changes during gestation and have not emphasised changes in shorter chain and saturated fatty acids; nor have changes in maternal fatty acid status across all trimesters been compared with the post partum period. In this study we report a full maternal erythrocyte fatty acid profile assessed at each trimester throughout pregnancy and at four months post partum.

## Methods

### Patient Recruitment and Sample Collection

Women ( $n = 47$ ) were recruited from the antenatal clinic, Princess Royal Maternity Unit, Glasgow Royal Infirmary, at their first antenatal appointment in the first trimester of pregnancy. None of the women had a medical history of cardiovascular or metabolic disease. None of the women recruited developed any metabolic complication of pregnancy which may affect fatty acid metabolism such as preeclampsia or gestational diabetes mellitus. None of them had hyperemesis gravidarum, and none reported significant vomiting. Ethical approval for this study was granted by the Glasgow Royal Infirmary Research Ethics Committee and all subjects gave informed consent to participate. The women were asked to attend for their first "study visit" during the first trimester. All women attended each visit after an overnight fast (>10 h) and

underwent testing between 0900 and 1100 hours. Patient characteristics were recorded at the first trimester visit from patient notes. Height, weight, waist circumference and hip circumference were measured by the same investigator (FS). Waist circumference was measured at the level of the umbilicus. Hip circumference was measured at the widest point over the buttocks. Waist and hip circumference were measured in duplicate to the nearest 0.5 cm. If the difference between the two measurements was greater than 2 cm, a third measurement was taken and the mean of the two closest measurements was calculated. Waist:hip ratio (WHR) was defined as waist circumference divided by hip circumference. Body mass index (BMI) was calculated as first trimester weight (kg) divided by height (m) squared. Deprivation category (DEPCAT score), a measure of socioeconomic status [13], was assigned using the Scottish Area Deprivation Index for Scottish postcode sectors, 1998. At this visit, further arrangements were made for the patient to attend in the second trimester and then again in the third trimester. At delivery, all patients were seen by the same investigator (FS) and arrangements made for a postnatal visit at circa three months. Details of gestation of delivery, mode of delivery, fetal sex, birth weight and placental weight were recorded from the patients' notes. Birthweights of offspring were normalised by gestation at birth, fetal sex and maternal parity [14], with a greater centile indicating a larger normalised birthweight. At each visit maternal venous blood was sampled into 1 mg/mL EDTA and packed blood cells collected by low-speed centrifugation. Blood samples were collected at a mean of 12.5 (range 8–14), 26.2 (range 24–28) and 35.5 (range 33–38) weeks' gestation. Post partum samples were collected at a mean of 18.1 (range 12–26) weeks after delivery.

#### Erythrocyte Membrane Fatty Acid Extraction

Preparation of a total fatty acid extract from erythrocyte membranes was performed by a modified Folch extraction [15, 16]. Packed red blood cells (400  $\mu$ L) were suspended in 10 mM *tris* buffer pH 7.0, and incubated at room temperature for 30 min. Suspensions were centrifuged in a Beckman (Fullerton, CA, USA) L8-60M Ultracentrifuge, Type 50.4 rotor, at 49,000 rpm and at 4 °C for 30 min. The erythrocyte pellet was resuspended in 200  $\mu$ L of distilled H<sub>2</sub>O and 150  $\mu$ L was transferred to a clean glass screw-top tube. Methanol:toluene (4:1, 2 mL) containing heneicosanoic acid internal standard (0.2 mg C<sub>21</sub>H<sub>42</sub>O<sub>2</sub>/mL toluene) was added, followed by 200  $\mu$ L of 100% acetyl chloride while mixing. Tubes were capped and sealed with teflon tape before heating at 100 °C for 1 h. After cooling, 10% K<sub>2</sub>CO<sub>3</sub> (3 mL) was

slowly added to each tube followed by 100  $\mu$ L toluene. After centrifugation at 3,000 rpm for 8 min at 5 °C, the upper toluene phase was transferred to gas chromatography (GC) vials and stored at –20 °C until ready for injection.

#### Gas Chromatography of Fatty Acids

Methyl fatty acids (FAs) were separated (1  $\mu$ L injection volume), identified and quantitated on a Shimadzu (Kyoto, Japan) GC 17A gas chromatograph with flame ionisation detection and Class VP software. A 30 m  $\times$  0.25 mm internal diameter DB-23 fused silica capillary column (J&W Scientific, Folson, CA, USA) with a film thickness of 0.25  $\mu$ m was used in conjunction with a Hewlett-Packard (Palo Alto, CA, USA) 7673B on-column auto-injector. Ultrahigh purity hydrogen and air were used as carrier gases at a flow rate of 2 mL/min. A temperature gradient programme was used with an initial temperature of 150 °C, increasing at 20 °C/min up to 190 °C, then at 5 °C/min up to 210 °C, then at 2 °C/min up to 230 °C and then at 4 °C/min up to 240 °C (final time 18.5 min), and with an equilibration time of 1 min. The total programme time was 22 min. Identification of fatty acid methyl esters was made by comparison with the retention times of authentic standard mixtures (fatty acid methyl ester mixture no. 189-19, product no. L9405, Sigma, Stockholm, Sweden).

#### Statistical Analysis

Values for biochemical variables are given as mean  $\pm$  standard deviation unless otherwise stated. Normality testing was carried out using the Ryan–Joiner test in Minitab (vs. 13.0). Percent 14:0, 16:0, 17:0, 18:0, 20:0, 24:0, 14:1*n*7, 16:1*n*7, 17:1*n*7, 18:1*n*9, 20:1*n*9, 20:2*n*6, 22:2*n*6, 22:5 *n*6, 20:5*n*3, and 22:3*n*3 were transformed to log values to achieve normality before significance testing. Absolute 12:0, 14:0, 17:0, 20:0, 20:1*n*9, 22:2*n*6 and 22:3*n*3 were transformed to log values and absolute 17:1*n*7, 18:2*n*6 and 20:5*n*3 were transformed to square root values to achieve normal distribution. For summary measures, percentage of MUFA, total *n*9, *n*6/*n*3 ratio and 20:4*n*6/22:6*n*3 were transformed to log values and total *n*7 transformed to square root values to achieve a normal distribution. Statistical analyses were performed using the JMP statistical analysis program (Version 5.1, SAS Institute, Cary, NC, USA). Each of the erythrocyte fatty acids were assessed for differences between the first, second and third trimesters by using one way analysis of variance, for repeated measures, with comparison for all

pairs using Tukey–Kramer HSD. Paired Student's *t*-tests were used for the comparison between the first trimester and the post partum values. Linear relationships between variables were estimated using Pearson's product moment correlation coefficients. Statistical significance was set at  $\alpha = 0.005$  for all analyses unless otherwise stated.

## Results

### Patient Characteristics

Baseline, first trimester, characteristics of the pregnant women studied are shown in Table 1. The characteristics of the women studied here are fairly typical for the Glasgow population when compared with first trimester characteristics of women enrolled in the Glasgow outcome APCR

**Table 1** Patient baseline and delivery characteristics for the current study and for women recruited to our previous Glasgow outcome APCR and LIPID (GOAL) pregnancy study [17]

Characteristic	Total ( <i>n</i> = 47)	GOAL [17] ( <i>n</i> = 4,218)
Age (years)	28.7 (5.0)	28.4 (5.8)
Smokers <i>n</i> (%)	17 (36.2)	1,701 (40.3)
Deprivation index <i>n</i> (%)		
Affluent (DEPCAT score 1–2) [13]	5 (10.6)	445 (10.6)
Intermediate (3–5)	17 (36.2)	1,788 (42.4)
Deprived (6–7)	24 (51.1)	1,754 (41.6)
Not known	1 (2.1)	231 (5.5)
Parity <i>n</i> (%)		
0	24 (51.1)	842 (43.7)
1–2	20 (42.6)	1,352 (32.1)
>2	3 (6.4)	289 (6.9)
Not known	0	735 (17.4)
BMI (kg/m <sup>2</sup> )	28.4 (6.1)	24.9 (4.7)
Waist (cm)	90.0 (15.5)	80.1 (10.5)
Waist:hip ratio	0.83 (0.11)	Not recorded
Gestation at delivery (days)	279 (10)	274 (15)
Mode of delivery <i>n</i> (%)		
Vaginal delivery	29 (61.7)	2,421 (57.4)
Assisted delivery	8 (17.0)	527 (12.5)
Caesarean section	10 (21.3)	874 (20.7)
Not recorded	0	419 (9.9)
Fetal sex <i>n</i> (%)		
Male	27 (57.4)	Not recorded
Female	20 (42.6)	
Birth weight centile	56.8 (33.2)	51.1 (29.6)
Placental weight (g)	770 (185)	674 (202)

and lipid (GOAL) pregnancy study [17] (Table 1) also carried out in our laboratory. However, the women studied here have a 3.5 kg/m<sup>2</sup> higher BMI than the mean for the Glasgow population.

### Gestational Changes in Maternal Erythrocyte Fatty Acid Composition

Maternal erythrocyte fatty acid profiles sampled at each trimester of pregnancy are shown expressed both as percentage total fatty acids (Table 2) and as absolute concentration (Table 3). There was a significant decrease in maternal 18:0 during pregnancy expressed as percentage total fatty acids; however, this was not reflected in a change in the absolute amount of this fatty acid. The significant increases in percentage of total fatty acids for 22:5*n*6, 18:3*n*3 and 22:6*n*3 were reflected in increases in the absolute amounts of these fatty acids of 25% ( $p = 0.0003$ ), 41% ( $p = 0.0007$ ) and 20% ( $p = 0.0005$ ), respectively. Furthermore, increases in the absolute amounts of 16:1*n*7 (22%,  $p = 0.0005$ ) and 24:1*n*9 (13%,  $p = 0.0032$ ) were observed in the absence of a significant change in their percentage contribution to total fatty acids. The rises in all of these fatty acids took place mostly between gestation at sampling of 12.5 weeks and gestation at sampling of 26.1 weeks, with the differences between the levels of fatty acids at 26.1 weeks' gestation and 35.5 weeks' gestation being nonsignificant upon post hoc testing.

### Correlation of Gestational Changes in Maternal Erythrocyte Fatty Acids with Maternal Characteristics

The change in absolute amount of 16:1*n*7 between a gestation at sampling of 12.5 weeks and a gestation at sampling of 35.3 weeks was inversely correlated with first trimester BMI ( $r = -0.41$ ,  $p = 0.005$ ) (Fig. 1) and first trimester waist circumference ( $r = -0.40$ ,  $p = 0.006$ ). Thus there appears to be a link between the accumulation of 16:1*n*7 and maternal central obesity. Change in 16:1*n*7 concentration was also weakly correlated with accumulation of 18:3*n*3 ( $r = 0.37$ ,  $p = 0.012$ ). There were weak correlations between change in 24:1*n*9 and 22:6*n*3 concentrations and placental weight ( $r = 0.33$ ,  $p = 0.024$  and  $r = 0.35$ ,  $p = 0.017$ , respectively). Finally, change in absolute amount of 22:6*n*3 was strongly associated with changes in absolute amounts of 24:1*n*9 and 22:5*n*6 ( $r = 0.70$ ,  $p < 0.001$  and  $r = 0.46$ ,  $p = 0.001$ , respectively) between gestations at sampling of 12.5 weeks and 35.3 weeks (Fig. 2). There were no relationships between changes in these fatty acids and maternal age, smoking status, deprivation category, parity, mode of delivery, gestation at delivery, fetal sex or birthweight centile.

### Comparison of Maternal Erythrocyte Fatty Acid Compositions at 12.5 Weeks' Gestation and at 18.1 Weeks Post Partum

In order to investigate whether fatty acids returned to baseline (gestation at sampling of 12.5 weeks) pregnancy levels within four months after delivery, the fatty acid composition after 12.5 weeks' gestation was compared with the erythrocyte fatty acid composition in samples collected a mean of 18 weeks after delivery (Tables 2, 3). The percentage contribution to total fatty acids was lower post partum than at 12.5 weeks' gestation for 14:0, 16:0 and 18:1*n*9, and higher post partum for 24:0, 18:2*n*6 and

20:4*n*6. However, a reduction in absolute amounts was only seen for 14:0. At a sampling time of 18.1 weeks post partum, 14:0 was 29% lower ( $p = 0.0002$ ) than for sampling at a gestation of 12.5 weeks. An increase in the absolute amount was only observed for 24:0, which was 15% higher ( $p = 0.0009$ ) than at a gestation at sampling of 12.5 weeks.

**Fig. 1** Relationship between first trimester BMI and change in 16:1*n*7 concentration (pmol/mL blood) between gestations at sampling of 12.5 and 35.3 weeks (SG 35.3–SG 12.5 weeks)

ratio decreased by 11% ( $p = 0.0019$ ) and the 20:4*n*6/22:6*n*3 ratio decreased by 23% ( $p < 0.0001$ ), but of these two ratios, only the 20:4*n*6/22:6*n*3 ratio increased by 24% in the post partum period ( $p < 0.0001$ ). The percent MUFA of total fatty acids decreased by 8% in the post partum period ( $p < 0.0001$ ), which is reflected in the total *n*9 fatty acids (9%,  $p < 0.0001$ ). Conversely, the percent PUFA of total fatty acids increased by 9% in the post partum period ( $p < 0.0001$ ), which is reflected in an increase in the *n*6 PUFA (11%,  $p < 0.0001$ ). The unsaturated index ( $p = 0.0013$ ), the average chain length ( $p = 0.0006$ ) and the C20–22 ( $p = 0.0005$ ) were all significantly higher in the post partum period.

**Fig. 2** Relationship between change in 22:6n3 concentration (pmol/mL blood) and changes in 24:1n9 and 22:5n6 concentration (pmol/mL blood) between gestations at sampling of 12.5 and 35.3 weeks (SG 35.3–SG 12.5 weeks)

## Discussion

This paper clearly describes the changes in fatty acids that occur throughout pregnancy and during the post partum period. Comparison of our selected group with the large cohort of Glasgow women ( $n = 4218$ ) indicates that the women sampled were typical of the general Glasgow population apart from having a higher BMI (Table 1). The fatty acids that increased significantly during pregnancy were 18:3n3, 22:5n6, 22:6n3, 16:1n7 and 24:1n9 (Tables 2, 3). These changes were observed predominately between gestations at sampling of 12.5 and 26.1 weeks. If, as is commonly believed, changes in erythrocyte composition integrate changes in fatty acid metabolism over the preceding 120 days, then these changes must be initiated soon after implantation. However, recent evidence demonstrating a more rapid (two-week) equilibration between at least some fatty acids in plasma and erythrocyte membranes [9] might suggest later initiation of fatty acid mobilization. A combination of increased lipolysis, regulated by human placental lactogen [18], differential elongation and desaturation regulated by oestrogen [19, 20] and differential placental uptake of fatty acids [3, 21] could be potential mechanisms initiating and/or mediating these changes in pregnancy. Further studies of plasma and erythrocyte fatty acid composition in the early weeks of

pregnancy are required to clarify the timing of fatty acid mobilization.

The limitations of this study include the lack of maternal dietary intake data, maternal weight gain data and breastfeeding information. These data are recognized as potential confounding variables that could not have been adjusted for in our analysis. However, despite the lack of data, our results relating to a drop in 22:6n3 levels during the post partum period are in agreement with others outlined in a review by Makrides and Gibson [22].

Our data on changes in 22:6n3 are broadly consistent with previous observations that 22:6n3 is mobilised from maternal stores in order to supply the growing fetus [5–7]. However, we did not observe a decline in 22:6n3 levels between gestations at sampling of 26.1 and 35.3 weeks, which may indicate that our pregnant population is not deficient in 22:6n3 as has been suggested for other populations [4, 8]. This would be supported by the significant decline in the n6/n3 ratio during pregnancy, indicating an enrichment of maternal erythrocyte LC n3 PUFA. An increased ratio of 22:5n6/22:6n3 has been reported to reflect an omega-3 or 22:6n3 deficiency [23]. The calculated mol/mol 22:5n6/22:6n3 ratios in our population (gestation at sampling 12.5 weeks 0.16, 26.1 weeks 0.17, 35.3 weeks 0.17, and sampling at 18.1 weeks post partum 0.20 mol/mol) were normal according to the cut-off values of >0.22 mol/mol for 22:6n3 marginality and >0.48 mol/mol for 22:6n3 deficiency suggested by Fokkema et al. [23]. An increase in fish consumption during pregnancy by our subjects could account for the maintenance of 22:6n3 levels in maternal blood, but we have no information on diet to confirm or refute this.

The 41% ( $p = 0.0007$ ) increase in maternal erythrocyte 18:3n3 during pregnancy that we observed could be due to its role as a precursor for 22:6n3 synthesis. This large increase in 18:3n3 during pregnancy was either reported but not commented on [4, 6, 12] because the focus of the research involved was on LCPUFA, or it was not detected [7] or reported [5]. 18:3n3 can be derived from green vegetables or cooking oils such as canola oil in the diet. In the absence of detailed dietary information, changes in intake cannot be discounted as an explanation for increased 18:3n3 concentrations. An alternative explanation might be increased mobilisation of 18:3n3 from maternal stores in order to provide substrate for LC n3 PUFA synthesis. Women tend to partition less 18:3n3 to  $\beta$ -oxidation than men [19], thus increasing availability for conversion to LCPUFA. 18:3n3 can be elongated and desaturated to 20:5n3, 22:5n3 and 22:6n3 in women of childbearing age [20], but only to 20:5n3 and 22:5n3 in men [24]. Women taking synthetic oestrogens had an increased capacity to convert 18:3n3 to 22:6n3 [20]. This gender difference underlines the potential importance of the capacity to

synthesise 22:6n3 during pregnancy and lactation, and it is possible that the rise in oestrogen during pregnancy regulates the conversion of 18:3n3 to LCPUFA [19]. The physiological relevance of the conversion from 18:3n3 can be questioned, as 18:3n3 supplementation during pregnancy did not result in increased maternal or fetal DHA levels [25].

Nervonic acid (24:1n9) was also increased during pregnancy (Table 3), and it is well documented that 24:1n9 is important for neural development, particularly for myelination [26, 27]. The increased levels of 24:1n9 could be explained by an increased mobilization of this fatty acid for fetal neural development from mid-gestation and particularly during the post partum period [26]. 22:6n3 is also important for proper neural development (reviewed in [28, 29]) and is also increased during pregnancy (Table 3). The strong correlation between 22:6n3 and 24:1n9 ( $r = 0.70$ ,  $p < 0.001$ ) (Fig. 2) suggests that the regulation of the synthesis and/or transport of these two fatty acids may be coordinated. Interestingly, the change in concentrations of these fatty acids during pregnancy was correlated to placental weight.

Palmitoleic acid 16:1n7 was also increased during pregnancy and is reduced during the post partum period (Table 3). The change in 16:1n7 during pregnancy was negatively associated with first trimester BMI and waist circumference (Fig. 1), indicating a relationship between levels of this fatty acid and central obesity. This relationship may be apparent in our study due to the wide range of first trimester BMI (18.0–46.3 kg/m<sup>2</sup>, Fig. 1). 16:1n7 is synthesised from 16:0 by stearyl CoA desaturase (SCD) [30], an enzyme whose expression is downregulated by leptin [31] and whose activity is associated with obesity [32, 33]. Our observation in pregnancy of an inverse association between the product of SCD and obesity is at odds with these published data. This discrepancy could be explained if 16:1n7 were not a good index of SCD activity in pregnancy or if leptin metabolism were different in pregnancy. There is a well-recognised increase in maternal leptin in pregnancy [34, 35], which is even higher in obese pregnant women [36]. It has been suggested that maternal leptin resistance may occur in pregnancy [34, 37], possibly mediated by an increase in the amount of a soluble isoform of the leptin receptor derived from the placenta, resulting in an increased proportion of bound, and hence unavailable, leptin in the maternal circulation with advancing gestation [37, 38]. This potential for leptin resistance in pregnancy may account for the counterintuitive inverse association between 16:1n7 and obesity in pregnancy observed using the two independent measures of BMI and waist circumference. It has recently been observed that the expression of genes involved in hepatic lipogenesis, such as SCD and PPAR $\gamma$ , is increased by fenofibrate, a PPAR $\alpha$  agonist, in

virgin but not pregnant female rats [39]. Thus our observation of altered regulation of SCD in pregnancy is not unique. The association between fatty acid metabolism in pregnancy and obesity warrants further investigation, especially in light of the increased first trimester BMI observed over the last decade in our hospital [40].

**Abstract** Atopy is a growing problem for Korean children. Since eicosapentaenoic acid is a precursor of less active inflammatory eicosanoids, n-3 polyunsaturated fatty acids (PUFA) may have a protective effect on atopy. This study was undertaken to determine whether n-3 PUFA in red blood cells (RBC) is lower in atopic than in non-atopic preschoolers. Three hundred and eight Korean children aged 4–6 years were enrolled. Total RBC fatty acid composition was measured by gas chromatography. The prevalence of atopic dermatitis, allergic rhinitis, or asthma was 29%. Total RBC n-3 PUFA were lower in preschoolers with atopy than controls ( $9.8 \pm 1.2$  vs.  $11.4 \pm 1.6\%$ ;  $P < 0.05$ ), while n-6 PUFA ( $33.0 \pm 1.4$  vs.  $32.2 \pm 1.0\%$ ;  $P < 0.05$ ) and n-6/n-3 PUFA ratio ( $3.4 \pm 0.6$  vs.  $2.8 \pm 0.5$ ;  $P < 0.05$ ) were greater. The following factors were also associated with an increase in atopy: higher saturated fatty acids ( $39.6 \pm 1.4$  vs.  $40.6 \pm 1.9$ ;  $P < 0.05$ ) and arachidonic acid ( $15.3 \pm 1.6$  vs.  $16.0 \pm 2.9$ ;  $P < 0.05$ ), and lower total PUFA ( $43.8 \pm 0.7$  vs.  $42.8 \pm 1.4$ ;  $P < 0.05$ ) and omega-3

index (EPA + DHA;  $9.1 \pm 0.8$  vs.  $7.8 \pm 0.5$ ;  $P < 0.05$ ) in RBC. Maternal history of atopy was a significant ( $P < 0.05$ ) risk factor, while lactation was not. The results suggest that a reduced content of n-3 PUFA in the RBC membrane could play a role in early children atopy.

### Introduction

In keeping with the rising incidence of allergies worldwide [1], incidences of atopic diseases have been increasing for the last few decades, Korea included. Genetic factors such as family history and maternal age at birth have been proposed as the important risk factors for atopy [2, 3]. A number of environmental factors, including air pollution [2], cigarette smoking of parents, dust mites [2], formula feeding [4, 5], and diet [2, 6, 7] have been suggested as factors in the increasing prevalence of atopic dermatitis, allergic rhinitis, and asthma.

Many foods have been implicated in food allergies, and fish is a common food allergen causing atopy [8]. Some studies have reported that a decrease in the intake of n-3 PUFA, and an increase in the intake of n-6 PUFA, particularly linoleic acid may lead to an increase in atopic diseases [6, 9–14]. Linoleic acid is a precursor of arachidonic acid, which can be converted to prostaglandin E<sub>2</sub> (PGE<sub>2</sub>), whereas n-3 PUFA, eicosapentaenoic acid (EPA; C20:5) and docosahexaenoic acid (DHA; C22:6) inhibits the formation of PGE<sub>2</sub> [15, 16].

Kankaanpaa et al. [7] observed that atopic infants had less n-3 PUFA in serum cholesteryl esters, but not trigly-

cerides (TG) and phospholipids. Dunder et al. [17] and Yu et al. [18] also reported that serum n-3 PUFA was significantly lower in atopic children. Mihrshahi et al. [9] showed that supplementation with n-3 PUFA reduced the prevalence of wheezing in high risk children. However, other studies that failed to show an association between n-3 PUFA and asthma [19–21].

Most research on atopic diseases has been focused on maternal diet [7, 22–24] and breast milk fatty acid composition [25, 26] among infant or young children. In addition, there is limited information on the relationship between RBC n-3 PUFA of preschool aged children and atopy especially among Koreans. The omega-3 index is a new blood test that measure EPA and DHA content in RBC and provide a good reflection of systemic n-3 PUFA levels [27]. The purpose of this study was to measure RBC fatty acid composition and plasma lipid profiles for Korean children aged 4–6 with and without atopy.

## Experimental Procedures

### Subjects

A total of 497 children aged 4–6 years in one district hospital of Pusan, on the Southern tip of the Korean Peninsula, were recruited. Blood samples were taken to determine the fatty acid composition of RBC from only 398 children. This study was approved by Pusan National University Hospital Institutional Review Board, and informed, written consent was obtained from the parents of all participants.

### Protocol

Height, weight, and body fat were measured, and fasting blood samples were obtained after fasting for 8 h. Family history, age of parents at birth of the child, length of lactation, and allergy symptoms were obtained from both questionnaires completed by parents of the child and from medical charts. The children's fish intake was assessed by parental response to "how often does your child eat non-fried fish?" in a questionnaire with "never", "once a week or less", and "more than once a week" as possible answers.

### Procedure

Blood was centrifuged for 15 min at 3,000 rpm and after removing plasma, the RBC pellet was left in the bottom of the tube and used for fatty acid analysis. Plasma was analyzed for total cholesterol, TG and high-density lipoprotein (HDL) cholesterol concentrations using a

dry-chemistry method with Vitros 250 (Johnson and Johnson, USA); very-low density lipoprotein (VLDL) and low-density lipoprotein (LDL) cholesterol concentrations were estimated by the Friedewald equation [28].

Red blood cell lipids were isolated using 0.005% butylated hydroxytoluene containing isopropanol and hexane. Fatty acid methyl esters were made from RBC membrane by heating the lipid extract with boron trifluoride (BF<sub>3</sub>) methanol-benzene and analyzed with a 30-m SP2330 capillary column (Supelco, Bellefonte, PA; 33). Fatty acids were identified by comparison with known standards. Samples were analyzed in duplicate, and with each run, a quality control sample was included. The control was made from pooled RBC and the CV was 5%.

### Statistical Analysis

Independent *t*-test was used to compare lipid profile, RBC fatty acid composition, lactating period, family history, and age of parents at birth of the child between children with and without atopy. A two-tailed *P* value of <0.05 was required for statistical significance.

## Results

### General Characteristics and Atopic Disease Distribution of Subjects

Twenty-nine percent of the children were diagnosed with one of following atopic diseases: atopic dermatitis, allergic rhinitis, and asthma. Table 1 shows the prevalence of each atopic disease, and atopic dermatitis was the most common. Although, there was no statistical difference, more female children than male had atopic diseases (53.3 vs. 46.7%), and prevalence of atopic diseases decreased with age (Table 2). Height, weight, and body fat did not significantly differ between children with and without atopic disease (Table 2).

### Length of Lactation

Length of lactation was divided into <1 month (44 vs. 41%), 1–6 months (31 vs. 31%), and >6 months (25 vs. 28%). There was no significant relationship between length of lactation and atopic diseases within and between groups.

### Family History and Age of Parents at Birth

Table 2 shows the relationship between family history and atopic diseases. Maternal history of atopy was significantly (*P* < 0.001) associated with risk for atopy, while paternal and sibling history was not. Mean maternal and paternal

age at birth were not significantly different between controls and atopic children.

#### Dietary Fish Intake

Overall, fish intake was not significantly associated with atopy, and 95% of children with and without atopy consume fish, more than a week.

#### Plasma Lipid Profile

There was no significant difference on total cholesterol (3.88 ± 0.60 vs. 3.87 ± 0.56 mmol/L), TG (1.04 ± 0.53 vs. 1.01 ± 0.49 mmol/L), HDL-cholesterol (1.41 ± 0.26 vs. 1.36 ± 0.28 mmol/L), and LDL-cholesterol concentrations

(1.99 ± 0.59 vs. 2.04 ± 0.51 mmol/L) between subjects with and without atopic diseases.

#### Red Blood Cell Fatty Acid Composition

Table 3 shows RBC fatty acid composition of subjects. PUFA was lower, while SFA was higher (*P* < 0.05) in subjects with than without atopic disease. MUFA was relatively low, and it was not significantly different in those with atopic disease and those without. Total n-3 PUFA was significantly higher, whereas total n-6 PUFA was significantly lower in children without atopic disease than those with. In addition, each n-3 PUFA such as EPA, DHA, docosapentaenoic acid (DPA, C22:5) and the omega-3 index (EPA + DHA) were significantly higher in subjects without atopic disease than those with. Stearic acid (C18:0) and arachidonic acid (C20:4) were significantly lower in subjects without atopic disease than those with atopic disease.

#### Discussion

The increased prevalence of atopy has been shown to coincide with the decreased intake of n-3 PUFA and the increased intake of n-6 PUFA [6, 9–14]. However, studies inconsistently show an improvement in asthmatics treated with fish oil [19–21]. Little information is available on the n-3 PUFA status of preschool aged children in relation to atopy.

In this study, we observed that RBC n-3 PUFA were significantly lower in preschoolers with atopy compared to those without, while n-6 PUFA and n-6/n-3 PFA ratios were significantly greater. These findings were consistent with the hypothesis that reduced tissue n-3 PUFA content (which naturally raises the n-6/n-3 PUFA ratio) is an important determinant of early childhood atopic diseases. Studies have suggested that n-3 PUFA affected immune response and expression of atopy by the modulation of the formation of cytokines and eicosanoids [22, 23, 29]. The levels of arachidonic acid, a precursor of PGE<sub>2</sub> were also higher in children with atopy than those without, suggesting an increased capacity for PGE<sub>2</sub> formation [15, 16].

Dunder et al. [17] reported that dietary fish intake was significantly lower in children (3–18 years old) with atopy than those without atopy. Similarly, serum cholesteryl ester DHA was significantly lower in those with atopic dermatitis. In addition, Yu et al. [18] observed that DHA (1.46 ± 0.54 vs. 1.90 ± 0.58%) and total n-3 PUFA (2.34 ± 0.67 vs. 2.80 ± 0.77%) in serum phospholipids were significantly lower in the allergic children aged 12–15 years than in the controls. Kankaanpaa et al. [7] also showed that atopic infants had less n-3 PUFA in serum

cholesteryl ester (1.37 ± 0.47 vs. 1.63 ± 0.40%), but not in TG and phospholipid fractions. However, Mahrshahi et al. [9] did not find a relationship between plasma n-3 PUFA and atopy in children aged 18 months after n-3 PUFA supplementation. Meta-analysis by Van Gool et al. [24] showed that treatment trials have failed to show consistent improvement of atopic disease. Little information is available on the n-3 PUFA status of young children in relation to atopy. Pusan is a major port famous for its fish market, thus people may have higher fish consumption.

Oliwiecki et al. [30] reported that children with atopy had higher plasma and RBC linoleic acid, SFA, MUFA than the controls. We also observed higher SFA, but linoleic acid and MUFA were not significantly different in the present study.

The prevalence of atopy has been shown to be lower in male children than in female children, and also to decrease with age [31]. However, we could not confirm this. The role of exclusive breast feeding in protecting against asthma is controversial. Businco et al. [32] and Gruskay et al. [33] found that breast feeding decreased the risk of

atopy in high-risk newborns. However, some studies reported that the effect of breast feeding in children diminished several years later [34, 35]. In the present study, breast feeding was not associated with the prevalence of atopy, which may be due to either the age of our children (4–6 years) as previous studies reported, or to short breast-feeding periods of most children (<1 month in 44% of control and 41% of children with atopy).

A family history of atopy is an important risk factor for atopy, and a maternal history of atopy is more important than paternal [36]. We also found that maternal history of atopy was significantly associated with atopy in children.

In summary, the amounts of RBC n-3 PUFA were significantly lower in preschoolers with atopy compared to those without atopy, while the amounts of n-6 PUFA were significantly higher, suggesting that the n-3 PUFA status of the RBC membrane could play a role in atopy in early childhood. Thus, membrane fatty acid disturbances may be an important determinant of early childhood atopic diseases. There is a need for further research into the role of n-3 PUFA supplementation in atopy, particularly for children.

**Abstract** The lipid quality of ruminant products is largely determined by the extent of rumen microbial biohydrogenation (BH) of polyunsaturated fatty acids (FAs) and the substances formed thereby. In vitro batch incubations with mixed rumen bacteria were tracked over 24 h to characterize the profiles and kinetics of the BH products from three lipid sources: pure linoleic acid (*c*9,*c*12–18:2), pure linolenic acid (*c*9,*c*12,*c*15–18:3) and linseed oil (mainly *c*9,*c*12,*c*15–18:3 in triacylglycerols). After 24 h of incubation biohydrogenation was more complete for *c*9,*c*12–18:2, which gave mainly stearic acid (18:0), than for *c*9,*c*12,*c*15–18:3, which yielded mainly *trans*-18:1 FAs. This suggests inhibition of the final BH step (18:1 to 18:0). Incubations of *c*9,*c*12–18:2 resulted in high levels of carbon 10- and 12-desaturated 18:1, *t*10,*c*12- and *c*9,*t*11-CLAs. Incubations of *c*9,*c*12,*c*15–18:3 resulted in high levels of *t*11–18:1, carbon 13- and 15-desaturated 18:1 as well as *t*11,*c*15–18:2 and 11,13-CLAs. A comparative study of linolenic acid and linseed oil kinetics revealed that the BH process was not significantly slowed by the esterification of polyunsaturated FAs, but may have been limited by the isomerization step in which the *cis*12 double bond goes to the *trans*11 position. The disappearance rates of *c*9,*c*12–18:2 and *c*9,*c*12,*c*15–18:3 ranged from 23.6 to 44.6%/h. The wide variety of BH intermediates found here underlines the large number of possible BH pathways. These data help provide a basis for dynamic approaches to BH processes.

## Introduction

In the anaerobic rumen microbial ecosystem, unsaturated fatty acids (FAs) can be used as electron sinks. The metabolites resulting from biohydrogenation (BH) are therefore specific to ruminants. Ruminant products such as milk and meat are thus richer in saturated FAs than products from monogastric animals [1]. The rumen microbial ecosystems also yields a range of BH intermediates such as monounsaturated *trans* FAs and conjugated linoleic acids (CLAs) that are transferred into ruminant products. These intermediates have varied nutritional properties. The ruminal BH of dietary 18-carbon unsaturated FA sources is a sequential process, beginning with lipolysis and followed by isomerization and hydrogenation of the double bonds, finally yielding saturated stearic acid (C18:0) together with a wide variety of monounsaturated, dienoic or trienoic intermediates with either a *cis* or *trans* stereoisomeric positioning of the double bonds. Rumen metabolism of linoleic acid (*c*9,*c*12–18:2) starts with a shift in the double bond position from carbon 12 to carbon 11, and then transisomerization to yield the CLA *c*9,*t*11–18:2, which is then reduced to vaccenic acid (*t*11–18:1) and finally to C18:0 [2, 3]. Similarly, BH of  $\alpha$ -linolenic acid (*c*9,*c*12,*c*15–18:3) yields the conjugated triene *c*9,*t*11,*c*15–18:3,

which is then sequentially hydrogenated into *t*11,*c*15–18:2, *t*11–18:1 and C18:0 [4]. These are the main known pathways for linoleic and  $\alpha$ -linolenic acids, but biohydrogenation, in fact, yields a wide variety of other BH intermediates, in particular *cis* and *trans* isomers of C18:1 and C18:2. The yield of BH intermediates depends on the amounts of dietary FAs, but may also depend on whether they are supplied in the free or esterified form. In the case of plant oils (compared with free FAs), the additional step of lipolysis may delay the process of microbial BH of polyunsaturated FAs and alter the formation of the various intermediates before saturated C18:0 is reached.

We sought to obtain a detailed description of the products of rumen microbial BH and isomerization of two pure unsaturated free FAs (*c*9,*c*12–18:2 and *c*9,*c*12,*c*15–18:3) in an in vitro batch system with mixed rumen bacteria and protozoa, and to examine the kinetics of these products over a 24 h incubation period. Linseed oil, which contains both *c*9,*c*12–18:2 and *c*9,*c*12,*c*15–18:3 in triacylglycerol form, was also monitored under similar conditions. In linseed oil, the amounts of unsaturated FAs and the preliminary lipolysis step were both different compared with the incubations of free FAs, and may modify the type and/or amount of BH intermediates and products. The rate of FA addition chosen (about 3% of substrate DM) was designed to mimic real animal feeding conditions.

## Materials and Methods

### In Vitro Batch Culture System

Each batch incubator was a 120 mL serum bottle closed by a crimped butyl septum containing rumen juice mixed with a buffer solution, substrates, and with or without supplementation with a FA source. Two sheep fitted with rumen cannulae were used as ruminal fluid donors. They were fed 1,200 g per day of a mixed diet composed of meadow hay (45%) and barley grain (55%) given in two equal meals at 9 AM and 4 PM. Rumen content was sampled through the cannula before the morning meal and then filtered on a metal grid (2 mm mesh size) in a low-oxygen environment to obtain rumen fluid. First, 15 mL of the filtrate was mixed with 25 mL Coleman buffer (Simplex type) [5] at 39 °C and introduced into the incubators, which had been previously filled with pure CO<sub>2</sub>.

Second, 500 mg of a ground substrate made of the same ingredients as the animals' diet was introduced into each incubator to feed the microbes. It consisted of a mixture of meadow hay and barley (45:55), with the following composition on a DM basis: organic matter 88.1%, crude protein 15.0%, NDF 43.0% and ADF 22.0%. This substrate supplied 1.15 mg *c*9,*c*12–18:2 and 0.23 mg *c*9,*c*12,*c*15–18:3

per incubator. Each series of incubations comprised four incubators for each incubation time: three experimental incubators supplemented with either pure *c*9,*c*12–18:2 (LA), pure *c*9,*c*12,*c*15–18:3 (LN) or linseed oil (LO), and one non-supplemented incubator used as control. About 13 mg of pure *c*9,*c*12–18:2 (99% pure; Biovalley, Marne-La-Vallée, France) was introduced into the LA incubators, 14 mg of pure *c*9,*c*12,*c*15–18:3 (99% pure; Biovalley, Marne La Vallée, France) into the LN incubators, and 13 mg of linseed oil obtained by cold pressing (Vandeputte, 7700 Mouscron, Belgium) into the LO incubators. The linseed oil contained 60.9% of *c*9,*c*12,*c*15–18:3, 15.0% of *c*9,*c*12–18:2, 15.0% of *c*9–18:1, 4.7% of 16:0 and 2.8% of 18:0. The filled incubators were gassed with CO<sub>2</sub> to eliminate oxygen and maintain anaerobic condition during fermentation, and were placed in a water bath at 39 °C. Fermentation gases were collected and analyzed every time incubators were removed to check for the absence of oxygen. The medium in each incubator was regularly mixed with a magnetic stirring bar (30 s every 4 min). One control incubator and one incubator from each experimental set (LA, LN and LO) were simultaneously removed after 0, 0.5, 2, 5 and 24 h of incubation. Four series were run on four different days. Samples were taken at the 0.5 h time point in only two of the four series.

### Extraction and Transmethylation of Lipids

These two steps were carried out on the whole content of the incubators immediately after removal from the water bath. Lipids were extracted according to the method described in Folch et al. [6]. As an internal standard, 500  $\mu$ L of pure methyl tricosanoate (400  $\mu$ g/mL in hexane) (Sigma, Saint-Quentin-Fallavier, France) was added to the tubes containing the final solution of lipids. Lipids were then transmethylated at ambient temperature using sodium methanolate followed by BF<sub>3</sub>-methanol according to the method described in Christie et al. [7].

The solutions of methyl esters were bleached through florisil columns and eluted with 10 mL of a mixture of hexane and diethyl ether (95/5 vol/vol). The solvents were evaporated under a gaseous nitrogen flow. The methyl esters were weighed and dissolved in 3 mL of hexane, and kept at –20 °C until analysis.

### Analysis of Methyl Esters

Fatty acid composition was determined by gas-liquid chromatography (GLC). Samples were injected by means of an autosampler into a Varian CP-3800 gas chromatograph equipped with a flame ionization detector. Methyl esters of FAs were separated on a 100 m  $\times$  0.25 mm i.d. CP-Sil 88 fused silica capillary column (Varian, Les Ulis, France). A mixture of 37 pure methyl esters

(Supelco™ 37 Component FAME Mix No. 47885-U, Supelco Inc., Saint-Quentin-Fallavier, France), a CLA isomer standard mixture composed of *c9,t11-*, *t10,c12-*, *c11,t13-*, *c9,c11-* and *t9,t11-18:2* (Matreya Inc., Pleasant Gap, PA), and pure *c9,c12-18:2* and *c9,c12,c15-18:3* (Matreya Inc., Pleasant Gap, PA) were used for peak identification and for quantitative calibration of response factors for individual FAs.

Fatty acid analyses were performed under the following conditions: 0.5–1  $\mu$ L methyl esters in hexane injected at a 50:1 to 90:1 split ratio, with injector temperature maintained at 250 °C and detector temperature set at 255 °C. The initial oven temperature was held at 70 °C for 1 min, then increased at a heating rate of 5 °C/min to 100 °C (held for 2 min), then increased at a heating rate of 10 °C/min to 175 °C (held for 40 min), and finally increased at 5 °C/min to the final temperature of 225 °C (held for 25 min) [8]. Hydrogen was used as the carrier gas. Injector pressure was held constant at 23 psi. Satisfactory separation of most *cis* and *trans* C18:1 and CLA isomers was obtained with a single chromatographic run.

#### Control of O<sub>2</sub> Absence in the Gas Phase of Incubators

Fermentation gases were collected in a syringe [9], and oxygen was quantified by gas-solid chromatography using a 2.3 m  $\times$  2.1 mm i.d. stainless steel column filled with 60/80 mesh Carboxen 1000 (Supelco), a thermal conductivity detector, with argon as the carrier gas.

#### Animal Care

The use of cannulated sheep was approved by the Ethics Committee of the INRA research center. The scientists and technicians involved in the experiment were licensed by the French Ministry of Agriculture to conduct experiments on living animals.

#### Computation and Statistics

Using the individual values measured for each FA at the different sampling times, the mean amounts of FAs over the 24 h incubation period were computed as the area under the curve divided by the total duration of incubation. Positive or negative balances of the different FAs were computed as the difference between the initial content and the incubator content following 24 h of incubation. The number of double bonds in the C18 FAs was computed for each sample based on the amount of each FA in moles and the number of double bonds in each FA molecule. To compare the BH kinetics of the different lipid sources, the quantities of double bonds and substrate FAs (*c9,c12-18:2*

and *c9,c12,c15-18:3*) remaining at the various sampling times were expressed as a proportion of their initial quantities. The evolutions of these proportions were adjusted to an exponential model. Given the shape of the curves and the aberrant values obtained with adjustment of the models integrating a lag time, we opted to use the following model without lag time:

$$Q_t(\text{quantity at time } t \text{ in \% of initial amount}) \\ = 100 - a \times (1 - e^{-b \times t})$$

where *a* is the maximum extent of BH (expressed in % of initial amount) and *b* is the disappearance rate (expressed in %/h). Parameters *a* and *b* were adjusted using the NLIN procedure of the SAS software package [10].

The individual values measured at the different sampling times were analyzed using the MIXED procedure of the SAS software package, with a fixed effect of lipid source, a random effect of repetition (series) and the REPEATED statement for time (unequally spaced measures, power covariance structure). Multiple comparison of means among sampling times and lipid sources was performed using Tukey's method. The mean amounts, balance data and kinetic parameters were compared using the MIXED procedure of the SAS software package, with a fixed effect of lipid source and a random effect of repetition. The significance level was set at *P* = 0.05.

#### Results

At the start of incubations, LA incubators contained a mean amount of 15.4 mg of *c9,c12-18:2*, LN incubators contained 2.1 mg of *c9,c12-18:2* and 15.8 mg of *c9,c12,c15-18:3*, and LO incubators contained 3.2 mg of *c9-18:1*, 4.5 mg of *c9,c12-18:2* and 8.6 mg of *c9,c12,c15-18:3*. None of the other C18 FAs were significantly different from the control incubators.

#### Mean Amounts of the C18 FAs

Table 1 gives the mean amounts of the different C18 FAs over the 24 h incubation period calculated from the areas under the kinetic curves (see Computations and statistics). In the LA incubations, the addition of *c9,c12-18:2* to the medium gave higher levels of nine 18:1 isomers (*t4-*, *t5-*, *t6 + 7 + 8-*, *t9-*, *t10-*, *t12-*, *c10 + t15-*, *c12-* and *c13-18:1*) and six 18:2 isomers (*t9,t11-*, *c9,t11-*, *c9,c12-*, *c9,t12-*, *c10,c12-* and *t10,c12-18:2*) compared with the control incubations. The isomer *t9,t11-18:2* may have been mixed with *t8,t10-18:2*, since these two FAs were not separated by the GLC method. Several C18:1 isomers and most of the C18:2 isomers had significantly different values between

**Table 1** Mean values ( $\mu\text{g}/\text{incubator}$ ) of C18 FAs during 24 h incubations with different lipid sources

CO Control (no lipids added), LA linoleic acid, LN linolenic acid, LO linseed oil. Results are expressed as LS means, *P* values indicate lipid substrate effect, and different superscript letters in the same row indicate significantly different values (*P* < 0.05)

the LA and LN incubations. Compared with the LN incubations, LA had significantly higher levels of *c*9,*c*12–18:2 (substrate), *t*10- and *c*12–18:1, *c*9,*t*11-, *c*9,*t*12-, *t*10,*c*12-, *c*10,*t*12-, *c*10,*c*12- and *t*9,*t*11–18:2. In the LA incubations, the two main C18:1 intermediates (*t*10 and *t*11) together accounted for about 50% of the total 18:1 intermediates, while the two main 18:2 intermediates (*c*9,*t*11 and *t*10,*c*12) similarly accounted for about 50% of the total C18:2 intermediates.

In the LN incubations, the addition of *c*9,*c*12,*c*15–18:3 gave higher levels of ten 18:1 isomers (*t*5-, *t*6 + 7 + 8-, *t*9-,

*t*11-, *t*12-, *t*13 + 14-, *c*10 + *t*15, *c*13-, *c*14 + *t*16- and *c*15–18:1) and nine 18:2 isomers (*c*9,*c*11-, *c*9,*t*12-, *c*9,*t*13-, *c*9,*c*15-, *t*9,*c*12-, *t*9,*t*12-, *c*11,*t*13-, *t*11,*t*13- and *t*11,*c*15–18:2) compared with the control incubations. Compared with the LA incubations, the LN incubations had much higher levels of *t*11,*c*15–18:2, and significantly higher levels of *t*13 + 14-, *c*10 + *t*15-, *c*13- and *c*15–18:1, *t*9,*t*12-, *c*9,*t*13-, *t*8,*c*13-, *c*9,*c*15-, *c*11,*t*13-, *c*9,*c*11- and *t*11,*t*13–18:2. Addition of pure  $\alpha$ -linolenic acid to incubators yielded high levels of *c*9,*c*12,*c*15–18:3 (substrate) and *trans*-18:3 (undetermined isomer(s) of C18:3 with at least one

*trans* double bond). In the LN incubations, the two main 18:1 products (*t*11 and *t*13 + 14) accounted for 61% of the total 18:1 intermediates, while the two main 18:2 products (*t*11,*c*15 and *t*11,*t*13) accounted for 75% of the total 18:2 intermediates. The other 18:1 and 18:2 BH intermediates showed no differences between the LA and LN incubations. Mean amounts of FAs in LO incubations ranged between control and LN values, except for *c*9–18:1 and *c*9,*c*12–18:2, which were supplied by linseed oil, thus giving higher levels in the LO than in the LN incubations. Mean levels of BH intermediates (18:1 and 18:2 isomers except *c*9–18:1 and *c*9,*c*12–18:2) were significantly lower in the LO incubations than in the LN incubations (4150 vs 9805 µg/incubator). After 24 h of incubation, the proportions of the main C18 FA (in % of total C18) were: 65% of 18:0, 6% of *c*9–18:1, 17% of other 18:1 isomers, 3% of *c*9,*c*12–18:2, 6% of other 18:2 isomers and 4% of *c*9,*c*12,*c*15–18:3.

### FA Balances

Table 2 presents C18 FA balances between start and end of incubations. In the LA incubations, the disappearance of *c*9,*c*12–18:2 (substrate) was mainly balanced by an increase in 18:0 (indicating complete BH of the substrate) and, to a lesser extent, in *t*10–18:1, *cis*-18:1 except *c*9–18:1, and in all CLAs. None of the other FAs had balances significantly different from zero.

In the LN incubations, the disappearance of 18:3 was mainly balanced by an increase in *trans*- and *cis*-18:1 except for *c*9–18:1, in *t*11,*c*15–18:2 and other non-conjugated 18:2, and mainly in 11,13 CLAs. The increase in 18:0 (complete BH) was close to significance ( $P = 0.056$ ), and was numerically higher than the increase in *t*11–18:1 (4.43 vs 3.43 mg/incubator).

The balance in the LO incubations was characterized by decreases in *c*9–18:1, *c*9,*c*12–18:2 and 18:3, which were all present in linseed oil. The main BH product was 18:0, but there were also significant increases in *trans*-18:1, *t*11,*c*15–18:2, and other 18:2 isomers. The increase in *t*11–18:1 during incubation was not significantly different from zero.

For all three lipid substrates, the overall balance of total C18 FA was negative, but not significantly different from zero.

### Dynamic Features

Figure 1 depicts the time course of the most characteristic FAs produced in the LA incubations. The levels of the substrate (*c*9,*c*12–18:2) were not significantly modified during the first 0.5 h ( $P = 0.41$  for the difference between 0 and 0.5 h) but then dropped rapidly to 5 h of incubation, and more slowly to the end of incubation ( $P = 0.02$  for the difference between 5 and 24 h). The CLA *c*9,*t*11–18:2 reached a peak (0.7 mg/incubator) at 0.5 h, and then remained constant between 2 and 24 h of incubation ( $P = 0.12$ ). The CLA *t*10,*c*12–18:2 also increased during the first 0.5 h ( $P < 0.0001$ ) and remained constant thereafter, always below 0.5 mg/incubator or 1.5% of the total C18 FAs. Vaccenic acid (*t*11–18:1) increased rapidly during the first 0.5 h ( $P = 0.002$ ), peaked between 2 and 5 h of incubation (2.6 mg/incubator), and slowly decreased thereafter ( $P = 0.04$ ) to reach 1.2 mg/incubator at 24 h. The amount of *t*10–18:1 increased from 0.5 to 5 h, and then decreased ( $P = 0.02$ ) to reach levels similar to *t*11–18:1 after 24 h. The amount of 18:0 did not significantly change during the first 0.5 h. It then increased to 2 h of incubation ( $P = 0.004$ ), and also increased between 2 and 24 h ( $P = 0.02$ ; the value after 5 h was intermediate, not significantly different from values at 2 and 24 h).

**Table 2** Balances of the C18 FAs (mg/incubator) between start and end of 24 h incubations with different lipid sources

LA Linoleic acid, LN linolenic acid, LO linseed oil. Positive values correspond to a net production of the FA whereas negative values correspond to a net disappearance of the FA. The last column gives  $P$  values for the lipid source effect, and different superscript letters in the same row indicate significant differences among LS means

	b	11.6	32.4	28.7	5.2	0.06

LA Linoleic acid, LN linolenic acid, LO linseed oil. The model used is  $Q_t$  (quantity at time *t* expressed in %  $Q_0$ ) =  $100 - a \times (1 - e^{-b \times t})$ , where *a* is the maximum extent of BH (expressed in % of the initial amount) and *b* is the disappearance rate (expressed in %/h). Values are LS means of the adjusted parameters

<sup>d</sup> There were only two adjustable curves for *c9,c12,c15-18:3* in LA incubations, so the corresponding SEM has to be multiplied by 1.41 for this lipid source

Figure 2 depicts the time course of the most characteristic FAs produced in the LN incubations. The substrate *c9,c12,c15-18:3* decreased as early as 0.5 h of incubation, dropped rapidly during the first 5 h of incubation, and then fell at a slower rate to 24 h. The *trans-18:3* remained low and constant throughout the incubation period (mean content 0.04 mg/incubator). The 18:2 isomers showed two main time course patterns. In the first pattern, as exemplified by *t11,c15-18:2* (see Fig. 2), the FAs peaked after about 2 h of incubation and decreased thereafter. The isomers *c9,t13-*, *c9,c15-*, *c9,c11-*, *c9,t11-*, *c10,t12-* and *c10,c12-18:2* also followed this pattern. In the second pattern, as exemplified by *t11,t13-18:2* (see Fig. 2), the FAs also increased at the beginning of incubation, but instead of decreasing after 5 h of incubation, they remained constant to 24 h. The isomers *c9,t12-*, *t9,c12-*, *t9,t12-*, *c11,c13-* and *c11,t13-18:2* followed this pattern. All 18:1 isomers increased steadily for the whole 24 h incubation period (e.g. *t11-* and *t13 + 14-18:1* in Fig. 2). Stearic acid (C18:0) increased slightly ( $P = 0.06$ ) during the first 0.5 h, and then remained constant throughout the 24 h incubation period.

The disappearance rates of *c9,c12-18:2* and *c9,c12,c15-18:3* were higher ( $P < 0.1$ ) in the LN incubations (41.9 and 44.6%/h, respectively) than in the LA incubations (23.6 and 33.9%/h, respectively) (Table 3). The substrate decreased as early as 0.5 h in the LN incubations, and less substrate remained at 2 h in the LN than in the LA incu-

**Fig. 2** Kinetics of the main FAs during linolenic acid incubations (mg/incubator). C18:0 and *c9,c12,c15-18:3* (lipid source) are presented as solid lines on the left scale. The biohydrogenation intermediates (*t11-* and *t13 + 14-18:1*, *t11,c15-* and *t11,t13-18:2*) are presented as dotted lines on the right scale

bations (52% of initial amount remained for *c9,c12,c15-18:3* in LN vs 74% for *c9,c12-18:2* in LA incubations;  $P = 0.07$ ). This was confirmed by a higher disappearance rate of double bonds ( $P = 0.03$ ) in LN (32.4%/h) than in LA incubations (11.6%/h). Most of the double bonds in the LN incubations disappeared during the first 5 h (the double bond numbers were not significantly different between 5 and 24 h of incubation;  $P = 0.30$ ). By contrast, the number of double bonds in LA incubations remained unchanged ( $P = 0.60$ ) during the first 2 h of incubation, decreased rapidly between 2 and 5 h of incubation ( $P = 0.02$ ), and continued to decrease at a lower rate between 5 and 24 h ( $P = 0.02$ ).

The LO incubations (Fig. 3) followed a general pattern similar to the LN incubations, i.e. a rapid increase in 18:2 BH intermediates and a steady increase in *trans*-18:1 throughout the 24 h incubation period, but yielded lower levels of all the BH intermediates. After 24 h of incubation, the C18 FAs were composed of 65% of 18:0, 6% of *c9-18:1*, 17% of other 18:1 isomers, 3% of *c9,c12-18:2*, 6% of other 18:2 isomers and 4% of *c9,c12,c15-18:3*. The kinetics of *c9,c12-18:2*, *c9,c12,c15-18:3* and double bonds were also very similar between the LO and LN incubations (Table 3), except that the disappearance rate of *c9,c12,c15-18:3* tended to be lower in LO (26.8%/h in LO vs 44.6%/h in LN;  $P = 0.1$ ).

**Fig. 3** Kinetics of the main FAs during linseed oil incubations (mg/incubator). C18:0 and *c9,c12,c15-18:3* (main lipid source) are presented in solid lines on the left scale. The 18:1 and 18:2 isomers (*c9-* and *t11-18:1*, *c9,c12-* and *t11,c15-18:2*) are presented as dotted lines on the right scale

## Discussion

### Validity of the in Vitro Model

In vitro incubations used to study the rumen metabolism of unsaturated FA often produce much higher levels of BH than those occurring in in vivo conditions. Several hypotheses can be put forward to account for these discrepancies: the absence of particulate matter may enhance the inhibiting effect of added lipids on microbes [11], the presence of oxygen in the medium may disrupt microbe metabolism, very high doses of supplemental lipids are sometimes used, and an excessive duration of incubations may induce a loss of activity of the microbes. We took precautions with regard to these factors to make the results more realistic. Thus we added particulate matter to the incubations (DM represented a mean 5.25% of incubator contents). We ensured by gas analysis that oxygen was not present in the incubators. We added only moderate amounts of lipids to the incubators (equivalent to 3% of DM), and limited the duration of incubations to 24 h. In these conditions, the composition of C18 FAs at the end of the LO incubations was comparable to that obtained in the duodenum of animals fed a high forage diet containing 3% of linseed oil (12): 65% (in the LO incubations) vs 66% (in [12]) of 18:0, 6% vs 3% of *c9-18:1*, 17% vs 23% of other 18:1 isomers, 3 vs 3% of *c9,c12-18:2*, 6 vs 3% of other 18:2 isomers, and 4 vs 2% of *c9,c12,c15-18:3*. The final products of in vitro BH were thus consistent with in vivo results, showing that the conditions used for the incubations allowed a normal microbial metabolism.

### Specificity of BH Products of *c9,c12-18:2* and *c9,t11,c15-18:3*

During the 24 h incubation period, results for the main FAs (Table 1) were consistent with the main metabolic pathways, with *c9,c12-18:2* generating *c9,t11-18:2* and *t11-18:1*, and *c9,c12,c15-18:3* producing *t11,c15-18:2* and *t11-18:1* [13]. However, a large number of 18:1 and 18:2 isomers were identified here, showing that there are several other “minor” BH pathways. This agrees with BH data obtained with plant oil supplements rich in unsaturated FAs in both in vitro [14] and in vivo [12, 15] studies. In the LA incubations, the fact that the two main C18:1 and C18:2 BH intermediates accounted for only 50% of total intermediates indicates that the “minor” pathways may in fact account for half of the total BH of *c9,c12-18:2*. The BH pathways of *c9,c12,c15-18:3* were probably less diversified than the 18:2 BH pathways, since the sum of the two main 18:1 and 18:2 BH intermediates accounted for 60–75% of the total intermediates.

The detailed examination of the BH products showed the specificity of most BH products: addition of *c9,c12-18:2* to the medium gave higher levels of nine 18:1 isomers and six 18:2 isomers compared with the control incubations. The main 18:1 isomers were those with double bonds in positions 10 and 12, while the main 18:2 isomers were 9,11- and 10,12- CLAs. Absolute amounts of *trans-18:1* with double bonds on carbon 4–9 also increased, but their proportions of total C18 FAs were similar to those of the control incubations. Such profiles are consistent with duodenal FA profiles already observed in vivo on animals fed diets supplemented with 18:2-rich plant oils [16–18]. In the LN incubations, in addition to the main products *t11,c15-18:2* and *t11-18:1*, the formation of *t13 + 14-*, *c13-*, *c10 + t15-*, *c15-18:1*, as well as several 11,13 CLAs and other 18:2 intermediates with a double bond on carbon 13 or carbon 15, was also promoted. This indicates that besides the most extensively described metabolic pathways involving carbon 11-desaturated FAs, the carbon 13- and carbon 15-metabolic pathways can be considered specific to the ruminal metabolism of *c9,c12,c15-18:3*. The accumulation of carbon 13- and carbon 15-desaturated metabolites confirms the low BH of the double bonds in these positions in both *cis* and *trans* configurations already reported by other authors [19, 20]. Among the 9,12–18:2 isomers, *c9,t12-* and *t9,c12-18:2* were increased by both *c9,c12-18:2* and *c9,c12,c15-18:3* supplementations, in accordance with the in vivo data [12, 15, 21], whereas *t9,t12-18:2* was only increased by *c9,c12,c15-18:3* and not by *c9,c12-18:2*.

#### Differences in BH Dynamics and Extent Between *c9,c12-18:2* and *c9,t11,c15-18:3*

The disappearance rate of *c9,c12-18:2* in the LA incubations was lower than the disappearance rate of *c9,c12,c15-18:3* in the LN incubations (Table 3). This result was confirmed by a lower disappearance rate of double bonds in the LA than in the LN incubations. The BH process had almost reached its maximum after 5 h of incubation in the LN and LO incubations, whereas significant amounts were still being hydrogenated between 5 and 24 h in the LA incubations. The slower BH of *c9,c12-18:2* compared with *c9,c12,c15-18:3*, which has already been reported (for example in [22]), may be due to a preferential uptake of *c9,c12-18:2* by bacteria [23], thus protecting it against BH, or to differences in microbial isomerase or saturase affinity between the two FAs. The disappearance rate of *c9,c12-18:2* found in this study was similar to that reported by Troegeler-Meynadier et al. [24] in very similar in vitro conditions (23.6 and 22.5%, respectively). The maximum extent of disappearance of *c9,c12-18:2* and *c9,c12,c15-18:3* (78.7–85.9% and 80–91.2% of initial amount,

respectively) was not significantly different among the three lipid sources, and was similar to mean in vivo BH data reviewed in [25].

The kinetics of the main FAs during incubations showed that 18:2 intermediates appeared first and were followed by a later increase in 18:1 intermediates, which fits the logical sequence of the BH process. In LA incubations, *t11-18:1* showed an earlier increase than *t10-18:1*, and the *t11/t10-18:1* ratio decreased over time, probably reflecting a short-term modification in the balance between the different metabolic pathways. The main difference between the LN and LA incubations was that the increase in 18:1 was transitory in the LA incubations, whereas the 18:1 intermediates accumulated between 5 and 24 h in the LN incubations, a feature also observed, though to a lesser extent, in the LO incubations. The balances of C18 FAs after a 24 h incubation period confirmed that the BH of *c9,c12-18:2* was more complete than that of *c9,c12,c15-18:3*: the main product of *c9,c12-18:2* BH was C18:0, whereas the main products of *c9,c12,c15-18:3* BH were *trans-18:1* isomers (Table 2). Two reasons may explain this result: some *trans-18:1* isomers specific to *c9,c12,c15-18:3* BH (for example carbon 13- or carbon 15-desaturated 18:1) are probably more resistant to BH than those specific to *c9,c12-18:2* BH [19]; for other intermediates (as *t11-18:1* present in both the LA and LN incubations), a partial inhibition of the last step of BH (from *trans-18:1* to 18:0) probably occurred in the LN incubations. This step is under the control of group B bacteria [26]. The inhibition may be due to a direct toxic effect of *c9,c12,c15-18:3* itself or of one of its BH intermediates on these microbes. Since the fastest increase in C18:0 occurred at the start of the incubations, when *c9,c12,c15-18:3* was at its maximum level, it is unlikely that *c9,c12,c15-18:3* was responsible for the inhibition. The hypothesis of inhibition by one or several BH intermediates is thus more probable, but no published data are currently available to confirm this hypothesis.

#### Effects of FA Esterification (Free FAs vs Linseed oil)

Since the amounts of unsaturated FAs supplied in free or triacylglycerol form in the medium of each incubator were similar for all the lipid sources, we were able to compare free FAs and triacylglycerols, and assess the production of the various BH intermediates according to the FA source.

The disappearance rate of *c9,c12,c15-18:3* in the LN incubations was slightly higher than in the LO incubations, which may be a consequence of the necessary prior lipolysis of the triacylglycerol form of C18:3 in linseed oil, causing a slow release of free FAs used as substrates in the subsequent steps of isomerization and BH. The LN and LO incubations differed not only in the esterification of FAs, but also in the fact that linseed oil contained significant

amounts of *c9,c12*–18:2. However, the disappearance rate of double bonds was similar between the LN and LO incubations, so the global BH was not slowed by the esterification in our conditions. This is confirmed by the similar disappearance rates of *c9,c12*–18:2 between the LA and LO incubations. The lipolysis was thus not a limiting factor, and the disappearance of the substrates was probably limited by one of the subsequent steps in the BH process. The slower disappearance of *c9,c12,c15*–18:3 in LO compared with LN may arise from competition between *c9,c12,c15*–18:3 and *c9,c12*–18:2 for the initial step of BH in the LO incubations, already hypothesized by other authors [24]. The isomerization of the *cis*12 double bond into *trans*11 is an obligatory step before saturation [2, 27], and is probably performed on the same site for *c9,c12*–18:2 and *c9,c12,c15*–18:3 [27]. Since LO contains both FAs, we can hypothesize that they compete for the sites, causing a slowing of *c9,c12,c15*–18:3 disappearance in the LO incubations at their start, without affecting the global BH (disappearance of double bonds). With a lipid supplementation level of about 3% of DM, the limiting step of LO hydrogenation seems to be the first isomerization step (*c12* to *t11*-double bond) rather than the lipolysis step.

## Conclusion

This in vitro study with moderate levels of added lipids was designed to be representative of in vivo BH in diets supplemented with realistic amounts of unsaturated FAs. It showed that for a similar amount of supplemental FAs, more 18:0 (corresponding to complete BH) and less intermediates were produced from *c9,c12*–18:2 than from *c9,c12,c15*–18:3. Incubations of *c9,c12,c15*–18:3 produced higher amounts of 18:1 intermediates, 74% of which were *t11*- and *t13* + 14–18:1. Esterification of *c9,c12,c15*–18:3 in the LO had no effect on BH rate or on maximum extent of BH, which suggests that the initial step of BH (*cis*12 double bond isomerization) was more limiting than the lipolysis step in these conditions. The detailed description of 18:1 and 18:2 isomers produced from *c9,c12*–18:2 and *c9,c12,c15*–18:3 BH underlines that the main isomers commonly described (*t11*–18:1, *c9,t11*- and *t11,c15*–18:2) give only a very partial view of overall BH products. There is a need for more mechanistic approaches to the BH that take into account all the various metabolic pathways and reflect the full diversity of the isomers produced in the rumen, which in turn influence the lipid profiles of animal products.

**Abstract** The total lipids of the *longissimus dorsi* muscle were analyzed from commercial adult Sarda sheep in Sardinia taken from local abattoirs, and in the subsequent year from three local farms in the Sassari region that provided some information on the amount and type of supplements fed to the pastured sheep. The complete lipid analysis of sheep meat included the fatty acids from *O*-acyl and *N*-acyl lipids, including the *trans*- and conjugated linoleic acid (CLA) isomers and the alk-1-enyl ethers from the plasmalogenic lipids. This analysis required the use of a combination of acid- and base-catalyzed methylation procedures, the former to quantitate the *O*-acyl, *N*-acyl and alkenyl ethers, and the latter to determine the content of CLA isomers and their metabolites. A combination of gas chromatographic and silver-ion separation techniques was necessary to quantitate all of the meat lipid constituents, which included a prior separation of the *trans*-octadecenoic acids (18:1) and a separation of fatty acid methyl

esters and the dimethylacetals (DMAs) from the acyl and alk-1-enyl ethers, respectively. The alk-1-enyl moieties of the DMAs were analyzed as their stable cyclic acetals. In general, about half of the meat lipids were triacylglycerols, even though excess fat was trimmed from the meat. The higher fat content in the meat appears to be related to the older age of these animals. The variation in the *trans*-18:1 and CLA isomer profiles of the Sarda sheep obtained from the abattoirs was much greater than in the profiles from the sheep from the three selected farms. Higher levels of 10*t*-18:1, 7*t*9*c*-18:2, 9*t*11*c*-18:2 and 10*t*12*c*-18:2 were observed in the commercial sheep meat, which reflected the poorer quality diets of these sheep compared to those from the three farms, which consistently showed higher levels of 11*t*-18:1, 9*c*11*t*-18:2 and 11*t*13*c*-18:2. In the second study, sheep were provided with supplements during the spring and summer grazing season, which contributed to higher levels of 11*t*-18:1 and 9*c*11*t*-18:2. The farm that provided a small amount of supplements during the spring had the better lipid profile at both time periods. The polyunsaturated fatty acid (PUFA) content was higher in the meat from Sarda sheep from the three farms than in the meat from those sheep obtained from commercial slaughter operations. The plasmalogenic lipid content ranged from 2 to 3% of total lipids, the alk-1-enyl ethers consisted mainly of saturated and monounsaturated moieties, and the *trans*-18:1 profile was similar to that of the FA. The n-6 (6–8%) and n-3 PUFA (2–3%) contents, the n-6/n-3 ratio (3:1), as well as the saturated fatty acid (SFA) content (42–45%) and the SFA to PUFA ratio (4:1 to 5:1) of the Sarda sheep from the three farms were comparable to sheep meat lipids

found in similar commercial operations in Europe. Inclusion of small amounts of supplements for the grazing Sarda sheep resulted in improved quality of sheep meat lipids.

LC	Long-chain
MUFA	Monounsaturated fatty acid
PUFA	Polyunsaturated fatty acid
SFA	Saturated fatty acid
TFA	<i>Trans</i> fatty acid

### Introduction

In the last 50 years, meat and dairy products from ruminants have received a negative image, largely based on their contents of cholesterol, total fat, and specifically saturated fatty acids (SFAs), which have been related to an increased risk of coronary heart disease [1]. However, meat is also a good source of essential amino acids, fat-soluble (A, D, E and K) and B-complex vitamins (riboflavin, niacin, B6 and B12), and minerals (Zn, Fe, Mg). In addition, it is a good source of essential fatty acids and their long-chain n-3 polyunsaturated fatty acid (LC n-3 PUFA) metabolites, such as eicosapentaenoic (EPA) and docosahexaenoic acids (DHA) that are related to improved health [2]. In the last few years there has also been an increased awareness of the potential benefits of conjugated linoleic acid (CLA) present in the fats of ruminants, specifically rumenic acid (9*c*11*t*-CLA), and vaccenic acid (11*t*-18:1), its metabolic precursor [3]. CLA has been shown to protect against cancer, inflammation and diabetes in experimental animals and cell models [4, 5], and some

recent studies suggest that it reduces the risk of certain cancers [6, 7] and acute myocardial infarctions in humans [8].

There are only a few reports that provide a comprehensive fatty acid (FA) composition of beef muscle, including all the *trans*-octadecenoic acids (18:1), CLA isomers, and the long-chain PUFAs [9–13]. The FA composition of sheep meat is generally less complete [14–19], except for a recent report by Bessa et al. [20]. The accurate determination of the LC n-3 PUFAs in meat lipids is essential for assessing their contribution to our diet. The current concern over *trans* fatty acids (TFAs) and their association with coronary heart disease [1, 21] and inflammation [22] includes meat and dairy products of ruminants, since they also contain TFAs. Even though at this time the TFA regulation excludes CLA from mandatory labeling [23], the exclusion does not apply to 11*t*-18:1, the metabolic precursor of 9*c*11*t*-CLA. Since the TFA isomers responsible for the negative effects have not been identified, it is difficult to assess whether the TFAs from industrial and ruminant fats pose a similar health risk [24]. Therefore, accurate analyses of the CLA, *trans*-18:1, *cis/trans*-18:2 and LC PUFAs are needed to provide a more reliable database that can be used to assess the possible involvement of these TFAs in health-related issues. Currently many feeding studies are designed to decrease the content of SFAs and increase the content of the n-3 PUFAs and CLA in the meat of ruminants [25–27]. However, this requires an accurate determination of all the CLA and TFA isomers, since dietary manipulations may not necessary increase the desirable isomers, i.e., 9*c*11*t*-CLA and 11*t*-18:1 [28, 29].

Diaz et al. [16] reported the FA compositions of lamb meat from different production systems, including lambs fed mainly pasture in Uruguay, high-concentrate diets in Spain, or a combination of the two systems in the United Kingdom and Germany. They reported individual PUFAs and total CLA contents, but not TFA and CLA isomer compositions. Very little is known about the FA composition of meat from sheep reared on marginal grasslands, and for this reason Sarda sheep raised in Sardinia were investigated. About 40% of the sheep industry in Italy is located in Sardinia, where over three million Sarda sheep are raised on about 15,000 farms (data from the Italian Institute of Statistics for 2002; see <http://www.istat.it>). The estimated value of this industry is about 350 million Euros/year. Eighty percent of the income from Sarda sheep derives from milk (350 × 10<sup>6</sup> L/year) and cheese production (56 × 10<sup>6</sup> kg/year), and 20% from the sale of meat of one-year-old lambs (12,600 heads)

(data from 2003 from [30]). However, about 1,000 muttons and 77,000 ewes are slaughtered every year and their meat is only used to a limited extent for human consumption.

The main purpose of the present study was to describe comprehensive methods for the complete analysis of total meat lipids. We chose to analyze the meat from adult Sarda sheep raised under typical commercial settings in Sardinia, because such information is not currently available and the results will serve to assess the quality of this meat in preparation for its potential use. The first group of sheep meat was sampled from commercial abattoirs, and the second group comprised sheep meat obtained from three larger commercial farm establishments with good feeding practices. A combination of methods was used to analyze the TFA and CLA isomers; a combination of GC with long polar capillary columns and silver-ion TLC ( $\text{Ag}^+$ -TLC) techniques was used to analyze the TFA isomers [28, 29, 31, 32], and  $\text{Ag}^+$ -HPLC was used to determine the CLA isomers [28, 33, 34]. In addition, we report here for the first time the complete lipid composition of the plasmalogenic lipids in meat. Plasmalogenic lipids are ubiquitous constituents in all meat products [35]. However, in recent years their content in meat appears to have been overlooked because of the widespread use of base-catalyzed methylation procedures to avoid isomerization of CLA during methylation [36]. The alk-1-enyl ether bond in plasmalogenic lipids is stable under alkali-catalyzed methylations, but not under acid-catalyzed methylation procedures [28, 29, 32, 37].

## Materials and Methods

### Materials

Several pure free fatty acids (FFAs) were obtained from Sigma-Aldrich (St. Louis, MO, USA) including

arachidonic (20:4n-6), linoleic (18:2n-6),  $\alpha$ -linolenic (18:3n-3), eicosatrienoic (20:3n-9), vaccenic (11t-18:1), and erucic acids (13c-22:1). In addition, several *trans*-18:1 (6t-, 7t-, 9t-, 11t-, 12t-, 13t- and 15t-), *cis*-18:1 (6c-, 7c-, 9c-, 11c-, 12c-, 13c- and 15c-) isomers and 20:3n-9 were obtained from Sigma-Aldrich. A GC reference standard (#463), a mixture of four positional CLA isomers (#UC-59M) and long-chain saturated fatty acid methyl esters (FAMES) (17:0, 21:0, 23:0, and 26:0) were obtained from Nu-Chek Prep. Inc., (Elysian, MN, USA). All chemicals and solvents were of analytical grade. Trimethylsilyl-diazomethane (TMS-DAM) was purchased from TCI America (Portland, OR, USA).

### Animals and Diets

In the first study, 80 adult Sarda sheep were randomly selected at several abattoirs in the northern regions of Sardinia during the months of April, May, June and July 2002. The sheep ranged in age from two to seven years. Samples of *longissimus dorsi* muscle were obtained 24 h post-slaughter and stored at  $-20^\circ\text{C}$  until analyzed. No information was available on the amount and type of feed supplements they received, if any. In the second study, 36 sheep were sampled from three established farms in the Sassari region during April and July 2003. The farms were selected based on location, good management practices, and knowledge of the supplement provided (Table 1). Even though the farms reported the type and average amount of supplement per sheep during the spring and early summer, this should be considered to be an estimate since actual consumption data were not measured and the switchover between diets was a transition and was not the same at all farms. In addition, the feed supplement was not analyzed. All muscles (*longissimus dorsi*) samples were obtained 24 h post-slaughter and stored at  $-20^\circ\text{C}$  until analyzed. The sheep ranged in age from three to eight years, had grazed freely, and

**Table 1** Supplements provided to pasture-fed sheep at three farm operations in the Sassari region of Sardinia

Time	Diet	Farms in the Sassari region		
		Muzzoni (M)	Area (A)	Piras (P)

April–July 2003	Pasture	Ad libitum	Ad libitum	Ad libitum
	Supplement	None	None	Commercial
	Amount (g/sheep/d)	–	–	200 g

had been provided with a limited amount of concentrate (Table 1).

#### Lipid Extraction and Preparation of FAs for UV Determination

To investigate the CLA metabolites, sheep meat (0.3–0.4 g) was ground using a mechanical grinder (Ultra-Turrax T8, S8N-8G, IKA-Werke, Staufen, Germany), and the total lipids were extracted [38] and stored in chloroform at  $-20^{\circ}\text{C}$ . The total lipids were quantitated using the method described by Chiang et al. [39]. Briefly, 0.25 mL of the lipid extract were added to a 1.5 mL potassium dichromate solution (2 g  $\text{K}_2\text{Cr}_2\text{O}_7$  and 4 mL  $\text{H}_2\text{O}$  were made up to 100 mL with concentrated  $\text{H}_2\text{SO}_4$ ) and heated for 30 min at  $100^{\circ}\text{C}$ . After cooling, 1.5 mL  $\text{H}_2\text{O}$  was added and the UV absorbance was measured at 600 nm.

An aliquot of the total lipids (3 mL) was mildly saponified in 5 mL of ethanol to which 100  $\mu\text{L}$  of Desferal (25 mg/mL  $\text{H}_2\text{O}$ ), 1 mL ascorbic acid (10 g/40 g  $\text{H}_2\text{O}$ ), and 0.5 mL 10 N KOH was added [40]. The solution was left at room temperature in the dark for 14 h. After the addition of hexane (10 mL) and  $\text{H}_2\text{O}$  (7 mL), and acidification with 37% HCl to pH 3–4, the hexane layer was clarified by centrifugation. The hexane phase was collected, and after removal of the solvent, the FFA residue was dissolved in 0.5 mL of 0.14%  $\text{CH}_3\text{COOH}$  in  $\text{CH}_3\text{CN}$ . Conjugated and unsaturated FFAs were analyzed using an HPLC system (Model 1100, Agilent Technologies, Palo Alto, CA, USA) equipped with a quaternary pump (G1311A), an autosampler (G1313A), and a diode array detector (G1315B). A reversed-phase C-18 column was used (Inertsil ODS-2, 5  $\mu\text{m}$  particle size,  $150 \times 4.6$  mm; GL Sciences Inc., CPS Analytica, Milan). The mobile phase was  $\text{CH}_3\text{CN}/\text{H}_2\text{O}/\text{CH}_3\text{COOH}$  (70/30/0.12) operated isocratically at a flow rate of 1.5 mL/min. Unsaturated unconjugated FFAs were detected at 200 nm and conjugated diene FA at 234 nm. The latter were confirmed via their second-derivative UV spectra generated using the Phoenix 3D HP ChemStation software (Hewlett-Packard, Palo Alto, CA, USA) [41, 42]. The second-derivative UV spectra showed two typical negative peaks at about 233–238 nm and 244–247 nm [41]. In addition, the presence of hydroperoxy-octadecatrienoic acids were identified at 234 nm in sheep meat lipids by RP-HPLC; these had been previously characterized by UV and mass spectrometry [43]. The FFAs were also converted to their FAMES using TMS-DAM for total FA determination [44].

#### Lipid Extraction and Preparation of FAMES for GC Determination

In the second study, total lipids were extracted from about 5 g of sheep meat using  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (1:1) after pulverization at dry ice temperature [45]. The total lipids were then partitioned in  $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$  (1:1:0.9) to remove any nonlipid material [46]. The chloroform layer was collected, and after removal of the solvent the total lipids were weighed and then dissolved in 15 mL chloroform and stored at  $-70^{\circ}\text{C}$  until analyzed. An aliquot of total lipids was saponified and analyzed by RP-HPLC as described above. Several sheep muscle lipids (3–4 mg) were analyzed by three-directional TLC to assess the relative distributions of all the sheep meat lipids, and test for the presence of plasmalogenic lipids after exposure of the TLC plates to HCl fumes following the first development [47].

Total sheep muscle lipids were separately methylated using acid- and base-catalyzed procedures. Acid-catalyzed methylations were performed to derivatize all lipids by reacting about 30 mg total lipids with 1 mL anhydrous HCl/ $\text{CH}_3\text{OH}$  (5% w/v) for 1 h at  $80^{\circ}\text{C}$ . The base-catalyzed methylation procedure was used to retain the CLA isomer profile [36] by reacting 2 mg of total lipids with 0.5 mL  $\text{NaOCH}_3$ /methanol solution (0.5 N methanolic base #33080, Supelco Inc., Bellefonte, PA, USA) in a 2 mL autosampler vial for 15 min at  $50^{\circ}\text{C}$  [28, 48]. The methylated products from the base method and one-tenth of those from the acid-catalyzed method were purified on precoated Silica G TLC plates (Fisher Scientific Inc., Ottawa, ON, Canada) using the developing solvent hexane/diethyl ether/acetic acid (85:15:1). The bands corresponding to FAMES in the base-catalyzed product, and FAMES plus dimethylacetals (DMAs) in the acid-catalyzed methylation, were located using UV light after spraying the plate with a 2',7'-dichlorofluorescein solution in methanol. After removal of the bands, the methylated products were eluted from the silica gel with hexane and concentrated for analysis by GC.

The remaining acid-catalyzed methylation products (about 28 mg of FAMES and DMAs) were applied onto a precoated Silica G plate using a TLC applicator (Applied Science, State College, PA, USA). The developing solvent was 1,2-dichloroethane in which FAMES eluted just ahead of the DMAs [49]. The bands corresponding to the FAMES and DMAs were removed with hexane after they were visualized by spraying with 2',7'-dichlorofluorescein and detected under UV light. The FAME and DMA fractions were analyzed separately by GC using the same column and chromatographic conditions.

### Analysis of Dimethylacetals (DMAs) by GC

The DMAs produced during acid-catalyzed methylation of the plasmalogenic lipids were not stable at the injector temperature of 250 °C in the GC, resulting in the partial loss of one methanol to form alk-1-enyl methyl ethers (AMEs) [50]. The AMEs can occur in both the *cis* and the *trans* configurations [51]. The more stable cyclic acetals were prepared by reacting the isolated DMAs with 1,3-propanediol in the presence of catalytic amounts of *p*-toluenesulfonic acid [52]. The GC elution order of a given alk-1-enyl ether moiety is AME < DMA < cyclic acetal.

### Gas Chromatography (GC)

The gas chromatograph (Model 5890, Series II, Hewlett-Packard, Palo Alto, CA, USA) was equipped with splitless injection port (flushed after 0.3 min), a flame ionization detector (FID), an autosampler (Hewlett-Packard, Model 7673), a 100 m CP-Sil 88 fused capillary column (Varian Inc., Mississauga, ON, Canada), and a Hewlett-Packard ChemStation software system (Version A.09). The injector and detector temperatures were both set at 250 °C, H<sub>2</sub> served as carrier gas (1 mL/min), and the FID gases were H<sub>2</sub> (40 mL/min), N<sub>2</sub> (30 mL/min), and purified air (300 mL/min). The temperature program was as follows: initial temperature was 45 °C held for 4 min, programmed at 13 °C/min to 175 °C and held for 27 min, then programmed at 4 °C/min to 215 °C and held for 35 min [28, 32].

### Analyses of *Trans* 18:1 FA Isomers by Ag<sup>+</sup>-TLC/GC

For complete separation and identification of all *trans*-18:1 isomers, the total FAME mixture of meat lipids was fractionated into saturated, mono-*trans*, and mono-*cis* plus conjugated FAMES using silver-ion-impregnated Silica G TLC plates [28, 32, 53, 54]. The developing solvent was hexane/diethyl ether (90:10). The bands were visualized under UV light after spraying with 2',7'-dichlorofluorescein, eluted from the silica gel and analyzed by GC. The FAME fractions were analyzed using a stepwise temperature program starting at 120 °C [28, 32]. In addition, the *cis* and *trans* fractions were analyzed at high and low sample loads to resolve the minor and major FAME isomers.

### Analyses of CLA Isomers by Ag<sup>+</sup>-HPLC

The FAMES obtained by base-catalyzed methylation were used to determine the CLA isomer composition by

Ag<sup>+</sup>-HPLC, because this methylation procedure retained the original CLA profile [36]. The HPLC system was similar to that described above for the UV analysis of free and conjugated FAs. The diode array detector was operated at 233 nm for CLA and at 205 nm for unsaturated FAMES. Three ChromSpher 5 Lipids analytical silver-ion impregnated columns (Varian Inc.) were used in series [33]. The mobile phase was hexane/acetonitrile/*tert*-butylmethyl ether (99.4:0.1:0.5) operated isocratically at a flow rate of 1.0 mL/min. A small amount of toluene was added to each sample to estimate the void volume and aid the identification of the CLA isomers relative to 9*c*11*t*-18:2 [34].

### Identification and Quantitation of FAMES and DMAs

The FAMES were identified by comparison with known FAME standards, which included GC standard mixture #463, CLA mixture #UC-59M with all four positional isomers, plus other FAMES (21:0, 23:0 and 26:0), all available from Nu-Chek Prep. (Elysian, MN, USA) [28, 32, 55, 56]. The DMAs were identified by their ease of cleavage under HCl fumes [47], their selective reactivity to only acid-catalyzed methylation [28, 32], their characteristic separation from FAMES by TLC using 1,2-dichloroethane as developing solvent [49], and by their GC chromatographic profiles. The individual DMAs were identified after conversion to cyclic acetals [52] and subsequent analysis by GC. No standards of DMAs or their cyclic acetals were available. Identification of the cyclic acetals was based on their relative elution order and their similarity to the FAME profiles. The structures of the major DMAs and cyclic acetals were confirmed by GC/MS.

Quantitation of the FAMES and DMAs was based on the FID response of the acid-catalyzed methylation products. The CLA isomers were quantitated using the GC FID response, while the relative proportion of most CLA isomers was complemented using the Ag<sup>+</sup>-HPLC separation [28]. Quantitation of the unresolved *trans* 18:1 isomers required a prior separation by Ag<sup>+</sup>-TLC and subsequent analysis of the *trans* fraction using a GC temperature program starting at 120 °C. The *trans*-18:1 isomers 6*t*- to 11*t*-18:1 were well separated and free of interferences after using both GC programs and therefore served as internal comparisons [28]. The sum of all DMA and AME peaks in the GC chromatogram from the acid-catalyzed methylation mixture was used to quantitate the total alk-1-enyl content of the meat lipids. The composition of the alk-1-enyl moieties was obtained by GC analysis of the cyclic acetals.

## Statistical Analysis

The data from the second study was analyzed as six separate treatments using the GLM procedure of SAS [57]. Farm and sampling times were not used as factors given that true farm and time effects could not be determined due to confounding dietary differences between farms. In addition, the amount of feed provided per sheep was an estimate based on the amount of feed provided to the herd, and no analysis of the feed was determined. Statistical differences between the groups were identified at  $P < 0.05$  using Duncan's multiple range test.

## Results

In the first study, 80 sheep were sampled with a mean age of  $4.5 \pm 1.1$  years (range 2–7 years), a mean live weight of  $42.5 \pm 5.7$  kg (range 30–56.5 kg), and a carcass mean weight of  $18.0 \pm 3.1$  kg (range 12–25.2 kg) after 1 h, and  $17.6 \pm 3.1$  kg (range 11.7–24.9 kg) after 24 h following slaughter. The slaughter yield was  $42.3 \pm 3.9\%$  and  $41.3 \pm 3.6\%$  after 1 and 24 h, respectively. The mean carcass pH after 1 h was  $6.7 \pm 0.2$  (range 5.5–7.5) and  $5.7 \pm 0.1$  (range 5.2–6.3) after 24 h. The pH declined markedly in the first 5 h after slaughter, from 6.4 to 5.9, and more slowly thereafter, reaching a final value of 5.7. The mean temperature of the carcasses was  $32.1 \pm 1.9$  °C (range 27.3–36.2 °C) after 1 h and  $3.8 \pm 1.9$  °C (range 1.1–9.0 °C) after 24 h. The cooling curve was regular, with the temperature falling below 7 °C in about 8 h and below 4 °C in about 12 h. For more detailed information on the characteristics of the Sarda sheep meat, see Mazzette et al. [58].

The mean total meat lipid contents of the 80 sheep randomly sampled at the abattoir in 2002 were  $47.1 \pm 26.0$  mg/g of wet weight of tissue in April,  $56.40 \pm 19.5$  in May,  $54.51 \pm 32.0$  in June and  $59.15 \pm 26.0$  in July. The variability among samples was high, and there were no significant differences among different time periods. The rainfall from January to July 2002 was 310 mm (<http://www.sar.sardegna.it>). The sheep were randomly selected after being raised in Northern Sardinia, and no diet information was available. In the following year (2003), Sarda sheep were sampled from three farm operations near Sassari, where information on the type and amount of feed supplemented was reported (Table 1), but the detailed FA composition was not determined. The total lipid content in the meat sampled in April was significantly higher than in July from farms M and A,

while farm P showed no significant differences between time periods (Table 2). In 2003 more rainfall was reported from January to July (355 mm) compared to the same period in 2002.

In this study, we report the FA and alkenyl ether compositions of total sheep meat available in a specific cut of *longissimus dorsi* muscle from sheep. No attempt was made to analyze neutral and phospholipids separately, or the individual lipid class, but superficial fat was trimmed. This was done to more accurately reflect the total lipids available in a common cut of Sarda sheep meat. The total meat lipids from a few sheep were analyzed for their complete lipid compositions in order to assess the relative lipid profile. The lipid subclasses were resolved using a three-directional TLC system (Fig. 1), and individual lipid classes were estimated by densitometry [47]. The major neutral lipids in sheep meat were triacylglycerol (TAG; ~50%) and free cholesterol (C; ~4%), while the major phospholipids were phosphatidylcholine (PC; ~23%), followed by phosphatidylethanolamine (PE; ~13%), diphosphatidylglycerol (DPG; ~4%) and sphingomyelin (SM; ~3%). There were small amounts of phosphatidylserine (PS), phosphatidylinositol (PI) and cholesterol esters (CEs). Each of the phospholipids may include different proportions of the 1,2-diacyl- and 1-alk-1-enyl, 2-acyl- structures that were not resolved by TLC. FFAs were present in the meat lipids since the cuts were obtained 24 h after slaughter, which would have caused some lipid autolysis. Every effort was made in the second study to minimize further endogenous lipase activity by freezing and storing the tissue, and pulverizing the meat tissue at dry ice temperatures [45]. Plasmalogenic lipids were detected, mainly in the PE and much less in the PC fractions of sheep meat lipids as determined by exposing the separated lipids on the TLC plate to HCl fumes after the first development and before the second TLC development [47]; these results are not shown here.

The variation in the FA compositions of Sarda sheep randomly selected from April to July 2002 study was extensive. Only selected data from the first study will be presented here to demonstrate these wide differences, even though it could be argued that they more accurately reflect the FA composition of Sarda sheep from Sardinia. The FA compositions of the *longissimus dorsi* muscles from the 36 sheep sampled in the second trial are shown in Table 2. The relative concentrations of *trans*-18:1, CLA and plasmalogenic lipids were corrected by combining the results from different chromatographic techniques; see the “Materials and methods” section. In general, the FA profiles for the muscles of the sheep in the second study showed only

**Table 2** Total lipid composition (% of total FID response) of Sarda sheep muscle sampled at three farms (Muzzoni, Area, and Piras) and at two time periods (April and July)

Values are means of six sheep sampled per farm and per time period. Means with different superscript letters are significantly different at  $P < 0.05$ . 9c-18:1 contains very small amounts of 10c-18:1, LC n-6 PUFAs include 20:2n-6, 20:3n-6, 20:4n-6 and 22:4n-6, and LC n-3 PUFAs include 20:5n-3, 22:5n-3 and 22:6n-3

Abbreviations: Branched-chain fatty acid (FA) iso and anteiso (ai), CLA conjugated fatty acid, DMA dimethyl acetal, FID flame ionization detector, LC long-chain, MUFA monounsaturated fatty acid, PUFA polyunsaturated fatty acid, SEM standard error of the mean, SFA saturated fatty acid

minor differences since all of the sheep were mainly pasture-fed, with minor differences occurring between the type and amount of supplements provided; climate and grazing conditions were also similar.

### Saturated Fatty Acids (SFAs)

The total SFA content ranged from 42 to 45% of total FA, and consisted mainly of 16:0 (21–24%) and 18:0 (15–17%), with minor amounts of 14:0 (1.6–2.0%), 17:0 (1%) and 15:0 (0.3%), and trace amounts of long-chain SFA (19:0, 20:0, 22:0, and 24:0). There were significant differences between the farms. Farm A consistently showed lower levels of total SFA than farm M,

specifically in 16:0 (Table 2). The difference in SFA could be related to the amount of supplement provided on farm M compared to farm A before April (300 vs. 100 g/sheep) (Table 1); both barley and peas contain appreciable amounts (about 23%) of 16:0. The relative difference in SFA and 16:0 persisted into the results obtained in July, which indicates that the actual switchover from supplement to pasture after April appears uncertain.

Branched-chain FAs are common constituents in the fat of ruminants. The sheep meat in the present study contained small amount of iso and anteiso FAs that ranged from 1.4 to 1.6% of total FAs. There were no differences in the contents of branched-chain FAs between the farms and sampling times. The feeding of cereal starches (mixtures of peas, barley and corn) is known to increase the level of branched-chain FAs in ruminants [59].

### Monounsaturated Fatty Acids (MUFAs)

The total content of *cis*-MUFA in the sheep meat ranged from 40 to 44% (Table 2), and consisted mainly of 18:1 (35–38%) and 16:1 (1.4–1.6%), with trace amounts of 20:1 and 24:1. Except for a higher content of total *cis*-MUFA at farm A in April, there were no significant differences in the *cis*-MUFA contents between farms and sampling times. The *trans*-MUFA consisted mainly of 18:1 (3–4%) and 16:1 (0.3–0.4%). In this case, farm A, which had the lowest supplementation of a barley concentrate, consistently showed the highest *trans*-18:1 and *trans*-16:1 contents in sheep meat, while farm M had the lowest TFA contents (Table 2).

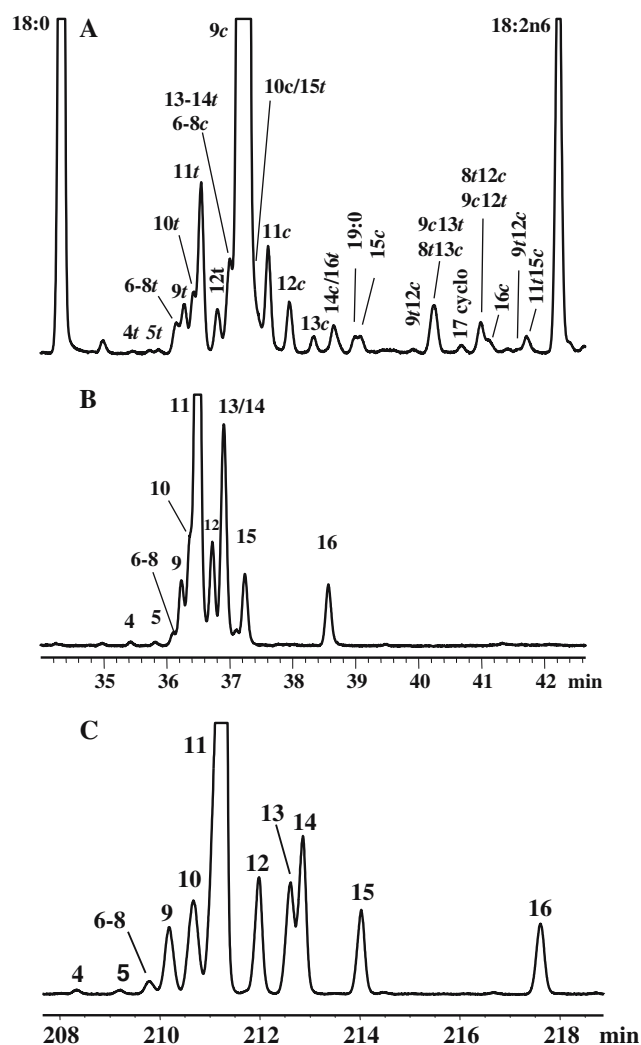

### *Cis*- and *Trans*-18:1 Isomers

There was extensive overlap of the geometric and positional 18:1 FAME isomers in the sheep meat fat

**Fig. 1** Three-directional TLC separation of total sheep muscle lipid classes on silica gel H plates. Solvent 1: chloroform/methanol/ammonium hydroxide (65:25:4), solvent 2: chloroform/acetone/methanol/acetic acid/water (50:20:10:15:5), solvent 3: hexane/diethyl ether/acetic acid (85:15:1). For the identities of the abbreviated lipid classes, see the “Results” section

**Fig. 2A–C** A partial GC chromatogram of the 18:0 to 18:2n-6 region of total FAME from sheep muscle fat (**A**), and the isolated *trans* band isolated by  $\text{Ag}^+$ -TLC (**B**), analyzed using a GC temperature program from 45 to 215 °C. The same *trans* band was analyzed by GC using an isothermal low temperature program starting at 120 °C (**C**)

(Fig. 2A), despite using a 100 m highly polar capillary GC column. The resolution of several 18:1 isomers was slightly improved by applying lower sample loads onto the GC. The content of 13*t*-/14*t*-18:1 is often overestimated because of a lack of baseline resolution from the dominant 9*c*-18:1 peak in ruminant fats, while 15*t*- and 16*t*-18:1 were not resolved from 9*c*-18:1 and 14*c*-18:1, respectively. Depending on the relative concentrations of 10*t*- or 11*t*-18:1 isomers, the quantitation of 6*t*-8*t*- to 11*t*-18:1 isomers is also an estimate (Fig. 2A). A more reliable analysis of all the *trans*- and *cis*-18:1 isomers requires prior separation of the FAMES by  $\text{Ag}^+$ -TLC followed by low-temperature GC analyses [28, 31, 32, 54, 55]. Figure 2B shows a GC separation of the isolated *trans* band of total sheep meat FAMES by

$\text{Ag}^+$ -TLC using the same temperature program, while Fig. 2C shows the improved separation of the *trans* band achieved by using a low-temperature GC program starting at 120 °C.

The relative compositions of the individual *trans*-18:1 isomers are presented in Table 3. The major *trans*-18:1 isomer was 11*t*-18:1, which ranged from 34 to 48% of the total *trans* 18:1 isomers, or 1.2–1.9% of total methylated lipids (Table 2). The content of 11*t*-18:1 was significantly ( $P < 0.001$ ) lower in sheep muscle from farm M compared to A and P at both sampling periods. The second most abundant *trans*-18:1 isomers were the combined 13*t*-/14*t*-18:1 pair that were significantly lower ( $P < 0.01$ ) in the July than in the April samples at farms A and P when expressed as percent of total *trans*-18:1 (Table 3), and significantly higher ( $P < 0.05$ ) at farm M compared to the other two farms when expressed as percent of total FAME (0.83 vs 0.77%). Of the remaining *trans*-18:1 isomers, five isomers ranged in content from 5 to 9% (9*t*-, 10*t*-, 12*t*-, 15*t*- and 16*t*-18:1), while the unresolved isomers 6*t*- to 8*t*-18:1 were present at 3–4%, and trace amounts of 4*t*- and 5*t*-18:1 were observed.

Figure 3 (top) shows a partial GC chromatogram of 6*t*-8*t*- to 13*t*-/14*t*-18:1 from selected sheep meat lipids, representing the maximum range in the *trans*-18:1 isomer distributions observed in the 2003 samples. In all cases 11*t*-18:1 was the dominant *trans*-18:1 isomer. This was in contrast to the larger variation in *trans*-18:1 isomer compositions observed in the sheep meat lipids from the 2002 study (Fig. 3, bottom) in which 10*t*-18:1 was the second most abundant *trans*-18:1 isomer. In addition, the total *trans*-18:1 content was significantly lower in the 2002 meat samples (2.7%) compared to 2003 (3.8%). The difference in the total *trans*-18:1 contents and relative distributions of the individual *trans*-18:1 isomers appears to reflect lower quality feed supplementation and/or consumption of poorer quality pasture. *Trans*-18:1 isomers are the products of partial biohydrogenation of precursor dietary PUFAs [3].

Of the *cis*-18:1 isomers, oleic acid (9*c*-18:1) accounted for 33–36% of the total methylated lipids (Table 2), or 95–96% relative to the other *cis*-18:1 isomers; there were no significant time and farm differences. The second most abundant *cis*-18:1 isomer was 11*c*-18:1 at 0.7–0.8% of total lipids, while the remaining *cis*-18:1 isomers were present at about 0.2% (12*c*-, 14*c*- and 15*c*-18:1) and 0.1% (13*c*- and 16*c*-18:1) of total lipids (Table 2). In general there were no significant time differences for any of the isomers, but farm A consistently showed higher values of 13*c*- and 15*c*-18:1 and a lower value of 12*c*-18:1 compared to the other two farms.

**Table 3** Relative distributions (%) of total *trans*-18:1 isomers in Sarda sheep muscle fat

Values are means for six sheep sampled per farm and per time period. Three farms (Muzzoni, Area, and Piras) were sampled at two time periods (April and July). Means with different superscript letters are significantly different at  $P < 0.05$ . For abbreviations see Table 2

### 16:1 Isomers

Total *trans*-16:1 contents ranged from 0.26 to 0.38% of total FAME in sheep muscle (Table 2). In general, the

**Fig. 3** Partial GC chromatograms of the *trans*-18:1 isomers from 6*t*/7*t*/8*t*-18:1 to 13*t*/14*t*-18:1. The total sheep meat FAMES were selected from the 2002 and 2003 studies that represent the maximum variations in the relative abundances of these *trans*-18:1 isomers

values appeared higher during the April than the July sampling, and higher at farm A than farm M. These differences in *trans*-16:1 content were similar to those observed for the *trans*-18:1 isomers. The relative contents of the *cis*-16:1 isomers showed no regional and time differences and ranged from 1.4 to 1.6% of total methylated lipids. The most abundant *cis*-16:1 isomer was 9*c*-16:1, and its relative abundance ranged from 31 to 35% of the total *cis*-16:1 isomers (data not shown).

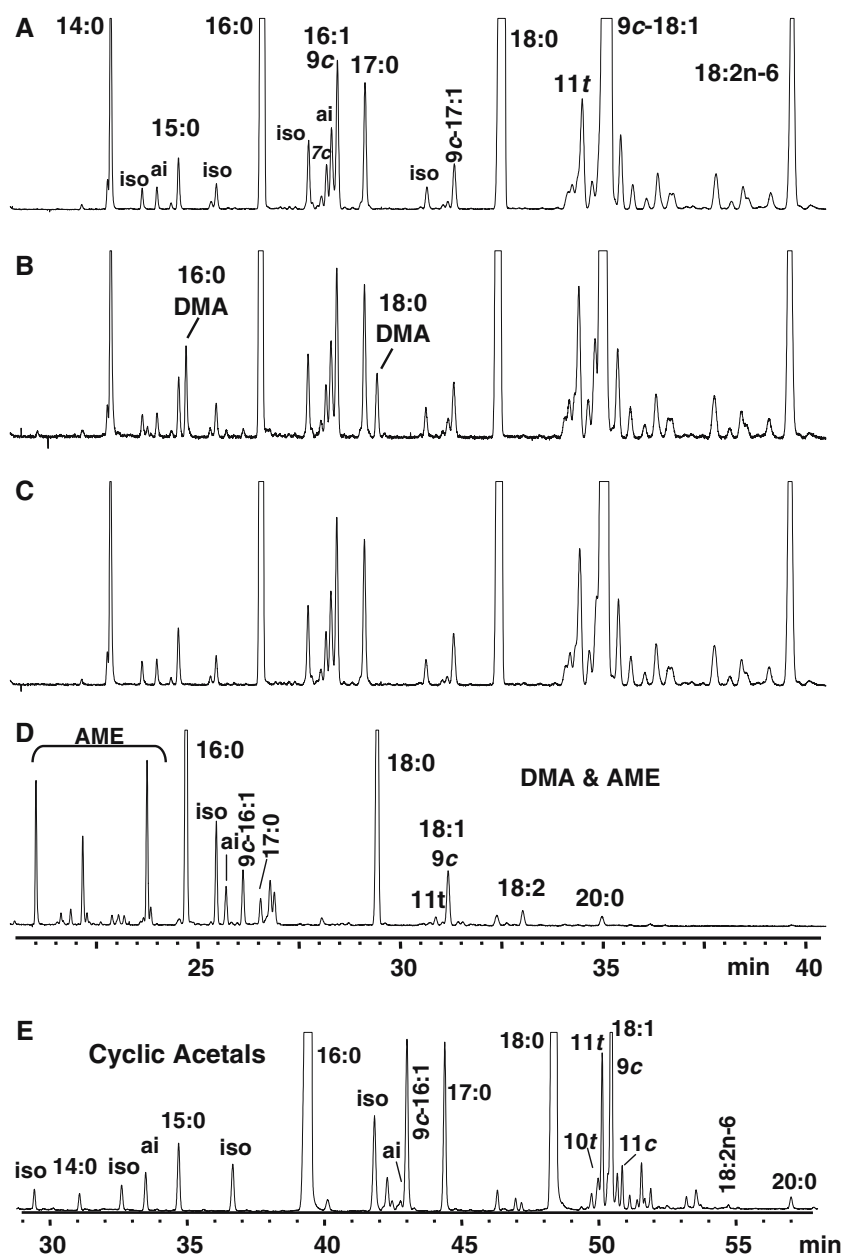

### Δ9 Desaturase Activities

The Δ9 desaturase activity was determined for a number of FA pairs, including 14:0/9*c*-14:1, 16:0/9*c*-16:1, 17:0/9*c*-17:1, 18:0/9*c*-18:1, and 11*t*-18:1/9*c*11*t*-18:2. There were no significant differences in the Δ9 desaturase ratios for each of the FA pairs (Table 2). Differences in amount and type of supplement added had little effect on the Δ9 desaturase activities.

### Dimethylacetals (DMAs) Derived from Plasmalogenic Lipids

A partial GC chromatogram of the 12:0 to 18:2*n*-6 FAMES from total sheep meat lipids is shown in Fig. 4. The total base- and acid-catalyzed methylation products are shown in Fig. 4A and B respectively, while the isolated FAME and DMA fractions obtained after TLC separation from the acid-catalyzed methylated meat mixture are shown in Fig. 4C and D, respectively. The same GC temperature program was used for all separations. The results clearly indicate that the base catalyst did not methylate plasmalogenic lipids (Fig. 4A), while the acid catalyst did (Fig. 4B). Thermal degradation of the DMAs [RCH<sub>2</sub>-CH(OCH<sub>3</sub>)<sub>2</sub>] in

**Fig. 4A–E** Partial GC chromatograms of total sheep lipids methylated using a base- (**A**) or an acid-catalyzed procedure (**B**). The acid-catalyzed methylation mixture (**B**) was resolved by TLC (developing solvent, 1,2-dichloroethane) into the FAMES derived from *O*-acyl lipids (**C**) and dimethylacetals (DMAs) from the plasmalogenic lipids (**D**). The DMA mixture was converted to the more stable cyclic acetals (**E**) used to determine the alk-1-enyl composition. All GC separations were performed using the same GC column and temperature program; see the “Materials and Methods” section. The temperature of the injection port (250 °C) caused partial loss of one methanol from the DMAs to form a mixture of alk-1-enyl methyl ethers (AMEs) and DMAs

the injection port during GC analysis resulted in the loss of methanol from DMA to form alk-1-enyl methyl ethers [AMEs;  $\text{RCH}=\text{CH}(\text{OCH}_3)$ ], as previously reported [50]. The identification of the resultant AMEs is complicated since they occur as mixtures of *cis* and *trans* conformations [51]. The extent of AME formation from DMA is a function of a number of variables, including the GC injection temperature, injection parameters, and mode of injection. Separation of the FAMES from the DMAs by TLC followed by GC analysis of the fractions permitted the identification of the peaks associated with the DMAs and AMEs (Fig. 4). The elution order for any specific alk-1-enyl

chain length was FAME > DMA > AME. On the 100 m CP Sil 88 column, the saturated 18:0 and 16:0 DMAs eluted at CN 17.05 and 15.05 relative to FAME, respectively, while the monounsaturated 9c-18:1 and 9c-16:1 DMA eluted at CN 17.68 and CN 15.68, respectively.

The plasmalogenic lipids in the total methylated reaction mixture were quantitated by adding the total area response for all DMA and AME peaks in Fig. 4B. These peaks were identified by comparing the GC results of the isolated DMAs obtained by TLC (Fig. 4D) to the total acid-catalyzed FAMES (Fig. 4B). To identify the alk-1-enyl moieties of the plasmalogenic

Values are means of six sheep sampled per farm and per time period. Three farms (Muzzoni, Area, and Piras) were sampled at two time periods (April and July). Means with different superscript letters are significantly different at  $P < 0.05$ . 9*c*-18:1 contains minor amounts of 13*t*-14*t*- and 10*c*-18:1. For abbreviations, see Table 2

lipids, the DMAs were converted to stable 1,3-dioxolane derivatives that are stable under GC conditions [52]. The plasmalogenic lipid content was determined by combining all the DMA and AME peaks in the acid-catalyzed mixture. The alk-1-enyl ether composition was obtained by analyzing the 1,3-dioxolane derivatives (Fig. 4E).

The total DMAs accounted for 1.9–2.9% of the total lipids in the sheep meat (Table 2). The relative composition of the alk-1-enyl chains of the plasmalogenic lipids in sheep meat is shown in Table 4. The alkenyl chains consisted mainly of saturated moieties (83–86%), mostly 16:0 and 18:0 (67–69%), but substantial amounts of iso (4.8%) and anteiso chains (4.7%) were also present. There were some significant differences between samplings but they were not consistently related to farm or time period. The *trans*-18:1 contents ranged from 2.2 to 4.9% with 11*t*-18:1 being the major isomer, and farm A showing consistently higher levels than farm M. The pattern for the *trans*-18:1 isomers and the relatively increased amounts of 11*t*-18:1 were similar to those observed for the *trans*-18:1 FAMES; see below. The total *cis*-18:1 alkenyl ethers ranged from 5.0 to 7.6% with 9*c*-18:1 being the predominant *cis*-18:1 isomer (87–92%); there were no consistent time or farm differences in any of the *cis*-18:1 isomers. Only trace amounts of 18:2 were detected. No peaks could be identified in the expected conjugated 18:2

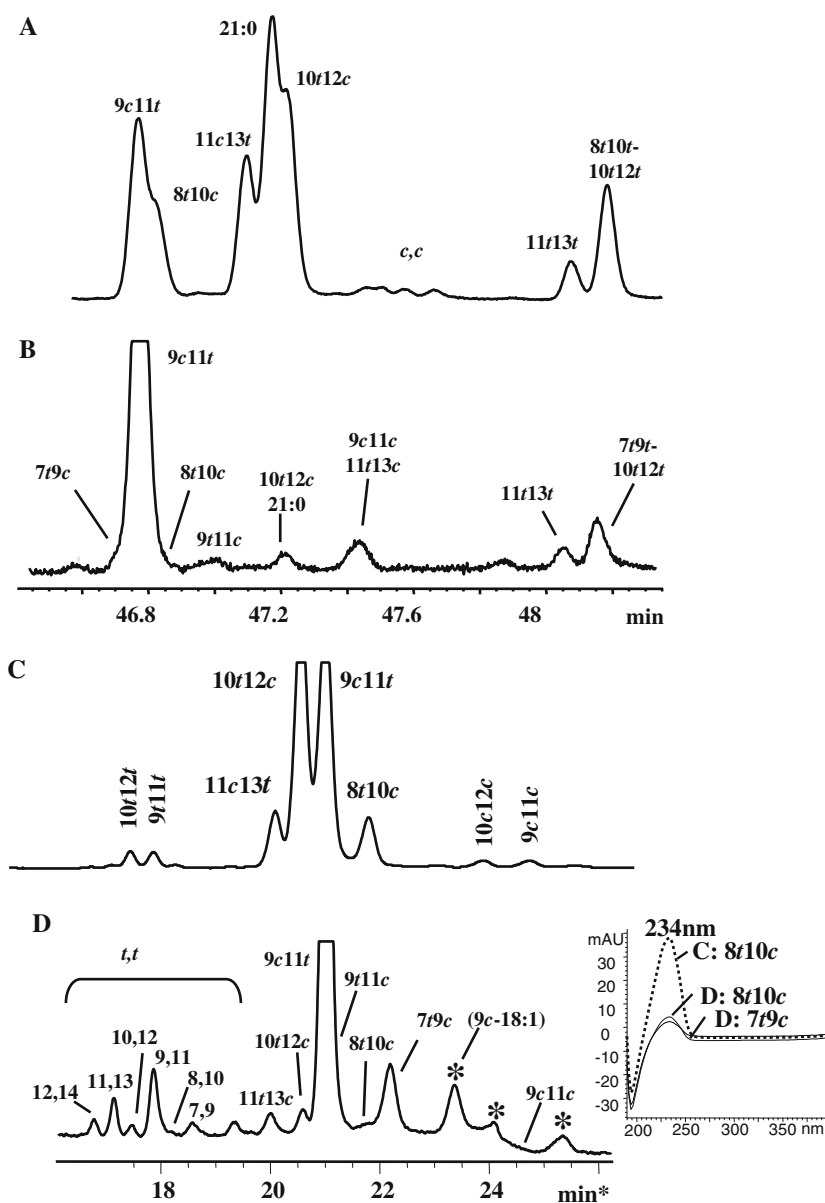

region, but that was difficult to ascertain since no standards were available.

#### Conjugated Linoleic Acid (CLA) Isomers

Figure 5 shows a comparison of the GC (5B) and Ag<sup>+</sup>-HPLC (5D) separations of a representative total sheep muscle FAME mixture. Only the base-catalyzed methylation mixtures were used for the assessment of the CLA region since acid-catalyzed methylation caused extensive isomerization [36]. The CLA isomers were identified by comparison to a CLA standard analyzed by GC (Fig. 5A) and Ag<sup>+</sup>-HPLC (Fig. 5C) that was spiked with 21:0 FAME [28]. The peak eluting between 9*c*11*t*- and 7*t*9*c*-18:2 by Ag<sup>+</sup>-HPLC was examined to see if it was 8*t*10*c*-18:2, or a conjugated triene. A conjugated triene would give a characteristic triplet absorption centered at 270 nm. As seen in the inset next to Fig. 5D, there appeared to be no evidence of a conjugated triene coeluting with 8*t*10*c*-18:2 in sheep meat lipids. Similar results were obtained when another milk fat was examined previously [34].

The total CLA contents ranged from 0.63% to 1.01% of total sheep muscle (Table 2). Table 5 shows the relative percentage of the CLA isomers in sheep meat collected during the April and July sampling. The 9*c*11*t*-18:2 isomer was the major CLA isomer of Sarda sheep muscle, accounting for 0.41–0.74% of total lipids

**Fig. 5A–D** Partial GC chromatogram of the CLA region of the standard CLA mixture (A) and a sheep meat total FAME mixture using a 100 m highly polar capillary column (B). Partial Ag<sup>+</sup>-HPLC separation of the CLA standard (C) and sheep meat total FAME (D) using three Ag<sup>+</sup>-HPLC columns in series. The UV spectra of several CLA isomers and the unknown peak eluting between 9*c*11*t*- and 7*t*9*c*-18:2 are shown in the inset of the lower Ag<sup>+</sup>-HPLC separation

(Table 2), or 60–71% of the relative CLA isomers (Table 5). The remaining CLA isomers of the sheep meat were those generally associated with either pasture (11*t*13*c*- and 11*t*13*t*-18:2; 8–12%) or concentrate feeding of ruminants (7*t*9*t*-, 9*t*11*c*-, 10*t*12*c*- and 9*t*11*t*-18:2; 12–16%) [28, 56, 60–63]. In general, farm A had the highest levels of 9*c*11*t*-18:2 and 11*t*13*c*-18:2 and the lowest levels of 7*t*9*c*-18:2, 9*t*11*c*-18:2 and 10*t*12*c*-18:2 compared to farm M during the April sampling, while the values were more similar in July, consistent with the claim that both herds were fed pasture. The difference in the contents of 9*c*11*t*-18:2 at these farms was also reflected in their relative contents of 11*t*-18:1 (Table 3). The conjugated metabolite derived from

18:3*n*-3, 9*c*11*t*15*c*-18:3, was identified in sheep meat, which eluted just before 22:0 using the 100 m CP Sil GC column and conditions. This GC peak was first thought to be 20:3*n*-9 based on the expected elution of this FA, but it was clearly distinguishable based on coinjection with a known standard of 20:3*n*-9. The identity of this conjugated 18:3 isomer was confirmed by reversed-phase HPLC analysis; see below.

Figure 6 shows a partial GC chromatogram of the wide differences in the CLA profiles of Sarda sheep meat encountered in commercial markets in Sardinia in 2002. The data from the first study showed that some sheep were mainly pasture-fed, characterized by high levels of 11*t*13*c*- and 11*t*13*t*-18:2 and 21:0 (uppermost

Values are means for six sheep sampled per farm and per time period. Three farms (Muzzoni, Area, and Piras) were sampled at two time periods (April and July). Means with different superscript letters are significantly different at  $P < 0.05$ . For abbreviations, see Table 2

CLA profile). On the other hand, other sheep meats contained less of the above and increasing amounts of 9*t*11*c*-, 10*t*12*c*- and 7*t*9*c*-18:2, typical of sheep fed concentrate or poor-quality pasture (lower CLA profiles). The complete identifications of 9*c*11*t*- and 7*t*9*c*-18:2, 11*t*13*c*- and 9*c*11*c*-18:2, and 10*t*12*c*-18:2 and 21:0 were achieved by comparing the GC and Ag<sup>+</sup>-HPLC separations, as shown in Fig. 5. The CLA isomer distribution in the sheep meat in the second study was less diverse, as shown in Table 5.

## PUFAs

The total n-6 and n-3 PUFA contents of Sarda sheep meat were averaged, yielding 5.4 and 2.3%, respectively (Table 2). The main n-6 and n-3 PUFAs in sheep meat were 18:2n-6 and 18:3n-3, present at about 4.2 and 1.3%, respectively, with a relative ratio of about 3:1 (18:2n-6/18:3n-3). There were some differences between farms and time periods, but the differences were not significant. The content of LC n-6 PUFAs (20:2n-6, 20:3n-6, 20:4n-6, and 22:4n-6) ranged from 1.0 to 1.3% of total lipids, and generally showed no

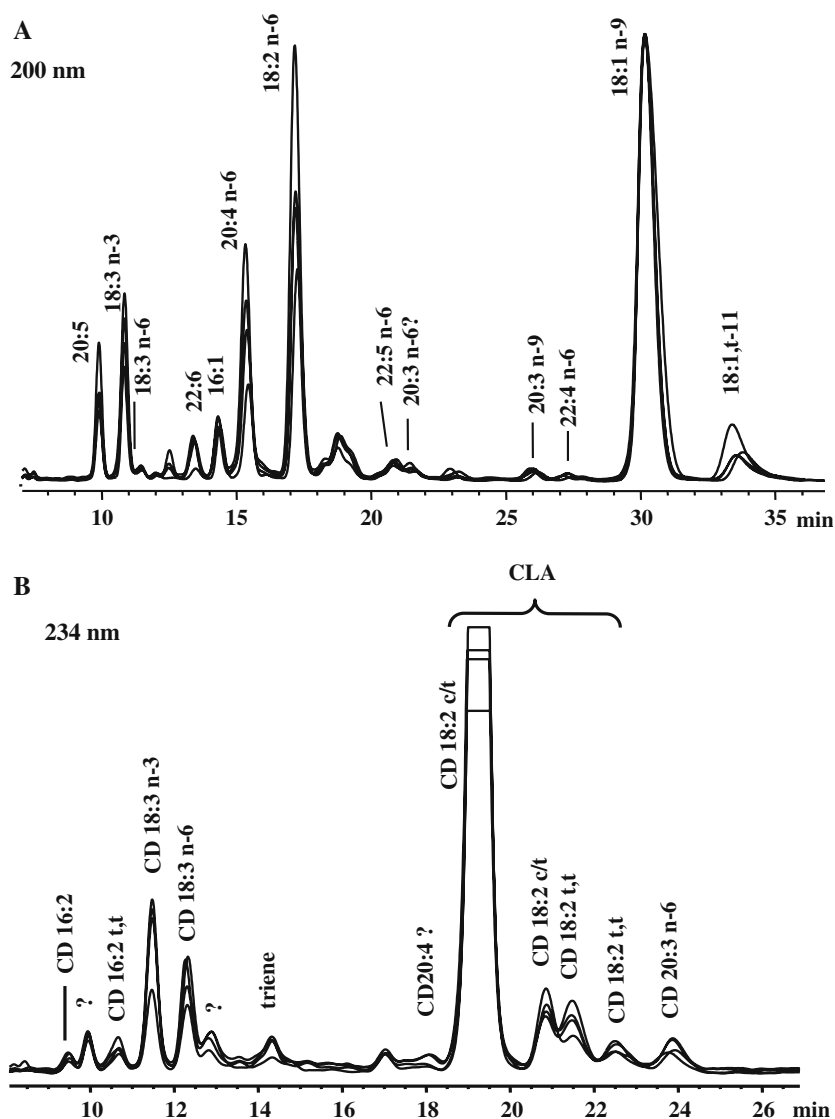

**Fig. 6** Partial GC chromatograms of the CLA region of the standard CLA mixture (upper graph) and five typical sheep meat total FAME mixtures, which represent the maximum variation observed in the CLA profiles in the 2002 study

significant farm or time differences. However, the total content of LC n-3 PUFAs (20:5n-3, 22:5n-3, 22:6n-3) in July (1.06%) was generally higher than in April (0.82%) (Table 2), which reflected the greater exposure of sheep to pasture during the early summer. The ratio of LC n-6 PUFA to LC n-3 PUFA ranged from 1.1:1 to 1.8:1. The content of LC-PUFAs relative to their essential FA precursors in sheep was 3.6:1 for the n-6 and 1.6:1 for the n-3 PUFAs.

## CLA Metabolites

The CLA metabolites were resolved by reversed-phase HPLC of their FFAs prepared from total sheep meat fat and detected using a diode array detector at 233 nm. Figure 7 shows typical separations of four total sheep muscle lipids in which the unsaturated FAs were recorded at 200 nm (Fig. 7A) and the conjugated dienes (CD) at 234 nm (Fig. 7B). The contents of the CLA metabolites in Sarda sheep muscle are summarized in Table 6. The major CD FA was 9*c*11*t*-18:2, and it was

**Fig. 7A–B** Partial RP-HPLC chromatograms showing the variation in unsaturated unconjugated FA contents recorded at 200 nm (**A**) and conjugated diene contents recorded at 234 nm (**B**) for four representative sheep muscle samples. Operating conditions: C18 reversed-phase column, mobile phase: CH<sub>3</sub>CN/H<sub>2</sub>O/CH<sub>3</sub>COOH (70/30/0.12)

significantly higher in the sheep meat from farm A than in that from farm M, consistent with the GC results (Table 2). Two separate CD 18:3 FA metabolites were identified derived from the n-3 or n-6 series of FA, as previously observed [41]. The CD derived from 18:3n-3 was the second most abundant CD FA in sheep meat, and it was identified as 9*c*11*t*15*c*-18:3 by GC. A number of additional minor CD metabolites were detected in sheep meat, including CD 16:2, CD 16:3, CD 18:3 and CD 20:3; their concentrations increased with increased levels of 9*c*11*t*-18:2 in the meat tissue.

## Discussion

The present study provides the first complete and detailed FA composition of meat from a ruminant animal

that includes the CLA and TFA isomers and their metabolites and the LC PUFAs, as well as the alk-1-enyl ethers from the plasmalogenic lipids and the long-chain SFAs from the sphingolipids in meat. Such an analysis requires a combination of several derivatization and separation techniques to obtain the complete profile of all acyl and alkenyl groups present in ruminant meats.

Commercial Sarda sheep were selected since their total lipid composition has not yet been reported. The meat from adult Sarda sheep have been used only to a limited extent for human consumption, and an evaluation of the quality of their meat lipids may open up potential uses for this product. The total fat content of the Sarda sheep meat was somewhat higher in the sheep randomly selected in 2002 (6–9%) compared to those raised in the Sassari region and sampled in 2003

Values are means for six sheep sampled per farm and per time period. Three farms (Muzzoni, Area, and Piras) were sampled at two time periods (April and July). Means with different superscript letters are significantly different at  $P < 0.05$ . For abbreviations, see Table 2

(4–7%). These values compare to ranges of 1.5–2.5% reported in some experimental sheep herds [14, 66], to 2–4% in others [17, 67, 68], and values as high as 5–6% [15, 69]. The high lipid content in the Sarda sheep appears to be related mainly to their age, with older sheep showing higher fat levels [16], and less to diet supplementation [14]. The high lipid content in Sarda sheep meat largely accounted for the higher levels of TAG in the sheep meat (TLC separation of total lipids Fig. 1), even though every effort was made to trim the excess fat from the sheep meat before analysis.

#### Acyl and Plasmalogenic Lipids in Meat

Meat lipids of ruminants are known to contain mainly acyl lipids in the form of TAG and phospholipids that are easily converted to their FAMES using base-catalyzed methylations. However, meat lipids also contain plasmalogenic lipids, mainly in the PE fractions that are stable to alkali conditions. Sheep muscle was reported to contain 31% as alk-1-enyl acyl PE and 5% as alk-1-enyl acyl PC [35]. Ignoring this amount of plasmalogenic lipids substantially underestimates the total lipid content of meat. Aldehydes released from the dietary plasmalogenic lipids in meats are readily oxidized to their corresponding FAs and enter the general FA pool. Characterization and analysis of plasmalogenic lipids is generally based on their stability to base-catalyzed methanolysis, and rapid conversion to their dimethylacetals under acid-catalyzed methanolysis conditions [28, 48, 69].

#### Methylation Procedures that Include Plasmalogenic and Sphingolipids

It would appear that the present attempts to avoid acid-catalyzed isomerization of CLA in ruminant fats [36] has resulted in the preferred use of base-catalyzed methanolysis for the analysis of meat (and milk) lipids. The attempt to successfully analyze the naturally

occurring CLA profile unfortunately ignored the presence of non-*O*-acyl lipids in meats. The initial concern over avoiding isomerization and artifact formation of CLA during methylation [36] was never intended to exclude major lipid classes such as plasmalogens and sphingomyelin [28, 32, 37, 56]. The exclusion of these two lipid classes applies to all base-catalyzed methylation procedures such as NaOCH<sub>3</sub>, trimethylsilyldiazomethane (TMS-DAM) or tetramethylguanidine [28, 32]. Alkali saponification has occasionally been used as an alternative method to prepare total FAMES from meat lipids. In that procedure, total meat lipids are first saponified using KOH/ethanol (or NaOH/ethanol) and then analyzed as such [41, 42], or converted to their FAMES using BF<sub>3</sub> [67, 70, 71], HCl [72, 73], or TMS-DAM [68] as catalysts. Even though the saponification/methylation method appears suitable since it retains the CLA isomer profile, it also lacks quantitation since the plasmalogenic and sphingolipids are again excluded from the total meat lipids. Occasionally acid-catalyzed methylation procedures were used to methylate meat lipids, but the expected DMAs were not reported [15, 16, 18, 74, 75], while others reported total DMAs in muscle phospholipids from two breeds of cattle (7.3–12.8%) but no TFA and CLA isomers [76]. Pork meat also contains plasmalogenic lipids [77]. On the other hand, Wolff [78] isolated plasmalogenic lipids from sheep heart and characterized the alk-1-enyl composition.

The general omission of both plasmalogenic lipids and sphingomyelins from the total lipids of meats underestimates the total lipid content in ruminant meats by about 8–15%, depending on the total meat lipids examined, and the relative content of phospholipids to TAG in the meat lipids since plasmalogenic lipids are present mainly in the phospholipid fraction. The plasmalogenic lipid contents of the Sarda sheep in the present study ranged from 2 to 3% of total lipids and there appears to be no difference in the meats selected (Table 2). If all the plasmalogenic lipids were

derived from PE this would represent about 15–20% in the PE fraction based on a PE content about 13% of total lipids (Fig. 1); no direct PE determinations were performed. The alkenyl composition of the plasmalogenic lipids of Sarda sheep meat consisted mainly of saturated and monounsaturated alkenyl moieties, with trace amounts of 18:2, which is consistent with previous findings [35, 78]. There was no evidence to indicate the presence of alk-1-enyl ethers containing conjugated moieties, which would suggest that CLA was not incorporated into plasmalogenic lipids. However, it was clearly evident that the *trans*-18:1 FA moieties were incorporated into the plasmalogenic lipids, since the isomer profiles of acyl and alkenyl ethers were very similar.

Sphingomyelins are generally present at about 3% in all muscular tissue from ruminants [79]. The *N*-acyl bond in sphingomyelin is stable under base-catalyzed conditions and requires an acid catalyst and extensive heating (i.e., 80 °C for 1 h) for complete methylation to FAMES [28, 32]. Therefore, this lipid fraction is also ignored when only base-catalyzed methylation procedures are used. The content of sphingomyelin in the Sarda sheep meat was estimated to be about 3–5% based on several meat lipids examined by TLC (Fig. 1). It should be noted that exclusion of sphingolipids from total meat lipid would also underestimate the SFA content, since this lipid fraction consists mainly of long-chain SFAs from 18:0 to 26:0 (data not included).

#### Recommended Methylation Procedures for Total Meat Lipids

The analytical approach used in this study for total meat lipid analysis consisted of a cold-temperature pulverization of the meat tissue to avoid lipid lipolysis, followed by extraction of total lipids using chloroform/methanol [45]. Three separate derivatization procedures were conducted. The first was an acid-catalyzed methylation using HCl/methanol at 80 °C for 1 h to obtain the total acyl and alk-1-enyl profile of meat lipids, i.e., FAMES from *O*- and *N*-acyl lipids, and DMAs from the alk-1-enyl ether lipids. This methylated mixture provided the quantitative composition of the total lipid content in meats. The second was a base-catalyzed methylation procedure using NaOCH<sub>3</sub>/methanol at 50 °C for 15 min to ensure retention of the CLA isomer profile. The third preparation involved a mild alkali hydrolysis of total lipids overnight at room temperature to prepare FFAs that were used to measure the conjugated FA metabolites using reversed-phase HPLC [41, 42]. This method provided confirmatory evidence of the CLA content, and the presence

of chain-elongated, desaturated and chain-shortened metabolites of CLA in ruminant meats. Both base-catalyzed procedures, unlike acid-catalyzed methylation, caused no isomerization of the conjugated double bonds or methoxy artifact formation [36]. However, the methylation products cannot be used to quantitate meat lipids since neither NaOCH<sub>3</sub>-catalyzed methylation or mild alkali hydrolysis included the plasmalogenic and sphingolipids.

#### *Trans* FA and CLA Isomers

Meat fat from ruminants contain TFA and CLA isomers formed as metabolic intermediates by isomerization and reduction of PUFAs in rumen bacteria [3]. The TFAs may be further metabolized by rumen bacteria to SFA, or taken up in rumen tissue lipids where some of the TFA isomers are converted to more unsaturated FAs by desaturases. All possible *trans* MUFAs from 16:1 to 22:1 have been found in ruminant fats including *trans* containing di- and tri-unsaturated FAs (28, 80, 81). The *trans*-18:1 and CLA isomer composition depends on the dietary source of PUFAs and on the amount and type of concentrate fed. Pasture-fed ruminants generally yield a high content of 11*t*-18:1, 9*c*11*t*-18:2 and 11*t*13*c*-18:2 compared to ruminants fed concentrate [56, 61, 63]. Grasses contain both essential fatty acids (18:3*n*-3 > 18:2*n*-6) that act as precursors for 11*t* containing FAs. Supplementing small amount of concentrate rich in 18:2*n*-6 and 18:3*n*-3 increases the levels of 11*t*-18:1 and 9*c*11*t*-18:2 in milk [62, 64, 82] and sheep meat lipids [19, 20, 68, 72, 74]. On the other hand, feeding concentrates high in digestible starch leads to increased levels of 10*t*- relative to 11*t*-18:1 in both meat [15, 20, 83, 84] and milk lipids [28, 61, 62, 85–87]. These changes are due to a reduction in the cellulolytic bacteria in the rumen population, specifically *Butyrivibrio fibrisolvens* [88–90] known to produce 11*t*-18:1 [91, 92], and a concurrent increase in the lactate-producing (*Streptococcus bovis*) and lactate-utilizing bacteria (*Selenomonas ruminantium* and *Megasphaera elsdenii*) that lead to the formation of 10*t*-containing FAs such as 10*t*-18:1 and 10*t*12*c*-18:2 [93, 94].

The sheep selected in the 2002 study indicated a wider range in the *trans*-18:1 (4.0–5.1%), total CLA (0.54–1.35%) and 9*c*11*t*-18:2 isomer (0.34–0.99%) contents. Some sheep appeared to have had access to good pasture, as evidenced by a relatively high level of 11*t*-18:1 compared to 10*t*-18:1, while other sheep had a relatively high 10*t*-18:1 to 11*t*-18:1 ratio. In addition to higher 10*t*-18:1, these sheep meats also contained higher levels of 7*t*9*c*-, 9*t*11*c*- and 10*t*12*c*-18:2, while

pasture-fed sheep had higher levels of 11*t*-18:1 and 9*c*11*t*-18:2 and 11*t*13*c*-18:2. Comparison of the present results for the *trans* 18:1 and CLA isomers in sheep meat with those reported by others was generally not possible, since a clear separation of 10*t*- and 11*t*-18:1 was not reported [14–19, 66–68, 70] and 9*c*11*t*-18:2 was generally overestimated by the amount of the coeluting 7*t*9*c*-18:2 isomer; the latter could only be resolved using a complementary Ag<sup>+</sup>-HPLC technique [28, 32, 33, 95]. The 7*t*9*c*-18:2 isomer generally occurs as the second most abundant isomer in bovine milk [60, 62, 95] and beef fat [9, 10, 12, 13, 95] when concentrate diets are fed, while in pasture-fed ruminants the second most abundant CLA isomer is 11*t*13*c*-18:2, and 7*t*9*c*-18:2 is greatly reduced [56, 61]. Bessa et al. [20] recently reported a more complete *trans*-18:1 composition for sheep meat that clearly showed increased levels of 10*t*-18:1 and 10*t*12*c*-18:2 in sheep meat when concentrates were fed and soybean oil was included in a forage diet.

These results from the 2002 study stand in contrast to the compositions found in the sheep selected in the 2003 study, when all the sheep meats showed 11*t*-18:1 as the predominant *trans*-18:1 isomer, and 9*c*11*t*-18:2 and 11*t*13*c*-18:2 as the major CLA isomers; the total contents of the *trans*-18:1 and the CLA isomers ranged from 3.44 to 4.25% and 0.63 to 1.01%, respectively. These results indicate the importance of good management practices where pasture-fed sheep are supplemented with moderate amounts of concentrate to provide additional PUFAs. The corn, peas and barley mixture given to the sheep at the Sassari farms provided about 51–56% 18:2*n*-6 from all three ingredients, and peas (9%) and barley (6%) provided additional 18:3*n*-3. Among the three farms, farm A generally showed the highest levels of 11*t*-18:1, 9*c*11*t*-18:2 and 11*t*13*c*-18:2, and the lowest levels of 7*t*9*c*-, 9*t*11*c*- and 10*c*12*t*-18:2. These results suggest that farm A was more successful in producing sheep meat that maximized the content and composition of *trans*-18:1 and CLA isomers, yielding a healthier image than the other two farms. The feeding records show that farm A achieved this by provided a smaller amount of supplement of barley rich in 18:2*n*-6 and 18:3*n*-3 in the spring, unlike farm M that provided a larger amount of supplement in the spring, or farm P that supplied a higher supplement throughout the whole period. A balanced feeding approach of adding supplements to pasture-fed ruminants resulted in improved meat quality based on the *trans*-18:1 and CLA isomer content and composition. A similar approach was successfully used to increase the 11*t*-18:1 and 9*c*11*t*-18:2 in milk fat by supplementing pasture fed cows with a minimum of crushed oil seeds or vegetable oil in the

diet [61, 64, 65], and similarly in meat lipids [19, 20, 68, 72, 74]. On the other hand, feeding consistently high levels of concentrates generally result in high levels of undesirable 10*t*-18:1 and CLA isomers, such as 10*t*12*c*-, 9*t*11*c*- and 7*t*-9*c*-18:2.

#### CLA Metabolites

The content of the conjugated FAs other than 9*c*11*t*-18:2 was significantly higher in sheep slaughtered in July than April, reflecting the higher content of pasture feeding during the early summer period. These non-CLA conjugated FAs were present in trace amounts and were identified as their FFAs by UV at 233 nm using RP-HPLC (Table 6). Generally these minor conjugated FAs could not be identified by GC, except for the conjugated 18:3 metabolite 9*c*11*t*15*c*-18:3 that was identified by RP-HPLC as well as GC. The 9*c*11*t*-18:2 CLA isomer was previously shown to convert to CD 18:3, CD 20:3 and CD 20:4 metabolites by endogenous desaturation and elongation in ruminants [41], rats [96, 97], and humans [98], or to CD 16:2 and CD 16:3 FAs by peroxisomal  $\beta$ -oxidation [43].

#### Essential Fatty Acids

The contents and relative compositions of the essential FAs and their LC derivatives are of interest when assessing the quality of meat lipids, since these PUFAs from meat serve as a source of essential FAs in our diet. The meat from the Sarda sheep provided both *n*-6 (6–8%) and *n*-3 PUFAs (2–3%), as well as their LC *n*-6 (1–1.3%) and *n*-3 (0.6–1.2%) PUFA derivatives. The *n*-6/*n*-3 ratio in the Sarda meat lipids from the selected farms in 2003 averaged 3.2 for all the PUFAs and 1.3 for the LC PUFAs; the latter included the C20 and C22 PUFAs. The results from the sheep randomly selected during the 2002 season showed greater variation and their *n*-6/*n*-3 PUFA (2.3) and LC *n*-6/LC *n*-3 PUFA ratios (0.8) were not as good. A number of factors contributed to the improved essential FA status in the meat lipids in 2003, such as the higher precipitation recorded in 2003 compared to 2002, possibly better forage quality, and management practices that included the addition of some supplements to provide dietary 18:2*n*-6 and 18:3*n*-3. Based on the amount and *n*-6/*n*-3 ratio of the PUFAs, most of the Sarda meat would appear to qualify as an acceptable source of essential FAs. However, it should be noted that meat quality characteristics such as tenderness, moisture and taste were not addressed in this study.

The PUFA contents in the sheep meat would have been influenced by the FA composition of the herbage

and supplemented diets provided, but that information was not available. A recent survey on the FAs available in several botanical groups typically found in Mediterranean pastures during the growth and reproductive stages of the plants [99] was helpful. The 18:3n-3 contents in all of the five forage species reported by Cabiddu et al. [99] were more than 60%, with a range of 18:3n-3/18:2n-6 of 3–7. However, this data was of limited value since such pastures might not have been available to the sheep, particularly during the dry spells common in Sardinia. Furthermore, supplements of unknown composition may have been provided to the sheep in the first study.

Despite the semiarid climate in Sardinia, the 18:2n-6 (4.2%) and 18:3n-3 (1.2%) contents in the commercial Sarda sheep compared well with those of commercial lambs surveyed from Germany (5.5 and 1.5%), the United Kingdom (3.9 and 1.6%) and Uruguay (5.1 and 3.3%) [16]. The average contents of 18:2n-6 and 18:3n-3 in three breeds of sheep raised on dried grass in the United Kingdom also showed similar levels (4.1 and 2.0%) [68]. However, the total LC PUFA content (2%; 20:3n-6, 20:4n-6, 22:4n-6, 20:5n-3, 22:5n-3 and 22:6n-3) in the Sarda sheep (2%) was less than that found in commercial sheep in Germany (2.7%), the United Kingdom (3.3%) and Uruguay (3.7%) [16], and in the study by Washira et al. [68] (3.9%). Lambs fed exclusively fresh pasture generally showed increased levels of C18 PUFAs and LC PUFAs, as observed in the Marino Branco lambs fed a lucerne grass diet in Portugal [20], and in a study conducted by Nuernberg et al. [66]. On the other hand, the feeding of concentrates enhanced the dietary FAs and their LC metabolites: 18:2n-6 and LC n-6 PUFAs when soybean oil was included [20], 18:3n-3 and LC n-3 PUFAs when linseed was included [68], the C18 PUFAs and the LC PUFAs when cereal grains were fed [16, 66], and LC n-3 PUFAs when fish oil was included in the diet [68]. Based on these findings, it is clear that the FA profile of Sarda sheep meat can be improved by optimizing the type and amount of concentrate provided to the pasture-fed sheep.

### Saturated Fatty Acids

The ratios of SFA to PUFA in the Sarda sheep ranged from 4:1 to 5:1, which is similar to the FA compositions of commercial sheep in different countries [16, 17, 68], but unlike sheep fed, under controlled conditions, diets rich in PUFA or exclusively rich pastures [20, 66, 68]. The high ratio of SFA to PUFA reflects the high content of TAG in Sarda sheep meat lipids and the inclusion of sphingolipids in the analysis.

**Abstract** The *sn* position of fatty acids in seed oil lipids affects physiological function in pharmaceutical and dietary applications. In this study the composition of acyl-chain substituents in the *sn* positions of glycerol backbones in triacylglycerols (TAG) have been compared. TAG from native and transgenic medium-chain fatty acid-enriched rape seed oil were analyzed by reversed-phase high performance liquid chromatography coupled with online atmospheric-pressure chemical ionization ion-trap mass spectrometry. The transformation of summer rape with thioesterase and 3-ketoacyl-[ACP]-synthase genes of *Cuphea lanceolata* led to increased expression of 1.5% (*w/w*) caprylic acid (8:0), 6.7% (*w/w*) capric acid (10:0), 0.9% (*w/w*) lauric acid (12:0), and 0.2% (*w/w*) myristic acid (14:0). In contrast, linoleic (18:2n6) and alpha-linolenic acid (18:3n3) levels decreased compared with the original seed oil. The TAG *sn* position distribution of fatty acids was also modified. The original oil included eleven unique TAG species whereas the transgenic oil contained sixty. Twenty species were common to both oils. The transgenic oil included trioctadecenoyl-glycerol (18:1/18:1/18:1) and trioctadecatrienoyl-glycerol (18:3/18:3/18:3) whereas the native oil included only the latter. The transgenic TAG were dominated by combinations of caprylic, capric, lauric, myristic, palmitic (16:0), stearic (18:0), oleic (18:1n9), linoleic, arachidic (20:0), behenic (22:0), and lignoceric acids (24:0), which accounted for 52% of the total fat. In the original TAG palmitic, stearic, oleic, and

linoleic acids accounted for 50% of the total fat. Medium-chain triacylglycerols with capric and lauric acids combined with stearic, oleic, linoleic, alpha-linolenic, arachidic, and gondoic acids (20:1n9) accounted for 25% of the transgenic oil. The medium-chain fatty acids were mainly integrated into the *sn*-1/3 position combined with the essential linoleic and alpha-linolenic acids at the *sn*-2 position. Eight species contained caprylic, capric, and lauric acids in the *sn*-2 position. The appearance of new TAG in the transgenic oil illustrates the extensive effect of genetic modification on fat metabolism by transformed plants and offers interesting possibilities for improved enteral applications.

## Abbreviations

ACP	Acyl carrier protein
APCI	Atmospheric pressure chemical ionization
AUC	Area under the curve
arb	Auxiliary gas pressure unit
CGC	Capillary gas chromatography
ESI	Electrospray ionization
FAME	Fatty acid methyl ester
HPLC	High-performance liquid chromatography
ITMS	Ion-trap mass spectrometry
MS <sup>n</sup>	Multistage sequenced mass spectrometry
MCFA	Medium-chain fatty acids
MCT	Medium-chain triacylglycerol
MUFA	Monounsaturated fatty acids
LC	Liquid chromatography
LCFA	Long-chain fatty acids

RP	Reversed phase
RT	Retention time
SAFA	Saturated fatty acids
<i>sn</i> -	Stereospecific numbering
TAG	Triacylglycerol
TIC	Total-ion chromatogram

## Introduction

The effort to refine vegetable oils for dietary, cosmetic or technical applications often requires alteration of the fatty acid composition. In this study the molecular structures of triacylglycerols (TAG) of native and transgenic rape seed oils enriched with medium-chain triacylglycerols (MCT), and the physiological consequences for dietary applications, are discussed. MCT oils, containing caprylic acid (8:0), capric acid (10:0), lauric acid (12:0), and myristic acid (14:0) have been used therapeutically since the 1950s. In the treatment of epilepsy with ketogenic diets, fat malabsorption of cystic fibrosis patients, human immune deficiency virus infected patients, and premature infants, MCT oils have been widely accepted. Physiologically, medium-chain fatty acids (MCFA) are digested, absorbed, transported, and metabolized more rapidly than long-chain fatty acids (LCFA) [1]. Milk formulas with MCT reduced lipid and lipoprotein oxidation in preterm infants [2]. In athletics, MCT are used as an ergogenic aid [3]. Recent studies have indicated the effective use of MCT in weight-reducing diets, because they enhance catabolic fat metabolism and modulate adipocyte accumulation and lipolysis [4–6].

MCT are synthetic oils based on coconut and palm kernel oil. Preparation requires acyl group modification by lipase-mediated transesterification or ester synthesis [7]. Rape seeds (*Brassica* sp.) are a frequent source of traditional or modified vegetable oils and raw material for margarine formulations. To provide new viable sources, several studies have been conducted to alter the expression pattern of MCT in rape seeds [8]. Unusual fatty acids in crop seed oils with industrial properties often occur in non-agronomic plant species which could be gene pools for biotechnological applications [9]. Transformation with medium-chain thioesterases derived from bay (*Umbellularia californica*), which inhibit acyl-chain elongation, has been found to efficiently increase MCFA in storage TAG [8, 10]. The bay MCFA-acyl carrier protein thioesterase, which induces fatty acid oxidation and biosynthesis, has been

expressed in rape to enhance MCT accumulation in the seeds [11]. In rape seed phospholipids and TAG are synthesized from the same diacylglycerol pool. Thus, the transformation of lysophosphatidic acid acyltransferase or diacylglycerol acyltransferase, both capable of efficiently incorporating MCFA into TAG, must be introduced in MCT-enriched transgenic systems [12]. The catabolic pathway, especially, has been suggested as a mechanism for engineering and controlling the fatty acid composition [12]. Different acyltransferases incorporate different MCFA at the *sn*-2 position, however [13, 14]. As a consequence, TAG structures of transgenic plants are modified. Transgenic expression of a yeast *sn*-2 acyltransferase gene or a lysophosphatidic acid acyltransferase from meadow foam into *Brassicaceae* has been reported to modify the stereospecific acyl distribution of TAG in seed oil [15, 16]. Knutzon et al. [13] increased the total laurate level of rape seed oil by transforming the lysophosphatidic acid acyltransferase of coconut endosperm, which mediates the insertion of laurate at the *sn*-2 position of TAG.

The regiospecificity of dietary TAG fatty acids affects lipid metabolism in humans. Several studies have shown that the fatty acid composition of blood and organs, for example the heart and liver, is affected by nutritional or pharmacological use of lipids [17]. In such applications the specific *sn* position of fatty acids can also determine metabolic processing. For example, digestibility in the gastrointestinal tract, absorption by intestinal enterocytes, and metabolic clearance of blood lipids might be accelerated, or the lipoprotein transport pathways of the portal or lymph system might be affected [18, 19]. In contrast with LCFA, which are transported via the lymph system, MCFA are transported via the portal vein directly to the liver for catabolism. Carvajal et al. [20] suggested that the *sn*-2 position of MCFA shifts the transport of dietary TAG to the lymphatic pathway with several consequences for lipid metabolism.

In addition to common methods for determination of the *sn* position of fatty acids by specific enzymatic digestion and subsequent liquid or gas chromatographic analysis [21], a variety of mass spectrometric methods are also available. Atmospheric-pressure chemical ionization (APCI) is a gentle ionization technique for amphiphilic molecules [22]. Multistage sequenced mass spectrometry experiments ( $MS^n$ ) with ion-trap detection enable fragmentation of defined ions and detailed analysis of molecular structure [23, 24]. Marzilli et al. [25] have analyzed TAG structures using an electrospray-ionization (ESI) source and  $MS^n$  experiments with ion-trap mass spectrometric (ITMS)

detection. This determination is based on the formation of *sn* position-specific acyl product ions and related acyl fragments, which are subject to a collision potential in MS<sup>3</sup> experiments. The ratio of the signal intensity of distinct fragment ions has been used to distinguish between *sn* position. To analyze the regio-specificity of neutral ether lipids of complex native matrices pre-separation of the TAG species is required. Hartvigsen et al. [26] suggested performing such analysis by reversed-phase high-performance liquid chromatography (RP-HPLC) coupled with single-quadrupole MS detection. The composition of TAG in rape seeds and several other vegetable oils has been characterized by RP-HPLC combined with APCI-MS [27].

In this study the molecular structures of TAG in rape-seed oil were analyzed after transformation with thioesterase and acyl-chain-condensing enzyme genes from the cigar flower (*Cuphea lanceolata*). The regio-specificity of TAG fatty acids was characterized by RP LC coupled with APCI-ITMS. The relative amounts of TAG species in original and transgenic rape oils were compared by RP-HPLC.

## Material and Methods

### Rape Seed Oils

The original oilseed was from *Brassica napus* L. variety Drakkar (summer rape). The transgenic oilseed was from the original-type Drakkar carrying the acyl-[ACP]-thioesterase gene *C/FatB4* and the 3-ketoacyl-[ACP]-synthase *KAS III* from *Cuphea lanceolata* (cigar flower) for control of the native seed-specific *Napin* promoter according to the gene construct description of the Federal Centre for Breeding Research on Cultivated Plants, Institute for Stress Physiology and Quality of Raw Materials, 18190 Gross Lüsewitz, Germany [28, 29].

### Lipid Extraction from Rape Seed

Rape seeds (300 mg) were homogenized in 3 mL petroleum ether by use of an Ultra Turrax homogenizer (IKA Werke; Janke-Kunkel, Staufen, Germany). After incubation for 30 min the clear supernatant was transferred into the exsicator. Total lipids were obtained by Soxhlet extraction assisted by ultrasound, in accordance with the method of Luque-Garcia and Luque de Castro [30]. The organic solvent was totally evaporated under vacuum. The remaining oil was used for the analysis.

### Fatty Acid Methyl Ester (FAME) Analysis by Capillary Gas Chromatography (CGC)

For derivatization, 100  $\mu$ L seed oil was dissolved in 2 mL methanol–hexane (4:1, *v/v*) plus 0.5% pyrogallol and methylation was conducted, in accordance with Lepage and Roy [31], with 200  $\mu$ L acetyl chloride at 100°C for 1 h. K<sub>2</sub>CO<sub>3</sub> (6%, 5 mL) was added and the mixture was centrifuged for 10 min at 2,200 $\times$ g. The upper hexane phase containing the FAME was removed. The FAME were analyzed by CGC with a 6890 N gas chromatograph (Agilent Technologies, Waldbronn, Germany) fitted with a cold on column injector to prevent fatty acid discrimination [32]. A chemically bonded DB23 (50% cyanopropyl methylpolysiloxane) capillary column, 60 m, I.D. 0.25 mm, film 0.25  $\mu$ m (JW Scientific, Agilent Technologies, USA) was used for separation of the fatty acids. The chromatographic conditions were: injector (COC): 65–270°C; carrier gas: hydrogen at a flow of 40 cm s<sup>-1</sup> flow. Compounds were monitored by flame-ionization detection at 250°C. Fatty acids were identified by comparison of their retention times with those of standards (GLC 85 standard mix; NuChekPrep, Elysian, MN, USA). The column oven temperature was maintained at 60°C for 0.5 min after injection then programmed at 40° min<sup>-1</sup> to 180°C (held for 2 min) then at 2° min<sup>-1</sup> to 210°C (held for 3 min) and finally at 3° min<sup>-1</sup> to 240°C (held for 10 min).

### Statistical Analysis

Data are given as mean  $\pm$  standard deviation. Inter-group comparisons between the two tested groups were performed by use of an unpaired *t*-test, using the software Statview 4.5 (SAS, USA). The *P*-value <0.05 was regarded as statistically significant.

### Determination of the *sn* Position of Fatty Acids in Linked TAG by LC–APCI-ITMS

Analysis of the *sn* position was performed by liquid chromatography–mass spectrometry with an LCQ Deca (Thermo Electron Corporation, San Jose, CA, USA). The distinct TAG subclasses were separated by reversed-phase chromatography on a 250 mm  $\times$  2.1 mm ODS-AQ C<sub>18</sub> RP column (YMC, Schermbeck, Germany). The mobile phase is described below. The flow rate was 0.2 mL min<sup>-1</sup>. The liquid chromatograph was coupled to the mass spectrometer by means of an online APCI source. To ionize the molecules 10% ammonium acetate was infused directly into the ion source, by syringe application, at a flow of 1  $\mu$ L min<sup>-1</sup>. The discharge

current was 5  $\mu\text{A}$ , the capillary potential 46 V, the capillary temperature 130°C, the vaporizer temperature 350°C, and the sheath gas flow rate 60 arbitrary units. Separation of the TAG species was visualized by use of the total ion chromatogram (TIC). The ion collision energy in the multistage sequenced MS experiments was adjusted to between 30 and 35%. The measurement range was between  $m/z$  200 and 1,500. The total measurement time was 50 min.

#### Separation of the TAG Species by RP-HPLC

The oil was dissolved in 1:1 ( $v/v$ ) chloroform–methanol at a concentration of 0.5–2.5  $\text{mg mL}^{-1}$ . HPLC separation of the TAG species was achieved with an Alliance 2695 chromatograph (Waters, Eschborn, Germany) coupled with a PL-ELS 1000 evaporative light-scattering detector (Polymer Laboratories, Darmstadt, Germany). Detection was performed at 30°C for the nebulizer and 35°C for the evaporator. Compounds were separated on a 250 mm  $\times$  4.6 mm, 5  $\mu\text{m}$  particle, end-capped ODS-AQ  $\text{C}_{18}$  RP column (YMC Europe, Schermbeck, Germany). The mobile phase was a gradient prepared from acetonitrile (component A) and isopropanol (component B) as described by Ando et al. [33]. All solvents were HPLC-grade or supra-solvent quality (Merck Eurolab, Darmstadt, Germany). The gradient was: start A–B (%) 80:20, 0–30 min A–B (%) 80:20 to 20:80, 30–40 min A–B (%) 20:80, 40–45 min A–B (%) 20:80 to 80:20, 45–50 min A–B (%) 80:20. The flow rate was 0.85  $\text{mL min}^{-1}$ . The distinct species were characterized by retention time and mass spectrometric

analysis. The standards used were: tridecanoyl-glycerol, tridodecanoyl-glycerol, 1,2-didodecanoyl -3-tetradecanoyl-rac-glycerol, tridecanoyl-glycerol, 1,2-ditetradecanoyl-3-dodecanoyl-rac-glycerol, tritetradecanoyl-glycerol, rac-1,2-ditetradecanoyl-3-octadecenoyl-glycerol, rac-1,2-di tetradecanoyl-3-hexadecanoyl-glycerol, tri(*cis*-9-octadecenoyl)-glycerol, 1,2-dioctadecenoyl-3-hexadecanoyl-rac-glycerol, 1,2-hexadecanoyl-3-octadecenoyl-rac-glycerol, trihexadecanoyl-glycerol, 1,2-dioctadecanoyl-3-hexadecanoyl-rac-glycerol, and trioctadecanoyl-glycerol (all Sigma Aldrich Chemie, Taufkirchen, Germany).

## Results

### Analysis of Fatty Acid Composition

Transformation of summer rape led to increased expression of caprylic, capric, lauric and myristic acids. In contrast, amounts of linoleic acid (18:2n6) and alpha-linolenic acid (18:3n3) decreased significantly ( $P \leq 0.0001$ ) compared with the original seed oil (Table 1). As a consequence of this the total amount of polyunsaturated fatty acids in transgenic rape seed oil decreased substantially compared with the original oil; the difference was 47.3% ( $P \leq 0.0001$ ). Efficient expression of MCFA reduced the amount of essential linoleic acid and alpha-linolenic acid.

The total saturated fatty acid content of the transgenic rape seed oil increased; the difference was 153% ( $P \leq 0.0001$ ) compared with the original oil. The total

**Table 1** Comparison of the fatty acid composition of original and transgenic rape seed oil

polyunsaturated fatty acids				

mono-unsaturated fatty acid content decreased slightly; the difference was 3.5% ( $P \leq 0.0001$ ). The amount of dominant oleic acid (18:1n9) of transgenic oil increased (the difference was 4.5%;  $P \leq 0.0001$ ) whereas the erucic acid (22:1n9) content decreased (the difference was 40.0%;  $P \leq 0.0001$ ) compared with the original oil. All other detected monounsaturated fatty acids were unaffected. The amount of palmitic acid (16:0) of transgenic oil decreased whereas stearic (18:0), arachidic (20:0), behenic (22:0), and lignoceric acids (24:0) increased compared with the original oil. No fatty acids with epoxy or hydroxy functions, conjugated double bonds, or branched structures could be detected after transformation.

### Analysis of TAG Structures

To determine whether this induced atypical accumulation of MCFA in rape seeds affects the TAG structure of transgenic oil, the *sn* position of associated fatty acids was determined by LC-APCI-ITMS (Fig. 1 and Table 2). The molecular species and the *sn* position of the acyl substituents were identified using product-ion spectra of major precursor ions. These were selected from the mass spectra averaged across the peaks in the TIC, utilizing the preferential loss of the acyl group in the *sn*-1 or *sn*-3 position. During the APCI process ammonium acetate was infused by syringe to enhance the reproducibility of *sn* position-specific cleavage of fatty acids. Acidification destabilizes the ester linkage between the fatty acid and glycerol. Possible effects on the cleavage properties of molecular structure, for example carbon-chain length and degree of saturation of the fatty acids, might be reduced.

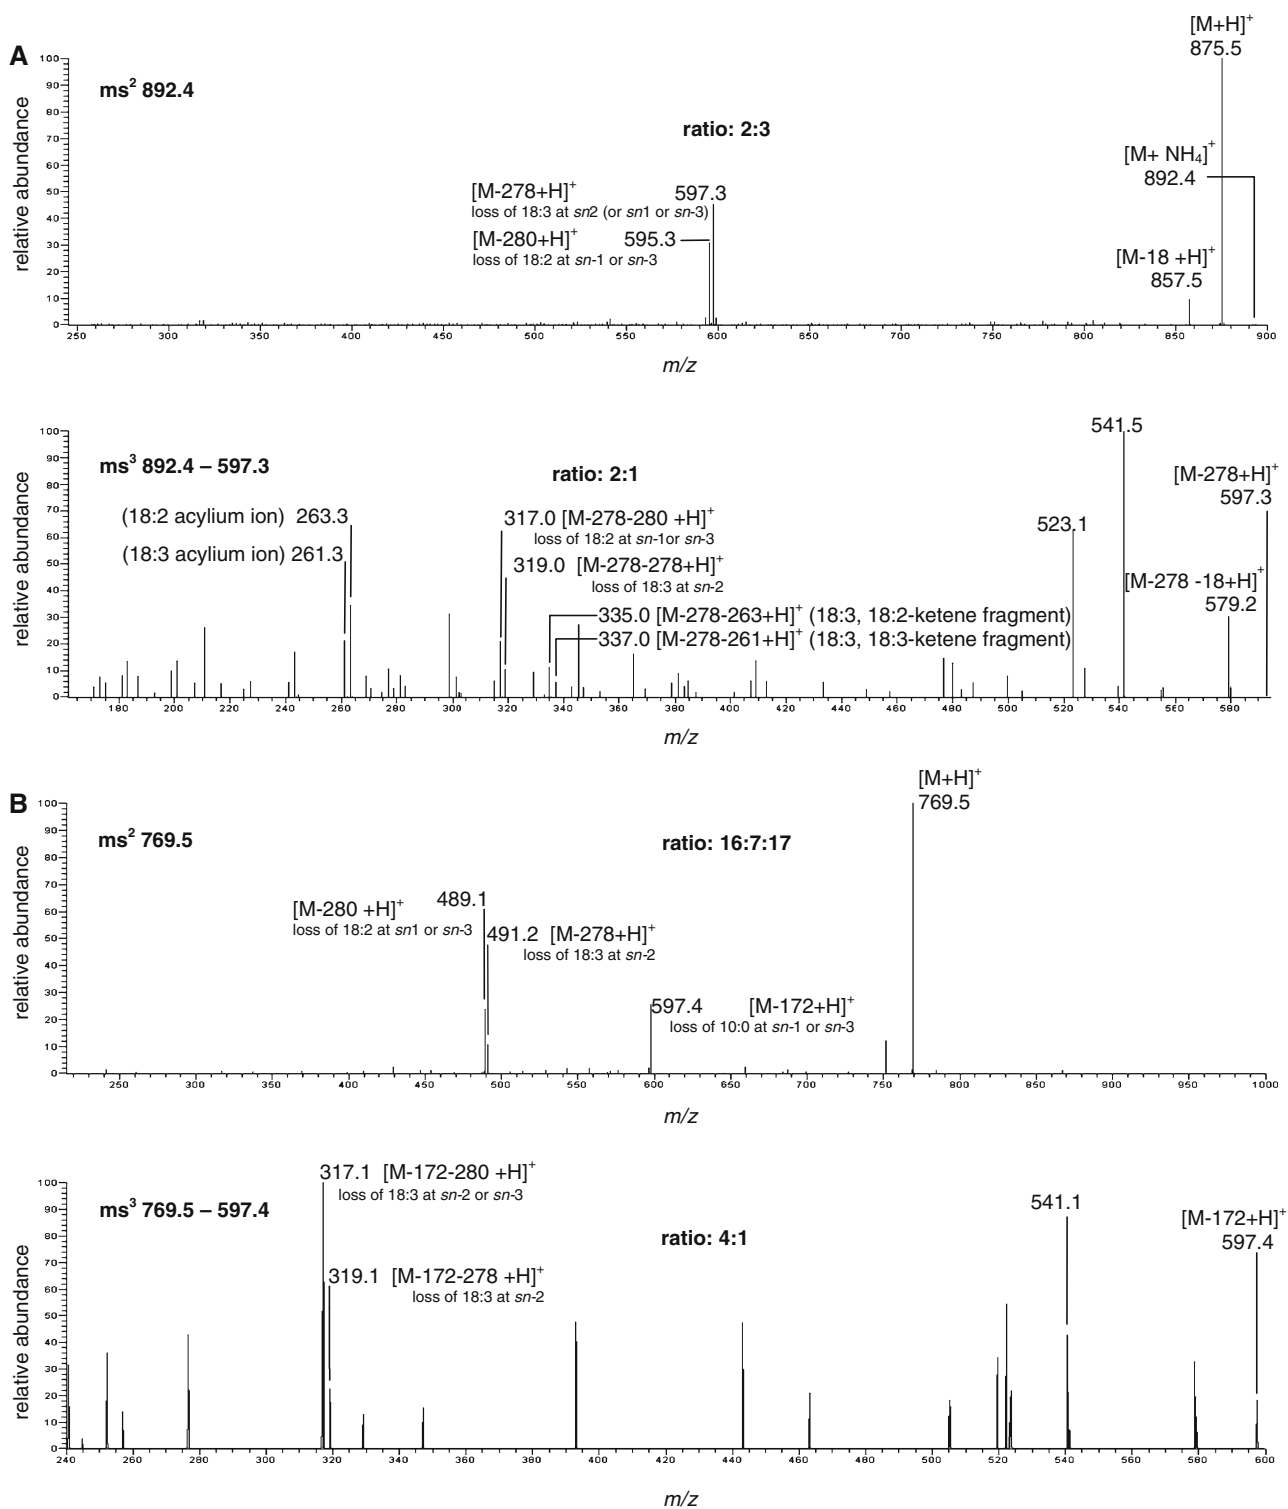

Because the location of integrated double bond fatty acids was not detectable by ITMS, the *n*-3, *n*-6, and *n*-9 families of the respective fatty acids were determined by CGC analysis. Figure 1a shows the MS<sup>2</sup> and MS<sup>3</sup> spectra of 1,2-dioctadecatrienoyl-3-octadecadienoyl-glycerol or 1-octadecadienoyl-2,3-dioctadecatrienoyl-glycerol (geometric isomer) derived from native rape seed oil. Fragmentation of the ion with an *m/z* of 892 revealed loss of ammonia resulting in a triacylglycerol ion of *m/z* 875. Because the samples were acidified with ammonium acetate during APCI, ammonium adducts of precursor ions were obtained from the TAG, in accordance with the literature [22]. The *m/z* 595 and *m/z* 597 fragments arose from cleavage of octadecadienoic acid  $[M - 280 + H]^+$  and octadecatrienoic acid  $[M - 278 + H]^+$ , respectively. Fatty acids at the *sn*-1 and *sn*-3 positions are preferentially cleaved from the glycerol backbone. In MS<sup>2</sup> experiments Marzilli et al. [25] observed different

relative abundance ratios of diacylglycerol ions derived from TAG containing two similar and one different saturated or monounsaturated fatty acid depending on their specific *sn* positioning. The predicted statistical ratio of such TAG fragments would be expected to be less than 1:2, because loss from the *sn*-2 position is energetically disfavored. The 2:3 ratio between the *m/z* 595 and *m/z* 597 fragments shown in Fig. 1a indicated that the octadecadienoic acid was mostly in the *sn*-1 and *sn*-3 positions whereas octadecatrienoic acid was in the *sn*-2 position. Laakso and Voutilainen [34] have demonstrated that the number of fatty acid double bonds affects the energetically favored fractionation pattern. Although the high unsaturation of octadecadienoic and octadecatrienoic acid might affect the fragmentation pattern, detection of the specific ratios was not affected. Differentiation between the *sn*-1 and *sn*-3 positions is impossible.

The MS<sup>3</sup> fragmentation of the *m/z* 597 ion (1–2 dioctadecatrienoyl-glycerol) resulted in fragments at *m/z* 317 and *m/z* 319, indicative of loss of octadecadienoic  $[M - 278 - 280 + H]^+$  and octadecatrienoic  $[M - 278 - 278 + H]^+$  acids, respectively. The 2:1 ratio between these fragments indicates that octadecadienoic acid was located at the *sn*-1 or *sn*-3 position and the octadecatrienoic acid at the *sn*-2 position.

Cleavage of the ester linkage between the fatty acids and the glycerol during APCI could result in the loss of acid fragments RCOOH and ketene fragments RCHCO, described in detail by Hsu and Turk [35]. In accordance to this, we observed signals of acylium ions of the cleaved fatty acids with *m/z* 261 for octadecatrienoic acid  $[R_{2/3}CO]^+$  and *m/z* 263 for octadecadienoic acid  $[R_1CO]^+$ . The corresponding *m/z* 335 and *m/z* 337 glycerol backbone-containing fragments  $[R_nCO+74]^+$  indicated loss of the octadecadienoic ketene fragment  $[M - 278 - 263 + H]^+$  and the octadecatrienoic ketene fragment  $[M - 278 - 261 + H]^+$ , respectively. Again, the type of fragmentation depended on the degree of saturation of the associated fatty acids. Linoleic, alpha-linolenic, and long-chain polyunsaturated fatty acids with more than three double bonds tended to form acylium ions during the APCI fragmentation process. More acylium ions resulted in fewer acid ions and vice versa.

The degree of saturation and the carbon-chain length of fatty acids seems to affect the binding energy of the TAG ester linkage. Analyses of neutral lipids by triple quadrupole FAB-MS and ESI-MS demonstrated, for increased chain length and number of double bonds, reduced loss of fatty acids [26]. We reduced the collision energy to suppress such ion formation (data not shown), because the ratios of acylium ions and corresponding

glycerol backbone-containing fragments do not reflect the *sn* position.

Interestingly, the released fatty acids seem to have reacted with each other to form anhydrides presented by *m/z* 541, [278 + 280 - 17 + H]<sup>+</sup>. The suggested

anhydride formation, which occurs irrespective of the degree of saturation of fatty acids and the collision energy, might be specific for APCI applications. Interpretation of these data needs further investigation, however.

◀ **Fig. 1** Determination, by LC–APCI–ITMS, of the *sn* position of 1,2-dioctadecatrienoyl-3-octadecadienoyl-glycerol (18:3/18:3/18:2), or geometric isomers, of original summer rape seed oil (**a**) and 1-decanoyl-2-octadecatrienoyl-3-octadecadienoyl-glycerol (10:0/18:3/18:2), or geometric isomers, of transgenic seed oil (**b**) transformed with medium-chain thioesterase. The compounds were separated on an end-capped ODS-AQ C<sub>18</sub> column. The mobile phase was a gradient prepared from acetonitrile (component A) and isopropanol (component B). The gradient was: start A–B (%) 80:20, 0–30 min A–B (%) 80:20 to 20:80, 30–40 min A–B (%) 20:80, 40–45 min A–B (%) 20:80 to 80:20, 45–50 min A–B (%) 80:20. The flow rate was 0.85 mL min<sup>-1</sup>. The mass spectra were acquired on a mass spectrometer with an on-line APCI source. The discharge current was 5 μA, the capillary potential 46 V, the capillary temperature 130°C, the vaporizer temperature 350°C, and the sheath gas flow rate 60 arbitrary units. The ion collision energy in the multistage sequenced MS experiments was adjusted to between 30 and 35%. The measurement range was between *m/z* 200 and 1,500

By using MS<sup>2</sup>, the 1-dodecanoyl-2-octadecatrienoyl-3-octadecadienoyl-glycerol (10:0/18:3/18:2) or the geometric isomer with *m/z* 769, derived from the transgenic seed oil was fragmented into *m/z* 489, *m/z* 491, and *m/z* 597 signals which represented a loss of dodecanoic (10:0), octadecatrienoic, and octadecadienoic acids, respectively (Fig. 1b). The corresponding 16:7:17 fragmentation ratios were a preliminary indication of respective *sn* positioning. The fragmentation of the *m/z* 597 ion in the MS<sup>3</sup> experiment revealed a 4:1 ratio between *m/z* 317 and *m/z* 319 fragments which represented a loss of octadecadienoic acid [M – 172 – 280 + H]<sup>+</sup> and octadecatrienoic acid [M – 172 – 278 + H]<sup>+</sup> corresponding to the *sn*-1/3 and *sn*-2 position, respectively. Again, the released fatty acids might form anhydrides, represented by *m/z* 541 [278 + 280 – 17 + H]<sup>+</sup>.

Table 2 gives an overview of different TAG species from native and transgenic seed oil. Although the objective of this rape transformation was MCT production, octanoyl (8:0/8:0/8:0), decanoyl (10:0/10:0/10:0), and dodecanoyl-glycerol (12:0/12:0/12:0) could not be detected in the transgenic oil. These data indicated that the acyltransferases link MCFA to the glycerol only in combination with LCFA. In consequence, the *sn* position distribution of fatty acids of storage TAG was modified. The original oil contained eleven unique distinct TAG species, the transgenic oil sixty. Twenty species were common to both oils (Table 2). The original and transgenic oil contained trioctadecenoyl-glycerol (18:1/18:1/18:1) and trioctadecatrienoyl-glycerol (18:3/18:3/18:3) whereas the native oil included only the latter. Although no trioctadecenoyl-glycerol could be detected in the origi-

nal, in the transgenic oil octadecenoic acid dominates in heterogeneous TAG structures.

### Quantification of Distinct TAG Species

Because the occurrence of new TAG species might affect the quantitative distribution of all TAG, the original and transgenic storage TAG were compared by analytical RP-HPLC (Fig. 2 and Table 2). Quantification of lipids by total-ion chromatography with ion-trap detection depends on the ionization properties of the molecule. To determine the relative amount (area under the curve, AUC) of neutral lipids irrespective of their ionization properties, which might restrict quantification, evaporative light-scattering detection was used. This technique enables quantification irrespective of the ionization or absorption properties of the mobile phase or samples [36].

Characterization of the TAG profile by RP-HPLC was based on the identical TIC of the MS experiments controlled with external standards (data not shown).

The original rape seed oil furnished 15 peaks, the transgenic oil 22 peaks; 14 peaks were common to both oils. The distribution of TAG fatty acids of the transgenic oil was more heterogeneous than that of the original. In the transgenic oil the new peaks were 1, 2, 3, 5, 8, 9, 12, and 16 (eight new peaks) and peak 6 of the original oil disappeared. The dominant peak 19 represented 50.2% of original oil and 52.2% of the transgenic oil, i.e. was approximately unchanged, whereas peak 17 which accounted for 27.5% of the original oil was reduced to 6.7% in the transgenic oil. Peak 11 represented 0.1% in the original oil and increased to 25.5% in transgenic oil. Peak 14 decreased from 11.1% in the original oil to 2.3% in the transgenic oil.

Because one peak included several co-eluting TAG species, distinct peaks of the oils represent several different clusters of TAG species. The transgenic oil mainly contained combinations of caprylic, capric, lauric, myristic, palmitic, stearic, oleic, linoleic, arachidic, behenic, and lignoceric acids representing 52% of the total fat content. The original oil was dominated by TAG combining palmitic, stearic, oleic, and linoleic acids to form 50% of the total fat content. The structural combination of palmitic, stearic, linoleic, and alpha-linolenic acids which accounted for 27% of the original oil TAG was reduced to 6.7%. In the transgenic oil new MCFA combinations with palmitic, stearic, and linoleic acids were detected. MCT with capric, and lauric acids combined with stearic, oleic, linoleic, alpha-linolenic, arachidic, and gondoic

**Table 2** Relative amounts of triacylglycerol species and *sn* position of integrated fatty acids of original and transgenic rape seed oil analyzed by LC–APCI–ITMS and RP–HPLC

	RT (min)	TAG species			Amount (% of AUC)

The TAG species were measured by LC–APCI–ITMS. The relative amounts of the TAG were measured by analytical RP–HPLC as percentages of the area under the curve (AUC)

acids dominated, and accounted for 25% of the total fat in the transgenic oil. We conclude that transformation of seed oil results in different TAG species with modified fatty acid compositions.

## Discussion

Stepwise metabolic engineering is one strategy for enhancing the capacity of plants to produce special

**Fig. 2** RP-HPLC separation of TAG species of original and transgenic rape seed oil. The compounds were separated on an end-capped ODS-AQ C<sub>18</sub> column. The mobile phase was a gradient prepared from acetonitrile (component A) and isopropanol (component B). The gradient was: start A–B (%) 80:20, 0–30 min A–B (%) 80:20 to 20:80, 30–40 min A–B (%) 20:80, 40–45 min A–B (%) 20:80 to 80:20, 45–50 min A–B (%) 80:20. The flow rate was 0.85 mL min<sup>-1</sup>. The samples were measured by evaporative light-scattering detection. TAG, triacylglycerol

foods or pharmaceutical compounds. For example, the over-expression of MCFA-specific thioesterase, alone or in combination with the respective chain-length-specific condensing enzyme, can affect the composition and positional distribution of fatty acids in growing and ripe transgenic rape seeds [37]. In this study the fat composition of seed oil from transgenic summer rape, modified with the acyl-[ACP]-thioesterase gene *CIFatB4* from *Cuphea lanceolata* (cigar flower) and the native seed-specific *Napin* promoter, was investigated. Mature seeds of cigar flowers contain up to 83% capric acid in storage TAG [38]. The thioesterase hydrolyzes the thioester linkage between synthesized fatty acids and the acyl carrier protein to inhibit acyl-chain elongation [28]. In this study the fatty acid composition of transgenic rape could be altered in favor of MCFA. The efficient expression of MCFA reduced the amount of essential linoleic acid and alpha-linolenic acid. This finding might diminish the nutritional value of this

transgenic oil for dietary applications. The same phenomenon has been described for transformation of rape plants to produce very-long-chain polyunsaturated fatty acids [39]. Because of the expression of eicosapentaenoic acid (20:5n3) a reduced amount of essential fatty acids of the transgenic seed oil was determined.

Although medium-chain thioesterase has been reported to inhibit acyl-chain elongation, the amounts of several monounsaturated and saturated fatty acids up to 18 carbon atoms in chain length increased in the transgenic oil. This might be because of limited expression of the engineered transgenes or because the carbon-chain elongation pathway is appropriately regulated [8, 10].

In addition to the induced over-expression of transgenic enzymes, other factors affecting the expression pattern of fatty acids might be relevant. Effects on anabolic and catabolic pathways might be

especially relevant in affecting fatty acid profiles of storage oils. Dittrich et al. [40] suggested that fatty acid elongation in yeast depends on the availability of malonyl-CoA, nicotinamide adenine-dinucleotide phosphate, and the chain-length of acyl primers, but not on respiratory competence. This offers several possibilities of affecting the composition of storage fat. Metabolic regulation, genetic prerequisites that encode fatty acid biosynthetic enzymes, and movement of fatty acids in the cell, determine the effect of transgenes on the phenotype and lipid composition of rape seed oils [41]. Thus, the whole metabolic environment of the synthesis should be considered for successful metabolic engineering.

The detailed analysis of TAG structures of native and transgenic vegetable oils in this study illustrates that APCI-ITMS is suitable for direct determination of the structures of TAG derived from native matrices. Because of the complex TAG pattern, however, pre-separation with a coupled LC is required. In contrast, in studies such as that described by Han and Gross [42] triple-quadrupole MS was used with direct infusion into the ion-source. Direct application of the sample with a syringe pump was unsuitable for our ITMS measurement, however. Ion suppression or space-charging overpopulation of the ion trap probably impaired efficient signal recognition by this technique. Thus, determination of the *sn* position of TAG-associated fatty acids was achieved by coupling MS measurement with RP LC to separate the different molecular species. The TIC was scanned manually or automatically (triple-play mode) within the range  $m/z$  200–1,500 to select specific ion signals. MS<sup>n</sup> experiments based on selected ions were then used to identify molecular species and the position of the acyl substituents. Although MS coupled RP-HPLC is sometimes a compromise in chromatographic and ionization requirements, sufficient separation of TAG species enables production of distinct molecular species for subsequent MS<sup>n</sup> experiments. Unexpected co-elution of TAG with different equivalent carbon numbers might occur because of matrix effects or because of the inadequate separating power of the microcolumn.

The appearance in the transformed seed oil of distinctive TAG species with dissimilar regioselectivities of associated fatty acids, compared to the original oil, is indicative of possible implications of genetic modification on the general fat metabolism of the transformed plant. The two inserted transgenes which are not involved in the biosynthesis of the TAG structure itself affected the acylation profile and *sn* positioning of the fatty acids of storage TAG. As recently discussed by several authors, distribution of the *sn* posi-

tions of MCFA might depend on different substrate affinities of acyltransferases in TAG biosynthesis, for example lysophosphatidic acid, diacylglycerol, and lysophosphatidylcholine acyltransferase [12, 14]. Although the transgenes inserted are not directly involved in TAG assembly, they are relevant to fatty acid synthesis. Introduction of new fatty acid species into the pool might affect the TAG composition. The non-physiological MCFA might therefore displace TAG associated LCFA, resulting in new heterogeneous TAG species. Analysis of control–transformation experiments with the vector but without the transgenes would exclude TAG alterations resulting from the transformation procedure itself, however.

In transgenic oil MCFA were mainly integrated into the *sn*-1/3 position in combination with essential linoleic or alpha-linolenic acids. Eight species were detected with caprylic, capric and lauric acids in the *sn*-2 position. In the transgenic and original oils polyunsaturated fatty acids were mainly associated with the *sn*-2 position of TAG. These structures afford interesting possibilities for improved enteral applications. Several studies have shown that the fatty acid composition of blood and organs, for example the heart or liver, can be affected by treatment with nutritional or pharmacological lipids [17]. Further studies have revealed that the specific *sn* position of fatty acids determines metabolic processing [18, 19]. LCFA are transported via the lymph, MCFA are transported via the portal vein directly to the liver for catabolism. It has been suggested that the *sn*-2 position of MCFA shifts transport of dietary TAG to the lymphatic pathway and modifies the chemical composition of chylomicrons with several consequences for lipid metabolism [20]. With animal models it has been demonstrated that structured TAG increase lymphatic absorption of tocopherol and retinol, both of which are important fat-soluble vitamins and anti-oxidants [43]. Because MCT are absorbed independently from lipases, they have beneficial effects on fat malabsorption or disturbed fat digestion. The remaining fatty acid at the *sn*-2 position after digestion of TAG with intestine-lipases is absorbed as monoacyl-glycerol. Structured TAG with a combination of MCFA at the *sn*-1 and *sn*-3 positions and long-chain fatty acids at the *sn*-2 position therefore support fat supply with reduced soap formation [7]. Preterm milk formulas with structured *sn*-2 palmitate TAG are targeted at reducing insoluble calcium soap formation and release of free fatty acids in the gut [44]. In a rat model dietary application of a structured lipid with LCFA combined with MCFA resulted in enhanced lymphatic absorption of these fatty acids [45]. In this respect, TAG found in the transgenic oil containing LA, ALA

primarily in the 2 *sn* position, and MCFA in the 1 or 3 *sn* position, may have the same physiologic effects. Such oils might have beneficial effects during malabsorption, within a postoperative phase or tube-feeding period. It has been suggested that structured TAG based on MCFA and LCFA reduce liver dysfunction in patients with long-term parenteral nutrition [46]. The current effort to establish structured MCFA with docosahexaenoic acid (22:6n3) and arachidonic acid (20:4n6) in algal single-cell oils for dietary use emphasizes the relevance of setting up non-synthetic sources for structured lipids with MCFA [47]. The transgenic oil analyzed in this study contains TAG species which could be suitable for those applications.

Analysis of TAG structures by use of LC coupled with ITMS might therefore be useful for characterizing the physiological value of oils. As a result of the use of ammonium acetate during the APCI process, 10–80 µg fat extract was sufficient for determination of TAG species with fatty acids up to 0.04% (*w/w*). Although the detection limit of LC–APCI–ITMS analysis of *sn* position is not comparable with that of enzyme/CGC analysis, the technique enables reproducible, sensitive, and rapid routine determination of the *sn* position of TAG-associated fatty acids.

Analysis of more than 50 different transformation experiments with summer rape and gene constructs containing thioesterases in combination with alpha 3-ketoacyl-[ACP]-synthase has indicated that the different distribution of regiospecific fatty acid linkages and the appearance of new TAG species in transformed seed oil, compared to the original oil, is distinctive for this type of transformation (data not shown).

## Conclusion

It can be concluded that APCI–ITMS is an applicable strategy for direct structural determination of TAG. Transformation of rape plants with two enzymes which are not directly involved in the biosynthesis of TAG but in the elongation of acyl chains alters the distribution of the *sn* position in TAG-associated fatty acids of the seed oil. The *sn* position-specific distribution of fatty acids in TAG of oils is important nutritionally, biochemically, technologically, and with regard to quality. Detailed analysis of end-products and possible contamination is therefore required. The appearance of different TAG species in the transgenic oil illustrates the extensive effect of genetic modification on the general fat metabolism of transformed plants and

affords interesting possibilities for improved enteral applications.

**Acknowledgments** The authors would like to thank Professor W. Friedt and Mr Christof Stoll, University of Giessen, Department of Agricultural Science, for providing the native and transgenic rape seed oils. The work for this publication was supported by the Federal Ministry for Consumer Protection, Nutrition and Agriculture under the grant number 22008801.

**Abstract** Two new monogalactosyl diacylglycerols (MGDGs) along with two known glycolipids were isolated from the moderate polar fraction of the methanolic extract of the brown alga *Sargassum thunbergii* by using reversed silica flash chromatography. Two new MGDGs were identified as (2*S*)-1-*O*-(5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-eicosapentaenoyl)-2-*O*-(9*Z*,12*Z*,15*Z*-octadecatrienoyl)-3-*O*- $\beta$ -D-galactopyranosyl-*sn*-glycerol (**1**) and (2*S*)-1-*O*-(9*Z*,12*Z*,15*Z*-octadecatrienoyl)-2-*O*-(6*Z*,9*Z*,12*Z*,15*Z*-octadecatetraenoyl)-3-*O*- $\beta$ -D-galactopyranosyl-*sn*-glycerol (**2**) by FAB tandem mass spectrometry, NMR techniques, and specific enzyme-catalyzed hydrolysis of the *sn*-1 fatty acyl linkage. The regiochemical attachment of the acyl chains in the glycerol moiety was established by 2D NMR correlations and confirmed by enzymatic hydrolysis.

HPLC	High performance liquid chromatography

### Introduction

The brown alga *Sargassum thunbergii* is widely distributed in the coastal areas of Korea. This alga produces biologically active substances such as antitumor polysaccharides [1], and peroxynitrite scavengers [2]. In addition, glyceroglycolipids, the major lipid components of the photosynthetic membrane in plants, algae and various bacteria [3, 4] were isolated. In our search for novel bioactive compounds from marine macro algae, we recently observed that the acetone fraction of the brown alga *Sargassum thunbergii* collected from the offshore area of the West Sea in Korea exhibited moderate antifungal effects on *Candida albicans*. We examined these antifungal effects by using the agar diffusion disk method and isolated two new monogalactosyl diacylglycerols (MGDGs), along with two known glycolipids. This paper describes the elucidation of the complete structure of these compounds by using tandem mass spectrometry, NMR techniques and hydrolysis of the specific enzyme, Lipase XI.

### Experimental Procedures

#### General Experimental Procedures

Optical rotations were measured on a JASCO DIP-1000 digital polarimeter. IR spectra were obtained on a Mattson

Galaxy spectrometer. The 1D and 2D NMR spectra were obtained on a Varian UNITY500 spectrometer working at 500 MHz for proton and 125 MHz for carbon. The  $^1\text{H}$  and  $^{13}\text{C}$  NMR chemical shifts were attributed to  $\text{CD}_3\text{OD}$  at 3.30 and 49.0 ppm, respectively. For all experiments, the temperature was stabilized at 297 K. The parameters used for 2D NMR spectra were as follows; The gradient COSY spectra were collected with a spectral width of 2,567 Hz in a  $512 (t1) \times 1,024 (t2)$  matrix, a pulse gradient with strength of 10 G/m for 1 ms and processed with a sinebell function. The gradient HSQC spectra were measured in a  $128 (t1) \times 1,024 (t2)$  matrix with  $J_{\text{CH}} = 140$  Hz, and to obtain a higher resolution, processed in a  $256 (t1) \times 1,024 (t2)$  matrix by a linear prediction method. The gradient HMBC experiment was optimized for a long-range coupling constant of 7 Hz. To reduce the artifacts in the spectra, the HSQC and HMBC experiments were utilized by the pulse gradients with strength of 10 G/m for 1 ms.

All mass spectrometric analyses were performed using a four-sector tandem mass spectrometer (JMS-HX110/110A, JEOL) with mass resolution set at 1,000 (10% valley). The ion source was operated in the positive-ion mode at 10 kV accelerating voltage. Ions were produced by FAB using the cesium ion beam, which was generated from the ion gun and accelerated to 22 kV. The samples were dissolved in a  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (2:1, by vol) solution. The solution of 1  $\mu\text{L}$  was mixed with 1  $\mu\text{L}$  of 3-nitrobenzyl alcohol saturated with NaI on the FAB probe tip. Precursor ions selected by the first mass spectrometer ( $E_1B_1$ ) were subjected to CID in the collision cell located between  $B_1$  and  $E_2$  and were floated at 3.0 kV. The resultant product ions were analyzed by B/E scan method of the second mass spectrometer ( $E_2B_2$ ). The collision gas, helium, was introduced into the collision chamber at a pressure that was sufficiently high to reduce the precursor ion signal by 70%.

#### Extraction and Isolation

The dried brown alga (1.5 kg), collected from the offshore area of the West Sea in Korea was subjected to extraction at room temperature using MeOH. The MeOH extract was partitioned between the *n*-BuOH and  $\text{H}_2\text{O}$  layers. The butanolic layer was evaporated under conditions of reduced pressure and repartitioned between a MeOH/ $\text{H}_2\text{O}$  (85:15, by vol) solvent system and *n*-hexane. The aqueous MeOH portion was subjected to reversed-phase flash chromatography using polar solvents that were ordered (MeOH: $\text{H}_2\text{O}$  = 70:30, 80:20, 90:10; 100% MeOH; acetone; EtOAc) to yield six fractions. The acetone fraction that showed strong signals of unsaturated protons in  $^1\text{H}$  NMR and a moderate antifungal effect on *C. albicans* (diffusion disk method, a clear zone of 9 mm), was separated by reversed-phase HPLC (YMC-A, 250 mm  $\times$  10 mm) with 100%

MeOH as an eluent. This separation yielded the four constituents, namely, the compound **1** (5.6 mg), **2** (4.2 mg), **3** (5.0 mg), and **4** (4.2 mg) at retention times of 68, 78, 64, and 84 min, respectively.

(i) Compound **1**  $[\alpha]_{\text{D}}^{25} -4.0$  (*c* 1.2, MeOH); IR  $\nu_{\text{max}}$  ( $\text{cm}^{-1}$ ) 3,360, 2,921, 2,860, 1,734;  $^1\text{H}$  NMR (500 MHz,  $\text{CD}_3\text{OD}$ ) 5.35 (16H, m, H-5', -6', -8', -9', -11', -12', -14', -15', 17', -18', -9'', -10'', -12'', -13'', -15'', -16''), 2.82 (12H, m, H-7', -10', -13', -16', -11'', -14''), 2.32 ( $\times 2$ ) (4H, t,  $J = 7.2$ , H-2', -2''), 2.12 (2H, m, H-4'), 2.07 (4H, m, H-19', -17''), 2.06 (2H, m, H-8''), 1.66 (2H, m, H-3'), 1.60 (2H, m, H-3''), 1.35 (8H, m, H-4'', -5'', -6'', -7''), 0.96 (6H, t,  $J = 7.6$ , H-20', 18''),  $^{13}\text{C}$  NMR (125 MHz,  $\text{CD}_3\text{OD}$ ) 175.0 (C-1'), 174.8 (C-1''), 132.8, 132.7, 131.1, 130.0 ( $\times 2$ ), 129.5, 129.2 ( $\times 4$ ), 129.1 ( $\times 2$ ), 128.9 ( $\times 2$ ), 128.2 ( $\times 2$ ) (C-5', -6', -8', -9', -11', -12', -14', -15', 17', -18', -9'', -10'', -12'', -13'', -15'', -16''), 35.1, 34.3 (C-2', 2''), 30.7, 30.3, 30.2, 30.1 (C-4'', -5'', -6'', -7''), 28.2 (C-8''), 27.5 (C-4'), 26.6 ( $\times 4$ ), 26.4 ( $\times 2$ ) (C-7', -10', -13', -16', -11'', -14''), 26.0 (C-3''), 25.9 (C-3'), 21.5 ( $\times 2$ ) (C-19', -17''), 14.7 ( $\times 2$ ) (C-20', 18'').

(ii) Compound **2**  $[\alpha]_{\text{D}}^{25} -4.5$  (*c* 0.9, MeOH); IR  $\nu_{\text{max}}$  ( $\text{cm}^{-1}$ ) 3,380, 2,930, 2,860, 1,735;  $^1\text{H}$  NMR (500 MHz,  $\text{CD}_3\text{OD}$ ) 5.35 (14H, m, H-9', -10', -12', -13', -15', -16', -6'', -7'', -9'', -10'', -12'', -13'', -15'', -16''), 3.83 (10H, m, H-11', -14', -8'', -11'', -14''), 2.33 (2H, t,  $J = 7.4$ , H-2''), 2.30 (2H, t,  $J = 7.4$ , H-2'), 2.10 (2H, m, H-5''), 2.08 (2H, m, H-8''), 2.06 (4H, m, H-17', -17''), 1.65 (2H, m, H-3''), 1.60 (2H, m, H-3'), 1.40 (2H, m, H-4''), 1.32 (8H, m,

H-4',-5',-6',-7'), 0.97 (6H, t,  $J = 7.6$ , H-18', 18"),  $^{13}\text{C}$  NMR (125 MHz,  $\text{CD}_3\text{OD}$ ) 175.0 (C-1'), 174.7 (C-1''), 132.8, 132.7, 131.1, 130.6, 129.5, 129.3 ( $\times 2$ ), 129.2 ( $\times 2$ ), 129.1, 129.0, 128.9, 128.3, 128.2 (C-9', -10', -12', -13', -15', -16', -6'', -7'', -9'', -10'', -12'', -13'', -15'', -16''), 35.0 (C-2''), 34.9 (C-2'), 30.5, 30.3, 30.2, 30.1 ( $\times 2$ ) (C-4', -5', -6', -7', -4''), 28.2 (C-8'), 27.9 (C-5''), 26.6 ( $\times 3$ ), 26.4 ( $\times 2$ ) (C-11', -14', -8'', -11'', -14''), 26.0 (C-3'), 25.6 (C-3''), 21.5 ( $\times 2$ ) (C-17', -17''), 14.7 ( $\times 2$ ) (C-18', 18'').

#### Preparation of *sn*-2 Acyl Lysogalactolipids

A solution of both the MGDG and Lipase XI (from *Rhizopus arrhizus*, Sigma: 1800 unit) in the presence of Triton X-100 (2.5 mg) in boric acid–borax buffer (0.63 ml, pH 7.7) was stirred for 1 h at 37 °C [5]. The reaction solution was adjusted to pH 4 by adding acetic acid, and subsequently quenched by adding 2 mL of  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (2:1, by vol) solution. The extracted organic phase was washed using 1 mL of 0.2 M  $\text{H}_3\text{PO}_4/1$  M KCl solution. The aqueous phase was re-extracted into  $\text{CHCl}_3$ , and the resulting organic phases were combined, dried, and redissolved in a minimal volume of the  $\text{CHCl}_3/\text{CH}_3\text{OH}$  (2:1, by vol). The resulting products were separated into lysogalactolipids and fatty acids by thin-layer chromatography (TLC) performed on a silica gel plate (K6 Silica Gel 60 Å; Whatman, Hillsboro, OR, USA) with  $\text{CHCl}_3/\text{CH}_3\text{OH}/\text{H}_2\text{O}$  (65:25:4, by vol). *Sn*-2 Acyl lyso components were identified by spraying the TLC plate with 0.01% primuline in a mixture of  $\text{Ac}_2\text{O}$  and  $\text{H}_2\text{O}$  (4:1, by vol) followed by illumination of the plate with ultraviolet light. The *sn*-2 acyl lyso components were located on the lowest part of the TLC plate.

#### Results and Discussion

Compound **1** was isolated in the form of an amorphous gum. From the sodium-adducted ion peak of  $[\text{M} + \text{Na}]^+$  at  $m/z$  821.5179 ( $\Delta -0.1$  mmu) in the high resolution FAB mass spectrum, the molecular formula of **1** was determined to be  $\text{C}_{47}\text{H}_{74}\text{O}_{10}$ . Its IR spectrum exhibited absorption bands corresponding to the hydroxyl ( $3,360\text{ cm}^{-1}$ ) and ester ( $1,734\text{ cm}^{-1}$ ) groups. The  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra of **1** showed the signals for carbon chains bearing a high number of methylene-interrupted double bonds, a sugar moiety, and two carbonyl groups. Further, from the results of the analysis of the  $^1\text{H}$ - $^1\text{H}$  COSY spectrum, it was deduced that compound **1** was a monoglycosyl diacylglycerol (Table 1).

As mentioned in a previous study, high-energy CID of the sodium-adducted molecular ions ( $[\text{M} + \text{Na}]^+$ ) of glycosyl diacylglycerol enabled the complete structural

analysis of the fatty acyl residues and the head group [6–8]. In particular, fragmentation along the hydrocarbon chains remote from the charge site allowed the determination of the position of the double-bond in the polyunsaturated fatty acyl groups. As shown in Fig. 1a, the fragmentation pattern observed in CID-MS/MS of compound **1** was very similar to that of the MGDG investigated in our previous work [8]. The fragmentation pathways and labeled product ions are also illustrated in Fig. 2. The  $^{15}\text{A}$ , B', B and C-2H ions at  $m/z$  157, 169, 185 and 201, respectively, provided the information on the monosaccharide as the head group. The fatty acyl composition in **1** was determined by a pair of G ion peaks resulting from the loss of free fatty acid moieties from each acyl group. Therefore, two strong ion peaks at  $m/z$  519  $[\text{M} + \text{Na}-\text{C}_{19}\text{H}_{31}\text{COOH}]^+$  and 543  $[\text{M} + \text{Na}-\text{C}_{17}\text{H}_{29}\text{COOH}]^+$  were indicative of the presence of C20:5 and C18:3 (carbon atoms:double bonds), respectively.

As shown in Fig. 1b, the positions of the double-bond in the fatty acyl chains were also determined by fragmentations occurring along the chains of fatty acids observed in the high mass region of the CID spectrum. The fragmentation of each fatty acid chain resulted in a series of product ions generated by the loss of  $\text{C}_n\text{H}_{2n+2}$  with neighboring peaks in the series separated by 14 u. The presence of a double bond in the chain reduced the separation between neighboring peaks to 12 u. Thus, homologous ions generated by the fragmentations of two different fatty acid chains can be divided into two groups in addition to the ions at  $m/z$  805, 791, 779 (=), where “=” represents the double-bond, 765, 751, 739 (=), 725, 711, 699 (=), 685 and 671 ions arising from cleavages of both fatty acid chains;

**Fig. 2** The fragmentation pathways and labeling product ions observed in the CID spectrum of  $[M + Na]^+$  ion (at  $m/z$  821) shown in Fig. 1

$m/z$  657, 643, 629 and 615 ( $^3I_2$ ) due to 9,12,15-octadecatrienoic acid chain (i.e.,  $\alpha$ -linolenic acid) and  $m/z$  659 (=), 645, 631, 619 (=), 605 and 591 ( $^3I_1$ ) due to 5,8,11,14,17-eicosapentaenoic acid (EPA) chain.

The linkage of two different fatty acid residues in the glycerol moiety was identified by a combination of the  $^1H$ - $^1H$  COSY and HMBC experiments. First, the proton signals of the three methylene units (H-2'-4') in the C20:5 chain were apparently resolved in the  $^1H$  NMR spectrum and readily assignable by the  $^1H$ - $^1H$  COSY spectrum. Next, the methylene protons at  $\delta$  1.65 (H-3') exhibited HMBC correlations with the carbonyl carbon at  $\delta$  175.0 (C-1') on the C20:5 chain, which showed further HMBC correlations with the methylene protons at  $\delta$  4.43 and 4.21 (H-1) in the glycerol moiety. On the other hand, in the HMBC spectrum, the methylene protons at  $\delta$  1.60 (H-3'') in the C18:3 chain were correlated with the carbonyl carbon at  $\delta$  174.7 (C-1''). This observation indicated that the C20:5 and C18:3 acyl chains were attached at positions C-1 and C-2 of the glycerol moiety, respectively. To confirm the

regiospecificity of the fatty acyl linkages, compound **1** was subjected to a regioselective enzymatic hydrolysis using Lipase XI (from *Rhizopus arrhizus*) that specifically cleaves the ester bond between the glycerol backbone and *sn*-1 fatty acyl group. FAB mass spectrum of the hydrolyzed product indicated that the peak at  $m/z$  537 corresponded to *sn*-2 acyl lysoglycerolipid with  $\alpha$ -linolenic acid at the *sn*-2 position.

As revealed by the HMBC correlation between the anomeric proton at  $\delta$  4.22 ( $J = 7.6$  Hz) and C-3, the sugar residue was linked to the C-3 of the glycerol moiety. Based on the information of the coupling constants for H-1'''/H-2''' ( $J = 7.6$  Hz), H-2'''/H-3''' ( $J = 9.7$  Hz) and H-3'''/H-4''' ( $J = 3.2$  Hz), and the NOE peaks H-1'''/H-3''' and H-1'''/H-5''', we classified the sugar as a  $\beta$ -galactopyranose; it was also shown that its  $^{13}C$  NMR resonances was identical to that reported for similar compounds [9].

The treatment of **1** with 15% NaOMe in MeOH afforded a glyceryl galactoside and a mixture of two fatty acid methyl esters. After partitioning, the optical rotation of the

aqueous fraction was measured to be  $[\alpha]_D^{25} \sim -6.0^\circ$  (*c* 0.15 H<sub>2</sub>O), which was very similar to that measured for (2*R*)-1-*O*-glyceryl- $\beta$ -D-galactopyranoside [10]. Based on this comparison, the stereochemistry of both the sugar and glycerol groups of **1** was established. Further, on the basis of chemical shifts of the allylic carbons ( $\delta$  25.6–28.2), the geometry of all the double bonds was determined to be in the *Z* form [11].

Accordingly, the structure of **1** was determined to be (2*S*)-1-*O*-(5*Z*,8*Z*,11*Z*,14*Z*,17*Z*-eicosapentaenoyl)-2-*O*-(9*Z*,12*Z*,15*Z*-octadecatrienoyl)-3-*O*- $\beta$ -D-galactopyranosyl-*sn*-glycerol.

Compound **2** was also isolated in the form of as an amorphous gum. The exact mass measurement of its  $[M + Na]^+$  at *m/z* 795 revealed the elemental composition to be C<sub>45</sub>H<sub>72</sub>O<sub>10</sub>Na (observed *m/z*, 795.5018; theoretical *m/z*, 795.5023). <sup>1</sup>H, <sup>13</sup>C NMR, and MS/MS spectra for **2** were closely similar to those observed for compound **1**. From the fragmentation patterns observed in the CID spectrum of its  $[M + Na]^+$ , compound **2** was observed to contain two polyunsaturated fatty acyl groups from the G<sub>1</sub> and G<sub>2</sub> ions at *m/z* 517 and 519, respectively; it contained the 9,12,15-octadecatrienoyl and 6,9,12,15-octadecatetraenoyl (i.e., stearidoenoyl) groups.

Similarly, the locations of two fatty acids in compound **2** were established by the correlations of HMBC and were confirmed by enzymatic hydrolysis. The key HMBC correlations in **2** also revealed the positions of two different acyl chains in the glycerol moiety. The methylene protons at  $\delta$  2.30 (H-2') within C18:3 chain were correlated with the carbonyl carbon at  $\delta$  175.0 (C-1'), which further exhibited the HMBC correlation with the methylene protons at  $\delta$  4.43 and 4.21 (C-1) on the glycerol group. This observation indicated the attachment of 9,12,15-octadecatrienoyl chain (C18:3) at the *sn*-1 position of **2**. The regiospecificity of the two fatty acyl groups was also confirmed by the specific enzyme-catalyzed hydrolysis of *sn*-1 fatty acyl linkage.

As mentioned above, compound **2** was determined to be (2*S*)-1-*O*-(9*Z*,12*Z*,15*Z*-octadecatrienoyl)-2-*O*-(6*Z*,9*Z*,12*Z*,15*Z*-octadecatetraenoyl)-3-*O*- $\beta$ -D-galactopyranosyl-*sn*-glycerol.

Compounds **3** and **4** were identified by comparing their spectral and physical data with compounds that were reported earlier.

The ( $\omega - 3$ ) family of polyunsaturated fatty acids present in these components occurs widely in algae. However, glycolipid compounds containing two useful ( $\omega - 3$ ) polyunsaturated fatty acids are not commonly observed. And in this case, the linkage of the polyunsaturated fatty acids in the glycerol moiety could be readily determined by the NMR techniques; this technique was preferred over both the enzymatic and alkaline hydrolysis that followed the LC–MS method.

# Plasma Lipoproteins and Triacylglycerol are Predictors of Small, Dense LDL Particles

Vasilis Tsimihodimos · Irene Gazi · Christina Kostara ·

**Abstract** Recently published data suggest that the assessment of LDL subfraction profiles may contribute to the determination of the cardiovascular risk. In this study, we tested the ability of various metabolic parameters to estimate the presence or the preponderance of small, dense LDL particles (sdLDL). One hundred and fifty individuals attending the Outpatient Clinics of the University Hospital of Ioannina for suspected metabolic abnormalities were included in the study. Individuals were excluded if they were found to be diabetic or if they had a history of cardiovascular disease. Patients with thyroid dysfunction, liver or kidney diseases as well as those receiving drugs that may interfere with lipids or glucose metabolism were also excluded from the study. The ability of the various parameters to identify individuals with pattern B LDL phenotype or, alternatively, with measurable quantities of sdLDL particles was tested with the calculation of the areas under the ROC curves. The ratio of triglycerides to HDL-C was the best predictor of the presence of the pattern B LDL phenotype. Nevertheless, when the variable of interest was the presence of measurable quantities of sdLDL subfractions, the ratio of apoB to apoAI had the best predictive

ability. In conclusion the ratios of apoB to apoAI and of triglycerides to HDL-C can reliably predict the presence of measurable quantities of sdLDL particles and of the pattern B LDL phenotype, respectively. However, since the quantitative determination of sdLDL concentrations may contribute to the determination of the cardiovascular risk, whereas the role of the LDL particle size remains controversial, apoB to apoAI ratio could provide more valuable information compared to markers that simply predict the presence of the pattern B LDL phenotype.

## Introduction

Low-density lipoprotein (LDL) concentrations represent a well-established predictor of cardiovascular morbidity and mortality [1]. Previously published studies have shown that LDLs are not the sum of identical particles but rather they consist of discrete subfractions that differ in respect to their size, density, composition, and other physicochemical properties [2]. These differences are, at least in part, responsible for the differences observed in the biological behaviour of LDL subfractions and more specifically in their ability to promote atherosclerosis [3]. Experimental studies suggest that the small, dense LDL particles (sdLDL) may exhibit greater atherogenic potential compared to larger and more buoyant LDL subfractions. This increased atherogenicity has been attributed to a number of biological properties of these particles, such as their increased permeability to the subendothelial space [4], their increased affinity for intimal proteoglycans [5, 6], their lower resistance to oxidative modification [7] as well

as to their higher residence time in the plasma due to their decreased affinity for LDL receptors [8].

The clinical studies that tested the contribution of LDL subfraction profile in the determination of the total cardiovascular risk revealed contradictory results. Thus, some studies supported that an LDL subfraction profile characterized by a preponderance of sdLDL particles may represent an independent risk factor for the subsequent development of cardiovascular events [9–11], whereas others failed to reveal an independent predictive value of the LDL subfraction profile when other common risk factors were included in the analysis [12–14]. Recently, the Quebec cardiovascular study as well as the Veterans Affairs High-Density Lipoprotein Intervention Trial (VA-HIT) results showed a strong independent linear relationship between sdLDL particle concentration and the risk for ischemic events, thus indicating that the determination of the concentrations of these particles may be of great clinical significance [15, 16]. More specifically in the Quebec study patients with elevated sdLDL concentrations (third vs. first tertile) had a relative risk of 2.5 for the development of cardiovascular events, whereas in the VA-HIT study the odds ratio for new events associated with a 1-SD (standard deviation) increment in the concentration of sdLDL particles was 1.44. Thus, it is evident that the increased concentrations of sdLDL subfractions (which do not necessarily represent a “preponderance” of these particles) may significantly contribute to the determination of the cardiovascular risk [15, 16].

Several methodologies have been developed for the subfractionation of apolipoprotein B (apoB)-containing lipoproteins and the assessment of the LDL subfraction profile. The most widely used technique in clinical studies was the determination of the peak LDL particle diameter (LDL-PPD) by gradient electrophoresis [17]. Based on the peak particle diameter individuals can be subdivided into those with a preponderance of dense particles (referred as pattern B LDL phenotype) and into those with a preponderance of large, buoyant particles (pattern A LDL phenotype) [18]. However, the peak LDL particle size is an indirect, qualitative marker of the relative distribution of LDL subfractions that does not provide direct information for the concentration of the atherogenic sdLDL particles. On the contrary, other methodologies [such as density gradient ultracentrifugation [19], nuclear magnetic resonance (NMR) spectroscopy [14], gradient electrophoresis followed by quantification of the individual subfractions [20, 21] and recently Lipoprint [22]] allow the direct determination of the concentrations of LDL subfractions and thus they could be more feasible for the study of LDL subfraction profiles. Indeed, it has been proposed that the quantitative assessment of LDL particles may provide more valuable information for the determination of cardiovascular risk than the simple determination of LDL

particle size. Thus, in a number of studies where LDL particle concentration and size were evaluated simultaneously multivariate analyses revealed that sdLDL concentrations were independently associated with the risk of cardiovascular events, whereas LDL size was not a significant predictor of cardiovascular risk [16, 23]. Similarly, in the Quebec cardiovascular study the LDL particle size did not differ significantly between patients with ischemic heart disease and control individuals [15].

Since most of the methodologies that have been used so far for the characterization of lipoprotein subfraction profile are expensive, time consuming and technically demanding their application in every day clinical practice remains limited. Thus, efforts have been made for the identification of simple serum markers that could predict with acceptable sensitivity and specificity the presence of elevated concentrations of the atherogenic sdLDL particles. The aim of our study was to evaluate the ability of various metabolic parameters to predict the presence of phenotype B or, alternatively, the presence of measurable quantities of sdLDL subfractions in a group of individuals referred to the outpatient clinics of our hospital for suspected metabolic abnormalities. The identification of a simple inexpensive marker of the presence of sdLDL particles may provide a useful screening tool that could guide the decision for a more definitive subfraction analysis.

## Methods

### Patients

The study population was consisted of individuals attending the Outpatient Clinics of the University Hospital of Ioannina for suspected metabolic abnormalities. Individuals were excluded if they were found to be diabetic (fasting glucose levels greater than 7 mmol/l) or if they had a history of cardiovascular disease. Patients with thyroid dysfunction, liver or kidney diseases (defined as a positive medical history or a threefold increase in serum aminotransferases and serum creatinine levels greater than 92  $\mu$ mol/l, respectively) as well as those receiving drugs that may interfere with lipids or glucose metabolism were also excluded from the study. After the application of these exclusion criteria a total of 150 patients were included in the study. All study participants gave a written informed consent prior to their enrollment in the study, which was approved by the Ethics Committee of the University Hospital of Ioannina.

### Analytical Methods

All samples for lipid and lipoprotein determinations were collected after an overnight fast. Serum levels of total

cholesterol, HDL-C and triglycerides were determined enzymatically on the Olympus AU600 Clinical Chemistry analyzer (Olympus Diagnostica, Hamburg, Germany). Serum LDL-C was calculated using the Friedewald formula (provided that triglyceride levels were lower than 3.95 mmol/l). In individuals with serum triglyceride concentrations greater than 3.95 mmol/l ( $n = 9$ ) LDL-C was not determined. Serum apolipoproteins AI and B (apoAI and apoB, respectively) levels were measured with a Behring Holding GmbH BN 100 Nephelometer (Liederbach, Germany).

#### LDL Subclass Analysis

Electrophoresis was performed using the Lipoprint LDL System (Quantimetrix, Redondo Beach, CA, USA) as previously described [24]. By definition (according to the manufacturer's instructions) a concentration of sdLDL-cholesterol greater than 0.16 mmol/l was considered to be representative of the presence of "measurable" quantities of sdLDL particles in the serum. LDL-PPD was determined using the  $R_f$  at the highest peak of LDL bands according to the equation proposed by Kazumi et al: LDL-PPD =  $(1.429 - R_f) \times 25$  [23]. Individuals with an LDL-PPD <25.8 nm were considered to have a pattern B LDL subfraction profile [25]. It should be noted that the subfractionation of apoB-containing lipoproteins was performed within 24 h after sample collection. Meanwhile the samples were stored at 4 °C.

#### Statistical Analysis

All values were checked for normality with the Kolmogorov–Smirnov test and were found to be normally distributed. Correlations between sdLDL particle indices and other metabolic parameters were estimated using linear regression analysis, whereas, multiple regression analysis was used for the multivariate assessment of the correlations between those variables. In all cases a  $P$  level of less than 0.05 was considered statistically significant. To test the ability of various measures to predict the presence of sdLDL particles we constructed Receiver Operating Characteristic (ROC) curves and calculated the areas under the curve (AUC). The best cut-off points in apoB to apoAI and triglyceride to HDL-C ratios were determined using the Youden's index [26].

#### Results

The clinical characteristics and the lipid profile of the study individuals are shown in Table 1. Most subjects were

middle-aged, whereas 58% of the study participants were women. Study individuals exhibited a wide spectrum of serum lipid concentrations (Table 1). As shown in the table, 39% of study subjects displayed a LDL-PPD lower than 25.8 nm (pattern B LDL phenotype). However, when study participants were evaluated for the presence of sdLDL particles 69% of them were found to have measurable quantities of these particles in their serum.

Table 2 displays the univariate, unadjusted correlations between sdLDL particle indices and various metabolic parameters. As shown, the serum concentrations of sdLDL particles were positively correlated with the concentrations of total, LDL and non-HDL cholesterol as well as with triglycerides and apoB. In addition, a significant negative correlation between sdLDL values and apoAI was also observed. The concentration of sdLDL particles was also positively correlated with the ratios of apoB to apoAI and triglycerides to HDL-C, whereas it was negatively correlated with the ratio of total cholesterol to triglycerides. As it is shown in Table 2 serum triglycerides along with the non-HDL cholesterol values showed the strongest correlations with the concentrations of sdLDL particles. Multivariate analysis (which included triglycerides, LDL-C, HDL-C and serum concentrations of apolipoproteins AI and B as predictors) revealed that serum triglycerides and LDL-C concentrations were the only important independent determinants of sdLDL cholesterol values (beta values

**Table 2** Correlations between small, dense LDL subfraction indices and various metabolic parameters

0.5 and 0.31 for triglycerides and LDL-C, respectively;  $P < 0.01$  for both correlations).

On the other hand LDL-PPD was positively correlated with the serum concentrations of HDL-C and apoAI as well as with the ratio of total cholesterol to triglycerides (Table 2). Conversely, LDL particle diameter was negatively correlated with total, LDL and non-HDL cholesterol, triglycerides and apoB as well as with the ratios of apoB to apoAI and triglycerides to HDL-C. Again, serum triglyceride concentration exhibited the strongest correlation with LDL-PPD. Surprisingly, the ratio of LDL-C to apoB [a marker widely used as indicative of the presence of sdLDL particles [27–29]] was only weakly correlated with the indices of sdLDL subfractions (Table 2). In multivariate analysis the serum concentration of triglycerides was the only significant independent determinant of LDL-PPD (beta value -0.46,  $P < 0.01$ ).

The ability of the lipoprotein variables that were most closely related to the concentrations of sdLDL particles to predict the presence of measurable quantities of sdLDL subfractions was evaluated with ROC analysis. The corresponding AUCs, their confidence intervals as well as their level of significance are displayed in Table 3. As can be seen, the AUC was greatest for the ratio of apoB to apoAI, whereas the serum concentration of triglycerides and the ratio of triglycerides to HDL-C gave slightly lower values. The same variables were also tested for their ability to predict the presence of the pattern B LDL phenotype. As shown in Table 3, the strongest predictor was the ratio of triglycerides to HDL-C, whereas serum triglycerides and the apoB to apoAI ratio revealed lower AUC values. In

agreement with the results of linear regression analysis, the ratio of LDL-C to apoB (which has been widely used as a marker for the presence of sdLDL) gave AUC values for the presence of sdLDL that differ substantially from those observed for the other parameters (Table 3).

The selection of a cut-off point for a particular test is a complicated procedure that is largely affected by two factors: disease prevalence and the relative “cost” of errors (false-positive and false-negative results) [30]. The Youden index is a prevalence-independent index that optimises the summary measures of sensitivity and specificity [26]. According to this index the best cut-off value for the ratio of apoB to apoAI was 0.687. This value predicted the presence of measurable quantities of sdLDL particles with a sensitivity of 86% and a specificity of 69%, respectively, whereas the corresponding positive (PPV) and negative predictive values (NPV) were 68 and 67%, respectively. Similarly, according to the Youden's index the best cut-off point for the ratio of triglycerides to HDL-C was 3.69 (when both parameters were expressed in mg/dl). This value predicted the presence of the pattern B LDL phenotype with a sensitivity of 81% and a specificity of 66%, whereas the corresponding PPV and NPV were 33 and 94%, respectively. Although the Youden index represents a useful tool for the comparison of multiple tests, it does not provide cut-off points that can be easily applied in every day clinical practice. Thus, if the surrogate markers of the presence of sdLDL particles are to be used as screening tools for deciding which subjects have a high probability of having measurable quantities or a preponderance of sdLDL subfractions (and thus are eligible for a more definitive subfraction analysis) cut-off values with higher specificity should be selected. In this context, the values of the ratios of apoB to apoAI and of triglycerides to HDL-C that

provide a specificity of 90% for the identification of individuals with measurable quantities or a preponderance of sdLDL particles were 0.85 and 5.45, respectively. The corresponding sensitivities, PPVs and NPVs were 56, 91 and 46% for the ratio of apoB to apoAI and 62, 53 and 92% for the ratio of triglycerides to HDL-C, respectively. On the other hand, if the aim of these screening tools is to identify nearly all the individuals with measurable quantities or a preponderance of sdLDL subfractions, a cut-off point with high sensitivity should be selected. The values of the ratios of apoB to apoAI and of triglycerides to HDL-C that gave a sensitivity of 90% were 0.61 and 2.77, respectively. The corresponding specificities, PPVs and NPVs were 38, 77 and 62% for the ratio of apoB to apoAI and 48, 27 and 97% for the ratio of triglycerides to HDL-C, respectively.

It must be noted that in our population, a ratio of triglycerides to HDL-C of 3.5 [that was shown to have the greatest discriminative value in previous studies [31]] predicted the presence of the pattern B LDL phenotype with a sensitivity of 80% and a specificity of 61%.

## Discussion

Previous studies have shown that LDLs comprise a heterogeneous group of particles that differ in respect to their physicochemical properties and to their biological behaviour [2]. Experimental and clinical data suggest that sdLDL subfractions exhibit greater atherogenic potential as compared to large, buoyant LDL particles [3]; consequently, the assessment of LDL subfraction profile may substantially contribute to the determination of the total cardiovascular risk. However, since most of the techniques currently used for the subfractionation of apoB-containing lipoproteins are expensive, time-consuming and technically demanding their application in every day clinical practice seems very difficult. In this study we tested the ability of various common metabolic parameters to predict the presence (or the preponderance) of sdLDL particles. In agreement with previously published studies we found that the ratio of triglycerides to HDL-C was the best predictor of the presence of pattern B LDL subfraction distribution [31, 32]. Nevertheless, when the variable of interest was the presence of measurable quantities of sdLDL subfractions in the serum (irrespective of LDL subfraction profile) the ratio of apoB to apoAI had the best predictive ability.

The determination of LDL-PPD with gradient gel electrophoresis, although more convenient for use in every day clinical practice compared to other techniques (NMR, density gradient ultracentrifugation), does not provide direct information concerning the concentration of the atherogenic sdLDL particles. On the contrary, it represents a rough, indirect, qualitative marker of LDL particles'

relative distribution and can be modified by changes not only in the concentrations of sdLDL subfractions, but also in the concentrations of large, buoyant particles as well as in the concentrations of subfractions of intermediate density. Although the LDL-PPD was the most widely used marker of LDL subfraction profile in the past, recently developed methodologies (NMR, Lipoprint) focus on the direct determination of the concentrations of the atherogenic sdLDL particles. Since recently published studies revealed that the increased concentration of these particles (which do not necessarily represent a preponderance) may contribute to the determination of the total cardiovascular risk [15, 16], whereas the LDL particle size is not an independent predictor of ischemic events [16, 23] this approach seems to be more sensitive and precise. Indeed, based on the LDL-PPD, a substantial proportion of subjects in our study (about 30%) would have been misclassified as having low cardiovascular risk (since they did not exhibit a pattern B LDL phenotype), whereas, Lipoprint analysis revealed that these patients had measurable quantities of sdLDL subfractions in their serum and thus, they may deserve further quantitative determination of the sdLDL concentration for the precise determination of their future cardiovascular risk. Consequently, the determination of the ratio of apoB to apoAI that predicts the presence of sdLDL particles seems to be more valuable than markers that simply predict the presence of a pattern B LDL phenotype.

The determination of the LDL subfraction profile is a complicated process involving the production and catabolism of apoB-containing lipoproteins as well as the intravascular remodelling of lipoprotein particles [33, 34]. Experimental and clinical studies have shown that the most important determinant of this process is the concentration of triglyceride-rich lipoproteins [18, 35]. As a consequence, patients with elevated triglyceride values usually exhibit a preponderance of dense LDL particles (pattern B LDL phenotype), whereas individuals with normal concentrations of triglycerides usually have a predominance of buoyant LDL particles (pattern A LDL phenotype) [17]. In this context it is not surprising that the ratio of triglycerides to HDL-C was the most important predictor of the presence of the type B phenotype, since triglycerides significantly affect the distribution of LDL particles. On the other hand, when the variable of interest was more "quantitative" i.e. the presence of measurable quantities of sdLDL particles the ratio of apoB to apoAI had the best predictive ability. A possible explanation for this difference could be that the numerator of this later ratio (which represents a marker of the sum of apoB-containing particles) includes, in addition to the "driving force" for the generation of sdLDL particles (triglyceride-rich lipoproteins), the substrate that is available for this generation (LDL particles). Thus, it could be expected that patients with high LDL values could

exhibit measurable quantities (but not predominance) of sdLDL particles even in the absence of elevated triglyceride concentrations. This assumption is indirectly supported by our data showing that LDL-C concentrations were significantly correlated with the concentrations of sdLDL particles, but not with the LDL-PPD that represents an indirect, qualitative measure of LDL subfraction distribution.

Another important issue that deserves special attention is the inverse relationship between the measures of high-density lipoproteins (HDL-C and apoAI) and sdLDL particle indices (sdLDL concentrations and LDL-PPD). Although this relationship has been observed in many studies [20, 29, 36] there is a discrepancy as to whether this correlation remains significant after the inclusion of triglycerides in the multivariate analyses. Thus, it is not known if HDL particles are directly implicated in the generation of sdLDL particles or if this correlation merely represents a consequence of the well-known inverse correlation between the concentration of triglycerides and that of HDL-C. Our data indicates that the incorporation of HDL indices in the ratios of triglycerides to HDL-C and apoB to apoAI, respectively, improves the ability of apoB and triglycerides to predict the presence of sdLDL particles. Nevertheless, further studies are needed to delineate the role of HDL in the process that generates sdLDL particles.

Recently published studies indicate that the ratio of apoB to apoAI is a very strong predictor of cardiovascular risk [37, 38]. Although pathophysiologically the prognostic ability of this measure can be easily explained by the inclusion of markers of the atherogenic apoB-containing particles and of the reverse cholesterol transport process (apoB and apoAI, respectively), it could be assumed that the significant relationship of this ratio with the concentrations of sdLDL particles may also contribute to its predictive value. In this context, Jungner et al. [29] recently proposed that the failure of LDL particle size to add predictive information to the apoB to apoAI ratio may just reflect that this ratio also captures the risk related to LDL size.

A potential limitation of our study is that a significant proportion of the study participants exhibited an abnormal lipid profile and elevated concentrations of sdLDL particles. Consequently, our sample is not representative of the general population. However, the predictive ability of the various metabolic parameters was assessed using measures that are not affected by the prevalence of the tested variable in the study population (such as sensitivity, specificity and AUC). In addition, our study population is representative of the individuals usually referred to outpatient clinics with suspected metabolic abnormalities; in this population the assessment of LDL subfraction profile is of potential clinical interest for the determination of the total cardio-

vascular risk. On the contrary, since the concentrations of sdLDL particles are significantly correlated with serum lipids, an LDL subfraction profile characterized by elevated concentrations of these particles can only exceptionally be observed in individuals with normal lipid values. This observation along with the lack of clinical guidelines and specific treatments for the reduction of sdLDL particle concentrations in otherwise healthy individuals, significantly limit the clinical value of the determination of LDL subfraction profile in the general population.

Recently published studies revealed a substantial heterogeneity of results and interpretations among the methodologies currently used for the analysis of LDL subfractions [39]. Thus, another potential limitation of our study is the use of the Lipoprint system which does not allow the comparison of our results with those in the literature obtained by other techniques. However, in the absence of a standardization program the same is also true for the other methodologies currently used for the subfractionation of apolipoprotein B-containing lipoproteins [39].

In conclusion, the ratios of apoB to apoAI and of triglycerides to HDL-C can reliably predict the presence of measurable quantities of sdLDL particles and of the pattern B LDL phenotype, respectively. However, since the increased concentrations of sdLDL particles may substantially contribute to the determination of the total cardiovascular risk, whereas the role of the LDL particle size remains controversial, the apoB to apoAI ratio may provide more valuable information compared to markers that simply predict the presence of a pattern B LDL phenotype.

**Abstract** A cholesterol-rich nanoemulsion (LDE) that mimics the composition of low-density lipoprotein (LDL) acquires apoE in the plasma and is taken-up by the cells by LDL receptors. In this study, to verify whether free cholesterol (FC) and the cholesteryl ester (CE) components of LDL are taken-up differently by the vessels. LDE labeled with  $^3\text{H}$ -cholesterol and  $^{14}\text{C}$ -cholesteryl oleate was injected into 20 coronary artery disease patients 24 h before a scheduled myocardial coronary artery bypass grafting. The plasma kinetics of both radiolabels was determined from plasma samples collected over 24 h, and fragments of vessels discarded during surgery were collected and analyzed for radioactivity. LDE FC was removed faster than CE. The radioactive counting of LDE CE was greater than that of LDE FC in the blood, but the uptake of FC was markedly greater than that of CE in all fragments: fivefold greater in the aorta ( $p = 0.04$ ), fourfold greater in the internal thoracic artery ( $p = 0.03$ ), tenfold greater in the saphenous vein ( $p = 0.01$ ) and threefold in the radial artery ( $p = 0.05$ ). In conclusion, the greater removal from plasma

of FC compared with CE and the remarkably greater vessel tissue uptake of FC compared with CE suggests that, in the plasma, FC dissociates from the nanoemulsion particles and precipitates in the vessels. Considering LDE as an artificial nanoemulsion model for LDL, our results suggest that dissociation of FC from lipoprotein particles and deposition in the vessel wall may play a role as an independent mechanism in atherogenesis.

### Introduction

The low-density lipoprotein (LDL) quasispherical particle is basically composed of a core of cholesteryl esters (CE) with residual triglycerides surrounded by a phospholipid monolayer that also contains free cholesterol (FC). Apolipoprotein B100, the single protein molecule on the particle surface mediates the removal of the lipoprotein from the circulation through binding of the particle to specific cell membrane receptors. In the circulation, CE molecules may shift from LDL to other lipoprotein classes by means of the cholesterol ester transfer protein, that can also transfer triglycerides and phospholipids [1]. In contrast, FC is able to freely diffuse from LDL to the surrounding aqueous medium. Therefore, FC is less stable in the lipoprotein structure than CE [1].

Cholesterol is esterified in the intravascular compartment by the action of lecithin cholesterol acyl transferase (LCAT) using apo A1 as a co-factor [2]. This reaction occurs mainly in HDL, which is the central esterification

site in the plasma. In LDL, the esterification reaction may occur only at very slow rates [2]. Cholesterol trapped by the cells of the vessel wall is esterified by acyl-CoA:cholesterol acyltransferase catalysis. The phenomena related with the uptake of the cholesterol contained in lipoproteins such as LDL by the arterial wall are of fundamental importance in the understanding of the mechanism of the lipid deposition and accumulation in the artery and atherogenesis.

Lipoproteins can be modeled by artificially made lipid emulsions [3–7]. We have shown that nanoemulsions (LDE) roughly resembling the lipidic structure of LDL particles, as described above, but made without protein, are taken-up by LDL receptors [3, 6]. In contact with plasma, LDE acquires apo E and other apolipoproteins from native lipoproteins. Apo E can be also recognized by LDL receptors and allows binding of the artificial emulsion to the receptors. Compared to native LDL, LDE is more rapidly removed from the plasma due to the differences in apolipoprotein profile on the surface of those particles. Apo E that binds to the LDE particle surface has been shown to possess several times greater affinity for the receptor than the unique LDL apolipoprotein, namely apo B100. In fact, when apo B100 was incorporated to LDE before the injection into rats, the removal from the plasma of the emulsion was markedly slowed down [8].

Compared with native LDL, the shorter testing period, uniformity of the preparation and ease of labeling with isotopic, fluorescent or other means are advantages of the LDE model that facilitate the performance of plasma kinetic studies. Thus, LDE has been used to investigate in subjects defects in the process of LDL removal from the plasma. Recently, we observed that after intravenous injection the removal of LDE FC was faster in patients with coronary artery disease (CAD) than in controls without the disease [9]. On the other hand, the removal of the CE of the nanoemulsion did not differ between CAD and non-CAD subjects. This suggests that in CAD, dissociation of the free form of cholesterol from the nanoemulsion particles, and for extension of native LDL, occurs with potential pathophysiological implications. In this study, the question was posed whether or not the two forms of cholesterol constituting the nanoemulsion particles are taken up at different rates by the blood vessels of CAD patients. To answer this question, LDE labeled with both  $^{14}\text{C}$ -cholesteryl oleate and  $^3\text{H}$ -cholesterol was injected intravenously in CAD patients that were scheduled for coronary bypass surgery within the next ensuing 24 h. After the injection, blood samples were taken and the arterial and venous fragments that were discarded during the surgical procedure were analyzed for radioactive counting.

## Methods

### Patients

Twenty patients (3 females and 17 males) with CAD who were scheduled for coronary artery bypass grafting (CABG) were selected from the infirmary of the Heart Institute. They were aged 41–79 years ( $59 \pm 9$ , mean  $\pm$  S.D.). The patients did not have concomitant metabolic diseases, renal or hepatic dysfunction, as evaluated by clinical and laboratory criteria. The patients had (in  $\text{mg dl}^{-1}$ ) total cholesterol  $204 \pm 12$ , LDL cholesterol was  $129 \pm 11$ , HDL was  $41 \pm 3$ , triglycerides  $170 \pm 23$ , and glucose  $114 \pm 9$  (mean  $\pm$  S.D.).

### Plasma Biochemical Determinations

Blood samples for determination of plasma lipids were collected after a 12-h fast on the same day the kinetic studies were performed. Commercial enzymatic methods were used for the determination of total cholesterol (Boehringer-Mannheim, Penzberg, Germany) and triglycerides (Abbott Laboratories, USA). HDL cholesterol was determined by the same method used for total cholesterol after lipoprotein precipitation with magnesium phosphotungstate. LDL cholesterol was calculated by the formula of Friedewald [10].

### LDE Preparation

LDE was prepared from a lipid mixture composed of 40 mg cholesteryl oleate, 20 mg egg phosphatidylcholine, 1 mg triolein and 0.5 mg cholesterol purchased from Nu-Check Prep (Elysian, USA).  $^{14}\text{C}$ -cholesteryl oleate and  $^3\text{H}$ -cholesterol purchased from Amersham International (Amersham, UK) were added to the mixture. Emulsification of lipids by prolonged ultrasonic irradiation in aqueous media and the procedure of two-step ultracentrifugation of the crude emulsion with density adjustment by addition of KBr to obtain LDE microemulsion was performed as described previously [3, 6]. LDE was dialyzed against saline solution and passed through a  $0.22\text{-}\mu\text{m}$  millipore membrane filter for injection into the patients.

### Dissociation of FC and CE from LDE and from Native LDL

To verify whether or not the dissociation of lipids from the LDE particles is similar to dissociation from native LDL, both LDE and LDL labeled with  $^{14}\text{C}$ -cholesteryl oleate and  $^3\text{H}$ -cholesterol were dialyzed against human plasma for

measurement of the radioactivity remaining in the dialysis bags during a 48-h period.

For this experiment, LDE was obtained and labeled with the radioactive lipids as described above. Native LDL was obtained from a healthy normolipidemic donor by sequential ultracentrifugation of the plasma aliquot using a SW41 rotor (Beckman, Palo Alto, CA, USA). For labeling with the radioactive lipids, the obtained LDL fraction was incubated with 1Ci  $^{14}\text{C}$ -cholesteryl oleate and 1Ci  $^3\text{H}$ -cholesterol dissolved in ethanol at 37 °C for 48 h [11, 12]. LDL was then separated from the unbound radioactive lipids using the same ultracentrifugation procedure described above. Five 0.5 ml aliquots of the labeled LDE and five of the native LDL were transferred to five dialysis bags, each one designed to the sequential dialysis times: 5 min and 1, 2, 8 and 48 h. After the dialysis against plasma, the volumes of the bags were transferred to counting vials for radioactive counting in a scintillation counter. The data of the radioactivity remaining in the LDE and LDL fractions into the dialysis bags were plotted against time and the AUC was calculated.

#### LDE Plasma Kinetics and Cholesterol Esterification

On the day preceding surgery, at approximately 9:00 a.m., the labeled emulsion (roughly 130 kBq  $^{14}\text{C}$ -cholesteryl oleate and 158 kBq  $^3\text{H}$ -cholesterol, 4 mg total lipid mass) was injected intravenously in a bolus, with the participants fasting for 12 h. During the study, they were allowed two standard meals, at approximately 12:30 p.m. and 7 p.m. Plasma samples were collected over 24 h, at intervals of 5 min and 1, 2, 4, 6, 8 and 24 h after the injection. Aliquots (1.0 ml) of blood plasma were transferred to counting vials containing 7.0 ml of scintillation solution (Ultima Gold XR, Packard, Groningen, The Netherlands). Radioactivity was counted using a Packard 1660 TR (Meriden, CT, USA) spectrometer.

To verify the kinetics of cholesterol esterification in the LDE remaining in the plasma after the injection into the patients, the sequential plasma samples collected for the clearance experiments were submitted to lipid extraction and resolved into lipid classes by thin-layer chromatography as described in our previous study [9]. Bands corresponding to free and esterified cholesterol were scraped and transferred into vials for  $^3\text{H}$  radioactivity counting.

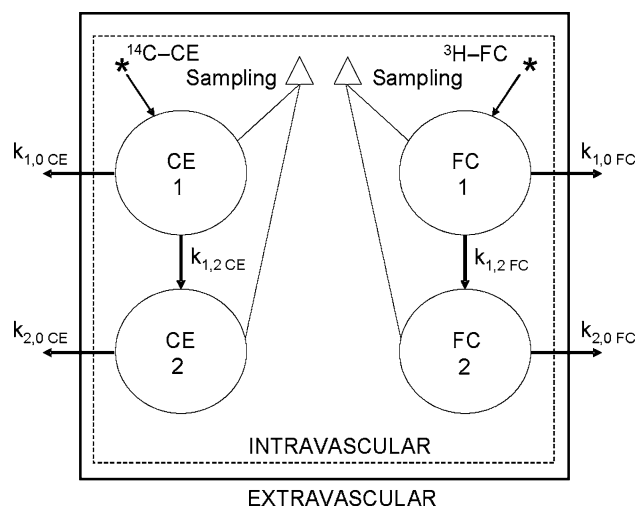

#### Estimation of Fractional Catabolic Rate

Fractional catabolic rates (FCR) of the LDE  $^{14}\text{C}$ -cholesteryl oleate and  $^3\text{H}$ -cholesterol, were calculated according to the method described by Matthews [13] as FCR, where  $a_1$ ,  $a_2$ ,  $b_1$  and  $b_2$  were estimated from

biexponential curves obtained from the remaining radioactivity found in plasma after injection, fitted by least squares procedure, as  $y = (a_1 \cdot e^{-b_1 t}) + (a_2 \cdot e^{-b_2 t})$  where  $y$  represents the radioactivity plasma decay as a function of time ( $t$ );  $a$  indicates the linear coefficient and  $b$ , the angular coefficient, which represents the FCR in  $\text{h}^{-1}$ . The FCR were estimated from parameters  $a_1$ ,  $b_1$  and  $b_2$  by the following equation:  $\text{FCR} = (a_1/b_1 + a_2/b_2)^{-1}$ . Calculations were performed using the ANACOMP software [14]. The compartment model used is illustrated in Fig. 1.

#### LDE Uptake by the Vascular Tissues

During the surgery, which occurred 20–24 h after LDE injection, the removed fragments of CABG were collected, separated and put into 0.9% cold saline solution and immediately transported to the laboratory for analysis. The fragments of vascular (aorta, radial, internal thoracic arteries and saphenous vein) and pericardium were then chopped and lipids from 0.1 g of both tissues were extracted with chloroform/methanol (2:1, v/v) and the radioactivity was measured in a scintillation solution.

**Fig. 1** Compartmental model used to analyze the kinetics of LDE FC and CE. The model consists of four discrete compartments: two for  $^{14}\text{C}$ -CE and two for  $^3\text{H}$ -FC labels. All compartments are in the intravascular space ( $I_{\text{CE}}$ ,  $2_{\text{CE}}$ ,  $I_{\text{FC}}$  and  $2_{\text{FC}}$ ). LDE  $^{14}\text{C}$ -CE and  $^3\text{H}$ -FC were injected intravenously in a bolus (arrow with asterisk) into compartment  $I_{\text{CE}}$  and  $I_{\text{FC}}$ , respectively. A fraction  $k_{1,0\text{CE}}$  and  $k_{1,0\text{FC}}$  of the labeled lipids is removed to the extravascular space. Competitively, fractions  $k_{1,2\text{CE}}$  and  $k_{1,2\text{FC}}$  of the injected lipids are converted into compartments  $2_{\text{CE}}$  and  $2_{\text{FC}}$  due to the incorporation of apolipoproteins available in the plasma. Subsequently, the materials of those compartments are transferred to the extravascular space following the  $k_{2,0\text{CE}}$  and  $k_{2,0\text{FC}}$  routes. The samplings, represented by triangles correspond to the indiscriminate combination of compartments 1 and 2

## Informed Consent and Radiological Safety

The experimental protocol was approved by the Ethical Committee of the Heart Institute and a written informed consent was given by all participants. The safety of the radioactive dose intravenously injected into the patients was assured according to the regulations of the International Commission on Radiological Protection, ICRP [15]. The injected dose in each experiment was 0.03 mSv, well below the 50 mSv annual limit for intake of radionuclides as described in our previous study [14].

## Statistical Analysis

Data normality was tested by the Kolmogorov–Smirnov procedure. Data are expressed as mean  $\pm$  standard error of the mean except for FCR and the constants ( $k$ ) of transference that are expressed as median and percentiles (25th; 75th) (Table 1). The FCRs of  $^{14}\text{C}$ -cholesteryl oleate and  $^3\text{H}$ -cholesterol were compared by the Mann–Whitney's rank sum test. Parametric tests, analysis of variance, were performed to compare the decay curves points of LDE radioactive labels, and the amount of  $^{14}\text{C}$  and of  $^3\text{H}$  radioactivity measured in fragments. In all analysis, difference of two tail  $p < 0.05$  was considered statistically significant.

## Results

Figure 2 shows the curves of disappearance from the dialysis bags of LDE and native LDL labeled with both  $^3\text{H}$ -FC and  $^{14}\text{C}$ -CE. It is apparent that there was no difference between LDE and LDL regarding the rates of desorption of

**Table 1** Fractional catabolic rate (FCR, in  $\text{h}^{-1}$ ) and the transfer constants ( $k$ ) of the  $^{14}\text{C}$ -cholesteryl oleate ( $^{14}\text{C}$ -CE) and  $^3\text{H}$ -cholesterol ( $^3\text{H}$ -FC) labels of LDE

Kinetic parameters	Labeled lipids	Median (25th;75th)	$p$ -value <sup>a</sup>

<sup>a</sup> Mann–Whitney rank sum test comparing the parameters of the CE with those of FC decay curve

the two radioactive lipids from the dialyzed preparations. As expected from the curve behavior, the AUC of the FC and CE of LDE were not different of those of native LDL.

Figure 2 shows the decay curves of the LDE radioactive labels. It appears that in the first 6 h the decay of  $^3\text{H}$ -FC is faster than that of the  $^{14}\text{C}$ -CE ( $p < 0.05$ ). Subsequently, the incline of both curves seems to be equal. Table 1 shows that the FCR of both labels is not different, presumably due to the trend of the two curves to become equal after the 6-h point. This could be ascribed to recirculation of the LDE-labeled lipids. Table 1 also shows the kinetic parameters derived from both the decay curves.

Figure 3 shows the average esterification curve of the LDE FC injected into the blood stream of the subjects. There was increasing esterification of FC so that by 8 h

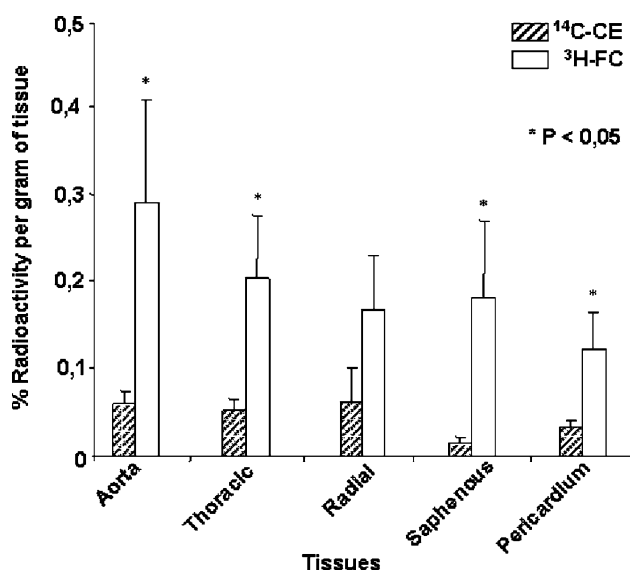

**Fig. 2** Dissociation of FC and CE from LDE and native LDL. LDE and LDL, both labeled with  $^{14}\text{C}$ -cholesteryl oleate and  $^3\text{H}$ -cholesterol were dialyzed against human plasma at for measurement of the radioactivity remaining in the dialysis bags during a 48-h period. After the dialysis, the volumes of the six bags, each one corresponding to a different period of dialysis (5 min and 1, 2, 8 and 48 h) were transferred to counting vials for radioactive counting. The data of the radioactivity remaining in the LDE and LDL fractions into the dialysis bags were plotted against time and the AUC was calculated. Experiments were performed in duplicate.

**Fig. 3** Kinetics of cholesterol esterification in the LDE remaining in the plasma after the intravenous injection. The sequential plasma samples collected over 24 h were submitted to lipid extraction and resolved into lipid classes by thin-layer chromatography;  $^3\text{H}$  radioactivity was measured in the bands corresponding to free and esterified cholesterol. In the average curve obtained from 12 patients, %  $^3\text{H}$  FC that was transformed into  $^3\text{H}$  CE is plotted against time

almost 60% of the FC of the LDE remaining in the plasma had been esterified, but thereafter a plateau was attained.

Figure 4 shows the amount of  $^{14}\text{C}$  and of  $^3\text{H}$  radioactivity measured in fragments of the aorta, internal thoracic and radial artery and saphenous vein. In all vessel tissues the amount of the LDE  $^3\text{H}$ -FC was greater than that of the  $^{14}\text{C}$ -CE: roughly fivefold greater in the aorta, four-

**Fig. 4** LDE  $^3\text{H}$ -cholesterol and  $^{14}\text{C}$ -cholesteryl oleate labels taken up 24 h after the injection into the patients submitted to coronary artery bypass grafting by the following fragments: 1 aorta ( $n = 7$ ); 2 internal thoracic artery ( $n = 14$ ); 3 radial artery ( $n = 7$ ); 4 saphenous vein ( $n = 10$ ) and 5 pericardium ( $n = 8$ ). Results are % of the radioactivity injected recovered per gram of tissue. Mean  $\pm$  standard error of the mean, asterisk represents  $p < 0.05$ , ANOVA

fold in the internal thoracic, threefold in the radial artery and tenfold in the saphenous vein ( $p < 0.05$ ). Comparing the uptakes of CE by the arterial tissues with that of the saphenous vein, they tended to be greater in the arteries, but this difference was statistically significant only between the aorta and the saphenous vein ( $p = 0.05$ ). There was no difference in the FC uptake between the saphenous vein and the arterial tissues. The uptake of FC was also greater than that of CE in the pericardium.

## Discussion

In this study, after the injection of doubly labeled LDE into CAD patients, the removal from the plasma of the FC was faster than that of CE in the first 6 h and, conversely, more FC than CE was taken up by the vessels.

In lipoprotein structure, FC, which is located in the particle surface, is more unstable than the CE located in the particle core. The esterified form largely depends on transfer proteins to exit the lipoprotein particle when is shuttled to other lipoprotein particles. Thus, CE is continuously kept sequestered into a more stable plasma cholesterol pool which exists in the lipoprotein core. Despite the action of transfer proteins, CE is a tracer of the lipoprotein particles and in fact the plasma kinetics of CE as a component of LDL is similar to that of apolipoprotein B [17]; apo B does not dissociate from the lipoprotein and is in fact the LDL marker in the circulation. In contrast, the unesterified form may diffuse into the surrounding aqueous media and thereafter may precipitate in the vessel wall.

Thus, since in the study patients, FC tended to be removed faster than CE of LDE, it can be assumed that the FC was being dissociated from the LDE particles in the circulation. FC that leaks from LDE may incorporate into other lipoprotein classes, a process that can be facilitated by phospholipid transfer proteins. In our study, however, it is unlikely that this had happened at substantial rates; native lipoproteins such as VLDL, LDL or HDL are removed from the plasma slower than LDE. If LDE FC were transferred to the native lipoproteins, the removal from plasma would be slower and not faster than that of LDE CE, as observed in this study. By showing that LDE releases FC and CE at rates similar to those of native LDL, the dialysis experiment illustrated in Fig 2 indicates that LDE is appropriate for exploring the phenomenon of FC dissociation that occurs in the plasma decaying curves of CAD patients (Fig 5).

It is likely that the precipitation of the dissociated molecules in the arterial wall would be the cause of the accelerated removal of the FC from the plasma. This is confirmed by the vessel tissue uptake experiments wherein there is more free than esterified cholesterol in the vessels.

**Fig. 5** Plasma decay curves of LDE  $^3\text{H}$ -cholesterol and  $^{14}\text{C}$ -cholesteryl oleate obtained from 20 patients. Labeled LDE was injected intravenously the day before the scheduled coronary artery bypass grafting and plasma samples were taken at predetermined intervals over 24 h for radioactive counting in a liquid scintillation solution. Data are expressed as mean  $\pm$  standard error of the mean, asterisk represents  $p < 0.05$ , ANOVA

Conceivably, the excess FC in the vessels corresponds to the direct deposition of FC dissociated from the LDE particles. On the other hand, the LDE CE present in the vessels should correspond to the whole particles taken-up by the cells via receptor-mediated endocytosis [16, 18–21].

It is also possible that, in addition to the deposition in the vessel wall, the LDE FC could also be trapped by blood cells. These were removed from the blood samples taken from the patients for the radioactive plasma counting and were not evaluated. In the pericardium, a greater uptake of FC than CE was found which suggests that in tissues other than vessels, this could be occurring. For ethical reasons this was not examined in our patients. Another important limitation of the study consisted of the impossibility of performing the vessel uptake experiments in non-CAD control subjects for comparison with the data of the CAD patients.

Nonetheless, in our previous study we compared the plasma kinetics of LDE FC and CE determined in CAD patients with the data of control non-CAD subjects [9]. In CAD patients there was leakage of FC from the LDE particles, as suggested by the increased removal of the FC relative to the esterified form, but this did not occur in the non-CAD controls. Because excess FC in the vessels is consequent to the loss of this component in the blood, it is not likely that the greater deposition of FC than CE could also be occurring in non-CAD subjects. Therefore, it is reasonable to presume that FC would be more prone to dissociate from the particles in patients with CAD than in subjects without the disease, and then precipitate this cholesterol in the vessel wall. It is difficult to ascertain whether or not this phenomenon is a consequence of the

atherosclerosis process or, otherwise, participate in mechanisms that originate the disease.

The plasma disappearance curve of the LDE FC was faster than that of CE in just the first 8 h after injection (Fig 5). This was translated into a greater  $k_{1,0}$  of FC than that of CE and suggests that FC dissociation from LDE would occur only in that initial period. However, lipoproteins are continuously being synthesized and introduced into the plasma compartment, so that there would be continuous, uninterrupted release of FC from lipoproteins in subjects predisposed to CAD, as pointed out in our previous study. Another interesting point is that also in the first 8 h after injection there was a progressive esterification of the  $^3\text{H}$  FC in the LDE particles remaining in the plasma that thereafter reached a plateau. This coincides with the behavior of the FC plasma decay curve that was faster than that of CE only in the first 8 h, suggesting a possible causal link between esterification and the desorption of FC from the lipoprotein particles.

Dissociation of the plasma kinetics of the two forms of cholesterol was also documented in our recent study involving patients with familial hypercholesterolemia (FH) [22]. As expected, the removal of the LDE CE was delayed in the hypercholesterolemic patients, as occurs with the kinetics of apo B of native LDL in this condition. As to the removal of FC, it was equal to that of the CE but the reduction in FH patients was not so marked as that of the CE. On the other hand, whereas the treatment with simvastatin normalized the removal of cholesterol esters, that of the FC was accelerated but at smaller rates. Those findings support the assumption that the two forms of cholesterol composing the structure of the same lipoprotein particles may undergo different metabolic fates.

The established mechanisms for the lipid deposition in atherosclerosis involve the arterial deposition of the entire lipoprotein particles. In the lipoprotein peroxidation mechanism, the most well known and documented proposal for the lipid deposit in atherogenesis, after peroxidation of the protein and lipid components of LDL, a process that occurs mainly in the subendothelial space, the modified lipoprotein is taken-up by the macrophages after recognition by the scavenger receptors [19–21]. Macrophage lipid plethora originate the foam cells that make-up the fatty streaks, the precursor lesions in atherogenesis [20–23].

The possibility that LDL FC may detach from the lipoprotein and move by aqueous diffusion to cellular membranes was raised by Lundberg and Suominen in an in vitro study with fibroblasts [24]. They postulated that unesterified cholesterol from LDL can move by aqueous transport, despite its low water solubility, and this transfer is facilitated by the addition of albumin to the medium. Ohmura et al. [25] showed that the FC content in the small dense LDL

subfraction particles is relatively depleted. Because this subfraction is considered the most atherogenic, this might suggest that FC impoverishment could be a contributing factor to the disease development.

In the past, many authors have been concerned with the form of cholesterol deposited in the arterial wall [ 26–31]. In the current study, the use of LDE double labeled with the two cholesterol forms and injected into the bloodstream allows the identification in the vessel of the original cholesterol form present into the nanoemulsion structure and injected into the patients, regardless of whether it was esterified or hydrolyzed subsequently to the injection [31].

It is interesting that not only in the artery the uptake of the FC of the injected LDE was greater than that of CE, but this also happens in the veins analyzed. In the vein, the FC/CE ratio seems greater than in the arteries, probably because the CE uptake, i.e., whole particle uptake, was smaller. Thus, the uptake of the LDE particles was smaller whereas the deposition of the dissociated FC was similar to that of the arteries. Although the vein is not prone to atherosclerosis, when grafted to the arterial system as in coronary artery saphenous bypass surgery may develop atherogenesis rapidly so that most grafted veins become occluded within 10 years in a typical atherosclerosis process. Nonetheless, the fact that the vein also shows a >1 FC/CE ratio may suggest that the FC deposit is not consequent to the atherosclerosis process.

Dissociation of the FC from lipoprotein particles may occur by several mechanisms, such as the activity of LCAT. FC is continuously esterified by the action of this enzyme, and a deficit in this action may facilitate dissociation. In severe cases of LCAT deficiency, precocious atherosclerosis develops. Likewise, other humoral or rheologic factors or combination of them may facilitate dissociation of FC.

The direct deposition of FC may disturb the metabolism of endothelial or smooth muscle cells such that secretion of pro-inflammatory factors or apoptosis may be induced. FC accumulation is a potent inducer of inflammatory cytokines and apoptosis in macrophages which represent two important features of advanced unstable plaques.

In conclusion, and in accordance with our previous study that showed greater removal of FC in CAD patients than in non-CAD subjects, there was a relatively greater deposition of the LDE <sup>3</sup>H-cholesterol than the LDE <sup>14</sup>C-CE in the vascular tissues. This result suggests that what may be occurring is dissociation of the FC from the LDE and for an extension from the LDL particles and deposition of this cholesterol in the vessel wall.

**Abstract** Alterations in plasma apolipoproteins levels can influence the composition, content, and distribution of plasma lipoproteins that affect the risk of atherosclerosis. This study assessed the relationship between plasma apolipoproteins levels, mainly apoAI, and HDL subclass distribution. The contents of plasma HDL subclasses were determined by two-dimensional gel electrophoresis coupled with immunodetection in 545 Chinese subjects. Compared with a low apoAI group, the contents of all HDL subclasses increased significantly both in middle and high apoAI group, and the contents of large-sized HDL<sub>2b</sub> increased more significantly relative to those of small-sized pre $\beta$ <sub>1</sub>-HDL in a high apoAI group. When apoAI and HDL-C levels increased simultaneously, in comparison to a low apoAI along with HDL-C concentration group, a significant increase (116%) was shown in HDL<sub>2b</sub> but only a slight increase (26%) in pre $\beta$ <sub>1</sub>-HDL. In addition, Pearson correlation analysis revealed that apoAI levels were positively and significantly correlated with all

HDL subclasses. Multiple liner regression demonstrated that the apoAI concentrations were the most powerful predictor for HDL subclass distribution. With the elevation of apoAI concentrations, the contents of all HDL subclasses increased successively and significantly, especially, an increase in large-sized HDL<sub>2b</sub>. Further, when apoAI and HDL-C concentrations increased simultaneously, the shift to larger HDL size was more obvious. Which, in turn, indicated that HDL maturation might be enhanced and, the reverse cholesterol transport might be strengthened along with apoAI levels which might be a more powerful factor influencing the distribution of HDL subclasses.

### Introduction

Most prospective epidemiological studies have firmly established that high density lipoprotein (HDL) as assessed by its cholesterol content is inversely correlated with the incidence and prevalence of atherosclerosis [1–3]. In recent years, it has been considered that changes in the distribution of HDL subclasses might be an important marker for susceptibility to the development of coronary heart disease (CHD) [4]. This anti-atherogenic action of HDL is probably related to the reverse cholesterol transport (RCT) by which excess peripheral cholesterol is returned to the liver.

HDL is highly heterogeneous with respect to the hydrated density, size, shape, charge and physiologic functions [5]. Using two-dimensional gel electropho-

resis and subsequently the immunoblotting method, HDL can be subdivided into large-sized (HDL<sub>2a</sub> and HDL<sub>2b</sub>) and small-sized subclasses (pre $\beta$ <sub>1</sub>-HDL, HDL<sub>3c</sub>, HDL<sub>3b</sub>, and HDL<sub>3a</sub>) and pre $\beta$ <sub>2</sub>-HDL [6, 7]. The protein components of HDL include apolipoprotein AI (apoAI; 70%), apoAII (20%), and small amounts of apoE and apoC<sub>s</sub>. As the principal carrier protein of HDL apoAI is believed to mediate the change of HDL size [8]. ApoAI is the activator of lecithin: cholesterol acyltransferase (LCAT) and LCAT may catalyze unesterified cholesterol to cholesterol ester and promote the conversion of pre $\beta$ <sub>1</sub>-HDL and HDL<sub>3</sub> to HDL<sub>2</sub> thus playing a functional role in the maturation process of HDL subclasses [9]. In addition, apoAI is a critical ligand of the HDL receptor scavenger receptor BI (SR-BI) and the interaction of apoAI and SR-BI may facilitate hepatic selective uptake of HDL-C in the RCT pathway [10]. Therefore, apoAI plays a vital role in the maturation and metabolism of HDL as well as the whole RCT process.

Our laboratory investigated the influence of plasmid lipids on the HDL subclass distribution and results suggested that with the increase of plasma triglyceride(TG), total cholesteryl (TC), and low density lipoprotein cholesteryl (LDL-C) levels as well as TG/HDL-C and TC/HDL-C ratios, or the decrease of plasma HDL-C levels, there was a general shift toward smaller-sized HDL [7, 11–14]. This indicated that HDL maturation might be abnormal and RCT might be weakened. In this work, we investigated the characteristic distribution of HDL subclasses along with relationship between apolipoproteins concentrations in particularly apoAI and alteration of HDL subclass distribution in the Chinese population. This might provide additional information about the potential role of HDL subclasses in the risk for CHD.

## Subjects and Methods

### Subjects

Six-hundred and twelve Chinese adults being either current or retired staff of the university were recruited to participate in a study examining plasma lipid and apolipoprotein concentrations. The study protocol was approved by an ethics committee, and all subjects gave informed consent. Exclusion criteria included the following: (1) presence of nephrosis, diabetes mellitus, hypothyroidism, hepatic impairment; (2) presence of major cardiovascular event (myocardial infarction, severe surgery), stroke; (3) taking lipid-altering

medications in the previous 1 month; (4) consuming alcohol, and smoking cigarettes in the previous week before the study. In addition, the women had not undergone administration of hormone replacement therapy or used oral contraceptives and were not pregnant. After applying the exclusions, 545 subjects (347 males mean age  $56.4 \pm 9.5$  years, 198 females mean age  $56.9 \pm 9.0$  years), 395 subjects were from the West China University of Medical Science, Sichuan University and Sichuan Normal University, in Chengdu, Sichuan Province, PR China. 150 subjects were from Nan Hua University, in Hengyang Hunan Province, PR China were included in our present study.

In order to investigate the impact of plasma apoAI levels on the distribution of the HDL subclasses, we divided the subjects into three groups according to apoAI concentrations. Firstly, frequency distribution of apoAI using the Kolmogorov–Smirnov test showed a normal distribution (Fig. 1). Considering that about 68% scores fell in the range of the mean (1248.1) plus or minus 1 SD (204.5), we used 1043.6 mg/L (1248.1–204.5) and 1452.6 mg/L (1248.1 + 204.5) as the two cut-out points. So, the subjects were further subdivided into a low apoAI group (apoAI  $\leq$  1043.6 mg/L), a middle apoAI group (apoAI 1043.6–1452.6 mg/L) and a high apoAI group (apoAI  $\geq$  1452.6 mg/L). To investigate further the influence of plasma apoAI and HDL-C levels on the distributions of HDL subclasses, we divided the subjects described above into three groups according to plasma HDL-C levels, that is, high ( $\geq$ 1.55 mmol/L), middle (1.03–1.55 mmol/L), and low ( $<$ 1.03 mmol/L). The HDL-C levels selected for classifica-

**Fig. 1** Frequency distribution of apoAI in total subjects

tion generally conform to Adult Treatment Panel III guidelines [15].

### Specimens

Whole blood specimens were drawn, after a 12-h overnight fast, into EDTA-containing tubes. Plasma was separated within 1–2 h. The plasma was then stored at 4 °C and used within 24 h for lipid and apolipoprotein analyses. An aliquot of plasma was stored at –70 °C for the determination of HDL subclasses.

### Plasma Lipid and Apolipoprotein Analyses

Plasma TG, TC and HDL-C were measured by standard techniques. TC and TG were determined with enzymatic kits (Beijing Zhongsheng Biotechnological Corporation, Beijing). HDL-C was determined after precipitation of the apolipoprotein (apo)B-containing lipoproteins by phosphotungstate/magnesium chloride [16]. LDL-C was calculated using the Friedwald formula ( $TG < 4.52 \text{ mmol/L}$ ) [17]. When plasma  $TG \geq 4.52 \text{ mmol/L}$ , LDL-C was determined using the precipitation method with polyvinylsulfate (enzymatic kits). Plasma apoAI, B100, CII, CIII and E were determined by radial immunodiffusion methods [18] using kits developed at the Apolipoprotein Research Laboratory, West China Medical Center, Sichuan University. The intra-assay CV for apolipoprotein concentrations was between 2.1 and 4.8%, inter-assay CV was 3.5–7.9% [19].

### HDL Subclass Analyses

For each of the enrolled subjects, apoAI-containing HDL subclasses were measured by nondenaturing two-dimensional gel electrophoresis associated with the immunodection method as described previously [7]. Briefly, 10  $\mu\text{l}$  of plasma was first separated by charge on 0.7% agarose gel, into  $\text{pre}\beta$  and  $\alpha$  mobility particles. After electrophoretic separation of lipoproteins in agarose gels, the developed lipoproteins on agarose gels along with a mixture of standard proteins (bovine serum albumin, ferritin, and thyroglobulin obtain from Pharmacia Uppsala, Sweden) were further separated by electrophoresis in 2–30% nondenaturing polyacrylamide gradient gel in the second dimension. In fact, after 2-D gel electrophoresis, plasma proteins and molecular markers were electrophoretically transferred to PVDF membranes, stained with 0.1% ponceau S, and the position of

molecular standard protein bands labeled by pencil, and destained by diffusion, then, using 5% dyllipid milk, recovered from the membrane, following interaction with horseradish peroxidase-labeled goat anti-human apo-AI-IgG. The relative concentration of each subclass was calculated as the percentage of plasma apoAI (%) according to the density of each spot. Particle diameters of the HDL subclasses were assessed by comparing the mobility of the sample with the mobility of calibration standard proteins. Then the relative percentage concentration of each HDL subclass was multiplied by apoAI concentrations in sample individuals, respectively. The result was the relative concentration of each HDL subclasses of apoAI(mg/L, apoAI in the subclasses). The inter assay CVs of relative content of  $\text{pre}\beta_1$ -HDL,  $\text{pre}\beta_2$ -HDL, HDL<sub>3c</sub>, HDL<sub>3b</sub>, HDL<sub>3a</sub>, HDL<sub>2a</sub> and HDL<sub>2b</sub> in plasma sample were 9.4, 9.8, 4.9, 6.2, 7.3, 11.1 and 7.9%, respectively ( $n = 5$ ).

### Statistical Analyses

All statistical analyses were performed using the statistical package SPSS Version 11.0 (SPSS Inc). The Kolmogorov–Smirnov test was applied to test normal distribution. Data were expressed as the mean  $\pm$  SD. The significant differences between two groups were analyzed by one-way analysis of variance (ANOVA). Multiple liner correlation and regression were calculated to study correlation. Differences were considered significant at  $P < 0.05$ .

## Results

### Concentrations of Plasma Lipids, Apolipoproteins and Contents of HDL Subclasses

Table 1 showed that in the population, the concentration of TG was  $2.4 \pm 1.7 \text{ (mmol/L)}$  which exceeds normal TG levels recommended in the third Report of the National Cholesterol Education Program (NCEP) (ATPIII) guidelines, which indicated a substantial proportion of subjects with hypertriglyceridemia. Meanwhile, concentrations of plasma lipids, lipoproteins along with contents of HDL subclasses were similar change in this population and the subjects with endogenous hypertriglyceridemia [12].

Furthermore, concentrations of TG, and the ratios of TG/HDL-C, TC/HDL-C were significantly lower while those of HDL-C, apoAI, HDL<sub>2a</sub> and HDL<sub>2b</sub> were significantly higher in female than in male.

### ApoA-I Contents of HDL Subclasses

Figure 2 shows the distributions of HDL subclasses for representative subjects from the group having normolipidemic (A) and from the hyperlipidemic groups. In the hyperlipidemic subjects, spots for the small-sized subclasses (preβ<sub>1</sub>-HDL, HDL<sub>3a</sub>, HDL<sub>3b</sub>, and HDL<sub>3c</sub>) were larger, whereas large-sized HDL<sub>2</sub> (HDL<sub>2a</sub> and HDL<sub>2b</sub>) had spots that were smaller in comparison with the normolipidemic subjects.

### Concentrations of Plasma Lipids, Apolipoproteins and Contents of HDL Subclasses According to the Levels of apoAI

As shown in Table 2, with the elevation of apoAI levels, concentrations of HDL-C significantly increased while those of TG decreased significantly. Moreover, all HDL subclasses increased successively and significantly both in males and females. In addition, compared with males in the middle and low apoAI group, the contents

of HDL<sub>2a</sub> and HDL<sub>2b</sub> were significantly higher for the females in the same apoAI group. In the high apoAI group, the contents of all HDL subclasses had no significant difference between males and females.

#### Characteristics of HDL Subclass Contents and Frequency Distribution According to apoAI Along with HDL-C

To further investigate the influence of plasma apoAI combined with HDL-C levels on the distributions of HDL subclasses, we designated apoAI ≥ 1452.6 mg/L together with HDL-C ≥ 1.55 mmol/L as the high concentrations group, apoAI 1043.6–1452.6 mg/L to-

gether with HDL-C 1.03–1.55 mmol/L as the middle concentrations group, and apoAI ≤ 1043.6 mg/L together with HDL-C < 1.03 mmol/L as the low concentrations group. As shown in Fig. 3, there were 180 (approximately 33%) subjects in the middle concentrations group and they occupied the highest percentage of the population.

Table 3 presented that with elevation of apoAI combined with HDL-C concentrations, all HDL subclasses increased significantly and successively; further compared to the low concentrations group, a significant increased (116%) in large-sized HDL<sub>2b</sub> but only a slight increase (26%) in small-sized preβ<sub>1</sub>-HDL were found in high concentrations group.

### Correlation Coefficients Between Apolipoproteins and Contents of Plasma HDL Subclasses

Correlation analysis revealed that apoAI levels were positively and significantly correlated with all HDL subclasses. Furthermore, apoB100, apoCII, apoCIII and apoE showed positive correlations with pre $\beta_1$ -HDL and HDL<sub>3a</sub> as well as negative correlations with HDL<sub>2a</sub>, HDL<sub>2b</sub>. No significant difference was noted between males and females (Table 4).

### Multiple Liner Regression Correlation Between Contents of Plasma HDL Subclasses and Apolipoproteins

Multiple liner regression showed that apoAI was associated independently and positively with all HDL subclasses and it was the most powerful predictor (SRC from 0.321 to 0.605, *P* < 0.001) for alterations of HDL subclass distributions. In contrast, other apolipoproteins showed positive correlation with pre $\beta_1$ -HDL but negative correlation with HDL<sub>2b</sub> (Table 5).

## Discussion

Numerous clinical and epidemiological studies have demonstrated the inverse and independent association between HDL-C and the risk of CHD [20]. HDL exerts various potentially antiatherogenic properties and until recently, the protective features of HDL had been attributed primarily to its classical function of removing cholesterol from peripheral tissues and transferring it to the liver in a process known as RCT. In vitro experiments as well as genetic family and population studies and the investigation of transgenic animal models have revealed that plasma HDL cholesterol levels do not necessarily reflect the efficacy and anti-atherogenicity of RCT [20–23]. Instead, the contents of HDL subclasses are important determinants of RCT and the risk of atherosclerosis [24]. Moreover, the physiologic basis of HDL subclasses has not been elucidated completely. It is necessary to disclose the alterations of distribution of HDL subclasses with the change of plasma apolipoproteins especially apoAI concentrations.

Our results showed that, with the elevation of apoAI levels, all HDL subclasses increased successively and significantly both in males and females. Studies in human apoAI transgenic mice have showed that the distribution of apoAI among the HDL subclasses was similar, suggesting that the content of apoAI in the major HDL subspecies was fixed and that excess apoAI was not present in HDL particles [25]. Kunitake et al. observed that pre $\beta$ -HDL (discoid shape) generally contain 2 copies, and other studies found that pre $\beta_1$ -HDL contain 1 copy whereas large-sized HDL<sub>2</sub> contain four copies of apoAI per particles [26–28]. Hence, apoAI levels might reflect the number of HDL particles, and with the elevation of apoAI levels, molecules of apoAI distributed to each of the subclasses increased which resulted in all HDL subclasses tending to increase. It has been postulated that RCT is

$\beta$ : standardized regression coefficients

indeed the mature and metabolic process that nascent pre $\beta$ -HDL converted to mature  $\alpha$ -HDL. Consequently, the contents of all HDL subclasses increased suggesting that speed of RCT might be enhanced.

Furthermore, the present study showed that the contents of large-sized HDL<sub>2b</sub> increased more obviously relative to those of the small-sized pre $\beta_1$ -HDL with the elevation of apoAI. In comparison to the same gender subjects in the low apoAI levels, there was an increase in HDL<sub>2b</sub> (79% in males; 68% in females) and an increase in pre $\beta_1$ -HDL (38% in males; 43% in females) for the subjects with high apoAI levels, which suggests that plasma apoAI levels have significantly important effects on the distributions of HDL subclasses. The variations of HDL subclass distributions are probably related to an increase in HDL-C concentrations and a decrease in TG concentrations for the subjects with high apoAI levels. Several studies have shown that enhanced LCAT, lipoprotein lipase (LPL) activities and impeded hepatic lipase (HTGL) are consistent with lower plasma TG levels [9, 29, 30]. The LCAT may catalyze unesterified TC to cholesteryl and promote the conversion of pre $\beta_1$ -HDL and HDL<sub>3</sub> to HDL<sub>2</sub>. LPL plays an important role in hydrolyzing TG transported in chylomicrons and very low density lipoprotein (VLDL) particles. When catabolized by LPL, chylomicrons (CM) and VLDL release TG, TC, PL, apoAI, and apoCs. Subsequent binding of these products to HDL<sub>3</sub> results in formation of HDL<sub>2</sub> particles. The HTGL activities promote the conversion of HDL<sub>2</sub> to HDL<sub>3</sub>, and furthermore, excess surface phospholipids and apoAI dissociated from HDL<sub>2</sub>, impaired HTGL activity must lead to the increase of large-sized HDL<sub>2</sub> particles and decrease of small-sized pre $\beta_1$ -HDL particles. In addition, it was demonstrated that LCAT activities also increased with high plasma

HDL-C levels [29]. Hence, with the increase of apoAI levels, not only the number of HDL particles increased but a lot of large-sized HDL<sub>2b</sub> was generated which indicated the speed and efficiency of RCT had been enhanced.

We further analyzed the combined impact of plasma apoAI and HDL-C levels on the alterations of HDL subclass distribution. Data obtained in the present study suggested that, with elevation of apoAI along with HDL-C levels, all HDL subclass levels increased gradually and significantly, meanwhile, compared with low the concentrations group (apoAI  $\leq$  1043.6 together with HDL-C < 1.03), the contents of large-sized HDL<sub>2b</sub> (116%) increased more significantly than those of small-sized pre $\beta_1$ -HDL (26%) which resulted in an elevation of the HDL<sub>2b</sub>/pre $\beta_1$ -HDL ratio (2.0 vs. 3.5) in the high concentrations group (apoAI  $\geq$  1452.6 together with HDL-C > 1.55). It indicated that alteration of the number of large-sized HDL particles might be more obvious with the increase of apoAI and HDL-C levels.

The correlation analysis also showed that the concentrations of apoAI had a significant positive correlation with all HDL subclasses and multiple liner regression revealed that apoAI might be a more powerful factor influencing the distribution of HDL subclasses. HDL is known to serve as a reservoir for apoC<sub>s</sub>, apoE. ApoCII is the activator protein for LPL. In contrast, apoCIII could inhibit the LPL activity. Evidently, changes in concentrations of other apolipoproteins (including apoB100, apoCII, apoCIII, apoE) may affect HDL subclass distribution.

In summary, our results reported in this work showed that with the increase of plasma apoAI concentrations, the contents of all the HDL subclasses rose gradually and significantly, especially, an increase in

large-sized HDL<sub>2b</sub> was very striking. Furthermore, when apoAI and HDL-C concentrations increased simultaneously, the trend toward larger HDL size was more obvious. Which, in turn indicated that the maturation of HDL might be enhanced and that RCT might be improved. In addition, Pearson correlation and multiple linear regression analysis revealed that apoAI levels revealed that apoAI levels might be a more powerful factor influencing the distributions of HDL subclasses.

## Metabolic Syndrome: Effects of n-3 PUFAs on a Model of Dyslipidemia, Insulin Resistance and Adiposity

**Abstract** Both genetic and environmental factors (e.g. nutrition, life style) contribute to the development of the plurimetabolic syndrome, which has a high prevalence in the world population. Dietary n-3 PUFAs specially those from marine oil (EPA and DHA) appear to play an important role against the adverse effects of this syndrome. The present work examined the effectiveness of fish oil (FO) in reversing or improving the dyslipidemia, insulin resistance and adiposity induced in rats by long-term feeding a sucrose-rich diet (SRD). We studied several metabolic and molecular mechanisms involved in both lipid and glucose metabolisms in different tissues (liver, skeletal muscle, fat pad) as well as insulin secretion patterns from perfused islets under the stimulation of different secretagogues. Dietary FO reverses dyslipidemia and improves insulin action and adiposity in the SRD fed rats. FO reduces adipocytes cell size and thus, the smaller adipocytes are more insulin sensitive and the release of fatty acids decreases. In muscle, FO normalizes both the oxidative and non-oxidative glucose pathways. Moreover, FO modifies the fatty acid composition of membrane phospholipids. In isolated  $\beta$  cells, lipid contents and glucose oxidation return to normal. All these effects could contribute to the normalization of glucose-stimulated insulin secretion and muscle insulin insensitivity.

**Keywords** n-3 PUFAs · Metabolic syndrome · Sucrose-rich diet · Dyslipidemia · Insulin resistance · Visceral adiposity

### Introduction

Both genetic and environmental factors (e.g. nutrition, life style) contribute to the development of the plurimetabolic syndrome. This syndrome, which has a high prevalence in the world population, refers to a cluster of metabolic abnormalities including among others: insulin resistance, dyslipidemia [increased triglyceride and decreased high density lipoprotein cholesterol (HDL) levels], hypertension, central obesity, glucose intolerance and type 2 diabetes. All of them are well-documented risk factors for cardiovascular disease [1].

The composition of the macronutrients in the diet plays an important role in modifying several key factors of this syndrome. In this regard, numerous clinical and animal studies on n-3 polyunsaturated fatty acids (PUFAs), especially those from marine oil—eicosapentaenoic acid (20:5n-3 EPA) and docosahexaenoic acid (22:6n-3, DHA)—have shown their beneficial effects impacting on normal health and chronic diseases (e.g. the plurimetabolic syndrome). In addition to their use as fuels and structural components of the cell, the dietary intake of marine n-3 PUFAs (fish oil) has proven to be effective in lowering both triglyceride (Tg) and VLDL-Tg concentration in experimental animals and normal and hypertriglyceridemic men (see review) [2, 3]. It has been shown that fish oil (FO) in rats decreases the mRNA encoding of several enzymes proteins involved in “the novo” hepatic lipogenesis suppressing the nuclear abundance and expression of sterol regulatory element binding protein 1 (SREBP-1),

and enhances fatty acid oxidation throughout a peroxisome proliferator-activated receptor (PPAR $\alpha$ )—stimulated process [4, 5]. Moreover, the effects of n-3 PUFAs includes the alteration of the fatty acid composition of membrane phospholipids that modify membrane-mediated processes such as insulin transduction signals, activities of lipases and biosynthesis of eicosanoids [6].

Numerous studies from our group (see review [2]) and others [7–10] have shown that normal rats fed a sucrose-rich diet for a short period (3–5 weeks) develop hypertriglyceridemia, increase plasma free fatty acid (FFA) levels and enhanced triglyceride accumulation in liver and heart muscle. This is accompanied by normoglycemia with hyperinsulinemia, insulin resistance, increase in the first peak of glucose stimulated insulin secretion in perfused islets and hypertension. A different picture emerges after a long-term feeding (15–40 weeks) of a sucrose-rich diet. In addition to the altered lipid metabolism and ectopic fat deposition in several non adipose tissues, rats develop visceral adiposity with a moderate increase in body weight, hyperglycemia with normoinsulinemia and a lack of the first peak with an increase in the second phase of glucose stimulated insulin secretion from perfused islets [2, 11–14]. Interestingly, this animal model exhibits many of the hallmarks present in the plurimetabolic syndrome in humans. Moreover, the temporal metabolic changes described may reflect the early start of type 2 diabetes mellitus, since many patients have chronically elevated plasma FFA and Tg levels, altered peripheral insulin sensitivity and loss of the first peak of insulin in response to glucose.

Most experimental studies examining the effect of dietary nutrients (e.g. n-3 fatty acids from marine source) on dyslipidemia and insulin resistance have focused on the development of the impairment. In this vein, it has been shown that FO prevents the onset of insulin resistance and dyslipidemia when fed to rats with high fat [2, 15–17] or high sucrose diets [2, 18, 19]. However, relatively few studies have examined the effectiveness of FO in reversing diet-induced insulin resistance [20–23]. Therefore, the rats fed a long-term sucrose-rich diet seem to be an appropriate experimental model to investigate the effect of dietary n-3 PUFAs (fish oil) to improve or reverse these metabolic abnormalities.

The present study was conducted on rats fed a SRD during 8 months, in which a stable dyslipidemia and insulin resistance had been present before the source of fat in the diet (corn oil) was replaced by an isocaloric amount of FO for the last 2 months. We analyzed several aspects of lipid and glucose metabolism in the liver, skeletal muscle and adipose tissue of these rats. In addition, we studied the insulin secretion patterns from “in vitro” perfused isolated islets under the stimulation of different secretagogues (glucose, palmitate) and peripheral insulin sensitivity (euglycemic–hyperinsulinemic clamp).

## Materials and Methods

### Animal Model and Diets

Two months old male Wistar rats, initially weighting 170–185 g were maintained under controlled temperature ( $22 \pm 1$  °C), humidity and air flow conditions, with a fixed 12 h light:dark cycle (light 07:00–19:00). After a 1-week acclimation period, the rats were randomly divided into two groups: experimental and control. The first group received a purified sucrose-rich diet (SRD) containing by weight 62.5% sucrose, 17% of vitamin free casein, 8% corn oil, 7.5% cellulose, 3.5% salt mixture (AIN-93-MX), 1% vitamin mixture (AIN-93M-VX), 0.2% choline chloride, and 0.3% methionine. The control group received the same semisynthetic diet but with sucrose replaced by starch (CD). The experimental group received the SRD for 6 months after which the rats were randomly divided into two subgroups. The rats of the first subgroup continued on the SRD up to 8 months. The second subgroup, SRD + fish oil, (SRD + FO) received the SRD in which the source of fat (corn oil 8/100 g) had been replaced by cod liver oil (7/100 g) plus (1/100 g) of corn oil during the last 2 months on the diet. The control group received the CD throughout the experimental 8-month period. The SRD without the addition of FO used from months 6 to 8 and the CD were balanced for cholesterol and vitamins D and A, present in the FO. Diets were isoenergetics, providing approximately 16.3 kJ/g of food and were available ad libitum. Diets were prepared every day by adding the oils and base mixture containing the other nutrients. The oils and base mixture were separately stored at 4 °C until preparation of the diet. Fish oil was kept under a nitrogen atmosphere during storage. The weight of each rat was assessed twice each week during the experimental period. At the end of the 8 months dietary period, except as otherwise indicated, the food was removed and experiments were performed between 09:00 and 12:00 h. The Human and Animal Research Committee of the School of Biochemistry, University of Litoral, Santa Fe, Argentina, approved the experimental protocol.

### Analytical Methods

Rats were anesthetized with intraperitoneal pentobarbital sodium (60 mg/kg body weight). Blood samples were obtained from the jugular vein, rapidly centrifuged, and plasma was either immediately assayed or stored at  $-20$  °C. Plasma triglyceride, FFA, glucose, leptin and adiponectine as well as immunoreactive insulin levels were determined as previously described [23]. Liver, pancreas, gastrocnemius muscle and white adipose tissue (epididymal and retroperitoneal) were rapidly removed from the

anesthetized rats, and except otherwise indicated they were frozen, clamped in liquid nitrogen and stored at  $-80^{\circ}\text{C}$ . The weight of the epididymal and retroperitoneal adipose tissue was recorded.

#### *Liver Tissue Assays*

Homogenates of frozen liver were used for the determination of triglyceride content [23]. A cytosolic fraction of liver homogenates samples was obtained by centrifugation at  $100,000\times g$ , and the fatty acid synthase (FAS) activity was assayed immediately as described by Halestrap [24]. Carnitine palmitoyltransferase I (CPT-I) activity was determined spectrophotometrically following the release of CoA-SH from palmitoyl-CoA in liver homogenates in the presence and absence of L-carnitine [25]. The fatty acid oxidase activity (FAO) was measured by a modification of the procedure reported by Vamecq [26] and the  $\text{H}_2\text{O}_2$  release was determined spectrophotometrically from a coupled peroxidative reaction [27]. The malic enzyme (ME) activity was assayed by the method proposed by Ochoa with a minor modification according to Hsu et al. [28]. Pyruvate dehydrogenase complex (PDHc), and glucose-6-P-dehydrogenase (G-6-PDH) activities were analyzed as previously described [21]. The triglyceride secretion rate (VLDL-Tg secretion) was evaluated in 12-h fasting rats following the procedure described by Lombardo et al. [20].

#### *Gastrocnemius Muscle Assays*

Triglyceride, long-chain acyl-CoA (LC ACoA), diacylglycerol (DAG), malonyl-CoA, glycogen, and glucose-6-phosphate content as well as the activities of glycogen synthase (GSa), PDHc and PDH kinase were analyzed in muscle homogenate as previously described [29]. Gastrocnemius lipids were extracted, total phospholipids separated by TLC and their fatty acid analyzed by a procedure described in detail by Brenner et al. [14]. The protein mass expression of nPKC $\theta$  in the cytosol and membrane fraction of the gastrocnemius muscle were measured as described by D'Alessandro et al. [29].

#### *Euglycemic Hyperinsulinemic Clamp Studies*

Whole body peripheral insulin sensitivity was measured using the euglycemic hyperinsulinemic clamp technique as described in detail elsewhere [12]. At the end of the second hour of the clamp studies, gastrocnemius muscles were quickly removed, frozen and stored at  $-80^{\circ}\text{C}$  for the assay of both glycogen and glucose-6-phosphate concentration and GSa activity [12].

#### *Adipose Tissue Assays*

##### *Preparation of Isolated Adipocytes*

The adipocytes were isolated from the epididymal fat pad according to the method described by Robdell [30]. Fat cell size, number and triglyceride content were determined in the isolated adipocytes [31]. Aliquots of isolated epididymal fat cells were incubated in a shaking Dubnoff water bath at  $37^{\circ}\text{C}$  for 1 h; glycerol release was measured under these experimental conditions as an index of basal lipolysis. More details of the methodology employed have been previously described [31]. Lipoprotein lipase (LPL) and G-6-PDH activities in epididymal fat pads were also measured as previously described [31].

##### *Total RNA Preparation and Relative Quantitative RT-PCR Analysis*

Adipose tissue total RNA was prepared from fat pad tissue (epididymal and retroperitoneal) of each dietary group. Total RNA samples were stored at  $-80^{\circ}\text{C}$  until quantification of the target mRNAs (ob mRNA and adiponectin mRNA). A real time, two-step RT-PCR assay was developed for mRNA relative quantification as previously described [23]. The relative-quantitative data were expressed as the ratio of the level of adiponectin or leptin mRNA to that of 18S rRNA in arbitrary units.

#### *Pancreas Tissue Assays*

##### *Perifusion of Isolated Islets*

Islets were isolated by collagenase digestion and collected under a stereoscopic microscope. After a 30 min prewash period, a group of 30–40 islets were perifused with a Krebs Ringer buffer pH 7.4 at  $37^{\circ}\text{C}$  ( $\text{O}_2$  95:CO $_2$  5) containing high glucose concentration (16.5 mM) or glucose 16.5 mM plus palmitate 0.5 mM until the end of the perifusion (40 min). In all the experiments, aliquots from the effluent for insulin assays were collected after different periods of time and stored at  $-20^{\circ}\text{C}$  until insulin analysis. More details of the methodology employed have been previously described [22]. Islet triglyceride content and PDHc activity were assayed in isolated islets as previously described [22].

#### *Statistical Analysis*

Results were expressed as mean  $\pm$  SEM. The statistical significant between groups was determined by one way analysis of variance followed by the inspection of all differences between pairs of means by the Newman Keul's

**Table 1** Blood variables in rats fed a control (CD), sucrose-rich (SRD) or SRD + fish oil (SRD + FO) diets

	Triglycerides (mmol/L)	Free fatty acids ( $\mu\text{mol/L}$ )	Glucose (mmol/L)
CD	0.64 $\pm$ 0.04 <sup>b</sup>	287.2 $\pm$ 18.0 <sup>b</sup>	6.40 $\pm$ 0.12 <sup>b</sup>
SRD	2.23 $\pm$ 0.10 <sup>a</sup>	794.0 $\pm$ 30.0 <sup>a</sup>	8.18 $\pm$ 0.10 <sup>a</sup>
SRD + FO	0.60 $\pm$ 0.06 <sup>b</sup>	295.1 $\pm$ 38.0 <sup>b</sup>	6.52 $\pm$ 0.20 <sup>b</sup>

Values are expressed as mean  $\pm$  SEM,  $n = 6$ . Values in a column that do not share the same superscript letter are significantly different ( $p < 0.05$ ) when one variable at a time was compared by the Newman Keul's test

SRD + FO group consumed the sucrose-rich diet for 6 months and the SRD diet containing FO for the last 2 months of the experiment

test.  $P$  values lower than 0.05 were considered to be statistically significant.

## Results

### Blood Variables

At the end of the dark period (7 AM), plasma triglyceride, FFA and glucose concentration were higher ( $p < 0.05$ ) in rats fed a SRD compared with age-matched controls fed a CD (Table 1). A complete normalization of all of these variables occurred in rats fed a SRD + FO during the last 2 months of the experimental period. Moreover plasma insulin levels did not differ between the groups (data not shown).

### Liver Tissue

#### *Main Effects of FO (n-3 PUFAs) on the Hepatic Liver Metabolism of SRD-fed Rats*

Both triglyceride content and VLDL-triglyceride secretion were significantly higher in the liver of rats fed a SRD

**Table 2** Liver triglyceride content, triglyceride secretion rate (VLDL-Tg) and enzyme activities in rats fed a control (CD), sucrose-rich (SRD) or SRD + fish oil (SRD + FO) diets

Diets	CD	SRD	SRD + FO
Triglyceride ( $\mu\text{mol/g}$ wet tissue)	12.60 $\pm$ 0.28 <sup>b</sup>	23.83 $\pm$ 2.35 <sup>a</sup>	11.20 $\pm$ 0.52 <sup>b</sup>
VLDL-Tg [nmol/(min $\times$ g body weight)]	161.5 $\pm$ 3.0 <sup>b</sup>	194.6 $\pm$ 8.5 <sup>a</sup>	120.3 $\pm$ 9.5 <sup>c</sup>

Malic enzyme (mU/mg protein)	1.14 $\pm$ 0.01 <sup>c</sup>	2.15 $\pm$ 0.15 <sup>a</sup>	1.68 $\pm$ 0.06 <sup>b</sup>
Glucose-6-phosphate dehydrogenase (mU/mg protein)	26.06 $\pm$ 2.19 <sup>b</sup>	36.00 $\pm$ 0.95 <sup>a</sup>	23.10 $\pm$ 2.00 <sup>b</sup>
PDHa (% PDHt)	35.02 $\pm$ 1.61 <sup>b</sup>	50.55 $\pm$ 3.04 <sup>a</sup>	36.33 $\pm$ 1.54 <sup>b</sup>
Carnitine palmitoyltransferase I (mU/mg protein)	1.20 $\pm$ 0.13 <sup>b</sup>	0.70 $\pm$ 0.03 <sup>c</sup>	1.92 $\pm$ 0.15 <sup>a</sup>
Fatty acid oxidase (mU/mg protein)	2.40 $\pm$ 0.17 <sup>b</sup>	2.45 $\pm$ 0.13 <sup>b</sup>	5.33 $\pm$ 0.35 <sup>a</sup>

Values are expressed as mean  $\pm$  SEM,  $n = 6$ . Values in a line that do not share the same superscript letter are significantly different ( $p < 0.05$ ) when one variable at a time was compared by the Newman Keul's test

PDHa active form of PDH complex, expressed as percentage of total PDHc activity (PDHa basal activity  $\times$  100/total activity). Total PDH activity (mU/mg protein) 8.01  $\pm$  0.99 for CD, 7.46  $\pm$  0.87 for SRD and 8.00  $\pm$  1.00 for SRD + FO

compared to those fed a CD (Table 2). The activities of the enzymes related to the "novo lipogenesis" were significantly increased in the SRD-fed rats, whereas the fatty acid oxidase (FAO) activity was similar and CPT-1 activity was significantly decrease compared to that in the control group fed a CD. The presence of FO in the SRD collectively acted to normalize or improve liver triglyceride contents and the VLDL-Tg secretion rate as well as the lipogenic enzyme activities, while increasing the mitochondrial and peroxisomal fatty acid oxidation (CPT-1 and FAO activities).

### Skeletal Muscle

#### *Effects of FO on Metabolite Concentrations, Enzyme Activities and PKC $\theta$ Mass Expression in Gastrocnemius Muscle of SRD-fed Rats*

Compared to CD-fed rats, the gastrocnemius muscle of dyslipemic insulin-resistant, SRD-fed rats at the basal state (ex vivo) shows a significant increase ( $p < 0.05$ ) of triglyceride, LC ACoA and DAG contents without changing malonyl-CoA levels (Table 3). Qualitative and quantitative analyses of Western blots showed that the relative abundance of nPKC $\theta$  isozyme was also significantly increased in the membrane fraction of the gastrocnemius muscle of the SRD, whereas the cytosol fraction was slightly but not significantly decreased. Moreover, both a reduced active form of PDHc and an increase in PDH kinase activities were observed in SRD-fed animals, suggesting an impaired glucose oxidation. Table 3 also shows that FO reduced the increased triglyceride contents to basal levels within the skeletal muscle cells, and restored the PDHc activity. Besides, FO improved long-chain acyl CoA and DAG concentration and the nPKC $\theta$  mass expression in the membrane fraction of the skeletal muscle of SRD-fed rats.

**Table 3** Gastrocnemius muscle metabolites, protein mass expression of nPKC $\theta$  and PDHc and PDH kinase activities of rats fed control (CD), sucrose-rich (SRD) or SRD + fish oil (SRD + FO) diets

Diets	CD	SRD	SRD + FO
Triglyceride ( $\mu\text{mol/g}$ wet tissue)	3.34 $\pm$ 0.44 <sup>b</sup>	8.01 $\pm$ 0.40 <sup>a</sup>	3.44 $\pm$ 0.51 <sup>b</sup>
LC ACoA ( $\mu\text{mol/l}$ )	8.72 $\pm$ 0.23 <sup>b</sup>	15.08 $\pm$ 1.44 <sup>a</sup>	10.14 $\pm$ 0.33 <sup>c</sup>
DAG (nmol/g wet tissue)	116.1 $\pm$ 10.0 <sup>c</sup>	177.2 $\pm$ 9.1 <sup>a</sup>	143.5 $\pm$ 7.2 <sup>b</sup>
Malonyl-CoA (nmol/g wet tissue)	1.36 $\pm$ 0.43	1.30 $\pm$ 0.58	1.05 $\pm$ 0.19
nPKC $\theta$ (densitometric units relative to control diet) Cytosol	100.0 $\pm$ 4.1	84.2 $\pm$ 6.2	88.3 $\pm$ 5.0
Membrane	100.0 $\pm$ 3.1 <sup>c</sup>	174.1 $\pm$ 8.0 <sup>a</sup>	143.2 $\pm$ 7.0 <sup>b</sup>
PDHa (% PDHt)	34.51 $\pm$ 1.20 <sup>a</sup>	18.70 $\pm$ 1.81 <sup>b</sup>	32.52 $\pm$ 1.60 <sup>a</sup>
PDH kinase (K/min <sup>-1</sup> )	1.55 $\pm$ 0.12 <sup>b</sup>	3.30 $\pm$ 0.24 <sup>a</sup>	1.60 $\pm$ 0.14 <sup>b</sup>

Values are expressed as mean  $\pm$  SEM,  $n = 6$ . Values in a line that do not share the same superscript letter are significantly different ( $p < 0.05$ ) when one variable at a time was compared by the Newman Keul's test

Long-chain acyl-CoA is expressed as  $\mu\text{mol/L}$  assuming that 80% of the tissue was water, PDHa active form of PDH complex (see Table 2), PDH kinase activity was assayed as determining the adenosine triphosphate-dependent inactivation of PDHc activity as a function of time (K/min<sup>-1</sup>) and was calculated from the first order kinetic constant

Values were still higher than those observed in the CD-fed rats.

On the other hand, dietary FO reversed the impaired insulin-stimulated glucose-6-phosphate concentration, glycogen storage and glycogen synthase activity during the euglycemic hyperinsulinemic clamp (Fig. 1). Moreover, the glucose infusion rate (GIR), which measures whole body peripheral insulin action "in vivo", was lower ( $p < 0.01$ ) in the SRD-fed group [ $24.17 \pm 4.34 \mu\text{mol}/(\text{kg min})$ ,  $n = 6$ ] compared to CD-fed rats [ $64.45 \pm 5.00 \mu\text{mol}/(\text{kg min})$ ,  $n = 6$ ]. However, in the SRD + FO group, the GIR did not differ from the controls [ $68.10 \pm 6.30 \mu\text{mol}/(\text{kg min})$ ,  $n = 6$ ].

The normalization of peripheral insulin sensitivity in the SRD + FO fed rats was accompanied by a significant increase in the n-3 PUFAs, specially EPA and DHA, in the

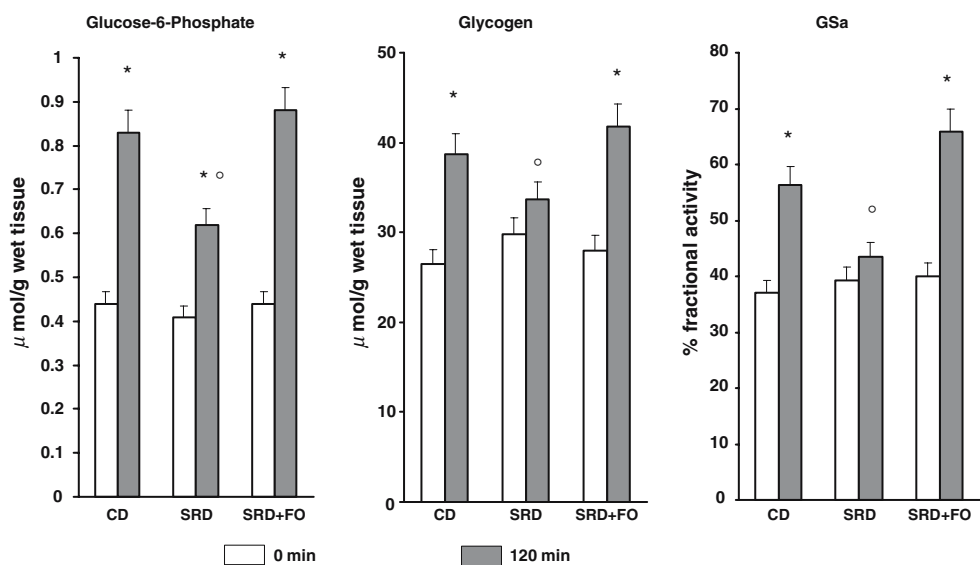

phospholipids of the gastrocnemius muscle. The n-3/n-6 ratio was significantly higher ( $p < 0.05$ ). Values were as follows: % fatty acids; n-3PUFAs (mean  $\pm$  SEM  $n = 6$ ): 13.61  $\pm$  0.44 in CD, 5.58  $\pm$  0.58 in SRD and 22.23  $\pm$  0.61 in SRD + FO. The ratio n-3/n-6 was 0.35 in CD, 0.14 in SRD and 0.81 in SRD + FO, respectively.

#### Adipose Tissue

##### Effects of Dietary FO on Body Weight, Fat Pad Morphology, Triglyceride Content and Enzyme Activities

Rats fed a SRD developed visceral adiposity (increase in epididymal and retroperitoneal fat tissues) and a moderate increase in body weight (Table 4). Isolated adipocyte from epididymal fat tissue showed a significant increase in

**Fig. 1** Glucose-6-phosphate and glycogen concentration and glycogen synthase (GSa) activity in gastrocnemius muscle at the start (*open bars* 0 min) and at the end (*closed bars* 120 min) of the clamp studies in rats fed control (CD), sucrose-rich (SRD) or SRD + fish oil (SRD + FO). Values are expressed as mean  $\pm$  SEM,  $n = 6$ . \* $p < 0.05$  120 versus 0 min in CD, SRD or SRD + FO; (*open circles*)  $p < 0.05$  SRD 120 versus CD and SRD + FO 120 min

triglyceride contents, and cell volume without changes in total cell number compared to CD-fed rats. Lipoprotein lipase and glucose-6-phosphate dehydrogenase activities were significantly increased ( $p < 0.05$ ) in the SRD. Dietary FO markedly reduced the fat pad mass and the hypertrophy of fat cells (decreased cell volume and triglyceride contents). However, only a slight but not significant decrease of total body weight was observed. In addition, we previously reported [31] that the histograms of adipose size distribution that showed a significant increase (37%) of the mean cell diameters in the SRD-fed rats compared to CD-fed animals were significantly improved in the group of rats fed the SRD + FO. The presence of FO in the SRD reduced the high levels of lipoprotein lipase and glucose-6-phosphate dehydrogenase activities. Basal lipolysis, which was significantly increased in isolated adipocytes of SRD-fed rats, was improved when FO replaced corn oil as a source of fat in the diet. Values were as follows (mean  $\pm$  SEM  $n = 6$ )  $\mu\text{mol glycerol}/(10^6 \text{ cells} \times \text{h})$ ;  $0.7 \pm 0.1$  in CD;  $3.4 \pm 0.3$  in SRD and  $1.3 \pm 0.2$  in SRD + FO,  $p < 0.05$  SRD versus CD and SRD + FO;  $p < 0.05$  SRD + FO versus CD.

#### Plasma Leptin and Adiponectin Levels and Gene Expression in White Adipose Tissue

Both plasma leptin and adiponectin levels were significantly decreased in the SRD-fed rats. By shifting the source of fat in the diet to FO, the plasma levels of both adipokines reached values similar to those found in the rats fed a CD (Fig. 2a). Figure 2b shows obmRNA in adipose tissue (epididymal and retroperitoneal) of various dietary groups. Ob mRNA in both adipose tissues did not change between the different groups. Adiponectin mRNA showed a similar profile in both white adipose tissues. The presence of FO

after the installation of insulin resistance induced by the SRD (Fig. 2b) had not additional effects. Therefore, Fig. 2b represents the obmRNA and adiponectin mRNA levels of both adipose tissues.

#### Pancreas

##### Insulin Secretion from Perfused Isolated Islets. Effect of Dietary Fish Oil

Perfused islets from SRD-fed rats showed an alteration in the biphasic patterns of glucose stimulated insulin secretion with an absence of the first peak and an increase in the second phase of hormone secretion compared to CD-fed rats. Dietary FO completely normalized glucose induced insulin secretion in the SRD-fed rats (Fig. 3a). Furthermore, as expected, a short-term exposure of  $\beta$  cell to 0.5 mmol/L of palmitate in the perfused fluid enhanced glucose stimulated insulin secretion in rats fed a CD. In the SRD-fed group, the presence of palmitate diminished both the first peak and the second phase of insulin secretion when compared to the CD group. Dietary FO enhanced the first and second phase of hormone secretion, which was greater ( $p < 0.05$ ) than those in the SRD group and comparable to the control group fed a CD (Fig. 3b).

##### Triglyceride Concentration and PDHc Activity in Isolated Islets

Figure 4a shows an increase ( $p < 0.05$ ) in the triglyceride content in SRD-fed rats that was accompanied by a decrease ( $p < 0.05$ ) in the PDHc activity (Fig. 4b). However, in the SRD + FO fed group neither variable differed from the CD group.

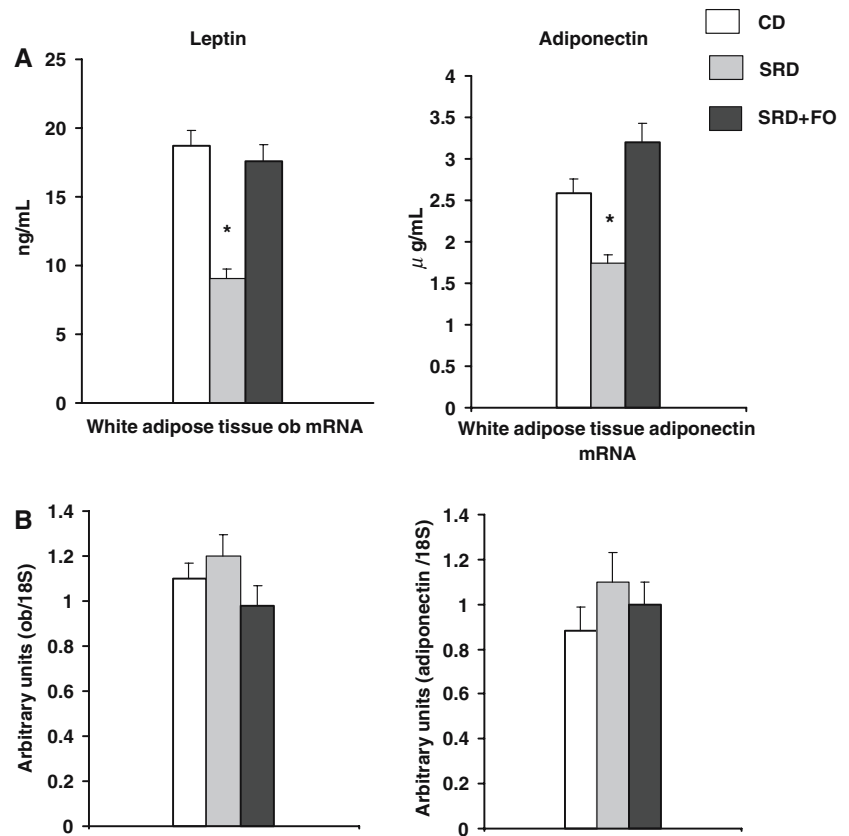

**Table 4** Body weight, adipose tissue weight, cell volume and number, triglyceride content and LPL and G-6-PDH activities in rats fed a control (CD), sucrose-rich (SRD) or SRD + fish oil (SRD + FO) diets

Diets	CD	SRD	SRD + FO

## Discussion

This work focused on the analyses of several metabolic and molecular mechanisms concerning the effect of fish oil (FO) on the reversion or improvement of dyslipidemia and insulin resistance ensuing a long-term feeding of a sucrose-rich diet to normal rats. The study shows that in this experimental model dietary FO is associated with a number of effects that collectively act to reduce dyslipidemia and improve insulin action.

### Effects on the Liver

The liver plays a central role in whole body carbohydrate and lipid metabolism and several metabolic pathways may be regulated by PUFAs through changes in the activity or abundance of different transcription factor families, among them, PPARs, SREBPs, and LXR  $\alpha$  and  $\beta$ . FO decreases plasma and liver triglyceride levels, VLDL-Tg secretion, and return plasma triglyceride to basal levels in SRD fed rats. Moreover, by shifting the source of fat in the SRD from corn oil to FO, the enzymatic activities of FAS, G-6-PDH, ME and PDHc, all of them involved with “the novo” lipogenesis, decreased to values similar to those recorded in the control fed rats while FAO and CPT1 activities were enhanced. Neschen et al. [32] have recently demonstrated that dietary n-3 PUFAs administered to rats increases the fatty acid oxidation capacity of tissues through their ability to function as ligand activators of transcription factor PPAR $\alpha$  and thereby induces the transcription of several gene-encoding proteins affiliated with fatty acid oxidation. Besides, the suppression of “the novo” lipogenesis and MUFA synthesis by n-3 PUFAs requires that the

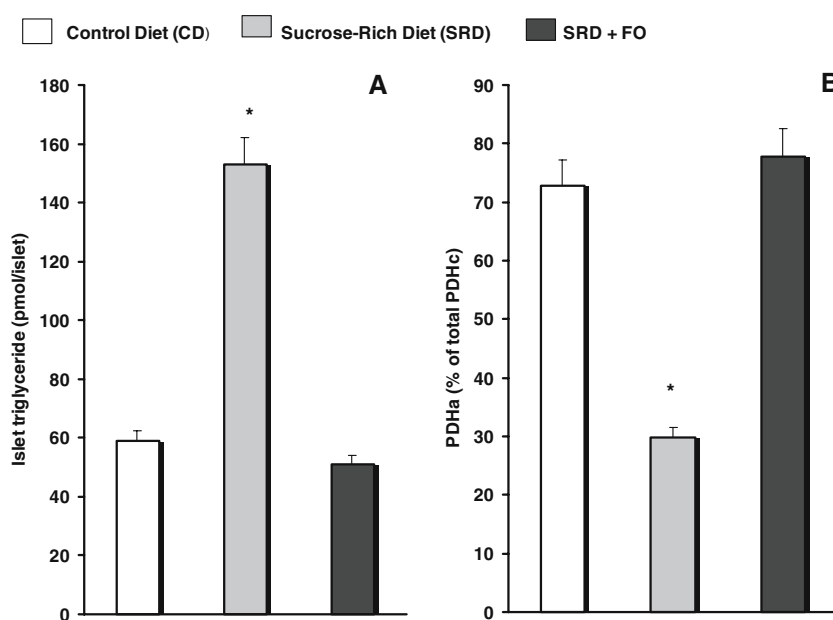

transcription factor SREBP-1c [4]. Thus, in the SRD-fed rats, the normalization of plasma and liver triglyceride levels suggests that the principal action of FO on hepatic lipid metabolism involves a shift from lipid synthesis and storage to lipid oxidation and therefore, both mechanisms, thus contributing to the hypolipemic effect of FO.

### Effects on Skeletal Muscle

In the skeletal muscle, the regulation of the glucose metabolism involves a complex interplay with the other fuels, especially free fatty acids. Studies in rats and humans [33] have shown that the degree of insulin resistance is strongly correlated with the muscle accumulation of triglycerides, and especially with LC ACoA. In the SRD-fed rats, D'Alessandro et al. [29] have recently demonstrated a significant increase in both triglyceride and LC ACoA contents within the gastrocnemius muscle which was accompanied by a significant increase in DAG and nPKC $\theta$  protein mass expression in the cell membrane fraction and a decrease in PDHc activity. LC ACoA by their esterification to DAG stimulate the PKC activity. Indeed, PKC disrupts the insulin signal via serine or threonine phosphorylation of insulin receptors, insulin receptor substrate 1, and potentially, other proteins such as glycogen synthase [34]. An increase in the LC ACoA concentration could also affect translocation of the glucose transport Glut 4 by acylating proteins involved in membrane fusion processes [35]. In addition, a significant reduction of flux through PDHc may limit glucose oxidation via the glucose–fatty acid cycle [29].

Fish oil normalizes and/or improves lipid storage and glucose oxidation within the skeletal muscle as well as

**Fig. 4** Triglyceride content **a** and pyruvate dehydrogenase complex (PDHc) activity **b** in isolated islets from rats fed control (CD), sucrose-rich (SRD) or SRD + fish oil (SRD + FO) diets. Values are mean  $\pm$  SEM,  $n = 6$ . \* $p < 0.05$  SRD versus CD and SRD + FO. PDHa, the active form of PDHc, was expressed as percentage of total PDHc activity (PDHt) (PDHa: basal activity  $\times$  100/total activity). To convert triglyceride contents to pmol, multiply ng by 1.13

nPKC $\theta$  proteins mass expression in the membrane fraction. Moreover, FO reversed the impaired insulin stimulated glycogen storage, glucose-6-phosphate concentrations, GSa activity and whole body insulin insensitivity, and returned plasma glucose and FFA levels to normal without changes in insulin levels.

The hypolipidemic effect of FO decreases the availability of the lipid fuel within the skeletal muscle and could, in turn, restore glucose oxidation and help to normalize insulin resistance. A recent study in healthy humans fed a high fat diet (75% fat) for 3 days showed an increase in PDH kinase and reduced PDHc activities in the skeletal muscle. In these people, the replacement of 15% of the fat by n-3 PUFAs decreased triglycerides and improved PDH kinase without changes in PDHc activities [36]. Moreover, Aas et al. [37] showed that the chronic exposure of EPA increased the uptake and oxidation of glucose despite a marked increase in fatty acid uptake and synthesis of complex lipids in cultured human skeletal muscle.

Increasing evidence suggests that the fatty acid composition of membrane phospholipids in the skeletal muscle and other target tissues is a critical factor that may induce changes in the structure and fluidity of cell membranes that could, in turn, directly affect insulin action. An increase in n-3 EPA and DHA as well as the n-3/n-6 ratio in the gastrocnemius muscle was observed after FO administration to SRD-fed rats, and this could also contribute to improve muscle insulin insensitivity. Moreover, Simonicova et al. [38] also demonstrated that substitution of fish oil into a high fat diet in rats led to an improvement of “in vivo” insulin action. The insulin sensitive effect of FO was accompanied by a decrease of plasma FFA, triglyceride and glycerol levels and a decrease of lipid content in liver and skeletal muscle. However, another study by Podolin et al. [18] demonstrated that when the sucrose diet containing menhaden oil was given to insulin-resistant rats, insulin action on the glucose metabolism remained impaired. Differences in the amount of FO present in the diet as well as the n-3/saturated ratio between the oils employed may contribute to the effectiveness of FO in reversing insulin insensitivity.

#### Effects on Adipose Tissue

Dietary FO was able to reverse the preexisting metabolic and morphological changes of visceral fat pad tissue, reduce the hypertrophy of fat pad cells and improve their altered size distribution in the SRD fed rats. We have also recently observed that both the inhibitory effect of high sucrose upon the antilipolytic action of insulin and the impaired insulin stimulated glucose transport were completely normalized (unpublished results). The changes induced by FO could be possibly via mechanisms that

include FO (specially EPA) binding and activation of the PPAR- $\gamma$ 2 isoform expression in white adipose tissue. PPAR- $\gamma$ 2 results in a coordinated increase in a large number of genes involved in lipid metabolism [39]. Moreover, PPAR- $\gamma$  remodels the adipose tissue in adult animals, driving the formation of small insulin sensitive white adipocytes. Rossi et al. [23] have recently shown that the adiposity and insulin resistance present in the SRD-fed rats were accompanied by a decrease of plasma leptin and adiponectin levels, while no changes in the gene expression of both adipokines in visceral fats (epididymal and retroperitoneal) were observed. Leptin and adiponectin play an important role in the lipid and glucose metabolism and their regulation by FO might be implicated in the functional and morphological changes present in the adipose tissue of SRD-fed rats. Indeed, by shifting the source of fat to FO, the plasma levels of both adipokines were increased without changes in their gene expression, while insulin insensitivity and dyslipidemia were reversed and adiposity improved. Although the mechanisms by which FO increase plasma leptin and adiponectin are still unclear, these results suggest that the normal levels reached by both adipokines might play an essential role in the normalization of insulin resistance and adiposity [23]. Recently, Yamauchi et al. [40] demonstrated that insulin resistance in lipoatrophic mice was completely reversed by a combination of physiological doses of adiponectin and leptin, but only partially when either adipokine was given alone, suggesting that leptin and adiponectin may work hand in hand to sensitize peripheral tissues to insulin. Although we cannot extrapolate these results to humans, Skurnick-Minot et al. [41] demonstrated a decrease of whole body adiposity and adipocyte size in type 2 diabetic insulin resistant patients after 2 months of treatment with FO capsules (1.8 g of n-3 PUFAs). In these patients, plasma adiponectin tended to increase without any deterioration or amelioration of insulin sensitivity at this stage.

#### Effects on $\beta$ Cell Function

A chronic exposure to hyperglycemia and high levels of plasma FFA has been shown to have a deleterious effect on both insulin secretion and action, a concept termed glucolipotoxicity. Several mechanisms have been proposed that could contribute to the dysfunction of the  $\beta$  cell such as changes in glucose oxidation, increase in triglyceride content within the islets, down regulation of several genes including glut 2 and glucokinase, stimulation of SREBP-1c and PPAR $\gamma$  among others (See [42] for a review). In long-term SRD-fed rats, we have recently demonstrated [22] highly deteriorated insulin secretion patterns in response to glucose stimulus. Furthermore, the islets acute exposure to palmitate in the perfusion medium did not improve insulin

release [22]. This was accompanied by an increase in the triglyceride storage within the islets that occurred concomitantly with a reduction of the PDHc activity. A decreased flux through the PDHc is associated with lower PDHa levels, and could involve activation of the PDH kinase. The inhibition of PDHc limits the oxidative glucose metabolism, a signal for insulin secretion and synthesis. These could play a key role in the abnormal insulin secretion of rats chronically fed a SRD. Moreover, the beneficial hypolipidemic effect of dietary FO on  $\beta$  cell dysfunction becomes evident since after FO administration all the above alterations were completely normalized. Interestingly, an improvement by fish oil of both insulin sensitivity and i.v glucose tolerance has been shown in patients with primary hypertriglyceridemia [43].

Finally, dietary FO appears to play an important protecting role against the adverse symptoms of the pluri-metabolic syndrome. The present work suggests some possible mechanisms through which FO improve or reverse dyslipidemia,  $\beta$  cell dysfunction and adiposity in rats fed a long-term a SRD. However, some effects of n-3 PUFAs on physiological processes such as the nature of the intracellular signal responsible for regulating the various affected transcription factors, both in human and experimental models, still remain unclear. Future research in this area will contribute to our understanding of how these singular lipids impact upon human health and disease.

**Abstract** Lipid peroxidation has gained renewed attention with increasing evidence showing its biological role in producing toxic compounds and cellular signaling mediators. The assessment of lipid peroxidation levels in vivo is difficult partly because lipids are oxidized by different oxidants by different mechanisms to give versatile types of products, which may undergo metabolism and secondary reactions. In the present study, total hydroxyoctadecadienoic acids (tHODE) and  $7\alpha$ - and  $7\beta$ -hydroxycholesterol (t7-OHCh) from 44 healthy human subjects were assessed as biomarkers after reduction with sodium borohydride followed by saponification with potassium hydroxide comparing with the prevailing standard 8-isoprostaglandin  $F_{2\alpha}$  (t8-iso-PGF $_{2\alpha}$ ). The average concentrations of tHODE, total 8-isoprostaglandin  $F_{2\alpha}$  (t8-iso-PGF $_{2\alpha}$ ), t7 $\alpha$ -OHCh, and t7 $\beta$ -OHCh were 203, 0.727, 87.1, and 156 nmol/l plasma and 1,917, 12.8, 1,372, and 3,854 nmol/l packed erythrocytes, respectively. The ratios of tHODE and t7-OHCh to the parent substrates were 194 and 3,519  $\mu$ mol tHODE/mol linoleates and 40.9 and 686  $\mu$ mol t7-OHCh/mol cholesterol in plasma and erythrocytes, respectively. It was found that (1) t7-OHCh in blood was unexpectedly high, as high as or even higher than tHODE, (2) the amounts of tHODE was

more than 100 fold higher than t8-iso-PGF $_{2\alpha}$  (3) the level of lipid oxidation products in erythrocytes was higher than that in plasma, and (4) lipid peroxidation products level tended to increase while antioxidant level decrease with age. These products may be used as potential biomarker for assessment of lipid peroxidation and oxidative stress in vivo.

## Introduction

Lipid peroxidation has been implicated in oxidative stress and accepted to be involved in various diseases [1]. It induces disruption of membrane organization, causing changes in fluidity and permeability, inhibition of metabolic processes, and alterations of ion transport. It oxidatively modifies low density lipoprotein (LDL) to become pro-atherogenic. It gives potentially toxic compounds. It has been also shown that lipid peroxidation products act as signaling mediators and induce adaptive response [2, 3]. It was found recently that various lipid peroxidation products induce phase II antioxidant proteins and enzymes by Nrf2-dependent pathway to enhance the defense capacity against subsequent oxidative stress [4–6]. Thus, lipid peroxidation in vivo has received renewed attention.

Lipid peroxidation gives vast numbers of products and the measurement of lipid peroxidation levels in vivo is not easy. Various products have been measured by diverse methods and techniques for that purpose. The oxidation of both fatty acids and cholesterol proceeds by enzymatic and non-enzymatic mechanisms [1]. Lipoxygenases and cyclooxygenases oxidize polyunsaturated fatty acids, while cytochrome P450s oxidize cholesterol specifically. The non-enzymatic oxidation by singlet oxygen and ozone proceeds stoichiometrically, while that by free radicals proceeds by chain mechanism. Importantly, the effectiveness of antioxidants depends on the type of oxidation. Isoprostanes are isomeric to prostaglandins but are formed via the free radical-mediated oxidation of arachidonic acid. Since their first discovery in 1990 [7], isoprostanes have emerged as an excellent biomarker of oxidative damage in vivo [8]. We have been interested in measuring the products from linoleates and cholesterol to measure the lipid peroxidation level in vivo [9]. The biological samples are first reduced and then saponified to convert hydroperoxides and ketones as well as hydroxides of both free and ester forms of linoleic acid and cholesterol to hydroxyoctadecadienoic acid (HODE) and hydroxycholesterol (OHCh), respectively. HODE and OHCh thus measured account for much of oxidized linoleates and cholesterol, respectively.

The mechanisms and products of linoleate oxidation have been studied extensively and are now well understood [10]. The oxidation of free linoleic acid and esters proceeds by the same mechanism to give the same products, although the rate may depend on the substrates and reaction

milieu. The oxidation by 12/15-lipoxygenase proceeds by regio-, stereo-, and enantio-specific mechanisms to give 13S-hydroperoxy-9Z, 11E-octadecadienoic acid (13(S)-(Z, E)-HPODE), while singlet oxygen-mediated oxidation gives 9-, 10-, 12-, and 13-(Z, E)-HPODE. On the other hand, the oxidation induced by free radicals yields both 9- and 13-(Z, E) and (E, E)-HPODE as primary products. They are racemic. HPODEs are readily reduced in vivo by reducing enzymes to give HODE. Thus, 9- and 13-(E, E)-HODE are specific products for free radical-mediated oxidation, while 10- and 12-HODE are specific markers for singlet oxygen oxidation. Cholesterol is oxidized by specific cytochrome P450: CYP7A1 oxidizes cholesterol to give 7α-hydroxycholesterol (7α-OHCh) [11]. Singlet oxygen oxidizes cholesterol to yield 5α-OOHCh, which undergoes isomerization to 7α-OOHCh [12]. On the other hand, free radical-mediated oxidation of free and esterified cholesterol gives several products including 7α- and 7β-hydroperoxycholesterol (7α- and 7β-OOHCh), 7α- and 7β-OHCh and 7-ketocholesterol (7-KCh). These products are converted to free 7α- and 7β-OHCh by the analytical procedures employed in this study.

In the present study, 9- and 13-(Z, E) and (E, E)-HODE and 7α- and 7β-OHCh as well as isoprostanes in plasma and erythrocytes of healthy human subjects were measured and compared. The total amounts of linoleates and cholesterol and low molecular weight antioxidants were also measured to compare the level of oxidation in plasma and erythrocytes and also antioxidant. It was found that the lipids in erythrocytes were oxidized relatively more than those in plasma and that cholesterol oxidation products were found as much as those from linoleates.

## Materials and Methods

### Materials

8-Iso-prostaglandin F<sub>2α</sub> (8-iso-PGF<sub>2α</sub>), 8-iso-prostaglandin F<sub>2α</sub>-d<sub>4</sub> (8-iso-PGF<sub>2α</sub>-d<sub>4</sub>), 13-hydroxy-9(Z), 11(E)-octadecadienoic acid (13-(Z,E)-HODE), 13-hydroxy-9(E), 11(E)-octadecadienoic acid (13-(E,E)-HODE), 9-hydroxy-10(E), 12(Z)-octadecadienoic acid (9-(E,Z)-HODE), 9-hydroxy-10(E), 12(E)-octadecadienoic acid (9-(E,E)-HODE), and 9S-hydroxy-10E, 12Z-octadecadienoic-9,10,12,13-d<sub>4</sub> acid (9-HODE-d<sub>4</sub>) were obtained from Cayman Chemical Company (MI, USA). Other materials were of the highest grade available commercially.

### Subjects

Forty-four healthy volunteers [male = 20, female = 24, age varying from 25 to 82 years (mean ± SD = 57.2 ± 15.2),

body mass index (BMI);  $22.4 \pm 2.8$ ] were enrolled in this study. None of the subjects had a history of any diseases or antioxidant supplements. BMI was not dependent on age in this study ( $r = -0.079$ ,  $P > 0.05$ ). This study was conducted in accordance with the principles of the Declaration of Helsinki and was approved by the local ethics committees of the National Institute of Advanced Industrial Science and Technology and Ikeda Municipal Hospital. All volunteers gave written informed consent after a complete explanation of the purpose of this study.

### Specimen Processing

Blood samples were collected in ethylenediaminetetraacetic acid (EDTA)-containing tubes after overnight fasting. The samples were placed on ice immediately after the collection. Plasma was obtained by centrifugation at  $1,580\times g$  for 10 min at  $4^\circ\text{C}$  and subjected to the analysis immediately. The erythrocytes were washed twice with a fourfold volume of saline and adjusted to hematocrit value (HV) around 40% with saline. Accurate HV was later determined by a hematocrit capillary (Cosmo-bio Ltd. Tokyo, Japan). The erythrocyte sample (HV ca 40%) was extracted with fourfold volume of methanol containing  $100\ \mu\text{mol/l}$  2, 6-di-*tert*-butyl-4-methylphenol (BHT) by vortexing and centrifugation ( $20,400\times g$  at  $4^\circ\text{C}$  for 10 min) and subjected to the analysis immediately.

### Analyses of Total HODE, 8-iso-PGF<sub>2x</sub>, and 7-OHCh

Total HODE (tHODE) and 8-iso-PGF<sub>2x</sub> were measured using a previously reported method, which was slightly modified [9]. Internal standards—8-iso-PGF<sub>2x</sub>-d<sub>4</sub> (50 ng for plasma and 100 ng for erythrocytes), 9-HODE-d<sub>4</sub> (50 ng for plasma and 100 ng for erythrocytes)—and 1 ml of methanol containing  $100\ \mu\text{mol/l}$  BHT were added to the 2 ml plasma and 1 ml extracts from the erythrocytes sample, followed by reduction of hydroperoxides and ketones with large amounts of sodium borohydride (4 mg) at room temperature for 5 min. Next, the reduced sample was mixed with potassium hydroxide in methanol (1 mol/l, 1 ml) under nitrogen and incubated for 30 min in darkness at  $40^\circ\text{C}$  on a shaker. The sample was centrifuged ( $3,000\times g$  at  $4^\circ\text{C}$  for 10 min); the supernatant was diluted with a fourfold volume of water (pH 3) and adjusted to pH 3 with HCl (2 mol/l). The acidified sample was centrifuged ( $3,000\times g$  at  $4^\circ\text{C}$  for 10 min) and the supernatant was subjected to solid phase extraction [9]. The eluent obtained was evaporated under nitrogen and  $30\ \mu\text{l}$  of the silylating agent N,O-bis(trimethylsilyl)-trifluoroacetamide (BSTFA) was added to the dried residue. The solution was

vigorously mixed by vortexing for 1 min and incubated for 1 h at  $60^\circ\text{C}$  to obtain trimethylsilyl esters and ethers. An aliquot of this sample was injected into the gas chromatograph (GC 6890 N, Agilent Technologies, Palo Alto, CA, USA) equipped with a quadrupole mass spectrometer (5973 Network, Agilent Technologies). A fused-silica capillary column (HP-5MS, 5% phenyl methyl siloxane,  $30\ \text{m} \times 0.25\ \text{mm}$ , Agilent Technologies) was used. Helium, at a flow rate of 1.2 ml/min, was used as the carrier gas. Temperature programming was performed from 60 to  $280^\circ\text{C}$  at  $10^\circ\text{C}/\text{min}$ . The injector temperature was set at  $250^\circ\text{C}$ ; the temperatures of transfer line to mass detector and ion source were 250 and  $230^\circ\text{C}$ , respectively. Electron energy was set at 70 eV. 8-Iso-PGF<sub>2x</sub> and HODE were identified based on their retention times and mass patterns ( $m/z = 571$  and 481 for 8-iso-PGF<sub>2x</sub>, and 440, 369, and 225 for HODE). The amounts of 8-iso-PGF<sub>2x</sub> and HODE were determined by using the fragment ions of 481 and 440, respectively. 8-Iso-PGF<sub>2x</sub>-d<sub>4</sub> ( $m/z = 485$ ) and 9-HODE-d<sub>4</sub> ( $m/z = 444$ ) were used as internal standards for quantifications of 8-iso-PGF<sub>2x</sub> and HODE, respectively.

Total 7-OHCh in plasma and erythrocyte was also measured as follows. The internal standards, 16-hydroxyhexadecanoic acid (70 ng), 7 $\alpha$ -OHCh-d<sub>7</sub> (180 ng), and 7 $\alpha$ -OHCh-d<sub>7</sub> (180 ng), and 500  $\mu\text{l}$  methanol containing  $100\ \mu\text{mol/l}$  BHT were added to plasma (500  $\mu\text{l}$ ) and the extracts from erythrocytes (500  $\mu\text{l}$ ). We have confirmed that the quantified values by using these internal standards did not differ among themselves and the more convenient 16-hydroxyhexadecanoic acid was used in further study. Reduction of 7-OOHCh and 7-KCh was carried out by the addition of large amounts of sodium borohydride (4 mg) to the solution followed by saponification under nitrogen. The reduced sample was suspended in potassium hydroxide in methanol (1 mol/l, 1 ml) and pure ether (2 ml) and mixed for 30 min in darkness at  $40^\circ\text{C}$  in a shaker. The mixture was acidified with 20% acetic acid in water (2 ml) and extracted with hexane (3 ml). The sample was evaporated to dryness under nitrogen and derivatized with BSTFA for 1 h at  $60^\circ\text{C}$ . An aliquot of this solution was injected into the same gas chromatograph equipped with a quadrupole mass spectrometer as mentioned above. The identification of 7-OHCh was conducted by retention time and mass pattern ( $m/z = 546$ , 456) and ions at 456 were selected for the quantification. 7 $\alpha$ -OHCh and 7 $\beta$ -OHCh were identified with retention times of 28.5 and 30.9 min, respectively. Ch ( $m/z = 458$ ) and linoleic acid ( $m/z = 337$ ) were simultaneously measured by this method.

Artificial oxidation of lipids during sample work-up was kept minimal by adding antioxidant and carrying out analytical procedures under nitrogen as much as possible. It was confirmed that the experimental errors were within  $\pm 10\%$  [9].

## HPLC Analysis

Plasma antioxidants were extracted by chloroform/methanol (2/1, by volume).  $\alpha$ - and  $\gamma$ -Tocopherol (T) were measured using an HPLC by an amperometric electrochemical detector (NANOSPACE SI-1, Shiseido Co. Ltd., Tokyo, Japan) set at 800 mV, with an octadecyl-bonded silica (ODS) column (LC-18, 5  $\mu$ m, 250  $\times$  4.6 mm, Sigma-Aldrich Japan, Tokyo, Japan) and methanol/*tert*-butyl alcohol (95/5 by volume) containing 50 mmol/l sodium perchlorate as an eluent at a rate of 1 ml/min. Plasma concentration of ascorbic acid was measured by an HPLC with UV detector (SPD-10AV, Shimadzu Corp., Kyoto, Japan, 263 nm). An NH<sub>2</sub> column (Wakosil 5NH<sub>2</sub>, 5  $\mu$ m, 250  $\times$  4.6 mm, Wako Pure Chemical Ind. Ltd., Tokyo, Japan) was used and 40 mmol/l phosphate-buffered saline (PBS)/methanol (1/9, by volume) was delivered as the eluent at a rate of 1 ml/min. Plasma was diluted with methanol (1/4, by volume) and mixed vigorously by a vortex mixer for 1 min, followed by centrifugation (20,400 $\times$ g at 4 °C for 10 min) and immediately an aliquot of the upper layer was injected into the HPLC column. Ubiquinols and ubiquinones in plasma were also measured by using HPLC with the same amperometric electrochemical detector (NANOSPACE SI-1), set at 700 mV. The samples were passed through a reverse phase column (LC-8, 5  $\mu$ m, 250  $\times$  4.6 mm, Sigma-Aldrich Japan, Tokyo, Japan), followed by a reducing column (RC-10, 30  $\times$  4 mm, Shiseido Co. Ltd., Tokyo, Japan). Methanol/*tert*-butyl alcohol (85/15, by volume) containing 50 mM sodium perchlorate was used as an eluent at a rate of 1 ml/min. Plasma was diluted with methanol and hexane (1/5/10, by volume) and mixed vigorously by a vortex mixer for 1 min followed by centrifugation (20,400 $\times$ g at 4 °C for 10 min) and immediately an aliquot of the upper layer was injected into the HPLC column.

## Measurements of Selenoprotein P (SeP)

Plasma SeP concentrations were determined with a sandwich ELISA using rat anti-human SeP monoclonal antibody BD1 and AH5 as described previously [13]. The optical density of the plates was measured at 450 nm using a Multiskan Ascent plate reader (Thermo Labsystems, Helsinki, Finland). All measurements were made in duplicate, and the average value was adopted.

## Statistics

Statistical analyses were performed on a Microsoft personal computer. Correlations were analyzed using the Pearson test, a *P* value of less than 0.05 was considered significant. Data are presented as the mean  $\pm$  SD.

## Results

### Lipid Peroxidation Level in Human Plasma and Erythrocytes

The levels of total HODE, 7-OHCh and 8-iso-PGF<sub>2 $\alpha$</sub>  were measured by the methods described above for plasma and erythrocytes from 44 healthy human subjects. The total HODE in plasma and erythrocytes ranged from 86.2 to 350 nmol/l plasma and 797 to 5,630 nmol/l packed cells, while total 7-OHCh ranged from 72.3 to 542 nmol/l plasma and from 1,860 to 11,100 nmol/l packed cells, respectively. The average concentrations of tHODE, t8-iso-PGF<sub>2 $\alpha$</sub> , and t7-OHCh were obtained as 203, 0.727, and 243 nmol/l in plasma, while those in erythrocytes were 1,917, 12.8, and 5,226 nmol/l packed cells for tHODE, t8-iso-PGF<sub>2 $\alpha$</sub> , and t7-OHCh, respectively (Table 1). Relatively more oxidation products were found in erythrocytes than in plasma, the ratio being 9.4, 18, and 22 fold for tHODE, t8-iso-PGF<sub>2 $\alpha$</sub> , and t7-OHCh, respectively. The stereo-isomer ratio of HODE, (*Z,E/E,E*), was lower than 1 in plasma, but higher than 1 in erythrocytes. More 7 $\beta$ -OHCh was found than 7 $\alpha$ -OHCh in both plasma and erythrocytes.

In order to compare the extent of oxidation more quantitatively, the ratio of oxidation products to the parent substrates was measured. The total linoleate (t18:2) and cholesterol (tCh) in plasma and erythrocytes were determined after saponification to measure both free and ester forms. Unfortunately, total arachidonate could not be measured. The results are summarized in Table 2. A statistically significant correlation was observed between tHODE/t18:2 and t7-OHCh/tCh for both plasma and erythrocytes (Fig. 1). The average molar ratio of products to parent substrates tHODE/t18:2 and t7-OHCh/tCh were obtained as  $1.94 \times 10^{-4}$  and  $4.09 \times 10^{-5}$  for plasma and  $3.52 \times 10^{-3}$  and  $6.86 \times 10^{-4}$  for erythrocytes, respectively. These results show that the relative oxidation ratio of plasma to erythrocytes is 1/18.1 for linoleates and 1/16.8 for cholesterol, showing that relative oxidation level in erythrocytes was much higher than that in plasma. Furthermore, the relative extent of oxidation of linoleates to cholesterol is 4.74 and 5.13 in plasma and erythrocytes, respectively. This may not necessarily suggest that linoleates are about five times more oxidizable than cholesterol *in vivo*, since the observed concentrations of products depend on the rates of metabolism and excretion as well as formation (see Discussion).

### The Antioxidant Level

The concentrations of representative antioxidants measured in plasma and erythrocytes are also included in Table 1. The concentrations of  $\alpha$ - and  $\gamma$ -tocopherol, ascorbic acid,

ratio correlated significantly with  $Q_{10}H_2$  (Fig. 2a) and total coenzyme Q (Fig. 2b), but not with tocopherols (data not shown).

#### Effect of Age on Oxidation Products and Antioxidant

The age of the human subjects tested in this study ranged from 25 to 82 years old. The effects of age on the lipid peroxidation products and antioxidants in plasma and erythrocytes are included in Table 1 and shown in Fig. 3. As a whole, the lipid peroxidation products tended to increase with age, while antioxidants decreased, although the statistical significance was observed only for 9- and 13- ( $E,E$ )-HODE (Fig. 3a), stereo-isomer ratio ( $Z/E/E,E$ )-HODE (Fig. 3b),  $Q_{10}H_2$  (Fig. 3c) and  $Q_{10}$  (Fig. 3d) in plasma and for  $\alpha$ -tocopherol ( $\alpha T$ ) (Fig. 3e) in erythrocytes. Furthermore, a statistical significance was observed for the correlation of tHODE/t18:2 ( $r = 0.483$ ,  $n = 39$ ,  $P < 0.01$ ) and t7-OHCh/tCh ( $r = 0.483$ ,  $n = 25$ ,  $P < 0.05$ ) in plasma with age (data not shown).

#### Discussion

Lipid peroxidation has gained renewed attention since its products can exert versatile beneficial functions and

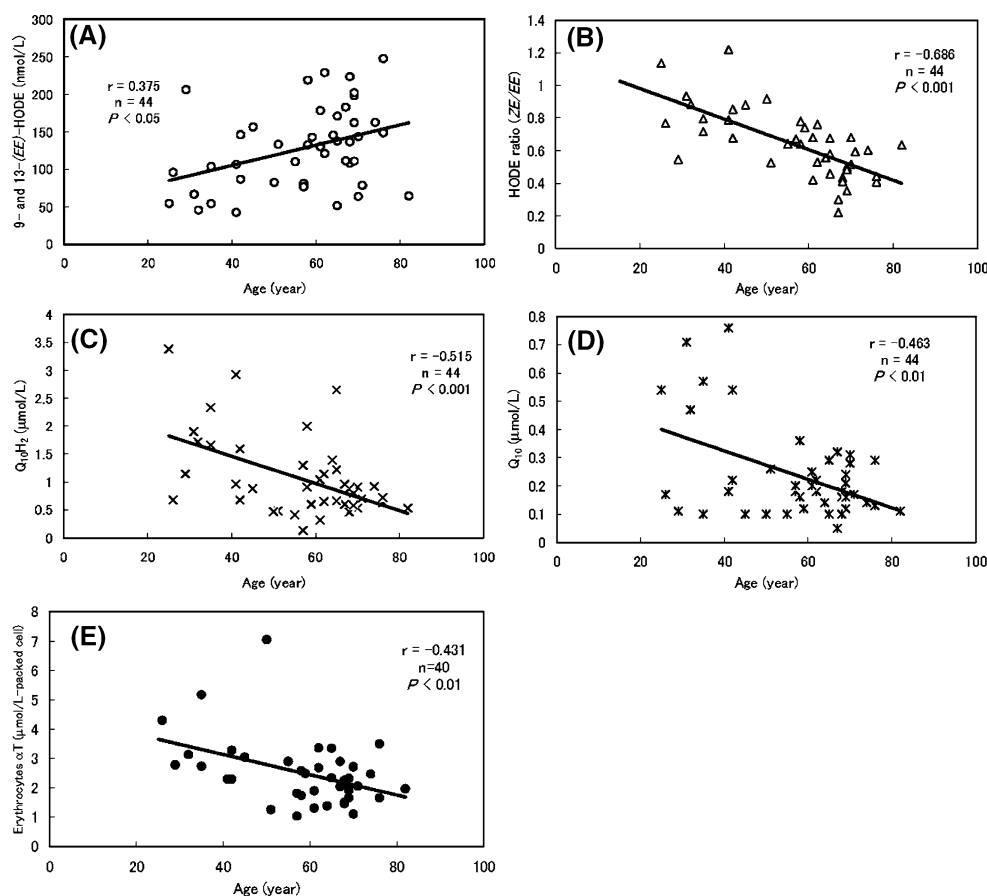

**Fig. 2** The plots of stereo-isomeric ratio of HODE ( $ZE/EE$ ) against ubiquinol-10 ( $Q_{10}H_2$ ) (a) and total CoQ10 ( $Q_{10}H_2 + Q_{10}$ ) (b) in plasma from healthy humans ( $n = 44$ ). Correlation coefficient,  $r$ , and  $P$ -values are shown in the figure

deleterious effects [2, 3]. Various biomarkers have been proposed and applied for assessment of lipid peroxidation in vivo. Isoprostanes, non-enzymatic oxidation products from arachidonic acid and its esters, are accepted to be the most reliable available marker of lipid peroxidation in vivo [8]. They are present in vivo in the free and esterified forms. In the present study, the plasma and erythrocytes were first reduced with sodium borohydride and then saponified with KOH to convert hydroperoxides and ketones as well as hydroxides of both free and esterified linoleic acid and cholesterol to tHODE and t7-OHCh, respectively. t8-Iso-PGF<sub>2 $\alpha$</sub>  was also measured similarly. The results thus obtained reveal several interesting facts.

Firstly, the amount of t7-OHCh was unexpectedly high. The absolute amounts decreased in the order of t7-OHCh  $\geq$  tHODE  $\gg$  t8-iso-PGF<sub>2 $\alpha$</sub>  in both plasma and erythrocytes. The ratios (tHODE/t18:2)/(t7-OHCh/tCh) = 4.74 and 5.13 in plasma and erythrocytes, respectively (Table 2) show that linoleates are oxidized about five times more than cholesterol in blood. It had been previously observed in the free radical-mediated oxidation of isolated LDL that the relative oxidizability decreased with decreasing number of double bond, that is, 22:6 > 20:4 > 18:2 > 18:1 > 16:0, and that cholesterol was oxi-

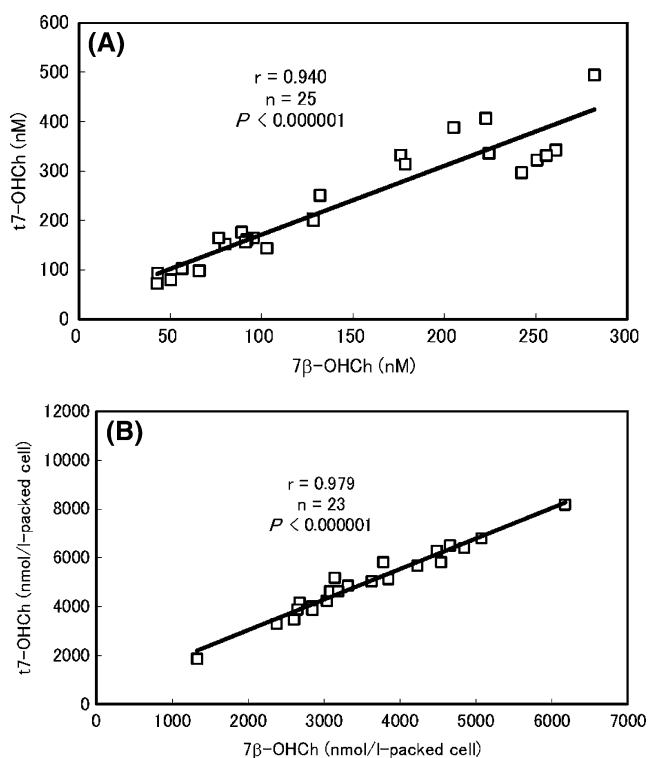

**Fig. 3** Age-related plots of 9- and 13-(*EE*)-HODE concentration (a), stereo-isomer ratio of HODE (*ZE/EE*) (b), concentrations of  $Q_{10}H_2$  (c) and ubiquinone-10 ( $Q_{10}$ ) (d) in plasma, and concentration of  $\alpha$ -tocopherol ( $\alpha T$ ) in erythrocytes from healthy humans [ $n = 44$ , except for  $\alpha T$  ( $n = 40$ )]. Correlation coefficient,  $r$ , and  $P$ -values are shown in the figure

dized only after most of unsaturated fatty acids were depleted [15]. However, we found in this study that the concentrations of  $t7$ -OHCh were higher than those of  $t$ HODE in both plasma and erythrocytes. Cholesterol is oxidized by three mechanisms: namely an enzymatic mechanism, a non-enzymatic, stoichiometric mechanism, and a free radical-mediated chain mechanism [12]. The typical oxidants for these three mechanisms are cytochrome P450, singlet oxygen, and peroxy radicals, respectively. The major products from the free radical oxidation of cholesterol are  $7\alpha$ - and  $7\beta$ -OOHCh,  $7\alpha$ - and  $7\beta$ -OHCh,  $7$ -KCh,  $5\alpha,6\alpha$ -EpoxyCh,  $5\beta,6\beta$ -EpoxyCh, and  $5,6$ -di-OHCh [12, 16–18]. The levels of oxysterols in human plasma or serum have been compiled by Brown and Jessup [17]. In the present study,  $7\alpha$ - and  $7\beta$ -OOHCh and  $7$ -KCh as well as  $7\alpha$ - and  $7\beta$ -OHCh were measured as  $t7$ -OHCh, but  $5,6$ -EpoxyCh and  $5,6$ -diOHCh were not assessed.  $24$ -,  $25$ -, and  $27$ -OHCh which are formed by cytochrome P450 were not assessed either in this study. Singlet oxygen oxidizes cholesterol to yield  $5\alpha$ -OOHCh, which may undergo isomerization to give  $7\alpha$ -OOHCh. However, the oxidation by singlet oxygen may not be important in vivo, except for skin. CYP7A1, cholesterol  $7\alpha$ -hydroxylase, is a microsomal liver-specific enzyme that

converts cholesterol to  $7\alpha$ -OHCh [11]. It has been reported that  $7\alpha$ -OHCh formed in the liver by CYP7A1 is leaked into the circulation and  $7\alpha$ -OHCh in serum was proposed to be a potential marker for the activity of this enzyme [19]. CYP7A1 only oxidizes the free form of cholesterol, not cholesterol esters in the lipoproteins. Thus, total  $7$ -OHCh measured in this study must contain  $7\alpha$ -OHCh formed by CYP7A1. It has been reported also that  $7$ -KCh is reduced stereo-specifically to  $7\beta$ -OHCh by  $11$ -betahydroxysteroid dehydrogenase type 1 [20–22]. These data suggest that  $t7\beta$ -OHCh may be a better marker for non-regulated oxidation of cholesterol in vivo. However, the correlation between  $t7$ -OHCh and  $t7\beta$ -OHCh was quite strong both for plasma (Fig. 4a) and erythrocytes (Fig. 4b).

The observed level of lipid peroxidation products is determined by a balance between the rates of formation, secondary reactions, metabolism, and excretion. Lipid hydroperoxides are reduced to the corresponding hydroxides by glutathione peroxidases and SeP. The oxidized phospholipids are metabolized by phospholipases. It has been shown that the rate of reduction of hydroperoxides by glutathione peroxidase decreases in the order of free fatty acid hydroperoxides > phospholipid hydroperoxides > cholesteryl ester hydroperoxides > cholesteryl

**Fig. 4** The correlations of  $7\beta$ -OHCh with  $t7$ -OHCh in plasma (a) and erythrocytes (b). The number studied, correlation coefficient,  $r$ , and  $P$ -values are shown in the figure

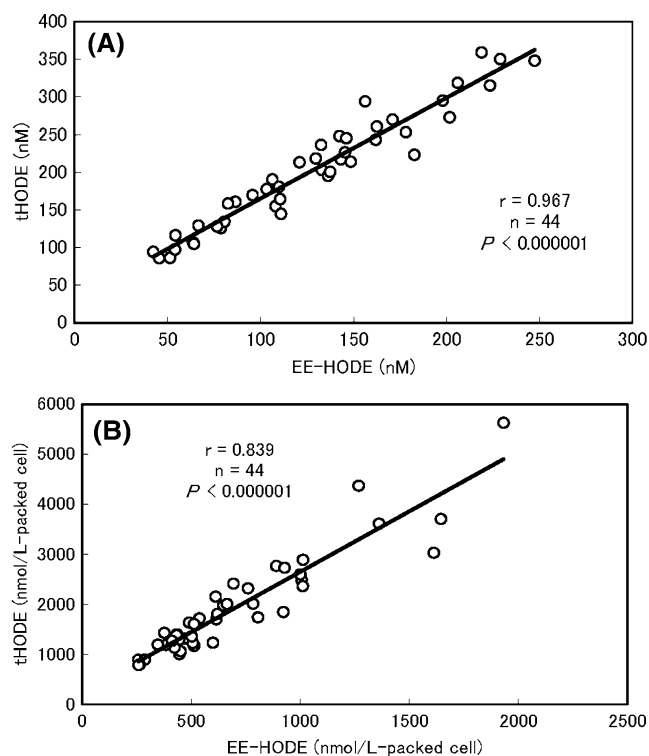

hydroperoxide [23]. The metabolism of oxidized cholesterol may be slower than oxidized fatty acids, which may account, at least in part, for the observed relatively high concentrations of oxidized cholesterol compared with oxidized fatty acids in plasma and erythrocytes.

Secondly, the concentrations of tHODE were more than 100 times higher than those of  $t8$ -iso-PGF<sub>2α</sub>. This is reasonable since the content of  $t18:2$  is much higher than that of  $t20:4$  in blood and linoleates are oxidized by a straightforward mechanism to give products which are counted as HODE, whereas the oxidation of arachidonates proceeds by a complicated routes and 8-iso-PGF<sub>2α</sub> is only one of the many minor products.

Like cholesterol, linoleates are oxidized by three mechanisms. Several subclasses of human lipoxygenases are known [24] and 15-LOX oxidizes linoleates to give 13(S)-(Z,E)-HPODE selectively. Singlet oxygen oxidizes linoleates to give 9-, 10-, 12-, and 13-(Z,E)-HPODE. The free radical-mediated oxidation of linoleates gives both 9- and 13-, (Z,E) and (E,E)-HPODE as the primary products, these four HPODEs being racemic. Thus, tHODE measured in this study may originate from these different mechanisms. The relative contribution of these mechanisms is difficult to evaluate from tHODE. It was reported previously that the ratio of enantio isomers 13(S)-HODE/

13(R)-HODE in human plasma was below 0.60 [25], implying that the 15-LOX-induced oxidation is at best 20%. However, it may be also added that the enantio specificity in the oxidation of plasma by mammalian 15-LOX was considerably lower than that in simple aqueous solution [24, 26]. In general, the free radical oxidation of linoleates gives same amounts of 9- and 13-HODE. But it was reported recently that the oxidation of linoleic acid bound to human serum albumin induced by free radicals was regio-selective with a larger accumulation of 13-HPODE with more *E, E*-stereoisomers [27]. It may be said that  $t9$ - and 13-(*E, E*)-HODE are a better marker for free radical-mediated oxidation of linoleates. It was found, however, that the correlation between (*E, E*)-HODE and tHODE was remarkably well (Figs. 5a, b).

Thirdly, this study showed that erythrocytes contained more oxidation products than plasma, the ratio of (tHODE/ $t18:2$ ) and ( $t7$ -OHCh/ $tCh$ ) in erythrocytes to that in plasma being 18.1 and 16.8, respectively (Table 2). This result was rather surprising, since it was observed before that plasma lipids were oxidized by free radicals faster than erythrocyte lipids in the oxidation of whole blood [28]. The reason is not clear at present, but this may be ascribed to a lower rate of metabolism for oxidized lipids in erythrocytes than those in plasma.

**Fig. 5** The correlations of 9- and 13-(*EE*)-HODE with tHODE in plasma (a) and erythrocytes (b). The number studied, correlation coefficient,  $r$ , and  $P$ -values are shown in the figure

## Lipid Peroxidation Products as Biomarker

An appropriate biomarker has been looked for to assess the extent of oxidative stress under normal physiological conditions and also to evaluate the antioxidant efficacy *in vivo*. Apparently, the oxidative stress is brought about by different oxidants and mechanisms, and it is quite difficult to develop a single biomarker which is valid for various oxidative stress. Among others, isoprostanes have been widely accepted as the most reliable marker of lipid peroxidation *in vivo* and applied for the assessment of oxidative injury (8 and references cited therein). Increased levels of isoprostanes, especially 8-iso-PGF<sub>2α</sub>, have been detected in tissues and fluids from human patients with various diseases [8]. The extensive multi laboratory work termed the Biomarkers of Oxidative Stress Study (BOSS) coordinated by National Institute of Health (NIH) of the USA shows promising results [29, 30]. We have proposed tHODE and t7-OHCh as potential biomarkers for oxidative stress and shown that they are useful for assessment of oxidative stress in several animal experiments induced by carbon tetrachloride [31], choline-deficient diet [32], light-exposure [33], and free radicals [34]. They have been also applied for the assessment of antioxidant efficacy *in vivo* [35]. Furthermore, we have recently reported that tHODE and t7-OHCh increased with increasing oxidation of LDL in healthy humans [36]. It may be said that tHODE and t7-OHCh could be good biomarkers for the early detection of adult diseases as well as the evaluation of disease progression which involves oxidative stress. It is recommended that BOSS should be expanded to include both tHODE and t7-OHCh as biomarkers. It may be also added that relative amounts of tHODE, t8-iso-PGF<sub>2α</sub>, and t7-OHCh depend on tissues. For example, the ratio of tHODE/ t8-iso-PGF<sub>2α</sub> is much smaller in the brain than in plasma (Yoshida et al., unpublished results).

One of the concerns about tHODE and t7-OHCh as biomarkers is that they are formed by different oxidants and by different mechanisms, some of which may not be relevant to oxidative stress. As described above, 13-HODE may be derived from both enzymatic and non-enzymatic oxidation. 10- and 12-HODE may be specific to singlet oxygen-mediated oxidation, while 9- and 13-(*E,E*)-HODE to free radical-mediated oxidation. The significance of isomerization from 9-(*Z,E*)-HPODE and 13-(*Z,E*)-HPODE to 13-(*E,E*)-HPODE and 9-(*E,E*)-HPODE, respectively, *in vivo* is not known. The levels of 9- and 13-(*E,E*)-HODE correlated quite well with those of tHODE (Figs. 5a, b), implying that both tHODE and t9- and 13-(*E,E*)-HODE may be appropriate biomarker for lipid peroxidation *in vivo*.

7α-OHCh is formed also by both enzymatic and free radical-mediated oxidation. Hepatic 7α-hydroxylation of

cholesterol by CYP7A1 is the rate-limiting step for bile acid synthesis [19], and this may not be relevant to oxidative stress. Therefore, 7β-OHCh may be a better biomarker for oxidative stress than 7α-OHCh, although quite a strong correlation was observed between the levels of 7β-OHCh and t7-OHCh for both plasma (Fig. 4a) and erythrocytes (Fig. 4b).

## Effects of Age on the Levels of Lipid Peroxidation and Antioxidants

It was observed that, as a whole, lipid peroxidation level increased and antioxidant decreased with age, although the statistical significance was observed for only five markers out of 25 (Table 1). The stereo-isomer ratio of HODE (*ZE/EE*) in plasma decreased quite significantly with age, suggesting a decrease in antioxidant capacity with age. The decrease in αT and ascorbic acid with age was not statistically significant, but both reduced and oxidized forms of Coenzyme Q<sub>10</sub> (CoQ10) significantly decreased with age. It was reported that the capability of tissues to synthesize CoQ10 decreased during aging [37]. The results of the present study on CoQ10 are in good agreement with this report. However, the effects of age on CoQ10 levels are still controversial [38, 39], and Miles et al. [40] found that plasma CoQ10 concentrations in healthy human adults were relatively constant independent of age (*n* = 148, ranging from 30 to 75 years). Kaikkonen et al. [41] reported from a wide-range epidemiological study (*n* = 518, aged 45–70 years) that plasma CoQ10 concentrations were affected by gender, lipid level, alcohol-consumption as well as age. Apparently, more studies are necessary with larger numbers to elucidate the effects of aging on lipid peroxidation and antioxidant levels.

**Abstract** Polymorphisms in the apolipoprotein E (Apo E) gene have been associated with lipid levels, carotid intima media thickness (CCA-IMT), inflammation and cardiovascular disease (CVD). Earlier findings suggested an association of the Apo E alleles with increased CCA-IMT following a recessive pattern. Whether associations might be independent of C-reactive protein (CRP), lipid levels and other CVD risk factors is not known. We investigated the relationships between Apo E ( $\epsilon 2$ ,  $\epsilon 3$  and  $\epsilon 4$  alleles) and CCA-IMT, measured by B-mode ultrasound, in dominant and recessive models in a community-based sample of 437 men 75 years of age. In men homozygous for the  $\epsilon 4$  allele CCA-IMT was significantly increased by 0.13 mm to  $0.86 \pm 0.16$  mm compared to  $0.73 \pm 0.19$  mm in non- $\epsilon 4$ -carriers ( $P = 0.0012$ ) and  $0.73 \pm 0.21$  mm in  $\epsilon 4$  heterozygous ( $P = 0.0044$ ) in unadjusted recessive models. The association between Apo E  $\epsilon 4$  genotype and CCA-IMT was independent of Apo E  $\epsilon 2$  and Apo E  $\epsilon 3$  alleles, CRP, lipid variables (TG, LDL, HDL) and other CVD risk factors (smoking, hypertension, body mass index, diabetes) ( $P = 0.018$ ). No relations between Apo E genotype and CCA-IMT were observed in dominant models. No significant associations between the Apo E  $\epsilon 2$  and  $\epsilon 3$  alleles and CCA-IMT were found. In this study, men homozygous with the ApoE  $\epsilon 4$  allele had thicker CCA-IMT, independently of Apo E  $\epsilon 2$  and  $\epsilon 3$  alleles, CRP, lipid variables (TG, LDL,

HDL) and other CVD risk factors (smoking, hypertension, body mass index, diabetes), suggesting CCA-IMT to be modified by the ApoE  $\epsilon 4$  genotype in a recessive pattern.

### Introduction

Cardiovascular disease (CVD) is the leading cause of morbidity and mortality in industrialized countries and atherosclerosis is the main underlying pathology. Common carotid artery (CCA) intima-media thickness (IMT) is commonly used as a surrogate measure of atherosclerosis [1].

Apolipoprotein E (Apo E) is a plasma protein of 299 amino acids, with a mass of 34 kDa and is produced mainly by the liver, brain, skin and tissue macrophages. The primary metabolic role for ApoE is to transport and deliver lipids from one tissue or cell type to another. It has three common isoforms (E2, E3 and E4) which are the products of three alleles ( $\epsilon 2$ ,  $\epsilon 3$  and  $\epsilon 4$ ). Allele  $\epsilon 3$  is most common and from which  $\epsilon 2$  and  $\epsilon 4$  differ by a single amino acid, although the  $\epsilon 4$  seems to be the ancestral one [2]. Associations between Apo E alleles and plasma lipid levels and cardiovascular risk have been well established [3]. Studies investigating associations between Apo E alleles and CCA-IMT have reported discordant results [4–19]. The larger, earlier, population-based studies of the association between Apo E genotype and CCA-IMT [4, 5, 9, 20] have regarded Apo E allele variations from a dominant Mendelian perspective. That is all carriers (not regarding the number of alleles) are at greater risk compared to  $\epsilon 3$  homozygous. We aimed to investigate the association between Apo E genotype and CCA-IMT in both dominant and recessive

models. This based on the findings of earlier studies that the Apo E  $\epsilon$ 4-homozygous tend to have increased disease burden [21], has been shown to suffer greater risk of cardiovascular death [22] and increased CCA-IMT [4, 5, 9, 20] compared to other variations of the Apo E genotype [4–19]. To study Apo E and CCA-IMT associations we used a community-based sample of 437 elderly men 75 years of age.

## Methods

### Study Sample

In 1970–1973, all men born in 1920–1924 and residing in Uppsala County were invited to a health survey aimed at identifying risk factors for cardiovascular disease. Of the invited subjects, 82% participated. The present study sample consists of the consecutive last 437 out of 1,221 to attend a re-investigation 20 years later in which an examination of the carotid arteries by ultrasound was performed on average 55 months following the major investigation [23]. The men investigated in this study were healthier than the consecutive first 784 men in all variables (anthropometrical, blood pressure, smoking, and diabetes) except regarding hyperlipidemia (serum cholesterol  $>6.5$  mmol/l and/or serum triglycerides  $>2.3$  mmol/l and/or lipid-lowering medications). Hyperlipidemia prevalence in the last 437 men was 40% and the first 784 men 33% [23]. All subjects gave written informed consent, and the Ethics Committee of Uppsala University approved the study. All procedures were performed in accordance with department guidelines.

### Clinical Examinations

Diabetes mellitus was defined as fasting plasma glucose  $\geq 7$  mmol/l or oral glucose tolerance test value  $\geq 11.1$  mmol/l or diabetes medication. Hypertension was defined as systolic blood pressure  $\geq 140$  mmHg or diastolic blood pressure  $\geq 90$  mmHg or hypertension treatment. CRP measurements were performed by latex enhanced reagent (Dade Behring, Deerfield, IL, USA) using a Behring BN ProSpec analyzer (Dade Behring). The intra-assay CV of the CRP method was 1.4% at both 1.23 and 5.49 mg/l. Assessment of smoking prevalence, blood pressures, anthropometrical measurements, fasting glucose and lipids levels were made as recently published [24] and on: <http://www.pubcare.uu.se/ULSAM>.

### Carotid B-Mode Ultrasound

A comprehensive two-dimensional Doppler ultrasound examination of the carotid arteries was performed with a

Sonos 1500 ultrasound unit (Hewlett Packard). A 7.5 MHz linear transducer was used for the B-mode examinations. All examinations were made with the subject in a supine position and the face directed away from the investigated side. The three technically best registrations were chosen and their average was calculated. All measurements were made on-line and stored in the computer of the ultrasonic unit for later printout. Three experienced vascular technologists performed the recordings. The readings of the images were done by one physician (B.A.), unaware of the clinical data of the subjects. CCA-IMT was measured using the leading edge-to-leading edge convention in the far wall of the CCA approximately 1 cm proximal to the carotid bulb [25]. The individual values used are the means of measurements of the two carotid arteries. The intra-observer variability of IMT was 2.6%.

### Genetic Analysis

We investigated relations of Apo E genotype to CCA-IMT using two sets of models: dominant and recessive.

1. Dominant models: To be consistent with previous publications, we defined three dominant ApoE genotype groups: (a) the ApoE  $\epsilon$ 2 group includes those men carrying the  $\epsilon$ 2/ $\epsilon$ 2 or  $\epsilon$ 2/ $\epsilon$ 3 genotype; (b) the ApoE  $\epsilon$ 3 group includes those men carrying the  $\epsilon$ 3/ $\epsilon$ 3 genotype; and (c) the ApoE  $\epsilon$ 4 group includes those carrying the  $\epsilon$ 3/ $\epsilon$ 4 or  $\epsilon$ 4/ $\epsilon$ 4 genotype. By this definition participants with the  $\epsilon$ 4/ $\epsilon$ 2 genotype ( $n = 5$ ) were excluded from the analyses.
2. Recessive models: To investigate Apo E genotype and CCA-IMT also in recessive models we divided the men by number of alleles of Apo E  $\epsilon$ 2,  $\epsilon$ 3 and  $\epsilon$ 4. No participants were excluded in this analysis.

The ApoE112 (rs429358) and ApoE158 (rs7412) SNPs were genotyped using a single-base primer extension assay with fluorescence polarization detection [26] using reagents from Perkin-Elmer. As two SNPs were genotyped the Apo E alleles are therefore unambiguous. The PCR primers (5'–3') were GCGGGCACGGCTGTCCAA (forward) and GCAGGTCATCGGCATCGC (reverse) for Apo E112 and, GGCCAGAGCACCGAGGAG (forward) and CACGCGGCCCTGTTCCAC (reverse) for ApoE158. The “minisequencing” primers were CTGGGC GCGGACAT GGAGGACGTG for ApoE112 and CCGGATGCCG ATGACCTGCAG AAG for ApoE158. Both minisequencing primers detected the nucleotides C and T in the coding DNA strand. The overall genotype call rate was 95.6%, and the accuracy was 99.2% according to duplicate analysis of 17% of the genotypes (347/2011). The genotype data from both SNPs conferred to Hardy–Weinberg equilibrium.

## Statistical Analyses

Univariate analyses were conducted to assess the distributional properties of the baseline variables. Skewed variables were logarithmically transformed to promote normal distribution. *T*-test and ANOVA was used to investigate CCA-IMT and covariates differences by Apo E groups and by number of alleles. Both unadjusted and multivariable-adjusted models were used adjusting for lipid variables (TG, LDL and HDL), CRP and clinical variables (body mass index [BMI], smoking, hypertension and diabetes prevalence). We also investigated interaction terms to evaluate variation in the relation of Apo E alleles to CCA-IMT outcomes according to all used variables. Two-tailed confidence intervals were used, with  $P < 0.05$  regarded as significant. Stata 8.2 software was used for calculations (Stata Corporation, College Station, TX).

## Results

The clinical characteristics of the study sample are shown in Table 1.

### Recessive Models

CCA-IMT was significantly increased by 0.13 mm to  $0.86 \pm 0.16$  mm in  $\epsilon 4$  homozygous compared to  $0.73 \pm 0.19$  mm in non- $\epsilon 4$ -carriers ( $P = 0.001$ , Table 1) and to  $0.73 \pm 0.21$  mm in  $\epsilon 4$  heterozygous ( $P = 0.004$ , Table 1). CCA-IMT was significantly associated with the Apo E  $\epsilon 4$  allele in the unadjusted recessive model ( $P = 0.006$ , Table 3) and this association also remained in the multivariable adjusted ANOVA model with Apo E  $\epsilon 2$  and  $\epsilon 3$  alleles, TG, LDL and HDL, CRP, smoking, hypertension, BMI and diabetes ( $P = 0.02$ , Table 3).

### Dominant Models

There were no significant differences in CCA-IMT between Apo E groups in unadjusted or multivariable adjusted dominant models (Table 2).

## Discussion

### Principal Findings

The principal finding of this study is the independent association in recessive models between Apo E  $\epsilon 4$  homozygous and increased CCA-IMT seen also after adjustment for lipid levels (TG, LDL and HDL), inflammation (CRP) and established CVD risk factors (smoking, hypertension, BMI and diabetes).

Calculations by ANOVA or *t*-test (=\*). CCA-IMT = Common carotid artery intima-media thickness. Multivariate models adjusted for: Apo E groups ( $\epsilon 2/\epsilon 2$  and  $\epsilon 2/\epsilon 3$  together,  $\epsilon 3/\epsilon 3$ ,  $\epsilon 3/\epsilon 4$  and  $\epsilon 4/\epsilon 4$  together), C-reactive protein, triglycerides, LDL-cholesterol, HDL-cholesterol, body mass index, diabetes, smoking and hypertension

**Table 3** Recessive ANOVA models of associations of CCA-IMT and Apo E alleles

Apo E genotypes	Apo E $\epsilon 4$ <i>P</i>	Apo E $\epsilon 3$ <i>P</i>	Apo E $\epsilon 2$ <i>P</i>
Unadjusted	0.0058	0.13	0.61
Multivariable adjusted	0.018	0.26	0.36

CCA-IMT = common carotid artery intima-media thickness. Covariates in multivariate model: Apo E  $\epsilon 2$ ,  $\epsilon 3$ ,  $\epsilon 4$  (for 0, 1 or 2 alleles), C-reactive protein, triglycerides, LDL-cholesterol, HDL-cholesterol, body mass index, diabetes, smoking and hypertension

### Recessive Models

When comparing the results of the present study with the findings of major studies [4, 5, 9, 20] there are noteworthy similarities suggesting recessive associations between the Apo E genotype and CCA-IMT. In the ARIC Study among Afro-American men,  $\epsilon 4/\epsilon 4$ -homozygous subjects had a statistically significant increased CCA-IMT. In the Rotterdam Study, men with the  $\epsilon 4/\epsilon 4$  genotype had slightly (not statistically significant) increased CCA-IMT, and also in the CUDAS study the bivariate analysis showed borderline significance ( $P = 0.07$ ) for increased CCA-IMT in  $\epsilon 4/\epsilon 4$ -homozygous men.

### Dominant Models

In the present study, no associations were found in dominant models. In the Framingham Offspring Study men suffering from diabetes in the Apo E4 group were associated with increased CCA-IMT. Also in women, a statistically significant increase in CCA-IMT was found in the Apo E 4 group in Framingham.

### Comparisons with Previous Studies

In the presented study, the investigated variables vary by a number of Apo  $\epsilon 4$  alleles in both recessive (CCA-IMT) and

dominant (lipids, diabetes) manners (Table 1). The findings in previous studies (as described above) and the presented study suggest that associations of the Apo E genotype with covariates should be investigated in both recessive and dominant models. That is, both as carrier-groups in dominant models (see Table 2) and by the number of alleles in recessive models (see Tables 1, 3). The difference in the findings presented among earlier studies are most likely due to differences in Apo E allele groupings, the use of  $\epsilon 3/\epsilon 3$ -carriers as controls and study material (age, sex, race, size, recruitment procedures), CCA-IMT measurement criteria (measurement sites, left, right or mean values) and data analysis (recessive/dominant models). The four major population-based studies with large samples (ARIC, Rotterdam, Framingham and Perth) all analyzed the associations of the Apo E genotype with CCA-IMT in dominant models with  $\epsilon 3/\epsilon 3$ -carriers as controls in all analyses. The reason for this grouping is probably the high frequency of  $\epsilon 3/\epsilon 3$ -carriers in western populations and the use of the lipid levels of the  $\epsilon 3/\epsilon 3$ -carriers as normal values, and a wish to maximize power by constructing as large E2 and E4 groups as possible.

The participants in the presented study were all men of 75 years of age and the mean ages in the larger population-based studies mentioned above were 54, 59, 69 and 53 years [4, 5, 9, 20]. This might partly explain the lack of significant associations in the studies above as CCA-IMT continuously increases with age [27] and increased CCA-IMT in the samples might not yet have reached significant levels for the Apo E genotype associations.

When comparing the man to woman ratio in the studies mentioned above they range from 41 to 59%. As findings of associations between CCA-IMT and Apo E genotypes differ between sexes in these studies one might assume mixed sample decreases the possibility of revealing significant associations.

The Framingham Offspring Study and the CUDAS/Perth papers report a diabetes mellitus prevalence of 14% in men and 10% in women (Framingham) and 2.2 and 2.0% in men and women (CUDAS/Perth). In this study the diabetes prevalence is 19%. Since the Framingham study reported an association in diabetic men between CCA-IMT and the Apo E4 group, one might assume this association becomes stronger as the number of diabetics increases to the levels of this presented study.

The Framingham and the CUDAS/Perth studies report the hypertension prevalence to be 31% in men and 26% in women (Framingham) and 24% in both men and women (CUDAS/Perth). In the present study, the hypertension prevalence is 69%. As an increased CCA-IMT is strongly associated with hypertension [4, 5, 9, 20] this study's sample have an increased disease burden and therefore increased CCA-IMT compared to healthier samples and significant associations might be easier to detect.

## Possible Mechanisms

The primary role for Apo E is lipid transport in an ‘‘endocrine-like’’ function and the different Apo E alleles have definite impacts on lipid levels [28]. The LDL-receptor family is a growing transmembrane receptor family composed of more than ten receptors with the very low density lipoprotein (VLDL) receptor and the Apolipoprotein E receptor 2 being most similar to the LDL-receptor structurally [29]. Growing experimental evidence suggests that members of the LDL-receptor family activate kinase-dependent intracellular signalling cascades after binding to adaptor proteins, often interacting with more than one receptor [30]. The reverse cholesterol transport is a critical way for maintaining cholesterol homeostasis in cells and Apo E uniquely facilitates this pathway by increasing the size of HDL particles as a component of a subclass of HDL (HDL with Apo E) [31] and recent findings suggest Apo E redistributes lipids in a ‘‘paracrine-like’’ function. Mice which only produce Apo E in macrophages were protected against atherosclerosis, even though plasma levels of Apo E were low and cholesterol levels high [32] and further, mice with the expression of Apo E normal except in macrophages were susceptible to increased atherosclerosis [33].

Apo E also influences the metabolism of lipoproteins not only as a receptor ligand. Accumulation of Apo E on the surface lipoproteins slows the lipolysis by lipase [34] and affects VLDL levels directly as increased Apo E synthesis by the liver is associated with increased VLDL synthesis [35].

CRP has also been shown to be a predictor of cardiovascular events [36] and immune system defects have been described in ApoE knockout mice [37]. In this study CRP was inversely related to the  $\epsilon 4$  alleles (Table 1). This relation has recently been shown in a sample of patients recruited at a coronary angiography center, where the presence of at least one  $\epsilon 4$  allele decreased CRP by 19% [38]. This raises the possibility that production, release or catabolism of CRP is related to the mevalonate pathway in the liver, as statins (inhibiting the rate limiting step of the mevalonate pathway) have been shown to lower CRP [39]. However, as CRP did not markedly attenuate the relationship between the ApoE  $\epsilon 4$  and CCA-IMT in the multivariable adjusted model, it is likely that the Apo E genotype influences CCA-IMT by other means than by a general inflammatory response.

## Strength and Limitations

The men investigated in this study are a part of a well-characterized population-based sample and this reinvesti-

gation includes 437 men 75 years of age to attend a reinvestigation 20 years after the first investigation. The so-called healthy cohort effect: dropout of the least healthy subjects and a selective survival may have influenced the investigated associations. The men included in this study were healthier than excluded men in all variables (anthropometrical, blood pressure, smoking, and diabetes) with the exception of hyperlipidemia [23]. However, both of these circumstances could only bias us toward the null hypothesis, and not lead to false positive results. Our homogenous sample makes it not possible to generalize the presented associations to any group other than white elderly men. The results obtained in this study are observational, thus no cause and effect conclusions of the presented associations can be made.

In conclusion, this study suggests ApoE  $\epsilon 4$  homozygous to be associated with thicker CCA-IMT, independent of inflammation, lipid levels and CVD risk factors in a population-based sample of elderly men, suggesting CCA-IMT to be modified by the ApoE  $\epsilon 4$  genotype in a recessive pattern.

**Acknowledgments** The SNPs were genotyped by the Wallenberg Consortium North (WCN) SNP technology platform. We thank Kristina Larsson for performing the genotyping assays. We thank the Swedish Heart and Lung Foundation for their support.

**Abstract** Head group behavior of nonionic amphiphilic compound, (poly(oxyethylene) hydrogenated castor oil, HCO), in aqueous dispersions were investigated by EPR (electron paramagnetic resonance) in conjunction with a modern slow-tumbling simulation. The aliphatic spin probes, 5-doxylstearic acid (5-DSA) and 3 $\beta$ -doxyl-5 $\alpha$ -cholestane (CHL), were used to obtain fluidity of the surface region of the membrane. The order parameter ( $S_0$ ) using the simulation for 5-DSA and CHL in the region were approximately 0.4 and 0.2, respectively. The ordering results suggest that the head group region of the membrane is somewhat fluid. The rotational diffusion coefficients ( $R_{\perp} \approx 1/(6\tau_R)$ ) for the probes were  $3.4 \times 10^7$  and  $7.1 \times 10^7$  s $^{-1}$ , respectively. Activation energies, calculated using the temperature dependence of diffusion coefficients, were 18 and 17 kJ/mol for the probes. The EPR results imply that the CHL probe in the HCO membrane has quite different behavior in comparison with that of PC (phosphatidylcholine) from egg. Thus, the present EPR analyses have provided quantitative insight into the surface region of the amphiphilic membrane.

**Keywords** EPR · Spin probe · Rotational diffusion coefficients · Activation energy · Amphiphilic compound

## Introduction

Behavior of the surface region of amphiphilic membranes provides very important clues for understanding the phys-

icochemical characteristics of the membranes. Knowledge of regional behavior is crucial for quantitatively understanding the membrane properties. Reliable information of the surface region can be obtained by EPR (electron paramagnetic resonance) as well as fluorescence spectroscopies [1, 2]. Investigations of the surface region have been performed using fluorescence in conjunction with aromatic molecular probes. The fluorescence probes, having a large aromatic ring and very different chemical structure relative to the lipid components, are normally used. Furthermore, the sensitivity of the fluorescence techniques is low because of the micromolar concentration of the probe. On the other hand, the 9 GHz EPR is not only sensitive to micro to nanomolar concentration but also the chemical structures of the aliphatic spin probes are more similar to the lipids. Thus, EPR is an excellent technique for investigating insights into regional behavior of the membranes. The probe tumbling times in the lipids are generally on the order of  $10^{-8}$ – $10^{-7}$  s. A modern slow-tumbling simulation analysis in conjunction with the spin probe method can extract detailed information regarding various probe motions in the membranes [3].

For over 25 years the various properties of biological membranes, in conjunction with the spin probes (doxylstearic acids), have been discussed as the results of conventional analysis using the so-called spectral parameter and order parameter [4, 5]. The conventional method determined the chain ordering of biological membranes employing EPR hyperfine-coupling constants of lipid incorporated probes [6, 7]. The conventional analysis of the membrane organization, such as order parameter, provides qualitative information about the membrane. The values do not reflect small changes of the EPR spectral pattern. The values only change when the hyperfine coupling constants are changed. Therefore, the detailed membrane character-

e-mail: nakagawa@fmu.ac.jp

istics should be extensively investigated by means of careful analysis of the corresponding EPR observations.

Nonionic surface-active agents have been of great interest in the fields of cosmetics as well as pharmaceuticals. In drug encapsulation, vesicle formation of the agent is necessary. Nontoxic and naturally degradable substances are also desired. Recently, poly(oxyethylene) hydrogenated castor oil (termed HCO), which is derived from one of the lipids and related natural products, was found to form vesicles [7]. A stable multi-lamellar vesicle with an average diameter of ~500 nm was observed. HCO is a physiologically nontoxic and naturally degradable substance. Furthermore, HCO has a unique chemical structure among triglyceride derivatives. It consists of a uniform fatty-portion structure embodying oxyethylene groups unlike most naturally occurring triglycerides, which are composed of mixed fatty-portions. Hence, HCO is a very interesting compound for investigation of lipid motions [1, 8, 9].

Detailed motions of aliphatic spin probes in the membrane were investigated [1, 9]. The activation energies obtained for the 7-, 12-, and 16-DSA are 19, 24, and 37 kJ/mol, respectively. The values indicate that the various probe moieties have a different temperature sensitivity in the range 20–50 °C. The area near the end of the membrane chain is sensitive to temperature. Furthermore, physicochemical characterization of the vesicle for the nonionic amphiphilic compound HCO could lead to detailed understanding of the bilayer behavior as well as its characteristics. Temperature dependence in relation to dynamic structure of membranes is an important subject in colloid interface and membrane sciences. Recently, it has been found that quantitative EPR investigations (e.g. an EPR spectral simulation) will lead to detailed understanding of the bilayer behavior directly related to characteristics of the membrane [1, 10].

In this investigation, a modern slow-tumbling simulation for EPR spectra was applied to reveal detailed probe behavior in the head group region of the HCO membrane. Detailed rotational diffusion coefficients of spin probes in aqueous dispersions of HCO membrane were analyzed as a function of temperature. The slow-tumbling simulation is advantageous for investigation of the head group behavior of the membrane. The results are also discussed in comparison with those for PC from egg.

## Materials and Methods

### Materials and Sample Preparations

Poly(oxyethylene) hydrogenated castor oil (HCO) of the highest quality was donated by Nikko Chemicals Co. Ltd. (Tokyo, Japan) and used as received. The HCO had about

ten oxyethylene groups per molecule. The molecular structures of HCO and the spin probes used in this study are depicted in Fig. 1. The oxyethylene groups attach to the 12th carbon from the carbonyl carbon of the main chain.

The spin probes 5-(4, 4-dimethyl-3-oxazolidinyl)oxy-octadecanoic acid, the so called 5-doxyloctadecanoic acid (5-DSA), and 3 $\beta$ -doxyl-5 $\alpha$ -cholestane (CHL) were obtained from Aldrich Chemical Co. (Tokyo, Japan). Lecithin (phosphatidylcholine, PC) from egg was purchased from Wako Pure Chemical Ind. Ltd., Japan. All chemicals were of the highest grade obtainable and used as received.

Sample solutions were prepared as follows: a weighed amount of HCO was dissolved in a few milliliters of chloroform. The spin probe was dissolved in ~0.3 ml of chloroform and mixed with the HCO solution. After evaporation of the chloroform in a rotary evaporator, a 10 wt% dispersion of HCO/spin probe in distilled water (Wako Pure Chemical Ind. Ltd., Japan) was prepared.

The spin probes were incorporated into the PC from egg in the same manner as the HCO. A ~0.8 wt% dispersion of PC/probe in 1 mM Tris-HCl buffer solution under a nitrogen atmosphere was prepared. The test tube containing the dispersion solution was agitated on a vortex mixer until completely dispersed. An aliquot of the dispersion was used for EPR measurements. The final concentration of the spin probe was approximately 100  $\mu$ mol for the measurements. A detailed description of the sample preparation is also presented elsewhere [1, 9].

**Fig. 1** Chemical structures of poly(oxyethylene) [11] HCO and the spin probes (5-DSA and CHL) used are depicted. It is notable that the fatty portion of HCO is composed of 18 carbon atoms

## Deoxygenation

The sample solutions (~0.15 ml) were deoxygenated for about 15 min in an AtmosBag (Aldrich) and the solutions were put into capillaries (i.d., 0.9 mm; o.d., 1.4 mm; Nippon Rikagaku Kikai Co. Ltd., Japan). A sample capillary was inserted in a 3-mm EPR tube (JEOL Datum Co. Ltd., Japan) in the AtmosBag and taped around the tube cap.

## EPR Measurements

EPR signals were measured by a JEOL FE1X X-band EPR spectrometer. This spectrometer is equipped with a TE<sub>011</sub> mode cavity. The sample temperature was controlled by nitrogen gas flow through the Dewar using a JEOL ES-DVT system. The EPR signals were digitized using a Scientific Software Services data acquisition system (Illinois, USA). The microwave frequency was measured using an EMC-14 X-band microwave frequency counter (Echo Electronics Co., Ltd., Japan). Typical EPR conditions were the following: microwave frequency, 9.18 GHz; microwave power, 5 mW; modulation amplitude, 0.32 G (Gauss); time constant, 1 s; scan rate, 3.125 G per min. All sample solutions were measured under identical conditions.

## Calculation of the Slow-Tumbling Spin Probe

The slow-tumbling motions ( $10^{-8}$ – $10^{-7}$  s) of the aliphatic spin probes were calculated using the nonlinear least-squares fitting program called NLLS to analyze the EPR spectra based on the stochastic Liouville equation [3, 11]. The simulation of the EPR spectra for spin probes incorporated into multilamellar vesicles was carried out using a microscopically ordered but macroscopically disordered (MOMD) model [12]. This model is based on the characteristics of the dynamic structure of lipid dispersions. For example, lipid molecules are preferentially oriented by the local structure of the bilayer, but the lipid bilayer fragments are distributed randomly overall. The spectrum from the sample can be regarded as a superposition of the spectra from all of the fragments.

The lipid and the probe molecules in the membrane bilayer experience ordering potentials, which restrict the amplitude of the rotational motion. The ordering potential in a lipid bilayer,  $U(\Omega)$ , determines the orientational distribution of molecules with respect to the local ordering axis of the membrane bilayer. It can be expressed in generalized spherical harmonics [13],

$$-U/kT = c_0^2 D_{00}^2(\Omega) + c_2^2 (D_{02}^2(\Omega) + D_{-2}^2(\Omega)) + \dots, \quad (1)$$

where  $\Omega = (\alpha, \beta, \gamma)$  are the Euler angles between the molecular frame of the rotational diffusion tensor and the local director frame. The  $c_0^2$  and  $c_2^2$  are dimensionless potential energy coefficients,  $k$  is the Boltzmann constant, and  $T$  is the absolute temperature.

There are two axes systems in the calculation of the rotational dynamics and orientational ordering of the spin probe. In the magnetic frame, the  $z$ -axis is parallel to the  $2P_z$  orbital of the N atom for doxylstearic acid, which is perpendicular to the N–O bond of the nitroxide probe as shown in Fig. 2. Then, the  $y$ -axis in the magnetic frame is perpendicular to both  $x$ - and  $z$ -axes, forming a right-handed axis frame. In the molecular frame, the  $z$ -axis is parallel to the symmetry axis of the probe molecule. For the spin probe doxylstearic acid, obviously, the  $z$ -axis is parallel to the long hydrocarbon chain, which coincides with the  $z$ -axis in the magnetic frame.

The rigidity (chain ordering),  $S_0$ , is defined as

$$S_0 = \langle D_{00}^2 \rangle = \left\langle \frac{1}{2} (3 \cos^2 \gamma - 1) \right\rangle = \frac{\int d\Omega \exp(-U/kT) D_{00}^2}{\int d\Omega \exp(-U/kT)}, \quad (2)$$

which measures the angular extent of the rotational diffusion of the nitroxide moiety. Gamma ( $\gamma$ ) is the angle between the rotational diffusion symmetry axis and the  $z$ -axis of the nitroxide axis system. The local or microscopic ordering of the nitroxide spin probe in the membrane is

**Fig. 2** Coordination of the spin probes, 5-DSA and CHL, for the NLLS calculations are presented. The  $z$ -axis is the membrane director

characterized by the  $S_0$  value. A larger  $S_0$  value indicates a more restricted motion. Therefore,  $S_0$  reflects the local ordering of bilayer molecules in the membrane.

Dynamics of the probe are described by the following parameters: rotational diffusion rates ( $R_{\perp}$  and  $R_{\parallel}$ ) along axes perpendicular and parallel to the molecular symmetry axes [13]. The perpendicular component ( $R_{\perp}$ ) represents the rotational wagging motion of the long axis of the hydrocarbon chain. This component can be correlated with the rotational correlation time ( $\tau_R \approx 1/(6R_{\perp})$ ) [11]. In the calculation of experimental spectra, the principal components for the probes obtained by the previous values were used [14, 15].

## Results and Discussion

In order to reveal the motional behaviors in the head group region, 5-DSA and CHL were used as the probes. Figure 3a shows the typical EPR spectrum of HCO/5-DSA in an aqueous dispersion at 20 °C. The EPR spectrum shows that the nitroxide probe is immobilized in the membrane and the parallel ( $2A_{\parallel}$ ) and perpendicular ( $2A_{\perp}$ ) hyperfine components as presented in the figure are clearly recognized. The anisotropic EPR spectral pattern is slightly different from the rigid spectral pattern, which was published previously [1]. The perpendicular hyperfine component was clearly observed. This indicates that the head group region is relatively flexible. The amphiphilic property may be due to hydration in the head group region.

**Fig. 3** Experimental (solid line) and simulated (dotted line) EPR spectra of 5-DSA in aqueous dispersions of HCO at 20 °C are presented. The conventional parallel ( $2A_{\parallel}$ ) and perpendicular ( $2A_{\perp}$ ) hyperfine couplings are depicted for reference

Figure 3b shows the EPR slow-tumbling simulation for the observed spectrum. The perpendicular rotational diffusion coefficient ( $R_{\perp}$ ) obtained at 20 °C was  $3.4 \times 10^7 \text{ s}^{-1}$ . The value of the chain ordering ( $S_0$ ) was approximately 0.3–0.4 which suggests comparatively low rigidity of the region in the membrane.

The values of  $R_{\perp}$  for 5-DSA probe are similar for both HCO and PC in the temperature range examined. It is interesting to note that the  $R_{\perp}$  value for PC from egg starts to increase slightly at around 30 °C. The results imply that the motion of the probe changes as the temperature increases.

Figure 4a shows the typical EPR spectrum of HCO/CHL in an aqueous dispersion at 20 °C. The spectral pattern obtained for CHL is similar to that previously reported [15]. The EPR spectral pattern also suggests that the head group region is relatively flexible. This is consistent with the low  $S_0$ -value (–0.2) obtained. The flexibility can be due to hydration induced by the oxyethylene groups in the region. Figure 4b shows the EPR slow-tumbling simulation of the observed spectrum. The perpendicular rotational diffusion coefficient for HCO/CHL obtained at 20 °C was  $7.1 \times 10^7 \text{ s}^{-1}$ .

Figure 5 presents perpendicular components of the diffusion coefficients for 5-DSA and CHL as a function of the temperature examined. The values of  $R_{\perp}$  for CHL have slightly faster diffusion coefficients than the one for 5-DSA. These results can be associated with the probe orientation as well as the moiety in the membrane (Fig. 2). The diffusion coefficients for both probes show similar temperature dependence.

**Fig. 4** Representative experimental (solid line) and simulated (dotted line) EPR spectra of CHL in aqueous dispersions of HCO at 20 °C are presented

**Fig. 5** Plot of the rotational diffusion coefficients ( $R_{\perp}$ ), 5-DSA (filled circles) and CHL (open circles), in aqueous dispersions of HCO as a function of the inverse of the absolute temperature. The 5-DSA (diamonds) and CHL (crossed circles) indicate the  $R_{\perp}$  values for PC from egg

The  $R_{\perp}$  value for HCO/CHL obtained at 50 °C was  $1.3 \times 10^8 \text{ s}^{-1}$ . The  $R_{\perp}$  value of  $3.6 \times 10^7 \text{ s}^{-1}$  for DPPC/CSL obtained at 50 °C is reported [16]. The value for HCO/CHL suggests a slightly faster motion. It is interesting to note that the values of  $R_{\perp}$  for PC/CHL are much higher than those of HCO/CHL and show that the rate of the probe motion is faster than that of HCO. The values for PC/CHL increase significantly at approximately 30 °C. The results obtained are consistent with those for HCO/5-DSA. The change can be correlated with a phase transition.

The activation energies using the diffusion coefficients resulting from the respective MOMD calculation were calculated based on the slope of the plot (Fig. 5). An Arrhenius type equation gives the activation energy ( $E_a$ ) for the spin probe in the HCO membrane [1],

$$R_{\perp} = R_{\perp}^0 \exp\left(\frac{-E_a}{RT}\right), \quad (3)$$

where  $E_a$  is the activation energy,  $R$  is the gas constant, and  $T$  is the absolute temperature. The activation energies for 5-DSA and CHL in the membrane are  $18 \pm 0.5$  and  $17 \pm 0.4 \text{ kJ/mol}$ , respectively. The higher activation energy calculated implies that the perpendicular motion of 5-DSA has a similar value to 19 kJ/mol of 7-DSA [1]. The activation energies are associated with the micro-viscosity around the spin probes.

In addition, these results can be associated with the amphiphilic membrane properties. Most likely  $\text{H}_2\text{O}$  easily

reaches the inner head group region. Because of the oxyethylene group in the region, significant dehydration may not occur even at higher temperatures. The surface region of the membrane can always make contact with  $\text{H}_2\text{O}$ . The rest of the lipids will change to a hydrophobic environment as the temperature rises. Therefore, the present EPR shows that the fluidity of the head group region does not change considerably throughout the temperatures examined.

## Conclusions

The current results obtained by the advanced EPR simulation provided quantitative insight into the behavior of the head group region of the nonionic amphiphilic membrane. The order parameter and rotational diffusion coefficients for the 5-DSA probe in the region were approximately 0.4 and  $3.4 \times 10^7 \text{ s}^{-1}$ , respectively. No abrupt change of the  $R_{\perp}$  value was observed for HCO/5-DSA and HCO/CHL. The activation energy of the probe in the range of 20–50 °C is close to the one in 7-DSA but the order parameter is lower than that of 7-DSA. The  $R_{\perp}$  values obtained for HCO/CHL implies that the probe moiety in the membrane is slow motion in comparison with PC/CHL. The results suggest that physicochemical dynamics of the HCO membrane is distinctive. Thus, the present evidence provides insights into quantitative understanding of the regional probe behavior as well as the amphiphilic membrane characteristics.

**Acknowledgments** The author thanks E. Yagi of Shiseido Research Center for useful suggestions of the sample preparations and Dr. Mingtao Ge of Cornell University for helpful discussions concerning the simulation. **Abstract** The evaluation of antioxidant activity in vivo is difficult. In this study, the effects of dietary natural and synthetic antioxidants on the lipid peroxidation in mice were assessed using a biomarker, total hydroxyoctadecadienoic acid (tHODE). Biological samples such as plasma, erythrocytes, and tissues were first reduced and then saponified to convert various oxidation products of linoleates to tHODE. Subsequently, the absolute concentration of tHODE and its stereoisomer ratio, [9- and 13-(*Z,E*)-HODE]/[9- and 13-(*E,E*)-HODE], which is a measure of the hydrogen donor capacity of antioxidants, were determined by gas chromatography–mass spectrometry (GC–MS) analyses. These were then compared with total 8-iso-prostaglandin  $F_{2\alpha}$  (t8-iso-PGF $_{2\alpha}$ ) which was also assessed after reduction and saponification. Remarkable increases in tHODE and t8-iso-PGF $_{2\alpha}$  levels were observed in the plasma, erythrocytes, liver, and brain of mice that were fed an  $\alpha$ -tocopherol ( $\alpha$ T)-stripped (E-free) diet for 1 month when compared with those of mice that were fed a standard diet ( $\alpha$ T = 0.002 wt%). When mice were fed for 1 month on an E-free diet supplemented with a lipophilic antioxidant (0.04 wt%), namely,  $\alpha$ T,  $\alpha$ -tocotrienol ( $\alpha$ T3),  $\gamma$ -tocopherol ( $\gamma$ T), or 2,3-dihydro-5-hydroxy-4,6-di-*tert*-butyl-2,2-dipentylbenzofuran (BO-653), a potent synthetic antioxidant, the increases of tHODE and t8-iso-PGF $_{2\alpha}$  in the plasma, erythrocytes, liver, and brain were suppressed to the levels lower than those of mice fed a standard diet. The (*Z,E/E,E*) HODE ratio was decreased in the plasma and erythrocytes

of mice fed the E-free diet when compared with that in mice fed the standard diet. This stereo-isomeric ratio was significantly recovered by the addition of  $\alpha$ T and BO-653. These results show that the tHODE level and the (*Z,E/E,E*) HODE ratio are useful biomarkers for the assessment of antioxidant capacity in vivo and that the antioxidant capacity decreased in the order: BO-653 >  $\alpha$ T3  $\geq$   $\alpha$ T,  $\gamma$ T, as assessed by tHODE levels from blood, liver, and brain.

### Introduction

Currently, it is generally accepted that lipid peroxidation is involved in the in vivo oxidative damage and pathogenesis

of several disorders and diseases that are induced by reactive oxygen and nitrogen species. Lipid peroxidation may directly damage biological molecules and membranes and may also induce the generation of toxic and signaling molecules [1, 2]. Accordingly, the potential role of antioxidant nutrients has been investigated in the prevention of cancer, cardiovascular disease, cataract, age-related macular degeneration, and aging. From this viewpoint, lipid peroxidation products have received considerable attention as biomarkers for the evaluation of antioxidants. Lipid hydroperoxides are formed as the major primary products during the oxidation of polyunsaturated fatty acids and their esters. However, these hydroperoxides are the substrates for many enzymes such as glutathione peroxidases and phospholipases, and they may readily undergo non-enzymatic secondary reactions [3]. Therefore, the amount of lipid hydroperoxides measured does not always reflect the extent of in vivo lipid peroxidation. F<sub>2</sub>-isoprostanes formed from arachidonic acid have been reported as the gold standard for the in vivo assessment of oxidative injury [4–6]; however, they are only one of the several minor products formed from arachidonates. Further, the use of thiobarbituric acid (TBA)-reactive substances (TBARS) is often debatable since TBA reacts with several oxidation products as well as with malonaldehyde to yield a pigment [7]. We have recently developed a method for the in vivo measurement of lipid peroxidation wherein total hydroxyoctadecadienoic acid (tHODE) is determined by gas chromatography–mass spectrometry (GC–MS) analysis of physiological samples after reduction with sodium borohydride followed by saponification with potassium hydroxide [8]. In this method, hydroperoxides and ketones as well as hydroxides of both the free and ester forms of linoleic acid are measured as tHODE. Further, both free and ester forms of 8-iso-prostaglandin F<sub>2α</sub> (8-iso-PGF<sub>2α</sub>), one of the major forms of F<sub>2</sub>-isoprostanes, can be assessed simultaneously with tHODE by using GC–MS. Linoleates are the major in vivo polyunsaturated fatty acids and their oxidation proceeds via a straightforward mechanism to yield 9- and 13-hydroperoxyoctadecadienoates (HPODE) as the major products [9]. Therefore, the tHODE measured by this method may account for a considerable amount of the in vivo lipid peroxidation.

Another advantage of using tHODE as a biomarker is that, in addition to its higher concentration than F<sub>2</sub>-isoprostanes, its regional and stereoisomers can be measured separately [8]. It is known that lipid peroxidation proceeds by different mechanisms depending on the oxidants to yield different isomers, and importantly, the efficacy of the antioxidants depends on the oxidants [10]. For example, the free radical-mediated oxidation of linoleates gives equal amounts of 9- and 13-HODE with both *cis*–*trans* and *trans*–*trans* isomers. The ratio of *cis*–*trans* to *trans*–*trans*

HODE is a measure of the capacity of hydrogen atom donation at the site of oxidation. This measurement, i.e., the (*Z,E,E,E*) HODE ratio, is practically important for the assessment and evaluation of the in vivo antioxidant capacity of natural and synthetic compounds, foods, and beverages as well as supplements and their components.

Vitamin E is a generic description of four isomers of tocopherol (T) and tocotrienol (T<sub>3</sub>) derivatives.  $\alpha$ -Tocopherol ( $\alpha$ T) is the most abundant form of vitamin E in vivo, although the level of  $\gamma$ -tocopherol ( $\gamma$ T) is often almost the same as or even higher than that of  $\alpha$ T in the diet and in plants. The role of  $\gamma$ T and tocotrienols has recently received considerable attention [11]. The synthetic antioxidant 2,3-dihydro-5-hydroxy-4,6-di-*tert*-butyl-2,2-dipentylbenzofuran (BO-653) has been designed to function as a potent radical-scavenging antioxidant [12]. It has been observed that BO-653 scavenges free radicals as rapidly as  $\alpha$ T; the aryloxy radical derived from BO-653 is considerably more stable than the  $\alpha$ -tocopheroxy radical [13], and BO-653 inhibits the oxidation of low-density lipoproteins [14] and plasma [15] more efficiently than  $\alpha$ T.

In the present study, we assessed the effects of the dietary lipophilic antioxidants mentioned above on experimental animals by the comparison of the tHODE level and the (*Z,E,E,E*) HODE ratio with those of total 8-iso-prostaglandin F<sub>2α</sub> (t8-iso-PGF<sub>2α</sub>).

## Experimental Procedures

### Reagents

BO-653 was kindly supplied by Chugai Pharmaceutical Co. Ltd. (Tokyo, Japan). Natural forms of  $\alpha$ T,  $\alpha$ T<sub>3</sub>, and  $\gamma$ T were kindly supplied by Eisai Co. Ltd. (Tokyo, Japan). 8-iso-PGF<sub>2α</sub>, 8-iso-prostaglandin F<sub>2α</sub>-d<sub>4</sub> (8-iso-PGF<sub>2α</sub>-d<sub>4</sub>), 13-hydroxy-9(*Z*),11(*E*)-octadecadienoic acid [13-(*Z,E*)-HODE], 13-hydroxy-9(*E*),11(*E*)-octadecadienoic acid [13-(*E,E*)-HODE], 9-hydroxy-10(*E*),12(*Z*)-octadecadienoic acid [9-(*E,Z*)-HODE], 9-hydroxy-10(*E*),12(*E*)-octadecadienoic acid [9-(*E,E*)-HODE], and 9(*S*)-hydroxy-10(*E*),12(*Z*)-octadecadienoic-9,10,12,13-d<sub>4</sub> acid (9-HODE-d<sub>4</sub>) were obtained from Cayman Chemical Company (MI, USA). Other materials were of the highest commercially available grade.

### Animals and Protocols

Male mice (specific pathogen free, C57BL/6J, weighing 19–24 g, and 11 weeks old) were purchased from Nippon Clea Co. (Tokyo, Japan). They were divided into six groups by the types of diet: a control diet containing 0.002 wt%  $\alpha$ T (cont), vitamin E-free (E-free) diet

(Funabashi Nojyo, Chiba, Japan), an E-free diet fortified with 0.04 wt%  $\alpha$ T (aT),  $\alpha$ T3 (aT3),  $\gamma$ T (gT), or BO-653 (BO). The composition of the E-free diet was summarized in our previous report [16]. The mice were kept under standardized conditions of light (7 a.m.–7 p.m.), temperature (22 °C), and humidity (70%). After 1 month, the animals were sacrificed under anesthesia with diethyl ether. The experimental protocols were approved by the Institutional Animal Care and Use Committee (IACUC) of the National Institute of Advanced Industrial Science and Technology.

#### HPLC Analysis

Plasma lipophilic antioxidants were extracted with chloroform–methanol (2:1, v/v). Mouse liver and brain were homogenized in saline (liver:saline = 1:3, w/w) with a Polytron PT3100 tissue homogenizer (Kinematica AG, Lucerne, Switzerland). Chloroform–methanol (100  $\mu$ L, 2:1, v/v) was added to the homogenized suspension (50  $\mu$ L, 25 w/w%) and the lipids and vitamin E were extracted by centrifugation (20,400 $\times$ g, 4 °C, 10 min) after mixing vigorously with a vortex mixer. Subsequently,  $\alpha$ T,  $\gamma$ T, and BO-653 were measured by an HPLC with an amperometric electrochemical detector (NANOSPACE SI-1, Shiseido Co. Ltd., Tokyo, Japan) set at 800 mV combined with an octadecyl-bonded silica (ODS) column (LC18, 5  $\mu$ m, 250  $\times$  4.6 mm, Sigma-Aldrich Japan Com., Tokyo, Japan); methanol-*tert*-butyl alcohol (95:5, v/v) containing 50 mM sodium perchlorate was used as the eluent at a rate of 1 mL/min. The level of vitamin C in the plasma and homogenates of liver and brain was measured by using an HPLC equipped with a UV detector (SPD-10AV, Shimadzu Corp., Kyoto, Japan; 263 nm). An NH<sub>2</sub> column (Wakosil 5NH<sub>2</sub>, 5  $\mu$ m, 250  $\times$  4.6 mm, Wako Pure Chemical Ind. Ltd., Tokyo, Japan) was used with 40 mM PBS-methanol (1:9, v/v) as the eluent delivered at a rate of 1 mL/min. Vitamin C was extracted from the samples with methanol (sample:methanol = 1:4, v/v) by the same method mentioned above; an aliquot of the upper layer was immediately injected into the HPLC column. Ubiquinols and ubiquinones were also measured simultaneously according to the method reported previously [17]. Briefly, they were measured by an HPLC with a NANOSPACE SI-1 set at 700 mV. The samples were passed through a reverse phase column (LC8, 5  $\mu$ m, 250  $\times$  4.6 mm, Sigma-Aldrich Japan Co., Tokyo, Japan) followed by a reducing column (RC-10, 30  $\times$  4 mm, Shiseido Co. Ltd., Tokyo, Japan); methanol-*tert*-butyl alcohol (85:15, v/v) containing 50 mM sodium perchlorate was used as the eluent at a rate of 1 mL/min. Ubiquinols and ubiquinones were extracted from the plasma and homogenates of liver and brain with methanol–hexane (sample:methanol:hexane = 1:5:10, v/v); an aliquot of the upper layer was immediately injected into the HPLC column.

#### Analyses of tHODE and 8-iso-PGF<sub>2x</sub> in the Plasma, Erythrocytes, Liver, and Brain

The tHODE and t8-iso-PGF<sub>2x</sub> were measured as follows by a slightly modified method reported previously [8]. Animal blood was collected from the inferior vena cava by using a heparinized syringe, and the erythrocytes and plasma were separated by centrifugation (1,580 $\times$ g, 10 min). Immediately after collection, the plasma (0.2 mL) was used for the analysis. The liver was also collected and stored at –80 °C until analysis. Internal standards—8-iso-PGF<sub>2x</sub>-d<sub>4</sub> (100 ng) and 9-HODE-d<sub>4</sub> (100 ng)—and 1 mL of methanol were added to the plasma (200  $\mu$ L) followed by reduction with an excessive amount of sodium borohydride at room temperature for 5 min under nitrogen. The liver and brain homogenates (25 wt%, 300  $\mu$ L) were diluted with saline (1,700  $\mu$ L). The internal standards and 1 mL of methanol were added to this solution followed by the reduction as described above. Subsequently, the reduced sample was mixed with 1 M KOH in methanol (1 mL) under nitrogen and incubated in a shaker at 40 °C for 30 min in the dark. The sample was centrifuged (1,580 $\times$ g, 4 °C, 10 min) and the supernatant was diluted with a fourfold volume of water (adjusted to pH 3, beforehand) and acidified (pH 3) using 2 N HCl. The acidified sample was centrifuged (1,580 $\times$ g, 4 °C, 10 min) and the supernatant was subjected to solid-phase extraction [8]. The eluted solution was evaporated with nitrogen gas and 30  $\mu$ L of a silylating agent, i.e., (*N,O* bis) trimethylsilyl trifluoroacetamide (BSTFA), was added to the dried residue. The solution was vigorously mixed with a vortex mixer for 1 min and incubated at 60 °C for 60 min to obtain trimethylsilyl esters and ethers. This solution was diluted with 70  $\mu$ L of acetone and an aliquot of this sample was then injected into the gas chromatography system (GC 6890 N, Agilent Technologies Co. Ltd., Palo Alto, CA, USA) equipped with a quadrupole mass spectrometer (5973 Network, Agilent Technologies Co. Ltd.). A fused-silica capillary column (HP-5MS, 5% phenyl methyl siloxane, 30 m  $\times$  0.25 mm, Agilent Technologies Co. Ltd.) was used. Helium was used as the carrier gas at a flow rate of 1.2 mL/min. The temperature was programmed to increase from 60 to 280 °C at 10 °C/min. The injector temperature was set at 250 °C and temperatures of the transfer lines to the mass detector and ion source were 250 and 230 °C, respectively. Electron energy was set at 70 eV. The amounts of t8-iso-PGF<sub>2x</sub> and tHODE were determined by using fragment ions of *m/z* 481 and 440, respectively. The internal standards used for the quantification of 8-iso-PGF<sub>2x</sub> and HODE were 8-iso-PGF<sub>2x</sub>-d<sub>4</sub> (*m/z* = 485) and 9-HODE-d<sub>4</sub> (*m/z* = 444), respectively.

## Statistical Analysis

Statistical analyses were performed on a Microsoft personal computer by variance analysis of using Tukey's test for multiple comparisons (ANOVA). Data are expressed as mean value  $\pm$  standard deviation (SD).

## Results

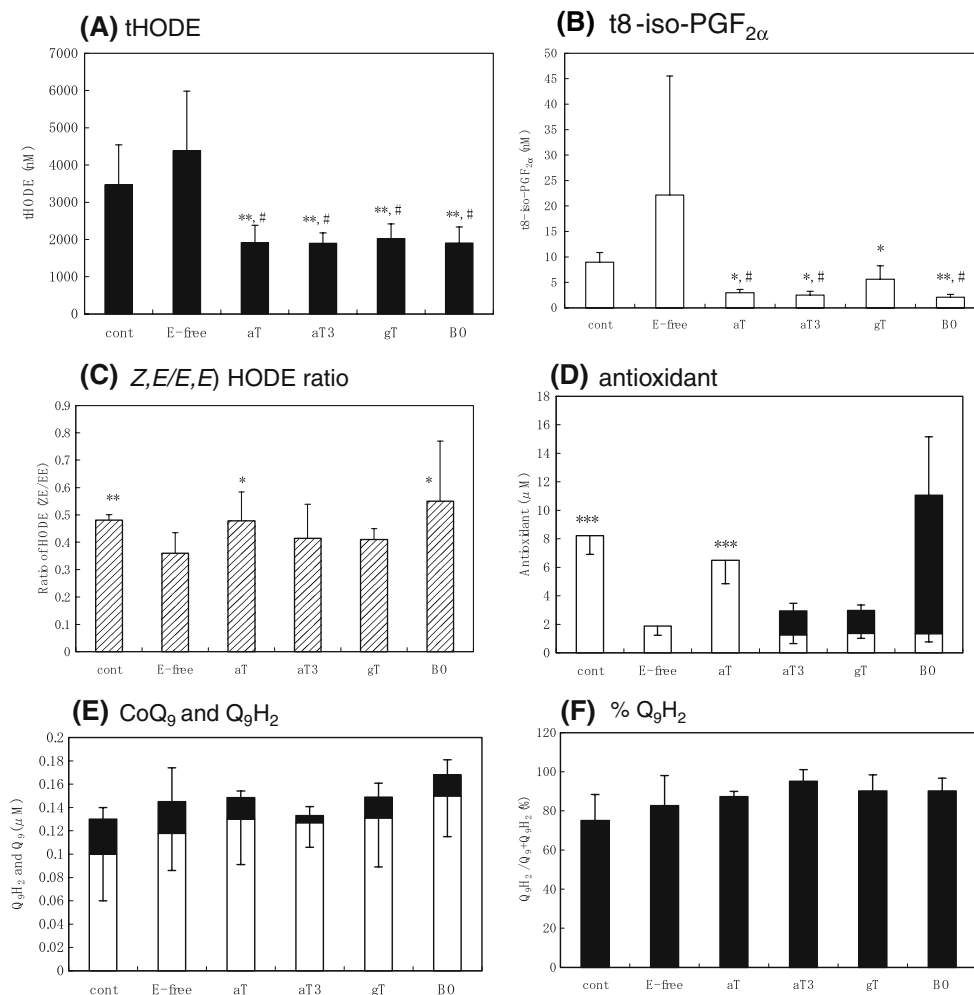

### Body Weight and Glutamic Pyruvic Transaminase (GPT) in Plasma

For 1 month, mice were fed either an E-free diet, a standard diet (cont-diet,  $\alpha$ T = 0.002 wt%), or an antioxidant-fortified diet that was prepared by the addition of  $\alpha$ T,  $\alpha$ T3,  $\gamma$ T, or BO-653 to the E-free diet. The body weight of the mice was measured once a week for 1 month, and it was found that among the six dietary groups, neither the weight nor the plasma GPT levels increased (data not shown).

### Plasma Levels of tHODE, t8-iso-PGF<sub>2 $\alpha$</sub> , and Antioxidants

As shown in Fig. 1, the E-free diet increased the plasma levels of both tHODE and t8-iso-PGF<sub>2 $\alpha$</sub> , while the antioxidants fortified decreased them. Thus, it was confirmed that the decrease in vitamin E increased lipid peroxidation in vivo. The tHODE concentrations were higher than those of t8-iso-PGF<sub>2 $\alpha$</sub>  by a factor of more than 100. It is noteworthy that the tHODE levels in the 0.04 wt% antioxidant-fortified groups were lower than that in the cont-diet (0.002 wt%  $\alpha$ T) group, suggesting every antioxidant tested was effective in reducing lipid peroxidation in vivo. The plasma levels of the antioxidants, namely,  $\alpha$ T,  $\alpha$ T3,  $\gamma$ T, BO-653, vitamin C, ubiquinol, and ubiquinone, were also assessed. The results are summarized in Fig. 1d–f. BO-653 and  $\alpha$ T were incorporated more efficiently than  $\alpha$ T3 and  $\gamma$ T. The fortified  $\alpha$ T3,  $\gamma$ T and BO-653 reduced the  $\alpha$ T level (Fig. 1d). There was no significant difference in the plasma levels of vitamin C among the different dietary groups

**Fig. 1** The plasma levels of tHODE (a), t8-iso-PGF<sub>2 $\alpha$</sub>  (b), the (Z,E/E,E) HODE ratio (c) and  $\alpha$ T (open bars) and the antioxidants corresponding to the diet types (solid bars) (d), ubiquinol-9 (open bars) and ubiquinone-9 (solid bars) (e), and ubiquinol-9 percentage (f) of mice fed either the standard diet (cont,  $\alpha$ T = 0.002 wt%,  $n = 10$ ), the E-free diet ( $n = 9$ ), or the antioxidant-fortified diet ( $n = 5$  in each group) for 1 month.  $\alpha$ T,  $\alpha$ T3,  $\gamma$ T, and BO-653 (0.04 wt%) were added to the E-free diet. Tukey's test for multiple comparisons (ANOVA) was carried out. Data are expressed as mean value  $\pm$  SD. The symbols \*, \*\*, and \*\*\* indicate  $P < 0.05$ ,  $P < 0.005$ , and  $P < 0.001$ , respectively, as compared to the E-free diet group and the symbol # indicates  $P < 0.05$  as compared to control diet group

(data not shown). The stereoisomer ratio (*Z,E/E,E*) HODE which is a measure of the hydrogen donor capacity of antioxidants decreased by the depletion of  $\alpha$ T, but recovered by the antioxidant, especially by  $\alpha$ T and BO-653 (Fig. 1c). The effect of  $\alpha$ T depletion and antioxidant supplementation did not affect coenzyme Q level.

#### Erythrocyte Levels of tHODE, t8-iso-PGF<sub>2 $\alpha$</sub> , and Antioxidants

Similar results were observed for erythrocytes as those for plasma. Vitamin E removal from diet increased both tHODE and t8-iso-PGF<sub>2 $\alpha$</sub>  and antioxidants fortified decreased them. The effects on t8-iso-PGF<sub>2 $\alpha$</sub>  were less significant than those for tHODE. BO-653 was incorporated into the erythrocytes to a considerable extent, although this level was lower than that of  $\alpha$ T (Fig. 2d). The (*Z,E/E,E*) HODE ratios in the cont-,  $\alpha$ T-,  $\alpha$ T3-,  $\gamma$ T-, and BO-diet groups were significantly higher than that in the E-free diet group (Fig. 2c).

#### Liver Levels of tHODE, t8-iso-PGF<sub>2 $\alpha$</sub> , and Antioxidants

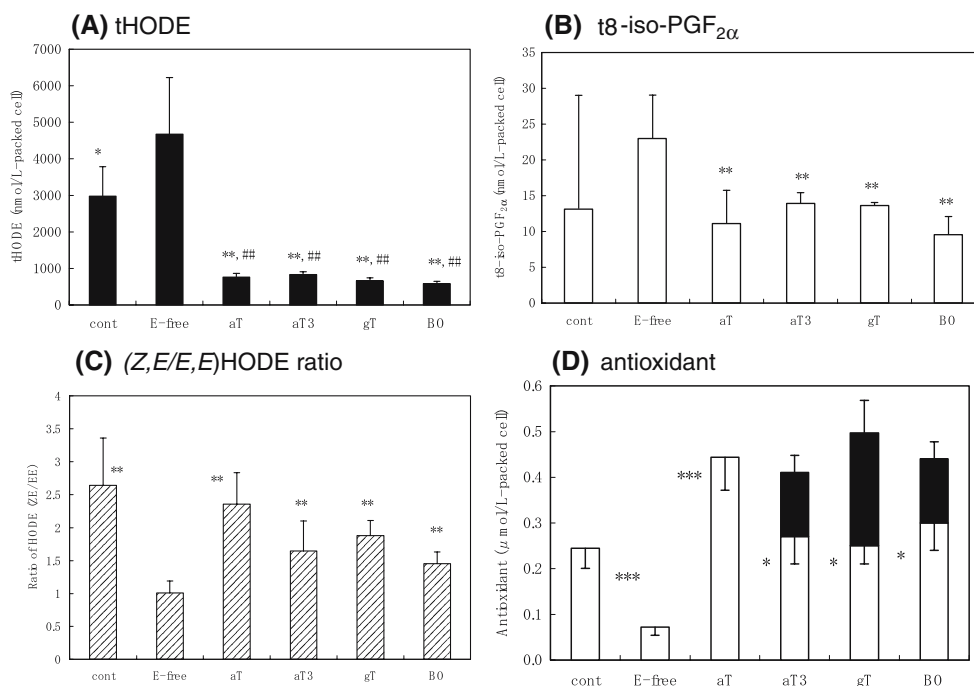

The effects of the antioxidants were clearly observed in the liver. As shown in Fig. 3a and b, the liver levels of tHODE and t8-iso-PGF<sub>2 $\alpha$</sub>  showed a significant increase by vitamin E depletion from diet, while the antioxidants lowered these lipid peroxidation products to the level less than those of

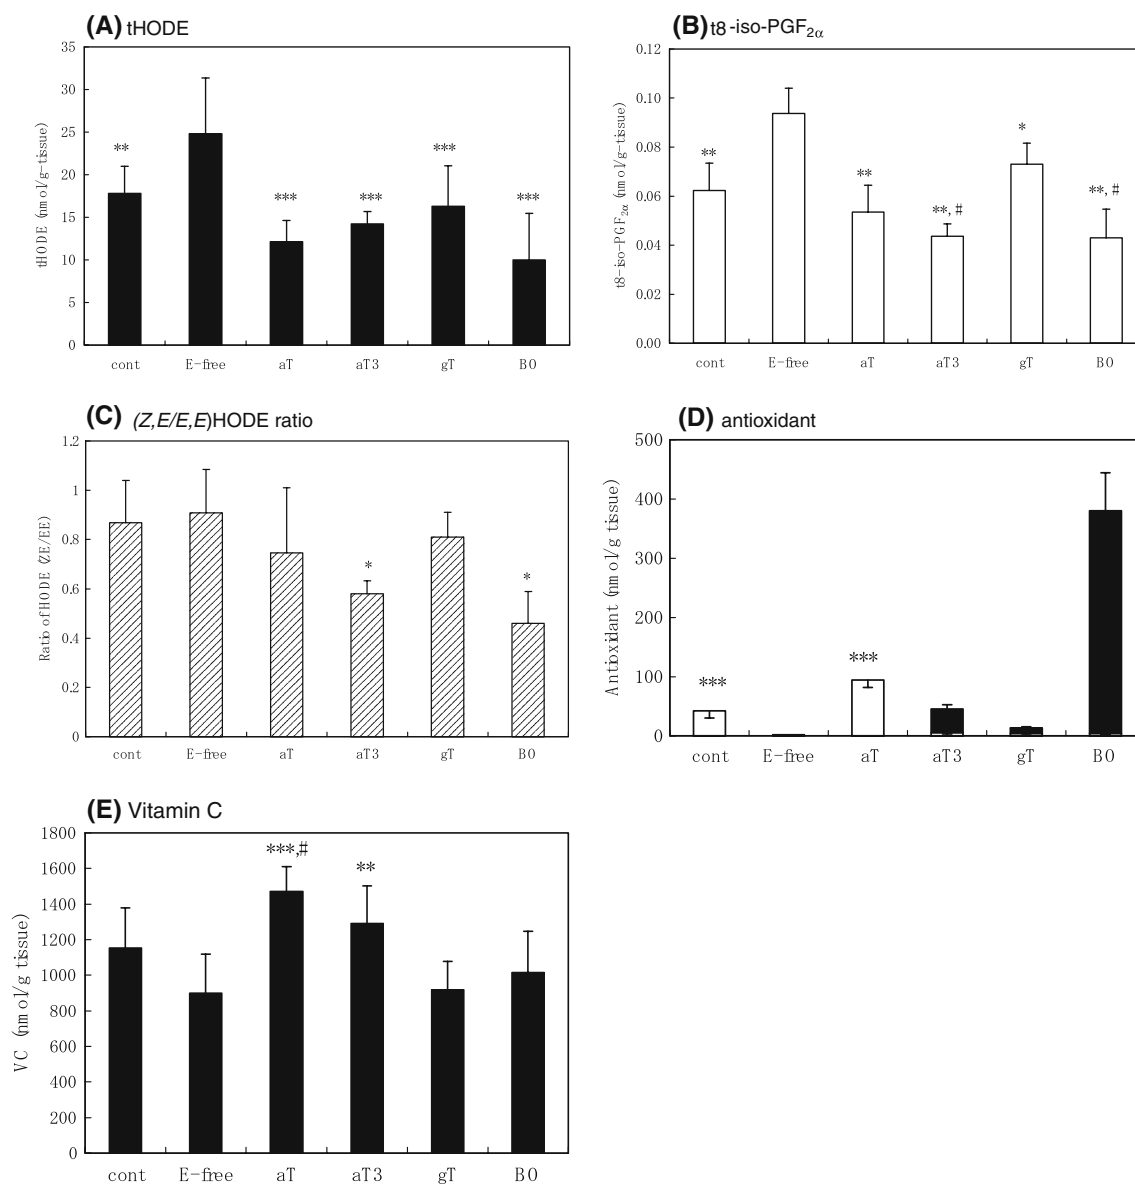

the control diet group. The liver levels of the antioxidants  $\alpha$ T,  $\alpha$ T3,  $\gamma$ T, BO-653, vitamin C, ubiquinol, and ubiquinone were also assessed and the data are summarized in Fig. 3d and e and Table 1. There was no significant difference among the dietary groups with regard to the liver levels of ubiquinol-9 or ubiquinone-9 (Table 1). The concentration of BO-653 in the liver of BO-653-diet group was much higher than that of  $\alpha$ T in the  $\alpha$ T-diet group (Fig. 3d), as observed previously [18]. The (*Z,E/E,E*) HODE ratios in the  $\alpha$ T3- and BO-653-diet groups were significantly lower than that in the E-free diet group (Fig. 3c).

#### Brain Levels of tHODE, t8-iso-PGF<sub>2 $\alpha$</sub> , and Antioxidants

The effects of antioxidants on the brain are of interest in connection with their potential use for neuronal diseases. The vitamin E removal from diet increased both tHODE and t8-iso-PGF<sub>2 $\alpha$</sub>  and the antioxidant fortification attenuated such increase (Fig. 4a, b). However, compared with plasma, erythrocytes, and liver, the effects of antioxidant removal and fortification were small in brain. For example, the vitamin E-free diet for 1 month decreased  $\alpha$ T concentration to less than 1/3 for plasma and erythrocytes and 1/10 in liver, but only 4/5 for brain. A few interesting data may be pointed out for brain. Firstly, the ratio of tHODE/t8-iso-PGF<sub>2 $\alpha$</sub>  in brain (35.6 mol/mol) was much smaller than that in plasma, erythrocytes and liver (387, 226, 278 mol/mol, respectively) in the control diet group.

**Fig. 2** The erythrocyte levels of tHODE (a), t8-iso-PGF<sub>2 $\alpha$</sub>  (b), the (*Z,E/E,E*) HODE ratio (c), and  $\alpha$ T (open bars) and the antioxidants corresponding to the diet types (solid bars) (d) in mice. The symbols and experimental conditions are the same as those in Fig. 1 except for the number of mice in E-free diet group ( $n = 7$ ). Tukey's test for multiple comparisons (ANOVA) was carried out. Data are expressed as mean values  $\pm$  SD. The symbols \* and \*\* indicate  $P < 0.01$  and  $P < 0.001$ , respectively, as compared to the E-free diet group and the symbol ## indicates  $P < 0.01$  as compared to control diet group

**Fig. 3** The liver levels of tHODE (a), t8-iso-PGF<sub>2α</sub> (b), the (Z,E/E,E)HODE ratio (c), αT (open bars) and the antioxidants corresponding to the diet types (solid bars) (d), and vitamin C (e) in mice. The symbols and experimental conditions are the same as those in Fig. 1 except for the number of mice in E-free diet group ( $n = 10$ ). Tukey's test for

multiple comparisons (ANOVA) was carried out. Data are expressed as mean value  $\pm$  SD. The symbols \*, \*\*, and \*\*\* indicate  $P < 0.05$ ,  $P < 0.005$ , and  $P < 0.001$ , respectively, as compared to the E-free diet group and the symbol # indicates  $P < 0.05$  as compared to control diet group

Secondly, the percentage of reduced form ubiquinol in total coenzyme Q is much smaller in brain than in liver and plasma (Table 1). Thirdly, the brain level of αT was higher than that of the other antioxidants. But, it is interesting that the net increase in αT3 was higher than that in αT (Fig. 4d).

## Discussion

The reactivity of radical-scavenging antioxidants in vitro may be determined quantitatively by several methods

and the correlation with structure has been documented extensively for various antioxidants. However, the antioxidant efficacy in vivo is determined by several factors such as concentration, localization, and mobility at the microenvironment, fate of antioxidant-derived radical, interaction with other antioxidants, bioavailability, that is, uptake, retention, metabolism, and excretion, as well as the chemical reactivity toward radicals [10, 19]. Therefore, the evaluation of antioxidant efficacy in vivo is difficult. One potential approach is to measure the effects of antioxidant supplementation or removal on the

**Table 1** Concentrations of ubiquinol-9 (Q<sub>9</sub>H<sub>2</sub>) and ubiquinone-9 (Q<sub>9</sub>) in plasma, liver, and brain of mice

Tukey's test for multiple comparison (ANOVA) was carried out. Data for Q<sub>9</sub>H<sub>2</sub> ratio are expressed as mean value ± standard deviation (SD). Significant difference against E-free diet, \*  $P < 0.01$ , \*\*  $P < 0.005$

Diet	Cont	E free	αT	αT3	γT	BO-653
Concentrations (Q <sub>9</sub> H <sub>2</sub> + Q <sub>9</sub> , mean)

oxidative status by using biomarkers. In the present study, the effects of αT removal from the diet and also of fortification of other antioxidants on the level of lipid peroxidation products, tHODE and t8-iso-PGF<sub>2x</sub> were investigated.

The effects of different diets on the increase or decrease in tHODE and t8-iso-PGF<sub>2x</sub> relative to control diet are summarized in Table 2. It can be easily seen that vitamin E removal from the diet increased both tHODE and t8-iso-PGF<sub>2x</sub> and every antioxidant decreased them. The tHODE and 8-iso-PGF<sub>2x</sub> patterns were largely the same in the plasma, erythrocytes, and liver, where the concentration of tHODE was approximately two orders larger than that of 8-iso-PGF<sub>2x</sub>. However, it is interesting that in accordance with the fact that the brain contains relatively higher amounts of arachidonic acid, the level of tHODE in the brain is only 10 to 30-fold higher than that of t8-iso-PGF<sub>2x</sub>. As mentioned previously [8, 20], this is reasonable since linoleates are the major in vivo lipids although they are less reactive toward free radicals than arachidonates; further, the oxidation of linoleates proceeds by a straightforward mechanism to give much simpler products than arachidonates [21, 22], thus the selectivity for the formation of HPODE is much higher than that of 8-iso-PGF<sub>2x</sub>.

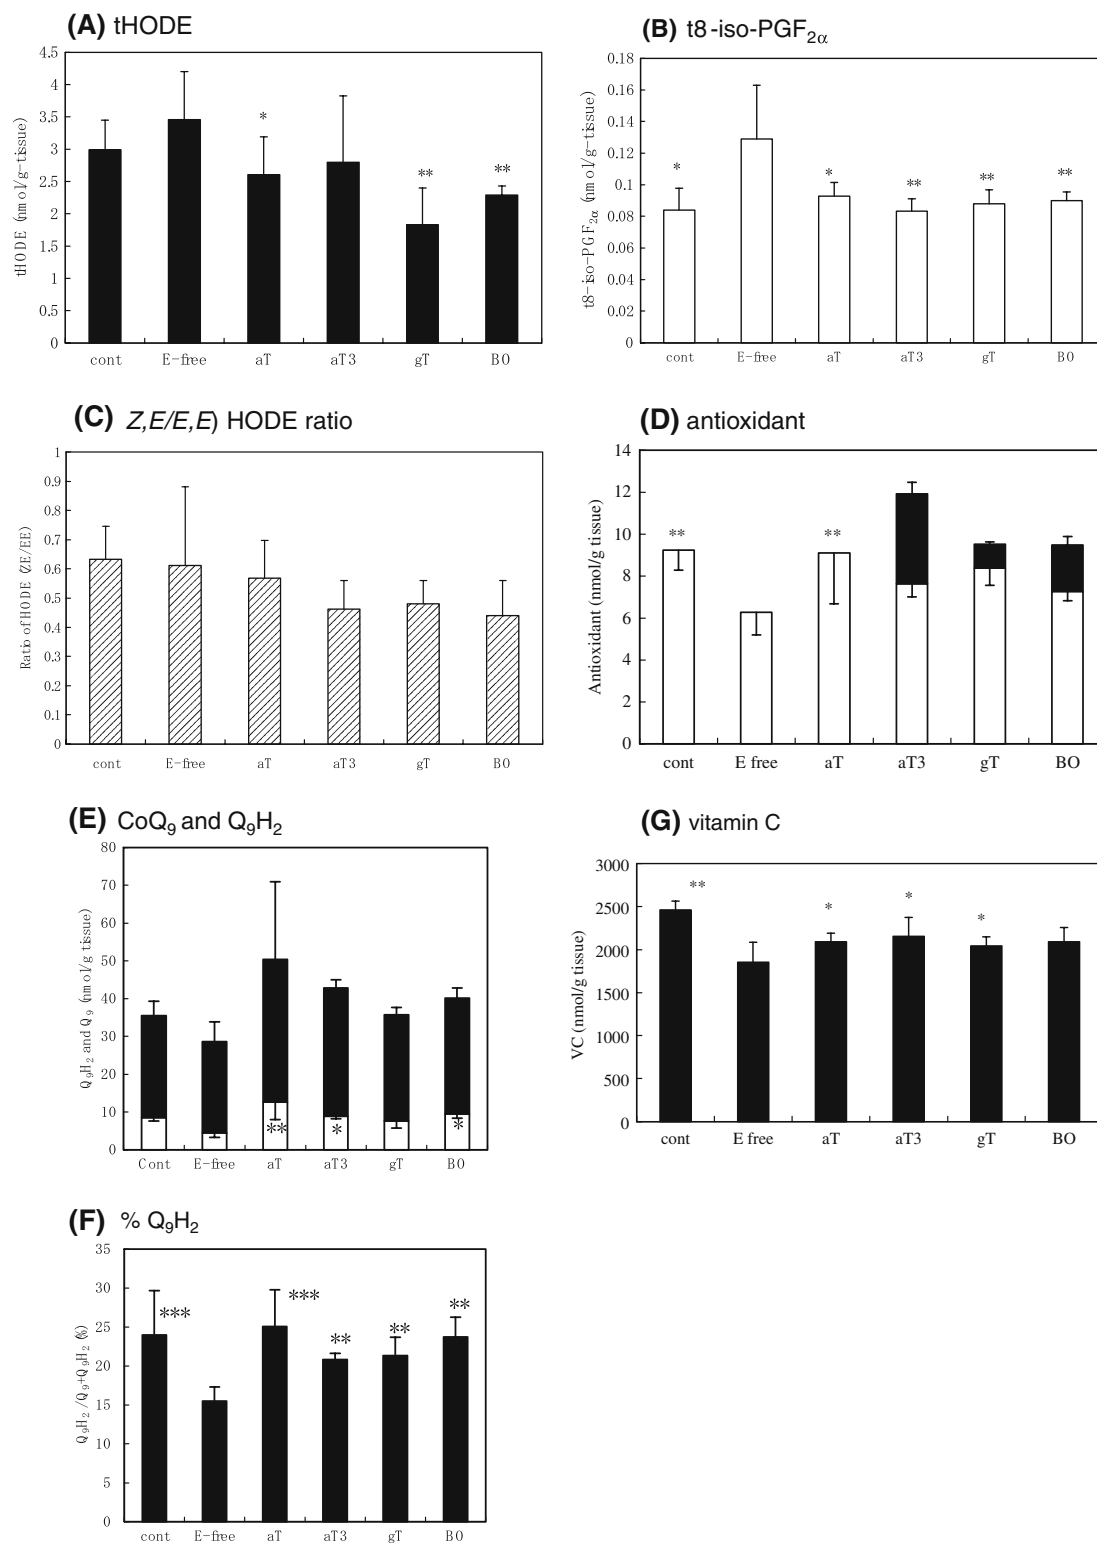

The ratio of *cis-trans* to *trans-trans* HODE is a measure of the capacity of hydrogen atom donation at the site of oxidation [23, 24]. We were able to evaluate the in vivo site-specific efficacy of the antioxidants based on the stereoisomer ratio (*Z,E/E,E*) HODE as observed in the previous reports [16, 24, 25]. For example, when compared with the E-free diet, the potent natural antioxidant αT resulted in low levels of tHODE and a high (*Z,E/E,E*) HODE ratio in the plasma, erythrocytes, liver, and brain. αT3, which is another potent isoform of vitamin E, was also found to be effective in vivo. It should be noted that the (*Z,E/E,E*) HODE ratio was clearly increased by αT, αT3,

and BO-653 in the plasma and erythrocytes depending on the antioxidant capacity; however, no increase was observed in the liver or brain. Further, αT3 as well as BO-653 induced a low (*Z,E/E,E*) HODE ratio only in the liver, although the tHODE levels were decreased in both groups when compared with that in the E-free diet group. The reason for this is unclear at present; however, the inhibition of enzymatic lipid oxidation may be at least partially responsible. In fact, 15-lipoxygenase is known to yield the regiospecific, stereospecific, and enantiospecific product 13(*S*)-(*Z,E*)-HPODE [26]. Khanna et al. [27] observed that a small amount of αT3, but not αT, suppressed glutamate-induced cell death by binding to the catalytic site of 12-lipoxygenase. Further studies are needed to clarify this observation.

The present study clearly shows that the efficacy of antioxidants in vivo can be evaluated reasonably well based on the tHODE level and its stereoisomer ratio and that the antioxidant capacity decreased in the order: BO-653 > αT3 ≥ αT, γT when tHODE levels in blood, liver, and brain were compared. However, needless to say, further study is required to evaluate the role and efficacy of antioxidants and nutrients in humans. The effects of αT on human health remain debatable since certain epidemiological and intervention studies have reported contradictory results [28, 29]. This may not be surprising because the lipid peroxidation must proceed by different mechanisms in vivo and the antioxidant activity must be determined based on several factors as mentioned above. The present study showed that tHODE and its stereoisomer ratio are promising tools for such evaluations.

In conclusion, this study shows that tHODE and its stereoisomer distribution as well as isoprostanes are appropriate biomarkers for the assessment of the antioxidant capacity of various foods, beverages, and supplements in vivo. Further studies are required to verify their efficacy in humans.

**Fig. 4** The brain levels of tHODE (a), t8-iso-PGF<sub>2α</sub> (b), the (Z,E/E,E) HODE ratio (c), αT (open bars) and the antioxidants corresponding to the diet types (solid bars) (d), ubiquinol-9 (open bars) and ubiquinone-9 (solid bars) (e), and ubiquinol-9 percentage (f), and vitamin C (g) in mice. The symbols and experimental

conditions are the same as those in Fig. 1 except for the number of mice in E-free diet group ( $n = 5$ ). Tukey's test for multiple comparisons (ANOVA) was carried out. Data are expressed as mean value  $\pm$  SD. The symbols \*, \*\*, and \*\*\* indicate  $P < 0.05$ ,  $P < 0.01$ , and  $P < 0.005$ , respectively, as compared to the E-free diet group

**Table 2** Relative ratio of tHODE and t8-iso-PGF<sub>2α</sub> in antioxidant-fortified (0.04 wt%) and vitamin E-free diet groups to that in control-diet (α-tocopherol, 0.002 wt%) group

	Plasma		Erythrocytes		Liver		Brain

# Rapid Analysis of Acylglycerols in Low Molecular Weight Milk Fat Fractions

R. J. Craven · R. W. Lencki

Received: 1 September 2006 / Accepted: 21 February 2007 / Published online: 3 April 2007  
© AOCS 2007

**Abstract** A suitable analytical method was required to facilitate development of an industrial-scale short-path distillation (SPD) process. Short-path distillation produces milk fat distillates (MFD) enriched in low molecular weight milk fat components—viz. free fatty acids, monoacylglycerols, diacylglycerols, cholesterol and low molecular weight triacylglycerols. In this case, solid-phase extraction (SPE) was considered a better alternative than thin-layer chromatography for separating polar and apolar lipid components in MFD samples due to its speed and near-complete recoveries. Solid-phase extraction of MFDs yielded two fractions, both of which are sufficiently pure for subsequent analysis by gas chromatography. This procedure provided rapid and complete chemical characterization (including mass balances) of low-molecular weight milk-fat fractions.

**Keywords** Minor lipids · Milk fat · Short-path distillation · Diacylglycerol · Gas chromatography

## Abbreviations

DAG	Diacylglycerol
FA	Fatty acid
FFA	Free fatty acid
FID	Flame ionization detector
GC	Gas chromatograph(y)
MAG	Monoacylglycerol
MF	Milk fat
MFD	Milk fat distillate

MFD170	MFD collected at 170 °C
MFD185	MFD collected at 185 °C
MFD195	MFD collected at 195 °C
MFD200	MFD collected at 200 °C
MW	Molecular weight
RT	Retention time
SE	Standard error
SP	Short-path
SPD	Short-path distillation
SPE	Solid-phase extraction
SPE-1	First SPE fraction
SPE-2	Second SPE fraction
TAG	Triacylglycerol
TLC	Thin-layer chromatography
TMS	Trimethyl silyl
TMSI	Trimethyl silyl imidazole

## Introduction

Milk fat (MF) is more challenging to characterize than most natural lipids due to its compositional diversity. Detailed chromatographic analysis is difficult due to the wide range of FA in MF acylglycerols and the presence of minor components—specifically cholesterol, DAG, MAG and FFA [1–3].

Milk fat contains many compounds with novel functionality (e.g. short-chain fatty acids) [4–7], and industrial-scale short-path distillation (SPD) is a popular technique for their separation and purification [8–10]. The development, optimization and control of a commercial MF SPD system requires an analysis technique that is fast, accurate and economical. Fractionation of MF by SPD enriches the

distillate fraction not only with low-MW TAG, but also with the minor components (*viz.* cholesterol, MAG, DAG and FFA) that have similar MW [8, 11–14]. Since low-MW TAG and DAG have similar retention times, their peaks overlap in the resulting gas chromatogram making their simultaneous analysis by GC-FID impractical [15].

No current analytical technology can easily achieve the simultaneous determination of both apolar (TAG) and polar (DAG, MAG, FFA and cholesterol) lipid fractions in MF. For this reason, methodologies generally rely on an initial separation of apolar and polar lipid fractions prior to chromatographic analysis [11, 14–21]. For instance, Itabashi, Myher and Kuksis [14] used thin layer chromatography (TLC) to separate TAG, DAG and MAG from a mixture produced by partial Grignard degradation of hydrogenated low MW MF TAG prior to analysis of the resulting DAG fractions by chiral-phase HPLC.

Classical lipid analysis techniques can provide excellent separations; however, these TLC-based methods are time-consuming and samples are subject to possible degradations and rearrangements (e.g. acyl migration) [18, 19, 22]. In addition, TLC is a subjective technique requiring a high degree of expertise and attention; it is not easily reduced to a set of uniform and repeatable steps, as is required for routine analysis. In recent years, solid-phase extraction (SPE) techniques have supplanted many TLC-related separations and liquid–liquid extractions due to their ease, reliability and near-complete recoveries [23–25]. Consequently, several approaches have been developed for the separation of lipid classes by SPE in vegetable and seed oils [26–28], and model biological extracts [25].

Thin layer chromatography has the unmatched flexibility and resolving power necessary for analyzing samples of unknown composition. On the other hand, SPE excels where samples are known to have similar composition and processing speed or the number of samples to be analyzed is important. A suitable SPE method for the analysis of milk fat distillate (MFD) produced by SPD would streamline laboratory, pilot plant scale-up, and quality control processes.

## Materials and Methods

Milk fat (Gay Lea, Guelph, ON, Canada) distillate (MFD) was produced in a 2" SPD unit (Pope Scientific, Menomonee Falls, WI, USA). All solvents were HPLC grade and all reagents and analytical standards were of the highest practical grade (Fisher Scientific, Mississauga ON; Sigma-Aldrich, St Louis, MO, USA). TLC bands and GC retention times were determined for FFA, MAG, DAG, cholesterol and TAG using appropriate standards (Sigma-Aldrich).

## Thin-Layer Chromatography

TLC plates, 20 × 20 cm with a 250 μm layer of silica G (Analtech Inc., Newark, DE, USA) were sprayed with a saturated solution of boric acid in water/methanol (25:75, by volume) and dried in a 120 °C oven for 30 min. Up to 10 mg of sample, dissolved in 200 μl chloroform, was applied in a thin line one inch from the bottom of the plate. Plates were developed with chloroform/acetone (96:4, by volume) and allowed to dry. To prepare samples for GC analysis, TLC plates were sprayed with a 0.05% solution of primuline (Sigma-Aldrich) in methanol. Lipid fractions were visible as blue bands when viewed under UV light. Lipid bands were marked, scraped from plates and extracted with chloroform. For direct observation of TLC separations, this procedure was followed with the following exceptions: small spots of sample were applied to the boric acid treated TLC plates; once developed and dried, plates were sprayed with 50% sulphuric acid and placed in a 180 °C oven for one hour [22, 29].

## Solid-Phase Extraction: Load Limit Determination

Known quantities of MFD (starting with 100 mg) were eluted through two stacked cartridges. These cartridges were treated as a single unit until the first lipid fraction (SPE-1) had been eluted. Afterwards, the cartridges were separated and eluted independently—the top cartridge for the second lipid fraction (SPE-2), and the bottom cartridge for SPE-1 and then for SPE-2. These steps were repeated with successively smaller samples until MAG and DAG were no longer detected in the SPE-2 fraction from the bottom cartridge [24].

## Solid-Phase Extraction: Sample Preparation

The MFD samples were separated on 3 ml SPE cartridges containing a 500 mg bed-weight of diol bonded phase (Supelco, Bellefonte, PA, USA). The packing material in each diol cartridge was washed with 4 ml of hexane and was not allowed to dry. MFD dissolved in approximately 500 μl hexane was transferred quantitatively to the top of each hexane-washed SPE cartridge and two fractions were collected: SPE-1—eluted with 6 ml of hexane/methylene chloride/diethyl ether (89:10:1, by volume); and SPE-2—eluted with 4 ml of chloroform/methanol (2:1, by volume). The solvent in each fraction was evaporated under a stream of nitrogen and samples were analyzed by GC. SPE-1 was dissolved in iso-octane and analyzed directly for TAG content, TMS derivatives were prepared for SPE-2 prior to GC analysis. Diol bonded phases are preferred for the isolation of DAG because they do not promote acyl migration [27, 28].

### Fatty Acid Methyl Ester Analysis

The SPE-1 samples were dissolved in 1 ml iso-octane and 100  $\mu$ l 2N sodium methoxide in methanol was added. Samples and reactants were thoroughly mixed using a vortex mixer for 1 min, then allowed to react at room temperature. After 5 min, 250 mg sodium bisulphate monohydrate was added and the sample vial was centrifuged for 3 min. For SPE-2 samples, half the amount of solvent and reagents was used. 2  $\mu$ l was injected onto a custom-made (1.5 m  $\times$  1/8") stainless steel column containing 10% Silar 9CP on 80/100 Chromosorb b WAW (Supelco) housed in a Hewlett Packard 5890 (Agilent, Palo Alto, CA, USA) GC equipped with FID. The carrier gas was nitrogen at 10 psi, the inlet and detector temperature were set at 235  $^{\circ}$ C, and the temperature was held at 34  $^{\circ}$ C for 2.5 min, increased to 155  $^{\circ}$ C at 17.5  $^{\circ}$ C/min, increased to 190  $^{\circ}$ C at 2.0  $^{\circ}$ C/min, increased to 230  $^{\circ}$ C at 17.5  $^{\circ}$ C/min, and held at 230  $^{\circ}$ C for 8 min [30–32].

### Trimethyl-Silyl Derivatives

Identification and quantification of FFA, MAG and DAG is greatly improved by preparing their trimethyl-silyl (TMS) derivatives. SPE-2 samples and TLC fractions were dissolved in 400  $\mu$ l pyridine, a vortex mixer being used to ensure complete dissolution. Then, 100  $\mu$ l trimethyl silylimidazole (TMSI; 98+%, Sigma-Aldrich) was added and the reaction mixture was once again blended thoroughly with a vortex mixer. The reaction was conducted in a dry nitrogen atmosphere and can be considered virtually complete within 5 min at room temperature [33]. For samples less than 10 mg, half the volume of pyridine and TMSI was used.

### GC Analysis of Acylglycerols

Fractions obtained by SPE and TLC were analyzed on a polarizable capillary column (30 m  $\times$  0.25 mm) (Restek MXT-65TG from Chromatographic Specialties, Brockville ON) with a crosslinked 65% diphenyl/35% dimethyl polysiloxane stationary phase that is stable to 370  $^{\circ}$ C. Polarizable columns separate acylglycerols primarily by carbon number and secondarily by their degree of unsaturation [34, 35]. The column was housed in a Hewlett Packard 6890 (Agilent) GC equipped with FID. 1  $\mu$ L of sample was injected manually and optimal sample loading was obtained by adjusting the split ratio manually. The split was adjusted so that for SPE-1 fractions the highest TAG peak was approximately 150 picoamperes (pA), and for SPE-2 fractions the highest peak (apart from cholesterol) was approximately 100 pA. Hydrogen carrier gas flowed at a rate of 2.8 ml/min, the injector and detector

were held at 330 and 370  $^{\circ}$ C, respectively, and the oven temperature was held for 2 min at 60  $^{\circ}$ C, increased to 275  $^{\circ}$ C at 15  $^{\circ}$ C/min, increased to 340  $^{\circ}$ C at 4  $^{\circ}$ C/min, increased to 360  $^{\circ}$ C at 30  $^{\circ}$ C/min, and held at 360  $^{\circ}$ C for 5 min. The extraordinarily large number of peaks in a MF chromatogram makes identification, integration and quantification exceedingly difficult—consequently, acylglycerols are typically identified and grouped by the number of acyl carbon atoms [19].

### Results and Discussion

To investigate the application of SPE to the analysis of low MW MF fractions prepared by SPD, four representative samples were selected. These MFD were collected at 170, 185, 195 and 200  $^{\circ}$ C and a pressure of approximately 6 mtorr—their corresponding yields were 2.26, 4.67, 6.64 and 17.17% (by mass) respectively. These samples were collected at the lowest (MFD170 collected at 170  $^{\circ}$ C), highest (MFD200 collected at 200  $^{\circ}$ C) and typical (MFD185 and MFD 195 collected at 185 and 195  $^{\circ}$ C, respectively) operating temperatures.

Load limit determination experiments are necessary to evaluate any SPE procedure prior to use. The load limit for a 500 mg diol bonded phase SPE cartridge was determined to be 12 mg of MAG and DAG. For analyses, samples weighing approximately 30 mg were separated by SPE—this is well below the load limit for 500 mg of bonded phase but 3 times the capacity of standard 20  $\times$  20 cm (250  $\mu$ m) TLC plates [18, 22].

Both qualitative and quantitative data are available from the same SPE experiment; complete mass balances are easily obtained and sample losses due to SPE are extremely low. This is demonstrated by high recovery and reproducibility of SPE separations reported in Table 1. Quantitative SPE data is determined gravimetrically—this non-destructive measurement leaves SPE fractions intact and unaltered for subsequent qualitative analysis. In contrast, quantitative and qualitative TLC are separate methodologies requiring dedicated technologies and sample treatments [18, 22]. Even when dedicated TLC techniques are applied, good

**Table 1** Yields of fractions obtained by solid-phase extraction (SPE-1 and SPE-2) of milk fat distillates (MFD) collected at 170, 185, 195 and 200  $^{\circ}$ C (average  $\pm$  SE,  $n = 6$ )

Fraction	Yield (mass %)			
	170 $^{\circ}$ C	185 $^{\circ}$ C	195 $^{\circ}$ C	200 $^{\circ}$ C
SPE-1	68.06 $\pm$ 0.16	78.23 $\pm$ 0.20	79.21 $\pm$ 0.65	86.65 $\pm$ 0.29
SPE-2	29.88 $\pm$ 0.38	20.51 $\pm$ 0.20	19.49 $\pm$ 0.08	12.25 $\pm$ 0.26
Total	97.94	98.74	98.70	98.90

quantitative accuracy is still difficult to achieve [18] and the various manipulations (e.g. plate-scraping, extraction, washing and the addition of acid and dye) required for qualitative TLC limit yields (to as little as 80%) and hinder precise quantitation [25].

The purity of SPE fractions produced from MFD was investigated by TLC. A sample of each MFD was separated by SPE and a boric acid treated TLC plate was spotted with each of the resulting fractions (Fig. 1). After development with chloroform/acetone (96:4, by volume), the plate was sprayed with 50% sulfuric acid and charred at 180 °C for one hour; this method makes as little as 1 µg of lipid visible [22, 29]. TLC spots were identified by comparison with standards and by referring to the current literature [14]. These experiments indicate that SPE-1 is mainly composed of TAG (fraction a), with additional spots in distillates collected at 185 and 170 °C (fraction c) indicating the presence of FFA and cholesterol. Between these, an extremely light band was observed (it is, however, not

**Fig. 1** Boric acid TLC analysis of fractions obtained by solid-phase extraction (SPE-1 and SPE-2) of milk fat distillates (MFDs) collected at 170, 185, 195 and 200 °C. For a typical boric acid TLC analysis these bands would be identified as: **a** TAG; **b** DAG (if present); **c** DAG (if present), cholesterol and FFA; **d** TAG (if present); **e** DAG; **f**, **g** DAG, cholesterol and FFA; **h** unknown; **i** 1- and 2-MAG; and **j** glycerol. They are, however, according to GC analysis (with their relative quantity in mass percent presented in brackets): **a** TAG (51.2); **b** TAG and cholesterol (5.0); **c** cholesterol (9.4); **d** TAG (0.7); **e** DAG with two long acyl chains (predominantly 1,2-DAG) and cholesterol (13.4); **f** DAG with one long and one short acyl chain (predominantly 1,3-DAG), cholesterol and FFA (14.7); **g** DAG with one long and one short acyl chain (1,3- and 1,2(2,3)-DAG), cholesterol and FFA (0.5); **h** nothing; **i** MAG and cholesterol (4.9); and **j** nothing

discernible in the printed figure) for distillates collected at 170 and 185 °C (fraction b). Though light, this band cannot be dismissed since it may indicate the presence of DAG in SPE-1 and thus, an incomplete separation by SPE—in which case this method may not be suitable for its intended purpose. For this reason, replicate samples of the SPE-1 fraction of MFD170 were separated by preparative TLC and analyzed in greater detail by GC.
