Figure 1 also shows that SPE-2 fractions had high concentrations of cholesterol (fraction f) and DAG (fraction e), smaller quantities of MAG (fraction i) and FFA (fraction g), and very small quantities of TAG (fraction d). This last band (fraction d) cannot be dismissed since it indicates the presence of TAG in SPE fraction 2. This band indicates incomplete separation by SPE and if the concentration of TAG is too high, this may interfere with proper integration of SPE-2 fractions during GC analysis. Consequently, MFD170 SPE-2 samples were also separated by preparative TLC and analyzed in greater detail by GC.

The SPE-1 and SPE-2 fractions of MFD170 were separated by preparative boric acid TLC and analyzed by GC to verify and quantify the potential impurities observed in Fig. 1. MFD170 was chosen because it has the highest proportion of SPE-2 (Table 1) and therefore the highest concentration of MAG and DAG. Three MFD170 SPE-1 fractions were separated by boric acid TLC—by dividing each fraction between two plates the sample load did not exceed 10 mg per plate. Plates were developed in chloroform/acetone (96:4, by volume) and TLC bands became visible under UV light after spraying with a solution of primuline. Whether visible or not, all three regions (i.e. fractions a, b and c) of the TLC plates were scraped, extracted, weighed and analyzed by GC. For the DAG region (fraction b) of the plates, silica gel scraped from all six TLC plates was combined to increase sample concentration, and the likelihood of detecting contaminants. Likewise, four SPE-2 samples were separated by boric acid TLC—since each of these samples was approximately 10 mg, only one TLC plate was required for each SPE-2 fraction. After spraying with primuline, then viewing and marking bands under UV light, all seven regions (fractions d through j) of each plate were scraped, extracted, weighed and analyzed by GC. For the TAG region (fraction d) and for fractions g, h and j of the plates, the silica gel from all four plates was combined to increase sample concentration and aid in detection.

Chromatograms of the main TLC fractions isolated from SPE-2 of MFD170 are provided in Fig. 2. For a typical lipid the length of acyl chains in DAG plays no role in their separation by TLC [30]. Boric acid TLC separates these DAG on the basis of their positional isomerism into two bands: 1,3-DAG and 1,2(2,3)-DAG. In native milk fat, however, the acyl chain lengths for 1,3- and 1,2-DAG are

**Fig. 2** Gas chromatographic analysis of boric acid TLC fractions isolated from the second solid-phase extraction fraction (SPE-2) of MFD collected at 170 °C (MFD170). Chromatograms labeled *e*, *f*, *g* and *i* correspond to TLC spots as they appear in Fig. 1. Fractions *e*, *f* and *i* are single samples, whereas, for fraction *g*, silica gel from four plates was combined and extracted. Peaks are identified by a single-letter prefix (*A* for FFA, *M* for MAG, *D* for DAG) followed by the total number of carbon atoms in the FA residues. <sup>a</sup>DAG with two long acyl chains (predominantly 1,2-DAG). <sup>b</sup>DAG with one long and one short acyl chain (predominantly 1,3-DAG). <sup>c</sup>DAG with one long and one short acyl chain (1,3- and 1,2(2,3)-DAG)

different due to the positional specificity with which acyl chains are placed on the glycerol backbone during milk fat biosynthesis [2]. In addition, TLC separation of milk fat DAG is based primarily on differences of acyl chain length and secondarily on positional isomerism. Thus, milk fat DAG produce an upper band containing DAG with two long acyl chains: 1,3-DAG (if present) above 1,2-DAG, and a lower band containing DAG with one long and one short acyl chain: 1,3-DAG above 1,2-DAG (if present). A detailed explanation of this phenomenon is provided by Itabashi, Myher and Kuksis [14]. Chromatograms for

fractions *e*, *f* and *g* in Fig. 2 show that these TLC bands each contain a portion of the complete DAG profile in addition to cholesterol and FFA. TLC band *e* contains the long- and medium-chain 1,2-DAG whereas TLC bands *f* and *g* contain DAG having at least one short chain and therefore, lower carbon numbers. Band *f* contains 1,3-DAG and in theory band *g* should contain pure 1,2-DAG formed, for the most part, from 1,3-DAG that have undergone acyl migration. However, it appears band *g* has been contaminated with material from band *f* and thus, contains both 1,2- and 1,3-DAG. This was difficult to avoid given the lack of clear delineation between bands *f* and *g* on the TLC plate, the relatively high concentration of band *f* (Table 2) and the fact that the chromatogram for band *g* was produced by combining and extracting the silica gel from four plates in order to increase its concentration.

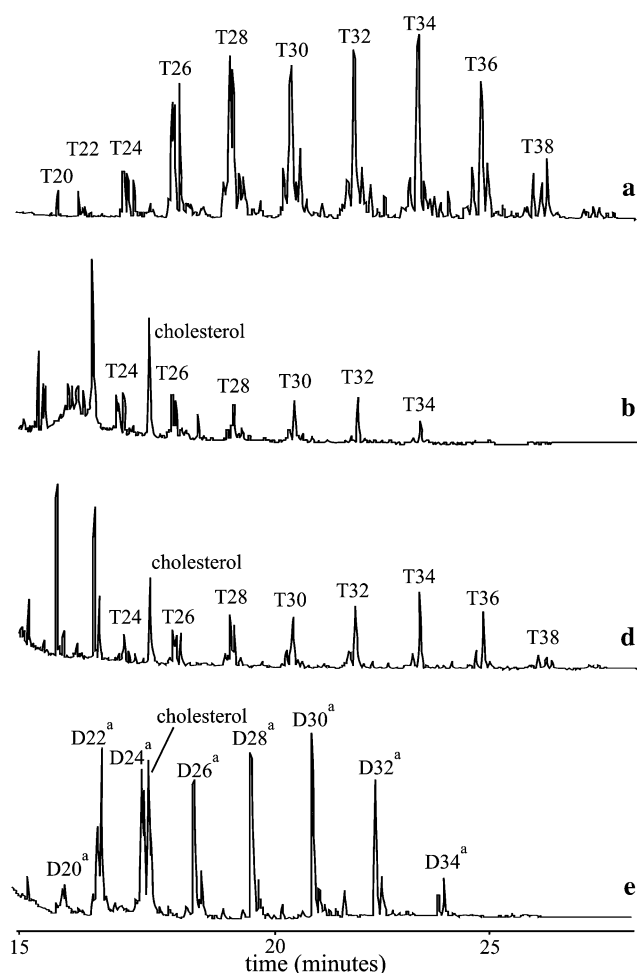

Chromatograms for fractions *e*, *f* and *g* also show that FFA is not distributed evenly on boric acid treated TLC plates—longer FFA are concentrated in fractions *e* and *f* while fraction *g* is enriched in shorter FFA. The chromatogram for fraction *i* shows this fraction contains the MAG (positional isomer was not determined) and some cholesterol.

The distribution of mass between the various TLC fractions is reported in the caption for Fig. 1. Based on differences in their relative sizes, the potential contamination of SPE-1 by DAG (fraction *b*) would be of greater concern than contamination of SPE-2 by TAG (fraction *d*). Chromatograms for both fractions of interest are shown in Fig. 3 (fractions *b* and *d*) along with a pure TAG fraction (*a*) and DAG fraction (*e*). Comparison of these four chromatograms demonstrates that there is no detectable DAG in fraction *b*; therefore, SPE-1 can be considered DAG-free. SPE-2, however, cannot be considered TAG-free since TAG are detectable in the chromatogram for fraction *d*. Nevertheless, peaks corresponding to TAG account for less than 33% (by mass) of those present in fraction *d*; therefore, the SPE-2 fraction is at most 0.67% (by mass) TAG. Since this mass is distributed over more than 100 peaks, the presence of TAG at these levels is unlikely to interfere

**Table 2** FFA determined by GC analysis of fractions obtained by SPE (SPE-1 and SPE-2) of MFDs collected at 170, 185, 195 and 200 °C (average  $\pm$  SE,  $n = 3$ )

Fraction	Relative response (%)			
	170 °C	185 °C	195 °C	200 °C

MFD (total)	12.30	6.50	6.09	3.36

**Fig. 3** Gas chromatographic analysis of boric acid TLC fractions isolated from fractions obtained by SPE of MFD collected at 170 °C (MFD170). Labels for chromatograms correspond to TLC spots as they appear in Fig. 1 and are (from top to bottom): **a** TAG band for the first solid-phase extraction fraction (SPE-1) (one sample), **b** any potential DAG in SPE-1 (three samples combined), **d** any potential TAG in the second solid-phase extraction fraction (SPE-2) (four samples combined), **e** DAG band for SPE-2 (one sample). TAG peaks are identified by the letter T followed by the total number of carbon atoms in the FA residues. Other peaks are identified as described for Fig. 2

markedly with detection or integration of MAG, DAG and cholesterol in SPE-2 fractions.

As demonstrated in the preceding experiments, SPE is effective for the separation of TAG from DAG, MAG and cholesterol. SPE-1 fractions contain TAG and some FFA, whereas SPE-2 fractions contain MAG, DAG, cholesterol and some FFA. Thus, following SPE, MAG, DAG, cholesterol and TAG can all be accurately resolved by GC. To measure the precision of SPE for the fractionation of MFDs, three replicates of each MFD were separated by SPE and each fraction (SPE-1 and SPE-2) was analyzed by GC-FID. Gas chromatograms for SPE fractions

**Fig. 4** Gas chromatographic analysis for the first solid-phase extraction fractions (SPE-1) of MFDs collected at 170, 185, 195 and 200 °C. Peaks are identified as described for Figs. 2 and 3

obtained from MFD170, 185, 195 and 200 are shown in Figs. 4 and 5.

Free fatty acid is present in both SPE-1 and SPE-2 fractions, and thus, it appears that FFA is distributed between, rather than separated into the two SPE fractions. When lipid samples are separated on untreated silica TLC plates developed with acid-free solvent the same thing happens; FFA are not separated, instead they produce vertical streaks [18]. Consequently, the FFA content of replicate fractions prepared by SPE will not be consistent and it is best to view integration for FFA as an estimate (Table 2). Also, TMS derivatives were not prepared for SPE-1 fractions, whereas they were prepared for SPE-2 fractions. Thus, integration for SPE-2 FFA content should be more accurate than integration for SPE-1 FFA. Additionally, to allow the many small MAG and DAG peaks in chromatograms for SPE-2 to be integrated automatically, integration of FFA was conducted manually afterwards, thereby introducing errors inherent in such processes. The

**Fig. 5** Gas chromatographic analysis for the second solid-phase extraction fractions (SPE-2) of MFDs collected at 170, 185, 195 and 200 °C. Peaks are identified as described for Figs. 2 and 3

standard errors for FFA in SPE-2 are high by GC analysis standards; nevertheless, when compared to those encountered in quantitative TLC (with relative errors as high as 20%) they appear quite reasonable [18]. If an accurate and rapid appraisal of overall FFA content is required, it may be better to obtain this by titration with sodium hydroxide (AOCS Official Method, Ca 5a-40).

Integration results for TAG in SPE-1, and MAG, DAG and cholesterol in SPE-2 fractions are presented in Tables 3 and 4. The relative detector response (in percent) has been reported in order to facilitate the comparison of standard errors. The standard errors reported demonstrate that the method presented is indeed precise. To quantify acylglycerols on a mass or molar basis, however, empirical response factors should be employed.

Triacylglycerol with extremely low carbon numbers of 20 and 22 are clearly delineated in the chromatograms of SPE-1 for MFD170 (Fig. 4), and of the TLC fraction of

SPE-1 for this same MFD (Fig. 3a). The detection of TAG with such low MW is not without precedent; Myher, Kuksis and Marai [13] have previously detected traces of T20 in a MFD sample using reversed-phase HPLC/MS.

Diacylglycerol with low carbon numbers of 16 and 18 are discernable in the chromatograms of all SPE-2 fractions (Fig. 5), and a TLC fraction (Fig. 2f) of SPE-2 for MFD170. These low MW DAG are most likely 1,3-DAG with a butyryl or acetyl group in the *sn*-3 position [14].

Monoacylglycerols were isolated by boric acid TLC from the SPE-2 fraction of MFD170 (Fig. 2i) and could be identified in three of the chromatograms for SPE-2 fractions (Fig. 5: 170, 185 and 195 °C). In these chromatograms, the MAG14 peak is super-imposed on the FFA18 peak. Baselines (drawn across the FFA18 peak) among sample replicates are not identical because the FFA18 content is not consistent between samples (see discussion above). As a result, the standard error for integration of MAG14 is quite high (Table 4), especially for the SPE-2 fraction of the MFD170.

FAME analysis results for SPE fractions of MFD are presented in Table 5. Methyl esters were prepared with methanolic sodium methoxide at room temperature. This procedure does not lead to the esterification of free fatty acid; therefore, proportions of FAME are for acyl groups on the glycerol backbone: i.e. TAG for SPE-1, and MAG and DAG for SPE-2 [31]. Proportions of FAME in SPE-1 and SPE-2 are different and changes in distillation temperature have different effects on their compositions. For example, the 4:0 content for SPE-2 changes radically over the four distillation temperatures, whereas for SPE-1 it changes very little. Thus, FAME profiles for TAG, MAG and DAG in MFD are different, and FAME analysis for a complete MFD is not indicative of the fatty acid profile of any single class of acylglycerol.

Methyl acetate (FAME of 2:0) was not quantified in the FAME analysis for SPE-1 or SPE-2 fractions (Table 5), although a peak corresponding to (or coincident with) methyl acetate was detected in all FAME analyses for the present study. This peak was confirmed by separate injection and co-injection of ethyl acetate transesterified with methanolic sodium methoxide. However, anything beyond detection, such as precise and accurate integration, of this volatile component would be difficult.

In conclusion, SPE provided accurate and precise results for resolving the acylglycerol composition of MFD. Accurate mass balances are critical for process development and were easily obtained by non-destructive means using SPE. Consequently, this method is well-suited to applications where speed is vital yet accuracy and detail must not be compromised (e.g. pilot plant trials).

**Abstract** A comparative study between two methods (lipid extraction followed by saponification and methylation, and direct methylation) to determine the fatty acids in egg yolk was evaluated. Direct methylation of the samples resulted in lower fatty acid content and greater variation in the results than the lipid extraction followed by saponification and methylation. The low repeatability observed for the direct HCl methylation method was probably due to a less efficient extraction and conversion of the fatty acids into their methyl esters as compared to the same procedure starting with the lipid extract. As the lipid extraction followed by esterification method was shown to be more precise it was validated using powdered egg certified as reference material (RM 8415, NIST) and applied to samples of egg, egg enriched with polyunsaturated omega-3 fatty acids (n-3 PUFA), and commercial spray-dried whole egg powder.

**Keywords** GC · Fatty acids · Eggs

### Abbreviations

n-3 PUFA	Polyunsaturated omega-3 fatty acids
BF <sub>3</sub>	Methanolic boron trifluoride
FAME	Fatty acids methyl ester
EPA	Eicosapentaenoic acid
DHA	Docosahexaenoic acid
SFA	Saturated fatty acid
RSD%	Relative standard deviation

### Introduction

Fatty acids in foods are mostly analysed by gas chromatography (GC) of their methyl esters [1]. The most common method of sample preparation used for the determination of fatty acids in eggs is lipid extraction with chloroform-methanol [2] followed by conversion of the fatty acids into methyl esters [3]. This methodology involves two steps; first, the lipid is heated with NaOH in methanol, forming glycerol and free fatty acids in approximately 5 min, and secondly, the free fatty acids are then esterified with methanolic boron trifluoride (BF<sub>3</sub>) for 2 min at 100 °C. This method has been adopted as the official method [4, 5]. However, transesterification of intact fats can be very quick in the presence of alkali in methanol, even at room temperature, producing methyl esters in 2–3 min [6]. With additional time or heat, the base will start saponifying the already formed esters, and part of the sample will be converted back into free fatty acids. Additionally it was observed that in the two-step method with BF<sub>3</sub> required 20 min of heating time to esterify 99% of the fatty acids. Apart from this, Ackman [6] recommended it because no alkali transesterification is needed. Over the years the work of Metcalfe et al. [3] has undergone modifications, giving rise to methods using other methanolic solutions of bases and acids [7–9]. However, the methylation methods using methanolic BF<sub>3</sub> are amongst those presenting the best results [9].

Recently, various other methods (direct HCl methylation, saponification, extraction with chloroform-methanol followed by saponification) have been compared for the determination of fatty acids in egg yolk [10]. The results showed less variation using the method of direct methylation than using the other methods. Direct methylation was more precise than extraction of lipids followed by saponification, due

to the smaller number of steps involved in the extraction and sample preparation processes. It consequently demonstrated better recovery and was also quicker and less costly [11].

The analysis of methyl esters by GC requires high resolution in order to separate the positional and configurational isomers. The fused silica capillary columns typically used in this type of analysis normally vary from 25 to 100 m [12]; 100 m columns with highly polar stationary phases, such as those filled with cyanoalkyl polysiloxane are the most recommended for the separation of isomers of conjugated, monounsaturated and polyunsaturated linolenic fatty acids as well as many of the 18:2n-6 and 18:3n-3 artifact isomers [13]. A more accurate analysis of *trans* fatty acids can be obtained from the association of gas chromatography with silver-nitrate thin-layer chromatography or silver-ion liquid chromatography [14].

Identification of the fatty acids present in foods is carried out by comparing the retention times of the methyl esters of the sample with those of the standards. For the non-identified compounds, some studies use equivalent chain length (ECL) values [15–17]. However, the combination of parameters such as retention time with structural information obtained from mass spectrometry constitutes one of the most precise methods for identifying complex organic compounds [12, 18, 19].

An internal standard is used to quantify the fatty acids in mg/100 g samples; nervonic (24:1n-9) and tricosanoic (23:0) fatty acids are the most commonly used internal standards, due to the similar response obtained by both with the ionisation detector. The nervonic fatty acid has the additional advantage of being highly soluble, although it is an unstable compound and can suffer losses by autoxidation [20]. On the other hand, tricosanoic fatty acid is stable but it has limited solubility [20,21]. However, 19:0 and 21:0 improved the accuracy and precision for the analysis of the PUFAs compared to 23:0 [22].

In the present study, the method involving lipid extraction with chloroform-methanol [2] followed by saponification and methylation with  $\text{BF}_3$  [21] was compared with direct sample HCl methylation [10], using GC with internal standardisation. Precision and accuracy was validated with reference material (RM 8415, NIST) and applied to samples of egg, egg enriched with polyunsaturated omega-3 fatty acids (n-3 PUFA) and commercial spray-dried whole egg powder.

## Material and Methods

### Solvents and Chemicals

The solvents sodium hydroxide (NaOH), methanol, isooctane and methanolic boron trifluoride ( $\text{BF}_3$ ) were of

analytical grade (Merck, Darmstadt, Germany) and *n*-hexane was HPLC grade (Mscience, Darmstadt, Germany). A total of 37 fatty acid methyl ester (FAME) standards from 4:0 to 24:0 (Supelco, Bellefonte, PA, USA) were used for identification. The internal standards used for quantification were the methyl esters of tricosanoic acid (23:0) and tridecanoic (13:0) acid (Sigma, St Louis, MO, USA) of 99% purity. The reference material (RM 8415), acquired from NIST (Gaithersburg, MD, USA) was used to verify the accuracy and precision of the method.

### Samples

Fresh eggs enriched with n-3 PUFA was used for the comparative study between the two methods. Commercial spray-dried whole egg powder (recently prepared), fresh eggs and eggs enriched with n-3 PUFA were used to verify the method. The fresh eggs and eggs enriched with n-3 PUFA were purchased directly from a local egg-processing plant and the commercial spray-dried whole egg powder was acquired directly from the factory (Mizumotu Alimentos Ltda, Guapirama, Paraná, São Paulo). In all the experiments, one pool of 12 yolks and one kg of spray-dried egg were homogenised in beakers, stirred with glass rods and analyzed in triplicate. The commercial laying hens were fed with base diets containing yellow corn, soybean meal and 3.00% of deodorized fish oil (diet 1) or 1.18% of soybean oil (diet 2) for production of the eggs enriched with n-3 PUFA or eggs, respectively (Table 1). Commercial spray-dried whole egg powder was produced with eggs of the laying hens that received diet 2.

### Experimental Correction Factor for the Fatty Acids EPA and DHA

The chemical and instrumental parameters were optimised to verify the detector response for a saturated fatty acid (16:0) in relation to the internal standard (23:0). The experimental correction factors for the fatty acids EPA and DHA were calculated in relation to the internal standard and compared to the theoretical correction factors [5, 23].

### Comparison of the Methods and Validation of the Method to Determine the Fatty Acid Composition

A comparative study between lipid extraction according to Folch et al. [2] followed by preparation of the methyl esters according to Joseph and Ackman [21] by saponification and methylation with  $\text{BF}_3$ , and direct sample methylation according to Wang et al. [10], was conducted. The method presenting the best results regarding accuracy and precision was validated using powdered egg certified reference

material (RM 8415, NIST) and applied to fresh samples of egg, egg enriched with n-3 PUFA, and commercial spray-dried whole egg powder.

#### GC Equipment and Conditions

A Varian 3400 CX gas chromatograph (Walnut Creek, California, USA) was used, equipped with a flame ionisation detector, split injector, CP-SIL 88 column (100 m, 0.25 mm, 0.20 µm) (Chrompack, Netherlands) and star workstation. The chromatographic conditions were: detector temperature 280 °C; injector temperature 250 °C; initial column temperature 120 °C for 8 min, programmed to increase at a rate of 15 °C per minute up to 160 °C and then at 4 °C per minute up to 195 °C, maintaining this temperature for 12 min and then increasing again at 15 °C per minute up to the final temperature of 220 °C, maintained for 12 min. The carrier gas was hydrogen at 1 mL/min with linear velocity of 33.95 cm/s, with a make-up gas of nitrogen at 30 mL/min and synthetic air at 300 mL/min. Split injection (1:50) and a volume of 1 µL were used. The split

injection mode was to empty the needle by, quick injection and a 5 s dwell time. Fatty acids were identified by comparing the retention times and relative retention times of the standards with those of the samples (Table 2). The quantification was by internal standardisation using the methyl esters of tricosanoic and tridecanoic acids as the internal standards. The results obtained in mg/100 g of the sample were calculated according to AOCS methodology [5].

#### Determination of the Lipid and Moisture Contents

Total lipids were determined using the gravimetric method of Folch et al. [2] and moisture content using the AOAC methodology [4].

#### Statistical Analysis

The Statistica 5.0 programme was used to analyse the experimental data. ANOVA was used for the results obtained and the means were compared by Tukey's test, with significance based on a 0.05 probability level.

## Results and Discussion

#### Experimental Correction Factor for the Fatty Acids Eicosapentaenoic (EPA) and Docosapentaenoic (DHA)

The methyl ester of palmitic acid (16:0) was used to verify the detector response for a saturated fatty acid with regard to the internal standard (23:0). The experimental correction factor for the detector response was  $1.004 \pm 0.03$ ; similar to the theoretical correction factor [5], demonstrating that the conditions for the application of the methodologies were optimal. The experimental correction factors for EPA and DHA obtained in relation to the methyl ester of tricosanoic acid, used as the internal standard, were  $1.07 \pm 0.12$  and  $0.97 \pm 0.01$ , respectively, values considered to be satisfactory since the theoretical correction factors [5] are 0.99 for EPA and 0.97 for DHA. The theoretical correction factors were used for the calculations of mg/100 g EPA and DHA in regard to the internal standard used. The other fatty acids were calculated according to AOCS methodology [5]. However, the AOCS method does not strictly demand the application of these factors by indicating that they only should be used for optimum accuracy. In addition, when theoretical correction factors are applied, systematic errors will usually be beyond 1%, whereas errors of more than 5% must be accepted with 23:0 as internal standard especially for EPA, even when the injection system is optimized [22].

ND not determined

<sup>a</sup> Eluated with solvent peak<sup>b</sup> Internal standard<sup>c</sup> (9-*trans*, 12-*trans*)

As the split injection mode used was optimized in this study, discrimination was not expected. Split injection at 250 °C and a split rate of 1:50 is recommended as the preferred injection technique, especially in vaporizing injectors, since it is the main source of error in quantitative analysis of the long-chain saturated fatty acids (internal standards) to a different extent to PUFAs [24]. In addition,

on-column injection as well as optimized split injection produced accurate results for PUFAs [22].

DHA in this work was submitted to brief exposure times and a mild column temperature not causing thermal losses. On the other hand, when the column temperature was programmed to 170 °C for 0.5 min, then 10 °C per minute to 240 °C for 22 min, a shortfall in

DHA of 10% was observed using ethyl or methyl esters 23:0 [25].

#### Comparison of the Methodologies of Joseph and Ackman [21] and Wang et al. [10] for the Determination of Fatty Acids in Egg

Table 3 shows the results of the comparative study between extracting the lipids according to Folch et al. [2] followed by preparation of the methyl esters according to Joseph and Ackman [21], and direct methylation of the sample according to Wang et al. [10]. Direct methylation of the samples [10] resulted in significantly lower ( $P < 0.05$ ) fatty acid contents and greater variation in the results when compared to the method of first extracting the lipids with chloroform-methanol [2], followed by saponification and methylation [21]. Despite the fact that the method of Joseph and Ackman [21] presented a greater number of steps, consequently increasing the time and cost of the analysis, it presented better repeatability, observed from the relative standard deviation (RDS%) (Table 3). The low repeatability observed for the direct methylation method proposed by Wang et al. [10] was probably due to a less efficient recovery and conversion of the fatty acids in the lipids into their methyl esters as compared to the same procedure but starting with the lipid extract. The present results, disagreed with the results of both Wang et al. [10] and Lepage and Roy [11].

The main problem for the analysis of n-3 PUFA is that PUFAs are rather unstable, so that calibration cannot be performed by using stored or opened containers of quantitative standards [22]. With official methods recommending 23:0 as the internal standard, however, it can lead to systematic overestimation of n-3 PUFAs, since the standard deviations of 22:6n-3 versus 21:0 and 20:5n-3 versus 19:0 were considerably smaller compared to 17:0 and 23:0 [22]. The aim of the present study was to compare the official method [5, 23] with the results of Wang et al. [10].

**Table 3** EPA and DHA contents of fresh eggs enriched with n-3 PUFA, determined by different methods

Fatty acid <sup>c</sup>	Joseph and Ackman[21]		Wang et al. [10]	
	M ± SD <sup>a</sup>	RDS (%) <sup>b</sup>	M ± SD <sup>a</sup>	RDS (%) <sup>b</sup>
EPA <sup>d</sup>	9.56 ± 0.4 a	4.2	4.78 ± 0.9 b	18.8
DHA <sup>e</sup>	118.20 ± 4.8 a	4.1	77.10 ± 15.0 b	19.5

<sup>a</sup> Mean ± standard deviation  $n = 10$ , Means followed by the same letter do not differ according to the Tukey test ( $P > 0.05$ )

<sup>b</sup> RDS (%) = relative standard deviation

<sup>c</sup> (mg/100 g of yolk, dry basis)

<sup>d</sup> (EPA, 20:5n-3)

<sup>e</sup> (DHA, 22:6n-3)

In addition, 21:0 was found in the eggs, so it will be impossible to use it as an internal standard. In order to improve the quantification 13:0 was also used as an internal standard.

#### Validation of the Methodology for the Determination of Fatty Acids in Eggs by Gas Chromatography Using Internal Standardisation

Since the method of Joseph and Ackman [21] was shown to be more precise, this method was validated using powdered egg certified reference material (RM 8415, NIST). Table 4 shows the results obtained for the fatty acids of the powdered egg reference material using the Joseph and Ackman method [21] and comparing these results with the values declared in the certificate. The results obtained were the same as those specified for the reference material.

#### Determination of the Total Lipid and Moisture Contents

Table 5 shows the results for total lipids and moisture content in eggs, eggs enriched with n-3 PUFA and whole spray-dried egg powder. The values for lipids in the egg

<sup>c</sup> mg/100 g, dry basis

yolk and those of the eggs enriched with n-3 PUFA were lower and the values of the whole spray dried powder higher than the values cited by the USDA [26]. The results for moisture content for all the egg samples were similar to those found by the USDA [26].

#### Application of the Methodology to Eggs

Table 6 shows the results calculated on the dry weight basis obtained for the composition of saturated, monounsaturated and polyunsaturated fatty acids and of *trans* fatty acids in eggs, eggs enriched with n-3 PUFA and whole spray-dried egg powder. Twenty-nine fatty acids were identified, and 14:0, 16:0, 18:0, 16:1n-7, 18:1n-9, 18:2n-6 and 18:3n-3 were found to be the principal fatty acids in all samples. In the whole spray-dried egg powder, the major fatty acids were *trans* fatty acids 18:1n-9. The following fatty acids were not identified in any of the egg samples: 4:0; 6:0; 8:0; 10:0; 11:0; 12:0; 13:0 and 23:0 and only traces (<1 mg/100 g) of the following: 15:1n-5, 22:1n-9

and 22:2n-6 were found. Although, the 18:0 was 23% higher, the other saturated fatty acids (SFA) showed a reduction of 31% in the eggs enriched with n-3 PUFA. The concentration of these acids in the eggs are little influenced by the lipid content of the diet [27, 28]. The concentration of 18:3n-3 and 22:6n-3 in the eggs enriched with n-3 PUFA were 30 and 100% higher, respectively, than the amounts found in other eggs. Among the important monounsaturated fatty acids, 16:1n-7 was 54% and 18:1n-9 was 37% higher than in other eggs. In contrast, production of a polyunsaturated fatty acid egg does not appear to be practical using dietary influences as well as strains of the hens [29].

In fresh eggs enriched with n-3 PUFA and eggs *trans* fatty acids (18:1n-9 and 18:2n-6) were found. As the concentration of *trans* fatty acids in eggs was low, it is probably due to the diet of the hens since the laying hens received a diet with soybean oil and deodorised fish oil (Table 1). Guardiola et al. [30] observed a good relationship between the proportion of commercial feed in the

hens' diet and the total content of *trans* monounsaturated fatty acid (16:1n-7 and 18:1n-9) in eggs. It is now well known that during deodorisation and/or refining of oil *cis-trans* isomerisation reactions could have occurred [31, 32]. Recent research has recommended that the deodorisation of marine oils should be conducted at a maximum temperature of 180 °C to avoid geometrical isomerisation [33, 34]. However the *trans* fatty acid isomers of EPA and DHA was not the subject of research in this study.

High concentrations of *trans* 18:1n-9 were observed in the whole spray dried egg powder, probably due to the high temperature required for the processing of these eggs [35] and the presence of the catalysts, nitric and nitrous oxides, produced during the spray-drying process by the direct heating of the air by gas combustion [36]. When heated in the presence of catalysts such as nitrogen oxides, unsaturated *cis* fatty acids are transformed into their *trans* stereo-isomers. In addition, nitrous oxide is considered to be a free radical, known to initiate the oxidation of unsaturated lipids in model systems [37].

From these results, it can be concluded that quantification of the fatty acids by internal standardisation according to the method of Joseph and Ackman [21] is more accurate and precise than the direct methylation method. Although it is necessary to extract the total lipids, this is easily carried out. By applying this methodology, it was shown that eggs enriched with n-3 PUFA showed a better lipid profile from the nutritional point of view than standard eggs. In addition, high contents of *trans* fatty acids were found in the whole spray dried egg powder. Considering that whole spray dried egg powder is used in the formulation of a variety of products, mainly infant foods, the presence of *trans* fatty acids represents a public health problem.

## Epidermal Lipoxygenase Products of the Hepoxilin Pathway Selectively Activate the Nuclear Receptor PPAR $\alpha$

**Abstract** Arachidonic acid can be transformed into a specific epoxyalcohol product via the sequential action of two epidermal lipoxygenases, 12R-LOX and eLOX3. Functional impairment of either lipoxygenase gene (*ALOX12B* or *ALOXE3*) results in ichthyosis, suggesting a role for the common epoxyalcohol product or its metabolites in the differentiation of normal human skin. Here we tested the ability of products derived from the epidermal LOX pathway to activate the peroxisome proliferator-activated receptors PPAR $\alpha$ ,  $\gamma$ , and  $\delta$ , which have been implicated in epidermal differentiation. Using a dual luciferase reporter assay in PC3 cells, the 12R-LOX/eLOX3-derived epoxyalcohol, 8R-hydroxy-11R, 12R-epoxyeicosa-5Z,9E,14Z-trienoic acid, activated PPAR $\alpha$  with similar in potency to the known natural ligand, 8S-hydroxyeicosatetraenoic acid (8S-HETE) (both at 10  $\mu$ M concentration). In contrast, the PPAR $\gamma$  and PPAR $\delta$  receptor isoforms were not activated by the epoxyalcohol. Activation of PPAR $\alpha$  was also observed using the trihydroxy hydrolysis products (trioxilins) of the unstable epoxyalcohol. Of the

four trioxilins isolated and characterized, the highest activation was observed with the isomer that is also formed by enzymatic hydrolysis of the epoxyalcohol. Formation of a ligand for the nuclear receptor PPAR $\alpha$  may be one possibility by which 12R-LOX and eLOX3 contribute to epidermal differentiation.

## Introduction

Genetic evidence suggests that a pathway for the transformation of arachidonic acid by two lipoxygenases (12R-LOX and eLOX3) plays a crucial role in epidermal differentiation [1, 2], as recently reviewed [3]. Inactivating mutations of either LOX have been found to result in a severe type of ichthyosis, (NCIE, non-bullous ichthyosiform erythroderma) associated with the loss of a functional epidermal water barrier. Initially, the lipoxygenases were identified through genetic screening of affected patients [1, 2], and their role in the formation of a specific epoxyalcohol product (hepoxilin), 8*R*,11*R*,12*R*-epoxyeicosa-5*Z*,9*E*,14*Z*-trienoic acid, was elucidated in biochemical studies using the recombinant enzymes [4, 5]. The primary hepoxilin product of the two LOX enzymes is enzymatically hydrolyzed in cells to a specific trihydroxy derivative (trioxilin) [5]. Several hepoxilin and trioxilin isomers have been detected in human skin [6–8], although the specific 12*R*-LOX/eLOX3 derived products have yet to be identified.

At the present state of knowledge, there are multiple potential mechanisms of action of the 12*R*-LOX/eLOX3 pathway products, and these include an action via a putative membrane receptor (ichthyin) implicated through genetic studies in ichthyosis patients [9], or an activity via activation of PPAR receptors, a possibility that we have initially evaluated in this study. There is accumulating evidence that peroxisome proliferator-activated receptors (PPAR) are important regulators of epidermal differentiation [10–12]. All three subtypes have been identified in human keratinocytes. Whereas PPAR $\delta$  is the predominant subtype expressed, PPAR $\alpha$  and PPAR $\gamma$  are present at lower levels but are upregulated during keratinocyte differentiation (e.g. Refs. [13, 14]). PPAR $\beta/\delta$  is not implicated in differentiation but is activated in inflammation and wound repair [15, 16]. The PPAR subtypes are activated by diverse lipid-derived molecules including fatty acids and eicosanoids [17, 18]. Here, we tested the hypothesis that the 12*R*-LOX/eLOX3-derived epoxyalcohol could be an activating ligand for the PPAR nuclear receptors. We also tested the trioxilin hydrolysis products of the unstable epoxyalcohol.

## Experimental Procedures

### Materials

12*R*-HPETE and 8*S*-HPETE were prepared by autoxidation of arachidonic acid and isolation using reversed phase and chiral phase HPLC as described previously [4]. [1-<sup>14</sup>C]12*R*-HPETE was prepared by the reaction of

[1-<sup>14</sup>C]arachidonic acid with recombinant human 12*R*-LOX [19]. The eLOX3-derived epoxyalcohol, 8*R*,11*R*,12*R*-epoxyeicosa-5*Z*,9*E*,14*Z*-trienoic acid (8*R*,11*R*,12*R*-epoxyalcohol), was prepared by the reaction of 12*R*-HPETE with recombinant human eLOX3 in Tris buffer (pH 6.0) as described [4]. 8*S*-HETE was prepared from 8*S*-HPETE by reduction with triphenylphosphine and purification using RP-HPLC. The synthetic ligands GW7647 (PPAR $\alpha$  ligand), GW7845 (PPAR $\gamma$  ligand) and GW1516 (PPAR $\delta$  ligand) were gifts from Dr. Raymond N. Dubois, who obtained these synthetic ligands from GlaxoSmithKline. PC-3 cells (ATCC CRL-1435) were cultured in Ham's F12K medium containing 10% fetal bovine serum (BioWhittaker, Walkersville, MD) at 37 °C, 5% CO<sub>2</sub>. Cells were typically split in a ratio of 1:6 every 3 days.

### Quantification of 8*R*,11*R*,12*R*-Epoxyalcohol

8*R*,11*R*,12*R*-epoxyalcohol exhibits only end absorbance in the UV and no synthetic standard is available, making it difficult to quantify. Here the quantitation was based on knowing the specific activity of a radioactive sample of its hydroperoxy precursor, [<sup>14</sup>C]12*R*-HPETE ( $\epsilon = 23,000$  at 235 nm [20]), and converting this to [<sup>14</sup>C]8*R*,11*R*,12*R*-epoxyalcohol using eLOX3, and using the HPLC-purified <sup>14</sup>C product as the quantified authentic standard. Triol hydrolysis products were quantified assuming an equimolar absorbance of hepoxilin and trioxilin at 205 nm measured on RP-HPLC.

### Acid-Catalyzed Hydrolysis of 8*R*,11*R*,12*R*-Epoxyalcohol

The 8*R*,11*R*,12*R*-epoxyalcohol was quantitatively hydrolyzed by treatment with 1% acetic acid in water at room temperature for 30 min. The mixture of diastereomeric trihydroxy-eicosatrienoic acids (trioxilins) was analyzed by RP-HPLC using a Waters Symmetry C18 5- $\mu$ m column (0.46  $\times$  25 cm) eluted with methanol/water/acetic acid (80/20/0.01, by volume) at a flow rate of 1 mL/min and monitoring at UV 205 nm. Products eluting between 5 and 6 min were collected and further resolved by SP-HPLC using a Beckman Ultrasphere 5- $\mu$ m silica column (0.46  $\times$  25 cm) eluted with hexane/isopropanol/acetic acid (90/10/0.1, by volume) at a flow rate of 1 mL/min. Further purification was achieved by chiral phase HPLC using a Chiralpak AD column (0.46  $\times$  25 cm) eluted with hexane/methanol/ethanol/acetic acid (95/5/10/0.1, by volume) at a flow rate of 0.5 mL/min. The position of the hydroxy groups along the carbon chain was determined by GC-MS after hydrogenation (Pd/H<sub>2</sub>) and derivatization to the methyl esters TMS ethers as described previously [5].

## PPAR Activation Using a Dual-Luciferase Assay

PPRE-tk-luc (PPAR reporter plasmid expressing firefly luciferase), pRL-SV40 (control plasmid expressing *Renilla* luciferase), and the expression plasmids containing full-length cDNAs for PPAR $\alpha$  in pBKCMV, PPAR $\gamma$ /pCDNA3.1 and PPAR $\delta$ /pCDNA3.1 were kindly provided by Dr. Raymond N. DuBois (Vanderbilt University, Nashville, TN). Assays were performed using PC-3 cells [21]; theoretically the dual luciferase assay can use any cell line because the proteins involved are over-expressed from the transfected plasmids, not endogenous proteins. PC-3 cells ( $1.0 \times 10^5$  cells/well using 24-well plates) were transfected using FuGENE 6 (Roche Molecular Biochemicals) at a lipid/DNA ratio of 3:1. Cells were exposed to a mix containing 150 ng/mL PPRE-tk-luc, 150 ng/mL of one of the three PPAR plasmids (PPAR $\alpha$ , PPAR $\gamma$ , or PPAR $\delta$ ), and 1.0 ng/mL pRL-SV40 in Ham's F12K medium. The transfection mixture was replaced after 4–5 h with 10% charcoal-stripped FBS containing media supplemented with either 0.1% vehicle (DMSO or ethanol) or the indicated compound. After 24 h, cells were harvested in 100  $\mu$ L/well  $1\times$  luciferase lysis buffer (Promega) for 20 min at room temperature using an orbital shaker. Relative light units from firefly luciferase activity were determined using a luminometer (MGM Instruments, Hamden, CT) and normalized to the relative light units from *Renilla* luciferase, which served as internal control for transfection efficiency (Promega). The effects of various compounds on activation of PPARs are presented as “fold activation” relative to the vehicle control values.

## Statistical Analysis

All data were analyzed using Prism 4 software (Graphpad software, Inc), and results are expressed as means and standard deviations; all tests were two-tailed. The unpaired Student *t* test was used to compare reporter activities between control and sample-treated groups. Differences were considered significant when *P* values were less than 0.05.

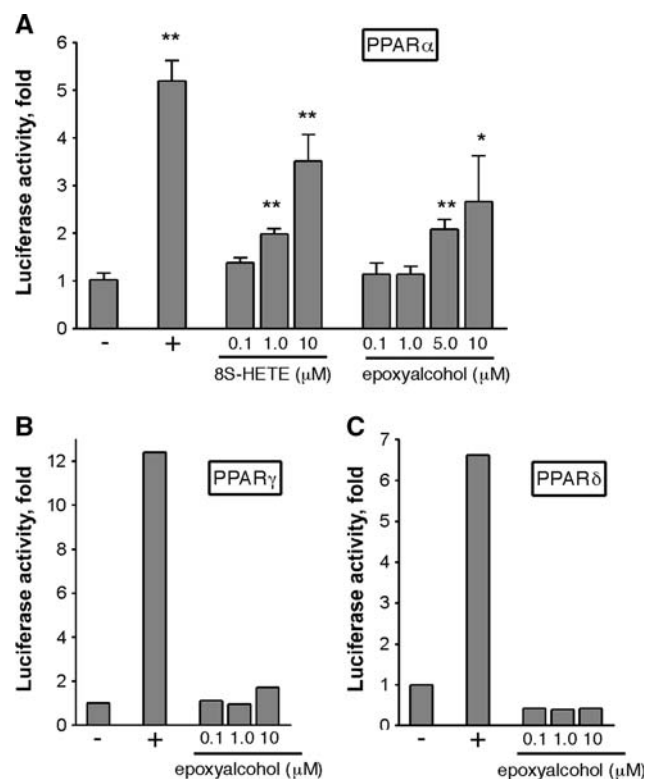

## Results

Activation of PPAR $\alpha$  by 8*R*,11*R*,12*R*-Epoxyalcohol

A PPAR transactivation assay was used to test whether the 12*R*-LOX/eLOX3-generated epoxyalcohol 8*R*-hydroxy-11*R*,12*R*-epoxyeicosa-5*Z*,9*E*,14*Z*-trienoic acid (8*R*,11*R*,12*R*-epoxyalcohol) could serve as an activating ligand for PPARs. In the assay, PC-3 cells are transiently co-transfected with PPRE-tk-luc plasmid (a PPAR reporter plasmid expressing firefly luciferase), pRL-SV40 plasmid (a control

plasmid expressing *Renilla* luciferase) and one of the three full length PPAR plasmids (PPAR $\alpha$ , PPAR $\gamma$ , or PPAR $\delta$ ). The transfected cells are treated with a synthetic ligand specific for each receptor or with increasing concentrations of the 8*R*,11*R*,12*R*-epoxyalcohol (0.1, 1.0, 5.0 and 10  $\mu$ M) and the relative activation over control cells is determined.

The 8*R*,11*R*,12*R*-epoxyalcohol showed dose-dependent activation of PPAR $\alpha$  at 5 and 10  $\mu$ M concentration (2.2- and 2.6-fold activation, respectively) (Fig. 1a). The specific synthetic ligand GW7647 (1.0  $\mu$ M) produced about five-fold activation relative to vehicle control. The known natural ligand 8*S*-HETE [22] showed a maximum activation of about 3.5-fold at 10  $\mu$ M concentration. In contrast to PPAR $\alpha$ , the isoforms PPAR $\gamma$  or PPAR $\delta$  were not transactivated by the 8*R*,11*R*,12*R*-epoxyalcohol (0.1–10  $\mu$ M) while the synthetic ligands GW7845 (100 nM) activated PPAR $\gamma$  about 12-fold and GW1516 (100 nM)

**Fig. 1** Activation of PPAR isoforms by the 8*R*,11*R*,12*R*-epoxyalcohol. **a** Activation of PPAR $\alpha$  by the epoxyalcohol and the natural ligand 8*S*-HETE is dose-dependent. One micromolar of the synthetic ligand GW7647 was used as a positive control (+). **b** The PPAR isoforms  $\gamma$  and  $\delta$  are not activated by the epoxyalcohol (0.1–10  $\mu$ M); the positive controls (+) are GW7845 (for PPAR $\gamma$ ) and GW1516 (for PPAR $\delta$ ), 100 nM each. The dual luciferase assay was performed using transiently transfected PC3 cells. Results are plotted as fold activation versus the DMSO control (mean  $\pm$  SD of three experiments each performed in triplicate). *P* values versus the DMSO control are presented in the figure. \* *P* < 0.05, \*\* *P* < 0.01

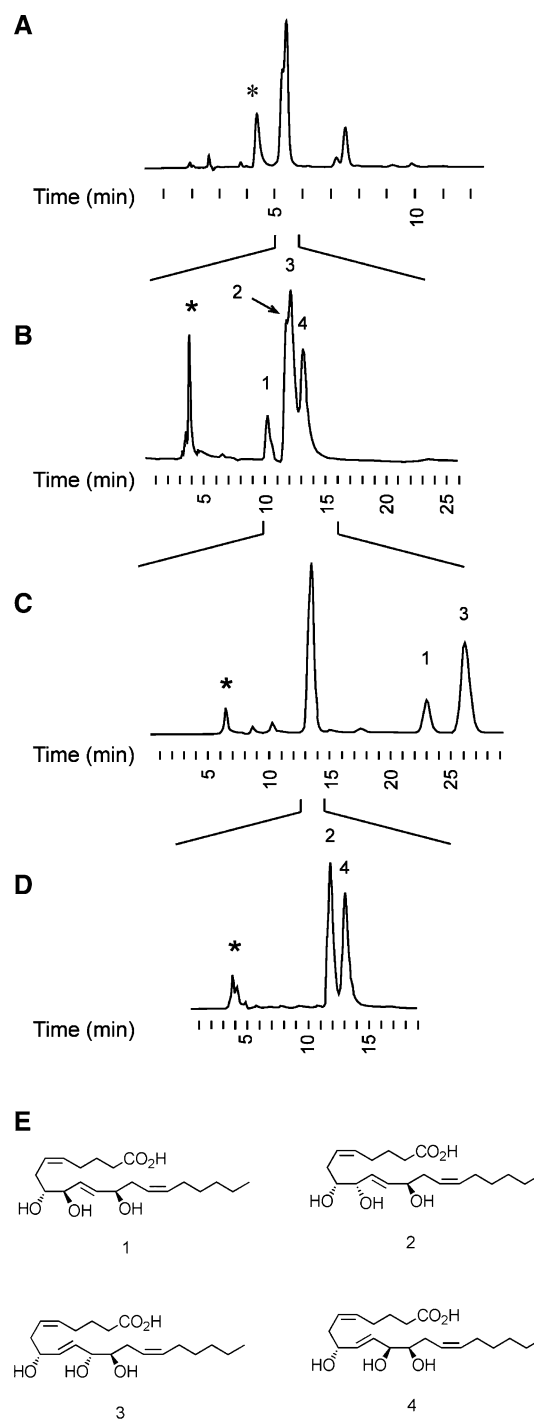

activated PPAR $\delta$  about six- to seven-fold, respectively (Fig. 1b, c)

In an earlier experiment we had used a chimeric receptor containing only the ligand-binding domain of PPAR $\alpha$  fused with the DNA-binding domain of the yeast GAL4 transcription factor. Neither the positive control 8S-HETE nor the epoxyalcohol activated the chimeric PPAR $\alpha$  receptor in PC-3 cells using this construct, although the synthetic ligand GW7647 was active (data not shown).

#### Hydrolysis of the 8*R*,11*R*,12*R*-Epoxyalcohol to Trioxilins

Acid-catalyzed hydrolysis of the 8*R*,11*R*,12*R*-epoxyalcohol gave a mixture of four trihydroxy products (designated 1–4) that were not resolved by RP-HPLC and only partially resolved using SP-HPLC (Fig. 2a, b). Using CP-HPLC as an alternative normal phase chromatography system a different elution pattern was achieved and products 1 and 3 were clearly resolved while products 2 and 4 eluted as a single early peak (Fig. 2c). Re-chromatography of the early peak collected from CP-HPLC using SP-HPLC resolved products 2 and 4 (Fig. 2d). LC-MS analysis in the negative ion mode of the crude hydrolysis mixture revealed a molecular ion of  $m/z$  353 ( $[M-H]^-$ ) for all four hydrolysis products, an increase of 18 mass units over the starting epoxyalcohol, compatible with a trihydroxy derivative of a C20 fatty acid containing three double bonds. GC-MS analysis of the reduced methyl ester, TMS ether derivatives proved that all of the four hydrolysis products are trihydroxy derivatives, and allowed assignment of the location of the hydroxy groups from the EI-MS fragmentation patterns (data not shown) [5]. Products 1 and 2 are 8,9,12-triols and products 3 and 4 are 8,11,12-triols.

We tentatively assigned the absolute configuration of the four triols according to observations made by Hamberg [23, 24]. Epoxyalcohols containing a 1-hydroxy-2,3-ene-4,5-epoxy structure are attacked by the solvent at carbons 2 and 4, giving 1,2,5- and 1,4,5-triol products. As a result, the configuration of carbons 1 and 5 is retained in the hydrolysis products. Thus, each of the four triols that are formed by acid hydrolysis of the 8*R*,11*R*,12*R*-epoxyalcohol are expected to retain the 8*R* and 12*R* configurations. In addition, according to Morris [25] and Hamberg [23, 24], the three diastereomers of trihydroxy fatty acids are less polar than the corresponding erythro compounds, which will result in an earlier elution time using SP-HPLC. Thus, the elution order on SP-HPLC was used to assign the absolute configuration of the third hydroxy group at C-9 and C11, respectively (Fig. 2b, d). Therefore, given that the 5*Z* and 14*Z* double bonds are unaffected by the hydrolysis reaction, peak 1 from SP-HPLC was tentatively identified

**Fig. 2** HPLC analysis of the acid-catalyzed hydrolysis of the 8*R*,11*R*,12*R*-epoxyalcohol. **a** RP-HPLC of the crude hydrolysis reaction; the trioxilin hydrolysis products elute at ~5.5 min; the epoxyalcohol starting material is quantitatively hydrolyzed (expected retention time ~10 min). **b** SP-HPLC of the crude hydrolysis reaction shows four partially resolved trioxilin products. **c** Chiral-phase HPLC analysis was used to resolve products 1 and 3. **d** SP-HPLC of the early peak collected from CP-HPLC resolved products 2 and 4. **e** Structures of the trihydroxy hydrolysis products 1–4. The HPLC conditions are described in Experimental Procedures. Detection: UV absorbance at 205 nm. The *asterisk* marks an injection artifact

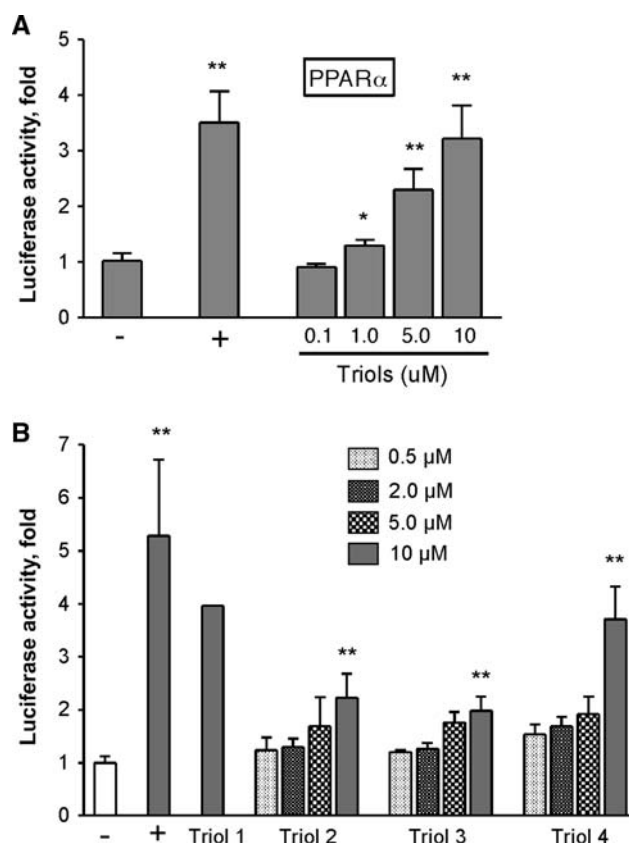

as the *8R,9R,12R*-diastereomer and peak 2 as the *8R,9S,12R*-diastereomer of *8,9,12*-trihydroxy-*5Z,10E,14Z*-eicosatrienoic acid. Similarly, peak 3 was tentatively identified as *8R,11R,12R*-trihydroxy-*5Z,9E,14Z*-eicosatrienoic acid and peak 4 as *8R,11S,12R*-trihydroxy-*5Z,9E,14Z*-eicosatrienoic acid (Fig. 2e). The hydrolysis product of the *8R,11R,12R*-epoxyalcohol formed by incubation with homogenates of human keratinocytes [5] co-chromatographed on SP-HPLC with triol 4 indicating that *8R,11S,12R*-trihydroxy-*5Z,9E,14Z*-eicosatrienoic acid is the likely endogenous metabolite in human skin.

#### Activation of PPAR $\alpha$ by Trihydroxy Metabolites of the *8R,11R,12R*-Epoxyalcohol

Although rather limited quantities were available, we tested the ability of the trihydroxy hydrolysis products of the *8R,11R,12R*-epoxyalcohol to activate PPAR $\alpha$ , initially by using a mixture of all four hydrolysis products and then by testing the individual isomers. Using the mixture of hydrolysis products a dose-dependent activation of PPAR $\alpha$  was observed; at 10  $\mu$ M concentration, the triols were as active as the natural PPAR $\alpha$  ligand, 8S-HETE (Fig. 3a). When the triols were tested individually, each product was found to be active although triols 1 and 4 showed the highest activity (Fig. 3b).

#### Discussion

Our finding that a specific hepoxilin isomer, *8R*-hydroxy-*11R,12R*-epoxyeicosa-*5Z,9E,14Z*-trienoic acid, can selectively activate the PPAR $\alpha$  subtype has significance both for functions in the epidermis and beyond. As a large class of fatty acid derivatives, the hydroperoxide-derived epoxyalcohols and related metabolites have not been tested as PPAR ligands, partly because they are not commercially available. One of the enzymes involved in the biosynthesis of epoxyalcohols, eLOX3, is not a functional LOX enzyme, but has catalytic activity as a hydroperoxide isomerase [4]. The hydroperoxide isomerase (epoxyalcohol synthase) activity was initially discovered for the transformation of the *12R*-LOX derived *12R*-HPETE. Since eLOX3 can also transform other fatty acid hydroperoxides like *12S*-HPETE and *15S*-HPETE, tissue-specific formation of a wide variety of epoxyalcohols from the coupling of eLOX3 with other lipoxygenases is possible yet unproven so far [26]. Although skin is where eLOX3 is most strongly expressed as judged by RT-PCR, selected other organs give positive signals [27]. For example, a recent report has implicated eLOX3 expression in facilitating the early stages of a classic model system, the PPAR $\gamma$ -induced differentiation of preadipocytes [26, 28].

**Fig. 3** Activation of PPAR $\alpha$  by trihydroxy hydrolysis products of the *8R,11R,12R*-epoxyalcohol. **a** Dose-dependent activation of PPAR $\alpha$  by a mixture of the 4 hydrolysis products. **b** Analysis of the activation of PPAR $\alpha$  by the four individual trihydroxy isomers shown in Fig. 2e. For triol 1, only 10  $\mu$ M concentration was tested due to limited availability of the compound. 8S-HETE (10  $\mu$ M) was used as a positive control (+). Results are plotted as fold activation versus the DMSO control (mean  $\pm$  SD of three experiments each performed in triplicate). *P* values versus the DMSO control are presented in the figure. \*\* *P* < 0.01

Epoxyalcohols are chemically unstable molecules and will be hydrolyzed in a cellular system either non-enzymatically or by the enzymes soluble epoxide hydrolase or hepoxilin hydrolase that are widely expressed [29]. Enzymatic hydrolysis of the *8R,11R,12R*-epoxyalcohol yields a specific triol, with the tentative structure of *8R,11S,12R*-trihydroxy-*5Z,9E,14Z*-eicosatrienoic acid, and this product showed among the highest activation of PPAR $\alpha$  in our studies. Whether only the hydrolysis products or also the parent epoxyalcohol (or both) are activators of PPAR $\alpha$  would be dependent on their relative stabilities and accumulation in vivo. Hepoxilin and trioxilin isomers have been detected in human epidermis and are elevated in psoriasis [7, 8], although the specific stereo configurations have yet to be assigned [3].

The *8R,11R,12R*-epoxyalcohol is comparable in potency to the known natural PPAR $\alpha$  activator, 8S-HETE, a product

of the 8S-LOX in mouse skin, and there is evidence that both the 8-LOX enzyme and its 8-HETE product are involved in murine epidermal differentiation [14, 30–32]. Additional genetic studies on ichthyosis patients have shown that inactivating mutations in an uncharacterized cytochrome P450 (CYP4F22, a putative fatty acid omega-hydroxylase) give a similar phenotype to that seen with the 12R-LOX or eLOX3 mutations [33]. The omega-hydroxylation of other eicosanoids such as the epoxyeicosatrienoic acids (EETs) strongly enhances their activity as PPAR activators [34]. In the case of the 8R,11R,12R-epoxyalcohol and its trioxilin hydrolysis product there is also the distinct possibility that metabolic activation could enhance the bioactivity, potentially a function of the CYP4F22 also involved in ichthyosis [33]. The formation of an activating ligand for PPAR $\alpha$  is one possibility of how the epidermal lipoygenases 12R-LOX and eLOX3 can contribute to epidermal differentiation. Whether there are other cellular targets for the epoxyalcohols or their downstream metabolites, for example a putative hepoxilin receptor [9] has yet to be established.

**Abstract** Stearoyl-CoA desaturase (SCD) is an enzyme responsible for the production of *cis*-9, *trans*-11 conjugated linoleic acid in ruminant fats, and for the synthesis of palmitoleoyl-CoA and oleoyl-CoA. To date, only one SCD isoform has been described in ruminant species, although multiple isoforms have been found in many other mammalian species. In this paper, we describe for the first time a second SCD isoform in cattle, which appears to be an ortholog of human SCD5 rather than a homolog of bovine SCD1 or any of the described murine SCD isoforms. As described in other SCD proteins, the predicted amino acid sequence of bovine SCD5 includes four transmembrane domains and three conserved histidine motifs. The amino-terminus of the predicted protein sequence of SCD5 lacks the PEST sequences typically found in SCD1 homologs, which are thought to target proteins for rapid degradation. Similar to human SCD5, the bovine SCD5 gene is organized into five exons and four introns, and is highly expressed in the brain. In other tissues examined, mRNA expression of SCD5 was minimal. Furthermore, the expression levels of SCD5 between brain gray and white matter are not different. This is the first description of a homolog of human SCD5 in a non-primate species.

## Abbreviations

bp	Base pair(s)
cDNA	DNA complementary to RNA
CLA	Conjugated linoleic acid
kb	Kilobase(s) or 1000 bp
PCR	Polymerase chain reaction
RACE	Rapid amplification of cDNA ends
RT	Reverse transcription
SCD	Stearoyl-CoA desaturase
UTR	Untranslated region

## Introduction

Conjugated linoleic acids (CLA) are an isomeric family of 18 carbon fatty acids with two conjugated double bonds. Several CLA isomers have been shown to exhibit beneficial health properties in animal models [1, 2]. For example, *cis*-9, *trans*-11 CLA, an isomer found in ruminant fats, is anticarcinogenic and antiatherogenic in animal models [3–5]. In ruminant species, stearoyl-CoA desaturase (SCD), a membrane bound protein of the endoplasmic reticulum, catalyzes the desaturation of *trans*-11 18:1, producing *cis*-9, *trans*-11 CLA [6, 7]. Although SCD produces CLA in several species [8, 9], this enzyme is mainly responsible for catalyzing the desaturation of saturated fatty acyl-CoA substrates, including palmitoyl-CoA and stearoyl-CoA, at the delta-9 position, resulting in the synthesis of palmitoleoyl-CoA and oleoyl-CoA [10].

Homologues of the *SCD* gene have been characterized in many mammalian species, including mouse, rat, hamster, sheep, goat, pig, cow, and human. Some mammalian genomes have been shown to contain multiple *SCD* isoforms. To date, four isoforms have been described in mice [11–14], and two isoforms have been described in humans [15, 16]. While the reason for the existence of multiple isoforms in some species is unclear, there is evidence for divergent tissue-specific expression of different isoforms. For example, in the mouse, *SCD1* is expressed predominantly in lipogenic tissues [13], *SCD2* is preferentially expressed in brain and neuronal tissues [11], *SCD3* is expressed in sebocytes, preputial gland and Harderian gland [14], and *SCD4* expression is restricted to the heart [12]. In humans, *SCD1* is most highly expressed in adipose tissue and liver while a second *SCD* gene, termed *hSCD5*, is highly expressed in brain and pancreas [15]. In addition to tissue specific expression, there is evidence to suggest that some *SCD* isoforms may differ in their preferred substrate specificity. For example, murine *SCD1*, *SCD2* and *SCD4* have been shown to desaturate both palmitoyl-CoA and stearoyl-CoA, while murine *SCD3* desaturates palmitoyl-CoA but not stearoyl-CoA [17]. The tissue and substrate specificity of *SCD* isoforms suggests that each may have a distinct physiological role.

Although the mouse and human genomes both contain multiple *SCD* isoforms, there appear to be differences in the evolutionary origins of these genes. In the mouse, all four *SCD* isoforms are contained within a 200 kb region of chromosome 19 and appear to have arisen from tandem gene duplication events [12]. In the human, the *SCD1* and *SCD5* genes are on separate chromosomes, suggesting that they are not the result of a similar gene duplication event. Furthermore, while the human *SCD1* gene appears to be an ortholog of mouse *SCD1*, *hSCD5* appears to be a distinct stearoyl-CoA desaturase gene rather than an ortholog of any of the mouse *SCD* isoforms [15].

Unlike humans and mice, only one *SCD* isoform has been characterized in the ruminant species examined, including goats [18], sheep [19], and cattle [20]. Because genome sequence information is incomplete in these species, we hypothesized that additional undiscovered *SCD* isoforms might exist. Here we describe a second bovine stearoyl-CoA desaturase gene that shares 90.1% identity to human *SCD5* at the amino acid level. As is the case in humans, the novel *SCD* gene is on a separate chromosome (chromosome 6) from *SCD1*, which in cattle is located on chromosome 26 [21]. This is the first report of a human *SCD5* ortholog in a non-primate species, and the first report of multiple *SCD* isoforms in a ruminant species. To be consistent with current proposed nomenclature, we have termed this new gene bovine *SCD5*.

## Experimental Procedures

### Animals

Adipose and liver samples were collected from cows slaughtered at a packing plant (Gaffney, SC). Adipose, liver, heart, brain, lung, spleen, and skeletal muscle tissues were collected from three bulls slaughtered by the Food Science Department at Virginia Tech. Brain white matter and gray matter samples were each collected from five animals (three steers and two cows) slaughtered at a packing plant (Rich Creek, VA). All tissues were snap frozen in liquid nitrogen and stored at  $-80^{\circ}\text{C}$  until use.

### cDNA Isolation and Characterization

Total RNA was isolated from bovine adipose tissue and liver using TRI reagent (Molecular Research Center Inc, Cincinnati, OH) according to the manufacturer's instructions. RNA pellets were resuspended in RNase-free water, and quantified using a spectrophotometer. 5' RACE-ready cDNA and 3' RACE-ready cDNA were synthesized using the SMART RACE cDNA Amplification Kit (Clontech, Mountain View, CA) according to the manufacturer's instructions. The resulting first strand cDNAs were used in 5' and 3' RACE PCR reactions with gene-specific primers localized to the known portions of *SCD5* sequence in conjunction with universal primers included in the RACE kit. Resulting PCR products were cloned using the TOPO TA Cloning Kit for sequencing (Invitrogen, Carlsbad, CA) and sequenced, and the cDNA sequence was submitted to GenBank with the accession number EF014951. Gene specific RACE primers are shown in Table 1. For GC-rich regions in exon one, PCR reactions were performed using the Advantage-GC 2 PCR Kit (Clontech, Mountain View, CA) according to the manufacturer's instructions.

### Genomic DNA Analysis

Genomic DNA was isolated from bovine blood using DNAzol (Molecular Research Center, Cincinnati, OH) according to the manufacturer's instructions. To confirm intron/exon boundaries, PCR was performed using intronic primers spanning each exon (Table 1). Reaction conditions were as follows: 35 cycles of  $94^{\circ}\text{C}$  for 30 s,  $58^{\circ}\text{C}$  for 30 s, and  $72^{\circ}\text{C}$  for 1 min. Resulting PCR products were sequenced to confirm the sequence at the splice junctions.

### Real Time PCR

Total RNA was extracted from snap-frozen tissues using TRI Reagent (Molecular Research Center, Cincinnati, OH) and was reverse transcribed (500 ng per reaction) into

**Table 1** PCR primers

cDNA using the Omniscript reverse transcription kit (Qiagen, Valencia, CA) according to the manufacturer's instructions. Real-time PCR reactions were performed using the Quantitect SYBR Green PCR kit (Qiagen, Valencia, CA) and an Applied Biosystems 7300 Real-time PCR machine (Applied Biosystems, Foster City, CA). Each reaction was performed in duplicate wells. Beta actin was used as an endogenous control gene. Spleen was used as the calibrator for making relative comparisons between tissues for the tissue distribution studies, and gray matter was used as the calibrator for the brain tissue comparison study. Fold change was calculated using the  $2^{-\Delta\Delta C_T}$  method [22]. For adipose, brain, heart, liver, lung, skeletal muscle, and spleen, data from three animals were used to calculate fold change. Data from five animals were used to calculate fold change between brain gray matter and white matter. Primer pairs are shown in Table 1 and reaction conditions were as follows: 35 cycles of 94 °C for 30 s, 58 °C for 30 s, and 72 °C for 1 min.

#### Phylogenetic Analysis

The phylogram was drawn using Molecular Evolutionary Genetic Analysis software MEGA version 3.1, available at <http://www.megasoftware.net>. The following amino acid sequences were included in the phylogenetic tree reconstruction: bovine SCD1 (GenBank Accession No. AAF22305.1), goat SCD1 (AAK01666.1), hamster SCD (AAC42058.1), human SCD1 (CAA73998.1), human SCD5 (AAP31443.1), mouse SCD1 (AAA40103.1), mouse SCD2 (AAH40384.1), mouse SCD3 (NP\_077770.1), mouse SCD4 (AAR06950.1), rat SCD1 (AAM34746.1), rat SCD2 (AAH61737.1), sheep SCD1 (NP\_001009254.1), and swine SCD1 (NP\_998946.1). The yeast SCD protein,

OLE1 (NP\_011460) was used as an out-group to root the tree. Bootstrap analysis with 500 replicates was performed to assess the statistical significance of the tree.

#### Statistical Analysis

The tissue distribution was statistically analyzed as an analysis of variance using the General Linear Model procedure of SAS (version 9.1.3) with animal and tissue included in the model. Treatment means were separated by Tukey's multiple comparison procedure. Gray and white matter data were compared similarly to tissue distribution with animal and brain matter type included in the model using the General Linear Model procedure of SAS.

## Results

#### Nucleotide Sequence of the Bovine *SCD5* Transcript

By BLAST searching the Ensembl bovine genome database (Btau 2.0), we were able to identify a region on chromosome 11 with homology to exons five and six of bovine *SCD1*. In addition, we located a region with homology to exons three and four of bovine *SCD1* on an unmapped "scaffold" (a set of ordered, oriented contigs). By performing RT PCR with bovine liver and adipose RNA, we demonstrated that these two regions were part of the same transcript. These results were confirmed by DNA sequencing of the amplified PCR product. Further BLAST searching of the Bovine Genome Project at the Human Genome Sequencing Center at Baylor College of Medicine (v.3.1) revealed that the *SCD5* gene is located on chromosome 6 (accession number CM000182), suggesting that

the portion of sequence we originally located on chromosome 11 was incorrectly assigned.

In order to examine the transcript of this putative new bovine desaturase gene, we performed 5' and 3' rapid amplification of cDNA ends, or RACE reactions and sequenced the resulting products (Fig. 1). During the time that this work was performed, a complete cDNA clone isolated from a Hereford cow hypothalamus cDNA library was submitted to Genbank under the accession number BC112711. This clone matched the cDNA sequence that we obtained by RACE amplification and included an additional 195 upstream base pairs of the 5' untranslated region of exon one, making the transcript 2.583 kb in length. The sequence we obtained by RACE PCR differs at two nucleotide positions from this cDNA clone, but neither of these potential nucleotide sequence polymorphisms results in an amino acid sequence change. Because the coding region of the transcript was found to have 89.4% homology to the human *SCD5* nucleotide sequence, we have named this novel desaturase gene bovine *SCD5*.

#### Amino Acid Sequence and Conserved Protein Features

The predicted amino acid sequence for bovine *SCD5*, shown in Fig. 2a, shares many of the characteristic features that are highly conserved among stearoyl-CoA desaturase

proteins, including three histidine motifs (HXXXXH and HXXHH) that are catalytically essential to fatty-acyl desaturase activity [23]. Sequence alignment shows 90.1% identity between bovine *SCD5* and human *SCD5* at the amino acid level. A Kyte-Doolittle hydrophathy plot (Fig. 2b) drawn from the amino acid sequence highlights the location of the four conserved transmembrane domains [24, 25]. The N-terminus of the bovine *SCD5* protein lacks the conserved PEST sequences that are present in mammalian *SCD1* proteins and are thought to play a role in their rapid degradation (Fig. 2c).

#### Phylogenetic Relationship of Mammalian SCD Isoforms

To determine the likely evolutionary relationship between bovine *SCD5* and mammalian *SCD1* orthologs, we compared the predicted protein sequence of bovine *SCD5* with the sequences of other mammalian SCD proteins. As shown in Table 2 and Fig. 3, bovine *SCD5* clearly shares much greater amino acid sequence identity and appears to have a much closer evolutionary relationship with human *SCD5* than with any other SCD protein, including bovine *SCD1*. Human and bovine *SCD5* share 90.1% sequence identity at the amino acid level. While the *SCD1* orthologs from ruminant species share significant homology

Percent identities were calculated by the ExPASy SIM Alignment Tool for Protein Sequences, using the BLOSUM62 comparison matrix with a Gap Open penalty of 12 and a Gap Extension penalty of 4

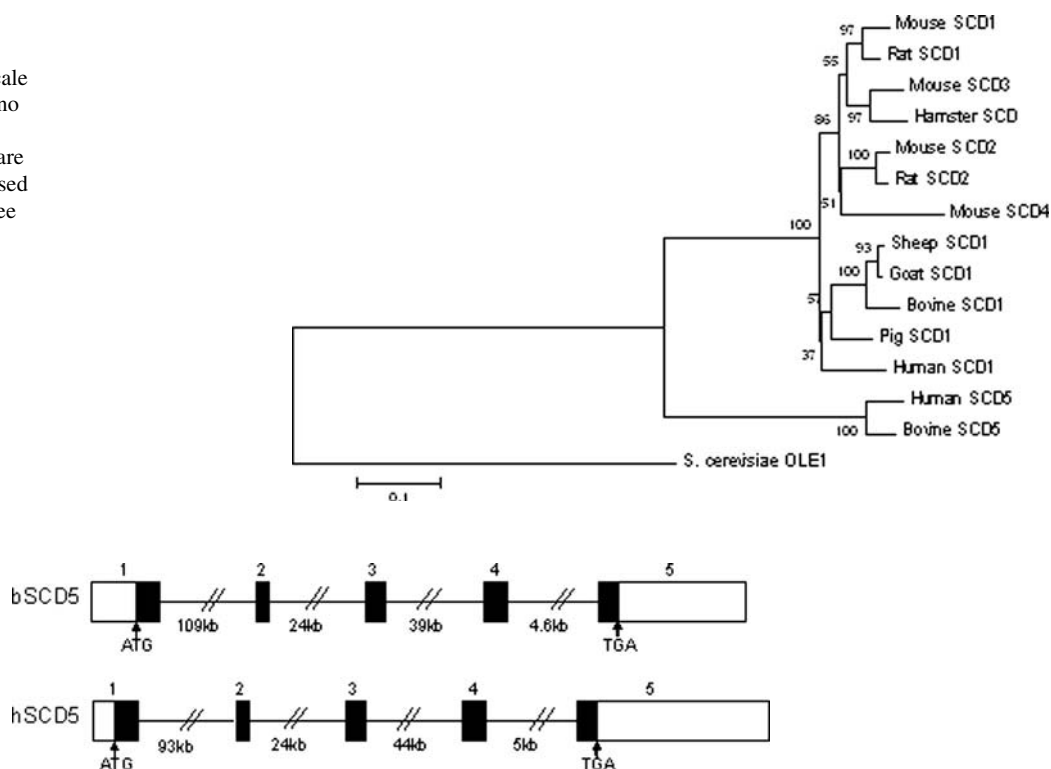

c caprine, o ovine, p porcine, b bovine, h human, m murine

(93.6–98.1%), none share greater than 65% identity with bovine SCD5. Phylogenetic analysis of mammalian SCD protein sequences shows that bovine SCD5 and human SCD5 are grouped together and are much more closely related to each other than to any mammalian SCD1 sequence (Fig. 3).

#### Genomic Organization of the Bovine SCD5 Gene

By comparing the cDNA sequence obtained from the RACE PCR to the available published bovine genomic DNA sequence, we determined that bovine SCD5 is organized into five exons and four introns (Fig. 4), spanning

**Fig. 3** Phylogenetic tree of selected mammalian SCD amino acid sequences. The scale bar indicates the unit of amino acid Poisson distance. The percentage bootstrap values are indicated. Yeast OLE1 was used as an outgroup to root the tree

**Fig. 4** Genomic structure of bovine *SCD5* deduced from known bovine genomic DNA sequence. Lines represent introns and boxes represent exons. White boxes represent untranslated regions, while black boxes represent the open reading frame

**Table 3** Exon–intron junctions of bovine *SCD5*

Exon	Exon size (bp)	5' splice donor	Intron size (kb)	3' splice acceptor
1	723	CTCTGGG <b>gt</b> gagtactctg	109	tgtgtcttgc <b>ag</b> CCTACTT

4	233	GCCATTG <b>gt</b> gagtgcggg	4.6	tttgtctcc <b>ag</b> GTGAAGG
5	1497			

Exon sequences are denoted by capital letters, and intronic sequences are in lowercase. The canonical dinucleotide gt (splice donor) and ag (splice acceptor) sequences are in bold

more than 175 kb. Splice site sequences were determined by PCR amplification of genomic DNA spanning each exon based on the published genomic sequence. Amplified products were sequenced to confirm the intron–exon junctions (Table 3).

#### Tissue Specific Expression of Bovine *SCD5*

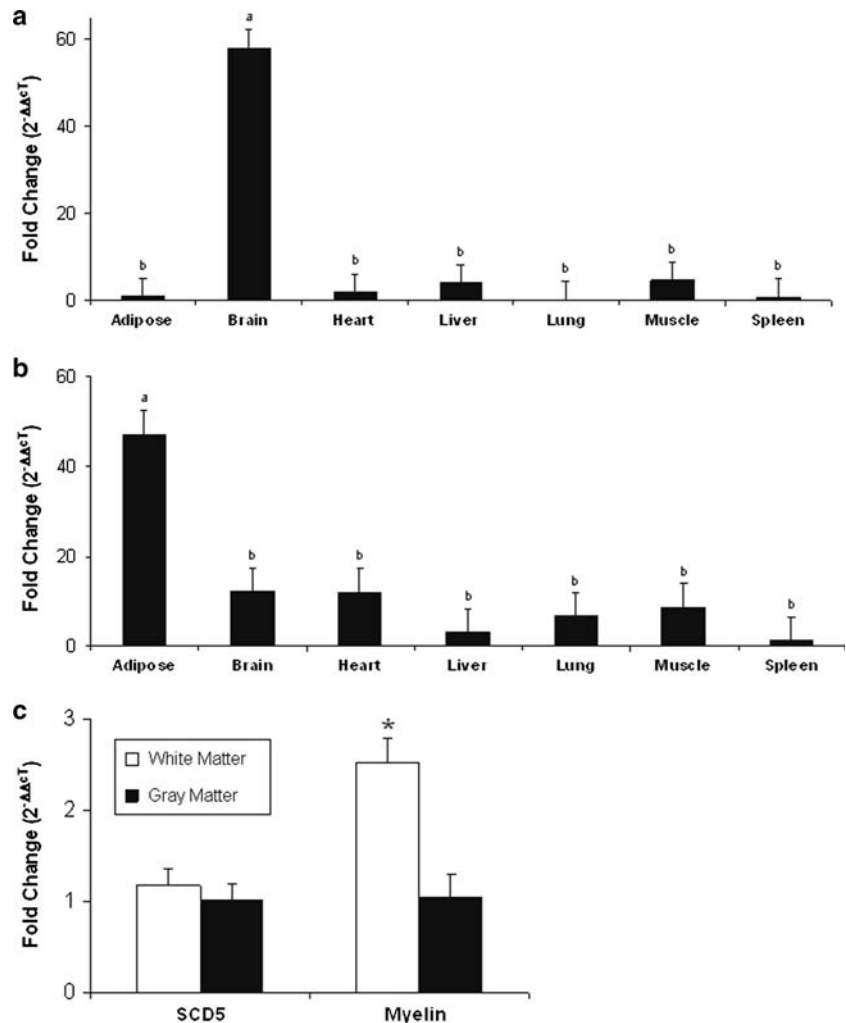

Because it has been shown that different *SCD* isoforms in mice have different tissue expression profiles, we examined a panel of bovine tissues (adipose, liver, heart, brain, lung, spleen, and skeletal muscle) using quantitative real-time PCR to determine tissue-specific expression of bovine *SCD5* and *SCD1*. The mRNA expression of *SCD5* was significantly greater in the brain compared to all other

tissues examined (Fig. 5a), whereas the mRNA expression of *SCD1* was significantly higher in adipose tissue (Fig. 5b). We next investigated whether *SCD5* expression differs between white matter and gray matter regions of the bovine brain. The mRNA expression of myelin basic protein was used as a control to validate separation of white matter and gray matter. No significant difference was found in *SCD5* mRNA abundance between these tissues (Fig. 5c).

#### Discussion

Ruminant fats are rich in saturated fatty acids as a result of the ruminal biohydrogenation of dietary unsaturated fatty acids. Stearoyl-CoA desaturase reduces the saturated fatty

**Fig. 5** Analysis of **a** bovine *SCD5* gene expression and **b** bovine *SCD1* gene expression using real-time PCR. Real-time PCR was performed using RNA extracted from bull tissues (adipose, brain, heart, liver, lung, muscle, spleen;  $n = 3$ ). Beta actin was used as the endogenous control gene, and spleen was used as the calibrator for making relative comparisons between tissues. Fold change was calculated using the  $2^{-\Delta\Delta C_T}$  method. Bars not sharing a common superscript letter differ ( $P < 0.001$ ). **c** Real-time PCR analysis of bovine *SCD5* gene expression using total RNA from brain white matter and gray matter ( $n = 5$ ). Myelin basic protein mRNA expression was used to validate separation of white matter and gray matter. Beta actin was used as the endogenous control gene, and gray matter was used as the calibrator for making relative comparisons between tissues. Fold change was calculated using the  $2^{-\Delta\Delta C_T}$  method. \* $P < 0.05$  within a transcript

acid content of ruminant fats and is important in determining ruminant fatty acid composition for this reason. Many mammalian genomes contain multiple stearoyl-CoA desaturase isoforms. Ruminant species, however, have so far been found to have only one *SCD* gene. In this paper, we describe for the first time a second *SCD* gene in cattle, which we have named bovine *SCD5*. This novel bovine desaturase gene appears to be an ortholog of the recently described human *SCD5* gene. In addition to humans, partial *SCD5* cDNA sequences have been found in other primate species such as chimpanzees and orangutans [15]. This is the first report of an *SCD5* ortholog in a non-primate species.

It has been hypothesized that the four *SCD* isoforms found in mice may be the result of multiple gene duplication events while human *SCD5* is a distinct stearoyl-CoA desaturase created by a single gene duplication event. This gene duplication event could have occurred prior to the divergence of mammals, and *SCD5* was then lost during the evolution of some species, such as rodents [15]. An alternate hypothesis is that the *SCD5* gene was acquired

only in primates later during evolution. Evidence to support the first hypothesis includes the fact that all four mouse isoforms are found within a 200 kb span of the same chromosome and share considerable amino acid sequence homology, and are therefore likely to be derived from relatively recent gene duplication events, while human *SCD1* and *SCD5* are on separate chromosomes and share much less sequence identity than the mouse isoforms. Further, while human *SCD1* appears to be an ortholog of mouse *SCD1* and other mammalian *SCD1* genes, human *SCD5* does not appear to be an ortholog of any of the four mouse isoforms or of any other mammalian *SCD1* gene.

The genomic organization of bovine *SCD5* closely resembles that of the human *SCD5* gene [26] and diverges from the highly conserved six exon, five intron structure of the bovine, caprine [18], porcine [27], and human [16], *SCD1* genes as well as all four murine *SCD* genes [11–14]. Further, phylogenetic analysis shows that bovine *SCD5* and human *SCD5* protein sequences are much more closely related to each other than to any mammalian *SCD1* protein. Taken together, these data support the idea that *SCD5* is a

distinct desaturase gene that existed before the divergence of mammals but was lost during the evolution of some species, and refutes the possibility that *SCD5* is a gene acquired later during the evolution of primates.

The human *SCD5* isoform was previously shown to be most highly expressed in brain and pancreas [15, 26]. Similarly, our results show that bovine *SCD5* is most highly expressed in the brain. We did not test the expression of *SCD5* in bovine pancreas, but *SCD5* message was detectable by RT PCR in all tissues examined, indicating that this transcript may be expressed at low levels in many tissues (data not shown). Within the brain, it has been shown that white matter tends to have much greater phospholipid concentrations of monoenoic fatty acids compared to gray matter [28]. However, the expression of *SCD5* mRNA does not appear to be different between bovine brain white matter and gray matter.

Mammalian SCD1 proteins have a short half-life of 3–4 h [29, 30] and are rich in PEST sequences made up of local high concentrations of proline, glutamic acid, serine, threonine, and aspartic acid residues, which are thought to target proteins for rapid degradation by the ubiquitin-proteasome pathway [31]. The PEST-rich 66 N-terminal amino acids of mammalian SCD1 proteins have been shown to play an important role in their rapid proteasomal degradation, and when this region is deleted, the half-life of the resulting protein increases significantly [32, 33]. Additionally, a conserved lysine residue at amino acid position 33 of the rat SCD1 protein has been shown to be important for conferring instability to the protein [34]. Interestingly, this N-terminal region of SCD1 is also the region of greatest sequence divergence between SCD1 and SCD5 proteins. In contrast to mammalian SCD1 proteins, the N-terminus of bovine SCD5 contains neither PEST sequences nor the conserved lysine residue. This suggests that SCD5 may exhibit greater protein stability than SCD1, or that its degradation may be regulated differently than SCD1.

The expression of rodent SCD1 is sensitive to dietary manipulations, being highly induced under fat-restricted diets, and rapidly down regulated by diets high in polyunsaturated fatty acids [33, 35] and regulation is facilitated by its short half-life [36]. Stearoyl-CoA desaturase 5 is highly expressed in the brain, a tissue enriched with long chain polyunsaturated fatty acids [28], and this may indicate that SCD5 is not as sensitive to polyunsaturated fatty acids as SCD1. The lack of PEST sequences in SCD5 suggests this protein may be more stable and therefore less sensitive to dietary regulation. The half-life of SCD5 is currently unknown, but future studies expressing the full-length protein will allow us to address the question of stability, as well as to determine substrate specificity of the enzyme. Different tissue-specific expression and N-termi-

nal sequences of SCD1 and SCD5 may reflect differences in the regulation and physiological roles of these isoforms.

Stearoyl-CoA desaturase produces almost all the mono-unsaturated fatty acids present in ruminant fats and is the major source of *cis*-9, *trans*-11 CLA in the milk fat of lactating dairy cows [6, 7]. Diet plays a major role in determining the CLA content of milk fat, and the concentration of *cis*-9, *trans*-11 CLA in milk fat increases as much as eight fold when cows are switched to a CLA inducing diet [37]. However, significant variation also occurs among cows on the same diet and this appears to be driven by variation in mammary desaturase activity [38]. Abundant SCD activity is present in the mammary gland of lactating dairy cows [39], but the relative expression of SCD isoforms in the mammary gland has not been examined. It is not currently known if SCD5 contributes to mammary SCD activity to account for some of the observed variation in CLA and desaturase activity in lactating cows.

One potential role for SCD activity in the brain may be to maintain optimal levels of oleic acid. Evidence suggests that oleic acid in the brain is not supplied by the diet, but rather is produced exclusively by de novo synthesis in the brain itself. Rats fed a diet devoid of oleic acid had much lower concentrations of oleic acid in many tissues, but not in brain, nerve endings, or myelin [40]. Experiments using deuterated fatty acids in milk substitute fed to rat pups during the developmental period of brain growth spurt prior to myelination showed that oleic acid in the brain was not supplied via circulation, but by de novo biosynthesis in the brain [41]. These data suggest that the nervous system synthesizes the oleic acid that it needs, regardless of dietary intake, thereby indicating a need for SCD activity in this tissue.

Oleic acid has several critical functions in the brain. First, oleic acid is a major component of myelin, which forms an insulating sheath around nerve fibers in both the central and peripheral nervous systems to greatly increase electrical impulse speed [42]. Demyelination of neurons is associated with several devastating neurodegenerative diseases, including multiple sclerosis, transverse myelitis, and chronic inflammatory demyelinating polyneuropathy. Second, oleic acid is a neurotrophic factor in the developing brain, promoting axonal growth and neural clustering, and inducing the expression and activation of growth associated protein-43 (GAP-43), a marker for neural differentiation and regeneration [43, 44]. These data indicate that the oleic acid synthesized by SCD is important for normal brain structure and development.

In conclusion, we have identified a second stearoyl-CoA desaturase isoform in cattle, which contains the conserved transmembrane domains and histidine residues characteristic of desaturase enzymes. Unlike other SCD isoforms, bovine SCD5 lacks PEST sequences, which are thought to

target proteins for rapid degradation, thereby facilitating rapid transcriptional regulation. This isoform has high sequence homology and similar gene structure to human *SCD5*, and, like human *SCD5*, does not have high homology with other isoforms identified in rodents. Furthermore, this is the first homologue identified outside primates. Like human *SCD5*, bovine *SCD5* exhibits significantly greater expression in the brain than lipogenic tissues.

**Abstract** Muskox (*Ovibos moschatus*) are ruminant animals native to the far north and little is known about their fatty acid composition. Subcutaneous adipose tissue (backfat) from 16 wild muskox was analyzed and compared to backfat from 16 barley fed beef cattle. Muskox backfat composition differed substantially from beef and the most striking difference was a high content of 18:0 (26.8 vs. 9.77%). This was accompanied by higher levels of most other saturated fatty acids except beef had more 16:0. Muskox backfat also had a lower level of *cis*-18:1 and this was related to a lower expression of steroyl-CoA desaturase mRNA. Beef backfat had a higher level of total *trans*-18:1 (4.25 vs. 2.67%). The most prominent *trans*-18:1 isomers in beef backfat were 10*t*-18:1 (2.13%) and 11*t*-18:1 (0.77%) whereas the most prominent isomers in muskox backfat were 11*t*-18:1 (1.41%), 13*t*/14*t*- (0.27%) and 16*t*-18:1 (0.23%). The total conjugated linoleic acid (CLA) content was higher in beef backfat than muskox (0.67 vs. 0.50%) with 9*c*,11*t*-18:2 as the most abundant CLA isomer. The second most abundant CLA isomer in beef backfat was 7*t*,9*c*-18:2 (0.10%) whereas in muskox it was 11*t*13*c*-18:2 (0.04%). Muskox backfat had a higher content of 18:3n-3 and its elongation and desaturation products 20:5n-3, 22:5n-3 and 22:6n-3 and a lower n-6/n-3 ratio. Overall, the high forage diet of muskox seemed to produce a healthier fatty acid profile and highlighted the need to develop feeding

strategies for intensively raising beef that will not negatively impacting fatty acid composition.

### Abbreviations

ACO	Acyl CoA oxidase
CLA	Conjugated linoleic acid
FAME	Fatty acid methyl esters
FAS	Fatty acid synthase
MUFA	Monounsaturated fatty acids
PUFA	Polyunsaturated fatty acids
SFA	Saturated fatty acids
SCD-1	Stearyl CoA desaturase-1
SFA	Saturated fatty acids

### Introduction

Muskox (*Ovibos moschatus*) are ruminant animals native to the far north and along with goats and sheep fall into the sub-family Caprinae of the Bovidae family. In Canada, muskox are found mainly on the Arctic islands and the majority of these can be found on Banks Island. Banks Island is the most western island in the Canadian Arctic Archipelago and covers an area of 70,266 km<sup>2</sup> and has a muskox population of approximately 65,000, representing about 47% of the total population of the Canadian Northwest Territories [1]. Muskox are harvested for local use, for export of highly valued quiviut and hides and also for developing markets for their meat. The nutritive value of

the meat is in part related to its fatty acid composition, but little is known about muskox lipid composition and nothing is known about the conjugated linoleic acid (CLA) or *trans*-18:1 content of its tissues. Adamczewski et al. [2] reported the content of lean, fat and bone in muskox and the percent lipid class distribution, but not their fatty acid compositions. Baker et al. [3] only reported the fatty acid composition of milk fat from muskox but did not include total nor individual CLA or *trans*-18:1 isomers.

Conjugated linoleic acid has many purported roles in the prevention and possible treatment of several diseases including diabetes, obesity and some types of cancer [4, 5]. Rumenic acid (9*c*,11*t*-18:2), the major CLA isomer in ruminant fats has been associated with beneficial effects, while the other CLA isomers, notably 10*t*,12*c*-18:2, have not [6–8]. In addition, vaccenic acid (11*t*-18:1), the major *trans*-18:1 isomer generally present in ruminant fats is equally effective in cancer prevention [9], because of its endogenous conversion to 9*c*,11*t*-18:2 in animals [10], humans [11], and human cell lines [12]. The health effects of several *trans*-18:1 isomers other than 11*t*-18:1, notably 9*t*- and 10*t*-18:1, were shown to be associated with negative plasma lipid and lipoprotein profiles [13, 14]. However, butter fat enriched in 11*t*-18:1 and 9*c*,11*t*-18:2 improved the plasma cholesterol profile in hamsters [15] and natural beef fat reduced the growth of human cancer cells [16].

The present communication reports the comprehensive fatty acid composition of subcutaneous adipose tissue (backfat) from wild muskox and compares it to the most commonly consumed adipose tissue of ruminant origin in Canada (i.e., beef) finished on a high barley diet at the Lacombe Research Centre. Additional mRNA analysis of fatty acid metabolizing enzymes was then conducted to help explain differences in the levels of saturated (SFA) and monounsaturated fatty acids (MUFA) between these ruminant species.

## Experimental Procedures

### Animals, Diets and Sample Collection

Sixteen muskox and 16 beef animals were used in this study. Beef animals were raised and both beef and muskox were slaughtered in accordance to principles and guidelines of the Canadian Council of Animal Care. The average age of the muskox was estimated to be 2.5 years and the beef animals 1.5 years. Wild muskox were harvested from Banks Island where a high proportion of their diet consists of sedges (*Carex aquatilis*, *Eriophorum* spp.; [17]) which are similar to grasses in composition with high fiber levels and relatively low protein contents [18]. Post-slaughter, muskox carcasses were rapidly chilled outdoors (–20 to

–25 °C with a wind chill of approximately –40 °C) and frozen carcasses were shipped to the Lacombe Research Centre. The beef animals were raised under typical cow/calf and feedlot conditions for Western Canada at the Lacombe Research Centre. In the last 75 days prior to slaughter, beef animals had ad libitum access to a finishing diet consisting of 22.0% barley silage, 73.3% barley grain, 1.6% molasses, 3.1% feedlot supplement (32% crude protein) and 22 mg/kg sodium monensin. Beef animals were slaughtered and processed at the Lacombe Research Centre abattoir and adipose tissue samples were collected from both muskox and beef animals between the fifth and sixth ribs at 5 cm off the midline and these samples remained frozen at –80 °C until analyzed.

### Feed Fatty Acid Analysis

Fatty acid methyl esters (FAME) from the beef feedlot diet and sedges grab sampled from Banks Island (i.e., muskox diet) were prepared according to Sukhija and Palmquist [19] and using a Varian 3800 GC (Varian, Walnut Creek, CA, USA) equipped with a Varian 8100 autosampler and a 30 m SP2340 capillary column (Supelco, Bellefonte, PA, USA). The system was operated under constant pressure (15 psi) using hydrogen as the carrier gas and a 20:1 split ratio. The injector and detector were held at 250 °C and the FAME were quantified using a flame ionization detector. Samples were injected (1 µl, 0.5 µg/µl) and the column temperature was held initially at 50 °C for 30 s, increased to 170 °C at 25 °C/min, held for 3 min, increased to 180 °C at 2 °C/min, then increased to 230 °C at 10 °C/min. Chromatograms were integrated using Varian Star Chromatography Workstation software.

### Adipose Tissue Analyses

Subcutaneous adipose tissue was directly methylated with sodium methoxide and the FAME were analyzed using the GC and Ag<sup>+</sup>-HPLC equipment and methods outlined by Cruz-Hernandez et al. [20]. The *trans*-18:1 isomers were, however, analyzed using two complementary GC temperature programs instead of a preparatory Ag<sup>+</sup>-TLC separation followed by GC separation at 120 °C. The first temperature program was as previously described (temperature program A; 45 °C held for 4 min, increased at 13 °C/min to 175 °C and held for 27 min, then increased at 4 °C/min to 215 °C and held for 35 min) [20]. The second program (temperature program B; 45 °C held for 4 min, increased at 13 °C/min to 150 °C and held for 47 min, then increased at 4 °C/min to 215 °C and held for 35 min) improved the resolution of some *trans*-18:1 isomers (6-8*t*- to 11*t*-18:1) and allowed for analysis of the remaining *trans*-18:1 isomers by difference.

For the identification of FAME by GC, the reference standard no. 461 from Nu-Check Prep Inc. (Elysian, MN, USA) was used. Branch-chain FAME were identified using a GC reference standard BC-Mix1 purchased previously from Applied Science (State College, PA, USA). All the geometric isomers of linoleic and linolenic acids were prepared by mild iodine isomerization [20]. The CLA isomers no. UC-59M from Nu-Chek Prep Inc. was used since it contained all four positional CLA isomers, and they were analyzed by GC and Ag<sup>+</sup>-HPLC [20]. Individual CLA isomers were obtained from Matreya Inc. (Pleasant Gap, PA, USA) and isomerized using iodine to obtain all geometric CLA isomers [20]. All chemicals and solvents were of analytical grade.

#### mRNA Analysis of Fatty Acid Metabolizing Enzymes

Total RNA was isolated from muskox ( $n = 8$ ) and beef ( $n = 8$ ) adipose tissue in ten volumes of the guanidium thiocyanate based TRI reagent solution in accordance with the manufacturer's specifications (Sigma, St Louis, MO, USA). A prior clean-up step was required after the adipose samples were dissolved in the TRI reagent to remove excess lipid by centrifugation at 10,000  $g$  at 20 °C and removal of the upper lipid fraction prior to addition of chloroform. Pools of cDNA were generated from each sample at 42 °C for 60 min (Sigma, St Louis, MO, USA) using: 5  $\mu$ g of total RNA primed with 300 ng of random hexamers, 200 U of MMLV-reverse transcriptase (RT) enzyme, 1 mM of dATP, dGTP, dTTP and dCTP, 10 mM DTT, and 10 U of RNase inhibitor in the manufacturer's RT buffer. The yield of cDNA was measured according to the polymerase chain reaction signal generated from the internal house keeping gene  $\beta$ -actin [21].

To generate PCR primers for the "comparative gene expression studies", new cDNAs were cloned and

sequenced from the muskox adipose RNA for the stearyl CoA desaturase-1 (SCD1), fatty acid synthase (FAS), acyl CoA oxidase (ACO) and  $\beta$ -actin mRNAs. To help standardized the gene expression analysis studies, PCR primers were designed to have 100% homology with their equivalent beef mRNAs, SCD1 (Gb no. AY241932), FAS (Gb no. AF285607), ACO (Gb no. BF230141), and 96% homology with  $\beta$ -actin (Gb no. AY141970) (Table 1). Sequence homologies between muskox and beef cDNAs were analyzed using the ClustalW program [22]. Primer sequences, which matched both muskox and beef cDNAs, were generated using the Primer3 program [23] and validated using the BLASTn program [24].

Gene expression activity in the beef and muskox adipose samples was measured using SYBR green labeled Real-time quantitative RT-PCR analysis method in a Stratagene Mx4000 machine (Stratagene, La Jolla, CA, USA). For each sample, cDNA was added to 1X Brilliant SYBR green QPCR master mix and then aliquoted into 20  $\mu$ L fractions. The specific gene primers were added to their independent fraction and run simultaneously in the Mx4000 machine. Gene expression activity was estimated by the number of PCR cycles required to reach a minimum threshold for cycle detection (Ct value). The signal for  $\beta$ -actin was used as an internal standard to normalize the estimates of FAS, ACO and SCD1 mRNA levels between species.

#### Statistical Analysis

Data were analyzed by ANOVA using the GLM procedure of SAS© software (SAS Systems, Release 8.2, SAS Institute Inc., Cary, NC, USA). Results were expressed as mean  $\pm$  SEM, and a  $P$  value of 0.05 was considered significant.

## Results and Discussion

### Diet

The fatty acid composition of the beef diet was typical for barley grain lipids with high levels of linoleic acid (18:2n-6; 48.9%), substantial amounts of linolenic acid (18:3n-3; 7.63%) and an 18:2n-6/18:3n-3 ratio of 6.4 (Table 2). The beef diet also contained intermediate amounts of 9c-18:1 and 16:0. The sedge lipids consisted mainly of SFAs (55.9%) that included 16:0 (23.3%), 18:0 (3.8%) and the long-chain SFAs 20:0 (6.4%), 22:0 (14.8%) and 24:0 (4.7%) (Table 2) which would be indicative of a high content of waxy cuticle [25] and a reduced feeding value for this forage. The sedges contained a higher level of 18:3n-3 relative to the beef diet, but the amount was lower than that reported in other leaf lipids [26]. Sedge lipids also contained substantial amounts of 18:2n-6 (15.9%) and had an 18:2n-6/18:3n-3 ratio of 1.4.

### Adipose Tissue SFA

Muskox subcutaneous adipose tissue had higher total SFAs than beef including most of the individual SFAs except beef adipose tissue had more 16:0 ( $P < 0.05$ ; Table 3), which may be indicative of a higher plane of nutrition and

increased rates of de novo fatty acid synthesis in beef fat. Of particular interest, muskox adipose tissue had higher levels of long-chain SFAs ( $\geq 18:0$ ;  $P < 0.05$ ), specifically 18:0 (26.8 vs. 9.8% in beef fat). High 18:0 levels were previously reported in the milk fat of muskox [3]. Finding a high SFA content in muskox adipose tissue was unusual since decreased levels of SFA are generally observed in animals living at low ambient temperatures, as expected in the Arctic, which maintains their fat in a liquid or semi-liquid state [27]. The high insulation value of the coat may negate their need for desaturation, as well as their higher content of low melting point branch-chain FAs (noted below). Sheep and goats are more closely related to muskox than beef cattle, and they also have been found to deposit high levels of 18:0 when grazing forages [28], but 18:0 is lower in lambs when fed a high-energy corn diet [29]. Comparably high levels of 18:0 have been found in other wild ruminants (elk, deer and antelope) under natural grazing conditions [30]. The high level of 18:0 in the fat of muskox could be related to the diet, to more extensive biohydrogenation of dietary polyunsaturated fatty acids

(PUFAs) compared to beef cattle and/or to reduced rates of 18:0 desaturation.

### Branched-Chain Fatty Acids

Muskox adipose tissue was found to contain higher levels of C14 to C18 branched-chain (iso and anteiso) fatty acids ( $P < 0.05$ ; Table 3). Short branched-chain fatty acids arise from deamination of branched-chain amino acids by rumen microorganisms [31] or by carboxylation of propionyl-CoA to form methylmalonyl-CoA [32]. These branched-chain fatty acids can then be incorporated during fat synthesis in ruminants to form longer chain branched-chain fatty acids [33]. Higher levels of branch-chain fatty acids typically result when readily fermentable carbohydrate sources are available, causing an increase in propionate production [27]. Given the relatively poor quality of forage available to muskox and lack of grain in their diet, synthesis of branched-chain fatty acids through carboxylation of propionyl-CoA seems unlikely. Furthermore, muskox may be predisposed to deposit higher levels of branched-chain FAs similar to sheep and goats who were shown to deposit greater levels of branched-chain FAs compared to cattle when fed the same diet [32].

### *cis*- and *trans*-MUFA

The separation of the *cis* and *trans*-MUFA, particularly of the 18:1 isomers remains a challenge, as evident from the partial GC chromatograms of beef (Fig. 1) and muskox backfat (Fig. 2). When *cis* and *trans*-MUFA are not pre-fractionated using  $\text{Ag}^+$ -TLC prior to GC, one deals with partial resolution of 10*t*- and 11*t*-18:1 because of the large differences in their relative abundance, and overlap of 13*t*- to 16*t*-18:1 with *cis*-18:1 isomers. To avoid this, two separate GC temperature programs were employed in this study to improve the resolution of 6-8*t*- to 11*t*-18:1 isomers by lowering the temperature during the plateau region from 175 to 150 °C (see inserts in Figs. 1, 2), and to determine the remaining *trans*-18:1 isomers by difference between the two separate GC chromatograms.

The most abundant *cis*-MUFAs in both beef and muskox adipose tissue were 9*c*-16:1 and 9*c*-18:1 and the latter contained trace amounts of 10*c*-18:1 (Table 4). The adipose tissue of beef contained much more 9*c*-18:1 (38.0 vs. 27.4%) and correspondingly less 18:0 than found in muskox (9.8 vs. 26.8%). Beef adipose tissue also contained significantly higher levels of most of the other *cis*-MUFA, some arising from  $\Delta 9$  desaturation of their SFA precursors, while others are possible intermediates of rumen biohydrogenation of PUFAs [34].

Beef adipose tissue contained more total *trans*-18:1 relative to muskox ( $P < 0.01$ ; Table 4) and this was

**Fig. 1** Partial GC chromatograms of the 18:1 region from representative adipose tissue FAME of barley fed beef adipose tissue showing the maximum range of 10*t*- and 11*t*-18:1 isomer distribution among samples using GC temperature program A (details in M&M section). *Insert* shows separation of partial *trans*-18:1 isomers of the same beef samples using GC temperature program B

**Fig. 2** Partial GC chromatograms of the 18:1 region from representative adipose tissue FAME of wild muskox adipose tissue showing the maximum range of 10*t*- and 11*t*-18:1 isomer distribution among samples using GC temperature program A (details in M&M section). *Insert* shows separation of partial *trans*-18:1 isomers of the same muskox samples using GC temperature program B

primarily due to a higher level of 10*t*-18:1 and slightly greater levels of 6-8*t*, 9*t* and 12*t*-18:1 ( $P < 0.01$ ; Fig. 3). Conversely, the most abundant *trans*-18:1 isomer in muskox adipose tissue was 11*t*-18:1 and its level was greater than that found in beef fat ( $P < 0.01$ ). The *trans*-18:1 content and composition was also more variable in beef than muskox fat as evident from the partial GC chromatograms presented in Figs. 1 and 2 demonstrating the range in *trans*-18:1 compositions encountered in beef and muskox, respectively.

Feeding high levels of concentrate significantly increases 10*t*-18:1 in adipose tissue of ruminants making it

**Fig. 3** Muskox and beef subcutaneous adipose tissue *trans*-18:1 composition. Bars and vertical lines represent mean  $\pm$  SEM,  $n = 16$  for each species. For each isomer, bars with asterisks are significantly different ( $P < 0.01$ )

the predominant *trans*-18:1 isomer irrespective of the grain type fed, whether corn [35], barley [36], a barley/oat mixture [37], or a mixture to several ingredients [38]. On the other hand, feeding a lower concentrate to forage ratio increases both 11*t*- and 10*t*-18:1, but 11*t*-18:1 remains the major *trans*-18:1 isomer [39–42]. Comparable changes in 10*t*-18:1 levels in milk fat have also been found when dairy cows are fed differing concentrate to forage ratios [43–46]. A recent study shows that the shift toward 10*t*-18:1 production can be eliminated by feeding a grass/hay basal diet supplemented with linseed oil when the forage to concentrate ratio is 64:36 [47]. The ionophore monensin has also been shown recently to increase 10*t*-18:1 in milk fat when dairy cows are fed a concentrate containing supplementary sunflower seed oil [48]. High levels of 10*t*-18:1 appear to be related to changes (and instability) in the rumen environment and altered bacterial populations when highly fermentable (i.e., pH reducing) diets are fed [36, 49, 50].

### CLA

The complete analysis of the CLA isomers in beef and muskox required a combination of GC and Ag<sup>+</sup>-HPLC, reference standard no. UC-59M from Nu Chek Prep Inc., and isomerization of individual CLA standards using iodine [20]. Peaks were identified by comparison to previously established elution orders by GC and Ag<sup>+</sup>-HPLC [20, 34, 51, 52]. The 7*t*,9*c*-18:2 isomer was observed as a distinct shoulder on the 9*c*,11*t*-18:2 peak in the GC chromatogram but by Ag<sup>+</sup>-HPLC these isomers were clearly resolved (Fig. 4). On the other hand, 9*c*,11*t*- and 9*t*,11*c*-18:2 were resolved by GC but co-eluted with using Ag<sup>+</sup>-HPLC (Fig. 4). The relatively high content of 21:0 observed in muskox lipids eluted in the region of the minor CLA isomers in the GC chromatogram and the presence of these isomers was confirmed using Ag<sup>+</sup>-HPLC (Fig. 4) [20, 34].

The adipose tissue of beef had significantly more total CLA than muskox (Table 5). The most abundant CLA isomer in both beef and muskox was 9*c*, 11*t*-18:2, which was significantly higher in beef than in muskox as a percent of total FAME (Fig. 5), but both had ~67% 9*c*,11*t*-CLA in total CLA. There were, however, significant differences in the remaining CLA isomers. Among the minor CLA isomers present, beef had significantly greater amounts of amounts of 7*t*,9*c*- and 9*t*,11*c*-18:2 ( $P < 0.01$ ; Fig. 5) and contained trace amounts of 10*t*,12*c*-18:2 (data not presented). The CLA profile of beef fat in this study was similar to that reported by others in beef [40, 53] and dairy cows [44, 54] fed concentrates. Muskox adipose tissue had significantly greater amounts of 11*t*,13*c*-18:2 ( $P < 0.01$ ; Fig. 5) and 11*t*,13*t*-18:2 (Fig. 4, Ag<sup>+</sup>-HPLC). For details regarding the identification of the CLA isomers see reference by Cruz-Hernandez et al. [20]. The minor *trans*, *trans*-CLA isomers

**Fig. 4** Partial GC and  $\text{Ag}^+$ -HPLC chromatograms of the CLA region of adipose tissue FAME from wild muskox and barley fed beef. Details of GC temperature program A and silver-ion HPLC separation are given in the M&M sections

(<0.02%) shown in Fig. 4 ( $\text{Ag}^+$ -HPLC separation) were included in total CLA, but are not reported or discussed separately.

The metabolic origin of some, but not all the different CLA isomers is understood. The  $9c,11t$ - and  $7t,9c$ -18:2 CLA isomers are synthesized in the tissues of ruminants from their respective *trans*-18:1 precursors by stearyl-CoA desaturase [55, 56]. The rate of their formation is considerably slower in muskox than in beef based on the lower desaturation ratio of  $9c,11t$ -18:2/ $11t$ -18:1 in muskox (Table 4). It has been suspected that the  $11t,13c$ -18:2 isomer was derived from  $18:3n-3$  [54] and this has now been confirmed showing  $9c,11t,15c$ -18:3 and  $11t,15c$ -18:2 are intermediates and the latter is then isomerized to  $11t,13c$ -18:2 [57].

#### Non-Conjugated *c/t* 18:2 Isomers

Although the content of the non-conjugated *c/t* 18:2 isomers is less than 1% of total adipose FAME in these two ruminants (Table 5), their occurrence and concentration does provide an indication of their respective metabolism of PUFAs by rumen bacteria, or subsequent tissue synthesis. Beef subcutaneous fat contained more *c/t* 18:2 metabolites than muskox supporting the suggestion that biohydrogenation is more complete in muskox than in beef. Most of the identified *c/t* 18:2 isomers were more abundant in beef, except the minor isomers  $8t,13c$ - and  $9t,12c$ -18:2 (Table 5). The relative high content of the  $18:3n-3$  metabolite  $11t,15c$ -18:2 was not surprising since both beef and muskox had access to feed containing  $18:3n-3$  (i.e., barley and sedges, respectively). The higher  $\Delta 9$  desaturation activity in beef (see below) would also explain the higher amounts of  $9c,13t$ - and  $9c,12t$ -18:2 in the adipose tissue of beef derived from the corresponding *trans*-18:1 precursors. The identity of some of the *c/t*-18:2 and *c/c/t*-18:3 isomers were

confirmed by comparison with iodine isomerized products of linoleic and linolenic acids [58].

#### PUFA

Dietary differences in the content of the essential fatty acid ( $18:2n-6$  and  $18:3n-3$ ) between these two ruminants (Table 1) were also reflected in the PUFA content in their adipose tissue (Table 5). Beef adipose tissue had more  $18:2n-6$  and its elongation and desaturation product  $20:3n-6$  ( $P < 0.05$ ), however, beef and muskox had similar levels of  $20:4n-6$ . On the other hand, muskox adipose tissue had significantly higher levels of  $18:3n-3$  and its elongation and desaturation products  $20:5n-3$ ,  $22:5n-3$  and  $22:6n-3$

**Table 5** Muskox and beef subcutaneous adipose tissue polyunsaturated fatty acid composition ( $n = 16$  in each group)

<sup>a</sup> The major  $18:3$  *c/c/t* isomers were  $9c,12c,15t$ - and  $9t,12c,15c$ -18:3 in about equal proportions, while  $9c,12t,15c$ -18:3 was present in trace amounts

\* $P < 0.05$ , beef differs from muskox

\*\* $P < 0.01$ , beef differs from muskox

**Fig. 5** Muskox and beef subcutaneous adipose tissue conjugated linoleic acid (CLA) composition of selected CLA isomers. Bars and vertical lines represent mean  $\pm$  SEM,  $n = 16$  for each group. For each isomer, bars with asterisks are significantly different ( $P < 0.01$ )

(Table 5). As a consequence, muskox adipose tissue had a lower n-6/n-3 ratio ( $P < 0.05$ ) and could contribute toward fulfilling dietary recommendations for improved cardiovascular health [59].

#### mRNA Analysis of Fat Metabolizing Enzymes

The higher than expected level of SFAs in muskox, particularly 18:0 (Table 3), was further investigated using mRNA analysis. Stearyl-CoA desaturase-1 (SCD1) desaturates 18:0 to 9*c*-18:1 and is the key enzyme in regulating levels of desaturation in de novo fat biosynthesis. We isolated and sequenced the muskox SCD1 mRNA to examine if it could further explain the lack of unsaturation in muskox adipose tissue. The cloned fragment of the muskox SCD1 mRNA (Genbank no. AY530631) had 99% homology with goat and sheep versions of the SCD1 mRNA and 96% homology with beef SCD1. This agreed with earlier phylogeny studies relating the muskox as a closer relative to Caprinae than Bovinae. Semi-quantitative measures of SCD1 mRNA in muskox adipose tissue showed one-third less expression than standardized bovine adipose tissue when measured against the house keeping gene  $\beta$ -actin (Genbank no. DQ017256).

A more intensive investigation compared the expression of SCD1 against the fat metabolic and catabolic indicator enzymes, palmitoyl fatty acid synthase (FAS) [60] and palmitoyl CoA oxidase (ACO) [61] in both muskox and beef samples (Fig. 6). Muskox adipose tissue again expressed lower levels of SCD1 mRNA relative to FAS and ACO mRNA when compared to bovine adipose tissue. This confirmed that muskox SCD1 expression was selectively lower relative to bovine adipose tissue, which would in large part explain the higher level of 18:0 in muskox. A lower expression of SCD1 might also in part

**Fig. 6** Relative gene expression of the lipid metabolizing enzymes fatty acid synthase (FAS), acyl CoA oxidase (ACO) and steroyl CoA desaturase (SCD1) in muskox and beef adipose tissue. The mRNA expression levels were adjusted relative to the  $\beta$ -actin signal (asterisks indicates difference  $P < 0.01$ ). Values  $\pm$  SEM,  $n = 16$  for each group

explain why muskox had a lower adipose tissue level of 9*c*, 11*t*-, 9*c*, 13*t*- and 9*c*, 12*t*-18:2 (Table 5), a higher SFA to MUFA ratio, and lower desaturation index for 14:0, 16:0, 17:0 and 18:0, as well as 9*c*, 11*t*-18:1 to 11*t*-18:1 (Table 4).

In summary, the fatty acid composition of wild muskox adipose tissue was substantially different from that of beef finished on a high barley diet. Even though the adipose tissue of wild muskox had a substantially higher content of SFAs and branch-chain fatty acids than beef, this was offset by a healthier fatty acid profile of *trans*-18:1 and CLA isomers, a higher n-3 PUFA content and a lower n-6 to n-3 ratio. On the other hand, beef adipose tissue had a significantly greater level 10*t*-18:1, which has been shown to negatively effect plasma lipoprotein profiles in rabbits [14], and had higher levels of 7*t*, 9*c*-CLA [44] and 9*t*, 11*c*-CLA [62] which have been linked to milk fat depression. Regarding current beef production practices, feeding higher levels of forage as opposed to grain should be encouraged to promote a healthier fatty acid profile and/or greater emphasis needs to be placed on developing feeding strategies to take advantage of intensive production without negatively impacting beef fatty acid composition. Specific areas that need further investigation include studying the effects of grain type, processing and how added oils interact with the dietary matrix in the production and deposition of individual CLA and *trans*-18:1 isomers.

**Abstract** The cyclopropane fatty acids 17-methyl-*trans*-4,5-methyleneoctadecanoic acid, 18-methyl-*trans*-4,5-methylenonadecanoic acid, and 17-methyl-*trans*-4,5-methylenonadecanoic acid were characterized for the first time in nature in the phospholipids (mainly PE, PG and PS) of the hermit-crab sponge *Pseudospongosorites suberitoides*. Pyrrolidine derivatization was the key in identifying the position of the cyclopropyl and methyl groups in the acyl chains and  $^1\text{H}$  NMR was used to determine the *trans* stereochemistry of the cyclopropane ring. The phospholipids from the sponge also contained an interesting series of *iso-anteiso*  $\Delta^{5,9}$  fatty acids with chain-lengths between 17 and 21 carbons, with the fatty acids (5*Z*,9*Z*)-18-methyl-5,9-nonadecadienoic acid and the (5*Z*,9*Z*)-17-methyl-5,9-nonadecadienoic acid being described for the first time in sponges. The *anteiso*  $\alpha$ -methoxylated fatty acid 2-methoxy-12-methyltetradecanoic acid was also identified for the first time in nature in the phospholipids of this interesting marine sponge. The novel cyclopropyl fatty acids could have originated from the phospholipids of a cyanobacterium living in symbiosis with the sponge.

FAME	Fatty acid methyl ester
GC–MS	Gas chromatography–mass spectrometry
PE	Phosphatidylethanolamine
PG	Phosphatidylglycerol
PS	Phosphatidylserine

## Introduction

Cyclopropane fatty acids (FA) are quite ubiquitous in seed oils, bacteria, and other microorganisms [1]. Since the discovery of lactobacillic acid (*cis*-11,12-methyleneoctadecanoic acid) in 1951, several interesting cyclopropyl FA have been identified in both Gram-negative and Gram-positive bacteria [2]. For example, the acid 9,10-methylenehexadecanoic acid was reported in the Gram-negative bacterium *Pseudomonas cepacia* [3]. The protozoan *Herpetomonas megaseliae* synthesizes de novo the *iso*-branched FA 17-methyl-*cis*-9,10-methyleneoctadecanoic acid [4], while the acids 9,10-methylene-5-hexadecenoic acid and 11,12-methylene-5-octadecenoic acid are present in the slime mould *Polysphondylium pallidum* [5]. The *cis*-9,10-methyleneoctadecanoic acid has been identified in the seeds of *Litchi chinensis*, in longan seed oil, and in trypanosomatids and is preferentially located at the *sn*-2 position of triglycerides [6–7]. At present there is no known role for these cyclopropane FA.

Although less ubiquitous, cyclopropane FA have also been reported in marine organisms. Sponges have provided some interesting examples. For example, the acid

19,20-methylenehexacosanoic acid was identified in the phospholipids of the sponge *Calyx niceansis* [8], while the sponge *Amphimedon* sp., collected in Australia, contains the acid 10,11-methyleneheptacosanoic acid, a topoisomerase I inhibitor with an  $IC_{50} = 1.2 \mu\text{M}$  [9]. More recently, majusculoic acid, a brominated diunsaturated cyclopropyl fatty acid with a *trans* cyclopropane ring between carbons 4 and 5, was isolated from a cyanobacterial mat assemblage [10]. Majusculoic acid exhibited antifungal activity against *Candida albicans* ATCC 14503 with a MIC of  $8 \mu\text{M}$  [10].

Aimed at discovering other unusual cyclopropyl FA in marine sponges, we investigated herein, for the first time, the phospholipid FA composition of the hermit-crab sponge *Pseudospongisorites suberitoides* (Class Demospongiae, Family Suberitidae) [11] and report on the occurrence of the novel cyclopropane FA **1–3** with an uncommon *trans* cyclopropyl group between carbons 4 and 5 of the acyl chain [12]. In addition, other previously unidentified phospholipid FA containing either the  $\alpha$ -methoxy substitution or the  $\Delta 5,9$  diunsaturation were also identified for the first time in nature in *P. suberitoides*.

## Materials and Methods

### Instrumentation

Fatty acid methyl esters (FAME) and pyrrolidides were analyzed by direct ionization using GC–MS (Hewlett-Packard 5972A MS ChemStation) at 70 eV equipped with a  $30 \text{ m} \times 0.25 \text{ mm}$  special performance capillary column (HP-5MS). The GC-temperature program was:  $130 \text{ }^\circ\text{C}$  for 1 min, increased at a rate of  $3 \text{ }^\circ\text{C}/\text{min}$  to  $270 \text{ }^\circ\text{C}$ , and maintained for 30 min at  $270 \text{ }^\circ\text{C}$ .  $^1\text{H-NMR}$  spectra were recorded on a Bruker DPX-300 spectrometer.  $^1\text{H-NMR}$  chemical shifts are reported with respect to internal  $\text{Me}_4\text{Si}$ , and chemical shifts are given in parts per million (ppm).

### Sponge Collection

The sponge *Pseudospongisorites suberitoides* (Class Demospongiae, Family Suberitidae) (Díaz, van Soest and Pomponi 1993) (Sandford and Kelly-Borges 1997) was collected from Mona Island (near Monito), Puerto Rico in July 2006 at 26 m depth by scuba. The sponge was freeze-dried and stored at  $-20 \text{ }^\circ\text{C}$  until extraction. A voucher specimen (IM06-06) is stored at the Chemistry Department of the University of Puerto Rico, Río Piedras campus.

### Extraction and Isolation of Phospholipids

The sponge (74 g of dry weight) was carefully cleaned and cut into small pieces. Extraction with  $2 \times 200 \text{ ml}$  of  $\text{CHCl}_3/\text{MeOH}$  (1:1) yielded the total lipids (8.4 g). The neutral lipids, glycolipids, and phospholipids (3.9 g) were separated by column chromatography on Si gel (60–200 mesh) using the procedure of Privett et al. [13]. The phospholipid classes were identified by  $R_f$  values using thin-layer chromatography using Si gel H plates and  $\text{CHCl}_3/\text{MeOH}/\text{NH}_4\text{OH}$  (65:30:5) as developing solvent. The main phospholipids identified were phosphatidylethanolamine (PE), phosphatidylglycerol (PG), and phosphatidylserine (PS).

### Derivatives

The fatty acyl components of the phospholipids were obtained as their methyl esters by reaction of the phospholipids with methanolic HCl followed by column chromatography on Si gel eluting with hexane/ether (9:1). An aliquot of the methyl esters were hydrogenated in 10 ml methanol with catalytic amounts of Pd/C (10%). The double-bonds, methyl-branching, and cyclopropane positions in these compounds were determined by pyrrolidide derivatization of an aliquot of the methyl esters following the preparation procedure previously described [14]. Mass spectral data for the novel compounds follows and/or are presented in Table 1.

## Results and Discussion

*Pseudospongosorites suberitoides* presented a typical sponge phospholipid profile where PE, PG, and PS were the most abundant phospholipids. Acid methanolysis of the

total phospholipids provided a rather complex and unusual phospholipid FA composition of around 51 identifiable FA as shown in Table 2. FA chain lengths ranged between 14 and 27 carbons, mainly consisting of methyl-branched fatty acids (75% of the total FA mixture). The  $\Delta$ 5,9 FA were particularly abundant in this sponge (25% of the total FA) but their chain lengths were atypical with respect to other sponge phospholipid  $\Delta$ 5,9 FA inasmuch as here the most abundant  $\Delta$ 5,9 FA had chain lengths between 17 and 20 carbons. Among the  $\Delta$ 5,9 FA the even-chain (5*Z*,9*Z*)-5,9-octadecadienoic acid was particularly abundant (7.8% relative abundance), a most unusual finding for sponges [15]. Around 66% of the total FA contained odd carbon chains. The isoprenoid FA 4,8,12-trimethyltridecanoic acid was also present in *P. suberitoides*. It is important to mention that this FA is a common constituent of the phospholipids of the sponge families Spirastrellidae and Clionidae [16].

The most interesting series of FA from *P. suberitoides* were the cyclopropane fatty acids 17-methyl-*trans*-4,5-methyleneoctadecanoic acid (**1**), 18-methyl-*trans*-4,5-methylenenonadecanoic acid (**2**), and 17-methyl-*trans*-4,5-methylenenonadecanoic acid (**3**), all FA with an unusual *trans* cyclopropane ring between carbons 4 and 5. The relative GC retention times and mass spectra of the methyl esters, the mass spectra of the corresponding pyrrolidide derivatives, catalytic hydrogenation, and <sup>1</sup>H NMR of the whole FAME mixture provided the basis for their characterization. For

<sup>a</sup> Unprecedented in nature

example, methyl 17-methyl-*trans*-4,5-methyleneoctadecanoate exhibited unusual chromatographic properties, namely an equivalent chain length (ECL) value of 19.15, for which the fractional value is well in agreement with a highly branched FA structure. The mass spectrum of methyl 17-methyl-*trans*-4,5-methyleneoctadecanoate contained a molecular ion peak at  $m/z$  324 ( $C_{21}H_{40}O_2$ ) and an intense peak at  $m/z$  101 (54%) as well as the classical McLafferty rearrangement peak at  $m/z$  74 (66%). Upon mild catalytic hydrogenation (Pd/C) the molecular ion of this methyl ester remained the same, while other monoenes and dienes in the FAME mixture incorporated hydrogen. Therefore, this experiment excluded the possibility of a monounsaturated methyl ester and suggests the presence of a cyclopropyl ring in the fatty acyl chain.

Pyrrolidide derivatization was instrumental in elucidating the basic structure of this FA. For example, in the mass spectrum of *N*-17-methyl-*trans*-4,5-methyleneoctadecanoylpyrrolidine the presence of a cyclopropyl group between carbons 4 and 5 was indicated from a difference of 12 amu between fragments at  $m/z$  126 ( $C_3$ ) and  $m/z$  138 ( $C_4$ ), and confirmed by a strong fragmentation peak at  $m/z$  166 ( $C_6$ ) arising from cleavage between carbons 5 and 6 at the other end of the cyclopropane ring. Previous work by Andersson on the mass spectra of pyrrolidides of FA containing cyclopropyl groups indicates that if an interval of 12 amu, instead of the regular 14, is observed between the most intense peaks of clusters of fragments containing  $n-1$  and  $n$  carbon atoms of the acid moiety, a cyclopropane ring occurs between carbon atoms  $n$  and  $n+1$  in the molecule [17]. However, caution should be exercised when dealing with pyrrolidides since the cyclopropane ring can

be located within one carbon position of its true location if the ring lies between carbons 6,7 and 16,17, but in our case such an exception does not apply since the ring lies between carbons 4,5 [17]. The presence of the *iso* terminal methyl branching in this compound was also clearly observed in the pyrrolidide mass spectrum since a diminished peak (and/or absent peak) at  $m/z$  334 with the corresponding intense peaks at  $m/z$  320 and 348 were also observed.

In order to corroborate the presence of the cyclopropyl group as well as to assign its *trans* stereochemistry  $^1\text{H}$  NMR was used [18]. Since the  $^1\text{H}$  NMR signals of a cyclopropane ring normally resonate at high-field it was possible to observe these signals in the  $^1\text{H}$  NMR spectrum of the whole FAME mixture without interference from other peaks. Proton signals were indeed observed as multiplets at  $\delta$  0.29 ppm and at  $\delta$  0.66 ppm, while no absorption was observed at  $-0.3$  ppm. This observation is indicative of a *trans* stereochemistry for the cyclopropane rings, since FA with a cyclopropane ring in *cis* configuration normally show absorptions at 0.6 ppm and at  $-0.3$  ppm for the two methylene cyclopropane hydrogens [18]. In the case of a *trans* cyclopropane ring these two methylene hydrogens are similar, due to a pseudo- $\text{C}_{2v}$  symmetry, and both resonate at around 0.2 ppm [10, 18]. Therefore, we can unequivocally assign as methyl 17-methyl-*trans*-4,5-methylenooctadecanoate our methyl ester in question.

The other cyclopropane fatty acids **2** and **3**, as well as their corresponding derivatives, displayed similar spectral characteristics as **1** that allowed their characterization as isomeric  $\text{C}_{21}$  members of the same family of cyclopropane FA. A slight difference in the spectral data was observed for methyl 17-methyl-*trans*-4,5-methylenonadecanoate, inasmuch as an ECL value of 20.24 indicated the presence of an *anteiso*  $\text{C}_{21}$  isomer. This structural assignment was further confirmed in the mass spectrum of *N*-17-methyl-*trans*-4,5-methylenonadecanoylpyrrolidine ( $\text{M}^+ = 377$ ) where a diminished peak (and/or absent peak) at  $m/z$  334 confirmed the C-17 methyl substitution.

Among the studied FA from *P. suberitoides* a novel  $\alpha$ -methoxylated fatty acid, namely **4**, was also characterized using GC–MS as well as gas chromatographic ECL values as compared to synthetic standards [14, 19]. The mass spectrum of the methyl ester of **4** displayed a molecular ion peak at  $m/z$  286 and a strong  $\text{M}^+ - 59$  peak at  $m/z$  227 (100%), together with a small peak at  $m/z$  104 (McLafferty rearrangement), all typical mass fragments for  $\alpha$ -methoxylated saturated methyl esters [14, 19]. The  $\alpha$ -methoxylation was further confirmed by  $^1\text{H}$  NMR spectroscopy since it was also possible to observe the characteristic signals of the  $\alpha$ -methoxy methyl ester in the  $^1\text{H}$  NMR spectrum of the whole FAME mixture without interference

from other peaks. In this case, the methoxy protons resonated as a singlet at  $\delta$  3.66 ppm, while the methine  $\alpha$ -hydrogen resonated as a multiplet at  $\delta$  3.75 ppm, all chemical shift values in agreement with other  $\alpha$ -methoxylated methyl esters [20]. The GC retention time of the methyl ester of **4** (ECL value of 15.93) suggested it to be an *anteiso* methyl-branched fatty acid [14]. A normal chain  $\alpha$ -methoxylated  $\text{C}_{15}$  FA methyl ester displays an ECL value of 16.20, while an *iso*  $\alpha$ -methoxylated  $\text{C}_{15}$  FA methyl ester displays an ECL value of 15.86. Therefore, based on this evidence the most logical structural assignment for the original acid is that of 2-methoxy-12-methyltetradecanoic acid (**4**), which has not been identified before in sponges. It should be pointed out that pyrrolidide derivatization has limited usefulness in locating methyl branching in  $\alpha$ -methoxylated fatty acids [14].

As we mentioned before *P. suberitoides* also contained a complete series (11% of the total phospholipid fatty acid composition) of *iso* and *anteiso*  $\text{C}_{17}$ – $\text{C}_{21}$  FA with the typical  $\Delta 5,9$  diunsaturation pattern of “demospongiac” acids [21]. Among these  $\Delta 5,9$  fatty acids the 18-methyl-5,9-nonadecadienoic acid (*i*-20:2 $\Delta 5,9$ ) and the 17-methyl-5,9-nonadecadienoic acid (*ai*-20:2  $\Delta 5,9$ ) appear not to have been identified before in sponges. In mass spectrometry the methyl esters of *i*-20:2 $\Delta 5,9$  and *ai*-20:2  $\Delta 5,9$  displayed the same molecular ion ( $\text{M}^+$ ) at  $m/z$  322. In addition, the  $\Delta 5,9$  diunsaturation was readily recognized from the characteristic base peak at  $m/z = 81$ , the allylic cleavage fragmentation between C-7 and C-8 at  $m/z$  141, and the fragmentation at  $m/z$  109 which results from the loss of methanol from the  $m/z$  141 fragment [22]. Pyrrolidides were also informative in characterizing these FA [22]. For example, in the mass spectrum of *N*-18-methyl-5,9-nonadecadienoylpyrrolidine the characteristic allylic cleavage between C-7 and C-8 was observed at  $m/z$  180 as well as cleavage between C-11 and C-12 at  $m/z$  234 [22]. Catalytic hydrogenation of methyl 18-methyl-5,9-nonadecadienoate and methyl 17-methyl-5,9-nonadecadienoate afforded methyl 18-methylnonadecanoate and methyl 17-methylnonadecanoate, respectively, as confirmed by their GC retention times and mass spectrometry, thereby confirming the terminal *iso-anteiso* methyl branching in these compounds. The mass spectrum of *N*-18-methyl-5,9-nonadecadienoylpyrrolidine also confirmed the *iso* methyl branching whereby a diminished (or absent peak) at  $m/z$  334 was also observed.

The results obtained for *P. suberitoides* are interesting for several reasons. The phospholipid FA composition of *P. suberitoides* is unusual in the sense that the main  $\Delta 5,9$  fatty acids present in the sponge have chain lengths between 17 and 21 carbons, in contrast to the typical FA composition of many sponges belonging to the Demospongiae where very long-chain  $\Delta 5,9$  FA with chain lengths between 25 and 29 carbons predominate [21, 23]. This finding could have significance in the chemotaxonomy of sponges belonging to the Suberitidae family.

The characterization of the novel cyclopropyl FA 1–3 in the phospholipids of *P. suberitoides* is also a rare finding, inasmuch as these fatty acids possess a *trans* cyclopropyl ring attached to carbons 4 and 5. This unusual 4,5 cyclopropane substitution seems to be specific for marine cyanobacteria since it has only been identified before in complex FA containing metabolites from the marine cyanobacterium *Lyngbya majuscula* and from other cyanobacterial communities [10, 12]. Our findings indicate that the more classical *iso-anteiso* FA can also exist with this type of 4,5 cyclopropyl substitution. Moreover, based on the highly methyl-branched nature of these FA it is very likely that they also originate from symbiotic microorganisms (bacteria or cyanobacteria) within *P. suberitoides*. If the latter is true, then we could be dealing with a novel marine bacterial strain previously unidentified since, to the best of our knowledge, there are no known marine bacteria with *iso-anteiso* FA with a 4,5 cyclopropyl substitution. More interesting could be the biological potential of these cyclopropyl FA as antimycobacterial agents (in particular against *Mycobacterium tuberculosis*) [24] or even against pathogenic fungi such as *Candida albicans* [10]. Further research is thus needed to put in perspective the pharmacological potential of these compounds.

**Abstract** Scientific investigation of lipids in Elasmobranchs has been conducted mainly on shark species. Because rays seem to be neglected, this study was performed to examine the complete fatty acid (FA) composition with a particular interest for long-chain polyunsaturated FA (PUFA) content in different tissues of three ray species including parts usually discarded. The total FA and PUFA profiles of total lipids were determined in muscle, liver, and gonad of *Rhinobatos cemiculus*, *Rhinoptera marginata*, and *Dasyatis marmorata*, the most often caught ray species from the East Tropical Atlantic Ocean. Fifty FA were characterized as methyl esters and *N*-acyl pyrrolidides by gas chromatography/mass spectrometry, showing significant levels of 20:5n-3 (EPA) (up to 5.3%) and 22:5n-3 (DPA) (up to 7.3%), high levels of 20:4n-6 arachidonic

(ARA) (4.8–8.6% of total FA) and 22:6n-3 (DHA) (up to 20.0%). The results show that muscle, liver and gonad of rays can provide high amounts of essential PUFA, specially DHA, for direct human nutrition or the food processing industry. High proportions of DHA were particularly found in all samples of *R. cemiculus* (11.6–20.0%), and in muscle and liver of *D. marmorata* (11.1–16.1%). Regarding the high amounts of (n-3) PUFA, this study shows that these rays deserve a better up-grading, including the normally discarded parts, and describes the occurrence of unusual NMID FA in all tissues studied. Five non-methylene-interrupted dienoic fatty acids (NMID FA) (0–3.4%) were reported, including previously known isomers, namely 20:2  $\Delta$ 7,13, 20:2  $\Delta$ 7,15, 22:2  $\Delta$ 7,13, 22:2  $\Delta$ 7,15, and new 22:2  $\Delta$ 6,14. These acids are quite unusual in fish and unprecedented in rays. The 22:2  $\Delta$ 6,14 acid occurred in gonads of male specimens of *R. cemiculus* at 2.9%.

MUFA	Monounsaturated FA
NMID FA	Non-methylene-interrupted dienoic FA

PUFA	Polyunsaturated FA
SFA	Saturated FA
TLC	Thin layer chromatography

## Introduction

In Mauritania, a small amount of ray flesh is consumed only after being air-dried or salted, a major part is commonly exported to South West African countries [1, 2]. The selected ray species for this study have not yet been investigated, although they are the most commonly caught. The main part of these rays caught is wasted.

The lipid content of fish has been studied for a long time mainly in the liver and edible parts such as muscles. The n-3 long-chain polyunsaturated fatty acids (PUFA), particularly eicosapentaenoic acid (20:5n-3/EPA) and docosahexaenoic acid (22:6n-3/DHA), have been proven to display a variety of beneficial effects for human health and nutrition in areas ranging from foetal brain development to alleged cancer prevention [3–12]. Fish are recognized as excellent sources of PUFA, particularly of the long-chain n-3 series [3, 9, 10, 12]. In the new millennium, there is a growing demand for marine fish oils, the main source of n-3 PUFA for the use in human food, nutraceuticals and pharmaceuticals [3, 12]. Due to the general decline of fish stocks, the investigation of unfished or less-exploited fish species is needed, and a better use of raw material is required, involving the evaluation of by-products from fisheries [12].

The coasts of Senegal and Mauritania, with alternating cold and warm marine currents, are the richest areas of West Africa for seafood resources, mainly fish [13]. Only a few detailed chemical reports of the lipid and fatty acid (FA) content of fish from this area are available, even for fish species most often locally consumed. We have investigated fish from these waters, e.g. *Sardinella maderensis*, *S. aurita* and *Cephalopholis taeniops* [14]. The flesh of the latter species contains high concentrations of n-3 PUFA, up to 29% including EPA and DHA as major components [14]. Furthermore, parts of fish such as skin, often discarded when fish are prepared for consumption, were found to be rich in these PUFA [14]. Thus, it was of great interest to evaluate the potential in lipids and essential PUFA of different organs of rays. For the ray fishery, only the caudal fins are utilized, since they are very much appreciated by Asian consumers in shark-soup. The head and viscera, including the liver, are thrown back into the sea. There is little information on lipids and FA composition of rays, although these are closely related to sharks [15]. Both species are members of the Class Chondrichthyes, or

cartilaginous fish, and belong to the Subclass Elasmobranchii [15]. We recently reported on FA distribution in muscle, liver and gonads of the Mauritanian rays *Dasyatis marmorata*, *Rhinobatos cemiculus* and *Rhinoptera marginata* commonly fished from the East Tropical Atlantic [16]. Considerable data are available on lipids and FA in shark tissues [17–19]. Published work on lipids of sharks and rays is often centered on the liver oil where it is assumed that fish concentrate fats. The liver oil of deep-sea sharks has attracted much attention, mainly for the often large amount of hydrocarbons including squalene, and also alkyldiacylglycerols [17, 18]. Studies on pelagic shark species revealed that the liver lipids contained high levels of n-3 PUFA, especially DHA (up to 28.4%) [18]. Lipids and natural antioxidants were recently reported in the liver oil of *Dasyatis brevis* and *Gymnura marmorata* rays captured in the Gulf of California and high levels of EPA and DHA were observed [20]. The liver lipid composition of the ray *Dasyatis bleekeri* from India was reported [21]. Lipid profiles and occurrence of carotenes and tocopherols have been reported in the liver oil of the ray *Rhinoptera steindechneri* [22]. As an important fishing resource along the Galician coast, the ray *Raja clavata* was studied for lipid changes in muscle tissue during processing and frozen storage [23, 24].

Our recent results regarding the three Mauritanian rays showed that rays are potential sources of n-3 PUFA and should be used in the diet of local populations [16]. These rays are found both in coastal waters and far out to sea [13]. Rays of various families are effectively known to migrate [25]. Thus, though mostly observed in inshore waters, Rhinobatidae can enter deep waters. In Californian waters, the guitarfish *Rhinobatos productus* shows seasonal variations in abundance [26], while reproduction-related migrations are observed in *Rhinoptera bonasus* from Chesapeake Bay [27].

On the basis of phylogenetic relationships, rays are divided into five groups [10]. The genus *Rhinobatos* belongs to the Rhibatoid group, while the genera *Dasyatis* and *Rhinoptera* belong to the Myliobatoid group. Principal component analysis allowed us to reveal significant differences in various FA distribution, related to the species and sex of the sampled fish [16]. About fifty FA were identified by gas chromatography–mass spectrometry (GC–MS) from muscles, livers and gonads of these species. Muscle is the major edible part of fish but liver oil is known as a good source of interesting FA. Therefore, we studied ray livers even if they represent a lower part of the fish mass than in sharks. The only complete FA compositions reported in our previous paper were that in male muscle for these species [16]. Therefore, the present report deals with the FA composition of different tissues, and describes the characterization of unusual FA with emphasis on the non-methylene-interrupted diunsaturated FA (NMID FA).

## Materials and Methods

### Fish Species and Sampling

Fish specimens were obtained from local Mauritanian fish markets in autumn and winter (i.e. November to February, 1996–1998). Fish specimens were mainly caught off Nouakchott, in the same area, in the South part of the Banc d'Arguin. They were identified as detailed in our previous paper [13, 16]. Samples were kept on ice from the market to the laboratory in Nouakchott before lipid extraction.

**Lipid extraction.** For each analysis, ~10 g of muscle, liver, and gonad were homogenized separately using a Waring Blender. Muscles were sampled under the skin on the dorsal side. Lipids were extracted according to a modification of the Bligh and Dyer method [28] using a mixture of 20 mL of methanol and 10 mL of chloroform for 5 min. After centrifugation, the lower chloroform phase was collected, dried with anhydrous sodium sulfate, and evaporated under vacuum to give the total lipids. A small amount of BHT was added to the lipid extracts and these were kept in dry ice during transfer to the laboratory in Marseille, France.

### Saponification and Fatty Acid Derivatives

Fatty acid methyl esters (FAME) were prepared by saponification of the total lipids (50 mg) with KOH-ethanol, 2 M (1 mL) [29] followed by recovery of the fatty acids, and acid-catalyzed methylation with methanolic hydrogen chloride. *N*-Acyl pyrrolidides were prepared by direct treatment of methyl esters with pyrrolidine/acetic acid (10:1, v/v) for 2 h under reflux and purified by TLC on silica gel layers using hexane/diethyl ether (1:2, v/v) [30].

### Gas Chromatography (GC)

A Delsi gas chromatograph equipped with a flame ionization detector (FID) and a fused silica capillary column (25 m × 0.28 mm i.d.) coated with Carbowax 20 M (0.2 μm phase thickness) was used for analyses (Delsi Instruments, Suresnes, France). Temperatures used were 180 °C for 10 min, then raised at 2 °C min<sup>-1</sup> to 220 °C for the column, and 250 °C for the inlet and detector.

### Gas Chromatography–Mass Spectrometry (GC–MS)

Fatty acids (FA) were characterized as their methyl esters and *N*-acyl pyrrolidides using gas chromatography and gas chromatography–mass spectrometry. Compounds are listed as saturated (SFA), monounsaturated (MUFA), diunsaturated (DFA), and polyunsaturated fatty acids (PUFA), and in the increasing order of chromatographic retention times

of their FAME on a DB1 column. Double bond positions were established by GC–MS of *N*-acyl pyrrolidides [16, 30]. GC–MS was performed on a Hewlett-Packard HP-5890 chromatograph linked to a HP-5989-A mass spectrometer (70 eV) equipped with a HP-9000/345 integrator, using a 30 m × 0.32 mm i.d. fused silica capillary column coated with DB-1 (0.25 μm phase thickness) (Palo Alto, CA). The carrier gas was He. The column temperature was programmed from 170 °C (4 min hold) to 300 °C at 3 °C min<sup>-1</sup> for methyl esters, and from 200 °C (4 min hold) to 310 °C for *N*-acyl pyrrolidides.

### Statistic Analysis

Statistical analysis of the data has been made as described in our previous paper [16]. Fifty-four samples were taken into account, i.e. three species, three years, three parts (gonad, muscle and liver), male and female. Fish specimens have been obtained for 4 months (November, December, January and February) including three replicates for each collect.

## Results

The livers of the three rays contained high amounts of lipids (30–50%) except female *R. marginata* with 16.2% (relative percentage of whole fresh organ), lipid contents were up to 1.7% for muscle and up to 5.4% for gonad [16]. Tables 1, 2 and 3 provide the FA profiles of muscle, liver and gonads of the three rays (male and female), respectively.

Analysis of the FA compositions from different organs of the rays revealed similarities and significant differences (Tables 1–3). The most abundant individual FA in all samples were myristic (14:0), palmitic (16:0), stearic (18:0), palmitoleic (16:1n-7), oleic (18:1n-9), vaccenic (18:1n-7), ARA, EPA, DHA and DPA. Odd numbered saturated and monounsaturated C<sub>15</sub> and C<sub>17</sub> FA are present in all samples and included *iso*-pentadecanoic, *iso*-heptadecanoic and *anteiso*-heptadecanoic acids.

### Saturated Fatty Acids (SFA)

SFA ranged from tetradecanoic to docosanoic acid in almost all the samples analysed. Palmitic (14.1–34.9% of total FA) and stearic (3.6–25.0%) were generally the most abundant saturated FA. Myristic acid was found at high level in gonads of *D. marmorata* (male and female, up to 19%), and *R. cemiculus* (female, 12%). 4,8,12-Trimethyltridecanoic acid, often present in marine organisms and known to originate from the degradation of the phytol in plants, was found in all samples at low amounts (0.05–2.54%) except in *D. marmorata* (3.7–4.6%).

### Monounsaturated Fatty Acids (MUFA)

Twenty MUFA were found in the samples. Several isomers were identified for each of the monoenoic 16:1, 17:1, 18:1, 20:1 and 22:1 FA by analysis of their pyrrolidide derivatives, whose mass spectra displayed the expected corresponding molecular ion, and a corresponding gap of 12 amu, instead of the usual gap of 14 amu, indicating the location of the double bond [16, 30]. Thus, the acids 16:1n-6, 16:1n-7, 16:1n-8 and 16:1n-10 were readily identified from their GC mobilities, a molecular ion peak at  $m/z$  307 and gaps of 12 amu instead of 14 amu between respectively,  $m/z$  210 and 222,  $m/z$  196 and 208,  $m/z$  182 and 194,  $m/z$  154 and 166. Palmitoleic acid 16:1n-7 (1.9–11.6%), oleic acid 18:1n-9 (3.8–11.3%), and vaccenic acid 18:1n-7 (0.5–7.3%) were the dominant MUFA identified. Other unusual FA such as 20:1n-10 and 22:1n-14 were identified with the same procedure. Palmitoleic acid was found at high levels in the liver of *D. marmorata* (up to 12%) and *R. cemiculus* (up to 9%), and to a lesser extent in the gonads of *D. marmorata* (up to 9%). Oleic acid was found at high levels in gonads of *R. cemiculus* (male and female, up to 11%), and in male *R. marginata* (about 10% vs. 4% for the female specimens). Several 22:1 isomers occurred, including the unusual 22:1n-14 and 22:1n-15 acids. The latter FA were found as a trace level except for the gonads of *R. cemiculus* (up to 1.7% for the males).

### Diunsaturated Fatty Acids (DUFA)

Seven DUFA were identified as pyrrolidides by GC–MS. Two methylene-interrupted FA occurred, namely linoleic acid 18:2n-6, and the rare 20:2n-8 (or 20:2  $\Delta$ 9,12). Linoleic acid (18:2n-6) was present in all liver and muscle of the three rays, while the eicosadienoic acid (20:2n-8) occurred only in female gonads of the three rays at very low levels. Mass spectra of these FA displayed the molecular ion at  $m/z$  333 and 361, respectively, and gaps of 12 amu between

$m/z$  196 and 208, and between  $m/z$  236 and 248, confirming the location of the double bonds between C-9 and C-10, and between C-12 and C-13, respectively.

The other DUFA identified in the FA mixtures were non-methylene-interrupted dienoic FA (NMID FA) as determined by mass spectrometry of their pyrrolidide derivatives and their GC mobility.

The already known 20:2  $\Delta$ 7,13, 20:2  $\Delta$ 7,15, 22:2  $\Delta$ 7,13 and 22:2  $\Delta$ 7,15 FA were identified as pyrrolidide derivatives from their mass spectra (Table 4). The ECL values found for the 22:2 NMID FA (GC phase: Carbowax 20 M) were similar to those reported on similar polar phases, e.g. 22.47 for 22:2  $\Delta$ 7,13, and 22.50 for 22:2  $\Delta$ 7,15 [31], and 22.44 for 22:2  $\Delta$ 7,15 [32] (Table 4).

An additional 22:2 NMID FA was identified from the mass spectrum of its pyrrolidide (Fig. 1). This mass spectrum displayed an abundant molecular ion at  $m/z$  389 (22:2 acid structure). The locations of the double bonds were established as  $\Delta$ 6 and  $\Delta$ 14, with the spectrum showing two gaps of 12 amu between the fragment ions at  $m/z$  154 and 166, and at  $m/z$  264 and 276, respectively (Table 4, Fig. 1). Thus, the novel NMI FA was 6,14-docosadienoic acid.

### Polyunsaturated Fatty Acids (PUFA)

All the PUFA present in all specimens belonged to the n-3 and n-6 series, except 16:3n-4 (Tables 1, 2, 3). All PUFA were identified as their pyrrolidide derivatives, whose mass spectra displayed the corresponding molecular ions, and the expected gaps of 12 amu the series of homologous fragment ions.

As examples, pyrrolidides of the 16:3n-4 and 18:3n-6 acids displayed molecular ions at  $m/z$  303 and 331, respectively, and the same gaps of 12 amu between  $m/z$  154 and 166 ( $\Delta$ 9), between  $m/z$  194 and 206 ( $\Delta$ 9), and between  $m/z$  234 and 246 ( $\Delta$ 12). In addition, GC mobilities of these derivatives were in good concordance with the standard FA structures.

DHA was the major PUFA, especially in the muscle of *R. marginata*, occurring at 18.7% (males) and at 20.0% (females). It should be noted that DHA was also present at high levels in liver (13.4% in of *D. marmorata*, male, and 13.1 and 13.2% in of *R. cemiculus*, male and female, respectively), and gonad (11.6–13.9% in gonads of *R. cemiculus*). ARA was the second most abundant PUFA, accounting for 5.5–8.0% in muscle of the rays, 5.1–7.8% in the liver, and 5.1–8.6% in the gonad. EPA occurred at levels of 2.2–5.3% in muscle, of 1.9–5.0% in liver, and of 3.0–4.9% in gonad. DPA was identified in all samples (up to 7.2%) with the exception for the male muscles of the three rays.

## Discussion

The percentages of n-3 PUFA found in the three rays were similar to those in fish used commercially as sources of PUFA and may be useful in the diet of local populations, including EPA, DHA and DPA [16]. This study shows that muscle of the rays contain high levels of DHA ranged from 10 to 20% of the total FA, with the exception for the males of *R. marginata* (3.74%). Thus, muscle seems suitable for consumption, and may provide an important amount of DHA as compared to the commercial fish oil [9, 10]. Furthermore, this study demonstrates that usually discarded parts of the rays, such as liver and gonad, contain high levels of lipid and of PUFA of current interest, e.g. EPA and DHA. DPA occurred in some FA mixtures analyzed and it could be noted that it is known to can be easily retroconverted to EPA [33]. The isomeric DPA and 22:5n-6 occurred only in muscle of females for the three rays. Livers of rays represent a relatively small part of the body but contain a considerable amount of lipids [20, 21], and they also contain high proportions of DHA except in the case of males of *R. marginata*. 16:3n-4 and 22:4n-6

occurred only in gonads of females suggesting a possible specific biological role. Occurrence of branched saturated and unsaturated C<sub>15</sub> and C<sub>17</sub> FA in the samples suggest a possible contribution of bacteria [34–36].

One of the most striking result of the present study is the finding of several NMID FA. Four previously known NMID FA were found in the selected tissues of the rays, namely 20:2  $\Delta$ 7,13, 20:2  $\Delta$ 7,15, 22:2  $\Delta$ 7,13 and 22:2  $\Delta$ 7,15 acids. The new 22:2  $\Delta$ 6,14 acid occurred as a minor component except in the muscle of male *R. cemiculus* (2.95%). The NMID were observed in all samples, and it is the first time that such FA are known to occur in rays. 20:2  $\Delta$ 7,13 was not present in the rays except as a trace level in muscle and liver of *R. marginata*. 20:2  $\Delta$ 7,15 was present in all FA mixtures except in female gonads of the three rays. 22:2  $\Delta$ 7,13 was identified in all FA mixtures, and it is the same for 22:2  $\Delta$ 7,15 except in male livers of the three rays.

NMID FA such as 20:2  $\Delta$ 5,11, 20:2  $\Delta$ 5,13 were not detected in any samples by means of a accurate GC–MS analysis of the corresponding expected area, even as trace amounts.

NMID FA are even quite rare in fish [42], although they are well known in other marine organisms [31, 32, 37–56]. They are widely represented in sponges, albeit with a high number of carbon atoms including dienoic and trienoic FA with the  $\Delta$ 5,9 unsaturation pattern [31, 32, 37–40]. In addition to these typical bis-methylene-interrupted 5,9-unsaturated FA, some sponges also contained FA such as 20:2  $\Delta$ 5,11, 20:2  $\Delta$ 5,13, 20:2  $\Delta$ 7,13, 22:2  $\Delta$ 7,13 and 22:2  $\Delta$ 7,15 [31, 32]. These last FA were also reported mainly from molluscs and other invertebrates [41–56]. Marine invertebrates in the Bivalvia and Gastropoda groups usually contain NMID FA in large amounts [50]. Marine bivalve molluscs were shown to have active FA elongation and desaturation systems and to be able to synthesize the acids 22:2  $\Delta$ 7,13 and 22:2  $\Delta$ 7,15 from acetate de novo [51, 52].

A recent study reported on fatty acid composition of some tissues from the deep-sea hydrothermal vent tube-worm *Riftia pachyptila*, including 20:2 and 22:2 NMID at high levels (up to 13% of total FA) and from other vent organisms [55, 56]. These deep-sea organisms are now well known to contain chemosynthetic microbes such as sulphur-oxidising bacteria. Recently, GC–MS characterization of FA from marine aerobic anoxygenic phototrophic bacteria showed, high amounts of the very unusual octadeca-5,11-dienoic acid present in 9 of the 12 strains analyzed [57].

Rays usually have been thought to obtain nutrition solely from ingestion of photosynthetically-derived plant material, but it is now known that rays primarily feed on benthic invertebrates (molluscs, crustaceans, worms), and occasionally smaller fish [58–61].

However, the preferred prey varies with the species: in Rhinobatidae, *Rhinobatos cemiculus* feed on various benthic organisms including sponges, mollusks and crustaceans, but they also eat small fishes [62–64] but *Rhinobatos percellens* prefers crustaceans [64]. Rhinopteridae eat bottom-living mollusks, crustaceans and fishes [63] but *Rhinoptera marginata* is known to prefer mollusks with hard shells, mainly bivalves, and large crustaceans [63]. Dasyatidae feed on benthic invertebrates: bivalves, crustaceans and worms but they also eat teleosts [65]. Some rays crush their prey between their blunt teeth. Thus, the stingray (*Dasyatis*) is known to be an active hunter that finds its food supply among invertebrates, small crustaceans and molluscs [65]. Thus, it appears that the three species of fish studied in the present work can feed on a great variety of items, mostly benthic invertebrates. However Rhinobatidae and Dasyatidae are also known to eat fish while these enter rarely the diet of Rhinopteridae.

Thus, the presence of NMI FA likely indicates a dietary contribution from invertebrates. As noted above, it is also possible that identified NMID FA arise from a symbiotic relationship of bacteria with the host cells of marine invertebrates [57].

In further studies, it will be interesting to examine which lipid classes contain these NMI-FA and to examine their specific role more precisely. Is there a distribution of NMI FA in rays dependent on taxonomic position, and the season of harvest? In addition, it would be interesting to expand the range of marine animals investigated.

**Abstract** Recent EU legislation (EC/2065/2001) requires that fish products, of wild and farmed origin, must provide consumer information that describes geographical origin and production method. The aim of the present study was to establish methods that could reliably differentiate between wild and farmed European gilthead sea bream (*Sparus aurata*). The methods that were chosen were based on chemical and stable isotopic analysis of the readily accessible lipid fraction. This study examined fatty acid profiles by capillary gas chromatography and the isotopic composition of fish oil ( $\delta^{13}\text{C}$ ,  $\delta^{18}\text{O}$ ), phospholipid choline nitrogen ( $\delta^{15}\text{N}$ ) and compound specific analysis of fatty acids ( $\delta^{13}\text{C}$ ) by isotope ratio mass spectroscopy as parameters that could reliably discriminate samples of wild and farmed sea bream. The sample set comprised of 15 farmed and 15 wild gilthead sea bream (*Sparus aurata*), obtained from Greece and Spain, respectively. Discrimination was achieved using fatty acid compositions, with linoleic acid (18:2n-6), arachidonic acid (20:4n-6), stearic acid (18:0), vaccenic acid (18:1n-7) and docosapentaenoic acid (22:5n-3) providing the highest contributions for discrimination. Principle components analysis of the data set highlighted good discrimination between wild and farmed fish. Factor 1 and 2 accounted for >70% of the variation in

the data. The variables contributing to this discrimination were: the fatty acids 14:0, 16:0, 18:0, 18:1n-9, 18:1n-7, 22:1n-11, 18:2n-6 and 22:5n-3;  $\delta^{13}\text{C}$  of the fatty acids 16:0, 18:0, 16:1n-7, 18:1n-9, 20:5n-3 and 22:6n-3; Bulk oil fraction  $\delta^{13}\text{C}$ ; glycerol/choline fraction bulk  $\delta^{13}\text{C}$ ;  $\delta^{15}\text{N}$ ; % N; % lipid.

## Introduction

The global demand for finfish and shellfish is increasing in line with the demands of increasing global populations. However, the food-grade capture fisheries have reached, or exceeded, their sustainable limits and increasingly the shortfall in supply must be met by aquaculture produce [1, 2]. While landings from capture fisheries are static, aquaculture production worldwide is increasing at around 10% per annum [2] and for this reason much more aquaculture produce is currently available to consumers. Currently, more than 30% of world seafood production is derived from aquaculture and this is likely to increase in the future [2].

Within the production chain, similar fish products can arise from different points of origin and there is consequently potential for fraud due to product mislabelling. As a result, in October 2002, the EC issued Commission regulation no. 2065/2001 to ensure that more details on labelling, packaging and traceability of fishery and aquaculture products would be available to retailers and consumers. The reason for this additional legislation is to

provide more and clearer information to retailers and consumers who are currently more aware of the food they eat and the consequences of different food production methods on nutritional quality and safety.

A number of recent reports have suggested that farmed salmon may contain higher levels of persistent organic contaminants, such as dioxins and PCBs [3], although the levels were well within the accepted range [4]. However, there is considerable evidence that suggests the benefits of eating fish, particularly oily fish, significantly outweigh any perceived risks [5, 6]. Highly unsaturated fish oils, and eicosapentaenoic acid (20:5n-3; EPA) in particular, are under clinical investigation to determine their therapeutic benefit in immunomodulated disease [7–10]. However, while the anti-inflammatory effects of EPA are well documented the functional activity of docosahexaenoic acid (22:6n-3; DHA) is also vital for normal cellular function. DHA is required for the normal growth and development of neural tissue in infants and is also essential for maintaining normal brain function in adults [11]. The importance of DHA is evidenced by the fact that over 20% of the brain dry weight is DHA and this is the most abundant fatty acid in neural tissues [12, 13]. As well as being linked with brain function, DHA deficiencies are also linked to reduced visual acuity, attention deficit hyperactivity disorder, cystic fibrosis, unipolar and bipolar depression, aggression and dysfunctions of the immune system [4, 14, 15].

In addition, the fishmeal and fish oil which have been used by the aquaculture industry as the basis of aquafeed formulations for over 30 years have reached limits of sustainable production [16] and new sustainable raw materials are now being tested and introduced in commercial aquafeeds. However, while the use of plant-derived raw materials can reduce the concentrations of organic contaminants in fish [17, 18] the concentrations of beneficial n-3 highly unsaturated fatty acids (HUFA), particularly EPA and docosahexaenoic acids (22:6n-3; DHA), are reduced as the cheaper vegetable oils likely to be used do not contain these n-3 HUFA [19]. Thus, farmed fish, cultured on diets containing lower levels of marine-derived raw materials, may have different lipid compositions compared with fish from wild capture fisheries [20, 21].

The present study examined whether farmed and wild gilthead sea bream (*Sparus aurata*) could be discriminated, in terms of their production origin, using a range of analytical measurements that have the potential to discriminate source terms, on flesh samples including fatty acid composition,  $\delta^{13}\text{C}$  of individual fatty acids,  $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$  of total flesh oil and  $\delta^{15}\text{N}$  of the choline fraction of phospholipid.

## Methods

### Samples

Farmed sea bream from Greece were supplied by Bernard Corrigan Ltd, Glasgow. Samples of wild sea bream were caught by gill net in the Bay of Cadiz in Spain and were supplied by Prof. Gabriel Mourente of the University of Cadiz. Details of the fish analysed in this survey are given in Table 1.

### Sample Preparation and Extraction of Lipids

The compositional and isotopic analyses were performed on the oil fraction obtained from sea bream flesh after evisceration using 0.88% KCl, filtration and extraction using isohexane:isopropanol (3:2 v/v). The lipid content (% lipid) was determined by the weight of oil extracted from a known weight of fish flesh. The flesh oil fraction was used to determine stable isotope ratios for  $^{18}\text{O}/^{16}\text{O}$  and  $^{13}\text{C}/^{12}\text{C}$  by elemental analyser-pyrolysis-isotope ratio mass spectrometry (EA-Py-IRMS) and elemental analyser-combustion-isotope ratio mass spectrometry (EA-IRMS [22]), respectively.  $^{15}\text{N}/^{14}\text{N}$  was determined on a concentrated glycerol/choline fraction by EA-IRMS. The glycerol/choline fraction was prepared by mixing 2–5 g of flesh oil with 50 ml of 1M KOH in ethanol followed by reflux extraction for 2 h at 100 °C. After cooling and addition of 25 ml distilled water the solution was acidified to ~pH 1 by dropwise addition of 37% (w/v) HCl. Twenty milliliter of distilled water was added to dissolve KCl salts and following four washes with 25 ml of cyclohexane the aqueous phase was dried by rotary evaporation at 50 °C. The resulting glycerol/choline was dissolved in 30 ml ethanol, filtered and washed with small amounts of ethanol and dried first by rotary evaporation and then for 1 h at 70 °C under vacuum. The sample was further dried under a stream of nitrogen for 1 h before the weight of the glycerol/choline fraction was determined. A portion of the oil fraction was saponified and the free fatty acids transmethylated to produce fatty acid methyl esters (FAMES),

which were analysed for fatty acid content by GC and  $^{13}\text{C}$  abundance by GC combustion IRMS (GC-C-IRMS).

#### Fatty Acid Analysis by GC

Fatty acid methyl esters (FAMES) were prepared from a small quantity (50–100 mg) of the dried flesh oil by alkali-catalysed transmethylation. Briefly, the oil was placed in a test tube with 2 ml of iso-hexane and 0.2 ml of 2M KOH in methanol. After shaking for 2 min the tube was centrifuged for 5 min at 1,000×g. One milliliter of the upper phase was removed and made to 10 ml with methanol in a volumetric flask. One milliliter of this diluted solution was mixed with 4  $\mu\text{L}$  of 200 g/mL butylated hydroxytoluene (internal standard) in iso-hexane in a GC vial. The sample was then ready for injection on the GC. FAMES were separated and quantified by gas chromatography (GC) in the presence of an internal standard. Separation of fatty acids and detection by flame ionisation detection (FID) was developed to quantify the composition of FAME in the fish lipid extracts on a percentage weight basis. FAMES were separated and quantified by GC using a Thermo Finnigan Trace 2000 GC (Thermoquest, Hemel Hempstead, UK) equipped with a fused silica capillary column (Chrompack CPWAX52CB, 30 m  $\times$  0.32  $\mu\text{m}$   $\times$  0.25 mm i.d.; Chrompak, London, UK) using hydrogen as carrier gas (2.0 ml/min constant flow mode) and detected by FID at 250 °C. The GC temperature program was: initial temperature: 50 °C, ramp 1: 40 °C/min to 150 °C, ramp 2: 2 °C/min to 225 °C, hold for 5 min at 225 °C. Cold on column injection was used (1  $\mu\text{L}$  of 1 mg/mL in iso-hexane). Thirteen peaks, identified as contributing to >95% of the FAME weight, were used. These were: 14:0, 16:0, 16:1, 18:0, 18:1n-7, 18:1n-9, 18:2n-6, 20:1n-9, 20:4n-6, 20:5n-3, 22:1n-11, 22:5n-3 and 22:6n-3. The identification was carried out in comparison to a standard solution composed of 12 of the above FAME (without 20:4n-6) in equal weights. The standard solution was a custom preparation from Supelco Inc. (Bellafonte, PA, USA).

#### Bulk IRMS Analysis of Fish Lipid Components

Isotope ratios ( $^{13}\text{C}/^{12}\text{C}$ ,  $^{18}\text{O}/^{16}\text{O}$ ,  $^{15}\text{N}/^{14}\text{N}$ ) determined by IRMS are expressed on a relative scale as the deviation, referred to in delta ( $\delta$ ) units with the notation ‰, parts per thousand or per mil with respect to the isotope ratio content of an international standard,  $R_{\text{std}}$ . The primary references standards are VSMOW (Vienna—standard mean ocean water) for  $\delta^{18}\text{O}$ ‰, PDB (Pee Dee Belemnite, a calcium carbonate) for  $\delta^{13}\text{C}$ ‰, and air for  $\delta^{15}\text{N}$ ‰. These international standards, or secondary standards calibrated against the primary standards, are produced and certified by the International Atomic Energy Agency (IAEA) in Vienna.

This  $\delta$  notation is routinely used by laboratories working in food and beverage authenticity using isotopic measurements by IRMS. The deviation of a measured isotope ratio from the ratio of a calibrated standard is given by

$$\delta_i [\text{‰}] = \left[ \frac{R_i}{R_{\text{std}}} - 1 \right] \times 1000$$

where  $R_i = ^{13}\text{C}/^{12}\text{C}$ ,  $^{18}\text{O}/^{16}\text{O}$ , or  $^{15}\text{N}/^{14}\text{N}$

Fish oil ( $\delta^{13}\text{C}$  and  $\delta^{18}\text{O}$ ), glycerol/choline ( $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$ ) and free fatty acids ( $\delta^{13}\text{C}$ ), produced from the oil fraction were analysed for their isotopic fingerprint.  $\delta^{13}\text{C}$  and  $\delta^{15}\text{N}$  provide information on the diet of the fish and the  $\delta^{18}\text{O}$  affords information on the geographical environment of the fish.

#### $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ Determinations

$\delta^{13}\text{C}$  (‰) and  $\delta^{15}\text{N}$  (‰) were measured separately using an elemental analyser (Carlo Erba 1500 N) coupled to an isotope ratio mass spectrometer (IRMSr; ThermoFinnigan, TracerMAT). Samples were weighed into tin capsules (4  $\times$  8 mm; Elemental Microanalysis, Okehampton, UK) and these were dropped automatically into the ‘‘hot-zone’’ of the reactor where they were oxidised at a temperature of 1,060 °C in a quartz reactor. The combustion gases ( $\text{CO}_2$ ,  $\text{H}_2\text{O}$ ,  $\text{NO}_x$ ) were swept by a flow of helium carrier gas through a bed of chromium oxide and silvered cobalt oxide granules. Nitrogen oxides were reduced to  $\text{N}_2$  over a bed of reduced copper wires, held at 650 °C and water vapour was removed by a chemical trap containing magnesium perchlorate, and, for nitrogen analysis,  $\text{CO}_2$  was removed using a carbosorb trap. The combustion gases then passed through a packed GC column filled with Porapak Q to separate  $\text{N}_2$  from  $\text{CO}_2$ . A portion of the effluent was allowed to flow into the ion source of the IRMSr. For  $\delta^{13}\text{C}$  determinations, the ratio of the ions at mass to charge ratio ( $m/z$ ) 45 ( $^{13}\text{C}^{16}\text{O}^{16}\text{O}$ ) to the ions at  $m/z$  44 ( $^{12}\text{C}^{16}\text{O}^{16}\text{O}$ ) in  $\text{CO}_2$  was determined (including correction for the contribution of  $^{17}\text{O}$  at  $m/z$  45; the Craig correction [23]) by comparison with a calibrated reference of known  $\delta^{13}\text{C}$  value. The working standard used was menhaden oil ( $\delta^{13}\text{C} = -24.96$ ‰; Sigma-Aldrich, Poole, UK), which was span-calibrated against international reference materials IAEA CH6 and CH7 [24].

For  $\delta^{15}\text{N}$  determinations the ratio of the ions at  $m/z$  29 ( $^{15}\text{N}^{14}\text{N}$ ) to the ions at  $m/z$  28 ( $^{14}\text{N}^{14}\text{N}$ ) in  $\text{N}_2$  was determined by comparison with a calibrated reference of known  $\delta^{15}\text{N}$  value. The working standard used was ammonium sulphate ( $\delta^{15}\text{N} = -0.86$ ‰; BDH, UK), which had been span calibrated against the international reference materials IAEA N1 and N2 [24]. The nitrogen content of the sample (% N) was determined by weighing the samples when

dispensed into tin capsules and relating the absolute amount of nitrogen (calculated from the nitrogen peak area relative to the ammonium sulphate standard of known nitrogen content) to the amount of sample.

### $\delta^{18}\text{O}$ IRMS Determinations

Samples were weighed into silver capsules ( $4 \times 6$  mm; Elemental Microanalysis, Okehampton, UK) and these are dropped automatically into the “hot-zone” of the reactor where they were pyrolysed at a temperature of  $1,080^\circ\text{C}$  in a quartz reactor (Carlo Erba, 1500N). The pyrolysis gases ( $\text{CO}$ ,  $\text{H}_2$ ,  $\text{N}_2$ ) were swept by a flow of helium carrier gas through a bed of nickelised carbon grit (50% nickel). The pyrolysis gases then passed through a carbosorb/magnesium perchlorate trap to remove traces of  $\text{CO}_2$  and water respectively and thereafter through a packed  $50\text{ cm} \times 6\text{ mm}$  ID GC column filled with molecular sieves of  $5\text{ \AA}$  held at  $30^\circ\text{C}$  to separate  $\text{H}_2$ ,  $\text{N}_2$ , and  $\text{CO}$ . A portion of the effluent was allowed to flow into the ion source of the IRMSr (ThermoFinnigan, TracerMAT) and the  $^{18}\text{O}/^{16}\text{O}$  ratio of  $\text{CO}$  was used to determine  $\delta^{18}\text{O}$ .  $\text{N}_2$  was clearly resolved from  $\text{CO}$ .

The ratio of the ions at  $m/z$  30 ( $^{12}\text{C}^{18}\text{O}$ ) to the ions at  $m/z$  28 ( $^{12}\text{C}^{16}\text{O}$ ) was determined by comparison with a calibrated working standard (menhaden oil,  $\delta^{18}\text{O}$  16.85‰ vs. VSMOW) which had been calibrated against a secondary international standard (IAEA CH6,  $\delta^{18}\text{O}$  36.4 vs. VSMOW). Preliminary work revealed a strong matrix specific effect which resulted in drift of the measured  $\delta^{18}\text{O}$  values throughout the analytical cycle, which was not apparent and could not be easily corrected for when using a carbohydrate standard (glucose  $\delta^{18}\text{O}$ , 29.32‰ vs. VSMOW). The use of a matrix standard allowed correction for this drift in addition to the normal drift correction, specific to the IRMSr. Samples were drift and linearity corrected against laboratory standards that were interspersed throughout the analytical cycle [25].

### $\delta^{13}\text{C}$ (‰) GC-C-IRMS Determinations of Individual Fatty Acids

FAMES were analysed by GC-C-IRMS to derive  $\delta^{13}\text{C}$  of the free fatty acids. Briefly, this technique uses gas chromatography to separate individual analytes in a continuous stream of helium, which passes through a combustion interface (to convert all analyte carbon to  $\text{CO}_2$ ) and subsequent analysis of ions  $m/z$  44, 45 and 46 in an IRMSr. Samples were analysed on an Isochrom III GC-C-IRMS system (GV Instruments, Manchester, UK). Briefly, the instrument consisted of an Agilent 6890 gas chromatograph coupled to an isotope ratio mass spectrometer, through a combustion interface. The gas chromatograph was

operated in splitless injection mode and was installed with a capillary column (Zebron ZB-Wax,  $30\text{ m} \times 0.32\text{ }\mu\text{m} \times 0.25\text{ mm}$  i.d.; Phenomenex, UK) to effect analyte separation. The injector temperature was  $250^\circ\text{C}$  and the carrier gas (helium) was controlled to maintain a constant column flow of  $2\text{ ml/min}$ . The GC operating conditions were as follows: initial temperature of  $80^\circ\text{C}$  held for  $4\text{ min}$ , ramp  $7.5^\circ\text{C/min}$  to  $150^\circ\text{C}$ , ramp  $2^\circ\text{C/min}$  to  $225^\circ\text{C}$ , hold  $5\text{ min}$ . The column flow was directed to a FID, via the heart-split valve (a pressure balanced micro-needle valve for directing column flow to either FID or IRMS), until the bulk of the solvent peak had eluted. The heart-split valve was closed to direct the column flow through the combustion interface, held at  $350^\circ\text{C}$ , and through the combustion furnace. The combustion furnace was made of similar materials as the oxidative furnace for bulk  $^{13}\text{C}$  analysis but of  $0.5\text{ mm}$  bore. It was held at  $800^\circ\text{C}$ . Downstream from the combustion furnace was the open split, where a portion of the gas stream was allowed to enter the IRMSr capillary. A cryogenic trap was operated ( $-100^\circ\text{C}$ , liquid  $\text{N}_2$ ), between the open split and the IRMS, to remove water from the carrier stream. The IRMS continuously monitored ions of  $m/z$  44, 45 and 46 and the proprietary software (Isochrom, GV instruments, UK) was used to integrate the major and minor peak areas with appropriate corrections for background and isotopic shift.

An internal standard [pentadecanoic acid (C15:0); Sigma-Aldrich, Poole, Dorset] was used as both chemical and isotopic standard. A portion of the standard was derivatised using acid catalysed transmethylation and the free fatty acid (FFA) and FAME form were analysed by bulk EA-IRMS (Costech EA—ThermoFinnigan, Delta XP) to determine  $\delta^{13}\text{C}$  and from the data,  $\delta^{13}\text{C}$  of the methyl carbon added by derivatisation by mass balance. Span calibration [24] against the international standards IAEA CH6 and IAEA CH7 resulted in  $\delta^{13}\text{C}$  FFA =  $-34.3\text{‰}$  and  $\delta^{13}\text{C}$  FAME =  $-34.94\text{‰}$  producing a derived  $\delta^{13}\text{C}$  =  $-44.53\text{‰}$  for methanol used in derivatisation. The methanol used for this calibration was also the same methanol used in all transmethylation reactions. Ten microliter of  $20\text{ mM}$  internal standard in isooctane were added to each  $100\text{ }\mu\text{L}$  of sample and samples were diluted to attain  $1\text{ mg FAME/mL}$  solvent.  $0.5\text{ }\mu\text{L}$  of analyte mix was injected, equivalent to  $200\text{ pMol}$  of C15:0 on column. Over a mean area ratio range of sample to internal standard of  $1.1\text{--}0.4$  (max  $1.62$ , min  $0.22$ ), a precision of  $0.3\text{‰}$  was attained ( $n = 12$ ). Over the area ratio range  $0.3\text{--}0.1$  (max  $0.4$ , min  $0.1$ ), a precision of  $1.2\text{‰}$  was attained. In practice, peaks with an area ratio of  $<0.2$  were not reliably quantifiable in terms of peak area and therefore in terms of isotopic composition. Samples were linearity corrected as previously described [25].

Statistical analysis: parameters were analysed by ANOVA with post-hoc analysis to determine parameters of

significant difference between wild and farmed sea bream. Principal components were conducted using the XLSTAT add-in for Microsoft Excel (Addinsoft France, Paris, France).

## Results

Wild sea bream had a significantly lower lipid content than farmed sea bream ( $P < 0.01$ ) with a concomitant higher nitrogen content in wild sea bream compared with farmed sea bream ( $P < 0.01$ ). A bivariate plot of the compositional data yielded discrimination simply on lipid and nitrogen content (Fig. 1). In terms of the fatty acid profiles, farmed sea bream contained significantly more 14:0, 16:1n-7, 20:1n-9, 22:1n-11, 18:2n-6, 20:5n-3 and 22:6n-3 but significantly less 16:0, 18:0, 18:1n-9, 18:1n-7 and 20:4n-6 compared with wild sea bream (Table 2). Wild sea bream contained significantly higher levels of 20:4n-6 and significantly lower levels of 18:2n-6 compared with their farmed counterparts. In addition, the wild fish contained higher 16:0 and 18:1n-9. The isotopic data showed that free fatty acid  $\delta^{13}\text{C}$  exhibited significant differences in  $\delta^{13}\text{C}$  values in 16:0, 18:0, 16:1n-7, 18:1n-9 and 18:1n-7 between farmed and wild sea bream (Fig. 2). Bulk  $\delta^{13}\text{C}$  analysis of the total oil fraction (Fig. 3) and glycerol/choline fraction (Fig. 4) yielded highly significant differences with farmed fish lighter than wild fish. Significant differences were also observed in the nitrogen content (Fig. 5) and  $\delta^{15}\text{N}$  (Fig. 6) of farmed versus wild sea bream. Analysis of  $\delta^{18}\text{O}$  from total oil extracted from flesh lipid of sea bream exhibited significant differences between farmed and wild sea bream (Fig. 7).

Principal components analysis (PCA) was used to examine the multivariate structure of the bream data set. Table 3 demonstrates that the first two factors account for over 70% of the variability within the data, with Table 4 indicating the contribution of the variables to the selected

factors. Plots of Factor 1 versus Factors 2, 3 and 4 all demonstrate clear separation of wild and farmed bream with factor 1 providing greatest discrimination (Fig. 8).

## Discussion

Recent EU legislation has dictated that the production origin of food must be clearly and verifiably defined for the consumer. The increase in aquaculture production to meet consumer demand for finfish has resulted in a number of farmed species entering the marketplace in the last decade. This includes gilthead sea bream (*Sparus aurata*). Gilthead sea bream were first cultured in Italy in 1970. Production has grown steadily over the past two decades with 2004 production reaching 91,000 metric tonnes with Greece, Turkey and Spain being the major producers [2]. The temptation to label farmed fish as wild fish by unscrupulous fish merchants, retailers and restaurateurs is significant because of the price premium commanded by wild fish. In order to combat such mislabelling and conform with the legislation, verifiable methods of distinguishing farmed from wild fish are required for consumer confidence and for local authority enforcement purposes. This study

**Fig. 8** Principle component analysis (PCA) plot of combined chemical and isotopic data measured from farmed and wild sea bream. Factor 1 and 2 combined account for 74.4% of the variation between data sets and afford discrimination of production origin

establishes the utility of chemical and isotopic fingerprinting as robust methodologies for distinguishing the production origin of gilthead sea bream (*Sparus aurata*).

Analysis of the fatty acid composition showed marked differences in the lipid profiles and lipid content of the fish. Farmed fish contained significantly more lipid (~5-fold more lipid) as a fraction of flesh composition. This may partly be due to the larger average weight of the farmed bream, although, while larger fish generally accumulate more flesh lipid it is also the case that wild fish are generally leaner than their farmed counterparts [26, 27]. Farmed fish also exhibited a lower nitrogen content com-

pared with wild fish. The lower nitrogen content cannot be simply explained by the dilution effect of higher lipid content and probably reflects a lower phosphatidylcholine:triacylglycerol ratio in farmed fish and a higher protein content of wild fish due to greater muscle mass. The fatty acid composition reflected the dietary sources of, particularly polyunsaturated fatty acids. The n-3/n-6 ratio was higher for wild fish compared with farmed fish [4.0 (0.4) vs. 3.4 (0.1)] although there were marked differences in the n-3 and n-6 profiles between production origin reflecting dietary intake of plant-derived 18:2n-6 and marine fish oil-derived 22:6n-3 in farmed fish and marine derived 20:4n-6 in wild fish. The commercial diet formulations for sea bream utilise a range of marine and terrestrial products. The terrestrial products can include soybean, wheat, maize, sunflower, pea, lupin and rapeseed meals, which can contain a significant lipid component [28]. The plant lipid, either from the plant meals described above or added directly as vegetable oil, explains the higher levels of 18:2n-6 in the farmed bream flesh compared to wild fish [29]. Wild fish also contained higher 16:0, 18:1n-9 and 20:4n-6 and evidence suggests that bream that tend to feed in inshore and estuarine waters often have fatty acid compositions that reflect the dietary fauna from those areas, whereas aquafeeds contain fish products obtained from the open oceans, which are quite different in their fatty acid compositions [30, 31].

Bulk  $\delta^{13}\text{C}$  analysis of the total oil fraction and glycerol/choline fraction yielded highly significant differences with farmed fish isotopically lighter than wild fish reflecting the lighter  $^{13}\text{C}$  content of farmed fish diets, probably containing significant terrestrial carbon input from vegetable meals and oils, as also evidenced by their fatty acid compositions as described above. Marine fish diets are isotopically heavier due to the source of carbon (dissolved inorganic carbon pool,  $\delta^{13}\text{C} \sim 0\text{‰}$ ) used by macroalgae and phytoplankton, which form the lower trophic levels of the marine food web, compared with terrestrial photosynthesis from atmospheric  $\text{CO}_2$  ( $\delta^{13}\text{C} \sim -7.8\text{‰}$ ). Furthermore, marine vertebrates, through their trophic sequestration of zooplankton and Crustacea, further enrich the isotopic signature to produce heavier  $\delta^{13}\text{C}$  values. The source of dietary lipids in farmed feed reflects a significant terrestrial signature of plant oils and appears largely to be of C3 origin, the photosynthetic pathway used by temperate plants, such as cereals likely to be used in aquaculture feeds [32].

The compound specific data highlight differences in the carbon isotope signatures of the major fatty acids between wild and farmed species. Whatever the route to C16:0 in wild fish, dietary or de novo synthesis, the source will be heavier than farmed fish, which will have a significant dietary input of C16:0 from terrestrial plant origin. The desaturation of the major saturated fatty acids appears to

reflect dietary origin of the saturated fatty acid. Significant differences were observed with the most abundant fatty acids probably reflecting the increased precision of analysis of the major analytes. Lower abundance analytes have poorer precision of analysis because they suffer to a greater proportion from baseline perturbations and present less  $\text{CO}_2$  to the ion source, which has a significant effect on precision. The choice of the internal standard method for quantitation ensured that accuracy was maintained (against an externally calibrated isotopic standard) and furthermore allowed the quantitation of analyte concentration because of the excellent area ratio response of the IRMSr to  $\text{CO}_2$  concentration [33]. This approach would not have been possible using the reference gas configuration, as is commonly used in GC-C-IRMS, and thus the analysis of compound specific fatty acid analysis also yields the fatty acid composition of the sample. Further analysis allows accurate reconstruction of the bulk  $\delta^{13}\text{C}$  value using mass balance equations (data not shown). Thus, the utility of compound specific analysis is clear, yielding fatty acid composition, individual fatty acid  $\delta^{13}\text{C}$  and bulk  $\delta^{13}\text{C}$ .

The expectation that wild fish are isotopically heavier than their farmed counterparts was observed in  $\delta^{15}\text{N}$ . This heavier signal reflects the higher trophic level of wild sea bream within marine food webs and, for farmed fish,  $\delta^{15}\text{N}$  reflects probably significant input of plant protein from terrestrial sources that are commonly included in aquafeed formulations [28]. However, extrapolating these observations across species should be undertaken with care because  $\delta^{15}\text{N}$  may be influenced by other factors including, maturity or growth rate, seasonal variations in  $\delta^{15}\text{N}$  in coastal marine environments and possible spoilage of the fish sample between collection and analysis. The sample fractions processed for choline analysis did not undergo a thorough 'clean-up' and may as a result be prone to contamination by spoilage amines of varying  $^{15}\text{N}$  natural abundance. The differences observed between farmed and wild sea bream  $\delta^{18}\text{O}$  may reflect the latitudinal differences in mean ocean  $\delta^{18}\text{O}$ , which will be in isotopic equilibrium with fish metabolic water and therefore may discriminate between fish caught in different geographical locations. This may have influenced the values in sea bream in the present study where farmed bream were from the Mediterranean while wild bream were from the Atlantic. Furthermore, although the geographical location of farmed fish is controlled, wild fish may migrate over large geographical regions, over the course of their life cycles, and the utility of using  $\delta^{18}\text{O}$  as a discriminatory factor between farmed and wild fish across species must be carefully considered.

These analytical methodologies provide the basis for discriminating between wild and farmed fish and have the potential to be used across species, particularly the isotopic fingerprinting of individual fatty acids. The decreasing

stocks of marine derived feedstuffs for the aquaculture industry entails that there will be an ever increasing terrestrial  $\delta^{13}\text{C}$  input to farmed fish diets, providing greater isotopic discrimination. As the industry strives to deliver a farmed product that reflects the wild product, sources and blends of terrestrial plants may be produced that mimic the fatty acid composition of wild fish more closely although the isotopic signature would still provide firm discriminatory evidence. The utility of nitrogen and oxygen isotopes, whilst useful, may be complicated by maturity, growth rate and regional variations in fish. The application of compound specific isotope analysis appears to provide robust and confirmatory data, which may be used in addition to, or in place of, simple fatty acid composition analysis. However, it is noteworthy that the present study is based on a relatively small sample set and future studies should seek to assess the usefulness of the described methods on fish samples derived from different species and geographical locations, from both the farmed and wild production sectors.

**Abstract** A 20-week feeding trial was conducted to determine whether increasing linolenic acid (18:3n-3) in vegetable oil (VO) based diets would lead to increased tissue deposition of 22:6n-3 in Nile tilapia (*Oreochromis niloticus*). Five isonitrogenous and isoenergetic diets were supplemented with 3% of either linseed oil (LO), a mixture of linseed oil with refined palm olein oil (PO) (LO–PO 2:1) and a mixture of refined palm olein oil with linseed oil (PO–LO 3:2) or with fish oil (FO) or corn oil (CO) as controls. The PO–LO, LO–PO and LO diets supplied a similar amount of 18:2n-6 (0.5% of diet by dry weight) and 0.5, 0.7 and 1.1% of 18:3n-3, respectively. Increased dietary 18:3n-3 caused commensurate increases in longer-chain n-3 PUFA and decreases in longer-chain n-6 PUFA in the muscle lipids of tilapia. However, the biosynthetic activities of fish fed the LO-based diets were not sufficient to raise the tissue concentrations of 20:5n-3, 22:5n-3 and 22:6n-3 to those of fish fed FO. The study suggests that tilapia (*O. niloticus*) has a limited capacity to synthesise 20:5n-3 and 22:6n-3 from dietary 18:3n-3. The replacement of FO in the diet of farmed tilapia with vegetable oils could therefore lower tissue concentrations of 20:5n-3 and 22:6n-3, and consequently produce an aquaculture product of lower lipid nutritional value for the consumer.

PER	Protein efficiency ratio
PO	Palm olein oil
PUFA	Polyunsaturated fatty acid
SFA	Saturated fatty acid
SGR	Specific growth rate
TL	Total lipid
VO	Vegetable oil

### Introduction

Polyunsaturated fatty acids (PUFA) are essential for normal growth, development and reproduction in all vertebrates, including fish and humans [1, 2]. The requirement is usually met by dietary linoleic acid (18:2n-6) and  $\alpha$ -linolenic acid (18:3n-3) which are then converted to the functionally essential C20 and C22 homologues, 20:4n-6, 20:5n-3 and 22:6n-3. For some species unable to perform the metabolic conversions at a sufficient rate the dietary EFA are the longer chain homologues.

The intake of n-3 PUFA, and specifically 20:5n-3 and 22:6n-3, is considered to be beneficial against many human health disorders. There is now compelling evidence from clinical and epidemiological research that increased intakes

of 20:5n-3 and 22:6n-3 are effective in the prevention or attenuation of many cardiovascular problems and inflammatory conditions [3]. The balance between dietary n-3 and n-6 PUFA is as important as the amount of PUFA and an altered n-3/n-6 ratio affects the haemostatic balance as well as the inflammatory and immune responses [4]. Today industrialised societies are characterised by an increase in energy intake, saturated fat and n-6 PUFA and a decrease in n-3 PUFA intake [5]. This has been linked with the occurrence of many health disorders, once considered a problem primarily of western societies, but rapidly becoming a major health problem in other parts of the world, including Asia [5, 6]. It is, therefore, recommended to increase the intake of n-3 PUFA, and particularly 20:5n-3 and 22:6n-3, and decrease the dietary intake of n-6 PUFA in the human diet [7].

Fish and marine mammals are by far the richest source of long chain n-3 PUFA in nature. Fish products comprise an important part of the human diet and demand is expected to increase [8]. Given static or declining wild fisheries [8], aquaculture has a significant role in ensuring fish supplies. Tilapia farming makes a large and growing contribution to global fish supplies [9]. As the farming of fish is becoming a major contributor to world fish supplies, it is important to maintain the high lipid nutritional quality of the product and continue to provide large amounts of the health-promoting n-3 PUFA for the consumer.

Freshwater fish species, generally, have higher capacities for the conversions of C18 PUFA to the longer C20 and C22 homologues than marine species, although this should not be treated as a general rule [2]. Tilapias are known to possess some ability to elongate and desaturate 18:3n-3 to 20:5n-3 and 22:6n-3 [10, 11]. Studies with salmonids have shown that the PUFA metabolic pathways are induced after removing C20 and C22 PUFA from VO-rich diets [12, 13]. Linseed oil has a high content (up to 56%) of 18:3n-3 and a much lower content of 18:2n-6 compared to other vegetable oils, so dietary LO has the potential for enhancing the n-3 content in fish flesh.

The aims of this study were: (1) to study the effects of variation in dietary n-3 and n-6 PUFA on the lipid nutritive value of tilapia (*Oreochromis niloticus*) for the human consumer and (2) to elevate the levels of elongation and desaturation products, 20:5n-3 and 22:6n-3, as well as of the n-3/n-6 PUFA ratio, in tilapia muscle tissue by feeding fish on diets high in 18:3n-3.

## Materials and Methods

### Experimental Diets

Five isonitrogenous (32% crude protein) and isoenergetic (17 KJ/g diet) diets were formulated (Table 1) to satisfy

the nutritional requirements of tilapia (*O. niloticus*). Dietary ingredients used in the five diets were identical except the natural oil or the mixture of oils used as the lipid source, which was added at a level of 3% of the total diet (by dry weight). The dietary fatty acid composition is shown in Table 2. Diets were prepared at the Charoen Pokphand Foods feed mill (Samut Sakorn, Thailand) by feed mill personnel and these were in the form of a water stable sinking pellet of 3 mm size. Portions of diet for analysis were stored at  $-20^{\circ}\text{C}$  otherwise bulk diets were stored in air-tight polyethylene bags at  $4^{\circ}\text{C}$  and used within 4 weeks. Proximate analysis of experimental diets was performed for moisture, protein, lipid, ash, crude fibre and energy according to the methods of AOAC [14].

### Experimental Fish and Culture System

Male sex-reversed tilapia fry (*O. niloticus*) of initial weight 0.5–2 g were obtained from the Asian Institute of Technology's hatchery (Pathumthani, Thailand). The fish were randomly distributed into 30 groups of 100 fry each and stocked into 30 net cages (3 m  $\times$  1.8 m  $\times$  0.8 m, 3 mm mesh size) that were suspended in an earthen pond (40 m  $\times$  40 m  $\times$  1 m). Each cage was covered with an anti-predator net (mesh size of 5 cm) and provided with a plastic feeding tray (55 cm length  $\times$  30 cm width  $\times$  25 cm height) attached and submerged to one side of the cage. Wooden walkways connected the cages to the pond bank. Water depth in the pond was maintained at 1 m throughout the experiment by adding water biweekly to replace evaporation and seepage losses. After initial stocking into the cages, fry were allowed to acclimatise for 1 day without feeding. The feeding trial was conducted for 20 weeks. Fish were bulk weighed biweekly and the daily food rations were adjusted accordingly. The daily feeding ration was divided into 4 equal portions (08.00, 11.00, 14.00, 17.00 h) until the end of the 6th week, then into 3 portions (08.00, 11.00, 16.00 h) until end of 14th week and into 2 portions (08.00, 15.00 h) thereafter. On the days of bulk weighing no feed was given as fish experienced stress. Feeding rates were 12% of body weight (b.w.) per day for the first 4 weeks, 10% of b.w. until the 6th week, 9% of b.w. until the 8th week, 6% of b.w. until the 10th week, 5% of b.w. until the 12th week, 3.5% of b.w. until the 14th week, 2.5% of b.w. until the 16th week, 2% of b.w. until the 18th week and 1% of b.w. until the end of the 20-week trial. No fertiliser was added to the experimental pond, neither prior to, nor during, the dietary trial in order to keep levels of pond natural food to a minimum and diminish their influence on dietary intake.

Values for proximate composition and energy represent means ±SD ( $n = 10$ ). Values presented for the different oils are in ml/100 g diet. All feed ingredients, mineral/vitamin premixes and oils (except linseed oil) were provided by CP Foods Plc, Bangkok, Thailand. Soybean meal is solvent extracted (defatted, 49% crude protein). Linseed oil was from ICN (Basingstoke, Hampshire, UK)

DCP dicalcium phosphate

<sup>a</sup> 1 kg of vitamin premix contained 0.26% vitamin B<sub>1</sub>, 0.31% vitamin B<sub>2</sub>, 0.1% vitamin B<sub>6</sub>, 0.24% vitamin B<sub>12</sub>, 2.86% vitamin C, 0.5% biotin, 6.67% choline, 0.26% folic acid, 2.51% nicotinic acid, 0.5% inositol, 0.1% pantothenic acid, 0.2% vitamin A, 0.1% vitamin D, 1% vitamin E, 0.59% vitamin K and 83.8% refined cassava flour

<sup>b</sup> 1 kg of mineral premix contained 10% magnesium, 6.67% potassium, 0.94% iron, 0.4% manganese, 0.2% copper, 0.1% chromium, 6.6% zinc and 75.09% refined cassava flour

### Fish Sampling

Prior to stocking, a total number of 20 fry from the initial stock were randomly sampled. After weighing, the dorsal muscle tissue of each fish was dissected, skin and blood-stains removed, and the muscle tissue frozen inside airtight clip bags at  $-20^{\circ}\text{C}$  until lipid analysis. A second sampling of the experimental fish was made on day 32 when the fish had reached a size of around 15 g. A total of six fish randomly selected from each cage (30 fish in total per treatment) were killed by a blow to the head and transferred straight to the laboratory for muscle tissue dissection as before. At the end of the 20-week feeding period a final sampling was made again of six fish from each cage.

### Water Quality

Water quality analysis was conducted biweekly by taking integrated water column samples at 10.00 h from three

points of the open water and three cages randomly chosen. Samples were also taken before the start of the experiment (day 0). Water samples were analysed for total ammonium nitrogen (TAN), total alkalinity, chlorophyll  $\alpha$ , total suspended solids (TSS) and total volatile solids (TVS) using standard methods [15]. Dissolved oxygen (DO), temperature and pH were measured at three different depths (25 cm below the water surface, middle, and 25 cm above pond bottom) at 06.00, 10.00, 14.00 and 18.00 h using a YSI model 54 oxygen meter (Yellow Springs Instruments, Yellow Springs, OH, USA) and a Hanna model HI8424 pH meter (Hanna Instruments, Rhode Island, USA), respectively. At the time of collecting water samples, Secchi disk visibility was measured in open water.

### Chemicals and Materials

Chloroform, methanol, iso-hexane and diethyl ether were HPLC grade from Fisher (Loughborough, Leicestershire,

UK). Concentrated sulphuric acid (Aristar grade) and Merck silica gel 60 thin layer chromatography (TLC) plates (no. 5721) and high performance TLC (HPTLC) plates (no. 5633) were obtained from VWR (Lutterworth, Leicestershire, UK). All other chemicals were from Sigma (Poole, Dorset, UK).

#### Lipid Extraction and Fatty Acid Analysis

The total lipid from wet muscle tissue and from diets was extracted and measured gravimetrically according to the method of Folch et al. [16]. Wet muscle samples and diets were homogenised in chloroform/methanol (C:M 2:1, by

vol.) using an Ultra-Turrax tissue disrupter (Fisher Scientific, Loughborough, UK). The homogenates were filtered and a Folch extract prepared. Samples were kept on ice under nitrogen between procedures and lipid extracts stored in C:M (2:1, by vol.) at a final concentration of 10 mg lipid/ml at  $-20\text{ }^{\circ}\text{C}$  under nitrogen. Solvents contained 0.01% (w/v) butylated hydroxy-toluene (BHT) as an antioxidant.

Lipid class analysis was performed using double development HPTLC as described by Olsen and Henderson [17]. Samples were chromatographed in methyl acetate: propan-2-ol: chloroform: methanol: 0.25% (w/v) KCl (25:25:25:10:9, by vol.) to separate phospholipid classes and iso-hexane: diethyl ether: glacial acetic acid (80:20:2, by vol.) to separate neutral lipids and cholesterol. Lipid classes were visualised by spraying with 3% cupric acetate (w/v) in 8% phosphoric acid (by vol.) and charred at  $160\text{ }^{\circ}\text{C}$  for 15 min. Lipid classes were quantified by scanning densitometry (370 nm) using a CAMAG TLC scanner 3 (version Firmware 1.14.16) and scanned images were recorded automatically in a computer using a special software (winCATS Planar Chromatography Manager, version 1.2.0).

Fatty acid methyl esters (FAME) were prepared by acid-catalysed transesterification of 1 mg total lipid plus 0.1 mg heptadecanoic acid (Sigma Chemical Company, St. Louis, USA) as internal standard using 2 ml of 1% (by vol.) sulphuric acid in methanol and 1 ml of toluene under nitrogen at  $50\text{ }^{\circ}\text{C}$  for 16 h [18]. Crude FAME were purified by TLC in iso-hexane: diethyl ether: acetic acid (90:10:1, by vol.) and visualised by spraying lightly the edge of the plate with 1% (w/v) iodine in  $\text{CHCl}_3$ . FAME were scraped from the plate and eluted with iso-hexane: diethyl ether (1:1, by vol.). Purified FAME were re-dissolved in iso-hexane containing 0.01% BHT and stored under nitrogen at  $-20\text{ }^{\circ}\text{C}$  prior to gas liquid chromatography.

Fatty acid methyl esters were separated and quantified by gas liquid chromatography (Fisons 8000 series, Thermo-Finnegan, Hemel Hempstead, UK) using a CP Wax 52CB fused silica capillary column ( $30\text{ m} \times 0.32\text{ mm}$  i.d.,  $0.25\text{ }\mu\text{m}$  film thickness) (Chrompak, London, UK). Hydrogen was used as carrier gas at a flow rate of 2.5 ml/min and temperature programming was from  $50$  to  $150\text{ }^{\circ}\text{C}$  at  $40\text{ }^{\circ}\text{C}/\text{min}$  and from  $150$  to  $225\text{ }^{\circ}\text{C}$  at a rate of  $2\text{ }^{\circ}\text{C}/\text{min}$  and the final temperature of  $225\text{ }^{\circ}\text{C}$  was maintained for 5 min. Individual methyl esters were identified by comparison to known standards (marine fish oil) and by reference to published data. Peak areas of fatty acids were quantified with reference to the peak area of 17:0 internal standard and computed automatically by a computing integrator (Chromcard for Windows, ThermoQuest, Milan, Italy).

## Statistical Analysis

Data from individual fish were treated as independent samples. Proximate composition of the diets, growth performance and feed utilisation efficiency parameters, muscle total lipid and fatty acid composition were all subjected to one-way analysis of variance (ANOVA) and differences were considered significant at an alpha value of 0.01. Analyses were performed using SPSS statistical package (version 10.0.1, SPSS Inc., Chicago, USA). Data that were identified as non-homogeneous (using Levene's test of homogeneity) were subjected to either log or power transformation before analysis. Differences between means were determined by Tukeys' test.

Data of the water quality parameters for cages and open water were analysed statistically with independent-sample *t*-test and data from the different sampling periods were analysed with paired-sample *t*-test. Differences were considered significant at an alpha level of 0.01.

## Results

### Growth Performance

All the parameters of water quality that were monitored during the course of the study were within the ranges considered suitable for the growth and survival of tilapia (*Oreochromis niloticus*). Values of water quality parameters between the cages and open water were not significantly different, indicating the homogeneous water environment that fish were reared during the course of the study.

At the end of the 20-week experimental period, the growth performance of fish fed the different diets and the feed utilisation were evaluated using a number of parameters that are shown in Table 3. There was no significant difference among dietary treatments in any of the performance parameters examined. Fish appeared healthy at the end of the trial with survival ranging from 86.2 to 92.3% among all groups of fish, while there were a number of mortalities unrelated to diet. Weight gain and specific growth rate (SGR) were in the ranges of 170.0–186.9 g and 3.42–3.46 (%/day), respectively. However, fish fed the FO diet displayed a slightly higher weight gain, but not significantly so, compared to the other groups of fish throughout the feeding trial. Protein efficiency ratios (PER) were within the range 1.52–1.55 and food conversion ratios (FCR) within the range 2.01–2.06 among all five dietary treatments.

**Table 3** Growth performance and feed utilisation efficiency of fish

Performance parameters <sup>a</sup>	PO–LO	LO–PO	LO	FO	CO
Initial weight (g)	1.09 ± 0.08	1.13 ± 0.08	1.06 ± 0.06	1.09 ± 0.05	1.18 ± 0.06
Final weight (g)	170.0 ± 12.4	177.7 ± 14.8	174.0 ± 10.8	186.9 ± 12.0	175.9 ± 11.3
Weight gain <sup>b</sup> (g)	168.9 ± 12.4	176.5 ± 14.8	172.9 ± 10.9	185.8 ± 12.1	174.7 ± 11.3
SGR <sup>c</sup> (%/day)	3.44 ± 0.10	3.44 ± 0.08	3.43 ± 0.05	3.46 ± 0.08	3.42 ± 0.08

Survival (%)	91.5 ± 3.2	90.8 ± 1.8	86.2 ± 9.6	86.8 ± 8.8	92.3 ± 5.1

<sup>a</sup> Values for weight gain, SGR, FCR, PER and survival are the means of 6 replicate groups of 6 fish. Values for the initial fish body weight are the means of 100 fish (initial fish population), while values for the final fish body weight are the means of all individual fish within the same group that survived after the 20-week course of the study. There was no significant difference ( $\alpha = 0.01$ ) between the treatments in any of the parameters examined

<sup>b</sup> Weight gain = mean final body weight (g) – mean initial body weight (g)

<sup>c</sup> Specific growth rate (SGR, %/day) =  $100 \times [(\text{Ln}(\text{mean final body weight}) - \text{Ln}(\text{mean initial body weight})) / \text{culture period (days)}]$

<sup>d</sup> Feed conversion ratio (FCR) = total dry weight of feed given (g)/wet weight gain (g)

<sup>e</sup> Protein efficiency ratio (PER) = wet weight gain (g)/crude protein fed (g)

### Total Lipid and Lipid Class Composition

The different groups of fish contained similar total lipid contents (TL) at both time points ranging from 9.11 to 9.84 mg/g wet weight tissue at day 32 and 7.03–7.82 mg/g wet weight tissue after 20 weeks (Table 4) with no significance between time points. There was also no significant difference in lipid class composition between the five dietary treatments. Triacylglycerol and cholesterol were the major neutral lipid classes found in the muscle tissues of all groups of fish, which accounted for 23.8–26.9% and 17.2–18.4% of TL, respectively. Phosphatidylcholine (PC) and phosphatidylethanolamine (PE) were the major polar lipid classes found in the muscle tissues of all groups of fish and these were in the range of 24.7–27.6% of TL and 13.3–15.8% of TL, respectively (data not shown).

### Fatty Acid Composition of Muscle Total Lipid

The fatty acid composition of the fish at the start of the feeding trial reflected the composition of the commercial weaning diet. Palmitic acid was the major FA followed by 22:6n-3 and 18:1n-9, smaller amounts of 18:0 and 18:2n-6 with 20:4n-6, 18:1n-7, 16:1n-7, 22:5n-3 and 22:5n-6 the only other FA present at more than 10 µg/mg TL (Table 5).

The FA composition of the fish quickly reflected that of the different diets and the FA composition was similar at day 32 and at the end of the trial at 20 weeks (Tables 5, 6). Fish from the five treatments contained similar amounts of 16:0, 18:0, 20:0, 22:0 and total saturated fatty acids (SFA), both after 32 days of feeding (Table 5) and at the end of the trial (Table 7), despite the fact that the five diets supplied significantly different amounts of these FA (Table 2). The concentrations of 14:0 and 15:0, however, were significantly higher in FO-fed fish at the end of the trial, due to the much higher supply of these two FA in the FO diet.

The amounts of total monounsaturated fatty acids (MUFA) were also not significantly different between the five dietary treatments (Tables 5, 6). 18:1n-9 was the most abundant MUFA in the muscle lipids of fish fed all five diets with no differences between treatments (Tables 5, 6). However, there were significant differences in the concentration of the individual monoenes among the five dietary treatments. FO-fed fish contained significantly higher amounts of 16:1n-7 than LO-fed fish and CO-fed fish (Table 6) and also significantly higher concentrations of 18:1n-7, 22:1n-11/n-9 and 24:1n-9 than in the other four treatments. Additionally, FO-fed fish contained increased amounts of the twenty carbon MUFA (20:1n-9 + 20:1n-7). The higher concentrations of all the above MUFA in the

**Table 4** Total lipid content of muscle tissue from tilapia after 32 and 140 days on the experimental diets (mg/g wet weight tissue)

lipids of FO-fed fish reflected the higher concentrations of 18:1n-7, 20:1n-9, 20:1n-7, 22:1 and 24:1n-9 in this diet compared to the other diets (Table 2).

The amounts of the individual PUFA varied greatly between the five dietary treatments (Tables 5, 6). The CO-fed fish contained the highest amounts of all n-6 PUFA, namely 18:2n-6, 18:3n-6, 20:2n-6, 20:3n-6, 20:4n-6, 22:4n-

6 and 22:5n-6 (Tables 5, 6), despite the fact that this diet contained similar amounts of all n-6 PUFA, except 18:2n-6, to the three LO-based diets. In contrast, FO-fed fish contained the lowest amounts ( $P < 0.01$ ) of 18:2n-6, 18:3n-6, 20:2n-6 and 20:3n-6 in their muscle lipids, and significantly decreased amounts of 22:4n-6 and 22:5n-6 compared to fish fed the PO–LO and CO diets (Tables 5, 6).

**Table 6** The fatty acid compositions ( $\mu\text{g}/\text{mg}$  of total lipid) of muscle TL of the initial fish population (day 0) and of fish fed the five diets after 140 days of feeding

Values are the mean of 6 replicate groups of 6 fish ( $\pm$ SD). *ND* not detected. Values in the same row, which do not share the same superscript letter are significantly different at  $\alpha = 0.01$

However, at the end of the 20-week feeding trial, FO-fed fish had similar concentrations of 20:4n-6 to fish fed the three LO-based diets, and about half the concentration of CO-fed fish (Table 6). The amounts of all n-6 PUFA increased as the amount of dietary LO decreased. Thus, LO-fed fish contained significantly lower amounts of 20:2n-6, 20:3n-6, 22:4n-6 and 22:5n-6 compared to those found in

PO–LO-fed fish (Tables 5, 6). LO-fed fish also contained decreased amounts of 18:3n-6 and 20:4n-6 compared to fish fed the PO–LO and LO–PO diets, but these were not significantly different.

The n-3 PUFA content of the muscle lipids of fish also showed significant differences between dietary treatments. Fish fed the CO diet contained the lowest amounts

**Table 7** The percentage retention of dietary fatty acids in the tissues of fish fed the five experimental diets for 140 days

Values represent means of six cages ± SD. Percentage retention >100 indicates tissue concentration higher than the dietary supply and implies synthesis and/or high retention of the tissue reserves. Values in the same row, which do not share the same superscript letter are significantly different at  $\alpha = 0.01$

Calculation:

For each FA,

FA assimilated in fish (g) = final FA content (g) – initial FA content (g) (1)

and therefore for each group of fish reared in a hapa

Initial total FA content (g) = average initial concentration of FA (g/g muscle tissue) × initial fish biomass (g) (2)

Final total FA content (g) = average final concentration of FA (g/g muscle tissue) × final fish biomass (g) (3)

Therefore FA assimilated by total biomass of fish/hapa = Eq. (3) – Eq. (2) (4)

Feed was provided on a tray and pellets rarely remained inside the tray so only a small proportion of feed was wasted. Therefore, assuming that 90% of total feed given was eaten,

Total amount of FA eaten (g) = 0.9 × total amount of FA given (g) (5)

Where total amount of FA given = concentration of FA in diet (g/g of diet) × total feed given to that hapa (g)

% Assimilation/hapa = Eq. (4) × 100/Eq. (5)

( $P < 0.01$ ) of all n-3 PUFA, namely 18:3n-3, 18:4n-3, 20:3n-3, 20:4n-3, 20:5n-3, 22:5n-3 and 22:6n-3 (Tables 5, 6). FO-fed fish had significantly decreased amounts of 18:3n-3 compared to the three LO-based treatments

(Tables 5, 6) due to the lower concentration of 18:3n-3 in the FO diet. Also, FO-fed fish contained significantly lower amounts of 20:3n-3 and 22:4n-3 compared to the three LO-based treatments, and significantly lower amounts of

20:4n-3 compared to the LO-fed fish (Tables 5, 6), despite the fact that the FO diet supplied a higher amount of the latter FA compared to the LO-based diets (Table 2). On the other hand, FO-fed fish had the highest contents ( $P < 0.01$ ) of 20:5n-3, 22:5n-3 and 22:6n-3 in their muscle lipids, both at day 32 of the feeding period (Table 5) and at the end of the dietary trial (Table 6).

The inclusion of increasing levels of LO at the cost of PO in the basal diet resulted in significant increases in tissue 18:3n-3, 20:3n-3 and 20:4n-3 (Table 6). However, the amounts of 18:4n-3, 22:5n-3 and 22:6n-3 were not significantly different ( $P > 0.01$ ) in the muscle lipids of fish fed the three LO-based diets, though in an increasing order with the higher inclusion of LO in the diet (Table 6). The amounts of 20:5n-3 and 22:4n-3 were also in an increasing order in fish fed the PO–LO diet to fish fed the LO–PO and LO diets and the concentrations of these two FA in the LO-fed fish were significantly higher than those found in PO–LO-fed fish (Table 6).

The n-3/n-6 PUFA ratio was the highest in FO-fed fish and LO-fed fish contained a significantly higher n-3/n-6 PUFA ratio compared to fish fed the PO–LO, LO–PO and CO diets (Table 6). The lowest n-3/n-6 PUFA ratio ( $P < 0.01$ ) was found in the muscle lipids of fish fed the CO diet and reflected the lower ratio supplied by this diet (Table 2). The ratio of 20:4n-6/20:5n-3, predictive of the production of series 2 and series 3 eicosanoids, was found to be the highest ( $P < 0.01$ ) in CO-fed fish, while FO-fed fish exhibited the lowest 20:4n-6/20:5n-3 value ( $P < 0.01$ , Tables 5, 6). Fish fed the three LO-based diets had moderate 20:4n-6/20:5n-3 ratios, which were in a significantly decreasing order in PO–LO-fed fish to LO-fed (Table 6).

## Discussion

The present study suggests that linseed oil and its blends with palm olein oil could totally replace fish oil without any negative effects on the growth and feed efficiency of tilapia (*O. niloticus*), consistent with the current trend towards replacement of fish oil in fish feeds. Survival rates of fish were high and consistent between treatments, while values of SGR were relatively high, without any signs of growth cessation. The relatively high values of FCR observed could be related to overfeeding and/or to the lower digestibility caused by the high inclusion level of soybean meal.

The study was not designed to define the precise requirements of tilapia for n-6 and/or n-3 PUFA but, nevertheless, suggests that both series of PUFA may be important for maximum growth of this species. Since the FO diet provided only 0.3% (by dry weight) of dietary n-6 PUFA and led to similar growth as the CO diet that pro-

vided 1.1% of n-6 PUFA, it appears that the requirement for n-6 PUFA may be as low as 0.3% of diet by dry weight. The FO diet with the highest content of long-chain n-3 PUFA gave the highest weight gain, although not significantly so, indicating that 20:5n-3 and 22:6n-3 may also have a growth promoting effect. Furthermore, the similar growth rates among fish fed the three LO-based diets suggest that the increases in dietary 18:3n-3 (from 0.5 to 1.1%) are not associated with depressed growth as reported in previous studies [19].

The TL content of the muscle tissue was not significantly affected by the different dietary treatments suggesting that the different oils did not have any significant effect upon muscle tissue adiposity, in agreement with previous studies (e.g. [20, 21]). However, other workers found differences in fillet and whole-body lipid levels of Nile tilapia (*O. niloticus*) depending on the source of dietary oil [22, 23], as was shown in salmonids [24].

Incorporation of FA into tissues is under various metabolic influences such as preferential incorporation,  $\beta$ -oxidation, lipogenic activity, and fatty acid elongation and desaturation processes [25] and may also be affected by environmental factors [26] or size or age of animals [27]. A mass balance approach can be used to give an insight into the catabolism or deposition of different fatty acids since the dietary intake of the different groups of fish was known accurately. For each dietary fatty acid, it is assumed that, from the total amount of this FA eaten, a proportion is retained in tissues and the rest is metabolised. Retention of a FA in fish tissues will also include de novo synthesis in the case of a SFA or MUFA. Utilisation includes the degradation of a fatty acid via  $\beta$ -oxidation for energy, and/or its utilisation as a substrate for desaturation and chain elongation to longer chain PUFA. In addition, utilisation (not retention) in this simplified model includes the proportion of the dietary FA that was not digested/absorbed.

In general, all groups of fish displayed low percentage retention of their dietary SFA (Table 7). However, the FA composition of the diet affected the extent to which the different SFA were retained (or synthesised de novo) by the fish. There was a distinct trend in which fish receiving a lower dietary amount of a certain SFA tended to retain this FA at a higher level compared to fish receiving a higher dietary amount of this SFA (Table 7). This was true for all individual SFA, including the two major saturates 16:0 and 18:0. These findings are consistent with a previous study with tilapia sampled from various culture systems and sites, where, despite differences in feed inputs, fish displayed similar levels of SFA in their muscle tissues [28]. Similar findings have been reported for salmonids [24, 29] and for a red hybrid of tilapia [23]. The pattern of retention was similar for MUFA. Again fish with a lower dietary intake of a certain MUFA tended to retain this at a higher level

compared to fish with a higher dietary intake and this trend was observed for all individual MUFA (Table 7). In general, all groups of fish metabolised the majority of their dietary MUFA. 18:1n-9 is known to be a preferred substrate for  $\beta$ -oxidation in fish [25].

Irrespective of the diet fed, fish showed a very low retention of dietary 18:3n-3 and 18:2n-6 (Table 7). Dietary 18:3n-3 was extensively utilised by fish and its retention was the lowest of any dietary FA. In rainbow trout the great majority of ingested 18:3n-3 was catabolised [13, 30]. Dietary 18:2n-6 was the next most utilised FA after 18:3n-3 (Table 7). The  $\beta$ -oxidation of FA in fish tissues is known to be a selective process [25], where, in general, SFA, MUFA and 18:2n-6 are preferred over C20 and C22 PUFA. Fish fed the LO-based diets retained dietary 20:4n-6 and 22:5n-6 at high levels, while the CO-fed fish retained these two FA at levels higher than their dietary supply (Table 7), perhaps implying synthesis from shorter chain n-6 PUFA. Fish fed the FO diet retained 20:4n-6 and 22:5n-6, as well as all other n-6 PUFA except 18:2, at higher levels than those of their dietary n-3 PUFA. The preferential retention of 20:4n-6 and 22:5n-6, irrespective of the diet fed, indicates the nutritional importance of these FA for tilapia. Those n-6 PUFA that were in very low concentrations (not detected) in the VO diets, such as 18:3n-6, 20:2n-6, 20:3n-6 and 22:4n-6, were preferentially retained by these fish (Table 7, values >100%). Similarly, those PUFA of the n-3 series that were in low concentrations in all diets, such as 20:3n-3, 20:4n-3 and 22:4n-3, were also preferentially retained by fish (Table 7). Dietary 20:5n-3 was retained at relatively low levels in all groups of fish (Table 7). However, fish fed the linseed oil-based diets retained their dietary 20:5n-3 to a greater extent than the FO- and CO-fed fish, suggesting a synthesis of this FA from 18:3n-3. On the other hand, fish fed the VO diets preferentially retained 22:5n-3 and 22:6n-3, while FO-fed fish retained these two FA at higher levels than other dietary n-3 PUFA. The best retained of the major FA in all four VO diets were 20:4n-6 and 22:6n-3 which are known to have essential roles in cellular physiology and membrane structure, and 22:5n-3 and 22:5n-6 which have not. While 22:5n-3 is an intermediate in the synthesis of 22:6n-3 and may accumulate because of the inherent inefficiency of the pathway, the accumulation of 22:5n-6 may indicate that this PUFA can partially substitute for 22:6n-3 in tilapia.

The muscle content of 18:2n-6 and 18:3n-3 strongly reflected dietary intake with the highest amounts of 18:2n-6 in fish fed the CO diet and 18:3n-3 in fish fed the LO diets, while fish fed the FO diet contained the highest amounts of long-chain n-3 PUFA. Fish fed the three LO-diets contained significantly higher amounts of all other individual n-3 PUFA compared to CO-fed fish, although all four VO diets supplied similar amounts of individual n-3 PUFA

except 18:3n-3. This indicates that there was desaturation and elongation of dietary 18:3n-3 in fish fed the three LO-based diets. Similarly fish fed the 18:2n-6-rich CO diet displayed the highest contents of all n-6 PUFA despite the fact that the CO diet and the three LO based diets differed only in their levels of 18:2n-6. This also suggests that there was a significant desaturation and elongation of dietary 18:2n-6 in the CO-fed fish. These findings are consistent with previous studies, which showed that Nile tilapia (*O. niloticus*) [10, 11], redbelly tilapia (*Tilapia zillii*) [31], and blue tilapia (*O. aureus*) [19] all possessed some ability to elongate and desaturate 18:3n-3 and 18:2n-6 to their longer chain derivatives.

The inclusion of increasing levels of LO in the diet, and thus graded amounts of dietary 18:3n-3, resulted in commensurate increases in tissue 18:3n-3 and all n-3 PUFA pathway anabolites, though the increases in 18:4n-3, 22:5n-3 and 22:6n-3 were not significant. The largest increase was in the elongation product 20:3n-3 which mirrored the change in 18:3n-3 content. Studies in animals [32, 33] and humans [34] have shown that there is an optimal amount of dietary 18:3n-3 that gives a peak in the synthesis of 22:6n-3 with a plateau or decline thereafter. Although we could not confirm this from the present experiment, it is clear that in tilapia the conversion of 18:3n-3 to longer chain n-3 PUFA derivatives is not efficient, and particularly the synthesis of 22:5n-3 and 22:6n-3 is low. When comparing the fish fed PO-LO and LO diets a 2.29-fold increase in dietary 18:3n-3 resulted in a 2.16-fold increase in tissue 18:3n-3 that in turn gave a 1.41-fold increase in tissue 18:4n-3, a 1.61-fold increase in tissue 20:4n-3, a 1.45-fold increase in tissue 20:5n-3, a 1.21-fold increase in tissue 22:5n-3 and only a 1.10-fold increase in tissue 22:6n-3. Thus, progressively less substrate reaches the end products indicating that further increases in dietary 18:3n-3 will not give meaningful increases in tissue 22:6n-3. The final muscle concentration of 22:6n-3 in the LO-fed fish fell compared to the FO-fed fish indicating a net loss of 22:6n-3. These findings are in agreement with studies in other fish species [13, 24, 30] and tilapia (*O. niloticus*) [11], which suggested that fish fed a vegetable oil diet were unable to maintain the tissue concentration of 20:5n-3, 22:5n-3 and 22:6n-3. This is a conclusion of great importance indicating that the replacement of FO with VO in diets for farmed fish lowers their content of the nutritionally important long-chain n-3 PUFA.

In fish fed the CO diet, where there was a large amount of 18:2n-6 and a small amount of 18:3n-3, the synthesis of 22:6n-3 will have been minimal, and all the tissue 22:6n-3 was probably derived from the fish meal in the diets. The CO-fed fish showed a weight gain of 175 g with a FCR of 2.01 and had a 22:6n-3 concentration of 29.2  $\mu\text{g}/\text{mg}$  TL with 7.03 mg TL/wet weight carcase. Assuming a uniform

body concentration of 22:6n-3 equivalent to the value found in muscle gives 35.9 mg 22:6n-3 per fish. The intake of 22:6n-3 from the diet was 105 mg so there was a turnover/ $\beta$ -oxidation equivalent to about twice the body 22:6n-3 content. Using the increment of 22:6n-3 concentration in the PO–LO-fed fish and LO-fed fish over the CO-fed fish it is possible to calculate the increment of 22:6n-3 due to synthesis in the LO-fed fish. In PO–LO-fed fish this gives 10 mg 22:6n-3 synthesised/g 18:3n-3 eaten and in the LO-fed fish 5.0 mg 22:6n-3 synthesised/g 18:3n-3 eaten confirming that the more 18:3n-3 ingested the less is converted to 22:6n-3.

Another finding of the study was that in FO-fed fish, tissue concentrations of 20:5n-3 were lower than the dietary concentration. This confirmed the findings of an in vivo study with Nile tilapia (*O. niloticus*) [10], and this FA is also extensively oxidised in Atlantic salmon [35]. This is consistent with our findings in a previous study where tilapia that had been raised on commercial diets containing high levels of fishmeal and FO contained low concentrations of 20:5n-3 (0.3–1.1% of total FA) compared to the concentrations of 22:6n-3 (7–10% of total FA) [28]. It is likely, therefore, that 20:5n-3 is selectively used as a substrate for  $\beta$ -oxidation in tilapia. While the retention of 20:5n-3 was low in all dietary groups, the concentration of 22:6n-3 in the FO-fed fish was higher than that supplied by the FO diet indicating selective retention.

Tilapia is a tropical non-migratory fish and the muscle lipid content of <1% wet weight lipid is low compared to a salmonid and some other migratory fishes but similar to a gadoid such as cod. Thus, although the intake of long-chain n-3 PUFA from consuming tilapia is low relative to a salmonid, it is a widely consumed fish species in many parts of the world and an important dietary resource for those populations who do not have access to oily fish or PUFA supplements. It is recommended that vegetable oil alternatives that are rich in 18:3n-3 and low in 18:2n-6 are used if the replacement of FO in fish feeds become inevitable. The inclusion of LO can maximise the retention of desirable 20:5n-3 and 22:6n-3 and can minimise the deposition of undesirable long-chain n-6 PUFA in the edible muscle tissue of fish compared to a vegetable oil that is rich in 18:2n-6. A possible solution could be that a diet containing LO is used to promote the growth of tilapia and a finishing diet containing FO is used to restore the levels of long-chain n-3 PUFA as this strategy has been shown to have promising results in salmonids [35].

**Abstract** The location and the resulting chemical microenvironment of the antioxidant propyl gallate (PG) was studied in micellar solutions using the cationic emulsifier cetyl trimethyl ammonium bromide (CTAB), the anionic emulsifier sodium dodecyl sulphate (SDS) and the non-ionic emulsifier Brij 58 (polyoxyethylene-20-cetyl ester).  $T_1$  relaxation time of the aromatic protons of PG was investigated in micellar solutions and compared with that in aqueous solution in the absence of emulsifier. The relaxation time of the PG portion that is solubilized in the micelle ( $T_{1,\text{eff}}$ ) was calculated from the partition behavior of PG in micellar solution. From the 1D- $^1\text{H}$  spectrum, the alteration in the electron density of the aromatic protons and the alteration in the peak shape of the emulsifier headgroup and alkyl chain proton signals were indicative of the location of propyl gallate in the different micelles. Nuclear Overhauser effects (NOE) made it possible to deduce the exact location of PG by calculation of the relative NOEs. Marked differences were found for the location of PG in CTAB, SDS and Brij 58 micelles. PG was found to be located in the palisade layer of CTAB micelles, in the region of the polyoxyethylene chain of Brij micelles and in the Stern layer of SDS micelles. For careful study of the location of antioxidants and therefore to be able to characterize the chemical microenvironment of the antioxidants is crucial for understanding differences in anti-

oxidant activities as a function of lipid surfaces. The application of spectroscopic methods may help to optimize the antioxidant activity to inhibit lipid oxidation at surfaces that are formed in a wide range of foods (emulsions), cosmetics, pharmaceuticals (emulsions and carrier systems) and of biological membranes (LDL-particles).

**Keywords** Solubilization · Antioxidant activity · Emulsifier · Surface active agent · CTAB · SDS · Brij · Propyl gallate · Stern layer · Palisade layer

## Abbreviations

alk	Alkyl chain protons of emulsifiers
Brij 58	Polyoxyethylene-20-cetyl ester
CTAB	Cetyltrimethylammonium bromide
$\text{H}_a\text{--H}_d$	Protons of propyl gallate
hg	Headgroup protons of emulsifiers
NOE	Nuclear Overhauser effect
PG	Propyl gallate
SDS	Sodium dodecyl sulfate

## Introduction

Many studies demonstrated that the activity of antioxidants can vary strongly depending on the systems in which they have been tested [1–8]. Pryor et al. [4], for example, observed that Trolox showed a fourfold higher protection of the oxidation of linoleic acid in hexadecyltrimethylammonium bromide micelles (HDTBr, positively charged) than in negatively charged micelles of sodium dodecyl sulphate micelles (SDS). The more hydrophilic ascorbic acid showed a 13-fold higher protection in HDTBr

micelles. Barclay and Vinqvist [5] demonstrated that Trolox significantly inhibited the oxidation of positively charged liposomes (dilinoleoylphosphatidylcholine with stearylamine) at pH 4.0 and 7.0 but had no effect when the surface of the liposome (dilinoleoylphosphatidyl glycerol at pH 7.0) was negative, and had low activity at pH 4.0 when the liposome was neutral. These results indicate that the positive charge of the surface increases and a negative charge decreases the activity of hydrophilic antioxidants. In contrast Stöckmann et al. [3] reported the strongest activity of propyl gallate (PG) in SDS emulsion and no activity in CTAB emulsion. Only little work has been done to characterize the function of antioxidants at surfaces regarding their interactions with surface active molecules on a molecular level. One parameter which has been well investigated is the partitioning of antioxidants, which offers information on a ‘phase level’. This means that the proportion of antioxidants was estimated present in aqueous environments vs. lipid particles or droplets and membranes [1–3, 6–8]. Furthermore, it was possible to differentiate between the proportion of an antioxidant solubilized by oil vs. surface active compounds (e.g. emulsifiers) [2].

As lipid oxidation is considered to occur at interfaces due to the polarity of the radicals involved in the reaction [4, 5], it was found to be crucial to understand the parameters which may affect the functionality of antioxidants at interfaces. Results reported by Stöckmann et al. [3] showed that the partitioning of antioxidants into interfaces does not provide enough information. E.g. the order of the antioxidant PG showed decreasing activity in the order SDS emulsion > Brij emulsion and CTAB emulsion. In contrast, the partitioning behaviour indicated an increasing proportion of PG in the opposite order, which should have resulted in higher antioxidant concentration and thus in a higher efficiency towards lipid radicals. Due to the two-state model, small molecules are dissolved either in the micellar interior or associated with the hydrophilic interface (palisade layer and Stern layer) [9, 10], which results in different types of chemical microenvironments for the small molecules. Therefore, characterizing the location, the chemical microenvironment and resulting interaction of small molecules at surfaces is a fundamental subject in lipid sciences. Careful analyses can provide detailed information on the functionality of small molecules at surfaces.

To characterize the location and the interactions, various studies on solubilization of solutes in micellar systems were carried out [11–22]. A number of techniques were found to be suitable to investigate solubilization properties [23]. Using spectroscopic methods like different NMR techniques, quantitative measurements of the interactions between emulsifier and solute are possible [19, 22, 24, 25].

$T_1$  relaxation measurements give direct information about interactions with the chemical environment due to the transfer of energy from the spin system to the medium [26–28]. In particular, nuclei on the surface like protons are dominated by intermolecular interactions with new available dipoles [29, 30] which lead to an interference of their local motion and can be observed by a strong reduction in the relaxation time [22, 24, 26, 31–33]. In the case of antioxidants in dispersed systems alterations in  $T_1$  relaxation times are indicative of the interactions in different phases or pseudophases. Alterations in the chemical shift give information on the electron density in the closed chemical environment of the solute. Solubilization of a solute in a hydrophobic environment causes a shift to lower frequencies compared to a hydrophilic environment [11, 12, 34]. This allows a differentiation in whether a solute is solubilized in the more hydrophilic or hydrophobic layer [11–16]. Likewise, the shape and width of the peaks of the 1D spectrum are of interest. In particular, emulsifier proton signal shapes give hints of a deposition or intercalation of a solute with increasing solute concentration [17, 18, 35, 36].

Nuclear Overhauser effects (NOEs) provide information on the location of solutes since this technique allows the characterization of the intensities of interaction and arrangement of several molecules in close proximity ( $\leq 5 \text{ \AA}$ ) [19–22]. Determining the volumes of the cross peak signal compared to its corresponding diagonal signal, the relative NOEs can be calculated [29].

The aim of this study was to evaluate the location and the chemical environment of antioxidants in model systems in order to extract information regarding the resulting interactions between antioxidants and surfaces. Propyl gallate was used as an antioxidant and SDS, CTAB and Brij to model surfaces with different chemical microenvironments. The experimental design should help to provide tools for biological systems and complex dispersed matrices such as foods.

## Experimental Procedures

### Samples

Cationic CTAB (cetyl trimethyl ammonium bromide,  $\geq 99\%$ ), non-ionic Brij 58 (polyoxyethylene-20-cethyl ether,  $>98\%$ ) and propyl gallate (trihydroxy benzoic acid propyl ester,  $>99\%$ ) were obtained from Sigma-Aldrich, Germany.  $D_2O$  ( $>99.8\%$ ) and anionic SDS (sodium dodecyl sulphate,  $\geq 99\%$ ) were purchased from Carl Roth, Germany. All chemicals were used without further purification.

Micellar stock solutions of 1.1% emulsifier were prepared in 50 mmol/l acetic buffer solution in bidistilled water, pH 5.00. The required amount of antioxidants was weighed (1–3.5 mg) and filled up with either buffer (control) or micellar solution to 900 mg, finally D<sub>2</sub>O were supplemented to 1,000 mg.

### <sup>1</sup>H NMR Measurements

<sup>1</sup>H NMR measurements were performed on a Bruker DRX500 ( $B_0 = 11.75$  T) spectrometer in a 5 mm multinuclear inverse probe and at a constant temperature of  $300 \pm 0.1$  K. Samples were measured in 5-mm sample tubes with deuterium lock and without spinning. Using the 180° pulse length, the pulse length of the 90° excitation were determined to periods between 9.8 and 12 s according to the individual sample. The acquisition and the processing of the spectra were carried out by XWinNMR software (Bruker). To get information about possible interactions between emulsifier and antioxidants, the NMR measurements were performed in the individual micellar solutions and referred to the corresponding measurements in buffer solution (control). Standard methods included in the Bruker pulse sequence library were modified and used to acquire the individual NMR spectra by different pulse programs. Since all samples contained 90% H<sub>2</sub>O, each NMR experiment was carried out with suppression of the HDO signal which allowed a pure phase NMR spectrum with a fundamental low and smaller HDO signal, at the highest possible sensitivity to be obtained. This approach (watergate, water suppression by gradient-tailored excitation) consisted of a gradient echo 3-9-19-pulse sequence [37, 38].

### Chemical Shift

1D <sup>1</sup>H spectra were acquired in 8 scans with a 30° pulse. Spectra were Fourier transformed and subsequently phase corrected. All chemical shifts of the proton signals were referenced to the CH<sub>3</sub>-signal of acetic acid (HAc = 2 ppm). The chemical shifts obtained are given with an accuracy of  $\pm 0.003$  ppm.

### <sup>1</sup>H $T_1$ Relaxation

The saturation-recovery method was used where a non-periodic sequence of 90° pulses was applied to achieve the saturation of the spin system. After the waiting time  $\tau$ , the decreased magnetization  $M_Z$  was transferred by a 90° pulse to the  $x$ - $y$  plane and detected. The period of the waiting time  $\tau$ , was randomly varied in the pulse sequence in order to minimize possible drift-effects during the measuring time [39, 40]. The spectra were recorded as a set of 1D

spectra in a 2D dataset and were processed accordingly. An experimental error was calculated by investigating the  $T_1$  relaxation of 0.2% PG in triplicate both in buffer solution and in the several micellar solutions. The  $T_1$  relaxation was collected for each proton signal and the relative experimental error for all  $T_1$  relaxation measurements were estimated to about 10%.

### NOESY

NOEs were obtained by 2D homonuclear correlation experiments. The pulse program consisted of three 90° pulses; the delay for the evolution time  $\tau_1$  was systematically varied to provide chemical shift information in the  $F_1$  domain. Mixing time  $\tau_m$  was set to 750 ms according to the highest signal intensity. During acquisition, 512 data points were recorded in  $t_1$  and 2,048 data points in  $t_2$ . Time domain data were processed with a squared cosine-function in  $F_1$  and  $F_2$  and zero-filled to a final matrix of  $1 \times 1$  k data points. 1D phase corrections were carried out for the  $F_1$  and  $F_2$  domain as well as for the base lines. The cross peaks were referred to the projection of the 1D <sup>1</sup>H spectrum in the  $F_1$  and the  $F_2$  domain. By integration of the cross-peaks and the related diagonal peaks by XWinNMR tools, the intensities of the NOEs were determined.

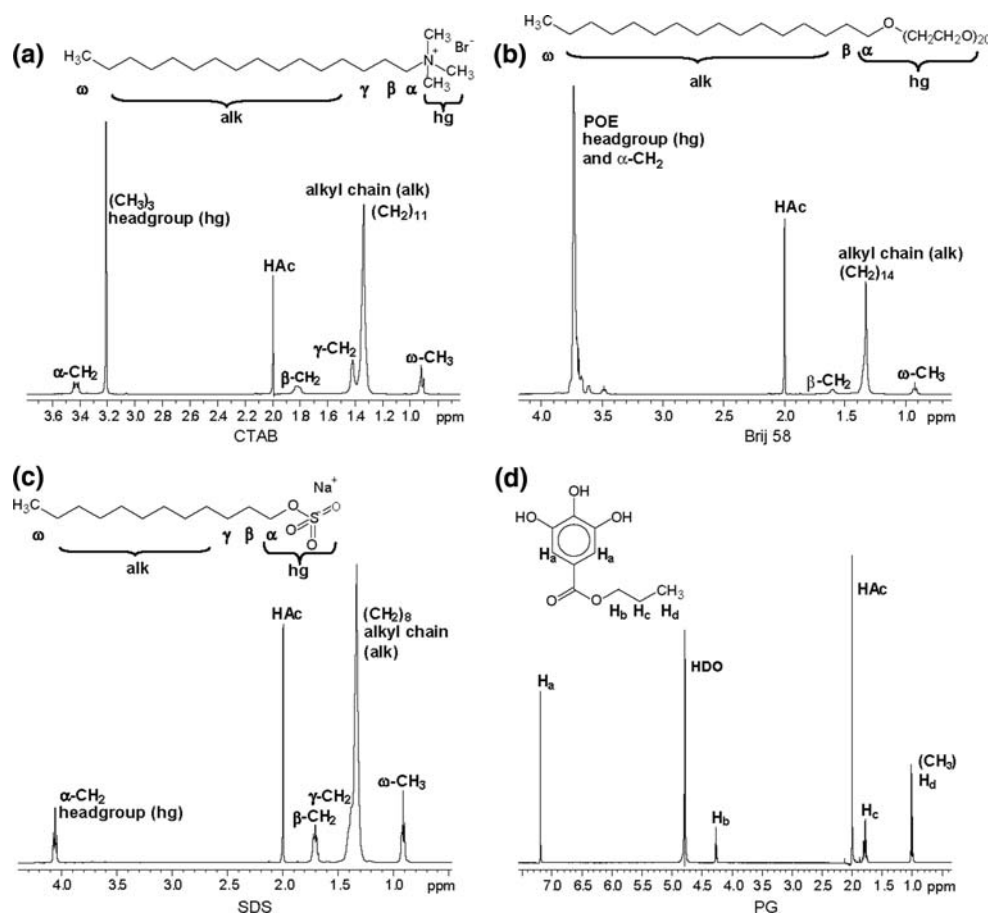

## Results and Discussion

1D <sup>1</sup>H reference spectra of the applied emulsifiers CTAB, Brij, and SDS as well as of the antioxidant PG in buffer solution are shown in Fig. 1 with the respective nomenclature. The emulsifiers showed signals for the specific headgroup region (hg) and the alkyl chain (alk) as well as for the individual methylene and methyl protons that split into a single multiplet ( $\alpha$ ,  $\beta$ ,  $\gamma$  and  $\omega$ ). The individual proton signals of PG were marked by H<sub>a</sub>–H<sub>d</sub> started on the aromatic ring with the protons closest to the hydroxyl groups H<sub>a</sub>. Assignment was continued for the gallate ester alkyl chain according to the number of methylene and methyl groups. The hydroxyl groups underwent exchanges with the surrounding water molecules so quickly that separate signals could not be detected. The protons H<sub>a</sub> were used as the indicator for the phenolic OH-groups, which demonstrate the antioxidant properties by radical-quenching.

### <sup>1</sup>H- $T_{1,eff}$ Relaxation Time

Since the exchanging process of the solute among the different phases is very fast, the observed relaxation time ( $T_{1,obs}$ ) is an average of the relaxation times in all different

**Fig. 1** 1D  $^1\text{H}$  reference spectra of the emulsifier CTAB (1%, **a**), Brij 58 (1%, **b**), SDS (1%, **c**), and of the antioxidant PG (0.25%, **d**). HAc is the acetate buffer peak; HDO is the water-deuterium peak

phases [32]. The portion of PG that is solubilized in the different micelles ( $f_{\text{sol}}$ ) was determined by ultra filtration method described by Stöckmann and Schwarz [2] and found in CTAB micelles of about 0.989, in Brij micelles of about 0.893, and in SDS micelles of about 0.735. Provided that the free mobility is the same for the portion of PG in the aqueous phase of the micellar solution as for PG in buffer solution  $T_{1,\text{sol}}$  the relaxation rate for PG solubilized in the micellar phase ( $T_{1,\text{eff}}$ ) was calculated by [41–45]

$$\frac{1}{T_{1,\text{obs}}} = \frac{1 - f_{\text{sol}}}{T_{1,\text{con}}} + \frac{f_{\text{sol}}}{T_{1,\text{eff}}} \quad (1)$$

Comparison of the  $T_{1,\text{con}}$  relaxation time of the  $\text{H}_a$  protons of PG in the aqueous phase with the  $T_{1,\text{eff}}$  relaxation time in the micellar phase showed reduced relaxation times in all emulsifier solutions (Fig. 2). This reduction could result from restricted motion of the antioxidant molecule caused by spatial proximity of the antioxidant and the emulsifier present [22, 24, 26, 31–33]. It could also be caused by the loss of tumbling of PG achieved by adopting the rotation of the micelle [27] or by molecular interactions [41]. Also differences in the solubilized proportion of PG could be observed for the different types of emulsifier. While  $\text{H}_a$  had

a relaxation time of 1.9 s in buffer solution, relaxation became significantly shorter when solubilized in micelles. Whereas in anionic SDS micelles a  $T_{1,\text{eff}}$  time constant of 1.6 s was found and in non-ionic Brij micelles it was 1.1 s, the  $T_{1,\text{eff}}$  time in CTAB micelles was reduced to 0.8 s. From the quantitative reduction of the  $T_{1,\text{eff}}$  relaxation time the strength and location of interaction or solubilization can be obtained [46, 47]. The different strength of interactions between PG and the emulsifiers were in the order CTAB > Brij > SDS. This clearly indicates different solubilization environments for PG offered by the emulsifier moieties. The region of the SDS micelles that solubilizes PG resembles the characteristics of the buffer solution, i.e. being very polar. In contrast, the environment offered by CTAB can be assumed to be markedly different of a buffer solution, since CTAB apparently formed much stronger interactions than SDS, causing a 50% reduction of the  $T_{1,\text{eff}}$  relaxation times relative to SDS. The differences in solubilization are due to molecular interactions which includes different kinds of intermolecular forces. These interactions include electrostatic interactions or Coulomb forces, H-bonds, and dispersion forces, which are all modulated by hydration effects [48]. However, it is impossible to correlate certain effects with individual forces due to an overlap

**Fig. 2** Comparison of the  $T_1$  relaxation time of the aromatic protons  $H_a$  of 0.25% PG in buffer solution ( $T_{1,con}$ ) and in the micellar phase of 1% CTAB, Brij, and SDS micellar solutions ( $T_{1,eff}$ )

of different interactions involved in the micellar environment of the headgroup, counterions and different segments of the alkyl chain [48].

To investigate the concentration dependency of the  $T_{1,eff}$  relaxation time, the  $T_1$  relaxation ratio was calculated using the following equation

$$T_{1,AH} = \frac{T_{1,eff}}{T_{1,con}} \quad (2)$$

This compares the effective relaxation times of the antioxidant solubilized in micelles  $T_{1,eff}$  with the relaxation times of the freely movable antioxidant in the aqueous phase  $T_{1,con}$ . The corresponding relaxation ratio for the emulsifier protons  $T_{1,em}$  is given by the equation

$$T_{1,em} = \frac{T_{1,AH\text{ present}}}{T_{1,AH\text{ absent}}} \quad (3)$$

and compares the relaxation time in the presence and absence of antioxidants. A  $T_1$  relaxation ratio value of 1 shows that the relaxation time of the antioxidant is the same in the micellar phase as in the aqueous phase, while lower  $T_1$  relaxation ratio values indicate a reduction of the relaxation time of antioxidants solubilized in the micelle.

For the different concentrations (0.1–0.35%) of PG investigated, no significant difference in the  $T_{1,AH}$  relaxation ratios could be observed between the individual emulsifiers and antioxidant protons, exemplifying the aromatic protons  $H_a$  of PG (Fig. 3a).

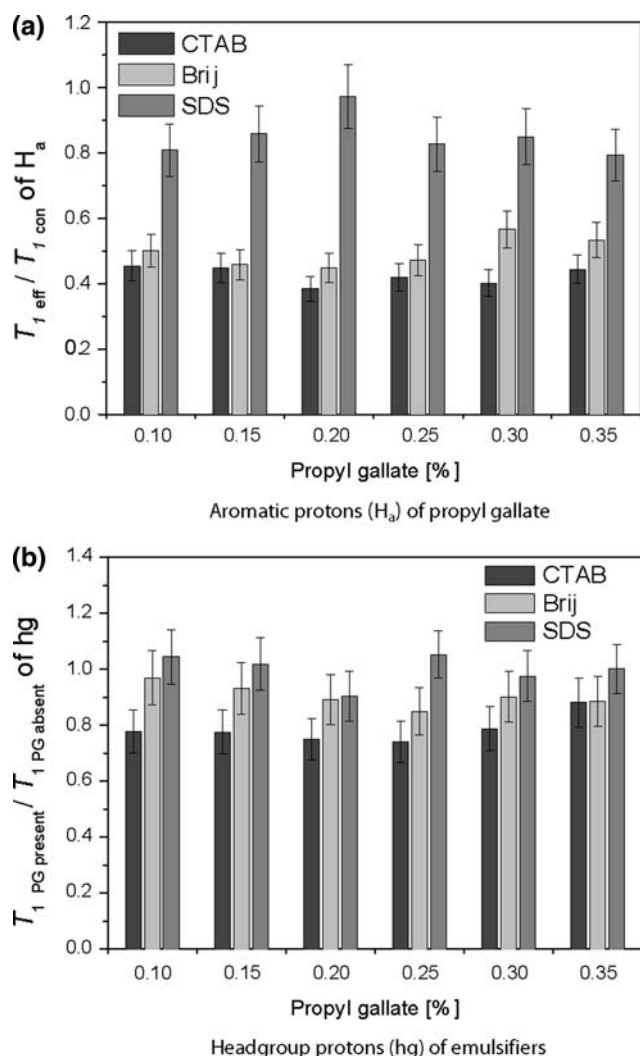

The interactions of the emulsifier protons with those of antioxidants were also investigated as a function of different antioxidant concentrations. The  $T_{1,em}$  relaxation ratios (Eq. 3) for the headgroup (hg) in the presence and absence of PG are shown in Fig. 3b. The headgroup

protons showed the same tendency of decreasing interaction strength as the PG aromatic protons in the order CTAB > Brij > SDS for the impact of PG. The CTAB headgroup protons revealed a significant reduction of the  $T_{1,em}$  relaxation ratio, i.e. below 1, but this was independent of the antioxidant concentration indicating a close proximity of PG and the CTAB headgroup protons [26–28]. In contrast, no significant reduction was observed for the headgroup protons of Brij and SDS. Since the  $T_{1,con}$  relaxation time is assumed to be constant in the different micellar solutions, this ratio is influenced only by the  $T_{1,eff}$  relaxation time of the portion of antioxidants solubilized in the emulsifier pseudophase. For a concentration range from 0.1 to 0.35% PG, the  $T_{1,AH}$  relaxation ratio of the portion solubilized in the emulsifier pseudophase showed no dependence on the antioxidant/emulsifier ratio of PG for all emulsifiers employed. This demonstrates a qualitative equivalence of interactions in the complete investigated concentration range.

#### Chemical Shift

The chemical shift of antioxidant signals, which is altered in micellar solution, is shown as the difference between the positions of a signal in the presence and absence of emulsifiers (Fig. 4). Positive differences in the chemical shift indicate a shift to lower frequencies (shielding) owing to electron density enhancement. In the opposite case of negative chemical shifts, a lower electron density of the proton is indicated by a shift to higher frequencies (deshielding) [49]. In general, shifts of the PG and emulsifier proton signals became stronger with increasing PG concentration (Fig. 4) since the concentration was not corrected by the partitioning of PG and the observed chemical shifts are the average of the shifts in all phases. Alteration in the chemical shift was strongly pronounced for  $H_a$  in CTAB, less in Brij and the least in SDS micellar solution (Fig. 4a).

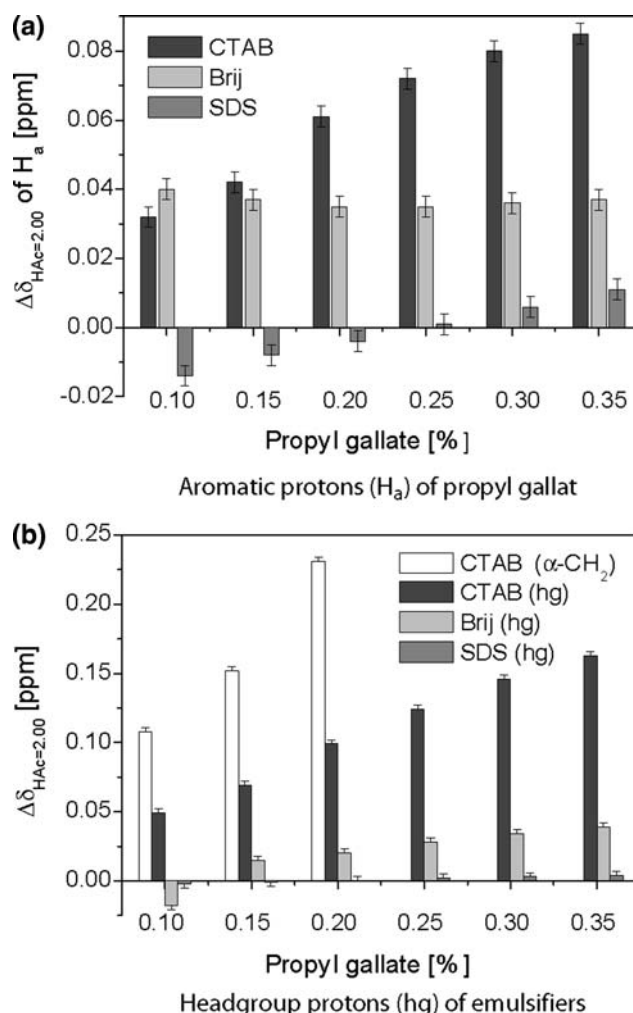

In Brij and CTAB micellar solutions, the position of the aromatic proton signals were shifted to lower frequencies corresponding to an increasing electron density. This is caused by the change in the chemical environment of the aromatic protons from the buffer solution to the less polar environment [11, 12, 34] offered by Brij and CTAB micelles. Since larger shifts were observed for PG in CTAB, PG can be assumed to be solubilized in a more water-deficient environment in CTAB than in Brij. The water content in micelles ranges from 40 to 53% [50], whereby water penetration into ionic micelles is markedly lower than in non-ionic micelles [51, 52]. In the headgroup region of Brij, which can be described as a concentrated solution of polyoxyethylene groups [53, 54], the main portion of the water is bounded as H-bond donors to the polyether oxygen

**Fig. 3** Comparison of the  $T_{1, \text{AH}}$  relaxation ratio for the aromatic protons  $H_a$  of different PG concentrations in buffer solution and in the micellar phase of 1% CTAB, Brij, and SDS micellar solution (a). Comparison of the  $T_{1, \text{em}}$  relaxation ratio of the corresponding emulsifier headgroup protons hg (b)

[55]. In addition, the larger volume of Brij than that of CTAB micelles offers a greater space to the solubilized PG in Brij micelles so that PG may not accumulate locally with increasing PG concentration. This in turn may explain why the aromatic proton signals of PG shifted uniformly in Brij micelles (Fig. 4a).

In SDS micellar solutions, the  $H_a$  proton signals of PG at a concentration of 0.1–0.2% were shifted to higher frequencies. At a PG concentration of 0.25%, the shift was the same as for the control and at 0.3–0.35% PG, a shift to lower frequencies was observed. This deshielding can be attributed to a decrease in the electron density of the aromatic protons. The surface of SDS micelles is strongly hydrophilic with adsorbed counterions, which are generally separated by a layer of water molecules [56]. Solubilized

**Fig. 4** Difference in the chemical shift of the aromatic protons  $H_a$  of PG in buffer and a 1% micellar solution of CTAB, Brij and SDS with different concentrations of PG (a) and of the corresponding headgroup (hg) proton signals (b). Positive differences in the chemical shift indicate a shielding (shift to lower frequencies), while negative differences in the chemical shift indicate a deshielding (shift to higher frequencies)

PG may alter the solvent structure in the Stern layer [57] accompanied with a displacement of counterions and dehydration [58]. That is, fewer dipoles are located in the Stern layer and the dielectric constant decreases [57, 59–61]. The deficiency of dipoles may lead in turn to a deshielding of the antioxidant protons and this may cause the decrease in the electron density of the aromatic protons. With increasing PG concentration, more PG molecules accumulate in the Stern layer, which may be associated with the  $\text{--SO}_3^-$  group of SDS by  $\pi\text{--}\pi$  interactions [51], leading again to an increase in electron density, so that a shielding was observed.

Alteration in the chemical shift that occurred for the emulsifier proton signals in the presence of PG is shown in Fig. 4b. CTAB showed the greatest difference in chemical

shift, but it was more pronounced for the  $\alpha$ -CH<sub>2</sub> group than for the headgroup signal entering into one peak with increasing PG concentration. Generally, increasing antioxidant concentration led to a greater positive shift for CTAB and Brij headgroup proton signals, whereas those of SDS were not shifted regardless of the PG concentration. This could indicate an electron density enhancement by the antioxidant aromatic ring in the palisade layer of CTAB, particularly in the region of the  $\alpha$ -CH<sub>2</sub> signal. The headgroup signals of SDS were not shifted, which is in accordance with a localization of PG in the outer region of the SDS micelle (Stern layer).

### Peak Shape

Increasing concentrations of PG influenced the peak shape of the emulsifier headgroup (hg) and the alkyl chain (alk) proton signals. Alterations in these peak shapes differed strongly for all emulsifiers employed. This makes conclusions possible on the type of interaction taking place between the emulsifier and antioxidant and, as a consequence, on the solubilization of the antioxidant. The peak shape of the alkyl chain and headgroup proton signal of CTAB, SDS, and Brij is shown in the presence of PG in concentrations varying from 0.1 to 0.35% (Fig. 5).

The CTAB alkyl chain signal (Fig. 5a, A) was found to be separated into a main alkyl chain signal and a small one at higher frequencies for the  $\gamma$ -CH<sub>2</sub> group (Fig. 1a). In the presence of the lowest PG concentration, the  $\gamma$ -CH<sub>2</sub> merged into the main signal. Upon addition of 0.15% PG, a new peak emerged at lower frequencies from the alkyl chain signal. When the PG concentration was increased further, the split alkyl chain peak broadened out and its intensity decreased. The signals of the headgroup and  $\alpha$ -CH<sub>2</sub> group (B) showed the clearest separation in the control CTAB solution. With addition of PG, the distance between them became smaller. Finally, both signals merged into one peak that broadened and decreased in intensity with increasing PG concentration. Both observations could be related to a strong electron density increase in the palisade layer owing to the intercalation of the aromatic ring into this region [17, 18, 35, 36]. Thereby, the aromatic ring is located closer to the  $\alpha$ -CH<sub>2</sub> group than to the headgroup protons indicated by a stronger shift of the  $\alpha$ -CH<sub>2</sub> proton signal and the final merge of both signals. The extreme broadening of both signals at higher PG concentration is accompanied by an increasing viscosity caused by a sphere-to-rod transition of the micelle [62]. A higher viscosity leads to a longer correlation time  $\tau_c$ , which is associated with shorter  $T_2$  relaxation times and ends up with broader signals in the spectrum.

The alkyl chain signal of Brij appeared in the pure micellar solution as a single peak (Fig. 5b, A). In the

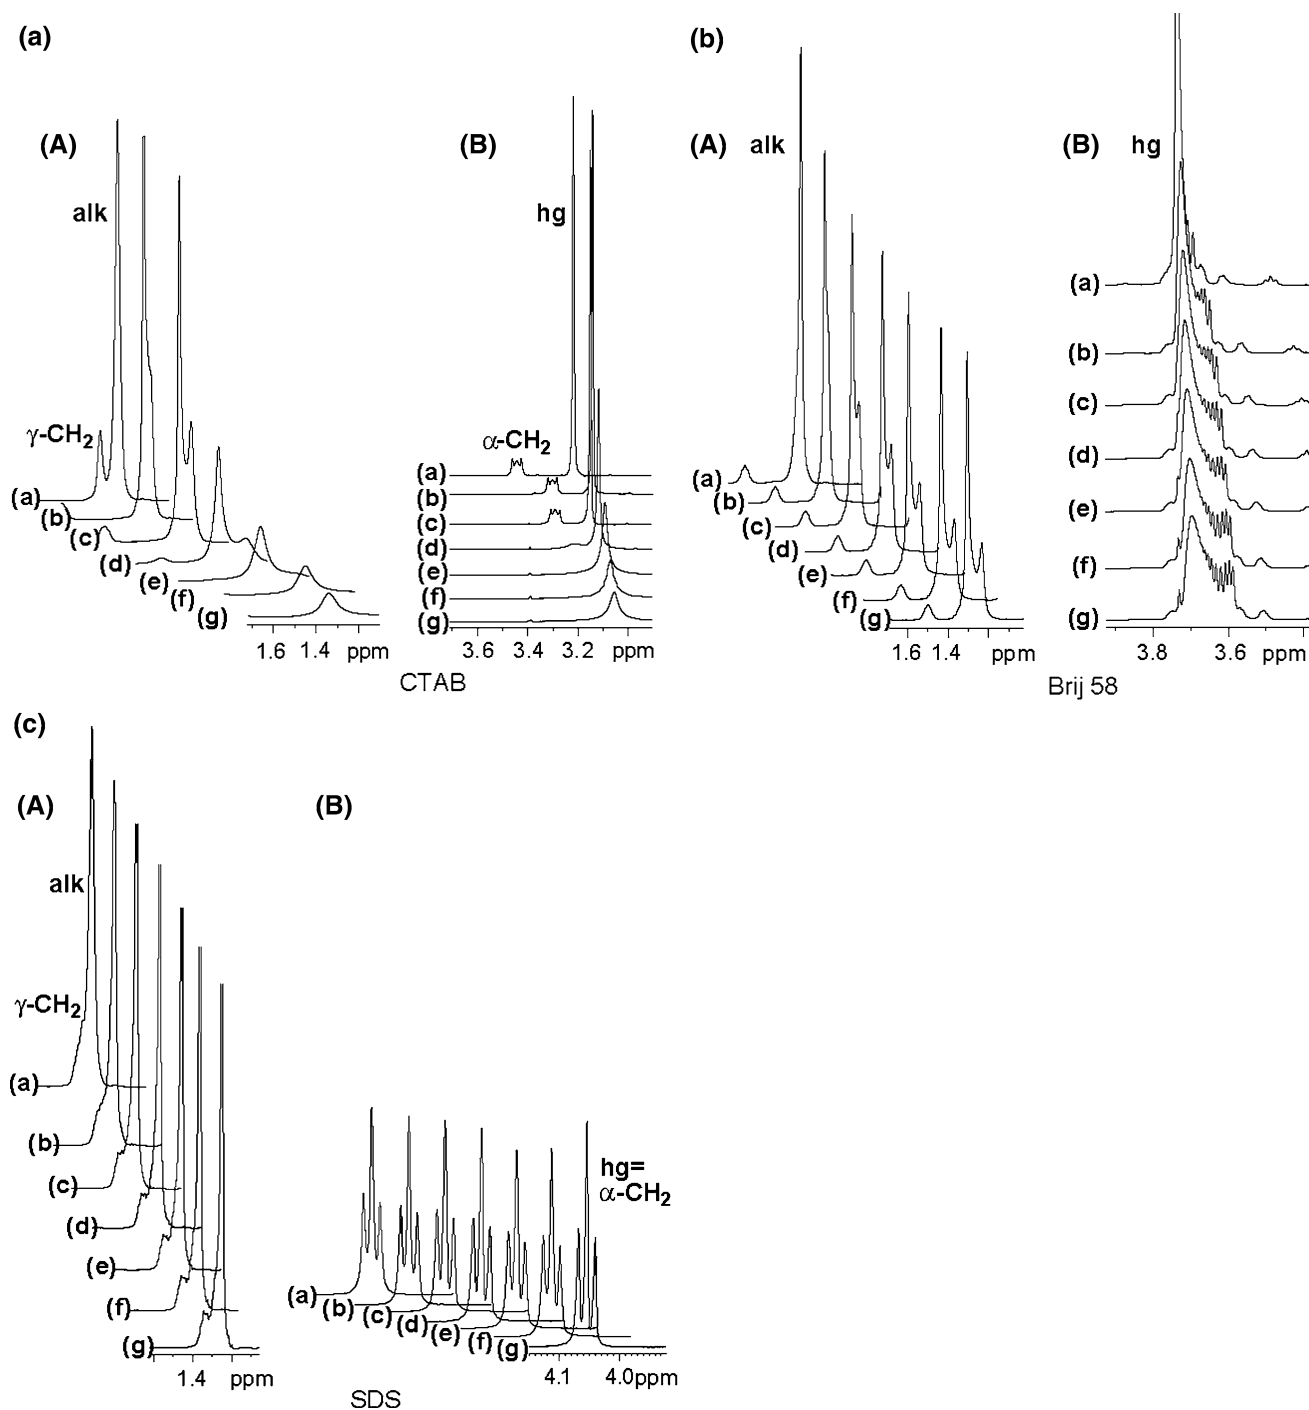

presence of 0.15% PG, the alkyl chain signal split into two peaks with the second smaller peak appearing at lower frequencies. The line widths of the split signal were slightly broadened and the second peak became more intense with further increase in the PG concentration. The headgroup signal (B) resulting from a polyoxyethylene chain showed extensive broadening of the line width with higher PG concentrations. This indicates the intercalation of PG into the hydrophobic part of the Brij micelle [17, 18, 35, 36]. Since the viscosity of the Brij micellar solution was not affected in the presence of PG [62], the broadening of the headgroup signal may be due to a restriction of the motion of the Brij headgroup by the intercalation of PG into the headgroup region.

In the absence of antioxidants, the SDS alkyl chain signal (Fig. 5c, A) appeared as one signal with the  $\gamma$ -CH<sub>2</sub> signal indicated as a small shoulder at higher frequencies (Fig. 1c). This  $\gamma$ -CH<sub>2</sub> signal separated more and more from the alkyl chain signal with increasing PG concentration. Also the headgroup signal (B) had a higher resolution with increasing concentrations of PG. The triplets were narrower and the lines within the triplet were closer to the baseline. Generally, a higher resolution of the NMR spectrum at the same field strength and without exchanging processes is the result of a higher mobility. Higher mobility is associated with smaller molecule aggregates [57, 60, 61] that may result from a lower dielectric constant of the Stern layer [57, 59–61] by solubilization of PG resulting in a displacement of counterions.

### Nuclear Overhauser Effects (NOEs)

From the intensities of the NOEs between antioxidants and emulsifiers, their stereoscopic arrangement can be derived. ROESY (NOE in the rotating frame) measurements exemplarily performed for PG and CTAB (data not shown) indicated that the appearance of cross-peaks is due to direct through-space dipolar coupling and not caused by spin diffusion [63]. When PG was solubilized in CTAB micellar solution, several NOEs were observed between the antioxidant and the emulsifier (Fig. 6a). All proton signals of PG demonstrated a distance smaller than 5 Å to the CTAB protons and in particular to the alkyl chain (alk) and the headgroup signal (hg). By integrating the cross peaks and placing them in relationship to the volume of the corresponding diagonal signal, the relative NOE or the strength of the interaction could be calculated (Table 1).

The strongest interactions were observed between the aromatic protons H<sub>a</sub> and first methylene group H<sub>b</sub> of PG and the alkyl chain of CTAB, whereas these PG protons showed less interaction with the headgroup protons. However, the headgroup protons of CTAB showed the highest NOE intensity with the H<sub>c</sub> proton of PG. The

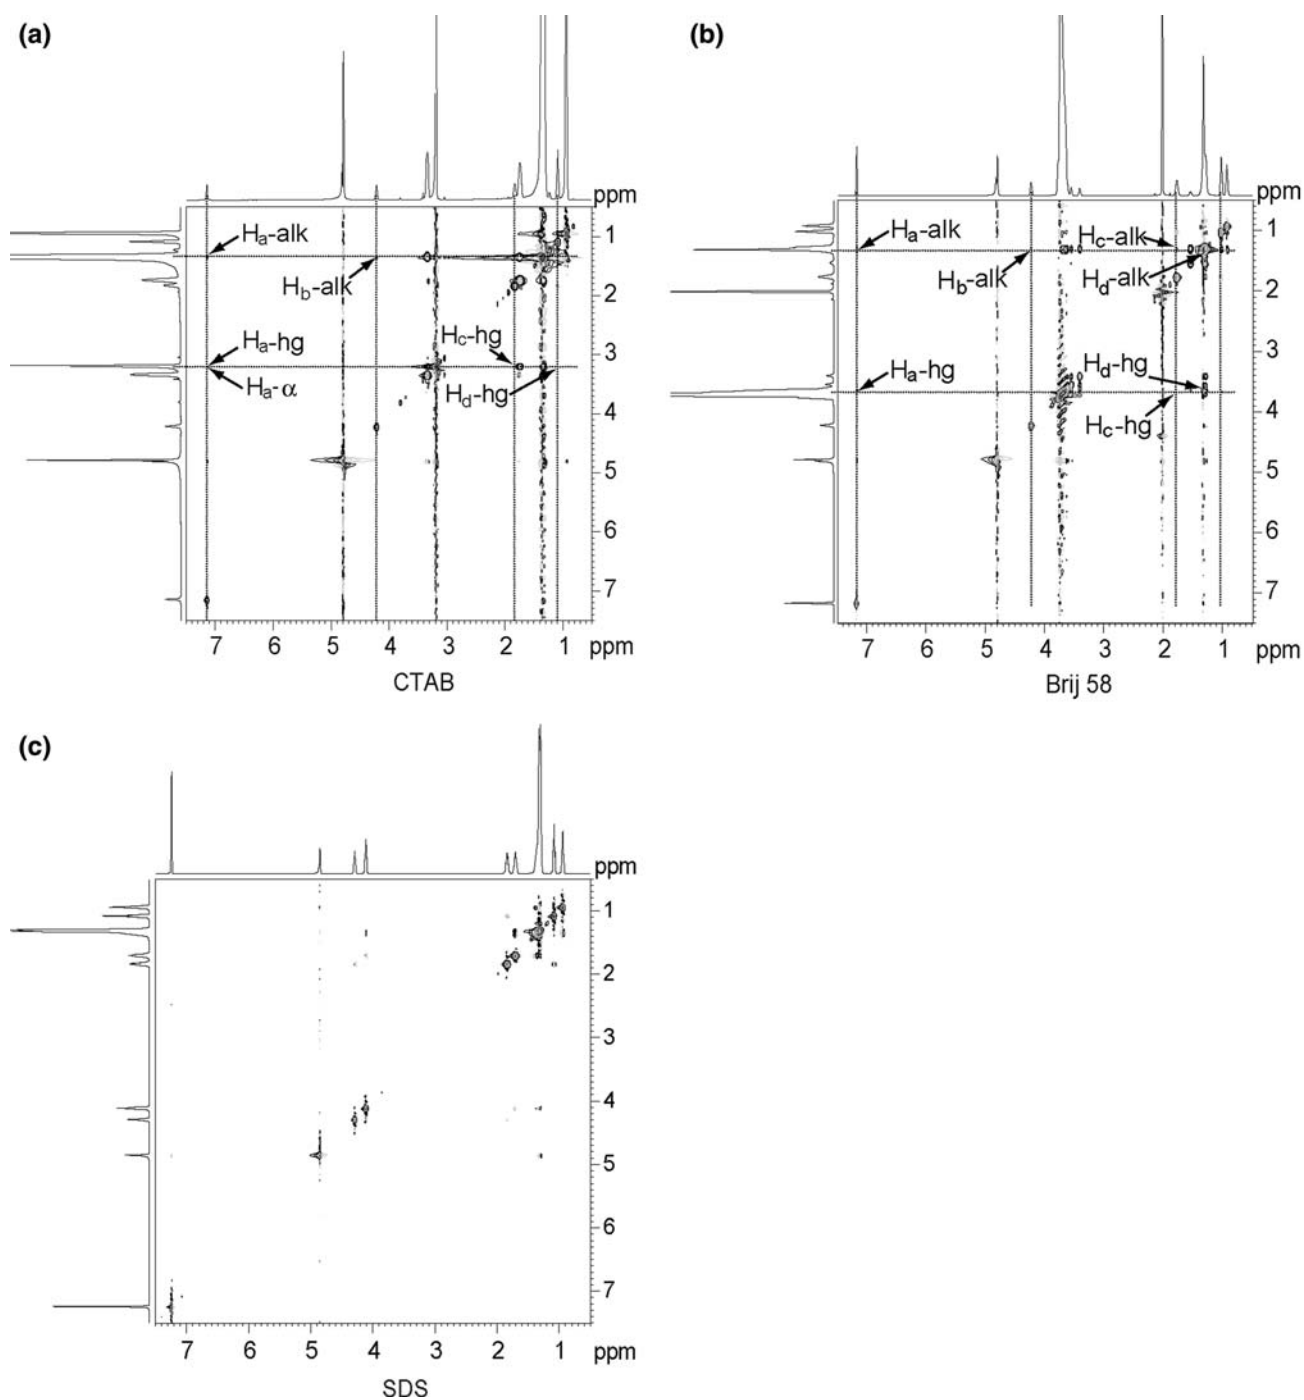

**Fig. 5** Alteration in the peak shape of the alkyl chain (alk and  $\gamma$ -CH<sub>2</sub>) (A) and the headgroup (hg and  $\alpha$ -CH<sub>2</sub>) (B) proton signals of 1% CTAB (a), Brij 58 (b), and SDS (c) in the presence of increasing PG

concentration [control (a), 0.1% PG (b), 0.15% PG (c), 0.2% PG (d), 0.25% PG (e), 0.3% PG (f), 0.35% PG (g)]

arrangement derived from this data shows a definitive intercalation of PG into the CTAB micelle with the aromatic ring is located next to the alkyl chain of CTAB [19, 22, 64]. It may be possible, that PG may be aligned with the aromatic ring towards the interior of the micelle, while the alkyl chain of PG may be positioned at the headgroup

of the CTAB micelle, although from the partial lipophilicity of the antioxidant the opposite alignment would be expected.

Likewise, intermolecular NOEs between all protons of the antioxidant and the alkyl chain (alk) as well as the headgroup (hg) protons of the Brij micelle were observed

**Fig. 6** Intermolecular NOEs ( $\tau_m = 750$  ms) between individual PG (0.25%) and CTAB (1%) protons (a) or Brij (1%) protons (b). NOEs could not be observed between PG (0.6%) and SDS (1%) protons (c)

for PG in Brij micellar solution (Fig. 6b). The intensities of the NOEs were weaker than those in CTAB micelles (Table 1). The interactions of the Brij alkyl chain with  $H_a$  to  $H_c$  were equivalent but increased by a factor of two with  $H_d$ . The intensities of the NOEs of the headgroup signals were generally lower and showed the strongest interaction with the aromatic proton  $H_a$  of PG. The uniform strength of

NOEs between Brij protons and the individual PG protons indicates a random orientation of the antioxidant in the headgroup region and the palisade layer. This in turn would mean a greater ability of PG to diffuse freely in these regions.

Contrary to the experiments in CTAB and Brij micellar solutions, no NOEs could be found between the protons of

**Table 1** Relative NOEs between PG Protons ( $H_a$ – $H_d$ ) and the Headgroup (hg) and Alkyl Chain (alk) Protons of CTAB and Brij ( $\tau_m = 750$  ms)

	Relative NOEs for corresponding diagonal-peak (%)			
	$H_a$	$H_b$	$H_c$	$H_d$
CTAB (hg)	0.90		3.99	0.89
CTAB (alk)	7.09	6.13		
Brij (hg)	1.95		0.85	1.12
Brij (alk)	2.59	2.37	2.49	4.60

PG and SDS micelles (Fig. 6c). PG could therefore be located in the outer hydrated layer of the SDS micelles like the Stern layer where it was not in close proximity to the alkyl chain or the headgroup protons ( $\alpha$ -CH<sub>2</sub>) of SDS.

## Conclusion

The present study demonstrates that differences in the chemical characteristics of the microenvironment of surfaces will result in a different location of PG in the surface due to interactions with the surfactant molecule. PG is found to be solubilized in the palisade layer of CTAB micelles orientated with its aromatic ring towards the hydrophobic interior. This results in a fixed position of PG due to very strong interactions particular between the aromatic protons of PG and the first adjacent methylene groups of the CTAB alkyl chain. Intercalation of PG in Brij micelles is suggested as taking place in the headgroup region and at higher concentrations additionally in the alkyl chain region. Brij reveals intermediate interactions with antioxidants relative to CTAB and SDS micelles. Antioxidant may still have the ability to diffuse freely within the Brij micelle. PG is located in the Stern layer of the SDS micelle undergoing only weak interactions, which are half as strong as those in CTAB micelles but probably changing the hydration of the SDS micelle. The location of PG in different surfaces will affect the functionality of antioxidants towards radicals. Moreover the polarity of radicals may also result in different location in interfaces. ESR experiments [65] showed different activity of antioxidants towards hydrophilic and lipophilic radicals. Although radical and antioxidants are both incorporated into the micelle the specific location within the micelle (surface) determines the functionality. Propyl gallate is able to reduce the lipophilic radical galvinoxyl to a higher extent in CTAB micelles than in SDS or Brij micelles. Further, MacFaul and co-workers [66] demonstrated that the H-abstraction kinetic of antioxidants in solvents strongly depends on the protic character of the solvent and thus on the chemical environment of the antioxidant. To study the

location of antioxidants and their chemical microenvironment carefully is therefore crucial to understand differences in antioxidant activities as a function of lipid surfaces. The application of spectroscopic methods may help to optimize the antioxidant activity and to inhibit lipid oxidation at surfaces that are present in a wide range of foods, cosmetics, pharmaceuticals (emulsions and carrier systems) and of biological membranes and surfaces (LDL-particles).

**Abstract** To characterize parameters influencing the antioxidant activity at interfaces a novel ESR approach was developed, which facilitates the investigation of the reaction stoichiometry of antioxidants towards stable radicals. To relate the activity of antioxidants towards the location of radicals at interfaces NMR experiments were conducted. Micellar solutions of SDS, Brij and CTAB were used to model interfaces of different chemical nature. The hydrophilic Fremy's radical was found to be solubilized exclusively in the aqueous phase of SDS micellar solution but partitioned partly into the hydrophilic headgroup area of Brij micelles. In contrast the hydrophobic galvinoxyl was exclusively located in the micellar phase with the increasing depth of intercalation in the order SDS < Brij < CTAB. Gallates revealed a higher stoichiometric factor towards galvinoxyl in CTAB systems, which is accounted to a concentration effect of antioxidant and radical being both solubilized in the palisade layer. In contrast, in SDS solutions hardly any reaction between galvinoxyl and gallates was found. SDS acted as a physical barrier between radical (palisade layer) and antioxidant (stern layer). The influence of the hydrophobic properties of the antioxidant was clearly seen in Brij micelles. Elongation

of the alkyl chain in gallate molecule resulted in increasing stoichiometric factors in the presence of galvinoxyl being located in the deeper region of the bulky headgroup area. The reverse trend was found in the presence of Fremy's radical being located in the hydrated area of the micelles.

**Keywords** Solubilization · Antioxidant activity · Emulsifier · Gallates · CTAB · SDS · Brij · ESR · Interfaces

## Abbreviations

alk	Alkyl chain protons of emulsifiers
BG	Butyl gallate
Brij 58	Polyoxyethylene-20-cetyl ester
CTAB	Cetyltrimethylammonium bromide
EG	Ethyl gallate
ESR	Electron spin resonance spectroscopy
$f_{sol}$	Portion of the antioxidant that is solubilized in the emulsifier pseudophase
GA	Gallic acid
hg	Headgroup protons of emulsifiers
MG	Methyl gallate
OG	Octyl gallate
PG	Propyl gallate
SDS	Sodium dodecyl sulfate
$S_{con}$	Stoichiometric factor in the control system
$S_{eff}$	Effective stoichiometric factor of the antioxidant in the emulsifier pseudophase
$S_{obs}$	Observed stoichiometric factor of the entire complex system

## Introduction

It is of current interest to understand the parameters that influence the activity of antioxidants in complex systems

and to develop methods that allow a systematic approach focusing on interfaces. Electron spin resonance experiments (ESR) allow estimating the potency of hydrogen atom donation of antioxidants in various systems measuring the reaction rate with stable radicals [1–3] or unstable radicals in the presence of spin trapping probes [4]. Since the ESR spin probe is applicable for investigating the actions of antioxidants in membranes and lipoproteins [1, 5], it can be likewise used for emulsions and micellar solutions [2, 3, 6, 7]. Stable radicals that are excellent spin probes for either lipophilic or hydrophilic phases and show good reactivity towards antioxidants are the hydrophilic Fremy's radical [2, 8, 9] and the lipophilic galvinoxyl [10, 11]. Alteration of the microenvironment are indicated by changes of line shape, width and intensity [12] changes in the hyperfine splittings of spectra give information on the solubilization of radicals in dispersed systems.

Fremy's radical can be used as a probe for the peroxy radical because of their similar reaction mechanism, their isoelectronically structure and their large dipole moment [2, 13]. This probe is of negative charge and posses a well-defined and sharp spectrum in an aqueous solution at room temperature. Galvinoxyl is a resonance-stabilized and sterically protected radical that is particularly applied to test the activity of lipophilic antioxidants [11]. In the presence of phenolic compounds it is reduced by hydrogen atom transfer, where the process is governed by O–H bond dissociation enthalpy of the donor group [14]. A comparison of antioxidant assays based on radical scavenging and lipid oxidation showed good correlations between the inhibition of oxidation products in lipids and the reaction with stable radicals like DPPH, Fremy's radical and galvinoxyl. It was concluded that investigation of stable radical scavenging is a suitable method to predict the antioxidant activity in bulk lipids [15]. However, in complex dispersed systems like emulsions, antioxidant activity is related to various parameters determined by the interface. Depending on the particular emulsifier used, an accumulation of antioxidants at the interface can be achieved [16, 17]. Although the interface is the main site of lipid oxidation [18–21] enrichment of antioxidants at the interface does not necessarily result in an enhancement of antioxidant activity [22]. The loss of efficiency may be related to interactions between antioxidants and emulsifiers at the interface, which may be hydrophobic in origin or due to hydrogen bonding [22]. These interactions may influence the characteristics of the phenolic OH-bond, thereby affecting the hydrogen atom transfer process from the antioxidant to the free radical [22–24]. Further, the location of radicals in the interface is not well known. Only a few data based on the dipole moment are available in the literature, suggesting that alkyl radicals are buried in the interface whereas hydroxy radicals are close to the aqueous environment [18, 19, 21].

The aim of this study was to investigate effects of different interfaces on the antioxidant efficiency. For this purpose, a novel ESR approach was developed using stable radicals with definite solubilization sites characterized by NMR. Interfaces were modeled by micellar solutions using cationic CTAB, anionic SDS and non-ionic Brij 58. Gallates with different alkyl chain length were used to vary the location of antioxidants in the interface.

## Experimental Procedures

### Chemicals

Cationic CTAB (cetyltrimethylammonium bromide,  $\geq 99\%$ ), non-ionic Brij 58 (polyoxyethylene-20-cethyl ether,  $>98\%$ ) and the gallates (Fig. 1): gallic acid ( $>99.9\%$ ), methyl gallate ( $\geq 98\%$ ), ethyl gallate ( $\sim 98\%$ ), propyl gallate ( $>99\%$ ), butyl gallate ( $>98\%$ ), and octyl gallate ( $\geq 99\%$ ) were obtained from Sigma-Aldrich, Germany. Fremy's radical (potassium nitrosodisulfate) and galvinoxyl (2,6-di-*tert*-butyl- $\alpha$ -(3,5-di-*tert*-butyl-4-oxo-2,5-cyclohexadiene-1-ylidene)-*p*-tolyl-oxy) were purchased from Sigma-Aldrich, UK. Anionic SDS (sodium dodecyl sulphate,  $\geq 99\%$ ) was obtained from Carl Roth, Germany. All chemicals were used without further purification.

### ESR Analysis

Electron spin resonance (ESR) measurements were carried out on a Bruker ECS 106 spectrometer at room temperature. It was operating at approximately 9.7 GHz (ECS 041 MR, microwave bridge X-band) and equipped with a TM<sub>110</sub> cavity. Spectra were analyzed using WinEPR software (Bruker). Spectra of the previously unreacted radical were recorded by ESR static measurements, after the required time by which the reaction had gone to completion from the mixing of the radical with the sample. Concentrations of the remaining radicals were calculated by double integration of the spectrum and referred to that of the individual control system consisting of buffer (ethanolic) or micellar solution and radical without any antioxidant present. After plotting the applied concentrations of

**Fig. 1** Structures of gallates

antioxidants against the remaining radical concentration the reaction stoichiometry could be obtained by linear fit. Reproducibility of the individual decay curves was in good accordance. The relative standard deviation for the antioxidant Trolox, a hydrophilic derivative of  $\alpha$ -tocopherol, was measured in triplicate. Two percentages were added for safety to determine an experimental error as a function of the system (Fremy's radical in buffer (3%), in SDS (4%) and in Brij (5%) solution; Galvinoxyl in ethanolic (3%), CTAB (3%), SDS (5%) and Brij (8%) solution).

#### Fremy's Radical

Stock solution (2 mmol/l) of Fremy's radical, 4% of SDS and Brij micellar solutions, and 4 mmol/l stock solutions of antioxidants in acetic buffer solution (0.2 mol/l, pH 5.00) were prepared (exception octyl gallate: 2 mmol/l and 2% micellar stock solution). At first the antioxidants were mixed in varying concentrations (0.1–0.5 mmol/l) either with 1.5 ml micellar solution or buffer solution to a volume of 3 ml. Equal volume of Fremy's radical stock solution were added. After 5 min of shaking and transferring into an ESR static quartz cell, the spectra of the low-field peak of the previously unreacted Fremy's radical were recorded [8, 9]. The spectra were obtained by following machine settings: centerfield: 3449.95 G, sweep width: 4.0 G, microwave frequency: approx. 9.73 GHz, microwave power: 2.01 mW, modulation frequency: 100 kHz, modulation amplitude:  $9.51 \times 10^{-2}$  G, receiver gain:  $2.5 \times 10^{+3}$ , conversion time: 20.48 s, time constant: 10.24 s.

#### Galvinoxyl

Stock solutions of 4 mmol/l galvinoxyl in ethanol, 2% micellar solution of SDS, Brij, and CTAB in buffer solution as well as 4 mmol/l antioxidants in ethanol were prepared. An aliquot of 500  $\mu$ l ethanolic galvinoxyl stock solution were filled up with micellar solution to 50 ml. For investigations in bulk solutions (control) the galvinoxyl stock solution was only diluted tenfold in ethanol. Dilution was repeated for the ethanolic antioxidant stock solutions. Buffer solution and antioxidant solution were premixed in varying concentrations in a total volume of 3 ml and finally an equal volume of the galvinoxyl containing micellar solution was added. After 5 min the reaction had reached completion [11] and the spectra were able to be recorded under the following conditions: centerfield: 3464.45 G, sweep width: 30.0 G (40.0 G in ethanol; The ethanolic solution was not deoxygenated for better handling, therefore the spectrum was getting broader), microwave frequency: approx. 9.73 GHz, microwave power: 2.01 mW, modulation frequency: 100 kHz, modulation amplitude: 1.07 G, receiver gain:  $8 \times 10^4$  ( $86.3 \times 10^4$  in ethanol),

conversion time: 81.92 s (40.96 s in ethanol), time constant: 40.96 s (20.48 s in ethanol).

#### $T_1$ Relaxation Time

$T_1$  relaxation time were performed on a Bruker DRX500 ( $B_0 = 11.75$  T) spectrometer in a 5 mm multinuclear inverse probe and at a constant temperature of  $300 \pm 0.1$  K. Performance of NMR-measurements is previously described in detail [25]. Experimental errors were calculated for each proton signal and were set on 10%. The individual emulsifier protons are shown in Fig. 2 their respective nomenclature for the specific headgroup region (hg), the alkyl chain (alk) as well as for the individual methylene and methyl protons that split into a single multiplet ( $\alpha$ ,  $\beta$ ,  $\gamma$  and  $\omega$ ).

## Results and Discussion

### Solubilization Sites of Fremy's Radical

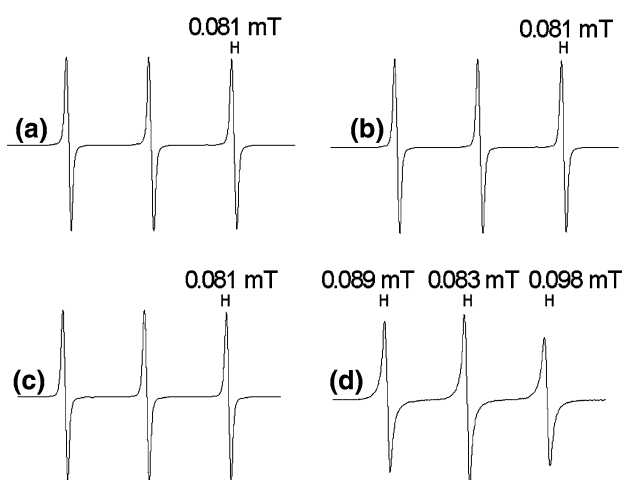

The isotropic spectrum of Fremy's radical consists of three single narrow peaks that arise from the interaction of the unpaired electron spin with the nuclear spins of nitrogen ( $I = 1$ ) (Fig. 3a). The anisotropic spectrum is characterized by axial symmetry; the peaks correspond to the extreme case of orientation of the principle axis parallel to the field (Fig. 3b).

Peak shapes and width of the spectra of Fremy's radical in buffer solution and SDS or Brij micellar solutions were equal and showed typical isotropic spectra (Fig. 4). In contrast, the spectrum of Fremy's radical in CTAB micellar solution showed anisotropic effects (Fig. 3b) due to the

**Fig. 2** Structures and nomenclature of the emulsifiers CTAB, Brij 58 and SDS: headgroup protons (hg), alkyl chain protons (alk), individual methylene and methyl protons ( $\alpha$ ,  $\beta$ ,  $\gamma$  and  $\omega$ )

**Fig. 3** Spectra and structure of Fremy's radical including  $g$  and  $A$  values, **a** isotropic spectrum of Fremy's radical in buffer solution at 20 °C, **b** anisotropic spectrum of Fremy's radical at -77 °C

**Fig. 4** Spectra of Fremy's radical in different micellar solutions including the peak width **a** in buffer solution, **b** in SDS solution, **c** in Brij solution, **d** in CTAB solution

broadening of the peaks (Fig. 4), particularly the first and the third peak.

To obtain additional information on the location of Fremy's radical, the  $T_1$  relaxation time of the individual emulsifier proton signals was measured in the presence of Fremy's radicals by NMR [25] (Fig. 5). The  $T_{1,r}$  relaxation ratio was defined by the relationship of the  $T_1$  relaxation time in the presence and absence of radicals by the following equation:

$$T_{1,r} = \frac{T_{1,\text{radical present}}}{T_{1,\text{radical absent}}} \quad (1)$$

None of the SDS emulsifier proton signals showed significant alteration in the  $T_{1,r}$  ratio. i.e., Fremy's radical is solubilized exclusively in the aqueous environment of SDS micellar solution. As the headgroups of SDS are negatively charged, a repulsive effect [2] in addition to the strong

**Fig. 5**  $T_{1,r}$  relaxation ratio of single emulsifier proton signals in the presence to the absence of Fremy's radical. [Emulsifier protons: headgroup protons ( $hg$ ),  $\beta$ -CH<sub>2</sub> protons ( $\beta$ ), alkyl chain protons ( $alk$ ) and  $\omega$ -CH<sub>3</sub> protons ( $\omega$ )]

polarity of Fremy's radicals determined the solubilization in the aqueous phase.

The Brij headgroup signal showed a marked reduction of the  $T_{1,r}$  relaxation ratio relative to that in pure buffer solution (Fig. 5), while the other signals had the same  $T_1$  relaxation time in the presence and absence of Fremy's radical. This provided evidence that Fremy's radical is partly solubilized in the large headgroup region of Brij. The headgroup region of Brij offers an environment resembling a concentrated solution of polyoxyethylene groups [26] with a high water content [27]. i.e. the hydrophilic Fremy's radical may partition between the aqueous environment and the headgroup area of Brij.

A precipitation of Fremy's radical was observed in CTAB micellar solution seen in the strong reduction of the  $T_{1,r}$  relaxation ratio of all CTAB proton signals (Fig. 5). This was in all likelihood caused by strong electrostatic

**Fig. 6** Concentration of Frey's radical in different micellar solutions as a function of time

interaction between the negatively charged Frey's radical and the positively charged headgroup of CTAB [2]. Therefore, systems containing Frey's radical and CTAB systems were excluded from further investigations.

Observation of the remaining concentration of Frey's radical in buffer and micellar solutions over a period of 20 and 30 min indicated a sufficient stability of the radical in buffer, SDS, and Brij micellar solutions. In contrast, Frey's radical content was reduced immediately by 60% in CTAB solution due to precipitation (Fig. 6).

#### Solubilization Sites of Galvinoxyl

Galvinoxyl demonstrates in ethanolic solution a characteristic isotropic spectrum consisting of a doublet of quintets which arise from the interaction of the unpaired electron with the nuclear spins of the proton on the central carbon and the four equivalent protons on the aromatic ring

**Fig. 7** Spectra and structure of galvinoxyl including  $g$ ,  $A$  values and peak width ( $pw$ ), **a** isotropic spectrum of galvinoxyl in deoxygenated ethanol solution at 20 °C, **b** anisotropic spectrum of galvinoxyl at -77 °C

( $I = 1/2$ ) (Fig. 7a). The anisotropic spectrum of galvinoxyl shows an enormous broadening of two large signals. The hyperfine splitting of the four aromatic ring protons completely disappeared and the distance between the left doublet signals was doubled compared to the isotropic spectrum (Fig. 7b).

The isotropic hyperfine splitting of galvinoxyl (Fig. 2a) was found to be particularly sensitive to changes in the microenvironment. The presence of oxygen interfered with the aromatic ring protons so that the hyperfine splitting nearly disappeared (Fig. 8). Therefore, it was necessary to deoxygenate the ethanol system prior to the addition of galvinoxyl. To dissolve galvinoxyl in micellar solutions and emulsions, an organic solvent was used as the carrier. In order to minimize interfering effects of the carrier solvent the volume had to be kept at minimum. Different solvents were tested for their impact on galvinoxyl. In hexane, the maximum amount of galvinoxyl that could be dissolved was fivefold and in octanol threefold higher than in ethanol (ethanol 20 mmol/l < octanol 33 mmol/l < hexane 100 mmol/l). The spectra of galvinoxyl dissolved in deoxygenated hexane or octanol, showed a similar hyperfine splitting compared to that in deoxygenated ethanolic solution (Fig. 9).

**Fig. 8** Spectra of galvinoxyl in ethanolic solution in the presence (a) and absence (b) of oxygen, including  $A$  values and peak width ( $pw$ )

**Fig. 9** Spectra of galvinoxyl in hexane (a) and octanol (b) including  $A$  values and peak width ( $pw$ )

Ethanol (1%) or octanol (0.6%) as carrier solvent in Brij micellar solution altered only slightly the hyperfine splitting compared with that of galvinoxyl dissolved in deoxygenated ethanolic solution. The distance between both doublet signals and the single quintet signals tended to increase and the separation was not as sharp as in ethanolic solution. Transfer of galvinoxyl into Brij micellar solution using hexane (0.2% carrier solvent was required) led to a completely different spectrum and the solution slowly became turbid accompanied by increasing viscosity (Fig. 10).

The reduction of the galvinoxyl concentration resulted in increasing sharpness of the hyperfine splitting. A tenfold lower concentration of galvinoxyl showed a spectrum quite similar to that in deoxygenated ethanolic solution (Fig. 11) as spin–spin interactions of galvinoxyl are reduced at lower concentration due to decreasing proximity.

When galvinoxyl was added in ethanol to the buffer solution without any emulsifier present, the hyperfine splitting was lost (Fig. 12) and brownish particles were formed, which were indicative of precipitation of galvinoxyl in aqueous solution. However, when it was added to micellar solutions, the hyperfine splitting was retained and

**Fig. 10** Spectra of 0.2 mmol/l galvinoxyl dissolved first in ethanol (a), octanol (b) or hexane (c) and subsequently transferred into Brij micellar solution

**Fig. 11** Spectra of galvinoxyl dissolved in ethanol and then transferred into Brij micellar solutions, recorded in the presence of 0.2 mmol/l (a) and 0.02 mmol/l (b) of galvinoxyl in micellar solutions including  $A$  values and peak width ( $pw$ )

**Fig. 12** Spectra of the galvinoxyl in buffer solution and different micellar solutions with the  $A$  values and peak width ( $pw$ ): a in buffer solution, b in SDS solution, c in Brij solution, d in CTAB solution

comparable to that of galvinoxyl dissolved in deoxygenated ethanol indicating that galvinoxyl is solubilized in the micelles of CTAB, SDS and Brij. The spectrum of galvinoxyl in CTAB micellar solution showed the most similarity compared with that recorded in deoxygenated ethanol. Small changes of the hyperfine splitting were observed in SDS micellar solution.

Further indication of the solubilization sites of galvinoxyl were found by the  $T_{1,r}$  relaxation ratio of single surfactant proton signals in the presence and absence of galvinoxyl (Eq. 1). This ratio decreased for all emulsifiers from the hydrophilic headgroup with approximately 1 to the lipophilic  $\omega$ -CH<sub>3</sub> signal indicating stronger interactions with galvinoxyl the more lipophilic the emulsifier protons. Whereas the  $\omega$ -CH<sub>3</sub> of CTAB decreased to 0.4, the same proton signal of Brij was only significantly reduced to 0.7 and that of SDS roughly to 0.9 (Fig. 13). As these data demonstrated that galvinoxyl is solubilized in the deeper

**Fig. 13**  $T_{1,r}$  relaxation ratio of single emulsifier proton signals in the presence of galvinoxyl. [Emulsifier protons: headgroup protons (*hg*),  $\beta$ -CH<sub>2</sub> protons ( $\beta$ ), alkyl chain protons (*alk*) and  $\omega$ -CH<sub>3</sub> protons ( $\omega$ )]

region of the palisade layer, it can be concluded that galvinoxyl is completely solubilized in the micelles of CTAB, SDS and Brij.

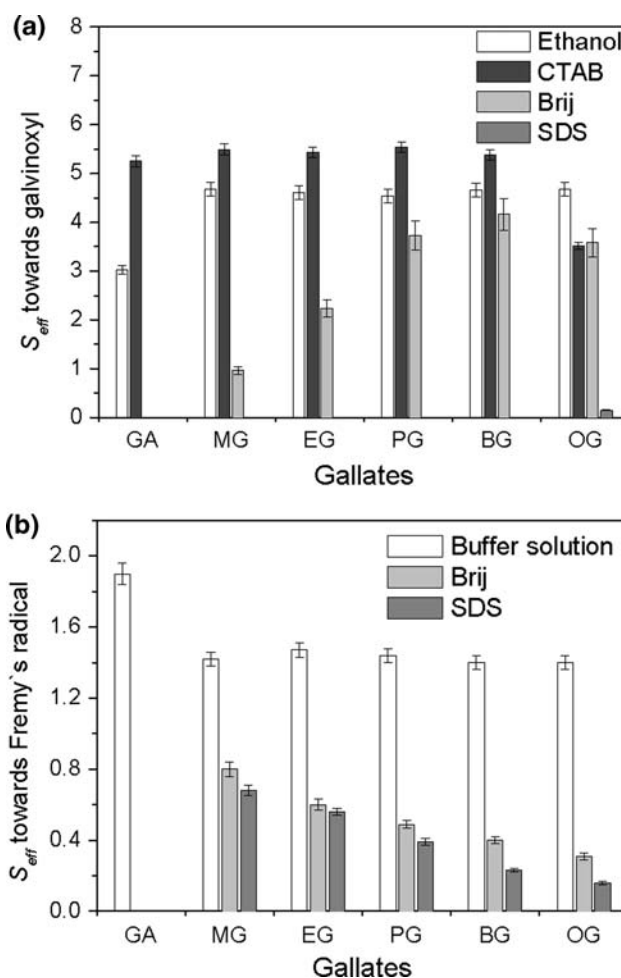

#### Activity of Gallates Solubilized in the Emulsifier Pseudophase of Micellar Solutions

Reaction stoichiometries for gallates were determined towards the hydrophilic Frey's radical and the lipophilic galvinoxyl. The exchange process of the solute between the different phases is very fast, so that the observed stoichiometry is actually an average of the ones in all different phases [28]. To calculate the effective stoichiometric factor  $S_{\text{eff}}$  of gallates in the interface (modeled by the surfactant micelles) the stoichiometric factor of the entire system  $S_{\text{obs}}$ , the portion of the antioxidant that is solubilized in the micellar pseudophase  $f_{\text{sol}}$  as well as the stoichiometric factor in the control system  $S_{\text{con}}$  need to be considered as expressed in Eq. 2 [29]:

$$S_{\text{obs}} = S_{\text{con}}(1 - f_{\text{sol}}) + S_{\text{eff}}f_{\text{sol}} \quad (2)$$

Thus, the values listed in the tables describe the antioxidant activities either of the entire system, i.e. micellar solution, buffer or ethanolic solution (control). For antioxidants partly partitioning into the micelles the effective stoichiometric factors  $S_{\text{eff}}$  are compared in Fig. 14a, b. For antioxidants that are only solubilized in the aqueous phase, comparison of the effective parameters obtained in individual phases was not useful and instead the observed stoichiometric factors  $S_{\text{obs}}$  (Table 1) were used for comparison.

The stoichiometric factors were equal for all gallates but gallic acid in buffer solution (Table 1). One gallate ester

**Fig. 14** Stoichiometric factors of various gallates towards Frey's radical in buffer solution and in the emulsifier pseudophases  $S_{\text{eff}}$  of SDS and Brij micellar solutions (a), and towards galvinoxyl radical in ethanol and in the emulsifier pseudophases  $S_{\text{eff}}$  of CTAB, SDS, and Brij micellar solutions (b).  $S_{\text{eff}}$  is calculated according to Eq. 2 including the following values for  $f_{\text{sol}}$  [30]: CTAB with GA = 0.493, MG = 0.86, EG = 0.939, PG = 0.989, BG = 0.996, OG = 1; Brij with GA = 0.226, MG = 0.5, EG = 0.654, PG = 0.861, BG = 0.951, OG = 1; SDS with GA = 0, MG = 0.297, EG = 0.506, PG = 0.689, BG = 0.824, OG = 1

molecule reacted on average with 1.4–1.5 molecules of Frey's radical, while GA was able to reduce on average 1.9 molecules of Frey's radical. Also all gallates with the exception of GA showed the same activity towards the lipophilic galvinoxyl radical in ethanolic solution and reduced on average 4.5–4.7 molecules galvinoxyl per molecule gallate. In the case of GA,  $S_{\text{eff}}$  was lower and amounted on average to 3.0.

#### Activity of Gallates in CTAB Systems

Solubilized in the CTAB emulsifier pseudophase, all gallates but OG showed the same activity of about

**Table 1** Observed stoichiometry  $S_{\text{obs}}$  of the reaction between various antioxidants and Fremy's radical or galvinoxyl in the control and in micellar solutions

BG	1.4 ± 0.04	0.5 ± 0.02	0.4 ± 0.02	4.7 ± 0.14	5.4 ± 0.11	4.2 ± 0.33	0.2 ± 0.01
OG	1.4 <sup>a</sup> ± 0.04	0.3 ± 0.02	0.2 ± 0.01	4.7 ± 0.14	3.5 ± 0.07	3.6 ± 0.29	0.2 ± 0.01

<sup>a</sup> Octyl gallate could not be dissolved in buffer solution. However, the stoichiometric factor was assumed to be equal to that of the other gallates

$S_{\text{eff}} = 5.4$  but being higher than in the control (Fig. 14a). As we found in studies investigating the location of antioxidants in dispersed systems [25, 31] the main proportion of these gallates partitioned into the CTAB emulsifier pseudophase and was solubilized in the palisade layer of CTAB (see caption of Fig. 14). Consequently, gallates can be in very close proximity to galvinoxyl, which is exclusively solubilized in the interior of CTAB micelles. Thus, the accelerated activity towards galvinoxyl may be attributed to a local concentration effect that can occur by the accumulation of both gallates and galvinoxyl in the CTAB micellar phase resulting in an increase of their collision frequency [32]. The stoichiometric factor for OG towards galvinoxyl indicated a deeper intercalation into the micellar interior. Deeper intercalation can be accompanied by stronger specific interactions with CTAB than found between the other gallates and CTAB [33].

#### Activity of Gallates in SDS Systems

The stoichiometric factors of the solubilized proportion of gallates towards galvinoxyl in SDS micelles solution were close to zero (Fig. 14a). This may be accounted to the difference in solubilization sites of gallates and galvinoxyl. Gallates were found to be solubilized in the Stern layer of SDS micelles [25, 31] and the galvinoxyl is located in the micellar interior (Figs. 12, 13). Thus, it can be concluded that the SDS micelle acted as a physical barrier, i.e. providing different environments and thereby segregating the radicals and the antioxidants [34–36]. The reduced antioxidant activities in SDS micellar systems were consistent with results of studies that investigated the influence of increasing chain length of vitamin C derivatives [2, 3, 37] and vitamin E derivatives [2, 3, 38].

Reaction of the solubilized proportions of gallates with Fremy's radical in the emulsifier pseudophase of SDS micelles decreased with increasing chain length (Fig. 14b). This may also be attributed to the solubilization of the

gallate ester in the Stern layer where two different processes may influence the radical quenching activity. Since Fremy's radical is negatively charged, it may be electrostatically repelled by the anionic headgroup of SDS, and solubilization of Fremy's radical in the Stern layer is not feasible. The longer the ester alkyl chain, the deeper the aromatic ring could be located in this layer reducing contact with Fremy's radical.

#### Activity of Gallates in Brij Systems

In the Brij emulsifier pseudophase, the stoichiometric factors of the different gallate esters towards galvinoxyl were found to be enhanced with increasing ester alkyl chain length up to PG, whereas the reaction stoichiometry from PG to OG was constant (Fig. 14a). Our studies showed that antioxidants were located in the headgroup region of Brij (polyoxyethylene chain) [25, 31] and with stronger antioxidant lipophilicity additionally in the palisade layer. Since the gallate esters up to PG were located closer to the micellar interior with increasing alkyl chain [33], this is consistent with the assumption that a closer proximity of antioxidant and radical would facilitate their reaction.

The stoichiometric factor of the solubilized proportions of gallates with hydrophilic Fremy's radical in the emulsifier pseudophase of Brij micelles gradually decreased with increasing gallate lipophilicity (Fig. 14b). Because the proportions of the individual gallates solubilized in the Brij emulsifier pseudophase were higher than in the SDS emulsifier pseudophase, this provided additional evidence that Fremy's radical is partly located in the hydrophilic region of the Brij headgroup (Fig. 5). Consequently, Fremy's radical and gallates were in closer proximity than in SDS micellar solutions. OG may penetrate deeper into the polyoxyethylene region, because of the longer alkyl chain and thus form stronger H-bonds with the oxygens of the polyether groups of Brij that reduce the H-atom abstraction kinetic [26, 39, 40].

The observed stoichiometric factor (Table 1) of GA in Brij micellar solution were the same as in pure buffer solution, as the majority of GA is solubilized outside the micelle and the effect of closer proximity in the micelle is not significant.

## Conclusion

The solubilization sites of the hydrophilic Fremy's radical and hydrophobic galvinoxyl at interfaces were characterized by ESR and NMR experiments. It was shown that the close proximity of radical and antioxidant is a crucial prerequisite for the radical reducing action of antioxidants. The depth of intercalation for galvinoxyl in the interface depended on the surfactant used and increased in the order SDS < Brij < CTAB. CTAB increased the antioxidant efficiency due to solubilization of antioxidant and hydrophobic radical in close proximity in the micelle interior and thereby elevating their concentrations. In interfaces modeled by Brij a longer alkyl chain of the antioxidant (from methyl to butyl) resulted in increasing antioxidant efficiency. In contrast, interfaces modeled by SDS micelles caused a segregation of galvinoxyl (palisade layer) and antioxidant (stern layer), thus no antioxidant action took place. The hydrophilic Fremy's radical was exclusively solubilized in the aqueous environment of SDS systems but partitioned partly into the large headgroup region of Brij micelles. As gallates were solubilized to substantial amounts in micelles, the antioxidant efficiency was higher in Brij than in SDS micellar systems. The data clearly demonstrated that information on the solubilization sites of antioxidants and radicals are essential to control the antioxidant activity at interfaces present in a wide range of foods, cosmetics, pharmaceuticals (emulsions and carrier systems) and of biological membranes.

## Macadamia Nut Consumption Modulates Favourably Risk Factors for Coronary Artery Disease in Hypercholesterolemic Subjects

Manohar L. Garg · Robert J. Blake · Ron B. H. Wills · Edward H. Clayton

Received: 11 January 2007 / Accepted: 17 February 2007 / Published online: 17 April 2007  
© AOCs 2007

**Abstract** Macadamia nuts are rich source of monounsaturated fats (oleic and palmitoleic acids) and contain polyphenol compounds, therefore, their consumption can be expected to impart health benefits to humans. This study was conducted to examine the effects of consuming macadamia nuts in hypercholesterolemic male individuals on plasma biomarkers of oxidative stress, coagulation and inflammation. Seventeen hypercholesterolemic male subjects were given macadamia nuts (40–90 g/day), equivalent to 15% energy intake, for a period of 4 weeks. As expected, monounsaturated fatty acids (16:1n-7, 18:1n-9 and 20:1n-9) were elevated in the plasma lipids of all volunteers following intervention with macadamia nuts. Plasma markers of inflammation (leukotriene,  $LTB_4$ ) and oxidative stress (8-isoprostane) were significantly lower ( $1,353 \pm 225$  vs.  $1,030 \pm 129$  pg/mL and  $876 \pm 97$  vs.  $679 \pm 116$  pg/mL, respectively) within 4 weeks following macadamia nut intervention. There was a non-significant (23.6%) reduction in the plasma  $TXB_2/PGI_2$  ratio following macadamia nut consumption. This study demonstrates, for the first time, that short-term macadamia nut consumption modifies favourably the biomarkers of oxidative stress, thrombosis and inflammation, the risk factors for coronary artery disease, despite an increase in dietary fat intake. These data, combined with our previous results on cholesterol-lowering effects of macadamia nuts, suggest that

regular consumption of macadamia nuts may play a role in the prevention of coronary artery disease.

### Introduction

Dietary factors known to alleviate lipid peroxidation and oxidative stress levels in humans include carotenoids, flavonoids, antioxidant vitamins (vitamin A, C and E), glutathione, uric acid and ubiquinone Q10. n-6 and n-3 Polyunsaturated fatty acids (PUFA) have been shown to favourably modify plasma lipid levels but are vulnerable to oxidative damage and may increase requirements for antioxidants to protect them from auto-oxidation and minimise oxidative damage in the body [1–3]. Saturated fatty acids in the diet, although not susceptible to oxidative deterioration, have been associated with an increase in total and LDL-cholesterol. Monounsaturated fatty acids (MUFA), shown to be cholesterol neutral or even cholesterol-lowering in several studies [4, 5], also have the potential to reduce demands for anti-oxidants, thus help reducing oxidative stress in vivo [6–8]. Research on whole foods containing factors with antioxidant activity is sparse.

The macadamia nut, a tree nut native to Australia, contains approximately 75% fat (w/w) and more than 85%

of its energy from fat. Macadamia nuts contain higher levels of monounsaturated fatty acids than any other food source known to-date (more than 60 g/100 g of edible whole nuts) [9]. Curb et al. [10] demonstrated that a macadamia nut-based diet is nearly as effective as a moderately low-fat diet (American Heart Association Step 1 diet) in reducing total plasma cholesterol and LDL cholesterol, in comparison to a typical American diet. We have recently demonstrated that replacing 15% dietary energy intake by macadamia nuts (40–90 g/day) lowers total and LDL-cholesterol and increases HDL-cholesterol in hypercholesterolemic subjects within 4 weeks [11]. In general, research on tree nuts has been limited to their ability to modulate plasma lipid levels and information on their potential to modulate other health risk factors, including oxidative damage, inflammation and clotting tendency, is lacking in the literature.

The current study was conducted to examine the effects of consuming macadamia nuts on plasma biomarkers of oxidative stress, coagulation and inflammation in subjects with an increased risk of coronary artery disease.

## Experimental Procedures

### Subjects

Seventeen male hypercholesterolemic subjects with a cholesterol range of 6.1–7.5 mmol/L were advised to maintain their regular lifestyle especially their physical activity throughout the study period.

### Study Design

Freshly roasted lightly salted and unsalted macadamia nut kernels (*Macadamia integrifolia*) were purchased from the Suncoast Gold Macadamias Ltd (QLD, Australia). Participants consumed macadamia nuts contributing an equivalent of approximately 15% of the total daily energy intake for a 4-week period. The absolute amount of macadamia nuts consumed ranged between 40–90 g/day, depending on subject's energy intake. Nuts were packed in separate bags containing only 1-day supply/bag. An extra colour-coded bag of macadamia nuts was given to the volunteers to share with family and friends in order to improve compliance. Compliance was measured by examining the incorporation of palmitoleic acid (16:1n-7) into plasma lipids following the 4 weeks intervention period. Fasting blood samples were collected by venipuncture on entry to the study and at the conclusion of the intervention. Fatty acid composition of macadamia nuts and nutrient intake of the study participants has been reported previously [11].

### Markers of Inflammation and Oxidative Stress

Venous blood for 8-iso-prostaglandin F<sub>2α</sub> (8-isoprostane) analysis was collected in tubes pre-coated with EDTA and containing 1 mg/mL whole blood of reduced glutathione (GSH) (Sigma Chemical Company, St Louis, MI, USA) as an antioxidant in order to prevent in vitro production of isoprostanes. Separated plasma was transferred to storage tubes, pre-coated with butylated hydroxytoluene as an antioxidant in order to further prevent in vitro production of isoprostanes, and stored at –70 °C until analysis. 8-Iso-PGF<sub>2x</sub> was determined using an 8-isoprostane EIA kit (Cayman Chemical Company, Ann Arbor, MI, USA). The ability of this assay to measure 8-iso-PGF<sub>2x</sub> was validated using a series of known amounts of 8-iso-PGF<sub>2x</sub> and a high correlation was found between the known positive control concentrations and the values determined using the kit.

Plasma leukotriene B<sub>4</sub> (LTB<sub>4</sub>) levels were determined on venous blood collected into tubes coated with EDTA using a commercially available LTB<sub>4</sub> EIA kit (Cayman Chemical Company, Ann Arbor, MI, USA).

### Thromboxane and Prostacyclin Assays

Plasma thromboxane (TXB<sub>2</sub>) concentrations were determined using a commercially available thromboxane B<sub>2</sub> EIA kit (Cayman Chemical Company, Ann Arbor, MI, USA). Venous blood was collected into an indomethacin coated blood tube, mixed gently by inversion, and then centrifuged at 3,000×g for 10 min at 4 °C. The plasma fraction was removed and stored at –70 °C until analysis.

An aliquot of <sup>3</sup>H-TXB<sub>2</sub> equivalent to 5,000 cpm was added to a 500 μL aliquot of plasma. The samples were deproteinated by the addition of 2 mL of ethanol, followed by vigorous mixing. Samples were allowed to stand at 4 °C prior to being centrifuged at 1,500×g for 10 min. 8 mL of 0.1 mM phosphate buffer (pH 4.0) was added to the ethanolic supernatant, followed by vigorous vortex mixing.

Samples were further purified by solid phase extraction. A reverse phase (C18) Sep Pak cartridge (Waters) was first activated by washing with 5 mL of ethanol followed by 5 mL of ultra-pure water. Samples were loaded onto the cartridge and purified by washing with 5 mL of ultra-pure water followed by 5 mL of hexane. The TXB<sub>2</sub> was eluted from the cartridge into a glass tube with 5 mL of ethyl acetate:methanol (99:1). The elute was evaporated to dryness under a stream of nitrogen and then dissolved in assay buffer.

Fifty microlitre aliquots of sample, standard or buffer were added to wells of a microwell plate coated with Mouse Anti-rabbit IgG, followed by 50 μL of TXB<sub>2</sub> acetylcholinesterase tracer, and then TXB<sub>2</sub> antiserum. The plate was then covered with plastic film and incubated at

room temperature for 18 h. The wells were then emptied and washed five times with wash buffer. About 200  $\mu\text{L}$  of Ellman's reagent was added to each well and the plate was covered with plastic film. The plate developed in the dark on an orbital shaker for between 60–90 min. Absorbance was read at 412 nm on a microplate reader and TXB<sub>2</sub> concentration determined from a standard calibration curve in pg/mL.

Plasma prostacyclin I<sub>2</sub> levels were determined on venous blood collected into tubes coated with EDTA using a commercially available prostacyclin EIA kit (Cayman Chemical Company, Ann Arbor, MI, USA).

### Fatty Acid Analysis

The lipid profile of the plasma was determined according to a modification of the method of Lepage & Roy using an acetyl chloride methylation procedure, as detailed previously [12]. Fatty acid methyl esters were quantified using a Hewlett Packard 6890 gas chromatograph and quantified by comparison with authentic fatty acid methyl ester standards (Nu Chek Prep).

### Statistical Analysis

Mean and standard error of mean are presented for each measurement. Data for TXB<sub>2</sub> and prostacyclin (PGI<sub>2</sub>) were not normally distributed and were transformed using square root transformation prior to analysis. The Student *t* test (paired, two-tailed) was used to compare baseline values with post-intervention values. Differences were considered significant at  $P < 0.05$ .

## Results

The average age of the hypercholesterolemic subjects was 54 years and a BMI of 26.24 at baseline. A high degree of compliance was evident from the increase in MUFA content in the plasma samples following intervention with macadamia nuts. Specifically, the levels of palmitoleic acid (16:1n-7), for which the unique dietary source is macadamia nut, were elevated in all volunteers (Table 1). Plasma saturated and polyunsaturated fatty acids (n-6 and n-3) were not affected by the intervention.

LTB<sub>4</sub> levels in the plasma were lower ( $P = 0.024$ ) post-intervention ( $679 \pm 116$  pg/mL) compared with the baseline values ( $876 \pm 97$  pg/mL) (Fig. 1). 8-Isoprostane concentration was significantly ( $P = 0.032$ ) reduced from  $1,353 \pm 225$ – $1,030 \pm 129$  pg/mL following the feeding of macadamia nuts to hypercholesterolaemic subjects.

**Table 1** Plasma fatty acid composition (% of total fatty acids) of hypercholesterolaemic subjects ( $n = 17$ ) at baseline and post-intervention with macadamia nuts

<sup>a</sup> Means ( $\pm$ sem) are significantly different from the pre-intervention means ( $\pm$ sem) ( $P < 0.05$ )

TXB<sub>2</sub> and PGI<sub>2</sub> concentrations were not significantly lower ( $122 \pm 23$  vs.  $90 \pm 14$  pg/mL;  $P = 0.177$  and  $192 \pm 31$  vs.  $177 \pm 26$  pg/mL;  $P = 0.269$ , respectively) following macadamia nut consumption for 4 weeks (Fig. 1). The mean thromboxane TXB<sub>2</sub> to prostacyclin ratio was reduced by 23.6% following macadamia nut consumption, however, this change was not significant (from  $0.82 \pm 0.12$  to  $0.62 \pm 0.10$ ;  $P = 0.094$ ).

## Discussion

Hypercholesterolemia is a major risk factor for coronary artery disease and reducing plasma cholesterol levels, in particular LDL cholesterol, reduces the risk of this disease. In addition, an increase in the plasma levels of biomarkers

**Fig. 1** Plasma markers of oxidative stress and inflammation including *A* isoprostane (empty squares) and leukotriene B<sub>4</sub> (squares with diagonal lines) and *B* thromboxane (B<sub>2</sub>) (squares with horizontal lines) and prostacyclin I<sub>2</sub> (hatched squares) in hypercholesterolemic ( $n = 17$ ) subjects prior to and following the consumption of macadamia nuts (15% of energy) for 4 weeks. Values are means  $\pm$  standard error of the means (pg/mL). Asterisks indicate significantly different values from pre-supplementation value analysed by paired *t* test (isoprostane and prostacyclin) or Wilcoxin ranked sums test (leukotriene and thromboxane)

of clotting tendency, lipid peroxidation and inflammation also contribute to the development and progression of atherosclerosis. Dietary strategies have been focussed mainly to reduce circulating levels of cholesterol, LDL-cholesterol and to date very little attention has been paid to other biomarkers of coronary artery disease. In a recent study, we demonstrated that replacing 15% of daily energy intake by macadamia nuts for 4 weeks results in a significant reduction in plasma and LDL-cholesterol with a concomitant increase in HDL-cholesterol [11]. In the current study, we report, for the first time, the risk factors (biomarkers of oxidative stress, clotting tendency and inflammation) other than plasma/LDL cholesterol in subjects with elevated levels of plasma cholesterol following the consumption of macadamia nuts for 4 weeks.

8-Isoprostane produced from arachidonic acid by a free-radical catabolized reaction is a reliable in-vivo marker of oxidative stress [13, 14]. Plasma levels of 8-isoprostane were reduced by 18.9% following macadamia nut intervention. Previous studies have demonstrated that diets rich in MUFA reduce oxidisability of LDL and lower plasma 8-isoprostanes [15] and, therefore, may be cardio-protective. It is, therefore, likely that MUFA present in the macadamia nuts are responsible for the reduction in 8-isoprostane levels in hypercholesterolaemic subjects. It is also possible that the phenolic compounds present in macadamia nuts contribute to the reduction in plasma isoprostane levels [16].

LTB<sub>4</sub> derived from arachidonic acid by the action of lipo-oxygenase are highly chemotactic substance and elevated levels are suggestive of increased inflammation.

Replacing 15% of daily energy intake for 4 weeks resulted in a 22.5% reduction of LTB<sub>4</sub> concentration in the plasma. Anti-inflammatory effects of tree nuts, including macadamia nuts, have not previously been reported. A recent study using walnuts as an intervention in hypercholesterolemic subjects reported 64% increase in endothelium dependent vasodilation (EDV) with a concomitant reduction of the vascular cell adhesion molecule (VCAM-1) by 20% [17]. The authors attributed the change in VCAM-1 and EDV to changes in the plasma lipid profile and  $\alpha$ -linolenic acid present in walnuts. However, it is also likely that components of nuts, yet unidentified, may be responsible for the observed anti-inflammatory effects.

TXB<sub>2</sub> is a potent pro-aggregatory and PGI<sub>2</sub> is an anti-aggregatory substance, and the plasma ratio of TXB<sub>2</sub>:PGI<sub>2</sub> is a reliable indicator of clotting tendency which has been reported to be increased in hypercholesterolaemic individuals [18]. Although not significantly different, TXB<sub>2</sub>/PGI<sub>2</sub> ratio was lowered by 23.6% by macadamia nut intervention. This reduction in biomarkers of clotting tendency may be due to the presence of MUFA and/or vitamin E present in macadamia nuts [19, 20]. It is also likely that macadamia nuts contain compounds yet unidentified that may reduce the levels of these eicosanoids. In this context, examination of other biomarkers of clotting tendency, such as fibrinogen and ex-vivo measurements of platelet or whole blood aggregation, may be worthy of further investigation.

Taken together, the results presented suggest that consumption of macadamia nuts as part of a healthy diet is associated with a reduction in biomarkers of coronary artery disease. Combined with our previous study on cholesterol lowering effects of macadamia nuts [11], this study demonstrates that short-term consumption of macadamia nuts, despite increasing the fat content of the diet, may be used as an adjunct to drug therapy to reduce risk of coronary artery disease. Jenkins et al. [21] demonstrated that diets low in saturated fat and high in viscous fibers and phytosterols, when combined with vegetable protein foods and nuts, reduce plasma cholesterol and C-reactive protein similarly to the initial therapeutic dose of first generation statin. This study demonstrates that macadamia nuts may make an important contribution to the heart healthy diet. Long-term health benefits of macadamia nut consumption remain to be elucidated. The constituents of macadamia nuts responsible for the reduction in biomarkers remain to be identified. In this respect, palmitoleic acid (16:1n-7) present in high amounts (approximately 20% of total fatty acids) in macadamia nuts may appear promising. Effects of palmitoleic acid on eicosanoid metabolism are not known at present and are worthy of further investigations. The current study not only provides a pathophysiological explanation for the beneficial effects of consuming

macadamia nuts on the heart, but it also clearly shows that this beneficial effect was independent of any other lifestyle factors.

## Incorporation of Arachidonic and Stearic Acids Bound to L-FABP into Nuclear and Endonuclear Lipids from Rat Liver Cells

**Abstract** The incorporation of exogenous fatty acids bound to L-FABP into nuclei was studied. Rat liver cell nuclei and nuclear matrices (membrane depleted nuclei) were incubated in vitro with [1-<sup>14</sup>C]18:0 and 20:4n-6 either free or bound to L-FABP, ATP and CoA. FA esterification in whole nuclei and endonuclear lipids was ATP-CoA-dependent, and with specificity regarding fatty acid type and lipid class. 18:0 and 20:4n-6, free or L-FABP bound, showed the same incorporation and esterification pattern in lipids of whole nuclei. Only 20:4n-6 L-FABP bound was less incorporated into TAG with respect to free 20:4n-6. In the nuclear matrix, 18:0 free or L-FABP bound was esterified with a higher specific activity (SA) into: PtdEtn > PtdIns, PtdSer > PtdCho. 20:4n-6 free or L-FABP bound was esterified into: PtdIns > PtdEtn > PtdCho. 20:4n-6: L-FABP was esterified in endonuclear total-PL and PtdIns with a greater SA with respect to free 20:4n-6 and with a minor one as FFA. To summarize, trafficking of FA to nuclei includes esterification of 18:0 and 20:4n-6 either free or L-FABP-bound, into nuclear and endonuclear lipids by an ATP-CoA-dependent pathway. Endonuclear fatty acid esterification was more active than that in whole nuclei, and independent of the nuclear membrane. Esterification patterns of fatty acids L-FABP-bound or free into whole nuclear lipids were the same whereas in the nuclear matrix, L-FABP could play an important role in the

mobilization of 20:4n-6 into specific sites of utilization such as the PtdIns pools.

### Introduction

The biological function of fatty acids has long been considered only as a source of nutrients, substrates of metabolic energy and structural components in membranes when esterified in glycerolipids, sphingolipids and cholesterol. Currently we are aware that fatty acids have per se physiological and pharmacological properties; they also regulate gene expression.

Gene expression regulation is an event, which develops within the nucleus of eukaryotic cells. It may be produced by a direct effect of fatty acids (FA) or acyl-CoAs on the regulation of the genetic expression, or through the activation of transcription factors that are translocated to the nucleus [1, 2]. The regulation of gene transcription by FA may be due to changes in the activity or abundance of at least four transcript factor families: PPAR, LXR, HNF-4 $\alpha$  and SREBP [1, 2].

Fatty acids are molecules of hydrophobic nature and poor water solubility. They are strongly reactive and easily esterified to other lipids, moving about within the cell when bound to the fatty acid binding protein (FABP). FABP is involved in fatty acid metabolism by modulating their cellular import, their distribution and the activity of enzymes.

Fatty acid binding proteins (FABPs) belong to a family of cytosolic fatty acid chaperones specifically localized in

different animal tissues [3]; only the so-called L-FABP is biosynthesized in rat liver [4], and it is located in the cytoplasm as well as in the nucleus of hepatocytes. FABPs have evolved over millenniums from ancestral forms, and their cellular role and mechanism of action are being visualized. L-FABP is a soluble low molecular weight protein (14.3 kDa) that corresponds to approximately 5% of cytosolic liver proteins [5]. It has a tertiary structure consisting of ten antiparallel  $\beta$ -strands that form a  $\beta$ -barrel, which is capped by two short  $\alpha$ -helices arranged as a helix–turn–helix segment [6]. L-FABP, different to other FABPs contains two FA binding sites [6], but it can also bind other hydrophobic ligands even acyl-CoAs [7].

Studies with a fluorescent analogue of FAs showed that transfer of FA from the L-FABP to phospholipid membranes is consistent with an aqueous mediated diffusion model mechanism and differs from heart H-FABP and adipocyte A-FABP that form a transient collisional complex with membrane-like acceptors [4, 8].

Fatty acids of cellular nuclei may come from cytosol where they are synthesized, incorporated from the diet, or generated from the hydrolysis of other nuclear lipid pools. Although we have previously demonstrated that arachidonic acid is also synthesized in the nucleus by  $\Delta 5$  desaturation of 20:3n-6 acid, 20:3n-6 fatty acid must have originated in the cytosol (ER) [9]. These days, the precise trafficking of fatty acids from cytosol to nuclear receptors, where they participate in the regulation of gene expression, has not been fully elucidated.

We have demonstrated that in nuclei isolated from rat liver cells, exogenous acyl-CoAs, saturated and polyunsaturated fatty acids are incorporated in the nuclei by an esterification mechanism by means of an acyl-CoA-dependent pathway [10, 11]. FA are mainly esterified in phospholipids, to a minor proportion in triacylglycerols, and also incorporated as free fatty acid (FFA) [11]. In addition, we have demonstrated that arachidonic acid synthesized in the nucleus by  $\Delta 5$  desaturation of 20:3n-6 is rapidly esterified into nuclear lipids [12]. We have also reported that in nuclei, phosphatidylcholine fatty acids can be remodeled by an acyl-CoA-dependent process, in which cytosolic proteins would be involved [13]. It is still unknown whether cytosolic FABP or ACBP is involved in this process, though the existence of L-FABP and ACBP in the nucleus was corroborated [14, 15]. It was also found that PPAR- $\alpha$  is activated by L-FABP bound fatty acids [7, 16].

Taking into account that the available information is poor, the aim of this work was to study the role of L-FABP in the trafficking of fatty acids from the cytosol to the nuclei. Metabolizable fatty acids were chosen as they are closely related to lipid pools as already demonstrated, through interactions, esterification and hydrolysis. 18:0 and

20:4n-6 fatty acids were chosen as they are the major saturated and polyunsaturated acids in rat liver cell nuclear and endonuclear lipid pools [17].

## Materials and Methods

### Materials

[1-<sup>14</sup>C] Arachidonic acid (55 mCi/mmol 98.1% radiochemically pure) and [1-<sup>14</sup>C] stearic acid (56 Ci/mmol, 99% radiochemically pure) were purchased from New England Nuclear Co., Boston, MA. Rat liver fatty acid binding protein (L-FABP) was a kind gift from Betina Córscico (INIBIOLP, La Plata, Argentina). The recombinant rat pET11-a-L-FABP plasmid was kindly provided by Dr. Alan Kleinfeld and Dr. Ron Ogata (Torrey Pines Institute for Molecular Studies, San Diego, CA). The protein was expressed in the *E. coli* BL21 (DER) expression system and purified as described by Hsu and Storch [19]. Cofactors were provided by Sigma Chemical Co. (St Louis, MO). Chemicals and solvents were of analytical and HPLC grade. TLC precoated silica gel G 20 × 20 cm plates with a concentrated zone of 2.5 × 20 cm was from Merck (Argentina).

### Animals

Experiments were performed on male Wistar rats of 60–70 days of age, weighing 180–200 g. Rats were housed in rooms with 12–12 h light–dark cycle (midnight being the midpoint of the dark period), and the experiments were performed in accordance with the Guide of Care and Use of Laboratory Animals (1996, National Academy Press). Animals were maintained on a commercial standard pellet diet (Cargill mouse and rat chow, Pilar, Argentina) and tap water *ad libitum*. The diet contained 24% proteins and 8% of total lipids with a fatty acid composition (wt%) of 1.7% 14:0, 20.3% 16:0, 1.8% 16:1, 11.4% 18:0, 27.5% 18:1n-9, 2.1% 18:1n-7, 31.4% 18:2n-6, 3.1% 18:3n-3, 0.2% 20:4n-6, and 0.6% 22:6n-3.

### Preparation of Homogenate, Subcellular Fractions and Membrane-Depleted Nuclei

Rats were killed at 8 a.m. to equalize circadian rhythm effects [18], and livers pooled from 3–5 animals were homogenized in 0.25 M sucrose TKM [0.05 M Tris–HCl, (pH 7.5), 0.0025 M KCl, 0.005 M MgCl<sub>2</sub>] 1:2 (w/v). Highly purified nuclei were isolated from liver homogenate by sucrose-gradient ultracentrifugation using the method of Blobel and Potter modified by Kasper as described in a previous publication [9]. All steps were carried out at 4 °C.

To obtain the nuclear matrix (the membrane-depleted nucleus), a quantitative removal of the nuclear envelope was performed as already described [17]. The double nuclear membrane was solubilized with the non-ionic detergent Triton TX-100 followed by separation over a sucrose gradient using the method of Vann et al. [19] slightly modified as follows: 0.5 ml aliquot of nuclei (8 mg prot/ml) in solution A [10 mM Tris-HCl (pH 7.5); 2 mM MgCl<sub>2</sub>; 0.25 M sucrose] was mixed with 20 ml of ice-cold suspension buffer [5 mM Tris-HCl (pH 7.4), 5 mM MgCl<sub>2</sub>, 1.5 mM KCl, 0.29 M sucrose, 1 mM EGTA] and incubated on ice for 20 min. TX-100 was added to this buffer before the addition of the nuclei to yield a final concentration of 0.08% (w/v). The nuclei were pelleted at 165×g for 6 min (4 °C), and the supernatant removed. The pellet was resuspended in solution A (5 ml) and a 10 ml cushion of [10 mM Tris-HCl (pH 7.5), 2 mM MgCl<sub>2</sub>, 0.5 M sucrose] was carefully laid beneath it and then centrifuged at 165×g for 6 min (4 °C). This procedure was repeated once again. Membrane-depleted nuclei were then resuspended in 25% glycerol, [10 mM Tris-HCl (pH 7.9)] and stored at -80 °C until used. Concentration of nuclei and nuclear matrices in terms of proteins was determined by the method of Lowry et al. [20] using crystalline bovine serum albumin as standard.

#### Criteria of Nuclear Purity

Nuclei and membrane-free nuclei preparations were checked for purity by electron microscopy as described previously [10, 17].

#### Fatty Acids Bound to L-FABP (FA:L-FABP)

FAs concentrations bound to L-FABP were chosen so as to saturate the first high affinity binding site of L-FABP [21, 22]. Therefore, equivalent concentrations of 2 μM [1-<sup>14</sup>C] arachidonic, or [1-<sup>14</sup>C] stearic acid and 2 μM L-FABP were incubated for 1 min at 36 °C in a solution of 0.15 M KCl, 0.25 M sucrose, 5 mM MgCl<sub>2</sub>, 1.6 mM *N*-acetylcysteine, and 41.7 mM potassium phosphate buffer (pH 7.4).

#### Incorporation of [1-<sup>14</sup>C] FA into Nuclear and Endonuclear Lipid Pools

Incorporation of [1-<sup>14</sup>C] arachidonic and [1-<sup>14</sup>C] stearic acids in rat liver cell whole nuclei and nuclear matrices was performed by incubating 6 mg proteins from each nuclear source. The incubation medium contained 0.15 M KCl, 0.25 M sucrose, 5 mM MgCl<sub>2</sub>, 1.6 mM *N*-acetylcysteine, 41.7 mM potassium phosphate buffer (pH 7.4) with 2 μM [1-<sup>14</sup>C]FA free or bound L-FABP in the presence or ab-

sence of 60 μM CoA and 1.3 mM ATP. The open tubes were incubated by gentle shaking at 36 °C with a total volume of 1.6 ml, for 1, 5 and 10 min. After incubation, the nuclei were separated from the incubation mixture by centrifugation at 2,000×g at 4 °C for 10 min.

#### Lipid Analyses

Lipids were extracted from rat liver cell nuclei by the procedure of Folch et al. [24]. Lipids were recovered from the original chloroform extract; phospholipids, triacylglycerols, diacylglycerols and free fatty acids were separated by thin-layer chromatography (TLC) on precoated silica gel G plates with a concentration zone, using hexane-diethyl ether-acetic acid (80:20:2 v/v/v) as the mobile phase. The different phospholipid classes were also separated by TLC on the same type of plates, but using chloroform-methanol-acetic acid-water (50:37.5:3.5:2 v/v/v/v) as the mobile phase [17]. They were located and identified by comparison with known lipid standards and visualized by exposure to iodine vapor. For individual phospholipid analysis, spots of unexposed sections were extracted from the plates for quantification by phosphorus spectrophotometric determination as already described [17]. Radioactivity incorporated in the different lipids was measured by radiochromatographic scanning on a Berthold Ld 2723, Dünnschicht Scanner (Wildbad, Germany).

#### Data Presentation and Statistical Analyses

Biochemical analyses were run in duplicate. All the experiments were carried out five times. Data are shown as mean ± SE. Significance was determined by Student's *t*-test for unpaired samples. Differences were considered significant at *P* < 0.05.

## Results

#### Experimental Conditions

In order to study the role of L-FABP in the trafficking of fatty acids from cytosol to the nuclei, two metabolizable fatty acids and nuclear fractions were chosen. 18:0 and 20:4n-6 fatty acids were selected as they are the major saturated and polyunsaturated acids in rat liver cell nuclear and endonuclear lipid pools as already described [17]. Whole nuclei and nuclear matrices isolated from rat liver cells were chosen as nuclear and endonuclear lipid pools. FAs concentrations bound to L-FABP were chosen so as to saturate the first high affinity binding site of L-FABP, considering that *K<sub>D</sub>* for 18:0 and 20:4n-6 are 9 and 110 μM, respectively [21, 22]. The fatty acid concentration utilized

was 2  $\mu$  M as in a previous work [11], since it corresponds to the fatty acid physiological concentration range of rat liver cell cytosol (20:4n-6 is 2–5  $\mu$ M [23] and 18:0 17.6  $\mu$ M [24]). FABPs cytosol concentrations in liver cells range from 0.2 to 1 mM [25–27], and under physiological conditions only 2% L-FABP would have a ligand bound [25–27]. Therefore our experimental conditions at 2- $\mu$ M L-FABP concentration with the high affinity binding site saturated by the fatty acid, would be within the physiological range conditions.

#### Electron-Microscopic Analysis of the Rat Liver Nuclear Matrix

Nuclear matrices were obtained from rat liver nuclei isolated as described previously [17], according to the procedure described by Vann et al. (1997). Mild concentrations of TX-100 were applied when the matrices were isolated from nuclei of rat liver cells. Rat liver nuclei were first isolated as described elsewhere [9], and the nuclear envelope was quantitatively removed with 0.08% (w/v) concentrations of TX-100, followed by separation over a sucrose gradient. The nuclear membrane removal was checked by electron microscopy as shown in Fig. 1. The isolated control nuclei (without TX-100 incubation) corresponded to whole nuclei with all their characteristic structures that include the double nuclear membrane, chromatin zones and nucleoli; ribosomes can also be observed associated to the external nuclear membrane, as shown in Fig. 1a. Figure 1b, c, and d, observed at different magnification powers, correspond to nuclear matrices; they show that the detergent removed the nuclear double membrane without visible alterations of the remaining endonuclear structure. Nuclear matrices were not collapsed nor deformed and conserved a spherical shape. These results were similar to those obtained by Vann et al. (1997) [19].

#### Incorporation of [1-<sup>14</sup>C]18:0 Acid Free and Bound to L-FABP into Nuclear Lipid Pools

Incorporation and esterification of exogenous [1-<sup>14</sup>C]18:0 fatty acid L-FABP-bound in nuclear lipid pools were studied by incubation in vitro of nuclei isolated from rat liver in the presence of either 2  $\mu$ M [1-<sup>14</sup>C]18:0 or [1-<sup>14</sup>C]18:0:L-FABP, ATP and CoA (Figs. 2, 3).

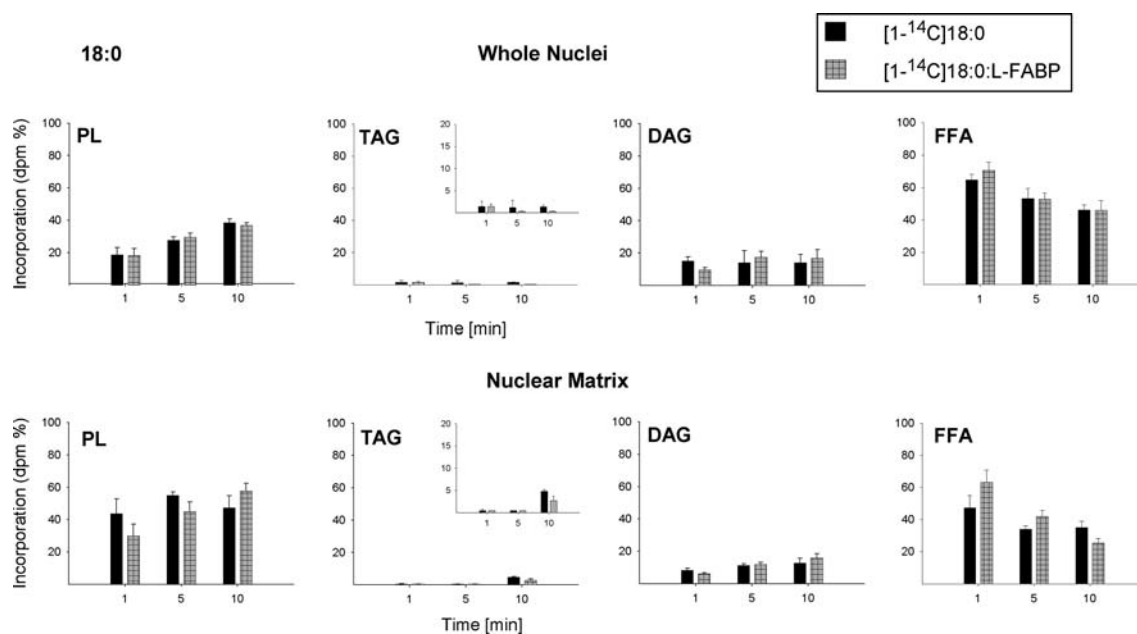

Under these experimental conditions [1-<sup>14</sup>C]18:0:L-FABP was esterified to PL (20%), DAG (10–15%), and mainly incorporated as FFA (60%) in rat liver cell nuclei (Fig. 2). After 10 min incubation, the radioactivity incorporated as FFA decreased as it was mainly esterified to PL (40%). DAG esterification was saturated from the starting point, and TAG esterification was very low (2%).

**Fig. 1** Electron micrographs of nuclear preparations. **a** Control rat liver cell nuclei (scale bar 0.10  $\mu$ M). The classical double membrane (DM) surrounds the nucleus. **b** Nuclear matrix obtained by treatment of nucleus with 0.08% (w/v) TX-100 (scale bar 2  $\mu$ M) that removes nuclear DM. **c** and **d** The nuclear matrix at higher magnification shows no nuclear envelope (scale bar 1.0  $\mu$ M and 0.2  $\mu$ M, respectively)

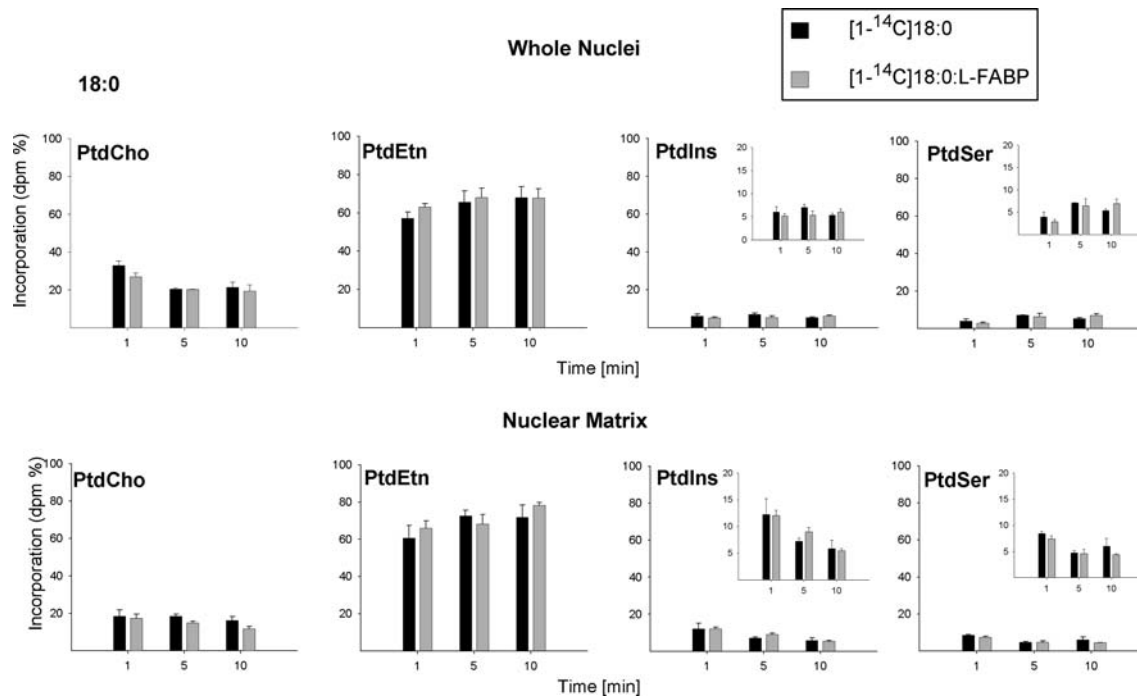

[1-<sup>14</sup>C]18:0 fatty acid, either free or bound to L-FABP was incorporated with the same pattern to nuclear lipid pools, as no significant differences were found between both groups. Table 2 shows the incorporation of 18:0 acid in nuclear lipid pools as nmol.mg total lipid (TL)<sup>-1</sup>. For the calculation it was taken into account that nuclei contain  $0.206 \pm 0.03$  mg TL.mg prot<sup>-1</sup> (data not shown).

Figure 3 shows the esterification of [1-<sup>14</sup>C]18:0 either free or bound to L-FABP in nuclear PL in the presence of ATP and CoA. Esterification percentages of [1-<sup>14</sup>C]18:0 either free or bound to L-FABP in each nuclear PL were not correlated with their relative mass. As already reported [17], liver cell nuclei have the following phospholipid composition: PtdCho (64%), PtdEtn (22%), PtdIns (10%), SM (1.9%) and PtdSer (1.6%). Figure 3 shows that 18:0 acid was esterified mainly in PtdEtn, though it is not the major nuclear PL. Esterification percentages of 18:0 acid in PL were as follows: PtdEtn (60–70%) > PtdCho (20–30%) whereas the lowest proportion was found in PtdIns (6%)

**Fig. 2** Time-course incorporation of  $[1-^{14}\text{C}]18:0$  and  $[1-^{14}\text{C}]18:0\text{:L-FABP}$  into nuclear and endonuclear lipid classes. Whole nuclei or nuclear matrices isolated from rat liver cells were incubated with  $[1-^{14}\text{C}]18:0$  or  $[1-^{14}\text{C}]18:0\text{:L-FABP}$  with ATP and CoA. At different time points, the incubation mixture was centrifuged to separate whole nuclei or nuclear matrices. Lipids were extracted and separated

by thin-layer chromatography (TLC). Scanning of thin-layer plates was performed as described in “Materials and Methods”.  $^{14}\text{C}$  was recovered in PL and in NL as TAG, DAG and FFA. Results are the mean of five experiments  $\pm$  SE. Statistical analysis was performed by the Student’s *t* test between results from incubations with FA bound to L-FABP (FA: L-FABP) with respect to free FA (FA)

**Fig. 3** Time-course esterification of  $[1-^{14}\text{C}]18:0$  and  $[1-^{14}\text{C}]18:0\text{:L-FABP}$  into nuclear and endonuclear phospholipids. Whole nuclei or nuclear matrices isolated from rat liver cells were incubated with  $[1-^{14}\text{C}]18:0$  or  $[1-^{14}\text{C}]18:0\text{:L-FABP}$  with ATP and CoA. Lipids were extracted and separated by thin-layer chromatography (TLC).

Scanning of thin-layer plates was performed as described in “Materials and Methods”.  $^{14}\text{C}$  was recovered in PtdCho, PtdEtn, PtdIns and PtdSer. Results are the mean of five experiments  $\pm$  SE. Statistical analysis was performed by the Student’s *t* test between FA bound to L-FABP (FA: L-FABP) with respect to free FA (FA)

and PtdSer (5%). Under the present experimental conditions [ $1\text{-}^{14}\text{C}$ ]18:0 acid, free or bound to L-FABP was esterified in all nuclear PL except in SM. These results are quite difficult to be explained as SM molecular species are characterized by an esterified saturated or monounsaturated fatty acid [28]. In addition, 18:0 acid was esterified in PtdSer, which is a minor nuclear PL as SM in nuclei, as we have already reported [17]. Then, one could discard the idea that the absence of 18:0 esterified in SM may be due to the low amount of SM in liver nuclei. It is clear that, 18:0 was selectively esterified to nuclear PtdEtn with respect to the other nuclear PL.

Table 3 displays esterification of 18:0 either free or bound to L-FABP as *specific activity* (SA). For the calculation it was taken into account that rat liver cell nuclei have  $39.2 \pm 0.1$  nmol PL mg prot $^{-1}$ , and the PL distribution already described [18]. 18:0 was esterified into each nuclear PL as follows: PtdEtn/PtdSer > PtdIns > PtdCho. These results confirmed that 18:0 was selectively esterified into nuclear PtdEtn and PtdSer regarding the total nuclear PL.

When the incubations were performed without ATP and CoA [ $1\text{-}^{14}\text{C}$ ]18:0 or [ $1\text{-}^{14}\text{C}$ ]18:0, L-FABP was not esterified in any nuclear lipid pool as it was exclusively incorporated as FFA (100%) (Table 1). Then 18:0 free or bound to L-FABP was esterified into nuclear lipid pools by an acyl-CoA mechanism as already reported for the free fatty acid [11].

#### Incorporation of [ $1\text{-}^{14}\text{C}$ ] 20:4n-6 Acid Free and Bound to L-FABP into Nuclear Lipid Pools

Figures 4 and 5 show the incorporation and esterification of exogenous 20:4n-6 acid into nuclear lipid pools, after in vitro incubation of nuclei isolated from rat liver cells in the presence of either 2  $\mu\text{M}$  [ $1\text{-}^{14}\text{C}$ ]20:4n-6 or [ $1\text{-}^{14}\text{C}$ ]20:4n-6:L-FABP, ATP and CoA.

Firstly, [ $1\text{-}^{14}\text{C}$ ]20:4n-6:L-FABP was mainly esterified in PL (40%) and incorporated as FFA (45%). After 10 min

incubation, 20:4n-6 decreased (30%) as FFA after esterification to PL (50%), and in a minor proportion to TAG (20%). [ $^{14}\text{C}$ ] was not found esterified in DAG. When [ $1\text{-}^{14}\text{C}$ ]20:4n-6 acid was bound to L-FABP, the fatty acid was esterified into nuclear TAG in a minor proportion with respect to free fatty acid.

Incorporation of 20:4n-6 fatty acid free or bound to L-FABP into nuclear lipid pools as nmol mg TL $^{-1}$  is described in Table 4. The comparison of Tables 2 and 4, showed that the amount (nmol.mg TL $^{-1}$ ) of arachidonic and stearic acids, esterified to nuclear PL was similar. When comparing the esterification of 20:4n-6 to that of 18:0 in nuclear lipid pools (nmol.mg LT $^{-1}$ ; Tables 2, 4), it was observed that 20:4 was mainly esterified in PL and TAG with respect to 18:0. Only 18:0 acid was esterified into nuclear DAG under the experimental conditions assayed.

The amount of 20:4n-6 esterified to nuclear TAG was greater than that of 18:0, but it was lower than the amount of 20:4n-6 that remained as FFA with respect to 18:0.

Figure 5 displays the esterification percentage of [ $1\text{-}^{14}\text{C}$ ]20:4n-6 acid either free or bound to L-FABP in each nuclear PL in the presence of ATP and CoA. No significant differences in nuclear PL esterification pattern were observed when 20:4n-6 acid was free or bound to L-FABP. 20:4n-6 acid was esterified into nuclear PL as follows: PtdCho (50–60%) > PtdEtn (20–30%) > PtdIns ( $\approx$  15%), and in a very low proportion PtdSer (1–2%). Under the present experimental conditions, [ $1\text{-}^{14}\text{C}$ ]20:4n-6 acid, either free or bound to L-FABP, was esterified to all PL nuclear classes except SM. It is well documented that SM molecular species have a saturated or monounsaturated fatty acid esterified in the molecule, but not a polyunsaturated fatty acid, such as 20:4n-6 acid [28].

It is interesting to note that exogenous 20:4n-6, free or bound to L-FABP, was esterified to nuclear PtdIns with a SA ([ $1\text{-}^{14}\text{C}$ ]20:4n-6 nmol. nmol PtdIns $^{-1}$ ) that doubles that of PtdCho and PtdEtn after 10 min of incubation (Table 5).

**Table 1** Effect of ATP and CoA on [ $1\text{-}^{14}\text{C}$ ]fatty acid free and bound to L-FABP incorporation into nuclear and endonuclear lipids pools

Incubation conditions	Incorporation of radioactivity as FFA (dpm%)							
	Whole nuclei				Nuclear matrix			
	18:0		20:4n-6		18:0		20:4n-6	
[ $1\text{-}^{14}\text{C}$ ] Fatty acid	FA	FA:L-FABP	FA	FA:L-FABP	FA	FA:L-FABP	FA	FA:L-FABP
With ATP and CoA	46	46	30	27	32	28	70	65
Without ATP and CoA	100	100	100	100	100	100	100	100

Liver nuclei or membrane-depleted nuclei were incubated with [ $1\text{-}^{14}\text{C}$ ]18:0 (FA), [ $1\text{-}^{14}\text{C}$ ]18:0:L-FABP (FA:L-FABP), [ $1\text{-}^{14}\text{C}$ ]20:4n-6 or [ $1\text{-}^{14}\text{C}$ ]20:4n-6:L-FABP fatty acids with or without ATP and CoA. After 10 min, the incubation mixture was centrifuged to separate whole nuclei or the nuclear matrices from the incubation mixture. Lipids were extracted and separated by TLC.  $^{14}\text{C}$  was recovered in PL and in NL when ATP and CoA were added as shown in Figs. 2, 3, 4, and 5.  $^{14}\text{C}$  was only recovered in NL as FFA (100%) when ATP and CoA were omitted. Results are presented as the percentage of total  $^{14}\text{C}$  radioactivity incorporated as FFA into nuclear and endonuclear lipid pools

Whole liver nuclei or nuclear matrix were incubated with [ $1-^{14}\text{C}$ ]18:0 or [ $1-^{14}\text{C}$ ]18:0:L-FABP, ATP and CoA for 1, 5 and 10 min. After incubation samples were assayed as described in ‘‘Materials and Methods’’. Results are presented as pmol of [ $1-^{14}\text{C}$ ]18:0 incorporated/nmol each PL class, and are the mean of five experiments ± SE. Statistical analysis was performed by the Student’s *t* test. No significant differences were found in FA:L-FABP respect FA. A letter denotes significant differences between data of 18:0 (Table 3) vs. the same data of 20:4n-6 in Table 5: <sup>a</sup> *P* < 0.001, <sup>b</sup> *P* < 0.01 and <sup>c</sup> *P* < 0.05

It was also observed that 20:n-6 was esterified with a greater SA in nuclear PtdCho and PtdIns with respect to 18:0, but in a minor proportion in PtdEtn and PtdSer (Tables 3, 5).

When incubations were performed without ATP and CoA in the incubation medium, [ $1-^{14}\text{C}$ ]20:4n-6 or [ $1-^{14}\text{C}$ ]20:4n-6: L-FABP was not esterified in any nuclear lipid pools; it was exclusively incorporated as FFA (100%) (Table 1). Then 20:4n-6, free or bound to L-FABP, was esterified to nuclear lipid pools by an acyl-CoA mechanism, as we have already reported for free 20:4n-6 [11].

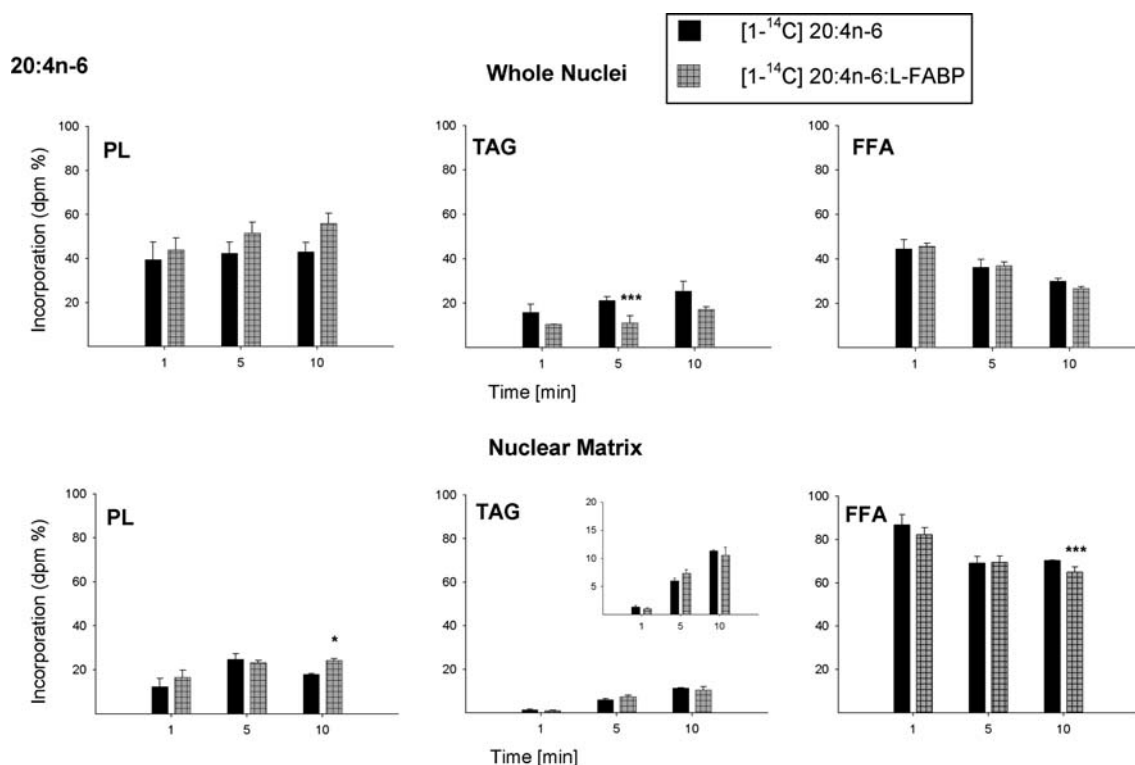

#### Incorporation of [ $1-^{14}\text{C}$ ]18:0 Acid, Free and Bound to L-FABP, into Endonuclear Lipid Pools

In order to determine the mechanism of incorporation and esterification of FA into endonuclear lipids, nuclear

matrices were incubated in vitro in the presence of [ $1-^{14}\text{C}$ ]18:0 or [ $1-^{14}\text{C}$ ]18:0:L-FABP, ATP and CoA (Figs. 2, 3). Each nuclear matrix was isolated by removing the double nuclear membrane, solubilized at low concentrations using a non-ionic detergent (TX-100) as indicated elsewhere (Fig. 1).

Exogenous 18:0 acid, free or L-FABP bound, was mainly esterified to PL (30–40%), a minor proportion to DAG (7%), and the remainder was incorporated as FFA (50–60%) into the nuclear matrices from rat liver cells (Fig. 2). After 10 min incubation, the incorporated radioactivity decreased as FFA since it was being esterified to PL (50–60%), to DAG (15%), and to TAG (3–5%).

The fact that 18:0 acid was free or bound to L-FABP did not modify the general pattern of incorporation and esterification of fatty acids in endonuclear lipid pools (Figs. 2,

**Fig. 4** Time-course incorporation of  $[1-^{14}\text{C}]20:4n-6$  and  $[1-^{14}\text{C}]20:4n-6\text{:L-FABP}$  into nuclear and endonuclear lipid classes. Whole nuclei or nuclear matrices isolated from rat liver cells were incubated with  $[1-^{14}\text{C}]20:4n-6$  or  $[1-^{14}\text{C}]20:4n-6\text{:L-FABP}$  with ATP and CoA. After the incubation samples were assayed as described in Fig. 2.  $^{14}\text{C}$

was recovered in PL and in NL as TAG and FFA. Results are the mean of five experiments  $\pm$ SE. Statistical analysis was performed by the Student's *t* test. FA: L-FABP significantly different from FA: \* $P < 0.001$  and \*\*\* $P < 0.05$

3). However, there was less dispersion of data over the incubation time when  $[1-^{14}\text{C}]18:0$  was bound to L-FABP compared with the free acid.

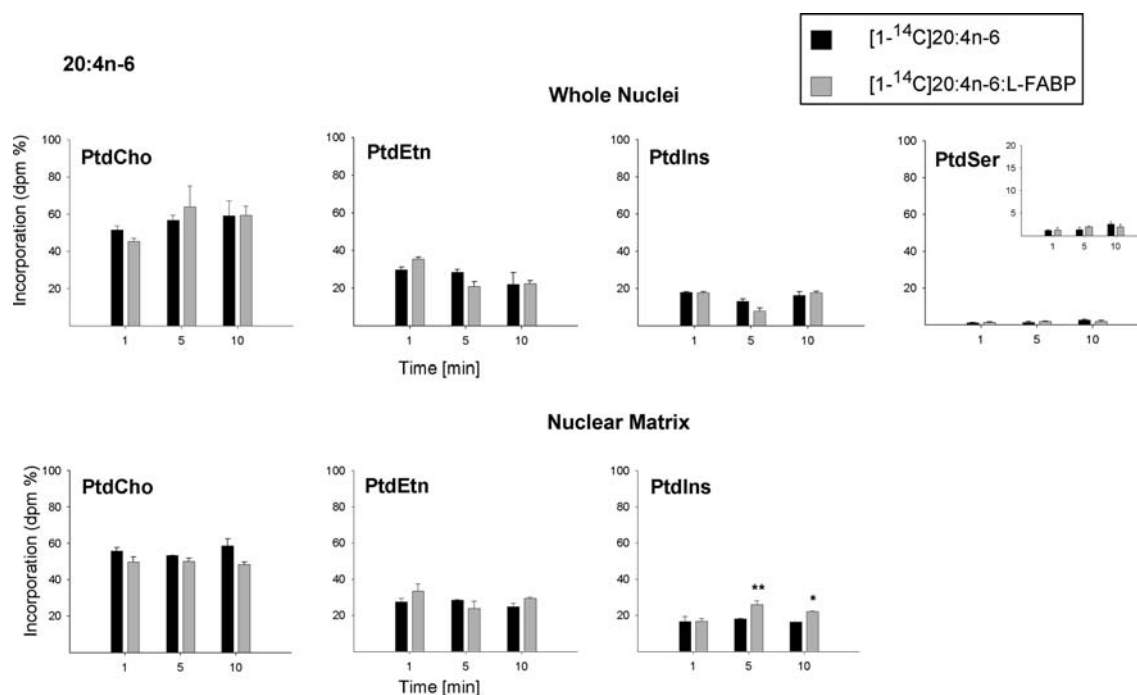

These results imply that esterification of fatty acids to endonuclear lipid pools, is an autonomous matrix mechanism, since it still occurs after the removal of the double nuclear membrane. Consequently, all the enzymes and factors involved must also have an endonuclear localization.

As reported in a previous work, endonuclear lipid pools have a relatively different composition with respect to whole nuclei [17]. Liver nuclear matrices contain 0.5 mg proteins.g liver<sup>-1</sup> and 8.5 nmol PL.mg prot<sup>-1</sup>. As already reported [17], they represent 25.8 and 22.6% of the respective whole nuclei components.

Table 2 shows FA incorporation and esterification into endonuclear lipid pools (nmol incorporated mg TL<sup>-1</sup>). It must be taken into account that nuclear matrices contain 0.032  $\pm$  0.01 mg TL.mg prot<sup>-1</sup> (data not shown). Results show that exogenous 18:0, either free or bound to L-FABP, was esterified to PL and DAG, and incorporated as FFA in a greater amount in the nuclear matrix than in the whole nucleus. Therefore, nuclear matrices have a more active fatty acid metabolism than that of whole liver nuclei.

As already observed in nuclear pools, esterification of exogenous 18:0 acid, free or bound to L-FABP, in each endonuclear PL did not correspond to their relative masses (Fig. 2). As previously described elsewhere rat liver cell matrices contained the following phospholipid composition: PtdCho (43%), PtdEtn (20%), PtdIns (9%)m SM (9%) and PtdSer (8%) and LysoPtdCho (10%) [17]. Esterification percentage of  $[1-^{14}\text{C}]18:0$  into each PL (Fig. 3) was as follows: PtdEtn (63%) > PtdCho (18%) > PtdIns (12%) > PtdSer (4–8%). We must bear in mind that nuclear matrices are enriched in SM with regard to nuclei, since the matrix contains 9% SM whereas the whole nucleus only 1.9% [17]. In spite of this, 18:0 acid, free or bound to L-FABP, was esterified in all endonuclear PL except SM (Fig. 3). These results corroborate that fatty acids are incorporated into SM during the de novo synthesis, which has been reported to take place in the cytosol [28].

Table 3 shows esterification of 18:0 acid, free or L-FABP bound, in each PL as specific activity (SA, pmol.nmol each PL<sup>-1</sup>). 18:0 acid either free or L-FABP bound was esterified in endonuclear PL with the following SA: PtdEtn > PtdIns/PtdSer > PtdCho. This esterification pattern of 18:0 acid free or L-FABP bound in each endo-

**Fig. 5** Time-course esterification of  $[1-^{14}\text{C}]20:4n-6$  and  $[1-^{14}\text{C}]20:4n-6:L-FABP$  into nuclear and endonuclear phospholipids. Whole nuclei or nuclear matrices isolated from rat liver cells were incubated with  $[1-^{14}\text{C}]20:4n-6$  or  $[1-^{14}\text{C}]20:4n-6:L-FABP$  with ATP and CoA. Lipids were extracted and separated by TLC. Scanning of thin-layer

plates was performed as described in ‘‘Materials and Methods’’.  $^{14}\text{C}$  was recovered in PtdCho, PtdEtn, PtdIns and PtdSer. Results are the mean of five experiments  $\pm$ SE. nuclear PL was different to that of the whole nucleus as already analyzed. It is important to note that 18:0 esterifies into endonuclear PtdEtn, PtdIns and PtdCho with a greater SA than in whole nuclei. These results imply that PL fatty acid remodeling in the nuclear matrix is a very active process.

When the incubations were performed without ATP and CoA,  $[1-^{14}\text{C}]18:0$  or  $[1-^{14}\text{C}]18:0:L-FABP$  was not esteri-

fied in any endonuclear lipid pools; it was exclusively incorporated as FFA (100%) (Table 1). Then 18:0, free or bound to L-FABP, could only be esterified into endonuclear lipid pools by an acyl-CoA mechanism. This mechanism appears to be independent of the double nuclear membrane and would also imply a matrix localization of nuclear long chain acyl-CoA synthetase, as already described in whole nuclei [10].

#### Incorporation of [ $1\text{-}^{14}\text{C}$ ]20:4n-6 Acid either Free or Bound to L-FABP into Endonuclear Lipid Pools

Figures 4 and 5 display the incorporation and/or esterification of exogenous 20:4n-6 acid, free or bound to L-FABP, into endonuclear lipid pools. Nuclear matrices were incubated in vitro in the presence of [ $1\text{-}^{14}\text{C}$ ] 20:4n-6, [ $1\text{-}^{14}\text{C}$ ] 20:4n-6:L-FABP, ATP and CoA.

[ $1\text{-}^{14}\text{C}$ ] 20:4n-6 acid free or bound to L-FABP was primarily incorporated into endonuclear lipid pools, either directly as FFA (89%) or esterified in PL (15%). After 10 min incubation, incorporated FA continues its esterification in PL (20%), and only in a minor proportion in TAG (10%). As already observed in whole nuclei, when 20:4n-6 acid was incubated with nuclear matrices, no [ $^{14}\text{C}$ ] could be detected in DAG. When 20:4n-6 acid is either free or bound to L-FABP, the percentage of fatty acid esterified in endonuclear TAG increased during the incubation time.

After 10 min incubation, 20:4n-6 acid bound to L-FABP displayed a greater esterification in endonuclear PL with respect to the free 20:4n-6, since it diminished as FFA (Fig. 4).

Table 4 shows that exogenous 20:4n-6 acid, free or L-FABP bound, was esterified (PL and TAG) and incorporated as FFA to a greater degree in endonuclear lipids pools than with whole liver nuclei.

In endonuclear lipid pools, the amount of 20:4n-6, free or bound to L-FABP, that esterifies in TAG was greater than with respect to 18:0. On the other hand, the amount of 18:0, free or bound to L-FABP, that esterifies in PL and DAG was greater with respect to 20:4n-6 (Tables 2, 4).

20:4n-6 acid free or L-FABP bound was esterified in all endonuclear PL, except in SM. Under the present conditions, neither 18:0 nor 20:4 acid were esterified in SM of

nuclear or endonuclear pools (Figs. 3, 5). These results imply that SM fatty acid remodeling does not occur in both nuclear fractions. Moreover, as we have already reported, 20:4-CoA was not incorporated into nuclear SM pools either [13].

Figure 5 shows that exogenous 20:4n-6 acid, free or L-FABP bound, was esterified in endonuclear PL as follows: PtdCho (≈55%) > PtdEtn(25–30%) > PtdIns (15–25%).

Table 5 shows that free or L-FABP-bound 20:4n-6 acid was esterified with greater specific activity in endonuclear PtdIns with respect to PtdCho and PtdEtn. These results are similar to those observed in whole nuclear pools (Table 5).

It is interesting to note that only when 20:4n-6 acid was bound to L-FABP, the fatty acid was esterified with a greater specific activity in endonuclear PtdIns than with respect to the free fatty acid (Table 5). It is evident that selectivity of 20:4n-6 acid for PtdIns is greater when the fatty acid is bound to L-FABP.

When the incubations were performed without ATP and CoA [ $1\text{-}^{14}\text{C}$ ]20:4 or [ $1\text{-}^{14}\text{C}$ ]20:4 L-FABP was not esterified in any endonuclear lipid pool; it was exclusively incorporated as FFA (100%) (Table 1). Then 20:4, free or bound to L-FABP, could only be esterified into endonuclear lipid pools by an acyl-CoA mechanism. This mechanism would be independent of the double nuclear membrane.

## Discussion

The aim of this work was to study the incorporation of exogenous fatty acids bound to L-FABP into nuclei.

We have demonstrated that exogenous fatty acids, either free or bound to L-FABP, were mostly incorporated as

FFA, and esterified in polar and neutral lipid pools by an acyl-CoA-dependent mechanism of whole nuclear and endonuclear lipid pools.

Although the mechanism through which cytosolic fatty acids reach the cellular nucleus is still unknown, it is postulated that FABPs could be the proteins involved in fatty acid cytoplasmic-nucleus transport. The size of the L-FABP with or without ligand would facilitate its transport to the cellular nucleus through the nuclear pore complex by means of simple diffusion as the active and regulated transport operates when molecules are greater than 60 kDa [16].

#### Whole Nuclei

The first experimental approach was done by incubating rat liver cell nuclei *in vitro* in the presence of the most abundant nuclear fatty acids, the [ $1\text{-}^{14}\text{C}$ ]18:0 and 20:4n-6, bound to L-FABP and in the presence of ATP and CoA.

Under these experimental conditions, 18:0 and 20:4n-6 acids, either free or bound to L-FABP, showed the same pattern of incorporation and/or esterification in polar and neutral lipids of whole nuclei. Only 20:4n-6 when bound to L-FABP was incorporated into TAG in a minor proportion when 20:4n-6 was free.

The free fatty acid nuclear pool where 18:0 and 20:4n-6 acids were incorporated, was metabolically active, and it decreased with incubation time when ATP and CoA were present (Figs. 2, 3, and 4). These results showed that this pool must be related to nuclear long chain acyl-CoA synthetase as already described, which would activate fatty acids to the respective acyl-CoAs prior to their esterification into nuclear lipids [10].

Esterification of fatty acids into nuclear lipid pools was found to be specific for the type of exogenous fatty acid tested and the lipid class.

These results imply that fatty acids, free or L-FABP bound, are incorporated into the nuclear FFA pool or trapped by acyl-CoA synthetase, and then an acyl-CoA transferase downstream from acyl-CoA synthetase would determine the metabolic fate of each fatty acid. Thus, 18:0 was esterified in PL with the greatest SA in PtdEtn and PtdSer whereas 20:4n-6 was esterified in PtdIns. These results suggest that nuclear PtdEtn and PtdSer present an active remodeling of 18:0, and still the biological implications of these results must be elucidated. On the other hand, in the neutral lipid pool, 18:0 acid was mainly esterified in DAG whereas 20:4n-6 was found to be in TAG. It is interesting to note that the fatty acid composition of nuclear neutral lipids is characterized by a much higher proportion of 18:0 than 20:4n-6, as already reported [13].

The high rate of esterification of arachidonic acid into PtdIns is consistent with the fact that PtdIns is the phos-

pholipid with greater affinity to esterify 20:4n-6 acid [29]. Moreover, around 80% of rat liver PtdIns molecular species contained 18:0–20:4 [29]. This process would account for the characteristic composition of the main PtdIns molecular species, 18:0–20:4 [37], since nuclear PtdIns would be transported from the cytosol where it is synthesized [37].

Huang et al. reported an increment in the nuclear uptake of fluorescent saturated and unsaturated fatty acids of medium and long chain in cells overexpressing L-FABP with respect to control cells that can not overexpress that protein [30]. In fact, the increment of fluorescence was mainly located on the internal face of the nuclear membrane, but it was not associated with the nuclear interior. It must be noted that the fatty acids utilized by these authors could not be esterified in the nuclear lipid pools like those used in our experiments. One could infer that the location of fluorescent fatty acids, observed by Huang et al, matches that of the pool of [ $1\text{-}^{14}\text{C}$ ] 18:0 and [ $1\text{-}^{14}\text{C}$ ] 20:4n-6, which remains as free fatty acids in the present experimental model [7].

Under the experimental conditions, L-FABP does not seem to specifically favor the interaction between FA and whole nuclei lipid pools. These results are consistent with those previously observed when nuclei isolated from rat liver cells were incubated *in vitro* with [ $^{14}\text{C}$ ] fatty acids and hepatic cytosol proteins [12]. The presence of cytosol in the incubation medium did not change the incorporation and esterification patterns of 18:0, 18:2n-6 and 20:4n-6 acids in nuclear lipid pools [12]. It must be noted that L-FABP was present in the incubation medium, since that binding protein corresponds to approximately 5% of total hepatic cytosolic proteins [14].

#### Nuclear Matrices (Membrane Depleted Nuclei)

In a second step, experiments were done with membrane depleted nuclei (nuclear matrices) in order to assess if fatty acids either free or bound to L-FABP could be incorporated and re-distributed in endonuclear lipid pools, disregarding their trafficking mechanism through the double nuclear membrane. With this purpose, rat liver nuclear matrices were incubated *in vitro* in the presence of the most abundant endonuclear FA, the [ $1\text{-}^{14}\text{C}$ ]18:0 and [ $1\text{-}^{14}\text{C}$ ] 20:4n-6 acids, either free or bound to L-FABP, ATP and CoA.

Exogenous fatty acids, either free or bound to L-FABP, were found to be incorporated mostly as free fatty acid, and esterified in polar and neutral endonuclear lipid pools by an acyl-CoA-dependent mechanism. Our results indicate that long chain acyl-CoA synthetase would be associated to the nuclear matrix, as well as the enzymes involved in FA esterification to endonuclear lipid pools. Both 18:0 and 20:4n-6 fatty acids, either free or bound to L-FABP, were

incorporated and esterified to endonuclear lipids, showing a larger SA than that in whole nuclei. It is evident that the nuclear matrix, a site of second messenger generation from compartmentalized lipid pools, has a more active lipid metabolism than that of whole liver cell nuclei.

As already shown in whole nuclei, the endonuclear FFA pool was a metabolically active lipid pool. It decreased during the incubation when ATP and CoA were present (Figs. 2, 3, and 4). Fatty acid esterification in endonuclear lipid pools showed specificity regarding the fatty acid type and the lipid class.

18:0 acid, either free or bound to L-FABP, was incorporated and esterified with the same pattern in endonuclear lipids (Figs. 2, 3, 4, and 5) as already observed in whole nuclei. 18:0 acid was esterified not only to PL and TAG, but also to DAG. In endonuclear PL, 18:0 either free or L-FABP bound, was esterified with a greater SA to PtdEtn, followed by PtdIns, PtdSer and PtdCho (Table 3).

The highest percentage of esterification of 20:4n-6, free or bound to L-FABP, in the different endonuclear phospholipid classes was observed in PtdCho, followed by PtdEtn and PtdIns (Table 5). This is not surprising since PtdCho was the major PL in matrices as previously reported [17]. As already shown in whole nuclei, 20:4n-6 was esterified with a higher SA in endonuclear PtdIns, with respect to total PL (Table 5).

In the matrix, L-FABP would seem to play an important role in the mobilization and redistribution of 20:4n-6 within nuclear lipid pools. When 20:4n-6 was bound to L-FABP, arachidonic acid was esterified to a greater degree in endonuclear total PL, particularly in PtdIns; then it diminished in the FFA pool, with respect to free 20:4 (Fig. 4). Under the experimental conditions assayed, we were unable to observe the same results when the nuclei were surrounded by the double nuclear membrane. These results suggest that L-FABP facilitates the mobilization of 20:4n-6 to specific sites of utilization. First L-FABP delivers 20:4n-6 to an acyl-CoA synthetase located in the nuclear matrix, and then to those enzymes (acyl-transferases) responsible for its esterification in PI.

An active endonuclear PtdIns metabolism is not something new, and according to the present results, L-FABP should be included as an important component of it. Nuclear signal transduction system of PtdIns was described a long time ago, and it was found to have protein and lipid components that are mostly associated or anchored to the nuclear matrix [32–33]. Yet, this endonuclear transduction system of PtdIns showed a cytosol-independent regulation [34].

Endonuclear arachidonic acid mobilized by L-FABP could be delivered to different fates other than esterification into glycerolipids within the nuclei. 20:4n-6 could be

metabolized to prostaglandins or leukotrienes [35]. Also it could activate PPAR- $\alpha$ , taking into account that the existence of a nuclear co-localization between L-FABP and PPAR- $\alpha$  has also been reported [16].

Hunt suggested that PtdEtn was the PL responsible for the supply of unsaturated fatty acids in nuclear matrices from neuroblastoma culture cells. However, our results showed that in rat liver cell matrices 18:0 and not 20:4n-6 fatty acid had the highest specific activity of esterification in PtdEtn [36, 37]. Esterification is a necessary step in fatty acid mobilization and remodeling; it is involved in fatty acid utilization. The apparent difference between our results in rat liver nuclei and those of others showing low levels of polyunsaturated acids in the cell nuclei is, in many cases, the consequence of using neoplastic cells. These cultured cell lines are generally characterized by low levels of essential fatty acids, and high levels of saturated and monoenoic fatty acids in their lipid pools [38, 39]. So the fatty acid composition of their nuclear lipid pools would be the consequence of the characteristic metabolism of neoplastic cells, and not the consequence of a specific and generalized nuclear localization as suggested [37].

Lawrence et al. [40] have studied the role of L-FABP in the transport of 18:1 toward the nuclear matrices of rat liver cells obtained using a concentration of 1% (wt/v) TX-100. One must take into account that these authors added neither ATP nor CoA to the *in vitro* incubation medium, and as demonstrated in the present work (Table 1), the exogenous FA can not be esterified into endonuclear lipid pools as they remained as FFA. On the other hand, they utilized 18:1 acid as exogenous FA, which is a minor component in the nuclear and endonuclear FA lipid pool of rat liver cells as already described [17].

Summarizing, esterification of exogenous 18:0 and 20:4n-6 fatty acids either free or L-FABP bound, into whole nuclear and endonuclear lipid pools is an ATP and CoA-dependent mechanism. In the nuclear matrix, fatty acid esterification is a more active process than that in the whole nucleus, and it is independent of the nuclear double membrane. The esterification patterns of fatty acids, either L-FABP-bound or free, into whole nuclear lipid pools showed no difference. L-FABP facilitates the mobilization of 20:4n-6 within nuclei from the FFA pool to PtdIns. First 20:4n-6 must be activated to acyl-CoA and then a downstream acyl-CoA transferase will determine its esterification into PtdIns.

**Abstract** Esterification of dietary phytosterols and glycerols may affect intestinal absorption of cholesterol and non-cholesterol sterols. We infused plant stanol esters in triacylglycerol (TAG) (F1) and diacylglycerol (DG) (F2) oils, and free plant stanols in F1 and F2 (F3) to the duodenum of healthy human subjects and sampled the contents from the proximal jejunum (PJ). Free and ester sterols were analysed from the infusates, and intestinal contents before and after ultracentrifuge separation of oil, micelle and sediment phases. During the 60-cm intestinal passage, over 40% of plant stanol esters were hydrolysed ( $P < 0.05$ ) but around 30% of the infused free plant stanols ( $P < 0.05$ ) and up to 40% of cholesterol ( $P < 0.05$ ) were esterified in PJ after infusions. TAG in F1 favoured accumulation of plant stanol esters in the oil phase of the PJ aspirates as compared with respective values of F2 and F3 ( $P < 0.05$  for both). About one third of free plant stanols of F3 had been esterified ( $P < 0.05$ ) and 17% precipitated mainly in free form in the PJ aspirates ( $P < 0.05$  compared with F1 and

F2). In conclusion, DG- and TAG-oils had no profound superiority over each other as intestinal carriers regarding hydrolysis/esterification of administered plant stanol esters and cholesterol and their partition in oil, micellar and sediment phases in the PJ. The unesterified plant stanols experienced partial esterification and sedimentation during their intestinal passage, which might influence their biochemical properties in that segment of the gut where cholesterol is absorbed.

**Keywords** Campestanol · Cholesterol · Intestinal absorption · Micellar solubility · Phytosterols · Sitostanol

## Abbreviations

ABC	ATP-binding cassette transporter proteins
EST%	Esterification percentage
DG	Diacylglycerol
F1	Plant stanol esters in triacylglycerol formula
F2	Plant stanol esters in diacylglycerol formula
F3	Free plant stanols in triacylglycerol and diacylglycerol formulas
LDL-C	Low-density lipoprotein cholesterol
PJ	Proximal jejunum
TAG	Triacylglycerol
TC	Total cholesterol

## Introduction

The amount and degree of esterification of dietary phytosterols affect the sterol composition of duodenal mixed micelles [1–3], which are crucial for the intestinal absorption of dietary and biliary cholesterol and fat-soluble

vitamins in the upper part of the human intestine [4]. The mixed micelles present cholesterol and phytosterols to the epithelial Niemann-Pick C1 Like 1 transporter proteins, which have been suggested to be one factor for their uptake from the intestinal lumen into the enterocyte [5]. Also ATP-binding cassette (ABC) transporter proteins, formed by the expression of *ABCG5* and *ABCG8* genes, are essential in determining the net absorption of sterols as they secrete plant sterols from the enterocyte back to the intestinal lumen and from the hepatocyte to the bile [6]. This may partly explain why the absorption efficiencies of campesterol (1.9–9.6%) and sitosterol (0.5–4.2%) are very low in short-term studies [7, 8], and their serum concentrations are normally about 0.2–0.005% of that of cholesterol [8]. The  $5\alpha$ -saturated derivatives of plant sterols—campestanol and sitostanol, have much lower absorption efficiencies (below 0.2%) and serum concentrations than the respective plant sterols [8]. Several putative mechanisms for the inhibitory effect of phytosterols on cholesterol absorption have been suggested: (1) displacing cholesterol from mixed micelles [1, 2, 9], (2) competitive blocking of cholesterol absorption from intestinal contents [7], (3) promoting cholesterol efflux from enterocytes back into the intestinal lumen [10] and (4) decreasing cholesterol esterification rate in the intestinal epithelium [11, 12]. Due to better fat-solubility of esterified derivatives of plant stanols and sterols as compared with crystalline or poorly soluble ones, they are particularly effective in inhibiting intestinal cholesterol absorption, which results in lowering of serum levels of total (TC) and low-density lipoprotein cholesterol (LDL-C) during short-term and long-term usage [13]. Addition of plant stanols in daily diet also lowers the absorption of plant sterols and their serum levels, while that of plant sterols increases their serum values [13]. This may be an important finding as plant sterols are recovered from the atheromatous plaques in relation to their serum levels [14].

Earlier findings indicate that, the magnitude of postprandial lipemia can be reduced by displacing dietary triacylglycerols (TAG) with diacylglycerols (DG) [15–18]. Animal studies with rabbits suggest that phytosterols dissolved in DG are more effective than respective TAG-based solutions in decreasing serum TC and preventing development of atherosclerotic lesions in the aorta [18]. A randomized crossover study showed that dissolution of phytosterols in DG had a better serum TC and LDL-C lowering effect than dissolution in TAG [19]. Phytosterols may have higher solubility in DG than in TAG, which is beneficial in their competition with dietary and biliary cholesterol in intestinal micelles. Furthermore, controlled feeding studies suggest that DG as opposed to TAG reduced abdominal fat accumulation, and, thus, DG might reduce the risks of visceral obesity [20]. According to this

data, an intriguing option would be to supply dietary plant stanols in DG oil-based products.

The aim of this gastrointestinal perfusion study was to elucidate the effects of esterified versus free phytosterols in TAG versus DG-based liquid formula phytosterol test meals on intestinal solubility of cholesterol and plant sterols in the upper part of the small intestine among healthy human subjects.

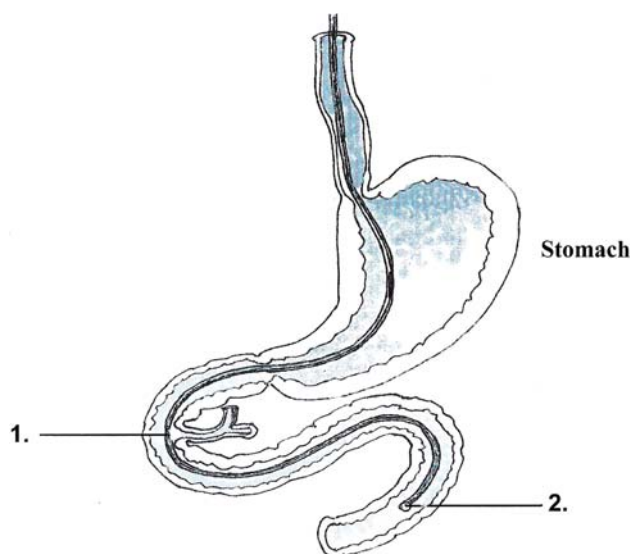

## Subjects and Methods

### Subjects

Fifteen healthy medical students (ten females, five males) with a mean ( $\pm$ SE) age of  $24 \pm 1$  years (range 19–35 years) volunteered for the study. Their body mass indexes were within normal limits (19–23 kg/m<sup>2</sup>). The study protocol followed the principles of the Helsinki declaration. The subjects were informed of the nature and purpose of the investigation, and a written informed consent was obtained from each subject. During X-ray guidance of the nasojejunal tube, the genitals of the subjects were covered with lead shielding. The study was approved by the Ethics Committee of the Department of Medicine, Helsinki University Central Hospital.

### Experimental Design

A double-lumen radiopaque tube (Medi-Line S.A, Angieur, Belgium) was used for the infusion of the liquid test meal formulas and for collection of samples from the proximal jejunum (PJ) for sterol analysis. The study subjects were fasted overnight. The tube was placed under X-ray control such that the proximal (infusion) outlet was in the middle of the second part of duodenum, i.e., adjacent to the ampulla of Vater (Fig. 1). The distal outlet was located 60 cm below the first one. The following liquid formulas were infused via the tube. The liquid formula 1 (F1) was TAG oil formula and it was prepared by sonication of 0.45 g of plant stanols (sitostanol/campestanol = 2.3) as their esters in 5 g of rapeseed oil (TAG) (Raisio Benecol Ltd, Raisio, Finland), half of an egg yolk, and to make the formula more soluble 2.5 g of glycerol-L-mono-oleate (Fluka AG, Switzerland), and 100 ml of water in a final volume of 110 ml. The liquid formula 2 (F2) was prepared otherwise similar to F1, but rapeseed oil was replaced by 5 g of DG oil (Kao Co, Tokyo, Japan). Two kinds of free (unesterified) plant stanol formulas (in DG- and in TAG-oils) were prepared identically to those of F1 and F2, but plant stanol esters were replaced by 0.45 g of plant stanols (sitostanol/campestanol = 2.3). For clarity and to enable statistical comparison with F1 and F2, the infusion results of suc-

**Fig. 1** Schematic drawing of the upper gastrointestinal tract showing the location of the nasojejunal perfusion tube and its proximal (1) and distal (2) outlets

**Fig. 2** Order of infusions of the test meal formulas F1 (*horizontal pattern*) ( $n = 11$ ), F2 (*vertical pattern*) ( $n = 12$ ) and F3 (*brick pattern*) ( $n = 6$ ) according to each study subject [1–15], each of whom received three infusions (I–III). Formula infusions with no data obtained and three plant sterol formula infusions are marked with black (see “Subjects and Methods”)

successful (volume sufficient in each case for ultracentrifugation, i.e., sample size more than 3 ml) DG- ( $n = 3$ ) and TAG ( $n = 3$ )-based free plant stanol formulas were com-

bined and called F3. Combination was considered appropriate, because the number of infusates was low, and the results of the aspirates of single DG- and TAG-based infusions were equally (in both groups) distributed above and below their combined mean values. In addition, plant sterol formulas (sitosterol/campesterol = 1.8), prepared identical to those of the plant stanol ones, were infused. All formulas were infused at a constant rate of 50 ml/h through the proximal outlet of the tube using an infusion pump (type 871 102, Braun B, Melsungen AG, Germany). The formulas were infused consecutively without a washout period each for 1 h in a different previously planned order (Fig. 2), so that each subject received three test meal infusions. Altogether 45 test meal infusions were given (15 subjects, each receiving three infusions), but 13 of them were excluded because of scanty intestinal fluid samples most probably due to bending of the tube in mucosal folds. During the infusions, four 15-minutes samples were collected from each subject at the PJ, starting aspiration 15, 30, 45 and 60 min from the beginning of each infusate via the distal lumen. As the first 15 min at the beginning of each infusion were needed to wash out the previous infusion, the first aspirated sample (at the 15-min) was not used for calculations. Samples aspirated at 30-, 45- and 60-min were pooled. The PJ samples (typical volume 5–6 ml) were placed in a water bath at 80 °C for 10 min to destroy the lipase and hydrolase activities, and then stored at –20 °C until analyzed. The total number of successful test meal infusions used for final analysis were 11, 12 and 6 in F1, F2 and F3, respectively. As only three of the infused sitosterol test meals (one sitosterol ester in TAG oil, one sitosterol ester in DG oil and one unesterified sitosterol in TAG oil) were sampled successfully, their results were omitted. Results from F1, F2 and F3 infusions were used for final statistical calculations as described below. The term phytoosterol will mean in the text saturated ( $5\alpha$ ) or unsaturated ( $\Delta^5$ ) sterols or their mixture.

#### Chemical Analysis

Separation of oil, micellar and sediment phases of total intestinal fluid were obtained by ultracentrifugation of samples for 1 h at 37 °C using a Beckman rotor type 50.4 Titan at a speed of 20,000 rpm corresponding to a  $g$ -force of 36,000 $g$  (the diameter and the length of the sample tube were 13 and 64 mm, respectively). Samples from both the total intestinal fluid and, after ultracentrifugation, from the oil droplet on the surface of the ultracentrifuged sample and from the micellar phase were collected. After removal of the oil phase and most of the micellar phase, sediment in a measured amount of micellar phase was also sampled.  $5\alpha$ -cholestane and epicoprostanol were added for internal markers to the samples and those of the three infusates,

which were then extracted with chloroform–methanol, evaporated and subjected to thin-layer chromatography in diethyl ether:heptane (50:50) solution to separate free and esterified sterols. The fractions were extracted from the silica gel plate with diethyl ether, and the ester fraction, containing also 5 $\alpha$ -Cholestane was saponified with 2 M KOH in 90% ethanol, and non-saponifiable lipids were extracted from the alkaline alcoholic–water medium with hexane. The sterol fractions were silylated, and free and ester sterols were quantified by gas–liquid chromatography on a 50-m long SE-30 capillary column (Ultra 1 column, Agilent Technologies, Wilmington, DE) with an automated electronic integrator (Sigma 10, Hewlett-Packard, Palo Alto, CA) for measurement of peak areas [21–23]. Epico-prostanol served as the internal standard for free sterols and 5 $\alpha$ -cholestane for ester sterols.

### Calculations

The esterification percentages of cholesterol, cholestanol, plant sterols (sitosterol and campesterol), stanols (sitostanol and campestanol), and their free, esterified and total concentrations were calculated in formulas, total intestinal fluids, and in micellar, oil and sediment phases of aspirated samples from the PJ (distal outlet). Since sitostanol was the largest phytosterol fraction in the formulas F1–F3 and was probably negligibly absorbed during the passage of the short upper intestinal segment, it was used as internal marker to correct dilutions [3, 7, 24, 25]. Sitostanol may be transiently taken up by the mucosa, but this occurs equally with each formula infusion. Thus, the absolute values (concentrations) of sterols and their esterified forms were calculated as ratios to respective sitostanol in order to evaluate the effects of the different infusate compositions and the duodenal transit. Free sterols in the micellar phase and sterols in the sediment phase of the PJ samples were calculated as percentage of the total amount of the corresponding sterol.

The hourly cholesterol flow in the PJ was calculated according to the following equation: net cholesterol flow in the PJ = sitostanol input (mg/h)  $\times$  cholesterol (mg) to sitostanol (mg) ratio in PJ – infused cholesterol (mg/h) [24, 25]. Thus, the net cholesterol flow in PJ is given by the difference between biliary cholesterol secretion and absorption of cholesterol during the 60-cm long passage. For campesterol and sitosterol this equation gives practically the difference between their biliary secretion and loss during the duodenal transit (absorption and transient mucosal uptake). Because each subject received his/her three infusates during the first three hours, and not in a steady state of biliary secretion, which begins after 6 h [24], the main emphasis of this study was not to measure biliary secretion of sterols or absorption of cholesterol.

The data were analyzed for significance and normality with the Number Crunching Statistical Software™ (NCSS™, Statistical Solutions Ltd, 2,000, Kaysville, Utah). Statistical analyses were carried out using Student's unpaired and paired *t* test. Logarithmic transformations were used with skewed distributions. Comparisons between the groups (F1–F3) were performed with one-way analysis of variance (ANOVA) and Kruskal-Wallis nonparametric ANOVA when the data were not normally distributed, with Bonferroni adjustment in both of them. The differences between the means were considered statistically significant if *P*-value was < 0.05. Mean  $\pm$  SE values are given.

## Results

### Test Meal Formulas

The contents of cholesterol, cholestanol and plant stanols were similar in the three formulas (Table 1). Plant stanols formed the predominant sterol proportion in the formulas, as their percentage amount varied from 71 to 74% of the total amount of sterols. It was due to rapeseed oil in F1 that its campesterol and sitosterol contents were higher than in F2. In F1–F3, cholesterol (90–94%), cholestanol (90–98%) and phytosterols (over 99%) were in the oil phase, whereas the micellar and sediment phases lacked phytosterols.

### Sterol Levels in Proximal Jejunal Contents

Comparison of the phytosterol content of the infusates with that of the PJ aspirates indicated that during the duodenal transit the infused phytosterols experienced a 5- to 7-fold dilution (Table 1). Use of sitostanol as an unabsorbable marker showed that cholesterol, in terms of mg/mg of sitostanol, increased by 3.8-, 3.7- and 3.3-fold (and that of cholestanol by twofold) from infusate to PJ in formulas F1–F3, respectively, probably due to biliary secretion of cholesterol. Due to biliary secretion also the respective ratios of campesterol and sitosterol increased (Table 1), while those of campestanol were unchanged in PJ as compared with the infusates. Biliary cholesterol secretion (mg/h) for campesterol was 17  $\pm$  14 with F1, 2  $\pm$  1 with F2, and 7  $\pm$  4 with F3 (NS), and for sitosterol 27  $\pm$  23 with F1, 3  $\pm$  1 with F2, and 11  $\pm$  8 with F3 (NS).

Hourly net cholesterol flow in the PJ (mg/h) was 172  $\pm$  46 with F1, 126  $\pm$  36 with F2, and 123  $\pm$  32 with F3 infusions (NS).

### Sterol and Stanol Esters During Duodenal Transit

Comparison of infusate cholesterol EST% (5%) in F1–F3 with their respective EST% in PJ aspirates revealed similar,

<sup>a</sup> *P* < 0.05, compared with corresponding value of infusate

<sup>b</sup> *P* < 0.05, compared with corresponding values of F1 and F2

i.e., about eightfold increases during the intestinal passage (*P* < 0.05) (Table 2). However, plant stanol, plant sterol and cholestanol esters had been hydrolyzed by ~39, ~28 and ~22%, respectively (*P* < 0.05 for all), during the intestinal passage of formulas F1 and F2 (Table 2). Opposite to those, almost one third of the practically unesterified plant stanols of the F3 infusate were esterified in PJ (*P* < 0.05), while the respective values of plant sterols remained practically unchanged, and that of cholestanol increased tenfold.

The respective EST%:s of sitostanol and campestanol were 59.7 ± 2.0 and 59.2 ± 2.0 in PJ during the F1 and F2 stanol ester formula infusions (calculated together, *n* = 23),

whereas the respective values during F3 were significantly lower, about 30% (Table 2).

The absolute concentrations of esterified cholesterol (mg/dl) were 4–5 times higher in PJ than the infusates F1–F3, but when standardized by infused total sitostanol the respective PJ-ratios were 29-, 20- and 27-times higher in F1–F3 (*P* < 0.05 for all), respectively (Table 3). The concentrations of all plant sterol and stanol esters decreased during the transfer to PJ. The PJ-ratios of esterified cholestanol were in F1 and F2 1.5- and 1.7-times (*P* < 0.05 for both), and in F3 25-times (*P* < 0.05 compared with the increase in F1 and F2) higher than the respective ratios in infusates.

Values are mean ± SE, concentrations are mg/dl, Δ ratios are differences of esterified sterol to sitostanol ratios (mg of esterified sterol per mg of respective total sitostanol (×1,000 for cholestanol and ×100 for other sterols)) between PJ and infusate

F1 stanol esters in triacylglycerol formula, F2 stanol esters in diacylglycerol formula, F3 free stanol formula, PJ proximal jejunum

<sup>a</sup> *P* < 0.05, compared with corresponding value of infusate

<sup>b</sup> *P* < 0.05, compared with corresponding values of both F1 and F2

<sup>c</sup> *P* < 0.05, compared with corresponding value of F2

<sup>d</sup> *P* < 0.05, compared with corresponding value of F1

During the intestinal passage, ratios of esterified plant stanols decreased in F1 and F2 infusions by 39 and 34% (*P* < 0.05 for both) for campestanol and by 39 and 34% (*P* < 0.05 for both) for sitostanol, respectively. In F3 infusion, esterified campestanol and sitostanol ratios increased by 71- and 70-fold (*P* < 0.05 for both), respectively (Table 3).

Respective ratios of plant sterols slightly increased.

#### Sterols in Sediment, Micellar and Oil Phases of Intestinal Contents

Calculations of sediment phase sterols in PJ aspirates showed that relative amounts of sedimented campestanol and sitostanol were higher with infusion of F3 than with infusions of the stanol ester formulas (Table 4, Fig. 3), and with F3 these stanols were predominantly hydrolyzed. Relative amount of sedimented cholesterol with infusion of F3 in PJ aspirates was lower than with the two stanol ester formulas F1 and F2, as calculated together (1.9 ± 0.4 vs. 5.1 ± 1.5; *P* < 0.05) (Fig. 3). Percentages of sterols and their EST% in the micellar phase were equal in the PJ as F1–F3 were compared with each other (Fig. 3).

Comparison of sterols in the oil phase of the PJ aspirates revealed 65–79% higher (*P* < 0.05 for both) relative amounts of sitostanol during the stanol ester than during free stanol infusion (Fig. 3). Furthermore, 86.9 ± 1.6% of

the oil phase sitostanol in PJ was esterified in F1, while the respective value was lower, 77.2 ± 1.9% in F2 and the lowest 65.3 ± 5.3% in F3, (*P* < 0.05 for all, compared with each other).

#### Discussion

The main new results of the present study were that, first, plant stanol ester hydrolysis and esterification of cholesterol were chiefly similar in TAG- and DG- based formulas F1 and F2 during the intestinal transit as compared with each other. In contrast, second, free plant stanols of F3 (mean of 3F1 and 3F2) were partly esterified during the transit, but to a lesser degree than remaining after hydrolysis of the two stanol ester formulas. Third, sedimentation of sitostanol and campestanol in PJ, mainly in free form, was more profound with the free than ester plant stanol formulas.

Accumulation of sterols and stanols in the oil phase of the infusates in F1–F3 is rational in the absence of bile salts, which are crucial for the intestinal micelle formation, and it parallels our earlier findings [1, 3], indicating that differences between stanol ester and unesterified stanol formulas reported here occurred during the duodenal transit. In our previous intestinal perfusion study [3] analogous to the present one, we compared biochemical

**Fig. 3** Columns show the amounts of sedimented sterols and esterified and free sterols in micellar and oil phases in PJ aspirates of test meal formulas F1–F3 as percentages. Concentrations of sterols (mg/dl) in total intestinal fluid samples are at the tops of the columns (mean ± SE). Free micellar sterols, percentage of total intestinal sterols, are marked in the columns (mean ± SE). Asterisks and daggers on the right-hand side of the columns indicate statistical significances ( $P < 0.05$ ) in percentages of oil and sediment phase sterols of total intestinal sterols in F3 compared with respective values of F1 and F2 separately (single asterisk) or with F1 and F2 calculated together (dagger), and respectively, a double dagger below the columns indicates esterification percentages of total intestinal sterols compared separately with F1 and F2 ( $P < 0.05$ , for both F1 and F2)

changes of sterols of a control rapeseed oil formula (very low phytosterol concentration) with a plant stanol ester formula during their duodenal transit. We found that the high micellar cholesterol fraction in the PJ after the control

infusion was 32% lower with the plant stanol ester formula, but, respectively, cholesterol fraction in the oil phase was over three times higher [3]. This suggested that mechanism of action of plant stanols might be displacement of cholesterol from the micellar phase [3]. In the present study, the micellar cholesterol fractions were of the same magnitude in each formula (Fig. 3) indicating that their efficacy with this respect remained equal. Net cholesterol flow in PJ tended to be ~38% higher (NS) with F1 infusion compared with F2 and F3 infusions. Thus, no significant difference could be seen in inhibition of cholesterol absorption between TAG- or DG-based stanol solutions. The reason for the relatively high values of particularly net cholesterol flow rate, but also of net campesterol and sitosterol flow rates in the PJ is that the administration of the test meal formulas caused a prandial state with gallbladder contractions and enhanced biliary secretion. These results are in accordance with those of Grundy and Metzger [24], who showed that a steady state in biliary output is reached after 4–6 h from the beginning of a formula infusion. Therefore, the hourly biliary secretion rate of phytosterols given in this study should not be considered as a daily secretion. As the physiological state was the same with infusions of the formulas studied here, the experimental setting used in this study allows their comparisons with each other.

Postprandial lipemia has been implicated in the risk of coronary artery disease and development of atherosclerosis [26]. Thus a rationale to consume DG instead of TAG in diet arises from the findings that DG could reduce the magnitude of postprandial lipemia [17]. Furthermore, hypolipidemic effects of dietary plant sterols dissolved in DG-based oil were better than in a control group using

TAG-based oil presumably due to better solubility of free plant sterols in DG [17]. With this respect our findings of very similar distribution of plant stanols and cholesterol in different intestinal fluid phases (higher oil phase stanol EST% in F1 than F2 and respective cholesterol EST% tended to be smaller) in these two oil solutions suggest that a putative difference in their hypolipidemic action is neither in micellar competition of plant stanols with cholesterol nor in precipitation of cholesterol. Murata and associates [15, 16] have suggested that the favorable effect of dietary DG on postprandial lipemia might be due to decreased intestinal re-esterification and chylomicron formation, to reduced secretion of chylomicrons into the circulation, and to altered fatty acid metabolism in the liver.

Numerous studies with Caco-2 cells, in experimental animals and in human subjects have tried to resolve the role of carboxyl ester lipase (CEL; also called as pancreatic cholesterol esterase) and acyl CoA cholesterol acyltransferase (ACAT) in intestinal absorption of cholesterol with controversial results (for a review see [27]). The former one is capable of hydrolyzing e.g., cholesterol and phytosterol esters, and it has been shown to mediate the intestinal absorption of esterified cholesterol in mice [28]. Dietary esterified cholesterol needs to be rapidly hydrolyzed by CEL during the intestinal passage in order to get penetrated into the micellar phase, which further presents cholesterol to the epithelial transporter proteins for absorption into the enterocytes. Results of our present and previous studies [3] indicate that esterified plant stanols are hydrolyzed by ~40% in the 60-cm long segment of the upper small intestine. Contrary to that, esterified fraction of infused free cholesterol was increased relatively and absolutely during the duodenal transit by factors 4–8. One putative explanation to the esterification could be reversed intraluminal action of pancreatic CEL and absorption of free cholesterol. This phenomenon favors free plant stanols to displace free cholesterol from the micellar phase, as cholesterol becomes esterified during the duodenal transit, and is accumulated into the oil phase. One could suggest that unesterified plant stanol preparations would be more beneficial with this respect, as their action would not depend on extensive hydrolysis [29]. However, the results of the present study showed that during the duodenal transit of the unesterified plant stanol formula F3, free plant stanols were esterified 70-fold. This suggests indirectly that they may lose part of their capacity to inhibit cholesterol absorption as compared to the optimal situation, in which administered free plant stanols would remain in their free form also in the PJ. Our results are in agreement with an earlier perfusion study among human subjects, which documented 3.5 times higher EST% of infused free sitosterol in the PJ compared to the infusate [1]. We are not able to provide clear explanation to the esterification of free

phytosterols, but reversed action of CEL could be suspected. Another possibility could be that the intestinal mucosa takes up free phytosterol in the short term thus increasing the intraluminal EST%. It is interesting to note that the EST% of cholesterol increased from about 5 to about 40% after F1, F2 and F3 in the PJ despite the fact that F3 contained virtually no plant stanol esters. Thus, the presumed reversed CEL action in cholesterol ester formation was not dependent on plant stanol esters. Duodenal esterification of free cholesterol and non-cholesterol sterols documented in our previous [3] and the present study needs further laboratory and clinical examination to reveal its biochemical background. Furthermore, a relatively high percentage of plant stanols in F3 infusion was lost in the sediment phase.

In addition to an average 40% hydrolysis of plant stanol esters in the upper part of the small intestine, their hydrolysis also continues more distally in the gut. This was evidenced in a study with colectomized subjects consuming daily 2 g of plant stanol esters with a spread, as their fecal analysis indicated total hydrolysis of 85% during the intestinal passage [30]. During the treatment period of 1 week, this led to average reductions of 16 and 40% in serum TC level and in cholesterol absorption efficiency, respectively [30]. Earlier human studies with normal intestinal tracts had showed that stanol esters were virtually absent in feces [31] indicating that only ~10% of their hydrolysis occurs in the colon. That hydrolysis of plant stanol esters occurs predominantly in a relatively short segment of the upper small intestine is crucial with respect to their desired action, as cholesterol is absorbed in that segment of the gut [25]. Also the type of plant stanol ester carrying vehicle and amount of dietary fat affect their hydrolysis [32]. Interesting with this respect is the finding that when plant stanol esters were consumed in pastilles having a fat free matrix by colectomized subjects, their hydrolysis was only about 60% in the whole small intestine [32]. This was probably due to low release of the stanol esters from the pastilles as compared with a spread, and presumably also to their fat free matrix. Parallel to this was also the finding that high amount of dietary fat favors the hydrolysis [32]. However, despite the reduced intestinal hydrolysis when plant stanol esters were consumed with pastilles, reductions in serum levels of TC and LDL-C and absorption efficiency of cholesterol were 9, 14 and 42%, respectively, in 1 week long study period [32]. This further indicates that only partial hydrolysis of plant stanol esters during the intestinal passage is sufficient. The amount of fat in the formulas examined in the present and our previous [3] study was relatively high with a prominent proportion of glycerol-L-mono-oleate. The results may not be applicable to a low-fat diet or to a diet with different fat composition.

Although plant sterols and stanols are differentially absorbed in the intestine, they have frequently been applied as internal markers in perfusion studies. Their differential absorption has to be taken into account when comparing the data based on sterol ratios. However, also sitosterol as a marker sterol has limitations as it is taken up by the intestinal mucosa in the short term, although to a lesser extent than other phytosterols [33]. In the setting of our study, this has most probably occurred to the same extent with F1–F3, and thus, has no influence on comparison between the formulas. However, mucosal uptake of a stanol marker may lead to overestimation of biliary secretion of sterols (according to the equation used [24]). It may also skew the change in EST% during the duodenal transit, as mucosal uptake may prefer the unesterified form.

In conclusion, plant stanol ester preparations were equally hydrolyzed in TAG- and DG-based formulas during their 60 cm long duodenojejunal transit, thus allowing equal formation of their free form, which is considered to be essential in micellar competition with cholesterol. Contrary to that, part of the free fraction of administered unesterified plant stanols are lost with their esterification and sedimentation.

## Absorption Properties of Micellar Lipid Metabolites into Caco2 Cells

Wakako Tsuzuki

Received: 16 February 2007 / Accepted: 10 May 2007 / Published online: 21 June 2007

**Abstract** To elucidate the absorption characteristics of dietary lipids in the human intestine, we investigated the cellular uptake of lipid metabolites using a differential monolayer of the Caco2 cells. As lipid metabolites, several free fatty acids and 2-monoacylglycerols, were formed a mixed micelle by bile salts and lysophospholipids and they were supplied to the Caco2 cells. To estimate the effect of the mixed micelles on the permeability of cells' membranes during incubation with the mixed micelles, the transepithelial electrical resistance (TEER) value was monitored, and no pronounced changes of TEER was detected. This suggested that mixed micelles did not affect their cellular properties of the barrier measured by TEER. The lipid metabolites transferred from the mixed micelle into the Caco2 cells were determined quantitatively by an enzymatic colorimetric method and were done by thin layer chromatography (TLC) for a species of acylglycerols. These highly sensitive methods enabled us to monitor the transepithelial transports of various kinds of non-isotope-labeled various lipid metabolites. Newly re-synthesized triacylglycerols were accumulated in Caco2 cells after 30 min incubation with the mixed micelles, and their amounts increased gradually for 4 h. The secretion of re-esterified triacylglycerols into a basolateral medium from the Caco2 cells began at 2 h after the mixed micelles were added to the apical medium. The intake of external lipid metabolites by the Caco2 cells were evaluated by an initial 2-h incubation with the mixed micelles. For example, 2-monomyristin and 2-monopalmitin were more rapidly transferred into the Caco2 cells from the mixed micelles

than 2-monocaprin was. On the other hand, the absorption rates of capric acid, lauric acid and myristic acid by the cells were larger than those of stearic acid and oleic acid. It revealed that the side-chain structure of these lipid metabolites affected their absorption by the Caco2 cells. The results of this study suggested that the Caco2 cell monolayer could be a useful model for investigating the involvement of dietary lipids in the transepithelial absorption in the human intestine.

### Introduction

Studies on the metabolism of lipids in the diet have become more important because of the increasing corpulence of populations around the world. The excess intake of dietary lipids induces several clinical diseases, especially in adult humans. On the other hand, the consumption of lipids is essential for the ingestion not only of energy but also of several essential fatty acids. Furthermore, the efficient uptake of lipophilic vitamins is strongly related to the simultaneous coexistence of lipids [1]. The appropriate intake of lipids is thus desirable from a nutritional viewpoint.

In the duodenum, dietary lipids, emulsified with physiological surfactants, such as bile salts and phospholipids, are hydrolyzed by a pancreatic lipase to produce 2-monoacylglycerols and free fatty acids. The latter two lipolytic products are then formed into mixed micelles by lysophospholipids, bile salts, and cholesterols, followed by absorption into the intestinal lumen. Their uptake by intestinal epithelial cells, the final step in the digestive

e-mail: wakako@affrc.go.jp

phase, is a rate-limiting step throughout the entire process of dietary lipid metabolism [2]. The transfer of lipid metabolites across the enterocyte membrane is thought to take place via facilitated diffusion and/or a membrane associated binding protein [3]. However, many aspects of the mechanisms underlying the intestinal absorption of lipid metabolites remain unknown.

The Caco2 cell line was established from a human colonic adenocarcinoma, expressing many phenotypic features of adult differentiated small intestinal enterocytes [4]. The cells have been used as a model for reproducing physiological events involving dietary nutrients at the small intestine. Previously, lipid metabolism was also studied in the Caco2 cells model for elucidating transcellular trafficking and intracellular compartmentalization of intestinal lipid metabolism. For example, the lipid metabolic capabilities of the Caco2 cells include absorption of lipid metabolites, re-synthesis of triacylglycerol and its secretion as triacylglycerol-rich lipoproteins. However, the amount of lipid metabolites, free fatty acids and 2-monoacylglycerols were too small to be monitored in the Caco2 cells model. In the previous studies, specific fatty acids, such as unsaturated fatty acids, 13-hydroxy octadecadienoic, were isotope-labeled and served in the Caco2 cells to monitor their behaviors [5–8]. Non isotope-labeled fatty acids were used in this cells model, only when their effects on transcellular permeation of other components, ions, proteins and so on, had been evaluated [9–12]. Therefore, little information has been available for the comparative study of transepithelial transport of various structured lipid metabolites in the Caco2 cells, because the kinds of isotope-labeled lipids metabolites used in the experiments were limited.

Recently, various structured lipids, defined as particular molecular species of triacylglycerols with specific fatty acids at specific positions of glycerol hydroxyl moieties, have been designed and produced. Their characteristic metabolic fates have been investigated in experimental animals [13–16]. These studies demonstrated that the intramolecular structure of a dietary triacylglycerol was strongly related to its nutritional and pharmaceutical property. The functional transepithelial transports of these structured lipids in intestinal absorption processes should be considered.

In this study, we firstly examined the introduction of one of the bile salts and lysophospholipid for making mixed micelles with lipid metabolites in order to enhance their uptake potentials by Caco2 cells. The previous study reported that absorption of the lipid metabolites by the Caco2 cells depended on the dissociation of micelles, the permeability coefficient and their monomer concentrations of lipid metabolites [16]. The formation of mixed micelles by several surfactants was expected to increase markedly the

monomer concentration of lipid metabolites exposed to the enterocyte membrane. Secondly, we investigated the intercellular trafficking property of each lipid metabolite in the Caco2 cells model system using non-isotope labeled 2-monoacylglycerols and free fatty acids. The object of the present study was to characterize the relationship between the lipid structure and its absorption property by the enterocytes. We then discussed the feasibility of the Caco2 cells as a model for studying the epithelial transport of dietary lipids.

## Materials and Methods

### Materials

Several acylglycerols and free fatty acids were purchased from Funakoshi Co. (Tokyo, Japan). The micelle mixture components—lysophosphatidylcholine (1-palmitoyl-*sn*-glycero-3-phosphocholine) (LysoPC) and taurodeoxycholic acid sodium salt (Tau)—were obtained from Sigma Chemical (St Louis, MO). The LDH-cytotoxic test kit was purchased from Wako Pure Chemical (Osaka, Japan). Other chemicals and solvents of analytical grade were purchased from Wako Pure Chemical and Kanto Chemical (Tokyo, Japan).

### Cell Culture

Caco-2 cells (American Type Culture Collection, Rockville, MD) were maintained in 10-cm dishes (Corning Glass Works, Corning, NY) containing Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum, 4 mmol/L L-glutamine, 40,000 U/L penicillin, 40 mg/L streptomycin, and 1% non-essential amino acids. DMEM medium contained 1 g/L glucose and the concentration of glucose was constant throughout the absorption experiments using the mixed micelles. The cells were kept at 37 °C in a humidified atmosphere of 95% air and 5% CO<sub>2</sub>. The growth medium was replenished every 2 or 3 days. Cells were reseeded when the cell monolayers became semiconfluent. For the experiments, cells at passages 25–50 were seeded in 12-well plates at  $1.2 \times 10^5$  cells per well and grown under the same conditions as those described above. For experiments on the secretion of lipids from Caco2 cells, the cells were seeded in transwell filter chambers (polycarbonate membrane, 0.4- $\mu$ m pore size, Costar, Cambridge, MA) at  $1.0 \times 10^6$  cells per well. The experiments were performed at 20–22 days post-seeding. Transepithelial electrical resistance (TEER) was measured at the end of the culture period using a voltmeter equipped with a chopstick-type electrode (EVOMX and STX2 electrode, World Precision Instruments, Sara-

sota, FL). The TEER value of Caco2 cultured in each transwell chamber was around  $330 \pm 26 \Omega$  indicating the formation of tight monolayers. At the end of the experiment for transepithelial transport of lipid metabolites, the TEER values were measured again. No pronounced changes of TEER could be observed, comparing with those values gained before the experiment. It was suggested that the incubation with the mixed micelles did not affect the physical property of the barrier measured by TEER.

#### Preparation of Mixed Micelles

Lipid metabolites were delivered as mixed micelles prepared by modified versions of previously described procedures [17–19]. Briefly, appropriate volumes of stock solutions of components were transferred to glass tubes, and the organic solvent was removed under a stream of argon. The residue was dissolved in serum-free DMEM (the concentration of glucose was constant (1.0 g/L)) and sonicated using a micro-equipped Astrason ultrasonic processor model W-380 (Heat-System Ultrasonics, Inc., Farmingdale, NY) until a predefined particle size distribution was achieved. The final concentration of each component in the medium was as follows: 2 mmol/L Tau, 0.2 mmol/L LysoPC, 0.1 mmol/L 2-monoacylglycerol, and 0.1 mmol/L free fatty acids. The resultant solutions were optically clear. The weight-averaged particle sizes of mixed micelles were determined from quasielastic light-scattering measurements (NICOMP model 380 ZLS; Particle Sizing Systems, Santa Barbara, CA). The particle diameters of the mixed micelles ranged from 20 to 100 nm.

#### Uptake of Micellar Lipids by Caco2 Cells

The differentiated monolayers of the Caco2 cells in a 12-well plate or on a 6-transwell plate were washed twice with 0.5 mL serum-free DMEM medium and then supplemented with 2 ml of the medium containing micellar lipids. For the epithelial absorption experiments, 2 ml of the medium containing micellar lipids was supplied into each well and the Caco2 cells were routinely incubated for 2 h. For the epithelial secretion experiments, 2 ml of the same medium was poured into each apical side of the transwell, and the 2.5 ml serum-free medium was added in the basolateral one.

#### Extraction of Lipids from Caco2 Cells or from a Basolateral Medium and Their Analyses

After incubation of the Caco2 cells with the mixed micelles, the cell monolayers were washed twice with 0.5 mL PBS containing 4 mmol/L Tau to remove surface-bonded lipids, followed by two additional washings with 0.5 mL

PBS. The washed cells were harvested in 1 mL PBS and collected by centrifugation at  $1,000 \times g$  for 5 min at 4 °C. The supernatants were discarded, and the cell pellets were homogenized with a microtube homogenizer in 0.5 mL PBS. An aliquot of each cell homogenate was taken to determine the protein content, according to the method of Lowry et al. [20]. Total lipids contained in the Caco2 cells were extracted by the method of Folch et al. [21]. Briefly, 0.75 mL chloroform/methanol (2:1, v/v) was added to the cell homogenate and mixed with the solution in a vortex shaker (NSD-12, Nissinrika Ltd., Tokyo, Japan) for 5 min following centrifugation at  $1,000 \times g$  for 2 min. The resultant lower layer of chloroform was withdrawn and transferred to another tube. The upper layer was similarly extracted with 0.75 mL chloroform/methanol (2:1, v/v). The chloroform layer was combined with the initial extract. The combined extract was dried under a stream of argon gas and dissolved in 0.5 mL chloroform/methanol (2:1, v/v). Then, 0.2 mL solvent was used for quantitative determination of acylglycerols by the Triglyceride-E Test Wako kit (Wako Pure Chemical). For the secretion experiments of lipid from the Caco2 cells, lipids in the basolateral medium was extracted and analyzed according to the methods described above.

#### Statistical Analysis

The data represent mean  $\pm$  SD. Statistical analysis were made by one-way ANOVA and Dunnett's or Scheffe's *F* test to identify significant differences between the groups.

#### Thin-layer Chromatography Analyses

To identify the acylglycerols species, the total lipid extracted from Caco2 cells were applied to a silica thin-layer chromatography (TLC) plate (silica gel 60, Merck) and developed in hexane/diethylether/acetic acid (8:2:0.1, by vol.) or chloroform/methanol (6:4, v/v). Lipid was visualized by the vapor off iodine or by spray with 50% phosphomolybdic acid/ethanol solution followed by charring at 200 °C.

## Results

#### Potential Cytotoxic Effects of Tau and LysoPC on Caco2 Cells Culture

In the previous works, lipid metabolites were dispersed or emulsified in the medium containing serum albumin before being supplied to the Caco2 cells [10–12]. In this study, the mixed micelles were formed by physiological surfactants, Tau and LysoPC to monitor the epithelial transport of the

**Table 1** Cellular acylglycerols/protein (nmol/mg) after 4 h incubation

	nmol	% <sup>a</sup>
Medium	0.162 ± 0.041	0.0
2 mmol/L Taurodeoxycholic acid sodium salt (Tau)	0.219 ± 0.030	7.6
0.2 mmol/L Lysophosphatidylcholine (LysoPC)	0.312 ± 0.038	20.1
2 mmol/L Tau + 0.2 mmol/L LysoPC (mixed micelles)	0.279 ± 0.033	15.6
0.1 mmol/L Oleic acid (dispersed)	0.352 ± 0.039	25.4
0.1 mmol/L Oleic acid/Tau + LysoPC (mixed micelles)	0.447 ± 0.040	38.1
0.1 mmol/L 2-Monoolein (dispersed)	0.371 ± 0.038	27.9
0.1 mmol/L 2-Monoolein/Tau + LysoPC (mixed micelles)	0.492 ± 0.046	44.1

0.1 mmol/L Oleic acid + 0.1 mmol/L 2-Monoolein/Tau + LysoPC (mixed micelles)	0.910 ± 0.052	100.0

<sup>a</sup> The relative values were calculated in comparison with that of the cellular TG re-synthesized from mixed micellar 2-monoolein and oleic acid, which was taken 100%

lipid metabolites into the Caco2 cells from mixed micelles. Previous work pointed out that these physiological surfactants affected the viability of the Caco2 cells [22]. We evaluated the toxicity of these surfactants, which were used as the components of mixed micelle in the epithelial transport of lipid metabolites in the Caco2 cells model in a pilot study. Actually, the release of cytoplasmic lactate dehydrogenase (LDH) from the Caco2 cells into the medium was measured during incubation with the medium containing 0.2 mmol/L LysoPC and 2.0 mmol/L Tau. Based on the values of LDH release, the loss of viability of the Caco2 cells was less than 1.0% of the cells after 2 h incubation, which suggested that injury of the cells was small. The concentrations of Tau and LysoPC for use in micelle mixtures were set at 2.0 mmol/L and 0.2 mmol/L, respectively. In addition, the concentration ranges of these physiological surfactants were not contradictory to those in the digestive organs *in vivo* [1].

#### Effects of the Components of the Mixed Micelle on the Re-esterification of Acylglycerols in Caco2 Cells

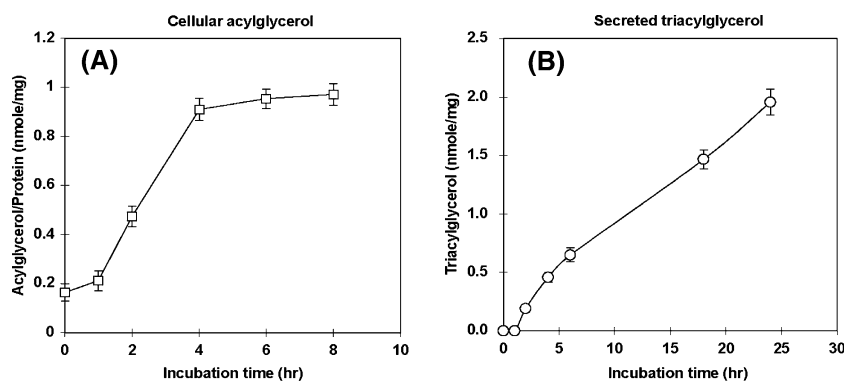

In this study, lipolytic products were mixed-micelled with Tau and LysoPC and then were supplied to the Caco2 cells plated on the wells. Previous works revealed that incubation with Tau or LysoPC alone involved the newly synthesis of lipids in the Caco2 cells [23, 24]. The effects of these micellar components on intercellular lipid levels in the Caco2 cells and on triacylglycerol secretion from the cells were to be addressed. We first evaluated the cellular acylglycerol amounts induced by each component of the mixed micelle. When both of lipolysis products, oleic acid and 2-monoolein, were mixed-micelled by Tau and LysoPC simultaneously followed by addition to the Caco2 cells, a considerable amount of triacylglycerol re-synthesis was induced in the cells for 4 h (0.910 nmol per mg of protein, which was taken 100%), as shown in Table 1. The addition of LysoPC, Tau and both induced an increase of

cellular acylglycerols by a modest 20%, 7%, and 15%, respectively (Table 1). Oleic acid dispersed in the medium was partially absorbed into Caco2 cells and stimulated corresponding triacylglycerol re-synthesis at the level of 25%. This result was consistent with the previous ones that only oleic acid stimulated lipoprotein production by increasing the synthesis and accumulation of cellular triacylglycerol [12, 25]. The other lipolysis product, 2-monoolein dispersed in the medium also facilitated the triacylglycerol re-synthesis in the Caco2 cells (27%). Meanwhile, the absorption amounts of the mixed-micellar oleic acid and 2-monoolein by the Caco2 cells were larger than those of the dispersed ones (Table 1). This result suggested that the formation of mixed micelle in the intestinal lumen would play an essential role in an efficient absorption of lipid metabolites.

#### Time Courses of the Uptake of Lipid Metabolites and the Secretion of Triacylglycerols by Caco2 Cells' Model

When the mixed micellar 2-monoolein and oleic acid were incubated with the Caco2 cells plated on wells or on transwells, the accumulation of re-synthesized triacylglycerols in the Caco2 cells and their secretion from the cells were traced in each defined incubation period. As shown in Fig. 1a, the cellular triacylglycerols in the Caco2 cells started to accumulate within 30 min after they were incubated with the mixed micellar lipids, and a proportional increase was found until around 4 h of incubation. After 2 h of incubation with micellar oleic acid and 2-monoolein, their transfers into the Caco2 cells was analyzed by the TLC method. As shown in Fig. 2a, neither oleic acid nor 2-monoolein existed in the Caco2 cells in this initial period of the incubation. The quick conversion process of these lipid metabolites into corresponding triacylglycerols by the Caco2 cells suggested that the absorption processes but not the re-synthesis of triacylglycerol processes was the rate

**Fig. 1** Time course of accumulation of cellular lipid in Caco2 cells (a) and that of the secretion of lipid from Caco2 cells (b) incubated with mixed micellar 2-monoolein and oleic acid. The data represent the mean  $\pm$  SD of six wells. Replicated experiments demonstrated a similar trend

limiting of whole processes of the accumulation of cellular triacylglycerol during the initial 2-h incubation. It could be concluded that the cellular triacylglycerol accumulation in the Caco2 cells during an initial 2 h was regarded as the absorption amounts of these lipid metabolites.

On the other hand, the secretion of newly re-synthesized triacylglycerols from the cells into the basolateral medium was detected after 2 h of incubation with the micellar

lipolytic products and increased gradually for at least 24 h. (Fig. 1b). The secreted lipids were also checked by the TLC method. Only triacylglycerol re-synthesized by the Caco2 cells was detected.

Based on the time course data of the cellular acylglycerol accumulation and of their secretion, the initial 2-h incubation with micellar lipolytic products was appropriate for the evaluation of their initial absorption of lipid metabolites by the Caco2 cells.

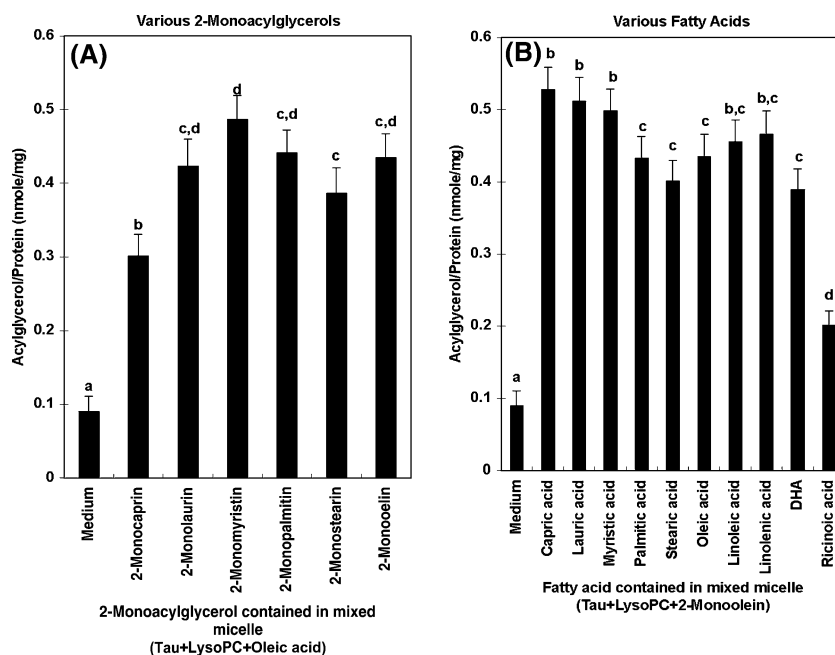

**Fig. 2** Thin layer chromatography of lipid extracted from the intact Caco2 cells, which were incubated with the medium alone [1], with the medium containing mixed micellar 2-monoolein and oleic acid [2]. The same sample were developed by hexane/diethyl ether/acetic acid (8:3:0.1, v/v) (a) and by chloroform/methanol (6:4, v/v) (b). 2Mmonoolein (2M), oleic acid (Oa) and triolein (TO) were also developed as references

#### Uptake of Lipolytic Products with Various Molecular Structures into the Caco2 Cells

Since absorption of non-isotope-labeled 2-monoolein and oleic acid in the Caco2 cells model were able to be evaluated, 2-monoacylglycerols with various length side chains were examined. In addition to 2-monoolein, 2-monocaprin, 2-monolaurin, 2-monomyristin, 2-monopalmitin, and 2-monostearin formed mixed micelle with Tau and LysoPC in the presence of oleic acid, followed by the addition to the Caco2 cells. Little difference was found in the accumulation amount of re-synthesized triacylglycerols using 2-monopalmitin, 2-monostearin, and 2-monoolein. Whereas, the accumulation of triacylglycerols re-synthesized by the Caco2 cells incubated with 2-monocaprin, 2-monolaurin, and 2-monomyristin, increased in this order (Fig. 3a).

In the next experiment, caprylic acid, capric acid, stearic acid, oleic acid, linoleic acid, linolenic acid, *cis*-4,7,10,13,16,19-docosahexanoic acid (DHA) and ricinoic acid were each introduced to be formed the mixed micelle with 2-monoolein, Tau and LysoPC. No free fatty acid could be detected by TLC methods in the initial 2-h incubation and all of them were re-synthesized into corresponding triacylglycerols (data not shown). It was concluded that the absorption amounts of lipid metabolites could be estimated by the measurements of cellular re-synthesized triacylglycerol one. As shown in Fig. 3b, epithelial transfer rates of middle length chain fatty acids (capric acid, lauric acid and myristic acid) to the Caco2

**Fig. 3** The accumulation amount of the cellular lipids of the Caco2 cells incubated with various 2-monoacylglycerols and oleic acid formed mixed micelles for 2 h (a). The accumulation amount of the cellular lipids of the intact Caco2 cells incubated with various free fatty acids and 2-monoolein formed mixed micelles for 2 h (b). The data represent the mean  $\pm$  SD of six wells. Replicated experiments demonstrated a similar trend. Statistical comparisons were made by Scheffe's *F*-test. Values not sharing a common letter in each line are significantly different from others ( $P < 0.05$ )

cells from the mixed micelles was larger than those of the long length and saturated fatty acids. (palmitic acid and stearic acid).

## Discussion

The final step in the lipid digestion process was the uptake of lipolytic products from the micelle mixture into the cell membranes of enterocytes *in vivo*. Due to the lipophilic nature of lipid metabolites, a passive diffusion and/or a protein-mediated energy-dependent uptake process, was thought to be their uptake pathways by enterocytes [3, 24]. However, these complicated uptake mechanisms of lipolytic compounds at the luminal cell surface, have not been resolved fully. The most significant finding in this work was that the behaviors of non-isotope-labeled lipolysis products could be monitored in the Caco2 cell model. This has allowed us to investigate the relationship between the molecular structures of lipids and their absorptive and secreting properties in the Caco2 cell model, using various kinds of lipolytic products. The introduction of non-isotope-labeled lipid metabolites into the Caco2 cell model was accomplished by following two improvements in the experimental procedures.

The first improvement was the successful introduction of highly sensitive detection methods to determine trace amounts of acylglycerols extracted from the Caco2 cells. The quantitative determination of acylglycerols was based on a commercially available kit. In addition, the TLC method was useful for discriminating among molecular species of acylglycerols. The detection limits of these

methods were at the level of 1–10 pmol. Because these methods were sensitive enough to measure the amount of the cellular lipid compounds, non-isotope-labeled lipid metabolites in the Caco2 cell model could be evaluated. Based on these methodological improvements, the absorption of other lipophilic nutrients materials in relation to the behavior of lipid metabolites, will be able to be analyzed in this Caco2 model in future.

In the second improvement in this study, all the lipolytic products were afforded as mixed micelles with physiological surfactants (Tau and LysoPC) to the Caco2 cells. Although 2-monoacylglycerols and free fatty acids with short or middle length chains can partially exist as free monomers in an aqueous solution, most of lipid metabolites have poor water-solubilities. It has long been known that the uptake by enterocytes depends on their monomer concentration in an aqueous phase and on that in the intermicellar concentration [2]. Previously, several surfactants, such as bovine serum albumin and phosphatidylcholine, were examined as materials for making micelles with lipid metabolites to increase the lipid metabolites absorbed by Caco2 cells [9, 22, 23]. In this study, Tau and LysoPC were successfully introduced to be components of mixed micelles. The enhancement of the monomerization of lipolytic products by the formation of mixed micelles contributes to their efficient transfer into the Caco2 cells.

This study revealed that 2-monoacylglycerol and fatty acid transferred from the mixed micelles were converted quickly into corresponded triacylglycerols in the cells and that very low amounts of intact types of lipolytic metabolites were contained in the cells in the initial incu-

bation (2 h). The initial accumulation rate of triacylglycerols re-synthesized by the Caco2 cells was taken as the initial absorption of exogenous 2-monoacylglycerol and fatty acid. Comparison of the absorption in using various lipid metabolites suggested that the molecular structure of lipolytic metabolites affected their absorption by the Caco2 cells. Thus information would help to consider the absorption properties of the structured lipids.

The absorption mechanism of lipids *in vivo* would be more complicated than that in the Caco2 cell model, because the contribution of an unstirred water layer and a mucin layer on the surface of the intestinal lumen should be considered in intestinal absorption *in vivo* [1]. In studies of the complicated absorption mechanisms in the intestine, information about transepithelial absorption processes of lipolytic products through the enterocyte membranes will be supplied using this Caco2 cell model. The cells have been widely utilized as an enterocyte absorption model for various dietary materials. As for lipid digestion, further investigation into the relationship between the molecular structures of lipolytic products and their absorption into the Caco2 cells will be undertaken in our laboratory using various structured lipids.

# A Green Tea Catechin Extract Upregulates the Hepatic Low-Density Lipoprotein Receptor in Rats

Christina A. Bursill · Paul D. Roach

**Abstract** Green tea extracts have hypocholesterolaemic properties in epidemiological and animal intervention studies. Upregulation of the low-density lipoprotein (LDL) receptor may be one mechanism to explain this as it is the main way cholesterol is removed from the circulation. This study aimed to determine if a green tea extract could upregulate the hepatic LDL receptor in vivo in the rat. A green tea extract (GTE) enriched in its anti-oxidant constituents, the catechins, was fed to rats ( $n = 6$ ) at concentrations of either 0, 0.5, 1.0 or 2.0% (w/w) mixed in with their normal chow along with 0.25% (w/w) cholesterol for 12 days. Administration of the GTE had no effect on plasma total or LDL cholesterol concentrations but high-density lipoprotein significantly increased (41%;  $p < 0.05$ ). Interestingly, there was a significant increase in LDL receptor binding activity (2.7-fold) and LDL receptor protein (3.4-fold) in the 2% (w/w) treatment group compared to controls. There were also significant reductions in liver total and unesterified cholesterol (40%). Administration of the GTE significantly reduced cholesterol absorp-

tion (24%) but did not affect cholesterol synthesis. These results show that, despite no effect on plasma cholesterol, the GTE upregulated the LDL receptor in vivo. This appears to be via a reduction in liver cholesterol concentration and suggests that the green tea extract was able to increase the efflux of cholesterol from liver cells.

## Introduction

The low-density lipoprotein (LDL) receptor is a cell surface protein that is present on the outer surface of most cells, but in particular liver cells. It is the main mechanism by which cholesterol-carrying LDL can be removed from the circulation [1]. There is, therefore, much interest in agents that increase LDL receptor activity and subsequently lower plasma cholesterol concentrations. Elevated LDL cholesterol levels are associated with increased risk of heart disease, one of the biggest killers in western societies [2].

There is evidence to suggest that green tea and its anti-oxidant constituents, the catechins, can upregulate the LDL receptor. This has evolved from epidemiological studies [3–5] showing that drinking between 5 and 10 cups of green tea per day is associated with lower plasma cholesterol concentrations. Intervention studies in rats, mice and hamsters have also found that green tea and green tea extracts enriched in catechins exhibit hypocholesterolaemic effects [6–10]. An increase in the LDL receptor may be one mechanism by which to explain this observed cholesterol-lowering ability of green tea extracts.

Studies in vitro [11–13] have provided more direct evidence that green tea extracts and its catechin constituents can upregulate the LDL receptor and modulate cholesterol metabolism in HepG2 cells. Indirect evidence that the LDL receptor may be upregulated by green tea extracts in vivo has also been found [14]. When rats were fed EGCG, the main catechin in green tea, the removal of intravenously injected  $^{14}\text{C}$ -cholesterol from the plasma was enhanced. This increase in the plasma clearance of cholesterol may be due to the upregulation of the LDL receptor [1] but was not assessed.

Currently, the inhibition of cholesterol absorption has been proposed as the mechanism to explain the cholesterol lowering effects of green tea in vivo. This is because the faecal excretion of total lipids and cholesterol were found to be higher in animals consuming green tea extracts [6, 7, 9]. The EGCG has also been observed to inhibit the uptake of  $^{14}\text{C}$ -cholesterol from the intestine [14]. This apparent reduction in intestinal cholesterol absorption has been ascribed to EGCG reducing the solubility of cholesterol into mixed bile salt micelles [15]. It has also been found that hamsters and rats fed green tea extracts had increased faecal excretion of bile acids [9, 10]. A study in rabbits found that a green tea extract also inhibited cholesterol synthesis [16]. Despite these effects on cholesterol absorption and synthesis, it does not rule out the possibility that an upregulation of the LDL receptor could also contribute to the hypocholesterolaemic effects of green tea. Evidence for this has been found in recently published work, where the administration of a green tea extract to rabbits significantly increased the hepatic LDL receptor in vivo [16].

The aims of this study were to determine if administration of a crude catechin extract from green tea could upregulate the hepatic LDL receptor in rats and subsequently lower plasma cholesterol in the rat.

## Experimental Procedures

### Catechin Extract

The crude catechin extract was prepared from commercially available “Special Gunpowder” green tea, packaged by the China National Native Products and Animal By-products Import and Export Corporation, Zhejiang Tea Branch, China. The method used was based on the method of Huang et al. [17]. Briefly, 15 kg of green tea was extracted with three volumes (v/v) of methanol at 50 °C for 3 h. Solvent was removed from the extract using a reduced pressure rotary evaporator. The residue was dissolved in two volumes of water (v/v) at 50 °C and extracted twice

with equal volumes of hexane (v/v) and once with an equal volume of chloroform (v/v). The remaining aqueous phase was then extracted once with an equal volume of ethyl acetate (v/v) which extracts the polyphenolic compounds including the catechins. The ethyl acetate was then evaporated, the residue redissolved in the minimum amount of warm water (50 °C) and freeze dried. The extract contained at least 58% (w/w) catechins and the composition of the measured constituents was: 30% EGCG, 21% ECG, 10% caffeine, 6% moisture, 4% EGC, 2% GCG and 0.5% theanine.

### Animal Study

Twenty-four male Sprague Dawley rats (IMVS, Gillies Plains, SA, Australia) were housed at the CSIRO Health Sciences and Nutrition Animal Facility (Kintore Avenue, Adelaide, SA, Australia) in surroundings of controlled temperature ( $20 \pm 1$  °C) and a 12 h light cycle (0600 to 1800). Ethics approval for the study was obtained from the University of Adelaide and CSIRO Health Sciences and Nutrition Animal Ethics Committees.

After an initial plasma collection from the tail vein, the rats were randomised into four different treatment groups. The crude catechin extract was mixed in with their normal rat chow at concentrations of 0, 0.5, 1 or 2% (w/w) along with 0.25% (w/w) cholesterol and fed to the rats for a period of 12 days. The rats were weighed every 2 days. After the 12 days dietary intervention the rats were fasted overnight prior to sacrifice.

Blood was collected into tubes containing EDTA (final concentration 1 g/L) from the abdominal aorta of rats under halothane anaesthesia. Plasma was isolated by centrifugation at  $1,500 \times g$  for 10 min and 1 mL aliquots were frozen at  $-20$  °C for later analysis. Liver tissue was also excised and immediately frozen in liquid nitrogen.

### Plasma Lipid Determinations

The LDL fraction ( $d = 1.019\text{--}1.063$  g/mL) was isolated from 2 mL of plasma by sequential ultracentrifugation. The high-density lipoprotein (HDL) fraction was obtained after precipitating apoB containing lipoproteins with polyethylene glycol 6000 (BDH Chemicals, Kilsyth, Victoria, Australia). Cholesterol in whole plasma and in the LDL and HDL fractions was measured on the Cobas Bio automated centrifugal analyser (Roche, Basel, Switzerland) by enzymatic methods using test kits (Roche Diagnostica, Basel, Switzerland) [18]. The triglyceride concentration of the whole plasma was also determined using enzymatic methods (Roche Diagnostica) on the Cobas Bio.

## Cholesterol Synthesis and Intrinsic Capacity to Absorb Dietary Cholesterol

Plasma lathosterol and phytosterols (campesterol and  $\beta$ -sitosterol) were measured by gas chromatography (GC) [19]. The ratios of serum lathosterol and phytosterol concentrations in the plasma to plasma cholesterol concentration, have been found to correlate with whole body cholesterol synthesis [20] and the intrinsic capacity to absorb dietary cholesterol [21], respectively.

## Hepatic LDL Receptor Binding Assay

To prepare LDL–gold conjugates, normolipidemic human blood (Australian Red Cross, Adelaide, Australia) was used to isolate LDL ( $1.025 < d < 1.050$ ) by sequential ultracentrifugation. Colloidal gold was prepared and the isolated LDL was then conjugated to the colloidal gold as previously described [22].

A 2–3 g piece of liver was homogenised and microsomal membranes (800–100,000 $\times$ g centrifuge fraction) were prepared and solubilised with 1% (w/v) Triton X-100, 5 mM phenylmethylsulfonyl fluoride and 5 mM *N*-ethylmaleimide, to prevent degradation and dimerisation of the rat LDL receptor protein. Once solubilised, Triton X-100 was removed using Amberlite XAD-2 [23] and the protein content of the microsomal membranes was determined.

To measure LDL receptor binding activity, 8  $\mu$ g of the solubilised liver membranes were applied to nitrocellulose paper (Schleicher and Schuell, Westborough, MA, USA) which was then blocked with 4% (w/v) bovine serum albumin solution [22, 24]. The nitrocellulose membranes were then incubated in buffer containing either 20  $\mu$ g/mL LDL–gold in the absence and presence of 20 mM EDTA to determine total and non-specific binding, respectively. The nitrocellulose paper was soaked in water for 30 min and then incubated with intense BL silver enhancement kit (Amersham, UK) for further 30 min. This was washed with water, dried and scanned using an LKB Ultrascan XL enhanced laser densitometer (Pharmacia LKB Biotechnology, North Ryde, NSW, Australia). The specific binding (total minus the non-specific binding) was taken to be the LDL receptor binding activity which is expressed as peak height, determined from the laser densitometer scan.

## Quantification of LDL Receptor Protein

To determine relative amounts of LDL receptor protein, solubilised rat liver membranes (150  $\mu$ g) were subjected to electrophoresis on 3–15% SDS polyacrylamide gradient gels and electrotransferred onto nitrocellulose paper. The membranes were then overlaid with a polyclonal antibody [24] against the LDL receptor (1:2,000) followed by an

anti-rabbit IgG antibody conjugated to horseradish peroxidase (Sigma, St Louis, MO, USA). The LDL receptor band was then detected on X-ray film (Hyperfilm-ECL, Amersham, North Ryde, NSW, Australia) using enhanced chemiluminescence (Amersham, North Ryde, NSW, Australia). Quantification of LDL receptor protein was performed by laser densitometry. Results are expressed as peak area, determined from the densitometer scan.

## Liver Lipid Determinations

Total cholesterol, unesterified cholesterol and triglycerides were measured on the liver homogenates. Liver preparations were initially sonicated then diluted 1:1 with a 2% (w/w) Triton X-100 and 2 mM  $\text{CaCl}_2$  solution. This was agitated on a rotating wheel for 30 min at 4 °C and protein content determined. Lipid measurements were performed using enzymatic methods on the Cobas Bio and expressed relative to the protein concentrations.

## Statistical Analyses

Results are expressed as mean  $\pm$  SEM. Percentage changes were calculated by determining the percentage change in the highest dose treatment group (2% w/w) relative to the control group. Similarly, fold changes were calculated by dividing the mean of the 2% (w/w) treatment group by the control group.

Statistical evaluation was done using a one way analysis of variance (ANOVA) and a Tukey's posthoc test. A value of  $p < 0.05$  was the criterion of significance. The statistics were performed using the SPSS statistics package.

## Results

### Crude Catechin Extract from Green Tea has No Effect on Plasma Lipids in Rats

There were no significant differences in plasma total cholesterol concentration between groups before intervention with the crude catechin extract (data not shown). There was also no significant changes in body weight between groups throughout the treatment period. This would indicate that there was no variability in food intake between groups, although this was not systematically measured. The inclusion of a green tea catechin extract to regular rat chow did not therefore affect the appetite of the rats.

Administration of the crude catechin extract along with 0.25% cholesterol for 12 days did not significantly change plasma total cholesterol, LDL cholesterol or triglyceride concentrations compared to the control group (Table 1). The HDL cholesterol concentrations were however,

**Table 1** Plasma lipid concentrations in rats after the administration of a crude catechin extract

	Crude catechin extract (%) (w/w)			
	0	0.5	1	2
Total cholesterol (mmol/L)	1.01 ± 0.10	1.39 ± 0.21	1.20 ± 0.12	1.49 ± 0.23
Triglycerides (mmol/L)	0.55 ± 0.04	0.68 ± 0.08	0.40 ± 0.03	0.52 ± 0.04
LDL cholesterol (mmol/L)	0.32 ± 0.06	0.39 ± 0.10	0.35 ± 0.07	0.44 ± 0.08
HDL cholesterol (mmol/L)	0.66 ± 0.05	0.87 ± 0.10	0.77 ± 0.05	0.93* ± 0.10

Values given as mean ± SEM. Twenty-four Sprague Dawley rats were divided into four different treatment groups of six rats each. The different treatment groups were fed a crude catechin extract for 12 days at concentrations of either 0, 0.5, 1.0, 2.0% (w/w) mixed in with normal rat chow and 0.25% cholesterol. Plasma lipids were determined using sequential ultracentrifugation and enzymatic methods on the Cobas Bio

\*  $p < 0.05$  (significant difference to control)

significantly increased (41%;  $p < 0.05$ ) in rats supplemented with the highest dose of crude catechin extract (2%) when compared with the control rats (Table 1).

#### Crude Catechin Extract from Green Tea Decreases Cholesterol Absorption

The ratio of plasma phytosterol to cholesterol was used as an index of the intrinsic capacity to absorb dietary cholesterol. Administration of the crude catechin extract was found to significantly decrease cholesterol absorption (24%) in the highest dose treatment group compared to controls (Table 2). No significant changes were seen in cholesterol synthesis between treatment groups.

#### Crude Catechin Extract from Green Tea Upregulates the Hepatic LDL Receptor

The calcium-dependant, LDL–gold binding capacity of solubilised liver membranes was used to determine hepatic LDL receptor binding activity. Administration of the highest dose of crude catechin extract (2% w/w) significantly increased (2.7-fold;  $p < 0.05$ ) the hepatic LDL receptor binding activity compared to the control (Fig. 1). Using a polyclonal antibody against the LDL receptor of liver homogenates, the relative amounts of LDL receptor protein was found to be significantly higher ( $p < 0.05$ ) in all the treatment groups compared to the control. It was at

its highest in the in the 2% (w/w) treatment group (3.4-fold higher than control) (Fig. 1).

#### Crude Catechin Extract from Green Tea Lowers Liver Cholesterol

Administration of the crude catechin extract significantly reduced ( $p < 0.05$ ) total and unesterified cholesterol in liver homogenates (40% for both) in the 2% (w/w) treatment group compared to controls (Fig. 2). Unesterified cholesterol constituted approximately 70% of the total cholesterol content and consumption of the crude catechin extract did not alter this percentage significantly. Administration of the crude catechin extract also significantly lowered triglyceride concentrations in liver homogenates by 40% (control:  $80.4 \pm 6.8$ , 0.5%: $74.7 \pm 10.0$ , 1.0%: $65.4 \pm 8.0$ , 2.0%: $49.0 \pm 4.0$  mmol/L;  $p < 0.05$ ).

## Discussion

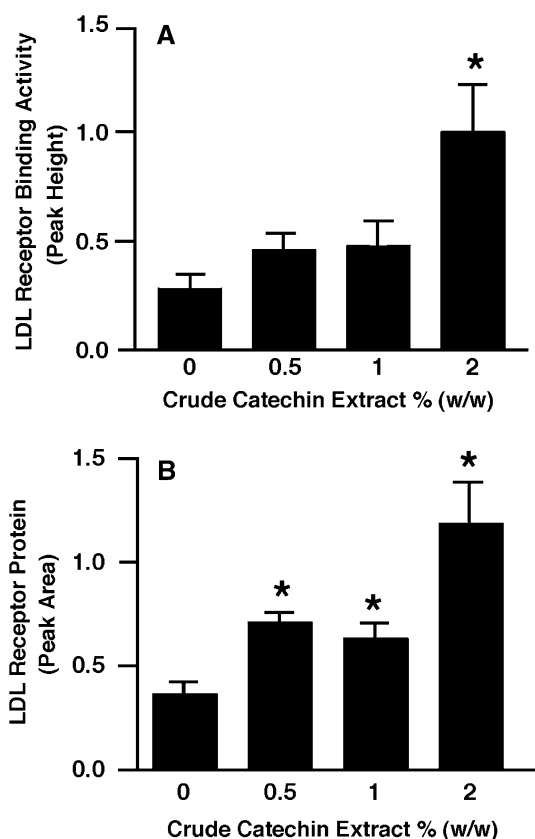

The aim of this study was to investigate if administration of a crude catechin extract, from green tea, could increase the hepatic LDL receptor in vivo in the rat. An upregulation of the LDL receptor would provide a mechanism to explain the hypocholesterolaemic effects of green tea that have been observed in epidemiological and animal intervention studies. In contrast with previous studies, administration of

**Table 2** Effect of a crude catechin extract on cholesterol absorption and cholesterol synthesis

	Crude catechin extract (%) (w/w)			
	0	0.5	1	2
Phytosterols/cholesterol ( $\mu\text{M}/\text{mM}$ )	21.92 ± 2.12	23.93 ± 2.85	19.75 ± 3.34	16.74* ± 1.70
Lathosterol/cholesterol ( $\mu\text{M}/\text{mM}$ )	0.11 ± 0.01	0.07 ± 0.005	0.10 ± 0.020	0.10 ± 0.032

Values given as mean ± SEM. Twenty-four Sprague Dawley rats were divided into four treatment groups of six rats each. The different treatment groups were fed a crude catechin extract for 12 days at concentrations of either 0, 0.5, 1.0, 2.0% (w/w) mixed in with normal rat chow and 0.25% cholesterol. Phytosterols, lathosterol and cholesterol were measured using gas chromatography

the crude catechin extract did not alter plasma total or LDL cholesterol concentrations. There was, however, a significant increase in HDL cholesterol. Interestingly, administration of the highest dose (2% w/w) of extract was able to significantly increase both LDL receptor binding activity and the relative amounts of LDL receptor protein. There were also significant reductions in liver total and unesterified cholesterol concentrations. In accordance with previous studies, there was a significant reduction in the intrinsic capacity to absorb cholesterol. Despite no effect on plasma cholesterol concentrations, the crude catechin extract used in this study upregulated the LDL receptor. This appears to be via a reduction in liver cholesterol concentrations, suggesting that the crude catechin extract increases the efflux of cholesterol from liver cells.

Upregulation of the LDL receptor is triggered when there is a reduction in intracellular cholesterol concentrations [1]. Administration of the crude catechin extract

**Fig. 2** Green tea extract lowers liver cholesterol. Twenty-four Sprague Dawley rats were divided into four treatment groups of six rats each. The different treatment groups were fed a crude catechin extract for 12 days at concentrations of either 0, 0.5, 1.0, 2.0% (w/w) mixed in with normal rat chow and 0.25% cholesterol. Total and unesterified cholesterol concentrations were measured on homogenised livers using enzymatic methods on the Cobas Bio. \* $p < 0.05$  (significant difference compared to the control)

lowered liver cholesterol and increased the hepatic LDL receptor. In particular there was a reduction in liver unesterified cholesterol which is thought to be the regulatory form of cholesterol [25]. These results are consistent with in vitro studies which found that incubation with green tea or ECGC increased the LDL receptor and decreased intracellular cholesterol concentrations in HepG2 cells [11, 12]. This work is also consistent with a recent study, which found that administration of a green tea extract to rabbits increased the hepatic LDL receptor and lowered intracellular liver cholesterol [16].

Liver cellular cholesterol concentration can be lowered by three main mechanisms: (1) a decrease in cholesterol entry to the cell, (2) an increase in the packaging of cholesterol into lipoproteins and secretion or, (3) an increase in bile acid production. The first mechanism is unlikely as there should have been an increase in cholesterol entry into the cell due to the increase in the LDL receptor. The third mechanism is possible. However, if bile acid production and excretion had increased, it would have been expected that the plasma cholesterol concentration would have subsequently decreased. As there was no change in plasma cholesterol concentrations it would seem that an increase in packaging of cholesterol into lipoproteins and secretion from the liver cells is most likely. So despite the increased entry of cholesterol into the cell via the upregulation of the LDL receptor, plasma cholesterol levels may not have been lowered due to the increased secretion of cholesterol back into the circulation. This apparent increase in LDL recycling

may be a beneficial effect of the crude catechin extract as the LDL particle would be in the circulation for less time, thus reducing its chances of being oxidised. Oxidised LDL has been found to be pro-atherogenic [26, 27].

An increase in cholesterol efflux from the liver cells is also consistent with *in vitro* HepG2 cell studies [11, 12]. Incubation with green tea and EGCG appeared to increase cholesterol efflux from the cells as cholesterol concentration in the cell media was significantly increased.

Administration of the crude catechin extract increased HDL cholesterol concentration. This increase in HDL concentration may have offset any potential reduction in plasma total cholesterol concentration. However, an increase in HDL cholesterol could potentially be an athero-protective effect of the crude catechin extract. The HDL is involved in a process called reverse cholesterol transport where it transfers cholesterol from the tissues and arteries and transports it back to the liver for processing [28]. Large clinical trials have also found that there is a strong inverse correlation between heart disease and plasma HDL concentrations [29, 30]. The mechanism for the increase in HDL cholesterol by the green tea extract is not known. It is possible that the crude catechin extract is able to upregulate the factors involved in the transfer of cholesterol from cells to HDL. The results from this study suggest that there is an increased efflux of cholesterol from liver cells. It is therefore likely that the crude catechin extract may have this effect in other cells, for example, in the tissues and arteries. This is supported in a recently published study [16] that found administration of a green tea extract to rabbits decreased cholesterol concentrations in the thoracic aorta. In this study, however, plasma cholesterol concentrations were significantly reduced which would also contribute to a lowering of cholesterol in the thoracic aorta.

Consistent with previous studies the crude catechin extract significantly reduced the intrinsic capacity of cholesterol to be absorbed. This was measured by the plasma ratio of phytosterols to cholesterol. Other studies have found that faecal excretion of total lipids and cholesterol were higher in animals consuming green tea extracts [6, 7, 9] and EGCG has been observed to inhibit the uptake of  $^{14}\text{C}$ -cholesterol from the intestine [14]. This apparent reduction in intestinal cholesterol absorption has been ascribed to EGCG reducing the solubility of cholesterol into mixed bile salt micelles [15]. It has also been found that hamsters and rats fed green tea extracts had increased faecal excretion of bile acids [9, 10]. Despite the reduction in cholesterol absorption, there was no reduction in plasma cholesterol concentrations. A reduction in plasma cholesterol concentration may have been expected as less cholesterol was entering the circulation. The reduction in cholesterol absorption is consistent, however, with the reduction in liver cholesterol concentrations and reinforces

that the crude catechin extract was increasing the efflux of cholesterol from the liver cells.

In contrast to previous studies, we did not find a hypo-cholesterolaemic effect with green tea. This indicates that the crude catechin extract used in this study, for this time period, must affect lipid metabolism differently in rats than observed in other studies. Previous studies have found that green tea extracts fed to rats, mice, hamsters and rabbits have significantly lowered plasma cholesterol concentrations [6–10]. It is possible that the 12 days dietary intervention was not sufficient as other studies tended to be longer (4–8 weeks). It may also be due to the particular strain of rats used in the present study having a different response [31].

The green tea extract used in this study contained 10% caffeine. There is evidence in the literature that unfiltered coffee has cholesterol-raising effects. This is thought to be due to components called diterpenes [32]. However, the effects of caffeine alone, as present in the green tea extract, are inconclusive [32]. It has been found, however, that caffeine can inhibit cholesterol absorption [33]. It is possible, therefore that caffeine had a minor effect on cholesterol absorption in this study. Catechins, particularly EGCG are also known to inhibit cholesterol absorption [6, 7, 9, 14], consistent the current study.

There is certainly no evidence that caffeine has an effect on the LDL receptor. In addition to this, previous studies by our group have found that purified, commercially purchased, catechins upregulate the LDL receptor [12]. This would suggest that it is the catechin constituents in the green tea extract and not the caffeine that are upregulating the LDL receptor in rats.

In conclusion, administration of a crude catechin extract from green tea upregulated the hepatic LDL receptor in the rats. This appeared to be due to an increase in the efflux of cholesterol from the liver cells into the circulation, as there was a decrease in liver intracellular cholesterol and no change in plasma cholesterol.

**Abstract** Cigarette smoke (CS) contains thousands of substances, mainly free radicals that have as a target the polyunsaturated fatty acids (PUFA). Long chain PUFA are produced through elongation and desaturation reactions from their precursors; the desaturation reactions are catalyzed by different enzymes: the conversion of 18:2n-6 (linoleic acid, LA) to 18:3n-6 by  $\Delta 6$  desaturase, while that of 20:3n-6 to 20:4n-6 by  $\Delta 5$  desaturase. The aim of this work is to evaluate the effect of serum exposed to cigarette smoke (SE-FBS) on (1) cell viability and proliferation, (2) [1- $^{14}$ C] LA conversion and desaturase activities in THP-1 cells, a monocytic cell line. In THP-1, CS inhibits cell proliferation dose-dependently, by producing a modification in the cell cycle with a reduced number of cells in synthesis and mitosis phases at higher concentrations. CS also decreases [1- $^{14}$ C] LA conversion to its derivatives in a concentration-dependent manner, inhibiting the activities of  $\Delta 6$  and mainly  $\Delta 5$  desaturase. In addition, CS does not modify the incorporation of LA into various lipid classes but it reduces cholesterol synthesis from radiolabelled acetate, and increases free fatty acid, TG and CE levels. In conclusion, CS affects lipid metabolism, inhibiting LA conversion and desaturase activities. CS also shifts the “de novo” lipid synthesis from free cholesterol to TG and CE, where LA is preferentially esterified.

**Keywords** Polyunsaturated fatty acids · Linoleic acid · Cholesterol · Human desaturases · Cigarette smoke

### Introduction

Cigarette smoke (CS) contains an extremely high number of products of various chemical nature, in both gas and tar phases, mainly free radicals ( $10^{15}$  free radicals/g of tar phase) [1], and it indirectly increases the production of reactive oxygen species, by activation of inflammatory cells [2]. Chronic cigarette smoke exposure is therefore associated with oxidative stress due to the increased free radical burden, followed by alteration of various oxidative stress indexes [3]. When free radicals are produced in excess or they are not efficiently removed, cellular damage (peroxidation of membrane lipids or oxidation of proteins and damage to DNA) occurs [4]. Lipids are among the compounds susceptible to free radical mediated alterations, and more specifically the polyunsaturated fatty acids (PUFA) are major targets of peroxidative processes and sources of lipid-derived radicals [4].

PUFA, especially the long chain PUFA (LC-PUFA) are endowed with biologically “essential” features, due to their basic contribution to membrane structures and cell functions. In addition, while the levels of the LC-PUFA of the n-3 series, e.g., docosahexaenoic acid (22:6n-3, DHA), in cells and tissues are largely dependent upon dietary intakes, PUFA of the n-6 series, i.e., arachidonic acid (20:4n-6, AA), is produced to a significant extent, by the endogenous conversion of linoleic acid (18:2n-6, LA), a relevant component of dietary fats. The conversion of LA and alpha linolenic acid (18:3n-3,  $\alpha$ -LNA) to their longer chain derivatives in both the n-6 and the n-3 pathways proceed through elongation and especially desaturation reactions. These are catalyzed by different enzymes, namely the  $\Delta 6$  desaturase on 18C and 24C, and the  $\Delta 5$  desaturase on 20C fatty acids.

The activity of human desaturases ( $\Delta 9$ ,  $\Delta 6$  and  $\Delta 5$ ) is modulated by different factors: it is inhibited by the meta-

e-mail: patrizia.rise@unimi.it

bolic products of desaturases [5] and by cholesterol rich diets [6]. In addition, the activity of  $\Delta 6$  desaturase is enhanced by low EFA intake, while diets rich in LA and in  $\alpha$ -LNA inhibit both  $\Delta 5$  and  $\Delta 6$  desaturase activities [6, 7]. These enzymes are also modulated by hormones (activated by insulin and reduced by adrenalin, glucagon, and steroids) [8] and by different classes of xenobiotics: peroxisome proliferators [9], calcium antagonists and some phenolic compounds [10], oxysterols [11], and statins [12, 13].

In addition, various studies have shown the effects of toxic compounds, i.e., CS on PUFA metabolism and/or their levels. In vitro CS negatively affects, in a concentration-dependent manner, LC-PUFA production. In mammary gland cells there is a decrease of DHA and EPA levels from  $\alpha$ -LNA, and of the 20:5/20:4n-3 ratio [14, 15].

In-vivo levels of LC-PUFA of the n-3 series, namely DHA, together with those of AA, were shown to be reduced, in milk from smoking- in comparison to non-smoking-mothers [16]; in addition, DHA is reduced in blood lipids of infants born to smoking mothers [17]. Finally CS decreases the 20:4/20:3n-6 ratio in plasma of subjects who smoke [18].

The rather limited data on the detailed effects of CS on n-6 PUFA metabolism indicate that this is an area that needs to be explored, especially since n-6 FA are certainly the major PUFA components of our diets in the form of LA, and also because the endogenous pools of AA, a key FA in the modulation of several functions in various cell types, appear to be largely dependent on its formation from LA [19]. In fact, LA and AA, in the body, are incorporated in different lipids (triglycerides, cholesterol esters and phospholipids).

On the basis of the above considerations, the purpose of this work was to evaluate the cell viability and proliferation after exposure to CS, and to study the detailed effects of CS exposed serum on labelled LA conversion and on desaturase activities. Finally, the effects of CS exposed serum on the synthesis of cholesterol from labelled acetate were also assessed. All these parameters were evaluated in THP-1 cells, a monocytic cell line that effectively is able to convert LA to its longer derivatives, while incorporating the labelled FAs mainly in the PL fraction [12]. This last feature will facilitate the detection of alterations in the fate of n-6 FA incorporation into different lipid pools following cell exposure to CS.

## Materials and Methods

### Materials and Reagents

The materials for cell cultures (RPMI 1640 medium, fetal bovine serum (FBS), penicillin, and streptomycin) were from Sigma (Sigma Aldrich S.r.l., Milan, Italy). Solvents

and TLC (thin layer chromatography) plates were from E. Merck (Darmstadt, Germany). The radiolabelled compounds [ $1\text{-}^{14}\text{C}$ ] LA (specific activity 55 mCi/mmol), [ $1\text{-}^{14}\text{C}$ ] acetic acid sodium salt (specific activity 58 mCi/mmol), and [ $6\text{-}^3\text{H}$ ] thymidine (specific activity 27 Ci/mmol), were from Amersham (Amersham Pharmacia Biotech, Little Chalfont, England). Simvastatin in lactone form (Merck, Sharp & Dohme Research Laboratories, Woolbridge, NJ) was dissolved in 0.1 M NaOH to give the active, open  $\beta$ -hydroxy acid form.

### Cell Culture

THP-1 cells, a human monocytic cell line [20], were grown in RPMI medium containing 10% FBS, 100  $\mu\text{g}/\text{ml}$  penicillin, 100 IU/ml streptomycin, and 2 mM l-glutamine.

### Smoking Machine

To expose cells to CS, a popular brand of Italian cigarettes was used, MS with filter. A device was developed to allow a controlled incorporation of CS, in appropriate and reproducible conditions, into the FBS, through aspiration by a pump under controlled vacuum, to obtain smoke exposed FBS (SE-FBS) [15, 21]. Specifically, smoke from two cigarettes was bubbled through 5 ml FBS for 5 min at 8 puffs/min. 100  $\mu\text{l}$  of SE-FBS correspond to 0.04 cigarettes (4% of one cigarette).

### Experimental Design

At the time of the experiments, cells were centrifuged at  $200\times g$  for 10 min, and the pellet obtained was resuspended in RPMI medium without FBS; the concentration of the cells was adjusted to  $10^6$  cells/ml. Cells were then incubated with different aliquots of SE-FBS (12.5–25–37.5–50  $\mu\text{l}$  corresponding to 0.005–0.01–0.015–0.02 cigarettes). At 24 h the appropriate labelled substrate ([ $1\text{-}^{14}\text{C}$ ] LA 0.1  $\mu\text{Ci}/10^6$  cells or [ $1\text{-}^{14}\text{C}$ ] acetic acid sodium salt 1  $\mu\text{Ci}/10^6$  cells) was also added for the additional 24 h. At the end of the incubation (48 h), cells were centrifuged, resuspended in a given volume of PBS, 50  $\mu\text{l}$  of which were counted with a cell counter, and the total lipids extracted according to Folch et al. [22]. Aliquots of total lipid extracts were counted in a  $\beta$ -counter in order to determine the radioactivity recovered in the samples.

### Time Course

Cells were incubated with different amounts of SE-FBS (25 and 50  $\mu\text{l}$  corresponding to 0.01 and 0.02 cigarettes respectively) for different time periods (4–8–16–24–48 h). [ $1\text{-}^{14}\text{C}$ ] LA (0.1  $\mu\text{Ci}/10^6$  cells) was added at the start of the

experiment for the 4–8–16 and 24 h, and after 24 h of incubation for the 48 h.

#### Polyphenol Assay

To standardize the procedure of SE-FBS preparation, the levels of polyphenols, after their extraction from SE-FBS [23], were measured as described by Visioli et al. [24]. Briefly, 50  $\mu\text{l}$  of folin and ciocalteu's phenol reagent (Sigma Aldrich S.r.l.) were added to increasing amounts of SE-FBS. After 3 min of incubation, 100  $\mu\text{l}$  saturated  $\text{Na}_2\text{CO}_3$  and distilled water were added to each sample (final volume 2.5 ml). Samples were analyzed spectrophotometrically at 725 nm after 1 h of incubation in the dark at room temperature.

#### TBARS Assay

TBARS levels, markers of the lipid peroxide production, were evaluated as described by Balla et al. [25]. Briefly, 400  $\mu\text{l}$  of total lipids, for each sample, were added to 600  $\mu\text{l}$  thiobarbituric acid reagent. After heating at 100 °C for 15 min, the samples were cooled at room temperature and were centrifuged at 10,000 $\times g$  for 10 min. The clear supernatants were analyzed spectrophotometrically at 532 nm.

#### Cell Proliferation

Cell proliferation was evaluated by the incorporation of [6- $^3\text{H}$ ] thymidine (1  $\mu\text{Ci}/10^6$  cells) into nucleic acids, after exposure to different amounts of SE-FBS (25–50–75–100  $\mu\text{l}$  corresponding to 0.01–0.02–0.03–0.04 cigarettes). At the end of the experiment aliquots of cell suspensions were counted in a  $\beta$ -counter in order to determine the radioactivity recovered in the samples.

#### Evaluation of Apoptosis

The percentage of apoptotic cells was evaluated as described by Abbracchio et al. [26]. Briefly, after exposure to SE-FBS, cells were centrifuged at 200 $\times g$  for 10 min and the pellet obtained was gently resuspended in 1 ml hypotonic fluorochrome solution (propidium iodide, PI 50  $\mu\text{g}/\text{ml}$  in 0.1% sodium citrate plus 0.1% Triton X-100; Sigma). Cells were analyzed after a minimum of 30 min of incubation in the dark at room temperature, and apoptosis was detected in individual cells using a flow cytometer (equipped with a single 488 nm argon laser; Becton Dickinson, San Josè, CA) by reduced fluorescence of PI in apoptotic nuclei.

#### Analysis of Labelled Fatty Acids by HPLC

LC-PUFA production from the precursor [1- $^{14}\text{C}$ ] LA was evaluated as radioactivity associated with different fatty

acid methyl esters and assessed by HPLC coupled with an on-line radiodetector (Flow Scintillation Analyzer 500TR Series, PerkinElmer), as previously described [12].

#### Separation of Lipid Classes

The incorporation of [1- $^{14}\text{C}$ ] LA and [1- $^{14}\text{C}$ ] acetic acid sodium salt in the various lipid classes (phospholipids PL, diglycerides DAG, free fatty acids FFA, triglycerides TG, and cholesterol esters CE) was evaluated after separation by a monodimensional thin layer chromatography (TLC, hexane/diethylether/acetic acid 70/30/1.5 by vol). To detect free cholesterol (Cho) and monoglycerides (MG) a different solvent system was used (chloroform/methanol 98/2 by vol). Lipids were visualized on plates by exposure to iodine vapours; spots were scraped off and the radioactivity was detected, after addition of 1 ml methanol/water (1:1 by vol) and 10 ml of scintillation fluid, in a  $\beta$ -counter.

#### Statistical Analysis

Significance of differences, when comparing control and treated cells, was assessed by the use of Student's *t*-test.

## Results

#### Standardization of the Method for the Preparation of SE-FBS

To validate the procedure for the preparation of SE-FBS, the levels of polyphenols, transferred from CS to serum, are evaluated. In fact, in control conditions (FBS not exposed to CS), polyphenols are detectable only in traces, whereas, when 5 ml FBS is exposed to one or two cigarettes (Fig. 1), there is a significant increase, with respect to control, of polyphenol levels of about  $46 \pm 1\%$  and  $89 \pm 4\%$ , respectively. There is a dose related accumulation of polyphenols, since their levels in the two cigarettes SE-FBS are double than those in the one cigarette SE-FBS, with a 1.99 ratio.

TBARS levels, a marker of oxidation, are also determined; a positive correlation between increasing amounts (corresponding to 200–300–400–500  $\mu\text{g}$  of total lipids) of SE-FBS and TBARS levels is found ( $R^2 = 0.997$ ) (Fig. 2).

#### Cell Viability and Proliferation

To evaluate the effects of CS on cell viability and proliferation, two different methods are used. As shown in Fig. 3, the incorporation of [6- $^3\text{H}$ ] thymidine in THP-1 cells, treated with different concentration of SE-FBS, decreases

**Fig. 1** Polyphenol levels in serum not exposed or in serum (5 ml) exposed to one or two cigarettes. The results are expressed as mg of polyphenols for ml of serum and represent means  $\pm$  SE of three independent experiments. Differences are significantly different from FBS at \*  $p \leq 0.001$

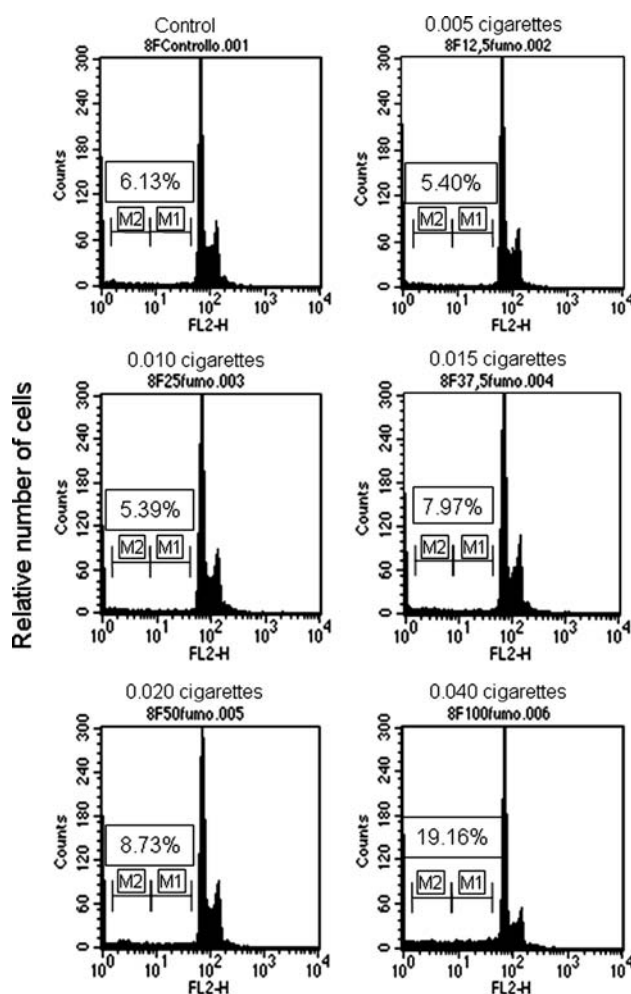

**Fig. 2** TBARS levels in increasing amounts of serum (from 120 to 300  $\mu$ l, corresponding to a range of 200–500  $\mu$ g of total lipids) exposed to cigarette smoke, prepared bubbling two cigarettes in 5 ml of FBS. Results are expressed as absorbance at 532 nm

**Fig. 3** [<sup>3</sup>H] thymidine incorporation in THP-1 cells after treatment with serum exposed to cigarette smoke (0.01–0.02–0.03–0.04 cigarettes). The results are expressed as cpm of [<sup>3</sup>H] thymidine  $\times$  1,000 for 10<sup>6</sup> cells and represent mean  $\pm$  SE of three independent experiments. Differences are significantly different from control at \*  $p \leq 0.001$ ; \*\*  $p \leq 0.005$ ; \*\*\*  $p \leq 0.05$

in a dose-dependent manner, with a significant reduction already at the lowest concentration of SE-FBS (0.01 cigarettes) used, from  $283.27 \pm 21.50$  to  $217.78 \pm 18.91$  cpm  $\times$  1,000/10<sup>6</sup> cells ( $-23\%$  with respect to control). At the highest concentration used (0.04 cigarettes) there is a decrease of 80% with respect to control. Figure 4 shows a representative experiment in which the apoptotic and necrotic processes are detected: there is a significant increase of apoptosis and necrosis (M<sub>1</sub> and M<sub>2</sub> segments, respectively) only at the highest concentrations used, from 6.13% in control cells to 8.73 and 19.16% with 0.020 and 0.040 cigarettes, respectively. In addition, when the same data are analyzed in a linear scale, there is a decrease of the number of cells in synthesis (S phase) and mitosis (G<sub>2</sub>–M phase) at the highest concentration used (0.04 cigarettes), of about 40% with respect to control (not shown).

**Fig. 4** Detection of apoptotic (M<sub>1</sub>) and necrotic (M<sub>2</sub>) processes in THP-1 cells treated with serum exposed to cigarette smoke (0.005–0.010–0.015–0.020–0.040 cigarettes) for 48 h. The results are expressed as relative number of cells. The percentages represent the apoptotic plus necrotic processes of a representative experiment

## LA Conversion

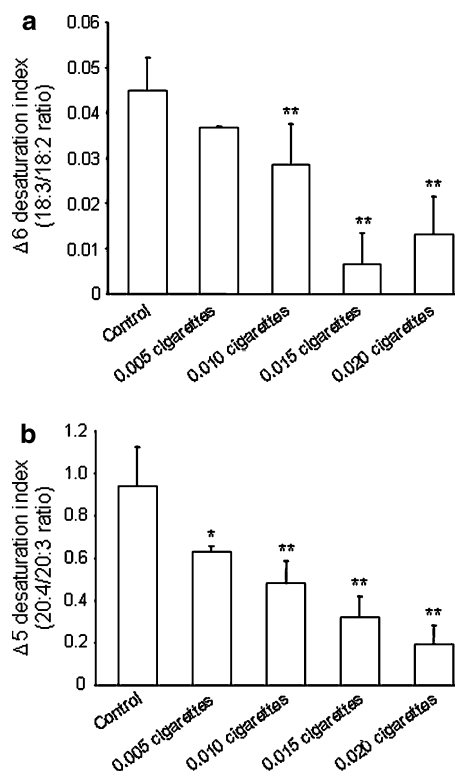

The total conversion of [ $^{14}\text{C}$ ] LA (calculated as the sum of the percentages of the radioactivity associated to its derivatives, 18:3, 20:3, 20:4 and 22:4n-6) is  $47.56 \pm 1.66\%$  in control cells. After treatment with CS, LA total conversion decreases in a dose-dependent manner and the reduction is already significant ( $-28\%$  with respect to control) with 0.01 cigarettes. At the highest SE-FBS concentration, the LA total conversion is reduced to  $22.54 \pm 2.43\%$  (Fig. 5).

With increasing concentrations of SE-FBS, the activities of both  $\Delta 5$  and  $\Delta 6$  desaturases (expressed as product/precursor ratios) decrease in a dose-dependent manner, although the effect is more pronounced on the  $\Delta 5$  desaturase, as shown in Fig. 6.  $\Delta 6$  desaturation, expressed as the 18:3/18:2n-6 ratio, is significantly decreased, from  $0.045 \pm 0.002$  in control cells to  $0.029 \pm 0.003$  and  $0.013 \pm 0.003$  with 0.01 and 0.02 cigarettes respectively (Fig. 6, panel A).  $\Delta 5$  desaturation (20:4/20:3n-6 ratio) significantly decreases already with the lowest SE-FBS concentration used (0.005 cigarettes), from  $0.94 \pm 0.06$  in control cells to  $0.63 \pm 0.04$ ; with the highest concentration of SE-FBS  $\Delta 5$  desaturation decreases to  $0.19 \pm 0.03$  (Fig. 6, panel B).

Table 1 shows the radioactivity associated to the LA metabolites. There is a significant reduction of 18:3, 20:4 and 22:4n-6 starting from 0.010 cigarettes. The percentage of 18:3 decreases from  $2.51 \pm 0.15\%$  in control cells to  $0.86 \pm 0.15\%$  at the highest concentration used (0.020 cigarettes). For 20:4 there is a reduction from  $17.79 \pm 2.01\%$  in controls to  $2.50 \pm 0.58\%$  with 0.020 cigarettes, and for 22:4 from  $1.55 \pm 0.33\%$  to  $0.19 \pm 0.09\%$ .

**Fig. 5** [ $^{14}\text{C}$ ] linoleic acid (LA) total conversion in THP-1 cells treated with serum exposed to cigarette smoke (0.005–0.010–0.015–0.020 cigarettes) for 48 h. The results are expressed as percentage of total LA conversion (calculated as the sum of the percentages of the radioactivity associated to its derivatives, 18:3, 20:3, 20:4 and 22:4n-6) and represent mean  $\pm$  SE of seven independent experiments. Differences are significantly different from control at \*  $p < 0.001$

**Fig. 6**  $\Delta 5$  and  $\Delta 6$  desaturation indexes in THP-1 cells treated with serum exposed to cigarette smoke (0.005–0.010–0.015–0.020 cigarettes) for 48 h. The results are expressed as product/precursor ratio (20:4/20:3 ratio for  $\Delta 5$  desaturase and 18:3/18:2 ratio for  $\Delta 6$  desaturase) and represent the mean  $\pm$  SE of seven independent experiments. Differences are significantly different from control at \*  $p < 0.05$ ; \*\*  $p < 0.001$

The relative percentage of the radioactivity associated to different lipid classes, after [ $^{14}\text{C}$ ] LA incubation, is not affected by SE-FBS, with about 75% of radioactivity recovered in PL and 20% in TG (Table 2).

## Time Course

The total conversion of [ $^{14}\text{C}$ ] LA increases, in control cells, from  $21.66 \pm 3.83\%$  at 4 h to  $45.75 \pm 0.90\%$  at 48 h (Fig. 7). LA conversion increases also in SE-FBS treated cells over time: from  $15.15 \pm 0.87\%$  at 4 h to  $33.20 \pm 4.48\%$  at 48 h with 0.01 cigarettes, and from  $12.93 \pm 0.04\%$  at 4 h to  $20.96 \pm 7.40\%$  at 48 h with 0.02 cigarettes. Otherwise the percentages of conversion with 0.02 cigarettes are lower than those of controls and of samples exposed to 0.01 cigarettes, at any time considered.

## Cholesterol Synthesis

SE-FBS significantly decreases the incorporation of radiolabelled acetate in free cholesterol (Table 3), from

**Table 1** Relative percentage of the radioactivity associated to linoleic acid metabolites, in THP-1 cells treated with increasing concentrations of serum exposed to cigarette smoke, after [1-<sup>14</sup>C] linoleic acid incubation

	Control	0.005 C	0.01 C	0.015 C	0.02 C

## Discussion

In order to expose THP-1 cells to CS the method of Bernhard et al. [21], modified by Marangoni et al. [15], was used. This method allows one to prepare an FBS containing the CS constituents similar in concentration and distribution to the in vivo situation [21]. The procedure was also standardized in our laboratory measuring the concentration of phenol derivatives and peroxidation products, that have been reported in CS [27], in relation to the number of cigarettes used.

In our experimental model, CS has a dose-dependent effect on the inhibition of cell proliferation: CS modifies the cell cycle with a significant reduction of the number of cells in synthesis and mitosis phases only at the concentration of 0.04 cigarettes. For this reason we have used (as the highest) the concentration of 0.02 cigarettes to evaluate the effects on LA conversion and on desaturation steps; at this concentration in fact, cell proliferation is inhibited, but apoptotic and necrotic processes are not observed.

CS inhibits the total conversion of LA (calculated as the sum of the percentages of the radioactivity associated to its derivatives, 18:3, 20:3, 20:4 and 22:4n–6) to its derivatives in a concentration-dependent manner; both  $\Delta 5$  and  $\Delta 6$  desaturations are also decreased. The inhibition of LA conversion by CS occurs starting from 4 h when the highest concentration is used, whereas the use of 0.01 cigarette inhibits LA conversion starting from 24 h of incubation. Our data are in accordance with those of Marangoni et al. [15] who have investigated the effects of CS on the n–3 FA pathway and reported that the incubation of mammary gland cells with SE-FBS determined a significant reduction of DHA production from  $\alpha$ -LNA and also a decrease of the 20:5/20:4n–3 ratio (an index of  $\Delta 5$  desaturase activity), in a dose-dependent manner [14, 15].

In addition, the decreased LA conversion and AA production that we have reported could explain the inhibition or reduction of eicosanoid synthesis observed both in vitro and in vivo in certain studies [28, 29].

In vivo studies concerning the effects of CS on PUFA metabolism are scarce. Pawlosky et al. [18] have evaluated the metabolism of deuterated LA in smoking and non-smoking subjects: in smokers there was a decrease (–37%) of the 20:3n–6 conversion to 20:4, with a reduction in the  $\Delta 5$  desaturation. Simon et al. [30] have also found a positive correlation between smoking and the levels of 20:3n–6 in PL, and negative correlations between smoking and arachidonic acid levels in PL and CE. It would appear therefore that in smokers the  $\Delta 5$  desaturation step is mainly affected in vivo but in vitro also the  $\Delta 6$  desaturation step is reduced.

$\Delta 5$  and  $\Delta 6$  desaturases are microsomal enzymes; they contain a N-terminal domain that is orthologous to the microsomal cytochrome *b*<sub>5</sub> [31], and it has been proposed that the cytochrome *b*<sub>5</sub> domain allows cytochrome *b*<sub>5</sub> reductase to transfer electrons to the catalytic domain of the desaturase and thereby eliminate the need for cytochrome *b*<sub>5</sub> protein per se [32]. It has been demonstrated that the content of cytochrome *b*<sub>5</sub> and the activity of its reductase were significantly reduced in animal (ferrets and mice) liver microsomes after exposure to tobacco smoke [33, 34]. This can explain the reduction of both  $\Delta 5$  and  $\Delta 6$  desaturations and consequently the decreased conversion of LA to its long chain derivatives, after CS exposure.

Our results show also that the relative percentage of the radioactivity associated to different lipid classes, after [1-<sup>14</sup>C] LA incubation, after exposure to different CS concentrations, is not significantly modified. This is somewhat predictable, since in THP–1 cells, at difference from hepatocytes, mainly characterized by metabolic functions, the endogenous FA pool is typically structural, and therefore accumulation of FA in storage lipids represents a minor pathway possibly less affected by CS [35].

Furthermore, CS increases significantly the FFA, and also TG and CE levels, while concomitantly reducing the conversion of acetate to cholesterol, in THP–1 cells. This is in accordance with the in vivo studies that have shown higher TG levels in plasma of smokers when compared to non-smokers [36, 37]. In addition, Maehira et al. [38] demonstrated a decreased activity of rat aortic cholesteryl ester hydrolases with a consequent increase in the CE content, after CS exposure. A shift of biosynthetic processes from acetate, in particular from the new cholesterol synthesis to the production of FFA and their final incorporation in TG and CE could be hypothesized.

Concerning the CS components responsible for the inhibition of LC-PUFA metabolism, Marangoni et al. [15] have found that cigarette smoke itself, and serum or buffer exposed to CS, contain mainly acetaldehyde, nicotine, limonene and phenol derivatives (2-methyl-phenol, 4-methyl-phenol and 2-methoxy-phenol) as typical components, and therefore the treatment of cells with a CS exposed serum reflects the effect of CS that occurs in smoking subjects. We have found that nicotine alone does not affect the LA metabolism (data not shown), which, therefore, appear to be affected by other CS components.

In conclusion, in THP–1 cells, CS inhibits the conversion of LA, the major PUFA in our diets, and the 18:3/18:2n–6 and 20:4/20:3n–6 product/precursor ratios, as an index of modified  $\Delta 6$  and  $\Delta 5$  activities. This is not directly related to a major cellular damage induced by CS at the concentration used (i.e., inhibition of cell viability and proliferation), as shown by our data. Therefore we hypothesize that the effect of CS on LA conversion is due to an inhibition of the desaturases possibly related to changes in their expression, a task for future studies.

**Abstract** The aim of this study was to clarify the contribution of cytochrome P450 (CYP)-dependent metabolism of vitamin E isoforms to their tissue concentrations. We studied the effect of ketoconazole, a potent inhibitor of CYP-dependent vitamin E metabolism in cultured cells, on vitamin E concentration in rats. Vitamin E-deficient rats fed a vitamin E-free diet for 4 weeks were administered by oral gavage a vitamin E-free emulsion, an emulsion containing  $\alpha$ -tocopherol,  $\gamma$ -tocopherol or a tocotrienol mixture with or without ketoconazole.  $\alpha$ -Tocopherol was detected in the serum and various tissues of the vitamin E-deficient rats, but  $\gamma$ -tocopherol,  $\alpha$ - and  $\gamma$ -tocotrienol were not detected. Ketoconazole decreased urinary excretion of 2,5,7,8-tetramethyl-2(2'-carboxyethyl)-6-hydroxychroman after  $\alpha$ -tocopherol or a tocotrienol mixture administration, and that of 2,7,8-trimethyl-2(2'-carboxyethyl)-6-hydroxychroman ( $\gamma$ -CEHC) after  $\gamma$ -tocopherol or a tocotrienol mixture administration. The  $\gamma$ -tocopherol,  $\alpha$ - and  $\gamma$ -tocotrienol concentrations in the serum and various tissues at 24 h after their administration were elevated by ketoconazole, while the  $\alpha$ -tocopherol concentration was not affected. The  $\gamma$ -tocopherol or  $\gamma$ -tocotrienol concentration in the jejunum at 3 h after each administration was also elevated by ketoconazole. In addition, significant amount of  $\gamma$ -CEHC was in the jejunum at 3 h after  $\gamma$ -tocopherol or

$\gamma$ -tocotrienol administration, and ketoconazole inhibited  $\gamma$ -tocopherol metabolism to  $\gamma$ -CEHC in the jejunum. These results showed that CYP-dependent metabolism of  $\gamma$ -tocopherol and tocotrienol is a critical determinant of their concentrations in the serum and tissues. The data also suggest that some amount of dietary vitamin E isoform is metabolized by a CYP-mediated pathway in the intestine during absorption.

**Keywords** Cytochrome P450 · Ketoconazole · Rats · Tocopherol · Tocotrienol · Vitamin E

## Abbreviations

$\alpha$ -CEHC	2,5,7,8-Tetramethyl-2(2'-carboxyethyl)-6-hydroxychroman
$\gamma$ -CEHC	2,7,8-Trimethyl-2(2'-carboxyethyl)-6-hydroxychroman
CYP	Cytochrome P450
$\alpha$ -TTP	$\alpha$ -Tocopherol transfer protein

## Introduction

Vitamin E is a potent fat-soluble antioxidant that inhibits lipid peroxidation in biological membranes. In nature, compounds with vitamin E activity are  $\alpha$ -,  $\beta$ -,  $\gamma$ - or  $\delta$ -tocopherol and  $\alpha$ -,  $\beta$ -,  $\gamma$ - or  $\delta$ -tocotrienol. Dietary vitamin E isoforms are absorbed in the intestine and secreted with triacylglycerol-rich chylomicron into lymph and blood [1, 2]. After lipolysis of chylomicron triacylglycerol by lipoprotein lipase, vitamin E isoforms are transported to the liver [3].  $\alpha$ -Tocopherol transfer protein ( $\alpha$ -TTP) in the liver catalyzes  $\alpha$ -tocopherol secretion by a non-Golgi-mediated

pathway, and  $\alpha$ -tocopherol is incorporated into VLDL and subsequently transported to the various tissues by lipoproteins [4, 5]. The other isoforms of vitamin E such as  $\gamma$ -tocopherol and tocotrienol are metabolized and excreted because their affinity for  $\alpha$ -TTP is much lower than that of  $\alpha$ -tocopherol [6]. Therefore, the  $\gamma$ -tocopherol and tocotrienol levels in the serum and tissues are extremely low. The importance of  $\alpha$ -TTP for the vitamin E distribution is also shown by the extremely low level of  $\alpha$ -tocopherol in plasma of the patients who have ataxia with vitamin E deficiency due to mutations in the  $\alpha$ -TTP gene [7] and in plasma and various tissues of  $\alpha$ -TTP-knockout mice [8, 9].

Vitamin E isoforms are known to undergo metabolism to phytyl chain-shortened metabolites, such as 2,5,7,8-tetramethyl-2(2'-carboxyethyl)-6-hydroxychroman ( $\alpha$ -CEHC) and 2,7,8-trimethyl-2(2'-carboxyethyl)-6-hydroxychroman ( $\gamma$ -CEHC), excreted into urine in human [10–12] and rats [13–15]. Pathway of the metabolism involves  $\omega$ -hydroxylation of phytyl chain and the following  $\beta$ -oxidation [16, 17], and the rate-limiting step is  $\omega$ -hydroxylation by cytochrome P450 (CYP) 4F [17, 18]. Ketoconazole, an imidazole antifungal agent, is known as a potent inhibitor of human CYP3A [19], and also inhibits the CYP4F-dependent vitamin E metabolism in cultured cells [20, 21]. Parker et al. [20] reported that ketoconazole inhibited the production of  $\gamma$ - and  $\delta$ -tocopherol metabolites in HepG2 cells, human hepatoblastoma, and that of  $\alpha$ - and  $\gamma$ -tocopherol metabolites in rat primary hepatocytes. You et al. [21] also reported that  $\delta$ -tocotrienol metabolite production was inhibited by ketoconazole in A549 cells, human lung epithelial cells. However, it is not known whether vitamin E metabolism affects tissue concentrations of vitamin E isoforms in vivo because their low affinity for  $\alpha$ -TTP is a critical role for their concentrations in the tissues. In this study, we examined the contribution of CYP-dependent metabolism of vitamin E isoforms to their concentrations in rat tissues using ketoconazole.

## Experimental Procedures

### Materials

RRR- $\alpha$ -Tocopherol, RRR- $\gamma$ -tocopherol and a tocotrienol mixture extracted from natural source were used for oral administration. The tocotrienol mixture composition was 339 mg/g  $\alpha$ -tocotrienol, 40 mg/g  $\beta$ -tocotrienol, 471 mg/g  $\gamma$ -tocotrienol, 110 mg/g  $\delta$ -tocotrienol and 1 mg/g RRR- $\delta$ -tocopherol.  $\alpha$ -,  $\beta$ - and  $\gamma$ -tocopherol were not detected in the mixture. Vitamin E,  $\alpha$ - and  $\gamma$ -CEHC were generously donated by Eisai Food and Chemical (Tokyo, Japan). Ketoconazole was purchased from Sigma (Tokyo, Japan). It was dissolved in ethanol and used for oral administration.

### Animals and Diets

Male Wistar rats (6 weeks old) were purchased from Japan SLC (Shizuoka, Japan) and maintained at 23 °C with a 12-h light cycle (lights on from 08:00 to 20:00 h). Before the start of the Experiments 1 and 2, rats were fed a vitamin E-free diet for 4 weeks to deplete tissue  $\alpha$ -tocopherol stores because it is difficult to be elevate the other isoform concentrations in  $\alpha$ -tocopherol-rich tissues. The composition of the vitamin E-free diet was as follows; 200 g casein/kg, 3 g L-cystine/kg, 35 g mineral mixture (AIN93-MX)/kg [22], 10 g vitamin mixture (vitamin E-free AIN93-VX)/kg [22], 2.5 g choline/kg, 70 g vitamin E-stripped corn oil/kg, 50 g cellulose powder/kg, 100 g sucrose/kg, 529.5 g corn starch/kg. This study was approved by the Laboratory Animal Care Committee of Nagoya University of Arts and Sciences, and all procedures were performed in accordance with the Animal Experimentation Guidelines of Nagoya University of Arts and Sciences.

### Experiment 1

Rats were administered an oral gavage of 1 ml of vitamin E-free emulsion (control group,  $n = 5$ ), vitamin E-free emulsion containing 50 mg ketoconazole/kg body weight (KCZ group,  $n = 5$ ), 10 mg of  $\alpha$ -tocopherol ( $\alpha$ T group,  $n = 5$ ), 10 mg of  $\alpha$ -tocopherol and 50 mg ketoconazole/kg body weight ( $\alpha$ T + KCZ group,  $n = 5$ ), 10 mg of  $\gamma$ -tocopherol ( $\gamma$ T group,  $n = 5$ ), 10 mg of  $\gamma$ -tocopherol and 50 mg ketoconazole/kg body weight ( $\gamma$ T + KCZ group,  $n = 7$ ), 29.5 mg of tocotrienol mixture (T3 group,  $n = 5$ ), or 29.5 mg of tocotrienol mixture and 50 mg ketoconazole/kg body weight (T3 + KCZ group,  $n = 5$ ). All the emulsions also contained 200 mg of sodium taurocholate and 200 mg of triolein. The rats had access to food until the oral administration and were deprived of food after the administration.

Twenty four hours after the oral administration, the rats were killed by decapitation, and the serum, liver, adrenal gland, spleen, lung, kidney, heart, thymus, soleus muscle, perirenal adipose tissue, epididymal fat, skin, brain and aorta were removed and stored at  $-80$  °C. The upper one-third section ( $\sim 25$  cm) of the small intestine between the stomach and cecum was taken and the upper 5 cm was cut off as the duodenum. The remaining section was sampled as jejunum and washed twice with 10 ml of saline using a syringe. The fluid was removed from jejunum with paper and stored at  $-80$  °C. For the last 12 h, the urine was collected in a test tube kept cool with dry ice as soon as the rats urinated on a plastic tray under each wire screen-bottomed cage. The urine was stored at  $-80$  °C under nitrogen until used for the determination of  $\alpha$ -CEHC and  $\gamma$ -CEHC concentrations.

## Experiment 2

Rats were administered an oral gavage of 1 ml of emulsion containing 10 mg of  $\alpha$ -tocopherol ( $\alpha$ T group,  $n = 18$ ), 10 mg of  $\alpha$ -tocopherol and 50 mg ketoconazole/kg body weight ( $\alpha$ T + KCZ group,  $n = 18$ ), 10 mg of  $\gamma$ -tocopherol ( $\gamma$ T group,  $n = 18$ ), 10 mg of  $\gamma$ -tocopherol and 50 mg ketoconazole/kg body weight ( $\gamma$ T + KCZ group,  $n = 18$ ), 29.5 mg of tocotrienol mixture (T3 group,  $n = 18$ ), or 29.5 mg of tocotrienol mixture and 50 mg ketoconazole/kg body wt (T3 + KCZ group,  $n = 18$ ). All emulsion also contained 200 mg of sodium taurocholate and 200 mg of triolein. The rats were deprived of food for 12 h until oral administration of the emulsion. At 0.5, 1 or 3 h after the oral administration, six rats of each group were anesthetized with diethyl ether, and the blood was drawn from the heart using a heparinized needle and syringe. The jejunum and liver were sampled and handled as described for Experiment 1.

## Experiment 3

Male Wistar rats (10 weeks old) were fed a commercial diet (CE-2, Clea Japan, Tokyo, Japan) for 5 days and deprived of food for the last 12 h. The rats were administered an oral gavage of 1 ml of emulsion containing 10 mg of  $\gamma$ -tocopherol ( $\gamma$ T group,  $n = 4$ ), 10 mg of  $\gamma$ -tocopherol and 50 mg ketoconazole/kg body weight ( $\gamma$ T + KCZ group,  $n = 4$ ), 29.5 mg of tocotrienol mixture (T3 group,  $n = 4$ ) or 29.5 mg of tocotrienol mixture and 50 mg ketoconazole/kg body wt (T3 + KCZ group,  $n = 4$ ). All emulsions also contained 200 mg of sodium taurocholate and 200 mg of triolein. At 3 h after each administration, the rats were anesthetized with diethyl ether, and the blood was drawn from the heart using a heparinized needle and syringe. The jejunum and liver were sampled and handled as described for Experiment 1.

## Vitamin E Concentration

Tissues were homogenized in distilled water. The tissue homogenate (0.5 ml) was put in a test tube, and 0.5 ml of ethanol containing 60 g/l pyrogallol and 0.45  $\mu$ g of 2,2,5,7,8-pentamethyl-6-chroman as an internal standard were added. Then, 0.1 ml of 600 g/l potassium hydroxide was added and saponified at 70 °C for 30 min. After the addition of 2.25 ml of 20 g/l sodium chloride, tocopherols and tocotrienols were extracted with 0.5 ml of hexane containing 10% (v/v) ethyl acetate. Serum (75  $\mu$ l) was put in a test tube, and 90 ng of 2,2,5,7,8-pentamethyl-6-chroman as an internal standard was added. After the addition of 0.5 ml of water and 1.0 ml of ethanol, vitamin E was extracted with 5 ml of hexane. Vitamin E concentration

was determined by HPLC [23]. The instrumentation used for HPLC was a Shimadzu LC-10AD (Shimadzu, Kyoto, Japan) with a Shimadzu RF-10AXL fluorescence detector (excitation 298 nm, emission 325 nm). The analytical column used was a Wakosil 5SIL (4.6  $\times$  250 mm, Wako Pure Chemical Industries, Osaka, Japan). The mobile phase was hexane containing 1% (v/v) dioxane and 0.2% (v/v) isopropyl alcohol with a flow rate of 1 ml/min.

## $\alpha$ - and $\gamma$ -CEHC Concentrations

Both conjugated and unconjugated  $\alpha$ - and  $\gamma$ -CEHC in the urine and jejunum were methylated and extracted by the method of Kiyose et al. [24], and the concentration was determined using HPLC with an electrochemical detector. One milliliter of the urine diluted with distilled water, or the jejunum homogenate with distilled water was added to 0.1 ml of 500 g/l ascorbic acid and 1 ml of 0.54 mmol/l EDTA. The sample was methylated in 3 mol/l methanolic hydrochloric acid at 60 °C for 1 h under nitrogen, and the methylated vitamin E metabolite was extracted with hexane. The hexane was evaporated by nitrogen, and the residue was dissolved in 200  $\mu$ l of 45% (v/v) acetonitrile containing 50 mmol/l sodium perchlorate; 10  $\mu$ l of this solution was subjected to HPLC. Instrumentation used for HPLC was a Shimadzu LC-10Ai with a Coulochem III electrochemical detector (MC Medical, Osaka, Japan) and an ODS-3 column (250 mm  $\times$  2.1 mm, GL Science, Tokyo, Japan). The mobile phase was 45% (v/v) acetonitrile containing 50 mmol/l sodium perchlorate, pH 3.6, and the flow rate was 0.2 ml/min. For coulometric detection, the analytical and guard cells were set to +0.4 and +0.45 V, respectively.

## Statistical Analysis

Data are presented as mean values  $\pm$  SEM,  $n = 5$  or 7 in Experiment 1,  $n = 6$  in Experiment 2, and  $n = 4$  in Experiment 3. They were analyzed by two-way ANOVA with Tukey's post-hoc test (Graph Pad Prism for Windows version 4.0, GraphPad Software Inc, CA, USA). When variances among groups were unequal, the data were logarithmically transformed before statistical analysis by two-way ANOVA. Differences were regarded as significant at  $P$ -value  $< 0.05$ .

## Results

### Experiment 1

Neither vitamin E ( $P \geq 0.05$ ) nor ketoconazole ( $P \geq 0.05$ ) administration affected the body and relative liver weights

(Table 1). Urinary excretion of  $\alpha$ -CEHC in the  $\alpha$ T + KCZ group was 5% ( $P < 0.05$ ) that in the  $\alpha$ T group. The  $\gamma$ -CEHC excretion in the  $\gamma$ T + KCZ was 17% ( $P < 0.05$ ) that in the  $\gamma$ T group. The  $\alpha$ - and  $\gamma$ -CEHC excretion in the T3 + KCZ group was 27% ( $P < 0.05$ ) and 57% ( $P < 0.05$ ) those in the T3 group, respectively.

The  $\alpha$ -tocopherol concentrations in the serum, liver, jejunum, kidney, adrenal gland, lung, heart, spleen, thymus, aorta and muscle of the  $\alpha$ T and  $\alpha$ T + KCZ groups did not differ, although those of the  $\alpha$ T group were higher ( $P < 0.05$ ) than those of the control group (Table 2).  $\gamma$ -Tocopherol,  $\alpha$ - and  $\gamma$ -tocotrienol were not detected in the serum and tissues of the control and KCZ groups. The  $\gamma$ -tocopherol concentration in the serum, liver, jejunum, kidney, adrenal gland, lung, heart, spleen, thymus, brain and muscle of the  $\gamma$ T + KCZ group was higher ( $P < 0.05$ ) than that of the  $\gamma$ T group (Table 3). The  $\alpha$ -tocotrienol concentration in the heart, thymus and muscle of the T3 group was higher ( $P < 0.05$ ) than the  $\gamma$ -tocopherol concentration in those tissues of the  $\gamma$ T group. The  $\alpha$ -tocotrienol concentration in the serum, liver, jejunum, kidney, adrenal gland, lung, spleen and brain of the T3 + KCZ group was higher ( $P < 0.05$ ) than that of the T3 group. The  $\gamma$ -tocotrienol concentration in the jejunum, heart and muscle of the T3 group and the  $\gamma$ -tocopherol concentrations of the  $\gamma$ T group did not differ ( $P \geq 0.05$ ), while the  $\gamma$ -tocotrienol concentration in the tissues of the T3 group was lower ( $P < 0.05$ ) than the  $\alpha$ -tocotrienol concentration. The  $\gamma$ -tocotrienol concentration in the liver, jejunum, kidney, adrenal gland, lung, heart, spleen, thymus and muscle of the T3 + KCZ group was higher ( $P < 0.05$ ) than that of the T3 group.

## Experiment 2

Jejunum  $\alpha$ -tocopherol concentrations of the  $\alpha$ T and  $\alpha$ T + KCZ groups at 0.5, 1 and 3 h did not differ ( $P \geq 0.05$ ) (Fig. 1A). The  $\alpha$ -tocopherol concentrations in the plasma (Fig. 1B) and liver (Fig. 1C) of the  $\alpha$ T and  $\alpha$ T + KCZ groups were elevated ( $P < 0.05$ ) at 3 h. Ketoconazole did not affect ( $P \geq 0.05$ ) the  $\alpha$ -tocopherol concentrations in the jejunum, plasma and liver. The jejunum  $\gamma$ -tocopherol concentration of the  $\gamma$ T group was lowered ( $P < 0.05$ ) at 3 h, but the  $\gamma$ -tocopherol concentration of the  $\gamma$ T + KCZ group was not changed ( $P \geq 0.05$ ) for 3 h (Fig. 1D). The  $\gamma$ -tocopherol concentration of the  $\gamma$ T + KCZ group at 3 h was 464% that of the  $\gamma$ T group. The  $\gamma$ -tocopherol concentration in the plasma (Fig. 1E) and liver (Fig. 1F) was not affected ( $P < 0.05$ ) by ketoconazole. Ketoconazole did not significantly change ( $P \geq 0.05$ ) the  $\alpha$ -tocotrienol concentration in the jejunum (Fig. 2A), plasma (Fig. 2B) and liver (Fig. 2C), but elevated ( $P < 0.05$ ) the  $\gamma$ -tocotrienol concentration in the jejunum

(Fig. 2D) and liver (Fig. 2F). The  $\gamma$ -tocotrienol concentration in the jejunum of the T3 + KCZ group at 3 h was 355% ( $P < 0.05$ ) that of the T3 group, and the concentration in the liver was 469% ( $P < 0.05$ ).

### Experiment 3

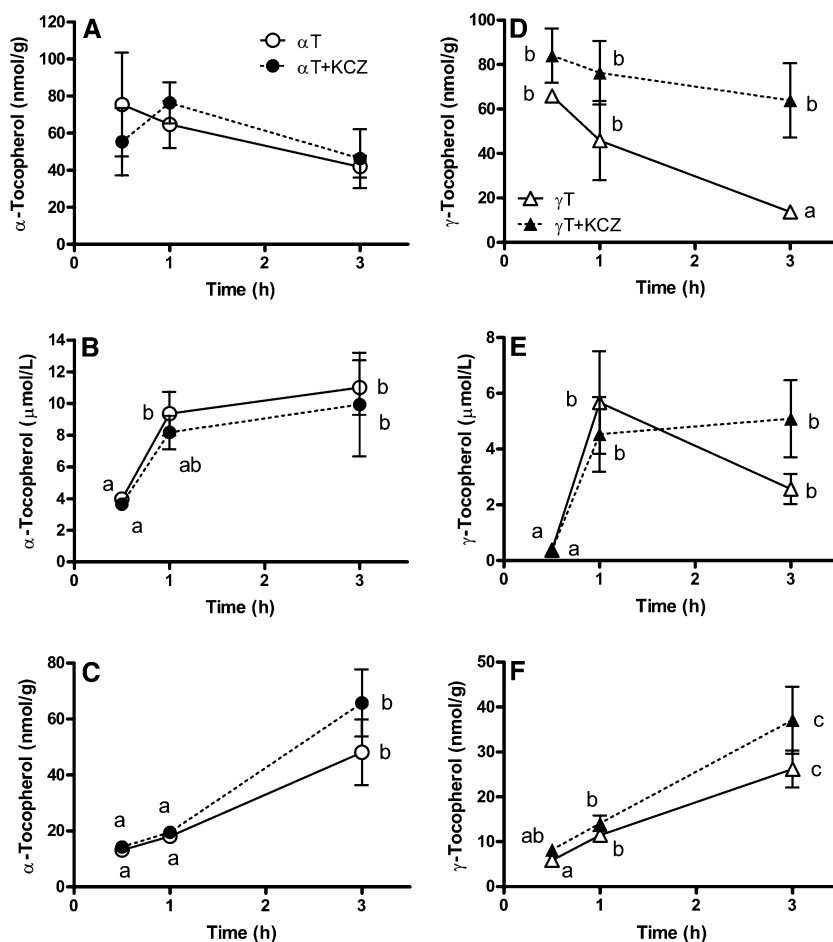

A small amount of  $\alpha$ -CEHC was detected in the jejunum of the T3 and T3 + KCZ groups, but the concentrations were not different from that of the rats without vitamin E administration (data not shown). However, the jejunum

$\gamma$ -CEHC concentration of the  $\gamma\text{T} + \text{KCZ}$  was markedly lower ( $P < 0.05$ ) than that of the  $\gamma\text{T}$  group (Fig. 3). The  $\gamma$ -CEHC concentration of the T3 + KCZ group tended to be lower than that of the T3 group.

### Discussion

Ketoconazole has been known as a potent inhibitor of human CYP3A [19] but it also inhibits various CYP isoforms because the nitrogen atom of the imidazole ring of

**Fig. 1**  $\alpha$ -Tocopherol concentration in jejunum (A), plasma (B) and liver (C) of rats administered  $\alpha$ -tocopherol ( $\alpha T$ ) or with ketoconazole ( $\alpha T + KCZ$ ), and  $\gamma$ -tocopherol concentration in jejunum (D), plasma (E) and liver (F) of rats administered  $\gamma$ -tocopherol ( $\gamma T$ ) or with ketoconazole ( $\gamma T + KCZ$ ) in Experiment 2. Values are mean  $\pm$  SEM,  $n = 6$ . Time effect was detected ( $P < 0.05$ ) in panels B–F, and KCZ effect was also detected ( $P < 0.05$ ) in panel D by two-way ANOVA. Mean values in a panel with *superscripts* without a common letter differ,  $P < 0.05$

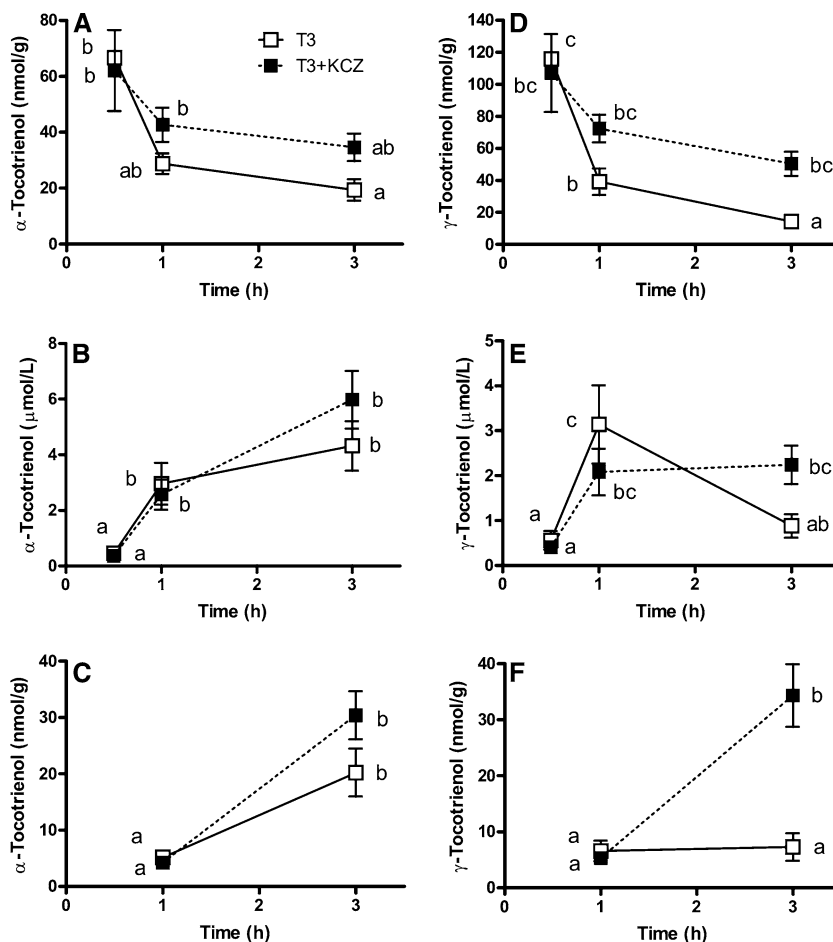

ketoconazole can bond heme iron of CYP isoforms. In fact, ketoconazole inhibits rat CYP1A, 2A, 2C, 2E and 3A [25, 26]. In addition, ketoconazole may inhibit CYP4F because of the potent inhibition of CYP4F-dependent vitamin E metabolism by ketoconazole in cultured cells [20, 21]. In order to clarify the contribution of CYP4F-dependent metabolism of vitamin E isoforms to their tissue concentrations, the effect of ketoconazole on tocopherol and tocotrienol concentrations in various tissues of rats was studied. We used vitamin E-deficient rats fed a vitamin E-free diet for 4 weeks in Experiments 1 and 2, because the other isoform concentrations were difficult to be elevated in the  $\alpha$ -tocopherol-rich tissues. The plasma pyruvate kinase activity, a marker for vitamin E deficiency, was not changed by the deficiency for 4 weeks (unpublished data), but the  $\alpha$ -tocopherol concentration in the plasma and liver was 16 and 20% those at the start of the experiment [27].

Ketoconazole decreased urinary excretion of  $\alpha$ -CEHC after administration of  $\alpha$ -tocopherol or a tocotrienol mixture, and that of  $\gamma$ -CEHC after administration of  $\gamma$ -tocopherol or a tocotrienol mixture (Table 1). Thus, the metabolism of vitamin E isoforms to their metabolites was clearly inhibited by ketoconazole in rats. The decrease of

urinary metabolite excretion by ketoconazole was accompanied by the marked elevation of the  $\gamma$ -tocopherol,  $\alpha$ - and  $\gamma$ -tocotrienol concentrations in the serum and various tissues (Table 3). These results show that CYP-dependent metabolism regulates the  $\gamma$ -tocopherol and tocotrienol concentrations in the tissues. The affinity of  $\gamma$ -tocopherol and  $\alpha$ -tocotrienol for  $\alpha$ -TTP is 9 and 12% that of  $\alpha$ -tocopherol, respectively [6]. Therefore, the regulation of vitamin E metabolism influences the tissue concentrations even though their affinity for  $\alpha$ -TTP is very low. In contrast, the  $\alpha$ -tocopherol concentration in the serum and various tissues was not affected by ketoconazole (Table 3), while the urinary  $\alpha$ -CEHC excretion was markedly inhibited by ketoconazole (Table 2). The reason of the different effect of ketoconazole on the  $\alpha$ -tocopherol and the other isoform concentrations is unclear. The  $\alpha$ -tocopherol concentration in the tissues after  $\alpha$ -tocopherol administration may be too high to be further elevated by ketoconazole.

We recently showed that Triton WR1339, an inhibitor of lipoprotein lipase, prevented vitamin E transport to the liver and subsequent transport to the various tissues [3]. The large amount of vitamin E associated with chylomicrons accumulated in the serum at 6 h after oral adminis-

**Fig. 2**  $\alpha$ -Tocotrienol concentration in jejunum (A), plasma (B) and liver (C) and  $\gamma$ -tocotrienol concentration in jejunum (D), plasma (E) and liver (F) of rats administered a tocotrienol mixture (T3) or with ketoconazole (T3 + KCZ) in Experiment 2. Values are mean  $\pm$  SEM,  $n = 6$ . Time effect was detected ( $P < 0.05$ ) in all panels, and KCZ effect was also detected ( $P < 0.05$ ) in panels D and F by two-way ANOVA. Mean values in a panel with *superscripts* without a common *letter* differ,  $P < 0.05$ . Neither  $\alpha$ - nor  $\gamma$ -tocotrienol was detected in the liver of the T3 and T3 + KCZ groups at 0.5 h

**Fig. 3** Jejunum  $\gamma$ -CEHC concentration at 3 h after oral administration of  $\gamma$ -tocopherol ( $\gamma$ T),  $\gamma$ -tocopherol with ketoconazole ( $\gamma$ T + KCZ), a tocotrienol mixture (T3), or a tocotrienol mixture with ketoconazole (T3 + KCZ) in Experiment 3. Values are mean  $\pm$  SEM,  $n = 4$ . There were effects of vitamin E isoform ( $P < 0.05$ ), ketoconazole ( $P < 0.05$ ) and their interaction ( $P < 0.05$ ) by two-way ANOVA. Mean values with *superscripts* without a common *letter* differ,  $P < 0.05$

tration of vitamin E with Triton, but there was a marked difference between each isoform concentration. The serum vitamin E isoform concentrations after each isoform

administration with Triton were as follows:  $\alpha$ -tocopherol, 102.3  $\mu$ mol/l;  $\gamma$ -tocopherol, 74.3  $\mu$ mol/l;  $\alpha$ -tocotrienol, 45.8  $\mu$ mol/l;  $\gamma$ -tocotrienol, 11.1  $\mu$ mol/l. In addition, rat CYP4F (CYP4F1, 4F4, 4F5 and 4F6) mRNA was detected in the jejunum (unpublished data). These results propose the hypothesis that some amount of vitamin E isoforms is metabolized in the intestine during their absorption. In order to see this hypothesis, the effect of ketoconazole on the vitamin E isoform concentrations in the jejunum, plasma and liver (Experiment 2), and the  $\gamma$ -CEHC concentration in the jejunum (Experiment 3) for 3 h after each administration was studied. The jejunum  $\alpha$ -tocopherol concentration was not affected by ketoconazole administration (Fig. 1A), but the  $\gamma$ -tocopherol (Fig. 1D) and  $\gamma$ -tocotrienol (Fig. 2D) concentrations 1 h after each administration tended to be elevated by ketoconazole administration, and those at 3 h were significantly elevated. The elevation of the jejunum  $\gamma$ -tocotrienol concentration by ketoconazole may be caused by the inhibition of its metabolism in the liver and the excretion through the bile, because the liver is a major tissue that metabolizes vitamin E isoforms, and the  $\gamma$ -tocotrienol concentration in the liver was markedly elevated by ketoconazole (Fig. 2F). Then,

we determined the  $\gamma$ -CEHC concentration in the jejunum (Experiment 3). A significant amount of  $\gamma$ -CEHC was detected in the jejunum 3 h after oral administration of  $\gamma$ -tocopherol or a tocotrienol mixture, and ketoconazole inhibited  $\gamma$ -tocopherol metabolism to  $\gamma$ -CEHC in the jejunum (Fig. 3). These results suggest that a certain amount of dietary vitamin E isoform is metabolized to its metabolite by CYP-dependent pathway in the intestine during absorption. Sontag et al. recently showed that the maximal specific activity ( $V_{\max}$ ) of human CYP4F2 for  $\gamma$ -tocopherol,  $\alpha$ - and  $\gamma$ -tocotrienol was much higher than that for  $\alpha$ -tocopherol in a kinetic study using human microsomes or insect microsomes expressing human CYP4F2 [28]. The affinity of  $\alpha$ - and  $\gamma$ -tocotrienol for the enzyme (apparent  $K_m$  value) was higher than those of  $\alpha$ - and  $\gamma$ -tocopherol. Thus,  $\gamma$ -tocopherol and  $\gamma$ -tocotrienol may be effectively metabolized to  $\gamma$ -CEHC in the intestine, while  $\alpha$ -tocopherol may be poorly metabolized.

The present study showed that CYP-dependent metabolism of vitamin E isoforms is a critical determinant of their tissue concentrations. This study also showed that  $\gamma$ -tocopherol and  $\gamma$ -tocotrienol are metabolized to  $\gamma$ -CEHC in the jejunum, and suggests that a certain amount of vitamin E isoform is metabolized by CYP-dependent metabolism in the intestine during absorption. Therefore, not only the discrimination of vitamin E isoforms by  $\alpha$ -TTP in the liver but also their metabolism by CYP-dependent pathway in the liver and intestine may regulate the tissue concentrations of vitamin E isoforms.

**Abstract** Structure and functioning of colonial pyrosomes are largely undescribed and their lipid characteristics have received limited attention. The aim of this paper is to fill this gap on one of the dominant species *Pyrosoma atlanticum*. Lipid content is tightly coupled to size and weight. Lipid composition shows a large dominance of structural polar lipids. Neutral lipids were dominated by sterols with low levels of acylglycerols and free fatty acids. Phospholipids show a dominance of PC with intermediate percentages of PE and DPG. Other constituents (PS, PI, LPC, sphingolipids) were present at lower levels. Fatty acid composition of DAG and TAG showed a dominance of saturated acids (16:0, 14:0), DHA and intermediate levels of MUFA. Phospholipids were dominated by DHA with values exceeding 30% of total FA in all categories except for PI, where lower percentages occurred. Saturated acids were second in abundance with MUFA showing intermediate concentrations. Sterols were dominated by 24-methylcholesta-5,22E-dien-3 $\beta$ -ol with more than 22% of the total sterol. Cholesterol (cholest-5-en-3 $\beta$ -ol) represented only 12 % of the total while 24-methylcholesta-

5,24(28)E-dien-3 $\beta$ -ol accounted for 11% of the total sterols. The low levels of triacylglycerols and free fatty acids, coupled with high concentrations of glycolipids and phytoplankton-derived degraded chloropigments, is evidence of a direct link with the digestive activity and substantiate the idea of a high physiological turnover as an alternative to large lipid accumulation. The fatty acid and sterol profiles are consistent with a diverse phytoplankton diet, and a strong contribution of phospholipid classes to energy needs, including locomotion.

## Introduction

Pyrosomas are a small group of holoplanktonic tunicates, currently including only 8 described species and 3 genera [1]. They are restricted to the warmer open ocean waters, between approximately 50°N and 50°S in all oceans [2]. Our knowledge of the lipid composition in tunicates remains fragmentary and detailed reports encompass essentially benthic tunicates, e.g. ascidians [3, 4] as well as salps, doliolids and appendicularians [5–8]. Knowledge of the lipid composition of *Pyrosoma* is limited to total fatty acid composition of *Pyrosoma atlanticum* reported by Culkin and Morris [9] and Jeffs et al. [10]. Both studies observed that the concentration of total lipids is generally low and dominated by structural lipids.

Neither of the two studies on *P. atlanticum* considered the lipid composition in terms of lipid classes and their related fatty acid structure. During the last leg of the ANTARES-4 cruise to the south Indian and the Southern oceans, substantial numbers of *P. atlanticum* colonies were observed in the region north of the Subtropical Front. As examination of biomarker lipid profiles from different lipid

classes may provide more detailed information pertinent to life cycle adaptation and food web research than is obtained from total fatty acid profiles, the availability of a sufficient number of samples prompted an investigation of the lipid constitution with special emphasis on the polar structural lipids.

## Materials and Methods

### Sampling

All samples were taken during the ANTARES-4 cruise of the research vessel *Marion Dufresne*, during the period 5 January–23 February 1999. The operational area was restricted between approximately 43–46°S and 61–65 °E, in the Indian sector of the Southern Ocean and the region of the Agulhas Front (for details see map in Perissinotto et al., 16). Colonies of *P. atlanticum* were collected only in the Agulhas Front region, north of the Subtropical Convergence, during the period 2–16 February at stations G4 (44°21'03S; 62°33'37E). Specimens were collected using a 160 cm-diameter Omori Net (1,000 µm mesh, towed obliquely from 200 m to the surface). Specimens were sorted out immediately, briefly rinsed with distilled water, blotted dry on sharkskin filter paper and deep frozen in liquid nitrogen. Samples were kept at –80 °C until return to the laboratory within 3 months.

### Size, Weight Measurements and Lipid Extraction

Entire specimens were placed frozen on crushed ice and brought to 0 °C. Size (total length = TL) and fresh weight (WW) were measured prior to lipid extraction according to the method of Bligh and Dyer [11]. The Bligh and Dyer method when used as published may not fully extract neutral lipids. This problem can be overcome using the same solvent ratios (i.e. one phase), and a longer extraction time. All lipid extracts were placed under nitrogen at –70 °C until analysis. Individual dry weight (DW) was recorded on sub-samples of 6 colonies dried at 70 °C for six days to obtain the dry weight/wet weight ratio.

### Lipid Analyses

Lipid classes were quantified after chromatographic separation coupled with FID detection on an Iatroscan MK V TH 10. Total lipid extracts were applied to SIII chromarods using a SAS A4100 autospotter set up to deliver 1 µl of chloroform extract on each rod. Analyses were done in triplicate. Neutral lipids were separated using a double development procedure with the following solvent systems: n-hexane: benzene: formic acid 80:20:1 (by volume)

followed by n-hexane:diethyl ether:formic acid 97:3:1.5 (v/v). Phospholipids were separated with chloroform: methanol: NH<sub>4</sub> 50:50:5 (v/v). Separation of glycolipids was achieved with chloroform/ethyl acetate/acetone/methanol/ acetic acid/water (60/12/15/16/3/3). Calibration was achieved using commercial standards (Tripalmitin, 1,2 di-palmitoyl-rac-glycerol, stearic acid, cholesterol, 3-sn-phosphatidyl-L-serine from bovine brain, L- $\alpha$ -phosphatidyl inositol from bovine liver, sphingomyelin from bovine brain and  $\alpha$ -lysophosphatidylcholine from egg yolk were obtained from Sigma; MGDG and DGDG from spinach were obtained from Larodan; L- $\alpha$ -Lecithin from egg yolk, L-phosphatidyl- ethanolamine from egg and cardiolipin from bovine heart were obtained from Avanti Polar Lipids).

Separation of neutral and polar lipids was achieved on a preparative scale by column chromatography on silica gel (Supelcosil A, Supelco). The neutral lipid fraction was eluted with six column volumes of chloroform, the acetone mobile compounds were eluted with four volumes of acetone and the phospholipids were eluted with six volumes of methanol. Each fraction collected was further separated by thin-layer chromatography (TLC) on pre-coated silica gel plates (Analtech, Uniplate) and developed with hexane : diethyl ether : acetic acid, 170:30:2 (v/v) for neutral lipids, or chloroform : methanol : aqueous ammonia 70:30:4 (v/v) for glycolipids, and chloroform: methanol: aqueous ammonia 50: 50: 5 (v/v) for polar lipids. All operations took place under nitrogen. Lipid classes were visualized using dichlorofluorescein and identification was achieved by comparison with standard mixtures. Acetone fraction was further separated on HPTLC using the same solvent system as TLC, but with specific detection of glycolipids made with Bial's Orcinol reagents (Alltech). No attempt was made to separate possible plasmalogen phospholipids.

Each band from TLC was scraped off and submitted to methylation. Fatty acid methyl esters (FAME) of total lipids were prepared with 7% boron trifluoride in methanol [12]. FAME were purified on TLC and recovered in hexane. Gas chromatography (GC) of all esters was carried out on a 30 m length x 0.32 mm internal diameter quartz capillary column coated with Famewax (Restek) in a Perkin-Elmer XL Autolab GC equipped with a flame ionization detector (FID). The column was operated isothermally at 185 °C for FAME. Helium was used as carrier gas at 7 psig. Injector and detector were maintained at 250 °C. Individual components were identified by comparing retention time data with those obtained from authentic (Nu-Check prep) and laboratory standards (capelin : menhaden oils 50:50). In addition to the examination of FAME as recovered, a part of all FAME samples was completely hydrogenated and the products examined qualitatively and quantitatively by GC. The level of accuracy is  $\pm 5\%$  for major components, 1 to 9% for intermediate components

and up to  $\pm 30\%$  for minor components. Additional GLC analysis was carried out on a 30 m length  $\times$  0.25 mm internal diameter non polar DB1 column (J&W Scientific) to resolve the co-elution of 20:1 and 18:5 fatty acids on Fawemawax.

Analysis of sterols was conducted on an aliquot of the separated sterol fraction after conversion to TMSi (trimethylsilyl) ethers using *N,O*-bis-(trimethylsilyl)-trifluoroacetamide (BSFA, 50  $\mu$ l) at 60 °C for 1 h. GC and GC-MS analysis of sterols was achieved as described in Jeffs et al. [10].

### Statistical Treatment

Allometric relationships between dry weight (DW) and length (TL) for the different colonies ( $DW = a * TL^b$ ) were computed after log–log transformation and model I regression [13]. Bivariate analyses were made with Statgraphics XV. Cluster analysis was based on Bray-Curtis distance and farthest neighbour clustering (see: 15).

Correspondence analysis [14] was performed on a reduced data matrix of fatty acids transformed to relative frequencies and scaled so that each row (or column) could be viewed as a row (or column) of conditional probability distribution. Distances between profiles were computed with  $\chi^2$  metrics. This distance gives symmetry to the two sets of data so that each factorial axis associated to the cluster of variables (fatty acids) corresponds to a factorial axis of the cluster of observations (phospholipids). Thus, it was possible to represent simultaneously descriptors and observations on the plane defined by the factorial axes. Details on the method and means of interpretation are given in Mayzaud et al. [16]. Computation of multivariate tests was made using the SPAD 5.5 software [17].

Six replicates were used to compute all means and standard deviations.

## Results

### Size, Weight and Lipid Relationships

The size of the colonies of pyrosomes collected during the ANTARES 4 cruise ranged from 13 to 25 cm. The corresponding wet and dry weight varied from 22 to 64 g and from 1.1 to 3.6 g respectively, with water content exceeding 90%. Lipid content on a dry weight basis was generally low and ranged from 5 to 7%.

The weight (DW) relationships with size or lipid content were established using specimens of different size. The assumption is that the increase in length and weight should reflect a fair degree of integration of the number and metabolism of the different individual zooids constitutive

of the colony. The log-linear regressions between size and weight (Fig. 1) were highly significant and resulted in an overall regression equation of:

$$\log DW = -1.804 + 1.69 \log TL \quad (R^2 = 0.906, F = 38.36, p = 0.003),$$

The relationship between DW and total lipids was also highly significant and is presented in Fig. 1. The resulting log linear regression is:

$$\log Lip_{tot} = 1.898 + 0.839 \log DW \quad (R^2 = 0.968, F = 120, p = 0.001).$$

A relatively low value for the allometric exponent  $b$  was observed, suggesting a slow rate of lipid accumulation with increasing weight.

### Lipid Class Composition

A detailed composition of the lipids from *Pyrosoma atlanticum* is presented in Table 1. Total lipid concentrations (% dry weight) ranged from 4.9 to 6.9 % with a mean value of  $5.7 \pm 0.7$  %. Neutral lipids were dominated by sterols with a mean value exceeding 8% of the total lipids, while low percentages of triacylglycerols (TAG), diacylglycerols (DAG) and free fatty acids were recorded. Polar lipids (% total lipids) were dominated by phosphatidyl-choline (PC) followed by phosphatidylethanol-

Free fatty acids	3.92 ± 0.98
Sterols	8.13 ± 0.60

Values expressed as mean ± standard deviation

amine (PE), diphosphatidylglycerol (DPG) with lower levels of phosphatidylserine+inositol (PS+PI), sphingomyelin and lysophosphatidylcholine (LPC). The lack of significant relationships between total lipids or lipid class per unit weight and either size or dry weight may be related to the small number of data points ( $n = 6$ ), or to the lack of direct interactions between body mass and lipid metabolism.

Two glycolipids fractions were found in concentrations exceeding 4% which can be attributed to the filter-feeding mode of the colonies. Their identification on HPTLC using Bial's Orcinol reagents, a sugar specific stain, showed that one fraction displayed the same  $R_f$  as commercial MGDG, while the second one run slightly faster than DGDG with the solvent system used. The high concentration of ingested chloropigments (from 0.3 to 1.6  $\mu\text{g colony}^{-1}$ , see Perissinotto et al., 18), suggests that the second fraction also originated from ingested phytoplankton. As discussed below, the high level of saturation of this later fraction (96% saturated acids) could explain the difference in migration as it is more saturated than the higher plant standard. This would agree with the possibility of a partial post ingestion modification.

#### Fatty Acid Composition of the Total and Neutral Lipids

The relative composition of the total fatty acids and the main neutral lipid classes is presented in Table 2. Fatty acid composition of the total lipids was driven by the abundance of polar lipids. Docosahexaenoic acid (DHA, 22:6n-3) dominated largely with more than 36% of the total fatty acids. Saturated acids were second in abun-

dance (> 30%) with palmitic (16:0) and myristic (14:0) as major components. Monounsaturated fatty acids (MUFA) showed intermediate percentages (12%), with 18:1n-9, 16:1n-7 and 18:1n-7 as major contributors. Among PUFAs other than DHA, eicosapentaenoic acid (EPA 20:5n-3) was the dominant pentaene, 18:2n-6, 18:3n-3 and 18:4n-3 dominated their respective group. DAG and TAG showed a dominance of saturated acids with 16:0 and 14:0, followed by 22:6n-3 with respective percentages of 18.6% and 21.9% of total fatty acids. Both the DAG and TAG fractions showed relatively high levels of 18:4n-3 (12.5 and 10.5%) and intermediate levels of MUFA with the same characteristic fatty acids. The two acylglycerols showed similar fatty acid composition, the only difference being the larger proportion of myristic acid (14:0) in DAG. The free fatty acid fraction was considered because of the high probability that it originates from digestive hydrolysis. Indeed, DHA showed the highest percentages with values ranging from 32 to 64% of the total fatty acids (mean 44.5%) despite the similar concentrations of free fatty acid contained in each specimen analyzed (3 to 4.5 % of total lipids). Stearic and myristic acids were the dominant saturated acids with respective ranges of 2 to 15% and 0.6 to 10%. EPA ranged from 3 to 12%, while oleic acid was the major MUFA with values ranging between 3.8 and 6.8%. Other MUFA and PUFA included 18:1n-7, 16:1n-7, 18:2n-6, 18:4n-3 and 20:4n-6 with percentages close to 2%. Odd branched chain acids (iso and anteiso) exhibited moderately high values in all neutral fractions, with percentages of iso15:0, anteiso15:0 and iso17:0 exceeding 1%.

#### Fatty Acid Fraction of the Glycolipids

The fatty acid composition of the two glycolipid fractions will only be summarized because of the unusual variability between replicates. The partial composition presented in Table 3, showed a large dominance of the saturated acids with 16:0 and 20:0 as main contributors for MGDG and DGDG respectively. DHA was second in importance but with values ranging from 2.8 to 20.4% for MGDG and from 1.1 to 25.9% for DGDG. Hence, the percent variability in fatty acid composition of MGDG, based on six replicates, is 13% for the saturated acids, 35% for the monoenes, 82% for 20:5 and 86% for 22:6. An increasing trend which agrees with the hypothesis of selective loss of polyunsaturated acids. The second fraction (DGDG-like) showed 40% variability for the saturated acids, 90% for the monoenes, and 120% for most unsaturated categories. Since the glycolipids originated from the phytoplankton chloroplast membranes, such extreme variance can only originate from different degree of digestive degradation.

### Fatty Acid Composition of the Total Phospholipids and Phospholipid Classes

Total phospholipids (PL<sub>T</sub>), like all phospholipid classes, were dominated by DHA with percentages exceeding 30% of the total fatty acids (Table 3), except for PI where lower percentages were recorded (23.6%). The saturated acids were second in abundance with palmitic acid and, to a minor extent myristic acid as the main constituents. PS showed a slightly different pattern with 16:0, 18:0 and 15:0 as the dominant saturates. MUFA showed intermediate concentrations with percentages ranging between 12 and 18% in total phospholipids, PC, PE, LPC, DPG and values higher than 20% in PS and PI (Table 3). Oleic (18:1n-9), palmitoleic (16:1n-7) and vaccenic (18:1n-7) acids were the main components, except in PS where 20:1n-7 accounted for 4.2% of the total fatty acids. Pentaenes repre-

sented the fourth largest group in abundance, with EPA as the main component with values exceeding 15% in PE, ranging from 7.5 to 9% in PC, DPG and PI. Lower EPA values were recorded in PC and LPC with percentages of 5–6%. Three other PUFA were present in smaller but significant concentrations: 18:4n-3 with values above 3% in PL<sub>T</sub>, PC, DPG, LPC and below 1% in the other polar lipids classes; 20:4n-6 with values above 4% in PE, PI and below 1.2% in PC, LPC; 18:3n-3 with percentages around 1% in all phospholipid classes.

Contrary to the pattern observed with neutral lipids, odd and even branch chain acids (iso15:0, iso16:0, iso18:0, anteiso15:0 and anteiso17:0) exhibited low concentrations with values below 0.5% of total fatty acid. Iso17:0 showed higher percentages with values ranging from 0.5 to 1.1, with maxima in PI and LPC.

### Sterol Composition

As indicated earlier, sterols made a large fraction of the total lipid. A total of 21 sterols were identified in *P. atlanticum* (Table 4). The sterol composition was dominated by 24-methylcholesta-5,22E-dien-3 $\beta$ -ol with more than 22% of the total sterol. Cholesterol (cholest-5-en-3 $\beta$ -ol), which usually dominates in most animal tissues, represented only 12% of the total while 24-methylcholesta-5,24(28)-dien-3 $\beta$ -ol (24-methylenecholesterol) accounted for 11% of the total sterols. Additional important constituents ranging from 5 to 9% included: 5 $\alpha$ -cholest-22Z-en-3 $\beta$ -ol (cis-22-dehydrocholestanol), 24-ethylcholest-5-en-3 $\beta$ -ol (24-ethylcholesterol), cholesta-5,22Z-dien-3 $\beta$ -ol (cis-22-dehydrocholesterol) and 5 $\alpha$ -cholestan-3 $\beta$ -ol (cholestanol). This composition contrasts with the large dominance of cholesterol classically reported for crustaceans [27] and suggests a large influence of ingested phytoplankton as suggested by the high chlorophyll content recorded in these specimens Table 5.

### Discussion

Pyrosomas are important tunicates that play a major role in food webs of many oceanic areas [19]. Yet, they are among the least investigated of all invertebrates, with very little information on their lipid structure. Their lipid class

\* C<sub>24</sub> stereochemistry not determined in this study, hence only systematic names rather than trivial names are given

composition is unknown, but the dominance of phospholipids is in agreement with data on other subtropical pelagic tunicates [6,7,10]. The low levels of triacylglycerols and free fatty acids, coupled with high concentrations of glycolipids, is also in agreement with the observation made by Deibel et al. [6] on a different pelagic tunicate, the larvacean *Oikopleura vanhoeffeni*. The concentration of glycolipids is likely related to the high levels of chloropigments (present as degradation products) recorded in *Pyrosoma atlanticum* [18] and substantiates the idea of a high physiological turnover as an alternative to large lipid accumulation. Indeed, pyrosomas are known to graze on a wide range of microplanktonic taxa, ranging from sub-micronic particles to large diatoms, and in warm oligotrophic waters are facing relatively continuous food supply. The presence of a pool of free fatty acids coupled with two phytoplankton glycolipid fractions seems indicative of such feeding activity and digestive processes [18]. The presence of phospholipids in excess of 70% of the total lipids seems a general feature of gelatinous pelagic

organisms and indicative of investment in cell membranes as reported for ctenophores [20, 21], larvaceans [6] and chaetognaths [22, 23]. In terms of polar lipid constituents, *P. atlanticum* follows the pattern described for most marine zooplankters, with PC as the main component followed by PE and DPG [24].

A comparison of the total fatty acid pattern among samples collected at different locations in the subtropical Atlantic Ocean by Culkin and Morris [9], the Pacific Ocean by Jeffs et al. [10] and the Indian Ocean in the present study shows a relatively similar composition, with very high levels of DHA, palmitic, oleic and myristic acids and EPA as main descriptors. Lower percentages of myristic, palmitic and palmitoleic acids associated with higher levels of DHA were observed in the present study, compared to the data of Culkin and Morris [9]. The variation in the fatty acid profiles may be attributed to differences in the diet of animals, temperature or to the analytical procedures. A cluster analysis of all data on *P. atlanticum* and other pelagic tunicates, such as *Salpa cylindrica* and *Dolioletta gegenbauri*, separated the older data from the more recent ones (Fig. 2), irrespective of the taxonomic group considered. Interestingly, the pelagic tunicate *Dolioletta gegenbauri* was clearly separated from *P. atlanticum* for both recent studies, based on higher levels of myristic, palmitoleic and arachidic acids and lower percentages of palmitic and oleic acids. The differences between the two taxa are likely related to the differences in phospholipid levels and composition. Higher percentages of polar lipids in *Pyrosoma* is translated in the total lipid fraction into lower myristic, palmitoleic and arachidic acids, which accounts for lower percentages than in neutral lipids.

The analysis of lipids in marine animals can often provide valuable insights into the trophic interactions between primary consumers and their food supply (see review by Dalsgaard et al., 25). Because tunicates are known to retain particles from less than 1  $\mu$ m in diameter to phytoplankton cells larger than 10  $\mu$ m size range [26], the presence of fatty acid markers of bacteria and phytoplankton in the neutral fractions (TAG, FFA and DAG) is consistent with a very diverse diet. In our study, diatom markers (16:1n-7; 16:4 PUFA, 20:5n-3) were recorded but in small proportion, illustrating either a small contribution to the total ingestion or a very high turnover rate. Prymnesiophytes and dinoflagellates markers (C<sub>18</sub> PUFA including 18:5n-3, 22:6n-3) dominated suggesting a large contribution of these two groups to the diet of *P. atlanticum*. Contribution of bacterial markers (iso and anteiso acids, 18:1n-7) was also present with relatively high percentages of iso 17:0 and 18:1n-7. An alternate approach was developed in Perissinotto et al. [18], using multivariate discriminant analysis, which coupled all data published on phytoplankton fatty acids and the pattern of both TAG and FFA

**Fig. 2** Cluster analysis of all published total fatty acid profiles for pelagic tunicates based on computed Bray-Curtis distance ( $x$  axis non dimensional). Symbols: P. atlant # = *Pyrosoma atlanticum* from the present study; P.a\_Jeffs # = *Pyrosoma atlanticum* from Jeffs et al.

(2004); P.a\_Culkin = *Pyrosoma atlanticum* from Culkin and Morris (1970); Doliioletta = *Doliioletta gengenbauri* from Pond and Sargent (1998); S. cylindrica = *Salpa cylindrica* from Culkin and Morris (1970)

acids recorded for the present samples. Results confirmed that both dinoflagellates and prymnesiophytes are dominant constituents in the ingested material. One question always open with colonial organisms is whether or not ingested chlorophyll has passed the plasma membrane of each individual. The actual process of ingestion and digestion is a complicated one and no direct microscopic observation could be made during this study. However, as shown by Perissinotto et al. [18], most chloropigments were in the form of pheopigments (80 to 90%) with a high rate of degradation into non-fluorescent compounds. Such a process only occurs during gut transit and strongly support the hypothesis that the phytoplankton cells were taken up by individual zooids and digested.

Information on sterol composition is scarce and the present data can only be compared with those of Jeffs et al. [10] for samples of *Pyrosoma atlanticum* and Makar'eva et al. [27] for samples of *Pyrosoma giganteum*. The patterns of sterols recorded for *P. atlanticum* show both similarities and differences. Both profiles show dominance of 24-methylcholesta-5,22E-dien-3(-ol, cholesterol, *cis*-22-dehydrocholesterol and similar levels of 24-ethylcholesta-5,22E-dien-3(-ol, 24-ethylcholest-5-ene-3(-ol and 24-norhydrocholesterol. However, our specimens from the Indian Ocean exhibit higher percentages of 24-methylene cholesterol and *cis*-22-dehydrocholestanol. They also lack in some of the major sterols observed off the New Zealand coast, e.g. 24-methylcholesterol and dinosterol. The differences are likely related to the heterogeneity of particles ingested at the two sites, which may differ substantially in their phytoplankton and microheterotroph-derived sterols. We have no knowledge of the sterol metabolism of tunicates, but the low level of cholesterol observed in *P. atlanticum* may suggest that the ability to convert phytosterols to cholesterol, reported for many crustaceans

[28] may not be as effective in *P. atlanticum*. Copepods, euphausiids, ostracods, phyllosomes and other invertebrates, such as siphonophores and ctenophores, show a large dominance of cholesterol in contrast to tunicates (ascidians and pyrosomes), which contain mostly algal-derived sterols (10, present study). In terms of trophic linkage sterol markers of diatoms (22-dehydrocholesterol, cholesterol, 24-methylenecholesterol), prymnesiophytes and dinoflagellates (24-methylcholesta-5,22E-dien-3(-ol, 24-ethylcholesta-5,22E-dien-3(-ol, 24-ethylcholest-5-ene-3(-ol, 24-methylenecholesterol) are present but as indicated by Volkman [29], many sterols are widely distributed and assignment to a specific algal class remains difficult. The lack of dinosterol in our samples may seem contradictory with the trophic link described earlier, but a number of dinoflagellate species do not contain dinosterol [30,31]. Hence, it may be that species of dinoflagellates lacking dinosterol dominated this component of its diet. In oligotrophic waters, such as those studied in this paper, the sterol composition would tend to support a diet dominated by dinoflagellates and prymnesiophytes [29].

Our knowledge of the phospholipid composition of pelagic marine organisms is, to a large extent, limited to a description of the main classes in crustaceans: i.e., copepods, euphausiids, decapods [24–34], and cnidaria (see review by Joseph, 35). Reports of fatty acid composition is generally limited to benthic ascidians and total polar lipid fraction [4], thus preventing meaningful taxonomic comparisons. Differences between fatty acid composition of the phospholipid constituents seem directly related to the specificity in the pathways of synthesis involved. In this study, a comparison of the various profiles was achieved using a factorial correspondence analysis (FCA). The first three factorial axes accounted for more than 90% of the total variance and projection of both fatty acid descriptors

**Fig. 3** *Pyrosoma atlanticum*. Correspondence analysis of the fatty acid structure of the main phospholipid classes. Projection in the factorial plane defined by axes 1 and 2. Filled triangles illustrate fatty acid descriptors and filled circles illustrate polar lipid fractions. PC phosphatidylcholine; PE phosphatidylethanolamine; PI phosphatidylinositol; PS phosphatidylserine and DPG diphosphoglycerols. Size of symbols is representative of significance on the plane of projection

and phospholipid constituents, on the plane defined by the first two axes (Fig. 3), discriminated between two groups. The first axis separated PC, PE, DPG on the one hand and PS, PI on the other, whereas it opposed PC to PE and PS to PI on the second axis. This is consistent with the concept of main interrelated synthetic routes via CDP-choline and CDP-ethanolamine leading to PC and PE and secondary transformations from PS to produce PE, and from CDP-diacylglycerol to produce PI [36]. In terms of fatty acid profiles, differences in PC were linked with 18:4n-3, 18:3n-3, 20:3n-3, 18:3n-6 and 14:0, while differences in PE were associated with EPA, arachidonic acid and 22:0. Discrimination between PI and PS were related respectively to arachidonic acid, 17:1, oleic and *cis* vaccenic acids and to 20:1n-7, 21:5n-3, 20:1n-9, 20:0 and 15:0.

The fatty acid composition of all polar lipid classes of *P. atlanticum* also shared several common features: a high degree of unsaturation with more than 35% of EPA and DHA; a relatively constant percentage of DHA; and similar levels of saturated acids, although with different constituents. Phospholipids containing high levels of DHA are often associated with the need for high energy processes. They have been proposed to be required as conformational co-factors for the functional assemblage of membrane proteins, ion pumps and/or complexes of the mitochondrial electron transport chain [37, 38]. In the specific case of *P. atlanticum*, locomotion is slow as a consequence of a slow continuous jet emerging from the cloacal aperture of the colony. The jet is produced by the ciliary activity of each individual zooid, which is under nervous control [2]. We have no knowledge of the energy needed and the complex ion and electron transport processes involved in this motion, but data agree with the hypothesis of a strong

contribution of all phospholipid classes. Within the membrane bilayer system, PC, PE and DPG are often associated with both passive and active transport, while PS and PI are linked to nervous stimulation and PI hydrolysis is associated to the production of intracellular messengers. Such a view is consistent with the processes controlling locomotion and the regulation of buoyancy, which utilizes sulphate exclusion [2].

In summary, new results for the lipid class and component fatty acid and sterol distributions of the gelatinous pelagic tunicate *P. atlanticum* collected from the Indian Ocean sector of the Southern Ocean have been obtained. The profiles are consistent with a high physiological turnover, diverse phytoplankton diet, and strong contribution of phospholipid classes to energy needs, including locomotion.

**Acknowledgements** We thank the French CNRS, the French Polar Institute (IPEV), the South African NRF and the University of KwaZulu-Natal (Durban, South Africa) for providing funds for this study. Finally, we like to thank the captain, officers and crew of the “RV *Marion-Dufresne*” for their assistance and cooperation during the ANTARES-4 voyage.

# Uniform Fatty Acid Mobilization from Anatomically Distinct Fat Depots in the Sable (*Martes zibellina*)

Petteri Nieminen · Anne-Mari Mustonen

Received: 27 March 2007 / Accepted: 30 March 2007 / Published online: 2 June 2007  
© AOCS 2007

**Abstract** The mobilization of fatty acids (FA) is a selective process in humans, rodents and the few previously studied carnivores. The FA composition of and mobilization from different fat depots reflect the functions of adipose tissues, e.g. in energy storage or insulation. Sixteen farm-raised sables (*Martes zibellina*), a terrestrial mustelid, were assigned into a fed control group or fasted for 4 days. The FA composition of the sable was relatively similar to other previously studied mustelids. The masses of the different fat depots decreased by 28–55% during fasting. The subcutaneous (sc) and intraabdominal (iab) fats had a uniform FA composition and the sable could mobilize both sc and iab FA. 18:3n-3, 18:4n-3 and 16:1n-7 were effectively mobilized, while long-chain saturated (SFA) and monounsaturated FA (MUFA) increased in proportion. Relative mobilization (RM) correlated inversely with the FA chain length and  $\Delta 9$ -desaturation increased RM of several MUFA compared to SFA. The results reinforce the hypothesis that the terrestrial sable can utilize sc and iab fat depots as energy reserves during nutritional scarcity. The natural history of the species is an important determinant of the FA composition and RM between anatomically different fat depots.

## Abbreviations

ANOVA Analysis of variance  
BM Body mass

BMI	Body mass index
DBI	Double bond index
$\Delta 9$ -DI	$\Delta 9$ -Desaturation index
EDTA	Ethylenediaminetetraacetic acid
FA	Fatty acid
FAME	Fatty acid methyl ester
FFA	Free fatty acid
FID	Flame ionization detector
iab	Intraabdominal
mes	Mesenteric
MUFA	Monounsaturated fatty acid
om	Omental
PG	Prostaglandin
PUFA	Polyunsaturated fatty acid
RM	Relative mobilization
rp	Retroperitoneal
sc	Subcutaneous
SFA	Saturated fatty acid
TACL	Total average chain length
UFA	Unsaturated fatty acid
VLCFA	Very-long-chain fatty acid
WAT	White adipose tissue

## Introduction

White adipose tissue (WAT) is presently considered to be an active organ and not just an inert energy store. WAT is endocrinologically active [1–2], it regulates the immune response [3] and reflects the long-term nutritional history of the individual [4]. In laboratory rats (*Rattus norvegicus*) the release of fatty acids (FA) from WAT reserves is selective and influenced by the carbon chain length and the

P. Nieminen (✉) · A.-M. Mustonen

e-mail: pniemine@cc.joensuu.fi

degree of unsaturation [5]. FA are mobilized more effectively if they have short carbon chains, are unsaturated and if their double bonds are located close to the terminal methyl group of the chain. In rats [6], American minks (*Mustela vison*) [7], raccoon dogs (*Nyctereutes procyonoides*) [8] and emperor penguins (*Aptenodytes forsteri*) [9], longer-chain saturated (SFA) and monounsaturated FA (MUFA) have relatively low mobilization rates. Also in the American marten (*Martes americana*), 20:0, 20:1n-11, 20:1n-9 and 22:1n-11 are poorly mobilized [10]. The differences in mobilization efficiency are independent of recent FA intake and probably caused by the structure of FA [11].

Many mammals inhabiting the boreal climate experience autumnal fattening followed by wintertime food scarcity and energy catabolism (for the sable *M. zibellina*, see [12]). This type of seasonal body mass (BM) fluctuation is considered nonpathological, while the human weight cycling caused by repeated dieting and weight gain is a health risk due to an increased incidence of e.g. cardiovascular diseases [13]. The sable is a terrestrial mustelid inhabiting Palearctic coniferous forests [14]. It is mostly carnivorous but feeds also on seeds and berries [15, 16]. At temperatures below  $-30^{\circ}\text{C}$ , the sable can stay in the den for several days [17]. As a consequence, the species probably experiences short-term food deprivation in its natural habitat. During a 4-day fasting period the farmed sable uses both subcutaneous (sc) and intraabdominal (iab) fat depots as metabolic energy [18]. Of these fat tissues, the relative loss of mass is the highest for retroperitoneal (rp) fat. In addition, the species utilizes body proteins during fasting indicated by e.g. increased plasma levels of urea and essential amino acids. It also experiences hepatic dysfunction evidenced by elevated plasma transaminase activities and liver triacylglycerol content. It can be hypothesized that the sable would exhibit active mobilization of diverse FA during fasting and there also exists the possibility of specialized roles of anatomically distinct WAT in the use of FA.

The specific aims of this study were (1) to determine the FA composition of sable plasma, liver and regional WAT depots after a balanced long-term feeding of the same diet, (2) to study the effects of food deprivation on the FA profiles of these tissues, (3) to determine the possible selectivity in mobilization of different FA and WAT depots during food deprivation and (4) to investigate the structural basis of this selectivity. Previous data on the physiology of the sable are scarce and basic information on the fat metabolism of the species can be useful not only in comparative physiology but also due to the status of the sable as a fur-producing species.

## Experimental Procedures

For these experiments 16 male sables born in spring 2004 were randomly divided into two experimental groups. The animals were housed singly in standard cages ( $85 \times 30 \times 46$  cm) with wooden nest boxes ( $24 \times 32 \times 35$  cm) suspended above ground in an unheated shed at a commercial fur farm in Himanka, Finland ( $64^{\circ}9'N$ ,  $23^{\circ}42'E$ ). Before the experiment the animals were fed for several months with a standard fur animal feed ( $200\text{--}220$  g or  $1,500\text{--}1,600$  kJ animal $^{-1}$  day $^{-1}$ ; slaughterhouse offal 35%, Baltic herring 24%, barley 14%, cooked cereal 5%, protein concentrate 4%, fox fat 4%, meat and feather flour 3%, mashed potatoes 2%; metabolizable energy 7,400 kJ kg fresh weight $^{-1}$ ; protein 13.6%, fat 9.8%, carbohydrates 13.9%; Himangan kala ja minkki Oy, Himanka). The FA composition of the diet is depicted in Table 1. The fasting experiment was conducted between October 29–November 1, 2004. Half of the animals were put to a total 4-day fast, while the other half was fed using the diet and procedure described above. The duration of the fast was determined to be safe for mustelids of this body size [7, 10, 18–21], yet long enough to detect the specific effects of fasting on the various FA in diverse WAT depots.

**Table 1** The proportions of the most abundant fatty acids ( $\geq 1$  mol%) in the diet of the sables (mean  $\pm$  SE;  $n = 5$ )

Fatty acid	mol% in diet
14:0	1.9 $\pm$ 0.1
16:0	21.0 $\pm$ 0.8
18:0	6.8 $\pm$ 0.3
$\Sigma$ :SFA	31.2 $\pm$ 0.9
16:1n-7	5.0 $\pm$ 0.2
18:1n-9	30.4 $\pm$ 1.0
18:1n-7	2.5 $\pm$ 0.1
20:1n-9	1.0 $\pm$ 0.1
$\Sigma$ :MUFA	41.8 $\pm$ 1.2
18:2n-6	16.4 $\pm$ 2.1
20:2n-6	1.6 $\pm$ 0.8
18:3n-3	2.0 $\pm$ 0.2
18:4n-1	1.6 $\pm$ 0.9
22:6n-3	1.7 $\pm$ 0.1
$\Sigma$ :PUFA	27.1 $\pm$ 1.7
n-6 PUFA	18.9 $\pm$ 1.6
n-3 PUFA	6.3 $\pm$ 0.3
n-3/n-6 PUFA ratio	0.3 $\pm$ <0.1
UFA/SFA ratio	2.2 $\pm$ <0.1

Also minor fatty acids not listed in the table are included in the sums SFA saturated fatty acid, MUFA monounsaturated fatty acid, PUFA polyunsaturated fatty acid, UFA unsaturated fatty acid

The fed group was fasted overnight before the sampling to avoid e.g. lipemic plasma caused by the eating of food remnants. The overnight fast was considered relatively short to allow sampling from the fed group during phase I of fasting. Water was available for both experimental groups ad lib. The experiment was approved by the Animal Care and Use Committee of the University of Joensuu and complied with current EU laws.

Body mass were recorded on the first day of the experiment and at sampling. Body lengths from the tip of the nose to the anus were also determined at sampling. Body mass indices (BMI) indicating body adiposity of the sable [18] were calculated with the formula  $BMI = BM \text{ (kg)} [\text{body length}^3 \text{ (m)}]^{-1}$ . The animals were anaesthetized with intramuscular ketamine (5 mg kg<sup>-1</sup>) and xylazine (2 mg kg<sup>-1</sup>). Blood samples were obtained sterilely by cardiac punctures and the animals were euthanized with an intracardial injection of a mixture of embutramide (60 mg kg<sup>-1</sup>), mebezonium (15 mg kg<sup>-1</sup>) and tetracaine hydrochloride (1.5 mg kg<sup>-1</sup>). Blood samples were placed into test tubes containing EDTA to prevent clotting, centrifuged for 15 min at 4,000g, after which the plasma was removed. The livers were dissected and the WAT samples collected as follows: sc scapular, sc rump, sc ventral, iab omental (om), iab mesenteric (mes) and iab rp. The sc samples were collected from the middle of each anatomical region and the mass of the sc depots was determined as a whole. The iab depots were dissected and weighed separately. The rp depot represents all WAT at the dorsal side of the abdominal cavity around the kidneys and the great blood vessels, while om fat and mes fat represent the whole of the omentum and mesentery, respectively. All samples were frozen immediately in Eppendorf vials with liquid nitrogen and stored at -80°C. The carcasses were frozen at -20 °C, thawed later and the remaining WAT were dissected and weighed.

The plasma free FA (FFA) concentrations were measured with the NEFA Non Esterified Fatty Acids reagents (Randox Laboratories Ltd, Crumlin, UK) using the Technicon RA-XT<sup>TM</sup> analyzer (Swords, Ireland). For the FA analyses, subsamples of WAT, liver and plasma were transmethylated according to Christie [22] by heating with 1% methanolic H<sub>2</sub>SO<sub>4</sub> under nitrogen atmosphere. The formed FA methyl esters (FAME) were extracted with hexane. The dried and concentrated FAME were analyzed by a gas-liquid chromatograph equipped with two injectors and flame ionization and mass detectors (GC-FID and GC-MS, 6890N network GC system with autosampler, FID detector and 5973 mass selective detector, Agilent Technologies Inc, Palo Alto, CA, USA). The GC-FID and GC-MS lines were both equipped with a DB-wax capillary column (30 m, ID 0.25 mm, film 0.25 µm, J&W Scientific, Folsom, CA, USA). The injection volume was 2 µl, and the

split ratio 1:20. The injectors were set at 250 °C, and the FID and mass interphases were at 250 and 200 °C. Helium was used as a carrier gas (1.8 and 1.0 ml min<sup>-1</sup> for FID and mass detecting lines). The initial oven temperature of 180 °C was held for 8 min, and then programmed to rise by 3 °C min<sup>-1</sup> to a final temperature of 210 °C, which was maintained for 25 min. The peaks were reintegrated manually and the mass spectra extracted using the Agilent ChemStation software (Agilent Technologies Inc). The FAME were identified based on the retention time, mass spectrum and comparisons with authentic (Sigma, St. Louis, MO, USA) and natural standards of a known composition and published reference spectra (WW Christie <http://www.lipidlibrary.co.uk/masspec.html>). Quantifications were based on FID responses. The peak areas of the FID chromatograms were converted to mol% by using the theoretical response factors [23] and calibrations with quantitative authentic standards. The FA were marked by using the abbreviations: [carbon number]:[number of double bonds] n-[position of the first double bond calculated from the methyl end]. If not stated otherwise, polyunsaturated FA (PUFA) were methylene-interrupted.

The double bond index (DBI) and the total average chain length (TACL) indicating the mean number of double bonds or carbon atoms per molecule were calculated according to standard formulae [24].  $\Delta 9$ -Desaturation index ( $\Delta 9$ -DI), the ratio of the most important potentially endogenous  $\Delta 9$ -MUFA to the corresponding SFA, was calculated as  $[(\text{mol}\% \text{ 14:1n-5}) + (\text{mol}\% \text{ 16:1n-7}) + (\text{mol}\% \text{ 16:1n-9}) + (\text{mol}\% \text{ 18:1n-9}) + (\text{mol}\% \text{ 18:1n-7})]:[(\text{mol}\% \text{ 14:0}) + (\text{mol}\% \text{ 16:0}) + (\text{mol}\% \text{ 18:0})]$ . The very-long-chain FA (VLCFA) were calculated as the sum of all FA with a chain length  $\geq 24$  carbons (i.e. 24:0 + 24:1n-9; ref. 25). Relative mobilization (RM) was calculated by the formula:  $[\text{mol}\% \text{ in the fed animals} - \text{mol}\% \text{ in the fasted animals}]:[\text{mol}\% \text{ in the fed animals}]$  [10]. The FA composition and RM were also determined for the total pooled sc (scapular, rump and ventral combined) and total pooled iab (om, mes and rp combined) fat depots.

Multiple comparisons were performed with the one-way analysis of variance (ANOVA) followed by the Duncan's post hoc test. The normality of distribution and the homogeneity of variances were determined with the Kolmogorov-Smirnov test and the Levene test. Comparisons between the two study groups were performed with the Student's *t* test for independent samples. In case of non-parametric data (normality of distribution and homogeneity of variances not attained after standard transformations), the Mann-Whitney *U* test was used. Significant differences in the time series (BM) were analyzed with the *t*-test for related samples. Correlations were calculated using the Spearman correlation coefficient ( $r_s$ ). The *P* value less than 0.05 was considered to be statistically significant. The re-

sults are presented as the mean  $\pm$  SE. FA with proportions  $> 0.1\%$  are presented in the tables, but also FA with trace amounts were included in the sums and used in the calculation of indices.

## Results

The initial BM of the fed ( $1.20 \pm 0.04$  kg) and the fasted sables ( $1.17 \pm 0.05$  kg) did not differ between the experimental groups, while the BM of the fasted animals was lower after the 4-day food deprivation period ( $1.14 \pm 0.03$  vs.  $0.98 \pm 0.03$  kg). Decreases in the absolute and relative masses of the specific fat depots due to fasting were as follows: total sc fat: fed  $59.0 \pm 7.1$  vs. fasted  $27.6 \pm 6.6$  g; difference 53%;  $P < 0.05$ ; om fat:  $9.2 \pm 1.0$  vs.  $6.3 \pm 1.6$  g; 32%; NS; mes fat:  $8.5 \pm 0.8$  vs.  $6.1 \pm 1.4$  g; 28%; NS; rp fat:  $13.8 \pm 2.4$  vs.  $6.2 \pm 1.4$  g; 55%;  $P < 0.05$  and total iab fat:  $33.5 \pm 4.2$  vs.  $19.6 \pm 4.6$  g; 41%;  $P < 0.05$ . The body fat% was significantly higher in the fed animals than in the fasted group ( $8.0 \pm 0.8$  vs.  $4.7 \pm 1.0\%$ ).

The concentrations of plasma FFA were higher in the fasted animals ( $0.6 \pm 0.18$  vs.  $2.6 \pm 0.57$  mmol  $l^{-1}$ ,  $P < 0.05$ ). The most abundant FA (proportion  $> 1\%$ ) in sable plasma were 16:0, 18:0, 18:1n-9, 18:1n-7, 18:2n-6, 20:4n-6, 20:5n-3, 22:5n-3 and 22:6n-3 (Table 2). Fasting caused decreases in the proportions of 15:0, 17:0, 18:0, 16:1n-9, 18:2n-6, total dienes and trienes, n-6 PUFA and total PUFA in plasma, while the proportions of 14:0, 16:0, total SFA, 14:1n-9, 20:1n-11, 20:1n-9, 22:1n-11, total MUFA and total n-3 PUFA as well as the n-3/n-6 PUFA ratios increased. The ratio of unsaturated FA (UFA) to SFA decreased in plasma. In liver, the most obvious decreases induced by fasting were in 17:0, 18:0, 22:0, 24:0, 20:4n-6, 22:4n-6, total n-6 PUFA and total PUFA, while the proportions of 12:0, 14:0, 14:1n-5, 18:1n-9, 20:1n-11, 20:1n-9 and total MUFA increased. The DBI and TACL decreased in liver due to food deprivation. In plasma and liver the proportions of 16:0, 18:0, 20:4n-6, 20:5n-3 and 22:6n-3 were higher than in the WAT, while the proportions of several MUFA, especially 16:1n-7 and 18:1n-9, were lower. The most abundant FA with decreased proportions in WAT due to fasting were 16:1n-7, 18:3n-3 and 18:4n-3, while the percentages of 14:0, 20:0, 22:0, 24:0, 20:1n-11, 20:1n-9, 22:1n-11 and 24:1n-9 increased (Tables 2, 3, 4). The n-3/n-6 PUFA ratio decreased in the pooled sc and iab fat depots as well as in the mes and rp fats. The sum of VLCFA increased in the pooled sc and iab fat depots.

Most FA increased in proportion in the WAT during fasting (Fig. 1). 20:0, 22:1n-11, 20:1n-11, 20:1n-9 and 22:5n-3 were mostly preserved, while 18:3n-3, 18:4n-3, 16:1n-7, 17:1n-8, 15:0 and 16:0 had high RM values. There were no differences in RM of FA between the different

WAT. RM of SFA correlated negatively with the chain length when all trunk WAT were analyzed as a whole ( $r_s = -0.127$ ,  $P < 0.01$ ; Fig. 2a). The same was observed in n-5 ( $r_s = -0.191$ ,  $P < 0.01$ ), n-7 ( $r_s = -0.285$ ,  $P < 0.01$ ) and n-9 MUFA ( $r_s = -0.366$ ,  $P < 0.01$ ; Fig. 2b). The influence of chain length on RM of PUFA was tested by comparing PUFA with the same degree of unsaturation and position of the first double bond but a different chain length. The difference was significant in five out of eight pairs in the way that the PUFA with the longer chain length had a lower RM value (Fig. 2c). When SFA and corresponding MUFA were compared, RM increased significantly with  $\Delta 9$ -desaturation in three out of seven pairs (Fig. 2d). The influence of unsaturation on RM of PUFA was studied by comparing PUFA with the same chain length and position of the first double bond but with a different double bond number. The difference was significant in one out of eight pairs in the way that the PUFA with the higher number of double bonds had a higher RM rate. The influence of positional isomerism on RM of MUFA was tested by comparing MUFA of the same chain length but different position of the double bond. The difference was statistically significant in 4 out of 11 pairs in the way that the MUFA with the double bond closer to the methyl end of the molecule had a lower (three cases) or a higher RM value (one case). When comparing PUFA with the same chain length and unsaturation but with a different position of the first double bond, the difference was statistically significant in one out of seven pairs in the way that the PUFA with the first double bond closer to the methyl end had a lower RM rate.

## Discussion

The FA composition of the tissues of the farmed sable was quite similar to another mustelid, the farmed American mink [7, 26–27] with 16:0, 18:0, 18:1n-9 and 18:2n-6 as the most abundant FA. The sc and iab WAT depots of the sable contained less total MUFA (46 vs. 52–55%) but higher proportions of total PUFA (20 vs. 10%) compared to the mink due to e.g. the high percentage of 18:2n-6 (16 vs. 7–8%). The FA profile of the sable was also very similar to the closely related farmed American marten [10], which had slightly more SFA, especially 14:0 and 20:0 in its fat tissues, while the percentages of MUFA, especially 18:1n-9, were higher in the sable. As the FA composition of the diets probably varied between the studies, the observed differences between the species could have been caused by different FA intake. The most abundant FA in the WAT of the farmed sable were also mostly the same as recorded previously for the wild raccoon dog, European brown bear (*Ursus arctos arctos*) and gray wolf (*Canis lupus*; 28).

**Table 2** Effects of fasting on the composition of the most abundant fatty acids (mol%) in total sc and iab fat tissues, plasma and livers of the sables (mean  $\pm$  SE)

sc subcutaneous, iab intraabdominal,  $\Delta$ 9-DI  $\Delta$ 9-desaturation index, PUFA polyunsaturated fatty acid, VLCFA very-long-chain fatty acid (chain length  $\geq$  24 C), UFA unsaturated fatty acid, SFA saturated fatty acid, DBI double bond index, TACL total average chain length. Also minor fatty acids not listed in the table are included in the sums

\* Significant difference between the fed and the fasted animals (*t* test, Mann–Whitney *U* test,  $P < 0.05$ ), means with no common letter indicate that the values of sc and iab fats differ at  $P < 0.05$  (one-way ANOVA)

The FA composition of the trunk WAT was very uniform in the sable and no clear differences could be detected in the FA proportions between the sc and iab fats. This is quite different from the related American mink, which has significantly lower proportions of total SFA but higher percentages of total MUFA in its sc fats compared to the iab depots [7]. In addition, the DBI and  $\Delta$ 9-DI are higher in the sc depots of the mink, which results from the high

proportions of longer-chain SFA in the iab fats. These FA have high melting points and could thus be at risk of solidification during swimming if they were concentrated in the sc depots of the mink. As a terrestrial species with good insulation against cold air, the sable does not seem to require similar FA gradients as a thermal adaptation. While it has been established that an unsaturation gradient exists also between the trunk fats and the body appendages in the

**Table 3** Effects of fasting on the composition of the most abundant saturated and monounsaturated fatty acids (mol%) in adipose tissues of the sables (mean  $\pm$  SE)

sc subcutaneous, PUFA polyunsaturated fatty acid, VLCFA very-long-chain fatty acid (chain length  $\geq$  24 C), UFA unsaturated fatty acid, SFA saturated fatty acid, DBI double bond index, TACL total average chain length. Also minor fatty acids not listed in the table are included in the sums

\* Significant difference between the fed and the fasted animals (*t* test, Mann–Whitney *U* test, *P* < 0.05)

**Fig. 1** In vivo relative mobilization of the most abundant fatty acids in the white adipose tissues of the sables fasted for 4 days, all trunk adipose tissues analyzed as a whole (mean + SE). *Positive values* indicate that the proportion of a fatty acid has decreased in the fasted animals compared to the fed control group, *negative values* signify that the proportion of a fatty acid has increased compared to the fed group. The *asterisk* indicates that the proportion (mol%) of a fatty acid in the fasted group is significantly different from the corresponding value of the fed animals

**Fig. 2** Effects of fatty acid structure on relative mobilization in the sables after 4 days of fasting, all trunk adipose tissues analyzed as a whole. *Positive values* indicate that the proportion of a fatty acid has decreased in the fasted animals compared to the fed control group, *negative values* signify that the proportion of a fatty acid has increased compared to the fed group. **a** Relative mobilization of saturated fatty acids (SFA) of different carbon chain lengths (mean + SE). **b** Correlation between relative mobilization and fatty acid chain length of monounsaturated fatty acids (MUFA), cir-

cles = n-5 MUFA, triangles = n-7 MUFA, squares = n-9 MUFA (mean ± SE). **c** Effect of fatty acid chain length on relative mobilization of selected polyunsaturated fatty acids (PUFA), \*significant difference in relative mobilization between PUFA with the same degree of unsaturation but different chain length (*t* test,  $P < 0.05$ ; mean + SE). **d** The influence of  $\Delta 9$ -desaturation on relative mobilization of selected fatty acids, \*significant difference in relative mobilization between SFA and corresponding MUFA (*t* test,  $P < 0.05$ ; mean + SE)

sable [29], it is more modest than in the American mink [7]. The terrestrial American marten also exhibits an indistinct FA gradient with a lower percentage of 18:0 and a higher proportion of 16:1n-7 in the sc fat compared to the iab depots but no differences in the total SFA, MUFA or fluidity indices, thus bearing close similarity to the sable [10].

Several changes in the relative proportions of minor FA were recorded in the fasted sables. Many of these statistically significant effects can be physiologically quite irrelevant by themselves, while the sum of these effects, e.g. changes in the n-3/n-6 PUFA balance can be important. Preferential hydrolysis of particular PUFA can have significant health effects (discussed later) or reveal details about the structural basis of FA mobilization, which has previously been shown to be selective in e.g. rats [6], American marten and mink [7, 10] and raccoon dogs [8]. According to Raclot et al. [11], the site of fat depot has no major influence on the mobilization of FA in rats and the same was established also for the American marten [10] and the sable. In contrast, the semiaquatic American mink mobilizes FA more efficiently from its iab depots compared to the sc fats probably as an adaptation to preserve fluidity in the sc depots for aquatic predation [7].

The shorter and more unsaturated FA of triacylglycerol molecules are supposedly distributed more peripherally in the lipid droplet at the water-lipid interface [30]. As a result, they could be more easily accessible to hormone-sensitive lipases and hydrolyzed during food deprivation leading to an increase in the relative amount of less polar FA in the WAT depots. This was observed also in the sables as chain length correlated negatively with RM in SFA, most MUFA and several PUFA. This seems to be a general feature of FA mobilization in mammals, as the same has been observed in rats [6], American marten and mink [7, 10] and raccoon dogs [8]. In these species, especially 20:0, 20:1n-11, 20:1n-9, 22:1n-11 and 24:1n-9 are poorly mobilized and similar phenomena were observed in the WAT of the fasted sables. Only the ventral sc fat diverged slightly from this by the relative preservation of especially 12:0, 14:0 and 14:1n-5. In addition, the proportion of 12:0 in liver increased over three-fold after 4 d of fasting. The increase in the percentages of 12:0 and 14:0 could have been caused e.g. by chain-shortening of longer FA. These mechanisms would decrease the undesirable fasting-induced changes in the fluidity by preserving those SFA that have relatively low melting points, especially in the ventral sc depot, which would be in the closest contact with snow in winter. In rats, for FA of the same carbon chain length, mobilization usually increases with the number of double bonds [6]. Similar results could be obtained from the sables, as the RM of MUFA was higher than that of the corresponding SFA in several cases. In

PUFA, there were no significant changes in RM with increasing unsaturation. These data were also quite similar to previous studies on the American marten [10].

The principle of competitive inhibition in the metabolism of PUFA in mammals suggests that n-3 PUFA are preferred over n-6 PUFA in the rate-limiting steps of desaturation reactions [31]. The more intensive RM of n-3 PUFA from the fat depots of the sable could be observed in the decrease of the n-3/n-6 PUFA ratio in the sc and iab fats. Opposite to this, the n-3/n-6 PUFA ratio and the proportion of n-3 PUFA increased in plasma as n-3 PUFA were released into the circulation to be utilized for metabolic energy. An exception was the unchanged WAT proportion of 22:6n-3, which is very important for biological membranes [32]. In fact, some of the observed decreases in the proportions of various n-3 PUFA could be due to their metabolic conversion into 22:6n-3. As a result, the relative abundance of circulating 22:6n-3 increased to be distributed to various tissues. Similar effects of fasting on n-3 and n-6 PUFA have been previously detected in the rat [30] and several carnivores [7–8, 10]. The fasted sables also had decreased proportions of 18:2n-6 in plasma, while in the other studied tissues the percentages of this important precursor of longer-chain n-6 PUFA were stable. The observed decrease could be due to altered lipoprotein profile in plasma due to fasting. It is also possible that 18:2n-6 could have been transferred into various tissues to be used in biosynthesis pathways causing the relative decrease in the plasma percentages.

It has been previously established that the lymphocyte count of the sable decreases during fasting indicating immunosuppression [18]. Important molecular regulators of the immune function derive from particular long-chain PUFA. 18:2n-6 is first metabolized into 18:3n-6, which is further converted into long-chain n-6 PUFA [31]. Of these, 20:3n-6 is the precursor of 1-series prostaglandins (PG), while 20:4n-6 and 22:4n-6 are transformed into 2- and 4-series PG. 18:3n-3 is converted via 18:4n-3 and 20:4n-3 into 20:5n-3, which is the precursor of 3-series PG, especially PGE<sub>3</sub> and leukotrienes. The decreases in 18:3n-3 and 18:4n-3 observed in the sc and iab fats of this study can be due to the conversion of these PUFA into 20:5n-3 to be used in PG synthesis. Yet also the percentages of longer-chain PUFA eventually decreased, as the 20:5n-3 proportion of WAT and the 20:4n-6 and 22:4n-6 percentages of liver decreased during fasting. This could indicate transformation of these PUFA into PGE<sub>3</sub> and 2- and 4-series PG. PGE<sub>3</sub> is especially important as it has beneficial health effects in humans, such as inhibition of lung cancer cell proliferation [33]. Increased proportions of n-6 PUFA predispose to cardiac diseases [34], while the proportions very-long-chain n-3 PUFA correlate inversely with the incidence of myocardial infarction [35]. These phenomena

could be among the causes of adverse health effects observed during prolonged food deprivation in various mammalian species experiencing preferential hydrolysis of n-3 PUFA.

The FA composition showed a high similarity between the sc and iab WAT in the terrestrial sable. The species was able to mobilize all its major sc and iab fat depots while preserving particular PUFA, such as 20:4n-6 and 22:6n-3, required for e.g. eicosanoid production and membrane stability. This was similar to another terrestrial mustelid, the American marten [10] but different from the semi-aquatic American mink, which displays a clear FA gradient of unsaturation between its sc and iab trunk fats and mobilizes FA from its iab depots more efficiently as an adaptation to aquatic predation [7]. The mechanisms of selective FA mobilization in the sable are most probably dictated by the structure of FA molecules. FA chain length and  $\Delta 9$ -desaturation seem to exert the strongest influence on the RM in the species.

# Cholesterol Oxidation is Increased and PUFA Decreased by Frozen Storage and Grilling of Atlantic Hake Fillets (*Merluccius hubbsi*)

Tatiana Saldanha · Neura Bragagnolo

Received: 30 October 2006 / Accepted: 30 March 2007 / Published online: 11 May 2007

**Abstract** Fresh fillets of Atlantic hake were stored at  $-18^{\circ}\text{C}$  for 120 days and changes in lipid composition and the formation of cholesterol oxidation products (COP) during storage and subsequent grilling were evaluated. Fresh hake showed low COP levels ( $8.0\ \mu\text{g/g}$ , dry basis); however, a significant increase in COP ( $P < 0.02$ ) and a concomitant decrease in the cholesterol and polyunsaturated fatty acids content during frozen storage and after grilling were observed. The main cholesterol oxides present in the analyzed samples were: 19-Hydroxycholesterol, 24(*S*)-hydroxycholesterol, 22(*S*)-hydroxycholesterol, 25-hydroxycholesterol, 25(*R*)-hydroxycholesterol and 7-Ketocholesterol. The oxides which were more influenced by the thermal treatment were 24(*S*)-OH and 25(*R*)-OH; however, after 120 days of storage 7-ketocholesterol was the main product formed. Frozen storage and subsequent grilling under domestic conditions are important factors in damage of cholesterol and unsaturated fatty acids levels, with consequent production of cholesterol oxides, although the mechanism of the formation of these compounds by the different processes is probably different.

**Keywords** Cholesterol · Cholesterol oxides · Storage · Heat treatment · Fatty acids

## Abbreviations

COP	Cholesterol oxidation products
FA	Fatty acids
SFA	Saturated fatty acids
MUFA	Monounsaturated fatty acids

PUFA	Polyunsaturated fatty acids
EPA	Eicosapentaenoic fatty acid
DHA	Docosahexaenoic fatty acid
19-OH	19-Hydroxycholesterol
24( <i>S</i> )-OH	24( <i>S</i> )-hydroxycholesterol
22( <i>S</i> )-OH	22( <i>S</i> )-hydroxycholesterol
25-OH	25-Hydroxycholesterol
25( <i>R</i> )-OH	25( <i>R</i> )-hydroxycholesterol
20 $\alpha$ -OH	20 $\alpha$ -Hydroxycholesterol
22( <i>R</i> )-OH	22( <i>R</i> )-hydroxycholesterol
7-keto	7-Ketocholesterol
$\beta$ -EP	5,6 $\beta$ -Epoxicholesterol
$\alpha$ -EP	5,6 $\alpha$ -Epoxicholesterol
7 $\beta$ -OH	7 $\beta$ -Hydroxycholesterol
7 $\alpha$ -OH	7 $\alpha$ -Hydroxycholesterol

## Introduction

Atlantic hake or Merluza is a member of the same family as the cod, a species economically important in South America, for normal consumption and for the processing industry. Fish is one of the main sources of animal protein available in the tropics and has been widely accepted as a good source of  $\omega$ -3 polyunsaturated fatty acids (PUFA) such as eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids. These acids appear to play a key role in neural development, functioning of the cardiovascular and immune systems [1], besides the prevention of some types of cancer, including colon, breast and prostate [2], brain aging and Alzheimer disease [3].

However, fish also show significant cholesterol contents. These two types of compounds,  $\omega$ -3 PUFA and cholesterol, are lipids susceptible to oxidation [4]. Cholesterol can

T. Saldanha · N. Bragagnolo (✉)

e-mail: neura@fea.unicamp.br

undergo oxidation to form a large amount of COP after heating at elevated temperatures for a certain period of time [5]. The triacylglycerols accelerate decomposition of cholesterol and the oxidized cholesterols are generated during peroxidation of these compounds by heating [6]. Another study [7] suggested that cholesterol in the raw materials of processed marine fish foods was oxidized in conjunction with the oxidation of polyunsaturated triacylglycerols during heat-processing and subsequent storage in air. Thus, the levels of COP in processed seafood were much higher than other food products [8].

Storage under frozen conditions has long been known as a technology for extending the shelf life of food products; however, fish and fish products can undergo undesirable changes during frozen storage and deterioration may limit the storage time [9]. Lipid deterioration is the main cause of the low shelf life of fatty fish due to progressive oxidation and enzymatic hydrolysis of unsaturated fatty acids in fish [10].

It has been reported that the intake an excess of COP may be linked to a series of physiological dysfunctions, including atherogenesis, cytotoxicity, mutagenicity, angiotoxicity, atherogenicity, carcinogenesis and cell membrane damage [11, 12]. The levels of cholesterol oxides found in various processed marine products raise some questions about the potential safety of these products, which are normally considered beneficial for the health [13]. There have been some studies [4, 7, 8, 14, 15] on the effect of heating on the formation of cholesterol oxides in complex food systems such as processed marine foods. However, studies on the effect of the frozen storage and cholesterol oxidation in fish samples have not been found.

The objective of this study was to verify the effect of grilling and domestic freezing on the formation of cholesterol oxides and alteration in the fatty acid composition in hake samples. Hake fish is commonly consumed in Brazil and the grilling and freezing reproduced the traditional way of cooking and storing them.

## Materials and Methods

### Sample Handling

Three kilogram of fresh Atlantic hake fillets were obtained from a local store in Sao Paulo, Brazil, and separated into five lots. One of them was analyzed on the day of the acquisition of the fish, corresponding to zero time. The other samples were packed in polyethylene film, stored at  $-18\text{ }^{\circ}\text{C}$  in a domestic freezer, and removed for analysis after 30, 60, 90 and 120 days. The hake fillets were thawed and cut lengthwise, one half being grilled and the other analyzed raw. The samples were grilled at  $175\text{ }^{\circ}\text{C}$  for

2 min on each side, until reaching an internal temperature of  $75 \pm 1\text{ }^{\circ}\text{C}$ . The temperature was monitored by contact, using a digital calibrated thermometer (Traceable Long-Stem, Friendswood, TX, USA). The samples were ground and homogenized in a multi-processor to obtain a homogeneous mass. Convenient aliquots were taken for the analyses, which were carried out in triplicate, and the experiment was carried out in duplicate.

### Methods

Moisture was measured as described by the AOAC [16]. The lipids were extracted and determined according to Bligh and Dyer [17]. The fatty acids composition of the hake samples was determined after methyl esterification according to Joseph and Ackman [18], followed by gas chromatography using a gas chromatograph (Varian 3400CX, Walnut Creek, CA, USA), equipped with a split injector (1:50), fused silica CP-SIL 88 capillary column  $100\text{ m} \times 0.25\text{-mm i.d.}$ ,  $0.20\text{-}\mu\text{m}$  film thickness (Chrom-pack, Middelburg, The Netherlands), flame ionization detector and workstation. The oven program was: initial temperature,  $120\text{ }^{\circ}\text{C}$  (8 min); a heating rate of  $15\text{ }^{\circ}\text{C}/\text{min}$  to a temperature of  $160\text{ }^{\circ}\text{C}$  (0 min); then a heating rate of  $4\text{ }^{\circ}\text{C}/\text{min}$  to  $195\text{ }^{\circ}\text{C}$  (12 min); and then a heating rate of  $10\text{ }^{\circ}\text{C}/\text{min}$  to a final temperature of  $230\text{ }^{\circ}\text{C}$  (25 min); injector and detector temperature  $280\text{ }^{\circ}\text{C}$ . The carrier gas was hydrogen at a flow rate  $1\text{ mL}/\text{min}$ , and nitrogen was used as the make-up gas as  $30\text{ mL}/\text{min}$ . Identification was done by comparison of the retention times of methyl ester standards (Supelco<sup>TM</sup> FAME Mix 18919-1AMP, Bellefonte, PA, USA) with those of the samples and quantification by internal standard using nonadecanoic methyl ester (Sigma, St. Louis, MO USA). The amounts obtained in  $\text{g}/100\text{ g}$  of oil were calculated according to Carpenter et al. [19].

Cholesterol and cholesterol oxides were extracted by direct saponification according to Saldanha et al. [20], and analyzed by high performance liquid chromatography. A liquid chromatograph (Shimadzu, Kyoto, Japan) equipped with UV-visible (SPD-10 AV<sub>VP</sub>) and refractive index (RID-10AV<sub>VP</sub>) detectors, rheodyne injector ( $20\text{-}\mu\text{L}$  loop), tertiary solvent delivery system (LC-10<sub>VP</sub>), oven heated column at  $32\text{ }^{\circ}\text{C}$  (CTO-10<sub>VP</sub>) and software (CLASS LC-10) was used. The analytical column used was a Nova Pack CN HP  $300\text{ mm} \times 3.9\text{-mm}$  column,  $4\text{ }\mu\text{m}$  (Waters, Milford, MA, USA), preceded by a Hypersil BDS CN  $7.5\text{ mm} \times 4.6\text{ mm}$ ,  $4\text{-}\mu\text{m}$  pre column (Alltech, Deerfield, IL, USA). The mobile-phase was *n*-hexane: 2-propanol (97:3, v/v) at a flow rate of  $1\text{ mL}/\text{min}$  and an analysis time of 30 min. Cholesterol, 5,6 $\beta$ -Epoxicholesterol ( $\beta$ -EP) and 5,6 $\alpha$ -Epoxicholesterol ( $\alpha$ -EP) were detected using a refractive index detector, and the other oxides were detected using the UV detector at 210 nm.

Identification was carried out by comparing the retention times of cholesterol, 19-Hydroxycholesterol (19-OH), 20 $\alpha$ -Hydroxycholesterol (20 $\alpha$ -OH), 22(*S*)-hydroxycholesterol (22(*S*)-OH), 22(*R*)-hydroxycholesterol (22(*R*)-OH), 25-Hydroxycholesterol (25-OH), 7-Ketocholesterol (7-keto), 7 $\beta$ -Hydroxycholesterol (7 $\beta$ -OH),  $\beta$ -EP,  $\alpha$ -EP (Sigma Chemical Company, St. Louis, MO, USA), 24(*S*)-hydroxycholesterol (24(*S*)-OH), 25(*R*)-hydroxycholesterol (25(*R*)-OH) and 7 $\alpha$ -hydroxycholesterol (7 $\alpha$ -OH) standards (Steraloids, Wilton, NH, USA) with the retention time of the samples. Quantification was done by external standardization, with a concentration range from 0.3 to 70  $\mu$ g/mL for the oxides and from 0.2 to 1.8 mg/mL for cholesterol. The quantification limits were 0.1  $\mu$ g/g for 19-OH and 20 $\alpha$ -OH; 0.18  $\mu$ g/g for 22(*R*)-OH, 24(*S*)-OH, 25(*R*)-OH and 25-OH; 0.2  $\mu$ g/g for 22(*S*)-OH, 7 $\beta$ -OH and 7 $\alpha$ -OH; 0.03  $\mu$ g/g for 7-keto; 0.02  $\mu$ g/g for cholesterol; and 0.5  $\mu$ g/g for  $\beta$ -EP and  $\alpha$ -EP. HPLC–APCI–MS was used to confirm the identity of cholesterol and cholesterol oxides in the fish samples [20].

A one-way analysis of variance (ANOVA) was applied to the data. The means of the different storage periods and preparation forms (raw and grilled) were compared using the Tukey multiple comparisons test, with  $P < 0.02$ . Software used was Origin 5.0 for Windows.

## Results and Discussion

### Moisture, Total Lipids and Cholesterol Contents

Moisture, fat and cholesterol contents in raw and grilled hake during storage time are presented in Table 1. The lipids and cholesterol were calculated on a dry weight basis.

The moisture levels ranged from  $81.8 \pm 0.2$  to  $70.3 \pm 0.3$  g/100 g in raw and grilled samples, during the storage time. Similar levels were determined by Méndez and González [21] in raw Atlantic hake (81.2 and 81.6 g/100 g) caught in March and September. Grilling affected the moisture contents significantly ( $P < 0.02$ ) as well as freezing after 60, 90 and 120 days of storage.

The lipid contents varied from  $12.6 \pm 0.6$  to  $7.9 \pm 0.7$  g/100 g in raw and grilled hake, over the storage time. After 120 days of storage a significant increase ( $P < 0.02$ ) in the lipid was observed in raw fillets. In refrigerated and frozen conditions, the published results [22–26] indicate that the extractability of the lipids may be affected by the changes in the protein–lipid complexes in the fish tissues during storage, which results in a more complete extraction by solvents and the proportion of fat increases. Thus, the changes observed in this experiment may be related to the weakening of the lipid–protein bonds that in turn facilitate the fat extraction from thawed hake. On the other hand,

**Table 1** Moisture (g/100 g), total lipid (g/100 g, dry basis) and cholesterol (mg/100 g, dry basis) levels in raw and grilled Atlantic hake during 120 days of storage

	Zero time		30 Days		60 Days		90 Days		120 Days	
	Raw	Grilled	Raw	Grilled	Raw	Grilled	Raw	Grilled	Raw	Grilled
Moisture	$81.80 \pm 0.2^A$	$73.30 \pm 0.5^a$	$80.90 \pm 0.9^{AB}$	$72.70 \pm 0.6^{ab}$	$80.10 \pm 0.9^B$	$71.90 \pm 0.4^b$	$79.50 \pm 1.0^{BC}$	$70.90 \pm 0.7^{bc}$	$78.80 \pm 0.3^C$	$70.30 \pm 0.3^c$
Total lipids	$9.40 \pm 0.2^D$	$7.90 \pm 0.7^d$	$10.70 \pm 0.7^C$	$9.20 \pm 0.5^c$	$11.40 \pm 1.0^{BC}$	$10.00 \pm 0.8^b$	$11.80 \pm 0.4^{AB}$	$10.50 \pm 0.5^b$	$12.60 \pm 0.6^A$	$11.40 \pm 0.4^a$
Cholesterol	$277.70 \pm 0.9^A$	$232.20 \pm 2.2^a$	$266.90 \pm 2.5^B$	$217.40 \pm 0.3^b$	$230.50 \pm 2.9^C$	$185.20 \pm 1.5^c$	$221.30 \pm 1.4^C$	$168.00 \pm 1.7^d$	$196.60 \pm 3.9^P$	$152.30 \pm 5.7^c$

Values are mean  $\pm$  standard deviation of the six analysis (two lots analyzed in triplicates). Values bearing different letters (capital letters) are significantly different ( $P < 0.02$ ) at the storage time in the raw samples. Values bearing different letters (small letters) are significantly different ( $P < 0.02$ ) at the storage time in the grilled samples. All the raw and grilled samples are significantly differences

Values are means ± standard deviation of the six analysis (two lots analyzed in triplicates). All the raw and grilled samples are significantly different ( $P < 0.02$ ). Values bearing and different letters (capital letters) have significant differences ( $P < 0.02$ ) at differing storage times in the raw samples. Values bearing different letters (small letters) have significant differences ( $P < 0.02$ ) at various storage times in the grilled samples

after grilling, significant ( $P < 0.02$ ) losses of the lipid contents were observed, from 9.5 to 16%. Although fish do not have adipose tissue, the fat excess is stored as peripheral triacylglycerols in muscle, a fact that may favour fat loss when a high grilling temperature is used to cook the fish [27].

The cholesterol content in fresh hake was  $277 \pm 1$  mg/100 g, and the levels were significantly lower ( $P < 0.02$ ) during frozen storage and after grilling. The loss of cholesterol by heating is extremely rapid when the heating temperature is above 175 °C [28]. Other studies [4, 29] showed a decrease in the cholesterol levels after heat treatment in fish samples. Some cholesterol contained in foods is subjected to oxidizing conditions during processing, preparation and storage [6]; thus, the changes in cholesterol content during this experiment could probably be attributed to the oxidative process.

### Fatty Acid Composition

The fatty acids composition and the effects of grilling and frozen storage on the individual fatty acids of Atlantic hake are presented in Table 2, expressed in g/100 g of oil.

In the total fatty acids (FA) determined in raw samples 29% corresponded to saturated fatty acids (SFA), of which palmitic acid was present in the highest amounts. Another 35% were monounsaturated fatty acids (MUFA), with oleic acid as the most abundant one. The percentage of polyunsaturated (PUFA) was 36%, consisting mostly of DHA and EPA fatty acids. These findings are in agreement with those obtained by other studies in hake samples [21, 29]. A significant ( $P < 0.02$ ) decrease was observed in the PUFA and *trans* fatty acids contents after 120 days of storage. Oxidative reactions occur in the lipid fraction of frozen foods, and tend to increase with higher oxygen permeability of the packing material and higher fat content in the muscle [30, 31]. These oxidative reactions are initiated in the highly susceptible membrane-bound phospholipids, and this process particularly affects unsaturated lipids [32]. In this study, the hake fillets were only stored in plastic film and under similar domestic conditions; moreover, the samples presented high contents of unsaturated fat, factors that can accelerate the oxidative peroxidation in hake samples, causing the important losses in the unsaturated fatty acids content. Another factor to be considered is the presence of the lipolytic enzymes that remain active in the uncooked fish during frozen storage at  $-18$  °C [33].

After grilling a significant decrease ( $P < 0.02$ ) was observed in the total amount of FA, mainly of MUFA and PUFA in all the analyzed times. The losses were between 12 and 13% in FA; 11 and 15% in MUFA, and from 14 to 22% in PUFA contents. As already observed, PUFA

are more susceptible to thermal oxidation than their MUFA analogues, especially at elevated temperatures. During the grilling process, fish are subjected to heating and atmospheric oxygen and these two factors can accelerate the oxidative deterioration of fish fat, and lipid oxidation in grilled hake should also be considered. Therefore, the loss of PUFA from grilling suggests the formation of hydroperoxides to some extent in the grilled samples [34]. In contrast, the content of *trans* fatty acids increased from between 24 and 48% after heat treatment, although Candela et al. [29] observed that the *trans* fatty acids were not uniformly affected by cooking in hake samples.

Eicosapentaenoic and DHA fatty acids are typical of fish fat, and these products have an essential role in human diet to prevent diseases. Fresh hake showed the highest levels of these  $\omega$ -3 fatty acids,  $6.2 \pm 0.3$  and  $18.9 \pm 0.8$  g/100 g for EPA and DHA, respectively. Grilling produced a significant reduction in these values, namely between 20 and 39% for EPA; 11 and 16% for DHA. These results are in agreement with other studies [7, 34], that reported a decrease in the EPA and DHA levels in fish samples during grilling. However, other authors observed that the heat treatment of the raw fish species did not cause a significant decrease in the EPA + DHA contents [35]. Candela et al. [36] observed that the changes in the EPA and DHA contents after cooking were related to the initial amount in the raw fish and therefore to the species, in addition, this change may be due to differences in cooking methods [35].

After 120 days of storage, a significant decrease ( $P < 0.02$ ) in EPA and DHA contents was observed, around 36% in raw hake samples. The losses of these compounds after grilling and during frozen storage probably have been related to the autoxidation of lipids.

The  $\omega$ 3/ $\omega$ 6 ratio was not uniformly modified in hake samples. During freezing this ratio remained constant after 30 and 60 days; however, an increase in the  $\omega$ 3/ $\omega$ 6 ratio after 90 and 120 days of storage was observed. No significant changes were observed in the  $\omega$ 3/ $\omega$ 6 ratio after grilling, only an increase at 60 days of storage. The ratio of PUFA/SFA was significantly reduced during frozen storage and after grilling in all evaluated samples.

### Cholesterol Oxides

Cholesterol oxides determined in hake samples (dry basis) are presented in Table 3. Six COP (Fig. 1) were determined in hake samples: 24(*S*)-OH, 22(*S*)-OH, 25(*R*)-OH, 25-OH, 19-OH and 7-keto, although twelve products were researched. The most oxides were originated from the cholesterol side chain, and only two oxides (19-OH and 7-keto) were originated from the main chain. In fish foods,

Values are means  $\pm$  standard deviation of the six analysis (two lots analyzed in triplicates). All the raw and grilled samples are significantly different ( $P < 0.02$ ). Values bearing different letters (capital letters) have significant differences ( $P < 0.02$ ) at different storage times in the raw samples. Values bearing different letters (small letters) have significant differences ( $P < 0.02$ ) at different storage times in the grilled samples

the B-ring oxidation products such as: 7-keto, 7 $\beta$ -OH, 7 $\alpha$ -OH, 5,6 $\alpha$ -EP and 5,6 $\beta$ -EP were dominant in the total of COP [4, 7, 8, 14, 15, 34]. Normally, 25-OH was the only side chain COP found in seafood products [15], even so under the chromatographic conditions used in the present study it was possible to separate and to identify a large number of the oxides originating from the lateral chain oxidation, normally not determined in food products.

Quantitatively, the most abundant oxides were 25-OH (4.1–23.8  $\mu\text{g/g}$ ) and 19-OH (2.1–15.2  $\mu\text{g/g}$ ) in raw and grilled samples. 7-keto, the major oxide found in food systems and considered an indicator of oxidation was not observed in fresh hake, only in the defrosted or grilled samples. Probably, this oxide had been formed by oxidative processes during frozen storage and after thermal treatment. It is likely that when different fats coexist, cholesterol is oxidized even when it is not heated. The presence of oxidized cholesterol in the nonheated or moderately heated processed marine products suggested that the degree of unsaturation of food fats may influence the production of these oxides [8].

The total COP contents increased significantly ( $P < 0.02$ ) after grilling, with rises between 57 and 131%, being his difference higher in zero time. In relation to the individual oxides 24(S)-OH and 25(R)-OH had more pronounced increases, with 350 and 335%. According to Osada et al. [8] the autoxidation of cholesterol may occur in a short time when subjected to temperatures above 120 °C. Moreover, the PUFA in seafood are oxidized during processing such as a heating at high temperatures during which peroxy radicals or singlet oxygen are formed. These radicals interact with cholesterol and promote oxidation of sterols [37]. According to Al-Saghir et al. [38] the higher degree of unsaturation, the higher the lipid oxidative process, and the more COP are formed. In another study, the levels of 7-keto were significantly higher when heating more unsaturated oils [28]. Considering the amounts of PUFA found in the fresh hake and the temperature of grilling, the increase in oxide formation after thermal treatment can be understood.

During frozen storage, the oxide contents exhibited a gradual and significant increase ( $P < 0.02$ ) in the evaluated samples. Among the COP, the 7-keto formation was the highest, followed by 22(S)-OH and 24(S)-OH. After 120 days of storage, the increase in the total of oxides in raw hake was 876%, demonstrating that the frozen storage in domestic conditions increases significantly the susceptibility to oxidation. According to the results obtained, it can be considered that the frozen storage brings about more oxide formation than the grilling.

Observing the degree of formation of the cholesterol oxides it can be concluded that the temperature employed is an important factor in the production of these

**Fig. 1** Chemical structures of cholesterol and cholesterol oxides found in raw and grilled Atlantic hake

compounds, although the mechanisms of formation by thermal treatment and frozen storage are probably different. In agreement, Kim and Nawar [39] suggested that in the cholesterol oxidative process, these reactions and interactions may be significantly influenced by the reaction conditions, e.g., temperature, type and concentration of the components.

## Conclusions

In this study it was evident that frozen storage at  $-18^{\circ}\text{C}$  and subsequent grilling are the important factors in the changes in the lipid profile and consequent rise of the cholesterol oxides in hake samples. Frozen storage had a greater effect on the production of oxides than grilling, and the mechanisms of formation for thermal treatment and frozen storage are probably different. Due to the complexity of the food itself, it is difficult to study cholesterol oxidation in real food systems. Therefore, more systematic research on cooking methods and prolonged storage under domestic conditions and its consequences for lipidic composition, with emphasis on cholesterol oxide production in fish samples is necessary.

**Abstract** In this study multivariate analysis of Raman spectra has been used to classify adipose tissue from four different species (chicken, beef, lamb and pork). The adipose samples were dissected from the carcass and their spectra recorded without further preparation. 102 samples were used to create and compare a range of statistical models, which were then tested on 153 independent samples. Of the classical multivariate methods employed, Partial Least Squares Discriminant Analysis (PLSDA) performed best with 99.6% correct classification of species in the test set compared with 96.7% for Principal Component Linear Discrimination Analysis (PCLDA). Kohonen and Feed-forward artificial neural networks compared well with the PLSDA, giving 98.4 and 99.2% correct classification, respectively.

## Introduction

The adulteration of foodstuffs is a major problem for the specialist food markets. Many foods can become contaminated through careless handling, or through unintentional or deliberate intervention. Many expensive products are adulterated with cheaper alternatives to increase profit margins, or expensive ingredients are replaced with a cheaper alternative. In some cases this action simply reduces the quality of the product, but such practices may even have moral and ethical implications. Many religions and cultures ban the consumption of various foodstuffs, and it is of particular interest to these religious groupings to prevent the inadvertent consumption of the prohibited substance. A rapid, non-destructive technique for classifying the species from which a fat originates would allow more extensive testing of samples than more laborious traditional methods (e.g. chromatography or “wet chemistry”). Traditional methods are necessarily confined to smaller sample sets for reasons of practicality.

The potential of Raman spectroscopy for the analysis of fats and oils has been recognised for some decades [1–3]. The main advantages of the technique are that no sample preparation is required (allowing in situ or on-line studies) and that it can be applied to any physical state including liquids, gels, amorphous solids and crystals. However, until

recently, adoption of Raman methods for routine analysis of fats and oils has been hindered by the high cost and complexity of the instrumentation required. This situation is now changing rapidly; a number of technological advances such as holographic notch filters for rejection of elastically-scattered light and the availability of long wavelength (750–1,064 nm) excitation lasers (which reduce background fluorescence problems) are making the technique more accessible than ever before and the introduction of simple-to-use commercial instruments means that it is straightforward for non-specialists to record good quality Raman data.

Since technical problems no longer dominate the field there are clear opportunities for routine analysis by Raman spectroscopy. Indeed, it has already been successfully used to determine important composition/physical structure parameters relevant to the analysis of animal fats. These include: *cis/trans* geometrical isomer ratio [4], molar unsaturation (C = C per molecule) [4], mass unsaturation (C = C per unit mass, molal, degree of unsaturation) [2, 5], conjugated double bond content [6], chain length [7], lipolysis [8], fatty acid composition [9, 10], crystal structure [11] and adulteration [12].

Due to the high information content of the Raman signal it is typically necessary to reduce the number of variables to a more manageable number. Multivariate statistics [13] are capable of simultaneously analysing multiple variables and combining interrelated variables such as the pattern of Raman bands that match particular components of a sample. Principal component analysis (PCA) is a nondirected, non-supervised method of data reduction, which determines the main sources of variation within the spectra, allowing transformation of several related data points into a single number. Projection to latent structures discriminant analysis (PLSDA) differs from PCA in that each source of variation is not ranked in relation to the overall variation, but according to how it accounts for variation between data subsets (groups). This has the consequence that PLSDA typically refines the discrimination by ignoring data variations that do not contribute to group separation, reducing any disruptive influence these sources may have. An alternative to multivariate statistics that has become popular in recent years is the use of non-linear algorithms based on the structure of animal brains. These artificial neural networks (ANN) are structured with an input that connects with hidden calculation 'neurons' that convert the input into an output. ANNs are capable of forming pathways between any 'neurons' in adjacent layers allowing complex non-linear connections to be made. As with animal brains these ANNs have to be trained first using training data in order to learn how to transform the data from the raw input into a reference value.

This paper is part of series investigating the application of Raman spectroscopy to the analysis of fatty acid based

fats and oils, from models systems to complex 'real life' samples [7, 9, 10, 14, 15]. The aim of this paper is to investigate the extent to which the species of an adipose tissue sample can be classified from its Raman spectrum.

## Experimental

The samples used in this investigation were subcutaneous adipose tissue dissected from above the longissimus dorsi muscle in the position of the 12th rib for beef, lamb and pork, and from above the breast for chicken. In order to obtain a wide range of variation within each species the samples were obtained from a number of commercial and experimental sources and included a wide variety of breeds and feeding regimes. Spectra were accumulated at ambient temperature (19–21 °C) from each side (towards the skin and inner) of the samples and were stored and processed separately, giving 2 spectra for each animal. A total of 255 spectra were recorded (84 pork, 82 beef, 53 lamb and 36 chicken). Samples were obtained from a number of research sources and were all dissected within 48 h of slaughter.

### Gas Chromatography

Fatty acid composition was determined on a subset of 74 of the samples following lipid extraction, preparation of fatty acid methyl esters and analysis by gas chromatography, as described previously [10]. The total combined abundance of PUFAs was determined by summing the relative abundances of all the polyunsaturated fatty acids including those only detected in pork and chicken (half of the samples).

### Raman Spectroscopy

Raman measurements were carried out using a home-built system previously described [9] with line-focused 785 nm excitation (typically 100–120 mW at the sample). The Raman signal was recorded from 270 to 1,900  $\text{cm}^{-1}$ , the region containing the C–C, C = C, C–O and C = O stretches and the C–H bends. The spectra were processed as described previously [9] using a standard 14-point linear baseline subtraction.

The classification of the spectra using a number of statistical routines was compared for PCA, PLSDA, Feed forward networks and Kohonen Maps. The data were normalised about the carbonyl stretching band at ca. 1,745  $\text{cm}^{-1}$  and mean centred prior to analysis. The data was split into a training (102 samples) and an independent test (153) set (replicates of any sample were retained in the same set). Comparison of the different methods was by the

percentage of the test-set samples which were classified as belonging to the correct species of origin for each sample. PLSDA and the PCA data reduction steps were carried out using Simca-P 8.0 (Umetrics, Umeå, Sweden), while Linear Discriminant Analysis (LDA) of the PCA-reduced Raman data was performed in SPSS V13.0. Feed forward networks and Kohonen maps were calculated using a beta version of a neural network package Antbrain, developed by CB.

## Results and Discussion

In our previous papers we investigated the effect of altering either chemical composition or physical state on the experimental and calculated Raman spectra of model FAMES [7, 14, 15]. We also investigated the use of Raman spectra to predict the fatty acid composition of clarified butterfat and adipose tissue [9, 10]. In this paper, an expanded adipose tissue data set was employed. The samples were again studied at ambient temperature where the physical state depends on the fatty acid composition, positional isomerisation and any inherent matrix ordering/disordering effects, which vary between species and to a lesser extent between individual animals of the same species. Since it was previously found that the variation in physical state caused by chemical differences between the samples enhanced the information content of the Raman spectrum of fatty acid lipids, use of ambient temperature measurements should maximise the spectral difference between species [10]. Figure 1 shows the average Raman spectrum of adipose tissue from each of the species used in this experiment and it is clear that the samples exhibited mixed phases, the spectra exhibit sharp solid phase bands (e.g. 1,060 and 1,130  $\text{cm}^{-1}$ ) superimposed on broad liquid phase bands (e.g. 1,090  $\text{cm}^{-1}$ ). Comparison with the spectra previously published on a smaller set of samples (20 for each species) shows that the expanded dataset retains the superficial similarities and differences observed in that set. The assignments of the major bands have been given previously [10].

## Classification

Much of the early work on Raman spectroscopic analysis of fatty acids concentrated on the bulk properties, and in particular unsaturation [2, 4, 16]. The average bulk properties of the adipose tissue of the four species investigated here were calculated from the GC profile of the fat extracted from a subset of samples [10] and are shown in Table 1. It is immediately apparent that the species differences between these average bulk parameters are small. For example,

**Fig. 1** Average Raman spectra for the four species investigated in this study (beef, lamb, chicken and pork), recorded using 785-nm excitation

**Table 1** The average chemical subunit content for each of the species, derived from the subset used for GC analysis

Parameter (per chain)	Species	Average	Standard deviation
Total number of carbons (No. of C)	Pork	17.573	0.053
	Chicken	17.383	0.024

	Chicken	0.872	0.096
	Pork	0.089	0.049

For each chemical subunit the samples are arranged in descending order

although there are detectable differences between pork and chicken adipose tissue (pork has a higher average chain length and higher average number of double bonds per molecule) there is a marginal difference in the main bulk

chemical properties of the lamb and beef adipose samples, apart from a slightly higher proportion of *trans* fatty acids in the beef within this subset of samples analysed by GC. At the simplest level, these changes in bulk composition are reflected in the average Raman spectra from each of the species (Fig. 1). Unsaturation gives rise to bands around  $1,270\text{ cm}^{-1}$  ( $=\text{C}-\text{H}$  bend) and  $1,660\text{ cm}^{-1}$  ( $\text{C}=\text{C}$  stretch)  $\text{cm}^{-1}$  and the spectrum of pork adipose tissue shows the largest bands at these positions, followed by chicken and then beef and lamb, which are both very similar, reflecting the expected composition of the four species. The largest difference between the beef and lamb spectra is the small shoulder at  $1,670\text{ cm}^{-1}$  on the  $1,660\text{ cm}^{-1}$  band of the lamb spectra, which corresponds to *trans* isomers. This indicates that the *trans* content of lamb in the expanded dataset for the Raman (Fig. 1) contains significantly more *trans* than the smaller GC subset (Table 1), illustrating the problem of depending on simple univariate measurements for discriminating species. In practice, we have found that it is not possible to reliably classify the species (75% correct classification) of a given sample on the basis of simple measurements of those band intensities that correspond to bulk properties. This can be attributed to the overlap in the values of various parameters between some species since the composition of each species is affected by many other factors including age, breed, feed, sex and climatic conditions [17–20].

Using the GC-calculated bulk properties simultaneously as input into PLSDA gives 93% correct classification (full cross validation), with 10% of the beef and lamb samples misclassified as each other. This is significantly better than the 75% correct classification rate obtained by using the classical spectroscopic method of a single band ratio. In Fig. 2, the score plot for the two most significant components from the PLSDA analysis of the bulk values, shows

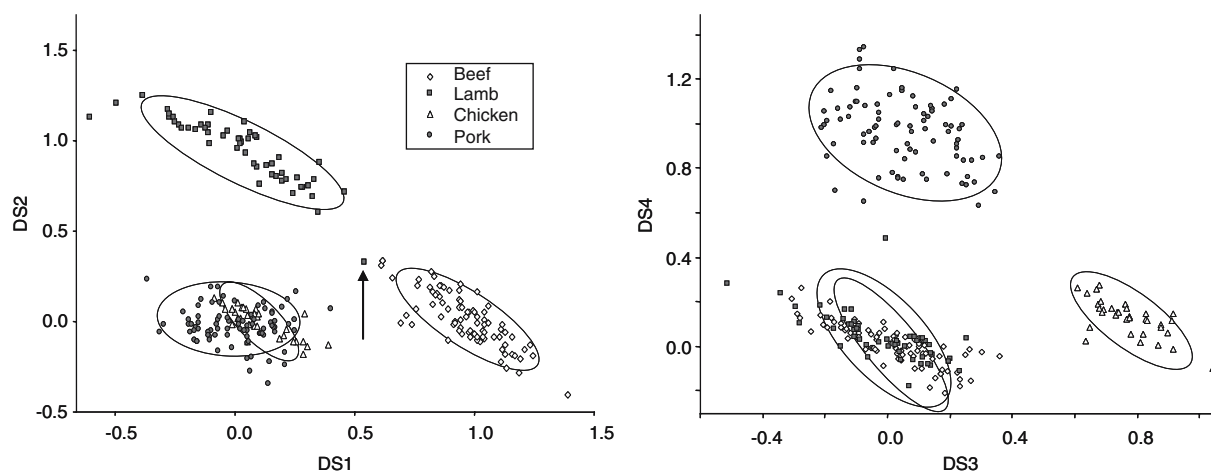

**Fig. 2** Score plot obtained from PLSDA of the bulk values of the adipose tissue, as calculated from fatty acid composition. The two ruminant species are not well separated by the major components, but they are isolated from the non-ruminant species

that the chicken and pork are well separated from each other and from the beef and lamb samples. Subsequent components improve the separation of the beef and lamb (data not shown). However, the beef and lamb do overlap considerably, accounting for the classification errors. Using the full fatty acid composition data obtained from the GC to classify the species was 100% successful when using all the fatty acids recorded, even if, for some of the species, they were below the cut off limit for detection on the GC instrument. This clearly demonstrates that a method capable of providing information on the detailed chemical composition of a lipid has the potential to classify the species of an adipose tissue sample.

Since we have previously demonstrated that multivariate analysis of Raman spectra can be used to quantify the relative abundances of various fatty acids in adipose tissue [10], it might be expected a similar level of differentiation between adipose tissue taken from different animal species could be achieved by using multivariate data analysis rather than the simple gross measurements of the intensities of the small number of well-known bands that correlate with bulk properties described above.

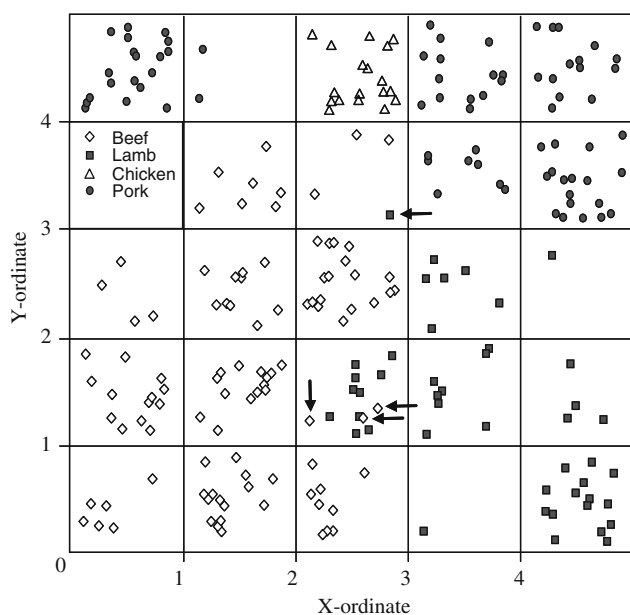

Multivariate data reduction combined with discriminant analysis was indeed found to be capable of accounting for the subtle differences between the species. PCA data reduction on the adipose Raman data set followed by LDA allowed 97.6% correct classification of the samples in LDA, while using the PLSDA method further improved the correct classification rate to 99.61% (Fig. 3), i.e. only one sample incorrectly assigned. The improvement given by the PLSDA method is expected since the data reduction step is designed to determine the variation that gives rise to the maximum group separation, in contrast the PCA reduction prior to LDA is based on variation without respect to the grouping of the samples. The PLSDA method used 80 % of the total variation within the dataset to explain the difference between the groups, which explains why the Raman spectrum is such a powerful discriminatory tool. By using simple manual measurements of the intensities of the characteristic marker bands we would reduce 1,152 variables (the number of data points in each spectrum) to around 10—thus using only ca. 1% of the information. However, by using multivariate data reduction fewer than 10 variables (factors) can retain 80% of the information contained in the original data with its 1,152 variables.

The data were then run on a Kohonen map, with PCA preprocessing at unit variance. The underlying structure of Kohonen maps is a grid of vectors (ca. average spectrum) that accounts for all the spectral variation observed, with incremental changes between each cell. The location of a sample within a particular square indicates it is most similar to that vector, and its distance from the centre relates

**Fig. 3** Discriminant score (calculated from a function of the eight components shown in Fig. 6) plots showing how the calculated discriminant score separates out the test set samples. 95% confidence intervals are shown, incorrectly classified samples are marked with an *arrow*

how similar it is to the vector for that square. This means that similar spectra group closely together, while dissimilar spectra will be well separated in the grid. The Kohonen map (Fig. 4) marginally improved the separation of PCA preprocessed spectra compared to LDA, but was not as successful as the PLSDA, since 1.6% of the samples (3 beef, 1 lamb) were incorrectly classified. The samples were also run on a feed forward network, using PCA preprocessing (scaled to unit variance) to obtain a regression to predict species. The feed forward network yielded a stan-

**Fig. 4** Kohonen map showing the separation of subcutaneous adipose tissue into different species (beef, lamb, chicken and pork), using the Raman spectra of intact adipose tissue, recorded at 19–21 °C. Key has been placed in empty cell for convenient reference. Misclassified spectra are indicated by *arrows*

dard error of prediction of just 0.027 (Fig. 5). Only two (0.8%) of the samples were incorrectly classified (less than 0.5 from the mean for the species), which is only one sample more than using the PLSDA method.

Figure 6 shows the loadings used by the PLSDA method to reduce the spectral data to the scores that were used in the discriminant analysis and the plot of those resultant scores in Fig. 3. The first two PLSDA components are the most important and are shown as a score plot in Fig. 7, in the figure there is a clear difference between the ruminant (beef and lamb) from the non-ruminant (chicken and pork) samples in the first component. Comparison of the Raman bands used in the relevant loading plot (Fig. 6, loading 1) with their assignments [10] show that the bands accounting for this divide are unsaturated (positive peaks, more intense

**Fig. 5** Feed forward network prediction of species using the Raman spectra of intact subcutaneous adipose tissue recorded at 19–21 °C. Incorrectly assigned samples marked with a *black arrow*

**Fig. 6** PLSDA loadings for the significant components used to reduce the Raman variables to a discriminant function allowing classification of the species of origin from a Raman spectrum of adipose tissue. The numbering refers to the order of significance of each loading from 1 for the most significant to 8, the least significant

**Fig. 7** Score plot of the two major components obtained from PLSDA of the Raman data. There is a clear separation of ruminant (beef and lamb) from non-ruminant (pork and chicken), but further components are required to separate each of these groups

in spectra of non-ruminant samples) against saturated (negative peaks, more intense in ruminant samples). This result agrees with the data presented in Table 1.

Component 2 partially separates lamb from the beef (Fig. 7) and the loadings appear to be a complex array of subtle physical changes in the Raman spectrum (Fig. 6, loading 2), with conformation-sensitive bands showing shifts in intensity such as the *trans/gauche* sensitive C–C

stretching modes between 1,060 and 1,130  $\text{cm}^{-1}$ , the  $\text{CH}_2$  twisting mode 1,293/1,305  $\text{cm}^{-1}$  and the olefinic conformation band at 1,655  $\text{cm}^{-1}$ . Also contributing is a negative component related to *trans* isomers of the olefinic bonds, which typically are implicated in the overall physical properties of fatty acid mixtures, even when in low abundance.

The higher numbered components are a complex mixture of other subtle physical interactions (conformation of the fatty acid chain and changes in chain packing) and chemical changes. For example the third loading is similar to the second but contains a significant contribution from the  $\text{CH}_2$  scissoring region (1,400–1,500  $\text{cm}^{-1}$ ), which is highly sensitive to the packing of the fatty acid chains and the extent of intermolecular order (as opposed to the intramolecular order reflected in the C–C stretching and  $\text{CH}_2$  twist regions mentioned above). The second and third components are superficially similar but there are a number of subtle, though significant, differences. This is explained by the fact that the inter- and intra-molecular properties of fatty acid chains are influenced by the same environmental parameters (hence broadly the same pattern of changes), but they react to the environment independently of each other (accounting for the subtle differences).

Interpreting each loading is beyond the scope of this investigation; however the overall understanding is that the discrimination is based on not just the chemical differences in the fatty acid composition of the different species, but also the complex physical variations that are a result of interactions between these various fatty acids.

Raman spectroscopy has many advantages in the analysis of food lipids in that it requires no sample preparation and yet has excellent prediction ability even for the species of origin (for example, where the fatty acids that show significant variation between lamb and beef fat are present at <2.3%) or the abundance of minor fatty acids [10]. It is also simple to adapt the method to a range of applications giving a range of levels of information, especially in combination with appropriate statistical methods capable of maximising the use of the information contained within the Raman spectrum. For example, here we have demonstrated that the spectrum that has been recorded can be used to accurately determine the species of the sample (this is most effective in conjunction with PLSDA) while previous studies showed that the level of unsaturation [7], the solid fat content [9], or the abundance of individual fatty acids [10] (in conjunction with PLS) can also be determined from Raman spectra. Another major advantage is the level of diagnostic capability arising from the well-understood relationship between the Raman spectrum and factors (chemical and physical) that influence it.

This study has clearly demonstrated that the combination of Raman spectroscopy with multivariate and neural

network analytical methods allows the species of an adipose tissue sample to be assigned according to its Raman signal with greater than 99% accuracy. It was found that classical univariate methods of using the Raman signal were unable to give a satisfactory classification as the differences between some of the species were very subtle and univariate methods only retain <1% of the spectral information. The type of multivariate analysis or neural network made little difference to the classification rate, though PLSDA and feed-forward networks performed slightly better than LDA and Kohonen networks, both employing PCA preprocessing.

## Arachidonic Acid but not Eicosapentaenoic Acid (EPA) and Oleic Acid Activates NF- $\kappa$ B and Elevates ICAM-1 Expression in Caco-2 Cells

**Abstract** In patients with inflammatory bowel disease (IBD), intestinal activation of the transcription factor NF- $\kappa$ B as well as intercellular adhesion molecule (ICAM)-1 expression, which is involved in recruiting leukocytes to the site of inflammation is increased. Moreover, colonic arachidonic acid (ARA) proportions are increased and oleic acid (OA) proportions are decreased. Fish oils are protective in IBD patients however, a side-by-side comparison between effects of fish oils, ARA and OA has not been made. We therefore, compared effects of eicosapentaenoic acid (EPA) versus ARA and OA on ICAM-1 expression in Caco-2 enterocytes. To validate our model we showed that dexamethasone, sulfasalazine and PPAR $\alpha$  (GW7647) or PPAR $\gamma$  (troglitazone) agonists significantly lowered ICAM-1 expression. ICAM-1 expression of non-stimulated and cytokine stimulated Caco-2 cells cultured for 22 days with ARA was significant higher as compared to EPA and OA. Furthermore, ARA increased NF- $\kappa$ B activation in a reporter cell-line as compared to EPA. Antibody array analysis of multiple inflammatory proteins particularly showed an increased monocyte chemotactic protein (MCP)-1 and angiogenin production and a de-

creased interleukin (IL)-6 and IL-10 production by ARA as compared to EPA. Our results showed that ARA but not EPA and OA activates NF- $\kappa$ B and elevates ICAM-1 expression in Caco-2 enterocytes. It suggests that replacement of ARA by EPA or OA in the colon mucosa might have beneficial effects for IBD patients. Finally, we suggest that the pro-inflammatory effects of ARA versus EPA and OA are not related to PPAR $\gamma$  activation and/or eicosanoid formation.

### Abbreviations

ARA	Arachidonic acid
CD	Crohn's disease
COX	Cyclooxygenase
EPA	Eicosapentaenoic acid
GRO	Growth regulated protein
IBD	Inflammatory bowel disease
ICAM	Intercellular adhesion molecule
IFN	Interferon
IL	Interleukin
MCP	Monocyte chemotactic protein
MIP	Macrophage inflammatory protein
MUFA	Monounsaturated fatty acid
NF- $\kappa$ B	Nuclear factor-kappa B
OA	Oleic acid
PGE <sub>2</sub>	Prostaglandin E <sub>2</sub>
PPAR	Peroxisome proliferator-activated receptor
PUFA	Polyunsaturated fatty acid
UC	Ulcerative colitis

## Introduction

Epidemiological studies have shown a low incidence of inflammatory bowel disease (IBD) in Eskimo's as compared to West-European populations [1] and increasing incidences of IBD in Japan [2]. These findings suggest that an increased dietary intake of n-6 polyunsaturated fatty acids (PUFA) and a lower intake of n-3 PUFAs contribute to the development of IBD. Thus, n-3 fish oil PUFAs may have anti-inflammatory effects as compared to n-6 PUFA [3]. Indeed, elevated proportions of the n-6 PUFA arachidonic acid (ARA) in colon mucosa of both ulcerative colitis (UC) and Crohn's disease (CD) patients as compared to those of control subjects have been shown [4–7]. Although the proportion of the n-3 PUFA eicosapentaenoic acid (EPA) in the mucosa was in most studies not statistically different between IBD patients and healthy controls, one study reported a tendency towards lower EPA proportions in IBD patients [4]. In contrast to EPA, the proportion of the fish oil PUFA docosahexaenoic acid (DHA) was elevated in colonic mucosa of IBD patients as compared to control subjects [4, 5, 7]. Interestingly, the proportion of the n-9 monounsaturated fatty acid (MUFA) oleic acid (OA) was lower in colon mucosa of IBD patients [4, 7]. Because of these observations, and because EPA is a more important precursor of eicosanoids than DHA [8], we decided to compare the effects of EPA versus ARA and OA in an in vitro model of intestinal inflammation. OA is already the most abundant fatty acid present both in our diet [9] as well as in colon mucosa [4]. Therefore, and because of differences in ability to compete with ARA for incorporation in tissue phospholipids [10, 11], it is probably easier to lower mucosal ARA levels by increasing fish oil intake than by increasing OA intake. Indeed, by increasing their intake of fish oil, ARA in the colon mucosa of IBD patients was replaced by EPA and DHA [12], which was associated with significantly reduced corticosteroid requirements [12] and lower relapse rates [13]. It should be noted however, that not all intervention studies using fish oils were that positive, although the overall conclusion is that fish oil supplementation shows at least minor protective effects [14].

The intercellular adhesion molecule (ICAM)-1 plays an important role in the pathology of IBD. In IBD patients intestinal ICAM-1 expression [15] and plasma levels of soluble ICAM-1 (sICAM) are increased [16], and IBD is associated with polymorphisms in the gene encoding for ICAM-1 [17]. Moreover, animal models [18, 19] and a human intervention study [20] have shown that ICAM-1 blocking inhibited intestinal inflammation. The transcription factor NF- $\kappa$ B is a key regulator of the inflammatory response and activation of NF- $\kappa$ B seems to play a critical role in the initiation and perpetuation of intestinal inflam-

mation in IBD [21, 22]. NF- $\kappa$ B activity in the colon is increased during active episodes in IBD patients and certain anti-inflammatory drugs commonly used for IBD appear to inhibit NF- $\kappa$ B [23–27]. In animal models, NF- $\kappa$ B blockade abolished experimental colitis [28, 29]. A side-by-side comparison of the n-3 PUFA EPA, the n-6 PUFA ARA and the n-9 MUFA OA on ICAM-1 expression and NF- $\kappa$ B activation of intestinal cells has, as far as we are aware of, never been performed. Therefore the aim of the present study was to compare the effects of EPA, ARA and OA on ICAM-1 expression and NF- $\kappa$ B activation in the human intestinal epithelial Caco-2 cell line in vitro.

## Materials and Methods

### Reagents

Bovine serum albumin (BSA; endotoxin and fatty acid-free), sulfasalazine, dexamethasone, GW7647, oleic acid (OA), arachidonic acid (ARA), eicosapentaenoic acid (EPA) and indomethacin were obtained from Sigma Chemical Company (St Louis, MO). Troglitazone was purchased from Biomol (Plymouth Meeting, PA). Recombinant human IL-1 $\beta$  and interferon (IFN) $\gamma$  were purchased from Roche Molecular Biochemicals (Mannheim, Germany). DMEM, trypsin, penicillin streptomycin (PS), sodium pyruvate (SP) and non-essential amino acids (NEAA) were obtained from Invitrogen Corporation (Paisley, UK). Fetal calf serum (FCS; South-American) was obtained from Greiner Bio-one (Frickenhausen, Germany).

### Intestinal Cell Cultures

The human cell line Caco-2 was purchased from the American Tissue Type Collection (ATTC). Caco-2 cells were cultured in DMEM supplemented with 10% heat-inactivated FCS and 1% penicillin streptomycin (PS), 1% sodium pyruvate (SP) and 1% non-essential amino acids (NEAA). Cells were cultured at 37 °C in a 5% CO<sub>2</sub> humidified atmosphere, refreshed every second day and separated by trypsin–0.03% EDTA, when they had reached 70–90% confluence. To evaluate the immune-modulating effects of different interventions, Caco-2 cells were plated in six well tissue culture plates at an initial density of  $0.5 \times 10^6$  cells/mL in a total volume of 1.5 mL. Medium was replaced every other day for 24 days. After 24 days Caco-2 wells were fully differentiated into small intestinal enterocytes [30]. First, effects of immune-suppressive pharmacological compounds (sulfasalazine, dexamethasone and troglitazone) were tested to validate the model. Although these pharmacologic compounds have known

immune-suppressive effects, effects on ICAM-1 expression in Caco-2 cells have—as far as we know—not been reported before. Therefore, after Caco-2 cells were fully differentiated, medium was replaced by medium containing the compound of interest in combination with an inflammation-inducing cocktail consisting of the cytokines IFN $\gamma$  (100 U/mL) and IL-1 $\beta$  (50 U/mL). The compounds of interest were pre-incubated 30 min (sulfasalazine) or 2 h (dexamethasone, troglitazone or GW7647) before stimulation with the cytokine cocktail. After 16 h of cytokine stimulation, cells were used to determine cell surface ICAM-1 protein expression.

### Fatty Acid Experiments

The effects of various fatty acids were evaluated using the same Caco-2 cell model. For this, various fatty acids were added at indicated concentrations 2 days after plating the cells and again for the following 22 days each time when the medium was refreshed. We used OA as a control n-9 MUFA because this is the most abundant fatty acid in the diet [9]. We further compared the effects of the n-6 PUFA ARA versus the n-3 PUFA EPA. We have explicitly chosen to use EPA instead of DHA since the proportion DHA in the colon mucosa of IBD patients was already higher as compared to control subjects [4, 5, 7]. In addition, EPA is most likely a more important eicosanoid precursor [8]. The fatty acids were dissolved in ethanol up to a final ethanol concentration in the medium of maximal 0.5% (v/v). To prevent cytotoxicity of the fatty acids the FA were bound to albumin, by pre-incubating the fatty acids dissolved in ethanol for 30 min at 37 °C in full culture medium together with 10% FCS, which also contained 0.1% BSA. Caco-2 cells were cultured with respectively 160  $\mu$ M OA [C18:1(n-9)] versus 130  $\mu$ M ARA [C20:4(n-6)] plus 30  $\mu$ M OA (in total 160  $\mu$ M fatty acids) or 6  $\mu$ M EPA [C20:5(n-3)] plus 154  $\mu$ M OA (in total also 160  $\mu$ M fatty acids). By this approach the total molarity of fatty acids supplied was similar in all experiments, while supplying different amounts of the fatty acid of interest (i.e., 130  $\mu$ M ARA or 6  $\mu$ M EPA). These relatively low concentrations of OA (160  $\mu$ M), ARA (130  $\mu$ M) and EPA (6  $\mu$ M) were chosen because they are four times higher than normally present in culture medium of Caco-2 cells containing 10% FCS. We have deliberately chosen for this low EPA concentration since the EPA concentration is very low in FCS. However, the EPA concentration used is—as for all fatty acids used in these experiments—already four times higher than normally present in culture medium. We cultured the cells for 22 days with these relatively low concentrations of fatty acids to simulate a realistic long-term in vivo change in dietary fatty acid intake. After 22 days culture with fatty acids, medium was replaced by medium enriched

with the different fatty acids plus the cytokine cocktail [IFN $\gamma$  (100 U/mL) and IL-1 $\beta$  (50 U/mL)]. After 16 h stimulation, ICAM-1 expression on living cells was measured and culture medium was collected to determine inflammatory protein expression profiles. To evaluate the effects of the fatty acids on NF- $\kappa$ B activity and the role of cyclooxygenase (COX)-enzymes, the experiments with the fatty acids ARA and EPA were repeated but now in our NF- $\kappa$ B reporter Caco-2 cell line with and without indomethacin (20  $\mu$ M) added 2 h before and during cytokine stimulation. Prostaglandin PGE $_2$  levels in the supernatant were quantitated using a PGE $_2$  Biotrak enzyme-immunoassay (EIA) system (Amersham Biosciences Ltd, Buckinghamshire, UK) according to the high sensitivity enzyme immunoassay protocol 2.

### Flow Cytometry Analysis of ICAM-1

In order to quantify cell surface ICAM-1 protein expression on living Caco-2 cells, we developed a flow cytometry assay. After 16 h of stimulation, the cells were washed three times with PBS and detached with trypsin–0.03% EDTA. Next, medium was added and cell suspensions were centrifuged for 5 min at 1,200 rpm at room temperature, followed by resuspending the pellets in 500  $\mu$ L PBS-1% BSA. Cells were counted and diluted to 10 $^6$  cells/mL in PBS-1% BSA. Recombinant-phycoerythrin (R-PE)-conjugated mouse-anti-human CD-54 monoclonal antibody (anti-ICAM-1) or isotype-matched control antibody (Becton Dickinson Biosciences, San Diego, CA; 20  $\mu$ L/10 $^6$  cells) was added and incubated for 30 min on ice in the dark. Next, cell suspensions were centrifuged for 5 min at 1,500 rpm and pellets were resuspended in 500  $\mu$ L PBS-1% BSA. The amount of fluorescence of 10,000 living cells was counted and analyzed with the FACSsort and CellQuest analysis software (Becton Dickinson, Franklin Lakes, NJ).

### Stable Transfection of NF- $\kappa$ B in Caco-2 Cells

For evaluating the effects of the various interventions on transcriptional activity of NF- $\kappa$ B, a stable NF- $\kappa$ B reporter Caco-2 cell line was created. The 6 $\kappa$ B-TK-luciferase (NF- $\kappa$ B reporter) plasmid and neomycin resistance plasmid were both kindly provided by Dr. R.C. Langen (Department of Pulmonology, Maastricht University, The Netherlands). Cells were transfected using Lipofectamine 2000 (Invitrogen Corporation, Paisley, UK) according the manufacturers' instructions. Positive clones were selected by culturing with geneticin (1 mg/mL). To determine luciferase activity, non-stimulated and 3 h cytokine (100 U/mL IFN $\gamma$  and 50 U/mL IL-1 $\beta$ ) stimulated cells were lysed in luciferase lysis buffer (Promega, Madison, WI) and stored at –80 °C. Luciferase (Promega) activity was measured

according to the manufacturers' instructions and expressed relative to total protein (Bio-rad assay; Bio-rad, Hercules, CA).

#### Peroxisome Proliferator-Activated Receptor (PPAR) $\gamma$ and PPAR $\alpha$ mRNA Expression of Differentiated Caco-2 Cells

Total RNA was extracted from differentiated Caco-2 cells with Trizol according to the manufacturers' instructions (Gibco BRL, Gaithersburg, MD). Next, cDNA was made as described [31], and mRNA expression of PPAR $\gamma$  and PPAR $\alpha$  was determined using commercially available Taqman gene expression assays (Applied Biosystems, Foster city, CA). Data were normalized against  $\beta$ -actin as housekeeping gene.

#### Fatty Acid Composition of Caco-2 Cells

Fatty acid incorporation into the Caco-2 cells was evaluated using extraction and analysis procedures as previously described [32]. Briefly, total lipids were extracted from 500  $\mu$ L cell suspension in PBS-1% BSA according to the method of Bligh and Dyer [33]. Aminopropyl-bonded silica columns (Varian, Harbor City, CA) were used to separate phospholipids from the total lipid extract [34]. The phospholipids were then saponified, and the resultant fatty acids were methylated into their corresponding fatty acid methyl esters (FAMES) [35]. Fatty acids were separated on an Autosystem (Perkin-Elmer, Norwalk, CT) gas chromatograph that was fitted with a silica-gel column (Cp-sil 88 for FAME, 50 m  $\times$  0.25 mm, 0.2- $\mu$ m film thickness; Chrompack, Middelburg, The Netherlands) with helium gas (130 kPa) as the carrier gas. Both the injection and detection temperatures were set at 300  $^{\circ}$ C. The starting temperature of the column was 160  $^{\circ}$ C. Ten min after injection, the temperature was increased up to 190  $^{\circ}$ C at a rate of 2.5  $^{\circ}$ C/min. After 20 min at 190  $^{\circ}$ C, the temperature was increased up to 230  $^{\circ}$ C at a rate of 4  $^{\circ}$ C/min. The final temperature of 230  $^{\circ}$ C was maintained for 10 min. Data were analyzed by using CHROMCARD software (version 1.21; CE Instruments, Milan, Italy). The fatty acid compositions of the Caco-2 cells are expressed in relative amounts (% of total fatty acids identified; w/w).

#### Inflammatory Protein Expression Profiles Using an Antibody Array

Protein expression patterns of multiple cytokines, chemokines and growth factors, were detected simultaneously in Caco-2 cell culture media with the human cytokine antibody array III (Ray Biotech Inc., Norcross, GA) according to the manufacturers' instructions. First, duplicates of cell

culture media of Caco-2 cells cultured with ARA and EPA after cytokine stimulation were pooled. One millilitre of the pooled samples was added to the array membranes. After incubating and washing, the protein-bound membrane was incubated with a cocktail of biotin-labeled antibodies, followed by the addition of horseradish peroxidase-conjugated streptavidin. Array spot intensity was detected by using a LAS-3000 Lite Image reader (Raytest GmbH, Straubenhart, Germany) based on chemiluminescence imaging. Intensity of the spots was quantified in arbitrary units (a.u.) by densitometry using Aida software version 3.50 (Raytest GmbH), thereby correcting for background staining of the gel. Comparison of protein expression profiles was possible after normalization of each spot on an array using the positive controls, provided by the manufacturer. The sensitivity of the array is not the same for the various proteins. Differences in heights of bars from different proteins do therefore not necessarily represent differences in concentrations. The cytokines used for stimulation (IFN $\gamma$  and IL-1 $\beta$ ) were excluded from analysis.

#### Detection of ICAM-1 on Caco-2 Frozen Sections

To determine the localization of ICAM-1 in our in vitro Caco-2 cell model, Caco-2 cells were cultured and differentiated into small intestinal enterocyte on collagen-coated polyfluoroethylene transwell membrane inserts with a 0.4  $\mu$ m membrane pore size (Corning Costar, Cambridge, MA). Differentiated Caco-2 cells were stimulated with IFN $\gamma$  (100 U/mL) and IL-1 $\beta$  (50 U/mL) for 16 h, embedded in Tissue-Tek (Sakura Finetek, Zoeterwoude, The Netherlands) and rapidly frozen in 2-propanol (Fluka, Zwijndrecht, The Netherlands), dry-ice-cooled and stored at -80  $^{\circ}$ C. Serial cryosections (10  $\mu$ m) were obtained using a Leica CM3050 cryostat (Leica Microsystems GmbH, Wetzlar, Germany) and thaw mounted on uncoated glass slides. Before processing or storage at -80  $^{\circ}$ C, the samples were air dried overnight. To detect ICAM-1 the sections were incubated 30 min in the dark at room temperature with recombinant-phycoerythrin (R-PE)-conjugated mouse-anti-human CD-54 monoclonal antibody or isotype-matched control antibody (Becton Dickinson Biosciences, San Diego, CA) 1:50 diluted in PBS-1% BSA. To detect cytokeratin (CK)-19 the sections were simultaneously incubated with a monoclonal antibody directed to CK-19, kindly obtained from Dr. E.B. Lane (University Dundee, Dundee, UK) 1:10 diluted. Then the sections were washed three times for 5 min in PBS. After that the secondary antibody goat anti-mouse IgG1 (ALEXA555) (Molecular Probes Europe, Leiden, The Netherlands) (1:500) against anti-CD54 (to evade fast quenching of the PE-label) and goat anti-mouse IgG2b (FITC) (Southern Biotech, Sanbio BV, Uden, The Netherlands) (1:50) against CK-19 diluted

in PBS-1% BSA was added to the sections and incubated for 30 min. Again the sections were washed three times for 5 min with PBS. Finally, sections were mounted in Mowiol-TRIS pH 8.5 (Calbiochem, Omnilabo International, Etten-Leur, The Netherlands) containing 0.5 g/mL 4–6-diamino-2-phenylindole (DAPI; Molecular Probes Europe) to stain the nuclei. All sections were examined using a Nikon E800 fluorescence microscope (Uvikon, Bunnik, The Netherlands) coupled to a Basler A101C progressive scan colour CCD camera. By just a simple shift in filters, images were grabbed in fluorescence using the ALEXA excitation filter (540–580 nm), the FITC excitation filter (465–495 nm) and DAPI UV excitation filter (340–380 nm) in the red, green and blue channel, respectively. The images acquired were merged to examine the cellular localisation and level of expression of ICAM-1.

### Statistical Analysis

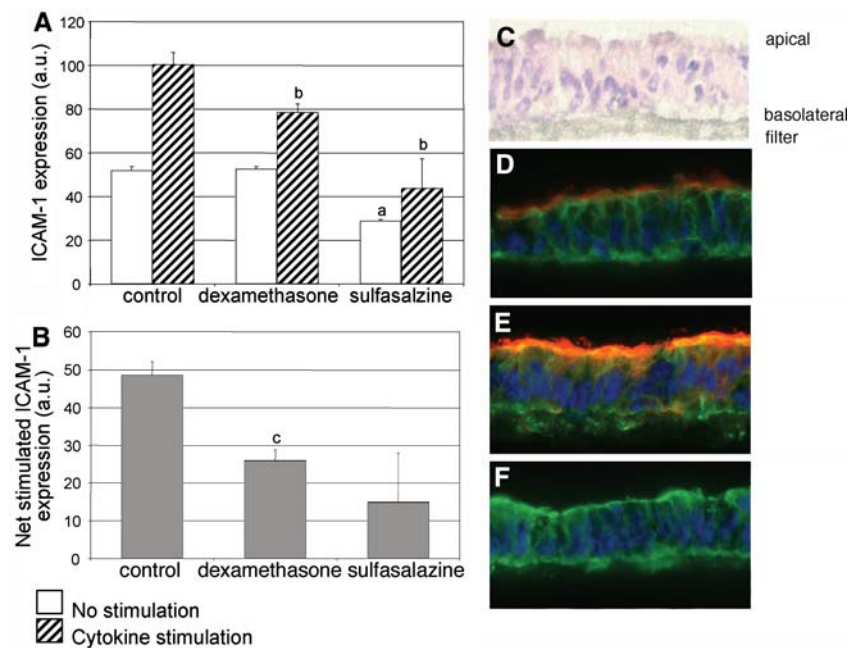

Data were expressed as means and standard deviations (SD) for the non-stimulated condition, the cytokine stimulated condition and cytokine stimulated–non-stimulated (called net stimulated) condition. To determine statistical significance unpaired *t*-tests (comparison between two

interventions) or ANOVA (comparison between three interventions) with a Bonferonni post-hoc test when differences between interventions were significantly different, were performed. First non-stimulated values between interventions were tested to examine differences in basal values. Then, net stimulated values between interventions were tested to examine differences in cytokine-induced changes. Furthermore cytokines stimulated values were tested to examine differences in “end” values. All statistical analyses were performed using SPSS 11 for Mac Os X (SPSS, Chicago, IL). *P*-values of less than 0.05 were considered statistically significant.

## Results

### Model Validation

Stimulation with IL-1 $\beta$  and IFN $\gamma$  increased cell-surface ICAM-1 protein expression on Caco-2 cells, which resulted in a net stimulated ICAM-1 expression of about 50 a.u. (Fig. 1, panels a and b). After pre-treatment of the cells for 2 h with dexamethasone, a corticosteroid with known therapeutic effects in IBD patients, the cytokine stimulated

<sup>c</sup>*P* < 0.05 versus control net stimulated. (**c–f**) Immunohistochemistry of ICAM-1 (red) on frozen sections of Caco-2 cells on a transwell showed increased apical expression after cytokine stimulation (100 U/mL IFN $\gamma$  and 50 U/mL IL-1 $\beta$ ). **c** Hematoxylin staining **d** Non-stimulated Caco-2 cells **e** Apical cytokine stimulated Caco-2 cells **f** Isotype control staining of ICAM-1. Red staining ICAM-1, green staining cytoskeleton (cytokeratin-19), blue staining nucleus. Magnification 40X

ICAM-1 expression was significantly decreased as compared to control ( $P = 0.044$ ). Also the net stimulated ICAM-1 expression (25 a.u.) was significantly reduced as compared to control ( $P = 0.019$ ). Next, we examined the effect of another frequently used therapeutic drug for IBD patients, sulfasalazine. Effects of sulfasalazine were comparable to those observed for dexamethasone. However, also ICAM-1 expression without cytokine stimulation ( $P = 0.004$ ) (Fig. 1, panel a) was lowered. Altogether, these results show that in our cell model ICAM-1 expression is related to the clinical outcomes of drugs proven to treat IBD and could therefore be used as the main outcome parameter in the following experiments. To further validate characteristics of our in vitro model, we also localized the site of ICAM-1 expression on the Caco-2 cells by means of immunohistochemistry on frozen sections. As shown in Fig. 1 (panels c–f), ICAM-1 was expressed on the apical (lumen) side of the polarized Caco-2 cells. Besides a low constitutive expression (panel d), there was a clear increase after stimulation with the cytokine cocktail (panel e). This localisation is in line with the apical ICAM-1 expression, as found in intestinal biopsies from IBD patients [36].

#### Effects of PPAR Agonists on ICAM-1 Expression and NF- $\kappa$ B Activation

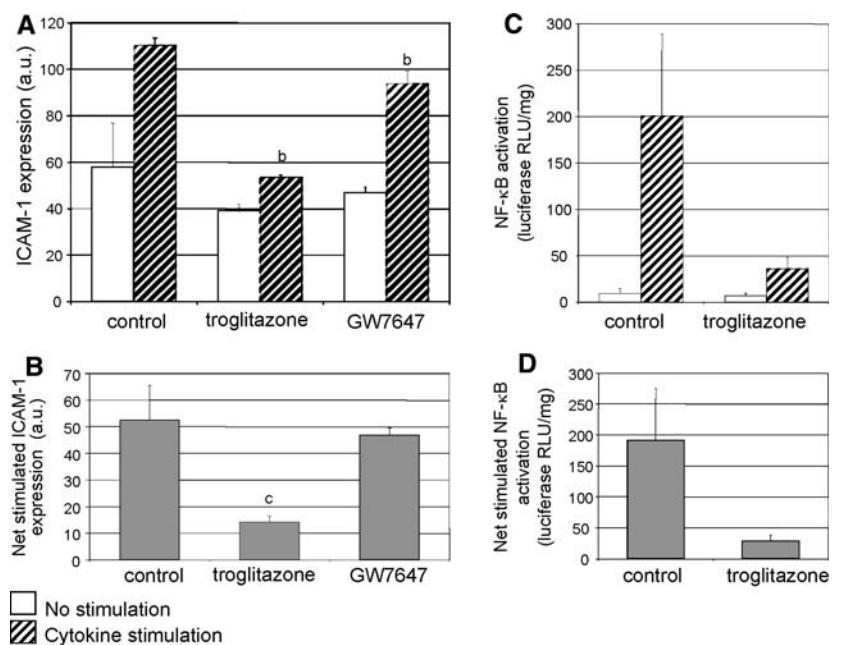

Since PPARs are known modulators of inflammation and fatty acids are natural ligands for PPARs, we first examined PPAR expression in our differentiated Caco-2 cells. We found that PPAR $\alpha$  and PPAR $\gamma$  mRNA are expressed in equal amounts (data not shown). Next we examined the effects of the PPAR $\gamma$  agonist troglitazone [a thiazolidin-

edione (TZD)] and the PPAR $\alpha$  agonist GW7647 on ICAM-1 expression. Although both troglitazone and GW7647 significantly lowered the cytokine stimulated ICAM-1 expression as compared to control ( $P < 0.001$  and  $P = 0.009$ , respectively), only troglitazone significantly ( $P = 0.008$ ) reduced the net stimulated ICAM-1 expression (Fig. 2, panels a and b). Troglitazone and GW7647 were used at a concentration where they are selective for their receptor subtypes [37, 38]. It is known that PPARs suppress inflammation by inhibiting the transcription factor NF- $\kappa$ B, which is a key regulator of inflammation [39]. Therefore, we also examined effects of troglitazone on NF- $\kappa$ B transactivation in our Caco-2 NF- $\kappa$ B reporter cell line. These results showed that the cytokine cocktail induced after already 3 h a more than 200% increase in NF- $\kappa$ B transactivation. This increase of NF- $\kappa$ B transactivation was significantly ( $P = 0.008$ ) lower after 2 h pre-treatment with the PPAR $\gamma$  agonist troglitazone (Fig. 2, panels c and d). Moreover, the inhibitory effect of pre-treatment with the PPAR $\gamma$  agonist troglitazone on cytokine induced NF- $\kappa$ B transactivation was significantly ( $P = 0.001$ ) larger as compared to pre-treatment with the PPAR $\alpha$  agonist GW7647 (data not shown).

#### Fatty Acid Incorporation in Phospholipids

Table 1 shows that the fatty acids kept for 22 days in the culture medium were incorporated into the phospholipid fraction (% of total fatty acids) of the Caco-2 cells. Fatty acid incorporation into phospholipids showed the same pattern as the fatty acid composition of total lipids (data not shown), although changes in the total lipids were more

**Fig. 2** a, b ICAM-1 expression (in arbitrary units a.u.) on living control Caco-2 cells and after pre-treatment with PPAR agonists (2 h; PPAR $\gamma$  troglitazone 100  $\mu$ M and PPAR $\alpha$  GW7647 1  $\mu$ M) and c, d NF- $\kappa$ B transactivation measured by luciferase activity (in RLU/mg) in a NF- $\kappa$ B reporter Caco-2 cell-line of control cells and after troglitazone pre-treatment with and without cytokine stimulation for 3 h (100 U/mL IFN $\gamma$  and 50 U/mL IL-1 $\beta$ ) and net stimulated (stimulated–non-stimulated). Results represent means  $\pm$  SD;  $n = 2$ . ARA arachidonic acid, EPA eicosapentaenoic acid, LA linoleic acid, MUFA monounsaturated fatty acids, OA oleic acid, PA palmitic acid, PUFA polyunsaturated fatty acids, SA stearic acid, SAFA saturated fatty acids,  $\Sigma$  sum, – non-stimulated, + cytokine stimulated

pronounced. Moreover, the fatty acid profiles of phospholipids (Table 1) and total lipids (data not shown) were similar in non-stimulated and stimulated Caco-2 cells. Cells cultured with ARA showed in particular an increase in the proportion of long chain n-6 PUFAs (mainly ARA) and a decrease in n-9 MUFAs (mainly OA) as compared with cells cultured with only OA. The cells cultured with EPA showed an increase in the proportion of n-3 fatty acids (mainly EPA) whereas the proportions of n-9 MUFAs and n-6 PUFAs did not change much as compared with cells cultured with only OA.

#### Effects of Fatty Acids on ICAM-1 Expression and NF- $\kappa$ B Activation

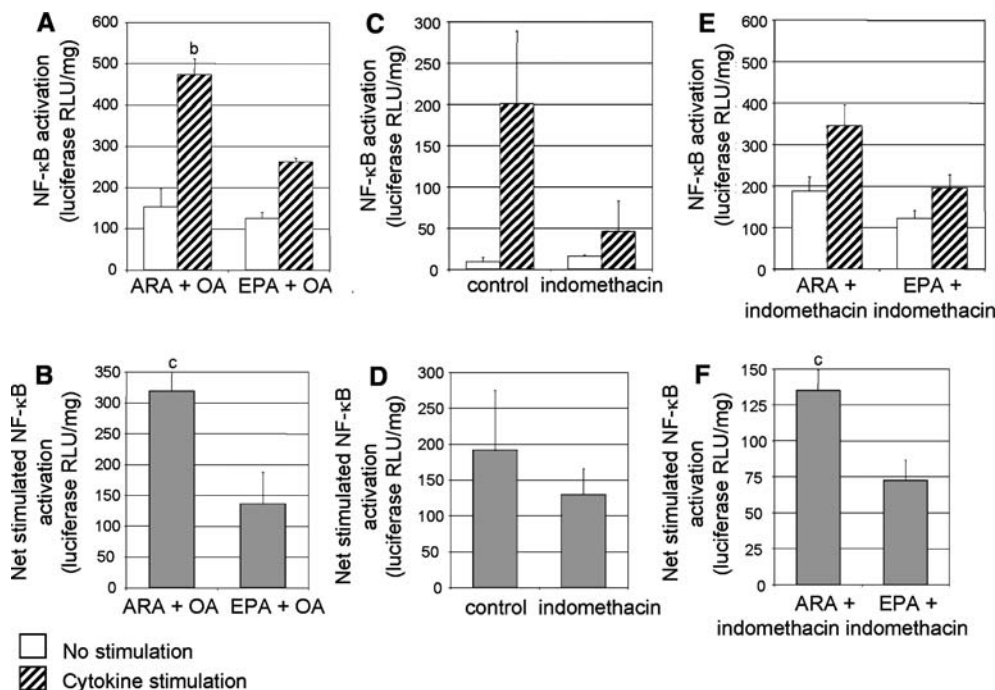

ICAM-1 expression was analyzed on living cells. FACS analysis did not show significant changes in cell populations cultured with the various fatty acids, suggesting no significant cell death. As shown in Fig. 3 (panel a), ARA significantly elevated ICAM-1 expression as compared to OA or EPA (non-stimulated  $P < 0.001$  ARA versus OA and ARA versus EPA, and stimulated  $P = 0.010$  ARA versus OA, and  $P = 0.013$  ARA versus EPA). Interestingly, stimulated and non-stimulated ICAM-1 expression on cells cultured with EPA did not significantly differ from those cultured with OA (Fig. 3, panel a). Despite these

clear differences in non-stimulated and stimulated ICAM-1 expression between ARA and EPA or OA, the net stimulated ICAM-1 expression did not differ between the groups (ANOVA  $P = 0.134$ ). Since dietary interventions aiming at lowering mucosal ARA content are most likely more successful by dietary EPA enrichments than by OA enrichment—because OA is the most abundant fatty acid present in our diet [9], making higher intakes not realistic—in further experiments we have focused on effects of ARA versus EPA. First, we examined the effects on NF- $\kappa$ B activation in the stable NF- $\kappa$ B reporter Caco-2 cell line (Fig. 4). NF- $\kappa$ B transactivation in stimulated Caco-2 cells cultured with ARA was significantly increased as compared to that in stimulated cells cultured with EPA (Fig. 4, panels a and b) (stimulated  $P = 0.017$  and net stimulated  $P = 0.001$ ). To evaluate whether the effects were related to the production of different families of eicosanoids we measured PGE<sub>2</sub> production and examined the effects of the different fatty acids in the presence of the cyclooxygenase (COX)-inhibitor indomethacin. As expected, PGE<sub>2</sub> production by Caco-2 cells cultured with ARA was significantly higher than by cells cultured with EPA (data not shown). Stimulation of the cells with the cytokine cocktail did however, not influence PGE<sub>2</sub> production. Since cytokine stimulation enhanced NF- $\kappa$ B activation, this suggests that PGE<sub>2</sub> is not directly involved in NF- $\kappa$ B activation.

**Fig. 3 a–b** ICAM-1 expression (in arbitrary units a.u.) on living Caco-2 cells cultured for 22 days with 160  $\mu$ M oleic acid (OA) or 130  $\mu$ M arachidonic acid (ARA) plus 30  $\mu$ M OA or 6  $\mu$ M eicosapentaenoic acid (EPA) plus 154  $\mu$ M OA with and without cytokine stimulation for 16 h (100 U/mL IFN $\gamma$  and 50 U/mL IL-1 $\beta$ ) and net stimulated (stimulated–non-stimulated). Results represent

means  $\pm$  SD;  $n = 2$ . Representative representation of two independent experiments. ANOVA between groups, non-stimulated  $P < 0.001$ , stimulated  $P = 0.006$  and net stimulated  $P = 0.134$ . <sup>a</sup>Bonferroni  $P < 0.05$  versus OA and EPA non-stimulated, <sup>b</sup>Bonferroni  $P < 0.05$  versus OA and EPA cytokine stimulated

**Fig. 4** NF- $\kappa$ B transactivation with and without cytokine stimulation for 3 h (100 U/mL IFN $\gamma$  and 50 U/mL IL-1 $\beta$ ) (a, c, e) and net stimulated (stimulated–non-stimulated) (b, d, f) in a NF- $\kappa$ B reporter Caco-2 cell line measured by luciferase activity (in RLU/mg). a–b Reporter Caco-2 cells cultured for 22 days with 130  $\mu$ M arachidonic acid (ARA) plus 30  $\mu$ M oleic acid (OA) or 6  $\mu$ M eicosapentaenoic acid (EPA) plus 154  $\mu$ M OA. c–d Control reporter Caco-2 cells and

after 2 h pre-treatment with the COX-inhibitor indomethacin (20  $\mu$ M). e–f Reporter Caco-2 cells cultured for 22 days with 130  $\mu$ M arachidonic acid (ARA) plus 30  $\mu$ M OA or 6  $\mu$ M eicosapentaenoic acid (EPA) plus 154  $\mu$ M OA and 2 h pre-treatment with the COX-inhibitor indomethacin (20  $\mu$ M). Results represent means  $\pm$  SD;  $n = 2$ . <sup>b</sup> $P < 0.05$  versus EPA cytokine stimulated, <sup>c</sup> $P < 0.05$  versus EPA or EPA + indomethacin net stimulated

Indomethacin decreased PGE $_2$  production of Caco-2 cells by approximately 70% (data not shown), but had no effect on NF- $\kappa$ B transactivation (Fig. 4, panels c and d) as compared to untreated Caco-2 cells. Also ICAM-1 expression was not affected (data not shown). However, as shown in Fig. 4, the effects of ARA versus EPA in the

presence of indomethacin treatment (panel e) showed an identical pattern as observed without indomethacin (panel a). Also in the presence of indomethacin the net cytokine stimulated NF- $\kappa$ B transactivation was significantly higher after ARA as compared to EPA ( $P = 0.047$ ) (Fig. 4, panel f). This indicates that the increased basal PGE $_2$  production

by ARA cannot explain the different effects of ARA and EPA on NF- $\kappa$ B activation.

### Effects of Fatty Acids on Inflammatory Proteins Expression Profiles

Finally, to explore the effects of ARA and EPA on a broader scale, we evaluated protein expression profiles consisting of various inflammatory mediators by using antibody arrays. Figure 5 shows that ARA treatment particularly increased expression of monocyte chemotactic protein (MCP)-1 and angiogenin, while EPA treatment increased IL-10, IL-6, macrophage inflammatory protein (MIP)-1 $\delta$ , and growth regulated protein (GRO) expression.

### Discussion

ICAM-1 seems important in the pathology of IBD [15]. Whether fish oils, which have been shown to protect against relapses in IBD patients on remission [13], have effects on ICAM-1 expression, is however, unknown. In addition, a direct side-by-side comparison of fish oils with ARA, which is postulated to have pro-inflammatory effects [40] and is elevated in the colon mucosa of IBD patients [4, 7], has never been made. The transcription factor NF- $\kappa$ B is important in regulating intestinal inflammation and is elevated in IBD patients [21, 22, 26]. We have now shown that the n-3 PUFA EPA, as compared to the n-6 PUFA

ARA, clearly reduced cytokine stimulated NF- $\kappa$ B activation and ICAM-1 expression in enterocytes in vitro. Moreover, effects of OA on ICAM-1 expression were comparable to those of EPA. Because EPA and OA resulted in comparable changes in the proportions of ARA in the phospholipids of the enterocytes, the reported effects may be ascribed to the increased ARA proportion in the ARA cultured cells. Thus, decreasing cellular ARA levels seems to be a crucial step. Since OA is already the most abundant fatty acid present in our diet [9] and in the colon mucosa [4], decreasing mucosal ARA levels may be easier by increasing fish oil intake than by increasing OA intake. Moreover, EPA does compete with ARA for incorporation into tissue phospholipids [10, 11].

Our data showed that replacing ARA for EPA or OA decreased ICAM-1 expression and NF- $\kappa$ B activation in Caco-2 enterocytes. In line with our observations in enterocytes, n-6 PUFAs also increased NF- $\kappa$ B activation as compared to n-3 PUFAs in monocytes [41] and macrophages [42]. Also, earlier in vitro studies have demonstrated that fish oils reduced cytokine stimulated ICAM-1 expression in endothelial cells [43] and monocytes [44] as compared to conditions without addition of fatty acids. Moreover, in vivo ICAM-1 expression (surface and mRNA) on peritoneal macrophages was reduced in mice fed fish oils compared to that in mice fed coconut oil [45]. In humans, dietary fish oil supplementation lowered expression of ICAM-1 on ex vivo stimulated monocytes as compared to no supplementation [46]. However, our study

**Fig. 5** Protein expression profile in the culture medium of Caco-2 cells cultured for 22 days with 130  $\mu$ M arachidonic acid (ARA) plus 30  $\mu$ M oleic acid (OA) or 6  $\mu$ M eicosapentaenoic acid (EPA) plus 154  $\mu$ M OA after 16 h cytokine stimulation (100 U/mL IFN $\gamma$  and 50 U/mL IL-1 $\beta$ ) measured with an antibody array. Results are represented as mean  $\pm$  SD;  $n = 2$ . CSF colony stimulating factor, ENA epithelial-derived neutrophil activating protein, MCP monocyte

chemotactic protein, MDC, macrophage derived chemokine, MIG monokine induced by gamma interferon, MIP macrophage inflammatory protein, SDF stromal cell-derived factor, GRO growth regulated protein, MCSF Macrophage colony stimulating factor, Tpo thrombopoietin, EGF epidermal growth factor, OSM oncostatin M, VEGF Vascular endothelial growth factor, SCF stem cell factor, IL interleukin, TNF tumor necrosis factor, Ang angiogenin

is the first that examined effects of EPA versus ARA on ICAM-1 expression and NF- $\kappa$ B activation in enterocytes. We however, realize that, although enterocytes play an important role in intestinal inflammation, immune modulating effects of fatty acids in CD patients will be influenced not only by enterocytes, but also the interaction with other intestinal immune and non-immune cells is important. Therefore, in future experiments effects on other cell types, e.g. isolated from mucosal biopsies of CD patients should be evaluated. Moreover, to validate if the effects of EPA versus ARA are also applicable in the pathogenesis or even the treatment of CD patients, these effects should be confirmed in appropriate animal models of IBD.

We used an approach of supplying different amounts of the fatty acids of interest (i.e., 130  $\mu$ M ARA or 6  $\mu$ M EPA), while the total molarity of fatty acids supplied was similar in all experiments by adding OA. These different concentrations of ARA and EPA were deliberately chosen because they were both four times the amount, in which the cells grow normally (i.e., the fatty acid composition of culture medium with 10% FCS). Since the EPA concentration is very low in FCS, we have deliberately chosen for a low EPA concentration. Higher concentrations of EPA would be interesting to examine, however, are difficult to be achieved with dietary interventions in vivo. Using isomolaric total concentrations of fatty acids is essential, because an increase in total fat can be immune suppressive [47]. Therefore, we used OA as a reference fatty acid to make total fatty acid concentrations between experimental fatty acid conditions iso-molaric, i.e. OA was exchanged for ARA or EPA. In addition, we evaluated the condition of OA only. The results of this latter condition showed that decreasing ARA levels in the mucosa seems to be more important than increasing EPA levels.

Regarding the pathways underlying the anti-inflammatory effect of fish oils, several suggestions have been made. As compared to n-6 PUFAs, n-3 PUFAs may have different effects on (I) signal transduction pathways, and (II) the types and levels of eicosanoids synthesized [40]. Regarding the first mechanism, our finding that EPA lowered NF- $\kappa$ B activation and ICAM-1 expression as compared to ARA indeed showed that EPA and ARA differently affected the NF- $\kappa$ B signal transduction pathway. In this respect, two peroxisome proliferators-activated receptors (PPARs), PPAR $\alpha$  and PPAR $\gamma$ , seem relevant, since fatty acids are natural ligands for these PPARs. Both PPARs seem to have anti-inflammatory effects by inhibiting NF- $\kappa$ B activation [48, 49]. In our in vitro model, the PPAR $\gamma$  agonist troglitazone inhibited NF- $\kappa$ B activation, and cytokine and net stimulated ICAM-1 expression, while the PPAR $\alpha$  agonist GW7647 only inhibited cytokine-stimulated ICAM-1 expression. This suggests that both PPAR $\gamma$  and PPAR $\alpha$  have anti-inflammatory effects on enterocytes, in which

effects of PPAR $\gamma$  seem more pronounced. This is in agreement with the finding that PPAR $\gamma$  agonists but not a PPAR $\alpha$  agonist inhibited IL-8 expression of Caco-2 cells and HT-29 cells [50]. Differences between fatty acids in activation of PPARs might explain the activation of NF- $\kappa$ B by ARA and not by EPA in our Caco-2 cells. However, our findings are not supported by the PPAR $\gamma$  binding affinities of EPA and ARA, which are about the same [51], while we used much lower EPA concentrations than ARA concentrations. Secondly, not only EPA but also OA lowered intestinal ICAM-1 expression while OA is a poor PPAR $\gamma$  ligand [51]. Therefore, although PPAR $\gamma$  activation certainly protects against inflammation, our results do not suggest that the protective effects of EPA and OA as compared to ARA on intestinal inflammation are PPAR $\gamma$ -mediated. Therefore, there should be another explanation why effects of OA and EPA were comparable but different from those of ARA.

The mechanism underlying a second possible explanation relates to the incorporation of fatty acids into cell membrane phospholipids and eicosanoids synthesis. Eicosanoids can modulate the intensity and duration of the inflammatory response. [8, 40] Replacement of ARA by EPA in the culture medium of the cells resulted in a decrease in the proportion of ARA in cell membranes and an increase in the EPA proportion and as expected the PGE<sub>2</sub> production of Caco-2 cells cultured with EPA was also lower than PGE<sub>2</sub> production of cells cultured with ARA. However, PGE<sub>2</sub> production was not different between non-stimulated and stimulated cells, while stimulation resulted in an abundant elevation of NF- $\kappa$ B activation. To our opinion this rules out the role of PGE<sub>2</sub> in the NF- $\kappa$ B activation of ARA and EPA. Moreover, although in our experiments indomethacin—a blocker of COX—indeed inhibited PGE<sub>2</sub> production, it did not lower NF- $\kappa$ B activation. This is in line with findings of De Catherina et al. [43] showing that in endothelial cells the effects of DHA on VCAM-1 expression could not be inhibited by indomethacin, although prostacyclin production was completely suppressed. Therefore, we fully agree that in an in vivo situation pro-inflammatory effects of ARA are probably mediated by eicosanoids synthesized from ARA, however, these effects are not derived from a direct eicosanoid mediated activation of NF- $\kappa$ B as shown in our model.

Finally, we evaluated inflammatory protein signatures of Caco-2 cell culture medium after 22 days treatment with EPA versus ARA. Since these signatures were analyzed in pooled material we cannot draw conclusions based on statistical analysis. However, this array was intended to generate hypotheses about differences in immune modulating effect of ARA versus EPA based on the protein expression profiles. These profiles indicate, that both fatty

acids induced specific changes in various inflammation mediators. Most of these proteins, but not all, are regulated by NF- $\kappa$ B. For example, IL-6 protein expression was higher after EPA as compared to ARA, whereas NF- $\kappa$ B activation was higher after ARA. It should however, be considered that although highly important, NF- $\kappa$ B is not the only transcription factor involved in the regulation of IL-6 and other inflammatory proteins. Thus, expression of individual proteins cannot be predicted by the level of NF- $\kappa$ B activation solely. In addition, we found clear differences between EPA and ARA, i.e., that some proteins were expressed higher after EPA (IL-6, IL-10, MIP-1 $\delta$  and GRO), while others were higher expressed after ARA (MCP-1, and angiogenin). The precise role of these individual proteins in the process of intestinal inflammation is not clear. However, the increased MCP-1 expression after ARA treatment is in line with the finding that MCP-1 expression is upregulated in the mucosa of IBD patients and correlates with disease activity [52]. The increased expression of the Th2 cytokine IL-10 after EPA treatment fits with the anti-inflammatory role for IL-10 in IBD pathology. In this respect, IL-10 knockout mice develop chronic intestinal inflammation and delivery of recombinant IL-10 to the intestinal mucosa by the bacterium *L. lactis* attenuated mucosal inflammation in two mouse models [53]. In humans, a pilot study using these bacteria showed also promising effects [54].

In conclusion, we have shown that ARA but not EPA and OA activates NF- $\kappa$ B and elevates ICAM-1 expression in Caco-2 enterocytes and we hypothesize that the effects are not related to PPAR $\gamma$  activation or eicosanoid formation.

**Acknowledgments** The authors thank Hasibe Aydeniz (Department of Human Biology, Maastricht University, The Netherlands) for analyzing the fatty acid composition of the Caco-2 cells, Maurice Konings (Department of Human Biology) for analyzing PPAR $\gamma$  and PPAR $\alpha$  mRNA expression in Caco-2 cells and Martine Hulsbosch (Department of Human Biology) for PGE<sub>2</sub> measurements.

**Abstract** Omega-3 polyunsaturated fatty acids (PUFA) affect immune response, partly by affecting cytokine secretion. Omega-3 PUFA decrease tumor necrosis factor (TNF)- $\alpha$  secretion by RAW 264.7 macrophages but increase TNF- $\alpha$  secretion by primary elicited peritoneal macrophages in vitro. In this study, the effects of omega-3 and omega-6 PUFA on lipopolysaccharide induced TNF- $\alpha$  and interleukin (IL)-10 secretion by murine primary resident and elicited peritoneal macrophages and by RAW 264.7 macrophages, were examined in vitro using an enzyme-linked immunosorbent assay. In addition, the effects of dietary omega-3 PUFA on the number of cells secreting these cytokines were examined with enzyme-linked immunospot assay. All cell types secreted more TNF- $\alpha$  but similar amounts of IL-10 when incubated with the omega-3 PUFA, eicosapentaenoic acid or docosahexaenoic acid, compared with that when incubated with the omega-6 PUFA, linoleic acid or arachidonic acid. Dietary fish oil did not affect the number of TNF- $\alpha$  secreting resident peritoneal macrophages but decreased the number of macrophages secreting IL-10 ex vivo. These results show that dietary omega-3 PUFA and omega-3 PUFA added to cells in vitro increase TNF- $\alpha$  secretion by resident peritoneal macrophages, probably by a direct effect on the cells. In contrast, omega-3 PUFA did not affect IL-10 secretion by the cells but decreased the number of cells secreting IL-10 ex vivo, possibly by affecting cell recruitment, maturation or proliferation.

**Keywords** Omega-3 fatty acids · Macrophages · TNF- $\alpha$  · IL-10

### Introduction

Dietary omega-3 polyunsaturated fatty acids (PUFA) have immunomodulatory effects that are thought to be anti-inflammatory based on human clinical and epidemiological studies, as well as murine models [7, 9, 14, 21]. The anti-inflammatory effects of omega-3 PUFA may partly be explained by their effects on lymphocytes, as omega-3 PUFA suppress T-cell proliferation and pro-inflammatory cytokine secretion [1, 13, 18, 19, 32]. In contrast to the anti-inflammatory effects of omega-3 PUFA on T-lymphocytes, results from our laboratory and others indicate that dietary omega-3 PUFA may have pro-inflammatory effects on cytokine secretion by resident peritoneal macrophages, as they increase lipopolysaccharide (LPS) induced tumor necrosis factor (TNF)- $\alpha$  secretion and decrease interleukin (IL)-10 secretion by these cells ex vivo [5, 6, 8, 10, 15, 24, 27, 38]. Dietary omega-3 PUFA also increase LPS induced TNF- $\alpha$  secretion by splenic macrophages and increase their IL-10 secretion [26]. The effects of dietary omega-3 PUFA on TNF- $\alpha$  secretion by murine elicited peritoneal macrophages varies, with some studies showing an increase in TNF- $\alpha$  secretion [31, 37], others showing no change [16, 33, 35, 37], and still others showing a decrease in TNF- $\alpha$  secretion [4, 29, 36, 40] compared with that by elicited peritoneal macrophages from animals fed a diet rich in omega-6 PUFA.

In contrast to the numerous studies examining the effects of dietary omega-3 PUFA on cytokine secretion by resident peritoneal macrophages ex vivo, to our knowledge no studies have examined the effects of omega-3 PUFA on

TNF- $\alpha$  and IL-10 secretion by murine primary resident peritoneal macrophages *in vitro*. Two studies have examined the effects of omega-3 PUFA on TNF- $\alpha$  secretion by primary elicited peritoneal macrophages, showing increased TNF- $\alpha$  secretion by elicited peritoneal macrophages when incubated with omega-3 PUFA compared with that by cells incubated without fatty acids or incubated with omega-6 PUFA [17, 34]. In contrast, results from studies using a murine peritoneal macrophage cell line, RAW 264.7, show that omega-3 PUFA decrease TNF- $\alpha$  secretion compared with that by cells incubated with omega-6 PUFA or control media [22, 25].

The objective of this study was to determine the effects of omega-3 PUFA on TNF- $\alpha$  and IL-10 secretion by murine primary resident and elicited peritoneal macrophages, and the macrophage cell line, RAW 264.7, *in vitro* and to examine the effects of dietary fish oil on the number of TNF- $\alpha$  and IL-10 secreting cells in the peritoneum of mice.

## Experimental Procedure

### Animals and Diets

All experimental procedures using laboratory animals complied with the National Research Council's Guide for the Care and Use of Laboratory Animals. Female BalbC mice (18–20 g) (Bomholtgaard, Copenhagen, Denmark) received standard diet (Special Diets Services, Witham, UK), water *ad libitum*, and were housed at 25 °C with a 12-h light:dark cycle. For feeding experiments, mice were randomly divided into two groups of ten mice each and housed five per cage at 25 °C with a 12-h light:dark cycle. Experimental diets were designed according to the American Institute of Nutrition (AIN)-93 guidelines [28] with modification in fat content. The experimental diets were based on a nutritionally complete diet made for the addition of 200 g/kg of fat (ICN Pharmaceuticals, Aurora, OH, USA). The fish oil diet contained 180 g/kg menhaden fish oil and 20 g/kg corn oil (ICN Pharmaceuticals, Asse-Rellegem, Belgium). The corn oil diet contained 200 g/kg corn oil. The fatty acid composition of the diets was analyzed as described previously [27] and is shown in Table 1. The antioxidant *tert*-butylhydroquinone (t-BHQ) (ICN Bio-medicals, Aurora, OH, USA) (1.2 mmol/L) was added to the oils to prevent their deterioration [12]. Diets were prepared in bulk and daily portions packed in zip lock bags, flushed with nitrogen, sealed and stored at –20 °C. Water and food were provided *ad libitum*. The mice were fed the experimental diets for 6 weeks. Mice were anesthetized with isoflurane (Abbot Scandinavia, Solna, Sweden) and euthanized by cervical dislocation. For induction of elicited peritoneal macrophages, mice were injected intra-perito-

**Table 1** Selected fatty acid composition (g/100 g) of the diets

<sup>c</sup> Fish oil diet contained 180 g/kg menhaden fish oil and 20 g/kg corn oil

neally with 0.8 mL of 3% thioglycolate (TG) broth (Difco, Becton Dickinson, Microbiology Systems, Sparks, MD, USA) 72 h before collection of cells.

### Preparation of Fatty Acids for Incubation

Fatty acids (Sigma, Steinheim, Germany) were dissolved in ethanol, flushed with nitrogen and stored at –20 °C. Fatty acids were incubated at 3:1 mole ratio with bovine serum albumin (BSA) (Sigma, Steinheim, Germany) at 37 °C for 16 h. The fatty acid–BSA complexes were stored in the presence of nitrogen for maximum of 7 days at 4 °C. The maximum final concentration of ethanol in the cultures was 0.05%.

### Isolation, Culturing and Activation of Resident and Elicited Peritoneal Macrophages

Resident and elicited peritoneal macrophages were collected in cold phosphate-buffered saline (PBS) without calcium or magnesium. Cells were washed with PBS and resuspended in Dulbecco's Modified Eagle Medium (DMEM) with Gluta-MAX-I, penicillin (100 U/mL), and streptomycin (100  $\mu$ g/mL), all from Gibco, Paisley, UK. Cells were counted in 0.4% Trypan Blue (Sigma, Steinheim, Germany) on a hemocytometer and  $1 \times 10^6$  cells/mL plated on a 48-well flat-bottomed multidish and incubated at 37 °C in 5% CO<sub>2</sub> atmosphere. Cells were cultured in DMEM with 10% fetal bovine serum (FBS) (Gibco, Paisley, UK) with or without 10–50  $\mu$ M concentration of linoleic acid (LA), arachidonic acid (AA), eicosapentaenoic acid (EPA), or docosahexaenoic acid (DHA), for 4–24 h. BSA and ethanol, in a concentration equal to that used for cells cultured with fatty

acids, was added to cells cultured without fatty acids. Fatty acids were replaced by fresh media and the cells stimulated with LPS (2  $\mu\text{g}/\text{mL}$ ) (*Escherichia coli* 055:B5, Fluka Chemie CmbH, Buchs, Switzerland) for 6–12 h.

#### Murine Macrophage Cell Line, RAW 264.7

The RAW 264.7 cell line was obtained from American Type Culture Collection (ATCC) (Manassas, VA, USA). Cells were maintained in DMEM with 10% FBS (ATCC, Manassas, VA, USA), penicillin (100 U/mL), and streptomycin (100  $\mu\text{g}/\text{mL}$ ) at 37 °C in 5% CO<sub>2</sub> atmosphere. Cells were counted, plated, and cultured as described above except that cells were allowed to adhere to culture plates for 2 h before incubation with fatty acids. All experiments were performed at passages 6–11.

#### TNF- $\alpha$ and IL-10 Determination

After centrifugation, supernatants were collected and stored at -70 °C. TNF- $\alpha$  and IL-10 were measured by enzyme-linked immunosorbent assay using DuoSet (R&D Systems, Minneapolis, MN, USA).

#### Determination of the Number of TNF- $\alpha$ and IL-10 Secreting Cells and Mean TNF- $\alpha$ and IL-10 Secretion per Cell

Numbers of TNF- $\alpha$  and IL-10 secreting cells and the mean TNF- $\alpha$  and IL-10 secretion per cell were evaluated by enzyme-linked immunospot (ELISPOT) assay (R&D systems, Minneapolis MN, USA). Cells were collected from the peritoneum of mice fed diets containing fish oil or corn oil and counted on a hemocytometer. Then,  $0.63 \times 10^4$  cells/well were incubated on a polyvinylidene difluoride microplate (Millipore, Moisheim, France) coated with anti-mouse TNF- $\alpha$  and  $2.5 \times 10^5$  cells/well on a plate coated with anti-mouse IL-10. Cells were cultured with or without LPS (2  $\mu\text{g}/\text{mL}$ ) for 24 h, the plates washed and incubated with biotinylated anti-mouse TNF- $\alpha$  or IL-10 overnight. After incubation with streptavidin-AP, spots were developed using 5-bromo-4-chloro-3-indolyl phosphate/nitro blue tetrazolium as chromogen (R&D Systems, Minneapolis, MN, USA). The number of TNF- $\alpha$  and IL-10 secreting cells per 1,000 cells and mean TNF- $\alpha$  and IL-10 secretion per cell (determined as area per spot) were automatically evaluated using a computer-assisted video image analyzer (KS ELISPOT, Version 4.8; Zeiss, Jena, Germany).

#### Statistical Analysis

Differences between treatments in vitro were analyzed using one-way analysis of variance, followed by Bonfer-

roni post hoc test. Differences between dietary groups were analyzed using unpaired *t*-test,  $P < 0.05$ , two-tailed. The statistical analysis was performed in Statsdirect (Version 2.5.4, Cheshire, UK).

## Results

### The Effects of Omega-3 PUFA on TNF- $\alpha$ and IL-10 Secretion by Resident Peritoneal Macrophages In Vitro

Resident peritoneal macrophages cultured with 50  $\mu\text{M}$  concentration of EPA or DHA, for 12 h, secreted 60 and 75% more TNF- $\alpha$  than macrophages cultured without fatty acids and 30 and 40% more than macrophages cultured with omega-6 fatty acids (Fig. 1). Resident peritoneal macrophages incubated with EPA for 8 h secreted similar amounts of TNF- $\alpha$  as resident peritoneal macrophages incubated with AA, whereas macrophages incubated with EPA for 12, 20, or 24 h secreted more TNF- $\alpha$  than macrophages incubated with AA for the same length of time (Fig. 2). Resident peritoneal macrophages incubated with 10 or 25  $\mu\text{M}$  of EPA secreted similar amounts of TNF- $\alpha$  ( $146 \pm 1$  and  $135 \pm 6$  pg/mL, respectively) as resident peritoneal macrophages incubated with 10 or 25  $\mu\text{M}$  of AA ( $136 \pm 1$  and  $122 \pm 2$  pg/mL, respectively). There was no difference in IL-10 secretion by resident peritoneal macrophages incubated without fatty acids or with 50  $\mu\text{M}$  concentration of the fatty acids LA, AA, EPA, or DHA (Table 2).

**Fig. 1** The effects of omega-6 and omega-3 polyunsaturated fatty acids on tumor necrosis factor (TNF)- $\alpha$  secretion by resident peritoneal macrophages. Resident peritoneal macrophages were incubated with or without linoleic acid (LA), arachidonic acid (AA), eicosapentaenoic acid (EPA), or docosahexaenoic acid (DHA) (50  $\mu\text{M}$ ) for 12 h. The fatty acids were removed and the cells stimulated with lipopolysaccharide (LPS) (*E. coli* 055:B5) (2  $\mu\text{g}/\text{mL}$ ) for 12 h. TNF- $\alpha$  was measured by enzyme-linked immunosorbent assay (ELISA). Values are means + standard error of the mean (SEM),  $n = 8$ –9. The results are pooled from three separate experiments. **a** Different from *No fatty acids* and *Omega-6 fatty acids* ( $P < 0.05$ )

**Fig. 2** Time course of the effects of EPA and AA on TNF- $\alpha$  secretion by resident peritoneal macrophages. Resident peritoneal macrophages were incubated with AA or EPA (50  $\mu$ M) for 8, 12, 16, 20, and 24 h. The fatty acids were removed and the cells stimulated with LPS (*E. coli* 055:B5) (2  $\mu$ g/mL) for 12 h. TNF- $\alpha$  was measured by ELISA. Values are means  $\pm$  SEM,  $n = 7$ –10, except for the 16-h time point,  $n = 4$ . The results are pooled from three separate experiments. The abbreviations used are the same as for Fig. 1. \* Different from the mean for cells incubated with AA at each time point,  $P < 0.05$

#### The Effects of Dietary Fish Oil on the Number of Resident Peritoneal Cells Secreting TNF- $\alpha$ and IL-10 Ex Vivo and Mean TNF- $\alpha$ and IL-10 Secretion per Cell

The effects of dietary fish oil on the number of cells secreting TNF- $\alpha$  and IL-10 were examined ex vivo. Dietary fish oil did not affect the number of resident peritoneal macrophages secreting TNF- $\alpha$  when stimulated with LPS ex vivo (Fig. 3a). In contrast, dietary fish oil decreased the number of resident peritoneal macrophages secreting IL-10 ex vivo (Fig. 3b) compared with the number of IL-10 secreting resident peritoneal macrophages from mice fed the corn oil-rich diet. The mean TNF- $\alpha$  secretion per cell (determined by ELISPOT as the area per spot) from the peritoneum of mice fed the fish oil diet ( $3,409 \pm 239$ ) was higher than the mean TNF- $\alpha$  secretion per cell from the peritoneum of mice fed the corn oil diet ( $2,352 \pm 230$ ,

**Fig. 3** The effects of dietary fish oil on the number of resident peritoneal cells secreting TNF- $\alpha$  or interleukin (IL)-10. BalbC mice were fed diets containing fish oil or corn oil for 6 weeks and resident peritoneal macrophages collected. Numbers of TNF- $\alpha$  (a) and IL-10 (b) secreting cells were determined by enzyme-linked immunospot (ELISPOT) assay. Values are means  $\pm$  SEM,  $n = 8$ –10. The abbreviations used are the same as for Fig. 1. \* $P < 0.05$

$P < 0.05$ ). There was no difference in the mean IL-10 secretion per cell from the peritoneum of mice fed the different diets ( $1,940 \pm 87$  vs.  $1,744 \pm 89$ , for the fish oil and the corn oil diets, respectively).

#### The Effects of Omega-3 PUFA on TNF- $\alpha$ and IL-10 Secretion by Thioglycolate-Elicited Peritoneal Macrophages In Vitro

Thioglycolate-elicited peritoneal macrophages incubated with 50  $\mu$ M concentration of EPA or DHA for 20 h se-

**Table 2** IL-10 secretion (pg/mL) by murine resident peritoneal macrophages, elicited peritoneal macrophages, and the RAW 264.7 cell line

	Treatment				
	No fatty acids	LA 50 $\mu$ M	AA 50 $\mu$ M	EPA 50 $\mu$ M	DHA 50 $\mu$ M
Resident peritoneal cells <sup>a</sup>	489 $\pm$ 16	511 $\pm$ 23	487 $\pm$ 22	460 $\pm$ 18	509 $\pm$ 18
Elicited peritoneal cells <sup>b</sup>	212 $\pm$ 35	164 $\pm$ 39	188 $\pm$ 44	208 $\pm$ 38	209 $\pm$ 33
RAW 264.7 cell line <sup>c</sup>	5,050 $\pm$ 392	4,690 $\pm$ 460	4,120 $\pm$ 640	4,910 $\pm$ 240	6,570 $\pm$ 307 <sup>d</sup>

Values are mean  $\pm$  SEM

<sup>a</sup> Incubated with the fatty acids for 12 h,  $n = 8$ –9

<sup>b</sup> Incubated with the fatty acids for 20 h,  $n = 5$ –6

<sup>c</sup> Incubated with the fatty acids for 20 h,  $n = 3$ , representative of three separate experiments

<sup>d</sup> Different from all other treatments,  $P < 0.05$

creted 90 and 175% more TNF- $\alpha$  than macrophages incubated without fatty acids, 120 and 235% more TNF- $\alpha$  than macrophages incubated with LA and 80 and 170% more TNF- $\alpha$  than macrophages incubated with AA (Fig. 4). Elicited peritoneal macrophages incubated with DHA secreted 50% more TNF- $\alpha$  than elicited peritoneal macrophages incubated with EPA (Fig. 4). There was no difference in IL-10 secretion by elicited peritoneal macrophages incubated without fatty acids or with LA, AA, EPA, or DHA (Table 2).

#### The Effects of Omega-3 PUFA on TNF- $\alpha$ and IL-10 Secretion by the Macrophage Cell Line, RAW 264.7, In Vitro

RAW 264.7 macrophages cultured with 50  $\mu$ M concentration of EPA for 20 h secreted 50 and 70% more TNF- $\alpha$  after stimulation with LPS than macrophages cultured without fatty acids or with LA (Fig. 5). RAW 264.7 macrophages cultured with DHA secreted 60–95% more TNF- $\alpha$  than RAW 264.7 macrophages cultured without fatty acids or with LA or AA (Fig. 5). There was no difference in IL-10 secretion by RAW 264.7 macrophages cultured without fatty acids or with LA, AA, or EPA (Table 2). However, RAW 264.7 macrophages incubated with DHA secreted 30% more IL-10 than macrophages incubated without fatty acids (Table 2).

## Discussion

The results from the present study show that omega-3 PUFA increase TNF- $\alpha$  secretion by primary resident and

**Fig. 4** The effects of omega-6 and omega-3 PUFA on TNF- $\alpha$  secretion by thioglycolate-elicited peritoneal macrophages. Thioglycolate-elicited peritoneal macrophages were incubated with or without LA, AA, EPA, or DHA (50  $\mu$ M) for 20 h. The fatty acids were removed and the cells stimulated with LPS (*E. coli* 055:B5) (2  $\mu$ g/mL) for 12 h. TNF- $\alpha$  was measured by ELISA. Values are means + SEM,  $n = 5-6$ . Results are pooled from two separate experiments. **a** Different from *No fatty acids* and *Omega-6* fatty acids, **b** Different from *EPA* ( $P < 0.05$ ). The abbreviations used are the same as for Fig. 1

**Fig. 5** The effects of omega-6 and omega-3 PUFA on TNF- $\alpha$  secretion by the murine peritoneal macrophage cell line, RAW 264.7. RAW 264.7 macrophages were incubated with or without LA, AA, EPA, or DHA (50  $\mu$ M) for 20 h. The fatty acids were removed and the cells stimulated with LPS (*E. coli* 055:B5) (2  $\mu$ g/mL) for 12 h. TNF- $\alpha$  was measured by ELISA. Values are means + SEM,  $n = 2-3$ . The results are representative of three separate experiments. **a** Different from *No fatty acids* and *LA*, **b** Different from *No fatty acids* and *Omega-6* fatty acids ( $P < 0.05$ ). The abbreviations used are the same as for Fig. 1

elicited peritoneal macrophages as well as the cell line, RAW 264.7. In addition, dietary omega-3 PUFA increased TNF- $\alpha$  secretion per cell ex vivo, as determined by ELISPOT assay, in the present study. These results are in accordance with results from several studies showing that dietary omega-3 PUFA increase TNF- $\alpha$  secretion by these cells ex vivo [5, 6, 8, 10, 15, 24, 27, 38]. That omega-3 PUFA have the same effects on TNF- $\alpha$  secretion by resident peritoneal macrophages in vitro as dietary fish oil has ex vivo indicates that the effects of omega-3 PUFA on TNF- $\alpha$  secretion may be due to incorporation of omega-3 PUFA into cell membranes and their effects on lipid mediator production or intracellular signaling molecules. It has previously been shown that the increase in TNF- $\alpha$  secretion by resident peritoneal macrophages from mice fed fish oil is partly explained by a decrease in prostaglandin (PG) E<sub>2</sub> production by these cells [16, 27]. Other mechanisms at work have not been identified but increased activation of extracellular receptor-activated kinases 1/2 and increased binding of early growth response-1 (Egr-1) to the TNF- $\alpha$  promoter have been shown to contribute to the increased LPS induced TNF- $\alpha$  secretion by macrophages treated with ethanol [30]. Reduced activation of mitogen-activated protein kinase (P44/P42) [23], AP-1 transcription factor [3], and transcription factor nuclear factor (NF)  $\kappa$ B [20, 25] have been proposed to mediate omega-3 PUFA induced decrease in TNF- $\alpha$  secretion by the murine macrophage cell line, RAW 264.7 whereas reduced LPS binding, suppression of CD14 upregulation [11], reduced nuclear p65 levels, and increased I $\kappa$ B $\alpha$  expression have been proposed to mediate omega-3 PUFA

induced decrease in TNF- $\alpha$  secretion by the human macrophage cell line, THP-1 [39].

In contrast to omega-3 PUFA increasing TNF- $\alpha$  secretion by primary resident peritoneal cells they had no effect on IL-10 secretion by these cells in vitro. In addition, there was no effect of dietary omega-3 PUFA on the average IL-10 secretion per cell ex vivo. On the other hand, there was a decrease in the number of cells from the peritoneum of mice fed the fish oil diet secreting IL-10 compared with that from the peritoneum of mice fed the corn oil diet. These results are in accordance with results from our previous study showing decreased IL-10 in the medium from peritoneal macrophages from mice fed fish oil compared to that in the medium from macrophages from mice fed corn oil. Thus, the decrease in IL-10 secretion by resident peritoneal macrophages from mice fed fish oil seen in a previous study [27] is explained by a decrease in the number of cells, secreting IL-10 upon stimulation with LPS ex vivo. The effect of dietary fish oil to decrease the number of IL-10 secreting cells in the peritoneum of mice may perhaps be brought about by an effect on cell recruitment to the peritoneum or by an effect on maturation or proliferation of peritoneal cells.

Although, to our knowledge, the present study is the first to examine the effects of omega-3 PUFA on TNF- $\alpha$  and IL-10 secretion by resident peritoneal macrophages in vitro, others have studied their effects on primary elicited peritoneal macrophages. Our results showing increased TNF- $\alpha$  secretion by elicited peritoneal macrophages incubated with omega-3 PUFA compared with that by cells incubated with omega-6 PUFA are in agreement with results from these other studies [17, 34].

The results from the present study showing increased TNF- $\alpha$  secretion by RAW 264.7 macrophages incubated with omega-3 PUFA compared with that when incubated without fatty acids or with omega-6 PUFA are in disagreement with results from previous studies [2, 22, 25]. In these studies, RAW 264.7 macrophages incubated with EPA or with Omegaven, a fatty acid emulsion consisting of various fatty acids, including EPA and DHA, secreted less TNF- $\alpha$  than cells incubated without EPA [22] or with Lipovenos, an omega-6 PUFA emulsion [25], respectively. In the latter study the cells were incubated with Omegaven for only 4 h and stimulated with LPS for 3 h. However, longer incubation and stimulation times do not seem to explain the different results obtained in the present study, because when we incubated the RAW 264.7 cells with omega-3 or omega-6 PUFA for 4 h and stimulated them for 6 h, cells incubated with omega-3 PUFA still secreted more TNF- $\alpha$  than cells incubated without fatty acids or with LA (results not shown). Neither is the difference in  $\alpha$ -tocopherol concentration in incubations in the two studies likely to explain the different results, as the  $\alpha$ -tocopherol

concentration in cultures with Omegaven [25] is below that shown to decrease TNF- $\alpha$  secretion by RAW 264.7 cells [39]. Whether the different source of omega-3 PUFA, inclusion of serum in the cultures, or different passages of the RAW 264.7 cells explain the differences in results between the present study and the one by Novak et al. [25] remains to be examined. Lo et al. [22] used a higher concentration of EPA than we used in the present study and a cytotoxicity assay with L929 cells to measure TNF- $\alpha$  but how these differences between the study by Lo et al. [22] and the present study can explain the contrasting results is difficult to envisage.

In summary, results from the present study show that omega-3 PUFA increase TNF- $\alpha$  secretion by primary resident and elicited peritoneal macrophages and the RAW 264.7 cell line but have little effect on IL-10 secretion by these cells. In addition, omega-3 PUFA have the same effect on TNF- $\alpha$  secretion by resident peritoneal macrophages in vitro as dietary fish oil has on TNF- $\alpha$  secretion by these cells stimulated ex vivo. Thus, omega-3 PUFA may be incorporated into the cell membrane and from there affect lipid mediator production or intracellular signaling and thereby TNF- $\alpha$  secretion. In contrast, the effects of dietary omega-3 PUFA on IL-10 secretion by resident peritoneal macrophages ex vivo is not mimicked by incubating these cells with omega-3 PUFA in vitro. These effects are probably due to an effect of dietary fish oil on the cell population in the peritoneum of mice in vivo, possibly brought about by an effect on cell recruitment, maturation, or proliferation. Although omega-3 PUFA may have an anti-inflammatory effect on lymphocytes, the results from the present study indicate that omega-3 PUFA have pro-inflammatory effects on macrophages. These effects may be important in maintaining the innate immune response.

## Conjugated Linoleic Acids Can Change Phagocytosis of Human Monocytes/Macrophages by Reduction in Cox-2 Expression

**Abstract** Prostaglandin E<sub>2</sub> produced endogenously (by cyclooxygenases) can regulate macrophage phagocytosis. Cyclooxygenase activity reduction (mainly through inhibition of inducible Cox-2) can induce PGE<sub>2</sub> synthesis depression and can activate the phagocytosis process. There are no reports in the literature explaining whether conjugated linoleic acid dienes (*trans*-10, *cis*-12 CLA and *cis*-9, *trans*-11 CLA) modify the phagocytic activity of human macrophages. For the purpose of this study, monocytes were isolated from venous blood, incubated for 7 days with 30 μM CLAs, and then (in some experiments) LPS (1 μg/mL) was added to the medium. Subsequently, monocyte/macrophage phagocytosis, NF-κB transcription factor activity, Cox-2 and PPARγ mRNA expression (and the amounts of Cox-2 and PPARγ proteins) and PGE<sub>2</sub> synthesis were determined. Both CLA isomers increased macrophage phagocytosis through inhibition of Cox-2 expression (might by inactivation the NF-κB pathway). The inhibition of mRNA Cox-2 expression contributed

(particularly with respect to *trans*-10, *cis*-12 CLA) to a decrease in protein Cox-2 synthesis and to reduction of prostaglandin E<sub>2</sub> content in the cell. The inhibition of PGE<sub>2</sub> synthesis (by CLA treatment) enhanced the phagocytosis process in macrophages.

**Keywords** Conjugated linoleic acid · Monocytes/macrophages · Phagocytosis · NF-κB · Prostaglandin E<sub>2</sub>

### Abbreviations

CLA	Conjugated linoleic acid
Cox	Cyclooxygenase
LPS	Lipopolysaccharide
NF-κB	Nuclear factor κB
PPAR	Peroxisome proliferator activated receptors
PGE <sub>2</sub>	Prostaglandin E <sub>2</sub>

### Introduction

Introduction of a specific diet may be highly important for the treatment of diseases with an inflammatory background, cancer or atherosclerosis [1]. Dietary fatty acids may change the activity of immune system cells through modification of the biological membranes composition [2], the effect on eicosanoid synthesis [3, 4] and gene expression regulation by, for example, PPAR family receptors [5]. Conjugated linoleic acid dienes (CLAs) are fatty acids which can modulate the function of immune system cells in human [6, 7] and animal bodies [8, 9]. Conjugated linoleic acids are positional and geometric isomers of linoleic acid with the presence of conjugated double bonds [10, 11]. In the human body, CLAs originate from two sources: from

food and from the conversion of other *trans* isomers of fatty acids [12]. Their content in human plasma depends on the dietary habits and rises upon diet supplementation with these fatty acids. Conjugated linoleic acids are transported to the tissues with plasma lipoproteins. The activity of intravascular lipoprotein lipase (LPL) leads to CLA uptake and their inclusion in the cellular metabolic pool, where CLAs serve as energetic material or may be built into membrane phospholipids [13].

Conjugated linoleic acids are considered to have anti-inflammatory [14], anti-atherogenic [9, 15, 16, 17], anti-diabetogenic [18, 19] and anti-adipogenic properties [20, 21].

Immune response may be triggered by bacterial infection. The presence of a microorganism in the body, stimulates the cells to activate the  $\kappa$ B transcription factor, to express pro-inflammatory enzymes, and to start the phagocytosis process. Many factors with immunomodulatory properties may enhance the phagocytosis process in macrophages. They also include fatty acids forming the phospholipids of cellular membranes [22]. Differences in fatty acid composition of the cellular membrane phospholipids in peripheral blood mononuclear cells (PMBC) correlate with differences in phagocytic activity of these cells [22, 23].

The transcription factor NF- $\kappa$ B is one of the key regulators of inflammation; the activated NF- $\kappa$ B can mediate the induction of more than 160 genes which have a crucial role in atherogenesis [24, 25]. The  $\kappa$ B sequence is located within the genes important for the processes of proliferation and apoptosis, participating in inflammatory processes [25]. NF- $\kappa$ B is a family of five transcription factors: p65 (rel A), c-Rel, Rel-B, p50 (NF- $\kappa$ B 1) and p52 (NF- $\kappa$ B2) [24, 26, 27, 28]. These proteins form homodimers or heterodimers, of which p65p50 is the most abundant [24]. In the cytoplasm, the inactive NF- $\kappa$ B complex remains bound to the inhibitor—I $\kappa$ Bs family proteins (I $\kappa$ B $\alpha$ , I $\kappa$ B $\beta$ , I $\kappa$ B $\epsilon$ , I $\kappa$ B $\gamma$ ); their function is to block the translocation of the active NF- $\kappa$ B complex into the cell nucleus [29, 30, 31]. NF- $\kappa$ B activation is mediated by the I $\kappa$ B kinase complex containing two catalytic subunits (IKK 1 and IKK 2) and a regulatory subunit; NF- $\kappa$ B essential modulator (NEMO). Upon stimulation, the IKK complex phosphorylates I $\kappa$ B inducing its degradation. NF- $\kappa$ B is then free to translocate to the nucleus, where it facilitates the transcription of genes with a promoter sequence present in the gene enhancer region GGGGACTTTCC [24]. NF- $\kappa$ B, through its participation in the stimulation of Cox-2 expression, has also an effect on prostanoid synthesis in cells [32].

PPAR $\gamma$  is a receptor that may play an important role in regulating inflammatory and immune responses through

modulation of the monocyte and macrophage activity [23]. The PPAR $\gamma$  are a subfamily of nuclear hormone receptors activated by dietary as well as endogenous fatty acids and their derivatives [33]. PPAR $\gamma$  agonists such as 15-deoxy- $\Delta$ -12, 14-prostaglandin J<sub>2</sub> or thiazolidinediones reduce acute inflammation [33], although in primary human monocytes they induce Cox-2 expression and PGE<sub>2</sub> secretion [34].

The expression of Cox-2 in macrophage cells may be regulated by a negative feedback loop mediated through PPAR $\gamma$  by interfering with the NF- $\kappa$ B pathway (by a PGD<sub>2</sub> metabolites) [35]. Conjugated linoleic acids increased PPAR $\gamma$  expression in macrophages [15] and in other cell types [36, 37]. The *trans*-10, *cis*-12 CLA isomer may be a direct ligand and activator of PPAR $\gamma$  [38].

Arachidonic acid metabolites—prostanoids are endogenous mediators of inflammation. Prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) which is a product of two cyclooxygenase isoforms—Cox-1 and Cox-2, plays an important role in this process [39]. Cox-1 is a constitutive enzyme with constant low activity whereas Cox-2 is inducible and its amount in the cell rapidly increases in inflammation [39]. Lipopolysaccharide (LPS) present in the bacterial wall is a strong Cox-2 activator in monocyte cells [40]. Cox-2 expression following LPS administration takes place via the NF- $\kappa$ B pathway [40]. An important source of PGE<sub>2</sub> in the place of inflammation are monocytes/macrophages [40]. PGE<sub>2</sub> synthesis (mediated by Cox-2 expression) dramatically increases in inflammation. The endogenously produced PGE<sub>2</sub> can regulate macrophage phagocytosis PGE<sub>2</sub> synthesis inhibition enhances phagocytosis while PGE<sub>2</sub> synthesis activation inhibits this process [41].

So far, few studies have been published to explain whether CLA isomers may modify immune functions of monocytes/macrophages. In the pioneering study by Kang [42] the *trans*-10, *cis*-12 CLA isomer was shown not to modify phagocytic capacity of cultivated polymorphonuclear cells (PMN cells). Nevertheless, PMN cell phagocytosis increased when the supernatant of peripheral blood mononuclear cells (PMBC) incubated with *trans*-10, *cis*-12 CLA was added to PMN cells [42]. The next study by Kang (published when this study was being edited) demonstrated that the *trans*-10, *cis*-12 CLA isomer might activate phagocytosis in (pig) PMBC through a PPAR $\gamma$ -dependent mechanism [23].

The objective of this study is to explain whether phagocytic capacity may be regulated in monocytes/macrophages incubated with CLAs through modifications of Cox-2 activity and of PGE<sub>2</sub> synthesis. Particular attention was paid in the study to the function of the Cox-2 and NF- $\kappa$ B transcription factor in phagocytosis.

## Experimental Procedure

### Reagents

Cell culture media and reagents were supplied by Gibco (Gibco, UK) and Sigma (Sigma-Aldrich Poland), indomethacin, Bradford reagent and lipopolysaccharide (*E. coli*) were supplied by Sigma-Aldrich, Poland. N-2-cyclohexyloxy-4-nitrophenyl-methanesulfonamide (NS 398) was supplied by Cayman Chemical (USA).

Lymphocyte separation medium was supplied by PAP Laboratories, Austria. Conjugated linoleic acids (*cis*-9, *trans*-11 CLA; *trans*-10, *cis*-12 CLA) were supplied by Nu-CheK Prep (98% purity) (USA). Phagotest was supplied by Opregen Pharma (Germany). All reagents and solvents for the PGE<sub>2</sub> extraction were supplied by Aldrich (Sigma-Aldrich, Poland). ELISA commercial kits for PGE<sub>2</sub> concentration measurements were supplied by R&D (R&D Systems, UK). The NF- $\kappa$ B p65/Rel A Transcription Factor Assay ELISA kit and Nuclear Extract Isolation Kit were supplied by Active Motif (Belgium). C<sub>18</sub> reverse phase columns were supplied by JT Baker, (USA) and the solid phase extraction–Vacuum Manifold system for PGE<sub>2</sub> extraction were supplied by Supelco (Supelco, Poland).

The mRNA isolation kit was supplied by Qiagen (USA). Reagents for real-time PCR: i.e. 5 $\times$  First Strand Buffer, oligo (dT) and DTT, were supplied by Sigma-Aldrich, deoxy-NTPs were supplied by Promega (USA) and SUPERScript II reverse transcriptase was supplied by Invitrogen (USA).

The monoclonal anti-Cox-2, and anti-PPAR $\gamma$  antibodies were supplied by Santa Cruz Biotechnology (USA). The anti- $\beta$ -actin monoclonal antibody was supplied by Sigma-Aldrich (Sigma-Aldrich, Poland).

### Preparation of Monocytes from Peripheral Blood Mononuclear Cells (PBMC)

Monocytes were isolated from peripheral blood of 55 healthy donors, Caucasian whites (31 males, 24 females), aged 20–25 years. Because age-related increase in Cox-2 expression in mononuclear cells was observed in humans [43], donors older than 25 years old and donors with a history of hypertension or diabetes were excluded from the study. Ten patients were ex-smokers and the remaining ones had never smoked. An average standard of living was found for all patients and there were no cases of malnutrition. Patients were fully informed as to the study objectives and benefits and provided their written consent prior to enrolment.

Cells obtained from 25, 15, 6, 9 and 3 donors were used for phagocytic activity quantification, PGE<sub>2</sub> concentration, measurement NF- $\kappa$ B activation determination, real-time

PCR and the Western blot analysis, respectively. In each single experiment (e.g. phagocytosis measurement), the cells obtained from one donor were cultured with BSA or separate CLA isomers. Blood sampling was performed in accordance with the principles outlined in the Declaration of Helsinki (Cardiovascular Research 1997; 35:2–3). First peripheral blood mononuclear cells (PBMCs) were isolated from anti-coagulated blood by lymphocyte separation media density gradient as described [44]. The cells were cultured at a density of  $3 \times 10^6$  cells/well in plastic culture dishes. Monocytes were isolated from lymphocytes by adherence to plates (2 h at 37 °C, 5% CO<sub>2</sub>) as described [44]. Then, the adherent cells were incubated in the RPMI 1640 medium supplemented with 10% autologous serum, penicillin (100 U/mL) and streptomycin (100 mg/mL) at 37 °C in 5% CO<sub>2</sub>. The cells were cultured with CLAs: *cis*-9, *trans*-11 C18:2; *trans*-10 or *cis*-12 C18:2, at final concentrations of 30  $\mu$ M in the medium for 7 days. The incubation time and fatty acid concentration were selected on the basis of the results obtained in preliminary experiments. Fatty acids were complexed to 1 mM fatty acid-free bovine albumin (1 mM BSA: 4 mM fatty acids) and added to medium as proposed [36, 45]. The medium was changed every 2 days for 7 days. The cells (after 7 days of incubation in the medium with autologous serum) were characterised by morphological criteria such as CD 14 and CD 68 antigen expression (BD Pharmingen, USA) The percentage of CD 14 and CD 68 cells was assessed by flow-cytometry (FACScan) using CellQuest software as previously described [46]. The resulting cells may be described as “monocyte-derived macrophages” [47] with CD 14 and CD 68 antigens expression.

Cells (after 7 days of incubation with BSA or CLAs) were scraped from the wells and their viability was assessed by trypan blue exclusion as described [44]. Cells whose viability exceeded 90% were used for the experiments.

### Quantification of Phagocytic Activity of Monocytes

Phagocytosis was measured using the PHAGOTEST kit. Before the measurement, the cells were incubated for 4 h at 37 °C with opsonised fluorescein isothiocyanate-labelled *E. coli* (20  $\mu$ L), in compliance with the manufacturer's instruction. The reaction was stopped by the addition of ice-cold quenching solution (100  $\mu$ L). At the completion of phagocytosis, monocytes/macrophages were fixed, and DNA was stained according to the manufacturer's instructions. Cell preparations were then analysed by flow cytometry in a flow cytometer (FACSCalibur, Becton Dickinson). Fluorescence data were collected on  $10 \times 10^4$  cells and analysed using the CELLQUEST software. The percentage of cells engaging in phagocytosis was

determined. In some experiments, the cells (cultured for 7 days with RPMI+10% autologous serum) were pretreated with the Cox inhibitor indomethacin (10  $\mu$ M) or NS 386 (4  $\mu$ M) for 30 min and then challenged with opsonised fluorescein isothiocyanate-labelled *E. coli* (20  $\mu$ L), as described above.

#### Measurement of NF- $\kappa$ B Activation

NF- $\kappa$ B activation was measured in nuclear extract with the NF- $\kappa$ B p65/Rel A Transcription Factor Assay kit. The active p65/Rel A was measured in cells cultivated with CLAs for 7 days. Subsequently, the cells were incubated with LPS (1  $\mu$ g/mL, 4 h at 37 °C in 5% CO<sub>2</sub>). To some cells LPS was not added.

The cells were briefly washed with ice-cold PBS, scraped into tubes and centrifuged. The pellet was lysed with the complete lysis buffer containing dithiothreitol and protease inhibitor cocktail of the Nuclear Extract Isolation Kit. After centrifugation at 5,000g and 4 °C for 20 min, protein concentration in the supernatant (whole cell extract) was determined with the Bradford-based assay. To determine the NF- $\kappa$ B activation with an ELISA-based kit, an oligonucleotide containing the NF- $\kappa$ B consensus binding site (5'-GGGACTTTCC-3') specific for the active form of NF- $\kappa$ B was immobilized on a 96-well plate and the well was filled with 10  $\mu$ g of the nuclear extract. After the incubation and washing, the primary antibody against the active form of NF- $\kappa$ B was added followed by the secondary antibody conjugated with horseradish peroxidase, to achieve a sensitive readout by spectrophotometry at 450 nm.

The experiments were performed in duplicate and the results were expressed as OD<sub>450 nm</sub> [48].

#### Measurement of PGE<sub>2</sub> Concentration

After 7-day incubation with fatty acids, the cells were exposed to a medium containing *E. coli* LPS (1  $\mu$ g/mL) according producer instruction. In some experiments, cells incubated for 7 days with RPMI with 10% autologous serum were pretreated for 30 min before LPS administration with indomethacin (10  $\mu$ M) or NS 386 (4  $\mu$ M) (stimulated cells). In other experiments, the cells were cultured for 7 days with BSA or CLAs, whereas LPS was not administered to them (at the end non-stimulated cells). After incubation, the supernatant was collected and PGE<sub>2</sub> in the supernatant was measured by enzyme immunoassay. The cells were scraped, washed twice with ice-cold PBSs (centrifuged at 2,000g for 10 min.), and protein concentration in the pellet was determined with a Bradford-based assay. For PGE<sub>2</sub> extraction, typical C<sub>18</sub> reverse phase columns (JT Backer, USA) and the solid phase extract

Vacuum Manifold system (Supelco, Poland) were used according to the R&D assay procedure.

#### PCR Reaction with the Analysis of Real-Time Product Quantity Increase (Real-Time PCR)

The Qiagen kit was used for isolation of m RNA from cells. In order to confirm enzymatic activity regulation, the quantitative expression analysis was performed by real time PCR using GAPDH as the reference gene, as described in details [49]. For the cDNA synthesis, 1  $\mu$ g of total RNA was reverse transcribed at 42 °C for 50 min in a total volume of 40  $\mu$ l of reaction buffer containing 5 $\times$ First Strand Buffer, oligo (dT), DTT, deoxy-NTPs, and 200 units of SUPERScript II reverse transcriptase. cDNA was subjected to real-time PCR in a reaction mixture containing the QuantiTect SYBR Green PCR (Qiagen) mix and primers. The sequences of primers used in this study:

Cox-2	Forward primer: 5'- ATGAGATTGTGGGAAAATTGCT-3'
	Reverse primer: 5'-GATCATCTCTGCCTGAGTATC-3'
PPAR $\gamma$	Forward primer: 5'-ATGACAGCGACTTGCCAA-3'
	Reverse primer: 5'-TCAATGGGCTTCACATTC-3'
GAPDH	Forward primer: 5'-GCCAGCCGAGCCACATC-3'
	Reverse primer: 5'-GCGCCAATACGACCAAA-3'

All real-time PCR reactions were performed on the DNA Engine Option II (MJ Research). The thermal profile included initial denaturation for 15 min at 95 °C, followed by 40 amplification cycles of denaturation for 30 s at 72 °C. Following the PCR amplification, melting curve analysis was performed with a temperature profile slope of 1 °C/s from 35 °C to 95 °C. A negative control without cDNA template was run with every assay to ensure overall specificity. The expression rates were calculated as described [49, 50].

#### Western Blot for Cox-2 Analysis

The cells were harvested in the lysis buffer at pH 6.8, as described [44]. The cellular debris was removed (14,000g for 15 min) and protein concentration was determined by the Bradford assay. Equal amounts of lysates were subjected to SDS-PAGE (7% polyacrylamide) and transblotted onto nitro-cellulose membrane. Membranes were incubated for 12 h/4 °C with antibodies directed against Cox-2 (1/1,000), PPAR $\gamma$  (1/600),  $\beta$ -actin (Sigma-Aldrich, Poland) was used as a control of protein loading [19]. The blots were incubated with peroxidase-conjugated secondary antibody (1/5,000) for 1 h at room temperature. The bands

were visualized by enhanced chemiluminescence (Amersham Pharmacia Biotech, USA) [51].

### Statistical Analysis

All results are expressed as mean values  $\pm$  standard deviation (SD). Before statistical analysis, normality of distribution was tested by the Shapiro–Wilk test. As the distribution in most cases deviated from normal, non-parametric tests were used. For related samples, the significance was first checked with Friedmann's ANOVA and then significant results were subjected to the Wilcoxon matched-pair test. The software used was Statistica 6.1 (Statsoft, Poland).

## Results

### CLAs Modified the Phagocytic Activity of Monocytes/Macrophages

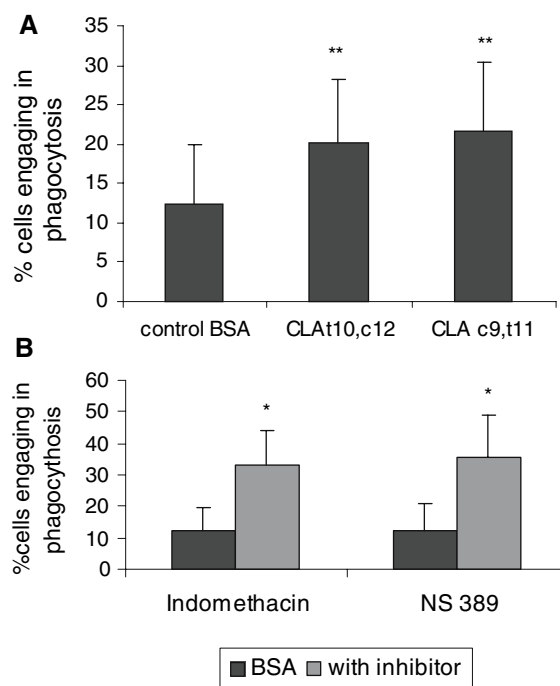

Significant changes in the phagocytic activity were observed ( $P < 0.0001$ ; Friedmann's ANOVA test). Both conjugated linoleic acids enhanced the percent of cells engaging in phagocytosis. The *trans*-10, *cis*-12 C18:2 isomer increased this process by 61% ( $P < 0.001$ ; Wilcoxon matched-pair test) as compared to control, and the *cis*-9, *trans*-11 C18:2 isomer increased phagocytosis by 73% ( $P < 0.001$ ; Wilcoxon matched-pair test) (Fig. 1a). The phagocytic capacity was induced by the addition of cyclooxygenase inhibitors indomethacin ( $P < 0.05$ ; Wilcoxon matched-pair test) and NS 386 ( $P < 0.05$ ; Wilcoxon matched-pair test) to the cells (Fig. 1b).

### CLAs Reduced the Amount of Active Form of NF- $\kappa$ B Transcription Factor

In this study, we investigated the effect of on NF- $\kappa$ B activity using the immunoenzymatic method in which the primary antibodies used to detect NF- $\kappa$ B recognise an epitope on p65/Rel A that is only accessible when NF- $\kappa$ B is activated and bound to its target DNA. As compared to control BSA, both conjugated linoleic acid dienes, reduced the activation of the p65/Rel A subunit of the NF- $\kappa$ B complex ( $P < 0.03$  for both CLA isomers; Wilcoxon matched-pair test) (Fig. 2). In LPS-stimulated cells, low activity of the p65/Rel A subunit was noted, without any visible effect of fatty acids.

### CLAs Decreased PGE<sub>2</sub> Synthesis

In non-LPS-stimulated cells incubated with CLAs, PGE<sub>2</sub> synthesis was low, without any significant effect of fatty

**Fig. 1** **a** Effect of conjugated linoleic acid on monocyte/macrophage phagocytic activity. Monocytes were incubated for 7 days with the 30  $\mu$ M *trans*-10, *cis*-12 CLA and *cis*-9, *trans*-11 CLA. Data were expressed as a percentage of cells engaging in phagocytosis and shown as the mean  $\pm$  SD (represented by vertical bars) in 16 separate experiments.  $**P < 0.001$  significant difference versus the corresponding control. **b** The effect of Cox inhibitors: indomethacin and NS 386 on the phagocytic activity. Cells were cultured for 7 days with BSA (control) or with Cox inhibitor indomethacin (10  $\mu$ M) or specific Cox-2 inhibitor NS 386 (4  $\mu$ M). The data were expressed as percentage of cells engaging in phagocytosis and shown as the mean  $\pm$  SD in five separate experiments (indomethacine) or four separate experiments (NS 386).  $*P < 0.05$  significant difference versus the corresponding control

**Fig. 2** Influence of conjugated linoleic acid dienes on NF- $\kappa$ B pathway activation. Monocytes were cultivated for 7 days in a medium containing 30  $\mu$ M fatty acids, then LPS (1  $\mu$ g/mL) was added or cells were cultured without LPS administration. A nuclear cell extract was obtained and NF- $\kappa$ B activation was measured using an ELISA-based kit. The data were expressed as OD<sub>450 nm</sub> and shown as the mean  $\pm$  SD (represented by vertical bars) in six separate experiments.  $*P < 0.05$  significant difference versus the corresponding control

acids on PGE<sub>2</sub> concentration in the culture. In LPS-stimulated cells, the synthesis of PGE<sub>2</sub> was enhanced (as compared to non-stimulated cells), and in cells incubated with CLAs, the PGE<sub>2</sub> production was reduced (Fig. 3). The changes in PGE<sub>2</sub> concentrations depending on the CLA isomer were statistically significant ( $P < 0.03$ , Friedmann's ANOVA test). Both CLA isomers significantly reduced PGE<sub>2</sub> production compared to the BSA control ( $P < 0.01$ ) (Fig. 3).

Both types of Cox inhibitors reduced PGE<sub>2</sub> synthesis. As compared to control, the NS 386 reduced PGE<sub>2</sub> concentration with this same intensity as indomethacin (near 80%) (Fig. 3).

#### Effect of CLAs on Relative mRNA and Protein Concentration of Cox-2 and PPAR $\gamma$ Expression and Enzyme Protein Synthesis

The *trans*-10, *cis*-12 isomer reduced Cox-2 mRNA expression in macrophages after 7 days of incubation. A strong trend towards mRNA expression reduction is manifested in cells incubated with the *cis*-9, *trans*-11 isomer (Fig. 4). The semi-quantitative measurement of Cox-2 protein contents (Western-blot method) showed both CLA isomers to limit the amount of this enzyme in the cell (Fig. 5).

In the cells incubated with both CLA isomers, a strong trend towards PPAR $\gamma$  mRNA expression increase was

**Fig. 3** The effect of conjugated linoleic acid and Cox inhibitors, indomethacin and NS 386, on the PGE<sub>2</sub> synthesis. Monocytes were cultivated for 7 days in a medium containing 30  $\mu$ M CLA. After incubation, some cells were stimulated by addition of 1  $\mu$ g/mL LPS for 4 h. The data were expressed and shown as mean PGE<sub>2</sub> (pg/ml  $\mu$ g protein)  $\pm$  SD in six separate experiments (cells stimulated) or nine experiments (cells unstimulated by LPS). In the experiments with Cox-2 inhibitors, the cells were incubated for 7 days with BSA (control) and with Cox inhibitor indomethacin (10  $\mu$ M), or NS 386 (4  $\mu$ M). After incubation the cells were stimulated by administration of 1  $\mu$ g/mL LPS for 4 h. The data were expressed and shown as mean PGE<sub>2</sub> (pg/ml  $\mu$ g protein)  $\pm$  SD in five separate experiments (indomethacin) or four separate experiments (NS 386). \* $P < 0.05$  significant difference of the mean versus the corresponding control

**Fig. 4** Effect of CLAs on the expression of Cox-2 and PPAR $\gamma$  genes verified by the quantitative real-time PCR. Data expressed as the relative gene expression ratio. The mean values  $\pm$  SD,  $n = 3$  done in triplicates are shown; \* $P < 0.05$  significant difference versus the corresponding control

noted (Fig. 4). The presence of PPAR $\gamma$  protein in these cells was confirmed by immunoelectrophoresis (Fig. 6).

#### Discussion

So far, only few studies have been published on the role of CLAs in modulating the phagocytic response of the cell [23, 42]. The study by Kang (published when this study was being edited) presenting the role of CLA—*trans*-10, *cis*-12 CLA in modifying the phagocytic capacity of peripheral blood polymorphonuclear cells (PMBC)—throws some light on this issue [23]. The study by Kang focused on investigation of changes in phagocytic capability through an effect on TNF- $\alpha$  synthesis via the PPAR $\gamma$ -dependent pathway [23]. On the other hand, this study investigates the potential participation of the Cox-2 and  $\kappa$ B transcription factor in this process. We were prompted to undertake the studies on the basis of the results indicating that phagocytosis in macrophages correlates with PGE<sub>2</sub> concentration

**Fig. 5** Role of conjugated linoleic acid in Cox-2 protein induction. The cells were incubated for 7 days in a medium containing 30  $\mu$ M CLA or BSA. Cox-2 proteins were determined by the Western analysis. Blots are representative of three independent experiments performed with different cell cultures

**Fig. 6** Role of conjugated linoleic acid in PPAR $\gamma$  protein induction. The cells were incubated for 7 days in a medium containing 30  $\mu$ M CLA or BSA. PPAR $\gamma$  proteins were determined by the Western analysis. Blots are representative of three independent experiments performed with different cell cultures

[41]. PGE $_2$  in macrophages is for the most part a product of Cox-2 [41], and NF- $\kappa$ B is the transcription factor regulating Cox-2 expression [32]. Because CLA isomers reduce PGE $_2$  release mainly through limiting Cox-2 expression [52], a decision was made to investigate whether CLAs may have an effect on phagocytic capacity of macrophages through an effect on expression of this enzyme.

As demonstrated by our observations, the *trans*-10, *cis*-12 CLA isomer reduced Cox-2 mRNA expression in macrophages, whereas the other isomer definitely reduced Cox-2 expression (although statistically significant results were not obtained in this case). Both isomers seem to contribute to limiting the Cox-2 protein quantities in cells. Similar results were obtained in lung cells incubated with CLA isomers [53]. Considerable (80%) inhibition of Cox-2 expression was noted in the presence of the *trans*-10, *cis*-12 CLA isomer. This inhibition was much lower in the presence of the *cis*-9, *trans*-11 CLA isomer. Proportionally to changes in Cox-2 expression, also PGE $_2$  synthesis was reduced in the cells. A similar tendency was noted in *in vivo* studies in mice receiving feed supplemented with CLAs. In these animals, a 30% reduction in Cox-2 mRNA expression and PGE $_2$  synthesis reduction was noted in the presence of the *trans*-10, *cis*-12 CLA isomer. The authors associate this phenomenon (Cox-2 mRNA reduction and PGE $_2$  synthesis lowering) with inhibition of the NF- $\kappa$ B pathway caused by CLA [53]. Also in cancer cells (canine mammary cells) and control cells (healthy cells) incubated with CLAs, both isomers inhibited Cox-2 protein expression. On the other hand, the *trans*-10, *cis*-12 isomer was a more potent repressor of Cox-2 synthesis in cancer cells [54].

Pronounced differences in intensity of phagocytosis in these studies were shown between control macrophages (incubated with BSA) and macrophages incubated with CLAs following the addition of an inflammatory factor

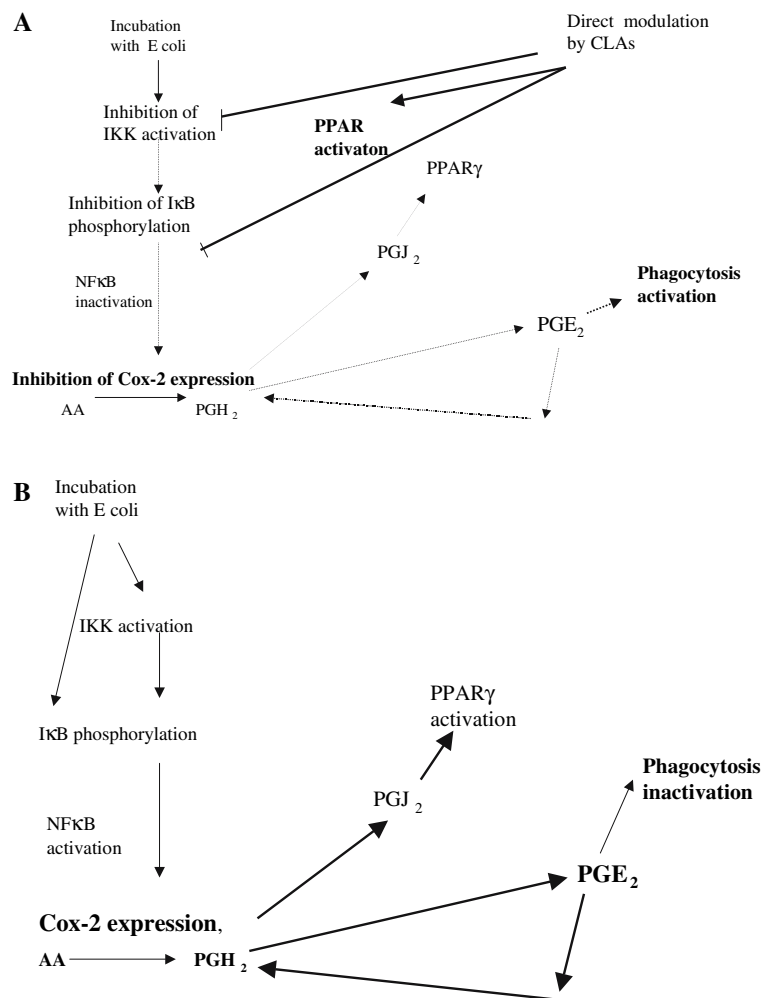

(LPS). When the cells were cultivated with BSA (control cells) the addition of bacteria (LPS) to the culture caused activation of the  $\kappa$ B transcription factor (NF- $\kappa$ B), which triggered Cox-2 expression. The increase in the amount of Cox-2 elevated the synthesis of PGE $_2$  in the cells. The increased amount of PGE $_2$  contributes to the inhibition of phagocytosis through the activation of PGE $_2$  receptors subtypes EP2 and EP4, and leads to an increase in cAMP concentration in the cell which additionally causes rebound activation of Cox-2 [41].

On the other hand, in cells incubated with CLAs both isomers activated phagocytosis. How can CLAs change this process? They might contribute to an inhibition of PGE $_2$  synthesis by reduction of mRNA Cox-2 expression and its activity. This may be evidenced by the reduced PGE $_2$  synthesis and concomitant activation of phagocytosis following the administration of NS 389—a selective Cox-2 inhibitor. NS 389 limited PGE $_2$  synthesis to the same extent as indomethacin, which implies that the factor primarily responsible for PGE $_2$  synthesis in the cell was Cox-2. The phenomenon of limiting Cox-2 expression by CLAs was also noted in murine macrophages (RAW 264.7), where the addition of *cis*-9, *trans*-11 CLA led to a reduction in Cox-2 expression (inhibition of Cox-2 promoter expression) and diminished PGE $_2$  synthesis [15].

In this study, Cox-2 expression reduction might take place through limitation of NF- $\kappa$ B activation—both CLA isomers inhibited activation of this transcription factor. This is not an isolated phenomenon—a reduction of the NF- $\kappa$ B pathway by fatty acids was reported previously, and it was shown that and other fatty acids may directly inhibit NF- $\kappa$ B [55, 56]. The mechanism which links with NF- $\kappa$ B inactivation, consists in the reduction of I $\kappa$ B kinase activity (leading to the inhibition of NF- $\kappa$ B phosphorylation). In these circumstances, dissociation of the NF- $\kappa$ B complex from its inhibitor, *i.e.* I $\kappa$ B, is decreased [57, 58]. Additionally, CLAs, like the other fatty acids (DHA and oleic acid) are likely to directly inhibit NF- $\kappa$ B activation through the effect on inactive NF- $\kappa$ B complex [55]. The inhibition of Cox-2 expression triggers a reduction in PGE $_2$  synthesis in the cell. A low amount of PGE $_2$  in the cells increased phagocytosis (Fig. 1). A similar phenomenon was observed in *in vivo* and *in vitro* studies conducted on mouse skin cells (in HR-1 hairless mouse skin). In these cells, the *cis*-9 *trans*-11 isomer inhibited the NF- $\kappa$ B dependent Cox-2 expression through blockade of activity of the IKK kinase [59] (Fig. 7).

The phenomenon of NF- $\kappa$ B inactivation in the presence of CLAs may also be associated with the expression and probable activation [38] of nuclear PPAR $\gamma$ . PPAR $\gamma$  are receptors which may interfere with NF- $\kappa$ B [25, 60]. The direct mechanism associating PPAR expression with NF- $\kappa$ B inactivation may be PPAR-forced reduction in I $\kappa$ B

**Fig. 7** Modulation of phagocytosis by CLAs, AA arachidonic acid, *IκB* inhibitor of *IκB*, *IKK* *IκB* kinase, *PPAR* $\gamma$  peroxysome proliferator-activated receptor  $\gamma$

kinase activity, inhibiting NF- $\kappa$ B/*IκB* complex dissociation and thus inhibiting NF- $\kappa$ B activation [25].

We concluded that CLA isomers increased macrophage phagocytosis through inhibition of Cox-2 expression what contributed to reduction of prostaglandin E<sub>2</sub> content in the cell. The inhibition of PGE<sub>2</sub> synthesis (by CLA treatment) enhanced the phagocytosis process in macrophages.

**Abstract** Cholesterol removal from tissues into HDL depends on the activity of lecithin-cholesterol acyltransferase (LCAT; E.C. 2.3.1.43) that is associated with lower cardiovascular diseases risk. HDL cholesterol concentration and LCAT activity can be modulated by dietary fatty acids. Original data with substrate models have shown a positive effect of myristic acid (MA) on the esterification rate of cholesterol. The purpose of this study was to examine the effect of moderate intakes of MA associated with recommended intake of alpha-linolenic acid (ALA) on LCAT activity in humans. Two experimental diets were tested for 3 months each. Diet 1-MA 1.2% of total energy (TE) and ALA 0.9% TE, diet 2-MA 1.8% and ALA 0.9% TE; a control diet (MA 1.2% and ALA 0.4% TE) was given 3 months before diet 1 and diet 2. The endogenous activity of LCAT was determined at completion of each diet. Compared with the control diet ( $13.2 \pm 3.1 \mu\text{mol CE}/(\text{L}\cdot\text{h})$ ), LCAT activity increased significantly ( $P < 0.001$ )

with diet 1 ( $24.2 \pm 3.6 \mu\text{mol CE}/(\text{L}\cdot\text{h})$ ) and diet 2 ( $33.3 \pm 7.4 \mu\text{mol CE}/(\text{L}\cdot\text{h})$ ); the increase observed with diet 2 was significantly ( $P < 0.001$ ) greater than that due to diet 1. These results suggest that ALA (from rapeseed oil, mainly in *sn*-2 position) and MA (from dairy fat, mainly in *sn*-2 position) favor LCAT activity, by respective increases of 83 and 38%. When they are supplied together, a complementary effect was observed (average increase of 152%). Moreover, these observations were associated with a decrease of the ratio of total to HDL-cholesterol. In conclusion, our results suggest that moderate supply of MA (1.8% TE) associated with the recommended intake of ALA (0.9% TE) contributes to improve LCAT activity.

**Keywords** Myristic acid · Alpha-linolenic acid · *sn*-2 position · Physiological intakes · Human study · Plasma lipid profile · LCAT activity

## Abbreviations

ACAT	Acyl-CoA:cholesterol acyltransferase
ALA	$\alpha$ -Linolenic acid
CE	Cholesteryl esters
LA	Linoleic acid
LCAT	Lecithin-cholesterol acyltransferase
MA	Myristic acid
PC	Phosphatidyl-choline
TE	Total energy

## Introduction

Lecithin-cholesterol acyltransferase (LCAT; E.C. 2.3.1.43) is an enzyme synthesized by the liver that in the blood

preferentially binds to HDL. Alterations in LCAT activity have been associated with changes in HDL cholesterol concentrations [1, 2]. The protective role of HDL is usually attributed to its ability to transport excess cholesterol from peripheral tissues back to the liver in a process termed reverse cholesterol transport. This reverse transport by HDL is intimately connected with the actions of LCAT, that converts cholesterol into long-chain cholesteryl esters (CE) on HDL and promotes cholesterol movement from tissues into HDL. Lecithin-cholesterol acyltransferase utilizes the *sn*-2 fatty acid of a phosphatidyl-choline (PC) molecule to convert cholesterol to CE, resulting in a shift from the particle surface to the core of HDL. The LCAT activity level depends on several factors that include dietary fatty acid composition, molecular species composition of plasma PC and specificity of LCAT towards various PC species [3]. Concerning dietary fatty acids, data from Thornburg et al. [4] have shown in monkeys that the diet composition has only small effects on the absolute amount of circulating enzyme. On the other hand, the composition of PC molecular species in circulating HDL is significantly altered by dietary fat intake. Positional specificity (>90% *sn*-2) of human LCAT has been well documented [5]. Nevertheless, when the *sn*-2 chain is very long (C20, C22), there is increased utilization of the *sn*-1 acyl chain [6, 7]. Other data indicate that the phospholipid environment in which LCAT contacts and binds its substrate may be important in determining the apparent affinity of the enzyme for any one substrate molecular species [8, 9]. Original data from Pownall et al. [8] have determined how molecular structure of PC independently regulate cholesteryl ester formation via LCAT action. Concerning dietary myristic acid (MA, 14:0), Loison et al. [10] have recently reported in hamsters a positive correlation between plasma HDL concentration and the amount of MA in the diet.

Data from two meta-analyses have shown that the SFA 12:0–16:0 [11–13], particular 14:0 [13], are far more HDL cholesterol increasing than MUFA or PUFA. Moreover, Tholstrup et al. [12] observed in humans the plasma HDL-cholesterol level was 8% higher with a diet providing 16% total energy (TE) as MA compared with a diet providing 16% TE as palmitic acid (respectively,  $1.10 \pm 0.06$  vs.  $1.01 \pm 0.05$  mmol;  $P < 0.006$ ). A recent study [14] has observed in humans an increase in HDL cholesterol concentrations by increasing SFA intake (from 8.4 to 11% TE), while plasma apo A-I concentration and LCAT activity both decreased ( $P < 0.02$ ). On the other hand, in hypertriglyceridemic patients, a high-fat diet significantly increased HDL cholesterol and LCAT, while a subsequent low-fat diet decreased HDL cholesterol and LCAT [15]. Recently, Wood et al. [16] showed that a carbohydrate restriction diet (i.e. 10% carbohydrate, 65% fat, and 25%

protein) resulted at the same time in increasing the HDL cholesterol concentration by 12% and LCAT activity by 55%, in overweight and slightly obese men.

In a previous study, we observed that intakes of MA (1.2 or 1.8% TE) and ALA (0.9% TE), both mainly provided in the *sn*-2 position of dietary triacylglycerols were associated with favourable lipoprotein and n-3 PUFA profiles [17]. These results are probably related to the protective effect of the *sn*-2 position on triacylglycerols towards fatty acid  $\beta$ -oxidation, improving the bioavailability of the fatty acid located in the *sn* position [18]. The aim of the present study was to evaluate the influence of long term moderate intakes of MA (1.2 or 1.8% TE) from dairy fat (mainly in the *sn*-2 position) associated with the recommended intake of ALA (0.9% TE) from rapeseed oil (mainly in the *sn*-2 position) on plasma LCAT activity, measured within the context of available substrate (endogenous substrate) and cofactors, due to importance of the phospholipid environment on LCAT activity.

## Materials and Methods

### Subjects

Thirty-two male monks of a Benedictine monastery (Randol Abbey) located in the center of France were enrolled for a 1 year interventional study. Twenty-nine of them were followed till the end of the study. They were between 25 and 85 years old (average, 57 years), weighed between 53 and 99 kg (average, 71 kg), and their body mass index (BMI) ranged from 28 to 18 kg/m<sup>2</sup> (average, 23 kg/m<sup>2</sup>). None of them were known to have dyslipidemia (according to NCEP ATP III) before the study and none of them were taking any lipid-lowering drug or medication affecting lipid metabolism. Most of them had a moderate amount of physical activity (e.g. working in the fields, regular walking). Physical activity and lifestyle were kept unchanged during the study. Anthropometric measurements and blood pressure were obtained for each subject at the baseline and at the end of the two dietary periods. The protocol and aim of the study were fully explained to the subjects and their written consent was taken. The research protocol was approved by the hospital ethics committee.

### Diets

The study design was described in details previously [17]. Briefly, it was the following. The study lasted 12 months, with four periods of 3 months: P<sub>3</sub>, P<sub>6</sub>, P<sub>9</sub> and P<sub>12</sub>. Twenty-nine monks consumed successively control diet (i.e. controlled fat intake of habitual diet) (P<sub>3</sub>), diet 1 (P<sub>6</sub>), control diet (P<sub>9</sub>) and finally diet 2 (P<sub>12</sub>). Control diet provided 32%

TE from fat (11% SFA, 1.2% MA), 13% MUFA and 8% PUFA, of which 5.5% LA and 0.4% ALA). Both interventional diets provided the same intake levels of SFA (11–12% TE), oleic acid (11% TE), linoleic acid (LA; 4.5% TE) and ALA (0.9% TE), but MA intakes were different in diet 1 (1.2% TE) and diet 2 (1.8% TE) (Table 1).

### Plasma Lipid Analysis

Fasting blood samples were obtained from all twenty-nine subjects at a baseline visit before the initiation of each interventional period and at the end of the two 3 months nutritional interventions. Total lipids were extracted from plasma with 5 ml hexane/isopropanol (3:2; v/v). Total cholesterol, HDL-cholesterol and triacylglycerols were analyzed enzymatically (17). LDL-cholesterol was calculated using the Friedewald equation. The apo A-I and apo B were measured using a turbidimetry method kLE LX 20.

### Plasma LCAT Activity

LCAT activity was assayed by conversion of [<sup>3</sup>H] unesterified cholesterol to [<sup>3</sup>H] esterified cholesterol, according to the method of Glomset and Wright [19]. Substrate for LCAT was prepared by incubating [<sup>3</sup>H] unesterified cholesterol–albumin suspension with heat inactivated normal human plasma (55 °C for 30 min) at 4 °C for overnight. For each determination, test plasma (75 µl) was added to 100 µl of labelled heat-treated plasma and mercaptoethanol

(0.15%, v/v) and incubated at 37 °C for 1 h. The reaction was stopped by addition of methanol and lipids were extracted three times with hexane. After evaporation of the organic solvent under nitrogen, free cholesterol and cholesterol esters were separated by thin layer chromatography developed in a hexane/diethyl ether/acetic acid (90:10:1; v/v/v). The cholesterol ester spot was visualized by exposure to iodine, transferred into liquid scintillant for measurement of radioactivity in a scintillation counter. The cholesterol-esterifying activity was expressed as micromoles of cholesterol esterified per hour per liter of plasma.

### Statistical Analysis

The Wilcoxon signed ranks test was used for comparisons of plasma lipid as described previously [17]. The LCAT activity differences in dependent variables between two experimental periods were analyzed by the Wilcoxon signed ranks test. Differences were considered significant at  $P < 0.05$ . The effect of ALA has been assessed by comparing data from baseline (control diet) and diet 1. Association ALA/MA has been analyzed by comparing data from baseline to diet 2 (Table 2).

## Results

### Plasma Lipids, Lipoproteins and Apo-Proteins (Table 2)

In comparison with the control values ( $P_3$ ) found before starting diet 1, lower concentrations of total cholesterol ( $P < 0.0001$ ), LDL-cholesterol ( $P < 0.001$ ), HDL-cholesterol ( $P < 0.05$ ) and triacylglycerols ( $P < 0.05$ ) were obtained after diet 1 ( $P_6$ ). The ratio of total to HDL-cholesterol decreased ( $P < 0.05$ ) and the ratio of apo A-I:apo B tended to increase. Compared to the previous control diet ( $P_9$ ), diet 2 was associated with a decreased concentration of triacylglycerols ( $P < 0.05$ ) and an increased HDL-cholesterol concentration ( $P < 0.05$ ); the ratio of total to HDL-cholesterol decreased ( $P < 0.05$ ). These differences were not significant by comparing with data from the first period of control diet ( $P_3$ ).

### Plasma LCAT Activity (Table 2)

In order to compare the effect of different intake levels of MA and ALA on the endogenous activity of LCAT, the cholesterol esterification rate was assessed in whole plasma at the end of each feeding period. Significant differences ( $P < 0.001$ ) in plasma LCAT activity (µmol CE formed/(L.h)) were observed between the four dietary periods. Compared to control diet (1.2% TE as MA; 0.4% TE as

LCAT activity	μmol/h/L plasma	13.2 ± 3.1	24.2 <sup>c</sup> ± 3.6	20.7 ± 7.5	33.3 <sup>c,c</sup> ± 7.4

Results are mean ± SEM of 29 monks in each group. Values for diet 1 and diet 2 with different lowercase superscript letters are significantly different from previous control diet (P<sub>6</sub> vs. P<sub>3</sub>, P<sub>12</sub> vs. P<sub>9</sub>); values with different uppercase superscript letters are significantly different from diet 1 P values: *a* < 0.05; *b* < 0.005; *c* < 0.001; *d* < 0.0001

ALA), both experimental diets contributed to increase LCAT activity values, by 83% with diet 1 that provided more ALA (0.9% TE), and by 152% with diet 2 that provided more ALA (0.9% TE) and more MA (1.8% TE). At the end of the 2nd period of control diet (P<sub>9</sub>), LCAT activity rate remained higher than that observed after the 1st control period (P<sub>3</sub>), i.e. 20.7 ± 7.5 versus 13.2 ± 3.1 μmol CE/(L.h). Thus, compared to the 2nd control period, diet 2 led to an increase in LCAT activity lower than that compared to the 1st period (61% vs. 152%).

## Discussion

Current evidence suggests that HDL facilitates reverse cholesterol transport, a process by which LCAT allows the removal of cholesterol from tissues and its transport to the liver to be eliminated [5]. There is a positive relation between HDL cholesterol concentration and LCAT activity in plasma; these two parameters can be modulated by dietary fatty acids. Lecithin-cholesterol acyltransferase is synthesized by the liver, the molecular mechanism that regulates the plasma LCAT concentrations is not well understood. The LCAT activity level seems to depend in part on the mass of the enzyme in plasma, and in part on the substrate and cofactors available to the enzyme. However, about the mass of the enzyme, a recent study has shown that LCAT production by Hep G2 cells was unaffected by palmitic acid and shorter saturated fatty acids [20], while the increase in HDL cholesterol concentrations by dietary SFA is well documented. Thus regulation of LCAT at the gene level seems not significant in vivo. Rather, LCAT activity appears to be regulated in plasma by the surface properties of its lipoprotein substrates.

The modulation of LCAT activity in vivo depends, most likely, on changes in substrate composition and structure, in

the various natural HDL subclasses that are chemically and physically heterogeneous particles, and on the presence of activators or inhibitors. For these reasons, in order to compare LCAT activity at completion of the different experimental diets, we preferred using the method with endogenous substrate that provides real environment of the enzyme in vivo action, with important factors, as apoproteins. For instance, apoA-I appears the best activator of LCAT, but apoE, apoA-IV, and apoC-I are good activators of LCAT to the extent that, in the absence of apoA-I in vivo, they may promote significant cholesterol esterification in plasma [5]. Moreover, the relative order of activation of LCAT by apoA-I and apoC-I depends on the phospholipid vesicle quality, i.e., apoC-I appears to be a more effective activator of LCAT than apoA-I with dimyristoyl PC model vesicles, while it is the opposite with palmitoyl, palmitoyl-PC. Besides, LCAT presents a molecular and interfacial selectivity for different PCs. It seems that in general, mixed chain PC particles are the preferred substrates of LCAT, followed by disaturated PCs of increasing chain length, and by long chain polyunsaturated-PC particles.

From the results of Pownall et al. [8], it can be concluded that the LCAT binding site for the acyl donor recognizes the phosphate glycerol backbone, has some selectivity for a basic head group, but not excluding other glycerophospholipid head groups, and favors the binding of shorter, saturated, less bulky chains. Based on these observations made on models in vitro [8], the objective of the present study was to ascertain whether MA favors LCAT activity in vivo.

Previous results [17] obtained from these subjects fed the same dietary protocol have shown that intakes of MA (1.2% TE) and ALA (0.9% TE), both mainly in the *sn*-2 position of dietary triacylglycerols, were associated with favourable lipid and n-3 PUFA profiles; moreover the red blood cell membrane fluidity increased (*P* < 0.001).

The aim of the present study was to evaluate the influence of moderate intakes of MA (1.2 or 1.8% TE) associated with the recommended intake of ALA (0.9% TE), both mainly supplied through the *sn*-2 position, on the plasma LCAT activity. We determined LCAT activity according to the method of Glomset and Wright [19], with endogenous substrate that provides a measure of enzyme activity within the context of available substrate and cofactors (endogenous LCAT activity).

#### Comparison of Diet 1 versus Control Diet

The diets were very similar, except for their fatty acid composition. Compared to the control diet, the major change in diet 1 concerned the increase in ALA supply (0.9% TE vs. 0.4% TE), from rapeseed oil in the two diets. MA content in diet 1 was the same as in the control diet (1.2% TE) and had the same origin (dairy products). Diet 1 led to an increase in LCAT activity that suggests this improvement was due to the increase in ALA supply, at the recommended value, mainly through the *sn*-2 position of dietary triacylglycerols. This effect was associated with a decrease in the ratio of total to HDL-cholesterol. ALA impact on LCAT was confirmed in the next period. After diet 1, a lower ALA intake level in control diet led to a lower LCAT activity rate. At the same time, the ratio of total to HDL-cholesterol increased. However, the baseline value ( $P_3$ ) was not restored.

#### Comparison of Diet 2 versus Diet 1

Results on ALA bioavailability at the end of both control periods ( $P_3$  and  $P_9$ ), assessed through the ALA percentage in fasting plasma CE showed equivalence ( $0.65 \pm 0.27\%$  and  $0.65 \pm 0.28\%$  of total fatty acids, respectively) [17]. So, diet 2 was compared to diet 1. Diet 2 provided the same total SFA intake as the control diet and diet 1 (11–12% TE). However, in diet 2, MA supply was higher than in control diet and diet 1 (1.8% TE vs. 1.2% TE). Diet 2 provided the same intake of ALA as did diet 1 (0.9% TE), that was more than two times higher ALA intake than the control diet did (0.4% TE). Compared to the baseline (control diet), diet 2 led to a greater increase in LCAT activity than diet 1 (152 vs. 83%). This effect probably resulted from the increase in MA intake. This effect of MA, is already known but at levels much greater than 1.2 and 1.8% of TE [12, 13].

Thus, in vitro rates of cholesterol esterification found in this study show that LCAT activity increases in response to an increase in ALA or MA intake. Moreover, an increased intake in both ALA and MA caused a more pronounced increase in LCAT activity suggesting a complementary effect of ALA and MA on LCAT activity.

In response to experimental diets, fatty acid compositions of plasma phospholipids and CE were modified [17]. Diet 1 was associated with an increase in ALA, EPA, and DHA levels in phospholipids and CE. Diet 2 was associated with an increase in ALA in phospholipids and CE [17]. Our results agree with those reported by Babin et al. [21] showing that, in preterm infants, ALA levels in CE can be considered as representative of ALA dietary intakes, mainly supplied via the *sn*-2 position of dietary triacylglycerols, whereas LA levels in CE appears as a poor marker of LA intakes. The authors found the ALA percentage in CE was very significantly correlated with the ALA intake level ( $r = 0.70$ ;  $P = 0.0001$ ), whereas the LA percentage in CE was not correlated with the LA intake level ( $r = 0.17$ ;  $P = 0.31$ ).

Thornburg et al. [4] proposed that in addition to direct effects on composition of phospholipids, as observed in our study, changes in the HDL PC molecular species might occur. On the other hand, Dorfman et al. [3] have found that LCAT endogenous and exogenous activities did not differ in response to saturated relative to polyunsaturated fat in hamsters. This may be due to lower levels of apo A-I and/or other factors such as a post-translational modification of LCAT protein, or different levels of other factors that may alter enzyme activity such as apo A-II, an inhibitor of LCAT activity, emphasizing the role of LCAT environment on enzymatic reactivity. Our results suggest that ALA and MA do not act on the same level towards LCAT. Thus, ALA, because of its incorporation within “substrate” phospholipids of LCAT could improve LCAT affinity for its substrate. On the other hand, MA would act upstream, by modulating the LCAT protein amount in plasma.

Our results on the LCAT endogenous activity contrast with those found by Bérard et al. [14]. The authors compared a diet providing 11% TE as SFA with a diet that supplied a lower SFA content (8.4% TE), compensated by a higher carbohydrate content (+8%). The diet enriched in SFA led to an increase in HDL cholesterol, while plasma apo A-I concentration and the activity of LCAT both decreased. These discrepancies with our results might be explained by the method applied for assessing LCAT activity, i.e. using exogenous substrate (proteoliposome models) or endogenous substrate (plasma lipoproteins). Recently, Wood et al. [16], using an endogenous substrate method, showed increased LCAT activity and HDL cholesterol concentration, resulting from a carbohydrate restriction diet at the expense of fat. These various observations are in accordance with several mechanistic studies which have shown the importance of the phospholipid environment on LCAT activity.

In conclusion, this current study suggests there would seem to be a complementary effect between MA and ALA

in the *sn*-2 position of dietary triacylglycerols, within the framework of combined physiological intakes, that exerts a positive impact on the metabolism of plasma HDL.

# Supplemental Conjugated Linoleic Acid Consumption Does Not Influence Milk Macronutrient Contents in all Healthy Lactating Women

**Abstract** The term “conjugated linoleic acid” (CLA) refers to a group of positional and geometric isomers that are derived from linoleic acid and are found primarily in meat and milk products from ruminant animals. Due to the array of putative benefits associated with various forms of CLA, there has been recent interest in supplementing human diets with these fatty acids especially when weight loss is desired. However, in many animal models, CLA has been shown to decrease milk fat production. There is some concern, therefore, that maternal CLA supplementation during lactation might inadvertently decrease nutrient supply to the nursing infant. However, there is only limited research on the effect of CLA consumption on milk fat content in women. Based on previously published work from our laboratory, we hypothesized that CLA supplementation would reduce the milk fat percentage in lactating women in a dose-dependent manner. Breastfeeding women ( $n = 12$ ) were assigned randomly to treatments of 4 g/day safflower oil (SFO), 2 g/day CLA plus

2 g/day SFO, or 4 g/day CLA in a double blind,  $3 \times 3$  Latin square design. Conjugated linoleic acid supplements contained approximately equal amounts of *cis*9,*trans*11–18:2 and *trans*10,*cis*12–18:2; the two most common isoforms of CLA. Milk was collected by complete breast expression on the last day (day 5) of each intervention period and analyzed for macronutrient and fatty acid composition. On day 4 of each intervention period, infant milk consumption was estimated by 24 h weighing of the infant. Washout periods were 9 days in length. We observed a dose-dependent increase in the concentrations of *cis*9,*trans*11–18:2 and *trans*10,*cis*12–18:2 in the milk fat. However, we detected neither a change in overall macronutrient composition nor infant milk consumption. These data do not support those obtained from animal models or our previous human work suggesting that consumption of CLA mixtures necessarily reduces milk fat. It is possible that either (1) the interpretation of our previously published data should be reevaluated, and/or (2) there are important intra- and inter-species differences in this regard.

## Introduction and Hypotheses

The term “conjugated linoleic acid” (CLA) refers to a group of positional and geometric isomers of linoleic acid

(18:2n-6) derived in the human diet primarily from meat and milk products from ruminant animals [1]. Interest in various CLA isomers has grown substantially in the past decade, primarily due to the finding that the *cis*9,*trans*11–18:2 isomer inhibits mammary cancer in animal models and cell culture systems [2–5]. In fact, the National Research Council in 1996 stated that CLA (or forms, thereof) is the only fatty acid shown unequivocally to inhibit carcinogenesis in experimental animals [6]. In addition to having anticarcinogenic properties, investigators using mixed isomers of CLA have reported antiatherosclerotic properties, effects on glucose tolerance, alterations in growth or body composition, and milk fat depression [7–12]. Some studies also suggest adverse effects of CLA on health such as those relating to decreasing HDL cholesterol, Lp(a), and endothelial function [13–15]. It is now generally accepted that different isomers of CLA have a wide variety of biological effects; some being potentially health-promoting and others being detrimental [16].

Aside from the potential to influence human health, there is also much interest in understanding the potential effects of CLA isomers in animal agriculture. For example, studies suggest that the *trans*10,*cis*12–18:2 (but not *cis*9,*trans*11–18:2) isomer of CLA is a potent inhibitor of milk fat synthesis in cows and mice [11, 17]. As such, consumption or infusion of commercially-produced CLA (mixed isomers) imparts milk fat depressing effects in cows and rats [18, 19]. These commercially available CLA mixtures often contain equal amounts of *trans*10,*cis*12 and *cis*9,*trans*11–18:2 isomers as well as other minor isomeric forms [20, 21].

Because of the myriad possible benefits of CLAs (e.g., their anticarcinogenic and antiadipogenic effects), there has been much interest in supplementing human diets with these fatty acids. Indeed, CLA supplements are readily available for purchase at many pharmacies and “health food” stores. However, one concern with consumption of CLA mixture preparations is the possibility that it might reduce milk fat in lactating women, ultimately causing reduced nutrient supply to the nursing infant. Unfortunately, studies of the effects of CLA in lactating women are limited and unclear. For example, work from our laboratory suggests a decreased milk fat percentage when women consume a commercially available CLA mixture as compared to an olive oil placebo [12]. However, data from other studies suggest that increased CLA intake from naturally CLA-enriched cheese (in which the predominant CLA isomer was *cis*9,*trans*11–18:2) does not alter milk fat percentage [22–24]. Thus, there exists limited but not completely convincing evidence that some, but not all, forms of CLA might decrease milk fat in women. Clearly, in order to understand the health implications of CLA supplementation in this important segment of the population, more research is required.

As such, the objective of this work was to further investigate the impact of consumption of mixed isomers of CLA on milk composition in lactating women. Specifically, we hypothesized that intake of commercially-available CLA supplements would reduce milk fat percentage in a dose-dependent manner. It is noteworthy that this study was specifically designed as an experimentally similar follow-up experiment to that done by us previously [12].

## Materials and Methods

### Subjects

Healthy, non-pregnant, lactating women ( $n = 12$ ) were recruited from the Moscow, ID and Pullman, WA area. Inclusion criteria were the following: (1) 6–10 months postpartum, (2) breastfeeding at least four times per day, and (3) feeding supplemental foods to their infants. It is noteworthy that, because our hypothesis predicted that our treatment would result in milk fat depression, we did not enroll women who were exclusively breastfeeding their infants. However, we systematically emphasized the importance of continuing to feed their infants on-demand during the duration of the study. These eligibility criteria were required by our Institutional Review Board.

Upon enrollment, subjects completed a questionnaire providing general information concerning maternal and infant health, and baseline measures of height and weight from subjects and their infants were recorded (Table 1). Maternal adiposity was estimated using dual-energy X-ray absorptiometry (DEXA, Hologic QDR 4500 Acclaim Series), and body mass index (BMI) was calculated (Table 1). A urine-based pregnancy test was administered to subjects to confirm non-pregnant status before each DEXA scan. The Washington State University Institutional Review

Board approved all procedures used in this study, and informed consent was obtained from all subjects.

### Experimental Design and Dietary Treatment

Subjects were assigned randomly to a treatment sequence in a  $3 \times 3$  Latin square design. In this way, each subject received each treatment and carry-over effects were controlled for. This study was conducted as a double-blind trial in which neither subjects nor investigators knew of the treatment sequence until the study was completed. Intervention periods were 5 days in length, with intervening 9 day washout periods.

During intervention periods, subjects ingested supplements containing safflower oil (SFO; Cognis Corp., LaGrange, IL, USA) and/or CLA (Tonalin<sup>®</sup> SG1000C; Cognis Corp., LaGrange, IL, USA) such that there were three treatments: 4 g/day SFO (considered the placebo or control period), 2 g/day SFO and 2 g/day CLA (considered the 2 g CLA period), and 4 g/day CLA (considered the 4 g CLA period). The SFO contained predominantly linoleic acid (18:2n-6), while *cis*9,*trans*11–18:2 and *trans*10,*cis*12–18:2 were the major fatty acids in the CLA supplements (Table 2). Subjects consumed approximately 1,263 and 2,527 mg/day CLA from the supplements during the 2 g/day and 4 g/day CLA interventions, respectively (Table 2). Subjects were asked to consume the supplements between 0700 and 0800 hours each day of each intervention period.

### Milk Collection

Milk samples were collected on the day immediately preceding the first intervention period, on the final day of each

**Table 2** Major fatty acid composition (% of total lipid) of safflower oil (SFO) and conjugated linoleic acid (CLA) capsules used in this study and total intake (mg/day) of these fatty acids during intervention periods from these capsules

Fatty acid	Individual capsules		Daily intake from capsules		
	SFO (% of total lipid)	CLA	SFO (mg/day)	2 g CLA	4 g CLA
16:0	6.45	1.85	258.0	166.1	74.2
18:0	2.37	2.57	94.9	99.0	103.0
<i>cis</i> 9–18:1	12.23	11.09	489.1	466.4	443.7
<i>cis</i> 9, <i>cis</i> 12–18:2	72.05	0.53	2,882.0	1,451.6	21.1

<i>trans</i> 10, <i>cis</i> 12–18:2	ND	31.70	ND	634.3	1268.5

During intervention periods, subjects ingested 4 g/day SFO (control period), 2 g/day SFO and 2 g/day CLA (2 g CLA period), or 4 g/day CLA (4 g CLA period)

ND not detectable

washout period, and on day 5 of each intervention period between 1300 and 1500 hours by complete breast expression using an electric breast pump provided by us (model SMR-B-R, Ameda-Egnell Inc., Cary, IL, USA) or one owned by the subject and with which she was comfortable. To decrease variability due to between-breast differences, breast fullness, and changes in milk composition over a breastfeeding bout, milk was always obtained from the same breast, at least 2 h after the previous feeding, and until milk flow ceased. Milk was stored at  $-80^{\circ}\text{C}$  until further analysis. Infant milk consumption was estimated on day 4 of each intervention period by weighing the infant before and after each nursing for a 24 h period.

### Milk Analysis

Milk lipids were extracted by a modified Folch procedure using chloroform:methanol (2:1), and percent lipid was determined gravimetrically for all milk samples prior to the methylation procedure [25]. Extracted lipids from day 0 and 5 of each period were methylated using base catalyzed transesterification [26]. The fatty acid methyl esters (FAME) were analyzed on a gas chromatograph (Hewlett-Packard 6890 Series with auto injector) fitted with a flame ionization detector and a  $100\text{ m} \times 0.25\text{ mm}$ , with  $0.2\text{ }\mu\text{m}$  film, capillary column (SP-2560; Supelco, Bellefonte, PA, USA). The identities of fatty acid peaks were established by comparing retention times to a mixture of 19 FAME (NuChek, Elysian, MN, USA) and a CLA mixture reference standard (Matreya, Pleasant Gap, PA, USA).

Protein and lactose concentrations of milk were measured spectrophotometrically using the Bio-Rad<sup>®</sup> Protein Assay kit (Bio-Rad Laboratories; Hercules, CA, USA) and the lactose assay procedure described by Polberger and Lönnerdal, respectively [27]. Cholesterol content of milk samples was determined using a modified procedure of Fletouris et al. [28].

### Statistical Analysis

Mean and variance estimates for maternal and infant descriptive statistics were generated using the “univariate procedure” of SAS (SAS v 9.1, Cary, NC, USA). Milk composition, milk yield, and fatty acid data were analyzed as a  $3 \times 3$  Latin square using the “mixed procedure” of SAS. Sources of variation in the model included effects due to subject, period (reflecting order of treatment), treatment (placebo vs. 2 g CLA vs. 4 g CLA) and residual error. To help control for subject variability, pretreatment milk composition values from samples collected on the day immediately preceding the first intervention period or on the last day of the preceding washout period for the second

and third intervention periods were used as covariates in the statistical analysis.

To investigate the possible interaction between maternal body composition and treatment on milk composition, subjects were also separated into high (% body fat > 34% or BMI > 27 kg/m<sup>2</sup>) and low (% body fat < 33% or BMI < 25 kg/m<sup>2</sup>) body fat or BMI, and this variable was initially tested statistically. However, body fat designation was eventually removed from the model due to lack of interactive or main effect. Similarly, there was no effect of order of treatment (entered in the model as “period”), although this variable was retained in all final models. Interactions were considered significant at  $P \leq 0.10$ , and main effects and individual differences at  $P \leq 0.05$ .

## Results

### Effect of Treatment on Infant Milk Consumption and Milk Composition

Milk consumption and composition data in each treatment period are provided in Table 3. Although infant milk consumption on day 4 of each intervention period was variable, ranging from 605 to 707 g/day, there was no overall effect of dietary intervention nor were their individual differences between treatments. Similarly, on day 5 of each intervention period mean milk fat percentages were similar regardless of treatment and ranged from 4.2 to 4.8% (wt:wt; SEM = 0.5%). Likewise, regardless of dose, CLA supplementation did not affect milk protein, lactose, or cholesterol content on day 5.

### Milk Fatty Acid Composition

There were few alterations in the composition of fatty acids in milk fat (Table 4). However, *cis9,trans11–18:2* was

**Table 3** Estimated infant milk consumption (day 4) and milk composition (day 5) from women ( $n = 12$ ) consuming the placebo (safflower oil) or conjugated linoleic acid (CLA) supplements; data represent means and pooled SEM

Milk consumption (g/day)	605	674	707	70.2
Milk composition				
Fat (%)	4.5	4.8	4.2	0.5
Protein (mg/ml)	8.4	8.8	8.7	0.5
Lactose (mg/ml)	60.3	60.8	63.8	1.8
Cholesterol (mg/dl)	14.8	15.7	13.8	1.1

During intervention periods, subjects ingested 4 g/day SFO (control period), 2 g/day SFO and 2 g/day CLA (2 g CLA period), or 4 g/day CLA (4 g CLA period)

increased ( $P < 0.02$ ) when subjects consumed 2 g/day CLA compared with they consumed the placebo (SFO). There was also a tendency ( $P = 0.11$ ) for *cis9,trans11–18:2* to be further increased when subjects consumed 4 g/day CLA compared with 2 g/day CLA. Similarly, *trans10,cis12–18:2* in milk fat increased ( $P < 0.03$ ) when subjects consumed 2 g/day CLA compared to they consumed the placebo. Again, there was a tendency ( $P = 0.09$ ) for 4 g/day CLA to further increase *trans10,cis12–18:2* compared with 2 g/day CLA. There were no other observed differences in fatty acid composition of milk due to treatment.

## Discussion

Results from the study presented here lead us to reject our a priori hypothesis that consumption of a supplement containing mixed CLA isomers necessarily results in milk fat depression in women; let alone in a dose-dependent manner. Clearly, these results present us and others studying the putative physiologic effects of CLA with a series of intellectual and logistic challenges. For example, were there important differences in subjects, experimental design, laboratory procedures, or statistical analysis between our previous study [12] and the one reported here that might explain these disparate and unexpected findings? Or are there factors of which we are unaware that might

**Table 4** Milk fatty acid profiles (mean and pooled SEM; % of total fatty acids) from women consuming the placebo (safflower oil) or conjugated linoleic acid (CLA)

Fatty acid	Placebo	2 g CLA	4 g CLA	SEM

interact with CLA consumption to influence its effect on milk fat content in women? As such, the remainder of this manuscript will discuss these issues and venture a conclusion as to why the findings are so clearly different than what we had hypothesized. Further, we discuss what might be investigated in the future to tease out the apparently complex and variable physiologic effects of CLA and other biologically active fatty acids on milk fat in humans.

First, we must examine the issue of whether differences in subject characteristics and/or experimental design might have possibly resulted in disparate findings between previously published work and that presented here. Compared to the women studied by Masters et al. [12] some of whom were still exclusively breastfeeding their infants; the subjects in the current study were approximately 2 months later in lactation, producing approximately 200 g/day more milk, and producing milk with substantially higher (~50%) milk fat. These differences were due largely to the as previously discussed, ethical considerations requiring that we study only women nursing older infants being fed significant amounts of supplementary foods. It is certainly possible that these factors (time postpartum, milk output, overall milk fat content, and infant feeding practices) might independently and/or interactively modulate the potential for CLA to influence milk fat. For example, the milk fat-depressing effects of CLA might only be experienced by women during the first months of lactation, or those producing milk of lower milk fat. Future studies might be designed to test these possibilities.

There were also slight differences in BMI between the two studies. Masters et al. [12] reported a mean BMI of 23.4 kg/m<sup>2</sup> compared with 26.3 kg/m<sup>2</sup> in the current study (% body fat was not measured by Masters et al. [12]). Consequently, it is possible that higher body fat content attenuates the potential negative effect of CLA on milk fat in humans. Interestingly, body fat content has been repeatedly shown to be related to milk fat in humans, although the mechanisms driving this association are unclear [29, 30]. Previous work from our group, in fact, has suggested the possibility of an interaction between body fat percentage and intake of other *trans* fatty acids on total milk fat in humans [21]. In that study, data indicated that women with lower body fat (<30% body fat) consuming high levels of *trans* fatty acids produced milk with lower ( $P < 0.05$ ) milk fat percentage when compared to when they consumed low levels of *trans* fatty acids. In contrast, milk fat of women with higher body fat (>30% body fat) was not responsive to *trans* fatty acid intake. It is noteworthy that the average body fat content of the women enrolled in the present study was 33.5%, a level that may have been high enough to counteract the potential milk fat depressing effects of the CLA isomers studied (both of which are *trans* fatty acids). We have also observed

*trans*10,*cis*12–18:2 induced milk fat depression in food-restricted (lean), but not ad libitum-fed, lactating rats (Mosley et al, unpublished data). However, we statistically tested for an interaction between treatment and body fat percent on milk fat in the present study and found no such association. Nonetheless, we believe that there might exist a physiologic interaction between body composition and CLA consumption on milk fat, and future studies should be designed such that the variation in body fat content of subjects is large enough to test this interaction more directly.

There are also several differences in experimental design between our previous study [12] and that presented here that might help to explain the disparate findings. As previously discussed, in the present study we were only allowed to study women who were feeding significant amounts of supplementary and complementary food to their breastfeeding infants; the past study allowed the enrollment of exclusively-breastfeeding women in earlier lactation. It is possible that, in later lactation and/or at a higher milk production level, the mammary gland is able to compensate for any milk-fat depressing effects that may occur due to CLA consumption. As such, it is quite possible that different recommendations concerning consumption of mixed CLA supplements should be made to lactating women depending upon their particular stage of lactation and milk production level. This would fit well with the current nutritional sciences and public health concept of “personalized diet prescriptions” [31]. Clearly, a one-size-fits-all approach to the study of nutrition and health including the effects of CLA is likely not optimal.

Another potentially important difference between our previous and present work is the choice of material used in the “placebo” supplement. The major fatty acid in the placebo (olive oil) used by Masters et al. [12] was oleic acid (18:1), whereas linoleic acid (18:2n-6) was the predominant fatty acid in the SFO placebos used here. Interestingly, we did not originally consider this a significant change in design. Instead, we simply made this change because in fact the CLA found in our supplements is chemically derived from SFO, and we felt that this “placebo” more closely mirrored our treatment capsules. However, we had no reason to believe prior to the initiation of the present study that using a different “placebo” would alter our results. Nonetheless, it is possible that the placebo used by Masters et al. [12] actually induced an increase in milk fat percentage, thus importantly changing the possible interpretation of the results reported for that study. Clearly, the only way to test this hypothesis is to conduct an additional intervention study designed to examine the effect of olive oil on milk fat; in this case it would be our recommendation that the placebo used be void of any fatty

acids or other known or potentially biologically active compounds.

Other possible differences between the previous and present studies include CLA dosages, duration of treatment and washout periods, number of subjects, and sampling schedules. In our previous work, subjects consumed 560 and 547 mg/day of *trans*10,*cis*12–18:2 and *cis*9,*trans*11–18:2, respectively. Because the study reported here was designed as a follow-up to the previous one, our lower dose (2 g CLA) provided similar amounts of CLA isomers (634 and 629 mg/day of *trans*10,*cis*12–18:2 and *cis*9,*trans*11–18:2, respectively). Thus, we do not believe that our dosage was insufficient. Further, both studies employed similar treatment durations (5 days), and the present study actually had longer washout periods (9 vs. 7 days, respectively). In addition, compared to our previous work, the present study had more women ( $n = 10$  vs. 12, respectively) and used the more powerful Latin square design instead of a simple cross-over, suggesting that statistical power was actually enhanced in this study. In addition, we used the exact same milk sampling schedules and procedures in both studies. We do not believe, therefore, that any of these factors were responsible for differences in study results.

Another issue that is always a concern when interpreting data collected in a human intervention trials is compliance. Indeed, there is no intervention if there is no compliance. In both studies, we relied on milk fatty acid values as our indicator of compliance as this measure is a sensitive gauge of dietary intake especially for minor fatty acids such as the CLA isomers. Our biochemical data suggest a high level of subject compliance both in the present study and in that conducted previously by us. In the study reported here, consumption of mixed isomers of CLA resulted in increased concentrations of *cis*9,*trans*11–18:2 and *trans*10,*cis*12–18:2 isomers of CLA in milk lipid in a dose-dependent fashion. Masters et al. [12] reported similar increases in the concentrations of *trans*10,*cis*12–18:2 and *cis*9,*trans*12–18:2 in milk. This suggests that, although these studies differ in their findings of a potential milk fat lowering effect of CLA mixtures, consumption of CLA mixtures resulted in somewhat similar effects on milk fatty acid profiles. These data again suggest that there may be a yet undescribed modulating factor that can either attenuate or enhance the potential milk-fat depressing effects of CLA in some women.

Thus, although the results obtained from the present study do not support our initial hypotheses, they raise important questions for future study. For example, were the conclusions made by Masters et al. [12] that CLA supplementation causes milk fat depression misinterpretations of the data, because the real effect was actually a milk fat-enhancing one of olive oil? Additionally, is there an interaction between maternal body fat content and CLA

intake on milk fat percentage? Clearly, because commercially-available CLA supplements are widely available for promotion of weight loss (something that is highly desirable in many postpartum women), understanding their effects on milk fat content in both lean and overweight lactating women is of both public health and scientific importance.

**Abstract** Pathologic plasma lipoprotein cholesterol levels play a key role in the development and pathogenesis of human atherosclerotic cardiovascular diseases. Plasma cholesterol homeostasis is regulated by genetic predispositions and environmental factors. Animal models showing aberrant plasma cholesterol levels are used for the identification and analysis of novel causative genes. Here, we searched for inherited hypocholesterolemia phenotypes in randomly mutant mice which may contribute to the detection of disease protective alleles. In the Munich ENU mouse mutagenesis project, clinical chemistry blood analysis was carried out on more than 15,500 G1 offspring and 230 G3 pedigrees of chemically mutagenized inbred C3H mice to detect dominant and recessive mutations leading to a decreased plasma total cholesterol level. We identified 66 animals consistently showing hypocholesterolemia. Transmission of the altered phenotype to the subsequent generations led to the successful establishment of 14 independent hypocholesterolemic lines. Line-specific differences were detected by clinical chemistry analysis of plasma HDL cholesterol, LDL cholesterol and triglycerides. Thus, we successfully established a novel panel of ENU-derived mutant mouse lines for their use in the identification of alleles selectively influencing the plasma

cholesterol homeostasis. Such findings may be subsequently used for humans and other species.

**Keywords** Cholesterol · Ethylnitrosourea · HDL · LDL · Phenotype-driven screen

## Introduction

Animal models are used to examine the causes as well as the pathogenesis and potential therapeutic strategies for multifactorial and polygenic human diseases. Development of atherosclerotic cardiovascular disease is influenced by dyslipidemia including increased values of the normal proportion of low density lipoprotein cholesterol (LDL-C) and high density lipoprotein cholesterol (HDL-C). Beneath a subset of rare monogenic forms, pathologic cholesterol levels often occur as a polygenic and multifactorial disorder [1–4]. Humans show predominantly LDL-C and are sensitive to diet-induced elevations of LDL-C. In contrast, mice exhibit high amounts of HDL-C and a low LDL-C level [5, 6]. Therefore, instead of acting as model to enlighten the pathogenesis of human cardiovascular diseases, mice are the animal model of choice to search for additional alleles influencing the plasma lipoprotein cholesterol homeostasis.

Phenotype-driven strategies for the genome-wide search of causative loci are carried out by examining the genetic polymorphisms which result in different plasma lipoprotein phenotypes of the already existing mouse strains as well as by the generation of novel mutant lines harbouring altered plasma lipoprotein levels. Mapping of genetic determinants of plasma cholesterol levels in independent and combined crosses of inbred mouse strains has been used to establish a mouse map of quantitative trait loci (QTL) controlling

HDL-C levels. Confirmation of most QTL in different crosses indicated the saturation of the mouse QTL map. The high degree of concordance between mouse and human QTL suggested that the underlying genes may be the same. Narrowing the genomic regions and further molecular genetic analyses will reveal the responsible polymorphisms both in mice and humans [7, 8]. In addition, genetic polymorphisms of heterogeneous stock mice influencing the total cholesterol level were examined by high-resolution whole-genome association studies of quantitative traits [9].

Random mutagenesis of the mouse genome and subsequent phenotypic analysis of the animals for defined alterations are carried out in various mouse mutagenesis programs using the chemical ethylnitrosourea (ENU) [10]. Specific pathologic states have been identified by appropriate routine procedures allowing the screening of large numbers of mice for a broad spectrum of parameters [11, 12]. In the Munich ENU mouse mutagenesis project, a screening profile of clinical chemistry blood parameters was established for the analysis of offspring of chemically mutagenized inbred C3H mice in order to detect phenotypic variants with defects of diverse organ systems or changes in metabolic pathways. Breeding of the affected mice and screening of the offspring confirmed the transmission of the altered phenotype to the subsequent generations, thereby revealing a mutation as cause for the aberrant phenotype [13, 14]. Mutant lines from the Munich ENU project with the causative mutation already identified are successfully used in different areas of biomedical research (e.g., [15, 16]).

We recently described the establishment of nine ENU-induced mutant lines with heritable hypercholesterolemia [17]. Here we report the generation and phenotypic description of mutant lines exhibiting primary hypocholesterolemia. These lines increase the panel of novel mouse mutants available for dissecting the genetic control of plasma cholesterol homeostasis.

## Experimental Procedure

### Mutagenesis and Breeding of Mice

The experiments were carried out on the inbred C3HeB/FeJ (C3H) genetic background as described [17]. Ten-week-old male mice (=generation G0) were injected intraperitoneally with ENU ( $3 \times 90$  mg/kg in weekly intervals).

The screen for dominant mutations was performed on G1 animals, which were derived from the mating of the mutagenized G0 males to wildtype C3H females. Inheritance of the observed abnormal phenotype was tested on G2 mice which were derived from the mating of the

affected G1 mouse exhibiting the altered phenotype and wildtype mice.

The screen for recessive mutations was carried out on G3 mice produced in a two-step breeding scheme from G1 mice. G1 males, which were excluded to exhibit dominant mutations by phenotypic analysis, were mated to wildtype females for the production of G2 animals. Subsequently, 6–8 G2 females were backcrossed to the G1 male to produce the G3 mice of the pedigree. The analysis of the inheritance of an observed abnormal phenotype in G3 mice was done on G5 mice. Therefore, the affected G3 mouse presumably harbouring a homozygous recessive mutation was mated to a wildtype mouse for the production of the presumably heterozygous mutant G4 mice with an inconspicuous phenotype. Subsequently, the G5 mice derived from the mating of G4 mice to each other were tested for the abnormal phenotype. Alternatively, G5 mice derived from the backcross of a G4 mouse to the affected G3 animal were examined.

After the identification of the causative mutation, the internal names of the established lines will be replaced according to the official nomenclature. Mouse husbandry was done under a continuously controlled specific pathogen-free (SPF) hygiene standard according to the FELASA protocols (<http://www.felasa.org>) [18]. Standard rodent diet (Altromin, Lage, Germany) and water were provided ad libitum. All animal experiments were carried out under the approval of the responsible animal welfare authority (Regierung von Oberbayern).

### Clinical Chemistry Analysis

Blood samples from 3-month-old G1 and G3 mice fasted overnight were obtained by puncture of the retroorbital sinus under ether anesthesia. Physiologic parameter values were determined in male and female C3H controls. Plasma from Li-heparin treated blood was analyzed using an Olympus AU400 autoanalyzer (Olympus, Hamburg, Germany) and the adapted reagents (Olympus). Calibration and quality control were performed according to the manufacturer's protocols. Total cholesterol, HDL-C and LDL-C were examined by enzymatic colorimetry tests using the reagents OSR6116, OSR6187 and OSR6183 (Olympus) with the linear measurement ranges of 25–700 mg/dl, 2–180 mg/dl and 10–400 mg/dl, respectively, for human samples.

In addition, the primary clinical chemistry screen included the following plasma parameters: substrates—creatinine, glucose, total protein, triglycerides, urea, uric acid; electrolytes—calcium, chloride, inorganic phosphorus, potassium, sodium; enzymes—alanine aminotransferase, alkaline phosphatase, aspartate aminotransferase, creatine kinase.

## Statistical Analysis

The statistical analysis of the data was carried out using the software program Microsoft Excel 2000 (Microsoft, Redmond, WA). Values are presented as means and standard deviations unless stated otherwise. Statistical significance (defined as  $P < 0.05$ ) was evaluated using Student's *t* test.

## Results

### Plasma Total Cholesterol in C3H Control Mice

Plasma total cholesterol was determined in 3-month-old inbred C3H mice after overnight fasting of the animals [17]. Four hundred and seventy male animals showed a range of 78–171 mg/dl (mean  $\pm$  standard deviation  $132 \pm 15$  mg/dl), whereas 407 females showed a range of 56–180 mg/dl ( $109 \pm 17$  mg/dl). The 95% range of the values (100–161 mg/dl in males and 76–141 mg/dl in females) corresponded to the data range including two standard deviations above and below the mean, which indicated the Gaussian distribution of the data. The values within this range were defined to be physiologic thereby eliminating outlier data [5]. Thus, hypocholesterolemia was defined in our analysis for male and female mice showing values below the cut-off levels of 100 and 75 mg/dl, respectively, in two measurements within a 3-week interval (Fig. 1).

### ENU-Induced Phenotypic Variants Showing Decreased Plasma Total Cholesterol

In the Munich ENU mouse mutagenesis project, more than 15,500 3-month-old G1 offspring of ENU-treated mice were screened for dominant mutations. About 60% of the mice screened for dominant mutations were male animals. Thirty-six male and 12 female mice showed decreased

**Fig. 1** Physiologic range of plasma total cholesterol (mg/dl) in 3-month-old C3H wildtype mice. The mean values are 132 mg/dl in males ( $n = 470$ ) and 109 mg/dl in females ( $n = 407$ ). 100 and 75 mg/dl were chosen as cut-off level in males and females, respectively, to detect hypocholesterolemia

plasma total cholesterol levels which were confirmed in a second sample taken 3 weeks later. The means of the two samples ranged between 64 and 98 mg/dl in the male phenotypic variants and between 44 and 70 mg/dl in the female phenotypic variants. For revealing recessive mutations, over 6,500 3-month-old G3 offspring were examined from more than 230 different pedigrees of ENU-treated animals. Eight male and ten female mice exhibited decreased plasma total cholesterol levels, with means of the two measurements ranging between 79 and 95 mg/dl and between 11 and 75 mg/dl, respectively (Table 1).

### Transmission of Hypocholesterolemia to the Subsequent Generations

The analysis of the inheritance of the hypocholesterolemic phenotype was carried out on G2 offspring from the mating of 25 G1 phenotypic variants to wildtype mice in the screen for dominant mutations and on G4 intercross or G4  $\times$  G3 backcross offspring after breeding 9 G3 phenotypic variants to wildtype mice in the screen for recessive mutations. When no offspring were generated, the phenotypic variants were mated to another wildtype animal. Sperm was cryo-conserved from most of the male phenotypic variants where no confirmation cross was set up (Table 1). Twenty of the 34 phenotypic variants (59%) mated produced no or negative offspring. The female phenotypic variant exhibiting 11 mg/dl plasma total cholesterol in both measurements also produced no offspring (Table 2). The observed illness and/or sterility in the phenotypic variants with no offspring may be due to pleiotropic effects of the mutations, to negative consequences of the decreased cholesterol levels on the reproductive system of the affected mice and/or to the appearance of additional detrimental mutations.

Fourteen of the 34 mated mice showing hypocholesterolemia (41%) produced phenotypic mutant offspring. Heritable hypocholesterolemia was diagnosed when plasma total cholesterol values below the cut-off level (male 100 mg/dl; female 75 mg/dl) were detected in offspring of the phenotypic variants in two measurements performed in a 3-weeks interval. Additional successful production of phenotypic mutant offspring was done with three animals (one G3 male, one G1 female and one G3 female) exhibiting plasma cholesterol levels in the first measurement above the cut-off level. Thus, in total 17 hypocholesterolemic mutants were obtained. However, the three female G3 mutants were derived from the same ENU-mutagenized G0 founder (Table 2).

The majority of the hypocholesterolemic founder mice showed no obvious deviations in the additional clinical chemistry plasma parameters measured (see “[Experimental Procedure](#)”) and also appeared normal in the general

**Table 1** Screen and analysis of the inheritance for hypocholesterolemia in ENU-mutagenized mice

	Dominant screen (G1) <sup>a</sup>	Recessive screen (G3)	Total

Pedigrees examined	ND	>230	
Variants <sup>b</sup> : <i>n</i> (m/f)	48 (36/12)	18 (8/10)	66 (44/22)
Variants mated: <i>n</i> (m/f)	25 (17/8)	9 (1/8)	34 (18/16)
Mutants <sup>c</sup> : <i>n</i> (m/f)	13 (8/5)	4 (1/3 <sup>d</sup> )	17 (9/8)

*m/f* Males/females, *ND* not determined

<sup>a</sup> 60% of the G1 mice screened for dominant mutations were male animals

<sup>b</sup> G1/G3 offspring of ENU-treated mice showing hypocholesterolemia (male ≤ 100 mg/dl, female ≤ 75 mg/dl) in two measurements of a 3-weeks interval

<sup>c</sup> The numbers of the mutants include three mice (one G3 male, one G1 female and one G3 female) which did not appear as mated variants because their plasma cholesterol level of the first measurement was above the cut-off level. Offspring were produced by mating the G1 phenotypic variants to wildtype mice (screen for dominant mutations) and from G4 intercross or G4 × G3 backcross approaches after breeding the G3 phenotypic variants to wildtype mice (screen for recessive mutations). Heritable hypocholesterolemia was diagnosed when offspring of the phenotypic variants occurred showing cholesterol levels below the cut-off level (male 100 mg/dl, female 75 mg/dl) in two measurements of a 3-weeks interval

<sup>d</sup> The three female G3 mutants were derived from the same ENU-mutagenized G0 founder

clinical examination. Thus, most lines harbour mutations in genes which do not cause hypocholesterolemia secondary to preceding alterations in other metabolic pathways, but primarily and selectively influence the plasma cholesterol homeostasis.

Breeding of the 17 confirmed mutants resulted in the successful establishment of 12 hypocholesterolemic lines harbouring dominant mutations (lines CHOLD01–D12) and three hypocholesterolemic lines harbouring recessive mutations (lines CHOLR01A, CHOLR01B, CHOLR02). Two additionally established lines from one G1 founder and one G3 founder were not preserved and, therefore, lost. The G3 founder mutants of the two lines CHOLR01A and CHOLR01B were derived from the same ENU-mutagenized G0 founder, therefore, both lines may have the same causative mutation. This may be tested by breeding heterozygous mutants between the lines.

Mutant offspring showing hypocholesterolemia below the cut-off level (male 100 mg/dl; female 75 mg/dl) were produced by mating heterozygous mutants to wildtype animals in the lines CHOLD01–D12 and by breeding heterozygous mutant mice in the lines CHOLR01–R02. The male and female phenotypic mutants of the 15 lines (Table 3) showed mean plasma total cholesterol levels between 62 and 95 mg/dl and between 53 and 68 mg/dl,

**Table 2** Transmission of hypocholesterolemia to the offspring of the male (*n* = 18) and female (*n* = 16) phenotypic variants mated

The phenotypic variants are classified according to their mean plasma total cholesterol level (mg/dl) of the two measurements. Animals within a range of 5 mg/dl plasma cholesterol were grouped

*D* phenotypic variants derived from the screen for dominant mutations, *R* phenotypic variants derived from the screen for recessive mutations

<sup>a</sup> Variants producing no offspring are included

<sup>b</sup> The three female G3 mutants (R) were derived from the same ENU-mutagenized G0 founder

<sup>c</sup> The three mutants exhibiting plasma cholesterol levels in the first measurement above the cut-off level are shown additionally in parentheses

respectively. In the lines CHOLD01–D12 harbouring dominant mutations, no homozygous mutant animals were produced to date.

Viable knock-out mice have been established as low-cholesterol and high-desmosterol model with the reduction of the liver and brain cholesterol levels by more than 90% and virtually undetectable plasma cholesterol levels with the consequence of exhibiting a relatively mild phenotype [19, 20]. Compared to these almost “cholesterol-free” mice [19], our lines showed “intermediate” levels of hypocholesterolemia.

The phenotypic penetrance of the decreased total cholesterol levels in the 15 lines was analyzed by defining 100% phenotypic penetrance in the case of the appearance of 50 and 25% hypocholesterolemic offspring after mating phenotypic mutants to wildtype mice in the lines with dominant mutations and after crossing heterozygous phenotypic mutant mice in the lines with recessive mutations, respectively. Without taking into account the sampling

**Table 3** Phenotypic penetrance and extent of hypocholesterolemia in the 15 preserved mutant lines

*m/f* Males/females

<sup>a</sup> CHOL, line showing hypocholesterolemia; D01–D12, dominant mutation; R01–R02, recessive mutation. The G3 founder mutants of the lines CHOLR01A and CHOLR01B were derived from the same ENU-mutagenized G0 founder. The established lines from the G1 founder mutant 10039669f and the G3 founder 10136667f were not preserved

<sup>b</sup> The mutant lines are listed according to the mean plasma total cholesterol level (mg/dl) of both measurements of the founder G1/G3 mutant of the line. For the founders of the lines D06, R01B and R02, the values of the second measurement are shown as the first measurement was above the cut-off level

<sup>c</sup> Offspring after mating heterozygous mutants to wildtype mice in the lines with dominant mutations and offspring of heterozygous mutant mice in the lines with recessive mutations

<sup>d</sup> Hypocholesterolemia in the offspring was defined by the appearance of total cholesterol levels below the cut-off level (male 100 mg/dl, female 75 mg/dl) in two subsequent measurements. 100% phenotypic penetrance is defined in our breeding scheme by the appearance of 50 and 25% hypocholesterolemic offspring in the lines harbouring a dominant and recessive mutation, respectively

variation, a high phenotypic penetrance of hypocholesterolemia was observed in 13 of the 15 lines which facilitates the effective subsequent phenotypic and molecular genetic analyses. The two lines CHOLD06 and CHOLD12 showed a low phenotypic penetrance. Both males and females showed a similar degree of the phenotypic penetrance within the lines. All mutant lines except of CHOLD11 were bred for multiple generations without losing their mutant phenotype. In all 15 preserved lines, the numbers of animals exhibiting plasma cholesterol levels below the cut-off level were significantly ( $\chi^2$ -test,  $P < 0.001$ ) higher than the expected 2.5% of the C3H mouse population (Table 3).

#### Additional Clinical Chemical Analysis of the Mutant Lines

For the detailed analysis of the hypocholesterolemic alteration, HDL-C and LDL-C levels were measured in the phenotypic mutants of ten selected lines. The proportions of HDL-C and LDL-C to the plasma total cholesterol levels were determined in the male and female phenotypic

mutants and compared to sex-matched littermate controls. The physiologic ranges greatly varied between the lines and/or analyses (mean value  $\pm$  standard deviation of HDL-C 78  $\pm$  3% to 95% in males and 77  $\pm$  7% to 96  $\pm$  4% in females; LDL-C 7  $\pm$  0.2% to 13  $\pm$  2% in males and 9  $\pm$  0.4% to 14% in females). Compared to the control values, the phenotypic mutants showed line- and/or sex-specific HDL-C and LDL-C values where the expected complementary shifts of the HDL-C and LDL-C proportions appeared in most of the 18 separate analyses (data not shown). The detection of the HDL-C values was carried out with reagents for human samples and included immunoinhibition steps (Olympus) which may result in species-specific inaccuracies and overestimation of the HDL-C values. In addition, some of the LDL-C measurements fell below the linear measurable range. In most cases the examination of additional mutants has to be carried out to obtain significant results. This may be done best after the causative mutation is discovered.

In humans, low HDL-C appears as a typical symptom of diabetic dyslipidemia together with hypertriglyceridemia

[21–23]. Therefore, the plasma parameters triglyceride and glucose were determined in the phenotypic mutants. The mean values of the phenotypic mutants within the litters were compared to the mean values of the sex-matched littermate controls. In most lines, the phenotypic mutants of both sexes showed lower mean triglyceride values in the majority of the litters examined. Abnormal lipid metabolism may affect the blood cholesterol levels in these lines. However, in line CHOLD07 the phenotypic mutants of both sexes showed higher triglyceride values. None of the mutant lines displayed significant elevations in plasma glucose which eliminates the possibility that the hypocholesterolemia phenotypes result as a consequence of diabetic dyslipidemia (data not shown).

## Discussion

High-throughput screening of a large number of randomly mutant mice for hypocholesterolemia resulted in the establishment of 14 independent lines harbouring dominant or recessive mutations in genes involved in the control of cholesterol levels. Most of the mutant lines showed selectively decreased plasma total cholesterol levels without obvious disturbances in any of the other metabolic pathways investigated, suggesting that the affected genes play a specific role for the regulation of cholesterol homeostasis.

In humans, primary hypolipoproteinemia is increasingly diagnosed in the course of population screening for high plasma cholesterol. Individuals with primary low plasma cholesterol levels normally do not seem to have any disadvantage unless the decrease is profound, e.g., as in abetalipoproteinemia. Indeed, their relative freedom from cardiovascular disease may lead to longevity. However, the discovery of the crucial role of cholesterol in human embryogenesis and the identification of several inherited rare disorders of cholesterol biosynthesis showed that hypocholesterolemia may have mild to severe consequences for human development and health [24]. Existence of mouse models enabled the detailed analysis of the pathophysiology of these disorders [25, 26]. Secondary symptomatic hypolipoproteinemia occurs more often due to acquired diseases such as malignancies or malabsorption [1]. In addition, hypocholesterolemia is discussed as a factor of predisposition for certain diseases [27]. Thus, our established panel of hypocholesterolemic lines may be used not primarily in the analysis of human hypocholesterolemic alterations but contribute to the detection of alleles protecting from atherosclerotic cardiovascular disease.

From more than 15,500 G1 offspring and G3 mice from over 230 pedigrees examined in the clinical chemistry

screen of the Munich ENU mouse mutagenesis program [13, 14], more than half of all mutants found with plasma substrate abnormalities in our screen showed an abnormal total cholesterol level (Rathkolb et al. unpublished results). This confirms the involvement of a large number of genes in the homeostasis of the blood cholesterol level.

Our previous screen for hypercholesterolemia resulted in the establishment of nine ENU-induced mutant lines. Breeding of almost ten phenotypic variants was necessary to establish one mutant line with hypercholesterolemia in this project. Three of the nine lines showed a low phenotypic penetrance of the mutation. In eight lines, the hypercholesterolemic mutants showed no other gross abnormalities indicating that the lines most likely harbour mutations in genes which primarily and selectively influence the plasma cholesterol homeostasis [17].

Compared to the breeding approaches for the establishment of ENU-derived mutant lines exhibiting hypercholesterolemia, transmission of hypocholesterolemia from the phenotypic variants to the offspring was successful in more than every third mating and, therefore, more efficient. Cryo-conserved sperm from the not yet mated phenotypic male G1/G3 variants may be used for the production of additional hypocholesterolemic lines. The penetrance of the mutant phenotype usually was high. As tendency, it increased with the age of the mice (not shown). The high phenotypic penetrance may be due to the correct choice of the cut-off level to define hypocholesterolemia. Our studies indicate that low plasma cholesterol phenotypes are more reproducible than high cholesterol phenotypes.

Extensive variations in the plasma cholesterol concentrations have been found in different genetic backgrounds (<http://www.jax.org/phenome>; <http://www.eumorphia.org>) [28]. Therefore, generation and subsequent analysis of hybrids and/or congeneric strains will give rise to variations in the appearance of hypocholesterolemia. In addition to our screen in the Munich ENU mouse mutagenesis project, the appearance of dislipidemic lines was reported in another ENU project. The lines were produced on a different genetic background (BALB/c × C3H) where additional mutations may occur to cause hypocholesterolemia [29].

Prerequisite for the selection of candidate genes is the determination of the chromosomal position of the causative mutation in every mouse line by linkage analysis. Therefore, two backcross generations are produced using a second inbred strain, and the subsequent offspring are phenotypically classified into mutant and non-mutant animals. Using a genome-wide polymorphic marker set, linkage analysis of the DNA samples will then reveal the chromosomal position of the mutation.

In this study we describe the successful establishment of 14 independent hypocholesterolemic lines in the Munich ENU mouse mutagenesis project. Due to the triggering of

random mutations by ENU, new genes and/or alleles not yet known to be involved in the plasma cholesterol metabolism may be discovered by molecular genetic analysis of our mouse mutants. In summary, we successfully established a novel panel of ENU-derived mutant mouse lines for their subsequent use in the identification of alleles influencing the plasma cholesterol homeostasis in humans and other species.

## Seasonal Variations of Lipid Content and Composition in *Perna viridis*

Duo Li · Yonghua Zhang · Andrew J. Sinclair

Received: 13 February 2006 / Accepted: 11 May 2007 / Published online: 19 June 2007  
© AOCS 2007

**Abstract** The total lipid content, composition of main lipid classes, composition of sterols and composition of fatty acids in the main glycerolipids of *Perna viridis* were analyzed through four seasons using TLC-FID and GLC. Mussel samples were collected during different seasons between 2003 and 2004 from Shengsi Island, Zhejiang Province, China and stored frozen prior to freeze-drying and lipid extraction. Ten grams of dried mussel powder of each season were analyzed. Total lipid content ranged from 14.5 g/100 g in spring month to 7.8 g/100 g dried mussel powder in autumn month. The predominant lipid in spring month was triacylglycerol (TAG), however, in the other three seasons the phospholipids (PL) was the main lipid class. The most abundant fatty acid in TAG, PL and phosphatidylcholine (PC) was 16:0, with the summer samples having the highest proportion (24–30% of total fatty acid) and winter the lowest (14–22%). In phosphatidylethanolamine (PE), the spring samples had the highest proportions of 16:0. The predominant polyunsaturated fatty acids (PUFA) were 22:6n-3 and 20:5n-3 in TAG, PL, PE and PC (25–40%). The proportions of 22:6n-3 and 20:5n-3 were higher in spring than in other seasons in PL and PE. There were nine sterols identified, with cholesterol being the predominant sterol, and other main ones were desmosterol/brassicasterol and 24-methylenecholesterol. Proportions of other fatty acids in different lipid fractions and the sterol compositions as well also varied seasonally.

There were subject to the seasonal variations. Differences in lipid content and composition, fatty acid composition in different lipid fractions may be caused by multiple factors such as lifecycle, sex, variation of plankton in different seasons and temperature, which could influence physiological activities and metabolism.

### Introduction

Mussels are easily cultured shellfish, which are cultivated worldwide. Mussels are widely distributed in China, and they

have been consumed for thousands of years. It is a significant source of long chain PUFA, especially n-3 PUFA, in China.

Qing et al. [1] analyzed lipid content and fatty acid composition of soft body, digestive gland and gonad in *Perna viridis*, and samples were cultured and collected in spring in Guangdong, China. The lipid content was significantly higher in the digestive gland than the soft body and gonad. Fatty acid composition was not significantly different between the three tissues, with the predominant fatty acid being 16:0, other main fatty acids were 20:5n-3, 16:1 and 22:6n-3.

Total lipid and phospholipid (PL) content in *Mytilus edulis* (Linne), samples were collected in Qingdao China, varied from the highest in March (spring) to the lowest in December (winter) and September (autumn), respectively. Major fatty acids in PL were 16:0, 20:5n-3 and 22:6n-3 [2].

Murphy et al. [3] examined the total lipid content, sterol and fatty acid compositions in the New Zealand Green Lipped Mussel (*Perna canaliculus*, NZGLM) and Tasmanian Blue Mussel (*Mytilus edulis*, TBM) (both species of mussels were collected in October, late spring). The predominant lipid was PL in both NZGLM and TBM. Cholesterol was the major sterol. The main fatty acids were 16:0, 20:5n-3 and 22:6n-3 in both species. In a later study by this group, there were no significant differences in the fatty acid and sterol proportions between different sample treatments (frozen and freeze-dried) in NZGLM from three sites in New Zealand [4].

Seasonal variation in fatty acid compositions in other bivalve species have also been reported in boreal freshwater fish species [5], wild marine shrimp [6], sea bream [7], horse-mackerel [8].

Phospholipids play an important role in ion transport, receptors and cell biosynthesis, while triacylglycerol (TAG) mainly serves as energy storage. To our knowledge, there is no data on the seasonal difference with respect to lipids and fatty acids in *P. viridis*. The aim of the present study was to investigate the seasonal variations of lipid content and compositions, and fatty acid compositions of *P. viridis*. The data may provide useful information for food industries and mussel aquaculture.

## Materials and Methods

### Sampling

About 20 kg (equivalent to 1,110 mussels for summer and autumn, 1,350 for winter and spring) of *P. viridis* were collected each season from Shengsi Island, Zhejiang Province, China, during 2003–2004 (Summer, July 28, 2003; Autumn, October 22, 2003; Winter, January 7, 2004; Spring, March 27, 2004), and stored at  $-80^{\circ}\text{C}$ . In the

middle of April 2004, shells of the mussels from the four seasons ( $n = 4,920$ ) were removed and the fleshy portion was cut into small pieces, which were then vacuum freeze-dried. The mean moisture content was 71.8%. Lipid extraction and analysis were performed in triplicate - analyses for the seasonal samplings originating from a single pooled tissue sample of the month of the season.

### Lipids Analysis

The lipids of *P. viridis* powders were extracted with chloroform:methanol (2:1, by vol.) containing 10 mg/l of butylated-hydroxytoluene (BHT, Sigma Chemical Co, St Louis, USA) [9]. Total lipid contents were determined by gravimetric analysis. Lipid compositions were analyzed by using an IATROSCAN TLC-FID Analyzer (IATRON Laboratories Inc., Japan) [10].

### Fatty Acid Compositions of Triacylglycerol and Phospholipid

TAG and PL fractions of *P. viridis* extract were separated by laboratory-prepared silica gel 60G (Merck, Darmstadt, Germany) thin-layer chromatography using the solvent system of petroleum ether:diethyl ether:acetic acid (85:15:2, by vol). The methyl esters of the fatty acids (FAME) of the TAG and PL fractions were prepared by using  $\text{H}_2\text{SO}_4$  in methanol (5%, vol/vol). The FAME was separated by Shimadzu GC 17A (Shimadzu Corporation, Japan) fitted with FID and a 60 m  $\times$  0.32 mm (I.D.) fused silica column bonded phase column (BPX70, SGE, Melbourne, Australia). Fatty acids were identified by comparison with standard mixtures of fatty acid methyl esters and the results were calculated using response factors derived from chromatograph of standards of known composition (Nu-Chek-Prep, Elysian, MN, USA) [11].

### Fatty Acid Compositions of Phosphatidylethanolamine and Phosphatidylcholine

Phosphatidylethanolamine (PE) and phosphatidylcholine (PC) fractions of *P. viridis* extract were separated by using a commercial silica gel 60 (Merck, Darmstadt, Germany) thin-layer chromatography plate using a solvent system of chloroform:methanol:acetic acid:water (100:75:7:4, by vol.), into distinct narrow bands capable of being visualized under UV light after spraying the plate with dichlorofluorescein. FAME preparation and determination were the same as above.

### Sterol Compositions

*Perna viridis* lipid extracts were treated with 5% of potassium hydroxide in methanol (wt/vol) for 3 h at  $80^{\circ}\text{C}$ .

The sterols were then extracted into hexane:chloroform (4:1, by vol, 3 × 1.5 ml). Then the sample was dried under nitrogen, and treated with *N*, *O*-bis-trimethylsilyl-trifluoroacetamide (BSTFA, 50 µl, 40 °C, 30 min) to convert the sterols to corresponding trimethylsilyl (TMSi) ethers. The sample was dissolved using chloroform after it was dried under nitrogen. The analyses were performed using a Shimadzu GC 17A (Shimadzu Corporation, Japan) fitted with an FID and a 50 m × 0.32 mm BPX5 5% Phenyl Polysilphenylen–Siloxane capillary column with 0.25 µm thick film thickness (SGE, Australia). Sterols were identified by comparison with mixtures of sterols from the New Zealand Green Lipped mussel, which had been previously identified by GC-MS [3].

## Results

### Total Lipid Content

The lipid content of *P. viridis* (g/100 g frozen dried sample) was significantly higher in spring than in the other three seasons (Table 1). There were five lipid sub-classes identified, sterol ester (SE), TAG, free fatty acids, sterols and PL. The predominant lipid in spring was TAG, however, in the other three seasons it was PL. All individual lipids showed a significant variation across the four seasons (Table 2).

### Fatty Acid Compositions of Triacylglycerol and Phospholipid

The most abundant fatty acid was 16:0, and the content varied throughout the seasons in both TAG and PL fractions, with summer having the highest and winter the lowest. The other three main fatty acids were 16:1, 22:6n-3 and 20:5n-3 in the TAG fraction and 22:6n-3 and 20:5n-3 in the PL fraction. In TAG fraction, there was a decreasing for 22:6n-3 proportion from summer to autumn to spring to winter, for 20:5n-3 proportion winter was higher than other three seasons, for 16:1 from spring to winter to autumn to summer. In PL fraction, there was a decreasing for 22:6n-3 proportion from spring to winter to summer to autumn, and also for 20:5n-3 proportion from spring to winter to autumn

**Table 1** Total Lipid content in *P. viridis* (g/100g dried mussel)

<i>P. viridis</i>	Lipid content
Spring (March)	14.49 ± 0.78
Summer (July)	8.39 ± 0.59
Autumn (October)	7.85 ± 1.08
Winter (January)	9.26 ± 1.07

All samples were analyzed in triplicate from a pooled sample from the particular season

**Table 2** Lipid class content of *P. viridis* (% of total lipid)

Lipids	<i>P. viridis</i>			
	Spring	Summer	Autumn	Winter
SE	8.23 ± 0.98	6.49 ± 0.12	10.32 ± 0.10	20.46 ± 0.26
TAG	44.68 ± 1.81	33.59 ± 1.08	24.59 ± 0.57	18.46 ± 0.51
FFA	2.53 ± 0.27	3.58 ± 0.10	2.62 ± 0.22	2.58 ± 0.06
Sterols	4.34 ± 0.40	8.56 ± 0.31	8.97 ± 0.22	6.63 ± 0.57
PL	40.22 ± 1.54	47.78 ± 1.19	53.50 ± 0.63	51.87 ± 0.95

All samples were analyzed in triplicate from a pooled sample from the particular season

SE sterol esters, TAG triacylglycerols, FFA free fatty acids, PL phospholipids

to summer. All fatty acids showed significant variations between seasons, except for 20:1n-9 in TAG, and 15:0, 20:3n-6 and 22:5n-3 in PL fraction (Tables 3, 4).

### Fatty Acid Compositions of Phosphatidylethanolamine and Phosphatidylcholine

The most predominant fatty acid in PE was 18:0 and in PC it was 16:0. The other two main fatty acids were 22:6n-3 and 20:5n-3 in both PE and PC fractions. The proportions of these fatty acids varied between the seasons (Tables 5, 6). The seasonal change of the 20:5n-3 proportion in PE and PC was similar, with spring having the highest, followed by winter, autumn, and summer contained the lowest proportion. The 22:6n-3 proportion in the PE fraction showed a decrease from spring to winter to summer to autumn, in PC from summer to winter to autumn to spring.

### Sterol Compositions

The predominant sterol was cholesterol, with autumn having the highest and spring the lowest proportion. Another main sterol was the peak containing both desmosterol and brassicasterol (desmosterol and brassicasterol have similar structures and they were not separated by the method used in the present study, but this peak did not show significant variations between the seasons. Other sterols in order from the highest proportion were 24-methylenecholesterol, *trans*-22-dehydrocholesterol, 24-methylcholesterol, 24-norhydrocholesterol, β-sitosterol and ocellasterol. Except for *trans*-22-dehydrocholesterol, the other sterols showed significant variations between seasons (Table 7).

## Discussion

The aim of the present study was to evaluate the composition of lipids, sterols and fatty acids in different lipid

\* The identify of this fatty acid is only tentative due to lack of a standard and GC-MS result

fractions of *P. viridis* sampled in four season months. From our knowledge, this is the first study that compares the different season's fatty acid compositions of the different lipid class in *P. viridis*. The data will provide useful information for food industries and mussel aquaculture.

## Lipids

Previous studies showed that accumulation and depletion of stored reserves of Mollusca are dependent mainly on the environmental influences on metabolic activities, and the

quantity and nutritional value of the food supply [12–14]. In the present study, the total lipid content was higher in spring than in the other seasons. This result is in agreement with the findings in *Mytilus edulis* (Linne) [2], which found that the highest lipid content was in March (spring). Total lipid contents of *P. viridis* in summer, autumn and winter in the present study (freeze dried powder) are consistent with the previous studies in freeze-dried NZGLM [4]. They collected samples from three different locations in March (autumn in New Zealand) and reported a total lipid content of 8.4 g/100 g freeze dried powder. In order to have suf-

All samples were analyzed in triplicate from a pooled sample from the particular season

\* The identify of this fatty acid is only tentative due to the lack of a standard and GC-MS result

ficient reserves for spawning, mussels store more energy as lipids before spawning [15]. We collected the spring sample in March, which was before spawning, and this had higher lipid content than the other three seasons. This result is agreement with studies in NZGLM [14] and in Chinese mussel *Mytilus edulis* (Linne) [2], and in other marine invertebrates such as *Silurus asotus* [16], *Ostrea edulis* (L) [17] and *Haliotis rubra* [18].

In spring, the predominant lipid was TAG, whereas in summer, autumn and winter months the main lipid was PL. This can be attributed to the fact that TAG is mainly used as energy, whereas PL is mainly a component of the cell

structures. The calculated PL content, based on total lipid × PL proportion revealed that in spring there was the highest PL content (6.0 g/100 g compared with values of 4.0, 4.2 and 4.8 g/100 g for summer, autumn and winter respectively). Similar calculations showed that the TAG content in spring was 6.5 g/100 g compared with 2.9, 1.9 and 1.7 g/100 g in summer, autumn and winter [19], respectively. After the spawning period, energy requirements are reduced, especially in the winter. In the colder seasons, mussels enter a winter dormancy period, where many of their metabolic processes are slowed or shut down. During this time, they grow very slowly, energy (lipid)

\* The identify of this fatty acid is only tentative due to the lack of a standard and GC-MS result

requirement is very low, because the TAG stores have been depleted this leads to a relatively increased PL proportion.

Phosphatidylethanolamine and PC make up more than 80% of PL, and are relatively rich in n-3 PUFA, especially 20:5n-3 and 22:6n-3, which play an important role in ion, receptors and cell biosynthesis [20]. The *P. viridis* contained a high proportion of PUFA, which accounted for 30–50% of total fatty acid in different lipid fractions. The 22:6n-3 and 20:5n-3 were the predominant PUFA in all lipid fractions. The 22:6n-3 and 20:5n-3 were also the predominant PUFA reported in total lipid of fresh NZGLM and TBM [3], in total lipid of frozen and freeze-dried NZGLM [4], and in PL in *Mytilus edulis* [2]. As similarly reported by Lin et al. [2] in *Mytilus edulis* (Linne), 20:5n-3 proportion in PL in *P. viridis* was significantly higher in spring than in other three seasons, and lowest in summer. The 20:5n-3 proportion in PC and PE fractions showed the same trend with PL in the present study. However, 22:6n-3

was higher in summer than in other three seasons in PC. The proportion of PUFA was higher for PL and PC in winter, for TAG in summer and for PE in autumn, whereas SFA were higher in summer than in other three seasons in TAG, PL and PC. Previous studies in fish and shellfish have reported that PUFA content varies inversely with the water temperature [21–23], while SFA content changes positively with the water temperature [13, 24], and that the increased PUFA at colder temperature was mainly due to a higher proportion of n-3 PUFA [24–26], it has been suggested that an increase in membrane PUFA and a decrease in SFA when the temperature falls could contribute to the maintenance of cell membrane fluidity, as PUFA has a lower melting point than do SFA. It has also been suggested that increased unsaturated fatty acids (PUFA and MUFA) of non-membrane lipids such as TAG in the flesh would also be expected to help maintain body flexibility for movement at reduced temperatures [24]. Fatty acids in

seafood vary depending on several biological and environmental factors, such as taxonomy, diet of the animals, seasonal changes in water temperature, and the latitude at which they were harvested [24, 27]. It has been documented that seasonal fatty acids changes could also be related to the reproductive cycles [28]

#### CE Versus Sterols

Invertebrates have been reported to contain a wide range of sterols [29]. There were 9 sterols identified in the present

study, however, the 17 had been identified previously in both the frozen NZGLM and TBM when the authors used GC-MS to identify the sterols, and 14 were identified from frozen and freeze-dried NZGLM [3]. Our results are consistent with the previous studies [3, 4], in that cholesterol and desmosterol/brassicasterol were the main sterols present, followed by 24-methylenecholesterol, and that their quantities varied seasonally.  $\beta$ -sitosterol, a predominant phytosterol, was only present in minor amounts (2–5% of total sterol) in *P. viridis*. Plankton is the predominant diet of mussels, which contains various sterols, and they can be

**Table 7** Sterol Composition of *P. viridis* (% of total sterols)

**Abstract** In order to study the mechanism of DHEA (Dehydroepiandrosterone) in reducing fat in broiler chickens during embryonic development, fertilized eggs were administrated with DHEA before incubation and its effect on lipid metabolism and expression of hepatic lipogenetic genes was investigated. The mRNA levels of acetyl CoA carboxylase (ACC), fatty acid synthase (FAS), malic enzyme (ME), apolipoprotein B100 (apoB100) and sterol regulator element binding protein-1c (SREBP-1c) were determined using real time quantitative PCR. Samples of livers were collected from the chickens on days 9, 14, and 19 of embryonic development as well as at hatching. Blood samples were extracted on days 14, 19 of incubation and at hatching. The results showed that DHEA decreased the concentration of triacylglycerol in the blood and the content in liver, and the mRNA levels of ACC, FAS, ME, SREBP-1c and apoB. This suggested that DHEA decreased the expression of hepatic lipogenetic genes and suppressed triglycerols transport, by which it reduced the deposition of fat in adipose tissue in broiler chickens during embryonic development and hatching.

**Keywords** Lipid metabolism · mRNA · Liver · Broiler · DHEA

## Introduction

In the last few decades, the aim of poultry production in many countries has been to increase the growth rates, but excessive fat deposition in the abdomen has been neglected. Fatness needs to be controlled, due to its negative effect on productivity. In meat-type chickens, excessive adipose tissue reduces both feed efficiency during rearing and the yield of lean meat after processing. In avian species, the liver is the main site of de novo fatty acid synthesis and accounts for 95% in young chicks [1, 2]. In consequence, most of the endogenous body lipids are of hepatic origin [3] and the development of adipose tissue depends on the availability of plasma triglycerides that are hydrolyzed prior to their utilization by adipocytes. Triglycerides are supplied specifically to adipocytes by specific lipoprotein classes: very low density lipoproteins (VLDL) transport de novo synthesized hepatic lipids [4, 5]. Thus a higher rate of triglyceride synthesis and transport from the liver is responsible for the higher weight of abdominal fat in chickens.

According to previous studies, differences in the degree of obesity are due to various steps of lipid metabolism, among which liver fatty acid metabolism has been considered as the main source of variability [6–9]. These results prompted researches into gene expression in the liver, especially those genes involved in fatty acid synthesis and secretion [10–11]. Accordingly, the present study focused on the expression of lipogenetic genes in liver. Acetyl-CoA carboxylase (ACC), the rate-limiting enzyme in fatty acid synthesis, catalyzes the carboxylation of acetyl-CoA to malonyl-CoA [12]. Fatty acid synthase (FAS) is a key enzyme in fatty acid synthesis that catalyzes the synthesis of long-chain fatty acid through the condensation of acetyl-CoA and malonyl-CoA in a

complex seven-step reaction [13]. Malic enzyme catalyzes the oxidative decarboxylation of malate to pyruvate and CO<sub>2</sub> simultaneously generating NADPH from NADP<sup>+</sup>. In the avian liver, most of the NADPH used by fatty acid for catalyzing the synthesis of palmitate is generated by the malic enzyme [14]. The availability of apoB plays a major role in determining the capacity of hepatocytes to assemble and secrete VLDL [15, 16]. SREBP (Sterol response element binding protein) is among many potential regulators. These transcription factors of the leucine zipper family have been described as regulators of biosynthesis of cholesterol and fatty acids in the liver [17]. SREBP-1c is preferentially involved in the activation of genes that control the synthesis of fatty acid [18, 19]. The gene for SREBP-1c is highly expressed in the liver. Moreover, different studies have shown that SREBPs can directly stimulate the transcription of genes encoding ACC [20–22], FAS enzymes [23], making them good candidates as common regulators of the lipogenetic genes. Therefore, expression of these hepatic lipogenetic genes plays a pivotal role in the process of de novo TG synthesis.

Dehydroepiandrosterone (DHEA, 3 $\beta$ -hydroxy-5-androsten-17-one)-a naturally occurring steroid, is secreted from the adrenal gland as a sulfate ester, which is interconvertible with free DHEA in vivo. DHEA is not a hormone but it is a very important prohormone [24], which exerts various physiological activities through intermediate products when administered to rats and mice. The studies from others have revealed that DHEA has various functions on the regulating of lipid metabolism, which includes decreasing the metabolic efficiency in mammalian species [25, 26], regulating the synthesis of fat, decreasing the number of adipocytes [27–29]. In rodents, long term DHEA treatment resulted in suppression of body weight gain without changes in food intake. During DHEA treatment, liver size is increased with decreasing hepatic lipogenesis [25, 30].

DHEA has a fat-reducing function. However, the mechanism of this physiological role of DHEA has not yet been fully clarified [31, 32]. Moreover, most of previous studies were focused on rodents with only a few studies on chickens and they indicated that DHEA did not significantly suppress body weight of chickens and liver size [33]. No detailed information was available about the effect of DHEA on lipid metabolism in broiler chickens during embryonic development. The fertilized egg would be an appropriate substance in studying the mechanism of DHEA in the regulation of fatty metabolism because the embryo is enclosed in an eggshell, and is hardly influenced by external factors [34].

The objective of the present study was to explore the effect of DHEA on lipid metabolism and hepatic lipogenetic

genes expression in broiler chickens during embryonic development which may help to identify the possible mechanism of DHEA in decreasing the deposition of fat in adipose tissue.

## Material and Methods

### Animal Experiment

Fertilized eggs of laying hens (Arbor Acres) used in this study were obtained from Jiangsu Wuxi Chicken Breeding Company (Wuxi, China). All eggs were numbered and weighed individually prior to the beginning of incubation. Afterwards, eggs were fumigated (80 g potassium permanganate in 130 ml 40% formaldehyde solution per m<sup>3</sup> for 20 min) and randomly divided into two groups. In the control group (CON group), the eggs were injected with 50  $\mu$ L DMSO, while in DHEA group, the eggs were injected with 50 mg DHEA (Sigma, USA) per kg eggs weight diluted in 50  $\mu$ L DMSO. All treatments were performed just prior to putting the eggs into the incubator. 50  $\mu$ L of solution were added to the air sac. Prior to injection, the blunt end of the egg was sterilized with 70% ethanol. A single hole was created with a dental drill bit without penetrating the chorio-allantoic membrane. Each solution was injected into the blunt end of the egg to a depth of 5.0 mm after drilling the shell. Micropipettes were used for injections (Sealpette, Jencons, Finland). After injection, the holes were immediately sealed with melted paraffin wax. They were placed into an electric forced-draft incubator at 37.5  $\pm$  0.5  $^{\circ}$ C and 60% relative humidity and turned every 2 h. All eggs were incubated in the same incubator. All eggs were candled before incubation and only unchipped and unbroken eggs were used in the experiment. All experimental procedures were performed according to the Guide for Animal Care and Use of Laboratory Animals in the Institutional Animal Care and Use Committee of Nanjing Agricultural University. The experimental protocol was approved by the Departmental Animal Ethics Committee of Nanjing Agricultural University.

Eggs were opened on days 9, 14, 19 of incubation. Samples of liver were collected, weighed and numbered at E9, E14, E19 and at hatching. All liver tissue samples were snap frozen in liquid nitrogen and stored at  $-80^{\circ}$ C prior to homogenization. Blood samples were collected from the blood vessel at E14d and the heart at E19d with a heparinized syringe. The blood was collected from the jugular vein at hatching. The blood samples were centrifuged at 4  $^{\circ}$ C, 9,000  $\times$  g for 4 min, and the serum was gathered and kept in a  $-40^{\circ}$ C freezer. The start of incubation was called day 1 (E1d) and after hatching called day 1 (H1).

## Measurement of Lipid Parameters

Total liver lipid content was determined on homogenized liver samples using a mixture of chloroform and methanol (2:1 v/v) according to the method of Folch et al. [35]. The levels of hepatic and serum triglyceride (TG) and total cholesterol (TC) content were determined using commercial kits (GPO-PAP and CHOD-PAP) purchased from the Nanjing Jiancheng Bioengineering Institute (NJBI). TG and TC levels in homogenates of liver and serum were evaluated following the manufacturer's protocols. The optic density of the samples was measured using a spectrophotometer three times at a wavelength of 546 nm. Total TG in liver and serum and TC in serum were calculated through absorption of the tested sample divided by standard sample and multiplied by TG and TC content in standard sample.

## RNA Extraction

Total RNAs were extracted from the liver using TRIZOL reagent (Takara, Japan) according to the manufacturer's protocols. Total RNA concentration was then quantified by measuring the optic density at 260 nm in a photometer (Eppendorf Biophotometer). Ratios of absorption (260/280 nm) of all preparations were between 1.8 and 2.0. Aliquots of RNA samples were subjected to electrophoresis through a 1.4% agarose formaldehyde gel to verify their integrity.

## Real-Time Quantitative RT-PCR

Reverse transcription was performed using the RNA (2 µg) described above in a final volume of 25 µL containing 10 units of MMLV reverse transcriptase (Promega, Belgium), 1 mM dNTP mixture (Promega, Belgium), 40 units of

recombinant RNasin ribonuclease inhibitor (Promega, Belgium) and 0.5 µg of oligo (dT) 18 (Promega, Belgium) in sterilized water and buffer supplied by the manufacturer. After incubation at 42 °C for 60 min, the mixture was heat treated at 95 °C for 5 min. An aliquot of cDNA samples was mixed with 25 µl SYBR<sup>®</sup> Green PCR Master Mix (Takara, Japan), in the presence of 10 pmol of each forward and reverse primer for acetyl CoA carboxylase (ACC), fatty acid synthase (FAS), malic enzyme (ME), apolipoprotein B100 (apoB100) and sterol regulator element binding protein-1c (SREBP-1c) (Table 1), and then subjected to PCR under standard conditions (40 cycles). As an internal control, the same RT products were also subjected to PCR in the presence of a second pair of primers specific to chicken  $\beta$ -actin RNA. Mixtures were incubated in an ABI Prism 7300 Sequence Detection System (Applied Biosystems) programmed to conduct one cycle (95 °C for 10 s) and 40 cycles (95 °C for 5 s and 60 °C for 31 s) or one cycle (95 °C for 10 min) and 40 cycles (95 °C for 15 s and 62 °C for 1 min). Results (fold changes) were expressed as  $2^{-\Delta\Delta Ct}$  with  $\Delta\Delta Ct = (Ct_{ij} - Ct_{\beta\text{-actin } j}) - (Ct_{i1} - Ct_{\beta\text{-actin } 1})$ , where  $Ct_{ij}$  and  $Ct_{\beta\text{-actin } j}$  are the  $Ct$  for gene  $i$  and for  $\beta$ -actin in a pool or a sample (named  $j$ ) and where  $Ct_{i1}$  and  $Ct_{\beta\text{-actin } 1}$  are the  $Ct$  in pool 1 or sample 1, expressed as the standard. All primers used were designed by Primes Premier 5 and synthesized by Shanghai Saibaisheng Biological Company (Shanghai, China).

## Statistical Analysis

The results were expressed as mean  $\pm$  SE and differences were considered significant when  $P < 0.05$  tested by two-way analysis of variance (ANOVA) (with treatments and developmental stages as the main effects) and the pair  $t$ -test with Statistical Packages for Social Science 12.0 and Excel 2003 in Microsoft.

## Results

### Effect of In Ovo Administration of DHEA on Body weights and Liver Weights at Embryonic Stages and Hatching

The effect of in ovo administration of DHEA on body weight, absolute and relative liver weights at embryonic stages and hatching was shown in Table 2. In both groups, body weights sharply increased with developmental stage ( $p < 0.05$ ). Body weight in the CON group was slightly higher than that in the DHEA group throughout the whole embryonic development ( $p > 0.05$ ). Daily gain in the CON group slightly exceeded that of the DHEA group throughout the whole embryonic development ( $p > 0.05$ ).

In both groups, absolute liver weights increased greatly with developmental stage and the values of the control were a little higher than those of in ovo administration of DHEA. But the difference was not significant ( $p > 0.05$ ). In both groups, relative liver weights (g liver/g embryo weight) in the CON group was insignificantly higher than that in the DHEA group during the whole embryonic development ( $p > 0.05$ ).

### Effect of In Ovo Administration of DHEA on Plasma and Liver Lipid Metabolism Parameters at Embryonic Stages and Hatching

The effect of in ovo administration of DHEA on total blood TG, TC and hepatic TG content of broiler during embryonic development and at hatching were shown in Table 3. In both groups, the TG content in the liver (mmol/g liver) greatly increased with developmental stages ( $p < 0.05$ ). The TG content in the liver (mmol/g) was similar between CON and DHEA groups at E9d. However, the TG content in CON group was significantly higher than that in DHEA group at E14d, E19d as well as at hatching ( $p < 0.05$ ).

The blood TG (mmol/L) contents in both groups gradually decreased with developmental stages ( $p > 0.05$ ). The TG content in the CON group was significantly higher than that in the DHEA group throughout the whole embryonic development ( $p < 0.05$ ).

The blood TC content remained relatively the same in the two groups during the embryonic development. However, the plasma TC content in the DHEA group was significantly higher than that in the CON group at hatching ( $p < 0.05$ ).

### Effect of In Ovo Administration of DHEA on Hepatic ACC Gene Expression During Embryonic Development and at Hatching

The effect of in ovo administration of DHEA on ACC gene expression during embryonic development and at hatching was investigated in this study and the results were shown in Fig 1. mRNA level of ACC increased with embryonic development proceeding, but it decreased significantly at hatching in both groups ( $p < 0.05$ ). Expression level of the ACC gene in CON group was significantly lower than that in DHEA group during embryonic 19 days ( $p < 0.05$ ). However, ACC gene expression in CON group was four fold higher than that in DHEA group at hatching.

### Effect of In Ovo Administration of DHEA on Hepatic FAS Gene Expression During Embryonic Development and at Hatching

We then studied the effect of in ovo administration of DHEA on FAS gene expression during embryonic development. The result showed that FAS gene expression levels were nearly the same in both groups during embryonic development (Fig 2). FAS gene expression of CON was 18-fold higher than that in DHEA group at hatching and this difference was significant ( $p < 0.05$ ). FAS gene expression exhibited an increase in the CON group during embryonic development and at hatching. However, FAS gene expression decreased sharply in DHEA group at hatching ( $p < 0.05$ ).

**Fig. 1** Effect of in ovo administration of DHEA on hepatic ACC gene expression during embryonic development and at hatching. RNA molecules extracted from liver of different stages of embryonic development or hatching were reverse transcribed to cDNA and analyzed by quantitative RT-PCR. For comparison between different samples, the ACC transcript level of each sample was normalized for the beta-actin level and expressed as a multiple of ACC level of E9. Each column represented the mean and standard error of results obtained with 6 experiments. Black bars, control group (CON); Blank bars, DHEA group (DHEA); Asterisks indicate the differences between CON and DHEA group are significant ( $P < 0.05$ )

**Fig. 2** The effect of in ovo administration of DHEA on hepatic FAS gene expression during embryonic development and at hatching—RNA molecules were extracted from the liver at different stages of embryonic development or at hatching and were reverse transcribed to cDNA and analyzed by quantitative RT-PCR. For comparison between different samples, the FAS transcript level of each sample was normalized for the beta-actin level and expressed as a multiple of the FAS level of E9. Each column represented the mean and standard error of results obtained with six experiments. Black bars, control group (CON); Blank bars, DHEA group (DHEA); Asterisks indicate the differences between CON and DHEA group are significant ( $P < 0.05$ )

### Effect of In Ovo Administration of DHEA on Hepatic SREBP-1c Gene Expression During Embryonic Development and at Hatching

The result of in ovo administration of DHEA on hepatic SREBP-1c gene expression during embryonic development and at hatching was shown in Fig. 3. SREBP-1c gene expression levels were the same in the DHEA group as in the CON group during the embryonic development. At hatching, SREBP-1c transcript level in the CON group was three-fold higher than that in the DHEA group. The difference was significant ( $p < 0.05$ ). SREBP-1c gene expression exhibited increasing with embryonic development in two groups. However, the expression level of SREBP-1c in the CON group increased more than that in the DHEA group.

### The Effect of in Ovo Administration of DHEA on Hepatic ME Gene Expression During Embryonic Development and at Hatching

In this study, we also investigate the effect of in ovo administration of DHEA on ME gene expression during embryonic development and at hatching. The result was shown in Fig. 4. The transcript level of ME in CON group was significantly higher than that in DHEA group from embryonic development of 14 days to hatching ( $p < 0.05$ ).

**Fig. 3** The effect of in ovo administration of DHEA on hepatic *SREBP-1c* gene expression during embryonic development and at hatching. RNA molecules extracted from liver of different stages of embryonic development or hatching were reverse transcribed to cDNA and analyzed by quantitative RT-PCR. For comparison between different samples, the *SREBP-1c* transcript level of each sample was normalized for the beta-actin level and expressed as a multiple of *SREBP-1c* level of E9. Each column represented the mean and standard error of results obtained with six experiments. *Black bars*, control group (CON); *Blank bars*, DHEA group (DHEA); *Asterisks* indicate that the differences between CON and DHEA groups are significant ( $P < 0.05$ )

**Fig. 4** The effect of in ovo administration of DHEA on hepatic *ME* gene expression during embryonic development and at hatching. RNA molecules extracted from liver of different stages of embryonic development or hatching were reverse transcribed to cDNA and analyzed by quantitative RT-PCR. For comparison between different samples, the *ME* transcript level of each sample was normalized for the beta-actin level and expressed as a multiple of *ME* level of E9. Each column represented the mean and standard error of results obtained with 6 experiments. *Black bars*, control group (CON); *Blank bars*, DHEA group (DHEA); *Asterisks* indicate the differences between CON and DHEA group are significant ( $P < 0.05$ )

Moreover, the CON to DHEA ratio of expression level increased with embryonic development. The expression level of *ME* decreased from E14 days to hatching.

### Effect of In Ovo Administration of DHEA on Hepatic *ApoB* Gene Expression During Embryonic Development and at Hatching

Finally, we studied the effect of in ovo administration of DHEA on *apoB* gene expression during embryonic development and at hatching, and the result was shown in Fig. 5. The expression level of the hepatic *apoB* gene significantly increased through the course of embryonic development ( $p < 0.05$ ). Measured by RT-PCR, the mRNA level of *apoB* in the CON group was significantly higher than that in DHEA treatment throughout all the stages of embryonic development ( $p < 0.05$ ).

### Discussion

Long term DHEA treatment results in suppression of body weight gain in rodents [36, 37]. However, no significant effect of in ovo administration of DHEA on body weight, body weight gain and absolute liver weight was observed in this experiment. In contrast to its effects on rats and mice, DHEA did not significantly depress body weight of chickens [33]. Rats fed with DHEA had a slower growth rate compared with rats fed with a control diet, whereas rats treated with DHEA i.p. had growth rates identical to those of controls. The liver weights of rats administrated DHEA p.o. or i.p. increased significantly compared to those of control rats [39]. In lean rats, DHEA treatment did not decrease liver weight [38]. Liver weights of DHEA treated rats were higher than those of control rats [39]. Administration of DHEA to rats results in lowered body weight, higher liver weights and DNA, RNA, and/or protein content, but lowered lipid and glycogen levels [40]. These data indicate that the effect of DHEA on body weight gain, food intake, and hepatic and peripheral adiposity are dependent on the species of animal, the adrenal status, the DHEA dose and the age of embryonic development at which measurements were made [41, 42].

DHEA has a fat-reducing effect, however, this effect may be exerted by different mechanisms [31]. It has been shown in this study that in ovo administration of DHEA to fertilized eggs before incubation reduced plasma and liver TG content. This result agreed with other studies in rodents. For example, the study by Mikheil and Leila [43] indicated that dehydroepiandrosterone influences on lipid metabolism - reduces the levels of TC, TG, LDL, VLDL. Mohan. PF and Cleary. MP [39, 40] suggested DHEA treatment reduced hepatic lipids in rats and under some circumstances, altered a number of serum factors including glucose, insulin, cholesterol, and triacylglycerol. Therefore, DHEA may reduce the adipose tissue by reducing the TG content in adipose tissue.

**Fig. 5** The effect of in ovo administration of DHEA on hepatic *apoB* gene expression during embryonic development and at hatching. RNA molecules extracted from liver of different stages of embryonic development or hatching were reverse transcribed to cDNA and analyzed by quantitative RT-PCR. For comparison between different samples, the *apoB* transcript level of each sample was normalized for the beta-actin level and expressed as a multiple of the *apoB* level of E9. Each column represented the mean and standard error of results obtained with six experiments. Black bars, control group (CON); Blank bars, DHEA group (DHEA); Asterisks indicate the differences between CON and DHEA group are significant ( $P < 0.05$ )

Other studies also indicated that DHEA treatment altered the activity levels of a lot of enzymes in the liver that are involved in lipid metabolism [40]. This could be one of the mechanisms of DHEA for decreasing the fat level of the animal. For example, Valentine et al. [33] reported that liver cytosolic malic enzyme activity were depressed in chickens treated with DHEA compared with that in untreated animals. This study showed that the expression level of the hepatic *ME* gene in DHEA group was lower than that in the CON group. The relative abundances of malic enzyme mRNAs were associated with malic enzyme activity and liver total lipid concentration [44]. The activity of the hepatic malic enzyme is positively correlated with the rate of fatty acid synthesis, the percentage of body fat, and the percentage of abdominal fat in chicks. Meanwhile, Casazza et al. [45] hypothesized that DHEA inhibited fat synthesis by diminishing the availability of NADPH, but no data gave support to the hypothesis that administration of DHEA resulted in decreased cytoplasmic NADPH in the liver of rats. In the avian liver, most of the NADPH used by fatty acid synthase to catalyze the synthesis of palmitate is generated by the malic enzyme [14]. Therefore, DHEA reduced hepatic *ME* gene expression so as to decrease the hepatic fatty acid synthesis and de novo TG synthesis.

In our published study, we suggested that expression of the key gene (*FAS*) in the liver was responsible for de novo synthesis of fatty acid prior to hatching and at hatching [46]. The rate of hepatic lipogenesis was decreased by approximately 70% in DHEA-treated mice [47]. Noteworthy, the fat-reducing effect of DHEA seems to be more evident at the level of visceral adipose tissue [31, 41].

Moreover, this study showed that DHEA significantly depressed the *FAS* gene expression at hatching. This means that DHEA decreased *FAS* gene expression to reducing fat especially at hatching.

In avian species, the development of adipose tissue depends on the availability of plasma triglycerides that are hydrolyzed prior to their uptake by adipocytes. They are specifically transported to adipocytes by specific lipoprotein classes: very low density lipoproteins (VLDL) transport de novo synthesized hepatic lipids [4, 5]. *ApoB* participated in the assembly of VLDL. This study showed DHEA decreased the *apoB* gene expression, which suggested that DHEA depressed the assembly of VLDL, resulting in the suppression of the transportation of hepatic TG to various tissues.

As one of potential regulators, *SREBP-1c* can directly stimulate the transcription of genes encoding *ACC* [20–22], *FAS* [23] enzymes. In this study, DHEA decreased the expression of both *SREBP-1c* and *FAS* genes throughout the whole embryonic development. However, DHEA significantly reduced the expression of all three genes, *SREBP-1c*, *ACC* and *FAS* at hatching. Our previous studies indicated that embryonic liver synthesized fatty acid prior to hatching or at hatching [46]. This suggested that by decreasing the expression of transcriptional regulator, DHEA altered the expression levels of various downstream genes that are involved in the synthesis of TG.

In conclusion, this study analyzed the effect of in ovo administration of DHEA on blood lipid metabolism and hepatic lipogenic genes expression in broiler chicken during embryonic development. The result indicated that DHEA significantly decreased liver weight, blood TG content, hepatic TG content and the expression levels of hepatic *ACC*, *FAS*, *ME*, *SREBP-1c* and *apoB* genes in broiler chicken during embryonic development. All of these affected genes are involved in the metabolism of fat tissue. A higher rate of triglyceride synthesis and secretion from the liver would be responsible for the higher abdominal fat weight in chickens. Over all, our data suggested that DHEA decreased the synthesis of TG in liver and its transport in circulation, which is probably the mechanism of DHEA in reducing the accumulation of fat in chicken.

**Abstract** Asperamides A (**1**) and B (**2**), a sphingolipid and their corresponding glycosphingolipid possessing a hitherto unreported 9-methyl-C<sub>20</sub>-sphingosine moiety, were characterized from the culture extract of *Aspergillus niger* EN-13, an endophytic fungus isolated from marine brown alga *Colpomenia sinuosa*. The structures were elucidated by spectroscopic and chemical methods as (2*S*,2'*R*,3*R*,3'*E*,4*E*,8*E*)-*N*-(2'-hydroxy-3'-hexadecenoyl)-9-methyl-4,8-icosadien-1,3-diol (**1**) and 1-*O*-β-D-glucopyranosyl-(2*S*,2'*R*,3*R*,3'*E*,4*E*,8*E*)-*N*-(2'-hydroxy-3'-hexadecenoyl)-9-methyl-4,8-icosadien-1,3-diol (**2**). In the antifungal assay, asperamide A (**1**) displayed moderate activity against *Candida albicans*.

## Introduction

Sphingolipids are commonly distributed among some of the bacteria and almost all eukaryotic organisms, such as fungi, sponges, higher plants, and mammals. They play an important role in recognition of pathogens, signal transduction, cell differentiation, and apoptosis of cancer cells. Many sphingolipids have been found to exhibit antihepatotoxic, antitumor, antifungal, antiviral, neuritogenic, and immunoregulatory activities [1–4] and have drawn more and more interest from chemical and medicinal researchers. Since the 1990s, marine derived fungi have been recognized as a rich source of novel bioactive metabolites because their environments differ from those of terrestrial fungi [5]. In the course of our investigation of the bioactive secondary metabolites of *Aspergillus niger* EN-13, an endophytic fungus isolated from marine brown alga *Colpomenia sinuosa*, two new sphingolipids (namely, asperamides A (**1**) and B (**2**), Scheme 1) with a previously unreported 9-methyl-C<sub>20</sub>-sphingosine moiety were characterized. This paper describes the isolation, structural determination, and antifungal activity of asperamides A (**1**) and B (**2**).

## Experimental Procedures

### Chromatographic and Instrumental Methods

Melting points were measured using a SGW X-4 micro-melting point apparatus and uncorrected. Optical rotations were obtained on a JASCO P-1020 digital polarimeter. IR spectra were taken on a NICOLET 510P FT-IR spectrometer in KBr discs. NMR spectra were recorded on a Bruker Avance 500 MHz spectrometer (500 MHz for  $^1\text{H}$  and 125 MHz for  $^{13}\text{C}$ ) using TMS as internal standard and chemical shifts were recorded as  $\delta$  values. Mass spectra were measured on VG AutoSpec 3000 mass spectrometer. GC-MS analysis was performed on an Agilent 6890-5973 GC-MS apparatus.

### Materials

Silica gel (200–300 mesh and GF-254) for column chromatography (CC) and preparative thin-layer chromatography were the products of the Qingdao Haiyang Chemical Group Co., Qingdao, China. RP-18 reverse-phase silica gel was the product of the Merck Corporation. Sephadex LH-20 was purchased from the Pharmacia Corporation. Amphotericin B was produced by the Sigma Corporation.

### Microorganism

The fungal strain *Aspergillus niger* EN-13 was isolated from the inner tissue of surface-sterilized fresh brown alga *Colpomenia sinuosa* (Roth) Derbeset Solier that was collected in May of 2004 along the Qingdao coastline of Shandong Province, People's Republic of China, according to a method we recently reported [6]. The taxonomic identification as *A. niger* was performed based on fungal morphology (both macroscopic and microscopic) by one of the authors (Y.Z.) and a voucher strain was deposited in the China Center for Type Culture Collection (depository number: CCTCC AF 206004).

### Fermentation

A small spoon of spores growing on malt agar slant was inoculated onto a malt agar plate and cultured at 28 °C for 7 days. Then a piece (size: 4 cm<sup>2</sup>) of mycelium was inoculated into 1,000-ml Erlenmeyer flasks containing 300 ml of a culture medium composed of glucose 2%, peptone 0.5%, malt extract 0.3%, yeast extract 0.3%, artificial sea salt 2.44%. The pH was adjusted to 7.4 before autoclaving. Static fermentation was carried out at 25 °C for 30 days.

### Extraction and Isolation

The culture broth (30 l) was filtrated and separated into mycelia and supernatant. Air-dried mycelia were smashed and extracted with 3 l of MeOH to give a MeOH-soluble extract. The supernatant was concentrated under reduced pressure to about 4 l, and then extracted three times with EtOAc to give an EtOAc-soluble extract. Since the two extracts displayed similar TLC and HPLC profiles, they were combined and evaporated under reduced pressure, resulting in a total extract (42.0 g). This extract was subjected to a silica gel CC eluting stepwise from  $\text{CHCl}_3$  to MeOH to give 14 fractions. Fraction VIII (3.0 g) was subsequently subjected to a silica gel CC eluted with  $\text{CHCl}_3/\text{MeOH}$  (30:1, by vol) to give six sub-fractions. Sub-fr. II (157 mg) was further separated with consecutive CC on silica gel eluted with  $\text{CHCl}_3/\text{MeOH}$  (40:1, by vol) and RP-18 (MeOH) to provide compound **1** (88 mg). Fraction XIV (960 mg) was subjected to a silica gel CC eluted with  $\text{CHCl}_3/\text{MeOH}$  (8:1, by vol) to give three subfractions. Sub-fr. II (220 mg) was successively purified by CC on RP-18 (MeOH) and Sephadex LH-20 (MeOH) to yield compound **2** (80 mg).

methyl ester **1a**, which could be identified as methyl 2-hydroxy-3-hexadecenoate through GC-MS showing the molecular ion peak at  $m/z$  284 and fragment ion peaks at  $m/z$  253  $[M - OMe]^+$ , 235  $[M - OMe - H_2O]^+$ , and  $m/z$  85  $[M - OMe - C_{12}H_{25}]^+$ . The aqueous MeOH layer was neutralized with saturated  $Na_2CO_3$ , concentrated to dryness, and extracted with EtOAc. The EtOAc phase was filtered, concentrated, and purified by CC over silica gel eluted with petroleum ether/acetone (5:1) to give a long-chain base (LCB, **1b**), which showed a pseudo-molecular ion peak at 340  $[M + H]^+$  in the EI spectrum.

### Methanolysis of **2**

Following the same method as that of **1**, compound **2** was also methanolized and analyzed by GC-MS, showing the same result as those of **1**.

### Antifungal Assay

The antifungal assay against *Candida albicans* (ATCC 10231) was performed by use of a modified Well Diffusion method that was referenced to the National Committee for Clinical Laboratory Standards (NCCLS) [8, 9]. Sabouraud dextrose agar plates were swabbed with the respective broth culture of *C. albicans* (diluted to 0.5 McFarland Standard with saline) and kept for 15 min for absorption to take place. Wells were made in agar plates using the broad end of a sterile Pasteur pipette (6 mm in diameter), and 20  $\mu$ l of 1 mg  $ml^{-1}$  sample dissolved in 5% aqueous DMSO was added to each well. Twenty micro liter of 0.1 mg  $ml^{-1}$  amphotericin B in 5% aqueous DMSO were used as positive control. The plates were incubated at 37 °C for 48 h and the diameters of the inhibition zones were measured in millimeter after the incubation period.

## Results and Discussion

The culture broth extract of *A. niger* was separated by CC on silica gel, RP-18, and Sephadex LH-20 to give compounds **1** and **2**. Their structures were elucidated as follows.

Compound **1** was obtained as white amorphous powder. The positive HRESI-MS spectrum exhibited a molecular ion peak at  $m/z$  592.5314  $[M + H]^+$  which suggested the molecular formula as  $C_{37}H_{69}NO_4$  (calcd. for  $C_{37}H_{70}NO_4$  592.5304). Its IR spectrum exhibited the absorption bands for secondary amide at 3,274 (spike) and 1,630  $cm^{-1}$  and for hydroxyl groups at 3,377 (broad)  $cm^{-1}$ . In the  $^{13}C$  and  $^1H$ -NMR spectra (Table 1), the tertiary carbon signal resonated at  $\delta_C$  173.0 was assigned to an amide carbon, while

five methine signals presented at  $\delta_C$  123.0 ( $\delta_H$  5.09), 127.1 ( $\delta_H$  5.55), 128.7 ( $\delta_H$  5.53), 134.0 ( $\delta_H$  5.80), and 136.3 ( $\delta_H$  5.90), and one quaternary carbon at  $\delta_C$  136.4 indicated the presence of three double bonds. The signals resonated at  $\delta_C$  14.1 ( $CH_3 \times 2$ ) and  $\delta_H$  0.88 (6H, *t*,  $J = 7.0$  Hz) indicated the presence of two terminal methyls. Additionally, the  $^{13}C$  and  $^1H$ -NMR spectra showed resonances for a hydroxymethyl at  $\delta_C$  62.1 ( $\delta_H$  3.95 and 3.73), two hydroxymethines at  $\delta_C$  73.2 ( $\delta_H$  4.54) and 74.3 ( $\delta_H$  4.31), a methine bonded to nitrogen at  $\delta_C$  54.5 ( $\delta_H$  3.89), and resonances for aliphatic chains among  $\delta_C$  28–32 ( $\delta_H$  1.25–1.31). The above spectral data and literature precedents enabled the structure of **1** to be established as (2*S*,2'*R*,3*R*,3'*E*,4*E*,8*E*)-*N*-(2'-hydroxy-3'-hexadecenoyl)-9-methyl-4,8-icosadien-1,3-diol. This conclusion could be further confirmed as follows. The methine proton at  $\delta_H$  3.89 (H-2) exhibited correlations in the COSY spectrum (Scheme 2) with the amide proton ( $\delta_H$  7.03, NH), the hydroxymethyl ( $\delta_H$  3.95 and 3.73, H-1a and H-1b), and the hydroxymethine ( $\delta_H$  4.31, H-3). The latter displayed further COSY correlation with an olefinic methine at  $\delta_H$  5.53 (H-4). In the HMBC spectrum (Scheme 2), the protons at  $\delta_H$  3.89 (H-2) and  $\delta_H$  3.73 (H-1b) exhibited correlations with the hydroxymethyl ( $\delta_C$  62.1, C-1) and the hydroxymethine ( $\delta_C$  74.3, C-3), respectively. The hydroxymethine at  $\delta_H$  4.54 (H-2') displayed correlations in the HMBC spectrum with the carbonyl at  $\delta_C$  173.0 and the olefinic methines at  $\delta_C$  127.1 (C-3') and 136.3 (C-4'). The above COSY and HMBC correlations indicated the presence of a 1,3-dihydroxy-4-en- unit in the sphingosine moiety and a 2-hydroxy-3-en- fatty acid moiety in **1**.

Acidic methanolysis of **1** (Scheme 3) produced a long chain fatty acid methyl ester **1a**, which was identified as methyl 2-hydroxy-3-hexadecenoate by GC-MS analysis as evidenced by a molecular ion peak at  $m/z$  284 and three characteristic fragment ion peaks at  $m/z$  253  $[M - OMe]^+$ , 235  $[M - OMe - H_2O]^+$ , and 85  $[M - OMe - C_{12}H_{25}]^+$ . The remained long chain base (LCB, **1b**) was suggested to be a  $C_{21}$  sphingosine as supported by a pseudo-molecular ion peak at 340  $[M + H]^+$  (attributed to  $C_{21}H_{42}NO_2$ ) in its EI spectrum. These two segments were also confirmed by the

**Scheme 2** Key HMBC and  $^1H$ - $^1H$  COSY correlations of **1**

**Scheme 3** Methanolysis of **1**

fragment ion peaks at  $m/z$  253 ( $C_{16}H_{29}O_2$ ), 323 ( $C_{21}H_{39}O_2$ ), and 338 ( $C_{21}H_{40}NO_2$ ) in the EI spectrum of **1**. The double bonds at the positions C-3' and C-4 were determined to be *trans*-type by the coupling constants ( $J_{3', 4'} = 15.2$  Hz and  $J_{4, 5} = 15.3$  Hz), while the double bond at C-8 was also identified as *trans*-type due to the chemical shift of C-9 methyl at  $\delta_C$  16.0 (C-21) in the  $^{13}C$ -NMR spectrum [10], and this was confirmed by the comparison with the chemical shift of the C-9 methyl ( $\delta_C$  15.9) of (2*S*,3*R*,4*E*,8*E*)-1-( $\beta$ -D-glucopyranosyl)-3-hydroxy-2-[(*R*)-2'-hydroxyheptadecanoyl]amino-9-methyl-4,8-octadecadiene [7]. Associated with the correlations observed in the HMBC and  $^1H$ - $^1H$  COSY (Scheme 2), the linear structure of the long chain fatty acid and the LCB were elucidated as 2-hydroxy-3*E*-hexadecenoic acid and (4*E*,8*E*)-2-amino-1,3-dihydroxy-9-methyl-4,8-dien-icosane, respectively.

The absolute stereochemistry for sphingolipids is commonly characterized by the comparison of the NMR data with related literature reports [1, 7, 11, 12]. For **1**, the configurations at C-2, C-2', and C-3 were determined based on the proton chemical shifts and coupling constants at  $\delta_H$  3.95 (*dd*, 11.4, 3.4, H-1a),  $\delta_H$  3.73 (*dd*, 11.3, 3.0, H-1b),  $\delta_H$  3.89 (*m*, H-2),  $\delta_H$  4.54 (*d*, 7.1, H-2'), and  $\delta_H$  4.31 (*dd*, 7.7, 3.8, H-3), which were identical to those of the previously reported for (2*S*,2'*R*,3*R*,3'*E*,4*E*,8*E*)-*N*-(2'-hydroxy-3'-octadecenoyl)-9-methyl-4,8-octadecadiene-1,3-diol (**3**), a sphingolipid previously isolated from *Penicillium funiculosum* (13). Meanwhile, the specific optical rotation of **1** ( $[\alpha]_D^{20} - 5.6$ ) was also in agreement with that of **3** ( $[\alpha]_D^{25} - 8.2$ ) [13]. Accordingly, the structure of **1** was established as (2*S*,2'*R*,3*R*,3'*E*,4*E*,8*E*)-*N*-(2'-hydroxy-3'-hexadecenoyl)-9-methyl-4,8-icosadien-1,3-diol, which was named as asperamide A.

Compound **2** was also obtained as a white amorphous powder and its formula was determined as  $C_{43}H_{79}NO_9$  by the HRESIMS at  $m/z$  754.5843  $[M + H]^+$  (calcd. for

$C_{43}H_{80}NO_9$  754.5833). Its IR spectrum was very similar to that of **1** except for the absorptive band at  $1,080\text{ cm}^{-1}$  attributed to C–O–C group. The  $^1H$  and  $^{13}C$ -NMR spectra (Table 1) were very similar to those of **1** while showing additional signals due to the sugar moiety including an anomeric proton at  $\delta_H$  4.29 (*d*,  $J = 7.7$  Hz), four protons geminal to the hydroxyl group between  $\delta_H$  3.22–3.37 and hydroxymethyl protons at  $\delta_H$  3.69 and 3.89 in the  $^1H$ -NMR spectrum as well as the presence of six additional oxygenated carbons at  $\delta_C$  104.7 (CH), 78.0 (CH), 77.9 (CH), 75.0 (CH), 71.6 (CH), and 62.7 (CH<sub>2</sub>) in the  $^{13}C$ -NMR spectrum. These data suggested that **2** was a  $\beta$ -D-glucopyranoside of **1**. The attachment of the glucose moiety at C-1 was proved by the significant downfield chemical shift ( $\Delta$  7.6 ppm) of the hydroxymethyl carbon at  $\delta_C$  69.7 (C-1) in the  $^{13}C$ -NMR spectrum and confirmed by the additional correlation between the anomeric proton ( $\delta_H$  4.29, H-1") and the hydroxymethyl carbon ( $\delta_C$  69.7, C-1) in the HMBC spectrum (Scheme 4). The coupling constant for the anomeric proton (7.7 Hz) indicated the  $\beta$ -configuration for the glucosyl moiety. Methanolysis of **2** also produced the same main product, methyl 2-hydroxy-3-hexadecenoate as that of **1**. The absolute configuration of the core structure at chiral centers 2, 3, and 2' was also determined as 2*S*, 3*R*, and 2'*R* with the same method as **1** by comparison with the reported  $^1H$  and  $^{13}C$ -NMR chemical shifts of two glycosphingolipids Pen II (the glucoside of **3**) [13] and cerebroside C [14]. Therefore, the structure of **2** was determined as 1-*O*- $\beta$ -D-glucopyranosyl-(2*S*,2'*R*,3*R*,3'*E*,4*E*,8*E*)-*N*-(2'-hydroxy-3'-hexadecenoyl)-9-methyl-4,8-icosadien-1,3-diol, which was named as asperamide B.

A literature survey revealed that sphingolipids containing a 9-methyl- $C_{18}$ -sphingosine moiety have been very commonly and frequently reported, both for natural occurring and synthetic ones [4, 15], while those possessing a 9-methyl- $C_{20}$ -sphingosine moiety have not been reported so far. To the best of our knowledge, compounds **1**

**Scheme 4** Key HMBC and  $^1H$ - $^1H$  COSY correlations of **2**

and **2** represent the first example of sphingolipids consist of a 9-methyl-C<sub>20</sub>-sphingosine moiety. They are also most likely the first new sphingolipids discovered in marine algal-derived fungi.

In the antifungal assay, compound **1** exhibited moderate activity against *Candida albicans*, with a faint while obvious inhibition zone ( $\varphi$  12 mm), compared to the clear inhibition zone ( $\varphi$  12 mm) of the positive control Amphotericin B.

**Abstract** The purpose of the study was to qualitatively characterize the major lipid species present in human meibomian gland secretions (MGS) by means of high-performance liquid chromatography with atmospheric pressure ionization mass spectrometric detection of the analytes (NP HPLC-MS). Two different NP HPLC-MS methods have been developed to analyze lipid species that were expected to be present in MGS. The first method was optimized for the analysis of relatively nonpolar lipids [wax esters (WE), di- and triacyl glycerols (DAG and TAG), cholesterol (Chl) and its esters (Chl-E), and ceramides (Cer)], while the second method was designed to separate and detect phospholipids. The major lipid species in MGS were found to be WE, Chl-E, and TAG. A minor amount of free Chl (less than 0.5% of the Chl-E fraction) was detected in MGS. No appreciable amounts of DAG and Cer were found in MGS. The second NP HPLC-MS method, capable of analyzing model mixtures of authentic phospholipids (e.g. phosphatidylglycerol, phosphatidylethanolamine, phosphatidic acid, phosphatidylinositol, phosphatidylserine, phosphatidylcholine, and sphingomyelin) in submicrogram/mL concentrations, showed little or no presence of these species in the MGS samples. These observations suggest that MGS are a major source of the nonpolar lipids of the WE and Chl-E families for the tear film lipid layer (TFLL), but not of the previously reported phospholipid components of the TFLL.

## Introduction

Lipids that are produced by human meibomian glands (MG) are an integral part of the tear film lipid layer (TFLL) which covers the ocular surface [1–4] and, among other functions, protects it from losing water due to excessive evaporation [3–6]. It is postulated that the lipids form the outermost part of the TFLL [1, 2]. The amount of produced lipid material and its composition largely determine the quality of the TFLL. Changes in lipid profiles of MGS were correlated with the development of dry eye syndrome (DES) [7–9] which is a wide-spread condition that severely deteriorates the quality of life of millions of people [10] and impairs vision [11, 12]. Therefore, qualitative and quantitative characterization of the lipids in MGS could provide vital information about the mechanisms that are central to the development of DES.

Previously, the major classes of MG lipids produced by different mammals have been characterized by thin layer chromatography (TLC, [13, 14]), gas chromatography (GC) [13, 15, 16], high-performance liquid chromatography (HPLC) with UV detection of the analytes [17–19], and <sup>31</sup>P nuclear magnetic resonance (<sup>31</sup>P-NMR) [20]. Most of the earlier research work has been done with animal models (e.g., steer [17, 21], hamster [15], and rabbit [20, 22]). Detected lipids represented a wide range of nonpolar lipids [sterol and wax esters (WEs), tri- and diacylglycerols, free cholesterol, and fatty acids) and a range of more polar lipids including primarily phospholipids. Limited information is available for human samples [13, 18, 19].

Though useful, many of the above techniques have their shortcomings and are not well-suited for analyzing small samples. The TLC-based experiments lack resolving power and specificity, which may lead to misidentification of the analytes. These methods are also prone to problems with sample degradation due to prolonged exposure to air, acids, and bases. GC, on the other hand, is a very sensitive and reproducible method, but it requires that samples be derivatized in order to become volatile. This typically involves partial hydrolysis and transesterification and/or silylation of complex higher molecular weight lipids,

e.g., wax esters (WE) and cholesteryl esters (Chl-E) [7, 13]. Reportedly, GC separation of the corresponding derivatives of the hydrolysis products took several hours and was conducted at high temperatures [13], which could compromise the analytes by inadvertent isomerization and/or decomposition of labile molecules. The higher molecular weight analytes (above C<sub>30</sub> equivalent chain length) were not successfully detected by this method [13]. The product yields and sample recovery during the derivatization procedures are also an issue. Another serious problem that arises from these types of experiments is that it is very difficult, if not impossible, to determine which combination of the resulting hydrolysis products existed in the precursor compounds. Therefore, no full precursor structures have been typically reported, only the corresponding hydrolysis products—fatty acids and alcohols in case of Chl-E and WE [7, 13, 23].

Currently, one of the more promising analytical approaches appears to be HPLC with atmospheric pressure ionization mass spectrometric (API MS) detection of the analytes [24, 25]. The HPLC-MS method combines the resolving power of modern HPLC columns with the high sensitivity and selectivity of the MS detectors. Importantly, API MS also provides critical information on the molecular masses of the analytes, which can be used to identify individual compounds in complex mixtures.

Therefore, the goal of this study was to determine which lipid classes were present in the individual intact samples of human MGS collected from normal subjects, using the HPLC technique combined with API MS detection of the lipids<sup>1</sup>. Compared with previously used procedures, this approach minimized inevitable losses and/or alterations of the analytes that were described above.

## Materials and Methods

The following equipment, reagents, and supplies were used in this study: acetic acid, *n*-hexane, methanol, propan-2-ol, HPLC grade water, and ammonium formate were purchased from Aldrich (Milwaukee, WI, USA) and/or from Burdick & Jackson (Muskegon, MI, USA) through VWR (West Chester, PA, USA). Lipid standards of highest purity available were products of Avanti Polar Lipids, Inc. (Alabaster, AL, USA) and Sigma Chemical Co. (St Louis, MO, USA). A Lichrosphere Si-60 silica gel column (3.2 mm × 150 mm, 5 μm) was a product of Supelco (Bellefonte, PA, USA). A Lichrosphere Diol HPLC column (3.2 mm × 150 mm, 5 μm) was obtained from Phenome-

<sup>1</sup> The results of this study were presented in part at 2006 ARVO Annual Meeting (Butovich et al, *IOVS* 2006;47:ARVO E-Abstract 5605).

nex (Torrance, CA, USA). A Waters Alliance 2695 HPLC Separations Module was purchased from Waters Corp. (Milford, MA, USA). An LCQ Deca XP Max MS<sup>n</sup> spectrometer equipped with an atmospheric pressure chemical ionization (APCI) ion source and an electrospray ionization (ESI) ion source was a product of Thermo Electron Corp. (San Jose, CA, USA).

#### Collection of the MGS

Meibomian gland secretions samples were collected from eight normal young volunteers (four male and four female, average age  $31 \pm 3$  years, with no signs and histories of ocular diseases, who underwent standard clinical tests for DES [26–31]). The samples were analyzed individually 2–4 times each. The study was approved by the Institutional Review Board. Informed consents were obtained from all participating subjects. The research was conducted in accordance with the principles of the Declaration of Helsinki. The samples were collected as follows. A clean, dry, pre-weighed glass vial was filled with ~1 mL of GC/MS-grade chloroform. The MGS were expressed by squeezing each of a subject's four eyelids using a plastic conformer and a cotton swab. The lipid samples were collected directly from the MG orifices with a polished platinum spatula. Care was taken to avoid scrubbing the eyelids. The secretions that had been expressed from the glands immediately solidified at room temperature to assume a waxy texture (Fig. 1). The sample was transferred into the vial with chloroform. The sample solution in chloroform was brought to dryness at room temperature under a stream of dry nitrogen and the vial with the sample was re-weighed to determine the weight of the dry lipid material. Depending on the donors, the dry sample weights were between 0.1 and 1 mg. The standard error of weighing was  $\leq 5\%$  for each of the samples. The average weight of the samples collected from eight individual subjects was 0.43 mg. The samples were stored in a nitrogen atmosphere at  $-80^\circ\text{C}$ . Under such conditions, dry samples were

**Fig. 1** A sample of human meibomian gland secretions at room temperature

stable for at least 2 months without apparent deterioration of the major lipid components.

#### HPLC-MS Analysis of Lipids

Considering that MGS were reported to be a complex mixture of nonpolar lipids and phospholipids [1, 2, 7–9, 13–23], two different API techniques were used—APCI, which is optimal for analyzing nonpolar to moderately polar compounds, and ESI, which is better suited for the analysis of complex molecules of moderately polar to polar nature. The choice of lipid standards was based on previously reported groups of lipids determined in mammalian and human MGS [1, 2, 7–9, 13–23]. Two different standard lipid mixtures were prepared. The first model mixture was composed of nonpolar to moderately polar lipids and included cholesteryl oleate (Chl-O, molecular mass 650.6), stearyl stearate (SS, 536.6), tripalmitoylglycerol (TP, 806.7), 1,2- and 1,3-diarachidoylglycerols (DA, 680.6), free cholesterol (Chl, 386.7), and C<sub>18</sub>- and C<sub>24</sub>-ceramides (Cer, 565.5 and 649.6, respectively). The second model mixture was composed of standard phospholipids (PLs): 1-palmitoyl-2-oleoyl-phosphatidylglycerol (C<sub>16:0</sub>/C<sub>18:1</sub>-PG, 748.5), 1,2-dipalmitoyl-phosphatidylethanolamine (C<sub>16:0</sub>/C<sub>16:0</sub>-PE, 691.5), 1-palmitoyl-2-oleoyl-phosphatidic acid (C<sub>16:0</sub>/C<sub>18:1</sub>-PA, 674.5), 1-stearoyl-2-arachidonoyl-phosphatidylinositol (C<sub>18:0</sub>/C<sub>20:4</sub>-PI, 886.6), 1-stearoyl-2-oleoyl-phosphatidylserine (C<sub>18:0</sub>/C<sub>18:1</sub>-PS, 789.6), 1-palmitoyl-2-oleoyl-phosphatidylcholine (C<sub>16:0</sub>/C<sub>18:1</sub>-PC, 760.6), and C<sub>18:0</sub>-sphingomyelin (C<sub>18:0</sub>-SM, 731.6).

#### Standard Nonpolar Lipids

Authentic nonpolar lipid standards were analyzed by normal phase (NP) HPLC-MS. A Lichrosphere Diol (3.2 mm  $\times$  150 mm, 5  $\mu\text{m}$ ) HPLC column was used. The samples were dissolved in a *n*-hexane/propan-2-ol/acetic acid (949:50:1, by vol) solvent mixture (HPA). Lipids were isocratically eluted from the column with the HPA solvent mixture at 30  $^\circ\text{C}$  and a flow rate of 0.3 mL/min. The solvent composition was chosen to ensure complete solubility of all the analyzed lipid samples in the indicated concentration ranges, as well as their effective separation and ionization under the tested conditions. In preliminary experiments, the samples (~10–20  $\mu\text{g}$  of total lipid/mL) were dissolved either in chloroform/methanol (2:1, by vol) mixture, or in the mobile phase. There were no differences in the results obtained with either approach. Because of: (1) known ability of chloroform to decompose releasing hydrochloric acid and phosgene, which are capable of deteriorating lipid samples, and (2) poorer miscibility of this relatively polar mixture with our mobile phase, which could change the retention times of the most nonpolar

compounds if injected in large volumes, we chose to dissolve samples in *n*-hexane/propan-2-ol mixtures. Between 1 and 10  $\mu\text{L}$  of the sample solutions were injected. The entire flow of the effluent was directed into an APCI ion source and analyzed either in the positive, or the negative ion modes. High-purity nitrogen was utilized as sheath gas. The following MS settings were used: sheath gas flow of 25 arbitrary units; auxiliary/sweep gas 5; vaporizer temperature 375  $^{\circ}\text{C}$ ; capillary temperature 300  $^{\circ}\text{C}$ ; capillary voltage 12 V (for positive ion mode experiments) and  $-15$  V (for the negative ion mode). The discharge current was set to be 5  $\mu\text{A}$ . The full MS spectra were typically collected between  $m/z$  values of 200 and 1,000 for the entire period of the experiment.

### Standard Phospholipids

The samples of standard PLs and their mixtures were analyzed by NP HPLC-MS using a Lichrosphere Si-60 (3.2 mm  $\times$  150 mm, 5  $\mu\text{m}$ ) HPLC column. HPLC separation of the polar lipids (mainly, PL) was performed using gradient elution of the lipids by *n*-hexane/propan-2-ol/5 mM aqueous ammonium formate mixtures at 30  $^{\circ}\text{C}$  according to the protocol presented in Table 1. The entire flow of the effluent was directed to the ESI ion source and analyzed either in the positive, or the negative ion modes. A mixture of standard PLs ( $\sim 1$   $\mu\text{g}/\text{mL}$  each) was dissolved in a *n*-hexane/propan-2-ol (95:5, by vol) solvent mixture (HP). No acetic acid was added to this solvent to avoid possible hydrolysis/isomerization of the compounds. Between 0.5 and 10  $\mu\text{L}$  of the sample solutions were injected. The following MS settings were used: sheath gas flow of 25 arbitrary units; auxiliary/sweep gas 0; capillary temperature 300  $^{\circ}\text{C}$ ; spray voltage 3 kV; capillary voltage 6 V (for positive ion mode experiments) and  $-21$  V (for the negative ion mode). The full MS spectra were typically collected between  $m/z$  values of 150–200 and 1,000 for the entire period of the experiment.

**Table 1** Gradient NP HPLC analysis of phospholipids on a Lichrosphere Si-60 column

Step	Time (min)	Flow (mL/min)	Propan-2-ol (%)	5 mM $\text{NH}_4^+\text{COO}^-$ in water (%)	<i>n</i> -Hexane (%)
1	0	0.5	40	2	58
2	5	0.5	40	2	58
3	25	0.5	40	5	55
4	40	0.5	40	5	55
5	41	1	40	5	55
6	60	1	40	5	55
7	61	0.5	40	2	58
8	70	0.5	40	2	58

For the compounds of phosphatidylcholine (PC) and sphingomyelin (SM) families, additional MS experiments were carried out that took advantage of the presence of a unique common positively charged phosphocholine fragment  $(\text{HO})_2\text{P}(\text{O})\text{O}-(\text{CH}_2)_2-\text{N}^+(\text{CH}_3)_3$  (theoretical molecular mass and  $m/z$  184.1) in both the PL families. The lipid components of the HPLC effluent were subjected to the ion source collision induced dissociation (IS-CID) at energy of 90 V and analyzed in the positive ion mode using the settings described above. When phosphocholine-containing lipids were present in the lipid mixture, a prominent fragmentation product with  $m/z$  value of 184.1 was invariably observed. This product ion was used as an analytical ion for detecting PC and/or SM in human MGS and model lipid mixtures.

### Meibomian Gland Secretions

Individual samples of MGS were dissolved in chloroform to bring the final concentration of their stock solutions to 500  $\mu\text{g}$  total lipid/mL. The working solutions of the analytes were made by dissolving the chloroformic stock solutions with the HP solvent. For nonpolar lipids analyses, the samples were diluted to 25  $\mu\text{g}/\text{mL}$  as the signals of the nonpolar lipids were strong. The injection volume was between 1 and 5  $\mu\text{L}$ . For routine lipid analyses in the negative ion mode, the optimal working sample concentration was found to be 100  $\mu\text{g}/\text{mL}$ , while the sample volume varied between 1 and 15  $\mu\text{L}$ . In an attempt to detect the very minor (phospholipid) components of MGS (see below), the stock sample solutions in chloroform were concentrated to  $\sim 3$  mg dry weight/mL, and the injected without diluting with the HPLC mobile phase. The injection volume was increased up to 20  $\mu\text{L}$ . The samples were analyzed exactly as described above for nonpolar lipids and phospholipids.

## Results

To analyze sub-milligram amounts of complex lipid mixtures that constitute human MGS, we needed to develop HPLC-MS protocols that would, firstly, provide adequate separation of the lipids of various classes, and, secondly, ensure sufficient sensitivity of the analyses. Considering wide diversity of the lipid species reported to be present in mammalian and human MGS [1, 2, 7–9, 13–23], we developed and tested two separate HPLC-MS protocols designed to analyze, correspondingly, (a) nonpolar lipids, and (b) relatively polar phospholipids. To maximize sensitivity of the MS analyses, nonpolar lipids were analyzed using APCI-MS detection of the analytes, while phospholipids were analyzed mostly using the ESI technique.

## HPLC-MS Analyses of Standard Nonpolar Lipids

A typical total ion chromatogram (TIC) of a nonpolar lipid mixture taken in the positive ion mode is presented in Figs. 2 and 3. The test mixture was composed of Chl-O, SS, TP, 1,2- and 1,3-DA, Chl, and C<sub>24</sub>- and C<sub>18</sub>-Cer, all of which were used in equimolar ratio. The effluent was monitored in the positive ion mode. There were six HPLC peaks detected in the positive ion mode (peaks I–VI, Fig. 2a), and only two in the negative ion mode (peaks VII and VIII, Fig. 3a).

The MS spectrum of peak I (Fig. 2a) showed the presence of the following major ions with *m/z* values of 369.6, 537.7, and 551.6. The reconstructed chromatograms of those ions revealed three coeluting peaks each with RT of ~3.1 min (Figs. 2b–d). In a separate experiment, it was observed that individually injected Chl-O, SS, and TP each had retention times (RT) of about 3.1 min (data not shown). These compounds coeluted regardless of the solvent composition or the HPLC column. Upon NP HPLC-MS analysis, Chl-O (and other Chl-Es) produced a characteristic fragment with an *m/z* value of 369.4 (Chl–H<sub>2</sub>O + H<sup>+</sup>; theoretical *m/z* 369.4) through a neutral loss of oleic acid (molecular weight 282.3). SS was detected as an intense ion with *m/z* 537.7 ([M + H]<sup>+</sup>; theoretical *m/z* 537.6), while TP was seen as a signal *m/z* 807.8 ([M + H]<sup>+</sup>; theoretical *m/z* 807.7) and a major fragment *m/z* 551.6 ([M – 256 + H]<sup>+</sup>). The later was formed from the precursor ion *m/z* 807.7 through an apparent neutral loss of palmitic acid (molecular weight 256.2). Therefore, peak I was identified as a mixture of coeluting Chl-O, SS, and TP.

High-performance liquid chromatography peaks II and III (Fig. 2a) produced identical signals *m/z* 663.6 (major) and 369.5 (minor). Fragment *m/z* 663.6 with all likelihood was identified as a product of DA dehydration ([M–H<sub>2</sub>O + H]<sup>+</sup>, theoretical mass 663.6), while ion *m/z* 369.5 was a product of neutral loss of arachidic acid residue (molecular weight 312.3). Because (a) the tested compound was a mixture of two positional isomers of DA (1,2- and 1,3-DA), and (b) 1,2- and 1,3-diacyl glycerols (DAG) are known to rapidly undergo spontaneous positional isomerization [32, 33] via acyl-migration, their order of elution remained unknown.

High-performance liquid chromatography peak IV of the nonpolar lipid mixture coeluted with individual Chl and gave one major signal with *m/z* 369.3, similar to the one observed in HPLC peak I. Therefore, both Chl and Chl-O produced identical characteristic fragments, which could be used to identify Chl-containing lipids in complex mixtures. Due to the substantial differences in the RT values between Chl-O (RT 3.1 min) and free Chl (RT 6.0 min), one can

easily discriminate between these two species if their RTs are known.

Peaks V and VI were C<sub>24</sub>- and C<sub>18</sub>-Cer (Fig. 2a). When injected individually, the longer-chain C<sub>24</sub>-Cer eluted faster than its C<sub>18</sub>-counterpart (RT 10.0 and 11.1 min, respectively). C<sub>24</sub>-Cer produced two characteristic peaks *m/z* 650.6 ([M + H]<sup>+</sup>) and 632.5 ([M–H<sub>2</sub>O + H]<sup>+</sup>), while C<sub>18</sub>-Cer gave ions *m/z* 566.4 ([M + H]<sup>+</sup>) and 548.5 ([M–H<sub>2</sub>O + H]<sup>+</sup>).

Interestingly, under the conditions of the NP HPLC-MS analysis in the HPA solvent mixture, all the tested nonpolar compounds, and their fragments, were easily detected as proton adducts. This finding simplified and streamlined the MS analyses of complex lipid mixtures compared to other published procedures that implemented alkaline cations to promote formation of their adducts with certain lipids [34].

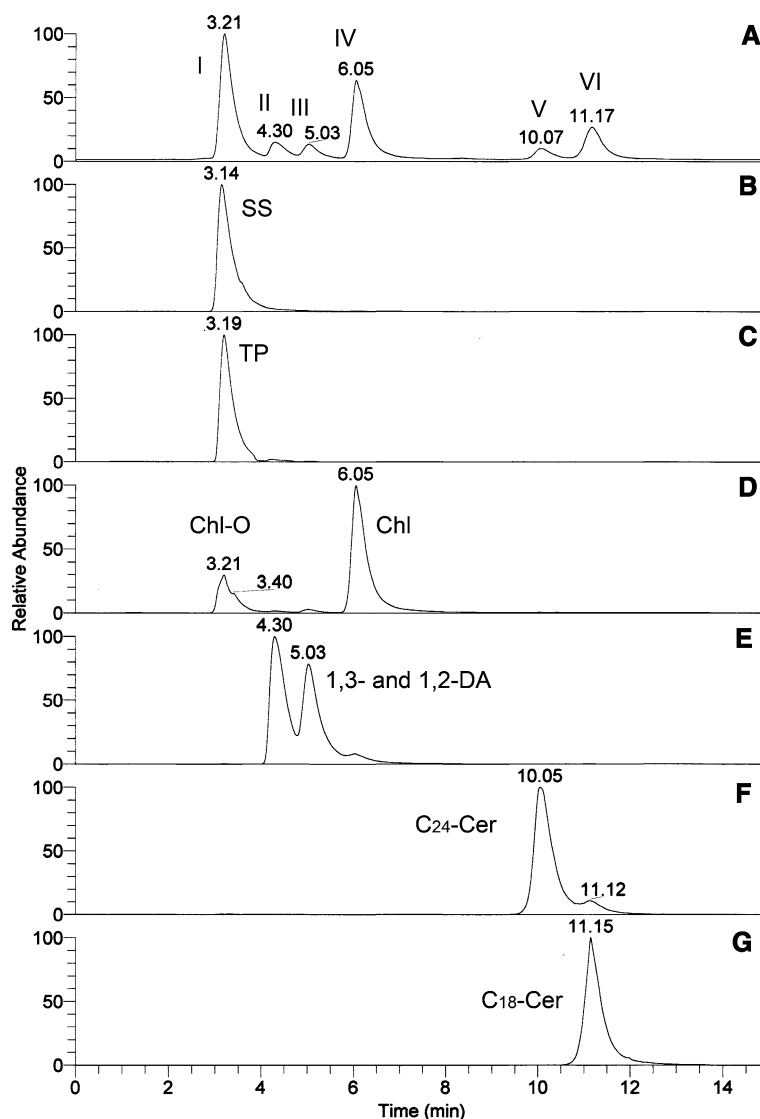

When the mixture of nonpolar lipids was analyzed in the negative ion mode, there were only two HPLC peaks detected with RT of 10.1 and 11.2 min (Fig. 3a–c). Their representative MS spectra (Fig. 3d and e) were indicative of, respectively, C<sub>24</sub>- and C<sub>18</sub>-Cer. Peak VII produced two ions *m/z* 648.7 (C<sub>24</sub>-Cer, [M–H]<sup>–</sup>, theoretical *m/z* 648.6) and 708.3 ([M + CH<sub>3</sub>COO]<sup>–</sup>, theoretical *m/z* 708.6). Peak VIII was identified as C<sub>18</sub>-Cer with *m/z* 564.6 ([M–H]<sup>–</sup>, theoretical *m/z* 564.5) and 624.2 ([M + CH<sub>3</sub>COO]<sup>–</sup>, theoretical *m/z* 624.6). No other tested standard nonpolar lipids produced detectable ions in the negative ion mode.

## NP HPLC-MS Analyses of Standard Phospholipids

Phospholipid analysis was carried out in the negative ion mode, where all of the tested compounds were easily detectable either as anions (M–H)<sup>–</sup> due to the presence of phosphoric acid residues in their structures, or as formic acid adducts [M + HCOO]<sup>–</sup>. A good separation of various PL was achieved using the protocol presented in Table 1 (Fig. 4). The RT values of C<sub>16:0</sub>/C<sub>18:1</sub>-PG, C<sub>16:0</sub>/C<sub>16:0</sub>-PE, C<sub>18:0</sub>/C<sub>20:4</sub>-PI, C<sub>16:0</sub>/C<sub>18:1</sub>-PA, C<sub>18:0</sub>/C<sub>18:1</sub>-PS, C<sub>16:0</sub>/C<sub>18:1</sub>-PC, and C<sub>18:0</sub>-SM detected were, respectively, 20.5, 25.6, 29.8, 31.4, 35.0, 38.1, and 39.4 min. Their characteristic ions that were used as analytical ions are presented in the legend to Fig. 4. The sensitivity of the analysis was sufficient for detecting ≤5 ng of each of the PL per injection. Comparable sensitivity was achieved in the positive ion mode, where most of the lipids were visible either as their molecular ions (M<sup>+</sup>, C<sub>16:0</sub>/C<sub>18:1</sub>-PC, and C<sub>18:0</sub>-SM), or their proton, sodium, and/or ammonium adducts (all the lipids, data not shown).

In a IS-CID experiment conducted in the positive ion mode, authentic C<sub>16:0</sub>/C<sub>18:1</sub>-PC released a phosphocholine ion with *m/z* 184.1. A reconstructed chromatogram of the ion is shown in Fig. 5a. Simultaneously, two precursor

**Fig. 2** Normal phase HPLC analysis of nonpolar lipid standards with APCI-MS detection in the positive ion mode. Panel **a** A TIC of a nonpolar lipid mixture composed of the proton adducts of SS (peak I), TP (peak I), Chl-O (peak I), 1,2- and 1,3-DA (peaks 2 and 3), Chl (peak 4), C<sub>18</sub>- and C<sub>24</sub>-Cer (peaks 5 and 6). Panels **b–g** Reconstructed ion chromatograms of SS (RT 3.1 min;  $m/z$  537.7,  $[M + H]^+$ ), TP (RT 3.2 min;  $m/z$  551.6,  $[M + H - \text{palmitic acid}]^+$ ), Chl-O (RT 3.2 min;  $m/z$  369.4,  $[M + H - \text{oleic acid}]^+$ ), and Chl (RT 6.1 min;  $m/z$  369.4,  $[M + H - H_2O]^+$ ), 1,2- and 1,3-DA (RT 4.3 and 5.0 min;  $m/z$  663.6,  $[M + H - H_2O]^+$ ), C<sub>24</sub>-Cer (RT 10.1 min;  $m/z$  650.5,  $[M + H]^+$ ) and C<sub>18</sub>-Cer (RT 11.2 min;  $m/z$  548.5,  $[M + H - H_2O]^+$ ). Conditions of the analysis: Lichrosphere Diol HPLC column; isocratic elution with HPA solvent mixture; flow rate 0.3 mL/min; column temperature 30 °C

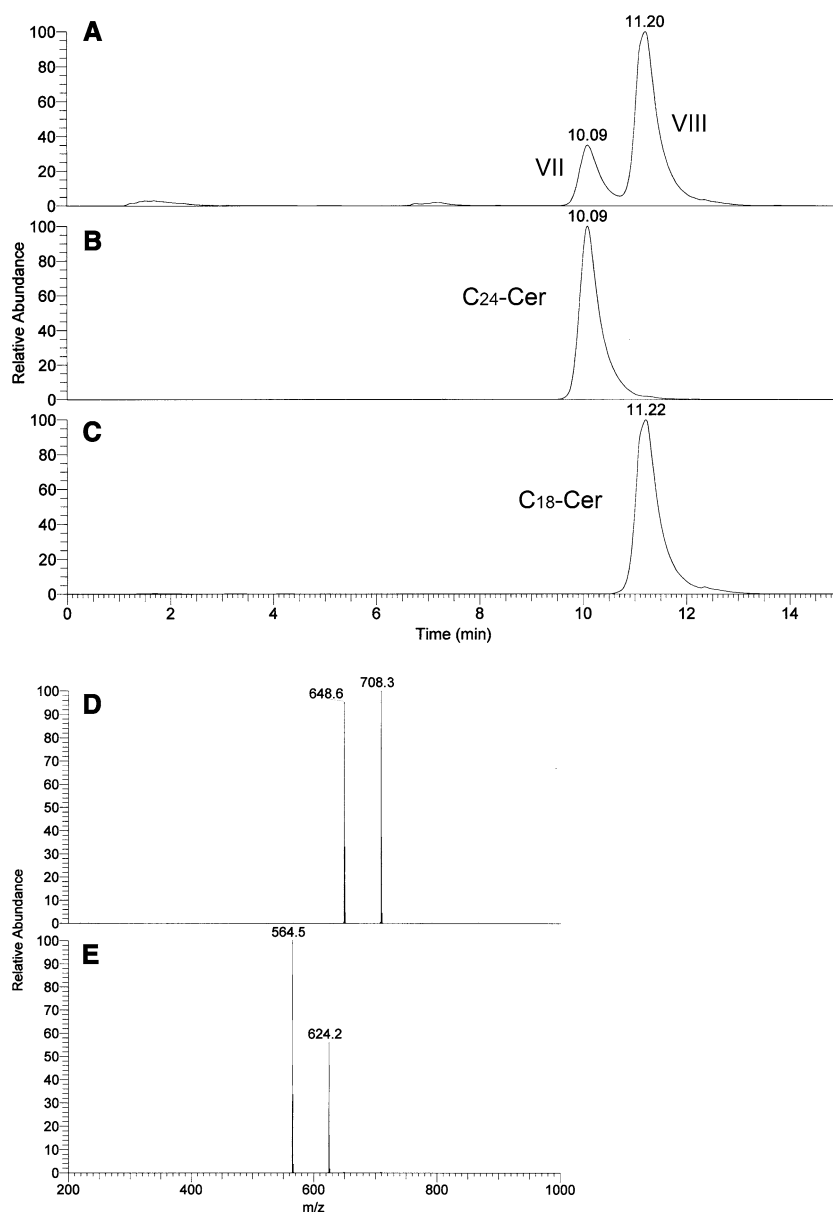

ions with  $m/z$  760.6 and 782.6 ( $M^+$  and  $[M - H + Na]^+$ ) were detected (Figs. 5b and c). Their retention times were identical to that of the phosphocholine ion. Using this method, the detection limit for determining C<sub>16:0</sub>/C<sub>18:1</sub>-PC was at least 0.2 ng or less per injected sample. Similar sensitivity of the analysis was achieved for C<sub>18:0</sub>-SM (data not shown). A few important observations were made as to how C<sub>16:0</sub>/C<sub>18:1</sub>-PC and C<sub>18:0</sub>-SM fragmented. Under the conditions of IS-CID at 90V, C<sub>16:0</sub>/C<sub>18:1</sub>-PC produced ( $M$ )<sup>+</sup> and ( $M - H + Na$ )<sup>+</sup> ions along with the phosphocholine ion  $m/z$  184.1 (see Fig. 5). The relative intensities of these signals were, correspondingly, 1:3:1.5. A similar pattern was observed for C<sub>18:0</sub>-SM (data not shown). Therefore, in such experiments, the phosphocholine ion was a prominent feature of the spectra for both the compounds—C<sub>16:0</sub>/C<sub>18:1</sub>-PC and C<sub>18:0</sub>-SM.

#### NP HPLC-MS Analysis of the MGS

Under the implemented conditions of isocratic NP HPLC-MS analysis in the positive ion mode, all of the tested individual samples of normal human MGS produced qualitatively similar results. The samples collected from the different individuals were remarkably similar to each other. There were no differences in the relative intensities of the major MS peaks seen in both the positive and the negative ion modes, with the exception OA ( $m/z$  283,  $[M + H]^+$ ), which fluctuated from sample to sample. Therefore, with the exception of OA, the chromatograms and mass spectra discussed below are representative of all samples studied (see below).

Analyzed in the positive ion mode using the APCI/MS technique, human MGS produced only one noticeable HPLC peak of nonpolar lipids with RT of 3.1 min

**Fig. 3** Normal phase HPLC analysis of nonpolar lipid standards with ESI-MS detection in the negative ion mode. Panel **a** A TIC of a nonpolar lipid mixture composed of SS, TP, Chl-O, 1,2- and 1,3-DA, Chl, C<sub>18</sub>- and C<sub>24</sub>-Cer. Panels **b** and **c**. Reconstructed ion chromatograms of, respectively, C<sub>24</sub>-Cer (peak VII; RT 10.1 min;  $m/z$  648.7, [M-H]<sup>-</sup>) and C<sub>18</sub>-Cer (peak VIII; RT 11.2 min;  $m/z$  564.6, [M-H]<sup>-</sup>). Other components of the mixture are not visible in the negative ion mode as they do not produce negative ions under the implemented conditions of APCI-MS analysis. Panels **d** and **e** Mass spectra of, respectively, C<sub>24</sub>-Cer (peak RT 10.1 min) and C<sub>18</sub>-Cer (peak RT 11.2 min). Note formation of acetic acid adducts of the compounds in addition to deprotonated species. Conditions of the analysis: Lichrosphere Diol HPLC column; isocratic elution with HPA solvent mixture; flow rate 0.3 mL/min; column temperature 30 °C

(Fig. 6a). The MS spectrum of this peak is presented in Fig. 6b. NP HPLC separation of the standard mixture of nonpolar lipids (Fig. 2) revealed that three distinctive classes of nonpolar lipids—Chl-O (a cholesteryl ester), SS (a WE) and TP (a triacylglycerol)—co-eluted as one peak with a very similar RT of 3.2 min. A strong peak with RT 3.1 min and a small NP HPLC peak of free Chl (RT 6.0 min) were detected in a reconstructed chromatogram of the same sample of MGS after extraction of ion  $m/z$  369.3 (Fig. 6c). The major component with  $m/z$  369.4 coeluted with Chl-O, and, therefore, was tentatively identified as a cholesteryl ester(s). The intensity of the second HPLC peak with  $m/z$  369.3 did not exceed 0.5% of that of the major peak. Its RT and  $m/z$  value were identical to those of free Chl, and, therefore, the compound was tentatively identi-

fied as free Chl. No major components in the MGS that would coelute with lipids of either the DAG or Cer families were detected in the samples. Relative abundances of the major ions detected in the analyzed samples in the HPLC peaks of nonpolar compounds (RT between 3 and 4 min) are presented in Fig. 7.

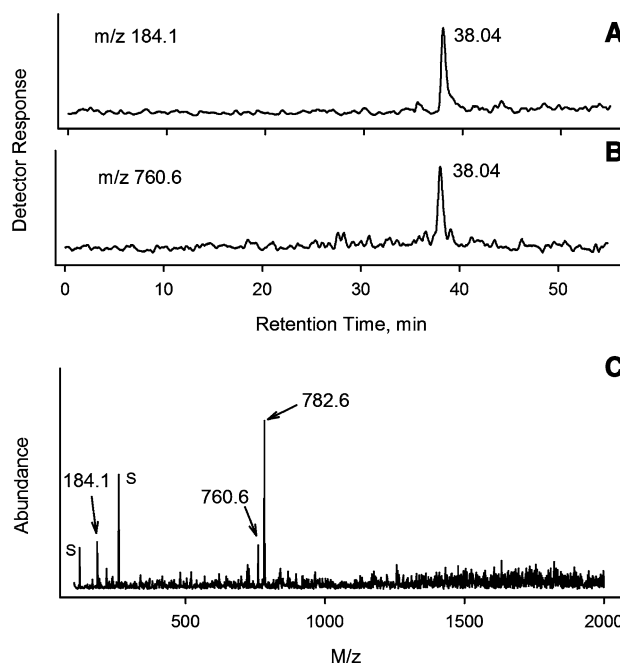

When the MGS were analyzed in the positive ion mode using NP HPLC-ESI/MS on a Lichrosphere Si-60 column for the expected presence of PLs, several minor HPLC peaks with RTs similar to standard PLs were detected (not shown). The peaks were too small to be reproducibly detected and analyzed. To answer a question whether these compounds were phosphocholine-containing lipids, the samples were analyzed in a IS-CID HPLC-ESI/MS experiment as described above for standard C<sub>16:0</sub>/C<sub>18:1</sub>-PC

**Fig. 4** Normal phase HPLC analysis of polar lipid standards with ESI-MS detection in the negative ion mode. Reconstructed ion chromatograms of, respectively, C<sub>16:0</sub>/C<sub>18:1</sub>-PG (RT 20.5 min; *m/z* 747.8; [M–H]<sup>−</sup>), C<sub>16:0</sub>/C<sub>16:0</sub>-PE (RT 25.6 min; *m/z* 690.6; [M–H]<sup>−</sup>), C<sub>18:0</sub>/C<sub>20:4</sub>-PI (RT 29.9 min, *m/z* 885.6, [M–H]<sup>−</sup>), C<sub>16:0</sub>/C<sub>18:1</sub>-PA (RT 31.4 min; *m/z* 673.7, [M–H]<sup>−</sup>), C<sub>18:0</sub>/C<sub>18:1</sub>-PS (RT 35.0 min; *m/z* 788.5; [M–H]<sup>−</sup>), C<sub>16:0</sub>/C<sub>18:1</sub>-PC (RT 38.1 min; *m/z* 804.8, [M + HCOO]<sup>−</sup>), and C<sub>18:0</sub>-SM (RT 39.4 min; *m/z* 775.6, [M + HCOO]<sup>−</sup>). Conditions of the analysis: Lichrosphere Si-60 HPLC column; gradient elution with a solvent mixture as described in Table 1; column temperature 30 °C

and C<sub>18:0</sub>-SM. However, no detectable HPLC peak was observed when the effluent was monitored at *m/z* 183–185 (Figs. 8a and b). At the same time, if a sample of MGS was pre-mixed with an internal standard (C<sub>16:0</sub>/C<sub>18:1</sub>-PC) to form a mixture of 2.4 mg/mL MGS and 1 μg/mL C<sub>16:0</sub>/C<sub>18:1</sub>-PC (the mass ratio of C<sub>16:0</sub>/C<sub>18:1</sub>-PC to MGS 1:2,400), the ion with *m/z* value of 184.1 was clearly visible (Figs. 8c and d) and eluted with the RT identical to that of authentic C<sub>16:0</sub>/C<sub>18:1</sub>-PC (Fig. 5). The practical limit of detection of the phosphocholine ion was found to be about ≤0.2 ng C<sub>16:0</sub>/C<sub>18:1</sub>-PC/mL (Fig. 5).

A single major HPLC peak was detected in the negative ion mode (Fig. 9a). The peak was composed of a series of apparently related compounds with the most prominent components possessing *m/z* values of 729.8, 757.9, 775.4, 803.3, and 831.3 (Fig. 9b). Its RT (about 1.6 min) was

**Fig. 5** Detection of phosphatidylcholine using IS-CID of the precursor(s). Panel a A reconstructed ion chromatogram of ion with *m/z* 184.1 generated from authentic C<sub>16:0</sub>/C<sub>18:1</sub>-PC (0.1 μg/mL). Panel b A reconstructed ion chromatogram of ion with *m/z* 760.6 generated from authentic C<sub>16:0</sub>/C<sub>18:1</sub>-PC (0.1 μg/mL). Panel c ESI-MS spectrum of the peak with RT 38.0 min. Conditions of the analysis: ESI-MS analysis in the positive ion mode. Injection volume 2 μL (=200 pg C<sub>16:0</sub>/C<sub>18:1</sub>-PC). Sample subjected to IS-CID at energy of 90 V. S—solvent ions/impurities present throughout the gradient

much shorter than those of standard phospholipids (20–40 min, Fig. 4) tested in identical conditions. When analyzed on a Lichrosphere Diol HPLC column in the HPA solvent mixture, the compounds with *m/z* values of 729.8, 757.9, 775.4, 803.3, and 831.3 had RTs of 4.0–4.5 min and eluted between WEs (RT 3.2–3.6 min) and DAGs (RT 4.5–6.0 min) (data not shown), and, therefore, belong to the family of nonpolar lipids. Finally, no discernible PL ions were detected above the noise level in the expected PL elution region (RT between 20 and 40 min, Figs. 9a and c).

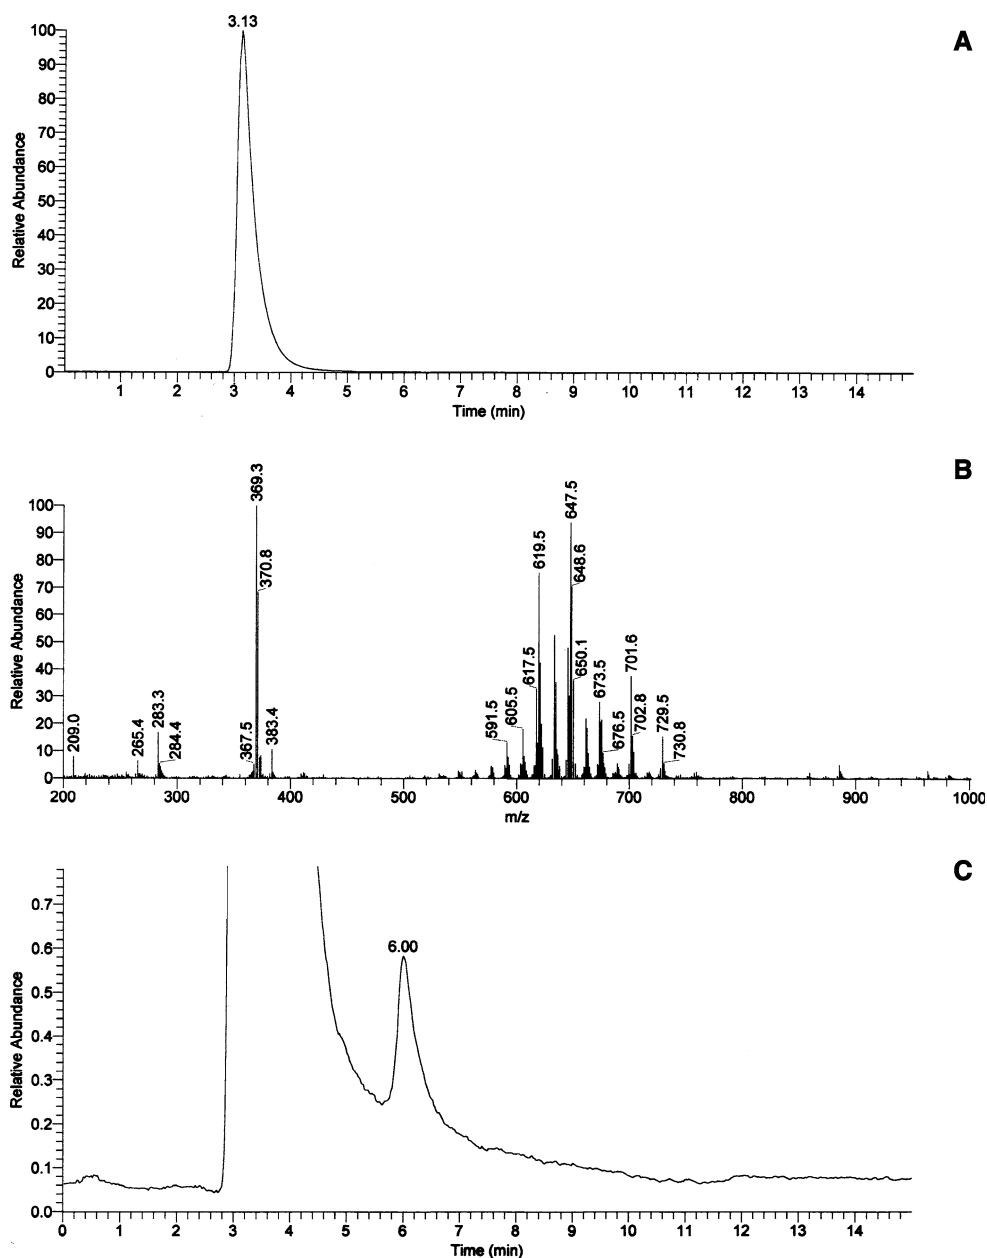

## Discussion

Evaluation of the lipid composition of human MGS is a challenging task because of the difficulties associated with collecting the samples from human subjects, small amount of the gathered secretions (an average sample of collected human MGS was ~0.4 mg), and the complex nature of the lipid mixtures.

To overcome these difficulties, we decided to implement a more sensitive method of HPLC analysis with API (in its

**Fig. 6** NP HPLC analyses of nonpolar lipids present in human MGS with APCI-MS detection in the positive ion mode. Panel **a** A TIC of a mixture of human MGS; Panel **b** Mass spectrum of the peak with RT 3.1 min; Panel **c** Reconstructed ion chromatograms of ion  $m/z$  369.3 (RT 3.1 and 6.0 min; Chl-E and Chl, respectively). Conditions of the analysis: Lichrosphere Diol HPLC column; isocratic elution with HPA solvent mixture; flow rate 0.3 mL/min; column temperature 30 °C

APCI and ESI forms) MS detection of the analytes. A series of different, but apparently homologues compounds was detected in the positive ion mode (Fig. 6). Inasmuch as (1) the MS analysis of the major MGS components produced ions that were characteristic of a mixture of WE with general formula  $C_nH_{2n-2}O_2$  (Fig. 6b); (2) none of them coeluted with standard DAG (Figs. 2 and 6a); and (3) no major ions with  $m/z$  values of 800 and above, which would be indicative of TAG species, were detected in MGS, (Fig. 6b), we concluded that the nonpolar component of MGS was composed mostly of WE, Chl-E, small amounts of Chl itself (Fig. 6c) and, possibly, TAGs [note a group of low intensity ions with  $m/z$  values of 850–890 (Fig. 6b)]. Coelution of WE and Chl-E under the conditions of NP-

HPLC is a well-known problem, which theoretically could have been resolved by using alumina HPLC method proposed by Moreau et al. [35], if not for the poor compatibility of their solvent mixture with mass-spectrometric detectors. Therefore, we are currently conducting a detailed MS/MS analysis of the detected nonpolar species, the results of which will be reported separately.

API MS is undoubtedly the de facto standard method of analyzing phospholipids [24, 25]. The method has also been previously used to evaluate the composition of the nonpolar lipids of the MGS [36, 37]. To our surprise, human subjects did not show a noticeable presence of any of the typical PL species (Figs. 6, 8, 9) in their MGS. At the same time, mixtures of various lipid standards could be

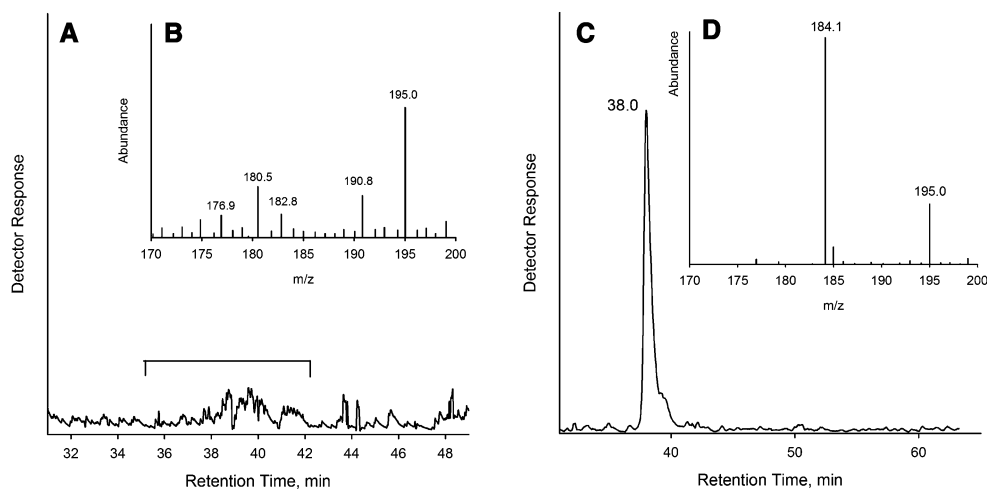

**Fig. 7** Relative abundances of the major ions detected in human meibomian gland secretions in the positive ion mode HPLC-MS experiments. The data obtained for eight individual study samples were taken from Fig. 6 (Panel b) and presented as mean values  $\pm$  standard errors. The most prominent signal  $m/z$  369 ( $[\text{Chl}-\text{H}_2\text{O} + \text{H}]^+$ ) was used as a reference point and assumed to be 100% for each of the samples

routinely and reliably analyzed at  $\leq 1$   $\mu\text{g}/\text{mL}$  levels with the injected volumes being 0.5–10  $\mu\text{L}$ , thus giving a sensitivity level of the analysis of 1 ng per injection and below (Figs. 2, 3, 4, 5). Considering that, firstly, the previously reported presence of PLs in the MGS was around 5% (w/w), of which PC and SM, depending on the publication, amounted to up to 50% of the entire phospholipid pool; and, secondly, that the concentrations of the MGS solutions used in our PL experiments were 0.1–3 mg/mL, the PC and SM species should have been readily visible at even lower (PC + SM)/total lipids ratios. The sensitivity of our current

HPLC-MS approach was such that tested PLs could be detected in complex mixtures if present in mass ratios of 1:2,400 (0.04%, w/w) or less (Fig. 8). The absolute sensitivity for the  $\text{C}_{16:0}/\text{C}_{18:1}$ -PC analysis was shown to be at least an order of magnitude better than that exceeding 0.1  $\mu\text{g}/\text{mL}$ , or 0.2 ng per injection (Fig. 5). Pre-separation of the lipid classes in the HPLC columns before the MS detection/analysis of the MGS samples should have helped in avoiding mass spectrometric interference from non-polar lipids and eliminating any chances of PL ion suppression by nonpolar lipids [9, 34].

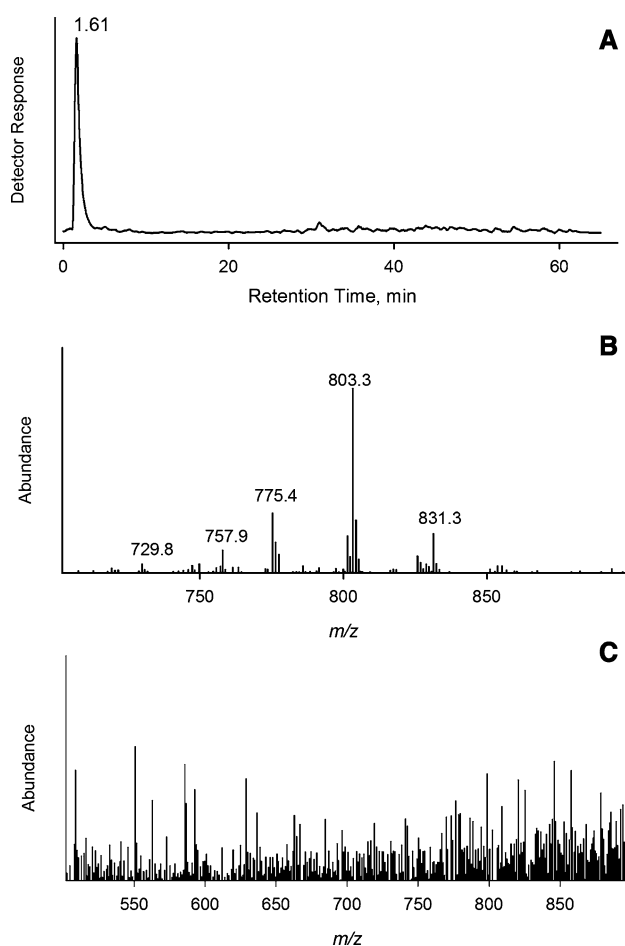

Minor compounds with HPLC mobilities comparable to those of  $\text{C}_{16:0}/\text{C}_{18:1}$ -PC and  $\text{C}_{18:0}$ -SM were shown not to have phosphocholine in their structures, as their fragmentation did not produce the phosphocholine ion  $m/z$  184.1 (Fig. 8). Therefore, HPLC-ESI/MS analysis produced no evidences of the presence of typical PLs—PC and SM—in individual normal human MGS, while showing the presence of a set of compounds, whose elucidation is currently underway.

The apparent absence of the phosphocholine product ion in the MS spectra of human normal MGS secretions was surprising as MGs are holocrine glands and their secretions were expected to contain some PLs originating from, at least, cell membranes. On the contrary, our experiments clearly demonstrated that phosphocholine-containing phospholipids were not nearly as dominant PL species in MGS as had been reported before. If PLs were present in our normal MGS samples, their mass ratio to other (non-polar) lipids must have been well below 1:2,400, or two orders of magnitude lower than previously thought. Such

**Fig. 8** NP HPLC-ESI/MS analysis of polar lipids present in human MGS in a collision-induced dissociation experiment in the positive ion mode. Panel **a** A TIC of a mixture of human MGS; Panel **b** Mass spectrum of the peak with RT 1.6 min; Panel **c** MS spectrum of the PL fraction (RTs between 20 and 42 min). Note the absence of clearly identifiable signals of PLs. Conditions of the analysis: Lichrosphere Si-60 HPLC column; gradient elution with a solvent mixture as described in Table 1; column temperature 30 °C

the low mass ratio could be indicative of a high prevalence of nonpolar lipids biosynthesis over the production of polar ones in MGs, or high a rate of phospholipid re-absorption/degradation ones the cells filled with large quantities of nonpolar lipids get released from the glands.

The discrepancy between the current findings and the much higher presence of, for example, PE, PC, and SM in MGS reported in the earlier studies [18, 19] could possibly be explained by a range of factors. Those could include, among others, (1) inadvertent contamination of those samples by cell debris originating from various epithelial and MG cells, and, possibly, with lipids produced by corneal epithelial cell, conjunctiva, and/or lacrimal glands; and (2) misidentification of the HPLC elution peaks. Complicating the previous analyses of human MGS was

the choice of the HPLC detection method: in the earlier experiments with human MGS, unmodified lipids were detected by using UV absorbance monitoring at 220 nm [18, 19]. This particular approach was not the best choice as the UV method of detection of lipids lacks sensitivity and specificity as most of the lipids do not have any specific UV chromophores and are virtually transparent at  $\geq 220$  nm. Identification of the analytes was based solely on comparison of their RTs with those of chemical standards [18, 19], which are prone to fluctuate and overlap. Our current techniques of collecting MGS samples and of their HPLC-MS analyses minimized the chances of the above problems and allowed positive identification of various compounds and/or their groups in complex mixtures. Considering that the RTs of some of the minor unidentified compounds detected in our experiments were close to those of  $C_{16:0}/C_{18:1}$ -PC and  $C_{18:0}$ -SM, PC, and SM species reported earlier [18, 19] could, in fact, have been the same unknown compounds that coeluted with the PL standards in our experiments.

With the exception of the  $^{31}\text{P}$ -NMR studies performed on homogenized tarsal plates of rabbits [20], little is known about MGS phospholipids as individual intact species. Their role in formation of TFLL and in the mechanisms underlying human DES remains to be detailed. Some animal species which have been reported to have PLs in their meibum (e.g., steer [17, 21], hamster [15], and rabbit [20, 22]) are not considered to be an ideal model of human DES [38, 39]. Importantly, it was shown by cauterization and subsequent gluing of the MG orifices that much of the lipids that form TFLL in rabbits are supplied by sources other than MG. Those sources were proposed to include ocular surface structures, Harder's gland, and sebaceous glands in the caruncle [39]. Pertinent to this discussion is an observation that large quantities of Chl-E and free Chl could be produced and excreted by corneal epithelial cells, possibly through the high-density lipoprotein-mediated reverse cholesterol transport mechanism ([40] and references cited therein). Therefore, we cannot rule out a priori a possibility that in humans lipids are supplied to the TFLL not only by MG, but by other sources too.

In conclusion, NP HPLC analysis with API detection of the analytes has proven to be an effective tool for evaluating the lipid composition of the human MGS collected from individual subjects. Our results suggest that MGs are a major source of nonpolar lipids of remarkably consistent composition (Fig. 7) for the TFLL, but not of more polar components of phospholipid and ceramide nature.

Values are means ± standard deviation of the six analysis (two lots analyzed in triplicates). All the raw and grilled samples are significantly different ( $P < 0.02$ ). Values bearing and different letters (capital letters) have significant differences ( $P < 0.02$ ) at differing storage times in the raw samples. Values bearing different letters (small letters) have significant differences ( $P < 0.02$ ) at various storage times in the grilled samples

## Selective COX-2 Inhibitors, Eicosanoid Synthesis and Clinical Outcomes: A Case Study of System Failure

M. J. James · R. J. Cook-Johnson · L. G. Cleland

Received: 10 December 2006 / Accepted: 2 April 2007 / Published online: 2 June 2007

**Abstract** Elucidation of differences between the active sites of COX-1 and COX-2 allowed the targeted design of the selective COX-2 inhibitors known as coxibs. They were marketed as non-steroidal anti-inflammatory drugs (NSAIDs) that had improved upper gastrointestinal (GI) safety compared with older non-selective NSAIDs such as diclofenac and naproxen. Two GI safety studies conducted with arthritis patients demonstrated that in terms of upper GI safety, celecoxib was not superior to diclofenac (CLASS study) but rofecoxib was superior to naproxen (VIGOR study). However, the VIGOR study revealed also that rofecoxib had increased cardiovascular (CV) risk compared with naproxen. This clinical outcome was supported by the existence of plausible eicosanoid-based biological mechanisms whereby selective COX-2 inhibition could increase CV risk. Nevertheless, the existence of CV risk with rofecoxib was successfully discounted by its pharmaceutical company owner, Merck & Co, with the assistance of specialist opinion leaders and rofecoxib achieved widespread clinical use for 4–5 years. Rofecoxib was withdrawn from the market when several clinical trials in colorectal cancer and post-operative pain revealed increased CV risk with not only rofecoxib, but also coxibs. The commercial success of rofecoxib provides a case-study of failure of the medical journal literature to guide drug usage. Attention to ethical issues may have provided a more useful guide for prescribers.

### Introduction

Cyclooxygenase (COX) is the target for the traditional non-steroidal anti-inflammatory drugs (NSAID), examples of which include indomethacin, naproxen, ibuprofen and diclofenac [1]. These drugs are effective in providing symptomatic relief from inflammation most likely because the COX product prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) is involved in vasodilation, extravasation of fluid, and hyperalgesia in inflammatory foci. However, PGE<sub>2</sub> also has a protective role in the stomach where it is involved in maintenance of the protective mucosal barrier [2]. Therefore, NSAID use for symptomatic treatment of inflammation is associated with gastropathies and these can be sufficiently severe to result in hospitalization and death [3].

The discovery of two COX isotypes and the further discovery that COX-2 was involved in production of PGE<sub>2</sub> in inflammatory sites whereas COX-1 was involved in maintenance of gastric mucosal protection, provided a face-value rationale for development of selective COX-2 inhibitors as anti-inflammatory agents with reduced upper GI adverse effects compared with traditional NSAID [2].

### Cyclooxygenase Isotypes and Selective Inhibitors

Both COX isotypes have long hydrophobic substrate binding channels with the channel being slightly larger in COX-2 than COX-1. Molecular modelling indicates the presence of a hydrophobic pocket that branches from the main substrate binding channel. However, access to the pocket is restricted

M. J. James (✉) · R. J. Cook-Johnson ·

e-mail: mjames@mail.rah.sa.gov.au

in COX-1 due to the presence at position 523 of a bulky isoleucine whereas in COX-2 this position is occupied by a valine [4]. This structural difference allowed the development of coxibs, a class of selective COX-2 inhibitors that exploit selective access to the side pocket in COX-2 [5]. However, some traditional NSAID also have selectivity for COX-2 inhibition when examined *in vitro*. There is a continuum of selectivities among traditional NSAIDs and coxibs ranging from COX-1 selective to COX-2 selective. For example, indomethacin is COX-1 selective, diclofenac and celecoxib are modestly COX-2 selective and each have similar selectivities for COX-2, whereas rofecoxib is highly COX-2 selective [6].

### Eicosanoid Synthesis: In Vitro Studies

Selective COX-2 inhibitors were developed with the goal of inhibiting PGE<sub>2</sub> synthesis in areas of inflammation but not in the stomach. However, this goal did not recognise that PGE<sub>2</sub> is not the immediate product of COX-1 or COX-2. Both COX-1 and COX-2 catalyse the same reaction, which with arachidonic acid as substrate, is the production of PGH<sub>2</sub>. PGH<sub>2</sub> is the common substrate for a number of prostaglandin synthases and thromboxane synthase (Fig. 1).

Inspection of Fig. 1 suggests that inhibition of COX-1 or COX-2 or both isotypes should decrease synthesis of all PGH<sub>2</sub> metabolites. However, selective COX-2 inhibition results in selective inhibition of PGE<sub>2</sub> rather than TXA<sub>2</sub> in monocytes [7] and selective inhibition of PGI<sub>2</sub> rather than TXA<sub>2</sub> in endothelial cells [8, 9]. This phenomenon is probably linked to the observations that early after monocyte or endothelial cell stimulation, only TXA<sub>2</sub> is produced whereas with increasing time to allow for induction of COX-2, there is an increase in monocyte PGE<sub>2</sub> or endothelial PGI<sub>2</sub> with little or no further increase in TXA<sub>2</sub> synthesis [7–11] (Fig. 2).

A possible explanation for all of these findings lies in the different  $K_m$  values of the synthase enzymes. TX synthase has a 17-fold lower  $K_m$  than PGE synthase [11] and indirect studies infer a similar situation for TX synthase versus PGI synthase [8]. Thus, in the early phase of endothelial cell stimulation when only constitutive COX-1 is present, the PGH<sub>2</sub> concentration is sufficient for TXA<sub>2</sub> synthesis but

**Fig. 1** Metabolism of arachidonic acid by cyclooxygenases

**Fig. 2** Depiction of changes in COX isotype expression and eicosanoid synthesis in stimulated endothelial cells [8, 9]

not substantive PGI<sub>2</sub> synthesis. With time there is induction of COX-2, which substantially increases PGH<sub>2</sub> concentration leading to PGI<sub>2</sub> synthesis. However, due to the lower  $K_m$  of TX synthase compared with that of PGI synthase, there is little if any further increase in TXA<sub>2</sub> synthesis due to saturation of TX synthase with substrate. Conversely, selective inhibition of COX-2 would decrease PGI<sub>2</sub> synthesis with little or no effect on TXA<sub>2</sub> synthesis, as has been observed in endothelial cells stimulated with IL-1 $\beta$  or platelets or hypoxia [8–10].

These findings from *in vitro* studies suggest that endothelial COX-2 has a protective anti-thrombotic role in response to stress.

### Eicosanoid Synthesis: In Vivo Studies

Although it is not possible to directly measure endothelial PGI<sub>2</sub> synthesis *in vivo*, human studies support the importance of COX-2 for PGI<sub>2</sub> synthesis. The selective COX-2 inhibitors, celecoxib and rofecoxib, decreased the urinary content of PGI<sub>2</sub> metabolites while having little or no effect on platelet TXA<sub>2</sub> synthesis in healthy volunteers [12, 13]. Whether or not the source of the PGI<sub>2</sub> metabolites in urine was the endothelium is not known. Also, whether or not COX-2 is present in unstimulated healthy endothelium is not known although it is clearly present in atherosclerotic vessels [14–16]. While laminar flow has been shown to up-regulate endothelial COX-2 *in vitro* [17], COX-2 is generally found in low levels or not detected in non-atherosclerotic endothelium [14].

Studies on COX-2 in the heart indicate that myocardial up-regulation of COX-2 is an important protective response to injury caused by anthracyclines or oxidative stress [18, 19]. Also, myocardial COX-2 upregulation and consequent PGI<sub>2</sub> production is a critical event in the protective effect of ischemic pre-conditioning [20].

Collectively, the studies on eicosanoid synthesis *in vitro* and *in vivo* suggest that COX-2 upregulation provides a cardioprotective response in stressed myocardium and an anti-thrombotic response in blood vessels. It is noteworthy that selective COX-2 inhibition has the opposite action of low dose aspirin in suppressing endothelial prostacyclin synthesis but not platelet thromboxane synthesis [21] (Fig. 3).

### Clinical Effects of Selective COX-2 Inhibitors

The first two coxibs approved for clinical use were celecoxib and rofecoxib, marketed as Celebrex and Vioxx, respectively. They both relieved the signs and symptoms of inflammation with efficacy similar to that of the conventional NSAIDs [5]. However, in order to claim that they had superior upper GI safety over the traditional NSAIDs, the regulatory authorities required clinical trials, in which measurement of upper GI safety was the primary aim. The most important measure of upper GI safety is that of ulcer complications, i.e. bleeds, perforations, obstructions. These events cause morbidity and hospitalisation and are potentially life-threatening. A less important measure is that of symptomatic ulcers because they are not life-threatening and are readily treated with medication that can be curative.

CLASS was a combination of two upper GI safety studies in osteoarthritis and rheumatoid arthritis where participants were allocated either to celecoxib or one of two conventional NSAIDs, diclofenac or ibuprofen. Low-dose aspirin, widely used as an anti-thrombotic agent, was allowed as indicated. Outcomes at 6 months of treatment were published and these showed a statistically significant advantage of celecoxib over the combined NSAID groups for the composite measure of ulcer complications + symptomatic ulcers; however there was no advantage of celecoxib for ulcer complications alone [22]. The

**Fig. 3** Scheme depicting endothelial and platelet COX isotypes, eicosanoid synthesis, and the effect of COX-2 inhibitors (Reproduced by permission of Lippincott Williams & Wilkins)

submission of these data to the FDA by GD Searle & Co indicated that the actual duration of the two safety studies was in fact 12 and 15 months. These were the durations required to reach the pre-specified end-point of at least 20 ulcer complications in each study or a maximum of 45 ulcer complications in both studies combined. The FDA analysis shows that at actual study completion, celecoxib was not superior to the combined NSAID groups for either of the upper GI safety measure [23]. It was revealed that the complete 12–15 month trial data for CLASS were available when the 6-month analysis was published. The FDA review also concluded that there was no evidence of cardiovascular risk with celecoxib from the CLASS study.

The adenoma prevention with celecoxib (APC) study examined colorectal cancer prevention with celecoxib versus placebo in participants with adenomatous colorectal polyps. While there was a decreased incidence of colorectal adenomas with celecoxib, there was statistically significant dose-related increase in thrombotic cardiovascular events with celecoxib [24].

As for celecoxib, rofecoxib also was examined for upper GI safety and later for colorectal cancer prevention. The upper GI safety study known as VIGOR allocated rheumatoid arthritis patients to either rofecoxib or the conventional NSAID, naproxen. Aspirin use or a requirement for aspirin use was an exclusion criterion. Unlike CLASS, VIGOR demonstrated superiority to the NSAID comparator, naproxen, for both upper GI safety measures, i.e. ulcer complications alone and the combined measure of ulcer complications + symptomatic ulcers [25, 26]. However, there was a four fold increase in myocardial infarction with rofecoxib [25, 26]. The FDA review showed that the increase in the combined thrombotic cardiovascular events with rofecoxib matched its upper GI benefits and therefore, the FDA review concluded that rofecoxib offered no overall safety advantage over naproxen [25]. By contrast, the New England Journal Medicine (NEJM) publication of the VIGOR trial concluded with no supporting evidence that the increased myocardial infarction with rofecoxib did not exist and that the results were due to a cardioprotective effect of naproxen. The overall conclusion was that VIGOR was a success in demonstrating upper GI safety [26].

A further study with rofecoxib, APPROVE, like the APC study with celecoxib, had the aim of examining colorectal cancer prevention. Patients with a history of colorectal adenomas were randomly allocated to rofecoxib or placebo. The trial was stopped early due to an approximate 5-fold increased risk of myocardial infarction and an approximate two fold increased risk of combined adverse cardiovascular events [27].

A randomised controlled trial of oral valdecoxib and its intravenous pro-drug, parecoxib, for analgesia in patients having coronary artery bypass surgery also showed an

approximate four fold increased risk of combined cardiovascular events [28].

Thus, evidence from these randomised controlled trials suggests that increased cardiovascular risk is a class effect with coxibs. Meta-analysis of database and case-control studies suggests that there is increased cardiovascular risk with many NSAIDs, although not with naproxen [29]. In that analysis, the highest relative risk was 1.40 and that occurred with diclofenac, which is also the most COX-2 selective of the traditional NSAIDs [6, 29].

### Marketing of the Coxibs and Maintenance of Uncertainty

The results of the CLASS and VIGOR trials were published in 2000. The respective publications declared celecoxib and rofecoxib to have superior upper GI safety to the comparator NSAIDs [22, 26]. However, the FDA reviews showed this was not true for celecoxib at the pre-planned time of study completion and showed that, when the increased cardiovascular events with rofecoxib were considered, it had no overall safety advantage [23, 25]. Notwithstanding the FDA analyses both drugs achieved “blockbuster” status in the marketplace [30].

It is accepted that most researchers and clinicians do not examine the FDA website for reviews of pharmaceutical company submissions. However, it is difficult to understand why there was an uncritical acceptance of the conclusions of the medical journal publications of CLASS and VIGOR. As discussed below it is difficult also to understand how the interpretations of data published in these prestigious journals survived disinterested critical review.

Even though only the 6-month data from CLASS were originally published [22], it was clear that celecoxib was not superior to the combined NSAID comparator group for the incidence of complicated upper GI events, which clinically is the more important outcome measure [31]. In the publication of the VIGOR results, it was clear that there was a 4-fold increase in myocardial infarction in the rofecoxib group [26]. Although this publication concluded that this result was due to a protective effect of naproxen, no evidence was presented for such an effect. In addition, it was soon followed by publication of the analyses of a large Medicaid database that concluded naproxen did not have a protective effect and that rofecoxib was associated with an increase in cardiovascular risk [32, 33].

Despite this published information, Vioxx exceeded US\$2 billion in sales per year for 2001–03 [34]. The principle that there should be caution with the prescribing of new drugs due to limited information about their effectiveness, long-term safety, and whether they offer an overall advantage over existing medications did not seem

to be applied [35]. A possible explanation is that clinicians were persuaded by consistently positive marketing messages. In the year after the launch of Vioxx, spending on direct to consumer advertising in the US for Vioxx exceeded the advertising expenditure for Pepsi and Budweiser [36]. Also, the US congressional hearings into the relationships between the FDA and the pharmaceutical industry revealed that Merck’s instructions to their sales representatives were designed to dampen any physician concerns about cardiovascular risk. If clinicians enquired about this risk, the sales representative handed them a “Cardiovascular Card”, which contained no data from the VIGOR study and in addition, claimed that Vioxx was actually 8–11 times safer than anti-inflammatory drugs like naproxen. When an FDA advisory committee recommended that clinicians should be informed of the cardiovascular results from the VIGOR study, the sales staff were specifically instructed not to initiate discussion with clinicians on the FDA Advisory recommendation [37].

Thus, one reason for the sustained blockbuster status of Vioxx and Celebrex is that clinician concerns were allayed by pharmaceutical company sales and marketing practices. However, this does not necessarily explain why there was not an appropriate response at the academic level to the medical journal literature. The reviewers of the NEJM submission on the VIGOR study should have insisted that the conclusion that naproxen had a cardioprotective effect was without merit [26]. They should also have insisted that the manuscript conclude that the study showed no overall safety advantage of Vioxx, when both serious upper GI events and cardiovascular events were taken into consideration.

Shortly after publication of the NEJM article on the VIGOR study, a pooled analysis of cardiovascular risk using data from Merck trials with rofecoxib was published in *Circulation* [38]. The study concluded there was no cardiovascular risk with rofecoxib relative to placebo and non-naproxen NSAIDs. However, the studies varied in duration from only 4 weeks to 15 months, five of the seven authors were Merck employees, and the manuscript was accepted one day after submission. None of these factors alone necessarily determines how one should assess the merits of a publication. However, one should be mindful that this publication served to reinforce the notion that naproxen was cardioprotective and that rofecoxib only appeared to increase CV risk against this comparator. At the very least, this apparently unrefereed publication in *Circulation* helped sustain uncertainty about CV risk with rofecoxib during the ensuing years until its withdrawal from the market.

Thus there was a second reason for the maintenance of Vioxx sales, i.e. there was a failure in academic and therapeutic medicine to deal with this uncertainty. Recourse to

the principles used by Research Ethics Committees/Institutional Review Boards (REC/IRB) would have provided a straightforward remedy. These committees deal routinely with such prominent uncertainty by simply informing the research participants of its existence. Thus, if presented with a clinical trial involving Vioxx, it is likely that the REC/IRB would have insisted that the cardiovascular results of the VIGOR study were communicated in the Informed Consent document. This is a simple way of dealing with uncertainty and it accords with the principle of patient or research participant autonomy, also expressed as respect for persons. This consideration, which is embraced in the institutional research environment was lacking in the therapeutic/marketing environment.

### Summary and Conclusions

An examination of this sequence of events shows inappropriate acts of omission, commission and lack of integration. The aims of VIGOR were to examine safety. However, the report in the NEJM [26] overemphasized upper GI safety and greatly downplayed CV safety to an extent which was an act of omission and to an extent that should not have been accepted by the reviewers or the journal. The subsequent FDA review of VIGOR was exemplary in concluding that, when the increase in adverse CV events is considered “This risk reduction in relevant GI events did not translate into an overall safety benefit of rofecoxib over naproxen.” and that “Information regarding cardiovascular thrombotic events should be added to the VIOXX label.” [25]. However, there was a delay of nearly two years in adding a CV warning to the prescribing information [37, 39]. Labelling delay notwithstanding, it is not clear that the label warning had a substantial influence on prescribing in the face of more than \$100 million per year spent on direct-to-consumer advertising and a sales force directed to use an information card for prescribers, the “cardiovascular card” that deliberately omitted mention of cardiovascular risk [36, 37, 39].

The omission by Merck of accurate information on cardiovascular risk in its advertising and sales force packages may or may not be illegal. This issue is currently playing out in the legal actions underway in the US jurisdiction. However, this omission was certainly unethical. It was a disregard for people’s right to information that was material in their decision making as to whether to take or to prescribe Vioxx. It was a disregard for the ethical principle of respect for a person’s autonomy. The omission of balanced discussion of CV risk in the NEJM publication of VIGOR is perplexing. Whether the reviewers of the article and the journal would have treated committed inaccuracies

more diligently than they treated this act of omission is unknown.

This sequence of events raises the question of who should have taken responsibility for integration of this information into a risk and benefit evaluation. While several individuals published concerns about CV risk with coxibs [33, 40, 41] the medical journal literature collectively served to promote efficacy but perpetuate uncertainty about CV risk. The interested pharmaceutical company downplayed or omitted mention of CV risk. However, the regulator, i.e. the FDA, dispassionately assessed Vioxx as having no net health benefit. It has been argued that the FDA should have acted quicker on the labelling change and that they should have mandated a CV safety study [39]. Their obligations in the regulation of Vioxx has been considered by the US Congress [37, 42].

As a postscript, it is worth noting that although the coxibs attracted premium pricing due to their claims of superior upper GI safety compared with traditional less-selective NSAIDs, the NSAID gastropathy epidemic had essentially finished before the introduction of coxibs. This is well illustrated by the following epidemiological study that used databases on >5,500 rheumatoid arthritis (RA) patients in the US and Canada. It showed that hospitalizations for NSAID-related gastropathies increased from 0.6% of this RA population in 1981 to a peak of 1.5% in 1992 whereafter it declined back to 0.5% in 2000 *with the main decline occurring before the introduction of the selective COX-2 inhibitors, celecoxib and rofecoxib* [3]. The decline was due to movement away from the most gastrotoxic NSAIDs and to moderation of doses. If this result had been reported during the development phase of the selective COX-2 inhibitors, the business projections may have been less enthusiastic.

## The Diversity of Health Effects of Individual *trans* Fatty Acid Isomers

**Abstract** There are multiple adverse effects of *trans* fatty acids (TFA) that are produced by partial hydrogenation (i.e., manufactured TFA), on CVD, blood lipids, inflammation, oxidative stress, endothelial health, body weight, insulin sensitivity, and cancer. It is not yet clear how specific TFA isomers vary in their biological activity and mechanisms of action. There is evidence of health benefits on some of the endpoints that have been studied for some animal TFA isomers, such as conjugated linoleic acid; however, these are not a major TFA source in the diet. Future research will bring clarity to our understanding of the biological effects of the individual TFA isomers. At this point, it is not possible to plan diets that emphasize individual TFA from animal sources at levels that would be expected to have significant health effects. Due to the multiple adverse effects of manufactured TFA, numerous agencies and governing bodies recommend limiting TFA in the diet and reducing TFA in the food supply. These initiatives and regulations, along with potential TFA alternatives, are presented herein.

### Introduction

Recent research has made evident the numerous adverse effects of *trans* fatty acids (TFA) as a group, and specifically those produced by partial hydrogenation on CVD, blood lipids, inflammation, oxidative stress, endothelial health, body weight, insulin sensitivity, and cancer. While it is clear that TFA intake from partially hydrogenated fats is associated with multiple harmful outcomes, it is not yet clear how specific TFA isomers vary in their biological activity and mechanisms of action. Evidence suggests that TFA from different sources, as well as individual isomers within these subgroups, elicit differential biological effects, both favorable and adverse. In this paper, we will review the current literature regarding the effects of TFA on various endpoints, while noting differences observed among various TFA isomers. In addition, we will address the regulatory issues related to TFA, initiatives to reduce TFA in the food supply, potential TFA alternatives, and looming challenges to food manufacturers and consumers, which were all discussed at a recent American Heart Association conference [1].

### Sources of TFA Isomers

There are two major sources of TFA, those that come from ruminant animals and those that are industrially produced. The concentration of TFA in meat and milk from ruminants (i.e., cattle, sheep, goats, etc.) ranges from 3 to 8% of total fat. The majority of TFA is found in partially hydrogenated vegetable oils (which contain 10–40% as TFA) [2]. The C18:1t isomers comprise approximately 80–90% of total TFA in foods [3]. Other TFA isomers include C16:1t, C18:2t, C18:3t, and long chain polyunsaturated TFA [4].

Elaidic acid (C18:1 $\Delta$ 9t) typically is the major isomer in industrial sources of TFA. However, there are many isomers of TFA in hydrogenated vegetable oils and C18:1 $\Delta$ 10t also can be a major component. The *trans* isomer of vaccenic acid (C18:1 $\Delta$ 11t), a precursor for conjugated linoleic acid (CLA), is the major TFA isomer in ruminant fat, and also is found in industrial TFA in lesser amounts [4]. CLA are a group of positional and geometric conjugated isomers of linoleic acid. The two predominant isomers, with known bioactive properties, are *cis*-9, *trans*-11 (c9t11), and *trans*-10, *cis*-12 (t10c12) [5]. There has been recent interest in CLA due to the beneficial effects on health outcomes observed in animal studies; however, more research is needed in humans [6–8]. Thus, individual isomers of TFA can elicit differential effects on various endpoints. It is hypothesized that ruminant TFAs, or certain TFA isomers from ruminant sources, may confer some health benefits; however, a strong database is lacking. Table 1 shows the common name, chemical name, and sources of major *trans* isomers.

### Health Effects of TFA

This section reviews the effects of TFA, as a group, on various disease endpoints. Furthermore, individual effects of CLA on these endpoints are summarized.

#### Cardiovascular Disease

Epidemiologic studies have consistently shown an association between intake of TFA and risk of CHD. Research

suggests that there is a stronger association with intake of TFA and CHD risk than that with intake of saturated fatty acids (SFA) [9]. In the Seven Countries Study, countries with high TFA intake, such as Northern European countries, had higher CHD mortality rates, while countries with low TFA intake, such as Mediterranean countries and Japan, had lower CHD mortality rates [10]. In this study, average intake of elaidic acid (C18:1t) was strongly associated with 25-year mortality from CHD ( $r = 0.78$ ;  $P < 0.001$ ). In the Nurses' Health Study, the relative risk (RR) of CHD across increasing quintiles of TFA intake was 1.5 (95% CI 1.12–2.00;  $P = 0.001$ ). This risk was higher for individuals whose margarine consumption did not change over the previous 10 years (RR = 1.67; 95% CI 1.05–2.66;  $P = 0.002$ ) [11]. The positive association between TFA intake and risk of CHD was accounted for by partially hydrogenated vegetable oil, while there was a nonsignificant inverse association with TFA from ruminant sources and CHD risk. In the Zutphen Elderly Study, a 2% increase in baseline total TFA intake resulted in a 29% increase in risk of 10-year incidence of CHD (RR = 1.29; 95% CI 1.09–1.52) [12]. There was no significant difference in RR for CHD between ruminant and industrially produced sources of 18:1 *trans* isomers. An analysis by Oomen et al. [12] used pooled data from four prospective cohort studies to indicate that an increase of 2% energy in TFA intake is associated with a RR of 1.25 (95% CI 1.11–1.40). Thus, removal of 2% of energy from TFA from the diet can significantly reduce CHD risk. In the Cardiovascular Health Study, red blood cell membrane levels of total TFA, a biomarker of total TFA intake, was associated with a modest increase in the risk of primary cardiac arrest [13]. However, after adjustment for EPA and DHA, this relationship was no longer significant. The C18:2t isomers, but not C18:1t isomers (C18:1 $\Delta$ 9t, C18:1 $\Delta$ 10t, C18:1 $\Delta$ 11t), were significantly associated with primary cardiac arrest, even after adjustment for EPA and DHA (OR = 3.05; 95% CI 1.71–5.44). Fatty acid analysis of plasma phospholipids showed that higher levels of plasma phospholipids C18:2t were associated with higher risk of fatal ischemic heart disease (IHD) (OR = 1.68; 95% CI 1.21–2.33) [14]. In contrast, higher levels of C18:1t, above the 20th percentile, were associated with a lower risk (OR = 0.34; 95% CI 0.18–0.63). Similarly, higher levels of C18:2t were associated with a higher risk of sudden cardiac death (SCD) (OR = 2.34; 95% CI 1.27–4.31), while higher levels of C18:1t were associated with a lower risk (OR = 0.18; 95% CI 0.06–0.54). The correlations for individual C18:2t and C18:1t isomers were not reported. There were no significant associations with plasma phospholipids levels of C16:1t and fatal IHD [14]. The results suggest that C18:2t isomers may be responsible for the increased risk for primary cardiac arrest, fatal IHD, and SCD in this study.

**Table 1** Major *trans* fatty acid isomers

Common name	Chemical name of common isomers	Major source
Palmitoleic acid	C16:1	Ruminant meat and milk
Elaidic acid	C18:1 $\Delta$ 9t <sup>a</sup>	Partially hydrogenated oils
Vaccenic acid <sup>b</sup>	C18:1 $\Delta$ 11t <sup>a</sup>	Ruminant meat and milk
Linolelaidic acid	C18:2-t9t12	Partially hydrogenated oils
Conjugated linoleic acid (CLA)	C18:2-c9t11 <sup>c</sup> C18:2-t10c12	Ruminant meat and milk

<sup>a</sup> C18:1t isomers comprise approximately 80–90% of total TFA in foods [3]

<sup>b</sup> Vaccenic acid constitutes 40–70% of total *trans* 18:1 [127]

<sup>c</sup> Predominant isomer of CLA (90%) [128]

However, it is important to note that C18:1t isomers comprise approximately 80–90% of total TFA in foods [3].

Results from studies investigating the association of TFA from ruminant sources and CHD risk have indicated no association or a potential beneficial association [11, 15, 16]. However, a recent review points out that most comparisons of sources of TFA in these studies are based on relative intake data from quintiles of intake [17]. When absolute amounts of TFA (0–2.5 g/day) were calculated and compared from these studies, there were no significant differences in risk of CHD for different sources of TFA [4]. Based on the analysis by Oomen et al., it was estimated that 2.5 g of TFA would be associated with a 15% increase in CHD risk. At intakes greater than 3 g/day, total TFA and industrially produced TFA were associated with an increased risk of CHD. Intakes of ruminant TFA were below this amount, thus conclusions could not be drawn about higher intakes of ruminant TFA.

### Blood Lipids

Randomized controlled trials consistently have shown that TFA increase LDL-cholesterol (LDL-C) similar to SFA, and decrease HDL-cholesterol (HDL-C) compared with SFA, resulting in a dose-dependent relationship between TFA intake and the ratio of LDL-C:HDL-C and TC:HDL-C that is stronger than that for SFA since SFA also increase HDL-C [18]. Results from a meta-analysis of clinical studies demonstrate that the replacement of carbohydrate with TFA causes an increase in the ratio of TC:HDL-C and that this effect is almost twice the magnitude of replacing a mixture of SFA for carbohydrate [19]. In the Nurses' Health Study, higher levels of total TFA in red blood cells were associated with increased LDL-C, HDL-C, and ratios of LDL-C:HDL-C. Furthermore, individuals who consumed the most TFA had a 3.3 times higher risk for developing CHD compared to those who consumed the least amount of TFA [20]. Lichtenstein et al. demonstrated that increases in TFA result in a dose-dependent increase in LDL-C and decrease in HDL-C. Six experimental diets that provided 30% energy from total fat were evaluated. Two-thirds of the fat was provided by either soybean oil (<0.5 g TFA per 100 g of fat), semi-liquid margarine (<0.5 g per 100 g), soft margarine (7.4 g per 100 g), shortening (9.9 g per 100 g), stick margarine (20.1 g per 100 g), or butter (1.25 g per 100 g). Compared with the butter diet, the vegetable fat diets elicited the following reductions in TC, LDL-C, and HDL-C: (1) soybean oil diet: 10, 12, and 3%, respectively; (2) the semi-liquid margarine diet: 10, 11, and 4%, respectively; and (3) the stick margarine diet: 3, 5, and 6%, respectively. The stick margarine diet

increased the TC:HDL-C ratio by 40%; the other vegetable fats decreased it. The diets containing the fats with the least TFA, the soybean oil and semi-liquid margarine diets, had the most beneficial effects on lipids/lipoproteins [21].

In addition to the effects on LDL-C and HDL-C, TFA increase triglycerides and Lp(a), when substituted for SFA [18]. It has been estimated that reducing TFA intake by 2% of energy would result in a decrease in triglyceride levels of approximately 3 mg/dl [22]. Furthermore, increasing amounts of TFA resulted in an increase in small dense LDL particles in a dose-dependent manner, when compared with a diet rich in SFA [23]. As reviewed by Ascherio [22], an estimated reduction in TFA intake of 2% of calories would result in a 7% reduction in CHD mortality due to the effects on the ratio of LDL-C:HDL-C. Compared to the estimates from epidemiologic studies, this lower estimate indicates that the adverse effects of TFA are more extensive than only their effects on blood lipids.

Intervention studies that demonstrate the specific effects of individual TFA isomers on blood lipids are lacking. In a randomized, parallel intervention study in 42 healthy young men, a vaccenic acid-rich diet (3.6 g/day of vaccenic acid) lowered TC and HDL-C by 6 and 9%, respectively ( $P \leq 0.05$ ), when compared with a control diet [24]. However, it was concluded that differences may have been due to higher MUFA and lower SFA in the vaccenic acid-rich diet rather than due to vaccenic acid alone. More research is needed to determine the effects of individual isomers on clinical endpoints.

All mechanisms by which TFA elicit their numerous effects remain unclear; however, it is clear that TFA affect lipid metabolism through multiple pathways. As recently reviewed by Mozaffarian et al. [25], TFA have been shown to increase rates of apolipoprotein (apo) A-I catabolism, decrease rates of LDL apoB-100 catabolism, decrease LDL-C particle size, and increase activity of cholesteryl ester transfer protein in humans; and increase secretion and cellular accumulation of free cholesterol and cholesterol esters in HepG2 cells. In vitro studies also have shown that TFA decrease HDL via inhibition of lecithin:cholesterol acyltransferase (LCAT) activity [26].

Results from studies investigating the effects of CLA supplementation on lipids and lipoproteins have been mixed [27–33]. Differential effects of t10c12 and c9t11 isomers have been reported in some studies [34, 35]. One study found that purified t10c12 CLA and a mixture of t10c12 and c9t11 CLA isomers (3.4 g/day) significantly decreased HDL-C by 4 and 2%, respectively, compared with placebo ( $P < 0.01$ ,  $P < 0.05$ ) [34]. In another study, t10c12 isomers (0.63, 1.26, and 2.52 g/day) increased the ratios of LDL-C:HDL-C and TC:HDL-C from baseline. In contrast, c9t11 isomers (doses of 0.59, 1.19, and 2.38 g/day)

decreased LDL-C:HDL-C and TC:HDL-C. There was no significant effect of dose of CLA isomers [35]. A recent study in moderately overweight subjects with LDL phenotype B compared the effects of a drinkable dairy product enriched with c9t11 or t10c12 (3 g/day, 3 weeks) on the lipid and lipoprotein profile [36]. There were no significant differences in the proportions of plasma small dense LDL or serum concentrations of LDL-C, HDL-C, and TG after either the c9t11 or t10c12-enriched products, compared to control product that was not enriched with CLA. The TRANSFACT study is a randomized, controlled, crossover trial specifically designed to compare the effects of industrial and natural sources of TFA on lipids and lipoproteins [37]. In this study, two specifically designed test fats (milk fat enriched in TFA and partially hydrogenated vegetable oil balanced in SFA) provide approximately 5.4% of energy from TFA in healthy individuals. Results from this study are expected soon.

### Inflammation and Oxidative Stress

Inflammation is an independent risk factor for CVD. Epidemiologic studies have suggested that TFA may have an adverse effect on inflammatory markers. In the Nurses' Health Study, TFA intake, assessed by semiquantitative food-frequency questionnaires, was positively associated with tumor necrosis factor receptor (TNFR) levels in healthy women ( $P$  for trend < 0.001), and was also associated with levels of C-reactive protein (CRP) and IL-6 in women with higher BMI ( $P = 0.03$ ) [38]. Regression analysis from a cross-sectional study of the Nurses' Health Study found that TFA intake was positively related to plasma levels of TNFR2 ( $P = 0.002$ ) and CRP ( $P = 0.009$ ), independent of BMI [39]. In patients with established heart disease, red blood cell membrane levels of TFA were positively associated with IL-1, IL-6, IL-10, and TNF $\alpha$  ( $P < 0.05$ ) [40]. In two of these studies, the association was due to C18:1t and C18:2t isomers, while no association was observed with C16t isomers [38, 39]. Results from RCTs have indicated a pro-inflammatory effect of TFA, which is consistent with epidemiologic data [41, 42]. A study by Han et al. [41] found that TNF $\alpha$  and IL-6 were 58 and 36% higher, respectively, after a stick margarine diet (6.7% energy from TFA) versus a soybean oil diet (0.6% energy from TFA). In a study by Baer et al. [42], a diet rich in TFA (8% energy enrichment from TFA) resulted in significantly higher levels of CRP versus a carbohydrate diet (8.5% of energy from fat replaced by digestible carbohydrate) ( $P < 0.05$ ).

There are mixed results from studies investigating the effects of CLA on inflammation. In randomized controlled trials, mixtures of c9t11, t10c12 CLA (3.4, 4.2 g/day)

caused a significant increase in CRP in healthy individuals and in those with metabolic syndrome [43, 44] and had no effect on TNF $\alpha$  and TNF $\alpha$  receptors in healthy individuals [43]. In a recent study, supplementation of 6.4 g/day of CLA for 12 weeks resulted in significant increases in CRP, IL-6, and white blood cells [45]. In contrast, in a study in subjects with type 2 diabetes, there was no effect of a CLA mixture (3 g/day) on CRP or IL-6 [46]. Furthermore, supplementation of either 3 g/day of c9 t11 CLA or t10 c12 CLA for 13 weeks in individuals with a high risk of CHD did not significantly affect LPS induced production of IL-6, IL-8, and TNF $\alpha$  by peripheral blood mononuclear cells, and whole blood as well as plasma CRP concentrations [47]. Studies in mice demonstrate that t10c12 CLA leads to induction of TNF $\alpha$  and IL-6 gene expression without affecting serum levels [48]. Mechanistically, t10c12 CLA was found to directly induce secretion of TNF $\alpha$  and IL-6 in adipocytes via nuclear factor kappaB and promote macrophage infiltration into adipose tissue [48].

### Endothelial Function

In addition to pro-inflammatory effects, evidence suggests that TFA also could impair endothelial function, and that these effects could be more substantial than those of SFA. Observational studies have shown that TFA intake is associated with higher levels of VCAM, ICAM, and E-selectin ( $P < 0.01$ ) [39]. In a randomized controlled trial, there was a 5.6% increase in E-selectin levels when TFA replaced 8% of energy for SFA [42]. In another study, flow mediated dilation was 29% lower on a TFA diet (9.2% energy from TFA) compared with a SFA diet [49]. Both epidemiologic and controlled trials indicate that TFA impair endothelial function more than SFA. Furthermore, endothelium-dependent vasodilation has been shown to be related to the fatty acid composition of serum lipids in healthy individuals [50].

There is little information about the effects of CLA on endothelial function. Treatment of human aortic endothelial cells with CLA did not alter cytokine-induced expression of VCAM, ICAM, and E-selectin [51]. In contrast, in another experiment, cytokine-induced monocyte adhesion to endothelial cells was inhibited dose-dependently by t10c12 CLA isomer [52]. Addition of the isomer in amounts of 6, 12.5, 25, 50  $\mu$ M resulted in inhibition of TNF $\alpha$ -induced monocyte adhesion by 30, 42, 50, 58%, respectively. In a recent study in 40 overweight men, a CLA mixture (4.5 g/day) reduced FMD by 1.3%, thus impairing endothelial function [53]. More clinical studies are needed to further examine the effect of CLA on markers of endothelial health.

## Body Weight and Body Fatness

Numerous animal and cell culture studies have found that CLA reduces body weight and fat deposition [54]. In a study in young, growing mice fed 1% CLA, there was a 60% decrease in body fat [55]. Most animal and cell studies have used mixtures of CLA isomers, although studies in which the ratio of specific isomers was varied indicate that the t10c12 isomer is responsible for the effects on body weight and body composition [54, 56]. Overall, clinical studies have shown no significant effect of CLA on body weight in humans [8, 54]. In a review of eight studies evaluating the effect of CLA on body composition in humans, there were no significant effects of the CLA group (CLA doses ranging from 0.70 to 6.8 g/day; t10c12 doses ranging from 0.35 to 2.0 g/day) compared to the control group for BMI, body weight, and lean body mass [57]. There was a significant effect on body fat (ranging from -3.7 to -22.2%) in the CLA group versus the control group in two of the studies [33, 58]; however, both of these studies included an exercise component, which may have influenced the results. Furthermore, there was no association with the dose of t10c12 isomer and the observed effect. In contrast, after supplementation with a CLA mixture in subjects with type 2 diabetes (8 g/day) for 8 weeks, t10c12 was inversely correlated with body weight changes ( $r = -0.43$ ;  $P < 0.05$ ) [59]. This study suggests that CLA supplementation at higher doses may promote weight loss in individuals with type 2 diabetes, although further research is needed. Two recent long-term studies in humans found that CLA supplementation of 3.4 g/day for 6 months [60] and 12 months [61] reduced body fat mass in overweight and overweight/obese individuals, respectively. However, in a recent study, CLA supplementation (3.4 g/day) for 1 year did not prevent weight or fat mass regain in moderately obese individuals [62].

## Insulin Sensitivity and Glucose Metabolism

In the Nurses' Health Study, dietary TFA was associated with an increased risk of developing type 2 diabetes [63]. For a 2% increase in energy from TFA, there was a 39% increase in risk (95% 1.15–1.67;  $P < 0.001$ ). In the Health Professionals Follow-Up Study, there was not a significant association with TFA at lower intakes (median intake 1.3% of energy from TFA) and diabetes risk [64]. This prompted the question of whether TFA affects insulin resistance, a major cause of type 2 diabetes. In controlled feeding studies in healthy individuals, there was no significant difference in insulin sensitivity, measured by frequently sampled intravenous glucose tolerance test, when comparing a TFA diet (5% total energy) to a monounsaturated

fat diet (MUFA; 5% total energy from oleic acid) [65] and a TFA diet (9% total energy) to a SFA diet (9% of energy as palmitic acid) [66]. In a study in hypercholesterolemic overweight adults comparing diets varying in TFA amount (3–7% total energy), insulin sensitivity, measured indirectly by fasting insulin levels, could not be attributed to the different fatty acid profiles of the various diets [67, 68]. A study in insulin resistant individuals with type 2 diabetes found that a high *trans* MUFA diet (20% total energy) resulted in a 59% higher postprandial insulin response ( $P < 0.05$ ) to a standardized meal compared to a *cis* MUFA diet (20% total energy), although this response was not significantly different than the response to a SFA diet [69].

Results from animal and human studies have suggested an adverse effect of CLA on insulin sensitivity, as reviewed by Wang and Jones [54]. CLA mixtures containing 0.7–2.0 g of the t10c12 isomer did not cause significant changes in plasma insulin levels [57]. In a RCT in obese insulin resistant men, individuals were given supplements (3.4 g) of a CLA mixture (50:50 c9t11 CLA, t10c12 CLA), purified t10c12 CLA, or placebo (olive oil) for 12 weeks [34]. Compared to placebo, insulin resistance, measured directly by euglycemic clamp, was increased by 19% after t10c12 CLA supplementation ( $P < 0.01$ ). In addition, this isomer significantly increased urinary F2-isoprostanes, a marker of oxidative stress ( $P < 0.0001$ ) [44]. The effect of the CLA mixture on insulin sensitivity was not significantly different from the placebo; however, it significantly increased fasting glucose concentrations and decreased HDL-C [34]. A subsequent study investigated the effect of a purified c9t11 CLA preparation in obese insulin resistant men and found that insulin sensitivity was decreased by 15% compared to placebo ( $P < 0.05$ ) [70]. These results recently were confirmed in a RCT in which CLA supplementation (50:50 c9t11 CLA, t10c12 CLA; 3 g/day) or placebo was given to individuals with type 2 diabetes for 8 weeks [46]. Compared to baseline, the CLA supplement resulted in an increase in fasting glucose concentrations by 6% ( $P < 0.05$ ), reduced insulin sensitivity by homeostasis model assessment ( $\Delta = 0.54$ ;  $P < 0.05$ ) and reduced oral glucose insulin sensitivity ( $\Delta = -11.24$ ;  $P \leq 0.05$ ). Other studies have found no significant changes in glycemia [27], glucose [31, 34, 35, 71], or insulin levels [27, 35, 53] after intake of CLA isomer mixtures.

Overall, the data suggest that TFA do not have a significant effect on insulin sensitivity in healthy normal weight individuals and overweight individuals with elevated cholesterol. In subjects with type 2 diabetes, high TFA intake could increase insulin resistance; however, more studies with larger numbers of participants are needed. The results of clinical studies with CLA isomers indicate that CLA has an adverse effect on insulin sensitivity in insulin resistant men.

## Cancer

Some epidemiologic studies have found that TFA intake is associated with increased risk of colorectal cancer [72] and prostate cancer [73]. Studies with CLA in cells and animals have suggested an anticarcinogenic property of CLA for various forms of cancer, including breast, gastrointestinal, colon, and prostate cancer, as summarized in a recent review [6]. In addition, some studies have found an anticarcinogenic effect of *trans*-vaccenic acid as a precursor to c9, t11 CLA [74, 75]. However, there is limited clinical research investigating the effect of CLA on cancer development in humans. Clinical studies have shown no clear association between dietary CLA, adipose or serum levels of CLA, and reduced risk for breast cancer [76–79]. There has been one human study that has suggested that intake of high-fat dairy foods and CLA reduces the risk for colorectal cancer [80]. In this prospective study, women who consumed  $\geq 4$  servings per day of high-fat dairy foods had a RR of 0.59 compared with women who consumed less than one serving per day of high-fat dairy (95% CI 0.44–0.79). The RR for CLA intake when comparing the highest and lowest quartiles of intake was 0.71 (95% CI 0.55–0.91). Although there are some data suggesting a beneficial association of CLA intake on cancer risk, intervention studies evaluating the effects of CLA supplementation on cancer risk are lacking.

## Position Statements, Regulations, and Initiatives on TFA

As reviewed above, substantial epidemiologic data demonstrate adverse effects of TFA on CVD risk, as well as other chronic diseases. Although a large-scale randomized trial to assess the effects of TFA on chronic disease risk has not been done and cannot be done, due to ethical considerations, clinical data also demonstrate the adverse effects of TFA on chronic disease risk factors and the pathogenesis of chronic disease. Therefore, numerous expert committees have made evidence-based statements that recommend limiting dietary TFA intake:

- Institute of Medicine, 2002—TFA consumption should be as low as possible [81].
- 2005 Dietary Guidelines Advisory Committee (DGAC), 2005—TFA consumption by all population groups should be kept as low as possible, which is about 1% of energy intake or less [82].
- 2005 Dietary Guidelines for Americans, 2005—keep TFA consumption as low as possible [83].
- WHO/FAO report, Diet, Nutrition, and Chronic Disease, 2003—the population nutrient intake goal for TFA is less than 1% energy from TFA [84].

- International Society for the Study of Fatty Acids and Lipids (ISSFAL), 1999—the maximum level of TFA should be 1% of energy [85].
- Nutrition and Diet for Healthy Lifestyles in Europe, EURODIET, 2000—a population goal of less than 2% energy from TFA [86].
- UK Ministry of Agriculture, 1998—less than 2% of energy [87].
- Netherlands Health Council, 2006—less than 1% of energy intake should be from TFA [88].
- National Cholesterol Education Program, 2001—intakes of TFA should be kept low [89].
- American Heart Association (AHA), 2006—less than 1% of energy as TFA [90].
- American Diabetes Association, 2007—intake of TFA should be minimized [91].

In addition to position statements by various agencies, governing bodies have mandated regulations regarding TFA in the food supply. In 2003, the Danish Government stated that industrially produced TFA, those from partially hydrogenated oils, should be limited to 2% of the total amount of fat or oil in a food [92]. The Danish government chose to use government regulations so that the responsibility was with the food industries unlike food labeling where the responsibility lies with the consumers. Following the Danish example, Health Canada's Trans Fat Task Force issued recommendations for regulating TFA in the food supply to the Minister of Health in June 2006 [93]. In *TRANSforming the Food Supply*, the task force recommended that: (1) TFA be limited to 2% of total fat content in all vegetable oils and soft, spreadable margarines to be sold or used in food preparation and (2) TFA be limited to 5% of total fat content in all other foods purchased by a retail or food service establishment for consumer sale or in food preparation, with the exception of food products for which the fat originates exclusively from ruminant meat or dairy products [93]. More recently, the New York City Board of Health placed a ban on TFA in foods, which was greatly opposed by the restaurant industry [94]. According to the ban, restaurants will have to eliminate oils, shortenings, and margarines used for frying and spreads with  $\geq 0.5$  g of TFA per serving by July 2007 [95]. Other USA cities, such as Boston, Chicago, and Los Angeles, have proposed similar bans on TFA in restaurant foods [96–98].

In contrast to Denmark and Canada, some countries, such as the Netherlands, have opted against government regulations, yet have made significant progress in reducing TFA in the food supply. The effort in the Netherlands was initiated by the food industry and continued via the Product Board for Margarine, Fats, and Oils (MVO), which represents all trade and production companies in

the Dutch edible oils and fats chain. MVO set up a Task Force for Responsible Fatty Acid Composition to campaign for the reduction of partially hydrogenated oils and SFA by using liquid frying oils in place of hard frying oils in restaurants [99]. Although this was not a government rule, 45% of all Dutch fast-food restaurants switched to using liquid frying oils containing less than 5% TFA, the goal set by the task force, within one year [99].

Although the Australian government is currently not regulating TFA in the food supply, it has issued a statement of support for the recently established National Collaboration on Trans Fats, consisting of the National Heart Foundation of Australia, the Dietitians Association of Australia, the Australian Food and Grocery Council and Food Standards Australia New Zealand. The National Collaboration on Trans Fat will propose initiatives aimed at reducing the amount of TFA in food sold in Australia [100].

An initiative set forth to reduce the amount of TFA in foods in the USA resulted from the settlement of a class action lawsuit against McDonald's. In March 2006, the American Heart Association received \$7 million to be used for: "(1) public education regarding TFA; (2) encouraging substitution of partially hydrogenated oils by the food industry; (3) holding conferences on health issues associated with TFA and the substitution of partially hydrogenated oils; and (4) other activities regarding the impact of TFA on public health" [101]. The strategic plan of the AHA TFA initiative focuses on consumer research, consumer education, industry conferences, NYC restaurants, and advocacy.

Given the considerable amount of evidence that TFA have adverse effects on cardiovascular health, along with other disease states, some have advocated government regulation in the USA. Currently, partially hydrogenated vegetable oils are allowed in USA food products under the category of GRAS, "generally regarded as safe". As pointed out by Willett [102], this contradicts current evidence which was considered strong enough to warrant the FDA to rule that the TFA content of foods be included on the Nutrition Facts Panel. In accordance with this, the Center for Science in the Public Interest submitted a petition to the FDA to remove TFA from partially hydrogenated vegetable oils from the GRAS category. If partially hydrogenated vegetable oils were removed from the GRAS category, less TFA would potentially be in the food supply and therefore the responsibility for lowering dietary TFA intake would be shared by consumers and the food industry. Removing all TFA from the food supply would be challenging due to the process of deodorization that is used to remove volatile components prior to human consumption. This process results in the production of

small amounts of TFA; however, not using this process results in oils that are less stable [103].

### TFA on the Food Label

Currently, the listing of TFA on the food label is the only federal regulation regarding TFA in the USA. As a result of an FDA ruling in 2003, the Nutrition Facts Panel includes the TFA content of most food products, effective 1 January 2006. According to the rule, TFA are defined as "all unsaturated FAs that contain one or more isolated double bonds in *trans* configuration" [104]. Since only TFA with non-conjugated double bonds are included in the FDA definition of TFA, CLA is excluded from the food label. However, other TFA of ruminant origin, such as *trans*-vaccenic acid, would be accounted for under the TFA definition.

If the TFA content of a product is greater than or equal to 0.5 g per serving, it must be stated on the Nutrition Facts Panel as a separate line item. If the TFA content of a product is less than 0.5 g per serving, it is expressed as 0 g TFA [104]. Therefore, it is important to educate consumers such that they are aware that if a product lists zero TFA it is not necessarily *trans* free. Additionally, a %Daily Value (%DV) is not listed as is done for other cholesterol-raising nutrients (i.e., SFA and dietary cholesterol) since there is no reference value from which a %DV can be set for TFA.

The FDA acknowledges the need for resolving some issues about the TFA information presented on food labels [105]. Therefore, the FDA issued an advance notice of proposed rule making (ANPR) the same day the food label ruling was issued. The goal of the ANPR is to elicit comments regarding: (1) definitions for nutrient content claims for TFA "free" and "reduced"; (2) limits on TFA amounts, in conjunction with SFA, for nutrient content claims, health claims, and disclosure and disqualifying levels; (3) a daily value; and (4) a footnote or disclosure statement for enhancing consumer understanding of cholesterol-raising lipids [105]. With consumers being held responsible for making healthy food decisions, specifically when choosing foods low in cholesterol-raising nutrients, extensive nutrition education on TFA will be necessary.

### Potential Challenges to Food Manufacturers

The primary challenge faced by food manufacturers relative to decreasing the TFA content of foods is the quality of the oils and fats available for food applications [106]. When considering TFA alternatives, food manufacturers are concerned with the functional characteristics of the finished products and how the products will be received by

the consumer [107]. When decreasing the TFA content of food products, the SFA content may increase and the shelf life of the finished product may decrease. Oils that are not hydrogenated are less stable and are more susceptible to oxidation than hydrogenated oils. Therefore, antioxidants may need to be added to these oils to overcome these challenges. Another concern of the food industry is the supply of TFA alternatives. If a restaurant is going to switch to a new TFA-free fat, it must be assured that there will be a consistent and adequate supply of the product. Furthermore, the production costs of TFA alternatives are greater than conventional hydrogenated oils [106, 108]. Therefore, suppliers of TFA alternatives want to assure a steady demand for their products to justify investing in the production of TFA alternatives. Suppliers also need to update equipment and technologies for producing new TFA alternatives [107].

### TFA Alternatives

TFA alternatives are being sought by the food industry due to the regulation of TFA in foods in some countries and the FDA-required food labeling in the USA. Food manufacturers are producing naturally stable oils that require little or no hydrogenation such as cottonseed, corn, high-oleic canola, high-oleic safflower, mid- and high-oleic sunflower, low-linolenic soybean oils and tropical oils (palm oil, palm kernel oil, and coconut oil) [107]. Food manufacturers consider tropical oils adequate replacements for partially hydrogenated oils in baked goods due to their high content of SFA and higher melting points [108]. As with fully hydrogenated vegetable oils, the use of tropical oils increases the SFA content of these products.

A variety of technologies are already being implemented while others are being developed and refined to reduce or eliminate TFA in food products [107, 108]. Interesterification rearranges the FA within triglycerides to yield customized melting characteristics. Another method for reducing TFA in food products is altering the hydrogenation process to yield partially hydrogenated fats lower in TFA. This is accomplished by using metal catalysts that prevent the formation of *trans* isomers [109–111] or promote the formation of *cis* isomers [109] and by changing the time and temperature of the hydrogenation process [107]. Numerous plant breeding and genetic engineering technologies are being used to manipulate the FA composition of oil seeds to increase oxidative stability during deep-fat frying and to extend shelf life by decreasing the amount of relatively unstable fatty acids (i.e., linolenic) or increasing the amount of relatively stable fatty acids (i.e., oleic) [107, 108].

While the AHA applauds efforts to reduce the consumption of TFA in restaurants, it cautions against the use of other “unhealthy oil products”. Therefore, the AHA recommends providing guidance to eateries on which oils to use and how to incorporate them and TFA-free shortenings into their menu and food preparation processes [112]. When restaurants use these TFA alternatives, it is important that the entire FA profile of them be considered. When available, healthy fats should be substituted for fats that contain TFA. Although there are some SFA with neutral effects on blood cholesterol, if TFA are simply replaced by cholesterol-raising SFA, the health effects might be negated, in part or almost completely.

### TFA in the Food Supply

A recent analysis (November 2004–September 2005) of popular foods (fries and chicken nuggets) from fast food chains, specifically McDonald’s and KFC, indicates that the TFA content of one large serving varies greatly between countries (<1 g/serving to 24 g/serving) and even within countries (<1 g/serving to 5 g/serving) [113]. However, the frying oil used in the food industry in the majority of European countries contains ~10% TFA, with foods from both chains in Denmark containing less than 1 g TFA. In contrast, the oils in the USA and Peru contain 23 and 24% TFA, respectively. Another analysis indicates that since the imposition of the Danish government rule, much fewer food products in Danish eateries contain more than 2% TFA when compared to an investigation of food samples in the same categories (baked products, potato products, and microwave popcorn) prior to the ruling [92].

A reduction in the TFA in food products may translate to a decrease in cardiovascular events [114]. Data from Costa Rica indicate that prior to industrial modifications that reduce TFA in foods (1994–1999), TFA intake in the highest quintile (median = 2.02 g/100 g) was associated with an increased risk of MI (OR = 4.76; 95% CI 2.24–10.11). However after industrial modification (2000–2003), TFA intake (median = 1.4 g/100 g) was not associated with an increased risk (OR = 1.15; 95% CI 0.80–1.64). The lack of association during the later years may be due to the lower TFA intake; mean TFA intakes were 4.1 and 2.9 g/day during 1994–1999 and 2000–2003, respectively. While associations between TFA intake and CVD biomarkers and events exist in populations with higher intakes of TFA (~4 g/day), none exist at lower intakes (~2 g/day) [114]. Therefore, reducing TFA in the food supply as low as possible will most likely translate to an overall decrease in the population intake and CVD risk.

Due to government regulations and the increasing awareness of the detrimental effects of manufactured TFA

on health, numerous chain eateries are eliminating or reducing TFA in their products. Fast food outlets in Denmark and the Netherlands have been very successful at maintaining the quality of their food products while considerably reducing the TFA content of them [92, 99]. Furthermore, the amount of SFA has slightly decreased with a concomitant increase in MUFA (18:1c) and PUFA (18:2Δ6c) [99]. Many common chain eateries in the USA, such as KFC, Wendy's, Taco Bell, and Starbucks, are following suit [115–119]. Other chain outlets are expected to change in the foreseeable future in the USA [99].

### Potential Challenges to Consumers

While the food industry is facing food production challenges, consumers are confronted with many decisions regarding their food choices for health. A new online resource to help consumers with these challenges is the AHA's Face the Fats website. Since the TFA content of foods with less than 500 mg of TFA per serving is listed as 0 g, consumers may unknowingly consume an unhealthy amount of TFA, especially if >1 serving is eaten. For this reason, recommendations should be made to read the ingredient list on the Nutrition Facts Panel, paying special attention to partially hydrogenated oils.

Consumers continue to struggle to understand the different kinds of fats, how they affect health, and how to incorporate fats into the diet [120–122]. Consumers should be advised to choose foods based on their overall nutrient profile including the amounts of all cholesterol-raising nutrients (SFA, TFA, and dietary cholesterol) they contain. Consumers are advised to consider both fully hydrogenated oils and partially hydrogenated oils listed in the ingredient lists of products. When vegetable oils are fully hydrogenated, stearic acid is the primary SFA produced [107], which has neutral effects on lipids and lipoproteins [123, 124]. The amount of SFA on the Nutrition Facts Panel will include stearic acid along with all other individual SFA. Therefore, checking the ingredient label for fully hydrogenated oils will indicate whether stearic acid is in the product. Since CLA is not included in the FDA definition of TFA, consumers should be aware that foods from animal sources may contain CLA. Thus, consumers are advised to refer to the food ingredient list to determine whether a food contains TFA from partially hydrogenated oils, stearic acid from fully hydrogenated oils, and CLA from meat and dairy products (i.e., milk). Reading and understanding the ingredient lists of foods presents another potential challenge to consumers whom already find it difficult to read and comprehend food labels and to understand how different kinds of fats effect one's health [120–122]. Furthermore, the production

costs of TFA alternatives are typically greater than those of partially hydrogenated oils. If this cost is defrayed by more expensive products, consumers will have to choose between cost and health [107].

### Effects of Substituting Stearic Acid for TFA

As reviewed by Kris-Etherton et al. [124], if a male (consuming 2,666 kcal/day) substituted stearic acid for 1% of energy from TFA (recommended upper intake level by 2005 DGAC and WHO/FAO report), it would result in stearic acid intakes of 11.2 g/day (8.2 g from usual diet plus 3 g from TFA substitution), or 3.7% of calories. If the required amount of stearic acid for substitution were double the intake of TFA, then stearic acid intake would be 14.2 g/day, or 4.7% of calories. At the upper end of TFA intake [3], which is 3.2% of calories, if a one-to-one substitution of stearic acid for TFA occurred, daily stearic acid intake would be 17 g, or 6% of calories. If the required amount of stearic acid for substitution were double the amount of TFA at this upper level of intake, then stearic acid intake would be 26 g/day, or 9% of calories. This higher level of intake is unlikely since multiple fats are proposed as substitutes for TFA [43]. To date, research suggests no adverse effects of stearic acid [123], although there is a suggestion that very high intakes (beyond what is expected with current intake practices and anticipated outcomes) may be associated with adverse consequences [125]. Research is needed to determine the consequences of substituting various FA, especially stearic acid and inter-esterified stearic acid, which are leading candidates for TFA substitutes for solid fat applications in the diet.

### Conclusions

There are many TFA isomers that have unique biological effects. Notwithstanding, the industrially produced TFA clearly have adverse health effects. Although there is evidence of health benefits of the animal TFA isomers on some of the endpoints that have been studied, these are not a major TFA source in the diet. Future research will bring clarity to our understanding of the biological effects of the TFA family. At this point, it is not possible to plan diets that emphasize individual TFA from animal sources at levels that would be expected to have significant health effects. Moreover, since TFA from animal sources accompany SFA, a message to emphasize is that increasing a single ruminant TFA in the diet is not appropriate because it will increase SFA. Thus, according to the American Heart Association, the best message for consumers presently is to limit TFA, SFA, and dietary cholesterol by following a

healthy overall dietary pattern that emphasizes fruits, vegetables, whole-grain foods, fat free and low fat dairy products, lean meats, poultry and fish twice a week. Following this dietary pattern will limit TFA and SFA intake and is consistent with current dietary recommendations made by many organizations worldwide.

**Abstract** This review explores the effects of dietary long chain polyunsaturated fatty acids (LCPUFA) on various aspects of early immune development and their potential role in the development or the prevention of immune disease. Modern diets have become increasingly rich in n-6 LCPUFA and relatively n-3 LCPUFA deficient. These potentially “pro-inflammatory” dietary changes have clear implications for the immature and developing fetal immune system. It is now well known that immunological abnormalities precede the development of allergic disease and are frequently evident at birth or in the first months of life. This has led to the hypothesis that potential effects of LCPUFA could be greatest in very early life before immune responses and clinical phenotype are established. Here we summarise the evidence that patterns of LCPUFA exposure in pregnancy can influence aspects of fetal immune in ways that are consistent with the immunological properties of these nutrients in adults. Specifically, human studies have shown that higher levels of n-3 LCPUFA are associated with reduction in neonatal oxidative stress, reduced production of inflammatory leukotienne B4 (LTB4) and altered T cell function. Inverse correlations between n-3 LCPUFA levels and neonatal T cell cytokine production, are consistent with adult studies showing reduction in T cell cytokine production with fish oil supplementation. At this stage the relevance of these effects in the prevention of

disease is unclear. Although there have been no effects of postnatal fish oil supplementation (from 6 months of age) on allergy prevention, preliminary studies suggest possible merits in pregnancy and there are ongoing pregnancy intervention studies to address this more definitively.

## Introduction

There is intensifying interest in the role of early life events and exposures in the aetiology and prevention of disease. Diet and nutrition in pregnancy have a fundamental influence on fetal development, and there is growing focus on the role of key dietary nutrients in subsequent health or disease. This review explores the effects of dietary long chain polyunsaturated fatty acids (LCPUFA) on early immune development and their potential role in the development or the prevention of immune disease.

This early critical period of development is of great interest for a number of reasons. Firstly, developing systems are more susceptible to influence while they are immature. Exposures during pregnancy when the immune system is less mature have been shown to significantly alter subsequent immune programming in both animals [1] and humans [2]. So far, this has mainly been studied in terms of microbial exposure, but it is likely that other environmental exposures, such as diet, could also have an effect. Secondly, immune diseases such as (such as atopic dermatitis and food allergy)

manifest very early in infancy, often within months of birth. This indicates that the events that lead to immune dysregulation are initiated very early in development, and further highlights the potential influence of antenatal exposures. The exponential rise in both allergic and autoimmune mediated immune diseases [3] provides compelling evidence for a role in relatively recent environmental changes in this epidemic. Although the reasons are not clear, a number of hypotheses have been presented. Broadly speaking, these models propose that modern environments are either “more inflammatory” or that there has been a relative “loss of protective factors” which normally inhibit development of inflammatory responses. While reduced microbial exposure is one of the most prominent theories to explain the rise in immune dysregulation [4], environmental changes have clearly been multi-factorial and there have also been persuasive arguments that suggest that dietary changes in the last 30–40 years may play a role [5–7].

### The Basis for Interest in Fatty Acids in Early Immune Development

The extensive immunomodulatory properties of LCPUFA are well recognised in adults and animal models, as reviewed elsewhere [8, 9], and mediate these effects through a number of potential mechanisms. Less is known about these effects in immature and developing systems. In addition to influences on production of eicosanoids, n-3 PUFAs can regulate T cell function directly through effects on cell membrane fluidity and consequent cell signalling and gene transcription (reviewed in [10, 11]). It has been logical to investigate how these effects influence early immune development.

Changing patterns of dietary LCPUFA intake are clearly relevant in pregnancy for the developing foetus. There has been a progressive decline in the intake of dietary anti-inflammatory omega 3 (n-3) PUFA in Western diets, and a corresponding increase in “pro-inflammatory” omega 6 (n-6) PUFA [5]. This has resulted in considerably higher ratios of n-6:n-3 LCPUFA (20–30:1) compared to the ratio in more traditional diets (1–2:1) [12]. These dietary changes are also reflected in the changing content of breast milk, which has similarly shown falling n-3 PUFA content and increasing n-6 PUFA levels over the last 20 years [13]. This, coupled with previously inadequate supplementation of milk formulae, has led to falling intake of anti-inflammatory n-3 PUFA during early life during the critical period of immune maturation.

Epidemiological and experimental data provide a plausible link between these dietary changes and the rise in allergic immune diseases (reviewed in [5, 6]). Although difficult to prove, these associations are supported by the well-described difference in the immune effects of n-3 and n-6 LCPUFA in vivo and in vitro.

Early population studies suggested that the risk of asthma may be higher in children with higher n-6:n-3 diets; either in association with low consumption of fish [14, 15], or high consumption of n-6 rich vegetable oils [16]. Several subsequent studies have also shown protective effects of fish oil. A well-known Australian study showed that children who regularly consumed oily fish were significantly less likely to develop asthma (odds ratio 0.26) [17]. Two more recent birth cohort studies have also reported that lower dietary n-6:n-3 intake (i.e. higher fish intake) reduced the risk of developing asthma [18, 19]. However, this has not been confirmed by all studies, and at least one large study found that higher fish intake was associated with a significantly higher prevalence of asthma (odds ratio: 1.117) [20]. In general, because of the limitations of these population-based studies, there has been a growing focus on well-controlled intervention studies (below).

Based on these observations and the limitations of population-based studies, we undertook the first human intervention study using high dose fish oil in pregnancy to investigate the effects of n-3 LCPUFA on early immune development [21]. We gave fish oil (3.7 g n-3 PUFA/ day) or a placebo supplements to allergic women ( $n = 98$ ) for the final 20 weeks of pregnancy [21–23]. Fish oil supplementation achieved significantly higher proportions of n-3 PUFAs in neonatal erythrocyte membranes compared to the control group ( $P < 0.001$ ) [21, 22]. Here, we review the effects on various aspects of immune function, where possible including relevant findings (from observational and animal studies) by other groups.

### Potential Pathways of Effect During Early Immune Programming

Inappropriate immune responses to environmental (allergens) or endogenous (self) antigens underpin most forms of immune disease. This review will focus principally on the events that occur during the initiation of exogenous environmental antigen responses. Although there is debate about when immune programming first occurs [24] it is clear that this occurs in the neonatal period, if not before. For this reason, the

capacity for LCPUFA to influence immune function during this period is of central interest.

A complex series of events occur during the programming of antigen-specific immune responses (as illustrated in Fig. 1). This typically begins in local tissues where antigen (allergen) proteins are first encountered by surveying antigen presenting cells (APC), such as tissue dendritic cells (DC), which ingest the proteins and digest them into small peptides. These are expressed on the cell surface with MHC class II receptors to effector T cells, after migration to the regional lymph nodes. The local tissue conditions play an important part in determining the maturation and activity of APC. This in turn has a significant effect on down-stream T cell programming (below). Local inflammation has a direct effect on increasing the expression of Class II, cytokines (such as interleukin [IL]-12) and co-stimulatory molecules on APC, which all act to promote an effector response. In contrast, the absence of inflammation is more likely to lead to T cell apoptosis, anergy and tolerance. Once activated, the pattern of APC cytokine production also determines the pattern of T helper cell differentiation. Type 1 (Th1) T cells develop under the influence of IL-12, whereas T cell producing Type 2 (Th2) cytokine responses develop in the relative absence of IL-12 (or the presence of pro-Th2 factors such as prostaglandin [25]). These differences in T cell cytokine production determine the pattern of B-cell antibody production; with Th2 cytokines (IL-4, IL-5 and IL-13) promoting IgE production and allergic inflammation whereas Th1 cytokines (IFN $\gamma$ ) largely inhibit this in favour of low level IgG production (Fig. 1). Tissue factors are again important in determining whether these immune responses result in clinically relevant disease (such as

asthma, allergic rhinitis or atopic dermatitis) although this is still not well understood. More recently there has been growing recognition of the role of specialised “regulatory” cells in immune programming and subsequent immune regulation. This encompasses a broad range of cells that regulate effector T cell responses through direct cell contact and/or production of regulatory cytokines such as IL-10 and TGF  $\beta$  (Fig. 1).

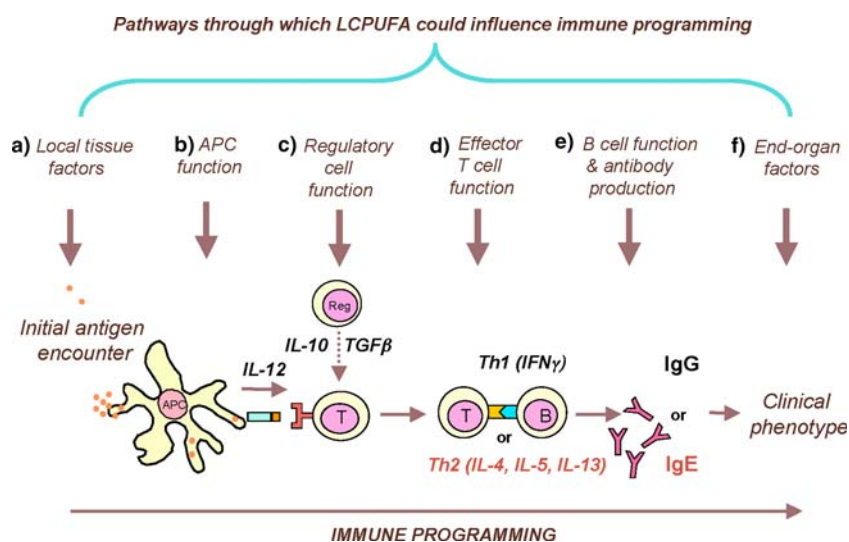

Variations in LCPUFA composition of neonatal cell membranes have the potential to influence immune programming at many levels during this complex process. Here we examine the evidence for effects on cells and mediators involved in each stage of the process described above and shown on Fig. 1.

#### Effects on Local Tissue Inflammation in Neonates

Firstly, we speculated that alterations in neonatal LCPUFA may influence local inflammatory responses through effects on the production of lipid derived inflammatory mediators by local tissue neutrophils (Fig. 2). As discussed elsewhere [26], these fatty acids are the major substrate for the production of eicosanoid mediators including prostaglandin and leukotrienes. Higher levels of n-6 LCPUFA (arachidonic acid [AA] 20:4n-6) lead to preferential production of the pro-inflammatory 2-series prostaglandins (such as PGE2) and the four series leukotrienes (LTB4) [27, 28]. In contrast eicosanoids (PGE3 and LTB5) produced from n-3 PUFA (eicosapentanoic acid [EPA] 20:5n-3 and docosahexaenoic acid [DHA] 22:6n-3) are far less potent than oxidative derivatives of n-6 PUFA [29].

Using fresh neonatal neutrophils isolated from cord blood samples from our pregnancy intervention study

**Fig. 1** Potential avenues of influence of LCPUFA on immune development

**Fig. 2** Potential influences on APC during initial antigen presentation

[21, 22], we tested the hypothesis that maternal fish oil supplementation would alter the pattern of neonatal LTB4 and LTB5 production. The characteristics of this cohort are well described elsewhere [21, 22]. Neutrophil samples were available from 30 neonates whose mothers had received a daily dose of 4 g of fish oil (containing 3.7 g n-3 LCPUFA as 56% DHA and 27% EPA) and 34 neonates whose mothers received the same amount of olive oil for the final 18–20 weeks of pregnancy. Following stimulation with calcium ionophore, production of proinflammatory LTB4 was significantly lower in the fish oil group ( $P = 0.03$ ). There was also a trend for higher LTB5 production (with 10–30 times less inflammatory potential than LTB4 [30]) in the fish oil group, although this was not statistically significant. This confirms that the maternal diet can have effects on the propensity of neonatal neutrophils to generate inflammatory products. To date, effects on neonatal prostaglandins have not been assessed in this context, but we speculate that this may be also altered in a similar pattern, with a relative shift from PGE2 to PGE3 with maternal fish oil supplementation.

Secondly, we examined the effects of maternal fish oil supplementation on neonatal oxidative stress. Excessive oxidative stress may play a role in inflammation and tissue damage. It has been demonstrated that changes in the oxidative status can influence APC during T cell programming by altering cytokine production. Improved oxidative balance can promote

pro-Th1 signalling by APC, by enhancing IL-12 production in mice [31] and humans [32]. In contrast, adverse oxidative balance (oxidative stress and reduced glutathione) promotes CD4 T cell Th2 differentiation [31] and the downstream production of IL-4 and IL-5 which contribute to allergic inflammation. We therefore assessed the effects of fish oil supplementation on oxidative stress in our pregnancy intervention study, using F<sub>2</sub>-isoprostanes as a robust measure of lipid peroxidation. Maternal fish oil supplementation resulted in significantly lowered plasma ( $P < 0.0001$ ) F<sub>2</sub>-isoprostanes [33]. Of note, although HLA-DR expression on APC was not different between the groups, there was a significant relationship between F<sub>2</sub>-isoprostanes and APC (monocyte) MHC Class II (HLA-DR) expression ( $P = 0.007$ ), although HLA-DR expression was not different between the groups. In multiple regression analysis, 28.8% of the variance in plasma F<sub>2</sub>-isoprostanes was explained by positive relationships with n-6 AA membrane levels and HLA-DR expression and a negative relationship with n-3 EPA. This shows that maternal supplementation with fish oil can attenuate neonatal lipid peroxidation, and suggests potential effects on APC function.

Thus, as shown schematically on Fig. 2, neonatal LCPUFA status has the potential to influence both the oxidative balance and the production of inflammatory mediators in local tissues. This is relevant to immune programming as variations in the local tissue milieu have the potential to influence APC function during initially antigen encounter (as discussed above) with potential implications for subsequent patterns of immune function. While we acknowledge that it is difficult to extrapolate relationships observed in cord blood to local tissues, it is not ethically possible to do more invasive studies in humans.

#### Effects on Neonatal APC

APC function is impaired in the neonatal period [34, 35], and appear to lack the capacity to deliver important Th1 polarising signals to T-cells [35–37]. This may contribute to an increased susceptibility to infection and tolerance induction, and a propensity for the induction of Th2 responses in early life. In the context of disease propensity, a number of investigators have highlighted important differences in APC function between atopic and non-atopic adults [38–40]. However, it is not clear whether altered APC function antedates sensitisation and the onset of allergic disease, or whether functional differences arise secondary to allergic inflammation. This issue can only be addressed

by examining APC function in early life, prior to allergic sensitisation.

Effects of n-3 LCPUFA on mature APC are well documented. Increasing the content of n-3 PUFAs in cell membranes reduces the capacity of APC to present antigen to T cells by inhibiting the upregulation of MHC class II receptors, cytokine production and expression of co-stimulatory molecules [41, 42]. The first studies to explore this in neonates used animal models, and showed that DHA inhibited the IFN $\gamma$ -induced MHC class II expression on neonatal murine APC [43]. In our own studies we examined the effects of maternal fish oil supplementation in pregnancy on various aspects of APC function including Class II expression (HLR-DR), cytokine production (IL-12 and IL-6) and nitric oxide production, but did not see any differences between the neonates in the fish oil compared with the olive oil placebo group. These findings do not support our hypothesis that n-3 LCPUFA supplementation may modify neonatal APC function. This is possibly because most aspects of neonatal APC function are already reduced in the neonatal period. While it could be argued that the olive oil placebo could also have had immunomodulatory effects, there were no differences in oleic acid levels between the groups.

#### Effects on Regulatory Pathways

This is another potential pathway through which LCPUFA could mediate effects on immune function. Because the role of specialised regulatory T cells has only been recognised recently there are still no studies examining the effects of LCPUFA on these pathways. However, there are a number of potential pathways through which LCPUFA could logically exert an immune effect through actions on these cells. Firstly, because recent studies have shown that PGE2 induces T regulatory cell function (and FOXP3 gene expression) [44] it is possible that LCPUFA could have an effect through altering PGE2 associated pathways. However, if this is the case it might be expected that n-3 LCPUFA (which inhibit PGE2 production) may also inhibit T regulatory function, which would not explain the immunomodulatory effects of these fatty acids. Alternatively, LCPUFA could have effects through microbial recognition molecules (Toll-like receptors [TLR]) that are found on both T regulatory cells and APC, and are important for activation of these cells. One recent study [41] has shown that the immunomodulatory actions of n-3 LCPUFA are mediated through TLR pathways on APC. It is possible, but not yet known if these effects are also relevant on other TLR expressing cells, such as T regulatory cells.

#### Effects on Neonatal Effector T Cell Function

Effects of modifying LCPUFA composition on T cell function have been extensively studied in adults. Many studies have demonstrated that dietary n-3 PUFA supplementation in both humans [27, 45–47] and rodents [48–50] significantly reduces lymphocyte proliferation to mitogens. In vitro studies in which peripheral blood mononuclear cells (PBMC) were incubated with fatty acids, have also generally shown a decrease in T cell responses to mitogens [51–53]. To our knowledge, there are only two studies to examine these in human neonates, including our own intervention study (above) [21, 23] and an observational study which examined the relationship between cord blood fatty acid levels and immune function in a Boston cohort [54].

In our own study, we looked (a) at the effects of maternal supplementation on circulating (in vivo) T cell cytokine levels in cord blood, (b) the effects on in vitro T cell responses to specific stimuli, and (c) the relationship between fatty acid levels and T cell cytokine responses (in vivo and in vitro). Firstly, we noted that there were significantly (65%) lower circulating Th2 IL-13 cytokine responses ( $P < 0.05$ ) in the fish oil group [23]. There were no differences in the levels of other cytokine levels (including Th1 IFN $\gamma$  which was only present at very low levels). Secondly, we noted consistent trends for lower neonatal cytokine responses to all allergens tested. There was a consistent trend for all cytokines studied (IL-5, IL-13, IL-10, IFN- $\gamma$ ) to be lower in the fish oil group (although this was statistically significant only for IL-10 responses to cat allergen) [21]. Thirdly, there were statistically significant inverse relationships between the n-3 PUFA content of neonatal erythrocytes and cytokine responses [21]. Although these relationships were most evident for IFN- $\gamma$  and IL-10 responses, the same trends were seen for most other Th2 cytokines. Conversely, there were significant positive relationships between the n-6 PUFA content of neonatal erythrocytes and the cytokine responses [21]. There was also an inverse relationship between the circulating IL-13 and the DHA content of neonatal erythrocytes [23].

The Boston observation study also examined the relationship between LCPUFA levels in cell membranes and in vitro immune responses. Consistent with our findings, they found that n-3 EPA levels were associated with reduced lymphoproliferation ( $n = 192$ ) and reduced IFN $\gamma$  cytokine production ( $n = 167$ ) [54]. They also noted that n-6 levels (linoleic acid) were associated with higher Th2 IL-13 responses (to house dust mite and cockroach). However in contrast to our

findings, they noted that higher n-6 (arachidonic acid) was associated with reduced lymphoproliferation and cytokines responses [54]. This significance of these contrasting effects is not clear, but the findings collectively suggest that LCPUFA in pregnancy has effects on neonatal immune function.

We also have (as yet unpublished) preliminary data that demonstrate the intracellular effects of maternal fish oil supplementation on neonatal T cells. Isolated T cells from the fish oil group showed differential expression of protein kinase C (PKC) isoenzymes compared with the control group, specifically with lower expression of PKC-alpha ( $P < 0.05$ ) and higher expression of PKC-zeta ( $P < 0.05$ ). The significance of this in relation to functional effects on T cell cytokine production are yet to be determined.

Monounsaturated fatty acid (MUFA), oleic acid (18n-1), is also recognised to have anti-inflammatory properties although these are generally thought to be less potent than n-3 PUFA effects. In our study, described above [21], we report a significant inverse association between oleic acid and allergen-specific (IL-5, IL-10, IL-13, IFN $\gamma$ ) cytokine responses (Table 1). Mitogen or bacterial lipopolysaccharide stimulated responses were not associated with oleic acid levels. In a previous study in adults, olive oil supplementation had little effect [55] however in animals, high-level oleic acid supplementation results in inhibition of lymphoproliferation, IL-2 responses, NK cell function and expression of IL-2 receptors and adhesion molecules [56]. To our knowledge, no previous studies have examined oleic acid and neonatal immune response or allergen specific responses in adults. The effect of oleic acid (Table 1)

was still evident after adjusting for PUFA levels which may indicate a selective effect of MUFA on low level T cell responses.

In summary, we (and others) have shown that LCPUFA status (and therefore maternal diet) can influence neonatal T cell function. Monounsaturated fatty acids found in dietary olive oil may also play a role in the regulation of T cell responses and further studies are required.

#### Effects on Infant B Cell Function and Subsequent Immunoglobulin Production

To our knowledge there have not been any studies to directly assess the relationship between neonatal LCPUFA status and B cell function directly. However, there are several logical pathways of influence. Firstly, variations in PGE<sub>2</sub> production could have direct effect on B cell maturation as PGE<sub>2</sub> is known to synergise with IL-4 to promote immunoglobulin IgE-isotype switching in B cells [57]. Secondly, the documented effects on neonatal T cell cytokine production are likely to have secondary effects on B cell function during T-B cell interaction (Fig. 1). We saw indirect evidence of B cell effects in our study, with a trend for reduced allergen-specific IgE production in the fish oil group at 12 months of age [21]. Specifically, children in the fish oil group were three times less likely to have egg-specific IgE (a positive skin prick test to egg) at 1 year of age (OR 0.34; 95% CI, 0.11–1.02;  $P = 0.055$ ). Further studies are needed to determine the clinical significance of this.

**Table 1** Association (regression coefficient) between neonatal erythrocyte membrane oleic acid (18:1n-9) and cytokine responses to OVA, cat and PHA

### Relationship Between Early LCPUFA Status and Subsequent Inflammatory Disease (Allergy and Asthma)

At this stage there is only very limited data on the relationship between neonatal LCPUFA status and subsequent risk of allergic disease. Existing data derived from both observational and intervention studies are limited (largely because of small sample sizes) and not definitive at this stage.

#### Observational Studies

A number of early observational studies suggested a link between cord blood n-6:n-3 ratios and allergy risk [58, 59]. However, all of these studies were too small (less than 60 subjects) to look at clinical outcomes definitively. They also only examined cord blood LCPUFA in relation to family allergy [58] or very early outcomes [60], which are also not definitive. At the time of this review there has only been one published study to address this in a large enough population with long-term follow up [61]. This UK-based observational study ( $n = 1238$ ) examined the relationship between cord blood LCPUFA and clinical allergy outcomes at 3.5 years of age [61]. Although they found that a higher cord blood n3:n6 ratio was associated with an increased risk of eczema ( $P = 0.04$ ) and late-onset wheeze ( $P = 0.019$ ), none of these relationships was significant after adjusting for multiple comparisons [61]. They concluded that LCPUFA is unlikely to be a major determinant of allergy and asthma risk.

#### Intervention Studies

Although we examined the effects of maternal fish oil supplementation on clinical outcomes in our intervention study, the findings cannot be viewed definitely because the study was designed to assess immune function rather than clinical effects (which would have required a larger population size). At this stage there are no other published intervention studies in pregnancy that have addressed this. However, there are several larger studies in progress (in Europe and Australia) which are specifically designed to assess this and the results are awaited with great interest. In our study [21], we did note that infants in the fish oil group were consistently less likely to develop clinical features including food allergy, recurrent wheeze, persistent cough, diagnosed asthma, angioedema, or anaphylaxis, compared to the control group [21]. Although there was no difference in the frequency of atopic dermatitis

at 1 year of age, infants in the fish oil group had significantly less severe disease (OR 0.09; 95% CI, 0.01–0.94;  $P = 0.045$ ). As noted previously, sensitisation to egg was also less common in the fish oil group. Although it is not possible to make conclusions from this, this study has provided justification for the larger, long-term studies.

The only other study to examine the role of fish oil supplementation in allergy prevention was initiated in the postnatal period. The Childhood Asthma Prevention Study (CAPS) was a randomised controlled trial which separately assessed the preventive effects (a) house dust mite avoidance and (b) increasing consumption of n-3 fatty acids. They recruited pregnant women ( $n = 616$ ) whose unborn children were to be deemed to be at risk of developing asthma (affected parents). Those assigned to the dietary intervention were randomised to receive a daily supplement of tuna fish oil (500 mg oil/day) along with margarines and cooking oils rich in n-3 fatty acids; the control group received a placebo supplement plus polyunsaturated margarines and cooking oils. This intervention commenced at 6 months of age or at weaning (which ever occurred first). The children were assessed clinically at 18 months [62], 3 years [63] and 5 years [64] of age. Although the initial findings were encouraging, with a reduction in respiratory symptoms such as reduced wheeze at 18 months [62], and reduced coughing (atopic infants only) in the “active” diet group at 3 years [63], there was no reduction in the development of asthma at this age. Furthermore, despite confirmed effects on LCPUFA status during the intervention [62], at 5 years of age there was no reduction in the prevalence of asthma, wheezing, atopic dermatitis, or allergic sensitisation in children who had received n-3 PUFA enriched diets [64]. They concluded that fish oil supplementation at this age had no place in preventing sensitisation, asthma or other allergic disease [64].

It is probable that if LCPUFA have clinical relevant effects, that these are more likely at a younger age before immune responses and clinical phenotype is established. We and others have shown that immunological abnormalities precede the development of allergic disease and are frequently evident at birth or in the first months of life [65–68]. This may also explain why intervention studies in later childhood to reduce symptoms in established asthma have only shown weakly beneficial effects [69] or had no effect [70]. As indicated previously, there are currently a number of other studies (still on going) that will assess the effects of earlier supplementation (from birth or in pregnancy) with higher doses of n-3 PUFA.

## Summary and Conclusions

There is now evidence that the patterns of LCPUFA exposure in pregnancy can influence aspects of fetal immune function in ways that are consistent with the immunological properties of these nutrients in more mature individuals. Namely, we and others have seen that higher levels of n-3 LCPUFA are associated with reduction in neonatal oxidative stress, reduced production of inflammatory leukotrienes (LTB<sub>4</sub>) and altered T cell function. Although we did not see any significant differences in neonatal APC function with maternal fish oil supplementation, we did see LCPUFA associated variations in APC MHC class II expression. This could be consistent with animal studies demonstrating reduced neonatal APC class II expression with n-3 LCPUFA supplementation *in vitro*. The inverse correlations between n-3 LCPUFA levels and neonatal T cell cytokine production, are also consistent with adult studies showing reduction in T cell cytokine production with fish oil supplementation. We have also provided preliminary evidence that maternal fish oil supplementation alters intracellular signalling pathways in neonatal T cells. These findings clearly illustrate that LCPUFA can influence perinatal immune programming at a number of different stages in this complex process (as summarised on Fig. 1). There is still a need to explore the potential effects of LCPUFA in regulatory pathways.

At this stage the relevance of these effects in the prevention of disease is unclear. Although there have been no effects of postnatal fish oil supplementation (from 6 months of age) for allergy prevention, preliminary studies suggest possible merits in pregnancy and there are ongoing studies to address this more definitively. There is also a need to examine the role of early LCPUFA status in the risk and modulation of autoimmune disease, although prevention studies are more difficult because these conditions occur at much lower prevalence than allergic disease.

In one intervention study the use of cod liver oil during the first year of life was associated with lower risk of childhood-onset type 1 diabetes [71]. This is also of growing interest given the parallel rise in autoimmunity and the reported benefits of n-3 LCPUFA in established autoimmune inflammation.

In conclusion, epidemiologic associations and biological properties of LCPUFA have provided a compelling case for investigating the effects of these dietary nutrients on immune development. Although we have now provided evidence of the immunomodulatory effects in this early period, it is still not clear what role dietary changes have in the rising rates of immune

diseases. While this issue may remain difficult to determine, the results of ongoing larger intervention studies will be of great importance in determining the role of fish oil supplementation in pregnancy on disease prevention.

# Membrane Fatty Acids as Pacemakers of Animal Metabolism

A. J. Hulbert

Received: 31 January 2007 / Accepted: 30 March 2007 / Published online: 27 April 2007  
© AOCs 2007

**Abstract** The recent discovery that the fatty acid composition of tissue phospholipids varies in a systematic manner among species has led to the proposal that membrane fatty acid composition is an important determinant of the metabolic rate characteristic for each species. Endotherms (mammals and birds) have a basal metabolic rate (BMR) that is several times that of ectotherms and have more polyunsaturated membranes. In both birds and mammals, as species size increases there is a decrease in mass-specific BMR and a decrease in membrane polyunsaturation. Membrane-associated processes are significant components of BMR and important membrane proteins operate at much faster rates in species with high BMR than in those with low BMR. A series of “species-crossover” experiments show that the rate of this molecular activity is largely due to the nature of the membrane bilayer surrounding these membrane proteins such that polyunsaturated membranes are associated with fast membrane-associated processes. It is suggested that this influence is due to the physical properties that such polyunsaturated membranes possess. This has been called the membrane pacemaker theory of metabolism and provides a framework to understand factors such as the influence of diet on metabolism. It is noted that in the rat membrane fatty acid composition is a regulated parameter being more influenced by the balance between n-3 and n-6 polyunsaturates in the diet than it is by general diet content of saturated, monounsaturated and total polyunsaturated fats.

## Introduction

The idea that “for many problems there is an animal on which it can be most conveniently studied” has been called ‘The August Krogh Principle’ after its first clear exponent [1] and nowadays this idea, also described by the concept of ‘model species’, permeates much biological investigation. There are many examples of such species. The most obvious modern ones being *Caenorhabditis elegans*, *Drosophila melanogaster*, *Mus musculus* and *Rattus norvegicus*. As well as being a Nobel laureate, August Krogh was one of the originators of zoo-physiology (now known as comparative physiology and biochemistry) and provided considerable insight into how living systems work by studying a wide range of different animal species [2]. Besides examining the biology of particular individual species, much insight was obtained by looking at the differences between species. Such a comparative perspective has recently yielded considerable insight into the influence of membrane lipid composition on the rate of animal metabolism. Specifically, it has become apparent that the fatty acid composition of membrane bilayers varies in a systematic manner among species. Furthermore, this variation is an important determinant of the pace of membrane-associated processes and, in turn, the metabolic rate of cells, tissues and consequently the whole organism. The concept that the fatty acid composition of membranes is an important determinant of the metabolic rate characteristic for each species has been called the “membrane pacemaker” theory of metabolism [3, 4] and is the subject matter of this contribution.

## Metabolic Rates of Different Animals

When comparing the rate of metabolism among species, it is normal to use the metabolic rate measured under a set of standard conditions. In endotherms (mammals and birds), this is normally the basal metabolic rate (BMR), which is the rate of metabolism of a fasting adult, during a state of rest in a thermoneutral environment. The BMR does not include the cost of growing, moving, thermoregulating or processing a meal and thus represents the minimal ‘cost of living’ for an endotherm. In ectotherms (i.e. most other animal species apart from mammals and birds), because body temperature is determined by environmental temperature, the temperature of measurement (and thus body temperature) needs to be also specified. For ectotherms this minimal ‘cost of living’ is called the standard metabolic rate (SMR—however, for convenience I will use BMR for both endotherms and ectotherms in the remainder of this contribution). When the BMR of endotherms is compared to the SMR of similar-sized ectotherms at the same body temperature, it is observed the minimal ‘‘cost of living’’ is much (7–10 times) greater in endotherms than in ectotherms [5, 6].

Within each of these groups, it was observed long ago that as the species increase in size the speed of their metabolism per unit mass decreases. Larger species obviously require more energy to live than smaller species, but metabolic rate does not increase in direct proportion to body mass. This is largely because of geometrical constraints. For every doubling of size, the surface area of an object increases by only 59% and not 100% (i.e. surface area is related to  $\text{mass}^{0.67}$ ). Basal metabolism similarly scales allometrically with body mass of a species and depending on the study is reported to increase by only 59–69% with every doubling of body mass, i.e. BMR is proportional to  $\text{mass}^{0.67-0.76}$  [7, 8]. The constraints on metabolic rate imposed by surface limitations are made especially obvious by the calculation that if a mouse-sized mammal increased in size to that of a horse without a change in its mass-specific BMR, then this horse-sized mouse would need a surface temperature of  $\sim 100^\circ\text{C}$  to rid itself of its resting heat production [5]. If mammals of different sizes are to maintain essentially the same body temperature, then metabolic rate must be modulated accordingly. The mass-specific BMR of a 10-g shrew is approximately 100-times that of 3,800-kg elephant, and approximately 30-times that of a 70-kg human. In mammals, for every doubling of body mass there is 15–20% decrease in mass-specific BMR (i.e. mass-specific BMR is proportional to  $\text{mass}^{-0.24}$ – $\text{mass}^{-0.33}$ ). The same modulation of BMR with changes in body size is also observed in birds, which evolved endothermy independently to mammals.

Although part of these substantial differences in BMR between (1) endotherms and ectotherms, and (2) between species that differ in body size can be explained by differences in the size of important internal organs and tissues, much of the explanation is related to systematic differences in the rate of cellular metabolism (see reference [4] for a more detailed discussion). It is the purpose of this presentation to briefly examine the evidence that the evolutionary modulator of cellular metabolic rate of different species is the fatty acid composition of cellular membranes.

## Membrane-Associated Processes Are Important Components of BMR

An interesting finding over the last couple of decades has been that, while the relative contribution of various cellular processes differs between cell types, membrane-associated processes are significant components of the resting metabolism of all cells. The data is most complete for rats, in which it has been estimated (when both the size and metabolic activity of various tissues have been collated) that of the oxygen consumed by a rat during BMR, 15% is non-mitochondrial oxygen consumption, 20% is consumption by mitochondria associated with proton leak (i.e. not due to ATP production) and 65% is used for mitochondrial ATP production. The main processes that consume energy in the form of ATP are (1) activity of the  $\text{Na}^+$  pump ( $\sim 25\%$  of total oxygen consumed during BMR), (2) protein synthesis ( $\sim 18\%$ ), (3)  $\text{Ca}^{2+}$  pump activity ( $\sim 5\%$ ), (4) muscle contraction ( $\sim 5\%$ ), (5) gluconeogenesis ( $\sim 7\%$ ) and (6) all remaining processes ( $\sim 5\%$ ) [9]. Thus the maintenance of two trans-membrane ion gradients (namely, the  $\text{Na}^+$  gradient across the plasmalemma, and the  $\text{H}^+$  gradient across the inner mitochondrial membrane) are together responsible for almost half of the energy consumption associated with BMR in mammals [9].

Another interesting finding has been that although overall cellular metabolic rate decreases in a systematic manner with increasing body mass in mammals, the relative contribution of various subcellular processes remains relatively constant. For example, when the respiration rate of isolated hepatocytes from eight mammalian species, ranging in size from mice to horses, were compared, the relative contribution of mitochondrial ATP production, mitochondrial proton leak and non-mitochondrial oxygen consumption to total hepatocyte respiration did not change with body mass even though total hepatocyte respiration decreased by 13% for every doubling of body mass (i.e. it was proportional to  $\text{mass}^{-0.20}$ ) [10]. The relative contribution of these processes to hepatocyte respiration is essentially the same in a mammal and a reptile (of the same size

and body temperature) even though there is a fourfold difference in the total respiration rate of hepatocytes from these species [11]. Similarly, it is estimated that the activity of the  $\text{Na}^+$  pump is a relatively constant proportion of tissue metabolic rate of liver and kidney even though tissue respiration varies significantly, both in mammals ranging in size from mice to cattle [12] and in a comparison of endotherms and ectotherms of the same size and body temperature [13]. The conclusion from these and other studies is that metabolism appears to be a series of linked processes, and that when BMR varies between species all subcellular processes that constitute metabolic activity seem to vary in unison (see [4]).

The maintenance of key ion gradients across membranes is a significant energetic cost of living. Two have been particularly studied in a variety of species. They are (1) the plasmalemmal  $\text{Na}^+$  gradient and (2) the  $\text{H}^+$  gradient across the mitochondrial inner membrane. Both of these gradients can be regarded as a means of storing energy for maintaining other functions. For example, the trans-plasmalemmal  $\text{Na}^+$  gradient is the source of energy for action potentials in excitable tissues, as well as the source of energy for cellular volume regulation, cellular pH regulation and cellular homeostasis for other ions and the active uptake of other molecules. The relative energy requirements for its maintenance varies between cell types, varying from about 60% of total cellular metabolic in nerves and kidney tubule epithelial cells to about 10% of total metabolic rate of liver cells [14], averaging out at about 25% of the BMR of the whole animal [9]. The homeostatic maintenance of a low intracellular  $\text{Na}^+$  concentration is due to a steady state where the extrusion of  $\text{Na}^+$  from the cell (by the membrane-associated  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase) equals the sum of “leaks” of  $\text{Na}^+$  into the cell. Cells of endotherms and ectotherms maintain essentially the same intracellular  $\text{Na}^+$  concentration but the cells of endothermic vertebrates (mammals and birds) are several times leakier to  $\text{Na}^+$  than are the cells of the ectothermic vertebrates (reptiles, amphibian, fish) and the cellular oxygen consumption devoted to providing ATP for operating the  $\text{Na}^+$  pump are consequently much greater in the endotherms [13, 15]. The greater extrusion of  $\text{Na}^+$  from the endotherm cells is not associated with a greater pump concentration per cell but is instead associated with a faster turnover rate for each individual  $\text{Na}^+$  pump in the endotherm cell compared to the ectotherm. For example, when measured *in vitro* at 37 °C, the molecular activity of the  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase isolated from kidney cells of the rat is about 8,000  $\text{ATP min}^{-1}$  compared to about 2,000  $\text{ATP min}^{-1}$  for kidney  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase from the similar-sized toad [16]. Essentially the same differences were also observed for the brain from these two species that differ dramatically in their BMR. Just as the plasma membrane is

leakier in cells of endotherms compared to those of ectotherms, so is the mitochondrial inner membrane of endotherms leakier to protons compared to similar-sized ectotherms [11, 17].

### Membrane Pacemaker Theory of Metabolism

Early analysis of the underlying basis of this variation in the speed of metabolism among species (described above) dismissed species-variation in chemical composition of cells as an explanation (see p. 191 of ref. 7). However, variation in the fatty acid composition of cellular membranes was not considered in that analysis. The first indication that different membrane fatty acid composition might be associated with the variation in metabolic rate among animal species comes from the observation, by Gudbjarnason and colleagues, of a strong positive relationship between the docosahexaenoic acid (DHA) content of cardiac phospholipids and the heart rate of mammals ranging in size from mice to whales [18]. As resting heart rate of a species is a correlate of its mass-specific BMR this was the first demonstration that mammals with fast BMR differed in their membrane composition to those with a slower BMR. It was later realised that this relationship was not restricted to cardiac phospholipids but was also observed in the phospholipids from several other important metabolic tissues, notably liver, kidney, and skeletal muscle [19]. In most tissues, the phospholipids (and thus membrane bilayers) of small mammals have a high DHA content compared to larger mammal species [19, 20]. This is not true for brain phospholipids which have a high DHA content irrespective of the size of the mammal species. Possible reasons for this will be discussed later.

The association of a high DHA content of membranes with a fast BMR is not restricted to mammals of different body size but seems to be a more general phenomenon. It is also observed in birds where the DHA content of phospholipids also decreases with increasing body size, in skeletal muscle [21], heart [22] as well as in other tissues such as liver and kidney but not brain (Hulbert, unpublished observations). It is also observed in the comparison of liver and kidney phospholipids from similar-sized mammals and reptiles with their substantial difference in BMR [23].

The DHA content of tissue phospholipids decreases with increasing body size in mammals and birds, however there is no change in the total content of all unsaturated fatty acids (UFA) in tissue phospholipids with body size [20, 21]. This lack of change in total UFA with body size is due compensatory changes in other fatty acid classes. For example, in phospholipids from both skeletal muscle and kidney of mammals there is an increase in monounsatu-

rated fatty acids (MUFA) with body size, while in heart phospholipids of mammals there is an increase in the omega-6 polyunsaturated fatty acids (n-6 PUFA) with body size [20]. The differences described above for the fatty acid composition of total tissue phospholipids appear to be general for subcellular membranes as they have also been observed liver mitochondria from mammals [24] and birds [25] and reptiles [11, 17] as well as for microsomes from mammals and birds (e.g. [26]). As an example of the general trends of changes membrane fatty acid composition with body size, the data for skeletal muscle phospholipids in mammals and birds is shown in Fig. 1.

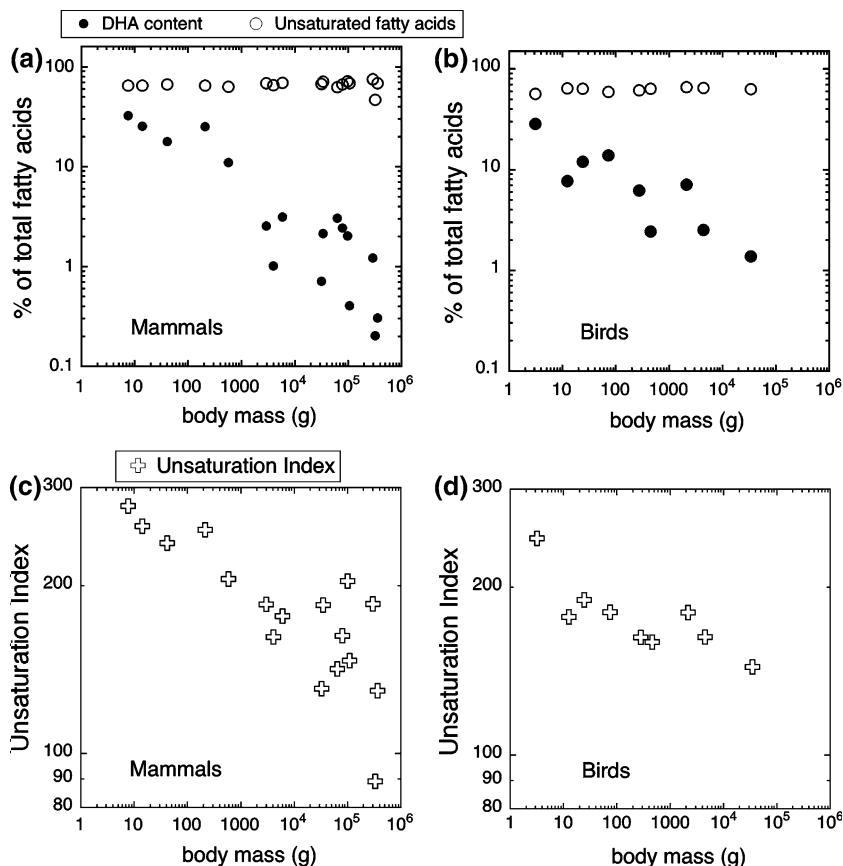

The general conclusion that emerges from these studies is that although there is essentially no difference in the percentage of UFA in cellular membranes of species that dramatically differ in their BMR, it is consistently observed that species with high BMR have a significantly greater density of double-bonded carbons ( $-C=C-$ ) in their cellular membrane bilayers than those species with lower BMR.

In the 1990s, the observation of a consistent pattern of membrane fatty acid composition associated with BMR in both the ectotherm–endotherm comparison and the comparison of different-sized mammals led to a hypothesis, described as the “membrane pacemaker” theory of

metabolism [3, 4]. It can be summarised by the following postulates:

1. Variation in BMR among species is associated with differences in both the size of metabolically active tissues and in the cellular metabolic rate of these tissues.
2. Membrane-associated processes are significant and substantial components of the resting metabolic rate of cells.
3. When BMR varies among species, all activities that make up this metabolic rate seem to vary in unison.
4. Species with high mass-specific BMR have membranes that have a higher degree of polyunsaturation than species with low BMR.
5. That DHA is an important (but not the sole) contributor to this high degree of membrane polyunsaturation.
6. That highly polyunsaturated membranes have physical properties that result in a faster molecular activity of membrane proteins.
7. Which, in turn, results in higher rates of membrane-associated activities, a faster rate of cellular metabolism, a faster rate of tissue metabolism and consequently a high BMR of the whole organism.

**Fig. 1** The relationship between body size of species and fatty acid composition of skeletal muscle phospholipids from mammals (graphs a, c) and birds (graphs b, d). Top two graphs (a, b) show total unsaturated fatty acids and docosahexaenoic acid (DHA) content as a percent of total fatty acids. Bottom two graphs show Unsaturation Index (= total number of double bonds per 100 fatty acids). Data for mammals are from reference [20] while those for birds are from reference [21]

As the initial development of the membrane pacemaker theory of metabolism was based on ectotherm–endotherm comparisons as well as studies of different-sized mammals, it was tested by examining of whether the same correlations observed in mammals were also present in the other vertebrate class that independently evolved endothermy; the birds. The results of the comparison of bird species ranging from 14-g zebra finches to 34-kg emus showed essentially the same body size trends as previously observed in mammals (e.g. 21, 25–27).

### Membranes Lipids and Molecular Activity of Membrane Proteins

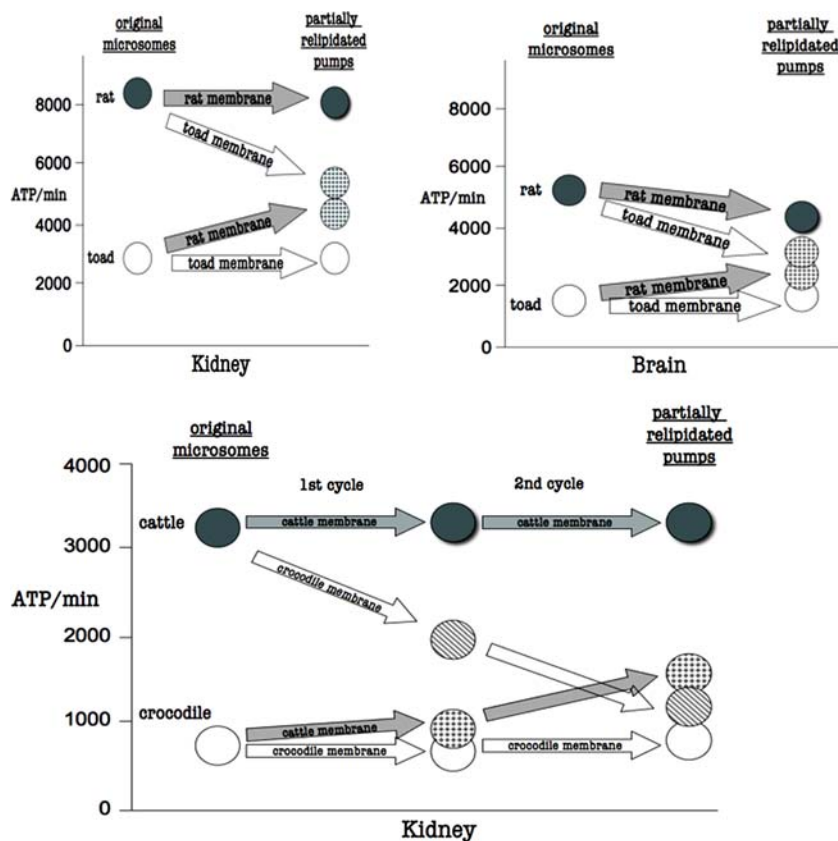

One of the main problems associated with these species-comparisons is that while they show correlations between membrane composition and metabolic rate, they do not, of course, demonstrate a ‘cause and effect’ relationship. In order, to experimentally test whether species-differences in membrane composition result in different activity of membrane proteins, a series of ‘species-crossover’ studies have been performed [28, 29]. The results of these studies are summarised in Fig. 2 and show, by partial delipidation–relipidation of the membrane-bound  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase, that the composition of the surrounding

membrane bilayer is an important determinant of the molecular activity of the sodium pump. Such experimental manipulations (e.g. [28, 29]) support the proposal that the correlation observed between membrane fatty acid composition and the molecular activity of the  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase (e.g. [30]) is one of cause and effect.

Although similar correlations between membrane composition and the molecular activity of some mitochondrial proteins from different species have been reported [31], they have not yet been tested by similar ‘species-crossover’ experiments. However, studies of cold acclimation in fish suggest a cause and effect relationship between membrane fatty acid composition and activity of membrane proteins. Mitochondrial membrane lipids extracted from cold-acclimated goldfish produce a greater reactivation of delipidated succinic dehydrogenase than do those from warm-acclimated goldfish [32]. Similarly, cold-acclimated trout increase their erythrocyte membrane polyunsaturation and sodium pump activity while the sodium pump number remains unchanged [33].

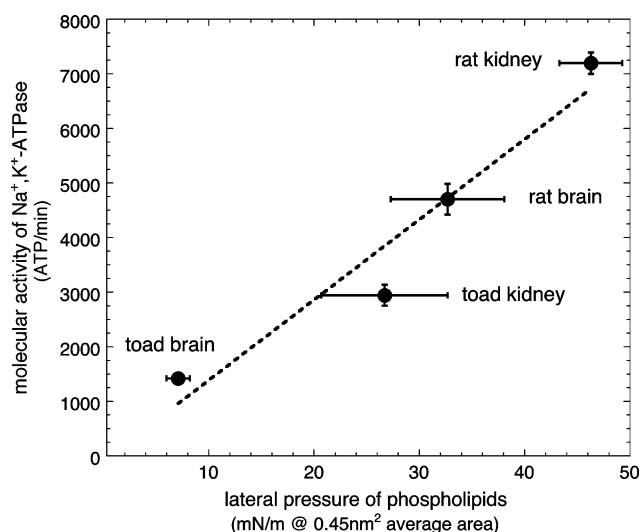

What is it about a highly polyunsaturated bilayer that results in enhanced activity of proteins in that membrane? It appears that the physical properties of such membrane lipids are important in this regard. Although there is no rotation around the *cis* double bonds of unsaturated fatty acid chains (and the double bonds themselves are rigid),

**Fig. 2** The effect of partial delipidation (by mild detergent treatment) followed by partial relipidation on the molecular activity (ATP/min) of microsomal  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase. Relipidation was either with membrane lipids from the same or the other species. The results of these partial ‘species-crossover’ experiments show that the source of the surrounding membrane lipids have a strong influence on the molecular activity of the membrane protein. The results for the rat–toad experiment are from reference [28], those for the cattle–crocodile experiment are from reference [29]

there are extremely low potential barriers to rotation around the carbon-carbon *single* bonds that occur on either side of the doubled bonded carbon units in fatty acid chains. This makes highly unsaturated PUFA molecules such as DHA very physically active and flexible molecules [34–36]. For an excellent illustration of the relative movement of DHA compared a saturated fatty acid, the reader is referred to Dr. Scott Fellers web-site (<http://persweb.wabash.edu/facstaff/fellers/>, see the bottom of the “lipid animations” page) where he has an animation of 0.5 nanoseconds (i.e. 1/100 millionth the duration of an action potential) in the life of a DHA-containing phosphatidylcholine molecule.

A rapidly moving polyunsaturated chain will exert lateral pressure on its neighbouring molecules within a membrane bilayer. When both (1) the molecular activity of  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase was measured in microsomes from different sources, and (2) the lateral pressure was measured in monolayers of phospholipids from the same sources, there were strong correlations between this physical property of the membrane lipids and the molecular activity of the individual  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase molecules [37]. The greater the lateral pressure in the membrane the greater the activity of the membrane-bound enzyme (Fig. 3). In this study, kidney and brain were used as the source of microsomes because of their very high tissue density of sodium pumps. Membrane fatty acid composition was also measured and it was

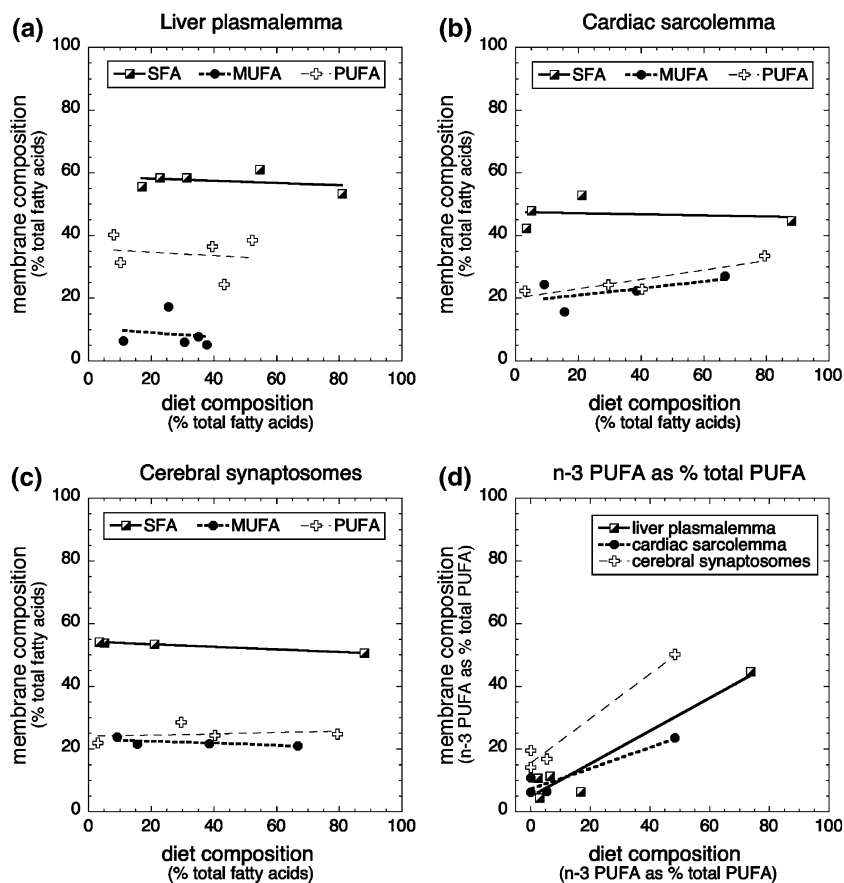

**Fig. 3** The relationship between the molecular activity (ATP/min) of microsomal  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase and the lateral surface pressure exerted by the surrounding membrane lipids. The lateral surface pressure was measured on monolayers of phospholipids extracted from the same microsomal preparation used for molecular activity measurements. Data are from reference [37]. Each data point is the average of six preparations and *error bars* represent  $\pm$ SEM. The lateral pressure is that is that measured when the average area occupied by each phospholipid molecule is 0.45 nm<sup>2</sup>. All measurements were made at 37 °C

observed that the molecular activity of  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase was more strongly correlated with the lateral pressure exerted by the membrane lipids than it was with any individual aspect of membrane fatty acid composition. It should be noted that although both kidney and brain are good sources of sodium pumps they have very different and distinctive fatty acid compositions of their phospholipids. Kidney phospholipids are very high in n-6 PUFA but very low in n-3 PUFA, while n-3 PUFA dominate in the brain.

It is appropriate to now return to possible reasons why the brain does not show the same body size trends in membrane fatty acid composition that exist in other tissues. While in the human, the concentration of PUFA (especially DHA) in brain is much higher than observed in other tissues, this is not the case for smaller species. For example in the mouse, DHA is equally common in membranes of all tissues [20]. To understand this tissue difference we need to appreciate that the first mammals were the size of mice. It was necessary to decrease mass-specific BMR (and its associated heat production) as some mammal species increased in body size over evolutionary time, in order for different-sized mammals to maintain essentially the same body temperature (as discussed earlier). The membrane pacemaker theory suggests that this was achieved by decreasing the degree of polyunsaturation of membrane lipids, which in turn resulted in a lower mass-specific BMR by slowing the activity of membrane proteins of larger mammals. Obviously, slowing the speed of membrane processes in nervous tissue such as the brain would likely be disadvantageous as it would presumably decrease the speed of behavioural response. We have suggested elsewhere [3] that this is likely the primary reason why brain phospholipids retain their high degree of polyunsaturation irrespective of the size of the species.

So far, in this contribution I have used the fatty acid composition of tissue phospholipids as a description of membrane fatty acid composition. Of course, this is a simplification of membrane composition. Polyunsaturated fatty acids are not randomly distributed within membranes, especially in the plasmalemma. Firstly, the external and cytoplasmic leaflets of the plasmalemma differ in the phospholipids headgroup composition, cholesterol content as well as fatty acid composition and this non-symmetric composition results in a transbilayer fluidity gradient regulated by unsaturated fatty acids [38, 39]. Secondly, the plasmalemma also contains lateral domains (lipid rafts/caveolae as well as non-raft domains) which differ in their lipid composition and protein distribution (for reviews see 40–42). For example, the  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase appears to be distributed primarily in the non-raft domains of the plasmalemma, at least in some cells [43, 44] and  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase activity is influenced by the transbilayer

**Fig. 4** The relationship between fatty acid composition of diet and the fatty acid composition of three different membranes in the rat. *Graph (a)* is for liver plasmalemma, *graph (b)* is for cardiac sarcolemma, and *graph (c)* is for cerebral synaptosomes. All *three graphs* show the data for percentage of saturated fatty acids (SFA), percentage of monounsaturated fatty acids (MUFA) and percentage of polyunsaturated fatty acids (PUFA). *Graph (d)* shows the relationship between dietary balance of n-3 PUFA and n-6 PUFA (expressed as percentage of total PUFA that are n-3 PUFA) and the membrane composition of all three membranes. Data sources are given in reference [61]

fluidity gradient [45–48]. Both space constraints and limited knowledge of the situation in a range of species limit consideration of this important aspect here.

### Influence of Diet on Membrane Composition and Metabolic Rate

A role for membrane polyunsaturation in the determination of metabolic rate may explain a number of observations. For example, fish-eating seals have a much higher BMR than is predicted from their body mass [49], and fish-eating seabirds also have relatively high BMR [50]. Termite-eating mammal species have a lower than predicted BMR [51]. It is tempting to speculate that the high n-3 PUFA content of fish and the low PUFA/high MUFA content of ants and termites are responsible for these BMR deviations. Other evidence that the type of fats in the diet influence metabolic rate are that the metabolic rate of rats are elevated when they are fed diets enriched with either n-6 PUFA [52] or n-3 PUFA [53]. Other studies also show that increased PUFA content of the diet increases metabolic rate of rats [54], baboons [55] and chickens [56]. Human studies have demonstrated similar enhancement of metabolic rate with elevated dietary PUFA (e.g. 57, 58).

Dietary polyunsaturated fats have also been shown to influence the pattern of and metabolic rate during torpor (hibernation) in some mammals and in such cases the influence of dietary polyunsaturates is almost certainly mediated by effects on membrane composition. In the chipmunk (*Eutamias amoenus*), mitochondrial membrane composition changes of ~20% have been recorded following manipulation of the polyunsaturated fat content of the diet [59] and increased unsaturation of dietary fats results in both extended length of torpor periods and a lower body temperature during torpor as well as a lower metabolic rate at these very low body temperatures [60].

The effects on metabolic rate are often not as large as the changes in dietary PUFA content and this is likely related to the degree of change in membrane composition following dietary changes. Membrane fatty acid composition is a regulated variable and is influenced by diet to only a limited extent. As is illustrated in Fig. 4, substantial changes in the percent content of SFA, MUFA and PUFA in the diet have a very limited influence on the total percent content of these fatty acid in membranes of the rat. Because animals can synthesise both SFA and MUFA from non-lipid sources but are incapable of de novo synthesis of either n-6 and n-3 PUFA (and are unable to interconvert these two types of PUFA), both n-6 and n-3 PUFA are

essential dietary components. As can be seen from Fig. 4, membrane composition however is much more responsive to the balance between n-6 and n-3 PUFA in the diet. Recent experiments have shown that this is also the case in the membranes of human cheek mucosal cells (Hulbert, unpublished results). The influence of diet on membrane composition (especially the balance between n-6 and n-3 PUFA) is an emerging factor that has important implications for metabolism and disease [61].

**Acknowledgments** I would like express my sincere gratitude to my colleagues (notably Dr Paul Else, Dr. Martin Brand, Dr. Patrice Couture, Dr. Ben Wu and Dr. Nigel Turner) who over the years have made significant and substantial input to ideas presented here. Much of the work by AJH cited in this contribution has been supported by grants from the Australian Research Council.

**Abstract** Healthy ageing is gaining attention in the lipid nutrition field. As *in vivo* biomarkers of healthy ageing, we have evaluated the survival, learning/memory performance, and physical potencies in rodents fed a diet supplemented with high-linoleic acid (LNA,  $\omega 6$ ) safflower oil or high- $\alpha$ -linolenic acid (ALA,  $\omega 3$ ) perilla oil for long periods. The results suggested that perilla oil with a low  $\omega 6/\omega 3$  ratio is beneficial for healthy ageing. In order to address this issue further, we determined the survival of stroke-prone SHR (SHRSP) rats fed a conventional rodent diet supplemented with 10% fat or oil. Survival was longer with  $\omega 3$ -rich oils compared with  $\omega 6$ -rich oils. However, some kinds of vegetable oils and hydrogenated oils shortened the survival of SHRSP rats to an unusual degree (ca. 40% compared with that of  $\omega 6$ -rich oil) that could not be accounted for by the fatty acid and phytosterol composition of the oils. The observed decrease in platelet counts was associated with pathological changes in the kidney and other organs. Dihydro-vitamin K1 is proposed as a likely candidate as a stroke-stimulating factor in hydrogenated oils. Thus, factors other than fatty acids ( $\omega 6/\omega 3$  balance) and phytosterols must be taken into account when fats and oils are evaluated in relation to healthy ageing.

LNA Linoleic acid

### Introduction

Caloric restriction is known to prolong the survival of rodents, and genes related to longevity have been identified [1]. However, the causes of death are variable among individuals and no simple *in vitro* markers seem to suffice as criteria for healthy ageing. In lipid nutrition, short-term and long-term dietary manipulations often result in different effects; hence long-term effects need to be evaluated when fats and oils are evaluated for their preventive effects on chronic diseases and healthy ageing.

One of difficulties in this field is that it takes  $\geq 3$  years using conventional rat strains to determine the survival times of groups fed different fats or oils. The SHRSP rat strain dies of cerebral bleeding at high frequencies particularly when salt is given, and its mean survival time is relatively short. Taking advantage of the relatively short survival of this strain, we began to estimate mean survival times of SHRSP rats fed a conventional diet supplemented with 10% fat or oil. In this review, we present an overview of the beneficial effects of oils with low  $\omega 6/\omega 3$  ratios

observed mainly in conventional rats and mice [2, 3], and on the anti-nutritional factors in some vegetable oils that have mainly been observed in SHRSP rats.

### Beneficial Effects of High-ALA Perilla Oil on Healthy Ageing of Rodents: An Overview

ALA-rich perilla oil or LNA-rich safflower oil was fed to a conventional strain of rats from weaning, mated at 11 weeks of age, and the survival was estimated for male rats ( $F_0$ ). The mean survival time of the perilla oil group was longer by about 10% compared with the safflower oil group. The male offspring ( $F_1$ ) were fed the same diet as the dams' and a brightness-discrimination learning task was imposed when their ages reached 80% of the mean survival time of the male  $F_0$  rats. The correct response ratio and memory retention were superior in the ALA-rich diet group compared with LNA-rich diet group [2]. Not only ALA-rich oil, but also fish oil diets enriched with DHA (docosahexaenoic acid,  $\omega_3$ ) lead to superior learning performance in a passive avoidance test compared with safflower oil in SHRSP rats treated with the test diets for 14 weeks [3]. Similarly in conventional male mice (ICR, Crj:CD-1), performance in the spatial learning test (Morris water-maze) was superior in the perilla oil group compared to the safflower oil group [4]. In senescence-accelerated mice (SAM P8), however, perilla oil was reported to improve learning performance in ageing but slightly shorten the survival compared with safflower oil [5]. The behavioral changes induced by dietary  $\omega_6$  and  $\omega_3$  fatty acids were associated with changes in lipid compositions, microscopic appearance (synaptic vesicle density) [6] and gene expression in the brain.

Except in the case of mutant mice (SAM), in which the site of the mutation(s) has not been identified, dietary oils with relatively low  $\omega_6/\omega_3$  ratios (e.g., perilla oil, flaxseed oil, and fish oil) were beneficial for the healthy ageing of rodents as measured by behaviors and survival rates.

### Factors that Shorten the Survival of SHRSP Rats

Perilla oil with a  $\omega_6/\omega_3$  ratio of 1/4, as well as fish oil, prolonged the survival of SHRSP rats by about 10% compared with safflower oil ( $\omega_6/\omega_3$  ratio of 20) and soybean oil ( $\omega_6/\omega_3$  ratio of ~10), suggesting that low  $\omega_6/\omega_3$  ratios of dietary oils are beneficial in this animal model as well. Canola oil (from double-low rapeseeds) with a relatively low  $\omega_6/\omega_3$  ratio (2.5) was expected to be beneficial for this rat strain, but unexpectedly it shortened the survival by ~40% with water, and by 10–20% with

1% NaCl as drinking water as compared with soybean oil [7, 8]. In these experiments, a test diet was prepared by mixing a standard diet containing 4% lipids and a fat or oil at a 9:1 ratio, and fed to male SHRSP rats from weaning at 4 weeks of age and survival was followed. The survival-shortening activity of canola oil was significant when it was diluted with soybean oil at a ratio of 1:3 (dose-dependency). Fish oil prolonged the survival in the absence of NaCl-loading but EPA (eicosapentaenoic acid ethyl ester,  $\omega_3$ ) shortened the survival with 1% NaCl-loading [9], possibly due to a decreased production of PGE<sub>2</sub> that is essential for the proper functioning of the kidney.

### The Presumed Factors Other than Fatty Acids

Soybean oil was relatively safe in this model as described above but partially hydrogenated soybean oil shortened the survival by >30% compared with soybean oil [10]. Ratnayake et al. [11, 12] added olive oil and corn oil to the group of oils with survival-shortening activity in SHRSP rats. Free fatty acid fractions from canola oil and hydrogenated soybean oil exhibited no or decreased survival-shortening activity despite little change in phytosterol composition [8], hence the presence in these oils of minor components that stimulate the onset of stroke and shorten survival was presumed.

### Phytosterols Proposed as a Part of Survival-Shortening Factor

Phytosterol was proposed as the survival-shortening factor by Ratnayake's group [12]. This proposal was based on the observations that the phytosterol contents of several vegetable oils were negatively associated with survival times, and that the addition of crystallized phytosterol shortened the survival although the amount of added phytosterol was two times greater than that of canola oil. Olive oil was exceptional in that its phytosterol content was the lowest but survival-shortening activity was the highest among the oils examined [12]. However, our data led to the proposal that factors other than phytosterols should be considered because, (a) phytosterol compositions were very similar but survival rates were much different between the high oleic type and high-linoleic type of safflower oil, and between soybean oil and hydrogenated soybean oil [13], (b) addition of five times more phytosterol was reported to be necessary to reproduce the activity of canola oil [14], and (c) a mixture of phytosterols with different structures is unlikely to crystallize and the presence of other minor components in this crystal (aggregates?) cannot be excluded.

## Pathological Changes Observed in the Tissues of SHRSP Rats Fed Canola Oil Compared With Soybean Oil

Pathological changes were observed in the kidney, bone marrow, brain and other tissues. The decreases in platelet counts, which were observed not only in rats but also in piglets fed canola oil [15, 16], were associated with kidney lesions, a decreased number of megakaryocytes in the bone marrow, and an increased number of megakaryocytes in the spleen, possibly through decreased erythropoietin [17]. The activity was partially separated using a CO<sub>2</sub>-supercritical liquid extraction method; a low-pressure extract exhibited essentially no survival-shortening activity while the residual oil fraction had high activity [17].

### Microarray Analysis of Gene Expression in SHRSP Rat Tissues

Significant differences in gene expression were detected in the tissues of the canola oil and soybean oil groups. Genes for some isoforms of K<sup>+</sup> channels were over-expressed while those for a few other K<sup>+</sup> channels were under-expressed in the liver of canola-oil group. Two to three vitamin K-related genes were over-expressed in the testis and adrenal of the canola-oil group (Table 1), suggesting that the putative factors affected vitamin K-related reactions.

### Dihydro-vitamin K1 as a Potential Stroke-Stimulating Factor in the Hydrogenated Soybean Oil

Vitamin K1 (phylloquinone) contents are relatively high in vegetable oils such as soybean oil (210 µg/100 g) and canola oil (120 µg/100 g). One of the 4 isoprenyl units of the side chain of vitamin K1 is unsaturated but is converted in many tissues of mammals into vitamin K2 (menaquinone 4) with 4 unsaturated isoprenyl units (Fig. 1). When vegetable oils are partially hydrogenated, the dihydro-form of K1 (dihydro-K1) is formed [18], which cannot be converted to K2 by animals [19, 20]. The physiological activities of K1 and K2 differ; dihydro-K1 is partially active in reducing the formation of PIVKA (protein induced by vitamin K absence) but is essentially inactive in restoring the formation of under-carboxylated osteocalcin in humans [19]. Thus, dihydro-K1 in the hydrogenated soybean and canola oils is a likely factor that accelerates bleeding tendencies, stimulates the onset of stroke and shortens the survival in SHRSP rats. Because dihydro-K1 is not a major component in common vegetable oils, the presence of substances with properties similar to those of dihydro-K1 is suspected in canola and other vegetable oils. Canola and hydrogenated soybean oil elicited common physiological effects on SHRSP rats including lesions in

the kidney and testis, decreased platelet counts, accelerated onset of stroke and shortened survival [10, 17 and unpublished observations].

### Inter-Esterified Oils between Animal Fats and High-ALA Vegetable Oils as Alternatives of Hydrogenated Vegetable Oils (*trans*-Fatty Acids)

Partial hydrogenation of vegetable oils produces isomers of *cis* and *trans*-fatty acids as well as dihydro-K1 described above. The *trans*-fatty acids have been recognized as a risk factor for coronary heart disease (CHD), although the relative risk from an increased intake of *trans*-fatty acid is relatively small (( 1.5) [21] and not always statistically significant [22]. However, partially-hydrogenated canola

**Fig. 1** Vitamin Ks and their physiological activities

and soybean oil are not safe in animal experiments; they shorten the survival of SHRSP rats compared with diets containing butter, lard and an oil prepared by inter-esterification between lard and perilla oil [23, 24]. Animal fats are safer than many kinds of vegetable oils with anti-nutritional activities as described further below.

### Cancer-Promoting Activities of Some Vegetable Oils

Another aspect to be considered is the cancer-promoting activity of some kinds of vegetable oils. We understand that an enhanced activity of the arachidonate (ARA) cascade and associated persistent inflammation are major causes for many types of cancers, and therefore oils with high  $\omega 6/\omega 3$  ratios promote and those with low ratios (perilla oil, flaxseed oil, fish oil) suppress carcinogenesis; oleate ( $\omega 9$ )-rich oils are generally weaker than LNA ( $\omega 6$ )-rich oils in promoting carcinogenesis [25]. Additional evidence that support these concepts is that many kinds of drugs that inhibit the LNA-ARA cascade suppress carcinogenesis, and that knockouts of genes related to the production of ARA-metabolites (eicosanoids) and their receptors are effective in suppressing carcinogenesis in mice.

However, the cancer-promoting activities of oils are not simply accounted for by their fatty acid compositions. For example, the relative activities of olive oil, high-LNA safflower oil and perilla oil were 4:2:1 in promoting colon carcinogenesis in rats [26]. Palm oil (palm-olein) with a fatty acid composition similar to that of olive oil was as active as high-LNA safflower oil in promoting colon carcinogenesis [27] while high-oleic safflower oil did not promote colon carcinogenesis in rats [28].

In clinical studies, the level of intake and the plasma concentration of ALA were positively associated with prostate cancer [29]. This is not consistent with the observation that the incidence of prostate cancer is higher but the intake and plasma level of ALA are lower in the USA as compared with those in Japan. Moreover, high-ALA perilla oil suppressed carcinogenesis in the prostate compared with animal fats in rats [30]. All these observations suggest that there are agents other than fatty acids present in some vegetable oils, which are associated with carcinogenesis [31].

The presumed anti-nutritional factors in some vegetable oils should not be overlooked and efforts to identify them need to be promoted.

### Conclusion

The consequences of long-term feeding must be evaluated in estimating the effects of fats and oils on healthy ageing.

Oils with relatively low  $\omega 6/\omega 3$  ratios (perilla oil, flaxseed oil, fish oil) are suggested to be beneficial for healthy ageing. The importance of putative anti-nutritional factors other than fatty acids (triacylglycerol) and phytosterols, e.g., dihydro-vitamin K1, is noted. Such factors appear to be associated with bleeding tendencies and cancer promotion, and hence with unhealthy ageing.

**Abstract** The purpose of this study was to determine whether OE treatment affects the expression of genes related to lipid metabolism under two physiological conditions: late pregnancy and mid-lactation, both characterized by lipid mobilization. Samples of periovarian and retroperitoneal adipose tissue from 21-day pregnant or 15-day lactating dams were used. The expression of LPL, FATP1, FABP4, HSL, ACC1, FAS, PEPCK, GLUT4, PDK4, SREBP1c, adiponutrin and leptin, were compared with their expression in virgin rats. In pregnant rats, FABP4, HSL, PEPCK and PDK4 were over expressed in the periovarian site compared to virgin rats, whereas adiponutrin, FAS, GLUT4 and SREBP1c were underexpressed; the retroperitoneal fat depot showed a similar pattern but ACC1 and leptin were also underexpressed. OE treatment caused a generalized decrease in gene expression in both adipose depots. In lactating dams, the gene expression profile at the periovarian depot was similar to that observed in pregnant rats. OE treatment mimicked the trend observed in pregnant rats, although the intensity of the gene expression changes was lower. After OE treatment, the retroperitoneal adipose depot showed a completely different pattern since the values were close to those of virgin rats. These results corroborate that OE effects in adipose tissue, lowering lipids and depressing their metabolism, already described under

other physiological situations, can be also found in late pregnancy and lactation.

**Keywords** Oleoyl-estrone · Gene expression · White adipose tissue · Late pregnancy · Mid-lactation

## Abbreviations

ACC1	Acetyl coA carboxylase 1
ARBP	Acidic ribosomal binding protein
FABP4	Fatty acid binding protein 4
FAS	Fatty acid synthetase
FATP1	Fatty acid transport protein 1
GLUT4	Glucose transporter 4
HSL	Hormone sensitive lipase
LPL	Lipoprotein lipase
OE	Oleoyl-estrone
PDK4	Pyruvate dehydrogenase kinase 4
PEPCK	Phospho enol pyruvate carboxy kinase
SREBP1c	Sterol regulatory element binding protein 1c
WAT	White adipose tissue

## Introduction

Oleoyl-estrone is synthesized from estrone by adipose cells [1] and released into the bloodstream. Treatment with OE leads to a decrease in food intake that is initially paralleled by a decrease in body weight. The experimental use of OE in rats cause a significant decrease in body fat, with no alteration in protein content [2, 3] consequently, it has been considered a lipostatic signal that can help regulate body fat mass [4] through the selective reduction at specific sites [5]. The mechanism of the action of OE remains yet to be

fully elucidated; however, the involvement of specific receptors other than classical oestrogen receptors has been postulated [6].

The administration of OE during the reproductive cycle provokes a pattern of body fat reduction similar to that of virgin rats [7]. Oleoyl-estrone effects can be detected both in the dam and her litter. In spite of their differential traits, physiological adaptation to pregnancy or lactation share huge metabolic pressure of energy demands that necessarily affect their lipid reserves [8, 9].

The changes elicited by OE treatment on adipose tissue are in part due to apoptosis [10], despite the lack of uniformity in the OE response in different adipose tissue sites. Induction of apoptosis coexists with changes in adipose tissue lipid metabolism [10].

The objective of the present study was to determine how OE treatment affects the expression of lipid metabolism related genes under the conditions of intense energy demands of late pregnant rats and mid-lactating dams.

## Materials and Methods

### Animals

Female virgin Wistar rats (Harlan-Interfauna, Sant Feliu de Codines, Spain) were used. A group ( $n = 6$ ) of intact animals was sacrificed and used as reference (virgin rats). The remaining stock ( $n = 24$ ) was mated with adult males until impregnation (detected by the presence of spermatozoa in daily vaginal smears). The day of impregnation was considered as day 0. The litters were limited to 10 pups immediately after delivery to limit the variability that may be derived from litter size. Animals were kept under standard conditions (12 h light cycle, 22 °C and 65% humidity) and had free access to standard chow pellet (Panlab, Barcelona, Spain) (digestible energy, 13.26 MJ kg<sup>-1</sup>) and water. All procedures were in accordance with the guidelines for the use of experimental animals established by the European Union, Spain and Catalonia, and were specifically approved by the Animal Handling and Ethics Committee of the University of Barcelona.

From days 11–21 of pregnancy, a group of six animals were given a daily intragastric gavage of 0.2 mL sunflower oil containing 10 μmol oleoyl-estrone kg<sup>-1</sup> of body weight (OED, Barcelona, Spain) (treated group). The control group ( $n = 6$ ) received a daily intragastric gavage of 0.2 mL sunflower oil during the same period (non-treated group). The remaining pregnant rats ( $n = 12$ ) were allowed to deliver normally and were randomly divided into two groups of six dams each: those in the first group received a

daily intragastric gavage (from day 1 to day 15 after delivery) of 10 μmol oleoyl-estrone kg<sup>-1</sup> (treated group); and the second group received only the vehicle (non-treated group). Each pregnant rat or dam plus its litter were placed in individual cages. Daily consumption of food and body weight, both of pregnant rats and lactating dams and of their respective offspring were measured. Pregnant rats were killed by decapitation on day 21, and lactating dams on day 15 after delivery.

### Tissue Samples

Periovarian and retroperitoneal WAT were dissected, immediately frozen in liquid nitrogen and stored at -80 °C until processed. DNA content was measured in WAT samples using a standard fluorimetric method with 3,5-diaminobenzoic acid (Sigma, MO, USA) using bovine thymus DNA as a standard [5]. Since all mammal cell nuclei contain the same amount of DNA (about 6 pg cell<sup>-1</sup>), we estimated the approximate number of cells in a given WAT depot by dividing its DNA content by the mean DNA content of a cell. The mean mass of the cells in a given WAT site was determined by dividing the weight of the tissue by the number of cells it contained [5].

### RNA Isolation

Total RNA was extracted from adipose tissue using the Tripure isolation reagent (Roche, Mannheim, Germany). RNA concentration and quality were measured by spectrophotometric analysis at 260 and 280 nm using a Nanodrop spectrophotometer (Wilmington DE, USA), RNA integrity was assessed by agarose gel electrophoresis.

### Real-Time PCR

The selected targets for Real-Time PCR were: LPL, FATP1, FABP4, HSL, ACC1, FAS, PEPCK, GLUT4, PDK4, SREBP1c, adiponutrin, leptin; ARBP was used as control gene.

Specific mRNA levels were determined by semi-quantitative real-time PCR. To disrupt the potential formation of secondary structures, 2 μg total RNA and 40 μg oligo dT primers (Roche) in 10 μL were incubated for 5 min at 70 °C and then chilled on ice. Complementary cDNA was synthesized by adding: 200 U MMLV RT (Promega, Madison WI, USA), 25 U RNAsin (Promega), 0.5 mM dNTPs (GeneCraft, Lüdinghausen, Germany) and MMLV RT buffer. Twenty-five μL of reaction mixture was incubated at 42 °C for 60 min with the cDNA product used for the subsequent PCR amplification with specific primers.

The PCR mixture (10  $\mu$ L final volume) contained ca. 8 ng cDNA, Power SYBR Green PCR Mastermix (Applied Biosystems), and 300 nM of forward and reverse primers. Taq Man primers and the probe for LPL (assay ID: Rn 00561482\_ml) were assay-on-demand (AoD) selected gene expression products (Applied Biosystems). The PCR mixture (10  $\mu$ L initial volume) contained 8 ng cDNA and 1X iQ Supermix (Bio-Rad, Hercules CA, USA), with a final concentration of 250 nM for the probe and 900 nM for each primer. The thermal conditions were: initial denaturation of cDNA (10 min at 95 °C); amplification of target cDNA (denaturation 15 s at 95 °C and 40 cycles of amplification for 1 min at 60 °C). A melting curve analysis was performed in the SYBR assay to identify the product and discard the presence of dimmers.

The real-time assay was performed using a 7900 HT instrument (Applied Biosystems, Foster City CA, USA). The expression of rat FAS, FATP1, FABP4, HSL, ACC1, PEPCK, GLUT4, PDK4, SREBP1c, adiponutrin, leptin and ARBP mRNA was analyzed using SYBR Green (Sigma, St Louis MO, USA), and LPL, using Taq Man methodology (Gene Link, Hawthorne NY, USA). The signals corresponding to ARBP mRNA were used to normalize the changes in mRNA levels for each gene.

Primers from genes analyzed by SYBR Green were designed (Primer 3 program) to be exon spanning to avoid amplification of genomic DNA. PCR products were resolved on 2% agarose gel to confirm the amplification length. Primer sequences are shown in Table 1.

#### Data Analysis

Results were calculated using the “comparative Ct method of quantification” ( $\Delta\Delta$  Ct). Each target gene was analyzed separately and normalized to the expression of the internal standard ARBP. The normalization accounts for the possible variability in RNA quantity and integrity and the different efficiency of the reverse transcription process. To determine the quantity of the target gene-specific transcripts present in treated and untreated samples, their respective Ct values were first normalized by subtracting the Ct values obtained from the Ct value of the ARBP gene ( $\Delta$  Ct = Ct target – Ct ARBP). The concentration of the gene-specific mRNA in treated and untreated samples relative to the virgin group was calculated by subtracting the normalized Ct values of the treated/untreated samples from the Ct values of the virgin group ( $\Delta\Delta$  Ct =  $\Delta$  Ct treated/untreated –  $\Delta$  Ct virgin). The relative concentration was determined by  $2^{-\Delta\Delta$  Ct} method (arbitrary units) [11]. Differences were calculated considering the virgin samples as a reference control. Statistical differences were calculated among the three groups.

#### Statistical Methods

Values for the real-time PCR analyses are expressed as the mean ( $\pm$ SEM). Data were evaluated using the unpaired Student's *t* test with Prism 4.0 software (GraphPad Software, San Diego CA, USA). Table 2 data have been analysed with an unpaired Student's *t* test and data are the mean ( $\pm$  SEM) of six animals. In both analyses, differences in *P*-values < 0.05 were considered statistically significant.

#### Results

Table 2 shows the body and adipose tissue depot weights of virgin, 21-day pregnant and 15-day lactating rats. Food intake was decreased in OE-treated groups both in pregnancy and lactation. OE-treatment decreased body weight in both pregnant and lactating versus non-treated dams; this is largely due to the marked loss of weight of white adipose tissue in the periovarian and retroperitoneal sites. In pregnant rats, these decreases were mainly the consequences of the loss of cells, which was not observed in lactating dams. In the latter, the periovarian depot showed a

Changes in cell mass and in cell number were calculated from the DNA content and the tissue weight. The results are the mean (± SEM) of six animals. Statistical differences (unpaired Student's *t* test): + = *P* < 0.05 versus virgin rats; \* = *P* < 0.05 versus Non-treated group

diminution in cell numbers while retroperitoneal WAT site increased the number of cells.

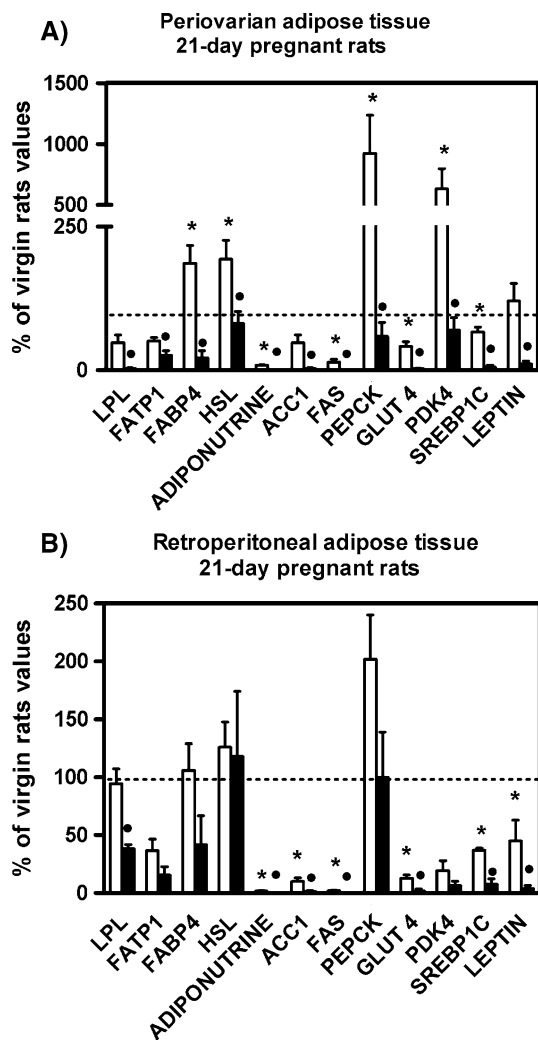

Figure 1 presents the effects of OE on the expression of different genes involved in lipid metabolism in two WAT locations of late pregnant rats. The dotted line represents the expression of these genes in virgin rats as it is used as a reference for intact rats. The effect of OE-treatment versus non-treated animals is also shown. In the periovarian site, OE induced a significant overexpression of FABP4, HSL, PEPCK and PDK4, and adiponutrin. FAS, GLUT4 and SREBP1c were underexpressed compared with virgin controls. OE treatment caused a generalized, significant decrease in the expression of all the genes analyzed. The gene expression pattern in retroperitoneal WAT was similar to that of the periovarian; in general terms, OE-treatment tended to lower gene expression.

Figure 2 shows the effect of OE-treatment on the expression of the same genes in mid-lactating rats compared with virgin controls. In lactating dams there was a general trend to under expression in periovarian WAT. The differences became statistically significant for FABP4, adiponutrin, ACC1, FAS, GLUT4, SREBP1c and leptin. In general, the effects of OE treatment were less marked than those observed in late pregnancy. Gene expression was significantly decreased for FABP4, HSL, PEPCK, PDK4, SREBP1c and leptin. The pattern of expression of retroperitoneal WAT was again different, since PEPCK was significantly over expressed in comparison with virgin controls, whereas practically all the other genes studied were under expressed; in comparison with the other tissues analysed retroperitoneal WAT gene expression tended to increase under OE treatment. The final expression levels

for most of these genes were in the same range of those of virgin rats. Nevertheless, the degree of over expression versus virgin controls was slightly lower in the retroperitoneal than in the periovarian WAT site; OE-treatment induced changes brought the expression of most of the studied genes closer to those of virgin controls.

## Discussion

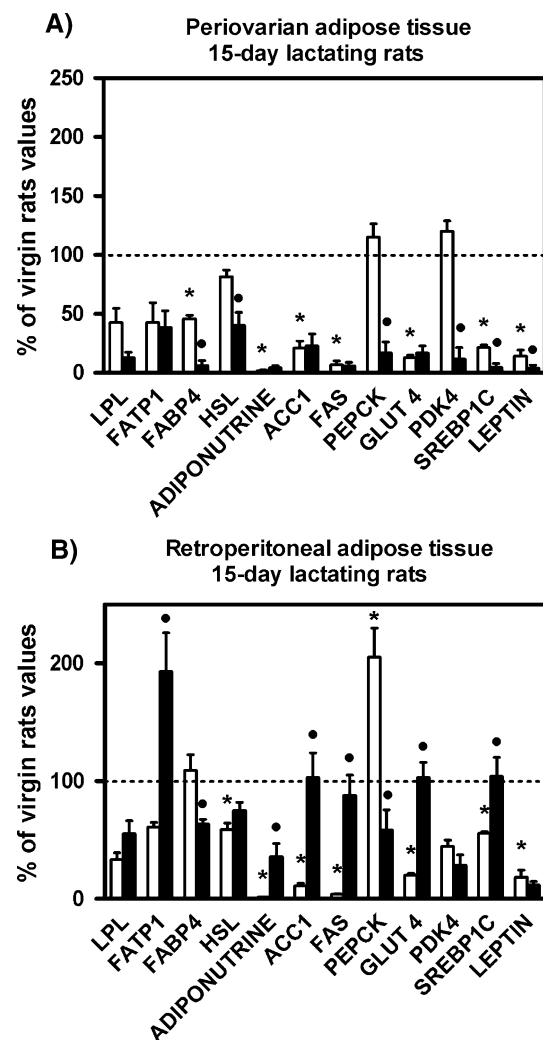

In the last third of pregnancy, the net lipolytic situation [12] may be the compounded consequence of increased expression of lipolytic (i.e., HSL) and decreased lipogenic enzymes (FAS, ACC1), thus shifting the equilibrium towards triacylglycerol mobilization. In previous studies [13], late pregnancy induced a decrease LPL and an increase HSL expression and activity in rat retroperitoneal adipose tissue. Our data reinforce these findings, although the main changes were only observed in periovarian WAT. In pregnant women, decreased GLUT4 expression has been reported [14], and can be linked to a decline in glucose uptake and further utilization during pregnancy. Thus, the increases in the PEPCK and PDK4 (a key regulatory component of the pyruvate dehydrogenase complex), the main control enzymes of the amino acid hydrocarbon skeleton catabolic pathway, imply the utilization of amino acids as fuel; as a consequence, there is an important *N* outflow that is compatible with the protein catabolic phase described in the last third of pregnancy [15]. In addition, the fatty acids released from triacylglycerols by lipases in WAT may be eventually used for the synthesis of triacylgly-

**Fig. 1** The effects of OE treatment on the expressions of different genes in periovarian (a) and retroperitoneal (b) adipose tissue of late pregnant rats are shown. cerols in the mammary gland, after their uptake by the liver and incorporation into Very Low Density Lipoproteins responsible for the late pregnancy hypertriglyceridemia [16].

The differences between the expression patterns found in these two WAT sites may be just a manifestation of their intrinsic metabolic differences since WAT site distribution deeply affects their handling of lipids, their sensitivity to hormones and their signalling protein patterns and effectiveness [17]. In late pregnancy, the low lipolytic capacity in the retroperitoneal WAT could indicate lower triacylglycerol degradation than periovarian WAT and thus

**Fig. 2** Effects of OE treatment on the expressions of different genes in periovarian (a) and retroperitoneal (b) adipose tissue of mid-lactating dams. coincide with the described storage role, ready to use, in the lactation period [18].

OE treatment induces a net reduction in the expression of key lipid metabolism enzymes in adipose tissue, especially in the periovarian site. This process is partly mediated by apoptosis [10], which justifies the changes in cellularity observed. The decreases in the expression of the lipogenic enzymes (ACC1 and FAS), and a decreased synthesis, as shown by the low SREBP1c expression [19], may contribute to the net lipolytic balance. This imbalance leads to the observed decrease in adipose tissue mass, which in turn results in lowered expression of leptin, as

indicator of fat store size [20]. The overall low gene expression levels caused by OE treatment in both tissue depots, confirms the importance of OE in the regulation of WAT lipid handling.

In mid-lactation, the high metabolic pressure exerted on the dam's own metabolism to produce the milk needed to rear the pups [9], results in a transient mobilization of subcutaneous adipose tissue lipids [21]. In consequence, the weights of individual adipose depots are close to those of virgin rats, but lower than those found in late-pregnant rats. It seems logical to assume that this may be a consequence of the low levels of expression of enzymes or transcription factors related to lipid synthesis and transport, such as ACC1, FAS, FABP4 and SREBP1c in the periovarian site. The decrease of leptin expression during lactation reflects the reduction of adipose mass [22]. The retroperitoneal pattern of expression differs from the periovarian in the potential decrease in lipolytic activity (HSL), which is accompanied by a parallel increase in the utilization of amino acid hydrocarbon skeleton mainly for glycerogenesis, as indicated by the PEPCK increase. Since the rate of fatty acids release from adipose tissue depends on the balance between lipolysis and re-esterification [23], we can postulate that in this adipose tissue depot, the shift is less lipolytic than in the periovarian, in spite of the low lipogenesis rate; this may help explain the lack of significant changes in the adipose tissue mass versus virgin rats.

The effects of OE treatment in lactation again result in marked differences between the adipose locations studied. In the periovarian depot, OE treatment tended to either maintain or decrease lipid metabolism gene expression, whereas in the retroperitoneal WAT, OE in general increased lipid metabolism and lipid content gene expression. This may be explained by the similarity in weight and cell number of this site in relation with non-treated dams. Thus, we can safely assume that retroperitoneal WAT is more sensitive to OE than periovarian. The results agree with OE inducing the recovery of normal metabolic parameters at the peak of lactation when the maximal metabolic pressure has been achieved [24]; from then on, lipids from adipose tissue use for milk production will sharply decrease [25]. The differential trend shown by these two adipose sites suggests that OE action on WAT is susceptible of adaptation to particular metabolic physiological situations.

The different metabolic and hormonal status that the physiological conditions studied represent, together with the specific hormonal or paracrine status of each adipose depot markedly influences gene expression. The effects of OE-treatment modify the expression of the genes analysed, both in pregnancy or lactation and in both tissue locations; the retroperitoneal adipose tissue of lactating rats being the most sensitive to OE-treatment. In any case, further studies

are necessary to determine the differential mechanism of action of OE in the adipose tissue locations.

**Abstract** Substantial research suggests that the *t10,c12*–18:2, but not the *c9,t11*–18:2, isomer of conjugated linoleic acid (CLA) reduces milk fat synthesis in lactating bovine and rodent species. Because fat is the major energy-yielding component in human milk, we were interested in whether this is true for women as well. Thus, the effects of *c9,t11*–18:2 and *t10,c12*–18:2 on milk fat were examined in breast-feeding women ( $n = 12$ ) in a double-blind, placebo-controlled, crossover study with latin-square design. The study was divided into six periods: baseline (3 days), three intervention periods (5 days each), and two washout periods (9 days each). During each intervention period,

women consumed 750 mg/day of a supplement containing predominantly *c9,t11*–18:2, *t10,c12*–18:2, or 18:1 (olive oil placebo). Milk was collected by complete breast expression on the final day of each period. Infant milk consumption was estimated by 24 h weighing on the penultimate day of each intervention and washout period, and maternal adiposity (% body fat) was determined at baseline using dual energy X-ray absorptiometry. Milk *c9,t11*–18:2 and *t10,c12*–18:2 concentrations were greater ( $P < 0.05$ ) during the corresponding CLA treatment periods as compared to the placebo period, providing strong evidence of subject compliance. Both CLA isomers were transferred into milk fat at relatively high efficiency; average transfer efficiency was estimated to be 23.3%. Compared to the placebo treatment, milk fat content was not reduced during either CLA treatment. Data indicate that body fatness did not modify any putative effect of isomeric CLA consumption on milk fat concentration. The evidence from this study suggests that the sensitivity of lactating women's mammary tissue to an anti-lipogenic effect of the *t10,c12*–18:2 isoform of CLA may be less than previously hypothesized.

NEFA	Non-esterified fatty acid
GC	Gas chromatograph
LBF	Low body fat
HBF	High body fat

## Introduction

Human milk provides optimal nutrition to the breast-fed infant. Although fat is the most variable component in milk, it consistently represents over 50% of the energy content of human milk [1]. Consequently, fat content is the primary determinant of the energy density of milk. To illustrate this basic concept, a longitudinal study [2] designed to document total nutrient intakes and growth patterns of breast and formula-fed infants during the first 12 months of life found that the energy density of milk and milk fat concentration are almost perfectly correlated ( $r = 0.99$ ).

Milk lipids are generally thought to be comprised of those coming directly from the maternal diet (~30%), de novo synthesis within the mammary gland (~10%), and synthesis in or mobilization from other tissues (~60%) [3]. Data are scarce regarding the relationship between the components of maternal diet and milk fat concentration in well-nourished women, and the few studies that have been conducted in this area involve small number of subjects, making it difficult to draw firm conclusions. Data suggest, however, that neither excess maternal intake of macronutrients nor moderate macro or micronutrient deficiency appreciably alters milk macronutrient composition (including total fat) [3, 4]. However, there appears to be a somewhat consistent positive relationship between maternal body fat and milk fat [2, 5], although the physiological mechanism by which these two factors are associated is not established.

Nonetheless, most research on this subject generally suggests that maternal diet does not influence milk fat percentages in women. It has been demonstrated, however, that certain forms of conjugated linoleic acids (CLA), and more specifically the *t10,c12-18:2* isomer of conjugated linoleic acid (CLA), is a potent inhibitor of milk fat synthesis in other mammals. In fact, CLA-induced milk fat reduction has been observed in bovine, ovine, and murine species [6–8]. Similarly, we have reported that consumption of a preparation consisting mainly of two CLA isomers (*c9,t11-* and *t10,c12-18:2*) reduced milk fat concentration by 23% in a group of well-nourished women [9], although more recent work from our group does not appear to support this [10]. A reduction in milk fat percentage was also observed in lactating women consuming large amounts of a *trans* fatty acid-containing margarine in comparison to when they consumed diets containing large amounts of a low *trans* fatty acid margarine [11]. In this study, *trans* fatty acid-induced milk fat reduction was observed only in the group of women with body fat percentages <30% in contrast to women with body fat percentages  $\geq 30\%$ . These data suggest that body fatness may modulate the effect of biologically active fatty acids on milk fat content.

The study reported here was designed to determine whether either of the two most common CLA isomers (*c9,t11-* and *t10,c12-18:2*) can independently result in a reduction in milk fat in women. The possible interaction between body fatness and CLA intake on milk fat was also examined. The following hypotheses were tested: (1) maternal supplementation with *t10,c12-18:2* - but not *c9,t10-18:2*-decreases the concentration of fat in human milk, and (2) high maternal body fat attenuates CLA-induced milk fat reduction.

## Experimental Procedures

### Subjects

Lactating women ( $n = 12$ ) between 2 and 24 months postpartum were recruited from the Pullman, WA-Moscow, ID area. Inclusion criteria of subjects included the following: at least 21 years of age, free from known chronic illness (e.g., heart disease, diabetes), and breast feeding their infants at least four times daily. Subjects who were pregnant or smoked were excluded, as well as those who reported that they were ill at any time during the study. All study procedures were approved by the Washington State University Institutional Review Board, and all participants provided written consent for themselves and their infants prior to enrollment.

### Study Design and Dietary Intervention

This 36 days study was designed as a randomized, double-blind, placebo-controlled, latin-square trial (a pair of replicated  $3 \times 3$  latin-squares, balanced for potential carry-over effects), consisting of a baseline period (3 days), three treatment periods (5 days each), and two washout periods (9 days each). During the baseline period, all subjects completed an initial questionnaire regarding maternal and infant health and demographic information; anthropometric measurements were also obtained at this time. Maternal and infant weights were measured using electronic scales (Seca Alpha, Model 770, Hamburg, Germany ( $\pm 0.1$  kg) and Seca Model 727, Hamburg, Germany ( $\pm 1.0$  g), respectively). Maternal height and infant length were measured using a wooden height board (Seca Measure-All<sup>TM</sup>, Hamburg, Germany ( $\pm 0.1$  cm)).

During each treatment period, subjects consumed either a placebo (750 g each; olive oil) or CLA supplement daily (750 mg each; *c9,t11-18:2* or *t10,c12-18:2*; Natural, Ltd., Hovdebygd, Norway) between 0700 and 0900 hours. No capsules were consumed during the washout periods. The

<sup>a</sup> CLA supplements consisted primarily of free fatty acids

<sup>b</sup> Olive oil supplements consisted primarily of triacylglycerides

predominant fatty acid profiles of the CLA supplements and placebo capsules are summarized in Table 1.

#### Determination of Maternal Dietary Intake

During day 4 and 5 of each intervention period, subjects were asked to weigh and record all foods and drinks consumed (excluding supplements). Selected data from dietary records were analyzed using a computerized dietary assessment program (Food Processor<sup>®</sup>, version 7.5; ESHA Research, Salem, OR, USA). The program was modified by us to include CLA contents of various foods [12, 13].

#### Determination of Body Fat

It is noteworthy that women were neither included nor excluded due to any criterion related to maternal body composition. However, because our previous work with *trans* fatty acids suggested an interaction between their consumption and body fatness on milk fat, we hypothesized that maternal body fat would interact with *t*10,*c*12–18:2 consumption to influence milk fat. We therefore measured maternal body fat as part of our study protocol. During the baseline period, maternal adiposity (% body fat) was determined using dual-energy X-ray absorptiometry (DEXA; Hologic QDR<sup>®</sup> 4500 Acclaim<sup>™</sup> Series, Bedford, MA, USA). A urine-based pregnancy test was performed (SureStep<sup>™</sup>, no. 6008; Applied Biotech, Inc., San Diego, CA, USA) to confirm non-pregnant status of each woman prior to her DEXA scan. In order to investigate the possible interaction between treatment and maternal body composition, each subject was also classified as being in a low

body fat (<30% body fat, LBF; *n* = 6) or high body fat (≥ 30% body fat, HBF; *n* = 5) group. This cut-off was used, because there was a natural separation of women into two groups at this level. It should be noted that we were unable to obtain DEXA data for one subject.

#### Collection of Milk Samples

On the final day of each intervention (day 5) and washout (day 9) period, milk samples were collected between 1700–1900 hours by complete breast expression using an electric breast pump (Model SMR-B-R, Ameda-Egnell, Inc., Cary, IL, USA). Subjects collected samples from the same breast throughout the entire study and were asked to pump 2–3 h after a previous complete breast expression, while nursing the infant on the other breast until the milk flow stopped. Milk samples were initially stored in polypropylene containers in subjects' refrigerators and transported within 2 h of collection to the laboratory where they were then stored at –70 °C.

#### Estimation of Infant Milk Consumption

Infant milk consumption was estimated by weighing the infant before and after each feeding session on day 4 of each intervention period using an electronic infant scale (Seca Model 727, Hamburg, Germany (±1.0 g)). Neither clothes nor diapers were changed between these weighings. The initial weight was subtracted from the final weight at each feeding session to determine milk consumption by the infant at that particular feeding, and values from all feeding sessions within a 24 h period were used to estimate total daily milk consumption by the infant.

#### Determination of Milk Fat Concentration and Fatty Acid Analysis

Milk lipid was extracted using a modified procedure by Ingalls et al. [14]. Briefly, milk (1 mL) was extracted using 4 mL chloroform:methanol (2:1, v/v; J. T. Baker, Phillipsburg, NJ, USA). After vigorous vortexing (2 min), samples were centrifuged at 2,500 rpm (12 min), and the chloroform layer was filtered through an anhydrous Na<sub>2</sub>SO<sub>4</sub> Pasteur pipette column. For quantitative analysis of total milk lipid, the extraction procedure was repeated and completed with a final column rinse of 200 µL chloroform:methanol (2:1, v/v). Samples were dried under nitrogen in a heated water bath and weighed. The intra and interassay coefficients of variation were 1.46 and 2.78%, respectively.

After extraction of milk fat, fatty acid methyl esters (FAME) were prepared using a method described by Christie [15]. With 2 mg lipid, 300 µg of methylheptacosanoate (C21:0; Matreya, Pleasant Gap, PA, USA) was added as an internal standard and dried under nitrogen. After adding 1 mL of diethyl ether, 20 µL methyl acetate, and 40 µL sodium methoxide (0.5 M), samples were agitated briefly to ensure thorough mixing and incubated for 15–20 min. Thirty µL of 50% oxalic acid in ether was added to stop the reaction, and the solution centrifuged for 2–5 min at 1,500 rpm to precipitate the sodium oxalate. The solvent was evaporated under nitrogen, and 1 mL hexane was added and filtered through a Pasteur pipette column filled with glass wool and silica gel. After drying completely under nitrogen, 100 µL hexane was added.

Samples were analyzed on a gas chromatograph (Hewlett-Packard 6890, Agilent Technologies, Wilmington, DE, USA) equipped with a capillary column (SP<sup>TM</sup>-2560; 100 m, 0.25 mm id with 0.2 µm film thickness; Supelco, Inc., Bellefonte, PA, USA) and helium as the carrier gas. Samples were injected in the splitless mode at an injection temperature of 255 °C. The identities of fatty acid peaks were established by comparing retention times to a mixture of 19 FAME (NuChek, Elysian, MN, USA) and a CLA mixture reference standard (Matreya, Pleasant Gap, PA, USA). Other fatty acids were not quantified in this study.

#### Determination of Milk Protein and Lactose Concentrations

Milk protein was analyzed using a modified spectrophotometric procedure for human milk described by Polberger and Lönnerdal [16]. Bovine serum albumin was used as a standard (Protein Assay Kit II, Bio-Rad, Hercules, CA, USA); samples were thawed at room temperature, diluted (1:20), and combined with 3 mL dye reagent. Absorbance was determined spectrophotometrically (595 nm) after a 5 min incubation. The intra and interassay coefficients of variation were 1.2 and 2.3%, respectively. Milk lactose was also analyzed spectrophotometrically as described by Polberger and Lönnerdal [16]. The β-galactosidase enzyme (Sigma Diagnostics<sup>®</sup>, St Louis, MO, USA) was used to cleave lactose into glucose and galactose, and milk glucose values were then used to calculate milk lactose concentration. The intra and interassay coefficients of variation were 1.44 and 2.45%, respectively.

#### Statistical Analyses

Data were analyzed as a latin-square design using standard ANOVA procedures (SAS Institute Inc., version 8.1; Cary,

NC, USA). Data analyses found no carry-over effects from one intervention period to the next. Thus, only data from the intervention periods (not washout periods) were considered in further analyses. Initial statistical models included body fat group (LBF or HBF), treatment (c9,t11–18:2, t10,c12–18:2, or placebo), and the treatment × body fat group interaction. Comparisons between means were made using Tukey-Kramer adjustments. Main effects and simple comparisons were considered significant at  $P < 0.05$ , and interactions were considered significant at  $P \leq 0.10$ .

## Results

### Subjects

All subjects ( $n = 12$ ) completed the study, and except for one woman who was not able to participate in the DEXA scan, data collection was complete for these subjects. Selected demographic information and anthropometric measurements of the participating women and their infants are shown in Table 2. On average, subjects were 31 week postpartum with mean body weight and height of 69.7 kg and 165.3 cm, respectively. There was no statistical effect of body fat group on any of these variables except percent (%) body fat and body mass index (BMI); by design LBF

LBF < 30% body fat ( $n = 6$ )

HBF ≥ 30% body fat ( $n = 5$ )

<sup>a</sup> Effect of body fat group ( $P < 0.0001$ )

<sup>b</sup> Effect of body fat group ( $P < 0.05$ )

women had less body fat and lower BMI values than HBF women ( $P < 0.0005$  and  $P < 0.05$ , respectively).

### Dietary Intake

Information regarding dietary intake of subjects during each intervention period is presented in Table 3. There was an interaction ( $P = 0.05$ ) between treatment and body fat group on total energy intake, such that compared to LBF women, the HBF women consumed more energy during the placebo period but not the CLA treatment periods. There was neither an interactive nor independent effect of body fat group on the intakes of any of the nutrient groups. Intake of polyunsaturated fatty acids was higher during the  $c9,t11-18:2$  period compared to  $t10,c12-18:2$  and placebo periods. Dietary intakes (excluding supplements) of  $c9,t11-18:2$  were similar across the treatments (data not shown) averaging  $133 \pm 10.3$  mg/day.

### Milk Composition and Infant Milk Consumption

Information regarding the effect of treatment on milk fat, protein, and lactose concentrations is shown in Table 4.

**Table 3** Daily maternal intakes of energy-yielding nutrients estimated by 2 days dietary records during each intervention period

**Table 4** Milk fat, protein, and lactose concentrations, and daily milk consumption by infants during each intervention period

Variable	Dietary treatment			SEM
	$c9,t11-18:2$	$t10,c12-18:2$	Placebo <sup>a</sup>	
Milk fat (%)	4.2	5.4	5.1	0.6
Milk protein (mg/mL)	8.0	8.4	8.2	0.4
Lactose (mg/mL)	59.8	58.8	59.3	1.2
Daily milk consumption (g/day)	734	756	716	80

Values represent means;  $n = 12$

<sup>a</sup> Olive oil

Neither a significant interaction between treatment and body fat group nor an independent effect of treatment or body fat was found for any of these variables. Similarly, there was neither an interaction nor independent effect of treatment or body fat group on infant milk consumption. No significant correlations were found between infant milk consumption and milk fat, milk lactose, or maternal body fat.

### Milk Fatty Acids

Predominant milk fatty acid profiles during each intervention period are presented in Table 5. Four of the fatty acids investigated revealed treatment by body fat interactions ( $P \leq 0.10$ ); these were 14:1, 15:0, 16:1 and 17:0. High body fat (HBF) women, but not LBF women, had higher concentrations of 14:1, 15:0 and 17:0 in their milk during the  $t10,c12-18:2$  period compared to the placebo ( $P < 0.05$ ). Low body fat (LBF) women, but not HBF women, had higher levels of 16:1 in their milk during the  $c9,t11-18:2$  period compared to  $t10,c12-18:2$  period ( $P < 0.05$ ). High body fat women had higher levels of 16:1 during both the  $c9,t11-18:2$  and  $t10,c12-18:2$  periods compared to the placebo ( $P < 0.05$ ). No independent effect of body fat was found for any fatty acid.

As expected, an independent effect of treatment was found for concentrations of both  $c9,t11-18:2$  and  $t10,c12-18:2$ . The concentration of  $t10,c12-18:2$  was higher during the  $t10,c12-18:2$  period compared to the  $c9,t11-18:2$  and placebo periods. Milk  $c9,t11-18:2$  concentration was higher during the  $c9,t11-18:2$  period compared to the other two periods.

### Discussion

The fundamental objective of this study was to determine whether either of the two most common CLA isomers

(*c*9,*t*11- or *t*10,*c*12–18:2) can independently result in a reduction in milk fat in women. The possible modulatory role of body fatness on CLA-induced milk fat response was also examined. Like our previous work [9], the current

study used a relatively powerful latin-square design balanced for carry-over effects in which each study subject served as her own control. However, in contrast to our previous work [9] the results from the current study did not suggest a reduction in milk fat in women supplemented with CLA regardless of the isomer consumed. Further, stratifying the study population into high and low body fat groups did not show a modulating effect of maternal body composition on CLA-induced milk fat depression. These data have therefore led us to reject both of our initial hypotheses, at least as they apply to healthy, lactating women of average body fat content like those who participated in this study.

Daily infant milk consumption and concentrations of milk fat, protein, and lactose were all within normal ranges, suggesting the subjects included in the study were representatives of a population of healthy, well-nourished lactating women [17–19]. However, milk fat percentage during the placebo period (5.1%) was somewhat higher than average milk fat concentration (3.0–4.1%) typically observed by others [2, 4] as well as our laboratory [9]. The physiologic and molecular regulators of milk fat in human milk are not well understood, but it is possible that CLA might only cause milk fat depression in women who inherently produce milk of lower fat content. Future studies might be designed to specifically enroll two groups of women: those whose milk fat is generally low (e.g., <3.5%) and those whose milk fat is generally high (e.g., >4%). This approach would require investigators to obtain several samples of appropriately collected milk from women prior to determining subject eligibility.

Of particular interest to us at the present time is the considerable variability of mean milk fat concentrations across studies completed by our own research group especially that of Masters et al. [9] as very similar collection methods were used in all of them. As previously described, body fatness is known to be positively associated with milk fat concentration [2, 5]. It is possible that differences in maternal adiposity among studies might contribute to differences we have seen in average milk fat concentrations in these studies. Although there were no appreciable differences in body fatness based on BMI values between the present study and that reported by Masters et al. [9], maternal body fat was not measured via DEXA in the previous study. Because BMI is not a particularly accurate measure of adiposity during the postpartum period, it is possible that maternal adiposity was in fact different between these investigations. Time postpartum, parity, and estimated dietary fat intakes were also similar between these studies.

Another possible factor that may have contributed to the difference in average milk fat concentrations between these two studies might be the relative fullness of the breast at

the time the milk was sampled. Hartmann et al. [4] have shown that the lactating human mammary gland is at its minimum “volume” (i.e., lowest fullness) in the evening in contrast to maximum “volume” (highest fullness) upon the first feeding bout in the morning. Accordingly, Hartmann et al. [4] concluded that minimum milk fat content will consequently occur at the highest mammary fullness, and maximum milk fat content will occur at the lowest mammary fullness. Thus, controlling for breast fullness is essential in studies of milk fat regulation. The effect of breast fullness at the time of milk sampling on milk fat concentration is, however, an unlikely explanation for the difference in milk fat observed in these two studies. This is because the women were advised similarly in both studies to collect the milk sample 2–3 h after a previous complete breast expression and to make sure that the breast was as empty as possible prior to cessation of milk collection. In summary, it is not evident to us why the average fat percentage was so much higher in the current study compared to that reported by Masters et al. [9] who studied the effect of CLA (mixture) supplementation on human milk fat. Indeed, understanding the physiologic mechanisms driving the relatively high inter-individual variation in human milk fat remains a fertile area of study and is deserving of more rigorous investigation.

It is also noteworthy that average milk volume was higher in the current study compared to that reported by Masters et al. [9] (735 g/day vs. 420 g/day, respectively). The reason for higher estimated milk volume in the present study could theoretically be due in part to more complete expression of milk; however, this would have consequently resulted in a relatively lower milk fat concentration which was not what we observed. Moreover, we had no qualitative indication of difficulty with milk pumping procedures in either study, and therefore the reason underlying this discrepancy remains unsolved.

Although comparable doses of  $t10,c12-18:2$  and  $c9,t11-18:2$  were used as treatments in the current study and that by Masters et al. [9], the total amount of CLA consumed was approximately 50% less in the current study. Thus, another explanation for the disparate findings of an effect (or lack thereof) of CLA on milk fat is that neither isomer supplied alone at this level produces a reduction in milk fat, but a combination of the two doses is required. Nonetheless, there is evidence both from lactating mice and cows that  $t10,c12-18:2$  inhibits milk fat synthesis, whereas the  $c9,t11-18:2$  form of CLA does not [9, 20]. In fact, the relationship between the dose of postruminally infused  $t10,c12-18:2$  and milk fat reduction is very close in lactating cows over a wide dose range [21]. Similarly, Chouinard et al. [22] conducted a postruminal infusion study using a mixture of  $c9,t11-18:2$  and  $t10,c12-18:2$  (7.2 and 7.1 g/day, respectively) and found a reduction in milk

fat that was comparable to the reduction that is produced by  $t10,c12-18:2$  alone [21] suggesting that the effect of  $c9,t11-18:2$  present in the mixture was neutral with respect to an effect on milk fat.

Indeed, correlating the postruminally infused dose of  $t10,c12-18:2$  and secretion of this isomer in milk fat using data from seven studies in lactating cows produces a nearly linear relationship, where the slope term indicates the efficiency of transfer from the intestine to milk [21]. These data suggest that the transfer of  $t10,c12-18:2$  in lactating cows is linear across a wide dose range averaging approximately 22%. Similarly, others have reported that the transfer efficiency of  $t10,c12-18:2$  is typically lower than that of other CLA isomers not involved in milk fat regulation [22, 23]. These observations point toward a relatively low transfer efficiency being a characteristic of CLA isomers that exert anti-lipogenic effects. Interestingly, a reduced transfer efficiency has been observed for another milk fat inhibiting CLA ( $c10,t12-18:2$ ) also tested in postruminally-infused lactating cows [24].

For comparison, we have estimated the transfer efficiencies of the two CLA isomers examined in the current study and that of Masters et al. [9]. These calculations suggest that within each of these studies the transfer efficiencies of the two isomers were relatively similar. However, the transfer efficiency of CLA isomers in the current study was markedly higher than that of the previous study (23.3 vs. 6.4%). Interestingly, this relatively high transfer efficiency would seem to indicate that the dose and delivery of the CLA isomers, especially  $t10,c12-18:2$  form, to the mammary gland should have been sufficient to exert its anti-lipogenic effect if the sensitivity of the human secretory tissue were comparable to that observed in the lactating cow. Furthermore, because the appearance of  $t10,c12-18:2$  in milk fat expressed as a proportion of total milk fat fatty acids correlated closely with the reduction in milk fat synthesis in cows [21], one would have expected that the concentration of this fatty acid in milk fat might be used to predict milk fat reduction in lactating women as well. An alternative explanation of these data is that, compared to our previous study, the women in the present experiment may have been inherently more able to incorporate dietary fatty acids into their milk fat. Several possibilities may account for this difference (e.g., alterations in lipoprotein lipase activity), and these may have resulted in a reduced responsiveness to CLA's capacity to inhibit the uptake of preformed fatty acids into mammary epithelial cells or reduce the synthesis of de novo fatty acids within the alveolar cells. Of course, this alternative explanation remains speculative and would require further experimentation in a larger number of more heterogeneous women.

It is perplexing that the enrichment of  $\text{t}10,\text{c}12\text{--}18:2$  in milk fat in the current study (3.57 mg/g of lipid) was comparable to that reported by Masters et al. [9], yet we found no evidence of milk fat depression. In fact, if one were to use this level of  $\text{t}10,\text{c}12\text{--}18:2$  enrichment in milk fat to estimate milk fat depression in the bovine, one would predict a milk fat reduction of over 40% [22]. Because we found no reduction in milk fat in the current study, these data suggest that the women enrolled in this trial were less sensitive to the anti-lipogenic effect of CLA than are lactating cows. Species differences in sensitivity to the anti-lipogenic effect of CLA have been observed previously. For example, when mice were supplemented with relatively pure  $\text{t}10,\text{c}12\text{--}18:2$  (10 g/kg of diet), its concentration in milk fat increased to 30 mg/g of lipid, but this enrichment was associated with only 25% decrease in milk fat percentage [8]. In lactating cows, milk fat reaches its nadir (50%) already when its concentration of  $\text{t}10,\text{c}12\text{--}18:2$  is 5 mg/g of lipid [22]. We speculate that these species differences may be largely due to the fact that human milk fat is thought to be synthesized primarily from preformed fatty acids, whereas de novo fatty acids produced in the mammary alveolar cells contribute a much larger percentage of the lipid in milk from other animals such as the cow.

In conclusion, the results from this study suggest that dietary supplementation with either  $\text{c}9,\text{t}11\text{--}18:2$  or  $\text{t}10,\text{c}12\text{--}18:2$  (750 mg/day) does not reduce milk fat in healthy, breast-feeding women. These data do not support our initial hypothesis and are contrary to our previous findings [9]. There is no simple explanation for the discrepant responses between the two studies, although the total CLA doses varied and average fat content of the milk produced by the women in the present study was higher than in previous studies. It is also possible that other minor fatty acids present in the previously used CLA mixture [9] were responsible for its milk fat lowering effect, although data from a more recent dose-response study conducted in our laboratory do not support this hypothesis [10]. Nonetheless, evidence from this study points toward the possibility that the sensitivity of the lactating woman's mammary tissue to the milk fat depressing effect of the  $\text{t}10,\text{c}12$  isoform of CLA may be less than previously thought.

**Abstract** CLA has been studied for its beneficial effects on health. However, the possibility of adverse effects, such as increased oxidative stress, must also be considered. The present work aims to assess the effect of CLA supplementation on the process of lipid autoxidation, both in the presence and in absence of an antioxidant. The investigation consisted in a biological assay with 60 rats divided into six groups: C (control), CE (control + vitamin E), AE (AdvantEdge<sup>®</sup>CLA), AEE (AdvantEdge<sup>®</sup>CLA + Vitamin E), CO (CLA One<sup>®</sup>) and COE (CLA One<sup>®</sup> + vitamin E). The CLA amount was 2% of feed consumption. Animals were supplemented for 42 days. As indicators of lipid autoxidation, peroxide (IP), malondialdehyde (MDA), 8-iso-PGF<sub>2</sub><sub>α</sub> isoprostane and catalase were determined. Hepatic IP results indicated that CLA increased oxidation: values for CLA-supplemented groups, particularly group CO (84.38 ± 10.97 mequiv/kg), were higher than those of the control group (54.75 ± 9.70 mequiv/kg). In contrast, serum MDA results showed that CLA reduces oxidation both for group AE (1.8 ± 0.67 mg of MDA/l) and for group CO (2.43 ± 0.61 mg of MDA/l) as compared to the control group (3.85 ± 0.24 mg of MDA/l). Serum catalase indicated a reduction of oxidation: groups AE and CO displayed 4734.23 ± 1078.93 kU/l and 5916.06 ± 2490.71 kU/l, respectively. These values are significantly lower than those of the control group. An increase in 8-iso-PGF<sub>2</sub><sub>α</sub> in urine was observed, particularly in group AE (95.13 ± 20.26 pg/ml) as compared to the control group (69.46 ± 16.65 pg/ml). It was concluded that the influence

of CLA on lipid autoxidation is dependent on supplement type, supplement dosage and chosen indicator, including its tissue and determination methodology.

## Introduction

Conjugated linoleic acids (CLA), a group of position and geometrical isomers with conjugated double bonds of the octadecadienoic acid (C18:2), is found in small amounts in a large variety of foods, and it is estimated that there are 56 possible isomers [1, 2].

Interest for conjugated linoleic acid (CLA) arose in 1979 when researchers found antimutagenic and anticarcinogenic substances, among them CLA, in grilled meats [3, 4]. Subsequently, numerous works demonstrated other beneficial health effects of CLA, including body composition change, reduction of arteriosclerosis, prevention and treatment of type 2 diabetes mellitus, enhancement of bone mineralization, immune system modulation, and an anti-thrombogenic effect [1]. Adverse effects of CLA supplementation have also been studied, particularly regarding increased susceptibility to lipid autoxidation [5–8]. CLA can be synthesized by ruminants by the biohydrogenation of unsaturated fatty acids by bacteria present in the rumen, in such a way that the predominant isomer is *cis*-9, *trans*-11 [9, 10]. The *cis*-9, *trans*-11 CLA isomer can be produced in mammary glands by the delta 9 desaturase path. The *trans*-10, *cis*-12 isomer is also believed to be one of the isomers synthesized in the rumen of polygastric animals [11]. Thus, significant concentrations of CLA, especially *cis*-9, *trans*-11 CLA, can be found in meats, milk, and their products [12].

Numerous commercial mixtures of CLA and its isomers have been studied for their physiological effects. The *cis*-9, *trans*-11 and the *trans*-10, *cis*-12 isomers have distinct biological activities. The *trans*-10, *cis*-12 isomer is more closely related to lipid and glucose metabolism and body fat reduction [13], whereas the *cis*-9, *trans*-11 isomer is associated to antioxidant and anticarcinogenic effects [14, 15].

Although CLA physiological effects have been widely studied, some of them are not completely elucidated, and further investigation is needed, particularly concerning biological lipid oxidation [6, 7, 16].

With the aim of investigating the influence of CLA on the lipid oxidation process, many compounds with specific chemical structures that lend themselves to determination by various methods are used as biological indicators. They may result from autoxidation or from the action of enzymes (cyclooxygenases and lipoxygenases). Quantification of primary and secondary autoxidation products, such as peroxides and malondialdehyde, respectively, or products of enzymatic oxidation such as 8-isoPGF<sub>2 $\alpha$</sub>  isoprostane, has been used to assess the degree of oxidative stress in biological systems subjected to CLA supplementation [6–8]. The determination of the activity of antioxidant enzymatic systems such as catalase is also used as a parameter to evaluate biologic lipid oxidation in CLA assays [5]. In view of a possible pro-oxidant action of CLA resulting from the fact that it is a conjugated diene, there is a hypothesis that its supplementation in association with the antioxidant protection provided by vitamin E could minimize the deleterious action of CLA on the process of biological lipid oxidation. Thus, the objective of the present study is to assess the effects of conjugated linoleic acid supplementation, both in the presence and in the absence of vitamin E, on the process of lipid autoxidation in healthy growing Wistar rats.

## Materials and Methods

### Supplements

Supplements used were linoleic acid 60% Sigma (code L 1376), the conjugated linoleic acid commercial mixtures 75% AdvantEdge<sup>®</sup> CLA (EAS<sup>™</sup>, Golden, CO, USA) and 75% CLA One<sup>®</sup> Free Fatty Acid Oil 1CLA1-FFBL-KG (Pharmanutrients, Gurnee, IL, USA), and DL- $\alpha$ -tocopherol acetate Ephynal<sup>®</sup> (Roche Brazil). Fatty acid composition of the linoleic acid supplement 60% Sigma (code L 1376) and the commercial conjugated linoleic acid mixtures 75% AdvantEdge<sup>®</sup>, CLA (EAS<sup>™</sup>), and 75% CLA One<sup>®</sup> Free Fatty Acid Oil 1CLA1-FFBL-KG (Pharmanutrients), expressed in g/100 g of fatty acids, can be seen in Table 1.

### Animals and Diets

For biological assays, albino male healthy recently weaned Wistar rats were used, aged 21–23 days, with a mean weight of  $59.7 \pm 5.84$  g, from the Multidisciplinary Center for Biological Investigation, State University of Campinas. Animals remained in individual growth cages for 38 days, and in individual metabolic cages for 4 days for urine collection. They received water and feed ad libitum; temperature and humidity were kept in the ranges of  $22 \pm 1$  °C and 60–70%, respectively, and the light/dark cycle was of 12 h. This work has been approved by the Animal Experiment Ethics Commission (CEEA - IB/UNICAMP, Protocol no. 564–1). Diet was powdered AIN93G, prepared according to the American Society for Nutrition [17], with a protein concentration of 12% [18]. The diet protein concentration was changed to 12% because this is a work on dietetic manipulation, and a diet with the original protein concentration would make it more difficult to observe the differences in animal growth that might result from CLA supplementation (Table 2).

### Experimental Design

The biological assay experimental protocol was as follows. Sixty rats remained in an adaptation period for 7 days, receiving the respective diets and drinking water ad libitum. After this period, animals were randomly divided into six groups of ten animals each in order to achieve body weight homogeneity within and across groups. Experimental groups were divided as follows: group C (control) received 60% linoleic acid; group CE received linoleic acid + DL- $\alpha$ -tocopherol acetate; group AE received AdvantEdge<sup>®</sup> CLA, group AEE received AdvantEdge<sup>®</sup> CLA + DL- $\alpha$ -tocopherol acetate; group CO received CLA One<sup>®</sup> Free Fatty Acid Oil; and group COE received CLA One<sup>®</sup> Free Fatty Acid Oil + DL- $\alpha$ -tocopherol acetate. Supplement dosage was 2% of daily feed consumption, and DL-alpha-tocopherol acetate dosage was 30 mg/day. Animals were supplemented daily for 6 weeks. Body weight and food consumption were determined every 2 days. The following determinations were done: hepatic peroxide index (primary lipid autoxidation products), serum and hepatic malondialdehyde (secondary lipid autoxidation products), plasma and urine 8-iso-PGF<sub>2 $\alpha$</sub>  isoprostane, and serum catalase activity. As described above, in the last four assay days animals remained in metabolic cages for urine collection. Lipid oxidation indicators were determined for eight animals of each group, because that was the number of available metabolic cages. For blood determinations, six samples were used, as two were discarded due to hemolysis.

CLA conjugated linoleic acid

## Supplementation

Animals were supplemented by orogastric intubation with 1 mL disposable syringes and gavage needles. The amount of supplement was calculated every other day on the basis of the average feed consumption of each group, so that supplementation followed normal feed ingestion. The amount of supplement varied from 0.25 to 0.49 mL and was calculated with help of the density. Supplements were aspirated with the syringe and kept away from light till the moment of administration. For the groups receiving DL- $\alpha$ -tocopherol acetate, this product was aspirated into the syringe before linoleic acid and conjugated linoleic acid supplements, and administered with the same syringe. Rats were removed group by group from the experiment room, placed in plastic boxes, and taken to the supplementation room. This procedure was done daily during daytime and always at the same time, since rodent have nocturnal habits.

## Determination of Fatty Acid Profiles of Linoleic Acid and Conjugated Linoleic Acid Mixtures

Methylation followed the Christie method [19]. About 50 g of each sample were weighed in conic bottom graduated

**Table 2** Mean values  $\pm$  standard deviation ( $n = 10$ ) of feed consumption, weight gain and feed efficiency of experimental and control groups over the 6-week intervention period

Groups	Consumption (g)	Weight gain (g)	Feed efficiency

Values not sharing similar letter in the same column are different ( $P \leq 0.05$ ) in the Tukey test

extraction tubes. Then 2 mL of 1% methanolic sulphuric acid were added. Tubes were capped and shaken in an electric agitator for 1 min. Tubes remained in water bath for 2 h; 5 mL of sodium chloride 5% were added, followed by 1 min shaking, 5 mL of hexane were added, and tubes were again shaken for 30 s. The supernatant (hexane and methyl ester) was transferred to another extraction tube, to which 4 mL of 5% potassium bicarbonate were added. Tubes were shaken in an electric agitator for 1 min, and phase separation occurred rapidly. The new supernatant was transferred to another extraction tube containing 1 g of sodium sulphate. The hexane was evaporated with help of a nitrogen flux under water bath at 40 °C. Finally, 2 mL of hexane were added, and the solution was transferred to a chromatography vial, labeled, and stored at –20 °C. Fatty acid profile was determined by gas chromatography with a capillary silica column CP SIL 88 (0.25 mm × 0.2 µm × 100 m) and a fire ionization detector (FID). A temperature gradient with initial temperature of 70 °C was used for 4 min, followed by an increase at the rate of 13 °C/min until 175 °C; after 27 min the temperature was raised again at the rate of 4 °C/min, to 240 °C where it remained for 4 min, totaling 70 min for the whole run. Injector and detector temperatures were 250 and 300 °C, respectively. Injection was in split mode with a ratio of 50:1. The carrier gas was hydrogen with a flux of 1.8 mL/min, and pressure of 36.3 psi at the column head [20]. Results were expressed in percentage of total fatty acids. The standard adopted was CRM-164 (Commission of the European Communities, Community Bureau of Reference, Brussels, Belgium), which has certified values for 11 fatty acids; they were used to establish the correction factor for each certified fatty acid in order to transform the peak expressed in percentage of area into mass (mg/g total fatty acids).

#### Collection of Serum and Plasma from Blood and Urine of Animals for Determination of Lipid Autoxidation Indices

Blood from the animals was collected under anaesthesia (sodium pentobarbital, Hypnol 3%, 46 mg/kg), by cardiac puncture after a 12-h fast at the end of each experiment. Blood samples were collected with 10 mL syringes and gently poured, without the needle, down the walls of polyethylene tubes, without anticlotter for serum, and with anticlotter for plasma. Tubes remained in a water bath at 37 °C for 30 min, and centrifuged at 3,000 rpm for 10 min. After that, supernatant serum and plasma were separated with a pipette, and stored in polypropylene microtubes in an Ultra Low Freezer at –80 °C until analysis. Urine was collected in 25 mL graduated cylinders with 1 mL of 20% sulfuric acid, kept for a period of 24 h, filtered, and stored at –80 °C until analysis.

#### Peroxide Index (Primary Lipid Autoxidation Products)

For the determination of the peroxide index, lipids were previously extracted from the liver of each rat by the method of Bligh and Dyer [21] with some modifications due to sample peculiarities. About 1 g of sample was homogenized in 5 mL of chloroform, 10 mL of methanol, and 4 mL of water, followed by continual rotary agitation for 30 min. After this, 5 mL of chloroform and 5 mL of 1.5% sodium sulphate aqueous solution were added, and the sample was vigorously and continually shaken for 2 min. After dilution and complete separation of phases, the upper methanol layer containing water and non-lipid compounds was aspirated, and the lower chloroform layer containing total lipids was filtered in quantitative paper filter to obtain a clear solution. Immediately after lipid extraction, peroxide index determination was performed according to the official AOAC method [22], which is based on the oxidation of iodine in the presence of potassium iodide by the peroxide present in the sample, assuming that all oxidizing substances in the sample are peroxides. For the computation of the peroxide index, the amount of lipids present in the chloroform solution resulting from the lipid extraction procedure of Bligh and Dyer [21] was used.

#### Malondialdehyde, MDA (Secondary Lipid Autoxidation Products)

Determination of thiobarbituric acid reactive substances was done for the serum and liver of each animal using about 1.5 mL and 0.2 g of samples, respectively, in triplicate. The method chosen for this analysis was proposed by Sinnhuber; Yu [23], and its basic principle is the formation of a pink-red pigment composed of two molecules of thiobarbituric acid and one molecule of malondialdehyde (MDA). Its absorbance was read in visible light with a wavelength of 535 nm, using a 1% solution of 2-thiobarbituric acid for calibration; results were expressed in mg malondialdehyde per kg of sample.

#### Determination of 8-iso-PGF<sub>2α</sub> Isoprostane

Determination of 8-iso-PGF<sub>2α</sub> isoprostane in plasma and urine of the rats was done by enzyme immunoassay using a commercial kit from Cayman Chemical, catalog number 516351. The method is based in the competition between 8-iso-PGF<sub>2α</sub> isoprostane and conjugated 8-iso-PGF<sub>2α</sub> isoprostane-acetylcholinesterase (marker) by a limited number of binding sites for the specific antiserum of 8-iso-PGF<sub>2α</sub> isoprostane. Results were expressed in pg/mL of sample.

## Catalase Activity Determination

For the catalase activity determination, the methodology described by Góth [24] was used. It consists in the determination of serum catalase by the reaction with hydrogen peroxide. Determination was performed as follows: 0.2 mL of serum were incubated in a substrate solution composed of hydrogen peroxide (65  $\mu$ mol) in phosphate buffer (60 mmol/L, pH 7.4), for 1 min at 37 °C. After the incubation period, the reaction was interrupted by adding 1.0 mL of ammonium molybdate (32.4 mmol/L). Absorbance of the yellow complex formed between ammonium molybdate and hydrogen peroxide was read at 405 nm. Results were expressed in kU/L, considering that one unit of catalase decomposes, in the conditions described above, 1 mmol of hydrogen peroxide per minute.

## Statistical Analysis

Results are expressed as mean  $\pm$  SD. Data were analysed statistically by ANOVA using Statistical Analysis System [25] to test the effect of CLA mixtures and the interaction between CLA mixtures and vitamin E. The effect of supplementation time on food consumption and growth was also examined. The Tukey test was used to test the differences among groups. Differences were considered significant at  $P < 0.05$ .

## Results

With regard to feed consumption, weight gain and food efficiency, Table 1 shows that differences were found only between groups CE and AE ( $P \leq 0.05$ ). Figure 1 represents the weight gain curve and feed consumption of the rats during the period of CLA supplementation, and shows that growth was normal.

With regard to effects of CLA on lipid autoxidation, it can be said that results obtained are in agreement with the literature, i.e., there is no consensus about the real effect of this supplement on the oxidation process of biological lipids: many of the results point to the investigation of antioxidant properties, and others to the investigation of a possible pro oxidant effect of CLA. In Table 3, the results of all lipid oxidation indicators determined in this experiment are described. There was a difference in hepatic peroxide index (IP) only between groups C and CO. Group CO did exhibit a higher IP value than group C ( $P \leq 0.05$ ), which might suggest that the CLA One<sup>®</sup> supplement had a more discernible influence on the process of biological lipid oxidation as compared with the AdvantEdge<sup>®</sup> CLA supplement, since the group of rats receiving the latter displayed a mean peroxide value similar to the control

group, and smaller than group CO. Serum malondialdehyde average values were significantly smaller in groups receiving CLA supplementation, both for CLA One<sup>®</sup> and AdvantEdge<sup>®</sup> CLA ( $P \leq 0.05$ ). Hepatic MDA values did not differ between control group ( $13.50 \pm 3.23$  mg/kg of sample) and groups receiving supplementation: AE ( $12.51 \pm 2.41$  mg/kg of sample) and CO ( $14.26 \pm 0.71$  mg/kg of sample). However, group AEE, which received CLA supplementation associated with vitamin E, exhibited significantly lower values ( $P \leq 0.05$ ). Regarding the 8-iso-PGF<sub>2 $\alpha$</sub>  isoprostane results, differences in plasma values were observed only between groups AE and COE ( $P \leq 0.05$ ). 8-iso-PGF<sub>2 $\alpha$</sub>  isoprostane values in urine for group AE were significantly higher, whereas for group CO values were significantly lower than those of the controls ( $P \leq 0.05$ ). Such results suggest that effects on the lipid autoxidation process can be different as a result of the characteristics of each supplement. Supplements used in the present research contained 79.27 and 73.08% CLA for the brands AdvantEdge<sup>®</sup> CLA e CLA One<sup>®</sup>, respectively, and the proportion between the predominant isomers *cis*-9, *trans*-11 and *trans*-10, *cis*-12 was approximately 1:1. The mean values expressing catalase activity were significantly lower ( $P \leq 0.05$ ) in the groups receiving CLA, with the exception of group CO. These findings suggest the possibility of an antioxidant effect of CLA, as this enzyme plays a major role in protecting the organism against damage of oxidative stress by means of the degradation of peroxides, which result from lipid oxidation.

## Discussion

Regarding feed consumption and weight gain of the rats during the supplementation period, it can be said that, even though differences between some of the groups were observed at certain moments, growth was normal. Feed consumption changes seen in the graph are a consequence of supplement amount correction. The administered concentration of CLA followed the feed consumption, i.e., as consumption rose, supplement quantity was raised, leading to a drop in feed consumption, because CLA, as a lipid, produced greater satiety in the rats. This occurred cyclically throughout the assay, but it is important to note that these oscillations did not compromise animal growth, as seen in the body weight curves (Fig. 1).

Regarding results on the influence of CLA on biological lipid oxidation, a point to be discussed is that PI results of a preliminary assay in our laboratory [26] represent a fairly strong indication of an increase of this indicator in groups receiving CLA supplementation, and those results were higher than in the present assay. The main objective of the previous assay was to standardize CLA supplementation

conditions. Growing male Wistar rats were supplemented for 21 days with *commercial conjugated linoleic acid mixture 75% AdvantEdge® CLA (EAS<sup>TM</sup>)* in the concentrations of 1, 2 and 4% of the daily feed consumption, having linoleic acid as a control. The concentration adopted for the present assay—2% of feed consumption—was chosen on the basis of results and operational conditions of

supplementation in the preliminary assay. As discussed above, the PI concentration in the present assay was higher. This observation might be explained by the duration of supplementation, which was greater in the present assay, coupled to the fact that peroxides are primary products of lipid oxidation, i.e., as supplementation time increases peroxide concentration diminishes due to their cleavage

into secondary products. This hypothesis can be confirmed by the results of malondialdehyde (MDA) shown in Table 3. Although there was no significant difference ( $P > 0.05$ ) between control groups and those receiving CLA without vitamin E (hepatic values), mean serum and hepatic values of malondialdehyde (MDA), a representative of secondary lipid oxidation, are higher in the present assay, in which supplementation ran for a period twice as long as the previous assay [26]. Results reported above are in agreement with works regarded as crucial for the reinvestigation of CLA effects on the lipid autoxidation process. Studies such as those by Cantwell et al. [5], Basu et al. [6] and Yamasaki et al. [7], which aimed at assessing the effect of CLA on lipid autoxidation, clearly point to the need for reinvestigating the antioxidant properties and the possible pro-oxidant effect of CLA.

The IP and MDA results of the present work are different from those reported by some research teams that studied antioxidant and pro-oxidant properties of CLA. The previously mentioned works [5–7] found MDA results that led to the conclusion that CLA acts as a pro-oxidizing agent. In a more recent work on the effect of CLA on low-density lipoprotein oxidation, Flintoff-Dye and Omaye [27] demonstrated that the four isomers under study (*cis*-9, *trans*-11; *trans*-10, *cis*-12; *trans*-9, *trans*-11; and *cis*-9, *cis*-11) promoted a significant increase in TBARS concentration in the samples.

Regarding 8-iso-PGF<sub>2α</sub> isoprostane, a product of non-enzymatic lipid oxidation and, according to the literature, the most specific biological indicator for the assessment of oxidative stress, results showed that when it was determined in the urine, AE supplement increased oxidation, whereas CO reduced it. Since the identification in the 1990s of series F prostaglandins, particularly 8-iso-PGF<sub>2α</sub> isoprostane, as fairly specific indicators of lipid autoxidation [28], many studies aimed at assessing oxidative stress by its determination in different experimental models, including humans. Works evaluating the influence of CLA on oxidative stress using series F prostaglandin determinations as indicators have been published only recently and are still scarce. Basu et al. [29], supplementing humans with abdominal obesity with CLA for one month, found urinary values of 8-iso-PGF<sub>2α</sub> isoprostane significantly higher than the group receiving placebo, and these values returned to basal levels after conclusion of CLA supplementation. In 2000, Basu et al. [6] categorically stated that CLA induces lipid peroxidation in humans after finding a significant increase of 8-iso-PGF<sub>2α</sub> isoprostane in urine, about four times higher than the basal amount, after supplementation with 4.2 g of CLA for 12 weeks.

There is an ongoing debate about the action of a specific CLA isomer in promoting a certain physiological effect, such as the case of total body fat reduction, one of the most

widely studied effects of CLA, and promoted mainly by the *trans*-10, *cis*-12 [30] isomer. There is no information, about which isomer is responsible for influencing lipid autoxidation in the studies of CLA and oxidative stress. It is believed that this influence is promoted by both predominant isomers, *cis*-9, *trans*-11 and *trans*-10, *cis*-12 [27]. In order to investigate whether the process of biological lipid oxidation is influenced by a specific isomer, Riséus et al. [31] supplemented men bearing metabolic syndrome with six capsules of 3.4 g per day of CLA isomer mixture, and the isolated isomer *trans*-10, *cis*-12 for a period of 12 weeks. The authors found urine values of 8-iso-PGF<sub>2α</sub> isoprostane 25 times higher in men receiving supplementation with a mixture of CLA than in the control group. This led to the conclusion that biological lipid oxidation is influenced by CLA, and that pure *trans*-10, *cis*-12 isomer had a more potent influence on the oxidation process. Similar results are reported in the work of Smedman et al. [32], which aimed at understanding the mechanism, by which CLA influences the oxidation process, and whether this influence is promoted by a specific CLA isomer. In a double-blind randomized study, Riséus et al. [8] supplemented obese men for a period of 12 weeks with 3 g/day of CLA mixture containing predominantly the *cis*-9, *trans*-11 isomer. Urine concentration of 8-iso-PGF<sub>2α</sub> isoprostane was 50% higher after supplementation with the CLA isomer, indicating that lipid oxidation is increased not only by isomer *trans*-10, *cis*-12 but by *cis*-9, *trans*-11 as well. Although this was not the only isomer in the mixture, it corresponded to 83% of it. Flintoff-Dye and Omaye [27] assessed the antioxidant and pro-oxidant properties of the CLA isomers *cis*-9, *trans*-11 and *trans*-10, *cis*-12 by means of the determination of LDL in human blood samples. Results indicated that both isomers influenced the lipid oxidation process in a similar way. Based on the phenomenon of hormesis, that characterizes the change in effect according to the dosage [33], the authors point out that CLA acts in a paradoxical way, in that it initially acts as a pro-oxidant (in low concentrations), then as an antioxidant (in intermediate concentrations), and finally as pro-oxidant again (in high concentrations), but they go on to conclude that, in general, CLA is a pro-oxidant agent because of the increase of oxidative stress observed in low concentrations, when an antioxidant effect would be expected.

The lower catalase activity would indicate smaller peroxide production, which in turn would indicate a lower degree of oxidative stress. In a work by Cantwell et al. [5] aiming at assessing the effect of CLA on the enzymatic system of antioxidant defense in hepatic cells of rats, it was demonstrated that CLA promoted a significant reduction of catalase activity when hepatocytes were exposed to a higher concentration (20 ppm). These results led to the conclusion that CLA could act as an antioxidant; however,

the authors point to the need of investigating long-term exposure to CLA. Catalase (EC 1.11.1.6, CAT), a tetrameric heme protein, is present in most aerobic cells, and is predominantly found in peroxisome, a cell organelle where oxidation of long-chain and very-long-chain fatty acids takes place. Peroxisome beta-oxidation results in the production of hydrogen peroxide ( $H_2O_2$ ), a catalase substrate.

The above discussion of the results can be supported by the influence of CLA on the expression of transcription factors, such as peroxisome proliferator activated receptors (PPAR), particularly PPAR  $\alpha$  and PPAR  $\gamma$ . Research works seeking to understand the action of CLA as activator or inhibitor of these nuclear receptors are somewhat conflicting, since both activation [34, 35] and inhibition [36, 37] are reported. Interpreting results of the present work on the assumption that CLA acts as a PPAR  $\alpha$  ligand, as shown by Moya-Camarena et al. [34], does not seem consistent, since the increase of PPAR  $\alpha$  expression would cause an increase in mitochondrial and peroxisome oxidation of fatty acids, and consequently an increase in  $H_2O_2$  production, leading to increased catalase activity, and this was not observed in the present research. On the other hand, looking at the same results considering the findings of Kang et al. [36] and Granlund et al. [37], who demonstrated that CLA inhibits PPAR  $\gamma$  expression, it can be said that the results of the present work are consistent. This seems to be confirmed by the work of Girnun et al. [38], which suggests that the increase in PPAR  $\gamma$  expression can increase catalase activity. Assuming that this relation is inversely proportional, a possible PPAR  $\gamma$  inhibition by CLA could lead to a decrease in catalase activity, as observed in the present research.

A further objective of this study was to assess the possibility of associating CLA administration to an antioxidant protection by means of a concomitant supplementation with DL- $\alpha$ -tocopherol acetate. It is widely accepted that supplementation with antioxidants, particularly  $\alpha$ -tocopherol, reduces oxidative stress [39], although there is some controversy. In recent years the scientific community has developed a new outlook about antioxidant supplementation, as a result of some evidence of adverse effects involving increased susceptibility to some diseases such as cancer and cardiovascular diseases. As a matter of fact, concerning cardiovascular diseases, the Dietary Guidelines of the American Heart Association say that there is no positive support for using antioxidant supplements in order to reduce the risk of cardiovascular diseases [40, 41].

There are practically no studies of CLA administered concomitantly with antioxidant protection, perhaps because there is a controversy surrounding its antioxidant properties [42, 43]. Results obtained in the present study showed that CLA supplementation concomitant with vitamin E did not

significantly reduce lipid oxidation ( $P > 0.05$ ). The group receiving supplementation of CLA One<sup>®</sup> + DL  $\alpha$ -tocopherol acetate (group COE) did not display values different from the group receiving CLA mixture only (group CO) in any of the parameters under study. However, the group receiving AdvantEdge<sup>®</sup> CLA +DL- $\alpha$ -tocopherol acetate (group AEE) had lower values ( $P \leq 0.05$ ) for hepatic TBARS and urinary 8-iso-PGF<sub>2 $\alpha$</sub>  isoprostane. It is widely known in the scientific community that vitamin E is one of the most potent antioxidants; however, factors such antioxidant dosage and bioavailability, and degree of exposure of the organism to oxidative stress must be taken into account. In a review by McCall and Frei [39], the real action of antioxidant compounds, including vitamin E, in the reduction of damage caused by oxidative stress was discussed. After considering the population, supplementation duration and dosage, lipid oxidation indicators and their determination methods, and the endpoints determined in the reviewed studies, the authors reported that vitamin E can protect the organism against lipid oxidation, but only in very high concentrations, far beyond the daily recommended values. The authors were led to conclude that further research is needed in order to clarify many doubts still surrounding the efficiency of antioxidant vitamin supplementation for oxidative stress prevention. From results of the present study, some hypotheses can be discussed in order to understand the low efficiency of vitamin E supplementation on most of the determined indicators, in addition to a possible inefficiency of antioxidant supplementation in some situations:

#### Supplement Dosage

The amount of DL- $\alpha$ -tocopherol acetate used in this work was 30 mg/day, a relatively high amount compared to values recommended by AIN93G [17], namely, 75 mg/kg of diet. According to this recommendation, the daily consumption of vitamin E through diet for the rats in the present experiment would be in the range of 1.5–3 mg (taking into account the feed consumption variation during the experimental period: 20–40 g/day). It should be pointed out that the amount of DL- $\alpha$ -tocopherol acetate used in the assay was chosen on the basis of previous works of this laboratory. In view of the above, it is plausible that the amount of supplement might have been excessive, preventing the detection of any difference that might exist among groups, since there is a debate about the inefficiency of even the adverse result of excessive supplementation. This hypothesis is based on the concept of the previously mentioned phenomenon of hormesis, which has already been documented for many compounds, including vitamins [33].

## Exposure to Oxidative Stress

It is important to point out that one of the objectives of the present research, based on the chemical structure of CLA, was to gather information to clarify the supposition that this supplement has a pro-oxidative effect. Thus, rats would be exposed to a pro-oxidative agent, and from this, protection of vitamin E against this agent would be assessed, since it can increase oxidative stability of unsaturated fatty acids with conjugated double bonds [44]. However, although the issue is still unresolved, there is a hypothesis that CLA acts as an antioxidant agent [42, 43], which would explain the results, as the rats would not have been so exposed to oxidative stress. Such a hypothesis would also lend some support to the conclusion that, if CLA really has an antioxidant effect, this effect is not enhanced by the presence of vitamin E.

## Conclusions

After examining the results of IP, MDA and 8-iso-PGF<sub>2α</sub> isoprostane, we conclude that the influence of conjugated linoleic acid on lipid oxidation, as measured by these indicators, depends on the CLA supplement type. Mean values expressing serum catalase were significantly lower in CLA supplemented groups, with or without vitamin E, than in the control group, suggesting antioxidative activity. The efficiency of vitamin E supplementation, particularly for the control group for the indicators catalase and 8-iso-PGF<sub>2α</sub> isoprostane, should be highlighted. Thus, the results of lipid autoxidation indicators are uncertain, but did warrant the conclusion that supplementation with conjugated linoleic acid influenced the process of biological lipid oxidation in different ways, and the influence is dependent on supplement type and the autoxidation indicator used, including its tissue and determination method.

**Abstract** Dietary conjugated linoleic acid (CLA) and the antihypertensive drug, telmisartan, have both been shown to modify cardiovascular risks. The effects of a combination of these two agents have, however, not been investigated. This 20 week study sought to assess the therapeutic potential of a CLA/telmisartan co-administration in rats fed a high-fructose high-fat diet. Thirty-three male Sprague–Dawley rats were randomly assigned to five experimental groups, including control, losartan, telmisartan, CLA, and CLA + telmisartan-treated animals. Body weight, blood pressure, and blood levels of lipids, glucose, insulin, and inflammatory markers were measured. Co-administration of CLA and telmisartan resulted in significant ( $P < 0.05$ ) reductions in body weight, visceral fat, serum total cholesterol, triglycerides, glucose, plasma insulin concentra-

tions, and systolic blood pressure compared with those in the control group. Moreover, plasma levels of IL1- $\alpha$  and IFN- $\gamma$  were reduced and levels of IL1- $\beta$ , IL-4, IL-6, and IL-10, plus TNF- $\alpha$  were increased in the co-therapy group, compared with controls. In conclusion, this study suggests that a combination of CLA with telmisartan may modify several risk factors of cardiovascular disease commonly seen in metabolic syndrome. This combination of nutraceuticals and pharmaceuticals may be a safe and cost-effective strategy in a number of high-risk subjects. Future studies will further document clinical benefits of such combination therapy.

## Abbreviations

ARB	Angiotensin II receptor blocker
AUC	Area under the curve
CLA	Conjugated linoleic acid
CVD	Cardiovascular disease
DBP	Diastolic blood pressure
FA	Fatty acid
HDL	High-density lipoprotein
HFHF	High-fructose high-fat
IL	Interleukin
INF	Interferon
ip	Intraperitoneally
LDL	Low-density lipoprotein
LPS	Lipopolysaccharide
MetS	Metabolic syndrome
OGTT	Oral glucose tolerance test
PPAR	Peroxisome proliferator-activated receptor

SBP	Systolic blood pressure
SEM	Standard error of the mean
SFO	Safflower oil
TC	Total cholesterol
TG	Triglyceride
TNF	Tumor necrosis factor
UCP	Uncoupling protein

## Introduction

Cardiovascular diseases (CVD) continue to be a major global epidemic and leading cause of morbidity and mortality. In addition to the conventional risk factors, such as hypercholesterolemia and hypertension, recent studies highlight the importance of other metabolic abnormalities, including obesity and type 2 diabetes on the worldwide heart-related mortality. Over the past few decades the incidence of these metabolic disorders has increased dramatically. Metabolic syndrome (MetS) is a cluster of central obesity, insulin resistance, hypertension, atherogenic dyslipidemia, and a pro-inflammatory state [1] that is now a subject of great scientific interest. Although the specific causes of the MetS are not completely recognized, an inappropriate lifestyle, including poor dietary habits, is believed to play a major role. In this regard, several studies suggest beneficial effects of dietary interventions along with daily life modifications in patients with MetS [2].

Primarily found in ruminant meat and dairy products, conjugated linoleic acid (CLA) is a mixture of positional and geometric isomers of linoleic acid (LA; 18:2n-6) that may generate cardiovascular health-promoting properties. CLA isomers have been widely known to have antiobesity, antidiabetic, anti-atherogenic, and anti-inflammatory [3–6] properties in animal models and human subjects. One potential mechanism for such effects may lie in CLA's ability to induce dose-dependent activation of the transcription factors peroxisome proliferator-activated receptor (PPAR)- $\alpha$  and  $\gamma$  subtypes [7, 8] that control the gene expression of several key enzymes of glucose and lipid metabolism. Similarly, telmisartan (Micardis), an angiotensin II receptor blocker (ARB), has been shown to serve as a partial agonist for PPAR- $\gamma$  [9]. Treatment with telmisartan reduced body-weight gain and decreased serum glucose, insulin, and triglyceride (TG) levels in rats fed high-carbohydrate high-fat diets [9]. Furthermore, telmisartan has been reported to reduce levels of glucose and insulin to normal values over eight weeks of treatment in patients with MetS [10].

On the basis of the current state of our knowledge and available lines of evidence, we sought to investigate

long-term benefits of a combination of dietary CLA with telmisartan against several known risk factors for vascular diseases in a wild-type rat model consuming a high-fructose high-fat (HFHF) diet over twenty weeks.

## Experimental Procedure

### Animals and Diets

Thirty-three, five-week-old male Sprague–Dawley (SD) rats were obtained from the Central Animal Care at the University of Manitoba (Winnipeg, MB, Canada) and housed in stainless-steel cages at an ambient temperature of 22–24°C and 12:12 h light–dark cycle. A HFHF diet, containing 60% fructose and 10% lard (TD.03293.PWD; Harlan Teklad, WI, USA) was used as “base diet”. The composition of this diet is summarized in Table 1. This diet was further supplemented with either 1.0% (w/w) safflower oil (SFO), or 1.0% (w/w) CLA. After 10 days of adaptation, the rats were randomly assigned to one of five treatment groups:

1. control group ( $n = 7$ ) fed SFO-supplemented diet;
2. losartan-treated group ( $n = 5$ ) fed SFO-supplemented diet and received losartan in drinking water at 5 mg kg<sup>-1</sup> body weight per day;
3. telmisartan-treated group ( $n = 7$ ) fed SFO-supplemented diet and received telmisartan in drinking water at 5 mg kg<sup>-1</sup> body weight per day;
4. CLA-treated group ( $n = 7$ ) fed CLA-supplemented diet; and
5. CLA + telmisartan-treated group ( $n = 7$ ) fed CLA-supplemented diet and received telmisartan in drinking water at 5 mg kg<sup>-1</sup> body weight per day.

The animals in these five experimental groups had comparable mean body weight and serum total cholesterol (TC) levels at baseline. CLA (Bioriginal Food and Science,

**Table 1** Composition of the high-fructose high-fat diet (TD.03293.PWD)

Ingredient	Diet (g kg <sup>-1</sup> )	Percentage
Casein	207.0	20.7
DL-Methionine	3.0	0.3
Fructose	600.0	60
Lard	100.0	10
Cellulose	42.0	4.2
Calcium carbonate (CaCO <sub>3</sub> )	3.0	0.3
Mineral mix, AIN-76	35.0	3.5
Vitamin mix, Teklad	10.0	1.0
Total	1000	100

SK, Canada) was composed of a 75% mixture of the *c9*, *t11* and *t10*, *c12* isomers in a 50:50 ratio, and 8.1% of other isomers. Telmisartan and losartan were received from St. Boniface General Hospital Pharmacy (Winnipeg, MB, Canada) and administered as previously reported [9]. To ensure accurate delivery of drug doses, drug concentrations were adjusted in the drinking water each week based on the average body weight and water consumption in each group, as previously described [9, 11]. Similar to telmisartan, losartan is an ARB commonly used to treat essential hypertension. However, unlike telmisartan, losartan does not seem to be partial agonist of PPAR- $\gamma$  [9] and was, therefore, used in this study as a “control drug” for telmisartan. Similarly, SFO, which is void of CLA was used as “control oil” for CLA and also to provide n-6 essential fatty acids (FA) for the control group. Table 2 summarizes the diet/drug treatment protocols. Daily food intake was estimated from the amount of food which disappeared from the animals’ cages. Animals’ body weights were recorded weekly whereas food and water intake were measured each day. Blood samples were obtained in a non-fed state by jugular venipuncture under light anesthesia (induced by 1–2% isoflurane) at baseline, week 4, and week 8 of the study. Sera were used for biochemical assays as described in following sections. The experiment lasted 20 weeks, during which time all animals looked healthy and active. On the morning of its last day on the treatment (week 20), each rat was intraperitoneally (ip) injected with 400  $\mu\text{g}$  of bacterial lipopolysaccharide (LPS; Sigma–Aldrich, ON, Canada) and 100 IU heparin (LEO Pharma, ON, Canada) 2 h and 10 min before sacrifice, respectively. A final blood sample was collected, after euthanization by  $\text{CO}_2$ , through cardiac puncture, and a complete autopsy was performed. The study was approved by the Animal Care Committee on the Use of Animals in Research at the University of Manitoba.

**Table 2** Summary of experimental groups and the diet/drug treatment protocols

Group	Diet/drug protocol
Control ( $n = 7$ )	Control diet [(high-fructose high-fat) <sup>a</sup> + 1.0% (w/w) safflower oil]
Losartan-treated ( $n = 5$ )	Control diet + 5.0 mg $\text{kg}^{-1}$ body weight per day losartan in drinking water
Telmisartan-treated ( $n = 7$ )	Control diet + 5.0 mg $\text{kg}^{-1}$ body weight per day telmisartan in drinking water
CLA-treated ( $n = 7$ )	High-fructose high-fat diet + 1.0% (w/w) CLA <sup>b</sup>
CLA + telmisartan-treated ( $n = 7$ )	High-fructose high-fat diet + 1.0% CLA + 5.0 mg $\text{kg}^{-1}$ body weight per day telmisartan in drinking water

<sup>a</sup> Contains 60% fructose and 10% lard

<sup>b</sup> Composed of 75% mixture of *c9*, *t11* and *t10*, *c12* in a 50:50 ratio

## Lipid Profiles

Serum TG, TC, and HDL-cholesterol concentrations were measured at baseline, week 4, and week 8 of the study using standard enzymatic methods (Diagnostic Chemicals, PEI, Canada) as previously reported [12–14]. A standard precipitation method [14] was used to prepare the HDL fraction. Serum LDL-cholesterol concentrations were calculated according to the Friedewald formula [15].

## Glucose and Insulin

Serum glucose levels were determined at baseline, week 4, and week 8 using a commercially available glucose-oxidase kit (Wako Chemicals, VA, USA; [16]). Plasma insulin levels were quantified at week 20 using ultra sensitive ELISA kit (Crystal Chem, IL, USA), as previously described [17].

## Blood Pressure

Systolic blood pressure (SBP) was recorded at weeks 12–14 using the standard tail-cuff method in conscious animals as previously reported [18]. Five readings were obtained from each rat and averaged after the highest and the lowest values were excluded as previously described [19]. Diastolic blood pressure (DBP) was then calculated using the equation  $\text{DBP} = [(3\text{MAP}) - \text{SBP}]/2$ , where MAP represents the mean arterial pressure [20].

## Glucose Tolerance Testing

Oral glucose tolerance test (OGTT) was carried out at the end of the study in conscious rats after administration of 100 mg/100 g body weight glucose (Sigma–Aldrich) by gastric gavage in an overnight-fasting state [9]. Immediately before, and 30, 60, and 120 min after oral administration of glucose, whole-blood glucose levels were recorded by use of a conventional blood-glucose meter (LifeScan, CA, USA), as previously reported [21]. Total area under the curve of glucose (AUC<sub>glu</sub>) response during the OGTT was calculated by the linear trapezoidal rule [22].

## Cytokine Profiles

Plasma samples from the final blood collection (week 20) of each experimental group were pooled and assayed by rat cytokine array techniques (RayBiotech, GA, USA), as previously described [23].

## Statistical Analysis

All values are expressed as mean  $\pm$  standard error of the mean (SEM) unless otherwise stated. Data were analyzed using SPSS 11.5 statistical software for Windows (SPSS, IL, USA). SBP, DBP, food, and water intake, AUCglu, and insulin data were statistically evaluated by one-way ANOVA followed by the Tukey test for comparisons across multiple groups. The differences among all dietary groups and time points (diet  $\times$  time interaction) for body weight, TG, TC, HDL-cholesterol and LDL-cholesterol, glucose, and the OGTT data were analyzed by repeated measures of ANOVA. To compare the effects of each treatment at a given time point, a separate one-way ANOVA was performed followed by Tukey multiple comparison tests. The level of statistical significance was set at  $P < 0.05$ .

## Results

### Body Weight

Rats in all the experimental groups gained weight throughout the study period. The extent of weight gain was, however, significantly lower in the CLA + telmisartan-treated rats than in the other groups. Starting at week 8, rats receiving CLA + telmisartan showed a significantly lower mean body weight relative to the control ( $P < 0.01$ ) or CLA-treated ( $P < 0.05$ ) groups. However, the differences in body weight between the two groups of combination therapy and telmisartan were not statistically significant. The diet/drug combination therapy group progressively gained less body weight throughout the study period. Figure 1 demonstrates body-weight gain among the experimental groups over the course of the study. Figure 1 also demonstrates that treatment with CLA, telmisartan, or losartan did not result in statistically significant differences in body-weight gain compared with controls.

### Amount of Visceral Fat

Figure 2 shows representative photographs of visceral adipose tissue among the experimental groups. The CLA + telmisartan-treated rats exhibited a remarkable diminution in the visceral fat pad size relative to other groups.

### Food and Water Intake

Calculated average daily food and water intake are shown in Figs. 3a and 3b, respectively. Average daily food consumption was similar ( $29.0 \pm 1.5$  g day<sup>-1</sup>) among the

different experimental groups. Similarly, average water intake ( $42.3 \pm 2.2$  mL day<sup>-1</sup>) was comparable in all five experimental groups.

## Serum Lipids

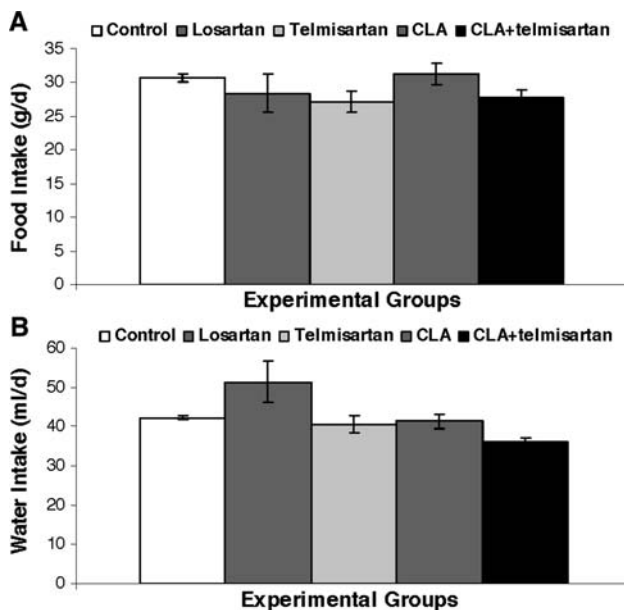

Compared with the baseline data the HFHF diet notably raised serum TG levels in all of the experimental groups by week 4 of the study (Table 3), at which time only the CLA + telmisartan-treated rats exhibited significantly lower ( $P < 0.01$ ) TG concentrations, compared with controls ( $1.0 \pm 0.2$  vs.  $2.3 \pm 0.2$  mmol L<sup>-1</sup>). At week 8, administration of telmisartan treatment was associated with a 90% reduction ( $P < 0.05$ ) in serum TG levels whereas CLA alone resulted in a non-significant 31% reduction compared with controls. The combination of CLA and telmisartan resulted in greater reductions in serum TG concentrations compared with the effects of each agent alone. At week 8, the CLA + telmisartan-treated group had significantly lower serum TG levels as compared with the control, losartan, or CLA-treated rats. Serum levels of TC were comparable in all of the experimental groups by week 4 of the study. However, a non-significant trend of reduced TC levels was observed in telmisartan, CLA, and CLA + telmisartan-treated rats compared with either control or losartan-treated rats. It should be mentioned that both TG and TC levels were comparable between the telmisartan and CLA + telmisartan groups. At week 8, only CLA + telmisartan-treated rats exhibited a significant ( $P < 0.05$ ) reduction of 48% in TC levels relative to the control or losartan-treated animals (Table 3). Serum HDL-cholesterol levels were slightly higher in the control and losartan-treated rats relative to those in other groups

**Fig. 1** Patterns of body-weight gain among the experimental groups during the course of the study. Values are mean  $\pm$  SEM,  $n = 7$ , for all experimental groups except the losartan-treated group ( $n = 5$ ). \* $P < 0.01$  versus control and  $P < 0.05$  versus CLA, \*\* $P < 0.01$  versus control and  $P < 0.05$  versus losartan, \*\*\* $P < 0.01$  versus control, CLA, or losartan. body-weight gain was comparable among CLA, telmisartan, losartan, and control groups

**Fig. 2** Representative photographs taken from the experimental animals at autopsy (week 20 of study). Animals from CLA + telmisartan group (e) show diminished visceral fat pad size compared with other groups (a–d) a control, b losartan, c telmisartan, d CLA, e CLA + telmisartan. Arrows indicate abdominal adipose tissue

**Fig. 3** Average daily food (a) and water (b) consumption by the experimental rats throughout the study period. Values are mean  $\pm$  SEM,  $n = 7$ , for all experimental groups except the losartan-treated group ( $n = 5$ )

throughout the study period (Table 3). This may reflect the higher levels of TC in these two groups of rats. Similarly, the levels of serum LDL-cholesterol were not significantly different among the experimental groups (Table 3). The CLA + telmisartan-treated rats, however, did show 22 and 13% less LDL-cholesterol levels at week 4 and week 8, respectively, compared with the controls.

#### Serum Glucose

Serum glucose levels of the rats at different times in the study are summarized in Table 3. Introduction of the HFHF diet did not significantly raise serum glucose levels

in the control group over 8 weeks of the experiment. At week 4, only losartan-treated rats showed a significant reduction of approximately 40% ( $P < 0.05$ ) in serum glucose levels, compared with those in the CLA-treated group, but not to the controls. At week 8, the losartan, telmisartan, and CLA + telmisartan-treated rats showed significantly ( $P < 0.05$ ) lower serum glucose concentrations (39, 23, and 30%, respectively) relative to the controls. Glucose levels in the CLA-treated animals and in the control group remained comparable throughout the study period. Similarly, both telmisartan and CLA + telmisartan groups had comparable serum glucose levels.

#### Systolic and Diastolic Blood Pressure

Administration of either losartan or telmisartan caused significant reductions in SBP. Losartan-treated rats exhibited significantly lower SBP as compared with the control group ( $113.0 \pm 4.0$  vs.  $138.0 \pm 8.0$  mmHg,  $P < 0.001$ ). The telmisartan-treated rats also showed a significant reduction in their SBP as compared with the controls ( $103.0 \pm 7.0$  vs.  $138.0 \pm 8.0$  mmHg,  $P < 0.001$ ). Similarly, the CLA + telmisartan-treated rats exhibited a significant reduction in SBP relative to the controls ( $121.0 \pm 13.0$  vs.  $138.0 \pm 8.0$  mmHg,  $P < 0.05$ ) however, the extent of reductions in SBP in the combination therapy group was lower than that in the telmisartan intervention group ( $121.0 \pm 13.0$  vs.  $103.0 \pm 7.0$  mmHg,  $P < 0.01$ ). The CLA-treated rats and the control group had comparable SBP. Animals on all the different diets showed comparable DBP. Data on SBP and DBP are summarized in Table 3.

#### Plasma Insulin

The co-administration of CLA and telmisartan resulted in significantly lower plasma insulin levels, as compared with

AUCglu: \*  $P < 0.05$  versus control and losartan

SBP: \*  $P < 0.001$  versus control, \*\*  $P < 0.001$  versus control or CLA and  $P < 0.01$  versus CLA + telmisartan, \*\*\*  $P < 0.05$  versus control

Insulin: \*  $P < 0.01$  versus control and  $P < 0.05$  versus losartan

the controls ( $P < 0.01$ ) or with the losartan-treated ( $P < 0.05$ ) rats at week 20 (Table 3).

#### OGTT and AUCglu

The CLA + telmisartan-treated rats showed significantly lower ( $P < 0.05$ ) whole-blood glucose concentrations at 0 time-point of OGTT, as compared with the control or CLA-treated rats. No statistically significant differences, however, were observed among the experimental groups 30, 60

and 120 min after OGTT (Fig. 4). AUCglu values were significantly lower ( $P < 0.05$ ) in the diet/drug co-therapy compared with values in the control or losartan-treated rats (Table 3).

#### Plasma Cytokines

The levels of various cytokines and the calculated differences between the control values and those from each treatment group are presented in Table 4. Plasma IL1- $\alpha$

**Fig. 4** Levels of whole-blood glucose during the oral glucose tolerance test (OGTT) at week 20 of the study. Glucose solution of 100 mg/100 g body weight was administered to each rat by gastric gavage. Values are mean  $\pm$  SEM,  $n = 7$  for all experimental groups except for losartan-treated group ( $n = 5$ ). \* $P < 0.05$  versus control or CLA-treated groups

levels were slightly higher in the telmisartan and CLA-treated rats but lower in the CLA + telmisartan-treated rats. Plasma IL1- $\beta$  levels were 35, 73, and 28% higher in the telmisartan, CLA, and CLA + telmisartan-treated rats, respectively, compared with controls. IL-6 levels were 50% higher in the telmisartan-treated rats and 36% higher in the CLA + telmisartan-treated rats, compared with controls. IFN- $\gamma$  levels were higher in the losartan and telmisartan-treated groups by 33 and 24%, respectively, compared with controls. The levels of IL-4 and IL-10 were higher in CLA-treated groups by 87 and 94%, respectively, and in the CLA + telmisartan-treated rats by 55 and 75%, respectively, relative to the controls. The levels of pro-inflammatory cytokine TNF- $\alpha$  were remarkably higher in all treated groups (108% in losartan, 239% in telmisartan, 249% in CLA, and 188% in CLA + telmisartan) relative to the controls.

## Discussion

Patients with MetS are at higher risk of CVD and diabetes and have increased CVD-related mortality [1, 24].

Globally, there has been growing interest in therapeutic approaches that can target the multiple risk factors within MetS simultaneously. This can be achieved through combination therapies or administration of multi-functional agents. Owing to its antihypertensive and antiglycemic properties, telmisartan can be one such agent [9, 25]. Another agent could be dietary CLA, which has been reported to improve glucose, lipid, and energy metabolism, probably through activation of PPAR- $\alpha$  and PPAR- $\gamma$  [7, 8, 26]. Although evidence of the effectiveness of such individual drug or dietary agent against cardiovascular risk is strong, the outcome of their combination has yet to be reported. Herein we report the effects of co-administration of CLA and telmisartan on a number of well-known cardiovascular risk factors in a rat model.

One of the most interesting findings of this study is the efficacy of CLA/telmisartan co-therapy in reducing the amount of abdominal fat and, thereby, maintaining lean body weight. In agreement with previous studies [27, 28], we observed no significant effect of dietary CLA alone on body-weight gain. Similarly, telmisartan alone did not significantly reduce body-weight gain in the rats. However, co-administration of CLA and telmisartan markedly attenuated the rats' body-weight gain throughout the treatment period. The autopsy inspection revealed that the reduction in body weight in the co-therapy group was mainly due to reduction in the amount of visceral fat. While the mechanisms responsible for such dramatic effect remain to be established, the effects on uncoupling proteins (UCPs), that are involved in the regulation of energy synthesis and expenditure, might be a possibility. With this regard, previous studies [29] reported an association between reduced body weight, an increase in UCP-2, and to a lesser extent UCP-3, mRNA levels in skeletal muscles of *c9*, *t11*-CLA-fed rats. Similarly, Ryder et al. reported that CLA (*c9*, *t11* and 50:50) intake upregulated UCP-2 mRNA abundance in muscle and adipose tissue in ZDF rats

**Table 4** Effects of diets on pooled plasma cytokine profiles at week 20

Analytes	Control	Losartan	Telmisartan	CLA	CLA + telmisartan
IL1- $\alpha$	659	646 (−2.0%)	844 (+28%)	821(+25%)	548 (−20%)
IL1- $\beta$	830	939 (+13%)	1124 (+35%)	1435 (+73%)	1059 (+28%)
IL-4	469	488 (+4%)	536 (+14%)	879 (+87%)	726 (+55%)
IL-6	529	583 (+10%)	794 (+50%)	537 (+15%)	722 (+36%)
IL-10	537	676 (+26%)	750 (+40%)	1040 (+94%)	938 (+75%)
IFN- $\gamma$	976	1294 (+33%)	1208 (+24%)	987 (+1%)	917 (−6%)
TNF- $\alpha$	1628	3385 (+108%)	5515 (+239%)	5680 (+249%)	4694 (+188%)

<sup>a</sup> Values are optical density with background subtraction

IL, interleukin; IFN, interferon; TNF, tumor necrosis factor

Numbers in brackets indicate the extent of changes relative to control values: − decreases, + increases

on high-fat diets [30]. Furthermore, one recent study has shown the ability of telmisartan to increase UCP-1 mRNA expression in brown adipose tissue in diet-induced obese mice [31]. Therefore, it is reasonable to speculate that the CLA/telmisartan co-administration might generate additive effects, and increased activities and/or expression of various UCPs. Data from this study and previous reports suggest investigation of such additive effects for CLA/telmisartan co-therapy in an appropriate model.

In humans, several studies have shown that increased visceral fat is an independent risk factor for metabolic disorders including atherosclerosis [32]. Several guidelines, therefore, have been developed to target the body mass index (BMI) at an acceptable range. Various strategies including lifestyle modifications, therapeutic approaches, and surgical procedures have been introduced for prevention of central obesity. With this regard, data from animal experiments suggest that dietary CLA may reduce energy intake [33] or increase energy expenditure [34], reduce fat cell size [27], alter preadipocyte differentiation [35], increase apoptosis of adipocytes [36], inhibit lipogenesis [37], and increase FA oxidation [38]. Similarly, one recent study has reported reductions in visceral fat and adipocyte size in rats treated with telmisartan [11]. In the current study the substantial reductions in the amount of visceral fat were associated with a significant reduction in serum TG levels in the combination therapy group, as compared with controls. Increased levels of serum TG are also an independent risk factor for atherosclerosis [39, 40]. Previous studies reported that both telmisartan and CLA, individually, reduce plasma TG levels in experimental animals [9, 41]. Our study further shows that the combination of these two agents seems to generate an additive or synergistic effect, as the extent of reductions of TG levels in the combination therapy group was greater than that in other groups of rats. It has been shown that CLA activates PPAR- $\alpha$ , and that hepatic PPAR- $\alpha$  activation is involved in regulation of energy balance, lipid homeostasis, and body-weight gain [42, 43]. The mechanisms underlying body weight and lipid-lowering effects of the CLA/telmisartan co-therapy might, therefore, be related, at least in part, to an increase in extent of PPARs activation.

The effects of CLA on glucose metabolism have not been entirely defined. Some studies have indicated that CLA improves insulin sensitivity in Zucker *fa/fa* rats [19, 44], while others have reported that CLA induces insulin resistance in C57BL/6J mice [33, 35]. Choi et al. [29] showed that a mixture of *c9*, *t11* and *t10*, *c12* CLA markedly reduces serum glucose and enhances glucose tolerance and insulin metabolism in SD rats. In another study, telmisartan treatment was associated with a 12% reduction in serum glucose levels in SD rats on a high-calorie diet [9]. In our current work we observed that a

combination of CLA and telmisartan reduces serum glucose levels by 30% over four weeks. This effect on glucose metabolism was associated with reduced plasma insulin concentrations in the combination group, compared with controls. These changes in glucose metabolism might be a result of reduced visceral fat, serum TG levels, and consequent alterations in FA metabolism.

Hypertension is a well-known independent risk factor for CVD [45]. Limited studies have shown anti-hypertensive effects of CLA in some rat models [46, 47]. On the other hand, telmisartan is widely known as a potent anti-hypertensive drug [48]. The current study not only failed to show a significant anti-hypertensive activity for CLA, but also suggested that CLA may partially mask telmisartan's antihypertensive effects. The extent of reductions in SBP of the combination group was lower than that of telmisartan-treated animals. At the moment, the reasons for this effect of dietary CLA are not clear. Despite changes in SBP, DPB remained comparable among all the experimental groups.

It is well-established that diabetes and atherosclerosis are generally associated with a pro-inflammatory state [49]. Several lipid-lowering or anti-hypertensive drugs have been shown to reduce the levels of pro-inflammatory mediators. Dietary CLA has been shown to reduce production of TNF- $\alpha$  both in human subjects and animal models [50]. Our study failed to reproduce similar effects. Levels of TNF- $\alpha$  increased substantially in all treatment groups compared with controls. One of the major sources of TNF- $\alpha$  production is adipose tissue. It is interesting that in the current study the plasma levels of TNF- $\alpha$  seem to be independent of the amount visceral fat. Plasma levels of TNF- $\alpha$  were comparable among the CLA/telmisartan co-therapy group (which had little or no visceral fat) and the other experimental groups (which had noticeable amounts of visceral fat). On the other hand, plasma levels of anti-atherogenic cytokines, such as IL-10, were notably increased in the CLA- and CLA+ telmisartan-treated rats relative to the controls. Many studies have reported an anti-atherogenic effect for IL-10 in both experimental animals and humans [51, 52]. At the same time, CLA/telmisartan co-therapy was not able to reduce the levels of pro-atherogenic cytokines IL-1 $\beta$  and IL-6. The importance of these observations in the context of reductions in body weight and abdominal fat, improvements in serum lipid profiles, blood pressure, and glucose metabolism warrants further investigation.

In conclusion, optimal therapeutic strategies that simultaneously reduce several cardiovascular risk factors in conditions such as MetS are in great demand. Such strategies could be achieved by combination of pharmaceuticals; several disadvantages, including undesirable drug–drug interactions, low cost-effectiveness, and low patient compliance, may limit this approach, however. In

contrast, these limiting factors may be reduced by a combination of pharmaceutical and nutraceutical means. Herein we report that a combination of dietary CLA and the anti-hypertensive drug telmisartan significantly reduced body weight, abdominal fat, serum TG and TC levels, and SBP, with improvements in glucose metabolism and a mixed response in several pro and anti-inflammatory markers. At present, the mechanisms involved in the generation of such effects remain to be completely defined. Nevertheless, our observations suggest that this combination may be an attractive strategy for further consideration in prevention/treatment of some of the abnormalities associated with MetS. In particular, the observed dramatic effect of the combination therapy on the amount of abdominal fat warrants extra investigation of the effectiveness of such intervention against the ever-escalating prevalence of obesity and its associated disorders. Although this approach seems safe and inexpensive, whether such a combination therapy results in clinical benefits has yet to be addressed. The animal model used in this study was not appropriate for testing the effects of this diet/drug combination on the development of atherosclerotic lesions. This can be potentially fruitful for future research before making suggestions of clinical benefits of such therapy for patients with CVD.

**Abstract** It has previously been shown that maternal nutrition affects the fetal environment, with consequences for the infant's health. From early pregnancy onwards participants here received a combination of dietary counseling and probiotics (*Lactobacillus* GG and *Bifidobacterium lactis* Bb12;  $n = 10$ ), dietary counseling with placebo ( $n = 12$ ), or placebo alone ( $n = 8$ ). The major differences in placental fatty acids were attributable to a higher concentration of n-3 polyunsaturated fatty acids in both intervention arms than in controls. Further, dietary counseling with probiotics resulted in higher concentrations of

linoleic (18:2n-6) and dihomo- $\gamma$ -linolenic acids (20:3n-6) compared with dietary counseling with placebo or controls.

**Keywords** Diet · Placenta · Polyunsaturated fatty acids · Probiotics

## Abbreviations

AA	Arachidonic acid
DHA	Docosahexaenoic acid
DHGA	Dihomo- $\gamma$ -linolenic acid
EPA	Eicosapentaenoic acid
LA	Linoleic acid
MUFA	Monounsaturated fatty acid
PUFA	Polyunsaturated fatty acid
SFA	Saturated fatty acid

## Introduction

The placenta regulates the nutritional, immunological, and endocrine environment of the fetus [1]. The importance of fatty acids, known to exert immunomodulatory effects via eicosanoid production [2], may culminate during pregnancy, their complex metabolism ranging from their deposition in maternal tissues in early pregnancy to their release during late pregnancy to supply fetal demands [3].

Earlier attempts to modify the pregnant mother's diet and thereby the nutritional and immunological environment of the fetus have focused on supplementation with long-chain polyunsaturated fatty acids (PUFA), fish oil [6], and probiotic bacteria [7]. Their synergistic effects [6, 7] imply the need to consider the overall diet.

Consequently, we chose dietary counseling together with probiotic supplementation to investigate whether

placental and umbilical cord serum phospholipid fatty acids and thus the fetal environment can be modified.

## Methods

### Subjects and Study Design

Placenta and umbilical cord serum samples were collected shortly after delivery from 30 healthy women participating in an ongoing mother–infant follow-up study, in order of enrolment [8]. Written informed consent was obtained from the participants and the study was approved by the Ethical Committee of the Hospital District of South-West Finland.

At the first visit, at 13.8 (SD 1.4) weeks of gestation, the recruited women were randomly assigned to three study groups. The dietary counseling groups received capsules of probiotics (diet/probiotics) containing *Lactobacillus rhamnosus GG* (ATCC 53103; Valio, Helsinki, Finland) and *Bifidobacterium lactis Bb12* (Chr. Hansen, Hørsholm, Denmark)  $10^9$  cfu day<sup>-1</sup> each, with demonstrated anti-inflammatory effects in young infants [9], or placebo (microcrystalline cellulose; diet/placebo), randomization proceeding in double-blind manner, while the control group received placebo (control/placebo) in single-blind manner.

Dietary counseling aimed at a dietary intake complying with that currently recommended [10], monounsaturated fatty acids (MUFA) contributing 10–15%, PUFA 5–10%, and saturated fatty acids (SFA) 10% or less of energy intake. Dietary counseling, supported with provision of conventional food products with favorable fat composition to be consumed at home, resulted in changes in dietary intake attributable to a higher intake of unsaturated and a lower intake of SFA, as reported in detail elsewhere [8]. Information regarding the course of pregnancy and infants' birth weights and heights was obtained from hospital records. The pre-pregnancy body-mass index was calculated using measured height and self-reported pre-pregnancy weight. Total gestational weight gain was calculated by subtracting the pre-pregnancy weight from that recorded at prenatal visit or delivery hospital within 1 week before delivery.

### Fatty Acid Analysis

To test the preservation of fatty acids during sampling and processing, one placenta was sampled 0.5, 1, 2, 4, 6, 12, and 24 h after delivery and analyzed for fatty acid concentrations. When stored at +4°C, the concentrations of PUFA remained relatively unchanged until 24 h after delivery, with a minor decrease at 12 h (data not shown).

To confirm the preservation of fatty acids placentas were sampled within 6 h and immediately frozen at -70°C. The blood samples were taken from the umbilical vessels directly after severing, and the serum was separated and frozen at -70°C.

Approximately 0.3 g placentas and 500 µL umbilical cord serum were used for analysis in duplicate. Placenta samples were homogenized on ice for 5 min using an Ultra-Turrax T8-homogenizer (IKA Werke, Staufen, Germany). The lipids in the placenta and cord serum samples were extracted with chloroform–methanol, 2:1 (v/v) [11] with dipentadecanoyl phosphatidylcholine (Larodan Fine Chemicals, Malmö, Sweden) as internal standard. Phospholipids were separated [12] using Sep-Pak Silica cartridges (100 mg; Waters, Milford, MA, USA). Fatty acid methyl esters were prepared by incubation in 1 mol L<sup>-1</sup> boron trifluoride in methanol at +100°C for 60 min and analyzed by gas chromatography [13]. Fatty acid contents were calculated from the respective methyl esters.

### Statistical Analysis

Results presented are the medians and interquartile ranges of the concentrations (mg g<sup>-1</sup> wet weight for placenta and mg mL<sup>-1</sup> for serum) and proportions (% w/w) of the fatty acids detected. Statistical differences among the three groups were analyzed by use of the Kruskal–Wallis test, and when significant, differences between two groups by use of the Mann–Whitney *U* test. Associations of the fatty acids in the placenta and the umbilical cord serum were assessed by Spearman's rank correlation test. SPSS for Windows (version 13.0; SPSS, Chicago, IL, USA) was used for statistical analyses.

## Results

The three study groups were comparable in terms of clinical characteristics (Table 1); the women were healthy and had no metabolic disorders. The pregnancies were uncomplicated and all infants were delivered at term.

The study groups differed in respect of placental fatty acids (Table 2). Evaluation in quantitative terms (mg g<sup>-1</sup>) showed dietary counseling to result in an increase in concentrations of the sum of n-3 PUFA and eicosatetraenoic acid (20:4n-3) in comparison of the diet/probiotics or diet/placebo groups with control/placebo. Assessment of proportional change in fatty acids showed higher proportion of dihomo- $\gamma$ -linolenic acid (20:3n-6, DHGA) in both intervention groups compared with control/placebo.

Comparison of the diet/probiotics group with the diet/placebo group showed administration of probiotics to affect placental fatty acids. The concentrations and propor-

tions of precursor fatty acids for eicosapentaenoic acid (20:5n-3, EPA) and arachidonic acid (20:4n-6, AA), 20:4n-3 and DHGA, respectively (Fig. 1), and the concentration of linoleic acid (18:2n-6, LA), were highest in the women receiving probiotics. For the proportion of DHGA and the concentration of 20:4n-3, the effect of combined dietary and probiotic intervention (diet/probiotics) was greater than that of dietary intervention alone (diet/placebo group), and changes in the proportion of AA and the concentrations of LA and DHGA could be attributed to probiotics.

Neither dietary counseling nor probiotic intervention caused changes in umbilical cord serum phospholipid fatty acids, except that the proportion of DHGA was higher with combined dietary counseling and probiotic intervention (diet/probiotics group) compared with control/placebo (Table 3; Electronic supplementary material). All PUFA in placenta and umbilical cord serum phospholipids were positively correlated ( $P < 0.05$ ; data not shown).

## Discussion

We showed here that placental phospholipid fatty acid content and composition may be modified by combined dietary and probiotic intervention. In view of the well documented role early nutrition plays in later life, culminating in early materno–fetal communication and transfer of fatty acids [14], health benefits may be expected.

The concentrations of PUFA in the placenta were comparable with those previously determined [15]. Nonetheless, dietary counseling resulted in increased dietary intakes of PUFA during pregnancy [8], reflected in higher concentrations of PUFA in placental phospholipids, but not in umbilical cord serum phospholipids, although placenta and cord blood fatty acids were correlated. The characteristics of umbilical cord blood, reflecting both the arterial and venal blood of the fetus, may confound the direct effect of maternal diet on cord blood composition, the association being nevertheless generally detected when comparing

dietary and serum fatty acid compositions [16]. Further, quantification of fatty acids as concentrations resulted in detection of differences amongst the study groups in respect of additional fatty acids, DHA and LA, not revealed by proportional profiles.

Although transfer of fatty acids across the placenta is partly determined by concentration gradient, the placenta has been shown to take up certain fatty acids selectively [17]. This was also reflected here, because the proportion of PUFA was greater in placental than in cord blood phospholipids, the difference being seen particularly in AA, the accumulation of which in placental phospholipids has previously been shown [18]. Fatty acids incorporated into phospholipids may be utilized in intrinsic placental fatty acid metabolism [19] to synthesize either longer-chain derivatives or inflammatory modulators. Importantly, they also serve as a reservoir to satisfy fetal demands for growth and development [19].

Beyond the effect of modification of maternal dietary lipid composition, also previously observed when comparing the placental fatty acids of vegetarian, omnivore, and diabetic mothers [20], administration of probiotics was seen here to modify placental phospholipid fatty acids. The mechanisms involved are poorly understood, but experimental evidence points to interplay between fatty acids and probiotics. First, one interaction may arise from effects of fatty acids on bacterial cell membranes [21] and hence on probiotic adherence and the intestinal epithelial cell innate immune response [22]. Second, probiotics and fatty acids may exert their systemic effects via similar signaling pathways, including soluble CD14 [23–25], or by control of proinflammatory cytokines [26]. Finally, the observed differences may result from the properties of probiotics in regulating desaturases involved in the metabolism of fatty acids to their longer-chain derivatives. It has been shown in rats that a range of probiotics affects the activity of liver  $\Delta 6$ -desaturase [27]. Clinical evidence is scarce regarding the interplay between probiotics and fatty acids, but in one study administration of formula supplemented with probi-

otics resulted in changes in the fatty acid composition of infants' serum phospholipids [28].

Dietary counseling and administration of probiotics during pregnancy were shown here to affect lipid metabolism, highlighting the synergistic effects of fatty acids and probiotics. This approach may initiate a cascade of events,

the effects being clinically manifested in health benefits at an early age, including promotion of neurological development [29] and alleviation of a range of immunoinflammatory disorders, for example allergic and cardiovascular diseases [30], not to mention the reduced maternal risk of pregnancy-related complications [31].

## Effect of Sterol Carrier Protein-2 Expression on Sphingolipid Distribution in Plasma Membrane Lipid Rafts/Caveolae

**Abstract** Although sphingolipids are highly important signaling molecules enriched in lipid rafts/caveolae, relatively little is known regarding factors such as sphingolipid binding proteins that may regulate the distribution of sphingolipids to lipid rafts/caveolae of living cells. Since early work demonstrated that sterol carrier protein-2 (SCP-2) enhanced glycosphingolipid transfer from membranes *in vitro*, the effect of SCP-2 expression on sphingolipid distribution to lipid rafts/caveolae in living cells was examined. Using a non-detergent affinity chromatography method to isolate lipid rafts/caveolae and non-rafts from purified L-cell plasma membranes, it was shown that lipid rafts/caveolae were highly enriched in multiple sphingolipid species including ceramides, acidic glycosphingolipids (ganglioside GM1); neutral glycosphingolipids (monohexosides, dihexosides, globosides), and sphingomyelin as compared to non-raft domains. SCP-2 overexpression further enriched the content of total sphingolipids and select sphingolipid species in the lipid rafts/caveolae domains. Analysis of fluorescence binding and displacement data revealed that purified human

recombinant SCP-2 exhibited high binding affinity (nanomolar range) for all sphingolipid classes tested. The binding affinity decreased in the following order: ceramides > acidic glycosphingolipid (ganglioside GM1) > neutral glycosphingolipid (monohexosides, hexosides, globosides) > sphingomyelin. Enrichment of individual sphingolipid classes to lipid rafts/caveolae versus non-rafts in SCP-2 expressing plasma membranes followed closely with those classes most strongly bound to SCP-2 (ceramides, GM1 > the neutral glycosphingolipids (monohexosides, dihexosides, and globosides) > sphingomyelin). Taken together these data suggested that SCP-2 acts to selectively regulate sphingolipid distribution to lipid rafts/caveolae in living cells.

## Introduction

Although the existence of transbilayer and lateral cholesterol-rich lipid domains in both model and plasma membranes was identified and characterized several decades ago [1], functional interest in these domains essentially lagged until the discovery that plasma membrane lipid rafts/caveolae were especially rich in signaling proteins [2, 3] and lipids involved in signaling lipids such as sphingolipids (sphingomyelin, gangliosides, ceramide), phosphatidylinositols, and diacylglycerol [4–8]. This was evidenced by the appearance of several thousand papers in the past decade correlating a growing diversity of activities to the lipid substrates of signaling proteins in lipid rafts/caveolae. The importance of lipid rafts/caveolae to these signaling protein functions is shown by the fact that disruption of cholesterol-rich microdomains inhibits activity [2].

It must be noted, however, that the above compositional studies of lipid rafts were performed with lipid rafts isolated from detergent and high pH bicarbonate buffer preparations, despite growing concerns that such preparations may not equate with lipid rafts/caveolae and not reflect the biological nature of intact cells [9–11]. These issues were recently alleviated in part by studies with lipid rafts/caveolae isolated without detergents or high pH carbonate buffers confirming that plasma membrane lipid rafts/caveolae domains are enriched in signaling proteins [12] as well as at least two lipids involved in signaling, i.e., sphingomyelin and less so phosphatidylinositol [13, 14]. However, while these studies suggest that intact lipid rafts/caveolae are required for organizing signaling lipid substrates and signaling proteins in close proximity, it is not completely clear which signaling sphingolipid species, other than sphingomyelin, are enriched in lipid rafts/caveolae, especially lipid rafts/caveolae isolated without detergents or high pH carbonate buffers. Furthermore, despite the significance of lipid rafts/caveolae in lipid mediated cellular signaling, relatively little is known regarding mechanism(s) whereby the level of lipid substrates such as sphingolipids in lipid rafts/caveolae are regulated and replenished. Since sphingolipids are synthesized in the endoplasmic reticulum and/or Golgi apparatus, both vesicular and non-vesicular pathways for preferential transport to plasma membrane lipid rafts/caveolae have been proposed [15–17]. In recent years, much attention has focused on vesicular pathways while, with the exception of the glycolipid transfer protein [18], almost nothing is known regarding the role(s) of proteins involved in regulating molecular sphingolipid transport and distribution of sphingolipid species (sphingomyelin, ceramide, neutral glycosphingolipids (monohexosides, dihexosides, globosides), and acidic glycosphingolipids

(ganglioside GM1)) to lipid rafts/caveolae. One candidate protein, caveolin-1, was shown to cross-link with photoactivatable gangliosides in the plasma membrane caveolae-suggesting that caveolin-1 is either a close neighbor of gangliosides, binds gangliosides, and/or possibly may be involved in ganglioside transport/targeting to caveolae [19]. A number of studies suggest sterol carrier protein-2 (SCP-2) as an additional candidate protein: (1) early *in vitro* studies with SCP-2 containing pH 5.1 supernatants from the liver showed that these supernatants markedly enhanced the transfer of sphingomyelin as well as neutral (globoside) and acidic (ganglioside) glycosphingolipids from model membranes to high density lipoproteins (HDL) or biological membranes [20, 21]. However, while SCP-2 is present in the pH 5.1 supernatant, this supernatant is also the starting fraction for purification of several other lipid transfer proteins including PITP, L-FABP, and others [22]. Furthermore, PITP itself has been shown to bind/transfer sphingomyelin [23, 24], (2) immunofluorescence confocal microscopy and immunogold electron microscopy show significant portions of SCP-2 are localized in the cytoplasm [25, 26], (3) immunoprecipitation, double immunofluorescence fluorescence resonance energy transfer (FRET) confocal microscopy, double immunogold electron microscopy, coimmunoprecipitation, yeast two hybrid, and plasma membrane fractionation into lipid rafts and non-raft domains show that SCP-2 directly interacts with caveolin-1 in plasma membrane lipid rafts, but SCP-2 is not associated with non-rafts [26, 27].

The purpose of the present investigation was to determine: (1) sphingolipid class distribution in lipid rafts/caveolae isolated by affinity chromatography without the use of detergents or high pH carbonate, (2) effect of SCP-2 expression on sphingolipid distribution to lipid rafts/caveolae vs non-rafts, and (3) lipid raft/caveolae sphingolipid class distribution correlation with SCP-2 affinity for these sphingolipid classes.

## Materials and Methods

### Materials

Lipid standards were from Matreya Inc., (Pleasant Gap, PA, USA) and Calbiochem (La Jolla, CA, USA). Concanavalin A (Con A) sepharose resin was purchased from Pharmacia (Piscataway, NJ, USA). Silica Gel G and Silica Gel 60 thin layer chromatography (TLC) plates were from Analtech (Newark, DE, USA) and EM Industries, Inc. (Darmstadt, Germany), respectively. NBD-sphingomyelin was purchased from molecular probes (Eugene, OR, USA). Sphingomyelin, galactosylceramide, ceramide, and ganglioside

GM1 were purchased from Avanti (Alabaster, AL, USA). Cerebrosides, lactosylceramide, glucosylceramides, and globosides were purchased from Matreya Inc. (Pleasant Gap, PA, USA). Rabbit polyclonal antisera to recombinant human SCP-2 was prepared as described previously [28]. Rabbit polyclonal anti-sera to caveolin-1 was purchased from BD Transduction Laboratories (Palo Alto, CA, USA). Rabbit anti-Na, K-ATPase was purchased from Novus Biologicals (Littleton, CO, USA). All reagents and solvents used were of the highest grade available and were cell culture tested.

#### L-Cell Culture

Murine L-cells were grown to confluence at 37 °C and 5% CO<sub>2</sub> in Higuchi medium, supplemented with 10% fetal bovine serum (Hyclone, Logan, UT, USA) as described earlier [29]. Control L-cells and L-cells transfected with the 15-kDa pro-SCP-2 cDNA were prepared as described earlier [30]. Western blot analysis performed on the SCP-2 expression cells revealed that levels of SCP-2 (0.036% cytosol protein) were in the physiological range found in animal tissues [31]. In untransfected and control/mock transfected cells, levels of these proteins were below the level of detection.

#### Isolation of Lipid Rafts/Caveolae and Non-Raft Enriched Fraction from L-Cell Fibroblasts

Plasma membranes were isolated from cultured L-cells as described earlier [14, 32, 33]. A non-detergent affinity chromatography method using concanavalin-A (ConA) sepharose 4B was then employed to isolate lipid rafts/caveolae and non-raft domains from the purified plasma membranes as described earlier [9, 14, 33, 34]. The basis for the isolation method ensued from the specificity of ConA for carbohydrates: (1) simple sugars and oligosaccharides that have D-manno or D-glucopyranoside configuration with unmodified hydroxyl groups at C-3, C-4, and C-6 of the  $\alpha$ (anomer, which is preferred over the  $\beta$  anomer) [35], (2) glycopeptides with a core structure of Man $\alpha$ 1  $\rightarrow$  3[Man $\alpha$ 1  $\rightarrow$  6]Man $\beta$ 1  $\rightarrow$  4GlcNAc $\beta$ 1  $\rightarrow$  4GlcNAc  $\rightarrow$  Asn [35]. Such carbohydrate receptor structures are present in several lipid raft/caveolae components such as SR-B1 [36] and glucosylceramide found in L-cells [37].

#### Sphingolipid Analysis of Lipid Rafts/Caveolae and Non-Raft Domains

Sphingolipids were extracted with chloroform/methanol/water/pyridine (60:30:6:1) and insoluble particulates were removed by filtration [37]. Pooled extracts were evaporated

to dryness under N<sub>2</sub>. Lipids were saponified using methanol in NaOH for 2 h at 37 °C followed by neutralization with acetic acid. The solvent was evaporated under N<sub>2</sub>, and the lipids were dissolved in MeOH/H<sub>2</sub>O/CHCl<sub>3</sub>, 94:96:6 (v/v/v). The organic phase was then desalted with a Waters Sep-Pak C18 column (Milford, MA, USA), pre-equilibrated with CHCl<sub>3</sub>/CH<sub>3</sub>OH (1:1). After the sample was loaded, the columns were washed twice with H<sub>2</sub>O, then eluted first with methanol followed by chloroform/methanol (1:1 v/v). The eluting fractions were pooled and the sphingolipids thus obtained were dried with N<sub>2</sub> and pumped under vacuum. The residue was dissolved in a minimum volume chloroform/methanol (1:1 v/v) and resolved along with appropriate lipid standards on Silica G60 TLC plates developed in chloroform/methanol/15 mM CaCl<sub>2</sub> (aq) (65:35:8). Lipids were visualized with the fluorescent dye primulin under UV irradiation [37] and analyzed by scanning densitometry using Scion image analysis software. Lipid content was quantitated by comparison to standard curves developed on each TLC plate and normalized to the total protein content to give units of nmol lipid/mg protein. Total protein was determined on the samples before extraction by Bradford reagent (Sigma, St Louis, MO, USA) with BSA used as the standard.

#### Western Blot Analysis of Lipid Rafts/Caveolae and Non-Raft Domains

The relative enrichment of plasma membrane protein markers (caveolin-1 and Na, K-ATPase) and the distribution of SCP-2 in the lipid rafts/caveolae and non-raft domains eluted from the ConA affinity column was determined by western blotting. Aliquots of each fraction were separated by SDS-PAGE and analyzed as follows: Samples (10  $\mu$ g) were run on tricine gels (12%) and transferred to nitrocellulose membranes. The blots were blocked in 3% gelatin in TBST (10 mM Tris-HCL, pH 8, 100 mM NaCl, 0.05% Tween-20) for 1 h at room temperature, then washed 2 $\times$  with TBST. The blots were incubated overnight at room temperature with the respective polyclonal rabbit primary antibodies at dilutions of 1:500 (anti-SCP-2 and anti-caveolin-1) or 1:1,000 (anti-Na, K-ATPase) in 1% gelatin in TBST. After several washes with TBST, the blots were incubated for 2 h at room temperature with the appropriate secondary antibody (alkaline-phosphatase conjugates of goat anti-rabbit IgG) diluted 1:4,500 in 1% gelatin TBST. The blot was washed 3 $\times$  with TBST and bands of interest were visualized by development with Sigma Fast 5-bromo-4-chloro-3-indolyl phosphate/nitro blue tetrazolium tablets (Sigma, St Louis, MO, USA) according to the manufacturer's protocol. Images of each blot were acquired using a single-chip CCD (charge couple device) video camera and a computer

workstation (IS-500 system from Alpha Innotech, San Leandro, CA, USA). Densitometric analysis of image files was then performed (mean 8 bit gray scale density) using NIH Image, available by anonymous FTP from zippy.nimh.nih.gov, to obtain relative levels of respective protein detected in each fraction expressed as integrated density values.

#### Analysis of Ganglioside GM1 Levels in Lipid Rafts/Caveolae and Non-Raft Plasma Membrane Domains

GM1 levels in each fraction were determined as described elsewhere [38]. Briefly, samples were spotted onto nitrocellulose membrane blots and washed with PBS. The blots were blocked in 3% (w/v) BSA in PBS and incubated with cholera toxin B (1 µg/ml) for 30 min at 4 °C. Membranes were washed and incubated with rabbit anti-cholera toxin B for 1 h, followed by incubation with alkaline phosphatase-conjugated swine anti-rabbit Ig for an additional 30 min. Sigma Fast 5-bromo-4chloro-3-indolyl phosphate/nitro blue tetrazolium tablets (Sigma, St Louis, MO, USA) were used to visualize spots. GM1 levels were quantitated by densitometric analysis as for protein analysis described above.

#### NBD-Sphingomyelin Binding to SCP-2

Recombinant human SCP-2 was isolated as described earlier [39]. The binding of SCP-2 protein to NBD-sphingomyelin was determined as described previously for other NBD-labeled lipids [40]. The NBD-sphingomyelin was excited at 480 nm and fluorescence emission spectra recorded from 490 to 600 nm at 25 °C on a PC1 photon counting spectrofluorometer (ISS Instruments, Champaign, IL, USA). Excitation and emission bandwidths (4 and 8 nm, respectively) were kept to a minimum to reduce photobleaching. The sample absorbance for NBD-labeled probes was kept below 0.1 to avoid the inner filter effect. Light scatter was reduced by the use of dilute samples and appropriate low fluorescence cutoff filters in the emission paths. Fluorescence emission was corrected for blank (without SCP-2 present) and background fluorescence.

SCP-2 binding affinity ( $K_d$ ) for NBD-sphingomyelin was calculated as described in [41, 42] using the following equation:  $1/(1 - F/F_{max}) = C_L/(F/F_{max}) \times (1/K_d - (nE_0)/K_d)$  where  $F$  and  $F_{max}$  are corrected measured and maximal fluorescence intensity of the ligand, respectively,  $C_L$  is the total ligand concentration, and  $E_0$  is the protein concentration. A plot of  $1/(1 - F/F_{max})$  versus  $C_L/(F/F_{max})$  yielded a linear function with a slope of  $(1/K_d)$  and an ordinate intercept of  $(nE_0)/K_d$  where  $n$  equals the number of binding sites. In order to determine the number of binding sites to a higher degree of accuracy, a reverse titration experiment

was performed in which increasing amounts of SCP-2 (100–795 nM) were added to a fixed concentration of NBD-sphingomyelin (220 nM) as described in [43]. The data were fit to equation  $Y = F_{max}X/(B + X)$  where  $X$  is the protein concentration,  $F_{max}$  is the maximal bound fluorescence intensity, and  $B$  is a fitting parameter. In order to convert the fluorescent intensities into ligand bound concentrations,  $F_{max}$  was divided by the fixed concentration of NBD-sphingomyelin. Fluorescent intensities from the previous titrations (non-reverse) were then converted to ligand bound concentrations and plotted as  $L_B/P_T$  versus  $L_F$  where  $L_B$  is bound NBD-sphingomyelin,  $P_T$  is total protein concentration, and  $L_F$  is the free NBD-sphingomyelin in solution. The data was fitted to equation  $Y = nL_F/(K_d + L_F)$  by non-linear regression to give the binding site saturation curve where  $n$  is the number of binding sites and  $K_d$  is the dissociation constant.

#### Displacement of SCP-2-Bound NBD-Sphingomyelin by Sphingolipids

The relative affinity of SCP-2 for non-fluorescent sphingolipids was determined by displacement of SCP-2 bound NBD-sphingomyelin basically as described earlier for other fluorescent lipids [44]. All NBD-sphingomyelin displacement studies were performed below the critical micelle concentration for each non-fluorescent sphingolipid ligand. The decrease in maximum fluorescence intensity of NBD-sphingomyelin at 540 nm was plotted versus the displacing ligand concentrations. From the plot, the  $I_{50}$  value was determined, and the equation,  $K_i = [I_{50}]/(1 + [L]/K_d)$ , was used to calculate the dissociation constant ( $K_i$ ) for each lipid examined where  $[L]$  was the NBD-sphingomyelin concentration used in the experiment, and  $K_d$  was the dissociation constant for NBD-sphingomyelin and SCP-2 binding ( $375 \pm 34$  nM). Measurements were corrected for the blank (ligand or protein only) and photobleaching as described above.

#### Determination of DHE Sterol Transfer in Lipid Rafts/Caveolae and Non-Raft Domains Isolated from L-Cell Fibroblast Plasma Membranes

Dehydroergosterol (DHE, a naturally fluorescent sterol) was incorporated into caveolae/lipid raft and non-raft domains as previously described [32]. The DHE sterol transfer between the isolated membrane fractions was measured over approximately 4 h according to a fluorescence polarization exchange assay previously described by our laboratory [32, 45]. Isolated lipid rafts/caveolae and non-raft membranes were resuspended in filtered (0.2 µm) buffer (2 ml, 10 mM PIPES, pH 7.4) and placed in thermostated ( $37 \pm 0.3$  °C) quartz cuvettes with temperature maintained

through use of a water heating bath (Fisher Scientific, Pittsburgh, PA, USA). The steady-state fluorescence polarization of DHE in the membrane fractions was measured on a PC1 spectrofluorometer with photon-counting electronics (ISS Instruments, Inc., Champaign, IL, USA) in the T-format with the emission monochromator set at 375 nm, with 16 nm spectral slit widths and KV-389 emission filters from Schott Glass Technologies, Inc., Duryea, PA, USA. Samples were stirred continuously with a magnetic stir bar below the level of the light beam. Residual light scatter from membranes contributing to polarization measurements was corrected by converting polarization to anisotropy according to  $r = 2P/(3-P)$  followed by subtraction of residual fluorescence anisotropy of both donor and acceptor membranes from all experimental data. To avoid inner filter artifacts, the absorbance of sample solutions at the excitation wavelength was maintained  $<0.15$  absorbance units. Kinetic parameters including initial rate of sterol transfer and the exchangeable sterol fraction were determined as described in [14].

#### Statistics

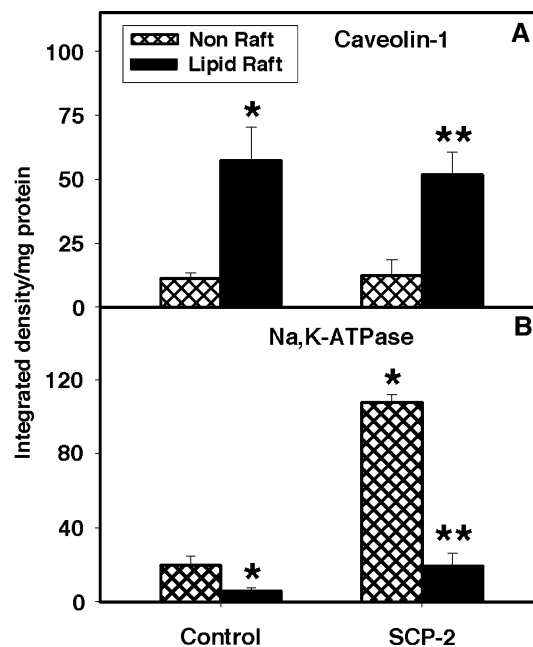

All values were expressed as the mean  $\pm$  SEM with  $n$  and  $p$  indicated in “Results”. Statistical analysis was performed using analysis of variance (ANOVA) combined with the Newman-Keuls multiple comparisons test (GraphPad Prism, San Diego, CA, USA) or Student’s  $t$  test. Values with  $P < 0.05$  were considered statistically significant.

## Results

### Total Sphingolipid (TSL) Content of Lipid Rafts/Caveolae and Non-raft Domains: Effect of SCP-2 Expression

Although several sphingolipid classes are enriched in lipid rafts/caveolae isolated by methods using detergents and/or high pH carbonate buffer, such methods are increasingly thought to themselves affect the distribution of lipids as well as proteins into lipid rafts/caveolae [46]. Therefore, a detergent-free, high pH carbonate buffer-free, ConA affinity chromatography method was used to simultaneously isolate lipid rafts/caveolae and non-raft domains from plasma membranes purified from L-cell fibroblasts as described in “Methods”. To confirm that the ConA adherent and non-adherent fractions isolated from control and SCP-2 expressing plasma membranes indeed represented lipid rafts/caveolae and non-raft enriched fractions, western blotting for marker proteins was performed to determine the presence of caveolin-1 (a lipid rafts/caveolae protein marker) and Na, K-ATPase (a non-raft protein marker). While

the transferrin receptor (also known as CD71) is an excellent protein marker for non-rafts in endothelial cells as well as other cells [47, 48], in the present work transferrin was not detectable (data not shown). However, when the non-adherent fraction isolated from control cells was tested for another non-raft protein marker Na, K-ATPase, a 3.2-fold enrichment was observed as compared to the ConA adherent fraction (Fig. 1b). To distinguish whether the ConA adherent fraction was enriched in lipid raft protein markers, western blotting was performed with the known lipid raft protein marker caveolin-1. The ConA adherent fraction isolated from control cells contained fivefold more caveolin-1 as compared to the non-adherent fraction (Fig. 1a, closed bar vs. hatched bar). In SCP-2 expressing cells, a similar pattern of lipid raft protein markers was observed, i.e., enrichment of caveolin-1 in the ConA adherent fraction. However, while Na, K-ATPase was enriched in the non-raft fraction isolated from SCP-2 cells (compared to the lipid raft fraction), a comparison between non-rafts isolated from control and SCP-2 expressing cells showed a 5.4-fold increase in Na, K-ATPase content in SCP-2 expressing cells (Fig. 1b). Concomitantly, levels of Na, K-ATPase in the lipid rafts/caveolae were increased 3.2-fold as compared to lipid rafts/caveolae isolated from control cells (Fig. 1b). In

**Fig. 1** Distribution of plasma membrane protein markers in lipid rafts/caveolae and non-raft fractions. Quantitative analysis of protein expression was performed to determine relative expression levels of caveolin-1 (Panel A) and Na, K-ATPase (Panel B) in lipid rafts/caveolae (closed bar) and non-raft (hatched bar) fractions isolated from control and SCP-2 expressing cells. Values represent mean  $\pm$  SEM ( $n = 3-4$ ). \* $P < 0.05$  versus non-raft fractions isolated from control cells; \*\* $P < 0.004$  versus non-rafts isolated from SCP-2 expressing cells

summary, western blotting of protein markers confirmed that ConA adherent fractions and non-adherent fractions were enriched in lipid rafts/caveolae and non-rafts, respectively, and expression of SCP-2 significantly increased the relative content of Na, K-ATPase in non-rafts and lipid rafts/caveolae as compared to control cells.

Next, lipids from lipid rafts/caveolae and non-raft domains were extracted, total sphingolipid mass was quantitated as described in “Methods”. Total sphingolipids were defined as the sum of ceramides, globosides, dihexosides, monohexosides, sphingomyelin, and ganglioside GM1 present in each fraction. Lipid rafts/caveolae isolated from control (i.e., mock transfected) L-cells contained significant levels of total sphingolipid ( $369 \pm 35$  nmol/mg protein) (Fig. 2). In control cells, the total sphingolipid content in lipid rafts/caveolae was higher than in non-rafts, however, this trend did not achieve statistical significance (Fig. 2). In contrast, SCP-2 expression significantly increased the lipid rafts/caveolae total sphingolipid mass/mg protein when compared to non-rafts isolated from SCP-2 overexpression cells or to lipid rafts/caveolae isolated from control cells (Fig. 2), suggesting that SCP-2 acts to selectively regulate sphingolipid distribution to lipid rafts/caveolae. In order to determine whether these results correlated with expression levels of SCP-2 in the isolated membrane fractions, western blot analysis was performed on plasma membranes, caveolae, and non-caveolae fractions isolated from control and SCP-2 expressing cells. In the plasma membranes isolated from control cells there was little to no SCP-2 present (Fig. 3a, lane 1). In contrast, SCP-2 was observed in plasma membranes (Fig. 3a, lane 2)

**Fig. 2** Total sphingolipid content of lipid rafts/caveolae and non-rafts isolated from plasma membranes from control and SCP-2 expressing cells. Total sphingolipids were extracted, quantitated, and expressed in units of nmol TSL/mg protein. Values represent mean  $\pm$  SEM ( $n = 7-11$ ).  $**P < 0.003$  versus non-raft fractions isolated from SCP-2 expressing cells; @ indicates  $P < 0.03$  versus lipid rafts/caveolae fractions isolated from control cells. TSL total sphingolipids

and lipid rafts/caveolae fractions (Fig. 3a, lane 4) isolated from SCP-2 overexpressing cells, with little to no SCP-2 observed in fractions isolated from non-caveolae (Fig. 3a, lane 3). Quantitative analysis showed that levels of SCP-2 in the caveolae fraction were increased 15-fold as compared to the non-caveolae fraction. In summary, these data show that: (1) in control cells total sphingolipid mass was only slightly higher in lipid rafts/caveolae than in non-rafts, and (2) SCP-2 overexpression significantly increased the total sphingolipid mass in lipid rafts/caveolae, but not non-rafts.

#### Mass Distribution of Sphingolipid Classes in Lipid Rafts/Caveolae and Non-Raft Domains: Effect of SCP-2 Expression

To determine if the lipid rafts/caveolae were enriched in select sphingolipid classes, total sphingolipids were resolved by thin layer chromatography, visualized, and quantitated as described in “Methods”. For the non-glycosylated sphingolipid classes, including sphingomyelin and ceramide, the mass of sphingomyelin, but not ceramide, in control cells was several fold higher in the lipid raft/caveolae fractions as compared to non-rafts (Table 1). SCP-2 overexpression abolished the difference in sphin-

**Fig. 3** Distribution of SCP-2 in plasma membrane, non-raft, and lipid rafts/caveolae fractions from control and SCP-2 expressing cells (Panel A). Western blot analysis was performed to determine expression levels of SCP-2 in L-cell plasma membranes (lane 1) and in plasma membranes (lane 2), non-rafts (lane 3), and lipid rafts/caveolae (lane 4) isolated from SCP-2 expressing cells (Panel B). Relative expression levels of SCP-2 in non-raft (hatched bar) and lipid rafts/caveolae (closed bar) fractions isolated from SCP-2 expressing cells were determined as described in “Methods”

gomyelin mass between lipid rafts/caveolae and non-rafts, while concomitantly increasing the mass of ceramide in lipid rafts/caveolae versus non-rafts (Table 1).

In control cells the mass of neutral glycosphingolipids, including monohexosides (glucosylceramide), dihexosides (lactosylceramide) and tetrahexosides (globosides) in lipid rafts/caveolae as well as non-rafts was lower than that of sphingomyelin and ceramide within these fractions (Table 1). Furthermore, the content of these neutral glycosphingolipids was markedly different in lipid rafts/caveolae as compared to non-raft domains. The content of monohexosides and globosides was 7 and 6.4-fold higher in the lipid raft/caveolae fraction as compared to the non-raft fraction of plasma membranes from control L-cells (Table 1). While the content of dihexosides also appeared greater in lipid rafts/caveolae, this difference did not achieve statistical significance. The SCP-2 overexpression markedly increased the content of monohexosides and globosides in both lipid rafts/caveolae and non-rafts (Table 1). Overall, neutral sphingolipids were enriched in lipid rafts/caveolae as compared to non-raft domains and SCP-2 overexpression significantly enriched the content of neutral sphingolipids, especially globosides and monohexosides to higher levels in lipid rafts/caveolae than in non-rafts.

Levels of the ganglioside GM1 in lipid rafts/caveolae of control L-cells were 4.1-fold higher than in non-raft domains (Table 1). Likewise, the GM1 content in lipid rafts/caveolae isolated from SCP-2 expressing cells was increased fourfold higher when compared to levels in non-rafts (Table 1). However, much like sphingomyelin, levels of GM1 were decreased 2.3-fold in the lipid rafts/caveolae isolated from SCP-2 expressing cells versus control cell lipid rafts/caveolae. Taken together, these data indicate that while lipid rafts/caveolae are enriched in sphingolipids such as sphingomyelin, GM1, and hexosides, these effects can be potentiated by SCP-2 expression.

#### Effect of SCP-2 Expression on the % Distribution of Sphingolipid Classes in Lipid Rafts/Caveolae and Non-raft Domains

When the sphingolipid mass data was expressed as % distribution, differences were also observed in lipid rafts/caveolae as compared to non-raft domains (Table 2). In control cells, the % distribution of sphingolipids in lipid rafts/caveolae was in the following order: ceramides > sphingomyelin > dihexosides > globosides > monohexosides > GM1 with the relative ratios being 19:18:6:5:3:1. The order of sphingolipid species % distribution was the same in non-rafts but the ratios were significantly different 106:25:13:2.8:1.6:1 due to the two and threefold lower percent sphingomyelin and GM1, respectively, in the non-raft fraction (Table 2).

SCP-2 overexpression significantly altered the % distribution of sphingolipids in both lipid rafts/caveolae and non-raft domains. The % distribution of sphingolipids in lipid rafts/caveolae in SCP-2 expressing cells was in the order: ceramides >> sphingomyelin > globosides > monohexosides, dihexosides > gangliosides with the relative ratios being 80:23:16:10:9.8:1. This order was the same in non-rafts, but the ratios were differed significantly (170:100:30:17:14:1). Overall, with the exception of sphingomyelin the overexpression of SCP-2 tended to reduce the difference in sphingolipid class % distribution between lipid rafts/caveolae and non-rafts. Furthermore, SCP-2 expression increased the proportion of ceramides in the lipid rafts/caveolae fraction while decreasing the % GM1 (2.9-fold), % sphingomyelin (2.2-fold) and % dihexosides (1.6-fold) (Table 2). Thus, the % distribution of sphingolipid classes differed significantly between lipid rafts/caveolae and non-rafts. Additionally, a comparison of % distribution of sphingolipids in the non-raft fractions isolated from control and SCP-2 expressing cells revealed that levels of sphingomyelin, monohexosides, and

<sup>#</sup>  $P < 0.05$  versus the same fraction in control cells

globosides were increased up to fivefold while levels of ceramides, dihexosides, and GM1 were decreased in non-rafts isolated from SCP-2 expressing cells. These results indicate that SCP-2 expression differentially alters the % distribution of select sphingolipid classes in both lipid rafts/caveolae and non-raft fractions—consistent with selective targeting and/or increased sphingolipid metabolism.

#### Interaction of SCP-2 with Sphingomyelin

Since SCP-2 overexpression clearly altered the mass and % distribution of sphingolipid classes in lipid rafts/caveolae versus non-rafts, it was important to demonstrate whether this was associated with direct binding of these lipids—something which had heretofore not been demonstrated (see “Introduction”). Therefore, the ability of SCP-2 to directly bind representative non-glycosylated sphingolipids (sphingomyelin, ceramide), neutral glycosphingolipids (monohexosides, dihexosides, globosides), and acid sphingolipid (GM1) classes was determined.

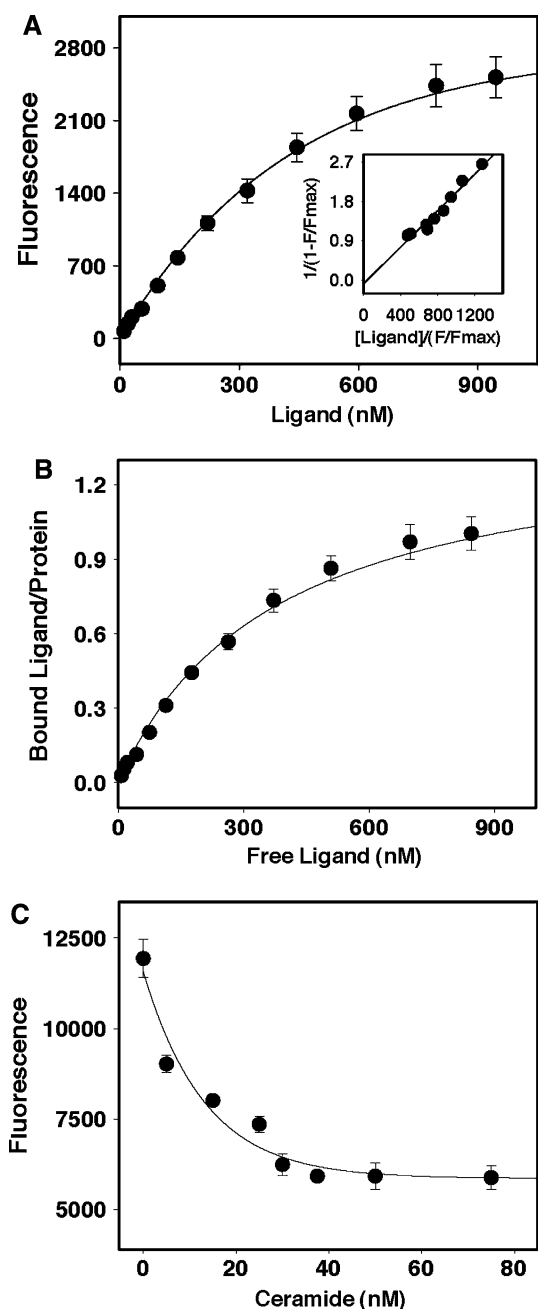

The SCP-2 binding of sphingomyelin was examined by use of a fluorescent sphingomyelin derivative (i.e., NBD-sphingomyelin). Although NBD-sphingomyelin in aqueous buffer fluoresces maximally near 540 nm, emission intensity was much less without SCP-2 present (data not shown). Plotting the maximal intensity of NBD-sphingomyelin emission at 543 nm versus increasing NBD-sphingomyelin concentration yielded a monophasic saturation binding curve (Fig. 4a). The double reciprocal of this binding curve was linear, consistent with the presence of a single binding site (Fig. 4a, inset). A reverse titration experiment in which increasing amounts of SCP-2 were added to a fixed concentration of NBD-sphingomyelin provided maximal fluorescence of completely bound NBD-sphingomyelin and allowed determination of the number of binding sites to a higher degree of accuracy (Fig. 4b). A plot of bound versus free NBD-sphingomyelin yielded a binding site saturation curve (Fig. 4b) where  $B_{\max} = 1.4 \pm 0.2$ , indicative of a single binding site for NBD-sphingomyelin,

and a dissociation constant ( $K_d$ ) for NBD-sphingomyelin binding to SCP-2 equal to  $375 \pm 34$  nM.

In order to resolve whether the NBD chemical moiety attached to sphingomyelin might itself impact the binding of sphingomyelin to SCP-2, SCP-2 bound NBD-sphingomyelin was displaced with increasing unlabeled sphingomyelin. When a complex of NBD-sphingomyelin and SCP-2 was incubated with increasing amounts of non-fluorescent sphingomyelin, the maximal fluorescence emission intensity of NBD-sphingomyelin was decreased in monophasic fashion—consistent with displacement of fluorescent NBD-sphingomyelin by non-fluorescent sphingomyelin at a single binding site (not shown). The concentration at which sphingomyelin displaced 50% of SCP-2 bound NBD-sphingomyelin intensity (i.e.,  $K_i$ ) was  $173 \pm 6$  nM (Table 3). Thus, the  $K_i$  for NBD-sphingomyelin displacement by sphingomyelin was about twofold lower than the  $K_d$  for NBD-sphingomyelin direct binding. In summary, SCP-2 exhibited high affinity in the nM range for sphingomyelin. This affinity was not an artifact due to the presence of the NBD chemical moiety in NBD-sphingomyelin since the  $K_d$  for binding NBD-sphingomyelin was within a factor of two of the  $K_i$  for displacement with non-fluorescent sphingomyelin.

#### Effect of the Phosphocholine Moiety of Sphingomyelin on Binding to SCP-2

Since ceramide is both the precursor of sphingomyelin and a product of sphingolipid degradation, the binding of ceramide to SCP-2 was also examined. Incubation of a SCP-2/NBD-sphingomyelin complex with increasing concentrations of ceramide resulted in displacement of NBD-sphingomyelin with a monophasic displacement curve (Fig. 4c). Analysis of multiple displacement curves yielded a  $K_i = 5 \pm 1$  nM (Table 3)—the highest affinity of SCP-2 for any sphingolipid class examined. By comparing the structures of ceramide and sphingomyelin it was clear that the absence the phosphocholine group increased SCP-2's

**Fig. 4** Ligand binding and displacement studies (*Panel A*). Titration of SCP-2 with NBD-sphingomyelin was followed by an increase in fluorescence, (excitation 480 nm, emission 540 nm). The data was fit to a simple, single binding site model as described in “Methods”. *Inset*, linear plot of  $1/(1 - F/F_{max})$  versus  $[ligand]/(F/F_{max})$  for titration of SCP-2 with NBD-sphingomyelin (*Panel B*). The binding site saturation curve was determined as described in “Methods” (*Panel C*). SCP-2 was preincubated with NBD-sphingomyelin, followed by addition of increasing concentration of displacing ligand ceramide. The fluorescence intensity decay in the presence of competitive non-fluorescent sphingomyelin was measured to determine  $K_i$  as described in “Methods”

**Table 3** Competitive inhibition of NBD-sphingomyelin binding to SCP-2 by non-fluorescent ligands

Ligand	$K_i$ (nM)
Sphingomyelin and precursor ceramide	
Sphingomyelin	173 ± 6
Ceramide	5 ± 1
Neutral glycosphingolipids	
Glucosylceramide (monohexoside)	101 ± 16
Galactosylceramide (monohexoside)	110 ± 10
Lactosylceramide (dihexoside)	116 ± 9
Globosides (tetrahexoside)	121 ± 2
Acidic glycosphingolipids	
Ganglioside GM1	43 ± 6

Values represent mean ± SE,  $n = 3$

Displacement assays were performed as described in “Methods”

Inhibition constants ( $K_i$ ) were calculated from a non-linear fit to an exponential decay curve of NBD-sphingomyelin fluorescence versus the competitor concentration

$K_i$  was equal to the ligand concentration at  $F_{max}/2$

affinity for this sphingolipid nearly 35-fold (Table 3). These data indicated that SCP-2 had significantly higher affinity for ceramide, both a precursor and metabolite of sphingomyelin and other sphingolipids.

#### Binding of Neutral Glycosphingolipids to SCP-2

Ceramide is metabolized not only to sphingomyelin, but is also glycosylated to form neutral sphingolipids including monohexosides (e.g., glucosylceramide, galactosylceramide), dihexosides (e.g., lactosylceramide), and tetrahexosides (e.g., globosides). Therefore, the effect of linking neutral sugars to ceramide on binding to SCP-2 was examined using the NBD-sphingomyelin displacement assay. Increasing concentrations of monohexosides such as glucosylceramide and galactosylceramide both resulted in displacement of SCP-2 bound NBD-sphingomyelin, yielding  $K_i$ s of  $101 ± 16$  and  $110 ± 10$  nM, respectively (Table 3). Covalently linking additional sugars as in lactosylceramide (a dihexoside) and globosides (tetrahexosides) also resulted in displacement of SCP-2 bound sphingomyelin, but these more complex neutral glycosphingolipids did not significantly further alter the  $K_i$ s which were  $116 ± 9$  and  $121 ± 2$  nM for lactosylceramide and globosides, respectively (Table 3). Thus, monoglycosylation of ceramide to form neutral glycosphingolipids decreased the binding affinity to SCP-2 more than 20-fold as compared to ceramide itself (Table 3). However, the presence of more extended sugar chains did not further

reduce binding affinity of the neutral glycosphingolipids to SCP-2.

#### Binding of Acidic Glycosphingolipid to SCP-2

In addition to sphingomyelin and neutral glycosphingolipids, ceramide can also be metabolized to form acidic glycosphingolipids by linking an acid sugar such as sialic acid. Gangliosides, such as GM1 represent typical acidic glycosphingolipids. The effect of linking an acidic sugar to the glycosphingolipids on binding affinity to SCP-2 was therefore examined using the NBD-sphingomyelin displacement assay. As observed with the neutral glycosphingolipids, increasing concentrations of the acidic glycosphingolipid ganglioside GM1 also displaced SCP-2 bound NBD-sphingomyelin, yielding a  $K_i$  of  $43 \pm 6$  nM for ganglioside GM1 (Table 3). Thus, covalently linking an acidic sugar to the glycosphingolipid enhanced the affinity of SCP-2 for the branched-chain GM1 nearly threefold as compared to neutral sphingolipids for SCP-2 (Table 3). Overall, these data indicated that SCP-2 exhibited the following order of affinities for sphingolipids:ceramides, GM1 > the neutral glycosphingolipids (monohexosides, dihexosides, and globosides) > sphingomyelin.

#### Spontaneous Sterol Transfer from Lipid Rafts/Caveolae Isolated from Plasma Membranes Purified from Control and SCP-2 Expressing Cells

Since SCP-2 was shown to selectively regulate sphingolipid distribution to lipid rafts/caveolae in living cells (as described above), the possibility that cholesterol dynamics were also affected was next examined using a sterol transfer polarization assay as described in “Methods”. Spontaneous sterol (DHE) transfer from purified lipid raft/caveolae donors (containing DHE) to lipid raft/caveolae acceptor (containing cholesterol but no DHE) was determined and compared to DHE transfer from lipid raft/caveolae donor/acceptor pairs isolated from SCP-2 expressing cells. When the DHE polarization changes during sterol transfer were kinetically analyzed, two kinetic domains were resolved in lipid rafts/caveolae: (1) a rapidly exchangeable sterol domain with  $t_{1/2}$  on the order of minutes, and (2) a slowly exchangeable sterol domain with  $t_{1/2}$  on the order of days. In control cells, the initial rate of molecular sterol transfer from lipid rafts/caveolae donors to acceptors was  $0.339 \pm 0.021$  pmole/min, twofold faster than that observed with domains isolated from SCP-2 expressing cells ( $0.166 \pm 0.024$  pmol/min, Fig. 5a). Concomitantly, the size of the rapidly exchangeable sterol domain was decreased from  $0.230 \pm 0.017$  to  $0.109 \pm 0.013$  in domains isolated from SCP-2 expressing cells (Fig. 5b). Thus, SCP-2 expression significantly altered the spontaneous sterol

**Fig. 5** Kinetic analysis of sterol transfer between lipid rafts/caveolae isolated from plasma membranes purified from control and SCP-2 expressing cells. Fluorescence polarization for DHE sterol transfer from lipid rafts/caveolae donors to acceptors was analyzed as described in “Methods”. The initial rate (Panel A) of sterol transfer and the fraction of sterol available for rapid exchange (Panel B) was determined by kinetic analysis of exchange curves as described in [14]. Values represent mean  $\pm$  SEM ( $n = 4$ ). \* $P < 0.002$  versus lipid raft/caveolae fractions isolated from control cells

dynamics in lipid rafts/caveolae to decrease the initial rate of sterol transfer and exchangeable sterol pool size.

#### Discussion

Despite the importance of sphingolipids to cell signaling at the plasma membrane, relatively little is known regarding factors that regulate sphingolipid distribution to plasma membrane lipid rafts/caveolae. While lipid rafts/caveolae are rich in cholesterol [14], these microdomains are also thought to be enriched in sphingolipids such as sphingomyelin, ceramide, and gangliosides [4–8, 49] and enzymes involved in sphingolipid signaling [2], conclusions based largely on work with lipid rafts/caveolae isolated by use of detergents or high pH carbonate buffer. However, increasingly there are growing concerns that methods using detergent or high pH carbonate buffer to isolate lipid rafts/caveolae (often starting from whole cell homogenates rather than purified plasma membranes) may not reflect the biological nature of lipid rafts/caveolae in intact cells [9–11]. To avoid these concerns, the current investigation determined the sphingolipid distribution of lipid rafts/

caveolae and non-rafts isolated from purified plasma membranes by affinity chromatography without the use of detergents or high pH carbonate buffer [9, 14, 33, 34]. Extending earlier work with whole cells [37], we examined for the first time: (1) the potential role of SCP-2 in regulating the distribution of individual sphingolipid classes to lipid rafts/caveolae and non-raft domains of plasma membranes from living cells, and (2) whether SCP-2 binds specific sphingolipid classes with high affinity.

First, it was shown that lipid rafts/caveolae isolated without the use of detergents or high pH carbonate buffers were enriched in sphingolipids. Not only sphingomyelin, but also monohexosides, globosides, and the ganglioside GM1 were highly enriched in plasma membrane lipid rafts/caveolae as compared to non-rafts isolated from control L-cells. The content of dihexoside also tended to be higher, but these trends did not achieve statistical significance. Quantitative and qualitative comparison of sphingolipid analyses shown herein versus sphingolipid analyses for lipid rafts/caveolae isolated by use of detergents or high pH carbonate buffers [4, 50] revealed important differences: (1) sphingomyelin and gangliosides were less highly enriched in lipid rafts/caveolae isolated without detergents or high pH carbonate buffer, (2) globosides were enriched only in lipid rafts/caveolae isolated without detergents, (3) ceramides and dihexosides were much less highly enriched in lipid rafts/caveolae isolated without detergents [4, 50], and (4) monohexosides were highly enriched in lipid rafts/caveolae isolated without, but not with, detergents [50]. Thus, while lipid rafts/caveolae isolated without the use of detergents or high pH carbonate buffer share some features with lipid rafts/caveolae isolated by the latter, important quantitative as well as qualitative differences exist.

Second, SCP-2 overexpression in L-cell fibroblasts significantly altered the mass content and % distribution of sphingolipids in lipid rafts/caveolae isolated from purified plasma membranes. As shown herein, the lipid rafts/caveolae isolated from purified plasma membranes derived from SCP-2 expressing cells contained close to twofold more total sphingolipid than the non-raft domains, reflecting significant increase in the mass content of ceramides (twofold), the neutral glycosphingolipids monohexosides (2.8-fold), dihexosides (2.9-fold), globosides (2.2-fold), and the acidic glycosphingolipid GM1 (fourfold). In contrast, SCP-2 expression had less effect on the mass distribution of sphingomyelin—consistent with the fluorescence binding data showing that SCP-2 exhibited the least binding affinity for sphingomyelin as compared to other sphingolipids. In keeping with this trend, those sphingolipids most strongly targeted to lipid raft/caveolae fractions (ceramides, GM1, and the neutral glycosphingolipids (monohexosides, dihexosides, and globosides)) were bound with highest affinity by SCP2.

The biological significance of altered sphingolipid composition to plasma membrane structure and function can be realized from in vitro studies using model membranes [51] and isolated plasma membranes from SCP-2 overexpressing cells [45]. These and other studies [14] showed a strong interaction between sphingomyelin and cholesterol such that membranes high in sphingolipid exhibited reduced size of exchangeable cholesterol domains in membranes, reduced spontaneous cholesterol efflux, and reduced ability of SCP-2 to potentiate cholesterol efflux therefrom [52, 53]. Furthermore, SCP-2 induced alteration of sphingolipid composition and content in lipid rafts/caveolae may also potentially enhance or disrupt signaling and/or vesicular transport activities in the cell since extensive studies have shown distinct roles for several sphingolipid species in these cellular processes [15, 54]. For example, increased levels of ceramides disrupt the organization of cholesterol in lipid rafts and thereby alter cholesterol efflux [15]. SCP-2 overexpression increased the level of ceramide in lipid rafts/caveolae and, as shown earlier, reduced HDL-mediated cholesterol efflux [52]. In the present work, the functional consequence of increased ceramide levels on cholesterol dynamics within lipid raft/caveolae was shown by measuring sterol transfer between lipid rafts derived from control or SCP-2 expressing cells. Analysis of kinetic parameters revealed that the initial rate of molecular sterol transfer from lipid rafts/caveolae donors to acceptors was twofold slower in the presence of increased SCP-2 and ceramides. The size of the exchangeable sterol pool was also two-fold smaller, suggesting SCP-2 significantly altered the spontaneous sterol dynamics in lipid rafts/caveolae by way of ceramide disruption of lipid rafts [55]. Overall, the molecular basis for the reduced cholesterol dynamics in sphingolipid-enriched lipid rafts may be related to the increased rigidity (reduced fluidity) of these domains [33]. The importance of membrane sphingolipids to biological activity is also reflected in the ability of certain viral and bacterial molecules to gain entry into the cell via binding to specific sphingolipids in lipid rafts/caveolae. Cholera toxin from *Vibrio cholera* and *Escherichia coli* bind to the ganglioside GM1 [56] while Shiga toxin from *Shigella dysenteriae* binds to globosides [57]. As seen herein, the mass of GM1, a specific ganglioside involved in signaling [14], as well as globosides, were significantly increased in lipid rafts as compared to non-raft fractions, whereas the effect of SCP-2 expression was to increase mass content of globosides and decrease GM1 as compared to lipid rafts isolated from control cells. Other signal transduction pathways mediated by sphingolipids and potentially regulated by SCP-2 expression include: Ca<sup>2+</sup> flux (dihexosides, globosides, GM1); differentiation (gangliosides); proliferation (gangliosides, dihexosides); cAMP accumulation (globosides), phosphorylation (dihexosides, gangliosides); and PLC signaling (GM1) [15].

Third, the ability of SCP-2 to alter sphingolipid distribution and targeting was correlated with its binding affinity for sphingolipids. The SCP-2 had a single binding site and bound sphingomyelin with affinity near 173 nM. All sphingolipids tested readily displaced SCP-2 bound NBD-sphingomyelin with  $K_i$ s in the nanomolar range of 5–121 nM. The relative order of displacement was: ceramide ( $K_i = 5$  nM) > acidic glycosphingolipid (ganglioside GM1,  $K_i = 43$  nM) > neutral glycosphingolipids ( $K_i$ s = 101–121 nM). Comparison with the effects of SCP-2 expression on altering the distribution of sphingolipid classes to lipid rafts/caveolae suggested that SCP-2 was most effective in mediating enrichment of sphingolipid classes in lipid rafts/caveolae for the sphingolipid class that was bound most tightly by SCP-2 (ceramide). The SCP-2 had the opposite effect on distribution to lipid rafts/caveolae of the sphingolipid class which it bound most weakly (sphingomyelin). Taken together, these findings suggest two potential mechanisms whereby SCP-2 may play a role in regulating distribution of sphingolipids to lipid rafts: (1) SCP-2 may directly transfer bound sphingolipid species to lipid rafts. Model membrane studies demonstrated that SCP-2 interacts directly with negatively charged membranes through its N-terminal amphipathic  $\alpha$ -helical domain to facilitate transfer of bound ligand [58, 59], (2) as a secondary effect SCP-2 may also influence sphingolipid distribution to lipid rafts by regulating vesicular transport. This possibility is supported by the fact that SCP-2 has high affinity for not only for sphingolipids involved in vesicular trafficking, but also for other ligands that regulate vesicle budding at the Golgi i.e., phosphatidylinositol [26] and fatty acyl CoA [60]. Interestingly, while sphingomyelin, along with cholesterol, is known to be enriched in plasma membrane lipid rafts/caveolae, in the present work sphingomyelin was also found in the non-raft fractions which may include lipids and proteins involved in non-caveolar endocytic pathways, i.e., macropinocytosis, clathrin-mediated, clathrin-independent, and caveolae-independent. Recently, by using a fluorescent analog of sphingomyelin, Pagano showed that sphingomyelin was internalized from the plasma membrane equally by clathrin-dependent and independent pathways [61], suggesting participation in both pathways. In SCP-2 expressing cells levels of sphingomyelin increased almost twofold in non-rafts as compared to non-rafts isolated from control cells. However, since SCP-2 was nearly absent from the non-raft fraction (Fig. 3a) and exhibited the least preference for binding to sphingomyelin (Table 3), it remains unclear whether increased targeting of sphingomyelin to non-rafts in SCP-2 expressing cells is SCP-2 mediated or facilitated by another protein enriched in the non-raft fraction. In conclusion, for the first time it was shown that SCP-2 exhibited high affinity for select sphingolipid classes and

that SCP-2 overexpression significantly altered both the mass and % distribution of sphingolipid classes in lipid rafts/caveolae. Taken together, these findings suggest that SCP-2 is a potential candidate for regulating sphingolipid distribution to lipid rafts/caveolae in the cell.

**Abstract** Sterol regulatory element binding proteins (SREBPs) are key transcription proteins that bind to sterol regulatory elements (SRE) of genes essential for cellular cholesterol and fatty acid homeostasis. Polyunsaturated fatty acids (PUFA) strongly inhibit SREBP processing at post-transcriptional levels. We questioned if delivering PUFA as part of a triglyceride (TG) molecule would have similar effects and efficiency as free non-esterified PUFA. CHO cells stably transfected with an SRE-promoter linked to the luciferase reporter gene were incubated for 8–24 h with linoleic acid (LA) complexed to BSA (molar ratios 0.5–4:1), VLDL-sized trilinolein emulsions (TL, 25–200 µg/ml), and chylomicron-sized soy oil emulsions in the presence and absence of apoE. Effects of LA and TL on decreasing SRE-luciferase activity were similar and dose and time dependent. Both TL and LA significantly and rapidly ( $\leq 2$ –12 h) reduced SRE-mediated gene expression by up to 75%. At equal fatty acid concentrations, SRE inhibition by TL was as effective as LA. ApoE addition increased inhibition by TL. Inhibition of gene expression was highly correlated to cell TG accumulation. We conclude that TG like fatty acids are rapid and efficient modulators of SRE-mediated gene expression.

**Keywords** SRE-mediated gene expression · SREBP · Trilinolein · Linoleic acid · De novo triglyceride synthesis

## Abbreviations

ACCoA	Acetyl CoA carboxylase
apoE	Apolipoprotein E
CHO	Chinese hamster ovarian
HSPG	Heparan sulfate proteoglycans
LA	Linoleic acid
LCT	Long chain triglyceride
LRP	Low-density lipoprotein receptor related-protein
mSREBP	Mature form of SREBP
OA	Oleic acid
SRE	Sterol regulatory element
SREBP	Sterol regulatory element binding protein
TG	Triglyceride
TGRP	Triglyceride-rich particle
TL	Trilinolein

## Introduction

Dietary fatty acids function in several roles such as a source of energy and provision of essential fatty acids [1]. They also regulate transcription of lipogenic and glycolytic genes [2–9], and this regulation, in part, is related to sterol regulatory element binding protein (SREBP) processing and binding to sterol regulatory elements (SRE) [10–14]. SRE are located in the promoter region of genes encoding key regulatory enzymes involved in fatty acid and triglyceride (TG) metabolism (i.e., responsive to SREBP-1a, SREBP-1c), and cholesterol synthesis (responsive to SREBP2) [15, 16]. In conditions of cellular sterol depletion, the mature forms of SREBP (mSREBP), the active transcription factors, are generated after a two-step prote-

olytic process. mSREBP translocate to the nucleus to bind to the SRE in the promoter regions of key genes of lipid metabolism [15]. Increasing cell sterols leads to suppression of gene transcription of SRE-promoter containing genes [17].

In addition to sterols [18, 19], unsaturated fatty acids regulate SRE-mediated gene expression [10–13, 20]. For example, mono- and polyunsaturated fatty acids down-regulate SRE-dependent HMG-CoA synthase gene transcription in vitro [10]. Moreover, suppression of SRE-dependent gene expression increases with the number of fatty acid carbons and double bonds [10].

A large fraction of dietary and endogenous fatty acids are delivered to tissues as part of a TG molecule. A number of studies have provided evidence that substantial amounts of triglyceride-rich particles (TGRP) can be taken up by tissues without substantial intravascular lipolysis [21]. Compared to free fatty acids, TG can undergo different pathways of intracellular metabolism [22, 23]. Thus, we questioned whether the regulation of SRE-dependent gene expression by fatty acid delivered as TG is different from free fatty acid. To address this, we used lipid emulsions as model TGRP and compared the effects of chylomicron-sized soy oil based TGRP, VLDL-sized trilinolein based TGRP, and linoleic acid (LA) complexed to albumin. Our findings indicate that polyunsaturated TG like polyunsaturated free fatty acid are also very efficient at down-regulating SRE-dependent gene expression.

## Experimental Procedures

### Materials

Linoleic acid and oleic acid (OA) were purchased from Sigma-Aldrich, Inc. (St Louis, MO). Trilinolein was purchased from Nu-Chek Prep, Inc. (Elysian, MN). Egg yolk phosphatidylcholine was obtained from Avanti Polar-Lipids, Inc. (Alabaster, AL). [9,10 <sup>3</sup>H (N)]—oleic acid and [9,10 <sup>3</sup>H (N)]—triolein were purchased from PerkinElmer Life and Analytical Science, Inc. (Shelton, CT). Purified recombinant apolipoproteinE<sub>3</sub> (apoE) produced in *E. coli* was provided by Biotechnology General (Rehovot, Israel). TRIZol and SREBP-1a primer were obtained from Invitrogen (Carlsbad, CA).

### Lipid Emulsions

Phospholipid-stabilized commercial emulsions of n-6 soy oil TG (LCT) provided by B. Braun Melsungen AG (Melsungen, Germany) contained 20 g TG/100 ml, and 2.5 g glycerol/100 ml, emulsified by 1.2 g/100 ml of egg

yolk lecithin. These TGRP contained ~54% of their triglyceride fatty acids as LA; their detailed composition has been published elsewhere [24]. Laboratory-made VLDL-sized trilinolein lipid emulsions were prepared using egg yolk phosphatidylcholine /trilinolein (1:4, by weight). The mixture was dried under N<sub>2</sub> gas and then desiccated under vacuum overnight. A vial containing the dried lipid mixture was vortexed with 8 ml of 150 mM NaCl and 0.24 mM disodium EDTA, after adding 0.8 g of sucrose (10%), pH 8.4, at 60 °C. The lipid mixture was then sonicated using a Branson Sonifier model 450 (Branson Scientific, Melville, NY) for 1 h at 40–42 °C, 140 W under nitrogen gas. Buffer solution was added every 10 min during sonication to keep the original volume. Following sonication, emulsion TGRP were dialyzed in buffer for 24 h to remove sucrose. Dialyzed TGRP were overlaid with buffer in a centrifuge tube (Beckman Coulter, Inc., Fullerton, CA) and centrifuged for 20 min at 40,000 rpm, 4 °C, in a Beckman SW 40 Ti rotor (Beckman, Fullerton, CA) to remove dense excess phospholipid-rich liposomes with trapped sucrose. The infranatant was transferred into another centrifuge tube and then overlaid with buffer and centrifuged for 18 h at 28,000 rpm 4 °C in the same rotor. The resulting top cream layer consisting of VLDL-sized emulsion particles and these were analyzed for the amounts of TG and PL by an enzymatic calorimetric assay using a triglycerides/glycerol blanked kit (Roche Diagnostics Corporation, Indianapolis, IN) and a phospholipid kit (Wako Chemicals USA, Inc., Richmond, VA) The triglyceride:phospholipid mass ratio was 5.0 ± 1.0:1 similar to that of VLDL-sized particles. Lipid emulsions contained <0.1% of total glycerols as free fatty acids.

For experiments to follow the cellular uptake and conversion of emulsion TG to free fatty acid, TL emulsions were radiolabeled with <sup>3</sup>H-triolein by incorporating <sup>3</sup>H-triolein with the dried lipid mixture. Following incubations the amount in TG versus free fatty acid was determined after Dole's extraction of cell lipids [25].

### Free Fatty Acids

Free fatty acids were dissolved in 100% ethanol and complexed to BSA as previously described [26]. Equal amounts of ethanol (<0.1% of medium volume) were added under control conditions and had no effects on reporter gene expression as described [10].

### Cells

Chinese hamster ovarian cells (CHO) were stably transfected with an SRE-promoter of HMG-CoA synthase linked to a luciferase reporter gene and luciferase activity

was measured as previously detailed [10]. The pSyn SRE plasmid contains a generic TATA and three SRE elements (–325 to –225) of the hamster HMG-CoA synthase promoter fused into the luciferase pGL2 Basic vector (Promega, Madison, WI). All incubations were carried out in serum-free Dulbecco's modified Eagle's media under conditions detailed in the figure legends.

#### Isolation of RNA and Real-Time Quantitative PCR

Total RNA was isolated from CHO cells with TRIzol and one microgram of isolated RNA was reverse-transcribed using iScript cDNA Synthesis kit (Bio-Rad Laboratories, Hercules, CA). The resulting cDNA was diluted 1:10 and quantitated for ACCoA and SREBP-mRNA levels using Mx3005P™ real-time PCR (Stratagene, La Jolla, CA) using  $\beta$ -actin as a reference gene. The sequences of primers were as follows: ACCoA, 5' primer 5'-ATGTGTGGAAGTCGATGTGC-3' and 3' primer, 5'-TTGCCAATTGTGATTCGGTA-3'; SREBP-1a, 5' primer, 5'-GCGCCATGGAGG-AGCTGCCCTTCG-3', and 3' primer, 5'-GTCAGTCTTGGTTGTTGATG-3';  $\beta$ -actin, 5' primer, 5'-CACCAGGGCGTGAT-GGTGGG-3', and 3' primer, 5'-GATGCCTCTCTTGCTCTGGGC-3' [27]. Real-time PCR analyses were carried out in duplicates and were repeated at least two times for consistency.

#### Statistical Analyses

The data were expressed as means  $\pm$  SEM. One-way analysis of variance (ANOVA) was performed to determine statistical significance at  $P \leq 0.05$ . A Bonferroni test was used for the post hoc multiple comparisons. All statistical analyses were performed with the use of SPSS software (version 11.5; SPSS Inc, Chicago, IL).

## Results

We first assessed the effect of soy oil based TGRP on SRE-mediated gene expression (Fig. 1a). Because these n-6 TGRP contain 53.9 and 23.8% of LA and OA, respectively, as their major fatty acid components, we next compared the effects of these two free fatty acids on SRE-mediated gene expression. Linoleate had significantly greater effect down-regulating SRE-mediated gene transcription than oleate (Fig. 1b) indicating that an increased number of double bond fatty acids resulted in more suppression of SRE-mediated gene expression. Thus, we chose to carry out most experiments comparing effects of LA with trilinolein (TL).

To determine whether TL would act as rapidly as LA in suppressing SRE expression, CHO cells were incubated with LA or TL for 2–24 h. Figure 2 shows that the inhib-

**Fig. 1** Effects of a soy oil TGRP (*LCT*), oleate, and linoleate on SRE expression in CHO cells. After 12 h of up-regulation in lipid-free medium, CHO cells stably transfected with an SRE-promoter reporter gene were incubated for 12 h with control medium alone (containing 1% BSA), medium containing *LCT* emulsion (200  $\mu$ g/ml) or cholesterol (10  $\mu$ g/ml with 1  $\mu$ g/ml of 25-OH cholesterol) (a), or medium supplemented with OA (C18:1n-9) (0.3 mM), LA (C18:2n-6) (0.3 mM), or cholesterol (10  $\mu$ g/ml with 1  $\mu$ g/ml of 25-OH cholesterol) (b). Luciferase activity and cell protein were measured. Data are expressed as percent of control (mean  $\pm$  SEM) from three experiments each performed in triplicate. § $P < 0.001$ ; \* $P < 0.05$ ; \*\* $P < 0.01$ ; \*\*\* $P < 0.001$  compared to control

**Fig. 2** Time-dependent effects of sterols, LA and TL on SRE expression in CHO cells. After 12 h of up-regulation, CHO cells stably transfected with an SRE-promoter reporter gene were incubated in control medium alone (*open diamonds*), medium supplemented with sterol (10  $\mu$ g/ml of cholesterol with 1  $\mu$ g/ml of 25-OH cholesterol) (*open squares*), medium containing LA (0.3 mM) (*filled triangles*), and medium supplemented with TL emulsion (200  $\mu$ g/ml) (*filled circles*) for 2, 4, 8, 12, and 24 h. Luciferase activity normalized to cell protein was measured. Data are expressed as percent of control (mean  $\pm$  SEM) from three experiments each performed in triplicate

itory effects of cholesterol, LA and TL on SRE-mediated gene expression were similar, although in this experiment molar amounts of TL fatty acid exceeded that of LA.

Although effects were maximal after 24 h of incubation, cell protein values decreased slightly with trilinolein emulsions at 24 h. Therefore, further experiments were performed within 12 h incubation periods. At this time point, as we have reported previously for free fatty acids [10], TG emulsions had no cell toxic effects.

Using emulsions with radiolabeled  $^3\text{H}$ -triolein we observed that after a 4-h incubation the amount of new TG in cells was  $4.6 \pm 0.5$  mg/mg cell protein ( $n = 3$ ), similar to our previous reported results. Cell TG decreased after removal of TG from the media at a rate of  $-0.20$  mg TG/mg cell protein/h. Also at 4 h, of total recovered counts 49% were found as FA increasing to 59% with a further 4 h incubation without lipids. These latter results show that emulsions were both taken up by cells, and efficiently converted to FA intracellularly.

To assess whether the regulation of SRE-dependent gene expression by free fatty acid versus TG was different or similar, we performed experiments with similar molar concentrations of LA as fatty acid and TG. Figure 3 indicates that the effect of FFA levels on suppression of gene expression occurs in a graded, concentration-dependent manner for both LA, and TL TGRP. At equal estimated FA concentrations (0.15, 0.45 and 0.6 mM), SRE inhibition by TL was equal as or more effective as LA.

To determine if decreases in SRE expression as measured by luciferase reported gene activity reflected changes in regulation of genes dependent on SREBP processing, we assayed expression of acetyl CoA carboxylase (ACCoA) in cells after incubation with LA and TL emulsions after a 4-h

**Fig. 3** Effects of increasing concentrations of LA and TL emulsion on SRE expression in CHO cells. Following 12 h up-regulation, CHO cells stably transfected with an SRE-promoter reporter gene were incubated in control medium alone (containing 1% BSA) and medium containing LA (filled triangles) at the following concentrations: 0.075, 0.15, 0.3, 0.45, and 0.6 mM, and medium supplemented with TL emulsion (filled circles) at 25, 50, 100, 150, and 200  $\mu\text{g}/\text{ml}$  to achieve equal concentrations of fatty acid as LA, respectively. Luciferase activity normalized to cell protein was measured. Data are expressed as percentages of control (mean  $\pm$  SEM) from three experiments each performed in duplicate.  $^\ddagger P < 0.01$ ;  $*P < 0.001$  compared to control;  $^\# P < 0.05$ ;  $^* P < 0.01$  compared to LA

incubation and a 12-h lipid free chase. ACCoA mRNA expression normalized by  $\beta$ -actin decreased by 65.6 and 51.3% for TL (200 mg/ml) and LA (0.3 mM), respectively, when compared to control incubations with albumin alone ( $n = 2$ ). Thus, decreases in SRE-luciferase activity were quite similar to levels of inhibition of expression of an SREBP1-regulated target gene, ACCoA.

Apolipoprotein E (apoE) plays a role as a ligand for lipoprotein uptake via receptor-related pathways, i.e., LDL receptor, LRP pathways [24, 28, 29]. In addition, apoE mediates TGRP uptake via non-receptor mechanisms such as cell surface proteoglycans [30–33]. ApoE added to TL-derived TGRP led to enhanced suppression of SRE-mediated gene expression (Fig. 4). In separate experiments adding lipid-free apoE alone without TGRP at similar concentration as used in incubation with the TRGP, there was no suppression of SRE-mediated gene expression (data not shown).

We questioned whether inhibition of SRE-mediated gene expression could be correlated to increased intracellular TG mass as a result of incubation with either LA or TGRP. Figure 5 depicts a close correlation between suppression of SRE-mediated gene expression and increases in cell TG mass ( $R^2 = 0.6733$ ), likely because higher cell TG provides a higher level of intracellular fatty acid release.

We examined whether changes in SREBP-1a mRNA levels (the SREBP isoform mainly found in cultured cells) contributed to regulation of SRE-mediated gene by TL or LA. Figure 6 shows that there were no significant differences in SREBP-1a mRNA levels of CHO cells incubated with cholesterol, LA, TL, or TL plus apoE. Thus, effects of TG on SRE-mediated gene expression, like those of free fatty acid, are mainly post-transcriptional.

**Fig. 4** Effect of apolipoproteinE-mediated TGRP uptake on suppression of gene expression. CHO cells stably transfected with an SRE-promoter reporter gene were incubated with TL or TL plus 5% apoE (weight/weight) for 12 h. Then luciferase and protein were assayed. Suppression of SRE expression shown by luciferase activity were compared to control incubations (1% fatty acid-free BSA). Data are expressed as mean  $\pm$  SEM from three experiments each performed in triplicate ( $*P < 0.05$ )

**Fig. 5** Correlation between inhibition of SRE-mediated gene expression and cell TG mass. CHO cells stably transfected with an SRE-promoter reporter gene were incubated with a range of concentrations of LA, TL, LCT, and TL in the presence of 5% apoE for 12 h. Luciferase activity, TG, and cell protein were assayed and SRE-mediated gene expression shown by luciferase activity was compared to net TG mass increases calculated by the TG mass differences from control cells not incubated with fatty acid or TG ( $R^2 = 0.6733$ )

**Fig. 6** Effects of linoleic acid, trilinolein, and cholesterol on SREBP-1a mRNA expression in CHO cells. Sterol-depleted CHO cells were incubated with cholesterol/25-OH cholesterol (10, 1  $\mu\text{g}/\text{ml}$ , respectively), LA (0.0375–0.6 mM), TL (12.5–200  $\mu\text{g}/\text{ml}$ ), in the presence or absence of apoE (5%, weight/weight) for 12 h. At the end of experiments, total RNA were isolated to determine SREBP-1a levels using real-time PCR as described in “Experimental Procedures”. Data were normalized by  $\beta$ -actin and expressed as percentages relative to control performed in duplicates. There were no significant differences between each group

## Discussion

Previous studies delineating effects of fatty acids on regulating SREBP processing have used albumin-bound fatty acids for in vitro analyses or dietary feeding of n-3 fatty acid enriched diets. Substantial amounts of dietary fatty acids are delivered to cells and tissues as part of a TG molecule. It remains an open question as to whether fatty acid-mediated decrease of SREBP processing requires delivery as a free fatty acid molecule cell, or whether intracellular delivery via TGRP can be equally effective. Studies of others have shown that in some tissues delivering free fatty acid versus TG has different effects on a number of parameters related to intracellular lipid metabolic endpoints such as energy

utilization [22, 34]. Our studies, using an in vitro cell culture approach, show that delivery of fatty acids as TG is equally or even more efficient at decreasing SRE-mediated gene expression than delivery of free fatty acid. Moreover, these effects are related to the amount of newly accumulating TG, either from uptake of free fatty acid or TG itself within cells. The effects of both TG and free fatty acids are posttranscriptional in that they do not affect expression of SREBP-1a mRNA, the relevant form of SREBP-1 in cell culture models.

Our current studies largely focused on LA complexed to albumin and trilinolein particles since, in previous studies, we showed that saturated fatty acids have little or no effect on SREBP processing, and in the current study, LA was more inhibitory than the previously reported effect of OA [10]. Our current studies show that uptake of both fatty acid and TG is rapid. This is in keeping with our previous studies where we showed rapid and efficient uptake by cultured cells with of model TGRP in the presence or absence of apoE, at concentrations similar to those used herein, [34, 35]. Moreover, under cell culture conditions used for our current studies, little or no lipolysis of TG takes place in cell media indicating that the effects we observed are not associated with hydrolysis of particle TG before uptake into cells [35, 36].

There are some limitations to our studies. Although in the incubation media we attempted to deliver equal amounts of LA as free fatty acid or TGRP, we could not precisely assess actual cellular uptake of LA or TGRP. Thus, we cannot determine if our results truly reflect exactly equal concentrations of LA delivered intracellularly. This would have been difficult to assess since internalized fatty acid and TG both shunt rapidly towards oxidation to  $\text{CO}_2$  and other intracellular pathways. Still, our experiments using radiolabeled TG showed not only substantial uptake of TGRP-TG by cells but also very efficient cellular catabolism to fatty acid. (Likely, both cell uptakes of TG and cell FA levels were underestimated as we did not measure their conversion to  $\text{CO}_2$ ). Usually, uptake of free fatty acids is studied over time periods of a few minutes [37] while studies on SRE-mediated gene expression need to be carried out over time periods of hours. Still we do not believe that this is a serious confounder in that even when delivered as TG, LA released intracellularly from TGRP led to effects of similar magnitude as that of LA complexed to albumin. It is also possible that apoE has distinct effects on SRE processing and SRE-mediated gene expression separate from effects on increasing TGRP cellular uptake [24, 31, 35]. However, in experiments where we added lipid free apoE in incubation with LA, we found no independent effects of exogenous apoE on SRE-mediated gene expression. Thus, we conclude the effects of apoE are linked to increasing intracellular delivery of TGRP.

The close correlation of inhibition of SRE-mediated gene expression with net accumulation of cell TG is of interest. Unsaturated fatty acids are most effective in decreasing SREBP in the presence of high TG mass. These findings raise the possibility that, early after uptake of free fatty acid or TG most TG fatty acid and fatty acid themselves are utilized for oxidation and only with ongoing continuous delivery of fatty acids or their metabolites to specific intracellular targets SREBP processing is affected. Likely, hydrolysis of intracellular TG provide a continuing intracellular source for fatty acids to inhibit SREBP processing. At this point, while speculative, it is possible that before acting intracellularly, free fatty acids must first be repackaged into intracellular TG followed by release of fatty acids to decrease the generation of mSREBP. This would result in less activation of genes involved in de novo fatty acid synthesis (such as fatty acid synthase) and result in decreased endogenous TG production (Fig. 7). Another open question is whether it is free fatty acids themselves or their metabolites that are active in suppressing and SREBP-mediated gene expression. While it is possible that the TG molecule itself might affect SREBP processing between the endoplasmic reticulum and the Golgi, we do not believe this to be likely since long chain TG molecules, such as TL, are generally regarded as an “inert” storage form for biologically active fatty acids. Because of the molecular

**Fig. 7** TG and FA as interactive partners in SREBP processing and suppression of SRE-mediated gene expression. As an example, SRE dependent expression of fatty acid synthase (FAS) is shown. Exogenous FA moves into the intracellular compartment (step 1), then it is either oxidized resulting in CO<sub>2</sub> production (step 2) or re-esterified to TG (step 3). Cell TG can also accumulate for exogenous TG (step 4) to be part of the TG pool. After hydrolyzing TG from the intracellular pool (step 5), released FA suppress SREBP processing (step 6) from its precursor form (pSREBP) to its mature form (mSREBP). As a result, SRE-dependent gene activity is decreased (step 7). With decreased FA synthesis (step 8), decreased de novo TG synthesis and deposition also occur (step 9)

properties of the very apolar TG, it is unlikely to be a direct effector. TG would need to break free from its aggregation state and require a protein for transport through an aqueous phase. In contrast, FA has molecular properties (and intracellular protein transporters) that allow its rapid diffusion anywhere in the cell.

Studies in human and animal models with intravenous TG emulsions have shown that provision of exogenous TG depresses de novo TG synthesis in liver and other tissues [38, 39]. During lipid-free intravascular nutrition support, increased endogenous TG synthesis and accumulation in liver has been documented [38]. Our findings are consistent with a mechanism whereby intracellular delivery of TG suppress de novo fatty acid synthesis by inhibition of SREBP-activated genes such as fatty acid synthase [12, 40] and as shown herein, ACCoA. To conclude, delivering exogenous fatty acid as part of a TG molecule is equally effective as free fatty acids in suppressing SRE-mediated gene expression and expression of genes involved in fatty acid and TG syntheses. Since normal humans have triglyceridemia post-prandially for many hours of a day, it is likely that direct delivery of triglyceride-rich particles to cells does have physiologically modulating effects on SRE-mediated gene expression.

**Abstract** Oxidized LDL (oxLDL) has been shown to activate the sphingomyelinase pathway producing ceramide in vascular smooth muscle cells. Therefore ceramide, which is a biologically active lipid causing apoptosis in a variety of cells, may be involved in the apoptotic action of oxLDL. In this study, we examined whether cholesterol enriched diets affected ceramide metabolism and oxidation product of LDL, represented by degradation of apolipoprotein B-100 (apoB) in apoE-deficient (apoE<sup>-/-</sup>) mice. ApoE<sup>-/-</sup> and wild type mice were fed a standard (AIN-76) diet or 1% cholesterol-enriched diet for 8 weeks. Tissue ceramide levels were analyzed using electrospray tandem mass spectrometry (LC-MS/MS). Ceramide levels in the plasma and the liver of apoE<sup>-/-</sup> mice were intrinsically higher than those of the wild type. In apoE<sup>-/-</sup> mice, dietary cholesterol significantly increased several ceramides and degradation products of apoB in plasma compared to those fed the control diet. Dietary cholesterol did not affect tissue ceramide levels in the wild type mice. Based on these results, plasma ceramides possibly correlate with the increase in LDL oxidation and are a risk factor for atherosclerosis.

**Keywords** Ceramide · Cholesterol ·  
Apolipoprotein B-100 · Oxidation · LC-MS/MS

## Abbreviations

ApoB	apolipoprotein B-100
ApoE <sup>-/-</sup>	apoE deficient
IMT	Intima-media thickness of the carotid artery
LDL	Low-density lipoprotein
oxLDL	oxidized LDL
SDS-PAGE	Sodium dodecyl sulfate polyacrylamide gel electrophoresis
SM	Sphingomyelin
SMase	Sphingomyelinase
SPT	Serine palmitoyl-CoA transferase
TG	Triglyceride

## Introduction

Ceramide has been implicated in regulating cell-cycle arrest, apoptosis, and cell senescence [1–3] and is reported to serve as an intracellular second messenger [4]. Therefore, ceramide has attracted much attention as a new lipid mediator. Ceramide consists of a fatty acid of C16–C26 chain length bound to the amino group of sphingosine. Ceramide is generated by sphingomyelin (SM) hydrolysis by sphingomyelinase (SMase) or by de novo synthesis starting from serine-palmitoyl transferase (SPT) [5]. A significant positive correlation was observed between plasma levels of SM and the severity of coronary heart disease [6], and plasma SM levels increased in human familial hyperlipidemias [7]. Recent studies have demonstrated correlations between sphingomyelin and atherogenic risk factors of plasma in humans [8] and inhibitions of de novo SM and ceramide biosynthesis reduced atherosclerotic lesion in apoE-deficient (apoE<sup>-/-</sup>) mice [9, 10].

We recently showed that ceramide concentrations in human plasma had a significantly positive correlation with lipid markers that associated with atherosclerosis [11]. Plasma ceramide concentration increased drastically at a high level of LDL cholesterol (more than 170 mg/dL). Therefore, an increase in ceramide may be a risk factor for atherosclerosis, like LDL cholesterol.

Oxidative modification of LDL is an important factor in the development of atherosclerosis [12]. Although LDL is composed of lipids, protein, and sugar chains, studies on the oxidation of LDL have mainly focused on lipid peroxidation [13]. The protein part of LDL, apolipoprotein B-100 (apoB), is also reactive to radical oxidation and it undergoes fragmentation and conjugation [14, 15]. Among the plasma proteins, apoB is unusually reactive to radical reactions compared to albumin and transferrin and even comparable to vitamin E, a typical radical scavenger [14]. Thus, both fragmented and conjugated apoB proteins are present in normal human serum and these oxidation reaction products of LDL tend to increase with age [15]. In addition, we reported that B-ox, namely the sum of fragmented and conjugated apoB proteins determined by an immunoblot assay, showed a significant positive correlation with IMT (intima-media thickness of the carotid artery) and LDL cholesterol, and a negative correlation with HDL cholesterol, and vitamin C [15]. These reports suggest that B-ox is a reliable mechanism-based indicator of atherosclerosis.

Proteolytic degradation of apoB has been shown to cause aggregation and fusion of LDL [16]. Aggregated LDL in atherosclerotic lesions is proposed as representing a central process in atherosclerosis [17] and is enriched with ceramide [18]. Furthermore, LDL treated with SMase induces foam cell formation in vitro [18, 19]. Based on these reports, a correlation between ceramide and oxLDL is suggested.

Dietary cholesterol raises LDL cholesterol levels and a very high intake of cholesterol causes atherosclerosis. The activity of SPT, which catalyzes the first step in ceramide synthesis, is augmented in the aorta of rabbits fed high cholesterol diets [20]. Treatment of mice with myriocin, a specific inhibitor of SPT, lowered plasma cholesterol levels of ceramide in a dose-dependent manner. Therefore, high cholesterol diets may affect ceramide synthesis. The apoE<sup>-/-</sup> mice exhibit high levels of plasma cholesterol as a result of impaired clearance of cholesterol-enriched lipoproteins [21]. Therefore, apoE<sup>-/-</sup> mice are more sensitive to dietary cholesterol. In the present study, we examine the effect of high cholesterol diets on the ceramide levels in plasma, liver, and adipose tissues of apoE<sup>-/-</sup> mice in comparison with wild-type mice. We also demonstrate that dietary cholesterol results in enhancement of oxidation of apoB, namely degradation of apoB, in apoE<sup>-/-</sup> mice.

## Experimental Procedures

### Materials

All solvents were purchased from Wako Pure Chemicals Co. (Osaka, Japan). All other reagents were obtained from Funakoshi Co. (Tokyo, Japan). A commercially available diagnostic kit for cholesterol and triglyceride (TG) were purchased from Wako Pure Chem. Co. (Osaka, Japan). Silica gel 60 TLC plates were purchased from Merck (Darmstadt, Germany). A Vectastain ABC-PO (goat IgG) kit was purchased from Vector Lab. Inc. (Burlingame, CA, USA). Anti-human lipoprotein B goat IgG was purchased from Sigma Chem. Co. (St. Louis, MO, USA). Polyvinylidene difluoride (PVDF) membrane filters were purchased from Millipore (Tokyo, Japan). Electrophoresis reagents were purchased from Nacalai Tesque Inc. (Kyoto, Japan).

### Animals and Diets

This study was approved by the Animal Care Committee of Nara Women's University. Eight-week-old male apoE<sup>-/-</sup> mice on C57BL/6J background mice were purchased from Jackson Laboratories (Bar Harbor, Me., USA). Eight-week-old male C57BL/6J mice were also obtained from Japan SLC Co. (Hamamatsu, Shizuoka, Japan). The animals were housed in a room at 24 ± 2 °C, with a 12/12 h light–dark cycle. A standard diet was formulated according to the AIN-76 formula. The control group was fed a standard diet, and the cholesterol group was fed a standard diet supplemented with 1% cholesterol. Mice were randomized into the two groups. Mice were fed these experimental diets ad libitum for 8 weeks. All mice were starved for 6 h before killing.

### Analytical Method

Mice were anesthetized with Nembutal, and blood samples were collected by right-ventricle puncture using a syringe containing sodium heparin as an anticoagulant. After perfusion, the liver and adipose tissues were dissected out. Blood was centrifuged to separate the plasma.

Plasma cholesterol and TG were measured using a commercially available diagnostic kit. Liver cholesterol concentration was analyzed by gas–liquid chromatography (GC-2014, Shimadzu, Kyoto, Japan) using 5 $\alpha$ -cholestane as an internal standard [22]. Liver TG was analyzed as described by Fletcher et al. [23]. Vitamin C was measured according to a specific and sensitive method involving chemical derivatization and HPLC [24].

## Ceramide Analysis

Lipid of each tissue was extracted according to the method of Folch et al. [25]. Lipid in the liver and the adipose tissues was dissolved in chloroform to perform silica gel 60 TLC (Merck, Darmstadt, Germany). TLC separation was performed as previously described [26].

Quantitative measurement of ceramide species was made using a triple-quadrupole mass spectrometer (Finnigan MAT TSQ 7000). ESI-MS/MS was performed as previously described [11, 26]. HPLC was conducted with a  $\mu$ -Bondasphere column (5  $\mu$ C18 100A Waters). Elution was performed at a flow rate of 0.2 ml/min with a mixture of 5 mM ammonium formate, methanol, and tetrahydrofuran at a volume ratio of 1:2:7. The mobile phase stream was connected to the ionspray interface of an ESI-MS/MS system. Standards and cellular ceramide extracts were stored at  $-20^{\circ}\text{C}$ . Mass analysis was performed in the positive mode in a heated capillary tube at  $250^{\circ}\text{C}$  with an electrospray potential of 4.5 kV, a sheath gas pressure of 70 psi, and a collision gas pressure of 1.6–2.0 mtorr. Under optimized conditions, monitoring ions were ceramide molecular species  $(\text{M}+\text{H})^{+}$  for the product ion at  $m/z$  264 of the sphingoid base. Standards and samples were injected with 5  $\mu\text{l}$  of 5 pmol C8:0-ceramide as an internal standard for ESI-MS/MS. The quantity of each ceramide was calibrated from each ceramide/C8:0-ceramide ratio, assuming that the calibration curve of ceramides bearing C16–24 acyl chains was similar to that of C16:0-ceramide as previously described [11, 26]. Each sample was analyzed in duplicate.

## Western Blot Analysis

For electrophoresis, the sample was applied to 4% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), and immunoblot analysis was performed, both as described previously [14, 15]. Proteins separated on the gel were electrophoretically transferred to PVDF membrane

filters and immunoblotting analyses of apoB were performed as previously described [14, 15].

Anti-mouse apoB antiserum was prepared by immunizing mouse LDL to a rabbit. Chemiluminescence was analyzed with ATTO Densitograph Software Library (CS Analyzer Ver2.0).

## Statistical Analysis

The data were expressed as mean  $\pm$  SE. Differences between group means were considered significant at  $P < 0.05$  using Fisher's protected least significant difference test (PLSD).

## Results

### Effect of Dietary Cholesterol on Body Weight and Lipids

The body weight of the apoE<sup>-/-</sup> control group was higher than those of the other groups (Table 1). Liver weight of apoE<sup>-/-</sup> mice was higher than that of the wild type control group. The weight of total white adipose tissue of the apoE<sup>-/-</sup> control group was higher than those of the wild control group and the apoE<sup>-/-</sup> cholesterol group. No differences were observed in daily food consumption among these four groups (data not shown).

Plasma cholesterol of apoE<sup>-/-</sup> mice fed a control diet was about 6.7 times higher than that of the wild type mice fed a control diet (Table 2). In the cholesterol group, plasma cholesterol of the apoE<sup>-/-</sup> mice was also about six times higher than that of the wild type mice. However, the liver cholesterol in the apoE<sup>-/-</sup> mice was not different from that of the wild type mice. Cholesterol levels of plasma and the liver in both the wild type and the apoE<sup>-/-</sup> mice fed cholesterol were higher than those in mice fed a diet without cholesterol. No difference was observed among all groups in plasma TG. However, the liver TG of the wild type control group was lower than that of the other groups.

**Table 1** Effect of dietary cholesterol on weights of body, liver, and white adipose tissue (WAT) of wild type and apoE<sup>-/-</sup> mice

	Wild control	Wild cholesterol	ApoE <sup>-/-</sup> control	ApoE <sup>-/-</sup> cholesterol
Body weight (g)	32.3 $\pm$ 0.9 <sup>a</sup>	33.8 $\pm$ 1.3 <sup>a</sup>	38.1 $\pm$ 1.3 <sup>b</sup>	35.1 $\pm$ 1.0 <sup>a</sup>
Liver weight (g)	1.30 $\pm$ 0.09 <sup>a</sup>	1.67 $\pm$ 0.12 <sup>ac</sup>	1.84 $\pm$ 0.11 <sup>bc</sup>	1.84 $\pm$ 0.18 <sup>bc</sup>
Epididymal WAT weight (g)	0.68 $\pm$ 0.11 <sup>a</sup>	1.12 $\pm$ 0.15 <sup>b</sup>	1.33 $\pm$ 0.13 <sup>b</sup>	0.76 $\pm$ 0.11 <sup>a</sup>
Perirenal WAT weight (g)	0.39 $\pm$ 0.07 <sup>a</sup>	0.47 $\pm$ 0.07 <sup>ac</sup>	0.68 $\pm$ 0.08 <sup>b</sup>	0.38 $\pm$ 0.08 <sup>a</sup>
Mesenteric WAT weight (g)	0.38 $\pm$ 0.06 <sup>a</sup>	0.50 $\pm$ 0.08 <sup>ac</sup>	0.63 $\pm$ 0.06 <sup>bc</sup>	0.33 $\pm$ 0.05 <sup>a</sup>
Total WAT weight (g)	1.49 $\pm$ 0.21 <sup>a</sup>	2.08 $\pm$ 0.30 <sup>ac</sup>	2.64 $\pm$ 0.27 <sup>bc</sup>	1.44 $\pm$ 0.22 <sup>a</sup>

The values were mean  $\pm$  SE for eight C57BL/6J and ten apoE<sup>-/-</sup> mice. Differences between group means were considered significant at  $P < 0.05$  using Fisher's protected least significant difference test (PLSD). Values with different superscript letters show significant difference at  $P < 0.05$

**Table 2** Effect of dietary cholesterol on plasma and liver lipids of wild type and apoE<sup>-/-</sup> mice

	Wild control	Wild cholesterol	ApoE <sup>-/-</sup> control	ApoE <sup>-/-</sup> cholesterol
Plasma cholesterol (mg/dL)	77.4 ± 12.7 <sup>a</sup>	140 ± 11 <sup>a</sup>	517 ± 46 <sup>b</sup>	873 ± 64 <sup>c</sup>
Plasma triacylglycerol (mg/dL)	30.4 ± 1.9	28.6 ± 2.0	42.4 ± 6.3	46.6 ± 13.4
Liver cholesterol (mg/g)	3.36 ± 0.44 <sup>a</sup>	14.3 ± 1.9 <sup>b</sup>	5.76 ± 0.48 <sup>a</sup>	15.2 ± 1.4 <sup>b</sup>
Liver triacylglycerol (mg/g)	44.2 ± 8.8 <sup>a</sup>	115 ± 30 <sup>b</sup>	179 ± 25 <sup>b</sup>	119 ± 21 <sup>b</sup>

The values were mean ± SE for eight C57BL/6J and ten apoE<sup>-/-</sup> mice. Differences between group means were considered significant at  $P < 0.05$  using Fisher's protected least significant difference test (PLSD). Values with different superscript letters show significant difference at  $P < 0.05$

### Effect of Dietary Cholesterol on Ceramide

Table 3 shows the distribution of ceramide species in plasma. A major ceramide in plasma was C24:0 in both wild type and apoE<sup>-/-</sup> mice. The plasma level of total ceramide of the apoE<sup>-/-</sup> mice fed a control diet was about six times higher than that of the wild type mice fed a control diet. In the cholesterol group, the plasma level of total ceramide in the apoE<sup>-/-</sup> mice was also about 5.1 times higher than that of the wild type mice. In apoE<sup>-/-</sup> mice, the plasma level of total ceramide of the cholesterol group tended to be higher than that of the control group ( $p = 0.08$ ), while C16:0, C24:1, and C24:2 of the cholesterol group were significantly higher than those of the control group. In the wild type mice, dietary cholesterol did not affect plasma levels of ceramide.

Table 4 shows the distribution of ceramide species in the liver. The major ceramide of the liver was also C24:0 in the wild type and the apoE<sup>-/-</sup> mice. In the liver, the total ceramide of the apoE<sup>-/-</sup> mice fed a control diet was about 1.5 times higher than that of the wild type mice fed a control diet. In the cholesterol group, the total ceramide of apoE<sup>-/-</sup> mice was not different from that of the wild type mice. Thus, the difference in total ceramide level between

wild type and apoE<sup>-/-</sup> mice in the liver was less than that in plasma. In addition, dietary cholesterol did not affect ceramide levels of the liver in either the wild type or the apoE<sup>-/-</sup> mice.

Table 5 shows the distribution of ceramide species in the mesenteric white adipose tissue. Major ceramides of white adipose tissue were C24:0, C16:0, and C24:1. The ratio of C16:0 and C18:0 in adipose tissues was higher than that in plasma and the liver. In the wild type mice and the apoE<sup>-/-</sup> mice fed cholesterol, the content of C16:0 of the adipose tissue was similar to that of C24:0. In the adipose tissue, the total ceramide of the wild type was not different from that of the apoE<sup>-/-</sup> mice. In addition, dietary cholesterol did not affect ceramides of the adipose tissue in either wild type or apoE<sup>-/-</sup> mice.

### Effect of Dietary Cholesterol on Cross-Linked and Fragmented apoB

The band, which was larger than the band of apoB (512 kDa) was assumed to be a cross-linking product as previously reported [15] and the band, which was smaller than the band of apoB was assumed to be a fragmented product. However, neither cross-linking nor fragmentation

**Table 3** Effect of dietary cholesterol on ceramide concentration (nmol/ml) in the plasma

	Wild control	Wild cholesterol	ApoE <sup>-/-</sup> control	ApoE <sup>-/-</sup> cholesterol
C16:0	0.75 ± 0.13 <sup>a</sup>	1.20 ± 0.18 <sup>a</sup>	4.11 ± 0.32 <sup>b</sup>	5.71 ± 0.42 <sup>c</sup>
C18:0	0.07 ± 0.01 <sup>a</sup>	0.10 ± 0.02 <sup>a</sup>	0.75 ± 0.11 <sup>b</sup>	0.85 ± 0.1 <sup>b</sup>
C22:0	3.05 ± 0.83 <sup>a</sup>	4.12 ± 0.80 <sup>a</sup>	25.5 ± 3.8 <sup>b</sup>	24.5 ± 3.3 <sup>b</sup>
C24:0	6.16 ± 1.54 <sup>a</sup>	9.04 ± 1.46 <sup>a</sup>	34.3 ± 2.8 <sup>b</sup>	41.5 ± 4.6 <sup>b</sup>
C24:1	3.36 ± 0.77 <sup>a</sup>	4.70 ± 0.98 <sup>a</sup>	15.3 ± 1.4 <sup>b</sup>	20.2 ± 2.2 <sup>c</sup>
C24:2	0.14 ± 0.03 <sup>a</sup>	0.22 ± 0.04 <sup>a</sup>	2.03 ± 0.38 <sup>b</sup>	5.01 ± 0.67 <sup>c</sup>
Total	13.4 ± 3.3 <sup>a</sup>	19.1 ± 3.3 <sup>a</sup>	80.6 ± 6.8 <sup>b</sup>	97.8 ± 11.0 <sup>b</sup>

The values were mean ± SE for eight C57BL/6J and ten apoE<sup>-/-</sup> mice. Differences between group means were considered significant at  $P < 0.05$  using Fisher's protected least significant difference test (PLSD). Values with different superscript letters show significant difference at  $P < 0.05$

**Table 4** Effect of dietary cholesterol on ceramide concentration (nmol/g tissue) in the liver

	Wild control	Wild cholesterol	ApoE <sup>-/-</sup> control	ApoE <sup>-/-</sup> cholesterol
C16:0	19.6 ± 3.0 <sup>a</sup>	22.3 ± 2.6 <sup>ab</sup>	28.5 ± 2.4 <sup>b</sup>	27.5 ± 3.2 <sup>b</sup>

Total	190 ± 19 <sup>a</sup>	228 ± 17 <sup>ab</sup>	281 ± 19 <sup>b</sup>	261 ± 23 <sup>b</sup>

The values were mean ± SE for eight C57BL/6J and ten apoE<sup>-/-</sup> mice. Differences between group means were considered significant at  $P < 0.05$  using Fisher's protected least significant difference test (PLSD). Values with different superscript letters show significant difference at  $P < 0.05$

**Table 5** Effect of dietary cholesterol on ceramide concentration (nmol/g tissue) in the mesenteric white adipose tissues

	Wild control	Wild cholesterol	ApoE <sup>-/-</sup> control	ApoE <sup>-/-</sup> cholesterol
C16:0	51.4 ± 4.7	52.7 ± 15.0	43.8 ± 10.0	55.9 ± 9.3
C18:0	16.9 ± 3.5	19.7 ± 5.2	10.8 ± 1.8	19.9 ± 4.4
C22:0	21.1 ± 2.9	17.3 ± 3.2	15.4 ± 2.8	16.9 ± 2.9
C24:0	63.0 ± 10.4	53.3 ± 11.1	49.6 ± 11.1	56.5 ± 11.7
C24:1	53.8 ± 9.0	47.6 ± 9.2	40.1 ± 8.4	49.6 ± 9.8
C24:2	8.40 ± 1.41	7.68 ± 1.69	6.09 ± 1.05	10.2 ± 2.2
Total	215 ± 30	198 ± 45	159 ± 34	209 ± 38

The values were mean ± SE for eight C57BL/6J and ten apoE<sup>-/-</sup> mice. Differences between group means were considered significant at  $P < 0.05$  using Fisher's protected least significant difference test (PLSD). Values with different superscript letters show significant difference at  $P < 0.05$

of apoB-48 (250 kDa) were detected (Fig. 1a). Western blot analysis of plasma revealed that apoB-100 with molecular weight of 512 kDa in the apoE<sup>-/-</sup> cholesterol group was lower than that in the apoE<sup>-/-</sup> control group (Fig. 1a, b). Though cross-linking of apoB-100 was not detected in apoE<sup>-/-</sup> mice, fragmentation of apoB-100 in the apoE<sup>-/-</sup> cholesterol group was 2.5 times higher than that in the apoE<sup>-/-</sup> control group (Fig. 1c). In the wild type mice, neither cross-linked nor fragmented apoB proteins were discernible (data not shown).

The amount of the aortic area covered with plaques was significantly greater in the apoE<sup>-/-</sup> mice fed cholesterol compared to the apoE<sup>-/-</sup> mice fed a control diet, as is well established (data not shown).

#### Effect of Dietary Cholesterol on Vitamin C

In plasma, vitamin C of apoE<sup>-/-</sup> mice was higher than that of wild type mice (Table 6). Vitamin C of both wild type and the apoE<sup>-/-</sup> mice fed a cholesterol diet was higher than for mice fed a control diet.

#### Discussion

Sphingolipids such as ceramide and sphingosine-1-phosphate are bioactive lipid mediators [27]. The importance of sphingolipids as mediators in cardiovascular pathophysiology has recently been reported [28]. In addition, it was shown that SPT activity was higher in apoE<sup>-/-</sup> mice compared with C57BL/6J mice [9]. In this study, it was shown that the total ceramide level in plasma and the liver of the apoE<sup>-/-</sup> control group was higher than that of the wild control group. Therefore, decreasing ceramide levels in plasma and the liver may be beneficial for prevention of atherogenesis.

**Fig. 1** ApoB and fragmented apoB-100 proteins in plasma of apoE<sup>-/-</sup> mice fed a standard diet and supplemented with 1% cholesterol. Plasma was loaded on 4% SDS-PAGE gel and Western blot analysis was performed (a). Densitometry of apoB (b) and fragmented apoB (c) in plasma of apoE<sup>-/-</sup> mice. The values were means ± SE for 4–5 apoE<sup>-/-</sup> mice and asterisks indicated significant differences from the corresponding the apoE<sup>-/-</sup> control group

**Table 6** Effect of dietary cholesterol on plasma Vitamin C concentration (nmol/mL) of wild type and apoE<sup>-/-</sup> mice

	Wild control	Wild cholesterol	ApoE <sup>-/-</sup> control	ApoE <sup>-/-</sup> cholesterol
Vitamin C	69.6 ± 8.5 <sup>a</sup>	96.3 ± 3.5 <sup>b</sup>	115 ± 6 <sup>b</sup>	146 ± 5 <sup>c</sup>

The values were mean ± SE for five C57BL/6J and six apoE<sup>-/-</sup> mice. Differences between group means were considered significant at  $P < 0.05$  using Fisher's protected least significant difference test (PLSD). Values with different superscript letters show significant differences at  $P < 0.05$

In the present study, we investigated the effects of dietary cholesterol on ceramide and oxidative products of apoB in apoE<sup>-/-</sup> mice, of which the plasma and aorta responded sufficiently to cholesterol-enriched diets. Our recent study demonstrated that the correlation coefficient between plasma cholesterol and total ceramide in human subjects was particularly high among lipid markers associated with atherosclerosis [11]. Treatment with myriocin, which is a potent and specific SPT inhibitor and is known to have an immunosuppressive activity [29], significantly lowered plasma cholesterol levels of apoE<sup>-/-</sup> mice in a dose-dependent manner [30]. In this study, we demonstrated that a cholesterol-enriched diet did not affect ceramide levels of the tissues in the wild type mice. However, in apoE<sup>-/-</sup> mice, the plasma levels of several ceramides in the cholesterol group were significantly

higher than those in the control group and the plasma level of total ceramides in the cholesterol group also tended to be higher than for mice fed a control diet. This result indicated a correlation between increased cholesterol intake and the elevation of the plasma levels of ceramide.

In the liver, the total ceramides of apoE<sup>-/-</sup> mice were higher than those of the wild control group. However, the difference of ceramides levels between the wild type and the apoE<sup>-/-</sup> mice in the liver was not so large as that in plasma. In plasma, the difference of total ceramides between the wild type and the apoE<sup>-/-</sup> mice coincided with the change of cholesterol. Furthermore, the cholesterol-enriched diet did not cause a significant increase in liver ceramide levels. Therefore, a relationship between cholesterol accumulation and ceramide metabolism change in the liver was not supported.

It is well known that a fat-enriched diet is an important factor in the development of atherosclerosis. Overnutrition leads to hypertrophy of adipocytes, and high-fat diets promote obesity [31]. The islet obese fa/fa Zucker diabetic fatty rats exhibit an increase in de novo synthesis of [<sup>3</sup>H]-ceramide from [<sup>3</sup>H]-palmitate [32]. Based on these reports, a correlation between ceramide and deposition of visceral fat is suggested. In this study, although the weight of total white adipose tissues in the apoE<sup>-/-</sup> control group was higher than in the other groups, ceramide levels in the white adipose tissue of the apoE<sup>-/-</sup> control group were not higher than those of other groups. Therefore, it is suggested that fat accumulation in the white adipose tissue did not increase ceramide content.

Oxidative modification of LDL and its recognition by macrophages have been suggested as being an initial event of atherosclerosis [17]. In this study, we analyzed the oxidation profile of apoB, namely the sum of fragmented and conjugated apoB proteins determined by an immunoblot assay. We reported that these oxidation products of apoB-100, termed B-ox are a reliable indicator of atherosclerosis [15]. In human plasma, the conjugated apoB-100 was higher than the fragmented apoB-100. However, conjugated apoB-100 was not detected clearly in apoE<sup>-/-</sup> mice. In addition, in plasma of apoE<sup>-/-</sup> mice it was reported that the major apoB is apoB-48 and the minor apoB is apoB-100 [33]. In this study, conjugated and fragmented apoB-48 were not detected in apoE<sup>-/-</sup> mice. It is necessary to examine the difference of apoB-100 oxidation between human and mice and the difference of oxidation between apoB-100 and apoB-48.

Our previous studies demonstrated that the reactivity of apoB toward radicals is extremely high and even comparable to vitamin E [14]. Hence degraded apoB fragments were present in normal human plasma and tended to increase with aging [15]. In this study, the apoE<sup>-/-</sup> chole-

sterol group, which demonstrated a significant increase in the size of lesions as is well established [33], also exhibited decreased apoB and increased fragmented apoB proteins compared to the control group. These results demonstrated that the cholesterol diet increased the development of atherosclerotic lesions and promoted oxidation of apoB in the apoE<sup>-/-</sup> mice. We reported that cross-linked and fragmented apoB-100 is a reliable index of atherosclerosis and oxidative stress [15]. Therefore, it is suggested that fragmentation of apoB is also a reliable indicator of atherosclerosis in apoE<sup>-/-</sup> mice as well as humans.

OxLDL have been shown to induce apoptosis of culture cells [34, 35]. Ceramides also have been shown to cause apoptosis in a variety of cells. Apoptosis of endothelial cells is widely implicated in the early stage of atherosclerosis. It was reported that oxLDL was involved in the formation of various sphingolipid mediators [36] and activated the generation of ceramide in endothelial cells [37]. Our results also demonstrated that apoE<sup>-/-</sup> mice, which showed increased size of lesions, exhibited higher ceramide levels and fragmented apoB in plasma. Based on these results, a correlation between increased oxLDL and ceramide is suggested. However, oxLDL-induced activation of the SMase-ceramide pathway has not yet been fully studied and is still controversial. Further studies are needed to clarify the relationship between LDL oxidation and ceramide metabolism.

Vitamin C is a potent water-soluble antioxidant that scavenges reactive oxygen species [38, 39]. Sublethal lipopolysaccharide, which is associated with oxidative stress, temporarily increased liver vitamin C in the mouse [40]. In addition, the deficiency of glutathione, which plays various important roles in the protection against oxidant stress [41], increased hepatic ascorbate synthesis in mice [42]. These studies indicate that vitamin C synthesis is enhanced by oxidative stress in mice. In this study, plasma vitamin C in apoE<sup>-/-</sup> mice was higher than that in the wild type mice. It is suggested that apoE<sup>-/-</sup> mice at this young age increased vitamin C production compared to the wild type mice to prevent increased oxidative stress. In addition, plasma vitamin C in the wild type and apoE<sup>-/-</sup> mice fed a cholesterol diet was higher than in those fed a control diet. The increase of B-ox in the apoE<sup>-/-</sup> mice fed a cholesterol diet suggested enhanced stress, which resulted in the elevation of plasma vitamin C just like in the mice under enhanced oxidative stress as described above [40, 42].

In conclusion, this study demonstrated that dietary cholesterol increased ceramide levels and products of oxidized LDL in plasma of the apoE<sup>-/-</sup> mice. In addition, we propose that ceramides, the toxicities of which are much higher than that of cholesterol, are a new risk factor for atherosclerosis.

**Abstract** Postprandial chylomicrons are potent ultimate acceptors of cell membrane cholesterol and are believed to accelerate reverse cholesterol transport (RCT). We compared the effects of meals rich in polyunsaturated fat (PUFA) and either high (605 mg) or low (151 mg) in cholesterol and a meal rich in dairy fat (DF) in the form of cream on net in vitro transport of red blood cell (RBC) membrane cholesterol to 4 and 6 h postprandial plasma in eight normotriglyceridemic (NTG-H) and eight hypertriglyceridemic (HTG-H) men with mild to moderate hypercholesterolemia. In HTG-H men, cell cholesterol accumulation in 6-h postprandial plasma was significantly ( $P = 0.02$ ) less after the PUFA-HC meal compared with the other meals. The significant ( $P < 0.001$ ) increase in cell plus endogenous cholesterol accumulation in the triglyceride-rich lipoprotein (TRL) fraction of 4 h postprandial plasma incubated with RBC was significantly ( $P = 0.007$ ) higher after the PUFA-HC meal compared with DF meal in HTG-H men. In NTG-H men, cholesterol accumulation in plasma and plasma lipoproteins in the presence and absence of RBC was not significantly affected by the type of meal ingested. These data suggest that addition of large amounts of cholesterol to a PUFA meal may impair diffusion-mediated transport of cell membrane cholesterol to postprandial plasma and that replacing DF with PUFA in a meal increases postprandial lipemia and may potentially increase cholesterol accumulation in atherogenic postprandial TRL in HTG-H men.

**Keywords** Postprandial lipemia · Reverse cholesterol transport · Dietary cholesterol · Polyunsaturated fat · Dairy fat · Hyperlipidemia

### Abbreviations

apoB	Apolipoprotein B
ABCA1	ATP binding cassette A1
ABCG1	ATP binding cassette G1
CE	Cholesteryl esters
CETP	Cholesteryl ester transfer protein
DF	Dairy fat
HDL	High density lipoprotein
HTG-H	Hypertriglyceridemic and hypercholesterolemic
LCAT	Lecithin:cholesterol acyltransferase
LDL	Low density lipoprotein
MUFA	Monounsaturated fatty acids
NTG-H	Normotriglyceridemic and hypercholesterolemic
PUFA-HC	Polyunsaturated fatty acid-high cholesterol
PUFA-LC	Polyunsaturated fatty acid-low cholesterol
RBC	Red blood cells
RCT	Reverse cholesterol transport
SAFA	Saturated fatty acids
SRB1	Scavenger receptor B1
TG	Triglycerides
TC	Total cholesterol
TRL	Triglyceride-rich lipoproteins
UC	Unesterified cholesterol
VLDL	Very low density lipoproteins

### Introduction

Reverse cholesterol transport (RCT) moves cholesterol from peripheral cells via the blood to the liver where

cholesterol can be metabolised and excreted from the body. Efflux of cell cholesterol to acceptors in plasma occurs by several mechanisms including passive, aqueous diffusion and pathways mediated by scavenger receptor B1 (SR-B1) and ATP-binding cassette transporters ABCA1 and ABCG1 [1, 2]. Recent evidence suggests that a large proportion of the cholesterol efflux from fibroblasts and cholesterol-enriched macrophages to human serum may be mediated by aqueous diffusion and independently of ABCA-1 and SR-B1 [3]. The diffusion-mediated cell cholesterol flux is bidirectional and relies on a concentration gradient in unesterified cholesterol (UC) between cell membranes and extracellular acceptors of cholesterol. High density lipoprotein (HDL) or its apolipoproteins are the main initial plasma acceptors of cell cholesterol and esterification of cholesterol by the associated lecithin:cholesterol acyltransferase (LCAT) enzyme maintains the UC concentration gradient for diffusion-mediated cell cholesterol efflux. Cholesteryl esters (CE) formed by LCAT activity are transferred by cholesteryl ester transfer protein (CETP) activity to apolipoprotein B (apoB)-containing lipoproteins for transport to the liver [4]. Red blood cells (RBC) are thought to efflux membrane cholesterol solely by aqueous diffusion [5]. They do not synthesize cholesterol and do not have intracellular membranes.

Postprandial lipemia and especially chylomicrons, increases net loss of cell cholesterol from cultured fibroblasts [6] and isolated red blood cells (RBC) [7] to postprandial plasma isolated from healthy subjects after a fatty meal. Chylomicrons are potent acceptors of cholesterol from cell membranes and from endogenous lipoproteins LDL and HDL via LCAT and CETP [7, 8]. Lipolytic remnants of chylomicrons are thought to transport this accepted cholesterol to the liver [5–8]. The cholesterol content and type of fat in a meal influence postprandial lipemia. Meals highly enriched in cholesterol (210–710 mg) increase large triglyceride-rich lipoprotein triglycerides in postprandial plasma of normolipidemic subjects [9]. In addition, there is evidence that postprandial lipemia is lower after ingestion of dairy fat (DF) compared with polyunsaturated fats (PUFA) [10, 11]. Hyperlipidemia may also influence cell cholesterol transport after a fatty meal. In baboons, dietary hypercholesterolemia inhibits normal stimulation of postprandial cholesterol metabolism and movement of cholesterol from RBC to postprandial plasma after a meal rich in saturated fat (SAFA) and cholesterol [12]. On the other hand, the efflux of radiolabelled cholesterol from cultured cells to postprandial plasma is increased in patients with type IIB hyperlipidemia after a fatty meal rich in PUFA and monounsaturated fat (MUFA) and low in cholesterol [13]. Few studies have compared the effect of meals rich in PUFA and high or low in cholesterol and meals rich in DF or PUFA on net transport of cell cholesterol to postprandial plasma in individuals with

mild to moderate hyperlipidemia. The type of fat and the cholesterol content of meals is relevant to dietary advice aimed at lipid lowering in hyperlipidemic individuals [14]. The aim of the present study was to compare the effect of meals rich in PUFA and low and high in cholesterol and meals rich in PUFA or DF, on in vitro transport of cholesterol from RBC to postprandial plasma and amounts of total, cell-derived and endogenous cholesterol that accumulate in plasma lipoproteins in men with mild to moderate hypercholesterolemia with or without hypertriglyceridemia.

## Subjects and Methods

### Subjects

We recruited 16 men ages 39–67 years with plasma cholesterol concentrations  $>5.2$  mmol/l and  $<7.9$  mmol/l and fasting plasma triglyceride (TG) concentrations  $<3$  mmol/l. These exclusion criteria were aimed at excluding men with severe familial hyperlipidemia and at including men with common forms of hyperlipidemia in the study population. Participants were recruited from respondents to notices placed in Dunedin Public Hospital and from hyperlipidemic individuals on a register maintained by the Human Nutrition Department, University of Otago. Men who expressed an interest in participating in the study were screened and those with plasma lipids in the appropriate range and who were non-smokers, had no history of serious illness and were not receiving medications were accepted into the study. None of the men was following a lipid-lowering diet. Subjects were divided into a hypertriglyceridemic group (HTG-H; plasma TG  $> 1.7$  mmol/l) or a normotriglyceridemic group (NTG-H; plasma TG  $\leq 1.7$  mmol/l). This cut-off point for plasma TG concentration has been used previously to identify the hypertriglyceridemic component of the metabolic syndrome [15]. The HTG-H men ( $n = 8$ ) had a mean age of  $51 \pm 6$  years and a mean BMI of  $28.5 \pm 5.0$  kg/m<sup>2</sup>. The NTG-H men had a mean age of  $54 \pm 7$  years and a mean BMI of  $25.1 \pm 2.7$  kg/m<sup>2</sup>. The study was approved by the Lower South Regional Ethics Committee and all participants gave written and informed consent before participation in the study.

### Study Design

The study had a single-blind, randomized, crossover design. Men were randomized to one of 6 sequences of the three test meals using random number tables. The last digit of a designated series of random numbers (ignoring digits 0, 8 and 9) was used to assign participants to a meal sequence. There was at least a week between each of the

meals. After an overnight fast, blood was taken in the early morning immediately before and at 4 and 6 h after the meals.

### Meals

The meals were given as milkshakes and contained safflower oil (90 g) or cream (238 g), trim milk (70–200 ml), egg white (30 g), yoghurt (10 g), and tinned apricots without syrup (50 g). Egg yolk (12 g) and soy lecithin (12 g) were added to the polyunsaturated fat-low cholesterol (PUFA-LC) milkshake. Egg yolk (48 g) was also added to the polyunsaturated fat-high cholesterol (PUFA-HC) milkshake. Soy lecithin was added to account for the extra egg yolk phospholipid in the PUFA-HC meal. Soy lecithin (12 g) and a small quantity of extra cream fat (3 g) were added to the milkshake rich in DF to give an equivalent fat intake compared with the other meals. All milkshakes contained chocolate flavoring (15 g, 92% sugar). The macronutrient composition of the meals is shown in Table 1. The men consumed the milkshakes within 15 min and ingested a volume of milkshake to give 40 g fat/m<sup>2</sup> body surface area. Participants were instructed to refrain from eating or drinking beverages excepting water during the postprandial period after the meals and were also instructed to maintain their usual diet during the non-intervention days of the study.

### Transport of RBC Cholesterol to Plasma

Transport of cell membrane cholesterol from autologous RBC to plasma in vitro was measured essentially as described previously [7]. Briefly, blood was collected in tubes containing dipotassium EDTA and the tubes were placed in an ice-bath immediately after collection. The blood was spun at 223g for 10 min at 4 °C. The plasma supernatant was collected and kept briefly at 4 °C leaving one third of the plasma trapped within packed RBCs. Packed cells (8 ml) were transferred into a plastic tube using a Gilson pipette with a wide-bore plastic tip. Plasma (1 ml) was added to the packed cells to give a twofold excess of RBCs to plasma. The remaining plasma was divided into two aliquots. One aliquot of plasma and the mixture of RBCs and plasma were incubated at 37 °C for 18 h without shaking. The other aliquot of plasma was maintained at 4 °C. At the end of the incubation period, the RBC-plasma mixture was centrifuged at 1,500g for 30 min at 4 °C and the plasma was harvested. Aliquots (2 ml) of this plasma and plasma incubated at 37 °C or maintained at 4 °C were adjusted to  $d = 1.006$  g/ml and ultracentrifuged in a Beckman type 50.3 Ti rotor for 18 h at 400,000 rpm

**Table 1** Composition of the meals

Nutrient	Meals		
	PUFA-LC	PUFA-HC	DF
Fat (g)	102	102	102
SAFA (g)	10	12	56
PUFA (g)	60	59	7
Carbohydrate (g)	33	33	34
Protein (g)	13	18	13
Energy (kJ)	4,574	4,657	4,590
Cholesterol (mg)	151	605	325
Fat (%E)	84	82	84
Carbohydrate (%E)	11	11	12
Protein (%E)	5	6	5

*PUFA-LC* polyunsaturated fat-low cholesterol, *PUFA-HC* polyunsaturated fat-high cholesterol, *DF* dairy fat, *SAFA* saturated fat, *E* energy

and 10 °C. The  $d < 1.006$  g/ml fraction containing very low density lipoproteins (VLDL) and chylomicrons, and the  $d > 1.006$  g/ml fraction were collected quantitatively by tube-slicing. HDL was isolated in the supernatant after precipitation of apoB-containing lipoproteins with dextran sulfate and magnesium chloride [16]. Cholesterol and TG in plasma and plasma fractions were measured enzymatically using an autoanalyzer (Abbott, ABA-100) and commercial kits and calibrators (Roche, Boehringer Mannheim). Plasma UC was measured by an automated colorimetric method using a reagent with a composition as described previously [17] plus methanol (58 ml/l) and Preciset cholesterol standards (Roche, Boehringer Mannheim). Cholesterol in the LDL fraction was calculated by subtracting HDL cholesterol (HDL-C) from cholesterol in the  $d > 1.006$  g/ml fraction. Cell cholesterol accumulation in plasma and total cholesterol accumulation (cell + endogenous) in plasma lipoprotein fractions was calculated as the difference between levels in plasma incubated at 37 °C in the presence of RBCs and plasma maintained at 4 °C. Cholesterol accumulation in lipoprotein fractions attributable to cell cholesterol was estimated as the difference between levels in plasma incubated at 37 °C with and without RBC. Endogenous cholesterol metabolism in plasma and plasma lipoproteins was estimated by the difference between cholesterol concentrations in plasma incubated at 37 °C or maintained at 4 °C.

### Statistics

Values are given as mean  $\pm$  SD unless stated otherwise. Repeated measures ANOVA with meals and time after meals as within-subject factors was used to analyse the data

**Table 2** Lipid and lipoprotein concentrations in control plasma during the meals

Lipids (mmol/l)	Time (h)	NTG-H ( <i>n</i> = 8)			HTG-H ( <i>n</i> = 8)		
		PUFA-LC	PUFA-HC	DF	PUFA-LC	PUFA-HC	DF

(SPSS 11.0). Sequence of meals was also included as a between subjects factor. Since there were no significant effects of meal sequence detected, the simplified models without a meal sequence term are reported. The relatively long period between the meals was designed to minimise any effect of meal sequence and carry-over on the data. Student's *t* test was used to compare unpaired data and the paired *t* test was used to compare paired data. Pearson's product-moment correlation coefficients were used to test for relationships between variables. Two-tailed tests of significance were used and a value of *P* < 0.05 was considered to be statistically significant.

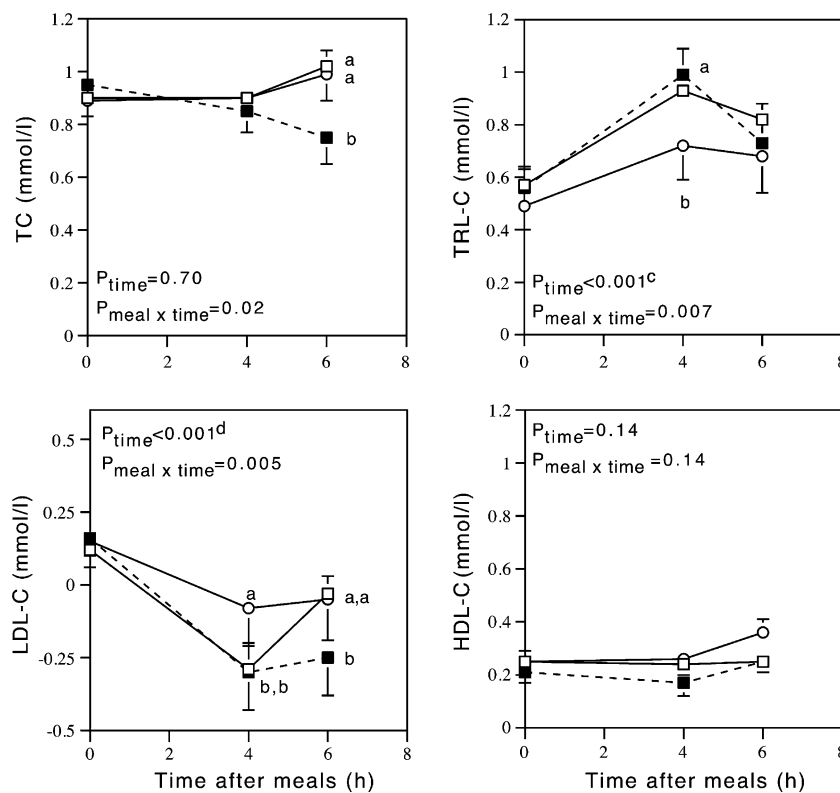

## Results

Table 2 shows plasma lipids and lipoprotein concentrations in the NTG-H and HTG-H men during the meals. In HTG-H men, the response of plasma TG was significantly (*P* = 0.008) different among the meals with a significant and 74% larger increase during 4 h after the PUFA-HC meal compared with the DF meal. Plasma TRL-TG concentrations paralleled these changes during the meals. In NTG-H men, postprandial changes in plasma lipids and lipoprotein lipids were not significantly different among the meals. Ultracentrifuge recovery in the separation of

TRL from LDL + HDL was  $96 \pm 2\%$  ( $n = 48$ ) in fasted plasma,  $97 \pm 3\%$  ( $n = 48$ ) in 4 h postprandial plasma, and  $98 \pm 2\%$  ( $n = 48$ ) in 6 h postprandial plasma. All data were corrected for ultracentrifuge recovery.

Figures 1 and 2 show cholesterol accumulation in plasma and plasma lipoprotein fractions calculated as the difference between values in plasma incubated with RBC at 37 °C and plasma maintained at 4 °C, in HTG-H and NTG-H men, respectively during the meals. The cholesterol accumulation in plasma indicates the amount of cholesterol that has been lost from RBC. The cholesterol accumulation in plasma lipoproteins includes both cell-derived and endogenous cholesterol. In HTG-H men (Fig. 1), the loss of RBC cholesterol to plasma tended to decrease during the PUFA-HC meal and tended to increase during the other meals and these trends were significantly ( $P = 0.02$ ) different at 6 h after the meals. The accumulation of cholesterol in the TRL fraction of 4 h ( $P < 0.001$ ) and 6 h ( $P = 0.02$ ) postprandial plasma incubated with RBC was significantly higher than baseline after all the

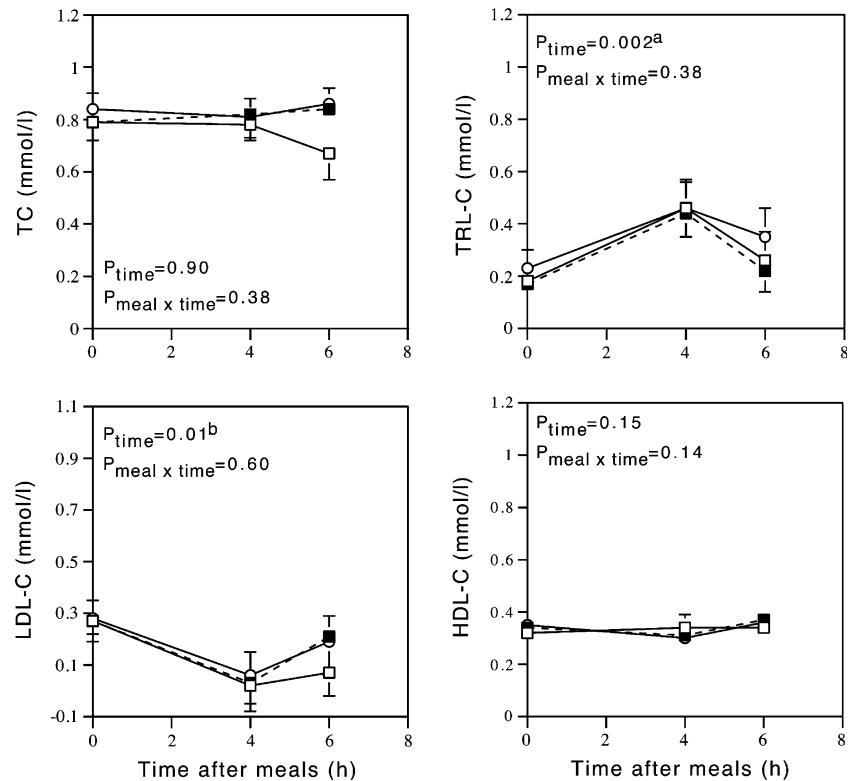

meals and was significantly ( $P = 0.007$ ) higher in 4 h postprandial plasma after the PUFA-HC meal compared with the DF meal. This increased accumulation of cholesterol in TRL was also higher during the PUFA-LC compared with DF meal but not significantly ( $P = 0.12$ ). During all the meals, the cholesterol content of the LDL fraction decreased significantly in postprandial plasma incubated with RBC. This depletion of cholesterol in the LDL fraction was significantly greater in 4 h postprandial plasma after both PUFA-LC and PUFA-HC meals compared with the DF meal and in 6 h postprandial plasma after the PUFA-HC meal compared with the other two meals. The cholesterol content of the HDL fraction did not vary significantly during incubation of RBC with plasma obtained during the meals. In NTG-H men (Fig. 2), the accumulation of cholesterol in the TRL fraction of plasma incubated with RBC was significantly ( $P = 0.005$ ) higher in 4 h postprandial and was not significantly different in 6 h postprandial plasma compared with fasting plasma. The corresponding accumulation of cholesterol in the LDL

<sup>b</sup>4 h < 0 h,  $P = 0.01$

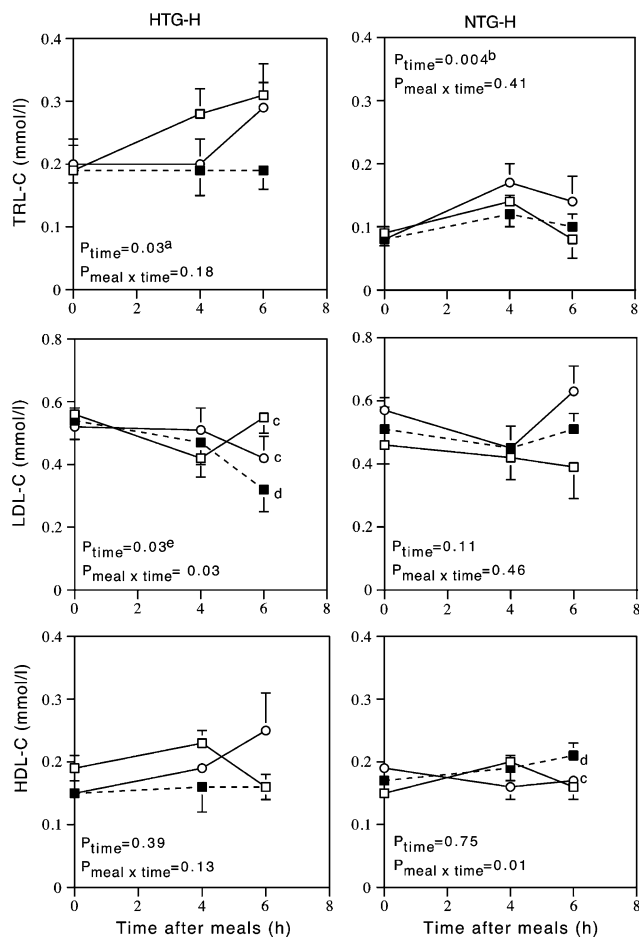

fraction of 4 h postprandial plasma was significantly ( $P = 0.01$ ) reduced after all the meals and these changes were not significantly different among the meals. Cholesterol accumulation in the HDL fraction and cell cholesterol accumulation in plasma during incubation of postprandial plasma with RBC did not change significantly from baseline during the meals. At baseline (first visit), cholesterol accumulation was significantly higher ( $P < 0.001$ ) in the TRL fraction and significantly lower in the LDL ( $P = 0.006$ ) and HDL ( $P = 0.01$ ) fractions in HTG-H compared with NTG-H men.

Figure 3 shows the distribution of effluxed cell cholesterol calculated as the difference between plasma incubated at 37 °C with and without RBC, among plasma lipoprotein fractions in HTG-H and NTG-H men during the meals. In HTG-H men, cell cholesterol content of the TRL fraction increased significantly 6 h after the meals mainly due to increases during the PUFA-LC and DF meals. Cell cholesterol content of the TRL fraction remained unchanged during the PUFA-HC meal but this response was not significantly different from the corresponding response during the other meals. Cell cholesterol content of the LDL fraction decreased significantly during the meals with a significantly larger decrease between baseline and 6 h after the PUFA-HC meal compared with the other meals. In NTG-H men, cell cholesterol content of the TRL fraction increased significantly between baseline and 4 h after the

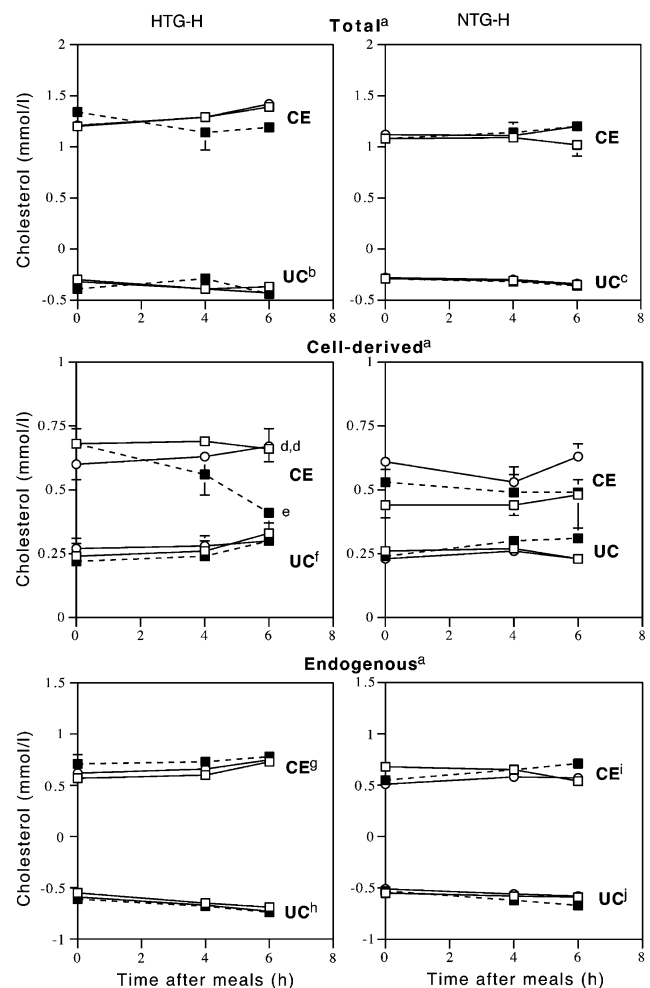

meals and this response was not significantly different among the meals. Cell cholesterol content in the HDL fraction of these men tended to increase during the PUFA-HC meal and tended to decrease during the DF meal and these trends were significantly different. At baseline (first visit), cell cholesterol accumulation in the TRL fraction of plasma incubated with RBC was significantly ( $P = 0.03$ ) higher in HTG-H men compared with NTG-H men. This difference remained significant during the meals.

Figure 4 shows the response of total, cell-derived and endogenous CE and UC in plasma incubated with or without RBC during the meals. In HTG men the total (cell-derived + endogenous) and endogenous plasma UC decreased significantly while the cell-derived plasma UC increased significantly during the meals without significant differences in response among the meals. Cell-derived plasma CE decreased significantly ( $P = 0.002$ ) between baseline and 6 h after the PUFA-HC meal and this change was marginally significantly different compared with the corresponding changes during the other meals ( $P_{\text{meal} \times \text{time}} = 0.05$ ). Endogenous plasma CE increased significantly at 6 h after the meals. In NTG-H men, total and endogenous plasma UC decreased significantly during the meals. The significant meal  $\times$  time interaction in the increase in endogenous CE content of plasma incubated at 37 °C was due to the significantly ( $P = 0.001$ ) higher value at baseline before the PUFA-LC meal compared with the other meals.

**Fig. 3** The effect of meals rich in polyunsaturated fat and low (squares) or high (filled squares) in cholesterol or rich in dairy fat (circles) on cell-derived cholesterol in plasma lipoproteins calculated as differences in plasma cholesterol and lipoprotein cholesterol between plasma incubated at 37 °C with and without red blood cells, in hypertriglyceridemic (HTG-H) and normotriglyceridemic (NTG-H) men with mild to moderate hypercholesterolemia. Values are mean  $\pm$  SEM,  $n = 8$ . <sup>a</sup>6 h > 0 h,  $P = 0.03$ . <sup>b</sup>4 h > 0 h,  $P = 0.003$ . <sup>c,d</sup>Different symbols indicate significantly ( $P < 0.05$ ) different meal  $\times$  time interactions between meals in repeated measures ANOVA. <sup>e</sup>4 h < 0 h,  $P = 0.04$ ; 6 h < 0 h,  $P = 0.03$

Figure 5 shows the changes in endogenous cholesterol in plasma lipoprotein fractions during incubation of plasma at 37 °C. In HTG-H men, accumulation of cholesterol in the TRL fraction was significantly increased from baseline at 4 and 6 h after the meals. In HTG-H and NTG-H men, cholesterol accumulation was significantly lower than baseline in the LDL fraction at 4 and 6 h and in the HDL fraction at 4 h after the meals. In NTG-H men, cholesterol in the TRL fraction increased significantly 4 h and was not significantly different from baseline 6 h after the meals. These changes were not significantly different among the meals. At baseline (first visit), endogenous cholesterol accumulation was significantly higher in the TRL fraction ( $P = 0.001$ ) and was significantly lower in the LDL

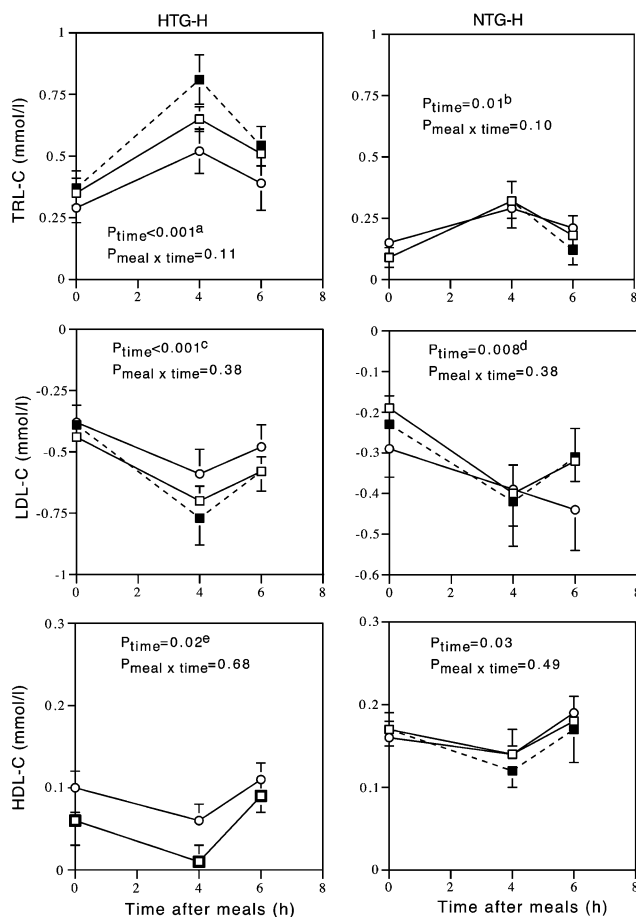

**Fig. 4** The effect of meals rich in polyunsaturated fat and low (squares) or high (filled squares) in cholesterol or rich in dairy fat (circles) on total, cell-derived and endogenous cholesterol esters (CE) and unesterified cholesterol (UC) in plasma incubated with and without red blood cells (RBC), in hypertriglyceridemic (HTG-H) and normotriglyceridemic (NTG-H) men with mild to moderate hypercholesterolemia. Values are mean  $\pm$  SEM,  $n = 8$ . <sup>a</sup>Total = difference between plasma incubated at 37 °C with RBC and plasma maintained at 4 °C; *Cell derived* = difference between plasma incubated at 37 °C with and without RBC; *Endogenous* = difference between plasma incubated at 37 °C and maintained at 4 °C. <sup>b,c</sup>Significant time effect. 6 h < 0 h,  $P = 0.001$ . <sup>d,e</sup>Different symbols indicate marginally significantly ( $P = 0.05$ ) different meal  $\times$  time interactions between meals in repeated measures ANOVA. <sup>f</sup>Significant time effect. 6 h > 0 h,  $P = 0.007$ . <sup>g</sup>Significant time effect. 6 h > 0 h,  $P = 0.008$ . <sup>h</sup>Significant time effect. 4 h < 0 h,  $P = 0.003$  and 6 h < 0 h,  $P < 0.001$ . <sup>i</sup>Significantly different ( $P < 0.01$ ) meal  $\times$  time interaction between PUFA-LC meal and other meals in repeated measures ANOVA. <sup>j</sup>Significant time effect. 4 h < 0 h,  $P = 0.02$  and 6 h < 0 h,  $P < 0.001$

( $P = 0.001$ ) and HDL fractions ( $P < 0.001$ ) in HTG-H compared with NTG-H men. These differences remained significant during the meals.

In the total study population, the amount of cell cholesterol that accumulated in plasma was correlated

**Fig. 5** The effect of meals rich in polyunsaturated fat and low (squares) or high (filled squares) in cholesterol or rich in dairy fat (circles) on differences in lipoprotein cholesterol concentrations between plasma incubated at 37 °C and plasma maintained at 4 °C, in hypertriglyceridemic (HTG-H) and normotriglyceridemic (NTG-H) men with mild to moderate hypercholesterolemia. Values are mean  $\pm$  SEM,  $n = 8$ . <sup>a</sup>4 h > 0 h,  $P < 0.001$  and 6 h > 0 h,  $P = 0.03$ . <sup>b</sup>4 h > 0 h,  $P = 0.009$ . <sup>c</sup>4 h < 0 h,  $P = 0.001$  and 6 h < 0 h,  $P = 0.01$ . <sup>d</sup>4 h < 0 h,  $P = 0.01$  and 6 h < 0 h,  $P = 0.02$ . <sup>e</sup>4 h < 0 h,  $P = 0.03$

significantly ( $r = 0.702$ – $0.913$ ,  $P \leq 0.002$ ) with the increase in plasma CE during incubation of RBC with fasted and postprandial plasma after all the meals. Also, the 4 h increases in total cholesterol accumulation in the plasma TRL fraction of plasma incubated with RBC were correlated significantly with the corresponding increases in plasma TG during the meals (PUFA-LC,  $r = 0.836$ ; PUFA-HC,  $r = 0.826$ ; DF,  $r = 0.750$ , all  $P \leq 0.001$ ). In HTG-H men, the 6 h decrease in cell cholesterol accumulation in the LDL fraction during the PUFA-HC meal was correlated significantly ( $r = 0.762$ ,  $P = 0.03$ ,  $n = 8$ ) with the corresponding decrease in CE derived from the esterification of cell cholesterol in plasma. At baseline (first visit), cell cholesterol accumulation in fasted and postprandial plasma was not correlated significantly or at marginal significance

with corresponding plasma concentrations of lipids and lipoproteins (data not shown).

## Discussion

This study has shown that addition of large amounts of cholesterol to a PUFA-rich meal decreases the accumulation of RBC cholesterol in postprandial plasma and LDL in vitro in HTG-H men. The magnitude of postprandial lipemia and the accumulation of cell plus endogenous cholesterol in the 4 h postprandial plasma TRL fraction were markedly higher during the PUFA-HC meal compared with the DF meal in these men. In NTG-H men, the type of meal did not differentially affect cell and total cholesterol accumulation in plasma and plasma lipoproteins. Our data suggest that the quantity of cholesterol and type of fat in the meal may influence transport of cell cholesterol to postprandial plasma, postprandial lipemia and the capacity of the postprandial TRL fraction to accumulate cholesterol in men with mild combined hyperlipidemia.

A previous study in normolipidemic subjects has reported that postprandial plasma isolated 4 h after a fatty meal accumulates 28% more cholesterol than fasted plasma during incubation with RBC [7]. However, our study in hyperlipidemic men has shown that while there was substantial net transport of RBC cholesterol to fasted plasma in vitro, this did not increase appreciably when cells were incubated with postprandial plasma obtained 4 h after a fatty meal (Figs. 1, 2). It is possible this failure of postprandial lipemia to accelerate cell cholesterol transport may be due to a hyperlipidemia-induced attenuation of cell cholesterol esterification in plasma. The quantity of cholesterol esterified did not increase appreciably (Fig. 4) and was closely correlated with the amount of RBC cholesterol transported to 4 h postprandial plasma during incubation with RBC. A close relationship between cholesterol esterification and net transport of RBC to plasma in vitro has been documented previously in normolipidemic subjects [7]. Also, the amount of plasma CE increased in line with the increase in RBC cholesterol transport to 4 h postprandial plasma [7]. Efficient esterification of UC by LCAT is essential for net transfer of RBC cholesterol to plasma. Previous studies have reported that inhibition of plasma LCAT activity [7] or absence of LCAT [18] increases influx of UC from plasma to cells preventing net loss of cell cholesterol to plasma in vitro. In baboons with diet-induced hypercholesterolemia, plasma cholesterol esterification is inhibited and movement of RBC cholesterol to postprandial plasma in vitro is reversed after a fatty meal [12]. On the other hand, increased plasma cholesterol esterification and efflux of radiolabelled cholesterol from cultured cells to dilute postprandial plasma from patients

with type IIB hyperlipidemia after a fatty meal has been reported previously [13]. However, the efflux of radiolabelled cholesterol does not measure net transport of cholesterol mass from cells. Other differences such as types of cells, between experimental models may also contribute to the differences in cell cholesterol transport to postprandial plasma among the studies.

The decrease in total cholesterol accumulation in 6 h postprandial plasma and its LDL fraction during incubation with RBC (Fig. 1) was mainly due to the corresponding decrease in cell cholesterol accumulation in LDL (Fig. 3), in HTG-H men after the PUFA-HC meal compared with other meals. Failure of cell cholesterol to accumulate in TRL also tended to contribute to this decrease in RBC cholesterol transport to plasma. These decreases in cell cholesterol accumulation in plasma and lipoproteins may be due to attenuated esterification of cell cholesterol in plasma and/or impaired ability of postprandial LDL to accept cell cholesterol transferred from HDL via LCAT and CETP. The decrease in cell cholesterol accumulation in plasma LDL was correlated with the concomitant decrease in cell-cholesterol derived CE in plasma. Impaired cell cholesterol esterification and transfer of CE to TRL might also contribute to the failure of cell cholesterol to accumulate in postprandial TRL during the PUFA-HC meal. The ability of postprandial LDL to bind CE transferred from HDL via LCAT and CETP may also be impaired in HTG-H men. A previous study has reported that fasting LDL has impaired ability to accept CE from HDL and has low affinity for the CETP protein in patients with combined hyperlipidemia [19]. Abnormal chemical composition including increased CE content and structure appear to underlie this defect in LDL [19]. Postprandial lipemia is known to alter the composition and properties of LDL [9, 20]. Also, there is evidence that the presence of chylomicrons in plasma impairs the ability of LDL and HDL to accept cell cholesterol *in vitro* [7, 8]. Thus, in the present study, it is conceivable that the particularly high level of postprandial lipemia following the PUFA-HC meal in HTG-H men may have altered the composition and properties of postprandial LDL including the ability to bind CE. This high level of postprandial lipemia may be due to the combined effect of high cholesterol content of the meal, abnormalities of TG metabolism, and efficient absorption of PUFA from the gut. A previous study has reported that ingestion of large amounts of cholesterol (700 mg) in a meal rich in PUFA and MUFA increases peak postprandial concentrations of large TRL-TG in normolipidemic men [9]. This effect of ingested cholesterol may be enhanced by inefficient clearance of postprandial TRL in hypertriglyceridemic subjects. There is evidence that PUFAs are more efficiently absorbed from the gut compared with long-chain saturated fatty acids in bovine fat [21].

Incorporation of cholesterol from cells and endogenous lipoproteins into TRL has been postulated as the initial step in a pathway that may enhance delivery of this cholesterol to the liver during the postprandial state [6–8]. Postprandial plasma TRL are potent acceptors of cholesterol from both cells and endogenous lipoproteins via LCAT and CETP [6–8]. In HTG-H men in the present study, the type of fat in the meal affected the total quantity of cholesterol (cell-derived + endogenous) that accumulated in the TRL fraction of postprandial plasma incubated with RBC. This cholesterol accumulation in plasma TRL was higher 4 h after meals rich in PUFA compared with DF. Higher levels of postprandial lipemia appeared to be mainly responsible for this increased accumulation of cholesterol in postprandial TRL after the PUFA-rich meals. The 4 h increase in TRL cholesterol in postprandial plasma incubated with RBC was correlated closely with the concomitant increase in plasma TRL-TG concentrations. The larger increase in total cholesterol accumulation in 4 h postprandial TRL after PUFA-rich meals appeared to be mainly due to increased transfer of cholesterol from endogenous lipoproteins via LCAT and CETP into postprandial TRL. The increase in cholesterol accumulation in the TRL fraction of plasma incubated at 37 °C essentially paralleled and accounted for most of the corresponding increase in total cholesterol accumulation in the TRL fraction of plasma incubated with RBC during the meals in HTG-H men (Figs. 1, 5). Plasma LDL supplied most of the endogenous CE that was transferred into postprandial TRL as indicated by the enhanced decrease in LDL cholesterol in postprandial plasma incubated at 37 °C. This finding is in keeping with previous studies indicating that LDL is a major donor of CE to postprandial TRL [8, 22].

Efficient hepatic clearance of TRL remnant lipoproteins from the circulation may accelerate the transport of cholesterol from cells and from LDL to the liver during postprandial lipemia [6, 8, 23]. However, when clearance is delayed increased levels of cholesterol-enriched, proatherogenic TRL remnant lipoproteins [24] may increase risk of atherosclerotic disease [25, 26]. In subjects with combined hyperlipidemia, transfer of CE from HDL to TRL is enhanced during fasting and postprandial lipemia [13, 27], clearance of postprandial TRL after a fatty meal is impaired [28] and risk of coronary artery disease is abnormally high. In the current study, accumulation of both cell-derived and endogenous cholesterol in TRL was higher and there was evidence that clearance of postprandial TRL was impaired in HTG-H men compared with NTG-H men. Accelerated transfer of CE into TRL may contribute to this higher accumulation of cholesterol in TRL and lower cholesterol accumulation in HDL in fasting and postprandial plasma from HTG-H men. Plasma TG

concentrations 6 h after the meals were clearly higher than fasted values in HTG-H men suggesting impaired clearance of postprandial TRL particles. Thus, enhanced accumulation of cholesterol from cells and endogenous lipoproteins in postprandial TRL after meals rich in PUFA compared with DF may not accelerate RCT and may increase the atherogenic potential of TRL remnant lipoproteins in these men. On the other hand, replacing DF with PUFA in the diet induces a chronic decrease in plasma LDL-C concentration that decreases risk of coronary artery disease.

In NTG-H men, the cholesterol content and type of fat in the meal did not influence appreciably postprandial lipemia and cholesterol accumulation in plasma and plasma lipoproteins during incubation with RBC. This finding may be due to relatively efficient TRL metabolism leading to lower plasma TRL concentrations and to the absence of LDL particles with abnormalities induced by hypertriglyceridemia.

This study has limitations. The number of subjects studied was small and all the participants were men. Thus care must be exercised in the extrapolation of the findings to other populations of hyperlipidemic individuals. Also, the fat composition of the habitual diet of the participants was not determined. The type of fat in the habitual diet influences the postprandial response of plasma lipoprotein lipid levels to ingested fat [29]. On the other hand, impaired TG metabolism in HTG-H men has a more potent impact on postprandial response of lipoproteins to fatty meals. The calculation of cell cholesterol accumulation in plasma lipoprotein fractions as the difference in lipoprotein cholesterol levels between plasma incubated with and without RBC, assumes that endogenous cholesterol metabolism in plasma is the same in the presence and absence of RBC. Any changes in plasma endogenous cholesterol metabolism in the presence of RBC could contribute to the differences in calculated cell cholesterol accumulation in plasma lipoprotein fractions among the meals in HTG-H men.

In conclusion, our data indicate that the effect of meals varying in cholesterol content and type of dietary fat on transport of cell membrane cholesterol to plasma, postprandial lipemia, and accumulation of cell and endogenous cholesterol in plasma TRL, is influenced importantly by fasting plasma TG levels in men with mild to moderate hypercholesterolemia. In HTG-H men, addition of large amounts of cholesterol to PUFA rich meals leads to postprandial plasma with impaired ability to support net transport of cell membrane cholesterol to plasma and its LDL fraction. In these men, postprandial lipemia is higher after meals rich in PUFA compared with DF increasing the capacity for cholesterol accumulation in potentially atherogenic CE-enriched TRL remnant lipoproteins. Whether

impaired diffusion-mediated cell membrane cholesterol transport influences cholesterol content of atherosclerotic lesions remains to be determined.

**Abstract** Obesity rates have dramatically increased over the last few decades and, at the same time, major changes in the type of fatty acid intake have occurred. Linoleic acid, an n-6 polyunsaturated fatty acid, is an essential fatty acid occurring in high amounts in several western diets. A potential role of this fatty acid on obesity has been suggested. Controversial effects of linoleic acid on insulin sensitivity have also been reported. Thus, the aim of this study was to examine the direct effects of linoleic acid on leptin and adiponectin production, two adipokines known to influence weight gain and insulin sensitivity. Because insulin-stimulated glucose metabolism is an important regulator of leptin production, the effects of linoleic acid on adipocyte metabolism were also examined. For this purpose, isolated rat adipocytes were incubated with linoleic acid (1–200  $\mu\text{M}$ ) in the absence or presence of insulin. Linoleic acid (1–200  $\mu\text{M}$ ) significantly decreased insulin-stimulated leptin secretion and expression ( $P < 0.05$ ), however, no changes in basal leptin production were observed. Linoleic acid also induced a significant decrease (~20%) in adiponectin secretion ( $P < 0.05$ ), but only in the presence of insulin and at the highest concentration tested (200  $\mu\text{M}$ ). This fatty acid did not modify either glucose uptake or lactate production and the percentage of glucose metabolized to lactate was not changed either. Together, these results suggest that linoleic acid seems to interfere with other insulin signalling pathway different from those

controlling glucose uptake and metabolism, but involved in the regulation of leptin and adiponectin production.

### Abbreviations

n-6 PUFA n-6 Polyunsaturated fatty acids

### Introduction

While the debate continues on whether dietary fat is the primary determinant of excessive body fat, the evidence is compelling for the greater importance of types of fat, rather than the total amount of fat, as a risk for chronic disease [1]. Thus, several studies have suggested that the type of fat ingested may be an important determinant in the development of obesity and other associated diseases such as insulin resistance, type 2 diabetes and cardiovascular diseases [2, 3]. In this sense, it has been demonstrated that saturated fat intake induces obesity and insulin resistance [4, 5] meanwhile diets rich in fish oils (n-3 PUFAs) seem to prevent the development of these diseases [6, 7]. Furthermore, body fat accumulation is greater in rats fed a beef tallow diet (rich in saturated fatty acids) than in rats fed on diets enriched with other types of fatty acids such as n-3 fatty acids [8] or n-6 PUFAs [9–11].

Concerning the intake of n-6 and n-3 polyunsaturated fatty acids (PUFAs), a striking rise in the linoleic acid/ $\alpha$  linolenic acid ratio has been observed during the last decades, which is likely related to an increase in linoleic acid

intake [12]. Linoleic acid (18:2n-6), is an essential fatty acid occurring in several edible vegetable oils such as corn, soy and safflower oil [13]. In fact, several western dietary patterns such as the North American diet are typically high in linoleic acid [1], and it has been suggested that the consumption of this fatty acid could also contribute to the onset of obesity and other related disorders such as insulin resistance. Thus, several trials have demonstrated that high n-6 linoleic acid consumption might aggravate insulin resistance in humans [14]. In fact, a positive correlation has been observed between linoleic acid concentration in muscle membrane phospholipids and insulin resistance [15], suggesting that rather than being beneficial, high n-6 PUFA diets may have some long-term side effects within the cluster of hyperinsulinemia, atherosclerosis and tumorigenesis [14]. In contrast, Vessby [16] observed that insulin resistance and disorders characterized by insulin resistance are associated with a specific fatty acid pattern of the serum lipids with reduced levels of linoleic acid.

Leptin and adiponectin are hormones secreted by white adipose tissue with important metabolic effects. In fact, leptin is involved in the regulation of body weight, body fat storage and insulin sensitivity [17]. Plasma adiponectin levels are positively associated with whole-body insulin sensitivity and are decreased in obesity [18]. A number of studies have demonstrated that insulin stimulates leptin gene expression and secretion by increasing the adipocyte glucose utilization [19]. Several studies have also suggested a role of insulin in the regulation of adiponectin secretion although data were conflicting [20, 21].

Several *in vivo* studies have observed that feeding rats with linoleic acid-enriched diets (high-safflower oils) induced an increase in body fat stores and also in the gene expression and circulating levels of leptin [8, 22]. To our knowledge, there are no data available regarding the potential actions of linoleic acid on adiponectin secretion by cultured adipocytes.

For this reason, the aim of the present study was to investigate the *in vitro* effects of linoleic acid on leptin and adiponectin production from primary rat adipocytes cultured in a collagen matrix for 96 h. The effects of linoleic acid on insulin-stimulated glucose utilization and lactate production were also studied on our adipocyte culture model.

## Methods

### Materials

Media (Dulbecco's modified Eagle's medium, DMEM), minimal essential medium amino acids, penicillin/strepto-

mycin, fetal bovine serum (FBS), and nystatin were purchased from Gibco-Invitrogen Life Technologies (Carlsbad, CA, USA; Grand Island, NY, USA). Bovine serum albumin fraction V, 4-(2-hydroxyethyl)-1-piperazineethansulfonic acid (HEPES), insulin, and linoleic acid were purchased from Sigma Chemical Co. (St Louis, MO, USA). Collagen (Vitrogen 100) was obtained from Cohesion Technologies (Palo Alto, CA, USA). Type I collagenase was purchased from Worthington Biochemical Corporation (Lakewood, NJ, USA).

### Animals

Male Wistar rats (250–280 g) obtained from the Applied Pharmacobiology Center (CIFA, Spain) were used to provide adipocytes isolated from the epididymal fat depot. These animals were housed in cages in temperature-controlled rooms ( $22 \pm 2^\circ\text{C}$ ) with a 12-h light–dark cycle. All experimental procedures were performed according to National and Institutional Guidelines for Animal Care and Use and approved by the Ethical Committee for Animal Care and Use at the University of Navarra, Spain. Animals were euthanized and epididymal adipose tissue was quickly removed.

### Adipocyte Isolation and Culture

Adipocytes were isolated from epididymal fat depots as previously described [23]. Epididymal fat was minced and digested in HEPES buffer (pH 7.4; containing 5 mM D-glucose, 2% BSA, 135 mM NaCl, 2.2 mM  $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ , 1.25 mM  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ , 0.45 mM  $\text{KH}_2\text{PO}_4$ , 2.17 mM  $\text{Na}_2\text{HPO}_4$ , and 10 mM HEPES) with type I collagenase (1.25 mg/ml per 0.5 g tissue) at  $37^\circ\text{C}$  with gentle shaking for 30 min. The resulting cell suspension was diluted in HEPES-phosphate buffer and the isolated adipocytes were then separated from the undigested tissue by filtration through a  $400\ \mu\text{m}$  nylon mesh and washed three times. Isolated adipocytes were then resuspended in DMEM supplemented with 1% FBS and incubated for 40 min at  $37^\circ\text{C}$ . The isolated adipocytes (150  $\mu\text{l}$  of 2:1 ratio of packed cells to medium) were then plated on 500  $\mu\text{l}$  of a collagen matrix (Vitrogen 100, Cohesion Technologies, Palo Alto, CA) in 6-well culture plates. After 50 min of incubation at  $37^\circ\text{C}$ , the culture media containing 0 or 1.6 nM insulin and the different concentrations (0, 1, 10, 50, 100, and 200  $\mu\text{M}$ ) of the assayed linoleic acid were added and the cells were maintained in an incubator at  $37^\circ\text{C}$  in 5%  $\text{CO}_2$  for up to 96 h. Aliquots (300  $\mu\text{l}$ ) of the media were collected at 24, 48, 72, and 96 h, and replaced with fresh medium containing the appropriate concentration of insulin and linoleic acid.

## Assays

Leptin concentrations in the medium were determined after 96 h of culture using a radioimmunoassay for rat leptin (Linco Research, St Charles, MO, USA). Adiponectin concentrations were analyzed using a mouse/rat adiponectin Elisa kit (B-Bridge International Inc., USA). Glucose and lactate concentrations in the media were measured by an autoanalyzer (Cobas Roche Diagnostic, Basel, Switzerland) [24].

## Analysis of mRNA

Leptin mRNA levels were determined by northern blotting [23]. The leptin cDNA probe was a 388 bp fragment of mouse leptin cDNA, which was kindly provided by Dr. Charles Mobbs (Mount Sinai School of Medicine, NY, USA). The 18S ribosomal probe was obtained from Ambion (Ambion, Austin, TX, USA). RNA was extracted according to the Gibco Life Technologies procedure using Trizol (Life Technologies Inc., Grand Island, NY, USA). The UV absorbance and integrity gels were used to estimate RNA. Leptin and 18S cDNA probes were labeled by random priming (Rediprime kit, Amersham, Buckinghamshire, UK) in the presence of  $^{32}\text{P}$  dCTP (3,000 Ci/mmol, Amersham, UK). Unincorporated nucleotides were removed using NucTrap probe purification columns (Stratagene, La Jolla, CA, USA). For each tissue sample, 7  $\mu\text{g}$  of total RNA were fractionated by electrophoresis on a denaturing 1% agarose gel containing 2.2 M formaldehyde and 1 $\times$  MOPS running buffer. One microliter of a 50  $\mu\text{g}/\text{ml}$  ethidium bromide (Gibco BRL, Gaithersburg, MD, USA) stock solution was added in order to check RNA integrity and even loading. After electrophoresis, RNA was transferred to nylon membrane (Duralon-UV, Stratagene, La Jolla, CA, USA) by overnight capillary transfer and UV cross-linked (Stratalinker 1800, Stratagene, La Jolla, CA, USA). Blots were then hybridized for 1 h at 68  $^{\circ}\text{C}$  in presence of labeled cDNA probe ( $2 \times 10^6$  cpm/ml Express Hyb solution, Clontech, Palo Alto, CA, USA and  $1 \times 10^6$  cpm/ml with the 18S cDNA probe). After washing at high stringency, blots were exposed to X-ray films with an intensifying screen at  $-80^{\circ}\text{C}$ . The expression level of 18S ribosomal RNA was used as an internal control to correct minor variation in total RNA amount.

## Intensity Light Scattering

This technique was used in order to test if linoleic acid is in the free form or the micellar form in our cell culture system when added at concentrations above 100  $\mu\text{M}$ . Several previous studies stated that linoleic acid has a critical micelle

concentration (CMC) of 150  $\mu\text{M}$  at pH 9 (in borate buffer at 20  $^{\circ}\text{C}$ ) and less than 100  $\mu\text{M}$  at pH 6.3 and 8 [25, 26]. In addition, it was observed that CMC at pH 7.4 and 37  $^{\circ}\text{C}$  was 75  $\mu\text{M}$  (Murphy E. J, personal communication). The scattered intensity was measured at a right angle with respect to the source (820 nm diode laser) with a photon correlation spectrometer Dyna-Pro MS/X. The temperature in the cell was set at 37  $^{\circ}\text{C}$ . Prior to each measurement, the sample was passed through 0.45  $\mu\text{m}$  nylon syringe filters. We did not detect the sharp increase in the scattered intensity typical of micellization within the range 0–500  $\mu\text{M}$  of linoleic acid. This led us to conclude that, under our experimental conditions (DMEM-1% FBS, pH = 7.4, 37  $^{\circ}\text{C}$ ), the linoleic acid must be in its monomer form, and that the critical micellar concentration (CMC) is higher than 500  $\mu\text{M}$  (data not shown). The differences between our data and the aforementioned studies could be due to the presence of FBS in our system, which could minimize the impact of micelles and perhaps reduce their formation.

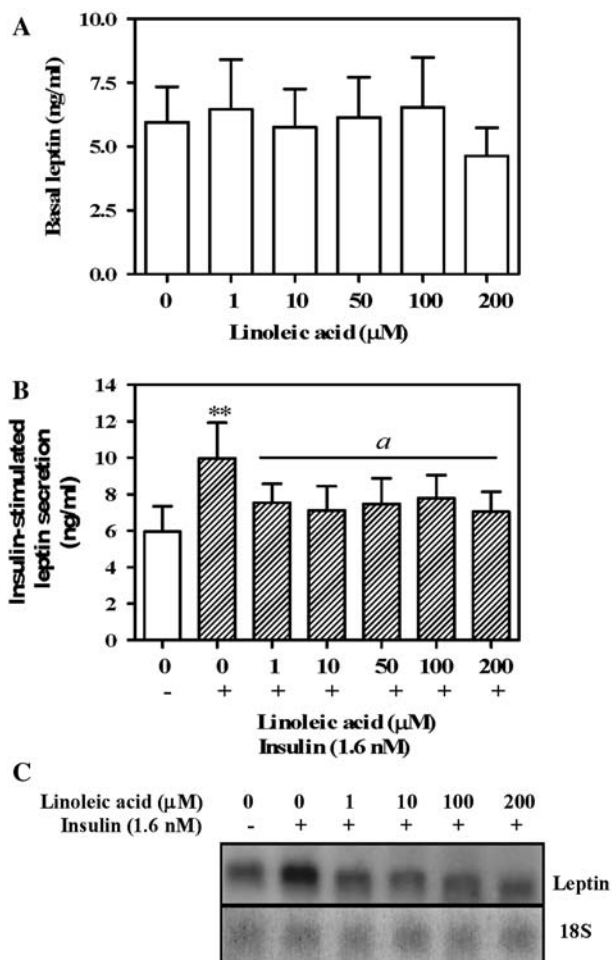

## Statistical Analysis

Glucose utilization was assessed by measuring the concentration of glucose in the media at 96 h and subtracting the value from the initial glucose concentration. Lactate production was calculated as the increase of media lactate at 96 h. The amount of carbon released as lactate per amount of carbon taken up as glucose over 96 h was calculated as  $\Delta[\text{lactate}]/\Delta[\text{glucose}]$  where  $\Delta$  is the difference, and was expressed as a percentage. In order to check if our data followed a normal distribution, two different methods (Kolmogorov–Smirnov and the Shapiro–Wilk tests) were used (SPSS/Windows version 11.0, SPSS Inc., Chicago, USA). The experimental results from each adipocyte suspension prepared from a single animal were analyzed in relation to a control well from the same suspension. For this reason, the statistical analysis of the data was performed by repeated measures ANOVA followed by a Dunnett's post-test (GraphPad Prism, GraphPad Software Inc., San Diego, CA, USA). Results were also analyzed and expressed as the percentage of the control. Differences were set as statistically significant at  $P < 0.05$ .

## Results

### Effects of Linoleic Acid on Leptin Expression and Secretion

Incubation of adipocytes over 96 h with linoleic acid (1–200  $\mu\text{M}$ ) did not modify basal leptin secretion as compared with control cells (Fig. 1a). As expected, insulin at 1.6 nM increased ( $P < 0.01$ ) leptin secretion by  $\sim 80\%$

**Fig. 1** Effects of linoleic acid (1–200 μM) on basal (a) and insulin-stimulated (b) leptin secretion by isolated rat adipocytes over 96 h in culture ( $n = 6$ , mean  $\pm$  SE)  $**P < 0.01$  versus control (cells without linoleic and insulin treatment) and  $^aP < 0.05$  versus cells incubated with insulin alone. Effects of linoleic acid (1–200 μM) on insulin-stimulated leptin mRNA expression, as assessed by northern blots (c). The expression level of 18S ribosomal RNA was determined and used as an internal control to correct minor variation in total RNA amount. Results are representative of at least two independent experiments

( $5.94 \pm 1.39$  vs.  $9.96 \pm 1.95$  ng/ml). Linoleic acid in the presence of insulin significantly decreased ( $P < 0.05$ ) leptin secretion by 15 to  $\sim 25\%$  at all concentrations tested (1–200 μM) (Fig. 1b). The patterns of linoleic acid's effects on leptin gene expression at 96 h of treatment were similar to those observed for leptin secretion; insulin-stimulated leptin gene expression was decreased by treatment with all concentrations of linoleic acid (Fig. 1c).

#### Effects of Linoleic Acid on Adiponectin Secretion

Linoleic acid at the concentration of 200 μM induced a significant decrease ( $P < 0.05$ ) by  $\sim 20\%$  in adiponectin secretion in presence of 1.6 nM insulin ( $277.7 \pm 99.4$  vs.

**Fig. 2** Effects of linoleic acid (100 and 200 μM) on adiponectin secretion by isolated rat adipocytes in presence of 1.6 nM insulin. ( $n = 3$ , mean  $\pm$  SE, expressed as percentage of the cells incubated with insulin alone).  $*P < 0.05$  versus insulin treated cells

$226.6 \pm 86.2$  ng/ml) (Fig. 2), while no significant changes were observed in adiponectin secretion in the absence of insulin (data not shown).

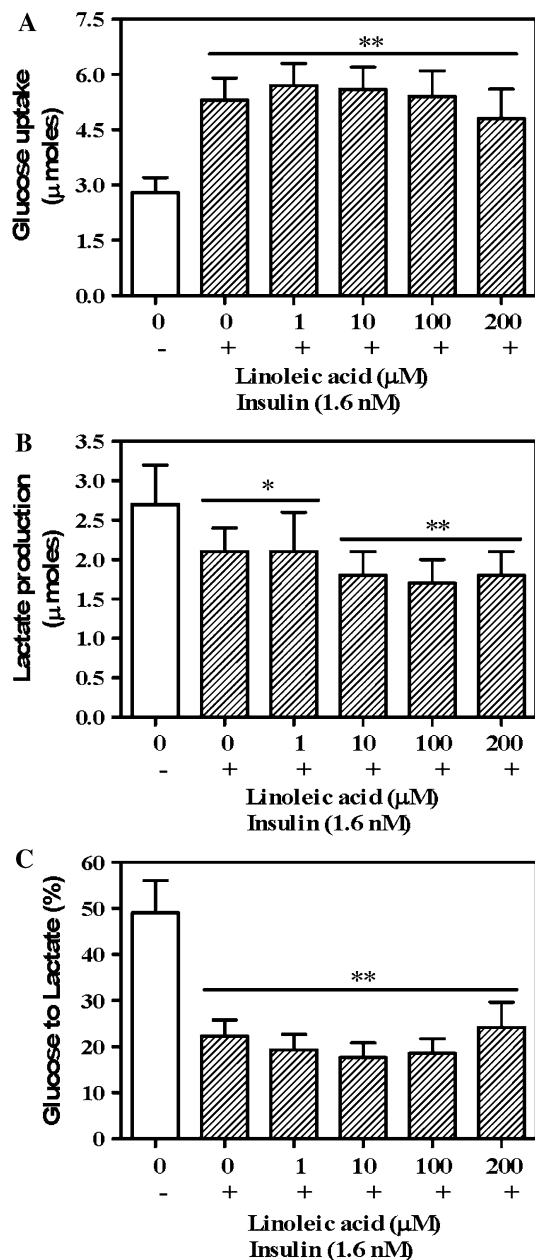

#### Effects of Linoleic Acid on Glucose Utilization and Metabolism

Linoleic acid did not affect glucose utilization and metabolism. Thus, this fatty acid did not modify either glucose uptake or lactate production in the presence of insulin at any of the concentrations tested (Fig. 3a, b). Thus, although a small decrease in glucose uptake was observed after treatment with 200 μM of linoleic acid ( $\sim 10\%$ ), it did not reach statistical significance. Furthermore, the proportion of glucose carbon metabolized to and released as lactate over 96 h was not affected by linoleic acid in presence of insulin at any of the assayed concentrations (Fig. 3c).

#### Discussion

Several in vivo studies have observed that a high fat diet rich in linoleic acid (safflower oil diet) induced a significant increase in epididymal and perirenal adipose tissues and also in leptin gene expression in comparison with a low-fat diet (as expected), while other high-fat diets rich in gamma-linolenic acid or in omega-3 fatty acids failed to do so [22, 27]. These observations suggest that although the adiposity is lower in all these diets rich in polyunsaturated fatty acids (linoleic acid, gamma linolenic acid or n-3 fatty acids) compared to the saturated fat rich diets as previously reported [8–11], the magnitude of their effects on adiposity vary.

**Fig. 3** Effects of linoleic acid (1–200 μM) on glucose uptake (a) lactate production (b) and the percentage of glucose carbon released as lactate (c) by isolated adipocytes over 96 h in culture. ( $n = 5$ , mean  $\pm$  SE) \* $P < 0.05$ ; \*\* $P < 0.01$  versus control (cells without linoleic acid and insulin treatment)

In the current study, we examined the direct effects of linoleic acid on leptin gene expression and secretion in primary cultured rat adipocytes, and observed that linoleic acid (1–200 μM) did not show any significant effect on basal leptin secretion and gene expression. Kang and Pariza [28] also observed a lack of effect of linoleic acid on basal leptin secretion in 3T3-L1 adipocytes and a study from Hutley et al. [29] also supports our results as they demonstrated minimal leptin gene expression changes in

human fat cell precursors after linoleic acid treatment (100 μM). These data suggest that the increased leptin mRNA levels observed in the aforementioned in vivo studies [22, 27] seem not to be due to a direct action of the fatty acid on leptin gene, but could be secondary to the increase observed in the white adipose tissue fat pads. Interestingly, the lack of effects on basal leptin secretion has been also described for other 18 carbons chain fatty acids such as oleic acid and  $\gamma$ -linoleic acid, as reported in the study of Cammisotto et al. [30]. However, a recent study by our group demonstrated that CLA (a group of positional and geometric isomers of linoleic acid) inhibited basal leptin production in primary cultured rat adipocytes [31]. Furthermore, several in vivo studies have showed that diets supplemented with CLA reduced body fat mass and also decreased circulating concentrations and adipose mRNA levels of leptin in rodents [32–35]. Therefore, the different actions observed on basal leptin production between linoleic acid and its isomers (CLA) suggest that the positional and geometric differences between the acids contribute specifically to their actions on leptin production.

On the other hand, both arachidonic acid (20:4n-6) and palmitic acid (16:0) have been reported to inhibit basal leptin secretion and expression in rat adipocytes [23, 30, 36] similarly to what was observed for CLA. In contrast, eicosapentaenoic acid (20:5n-3) (10–200 μM) showed a significant stimulatory effect on leptin production by cultured rat adipocytes [37].

Our present data also showed that the well-known stimulatory effect of insulin on leptin gene expression and secretion was prevented by linoleic acid at all concentrations tested (1–200 μM). Levy et al. [38] published that basal and insulin-stimulated leptin secretion are regulated by independent mechanisms. These observations could indicate that linoleic acid interfered only with the mechanisms involved in the stimulation of leptin production by insulin and not with those involved in basal leptin secretion. It has been demonstrated [19, 39, 40] that insulin-stimulated glucose metabolism rather than insulin per se is a major determinant of leptin production in both rodents and humans. Thus, inhibitors of glucose uptake and metabolism inhibit insulin-stimulated leptin secretion in proportion to their metabolic effects [19]. Takahashi and Ide [22] observed a down-regulation of the glucose transporter 4 (insulin-dependent glucose transporter-4) mRNA levels in white adipose tissue after feeding animals with a high safflower oil diet, suggesting a decrease in the insulin-stimulated glucose uptake by the adipocytes. In addition, Hutley et al. [29] also observed a significant decrease in insulin-stimulated glucose uptake after 100 μM linoleic acid treatment in human preadipocytes. These results suggest that the inhibitory actions of linoleic acid on insulin-stimulated leptin secretion could be secondary,

at least in part, to a decrease in glucose uptake. However, in the present study we did not find significant changes in insulin-stimulated glucose utilization. Previous reports showed that leptin secretion is inversely related to the proportion of glucose that is metabolized to lactate [19, 23, 41, 42]. In fact, the inhibitory actions of CLA and the n-6 arachidonic acid on insulin-stimulated leptin production were correlated with the increase observed in the anaerobic metabolism of glucose to lactate [23, 31]. However, in the present study, neither lactate production nor the percentage of glucose that was anaerobically metabolized to lactate were affected by incubation with linoleic acid, suggesting that other mechanisms are involved in the inhibitory actions of linoleic acid on insulin-stimulated leptin production. Thus, the current data suggest that linoleic acid and its isomers act on the adipocyte metabolism in a different way. Furthermore, although both linoleic and arachidonic acid are n-6 fatty acids, their actions on glucose metabolism and leptin production seem to be different.

Circulating adiponectin concentrations are reduced in obese individuals and negatively correlated with increasing adiposity in humans and animals [18, 43–45]. However, there are no studies on the potential direct effects of linoleic acid on adiponectin production by cultured adipocytes. Thus, in the present study, we demonstrated for the first time that linoleic acid had no effects on basal adiponectin secretion (as observed with leptin) but it inhibited adiponectin secretion in the presence of insulin at the highest concentration tested (200  $\mu\text{M}$ ). Again, the results herein described are in contrast to those observed with the CLA, which inhibited basal adiponectin secretion (50–200  $\mu\text{M}$ ) but, on the other hand, it did not affect the adiponectin secretion in the presence of insulin [31]. Furthermore, the inhibitory action of linoleic acid on adiponectin secretion in the presence of insulin were less potent than that observed on insulin-stimulated leptin secretion, which was detected from the lowest concentration of linoleic acid tested (1  $\mu\text{M}$ ), suggesting that linoleic acid specially interfered with the mechanisms involved in the regulation of leptin production by insulin.

The biological actions of insulin in the adipose tissue are mediated by high-affinity cell-surface receptors with intrinsic tyrosine kinase activity [46]. Binding of insulin to its transmembrane receptor leads to the activation of two major signalling cascades, the Akt and the Erk pathways, which mediate most metabolic and transcriptional effects of insulin in adipocytes [47]. Gao et al. [48] observed in their study that linoleic acid (300  $\mu\text{M}$ ) induced insulin resistance in 3T3-L1 adipocytes by decreasing insulin-stimulated glucose uptake and also inducing a serine phosphorylation in IRS-1 [48]. However, the lack of effects of linoleic acid on insulin-stimulated glucose uptake observed in the present study could suggest that this fatty acid

did not interfere with the Akt pathway which is responsible for the glucose uptake. On the contrary, linoleic acid might interfere with the Erk pathway, which has also been involved in the regulation of leptin and adiponectin production [47, 49].

In summary, our data showed a direct inhibitory effect of linoleic acid on leptin and, to a lower extent, on adiponectin production in the presence of insulin. These linoleic acid actions do not seem to be related to alterations in adipocyte glucose uptake and metabolism. The inhibition of leptin and adiponectin production by linoleic acid could also contribute to a decrease in whole-body insulin sensitivity, as suggested by previous studies in humans.

**Abstract** We investigated how virgin olive oil (VOO) affected platelet and hypoxic brain damage in rats. Rats were given VOO orally for 30 days at 0.25 or 0.5 mL kg<sup>-1</sup> per day (doses A and B, respectively). Platelet aggregation, thromboxane B<sub>2</sub>, 6-keto-PGF<sub>1α</sub>, and nitrites + nitrates were measured, and hypoxic damage was evaluated in a hypoxia–reoxygenation assay with fresh brain slices. Oxidative stress, prostaglandin E<sub>2</sub>, nitric oxide pathway activity and lactate dehydrogenase (LDH) activity were also measured. Dose A inhibited platelet aggregation by 36% and thromboxane B<sub>2</sub> by 19%; inhibition by dose B was 47 and 23%, respectively. Virgin olive oil inhibited the reoxygenation-induced increase in lipid peroxidation (57% in control rats vs. 2.5% (*P* < 0.05) in treated rats), and reduced the decrease in glutathione concentration from 67 to 24% (dose A) and 41% (dose B). Brain prostaglandin E<sub>2</sub> after reoxygenation was 306% higher in control animals, but the increases in treated rats were only 53% (dose A) and 45% (dose B). The increases in nitric oxide production (213% in controls) and activity of the inducible isoform of nitric oxide synthase (175% in controls) were both smaller in animals given VOO

(dose A 84%; dose B 12%). Lactate dehydrogenase activity was reduced by 17% (dose A) and 42% (dose B). In conclusion, VOO modified processes related to thrombogenesis and brain ischemia. It reduced oxidative stress and modulated the inducible isoform of nitric oxide synthase, diminishing platelet aggregation and protecting the brain from the effects of hypoxia–reoxygenation.

**Keywords** Olive oil · Platelets · Oxidative stress · Nitric oxide · Brain

### Abbreviations

cNOS	Constitutive isoform of nitric oxide synthase
GSH	Reduced glutathione
GSSG	Oxidized glutathione
GSHpx	Glutathione peroxidase
GSHtf	Glutathione transferase
iNOS	Inducible isoform of nitric oxide synthase
LDH	Lactate dehydrogenase
NO	Nitric oxide
NOS	Nitric oxide synthase
NO <sub>2</sub> <sup>-</sup> + NO <sub>3</sub> <sup>-</sup>	Plasma nitrite + nitrate
PGE <sub>2</sub>	Prostaglandin E <sub>2</sub>
TxB <sub>2</sub>	Thromboxane B <sub>2</sub>
TBARS	Thiobarbituric acid reactive substances
VOO	Virgin olive oil

### Introduction

Scientific evidence from several sources has accumulated on the beneficial effects of the Mediterranean diet in

preventing cardiovascular disease [1–3] and cancer [4], and in reducing overall mortality [4, 5]. The nutritional guidelines of several international scientific organizations now recommend a healthy diet compatible with the main characteristics of the “Mediterranean diet model” [6, 7] to prevent cardiovascular disease, obesity, diabetes, cancer, and other conditions related to oxidation processes [8, 9]. The benefits of the Mediterranean diet have been attributed, in part, to the antioxidant effect of some of its components. A key component of this diet is olive oil, which contains monounsaturated fatty acids and polyphenols, compounds with a clear antioxidant effect [10].

In humans several factors are involved in the process of brain ischemia. A key event, in which platelet and endothelial functions play a major role, is the formation of an arterial thrombus. Another key factor is the activation of biochemical pathways such as oxidative stress and the nitric oxide pathway, which lead to irreversible neuronal damage [11, 12].

Because of its importance in the Mediterranean diet, olive oil may be a key element in the prevention of cardiovascular disease; we therefore wished to examine its effect on these biochemical pathways. The objective of this study was to investigate, in rats, how virgin olive oil (VOO) consumed as part of the diet affected basic mechanisms of brain ischemia, i.e. platelet and endothelial functions and biochemical pathways that are activated at a tissue level during this process.

## Experimental Procedures

### Materials

Lactate dehydrogenase reagent kits were obtained from Biosystem (Barcelona, Spain). L-[<sup>3</sup>H]Arginine, thromboxane B<sub>2</sub>, 6-keto-prostaglandin F<sub>1α</sub> and prostaglandin E<sub>2</sub> enzyme immunoassay kits were from Amersham International (Little Chalfont, Buckinghamshire, UK). The nitrite/nitrate ELISA kit was obtained from Cayman Chemical (Ann Arbor, MI, USA). All other reagents were from Sigma Chemical (St Louis, MO, USA). Olive oil used was VOO of the Hojiblanca variety and was purchased from local department stores. The composition of the VOO oil administered to rats is shown in Table 1.

### Study Design

The experimental animals ( $n = 45$ , 15 rats per group) were 2-month-old adult male Wistar rats (body weight 200–250 g). All rats were used in accordance with current Spanish legislation for animal care, use, and housing (RD 223/1998, based on European Directive 86/609/CEE). The

**Table 1** Main composition of the virgin olive oil administered to rats

Fatty acids	%
C16:0	14.7

β-Sitosterol (mg kg <sup>-1</sup> )	1.4

recommendations in the Guide for the Care and Use of Laboratory Animals (NIH publication No. 86–23, revised 1985) were followed, and, where applicable, Spanish Law on the Protection of Animals. The study protocol was approved by the University of Malaga Ethics Committee for the Use of Animals. The rats were allocated randomly to three groups of 15 animals each:

control-group animals treated with daily saline p.o., studied for 30 days;

animals treated with 0.25 mL kg<sup>-1</sup> per day p.o. VOO for 30 days; and

animals treated with 0.5 mL kg<sup>-1</sup> per day p.o. VOO for 30 days.

Chow and water were self-administered ad libitum. Either saline or VOO were administered from 9:00 to 10:00 a.m. The last dose was administered 2 h before the animal was killed. We initiated treatment at a rate of two rats per day in order to process two rats per day at the end of the treatment period. The doses of VOO were chosen according to previously published data [13] by interpolation of the dose used in this study in healthy humans (25 mL day<sup>-1</sup>).

### Sample Processing

At the end of day 30 all animals from all groups were anesthetized with pentobarbital sodium (40 mg kg<sup>-1</sup> i.p.). A medial laparotomy was made to withdraw blood from the vena cava; 3% sodium citrate at a proportion of 1:10 was used as anticoagulant. The rats were decapitated with a

guillotine and the thoracic and abdominal aorta and brain were removed. Part of the blood was centrifuged at 2,000g for 10 min at 4°C, and the supernatant (plasma) was frozen at –80°C until the experiment.

#### In-vitro Model of Rat Brain Hypoxia–Reoxygenation

We used a previously described in-vitro method of hypoxia–reoxygenation in brain slices [14]. The cortex and midbrain were coronally cut into 1 mm slices with a vibrating microtome (Capdem Instruments, San Francisco, CA, USA). The slices were placed in buffer (composition mmol L<sup>-1</sup>: 100 NaCl, 0.05 KCl, 24 NaHCO<sub>3</sub>, 0.55 KH<sub>2</sub>PO<sub>4</sub>, 0.005 CaCl<sub>2</sub>, 2 MgSO<sub>4</sub>, 9.8 glucose, pH 7.4) and perfused with a mixture of 95% O<sub>2</sub> and 5% CO<sub>2</sub>. After 30 min to reach equilibrium the slices were placed in fresh buffer of the same composition except that the concentration of CaCl<sub>2</sub> was 3 mmol L<sup>-1</sup>, that of MgSO<sub>4</sub> was 0.001 mmol L<sup>-1</sup>, and no glucose was included. This solution was perfused with a mixture of 95% N<sub>2</sub> and 5% CO<sub>2</sub> for 20 min (hypoxia). The slices were then placed in fresh buffer containing glucose and the solution was perfused with a mixture of 95% O<sub>2</sub> and 5% CO<sub>2</sub> (reoxygenation).

Brain slices (two per analytical test) were analyzed:

1. after 30 min of incubation and before N<sub>2</sub> perfusion;
2. after 20 min of perfusion with N<sub>2</sub>; and
3. after 180 min of reoxygenation.

For all studies the tissues were quickly frozen in liquid nitrogen and stored at –80°C until the day of the experiment, which was conducted no longer than 7 days after freezing.

#### Analytical Techniques

All techniques were run in a single-blind manner, i.e. the persons who did the assays were unaware of the origin and nature of the samples. Some measurements (plasma glucose levels and the basic plasma lipid profile) were done automatically at the Analytical Laboratory, Hospital Universitario Carlos Haya, Málaga, Spain.

#### Platelet Aggregometry

Platelet aggregation in whole blood was tested at 37°C by the electrical impedance method (Chrono-Log aggregometer; Izasa, Madrid, Spain). Collagen (10 µg mL<sup>-1</sup>) was used as the inducing agent. All measurements were performed within 1 h of obtaining the blood. Maximum change in impedance after 10 min of induction was recorded as maximum intensity of platelet aggregation.

#### Platelet Thromboxane B<sub>2</sub> (TxB<sub>2</sub>)

After 10 min aggregation was complete; then 100 µmol L<sup>-1</sup> indomethacin was added and the blood sample was centrifuged at 10,000g for 5 min, and the supernatant was frozen at –80°C until quantification of thromboxane B<sub>2</sub> (stable thromboxane A<sub>2</sub> metabolite) with a commercial immunoenzyme assay kit. The entire process was performed within 1 h of obtaining the blood, and TxB<sub>2</sub> was measured within one week after freezing the samples. Automated cell counts (Cell Counter Baker 8000; Menarini, Barcelona, Spain) were obtained in whole blood before platelet aggregation started.

#### Vascular 6-Keto-Prostaglandin F<sub>1α</sub>

An aortic ring was incubated at 37°C in buffer containing (mmol L<sup>-1</sup>): 100 NaCl, 4 KCl, 25 NaHCO<sub>3</sub>, 2.1 Na<sub>2</sub>SO<sub>4</sub>, 20 sodium citrate, 2.7 glucose, and 50 Tris (pH 8.3), and calcium ionophore A23187 (1 µmol L<sup>-1</sup>) was added. Five minutes later the sample was dried and weighed, and the supernatant was frozen at –80°C until the assay. Production of 6-keto-prostaglandin F<sub>1α</sub> (stable metabolite of prostacyclin) was quantified with a commercial immunoenzyme assay kit.

#### Plasma Nitrite + Nitrate (NO<sub>2</sub><sup>-</sup> + NO<sub>3</sub><sup>-</sup>)

As an indirect indicator of overall nitric oxide (NO) production in each animal, we determined plasma nitrite + nitrate levels. Blood was centrifuged at 10,000g for 10 min, and the supernatant was filtered through Ultrafree MC microcentrifuge filters to remove hemoglobin released by cell lysis. The nitrite + nitrate level was measured with a commercial kit.

#### Lipid Peroxidation

To quantify lipid peroxidation we measured thiobarbituric acid-reactive substances (TBARS) [11] in cell membrane-enriched fractions [15]. Absorbance was determined spectrophotometrically at 532 nm (Perkin–Elmer, USA, C-532001 spectrophotometer). The results were expressed as µmol TBARS mg<sup>-1</sup> protein; the latter was determined by the method of Bradford et al. [16].

#### Glutathione Levels

Total glutathione was measured spectrofluorimetrically [17]. Brain tissue was homogenized in 0.1 mol L<sup>-1</sup> sodium phosphate buffer (pH 8.0) with 25% phosphoric acid in the proportion 1:20, then centrifuged at 13,000g for 15 min at

4°C to obtain the supernatant. Cuvettes were prepared for spectrofluorimetry with sodium phosphate buffer, the supernatant for each sample, and *o*-phthaldehyde. To determine the proportions of oxidized and reduced glutathione we incubated the supernatant from each sample with 4-vinylpyridine, then proceeded as for as total glutathione.

#### *Enzyme Activity Related to Glutathione*

Glutathione peroxidase (GSHpx) and glutathione transferase (GSHtf) were determined by spectrophotometric kinetics [18, 19]. Tissue samples were diluted with 0.1 mol L<sup>-1</sup> phosphate-buffered saline (pH 7.0) and 25% phosphoric acid. The mixture was homogenized and centrifuged at 13,000g for 15 min at 4°C. The supernatant was used to determine protein concentration after neutralization with 0.1 mol L<sup>-1</sup> NaOH, and to determine enzyme activity as described below.

#### *Glutathione Peroxidase*

A volume equivalent to 25 µg protein was taken from each supernatant and 0.1 mol L<sup>-1</sup> phosphate-buffered saline was added to a volume of 880 µL, together with 53 µL glutathione reductase, 133 µL GSH, 100 µL nicotinamide-adenine dinucleotide phosphate (NADPH), and 100 µL tertbutyl-hydroperoxide. The preparation was read at 340 nm and the decrease in absorbance was recorded every 30 s for 5 min.

#### *Glutathione Transferase*

One hundred microliters of GSH was added to the volumes of sample and buffer indicated above for glutathione peroxidase, and the test was conducted in the same way.

#### *Lactate Dehydrogenase (LDH) Assay*

Tissue damage was measured by examining the LDH efflux [20]. The enzyme activity was measured spectrophotometrically at 340 nm by recording oxidation of NADH in the presence of pyruvate.

#### *Brain Nitrite + Nitrate Concentration*

One milliliter of the perfusion buffer was used to determine nitrite + nitrate using the same method as in plasma.

#### *Nitric Oxide Synthase Activity (NOS)*

Samples were homogenized (1:5 w/v) in buffer containing 10 mmol L<sup>-1</sup> HEPES, 320 mmol L<sup>-1</sup> sucrose, 1 mmol L<sup>-1</sup>

EDTA, 1 mmol L<sup>-1</sup> DL-dithiothreitol (DTT), 10 µg mL<sup>-1</sup> leupeptin, and 2 µg mL<sup>-1</sup> aprotinin, at 0°C. The homogenates were centrifuged at 12,000g for 20 min at 4°C, and the supernatant was used to measure NOS synthase. Enzymatic reactions were tested at room temperature for 30 min with a mixture of 40 µL supernatant and 100 µL 40 mmol L<sup>-1</sup> potassium phosphate buffer (pH 7.0) consisting of 4.8 mmol L<sup>-1</sup> *dl*-valine, 1 mmol L<sup>-1</sup> NADPH, 1 mmol L<sup>-1</sup> MgCl<sub>2</sub>, 2 mmol L<sup>-1</sup> CaCl<sub>2</sub>, 20 µmol L<sup>-1</sup> L-arginine and 1.25 µL mL<sup>-1</sup> L-[<sup>3</sup>H]arginine (59 Ci per mole, Amersham Life Science). For each assay three parallel samples were run:

1. a sample prepared as described above;
2. a sample that included 1 mmol L<sup>-1</sup> <sup>14</sup>N-methyl-L-arginine (non-specific activity); and
3. a sample without calcium salts but containing 1 mmol L<sup>-1</sup> EDTA and 1 mmol L<sup>-1</sup> ethyleneglycol-tetraacetic acid (EGTA).

In all cases the reaction was stopped by adding cold buffer consisting of 0.2 mmol L<sup>-1</sup> EDTA. The samples were assayed with 50W-XA Dowex resin columns (Na<sup>+</sup> form). One hundred microliters of supernatant was added to 5 mL scintillation fluid, and counts per minute (cpm) were recorded.

#### *Quantification of Prostaglandin E<sub>2</sub> (PGE<sub>2</sub>)*

The samples were homogenized (1:10 w/v) in 15% methanol with 0.1 mol L<sup>-1</sup> phosphate-buffered saline (pH 7.5), then centrifuged at 37,000g for 15 min at 4°C. The supernatant was run through a C<sub>18</sub> column (Bio-Rad Laboratories, Hercules, CA, USA). Prostaglandins were eluted with methyl formate. The samples were then dried under a nitrogen current and reconstituted with phosphate-buffered saline. The concentration of PGE<sub>2</sub> was measured with a commercial enzyme immunoassay (Amersham International).

#### *Statistical Methods*

The data in the text, tables, and figures are expressed as the mean ± standard error of the mean for 15 animals or measurements. All statistical analysis was performed with the Statistical Program for Social Sciences v. 12.0 (SPSS, Chicago, IL, USA). One-way analysis of variance followed by Bonferroni transformation and paired Student's *t* test were used, and differences were considered significant when *P* < 0.05.

## Results

### Basic Parameters

After 1 month of treatment with VOO there were no statistically significant differences between groups in basic zoometric parameters, blood glucose levels, and plasma lipid profiles (Table 2).

### Platelet and Endothelium Biomarkers

Collagen-induced platelet aggregation was inhibited by VOO at 0.25 (36.1% inhibition with respect to the control group) and 0.5 (47.3% inhibition) mL kg<sup>-1</sup> per day p.o. Platelet production of thromboxane B<sub>2</sub> was significantly inhibited by VOO at 0.25 (19.5% inhibition) and 0.5 mL kg<sup>-1</sup> per day (26.3% inhibition) with respect to the control group. Aortic 6-keto-PGF<sub>1α</sub> did not change significantly after treatment with VOO. The thromboxane/prostacyclin ratio was significantly reduced after both 0.25 (19.0%) and 0.5 (33.2%) mL kg<sup>-1</sup> per day p.o. Plasma nitrite + nitrate concentration did not change after 30 days of treatment with VOO (Table 3).

### Biochemical Changes in Rat Brain Slices after Hypoxia–Reoxygenation

After 20 min of hypoxia the differences for all parameters were not statistically significant in comparison to pre-hypoxic values. The results obtained after reoxygenation will therefore be reported below. In brain slices subjected to hypoxia–reoxygenation there was an increase in TBARS production, which rose by 57.8 ± 7.0% after 180 min of reoxygenation in comparison with the pre-hypoxia value. Reduced glutathione levels decreased by 67.2 ± 5.7%. The percentage of oxidized glutathione increased by

31.5 ± 3.5%, and GSHpx activity increased by 7.6 ± 0.4%, whereas GSHtf activity decreased by 31.1 ± 3.1%. Brain PGE<sub>2</sub> production was 3.06-fold the pre-hypoxic values. Nitrite + nitrate concentration increased by 213 ± 45%, cNOS activity decreased by 77.1 ± 8.3%, and iNOS activity increased by 175 ± 19%. Efflux of LDH into the incubation medium increased by 96.8 ± 9% after 180 min of reoxygenation (Fig. 1; Table 4).

### Effects of Virgin Olive Oil in the Brain Hypoxia–Reoxygenation Model

None of the parameters measured in pre-hypoxic brain slices (baseline values) differed significantly between rats that were given VOO and untreated animals. The increase in TBARS concentration after reoxygenation was almost completely abolished in rats treated with VOO; with respect to reoxygenated slices from untreated rats the increases were 2.7% after dose A, and 2.5% after dose B (Table 4). The reduction in reduced glutathione after reoxygenation was significantly smaller in rats given VOO (41% after 0.25 mL kg<sup>-1</sup> per day and 24% after 0.5 mL kg<sup>-1</sup> per day) than in untreated rats (Table 4). The increase in the percentage of oxidized glutathione after reoxygenation was similar in rats given VOO and in untreated animals (*P* > 0.05 with respect to the control group) (Table 4). The increase in GSHpx activity did not differ significantly with respect to untreated rats, and the reduction in GSHtf was not modified (Table 4). The increase in NO production in brain slices after reoxygenation in rats treated with VOO at 0.5 mL kg<sup>-1</sup> per day p.o. was significantly lower (84 ± 9% with respect to pre-hypoxic values) than in the control group. Moreover, the reduction in cNOS activity observed in untreated rats was smaller in VOO-treated rats (53 ± 6% after 0.25 and 50 ± 5% after 0.5 mL kg<sup>-1</sup> per day, respectively), and the increase in

## Discussion

Our results show that the daily oral administration of VOO in healthy rats modified platelet and endothelial biomarkers and acted on some of the biochemical pathways involved in brain damage. The findings of earlier research, however, are ambiguous, ranging from a clear antiaggregant effect in humans [21] and rabbits [10] to the absence of effect in humans both in vitro [22] and ex vivo [23]. Some studies have even reported that a diet enriched with unsaturated fat (mainly linoleic acid) stimulated platelet aggregation [24]. In healthy human volunteers who consumed a diet enriched with VOO, an antiaggregant effect was seen after 8 weeks, but the effect was significantly blunted after 16 weeks [21]. All earlier studies used higher doses of VOO than those used in our experiments. Animals treated with VOO showed not only inhibited platelet aggregation, but also reduced production of thromboxane, an agent that favors aggregation and vasoconstriction. At least one study in humans also reported a reduction in thromboxane production [25].

Inhibition of cyclooxygenase activity after administration of monounsaturated and/or polyunsaturated fatty acids is well documented in several models [26–29]. This effect was responsible for the beneficial effect of VOO on the thromboxane/prostacyclin ratio, an important factor in the prevention of thrombosis. The weak effect of VOO on endothelial pathways of platelet inhibition (prostacyclin and NO) may reflect the fact that our experimental animals were healthy at the start of our experiments. Treatment with VOO also reportedly had a weak effect on biochemical parameters in non-stimulated human endothelial cells [30]. The administration of VOO to healthy rats thus had an inhibitory effect on platelet function and led to a favorable change in the thromboxane/prostacyclin ratio.

Our findings in the model of brain hypoxia–reoxygenation showed that in rats treated with VOO, brain cell death caused by hypoxia–reoxygenation, measured as LDH efflux, was 42.5% lower than in untreated rats. Virgin olive oil thus modified all three of the pathways of cerebral cytoprotection we investigated. It curtailed the increase in lipid peroxides in brain tissue, limited the reduction in glutathione stores, and inhibited the overproduction of prostaglandin  $E_2$  and NO, mainly by inhibiting iNOS activity.

The antioxidant effect of VOO in the brain of healthy rabbits has been reported previously [31]. Some components of virgin olive oil, specifically polyphenols and vitamin E, have clear antioxidant effects in some cells and tissues [32–34]. Although TBARS determination is a non-definitive and inexact representation of lipid peroxidation in comparison with other methods, the percentage differences between groups represents the qualitative changes in

this parameter. Researchers who have investigated the effect of different types of oil and their components on the glutathione system mostly concur that changes in this system are not dependent on the fatty acid composition of the oil, but rather on non-glyceride components, especially vitamin E and polyphenols [27, 35–38]. We found no reports of this effect in the model of brain ischemia–reperfusion we used.

In ischemia or in neuronal degeneration processes, prostaglandin synthesis is known to result from stimulation of inducible cyclooxygenase (cyclooxygenase-2) [39]. However, there is evidence that type-1 cyclooxygenase is induced under certain circumstances, for example global cerebral ischemia [40], *N*-methylaspartate-induced excitotoxicity [41], traumatic brain injury [42], and activated microglia associated with amyloid plaques [43]. This is consistent with the marked increase in prostaglandin E<sub>2</sub> production after reoxygenation in our experimental model. Accordingly, despite the clear effect of VOO on the accumulation of prostaglandin E<sub>2</sub> in reoxygenated slices, our findings do not suggest which cyclooxygenase isoform was affected by VOO in our experimental model.

The effect of VOO on NO accumulation suggests that the components of this oil may affect iNOS activity or the inflammatory mediators that stimulate this enzyme [30]. Vitamin E has been found to inhibit the expression and synthesis of iNOS [44], and polyphenols have been shown to significantly reduce peroxynitrite formation in humans [32, 45]. In addition, cell culture experiments have shown that these phenols increase the overall production of NO [34]. However, the free radical-scavenging capacity of these phenols has been shown to prevent the formation of peroxynitrite [30, 32, 34]. Thus the effect of VOO on the expression and formation of iNOS, and its antioxidant effect and ability to prevent peroxynitrite formation, might account for the decrease in iNOS activity in brain tissues from animals treated with VOO and then subjected to hypoxia–reoxygenation.

Because VOO polyphenols are the components most likely to be responsible for the antioxidant effect of this Mediterranean fat, it is important to know whether they are detectable in the rat brain after oral intake. We have found no published studies that investigated polyphenols, although D'Angelo et al. [46] measured hydroxytyrosol in

the rat brain 1 h after a single intravenous injection of 1.5 mg of this antioxidant from VOO per kg body weight, and found the brain tissue to contain 0.31% of the maximum plasma concentration. Schaffer et al. [47] recently showed that a hydroxytyrosol extract prepared from olive mill wastewater (45.5% hydroxytyrosol) reduced neuronal damage induced by ferrous salts or sodium nitroprusside as oxidative inducers.

This study has two main limitations—lack of a negative control group (i.e. refined olive oil) and the poor polyphenol content of the VOO used. In preliminary unreported experiments we are confirming the absence of effect on the variables determined in this study when refined olive oil is administered to rats; moreover, a similar amount of the polyphenol mixture measured in the VOO used has a similar effect on brain oxidative status in healthy rats.

Some criticism [48] has been raised about recommending VOO consumption to protect against cardiovascular diseases because it is presumed to increase the risk of becoming overweight. In our experimental model a greater increase in the body weight was observed for rats treated with 0.5 mL kg<sup>-1</sup> day<sup>-1</sup> than in the control group (0.91% with respect to control group), which was not statistically significant. Bes-Rastrollo et al. [49] demonstrated that a consumption during a mean of 28.5 months of 0.15 mL kg<sup>-1</sup> day<sup>-1</sup> by an apparently healthy population increased the body weight by 1.14%, concluding that even consumption of a large amount of olive oil is not associated with greater weight gain.

In conclusion, administration of VOO modulates a series of biochemical phenomena that play a key role in the process of thrombogenesis and brain ischemia. These effects of VOO are the result of its ability to reduce oxidative stress and, possibly, regulate inducible enzyme pathways; these biochemical effects make VOO a potentially ideal candidate for prophylactic treatment against thrombogenesis and brain ischemia, either alone or as an adjuvant to medication.

Despite the absence of cohort studies of stroke prevention in people who consume a Mediterranean type diet [29], the beneficial effects of this diet on cardiovascular risk factors [50] may well be valid for cerebrovascular ischemic processes also [51, 52]. Our experimental study supports a possible role of VOO in the prevention of ischemic stroke. Further studies including clinical trials in humans will be needed to test the ability of virgin VOO to prevent ischemic stroke.

**Abstract** As part of our effort to identify enzymes that are critical for producing large amounts of ricinoleate in castor oil, we have isolated three cDNAs encoding acyl-CoA synthetase (ACS) in the castor plant. Analysis of the cDNA sequences reveals that two of them, designated RcACS 2 and RcACS 4, contain complete coding regions corresponding to 694 and 690 amino acids, respectively. The third cDNA, RcACS 1, encodes a truncated gene sequence. The RcACS 2 and RcACS 4 share 77% identity at the amino acid sequence level. Complementation tests showed that both RcACS 2 and RcACS 4 successfully restored growth of a yeast mutant strain (YB525) deficient in ACS. Lysates from yeast cells expressing RcACS 2 and 4 were enzymatically active when using  $^{14}\text{C}$ -labeled oleic acid as a substrate. A cell fractionation study indicates that RcACS 2 and 4 are mainly associated with membranes. Substrate specificity assays indicate that the RcACS 2 preferentially activates ricinoleate, while the RcACS 4 has a preference for nonhydroxy fatty acids.

RcACS	acyl-CoA synthetase from <i>Ricinus communis</i>
RT-PCR	Reverse transcription-polymerase chain reaction
SD	Standard deviation
SDM	Synthetic defined media
U	Uracil

### Introduction

The castor plant (*Ricinus communis*) produces a seed oil of unique composition, with up to 90% of the fatty acid content as ricinoleate (12-hydroxy oleate). As a result of the hydroxy group, the oil has physical and chemical properties that make it desirable for numerous industrial uses, such as lubricants, coatings, plastics and cosmetics [1]. However, production of castor oil is seriously hindered by the presence of the highly toxic protein ricin, its homologue *Ricinus communis* agglutinin, and potent allergens in the seeds. Because of the potential for expanded use of castor oil in industrial and biodiesel applications, it is of great interest to develop a safe domestic source of castor oil. One logical approach is to genetically modify a commodity oilseed to produce castor oil. The feasibility of altering the oil composition of oilseeds has been amply demonstrated [2–4], but the results have been disappointing in most cases. The

enzyme responsible for synthesis of ricinoleate in castor plant is the oleoyl-12-hydroxylase (FAH), and it was cloned previously [5]. To date, oilseeds transformed to express FAH produce less than 20% hydroxy fatty acid content in oil [6], much less than the 90% present in castor oil. It has been hypothesized that excessive accumulation of ricinoleate in lipid disrupts membrane integrity and impairs normal plant growth and development. Plants appear to have “editing” mechanisms that exclude unusual fatty acids from the membrane [7]. However, the castor plant has evolved the enzymes needed to produce and incorporate ricinoleate into storage lipids at a high level [8]. Thus, we initiated an approach to identify additional enzyme components in castor that enable it to produce oil with 90% ricinoleate [9].

We have previously cloned a diacylglycerol acyltransferase type 1 gene from the castor plant (RcDGAT), and demonstrated that the gene product has a twofold preference for acylation of diricinolein substrate versus other diacylglycerols in the final step of oil biosynthesis [10]. We believe that this RcDGAT is one of the necessary components for high accumulation of ricinoleate in transgenic plants. Based on our previous work [9], additional enzymes are also required for high ricinoleate production in castor. Since acyl-CoA is the acyl donor for DGAT activity and the acyl-CoA synthetase (ACS) plays a central role in the metabolism of free fatty acids in plants and their incorporation into storage lipids in seed, we hypothesized that ACS may be involved in enhancing ricinoleate incorporation into TAG. Multiple isoforms of ACS have been isolated from many organisms, these isoforms differ in fatty acid preference, subcellular location and regulation [11–13]. In this paper, we report the isolation of ACS genes from castor plants, complementation of these ACS genes in a yeast mutant strain deficient in ACS and studies of their enzymatic specificity.

## Experimental Procedures

### Cloning of ACS cDNAs from *R. communis*

Degenerate primers were designed based on the nucleic acid sequences of conserved regions of known ACS sequences. The primers are for ACS 1: 5'-ACTGGTGAYCCNAARGGAGT-3' and 5'-TCWGTWAGACCRTATCCTTG-3'; ACS 2: 5'-GACTACAAATGGATGAC-3' and 5'-TCCCCTTGGTAGAAHCCAA-3'; ACS 4: 5'-GAAGGMTAYGGAATGAC-3' and 5'-TTGAARATGTTCTTYTCC-3'. Reverse transcription (RT)-PCR was performed following the Gibco BRL SuperScript First-Strand Synthesis System for RT-PCR instruction (Grand Island, NY) using these primers and a mixture of RNA samples

extracted from different castor tissues including leaf, stem, root and germinating seeds according to the method of Gu et al. [14]. The sequences of the PCR products obtained were used to generate gene-specific primers for 3'- and 5'-RACE (rapid amplification of cDNA ends) [15]. Finally, primers for end-to-end amplification were designed to obtain the complete genes from the RACE-ready cDNA template following the manufacturer's instruction (Invitrogen, Carlsbad, CA). The full-length cDNAs were then cloned into a pCR4-TOPO vector using TOPO TA Cloning Kit for Sequencing (Invitrogen) and completely sequenced in both directions using ABI3100 DNA analyzer and ABI PRISM Big Dye Terminators v3.1 Cycle Sequencing Kit (Applied Biosystems, Foster City, CA).

### Cloning of Castor ACS Genes in Yeast Cells

The coding regions of ACS genes were reamplified using new primers: 5'-AGAAATGGACATGGATTCAGCTCAACG-3' and 5'-CAGTTTCGGGGAGGGATCGGAC-3' for RcACS 2; 5'-GACAATGGAATCAACAACAGCTCAACG-3' and 5'-ATCCAAGGTAGCAGTCTCAGC-3' for RcACS 4, and cloned into a yeast expression vector, pYES2.1/V5-His-TOPO (Invitrogen). The translation stop sites were removed to fuse the genes in frame with the V5 epitope and polyhistidine tag for detection and purification of the proteins. The recombinant vectors were first transformed into competent *E. coli*. Plasmid DNA from the bacterial colonies was then transformed into yeast YB525 cells, kindly provided by Professor J.I. Gordon, Washington University, St Louis [16] that had been made competent for chemical transformation using the S.c. EasyComp kit (Invitrogen).

### Expression of ACS in Yeast Cells

Yeast YB525 cells containing the expression constructs were selected on Synthetic Defined Media (SDM)-uracil (U) plates consisting of 0.17% yeast nitrogen base, 0.5% ammonium sulfate, 2% dextrose, 0.08% complete supplement minus uracil, and 1.7% agar (BIO 101 Systems 4813-075, Q-Biogene, Irvine, CA). Overnight cultures from single colonies grown in SDM-U liquid medium were induced to express transgenes from the Gal1 promoter of the vector by adding galactose to a concentration of 2% (w/v). Yeast cells were harvested after growing 12–18 h in induction medium at 30 °C. Microsomes were isolated from the harvested yeast cells as described by Urban et al. [17] and resuspended in 0.1M Tris-HCl, pH 7.0, containing 20% glycerol and used as enzyme sources for the ACS assay. To test the constructs for their ability to complement the phenotype of yeast strain YB525, aliquots of each culture containing these constructs were plated on SDM-U

plates with galactose plus 500  $\mu\text{M}$  myristic acid and 25  $\mu\text{M}$  cerulenin and incubated at 30  $^{\circ}\text{C}$  for 2–3 days.

#### Western Blot Analysis

Yeast cells were resuspended in breaking buffer (50 mM sodium phosphate, pH 7.4, 1 mM EDTA, 5% glycerol and 1 mM PMSF) to obtain an  $\text{OD}_{600}$  of 50 and lysed by adding an equal volume of acid-washed glass beads (0.4–0.6 mm size from Sigma-Aldrich, St Louis, MO) and beating for 4 min at 4  $^{\circ}\text{C}$  on a Mini-BeadBeater-8 (Biospec Products, Bartlesville, OK). The lysate collected was centrifuged at 10,000g for 10 min to remove cell debris. The supernatant used as total protein fraction (T) was centrifuged again at 100,000g for 1 h to obtain a water soluble fraction (S) and a membrane fraction (P). Protein samples (10  $\mu\text{g}$ ) from each fraction were separated by SDS-PAGE and electrotransferred to PVDF membranes. The membranes were incubated with the anti-V5 antibodies (Invitrogen) at 1:5,000 dilution and horseradish peroxidase-conjugated goat-anti-mouse secondary antibodies (Roche, Indianapolis, IN) at 1:1,000 dilution. Horseradish peroxidase activity was visualized by chemiluminescence using the ECL kit (Amersham, Arlington Heights, IL).

#### Assay for ACS Activity

The *in vitro* ACS assays were performed as in Shockey et al. [18] with minor modification. The reaction mixture (100  $\mu\text{L}$ ) consisted of 100 mM bis-tris-propane (pH 7.6), 10 mM  $\text{MgCl}_2$ , 5 mM ATP, 1 mM CoA, 2.5 mM dithiothreitol, 0.1% bovine serum albumin (BSA), 20  $\mu\text{M}$  1- $^{14}\text{C}$  fatty acid (specific activity 49–56  $\text{mCi mmol}^{-1}$ , from American Radiolabeled Chemicals, St Louis, except 1- $^{14}\text{C}$  laurate and 11- and 12-hydroxy laurates from Cypex Ltd., Dundee, Scotland) and 20  $\mu\text{g}$  yeast microsomal protein. The reaction was incubated at 25  $^{\circ}\text{C}$  for 20 min and stopped by addition of 100  $\mu\text{L}$  of 10% (v/v) acetic acid in isopropanol and extracted twice with 900  $\mu\text{L}$  of hexane saturated with 50% (v/v) isopropanol.

Enzyme activity was determined by measuring the counts in the aqueous phase using a liquid scintillation counter (Packard Instrument Company, Downers Grove, IL). Each assay was performed in duplicate and all experiments were repeated 3 times.

#### RNA Extraction and Real-time PCR

RNA samples were extracted from germinating seeds (3 days after imbibition), developing seeds (33 days after pollination), and cotyledons, roots, hypocotyls, leaves at 16 days after imbibition using method of Gu et al. [14]. The first-strand cDNA was synthesized using 5  $\mu\text{g}$  of total RNA as template and oligo (dT) as primer following the Gibco BRL SuperScript First-Strand Synthesis System for RT-PCR instruction (Grand Island, NY). Real-time PCR mixture (25  $\mu\text{L}$ ) contained one tenth of the first-strand cDNA, 1x iQ SYBR Green I Supermix (Bio-Rad, Hercules, CA) and 300 nM forward and reverse primers. The Bio-Rad iCycler iQ-system was used for all PCRs. The PCR protocol applied consisted of an initial denaturation step of 95  $^{\circ}\text{C}$  for 3 min, followed by 40 repeats of 95  $^{\circ}\text{C}$  for 10 s and 55  $^{\circ}\text{C}$  for 30 s. A melt-curve protocol immediately followed the amplification with 95  $^{\circ}\text{C}$  for 1 min and 50  $^{\circ}\text{C}$  for 1 min, followed by 80 repeats of heating for 10 s, starting at 50  $^{\circ}\text{C}$  with 0.5  $^{\circ}\text{C}$  increments. PCR product specificity was confirmed by melting-curve analysis and electrophoresis on 4% agarose gel. The information for the optimized primer pairs is listed in Table 1.

#### Real-time Quantitative PCR Data Analysis

The method of Pfaffl [19] was applied to calculate comparative expression levels between samples. Castor actin gene (a house keeping gene) was used as an internal reference to normalize the relative amount of mRNAs for all samples. For each tissue, triplicate sets of PCR including the target genes, actin gene and negative controls (reaction without cDNA template) were performed. The SYBR fluorescence was analyzed by iQ iCycler software and the  $C_T$

**Table 1** Primer sequences, size of amplification products, and PCR efficiencies

Gene name	Forward primer reverse primer	Amplicon size (bp)	PCR efficiency
RcACS 1	TAGTAGCATATTCTTGGGAGG TCACACTCTCAAGTAGCC	195	102
RcACS 2	GACTACGGGAGAGGTTATTTAATG TTACACGCCCAACAAAGC	210	106.2
RcACS 4	TCGCCTGACATAATGGACTTTC ACTTCTCTCGTCTGGACACC	281	101.9
Actin	GAATCCACGAGACTACATACAAC TTATGAAGGTTATGCTCTC	176	95.4

value for each gene was reported. The average  $C_7$  value for RcACS4 in seed samples was calibrated as one copy number. The PCR experiments were repeated to ensure similar results were obtained.

## Results and Discussion

### Cloning of cDNAs Coding for Acyl-CoA Synthetases in *R. communis*

Highly conserved regions of ACS genes were identified by sequence comparison of known ACSs. Degenerate primers were generated based on corresponding DNA sequences of these conserved regions. Three cDNA fragments were obtained by RT-PCR using these primers and RNA samples extracted from castor. The sizes were 563 bp for RcACS 1, 1,665 bp for RcACS 2 and 326 bp for RcACS 4, respectively. Based on the sequences of these fragments, gene-specific primers for 3′- and 5′-RACE were designed and amplification of full-length cDNAs for RcACS 1, 2, and 4 were attempted. Sequence analysis indicated that the cDNAs for RcACS 2 (GenBank accession number DQ300358) and RcACS 4 (DG300359) were 2,545 bp and 2,367 bp long with 202 bp and 47 bp 5′-untranslated regions, and 258 bp and 247 bp 3′-untranslated regions, respectively. Both cDNAs contained sequences encoding full-length enzymes of 694 and 690 amino acids. For RcACS 1 (DQ300357), the cDNA obtained was 2,215 bp long and BLAST similarity search results suggested that the coding sequence at the 5′ end is truncated. The deduced amino acid sequences of RcACS 2 and RcACS 4 share 77% identity (Fig. 1). The most notable motif identified by ScanProsite Results Viewer (<http://us.expasy.org/prosite/>) in both proteins is the AMP-binding domain signature: ICYTSGTTGTPK and GYGMTE, which is highly conserved in members of the AMP-binding protein (AMPBP) superfamily [20]. When aligned with all nine LACS isoforms in *Arabidopsis* [18], RcACS 2 is most closely related to AtLACS 6, a well-characterized peroxisomal ACS (data not shown). The amino acid sequences of RcACS 2 and AtLACS 6 are 79% identical (Fig. 1).

### Functional Expression of Castor ACS Genes in Yeast

To determine whether these cloned RcACS cDNAs encode active acyl-CoA synthetases and to further characterize their activity, we cloned RcACS 2 and 4 into the pYES2.1/V5-His-TOPO vector and transformed them into *S. cerevisiae*, YB525 strain. This strain contains insertional disruptions in two of its fatty acid activation (FAA) genes, FAA1 and FAA2, encoding acyl-CoA synthetases that account for 99% of total cellular myristoyl-CoA and

palmitoyl-CoA synthetase activities [16, 21]. It is not viable in media containing cerulenin, because cerulenin specifically inhibits the fatty acid synthetase complex, which catalyzes de novo synthesis of long chain acyl-CoAs. Growth of YB525 on media containing cerulenin and fatty acids such as myristate, palmitate or oleate can be restored by introducing an active ACS into cells, as the ACS activates the imported fatty acids to form acyl-CoAs.

Yeast YB525 colonies bearing constructs expressing RcACS 2 or RcACS 4 were selected from SDM-U plates containing 2% galactose, 500  $\mu$ M myristate, plus 25  $\mu$ M cerulenin and grown in aliquid medium. The ability of RcACS 2 and 4 to complement the YB525 mutant phenotype was evident based on colony vigor. To identify the gene products of RcACS 2 and 4 in yeast cells, cell-free lysates were prepared from cells induced with galactose for different time periods and examined by western blot analysis. The size of the RcACS 2 and 4 detected was very close to the predicted molecular weight of these proteins (77 kDa, plus 5 kDa from V5 epitope and the polyhistidine tag) (Fig. 2a) and the highest levels of RcACS 2 and RcACS 4 were detected after induction for 18 and 12 h, respectively (data not shown). The lysates from cells at these stages were used as enzyme sources for ACS activity assays. Lysates with RcACS 2 and 4 were enzymatically active, compared to lysate from cells with an empty pYES vector (Fig. 3). The western blot of proteins from cell fractionation indicates that RcACS 2 and 4 are highly enriched in membrane fractions (Fig. 2b), which is consistent with previous observations [22, 23]. Therefore, membrane fractions (microsomes) were used as the enzyme source in further characterization studies.

### Fatty Acid Substrate Specificities of RcACS 2 and RcACS 4

One of the ACS functions is to make fatty acids available for TAG biosynthesis by activating free fatty acids to acyl-CoA thioesters. Castor seed contains 90% ricinoleate in its oil, and we thought it possible that castor possesses a distinct ACS enzyme, which could preferentially catalyze the formation of ricinoleoyl-CoA to be used for synthesis of TAG. We thus measured acyl-CoA synthetase enzyme activity by in vitro assay using microsomes prepared from YB525 cells expressing RcACS 2 and 4. Eight different fatty acids were included in substrate specificity assays. As reported for ACS from other organisms [18, 24], both RcACS 2 and 4 utilized a range of substrates. Overall, the enzymatic activity was relatively higher when using microsomes expressing RcACS 2 versus RcACS 4 for the fatty acids tested (Fig. 4), although the RcACS 2 expressed in microsomes detected by western blot was repeatedly less abundant than RcACS 4 (Fig. 2b). This observation sug-

**Fig. 1** Alignments of deduced amino acid sequences of acyl-CoA synthetases in *Ricinus communis* (RcACS) and *Arabidopsis thaliana* (AtLACS 6). Alignments were generated by using the Clustal W program, version 1.83, which is freely available at <http://www.ebi.ac.uk/clustalw/>. The GenBank accession numbers for AtLACS 6, RcACS 2 and RcACS 4 are AB030317.2, DQ300358 and DQ300359. The identical residues among the three proteins are labeled with an asterisk under them. The putative AMP-binding domain signature is shaded in gray

Table showing amino acid sequence alignments for AtLACS6, RcACS2, and RcACS4. The sequences are aligned in columns with residue numbers on the right. Asterisks indicate identical residues. A putative AMP-binding domain signature is shaded in gray in the original image.

gests that the RcACS 2 is more active than the RcACS 4. The most remarkable result observed from the comparison of enzyme activity with the eight fatty acids was the strong preference of RcACS 2 for ricinoleate, the unusual fatty acid found in castor oil. The activity of RcACS 2 using ricinoleate is over 60% higher than that using other fatty acids. The RcACS 2 also shows slight preference for the hydroxy-laurate fatty acids versus laurate. In contrast, RcACS 4 has low activity toward hydroxy fatty acids, and does not have obvious specificity as the activation rates for all the non-hydroxy fatty acid substrates are fairly similar.

**Expression of RcACS in Castor Plants**

To examine the expression pattern of RcACS genes in castor plants, real-time PCR was performed using an equal amount of total RNA from germinating seeds (G.seeds),

developing seeds (D. seeds), cotyledons, roots, hypocotyls and young leaves. The three ACS genes isolated from castor plant were analyzed using optimized primer pairs (Table 1). The actin gene was used as the internal control to ensure the amount of RNA used is equal. To compare the relative amount of target in different samples, the average  $C_T$  value for RcACS 4 in seed sample was arbitrarily chosen to be calibrated as one copy number because it has the lowest expression level. The results from real-time PCR assay indicate that the three RcACS genes are expressed in all tissues tested, but the expression patterns vary greatly (Fig. 5). The most distinctive result is the high accumulation of RcACS2 in germinating seeds. Based on the sequence similarity of RcACS 2 to the peroxisomal ACS, AtLACS 6 (Fig. 1) and the presence of a moderately rare type 1 peroxisomal targeting sequence [25] at the extreme C-terminus, RcACS 2 is likely to be a peroxisomal

**Fig. 2** Expression of RcACS 2 and 4 in yeast cells. **a** Western blot of cell-free lysate proteins (50 µg/lane) extracted from yeast YB525 cells transformed with pYES2.1 empty vector (lane 1), RcACS 4 (lane 2) and RcACS 2 (lane 3). Overnight cultures were harvested after 12 (RcACS4) and 18 (RcACS2) hours induction with 2% galactose. The blot was probed with anti-V5 antibodies. **b** Western blot of proteins (10 µg/lane) extracted from different fractions of yeast YB525 cells transformed with RcACS2 and RcACS4. Overnight cultures were harvested after 12 (with RcACS4 cells) and 18 (with RcACS2 cells) hours induction with 2% galactose. Proteins from cell-free lysate (T), soluble (S) and membrane (M) fractions were separated on a SDS-PAGE and transferred to a PVDF membrane. The membrane was then probed with anti-V5 antibodies

**Fig. 3** ACS enzyme activities in cell-free lysates of yeast YB525. Yeast cells carrying the indicated plasmids were harvested after galactose induction. Cell-free extracts were prepared by beating cells with glass beads and used as enzyme sources in ACS enzyme assays. 1- $^{14}\text{C}$  oleic acid was used as a substrate. Enzyme activities were measured based on the  $^{14}\text{C}$  label incorporated into the acyl-CoA fraction (aqueous-soluble counts) per assay. Values are means of triplicate with standard deviation (SD)

ACS isoform. The high expression of RcACS 2 in germinating seeds indicates that the plant has a strong demand for the enzyme at this stage, when peroxisomal ACSs are actively involved in  $\beta$ -oxidation. The castor seeds contain 90% ricinoleate, and large amounts of fatty acids (mostly ricinoleate) are released from the oil bodies upon germination. These fatty acids require activation to acyl-CoA by

**Fig. 4** Substrate specificity of RcACS 2 (**a**) and RcACS 4 (**b**) using eight different fatty acid substrates. Batches of microsomes (with 20 µg of total microsomal protein) extracted from cells expressing RcACS 2 or RcACS 4 were used as enzyme sources and incubated with 20 µM 1- $^{14}\text{C}$  fatty acids for 20 min at 25 °C. Assays were then terminated by adding equal volume of 10% acetic acid in isopropanol. Enzyme activities were measured based on the  $^{14}\text{C}$  label incorporated into the acyl-CoA fraction (aqueous-soluble counts) per assay. Values are means of triplicate with SD

ACS for degradation through  $\beta$ -oxidation. The RcACS 2 has the ability to efficiently activate ricinoleate and provide the seedling with adequate metabolic energy. The expression patterns of the RcACS genes measured by real-time PCR indicate that none of these genes is seed specific or upregulated in developing seeds. It is possible that additional ACS genes may exist for fatty acyl-CoA metabolism in developing seeds, although all three appear to be present in developing seeds.

One of the major challenges in plant lipid biochemistry is understanding how plants such as castor can produce a seed oil containing high levels of a single FA, especially one with a polar substituent, like ricinoleate. We have previously inferred that, besides the hydroxylase required for ricinoleate biosynthesis, other enzymes involved in castor oil biosynthesis are necessary to produce high levels of ricinoleate [26, 27]. The ACSs catalyze many important steps in numerous pathways involving fatty acid and lipid metabolism, and an *in vitro* study on the ACS activity present in developing castor seeds showed that ricinoleate is an efficient substrate at low concentrations [28], therefore,

**Fig. 5** Expression of RcACS genes in the castor plant. Aliquots of total RNA were analyzed for expression of each gene in different tissues by real-time PCR using gene-specific primer pairs. The average  $C_T$  value for RcACS 4 in seed was calibrated as one copy number and used to calculate the relative amounts of other genes. Values are means of triplicate with SD

the ACS enzymes are logical choices for contributing to high ricinoleate incorporation in castor oil. ACS genes have been cloned from several plant species [11, 18] and most ACS enzymes display highest levels of activity with the fatty acids that make up the common structural and storage lipids in the plant. In this study, we were particularly interested in the substrate specificities of RcACSs because one of the reasons for high accumulation of ricinoleate in castor seeds could be that one of the ACSs in castor can efficiently activate ricinoleate to ricinoleoyl-CoA for TAG synthesis. We found that both RcACS 2 and 4 were active in microsomal fraction from yeast cells. The RcACS 2 was distinguishable from RcACS 4 on the basis of fatty acid incorporation, using hydroxy fatty acids preferentially, while the RcACS 4 uses the more non-polar fatty acids. The greatest activity observed in the series of assays was the RcACS 2 acylation of CoASH with ricinoleate. Since our long-term goal is to understand the specific role of ACS and create new oilseed species with high ricinoleate content in oil, RcACS 2 could be an attractive target for manipulation of ricinoleate incorporation in oilseeds.

**Abstract** There is limited methodology available to quantitatively assess the activity of the  $\Delta^9$ -desaturase enzyme in vivo without chemically inhibiting the enzyme or using radioactively labeled substrates. The objective of these experiments was to develop methodology to determine the incorporation and desaturation of  $^{13}\text{C}$ -labeled fatty acids into milk lipids. In a preliminary experiment, 3.7 g  $[1-^{13}\text{C}]$ myristic acid ( $[1-^{13}\text{C}]14:0$ ), 19.5 g  $[1-^{13}\text{C}]$  palmitic acid ( $[1-^{13}\text{C}]16:0$ ), 20.0 g  $[1-^{13}\text{C}]$ stearic acid ( $[1-^{13}\text{C}]18:0$ ) were combined and infused into the duodenum of a cow over 24 h. In a following experiment, 5.0 g  $[1-^{13}\text{C}]14:0$ , 40.0 g  $[1-^{13}\text{C}]16:0$ , and 50.0 g  $[1-^{13}\text{C}]18:0$  were infused into the abomasums of separate cows as a bolus over 20 min or continuously over 24 h. Milk fat was extracted using chloroform:methanol. Fatty acids were methylated, and fatty acid methyl esters (FAME) were converted to dimethyl disulfide derivatives (DMDS). The FAME and DMDS were analyzed by gas chromatography mass spectrometry. In the preliminary experiment,  $^{13}\text{C}$  enrichment in 14:0 but not 16:0 or 18:0 was observed. When dosage amounts were increased in the following experiment, peak enrichments from the bolus infusion were observed at 8 h. Enrichments for continuous infusion peaked at 16 h for 14:0 and 18:0, and at 24 h for 16:0. The  $\Delta^9$ -desaturase products of these fatty acids were estimated to be 90% of *cis*-9 14:1, 50% of *cis*-9 16:1, and 59% of *cis*-9 18:1. This study demonstrates that  $^{13}\text{C}$ -labeled fatty

acids may be utilized in vivo to measure the activity of the  $\Delta^9$ -desaturase enzyme.

## Abbreviations

CE	Cholesterol ester
CLA	Conjugated linoleic acid
DM	Dry matter
DMDS	Dimethyl disulfide
E	Enrichment
FAME	Fatty acid methyl ester
MDG	Mono and diacylglycerols
MUFA	Monounsaturated fatty acids
$[1-^{13}\text{C}]14:0$	$[1-^{13}\text{C}]$ myristic acid
NEFA	Non-esterified fatty acids
$[1-^{13}\text{C}]16:0$	$[1-^{13}\text{C}]$ palmitic acid
PL	Phospholipid
PUFA	Polyunsaturated fatty acids
SFA	Saturated fatty acids
$[1-^{13}\text{C}]18:0$	$[1-^{13}\text{C}]$ stearic acid
TTR	Tracer to tracee ratio
TG	Triacylglycerol
VA	Vaccenic acid

## Introduction

Impact of the ruminant diet on the fatty acid profile of milk fat and total fat production is an active area of research. Academic and industry recommendations for “ideal” milk fatty acids [1] included changing the fatty acid profile from the typical 5% polyunsaturated fatty acids (PUFA)

including n-3 fatty acids, 70% saturated fatty acids (SFA), and 25% monounsaturated fatty acids (MUFA) to 10% PUFA, up to 8% SFA with the remainder (>80%) being MUFA. Some reasons for altering the fatty acid profile are to benefit consumer health by decreasing the content of saturated and *trans* fatty acids, and increasing the content of mono and polyunsaturated fatty acids, which are generally considered healthier for the consumer [2]. Included in the mono and polyunsaturated groups of fatty acids are the products of the  $\Delta^9$ -desaturase enzyme, *cis*-9 mono and diunsaturated fatty acids, such as *cis*-9, *trans*-11 18:2 (conjugated linoleic acid; CLA).

One mechanism for specifically altering the *cis*-9 monounsaturated and *cis*-9, *trans*-11 CLA content of milk fat is via the  $\Delta^9$ -desaturase enzyme. The  $\Delta^9$ -desaturase enzyme is present in many tissues within the cow and is very active in the mammary gland inserting a double bond at carbon 9 into saturated fatty acids [3]. The  $\Delta^9$ -desaturase enzyme is important in maintaining liquidity of the milk fat globule [4]. This enzyme uses myristic (14:0), palmitic (16:0) and stearic acid (18:0) as substrates for its actions creating myristoleic (14:1), palmitoleic (16:1) and oleic (18:1) acid, respectively [5]. Additionally, *cis*-9, *trans*-11 CLA can be made from *trans*-vaccenic acid (*trans*-11 18:1; VA) by the action of the  $\Delta^9$ -desaturase in the mammary gland [6, 7]. The substrate product pairs of this enzyme represent approximately 75% of the total fatty acids in milk fat [8]. Thus, the  $\Delta^9$ -desaturase enzyme is a very important determinant for the fatty acid content of milk fat.

One approach that has been explored in the research of the  $\Delta^9$ -desaturase enzyme is to genetically modify ruminant animals to increase the expression of the  $\Delta^9$ -desaturase enzyme gene [9]. However, the use of genetically modified dairy cattle for milk production may not be well received by the consumer. Additionally, its implementation into large commercial production settings may be impractical. On the other hand, understanding the regulation of the  $\Delta^9$ -desaturase enzyme may lead to new management strategies that would result in altered milk fatty acid profile.

Understanding and controlling the activity of the  $\Delta^9$ -desaturase enzyme could lead to increased MUFA content resulting in an improved milk fatty acid profile. The use of *in vivo* measurements of the enzyme's activity in response to various dietary manipulations would provide information on the impact of diet and regulation of the enzyme. A long term goal would be to alter the  $\Delta^9$ -desaturase enzyme activity using nutrients provided in the diet. The first step in this process is to develop an *in vivo* assay of  $\Delta^9$ -desaturase enzyme activity. The objective of these preliminary studies was to determine the methodology necessary to use  $^{13}\text{C}$ -labeled fatty acid substrates to measure the activity of the  $\Delta^9$ -desaturase enzyme *in vivo* in lactating dairy cattle.

While the experiments described only utilized one cow per fatty acid per infusion treatment, the data yielded have provided valuable information in the implementation of this methodology. For example, these data provided the methodology necessary to demonstrate the conversion of [ $^{13}\text{C}$ ]vaccenic acid to *cis*-9, *trans*-11 CLA *in vivo* in lactating dairy cattle and women by our lab [6, 10]. Without the data from each of these cows, we would be limited in our attempts to develop new and innovative techniques.

## Materials and Methods

The University of Idaho Animal Care and Use Committee preapproved all of the procedures involving cows. All cows were housed in tie-stalls and had *ad libitum* access to feed and water. Dietary dry matter (DM) was ~64% and the ingredients were alfalfa silage, barley silage, whole cottonseed, alfalfa hay, and a concentrate pellet. The diet contained 18.1% crude protein, 26.8% neutral detergent fiber, 20.4% acid detergent fiber, and 6.1% ether extract on a DM basis.

In the preliminary experiment, one multiparous Holstein cow received 3.7 g [ $^{13}\text{C}$ ]myristic acid ([ $^{13}\text{C}$ ]14:0), 19.5 g [ $^{13}\text{C}$ ]palmitic acid ([ $^{13}\text{C}$ ]16:0), and 20.0 g [ $^{13}\text{C}$ ]stearic acid ([ $^{13}\text{C}$ ]18:0) delivered in a semi-continuous manner every 3 h over a 24 h period via a duodenal cannula. The cow was milked every 6 h for 36 h prior to the infusion, and every 6 h for 60 h after the initial infusion. At 60 h post infusion, the cow was returned to the milking herd, and milk samples were taken in the parlor every 12 h for 24 h. Blood samples were taken via a jugular catheter at each milking and infusion time. This frequent collection of milk and blood served as the template for determining adequate  $^{13}\text{C}$  labeled fatty acid dosage and sample times in the subsequent experiment.

Three primiparous ruminally cannulated Holstein cows (~150 days in milk, consumed (mean  $\pm$  SE) 18.3  $\pm$  0.8 kg DM, and produced 35.1  $\pm$  0.8 kg of milk per day with 3.5  $\pm$  0.1% fat) each received infusions of different  $^{13}\text{C}$ -labeled fatty acids. Infusion lines were passed through the rumen cannula and secured in the abomasum with a rubber flange. The fatty acids were delivered as a bolus infusion over 20 min or continuous infusion over 24 h. Infusion periods were separated by a 7-day washout period. The free fatty acids (5.0 g of [ $^{13}\text{C}$ ]myristic acid, 40.0 g of [ $^{13}\text{C}$ ]palmitic acid, or 50.0 g of [ $^{13}\text{C}$ ]stearic acid (Isotec, Miamisburg, OH, USA)) were converted to potassium salts and combined with 5 or 15 L of water for the bolus or continuous infusion, respectively. For the bolus infusion period, the cows were milked every 6 h for 24 h prior to the infusion, and every 4 h for 48 h after the

infusion began. At 48 h post infusion, the cows were returned to the milking herd, and milk samples were taken in the parlor every 12 h for 24 h. Prior to each machine milking and every 2 h for 48 h after the infusion began, additional milk samples were taken by hand. Blood samples were taken via a jugular catheter at each hand milking and at times 0.25, 0.5, 0.75, 1, 1.5, 2.5, 3, 3.5, 5, and 7 h after initiation of infusion. Fecal samples were also taken at each hand milking time. For the continuous infusion period, milk and fecal samples were taken as in the bolus period. Blood samples were taken at the hand milking times. Heparinized blood samples (10,000 U/L) were centrifuged for 20 min at  $1,000\times g$  at 4 °C, and the plasma was collected. All plasma, milk, and fecal samples were stored at -20 °C.

Milk and plasma lipids were processed as previously described by Mosley et al. [10]. Freeze-dried ground fecal samples were methylated in a two-step procedure using methanolic-HCl and sodium methoxide [11]. The fatty acid methyl esters (FAME) (<1 mg) of milk, plasma lipid fractions (triacylglycerols (TG), cholesterol esters (CE), mono and diacylglycerols (MDG), phospholipids (PL), and non-esterified fatty acids (NEFA)), and feces were converted to dimethyl disulfide (DMDS) derivatives, and the FAME and DMDS derivatives were analyzed by GC and GC-MS as previously described [6].

#### Data Analysis

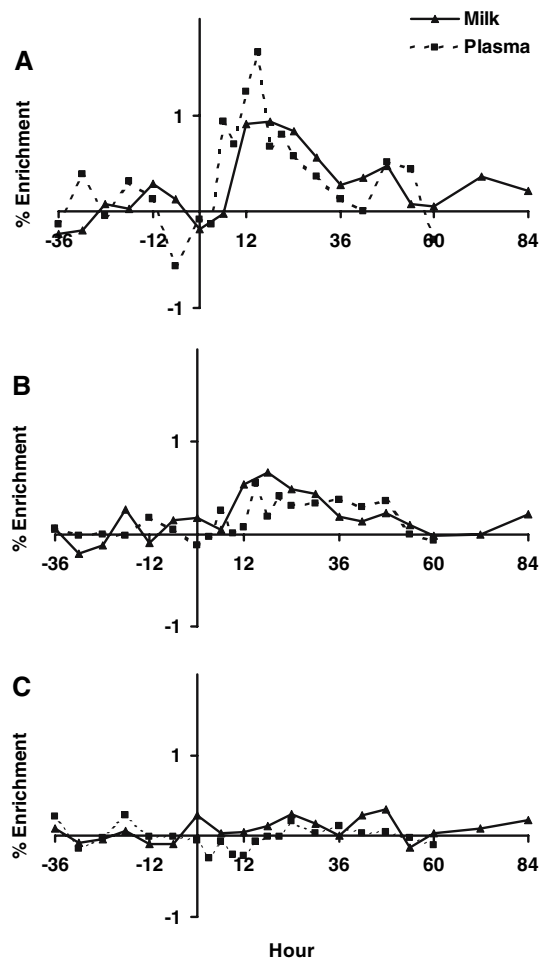

For saturated fatty acids, the tracer to tracee ratio (TTR) was calculated from the mass abundance of the molecular ion ( $M$ ) and  $M + 1$  fragments using the equation  $TTR = (M + 1)/M$ . For monounsaturated fatty acids, the TTR was calculated from analysis of the DMDS of FAME. The DMDS derivatives produce distinctive spectral fragments that are indicative of the double bond position when analyzed by mass spectrometry. The TTR was calculated from the mass abundance of the  $^{12}C$  and  $^{13}C$  fragments (mass fragments 217 and 218) using the equation  $TTR = ^{13}C/^{12}C$ . In order to account for the natural levels of  $^{13}C$ , the mean TTR of samples taken before the infusion was subtracted from the TTR of all samples. Therefore, enrichment ( $E$ ) of the fatty acid with  $^{13}C$  at each sample period was calculated as  $(TTR - \text{mean } TTR_{\text{prior to infusion}}) \times 100$ . The calculated  $E$  was adjusted for spectrum skew [12].

Data from the enrichment of milk fatty acids in the bolus and continuous infusions were used to calculate an estimate of the desaturation of the  $^{13}C$ -labeled saturated fatty acids. Trend lines were fit to the observed data from each cow. Area under each curve was calculated and used to determine the percent of the substrate fatty acid desaturated, as previously described [6]. Statistical analyses were not performed on data from either experiment because there

was only one observation per time per treatment per fatty acid. Therefore, the data will only be described.

#### Results

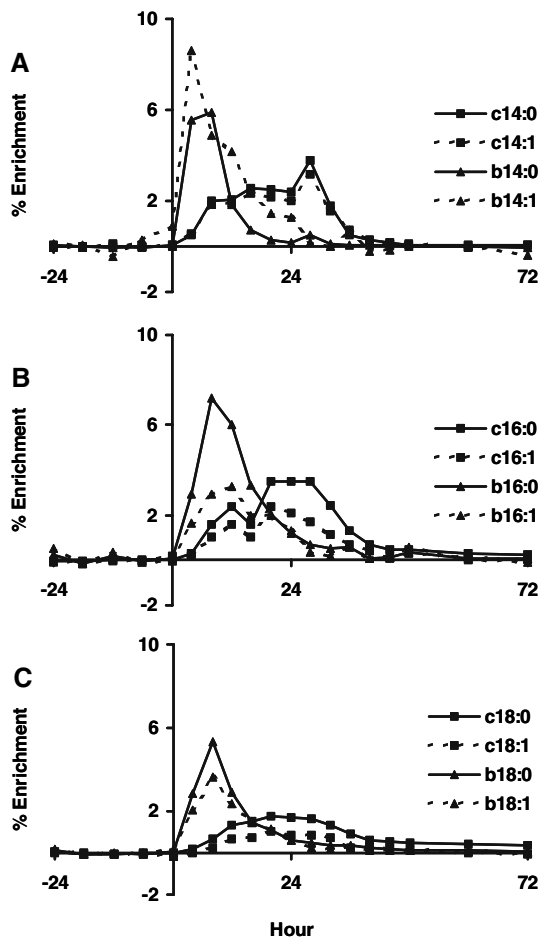

Milk production parameters were not affected by the duodenal or abomasal infusion of  $^{13}C$ -labeled fatty acids. For the preliminary experiment (Fig. 1), average enrichment pre-infusion was 0% for 14:0, 16:0, 18:0, and the  $\Delta^9$ -desaturase products of these fatty acids (data not shown) in milk fat. Enrichment was only detected in 14:0 and 16:0 in milk fat. Enrichment values did not increase for 18:0 or any of the  $\Delta^9$ -desaturase products of these fatty acids in milk fat due to inadequate dosage of the  $^{13}C$ -labeled fatty acids. Similar results were observed when plasma lipid was analyzed (Fig. 1).

**Fig. 1** Enrichment of  $^{13}C$  in **a** myristic, **b** palmitic, and **c** stearic acid of milk and plasma from one lactating cow receiving a semi-continuous duodenal dose of 3.7 g  $[1-^{13}C]$ myristic acid, 19.5 g  $[1-^{13}C]$ palmitic acid, and 20.0 g  $[1-^{13}C]$ stearic acid. Infusions started at hour zero

In the subsequent experiment, in milk fat the  $^{13}\text{C}$  enrichments from the bolus infusion peaked at 8 h and then declined until not detected after 24 h (Fig. 2). Enrichments for the 24 h continuous infusion reached a plateau from about 12–30 h after initiation of the infusion and then declined. Enrichment was detected in  $\Delta^9$ -desaturase products for both bolus and continuous infusions, with enrichment patterns similar to the saturated substrate. Milk samples taken by hand prior to machine milking for both bolus and continuous abomasal infusions of fatty acids yielded data similar to that from milk fat obtained during machine milking (data not shown). Using area under the curve analysis and FAME data (Table 1), the percent of the product originating from the substrate for the bolus and continuous infusions, respectively, was calculated as 90 and 92% for myristoleic, 51 and 56% for palmitoleic, and

**Fig. 2** Enrichment of  $^{13}\text{C}$  in myristic acid (14:0; A), myristoleic acid (14:1; A), palmitic acid (16:0; B), palmitoleic acid (16:1; B), stearic acid (18:0; C) and oleic acid (18:1; C) of milk during either a bolus (b) or continuous (c) abomasal infusion of (a) 5 g [ $^{13}\text{C}$ ]myristic acid, (b) 40 g [ $^{13}\text{C}$ ]palmitic acid, or (c) 50 g [ $^{13}\text{C}$ ]stearic acid. Bolus infusions were delivered within 20 min while continuous infusions were delivered over 24 h. Infusions started at hour zero. Each panel represents data from a single cow

Values represent a mean of all samples taken in each experimental infusion period. Data for preliminary infusion are mean ± SD from 20 measurements taken from one cow. Data for bolus and continuous infusions are mean ± SD from 33 measurements taken from each of three cows during each infusion

<sup>a</sup> *trans*-18:1 sum of all *trans*-18:1 isomers

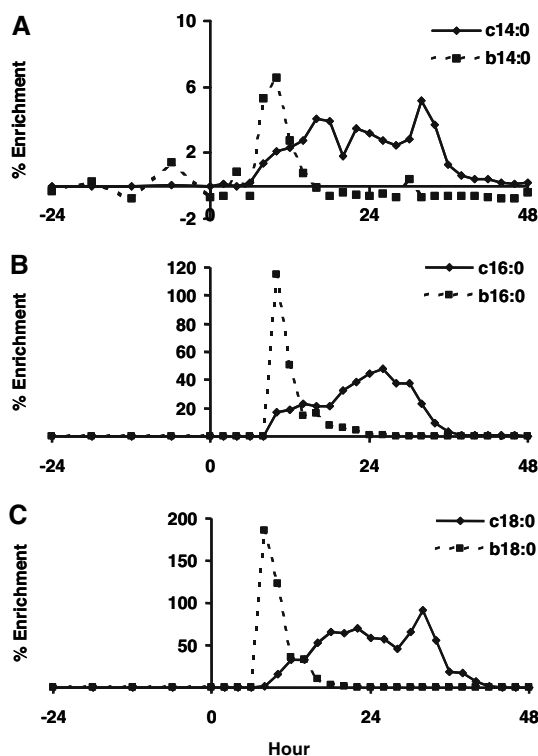

<sup>b</sup> *cis*-18:1 sum of all *cis*-18:1 isomers excluding *cis*-9

74 and 43% for oleic acid, resulting in 5.2 and 7.0% of myristic acid, 2.6 and 2.5% of palmitic acid, and 60.3 and 48.7% of stearic acid being desaturated by the  $\Delta^9$ -desaturase enzyme.

Furthermore,  $^{13}\text{C}$  enrichment was observed in 14:0, 16:0, and 18:0 in the TG, CE, NEFA, and PL of plasma in the bolus infusion. Between 1.5 and 3 h post-infusion, maximal enrichments for TG, CE, NEFA, PL, and total plasma 14:0 were 81.1, 2.6, 3.8, 15.4, and 33.5%, respectively. Between 2 and 3 h post-infusion, maximal enrichments for TG, CE, NEFA, PL, and total plasma 16:0 were 92.6, 5.2, 5.2, 1.4, and 9.0%, respectively. Maximal enrichments for TG, CE, NEFA, PL, and total plasma 18:0 were also detected between 2 and 3 h post-infusion (26.5, 9.1, 7.5, 0.4, and 3.3%, respectively). Maximal enrichments detected in the continuous infusions occurred at later times than was observed in the bolus period. For example,

maximal enrichment of TG, CE, NEFA, PL, and total plasma 14:0 occurred between 8 and 24 h post-infusion (13.4, 2.2, 1.2, 3.0, and 5.1%, respectively), between 20 and 24 h post-infusion for 16:0 (6.2, 0.3, 0.5, 1.8, and 1.8%, respectively), and again between 8 and 24 h post-infusion for 18:0 (2.4, 2.0, 0.2, 0.6, and 0.9%, respectively). However, enrichment was not observed in the MDG fractions for either the bolus or continuous infusions. Unlike the enrichment of the infused saturated fatty acids in plasma lipid fractions, the  $\Delta^9$ -desaturase products of these fatty acids were not enriched at any time with  $^{13}\text{C}$  in any plasma lipid fraction (data not shown).

In fecal samples (Fig. 3),  $^{13}\text{C}$  enrichments from the bolus infusion were maximal from 8 to 10 h and then declined until not detected after about 20 h. The  $^{13}\text{C}$  enrichments from the continuous infusion reached a plateau from about 16 to 30 h and then began to decline. No enrichment was detected for any of the  $\Delta^9$ -desaturase products of these fatty acids in fecal lipid during either the bolus or continuous infusions (data not shown). The ratio of the area under the bolus and continuous enrichment curves was 0.43, 0.56, and 0.57 for myristic, palmitic, and stearic acids, respectively.

**Fig. 3** Enrichment of  $^{13}\text{C}$  in myristic acid (14:0; A), palmitic acid (16:0; B), and stearic acid (18:0; C) of feces during either a bolus (b) or continuous (c) abomasal infusion of (a) 5 g [ $^{13}\text{C}$ ]myristic acid, (b) 40 g [ $^{13}\text{C}$ ]palmitic acid, or (c) 50 g [ $^{13}\text{C}$ ]stearic acid. Bolus infusions were delivered within 20 min while continuous infusions were delivered over 24 h. Infusions started at hour zero. Each panel represents data from a single cow

## Discussion

Industry and academic recommendations for altering the profile of milk fatty acids included decreasing SFA and increasing unsaturated fatty acids, MUFA and PUFA [1]. While the recommendations may be dated, there is still strong desire to enrich milk with MUFA while reducing SFA [13]. For example, conversion of SFA to MUFA in milk fat would be beneficial to the human consumer by reducing their risk of coronary heart disease [14]. Understanding and controlling the activity of the  $\Delta^9$ -desaturase enzyme would lead to increased MUFA, thereby improving the milk fatty acid profile.

The  $\Delta^9$ -desaturase enzyme is present in many tissues within the cow and inserts a double bond at carbon 9 into saturated fatty acids [3]. The enzyme in bovine tissues occurs primarily in mammary [15] and adipose tissue [16, 17] while rates of desaturation in liver are quite low [18]. Variability in desaturase activity between tissues may be explained somewhat by dietary [19] and breed differences [20]. Our data agree that the majority of *cis*-9 desaturation of fatty acids occurs primarily in the mammary gland within 24 h of absorption. However, the lack of detection of  $^{13}\text{C}$  in the plasma of  $\Delta^9$ -desaturase products indicates that tissues other than the mammary gland do not contribute to their synthesis. However, the lower activity of the  $\Delta^9$ -desaturase enzyme in tissues other than mammary and the rate of turnover of individual fatty acids between lipid pools may simply be beyond the detection limits of the assay. It may be possible to detect these changes using continuous infusions longer than 24 h with higher doses of the  $^{13}\text{C}$  tracer.

It is also interesting to note the differences in maximal enrichment detected in the various plasma lipid fractions. In our initial experiment, we only measured total plasma enrichment (Fig. 1). It was evident that the enrichments achieved in milk fatty acids were not possible unless lipid classes within the total plasma had enrichment that exceeded that which was measured in milk. For example, we labeled only a small lipid pool in the plasma and larger unlabeled lipid pools essentially diluted the total enrichment values. This is supported by our second experiment where the TG pool contained the greatest maximal enrichment regardless of infusion type. As we would not be able to attain enrichments in the final pool (milk fatty acids) that was greater than our starting material (the plasma lipid pool utilized by the mammary gland to extract fatty acids), our data indicate that the TG pool is the primary pool utilized for delivering preformed fatty acids to the mammary gland. More research is needed for further analysis of fatty acid transfer between the various plasma lipid classes and the mammary gland. This type of data could be used to determine the actual contribution of each

plasma lipid class to the fatty acids extracted for milk fat synthesis by the mammary gland.

This study utilized  $^{13}\text{C}$ -labeled fatty acids to develop an *in vivo* assay of  $\Delta^9$ -desaturase enzyme activity in lactating dairy cattle. Typically, enzyme assays utilize a radiolabeled substrate and microsomal preparations from collected tissue in an *in vitro* system [16, 21]. The conditions used to isolate microsomal protein for *in vitro* assays and the detection limits associated with these methods may inhibit one's ability to quantitatively determine the conversion of substrate to product as it relates to *in vivo* metabolism. For example, *in vitro* estimates of mammary desaturation of 18:0 are only ~31% [21] while *in vivo* calculations provide an estimate of ~52% [22]. The development of an *in vivo* assay (i.e., utilizing metabolic tracer methodology coupled with measurements of gene expression changes) may prove useful when quantitatively determining treatment effects on the  $\Delta^9$ -desaturase enzyme while examining all of the fatty acid substrates simultaneously. Similar concepts for the *in vitro* assay are used for the *in vivo* assay, without using a radioactive fatty acid and with minimal disruption of the physiological state of the animal. The stably labeled fatty acid is used as a metabolic tracer, preferably with a dose that does not alter the fatty acid pools within the animal. Additionally, the stable tracer may be detected in the blood and milk. This labeling of two pools allows for identification of desaturation occurring in the mammary gland versus the rest of the body tissues. A drawback of this method is that liver, adipose, and other tissues cannot be distinguished from each other.

Reports of alterations in the synthesis of  $\Delta^9$ -desaturase enzyme products generally focus on relative changes in some ratio of the milk fat concentrations of the product to substrate, also referred to as the desaturase index. The desaturase index does not provide a quantitative measurement of  $\Delta^9$ -desaturase enzyme activity, it only serves as a proxy measurement. In order to estimate the actual enzyme activity, one approach is to assume that 100% of myristoleic acid is derived from the  $\Delta^9$ -desaturase enzyme and then chemically inhibit the enzyme, again assuming 100% efficiency [7]. Alternatively, estimates of  $\Delta^9$ -desaturase enzyme activity may be based on the duodenal flow of the  $\Delta^9$ -desaturase substrates and milk fat composition of the products and substrates [23] or arterio-venous differences in the  $\Delta^9$ -desaturase enzyme products and substrates [22].

Our data show that ~90% of myristoleic and ~50% of palmitoleic acids are synthesized by the  $\Delta^9$ -desaturase enzyme. We are unaware of any *in vivo* estimates for the synthesis of myristoleic or palmitoleic acids in the lactating bovine. Previously, the desaturation of stearic to oleic acid was calculated to be 52% based on arterio-venous differences [22]. Our data show that during a continuous infusion, ~49% of the stearic acid pool is desaturated, yielding

~43% of the oleic acid in the milk fat. However, during the bolus infusion, the conversion was increased to ~60%, yielding ~74% of the oleic acid. It is likely that the 50 g bolus dose of [1- $^{13}\text{C}$ ]18:0 increased the typical quantity of stearic acid available to be absorbed from the intestine. This is supported by differences in the label recovered in the feces. In all instances, approximately two times more label was recovered in the feces during the continuous infusions. The  $^{13}\text{C}$  enrichment of stearic acid in milk was most affected. One possible explanation is the preferential use of specific fatty acids for various metabolic functions. Another consideration would be differences in the digestibilities of the various fatty acids, as shorter chain fatty acids are considered more digestible [24]. We did not evaluate these types of factors, however, it is an area for future investigations utilizing  $^{13}\text{C}$ -labeled fatty acid methodology. Despite these effects due to type of infusion, the methodology does yield similar results when compared to other data, as demonstrated in our infusion of [1- $^{13}\text{C}$ ]vacenic acid in lactating dairy cows [6].

The  $^{13}\text{C}$  enrichment detected is dependent on the dose of  $^{13}\text{C}$ -labeled fatty acid. In the preliminary experiment, the dose of  $^{13}\text{C}$ -labeled fatty acids delivered was underestimated because the dose was initially calculated based on the daily output of each fatty acid in milk. The  $^{13}\text{C}$  enrichment was only detected in 16:0 and 18:0 when the dose was about 12% of the milk output of both substrate and product (Table 2). The 14:0 dose was acceptable in both experiments. However, the higher dose used in experiment 2 was needed to detect the  $^{13}\text{C}$  enrichment in desaturase products. The comparison of bolus versus continuous administration of the  $^{13}\text{C}$ -labeled fatty acids also showed a relationship between dose, maximum enrichment detected, and route of administration. While both types of infusion provide information about the utilization of the  $^{13}\text{C}$ -labeled fatty acids *in vivo*, the bolus infusion resulted in greater  $^{13}\text{C}$  enrichment values for the same mass of fatty acids delivered continuously over 24 h. Because of the expense of  $^{13}\text{C}$ -labeled fatty acids and the analytical

**Table 2** Dose of  $^{13}\text{C}$ -labeled fatty acids based on milk fatty acid output

Fatty acid	Preliminary experiment			Bolus versus continuous experiment		
	Dose (g)	Output (g)	%	Dose (g)	Output (g)	%
14:0 + <i>cis</i> -9 14:1	3.7	120	3.1	5.0	98	5.1

18:0 + <i>cis</i> -9 18:1	20.0	420	4.8	50.0	476	10.5

%, dose as a percent of output

techniques utilized, the ability to maximize  $^{13}\text{C}$  enrichment with minimal input is desirable.

This study demonstrates that  $^{13}\text{C}$ -labeled fatty acids may be utilized in vivo to measure the activity of the  $\Delta^9$ -desaturase enzyme. Doses of the  $^{13}\text{C}$ -labeled fatty acids are dependent on the production level of the animal and preliminary measurements of milk fat would be warranted for determination of an appropriate dosage level. This methodology will provide a powerful tool in assessing dietary impacts on  $\Delta^9$ -desaturase enzyme activity. In the future, this in vivo assay of enzyme activity may be coupled with other techniques such as gene expression analyses in order to provide more insight on the impact of treatments on the  $\Delta^9$ -desaturase enzyme.

**Abstract** We report here a two-step process for the high-yield enzymatic synthesis of 2-monoacylglycerides (2-MAG) of saturated as well as unsaturated fatty acids with different chain lengths. The process consists of two steps: first the unselective esterification of fatty acids and glycerol leading to a triacylglyceride followed by an *sn*1,3-selective alcoholysis reaction yielding 2-monoacylglycerides. Remarkably, both steps can be catalyzed by lipase B from *Candida antarctica* (CalB). The whole process including esterification and alcoholysis was scaled up in a miniplant to a total volume of 10 l. With this volume, a two-step process catalyzed by CalB for the synthesis of 1,3-oleoyl-2-palmitoylglycerol (OPO) using tripalmitate as starting material was established. On a laboratory scale, we obtained gram quantities of the synthesized 2-monoacylglycerides of polyunsaturated fatty acids such as arachidonic-, docosahexaenoic- and eicosapentaenoic acids and up to 96.4% of the theoretically possible yield with 95% purity. On a technical scale (>100 g of product, >5 l of reaction volume), 97% yield was reached in the esterification and 73% in the alcoholysis and a new promising process for the enzymatic synthesis of OPO was established.

## Introduction

Arachidonic acid (ARA or C20:4n-6), docosahexaenoic acid (DHA or C22:6n-3) and eicosapentaenoic acid (EPA or C20:5n-3) are polyunsaturated fatty acids (PUFA) involved in a wide range of biologically relevant functions and have strong effects on human health [1, 2]. ARA is an essential fatty acid in human nutrition and a major component of human milk and necessary for the cognitive development of infants. ARA is also a precursor of biologically active prostaglandins and leukotrienes, involved in inflammatory processes [3–5]. DHA is important for the development of the central nervous system [3]. EPA shows significant effects in preventing heart diseases and lowering blood cholesterol levels and thus reduces the risk of arteriosclerosis [6, 7]. The fatty acid distribution on the glycerol backbone influences the adsorption and tissue uptake of glycerides [8, 9]. Generally speaking, 2-monoacylglycerides (2-MAG) are most readily absorbed through the intestinal mucosa and are also the most rapidly absorbed among PUFA derivatives. 2-MAG have very good emulsifying properties and are physiologically essential molecules involved in lipid absorption. In vertebrates, 2-MAG and not glycerol is preferentially utilised for triacylglycerol and phosphatidylcholine biosynthesis [10]. Up to now, these molecules only have limited industrial applications because of difficulties in their synthesis. The chemical synthesis takes several steps, a costly purification and often results in very low yields [11]. Enzymatic synthesis of 2-MAG usually depends on two types of li-

pase: an unspecific enzyme for the esterification and an *sn*1,3-specific lipase for the alcoholysis (usually ethanololysis) reaction to the 2-MAG.

The type of fatty acid in the 1,3-position of triglycerides [12] also influences the intestinal adsorption as 2-MAG after the TAG are regiospecifically hydrolyzed in mouth, stomach and small intestine. Symmetrically structured triglycerides incorporate the same fatty acids in *sn*1 and *sn*3 position (ABA type). ABA with medium chain fatty acid groups (C<sub>6</sub>–C<sub>10</sub>) in the outer positions and a PUFA in the middle position have excellent dietary and absorption characteristics. Additionally the PUFA residue is protected against oxidation by the two saturated fatty acid residues protecting the more oxidizable PUFA in the middle position from oxygen (sterical reasons). Several experiments by Endo and colleagues proved that 1,2-dipalmitoyl-3-PUFA-glycerol is oxidised much more readily than 1,3-dipalmitoyl-2-PUFA-glycerol [13, 14]. The medium-chain fatty acids are easily hydrolyzed in the gastrointestinal tract by the pancreatic lipase. The resulting 2-MAG are readily absorbed and used either as a high-energy resource or for several health-protecting actions [8, 15, 16].

Fish oil, especially tuna and salmon oils, are well-known and inexpensive natural sources of PUFAs. A large variety of health products are made of or contain fish oil-derived compounds, e.g., the encapsulation of these oils in gelatine is of interest as a health food supplement for the prevention and treatment of cardiovascular diseases, neurodegenerative disorders and cancer [9, 17].

1,3-Oleoyl-2-palmitoylglycerol (OPO) is an important ABA-type TAG in infant nutrition. Human milk fats contain palmitic acid predominantly in the *sn*2-position of TAG. Often infant formulas contain palmitic acid in *sn*1,3-positions, which leads to the formation of calcium soaps after their release. These soaps are only poorly absorbed by the intestine, which results in indigestion and loss of calcium [18].

We have developed a two-step process leading to 2-monoacylglycerides which is enzymatically catalyzed by lipases. Lipases [triacylglycerol-hydrolases (EC 3.1.1.3)] catalyze the hydrolysis of triacylglycerols at the interface between water and the hydrophobic substrate. Besides the hydrolysis of triacylglycerols, lipases also catalyze the enantio- and regioselective hydrolysis or synthesis of a wide range of natural and unnatural esters [19, 20]. Especially lipases from microorganisms have received a lot of interest because they are useful catalysts for many industrial applications [21, 22] such as ester synthesis, optical resolution [23–25], transesterification or washing processes [26]. In the process described here the same lipase was used for both steps - the esterification as well as the following alcoholysis: Lipase B from *Candida antarctica* (CalB) [27]. CalB reveals high enantioselectivity against secondary alcohols and, due

to its extraordinary stability in organic solvents and at high temperature, has become one of the most frequently used enzymes in industrial applications [28]. For hydrolysis or transesterification of TAG, CalB is classified as an *sn*1,3-specific lipase. On the other side it is known that in esterification, CalB forms homogeneous TAG (AAA type). Starting from this knowledge, our strategy was first to synthesize a homogeneous TAG of PUFAs followed by the conversion to the desired 2-MAG. In the present work we synthesized the 2-MAG of three different PUFA: ARA, DHA and EPA all in gram quantities and high purities. We also showed that 2-MAG of short and medium chain length can be synthesized by the same method.

After this process was successfully established on a laboratory scale it was transferred and scaled up to a miniplant (total reaction volume up to 10 l). A miniplant is a minimized production line involving all processing steps regarding different parameters such as temperature, pH value and mass transfer.

For the synthesis of OPO, a CalB-driven two-step miniplant process was established. Starting with tripalmitate, the substrate was first converted to the corresponding 2-monopalmitate in an alcoholysis reaction followed by an esterification with oleic acid. Again only CalB was used as the biocatalyst.

## Materials and Methods

### Lipases and Chemicals

Lipase CalB (Novozym 435) was from Novozymes (Bagsvaerd, Denmark). The lipase gene was derived from *Candida antarctica* and transferred to the host organism *Aspergillus oryzae* in which the lipase was expressed. The purified lipase was immobilized on a macroporous acrylic resin. All lipases were purchased from Fluka. Immobilized CalB was removed after the reaction by filtration, washed three times, dried in a desiccator and afterwards could be used again. All chemicals except the PUFAs and solvents used were of analytical reagent grade and purchased from normal suppliers (Sigma, Fluka and Riedel de Haën). PUFAs were supplied by Nu-Chek Prep (Elysian, USA). References of MAG, DAG and TAG for GC/MS analysis were also supplied by Nu-Chek Prep.

### Esterification Reaction

Purified 2-MAG (100 mg, obtained from alcoholysis reactions) or glycerol and fatty acids (molar ratio 1:3) [29] were dissolved in 20 ml *n*-hexane. The water, generated during the reaction was removed by addition of 200 mg activated molecular sieve (pore diameter 3 Å, bead

diameter ~2 mm, UOP Type 3A, Fluka, Buchs, Switzerland). The mixture was stirred magnetically (level 10 on a RCTbasic, IKA Labortechnik, Staufen, Germany) and incubated at 50 °C. The reaction was started by adding 100 mg immobilized lipase (CalB). After 24 h the reaction was stopped by removing the lipase (Fig. 1) as described above.

### Alcoholysis Reaction of Triglycerides

The homogeneous TAG of PUFA or other TAG (100 mg) were mixed with pure ethanol (molar ratio TAG:ethanol is 1:4) and emulsified for 30 min at 25 °C. The reaction was started by adding CalB (100 mg) and stopped after 4–5 h by filtration of the catalyst (Fig. 1). The reaction process was monitored using TLC.

### Reactions on a Technical Scale (Reaction Volume: 8 l)

The miniplant was built by the Institute of Biochemical Engineering (IBVT, University of Stuttgart, Germany) within a Bosch-Rexroth frame (UTZ Ratio Technik, Korb, Germany). Process control equipment and software were supplied by National Instruments Germany GmbH, München and National Instruments (Labview®, Austin, TX, USA), respectively. The enzyme reactions were performed in a 10 l glass-vessel (Type BDAV, HWS Labortechnik, Mainz, Germany). The reaction mixture was stirred by air-driven stirrers (Gebr. Buddeberg GmbH, Mannheim, Germany). The temperature was controlled by a thermostat (F33, Julabo, Seelbach, Germany) [30].

The reactions in the miniplant were performed as batch processes under a nitrogen atmosphere. The amounts of

**Fig. 1** Two-step synthesis of 2-monoglyceride of DHA catalyzed by CalB. The process consists of two steps. First esterification of glycerol and free fatty acids leads to homogeneous TAG and water. TAGs are further converted in an alcoholysis reaction to the corresponding 2-MAGs and ethyl esters. The ethyl esters are removed in the following purification step in a two-phase (acetonitrile/water and *n*-hexane) system via a separatory funnel. Both steps are catalyzed by CalB which acts unspecific in the esterification and *sn*1,3-specific in the following alcoholysis. Synthesis of the 2-MAGs of AA and EPA was achieved according to the same scheme (D, DHA: Docosahexaenoic acid; DHAEt: DHA ethyl ester)

chemicals and lipase were calculated to the working volume of the miniplant which was 8 litres.

Because of the high price of highly purified PUFA, erucic acid (EA or C22:1n-9), a cheaper, long-chain unsaturated fatty acid was used as a model substrate for the esterification with glycerol. 8 l *n*-hexane, 304 g erucic acid, 37 g glycerol, 60 g immobilized CalB and 500 g molecular sieves (pore diameter 3 Å, beads diameter ~2 mm, UOP Type 3A, Fluka, Buchs, Switzerland) were applied.

In the alcoholysis reaction tripalmitate was converted to 2-monopalmitate. TAG and ethanol were emulsified in a molar ratio of 1:10 and then the vessel was filled up with acetone to the working volume (8 l acetone, 283 g tripalmitate, 161 g ethanol and 60 g immobilized CalB).

This product was afterwards esterified with oleic acid leading to OPO (8 l *n*-hexane, 84 g 2-monopalmitate, 260 g oleic acid, 60 g immobilized CalB and 500 g molecular sieves; Fig. 2).

### Purification of 2-Monoacylglycerides and Triglycerides

For purification of 2-MAG of PUFA, the solvent was evaporated and the concentrate was dissolved in acetonitrile/water (95:5 v/v, 10-fold volume compared to the concentrate) and washed three times with the same volume of hexane for ethyl ester removal [31]. The pure 2-MAG are found in the acetonitrile/water phase.

2-Monopalmitate was purified via crystallization. After filtering off the catalyst, the excess solvent was evaporated and the residue was dissolved in *n*-hexane:methyl-*tert*-butylether (MTBE) (70:30 v/v, 10-fold volume compared to the concentrate) and stored for 1 h at –25 °C. After this period, the white crystals formed were collected by filtration at –25 °C. The supernatant containing ethyl esters, fatty acids, and a small amount of diglycerides was

**Fig. 2** Two-step synthesis of OPO catalyzed by CalB. Starting substrate for OPO synthesis is tripalmitate, which is converted to 2-monopalmitate in an alcoholysis reaction and afterwards purified by crystallization. The following reaction consisted of esterification of 2-monopalmitate with oleic acid to OPO, which was purified via a silica-gel column. Both steps were catalyzed by CalB (PAEt: Palmitic acid ethyl ester)

discarded. The 2-MP was recrystallized until the TLC plate showed only one band of 2-MP. The purity of 2-MP was confirmed by GC/MS analysis.

For purification of TAG, the solvent was evaporated and the TAG purified by silica gel column chromatography eluted with *n*-hexane/methyl-*tert*-butylether (MTBE) (70:30 v/v). The TAG are eluted first followed by ethyl ester, fatty acids, di- and finally monoacylglycerides.

### TLC Analysis

For rapid analysis during the process, thin-layer-chromatography (TLC) was performed using aluminium sheets with silica gel (Merck KGaA, Darmstadt, Germany) as the stationary phase; *n*-hexane/MTBE (70:30 v/v) was the mobile phase. TLCs were developed in a staining solution (10 g cer(IV)-sulphate, 2 g molybdato-phosphoric acid, 10 ml concentrate sulphuric acid, 100 ml water) for 30 s and afterwards dried with a heat gun. The spots were identified using the corresponding references.

### GC/MS Analysis

For GC/MS analysis, samples were derivatized with 1% of trimethylchlorosilane in *N,O*-bis(trimethylsilyl)trifluoroacetamide. The derivatization reagent converts all hydroxyl- and carboxyl groups to the corresponding trimethylsilyl ethers and -esters. After addition of the derivatization solution, samples were incubated for 30 min at 60 °C.

Products were identified on a Shimadzu GC/MS-QP2010 (Shimadzu Corporation, Kyoto, Japan) equipped with a 30 m FS-Supreme-5 column (5% diphenyl polysiloxane/95% dimethyl polysiloxane, internal diameter 0.25 mm, film thickness 0.25 µm) using helium as the carrier gas at a linear velocity of 30 cm s<sup>-1</sup>. Analysis of mono-, di- and triglycerides was performed using the following program: 200 °C followed by heating (8 °C/min) to 360 °C. Using the GC/MS software GC/MS-solution® (Shimadzu Corporation, Kyoto, Japan) the amounts of substrate and products as well as the yield were calculated. For product identification the respective references were measured on the GC/MS and the reaction products compared in terms of retention time and mass spectra.

## Results

### Synthesis of PUFA 2-Monoacylglycerides

So far, direct esterification of PUFA and glycerol or an adequate interesterification leading to 2-MAG of PUFA has been impossible because there is no *sn*-2 specific lipase known. Therefore we developed a two-step process

including esterification of glycerol and PUFA leading to TAG followed by ethanolysis resulting in the desired 2-MAG (Fig. 1). The potential of CalB for synthesis of triglycerides in an unspecific manner has already been described [29]. A glycerol:PUFA ratio of 1:3 was found to be the optimum for the reaction. Excess of glycerol or fatty acids is inappropriate because of the production of large amounts of MAG and diacylglycerols (DAG) decreasing the yield of TAG.

For the *sn*1,3-specific alcoholysis, several lipases classified as *sn*1,3-specific were tested: *Candida antarctica* B lipase (CalB), *Penicillium camembertii* lipase, *Pseudomonas fluorescens* lipase, *Rhizomucor mihei* lipase, *Rhizopus javanicus* lipase and *Rhizopus oryzae* lipase [32]. Only CalB was able to convert all three TAG of PUFA to the desired 2-MAG. The lipase of *Rhizopus oryzae* was able to convert the TAG of ARA to the 2-MAG, but failed in the case of TAG of DHA (DDD) and EPA (EEE). For most lipases, the substrates seem to be too sterically demanding for their substrate-binding-site and therefore cannot be converted. Interestingly CalB, which acts in the first reaction as an unspecific catalyst is able to convert the substrates regioselectively to 2-MAG.

The alcoholysis reaction was very fast (Fig. 3). After 240 min the reaction was completed and almost no TAG was detected by TLC anymore. The reaction rate was constant from the beginning till the end of the reaction after 240 min. No DAG or free fatty acids were detectable. Fatty acid ethyl ester was able to be completely removed by liquid-liquid extraction. No isomerization of MAG was observed. TLC-analysis revealed a single spot of 2-MAG.

No acyl migration was observed when the alcoholysis reaction was performed in a temperature range from 25 to 30 °C. Temperatures higher than 40 °C led to increasing acyl migration and partial deacylation to glycerol.

The 2-MAG of the three model PUFA (ARA, DHA, EPA) were synthesized in gram quantity with purities higher than 85% and yields up to 96% (Table 1).

**Fig. 3** Product formation during the alcoholysis reaction of DDD and EEE. The reaction is catalyzed by CalB and the product formation proceeded continuously until 240 min where the amount of product reached its final plateau

**Table 1** Mass, purity and yields of PUFA-2-monoacylglycerides performed in lab scale

2-Monoacylglyceride of	Isolated yields (g)	Purity (%)	Yield (%)
Arachidonic acid (ARA)	1,4	86	84
Docosahexaenoic acid (DHA)	1,2	86	72
Eicosapentaenoic acid (EPA)	1,6	95	96

**Table 2** Mass, purity and yields of products from miniplant reactions

Reaction	Isolated yield (g)	Purity (%)	Yield (%)
Esterification of glycerol with erucic acid (TAG Synthesis)	352	95	97
Alcoholysis of tripalmitate (synthesis of 2-MP)	84	77	73
Esterification of 2-MP with oleic acid (OPO Synthesis)	198	95	90

The same process was proven to be usable for the synthesis of 2-MAG of short and middle-chain fatty acids such as caprylic- (C8), palmitic- (C16) and oleic- (C18:1) acid. The corresponding 2-MAG were not purified as these studies were only performed to explore the range of 2-MAG accessible by the technology described herein. So the substrate spectra of the 1,3-specific alcoholysis reaction with CalB covers all chain lengths from short to long and saturated or polyunsaturated.

### Synthesis of Triglycerides in the Miniplant

For upscaling, erucic acid was chosen as a cheap substrate since it is available in large quantities with high purity. The CalB-catalyzed esterification yielded 352 g of triglyceride of erucic acid corresponding to 97% of the theoretically possible yield (Table 2). The glycerol:fatty acid ratio of 1:3 led to a highly efficient esterification and less than 5% of by-products like mono- and diglycerides.

### Synthesis of OPO in the Miniplant

OPO was synthesized in the miniplant starting with tripalmitate as substrate. In the first step, tripalmitate was converted to 2-monopalmitate (2-MP) in an alcoholysis reaction, followed by esterification of 2-MP with oleic acid to OPO (Fig. 2). The yield of 2-MP was 73% corresponding to 84 g (77% purity). The esterification led to 198 g of OPO (yield 90%) with a purity of 95% (Table 2).

During the alcoholysis reaction no acyl migration was detectable.

In general, immobilized CalB could be reused after filtration, washing and drying at least three times without any loss of activity.

### Discussion

In our study we showed that it is possible within a two-step process to synthesize several 2-MAG without limitations regarding chain-length and saturation degree with just one biocatalyst. The reactions were successfully scaled up to 8 l scale and also a two-step process for the synthesis of OPO was established.

The easiest and most effective route towards 2-MAG would be the application of an *sn2*-specific lipase which would allow to synthesize these desired molecules in a one-step reaction. With such an outstanding catalyst it would be possible to perform a direct esterification of glycerol and fatty acids (glycerolysis) leading to 2-MAG or to perform an interesterification reaction between two homogeneous triglycerides leading to an ABA type TAG. Such an enzyme would be an outstanding innovation in the field of enzyme technology. Up to now only very few lipases like Lipase A from *Candida antarctica* (CalA) [33] have been described to show significant preference for position *sn2* of glycerides. For other enzymes this characteristic is discussed, as, for example, the lipases from *Vernonia anthelmintica* [34] or *Candida parapsilosis* [35, 36]. Recently the expression of CalA in *E. coli* on a microtiter plate scale has been described allowing directed evolution of this lipase [37]. So the prerequisites for a possible tailoring of CalA towards an *sn2*-specific lipase via directed evolution are fulfilled.

The results of the esterification and alcoholysis reactions showed that CalB displays either an unspecific or a very strict *sn1,3*-specific behaviour depending on the reaction conditions. We also observed that, after complete conversion of TAG to 2-MAG, the catalyst starts to hydrolyze the 2-MAG leading to glycerol and ethyl esters. So the reaction has to be stopped by removing the lipase directly after the TAG are converted quantitatively. These results indicate that CalB is not a “classical” or “totally” *sn1,3*-specific lipase because it is also able to convert 2-MAG. 2-MAG are not hydrolyzed at all by highly *sn1,3*-specific lipases, e.g., the *Rhizomucor mihei* lipase. It is probable that the addition of ethanol converts CalB from an unspecific to a more 1,3-regiospecific enzyme. A possible reason for this behaviour might be decreased flexibility of the tertiary structure of CalB caused by ethanol, hindering the substrate from accessing the catalytic binding pocket with the acyl group in the middle position [31]. This increased rigidity should also be favoured by decreasing the reaction temperature to 25 °C. Thus CalB should be classified as an

unspecific lipase which can be tailored by reaction engineering to a more *sn*1,3-specific enzyme. The most important advantage over all other *sn*1,3-specific lipases tested in our work is the ability of CalB to convert the sterically demanding TAG of PUFAs which do not fit into the substrate binding pockets of other lipases (e.g., the *Rhizopus* lipases).

Reduced acyl migration has been reported when lowering the water content of the reaction mixture or adjusting the water activity [38]. In the reactions described here the water content was adjusted to a low level by addition of molecular sieve. Even though in other processes the water activity is exactly adjusted [39] we did not detect any effect of acyl migration in our miniplant reactions. Accordingly the temperature was the most determinant parameter for acyl migration.

In a first attempt the alcoholysis reaction in the miniplant was performed in pure ethanol as solvent and co-substrate, which ended in very weak product formation and low yield. Ethanol inhibits the lipase activity: after a certain amount of time the reaction stopped although most of tripalmitate was not converted. After filtration of the lipase and removing the ethanol, the enzyme was active again. This indicates a kind of inhibitory complex that is formed between the enzyme and ethanol. Still the alcoholysis reaction in pure ethanol worked fine on a small scale. This may be due to significantly higher lipase concentration on a small scale compared to technical scale. Consequently, the amount of ethanol was decreased in the miniplant reactions. In this case no inhibition of the lipase was detectable.

Inhibition of the alcoholysis reaction by ethanol in the miniplant was surprising. It is even more surprising that the reaction performed well in an acetone/ethanol mixture since this kind of mixture has been said to inactivate lipases [40, 41]. The results presented here show that high-yield production of 2-monopalmitate in acetone is possible. As acetone is regarded as food-safe, the process is suitable for the production of nutrition-related materials.

The purification, taking advantage of the high solubility of 2-MAG in acetonitrile/water (95:5 v/v), while more hydrophobic by-products are more soluble in *n*-hexane, allowed an easy and fast purification of the 2-MAG of PUFA. Monoacylglycerides and ethyl esters could be clearly separated. Usually the purification of 2-MAG is performed via crystallization as in the case of 2-MP. This is unsuitable in the case of PUFA because of their very deep freezing point. A possible alternative that also has been tested is the purification via a silica gel column treated with boric acid. In that case, large amounts of organic solvents were necessary and significant acyl migration was detected (up to 40%).

Yield and purity of OPO synthesized in the miniplant with CalB was slightly lower than in a similar process

catalyzed by *Rhizopus* (*Rhizopus delemar*, *Rhizopus oryzae* and *Rhizomucor mihei*) lipases [39]. In the alcoholysis reaction a yield of 85% with a purity >95% was described. Still this process was performed on a laboratory scale whereas in our case we reached a technical scale (>100 g of product) indicating further upscaling for industrial production is possible. Processes for OPO synthesis have been described using two different lipases with distinct regioselectivity for the ethanolysis and esterification reaction [42]. The use of only one enzyme as suggested in our work will facilitate industrial applications.

The potential of our approach is further underlined by comparison of the results to the latest literature on 2-MAG synthesis. A lab-scale process for the enzymatic synthesis (by ethanolysis) of 2-MAG described by Shimada and colleagues yielded only 28–29 mol% of 2-MAG content [43]. Yang and colleagues described a CalB-driven glycerolysis process yielding 2-MAG of PUFA [44]. Still the yield in the stirred tank just reached 70% and unfortunately they had to work with a multiphase-system.

With respect to process development and further upscaling, the use of only one lipase for the unspecific esterification and the *sn*1,3-selective alcoholysis is a big advantage of the process described here. Reusability of immobilized CalB in the batch processes indicates that establishment of continuous production processes is possible. Thus new promising applications of this outstanding biocatalyst might arise.

2-methoxyethyl, and C<sub>2</sub>–C<sub>4</sub> *n*-alkyl esters from TAG, phospholipids, methyl esters, and intact lipids. It involved transesterification under base-catalyzed conditions using potassium alkoxides, which were prepared by proton exchange between potassium *tert*-butoxide and the corresponding primary alcohols. Mild reaction conditions allowed complete derivatization, i.e., picolinyl ester from TAG and phospholipids, 2 min at room temperature [9]; and 2-methoxyethyl and *n*-alkyl esters from TAG, 15 min at 40 °C [10]. Dubois et al. [11] reported complete derivatization of methyl esters to picolinyl esters in 45 min at 45 °C. Because 9-anthrylmethyl esters are also esters of a primary alcohol, this methodology is applicable to their synthesis.

This paper proposes a one-step method for rapid preparation of fatty acid 9-anthrylmethyl esters using base-catalyzed transesterification. The aim of the present study is to reveal properties of the new method and to assess its utility in fatty acid analysis of TAG in the ranges 0.1–5 µg or 0.1–5 nmol. For this purpose, some standard and natural TAG were subjected to this method, and the products were analyzed by reversed-phase HPLC with fluorescence detection. Fish oils TAG, containing a wide variety of fatty acids, were used as the natural TAG samples.

## Materials and Methods

### Reagents

Potassium *tert*-butoxide (1.0 mol L<sup>-1</sup> solution in tetrahydrofuran (THF)) and 9-anthracenemethanol (98%) were purchased from Aldrich Chemicals (Milwaukee, WI, USA) and Acros Organics (Geel, Belgium), respectively. THF anhydrous (99.5%, stabilized with BHT, Kanto Chemical, Tokyo, Japan) was distilled once and stored in the dark in the presence of molecular sieves 4A (powder, Nacalai Tesque, Kyoto, Japan). Dichloromethane anhydrous (99.5%) and cyclohexane (99.5%) were products of Kanto Chemical, and the former was dried over molecular sieves 4A.

Standard TAG used were tripalmitoylglycerol (16:0-TAG; Extrasynthèse, Genay, France), trionadecanoylglycerol (19:0-TAG; Sigma Chemical, St Louis, MO, USA), trilinoleoylglycerol (18:2-TAG; Sigma Chemical) and tridocosahexaenoylglycerol (22:6-TAG; Nu-Chek-Prep, Elysian, MN, USA). The 22:6-TAG was purified by thin-layer chromatography on silica gel 60G (Merck, Darmstadt, Germany) with hexane/diethyl ether (90:10, *v/v*) for development. The other standards were used without purification. Fish oils TAG, bonito head oil TAG and cod liver/mackerel oil TAG, were isolated from industrial oils by column chromatography on silica gel 60 (Merck) with hexane/diethyl ether (95:5 and 90:10, *v/v*) for elution [1].

### General Procedure for Synthesis of 9-Anthrylmethyl Esters

9-Anthracenemethanol (60 mg) and potassium *tert*-butoxide in THF (1.0 mol L<sup>-1</sup>, 20 µL) were taken in a screw-capped glass vial (0.6 mL-volume). Anhydrous THF (200 µL) was added to the vial and vigorously mixed with a vortex mixer to produce a saturated solution of potassium 9-anthracenemethoxide. The mixture was dried over 40 mg of anhydrous calcium sulfate for 1 h at room temperature. The supernatant was used as potassium 9-anthracenemethoxide reagent within one day.

TAG (0.1–5 µg) and 19:0-TAG (100 pmol = 93.4 ng) as an internal standard were dissolved in 10 µL of anhydrous dichloromethane in a screw-capped 0.6 mL-volume glass vial. The potassium 9-anthracenemethoxide reagent (10 µL) was added to the solution, and vigorously mixed with a vortex mixer for 10 s. After the mixture was left to stand for 10 min in the dark at room temperature, 2 µL of acetic acid/dichloromethane (1:10, *v/v*) was added to stop the reaction. After removing the solvents in a stream of nitrogen, resulting fatty acid 9-anthrylmethyl esters were taken up from the residue into 160 µL of cyclohexane, and 10 µL of the solution was subjected to reversed-phase HPLC.

### HPLC

Reversed-phase HPLC was done with a Hitachi L-6200 pump (Hitachi, Tokyo, Japan), a Shimadzu RF-10A<sub>XL</sub> fluorescence detector (Shimadzu, Kyoto, Japan) and a Shimadzu C-R6A integrator. A column of Supersphere 100 RP-18e (25 cm × 4 mm i.d., 4 µm particles, Merck) was used with HPLC-grade acetonitrile, ethanol and hexane as mobile phase at a flow rate of 1.0 mL min<sup>-1</sup>. A linear gradient of acetonitrile to acetonitrile/ethanol/hexane (30:40:30, *v/v/v*) was generated over 20 min. The column temperature was held at 10 °C with a Shimadzu CTO-10AS<sub>VP</sub> column oven. Peaks were detected at the excitation and emission wavelengths of 365 and 412 nm, respectively. Flow cell temperature of the detector was set at 20 °C.

## Results and Discussion

### Formation of Fatty Acid 9-Anthrylmethyl Esters

Figure 1 shows HPLC profiles of the reaction products formed from standard and fish oils TAG by the present method. Formation of fatty acid 9-anthrylmethyl esters was checked by comparison of the chromatographic behavior of

the products with those of standard esters. As the standards, authentic free fatty acids were converted to 9-anthrylmethyl esters by using ADAM reagent [8]. In the HPLC of the products formed from a mixture of 16:0, 19:0, 18:2, and 22:6-TAG, four peaks appeared in the chromatogram (Fig. 1a). Elution times of these peaks corresponded to those of the standard 16:0, 19:0, 18:2 and 22:6 esters. It is apparent that 9-anthrylmethyl esters are synthesized from TAG by the one-step method.

A blank test of the present method, including the reversed-phase HPLC, was carried out by using 100 pmol of 19:0-TAG internal standard (Fig. 1b). At earlier elution times, many unidentified large peaks appeared, whereas there was practically no peak after 8 min except for one peak of 19:0 ester. Under the HPLC conditions used in this study, all of the identified peaks eluted after 8 min (Figs. 1c, d). The 9-anthrylmethyl esters produced by the present method can be directly subjected to reversed-phase HPLC without purification.

#### Yield of 9-Anthrylmethyl Esters

Time-course changes of formation of fatty acid 9-anthrylmethyl esters were investigated by using an equimolar mixture of 16:0, 19:0, 18:2, and 22:6-TAG (each 100 pmol) at room temperature (20–22 °C) (Fig. 2). Peak

areas of the 9-anthrylmethyl esters rapidly increased, reached maxima at 2–5 min, and then tended to somewhat decrease (10 and 20 min). During the first 10 min, the 22:6 ester was found to change in a manner somewhat different from those of the other esters. The 22:6 ester reached maximum faster (2 min) and the maximum level was higher. The transesterification of 22:6-TAG seems to proceed at a higher rate. In contrast, after longer reaction time (10–20 min), the four fatty acid esters had changed very little. The changes were parallel to each other. Differences in the peak areas of the four esters were less than 4% at both 10 and 20 min.

In order to determine theoretical yield of the 9-anthrylmethyl esters, 18.75 pmol of standard 16:0 ester, corresponding to 100% yield of this ester, was injected for reversed-phase HPLC. The peak area was  $15.8 \times 10^4$  units (mean of triplicate determinations). Theoretical yields calculated for the above four esters were 83–92% (2 min), 85–91% (5 min), 82–85% (10 min), and 80–83% (20 min). This result shows that the conversion of TAG to fatty acid 9-anthrylmethyl esters is not complete. Lower yields were observed for reactions with no or insufficient dryness of the potassium 9-anthracenemethoxide reagent and solvents with desiccants (data not shown). It is probable that the incomplete conversion resulted from hydrolysis (saponification) of TAG and 9-anthrylmethyl esters caused by moisture remaining in the reaction system.

**Fig. 1** HPLC profiles of fatty acid 9-anthrylmethyl esters produced from standard and fish oils TAG. **a** Mixture of 16:0, 19:0, 18:2, and 22:6-TAG (each 100 pmol); **b** 19:0-TAG (100 pmol) used as an internal standard; **c** bonito head oil TAG (0.5 µg) mixed with 19:0-TAG (100 pmol); and **d** cod liver/mackerel oil TAG (1 µg) mixed with 19:0-TAG (100 pmol). The numbered peaks were identified by using standard esters as follows: 1, 18:4n-3 + 18:4n-1; 2, 20:5n-3; 3, 22:6n-3; 4, 18:3n-3 + 18:3n-6 + 16:2 + 12:0; 5, 20:4n-3; 6, 22:5n-3; 7, 20:4n-6; 8, 22:5n-6; 9, 16:1 + 18:2n-6 + 20:3 + 22:4n-6; 10, 14:0; 11, 17:1n-8; 12, 15:0; 13, 20:2n-6; 14, 18:1; 15, 16:0; 16, 17:0; 17, 20:1; 18, 18:0; 19, 19:0; 20, 22:1; 21, 20:0; and 22, 24:1

**Fig. 2** Time-course change of formation of fatty acid 9-anthrylmethyl esters from TAG. A mixture of 16:0, 19:0, 18:2, and 22:6-TAG (each 100 pmol) was converted to the 9-anthrylmethyl esters at room temperature (20–22 °C). Peak areas were obtained by HPLC under the conditions described in the text. Data represent mean  $\pm$  standard deviation of triplicate reactions

**Fig. 3** Plots of the amounts of 9-anthrylmethyl esters versus TAG subjected to the synthesis. An equimolar mixture of 16:0, 19:0, 18:2, and 22:6-TAG was subjected to the reactions conducted for 10 min at room temperature (20–22 °C). Peak areas were obtained by HPLC under the conditions described in the text. Data represent mean  $\pm$  standard deviation of triplicate reactions

### Standard Curves

Detection limits of the fatty acid 9-anthrylmethyl esters were determined by using the above 10-min reaction products. The esters corresponding to each 91.5 fmol of the 22:6, 18:2, 16:0, and 19:0-TAG were injected for reversed-phase HPLC. Detection limits ( $S/N = 3$ ) were all 26 fmol as the standard monoacid TAG. Calculated from the yields of 9-anthrylmethyl esters (82–85%), detection limits of the esters were about 65 fmol ( $S/N = 3$ ).

The amount of fatty acid 9-anthrylmethyl esters as a function of the amount of starting TAG was also checked by using equimolar mixtures of standard TAG (Fig. 3). The reactions were conducted at room temperature for 10 min. Excellent linear relationships were observed for all TAG standards ranging from 10 to 250 pmol. The correlation coefficients of individual fatty acids were more than 0.999. The present method appears to be usable for fatty acid analysis of a mixture of 10–250 pmol of TAG molecular species. The slopes of the plots were not identical among the four standards. However, differences in the slopes were calculated to be less than 5%.

### Fatty Acid Analysis of Fish Oils TAG

The present method was applied to fatty acid analysis of bonito head oil and cod liver/mackerel oil TAG (Figs. 1c, d). Peak components were identified by comparing the elution times with those of authentic fatty acid esters. Table 1 shows the compositions of fatty acid 9-

anthrylmethyl esters produced from 0.1 to 5  $\mu$ g of the fish oils TAG. In both fish oils, almost consistent compositions were observed in the analyses of 0.5–5  $\mu$ g of TAG. For example, major fatty acids in the bonito head oil TAG, 22:6n-3, 18:1 and 16:0, were found at concentrations of 31.2–31.8, 17.5–18.1, and 11.3–11.9 mol%, respectively. The 20:5n-3 ester was 8.5–8.6 mol%. In the cod liver/mackerel oil TAG, major fatty acids were found at 14.3–14.5 mol% (18:1), 12.3–12.7 mol% (16:0), 11.8–12.2 mol% (20:1), and 12.8–13.3 mol% (22:1). The 20:5n-3 and 22:6n-3 esters were 9.3–9.4 and 7.7–8.0 mol%, respectively. In the analyses of 0.1 and 0.2  $\mu$ g of TAG, minor fatty acids could not be determined. However, major fatty acids showed the percentages not very different from those observed in the analyses of 0.5–5  $\mu$ g of TAG.

Table 1 also shows the compositions obtained by other methodologies. One of them was determined by HPLC of 9-anthrylmethyl esters prepared by ordinary multi-step methodology, where 10 mg of the TAG were saponified by the method of Christie [1] and a portion of resulting free fatty acids (50  $\mu$ g) were converted to 9-anthrylmethyl esters in a methanolic solution of ADAM reagent [8]. The other one was determined by gas-liquid chromatography (GLC) of fatty acid methyl esters (FAME) prepared by transmethylation of 2 mg of TAG using sodium methoxide in methanol [1]. The compositions of fatty acid 9-anthrylmethyl esters prepared by the present one-step method were similar to those determined by the ADAM-HPLC and FAME-GLC methods. This result indicates that fatty acid composition of fish oil TAG determined by way of the present one-step synthesis is comparable to those

**Table 1** Fatty acid compositions of fish oils TAG, obtained by the present and other methods (Mol%, mean  $\pm$  standard deviation)

determined by ordinary methods. It is apparent that fatty acid analysis of 0.5–5 µg or less of TAG can be carried out by using the one-step transesterification.

#### Advantages of the Present One-Step Method

The present method is based on the methodology developed for rapid preparation of fatty acid picolinyl esters [9, 11], C<sub>2</sub>–C<sub>4</sub> *n*-alkyl esters and 2-methoxyethyl esters [10]. However, some improvements were also required. Differing from the preceding cases, 9-anthracenemethanol is a solid alcohol. Because of its limited solubility, the concentration of the potassium 9-anthracenemethoxide reagent is much lower than those of the previous alkoxides. Moisture in the solid 9-anthracenemethanol was removed by adding anhydrous calcium sulfate after preparation of the reagent. The transesterification was stopped by adding acetic acid in accordance with methods for transmethylation [1]. The reagent was precipitated by exchanging the solvent (mixture of dichloromethane and THF) for a non-polar solvent (cyclohexane), and 9-anthrylmethyl esters were taken up in the cyclohexane. Repeated injections of this solution did not have negative effect on the reversed-phase HPLC.

In the present study, the new method was revealed to be usable for synthesis of fatty acid 9-anthrylmethyl esters from TAG. It was also revealed that the resulting 9-anthrylmethyl esters are usable for fatty acid analysis of 0.1–5 µg of natural TAG including those from fish oils. The esters can be synthesized in 10 min, and subjected to HPLC after a few min. Compared with multi-step methodology taking about 1.5 h for preliminary hydrolysis, the present method seems to be great improvement of the derivatization time. Precision of fatty acid analysis also seems to be improved, because of much less use of reagents, solvents, apparatuses, and their handling. The

present method is the most rapid and convenient synthesis of 9-anthrylmethyl esters from TAG, and very effective to facilitate fatty acid analysis of small amount of natural TAG.

# Important Differences Exist in the Dose–Response Relationship between Diet and Immune Cell Fatty Acids in Humans and Rodents

Kevin Fritsche

Received: 21 February 2007 / Accepted: 16 July 2007 / Published online: 23 August 2007  
© AOCS 2007

**Abstract** Omega-3 polyunsaturated fatty acids (n-3 PUFA) are noted for their ability to diminish inflammatory and immune responses in vitro and in a variety of animal-based models of autoimmunity and inflammation. Yet, recent systematic reviews suggest that the evidence for these fatty acids having beneficial effects on inflammation or autoimmunity in humans is equivocal. A possible explanation for these disappointing and somewhat paradoxical findings emerged from the analyses described in this review. The available data on the changes in immune cell fatty acid profiles in mice, rats and humans, fed various forms and amounts of n-3 PUFA are summarized and displayed graphically. The dose–response curves generated provide new insights into the relationship between dietary n-3 PUFA and immune cell fatty acid profiles. The author suggests that the poor predictive value of most in vitro as well as many animal trials may, in part, be a consequence of the frequent adoption of experimental conditions that create differences in immune cell fatty acid profiles that far exceed what is possible in free-living humans through dietary intervention. Recommendations for improving the preclinical value of future in vitro and animal-based studies with n-3 PUFA are provided.

## Introduction

The ability of certain fatty acids to influence the immune system and the function of its various cellular components has been recognized for nearly 30 years [1]. Most of the research on this topic has focused on polyunsaturated fatty acids (PUFA). There are two major families of PUFA, the omega-6 (n-6) and the omega-3 (n-3). These fatty acids cannot be synthesized *de novo* in animals, thus they must be provided in the diet. Evidence for the essentiality of these PUFA is unequivocal [2]. In most Western societies dietary intake of n-6 PUFA greatly exceeds that of PUFA from the n-3 family [3, 4]. This imbalance between n-6 and n-3 PUFA intake has been blamed for the high rate of numerous chronic diseases, including inflammatory and autoimmune diseases [5, 6].

The principle mechanism underlying this diet-disease paradigm is thought to be the accumulation of tissue

arachidonic acid (AA), an n-6 PUFA, at the expense of unsaturated fatty acids of the n-3 family, particularly docosahexaenoic acid (DHA). AA serves as a precursor to cellular biosynthesis of eicosanoids, a large family of lipid mediators, many of which have pro-inflammatory and immuno-regulatory activity [7]. Lipid mediators derived from n-3 PUFA, however, tend to have biological activities that differ from those derived from AA [8]. Referred to as “resolvins” and “protectins”, some n-3 PUFA-derived mediators have been shown to promote resolution of inflammation and to protect cells from oxidant-induced cell death [9, 10].

The amount and type of fat people consume affects the balance between n-6 and n-3 PUFA in their tissues. Specifically, as diet n-3 PUFA intake increases, tissue AA declines and n-3 PUFA accumulate. Measuring cellular fatty acids is a relatively simple and reliable means to discern exposure to n-3 PUFA, whether through diet or experimental *in vitro* manipulation. More than a decade ago a leading researcher in the field developed a series of equations for predicting this diet-tissue PUFA relationship, first in rats [11], then in humans [12]. These equations are based on fatty acid profiles of circulating lipids (i.e., triglycerides and phospholipids) and may be particularly useful in predicting short-term PUFA intake in free-living humans. However, the dose–response relationship between dietary PUFA and immune cell fatty acid profiles has not previously been examined in a comprehensive manner. Thus, the primary objective of this review is to describe the quantitative relationship between diet and immune cell PUFA content and compare and contrast this relationship in humans, rats, and mice. Such analyses should address the question of whether rodent and human immune cells respond to dietary n-3 PUFA in a quantitatively similar manner.

## The Evidence

What is described in this review is a cross-study meta-regression dose–response analyses of the effect of dietary n-3 highly unsaturated fatty acids (HUFA, fatty acids with greater than three double bonds) on the arachidonic acid (AA) content of human, murine, and rat immune cells. Studies that met the following criteria were included in the analyses: (1) dietary n-3 HUFA (i.e., EPA and/or DHA) or AA intake was a dependent variable in the study design; (2) the fatty acid profile of an identifiable immune cell population was reported; (3) data were published and identified in PUBMED (National Library of Medicine, Bethesda, MD, USA) through December of 2006.

To accomplish the primary objective of this review, fatty acid intake in human and animal-based studies must

be expressed in a way that allows for direct comparison. In most human trials, n-3 PUFA intake is most often expressed as grams consumed per day, or occasionally, on a body weight basis (i.e., mg/kg/day). In contrast, most animal studies provide information about total fat content and the relative amount of various individual fatty acids (i.e., g/100 g of total fatty acids) in the fat/diet. Information about food intake is rarely provided and difficult to measure accurately in rodent studies. Expressing n-3 PUFA intake as a percentage of energy (en%) in the diet obviates the need to measure food intake in rodent studies and allows for meaningful comparisons between human and animal-based studies in this field. Therefore, in this review, dietary n-3 PUFA will be expressed as a percentage of energy (en%) consumed (humans) or provided by the diet (rodents).

The data in Tables 1 and 2 are organized according to species and/or dominant immune cell type/source. This review focuses on diet-induced changes to immune cell highly unsaturated fatty acids (i.e., those with four or more double bonds; HUFA). HUFA are much more potent modulators of inflammation and immune cell function than their 18-carbon PUFA precursors (i.e., linoleic and  $\alpha$ -linolenic acids, n-6 and n-3 PUFA, respectively). Since mice and rats are the most frequently used animal models for studying the impact of dietary fats on the immune response, the data in these tables are derived from these two rodent species as well as from humans. Fatty acid data from other animal species exist, but were not included in these tables because of the limited nature of these data sets and space considerations. To simplify comparisons and clarify trends across studies most of the fatty acid data presented in Tables 1 and 2 have been rounded off to the nearest whole integer. In situations where meaningful information may have been lost by such rounding off, values were reported to the nearest single decimal.

The spleen and peritoneal cavity have been the source of immune cells most frequently used in rodent studies. In contrast, the peripheral blood has been the sole source of immune cells in human studies. Generally, immune organ or whole blood leukocyte preparations are fractionated via density gradient centrifugation prior to analyses. With blood samples this procedure separates the erythrocytes and polymorphonuclear cells (e.g., neutrophils) from peripheral blood mononuclear cells (PBMC). PBMC consist of T- and B-lymphocytes primarily, and lesser numbers of natural killer cells and monocytes.

## Marine n-3 HUFA and Lymphocyte HUFA Content

Baseline fatty acid profiles are remarkably similar between rodent splenocytes and human peripheral blood

mononuclear cells (PBMC). For example, these lymphocyte-rich immune cell preparations are rich in arachidonic acid (AA, 20:4n-6). AA typically accounts for 19 to 23% of total fatty acids in these cells. Furthermore, these immune cells generally contain 2–3% n-3 HUFA, primarily docosahexaenoic acid (DHA, 22:6n-3). The presence of other n-3 HUFA, such as eicosapentaenoic acid (EPA, 20:5n-3) and docosapentaenoic acid (DPA, 22:5n-3), in immune cells is more variable and typically is lower than DHA content. The impact of varying dietary n-3 PUFA on the HUFA content of lymphocyte-rich immune cell preparations from human blood and rodent spleens is summarized in Table 1. Data from human subjects are provided first, followed by data from mice, and finally rats. On some occasions the researcher did not isolate immune cells (i.e., splenocytes) prior to conducting fatty acid analysis of the spleen. The spleen is rich in erythrocytes, thus these data reflect a combination of lymphocyte and erythrocyte fatty acid profiles. However, the presence of erythrocytes did not seem to significantly affect the ability to detect diet-induced changes in fatty acid profiles. In fact, diet-induced changes in erythrocyte and PBMC appear to be quite similar in magnitude [13]. Furthermore, omitting the data from studies using whole spleen (1 of 6 rat studies; 3 of 7 mouse studies) did not significantly change the shape of the rodent lymphocyte fatty acid profile curves.

As n-3 HUFA content of the diet increases, lymphocyte AA content declines in a curvilinear fashion (Fig. 1). The data displayed in this figure are derived from 17 of the 18 studies in Table 1. One study (i.e., Jenski) was omitted from Fig. 1, because the initial AA content of the mouse splenocytes was inexplicably low (i.e., 4%). Also, the absence of DHA in the splenocytes of control mice reported in this study suggests that the authors may have experienced some technical problems with their fatty acid analyses. Note that in human studies n-3 HUFA in the diet never exceeded three percent of total energy (i.e., 3 en%) intake, while intake in most of the rodent studies was considerably higher. Importantly, these data suggest that at lower levels of n-3 HUFA intake, rodent lymphocytes appear to be much more responsive than human to the effects of n-3 HUFA on lymphocyte AA content. This rodent-only response is best described by a two-phase exponential decay curve ( $R^2 = 0.95$ ) and is depicted in Fig. 1 by the line with alternating dots and dashes.

One possible explanation for this differential responsiveness is that human diets routinely contain some n-3 and n-6 HUFA, while experimental rodent diets are typically devoid of all HUFA. Thus, it may be that a small amount of n-3 HUFA has a greater impact on immune cell AA when incorporated into a diet devoid of n-3 and n-6 HUFA (as was the situation in all rodent studies), than when some n-3 PUFA are already present in the diet, as was the case with

most free-living human subjects. A second, alternative, explanation for this differential responsiveness between rodents and humans may relate to immune cell source, in other words peripheral blood lymphocytes maybe less responsive than tissue lymphocytes to dietary n-3 HUFA. Surprisingly, not a single study exists for which fatty acid data are reported for immune cells isolated from blood and a tissue in the same animal or human subject following n-3 PUFA intake. A third possible explanation relates to the differential predominance of T- versus B-lymphocytes in PBMC and rodent spleen, respectively. Evidence from one study suggests that diet-induced changes in fatty acid profiles of various immune cell subtypes found in the blood may not be similar [14]. Their data indicate that high-dose fish oil supplementation failed to reduce human monocyte AA content, but led to a 10, 20, and over 40% reduction in neutrophils, B-cells, and T-cells, respectively. Finally, it is possible that human immune cells are simply more resistant to n-3 HUFA-mediated changes in AA content compared to rodent immune cells.

Lymphocyte EPA content in free-living human subjects and in the rodents fed low n-3 PUFA “control” diets is generally quite low (e.g., typically undetectable to less than 1% of total fatty acids). Because of these very low and variable initial levels, expressing diet-induced changes in EPA content as a “fold-change” or “percent change” is problematic, and is best avoided. The actual amount of EPA in the cell is likely to have more biological relevance than the fold-change. Therefore, data for EPA and other N-3 HUFA in tables and figures are presented simply as a percentage of total cellular fatty acids.

Providing a source of pre-formed EPA in the diet results in its rapid accumulation in human and rodent lymphocytes (Table 1). The relationship between dietary EPA and lymphocyte EPA appears to be curvilinear for EPA intake ranging from 0 to over 4 en% in the diet (Fig. 2). This relationship is best represented by the following equation:  $Y = 0.27 + 4.28X - 0.453X^2$  ( $R^2 = 0.89$ ). Note that EPA accumulation in human lymphocytes never exceeded 4% of total lymphocyte fatty acids. In contrast, it appears that rodent lymphocytes can accumulate considerably more EPA (e.g., up to 12% of total fatty acids). However, one possible explanation of this observation is that dietary EPA intake was considerably lower in the human studies compared to the rodent studies. For example, three of four doses of EPA provided in the human trials were less than 1 en% EPA, with the highest intake less than 2 en%. In contrast, the majority of studies with rodent lymphocytes provided EPA at levels exceeding 2 en% of the diet.

Following EPA consumption, its elongation product, DPA generally increased in the lymphocyte enriched immune cell preparations (Table 1). These changes as well as the relative content of lymphocyte DPA were greater in

**Table 1** Summary of data demonstrating the effect of dietary polyunsaturated fatty acids (PUFA) to alter arachidonic acid (AA), eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA), and docosahexaenoic acid (DHA) content of human versus rodent lymphocyte-rich immune cells/tissues

<sup>b</sup> Fat source in parentheses designates the placebo/control oil/fatty acid; data from plant sources of (n-3) PUFA are shown in italics

<sup>c</sup> Energy % (en%) calculations for humans are based on a 2,000 kcal/day intake

<sup>d</sup> Fatty acid data are presented as the value before and after or without and with dietary treatment with n-3 PUFA, expressed as a % of total fatty acids present. For AA only, the relative change, pre- versus post-treatment, is indicated as a percentage within the parenthesis. Most values have been rounded off to the nearest integer

**Fig. 1** Cross-study meta-regression dose–response analyses of the effect of dietary n-3 highly unsaturated fatty acids (HUFA) on the arachidonic acid (AA) content of human, murine, and rat lymphocytes. Studies that met the following criteria were included in the analyses: (1) dietary n-3 HUFA (i.e., EPA and/or DHA) intake was a dependent variable in the study design; (2) the fatty acid profile of an identifiable immune cell population was reported; (3) data were published and identified in PUBMED (National Library of Medicine, Bethesda, MD, USA) through December of 2006. N-3 PUFA intake is expressed as a percentage of total energy consumed (i.e., en%). In most studies, daily caloric intake was not reported. Thus, the following assumptions were made: (1) human subjects consumed 2,000 kcal/day; (2) rodents consumed the same calories across diet treatment groups. AA data are expressed as a percent change from basal or “control” (i.e., lowest n-3 PUFA treatment group). Best-fit lines/curves and the 95% confidence limits (dotted lines) were generated using Prism software (v. 4.0b, GraphPad, San Diego, CA, USA). The equation for the AA curve in this figure is as follows:  $y = -4.87 + -14.2x + 0.776x^2$ ,  $r^2 = 0.85$ . At lower levels of n-3 HUFA intake, rodent lymphocytes appear to be much more responsive than human to the effects of diet n-3 HUFA on lymphocyte AA content. This rodent-only response is best described by a two-phase exponential decay curve ( $R^2 = 0.95$ ) and is depicted in Fig. 1 by the line with alternating dots and dashes

rodent lymphocyte preparations compared to those from human subjects. To date direct evidence that DPA affects immune cell function is lacking. Yet, it is present in immune tissues in significant amounts particularly when EPA is provided in the diet. Recent findings of the potent anti-inflammatory activities of EPA- and DHA-derived metabolites suggest that DPA might also be metabolized to biologically active agents. Investigating the potential function of DPA in these and other cells where it is found in significant quantities seems warranted.

Only two studies investigated the impact of EPA by itself on immune cells DPA and DHA content. In one study [15], mice were fed a diet containing 0.3 en% EPA, as an ethyl ester, for 10 days prior to immune cell isolation and analyses. EPA, DPA and DHA content of murine splenocytes increased significantly. In contrast to these findings, Fujikawa et al. [16] reported that feeding mice 4 en% EPA

**Fig. 2** Cross-study meta-regression dose–response analyses of the effect of dietary eicosapentaenoic acid (EPA) on the EPA content of human, murine, and rat lymphocytes. Refer to the legend in Fig. 1 for criteria for study inclusion and a description of how the data in the figure were analyzed. EPA data are expressed as a percentage of total fatty acids (i.e., g/100 g) present in the cells. The relationship between dietary EPA and lymphocyte EPA appears to be curvilinear for EPA intake ranging from 0 to over 4 en% in the diet. The best-fit equation for the EPA curve depicted is as follows:  $y = 0.27 + 4.28x + -0.453x^2$ ,  $r^2 = 0.89$ . Note that EPA accumulation in human lymphocytes never exceeded 4% of total lymphocyte fatty acids. In contrast, it appears that rodent lymphocytes can accumulate considerably more EPA (e.g., up to 12% of total fatty acids)

as the sole n-3 PUFA in the diet increased splenocyte EPA and DPA, but left DHA content unchanged. Feeding mice only DHA (0.7 en%) greatly enriches splenocyte DHA, but is much less effective than a smaller amount of dietary EPA at elevating immune cell EPA and DPA.

The relationship between dietary DHA on lymphocyte DHA content is shown in Fig. 3. Consuming more DHA results in an increase in immune cell DHA content, but the effects in rats and humans were not as pronounced as those frequently noted for immune cell EPA or DPA. This may be due, in part, to the relatively higher initial DHA content of these cells. Rat splenocytes and human PBMC typically contained between 2 and 3% DHA. This is true even when rats are fed diets devoid of n-3 PUFA. In human trials, DHA intake prior to supplementation was rarely measured. However, it is estimated that n-3 HUFA intake by individuals in Western societies is approximately 200 mg/day (i.e., 0.1 en%) [4, 17].

The data in Fig. 3 illustrates how DHA content of lymphocytes-rich cell preparations from both rats and humans modestly increased in a linear fashion as DHA in the diet increases. This relationship is represented by the following equation:  $Y = 2.2 + 1.43X$  ( $r^2 = 0.75$ ). In contrast, the response in mice is quite different to that observed in rats and people. This relationship is curvilinear with the best-fit line and 95% confidence intervals depicted on

**Fig. 3** Cross-study meta-regression dose–response analyses of the effect of dietary docosahexaenoic acid (DHA) on the DHA content of human, murine, and rat lymphocytes. Refer to the legend in Fig. 1 for criteria for study inclusion and a description of how the data in the figure were analyzed. DHA data are expressed as a percentage of total fatty acids (i.e., g/100 g) present in the cells. The best-fit equation for the diet-lymphocyte DHA response in humans and rats was linear with a best-fit equation represented as follows:  $y = 2.2 + 1.43x$  ( $r^2 = 0.75$ ). In contrast, the diet-lymphocyte DHA response in mice was curvi-linear, with the best-fit equation as follows:  $y = 5.13 + 5.1x + -0.7x^2$ ,  $r^2 = 0.80$

Fig. 3. This best-fit line is represented by a second order polynomial equation (i.e.,  $Y = 5.13 + 5.1X + -0.7X^2$ ;  $R^2 = 0.80$ ).

Interestingly, the initial DHA content of murine lymphocytes averages more than twofold greater than lymphocytes from rats or human subjects. DHA content of murine lymphocytes appears to plateau at  $\sim 12\%$  of total fatty acids, while only occasionally reaching 6% of the total fatty acids in rat or human lymphocytes. This differential response of murine immune cells to become more enriched with DHA relative to rats and humans is evident even at comparable levels of DHA in the diet. These data are consistent with the observations of Hulbert et al. [18] They reported that DHA content of phospholipids from various tissues (i.e., heart, liver, kidney and skeletal muscle) is significantly and inversely correlated with body mass. For example, DHA content of kidney microsomes in mice and rats was reported to vary by  $\sim 6$ -fold (i.e., 29 vs. 5% of total fatty acids). This large difference in membrane DHA content appeared to have a genetic basis, since both rodent species were being fed the same diet in this study [19].

#### Plant-based n-3 PUFA Affect Lymphocyte HUFA

Current estimates suggest that the average U.S. citizen consumes 0.6 en% n-3 PUFA and that  $>90\%$  of this is in the form of alpha-linolenic acid (ALA, 18:3n-3) from plant

sources, such as soybean and canola oils [17]. Direct comparisons between plant-based sources of n-3 PUFA with preformed EPA and DHA to affect immune cell HUFA content were conducted in humans and rodent studies. The data in Table 1 suggest that mice are more capable of converting ALA into n-3 HUFA than rats or humans. In humans, ALA is approximately one-tenth as effective as n-3 HUFA at lowering AA and raising EPA, but fails to elevate DHA content of PBMC [20]. This species difference may be a consequence of the higher desaturase activity in rodents compared with humans [21]. Another contributing factor to this observed difference is that the rodents in these studies were “young” relative to the human subjects. It is well known that desaturase activity declines substantially with age [22]. Another factor that may contribute to the relative inefficient conversion of ALA to HUFA in humans is the presence of HUFA in the typical human diet. Dietary HUFA are quite effective at depressing hepatic desaturase activity [23].

A novel plant-based n-3 PUFA, stearidonic acid (SDA; 18:4n-3) may be considerably more effective than ALA at enriching tissue n-3 HUFA [24]. When healthy male subjects consumed 0.4 en% of SDA (i.e., 1 g/day) from Echium oil there was a modest increase in both EPA and DHA content of PBMC, from 0.4 to 0.9% and 1.8 to 3% of total fatty acids, respectively [25]. SDA had no impact on PBMC AA content. Studies in which the impact of both ALA- and SDA-rich oils are directly compared relative to modulation of immune cell HUFA profiles do not exist presently. Although limited in scope, these data suggest that SDA is more effective than ALA at affecting immune cell HUFA content.

#### Monocyte/M $\phi$

In addition to lymphocytes, monocyte/M $\phi$  are the other immune cell type for which considerable data exist regarding the impact of dietary PUFA on their fatty acid composition. Monocytes/M $\phi$  are part of the innate immune system [26]. These cells are responsible for engulfing bacterial pathogens, dead cells and processing and presenting foreign antigens to T- and B-lymphocytes. By producing pro- and anti-inflammatory eicosanoids and cytokines, these cells play a central role in initiating and resolving inflammation and tissue injury [27].

In rodent models the peritoneum has served as the primary source of M $\phi$ , which typically make up approximately 50% of the resident cells. After collection, in vitro adherence followed by vigorous washing is frequently employed to increase the purity of this cell preparation (e.g., typically  $\sim 90\%$  M $\phi$ ). Also, it is common for researchers to inject a sterile inflammatory agent (e.g., thioglycolate broth,

proteose peptone, or glycogen) into the peritoneum of rodents prior to cell collection. These agents greatly enhance immune cell yield by tenfold or more. Another benefit of eliciting immune cells is the increase in homogeneity within the immune cell population harvested. For example, when cells are collected within the first 12–24 h post-elicitation, neutrophils make up greater than 85% of the total cells. [28] In contrast, M $\phi$  are the predominant cell type present when collection occurs 3–4 days later.

These “elicited” M $\phi$  are derived primarily from blood monocytes that migrate to the inflammatory site (i.e., peritoneum). In fact, it is widely thought that tissue M $\phi$  are primarily derived from peripheral blood monocytes [29]. This relationship, as well as functional similarities between monocytes and tissue M $\phi$ , served as the primary justification for grouping these immune cell populations together in Table 2. Elicited M $\phi$  differ from resident peritoneal M $\phi$  in several important ways, including: cytokine and eicosanoid production [30–32]. Therefore, fatty acid data for resident and elicited M $\phi$  were presented separately. Interestingly, the fatty acid data suggest that these two immune cell populations also differ in responsiveness to dietary HUFA treatment.

#### Marine n-3 PUFA and Monocyte/M $\phi$ HUFA

AA and DHA content of monocyte/M $\phi$ -rich cell preparations tended to be much more variable than lymphocyte-rich immune cell preparations. For example, AA content of M $\phi$  from mice and rats fed control diets across the 10 studies included in Table 2 ranged from 8 to 28% of total fatty acids. Rodent M $\phi$  DHA content varied from 0 to 7% of total fatty acids in these same studies. Some of the factors that may have contributed to this variability in basal HUFA, include: genetic/species differences, differences in dietary PUFA content of background/control diets, differences in cell purity, and differences in analytical procedures used by the various investigators. Whatever the underlying cause(s), this variation makes direct comparisons between studies problematic. Thus, diet-induced changes in fatty acid AA and DHA content are described in the context of fold-change as well as in terms of actual percentage of total fatty acids. However, caution should be exercised in the interpretation of these data. For example, it is unclear whether a doubling of immune cell DHA from an initial low value (e.g., from 0.5 up to 1%) is functionally equivalent to the same fold increase in cells containing substantially more initial DHA (e.g., from 3 up to 6%). Additionally, it is uncertain whether a 50% decline in AA will have the same physiologic consequence if cells start out with vastly different initial AA content.

Similar to lymphocyte-rich immune cell populations, the inclusion of n-3 HUFA in the diet of rodents, as well as human subjects, can have a significant effect on the AA content of monocytes/M $\phi$ . As n-3 HUFA intake increases, M $\phi$  AA levels decline in a curvilinear fashion (Fig. 4). The decline appears to plateau at reduction in AA content of ~50% of the original content, once n-3 HUFA intake reaches 3 en%. The best-fit line and 95% confidence intervals is depicted on the figure and are represented by a one-phase exponential decay equation:  $Y = 50.9 \exp(-1.1X) + -50.1$  ( $R^2 = 0.72$ ). The data from human subjects suggest that peripheral blood monocytes may be less responsive to n-3 HUFA-mediated changes in AA content than rodent M $\phi$ . However, the human monocyte data are too limited to analyze separately.

The dose–response relationships between EPA intake and monocyte/M $\phi$  EPA accumulation is illustrated in Fig. 5. EPA accumulation in human monocytes and elicited rodent peritoneal M $\phi$  increases in a curvilinear fashion with increasing dietary EPA. This relationship is represented by the following equation:  $Y = 0.29 + 2.58X + -0.436X^2$  ( $R^2 = 0.86$ ). Accumulation of EPA in monocyte/M $\phi$  plateaus at ~4% of total fatty acids, which is only half as much observed in lymphocyte-rich cell preparations. In contrast to human monocytes and elicited peritoneal M $\phi$ , the relationship between dietary EPA and EPA content of resident peritoneal M $\phi$  is linear (i.e.,  $Y = 0.4 + 3.3X$ ;  $r^2 = 0.89$ ). Interestingly, resident M $\phi$  from the peritoneum of rodents accumulate more EPA than human monocytes and elicited M $\phi$  rodents at each level of dietary EPA intake. Yet, only a single research group directly compared the response of resident and elicited M $\phi$  to diet n-3 PUFA treatment [33]. Those data, however, follow the same general pattern illustrated in Fig. 5 in that the dose–response relationship between EPA intake and cellular EPA is steeper in resident than elicited M $\phi$ .

DHA content of monocyte/M $\phi$  increases in a linear fashion in response to increasing DHA intake (Fig. 6). However, these data are quite variable (i.e.,  $Y = 3.8 + 1.7X$ ;  $r^2 = 0.42$ ). The “fit” was only slightly improved when non-linear functions were used to represent these data. Unlike lymphocytes, a “species effect” in the dose–response relationship between dietary DHA and DHA in the monocyte/M $\phi$ -rich populations is not readily apparent. Yet, human blood monocytes seem relatively resistant to the accumulation of DHA. Figure 6 shows that DHA content of rodent M $\phi$ , elicited and resident alike, exceed that found in human monocytes at every level of dietary DHA intake. Surprisingly, direct evidence that blood monocytes and tissue M $\phi$  are differentially responsive under identical experimental conditions (i.e., same subject on the same dietary treatment) is lacking.

**Table 2** Summary of data demonstrating the effect of dietary polyunsaturated fatty acids (PUFA) to alter arachidonic acid (AA), eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA), and docosahexaenoic acid (DHA) content of human versus rodent innate immune cells/tissues

<sup>b</sup> Fat source in parentheses designates the placebo/control oil/fatty acid; data from plant sources of (n-3) PUFA are shown in italics

<sup>c</sup> Energy % (en%) calculations for humans are based on a 2,000 kcal/day intake

<sup>d</sup> Fatty acid data are presented as the value before and after or without and with dietary treatment with n-3 PUFA, expressed as a % of total fatty acids present. For AA only, the relative change, pre- versus post-treatment, is indicated as a percentage within the parenthesis. Most values have been rounded off to the nearest integer

**Fig. 4** Cross-study meta-regression dose–response analyses of the effect of dietary n-3 highly unsaturated fatty acids (HUFA) on the arachidonic acid (AA) content of human, murine, and rat monocytes/macrophages (M $\phi$ ). Refer to the legend in Fig. 1 for criteria for study inclusion and a description of how the data in the figure were analyzed. The best-fit line and 95% confidence intervals is depicted on the figure and are represented by a one-phase exponential decay equation:  $Y = 50.9 \exp(-1.1X) + -50.1$  ( $R^2 = 0.72$ ). The data from human subjects suggest that peripheral blood monocytes may be less responsive to n-3 HUFA-mediated changes in AA content than rodent M $\phi$ . However, the human monocyte data are too limited to analyze separately

**Fig. 5** Cross-study meta-regression dose–response analyses of the effect of dietary eicosapentaenoic acid (EPA) on the EPA content of human monocytes, as well as resident and elicited peritoneal macrophages (M $\phi$ ) from mice and rats. Refer to the legend in Figs. 1 and 2 for criteria for study inclusion and a description of how the data in the figure were analyzed and presented. The equation for the EPA curve for human monocytes and elicited peritoneal M $\phi$  from rodents was:  $y = 0.29 + 2.58x + -0.436x^2$ ,  $r^2 = 0.86$ ; while the best-fit for EPA in resident peritoneal M $\phi$  (is linear:  $y = 0.4 + 3.3x$ ;  $r^2 = 0.89$ )

#### Plant-based n-3 PUFA Affect Monocyte/M $\phi$ HUFA

As with lymphocytes, dietary ALA appears to be considerable less effective at reducing AA and elevating n-3 HUFA in M $\phi$ . For example, Whelan et al. [34] conducted a carefully designed experiment to directly compare the potency of n-3 HUFA from fish oil to the shorter-chain

**Fig. 6** Cross-study meta-regression dose–response analyses of the effect of dietary docosahexaenoic acid (DHA) on the DHA content of human monocytes, as well as resident and elicited peritoneal macrophages (M $\phi$ ) from mice and rats. Refer to the legend in Figs. 1 and 3 for criteria for study inclusion and a description of how the data in the figure were analyzed and presented. The equation for DHA is:  $y = 3.8 + 1.7x$ ,  $r^2 = 0.42$ . The “fit” for the DHA data is not significantly improved when non-linear functions are used (data not shown). Human blood monocytes seem relatively resistant to the accumulation of DHA. Furthermore, DHA content of rodent M $\phi$ , elicited and resident alike, exceed that found in human monocytes at every level of dietary DHA intake

length precursor n-3 PUFA (i.e., ALA) at three different levels in the diet (i.e., ~0.5, 1 and 3 en%). They formulated experimental diets to contain similar amounts of total fat, but variable levels of n-3 HUFA from fish oil or a manufactured tri-ALA. Their data indicate that consuming a diet with 3 en% ALA for two weeks was nearly as effective as 0.4 en% n-3 HUFA at lowering resident murine M $\phi$  AA and elevating EPA, DPA, and DHA content. Brouard et al. [35] reported that 2 en% ALA from linseed oil was nearly as effective as 1.2 en% n-3 HUFA from fish oil at lowering AA and elevating DPA content in rat resident peritoneal M $\phi$ . Yet, this plant-derived n-3 PUFA was much less effective at elevating EPA and did not change DHA content of these immune cells.

There is only a single report describing the impact of dietary AA on immune cell fatty acid profiles [36]. As expected, the addition of preformed AA to the diet (i.e., 1.3 or 3.7 en%) enhanced resident murine M $\phi$  AA content by 57 and 68%, respectively, but had no effect on DHA levels (data on EPA and DPA were not reported). In contrast, when LA intake of mice was increased from ~4 to 8% of total calories, neither hepatic lipids or resident peritoneal macrophage phospholipid AA content were significantly increased.

#### Neutrophils

Neutrophils are the predominant leukocyte in human blood and play a central role in early “innate” host

defense against bacterial infection. Yet, the data on diet-induced changes of their PUFA content are limited to three studies with human neutrophils, one study comparing five different rat strains, and a possibly a single mouse study (Table 2). There is some uncertainty about the identification of the immune cells analyzed by Lokesh et al. [37]. These researchers indicated that they were working with macrophages, yet the cells isolated were from the peritoneum of mice 30 min following the injection of an inflammatory agent (i.e., zymosan). The predominate immune cell that would have been recovered under these circumstances would have been neutrophils, not macrophages. Therefore, this study has been included in this section of the Table 2.

Overall, the data in this section of Table 2 indicate that neutrophil HUFA content can be affected by dietary n-3 PUFA. In fact, the amount of EPA that rat neutrophils incorporated in response to n-3 HUFA intake was striking (i.e., from undetectable levels to greater than 12% of total fatty acids). This response in rats contrasts sharply with the more modest accumulation of EPA observed in human neutrophils, that was never reported to exceed 3% of total fatty acids. Accumulation of DPA and DHA in neutrophils following n-3 HUFA supplementation was similar among rats and humans; was considerably lower than that seen with EPA.

Kew et al. [38] directly compared the impact of EPA to DHA on human neutrophil fatty acid profiles and function. They found that consumption of 2 en% EPA for 4 weeks resulted in only a modest increase in EPA and DPA, but with little detectable change in either AA or DHA. In contrast, intake of a similar amount of DHA decreased AA by 20% and increased DHA content from 3 to 5% of total fatty acids, while EPA and DPA were also modestly increased. These data suggest that DHA-enriched oils may be more effective at changing the fatty acid profiles of some human immune cells compared to EPA-rich oils.

Cleland et al. [39] directly compared the impact of a fish oil source of n-3 PUFA (i.e., MaxEPA) with a plant-based source (i.e., linseed oil) on the fatty acid profiles of neutrophils from five different strains of rats. They demonstrated that compared to 5.5 en% n-3 HUFA, 9 en% ALA resulted in more modest reductions in AA and increases in EPA in these immune cells. However, DPA and DHA accumulation was modest and similar between the fish oil-derived and plant derived sources of n-3 PUFA. Surette et al. [40] reported that ALA and SDA from Echium oil, a novel plant source of n-3 PUFA, were able to modestly affect human blood neutrophils fatty acid profiles. After 4 weeks of consuming 1.9 en% ALA along with 0.8 en% SDA, neutrophil EPA increased from 0.1 to 0.5% and DPA doubled (i.e., 0.6–1.2%), while AA and DHA levels were not significantly affected.

In contrast to these studies with dietary n-3 PUFA, intake of LA over a broad range failed to alter AA content of human neutrophils or plasma lipids [41]. Yet, in rats increasing dietary LA over a range of 0.3–7 en% was associated with a modest increase in the AA content in elicited peritoneal macrophages [41].

## Kinetics

Data from time course studies with mice [42] and humans [43] suggest that diet-induced changes in immune cell fatty acid profiles occur rapidly (i.e., within a few weeks). This time frame is quite similar to that observed with other tissues, such as heart, liver and kidney [44]. In recognition of the rapid response of tissues to n-3 HUFA, many researchers using animal models feed experimental diets for 4 weeks or less. This appears to be sufficient to alter rodent immune cell fatty acid composition, and in most cases, *in vitro* functions. In contrast, most human studies use fatty acid treatment periods extending several months, and in one case, a year. Presumably, extended treatments are done to increase the likelihood of observing treatment effects at more modest doses of n-3 PUFA. The data suggest that HUFA incorporate into cell membranes in proportion to their availability (i.e., concentration in the plasma or extracellular milieu), with the length of time they are exposed being much less important. For example, changes in fatty acid profiles for human PBMC were similar at 3 versus 6 months of dietary n-3 PUFA supplementation [45]. Extended treatment periods make subject recruitment more difficult, reduces overall subject compliance, increases dropout rates, and is more costly. For example, the impact of fish oil supplementation on HUFA content of PBMC from 31 Crohn's patients appeared to peak at 8 week, then declined as the supplementation period extended to 16 and 24 week. All of these outcomes would detract from, rather than, strengthen a clinical trial. Clinicians should reconsider the need for using extended treatment periods in clinical trials with fatty acids, unless there are clear and compelling reasons for doing so.

In an interesting and clinically-relevant approach to study kinetics and dose-response, Broughton and Morgan [46] investigated the impact of periodicity of n-3 HUFA intake on tissue fatty acid composition and eicosanoid biosynthesis. For this study, mice were offered diets enriched with EPA (~2 en%) and DHA (~1 en%) for one or more days per week. As the number of days mice consumed the fish oil-containing diet increased there was a frequency-dependent reduction in immune cell AA; elevations in EPA, DPA and DHA. Changes in eicosanoid biosynthesis were statistically different only when the n-3 PUFA enriched diet was consumed at least on an every

other day basis, while tissue fatty acid changes differed with n-3 PUFA intake occurring as infrequently as once every 5 days. This study is intriguing because the experimental feeding approach closely mimics the pattern of n-3 HUFA intake that occur with free-living individuals whom might occasionally consume cold-water, fatty fish (e.g., tuna, salmon, herring) or fish oil supplements.

## Discussion and Recommendations

The major objective of this review was to provide readers with a better understanding of the dose–response relationship between diet and subsequent immune cell HUFA content. Inclusion of n-3 HUFA in the diet of humans and laboratory rodents produces a predictable pattern of changes in immune cell fatty acid profiles: AA content diminishes, while n-3 HUFA accumulate. It is clear from these data that preformed n-3 HUFA are significantly more effective at inducing these changes compared to plant sources of n-3 PUFA (e.g., alpha-LNA). Furthermore, consumption of preformed AA does appear to elevate immune cell AA. Unfortunately, the diet AA data are too limited to draw conclusions about dose–response relationships, differential responsiveness among types of immune cells or across species. This is particularly unfortunate since human diets routinely contain AA and understanding the impact of this fatty acid on the accumulation of n-3 HUFA as well as the reduction of immune cell AA may be central to improving the outcome of ongoing human n-3 PUFA clinical trials.

Clear identification of the immune cell population under study was an important consideration in the presentation and interpretation of these data. While the functional differences between various types of immune cell are well recognized, potential biochemical distinctions are less well defined. Collectively the data presented in this review suggest that the nature of the immune cell population under study affect both the initial, as well as diet-induced changes in, fatty acid content. However, changes in PUFA or HUFA intake do not appear to significantly affect immune cell subset distribution in humans or rodents [47, 48]. Therefore, it seems reasonable to conclude that changes in fatty acid profiles within a given study noted in this review are not a consequence of diet-induced shifts in immune cell distribution. While n-3 PUFA intake induces similar patterns of change in fatty acid profiles among the various immune cell populations examined, significant differences existed for individual HUFA. Though limited (i.e.,  $n = 8$  subjects), data from a single study suggest that human B-cells may contain lower amounts of AA and DHA, than T-cells. The relative proportion of T- and B-cells in human blood [i.e., 6:1] is quite different than that found in the

rodent spleen, which contains one T-cell for every three B-cells. At the present time it is unclear to what extent tissue of origin or species of origin may be contributing to some of the differences observed in humans and mice regarding their response to dietary n-3 PUFA exposure. Furthermore, it is possible that differences in cellular activities for tissue versus blood-borne immune cells may contribute to some of the differences in HUFA incorporation noted in this review. What is needed to resolve this issue are data from blood and tissue immune cells obtained from the same experimental subjects following consumption of diets enriched with n-3 PUFA. Such studies would help discern the independent contribution of cell source on dietary n-3 PUFA-driven changes to immune cell HUFA content.

Importantly, while humans and rodents share similar patterns of changes in immune cell HUFA content, they do not appear to be equally responsive to dietary n-3 HUFA. N-3 HUFA do not appear to lower AA, nor enrich n-3 HUFA, in human blood monocytes as much as in tissue  $M\phi$  from either rats or mice. These data may also be interpreted to mean that responsiveness to n-3 PUFA enrichment for circulating immune cells is not the same for tissue immune cells within the same lineage. For example, cells of the monocytic lineage differ in responsiveness as follows: resident  $M\phi >$  elicited  $M\phi >$  blood monocytes. The absence of fatty acid data from blood monocytes and tissue  $M\phi$  from the same human subjects or animals after n-3 PUFA supplementation makes it impossible to distinguish between these two equally plausible explanations. For lymphocytes, there is solid evidence for differential responsiveness to diet n-3 HUFA between species. For example, the reduction in AA content in response to low doses of n-3 HUFA intake (i.e., 0–1 en%) appears to be much greater in rodents than humans. Furthermore, murine lymphocytes start out with, and accumulate more, DHA than human or rat lymphocytes in response to n-3 PUFA intake. The underlying mechanism(s) for, and biological significance of, such differences in immune cell responsiveness to n-3 PUFA are unclear at this time, but warrant further study.

The data presented in this review may help explain, in part, the paradox of equivocal results from human clinical trials with n-3 PUFA to treat inflammatory and immune-mediated diseases [49]. In contrast, there have been many positive outcomes reported for animal(rodent)-based models of such diseases. First, as noted in this review, the relative amount of n-3 PUFA provided to animals in most “immune-focused” studies far exceed what is achievable in free-living humans. This difference in n-3 PUFA intake results in changes in HUFA profiles in rodents immune cells that surpass those achieved in humans. Though unproven, it is widely presumed that changes in immune cell membrane phospholipids fatty acid content are both

**Table 3** Recommendations for improving the preclinical value of animal- and cell culture-based experiments with n-3 PUFA

## Animal-based n-3 PUFA/HUFA diet studies:

Good: Design experimental diets to provide a level of n-3 PUFA intake that is achievable in humans (e.g., ~1 en% or less)

Better: Only provide an amount and form of dietary n-3 PUFA in animal diets that reproduces the changes in fatty acid HUFA content previously reported in humans

Best: Provide a source of pre-formed AA in the control and n-3 PUFA treatment diets

## Cell culture (in vitro) studies:

Good: Introduce fatty acids in a physiological context (i.e., complexed to albumin)

Better: Check fatty acid profiles of cells prior to treatment. It is not uncommon for cells maintained in culture for prolonged periods of time to be depleted of HUFA. Normalization of cell HUFA levels in cell lines will avoid problems associated with essential fatty acid deficiency. The goal of this normalization process should be to reproduce the fatty acid profile found in freshly isolated primary cells prior to in vitro HUFA treatment

Better: Avoid using HUFA concentrations in vitro that exceed those typically observed in vivo (i.e., 10  $\mu$ M)

Better: Extend fatty acid treatment beyond 24 h to model in vivo exposure via diet and to avoid acute treatment artifacts (e.g., membrane disruption, triacylglyceride accumulation)

Best: Use treatment conditions that mimic the quantity and quality of fatty acid changes noted in these same cells following dietary n-3 PUFA supplementation. One way to accomplish this outcome is to use of mixtures of various fatty acids, rather than just adding one single fatty acid

necessary and sufficient to affect immune cell function (e.g., eicosanoid production, cytokine biosynthesis, receptor function, and cell signaling). Therefore, if health benefits associated with dietary n-3 PUFA require changes in immune cell function, then the poor outcome of most clinical trials might have been predicted on this basis alone. Another, important and often overlooked, difference between most animal-based studies and human clinical trials is that in the former test subjects are provided high n-3 diets BEFORE and during the disease development. In human clinical trials published to date, subject selection is based on the individual already suffering clinical signs of the “disease” for which n-3 PUFA are supposed to treat.

One way to look at these findings is that for animal-based studies to have greater preclinical value, diets should be designed to include only enough n-3 PUFA to reproduce the changes in immune cell HUFA noted in human clinical trials. However, it is not known if changes in immune cell HUFA content simply correlate with or are necessary for changes in immune cell function and subsequent in vivo inflammation and immune responses.

Another factor that may be contributing to the greater frequency of positive outcomes in rodent-based studies of n-3 PUFA is the fatty acid composition of “control” diets. Most rodent studies of n-3 PUFA bioactivity use vegetable oil (e.g., corn and soybean oils) as the fat source in the diet of the control group animals. These fats contain high levels (i.e., 50%) of linoleic acid (18:2n-6) and no preformed AA or n-3 HUFA. Yet, intake of AA and n-3 HUFA for non-vegetarian individuals is common. The inclusion of small amounts of AA and n-3 HUFA to match current average daily intake in humans to “control” as well as “experimental” rodent diets may significantly improve how well rodent studies extrapolate to human n-3 PUFA

supplementation trials. Similarly, investigators using in vitro fatty acid treatment to explore mechanism by which n-3 PUFA affect immune cell function may wish to establish treatment modalities that mimic the pattern and amount of fatty acid changes described here in Tables 1 and 2. The author’s experience is that it is all too easy to induce changes in cellular fatty acid profiles in vitro that far exceed what can be achieved by dietary intervention.

Finally, the recent generation of a line of transgenic mice (i.e., *fat-1* mice), that are capable of synthesizing n-3 PUFA from endogenous n-6 PUFA, has created many new opportunities to study the biological effects of these essential nutrients [50]. Compared to wild-type mice, *fat-1* mice are protected from dextran sulfate-induced colitis and show diminished growth of implanted B16 melanoma cells [51, 52]. Tissues of *fat-1* mice possess lower n-6 and higher n-3 HUFA compared to their wild-type littermates. These differences occur in the absence of any dietary manipulation. It appears that the changes in n-3 and n-6 HUFA content of some tissues of *fat-1* mice mimic the sort of changes that occur upon feeding wild-type mice diets rich in n-3 PUFA. However, no data on immune cells from these mice have been published to date. Generation of *fat-1* mice, as well as the recently developed *fat-1* pigs [53], provide researchers with a powerful tool to study underlying mechanisms potentially responsible for some of the health benefits associated with increased dietary intake of n-3 PUFA. Yet, results from studies with these novel transgenic animals should be viewed with caution until it is clear that this genetic modification accurately models diet-induced changes in tissue fatty acid profiles and function.

There is nearly universal agreement that current intake levels for n-3 PUFA by most individuals in the USA and other westernized societies are less than optimal. In the

past few years many countries have adopted dietary guidelines that call for increasing intake of n-3 PUFA. Yet, the evidence that such a change will have the expected beneficial outcomes remains equivocal. It remains unclear what form, how often, and how much n-3 PUFA individuals need to consume to obtain a health benefit. On what basis should dietitians and other health professionals advise people on this issue? Evidence from randomized clinical trials (RCT) is the gold standard in clinical medicine. Yet, RCT are very expensive and in many ways impractical for establishing dietary guidelines. Current recommendations for n-3 PUFA are based largely on epidemiological evidence. Thanks largely to advances in micro-encapsulation new food products enriched with n-3 PUFA are entering the marketplace at a rapid pace. Widespread distribution and consumption of such products will undermine the reliability of existing nutrient databases to accurately estimate n-3 PUFA intake patterns in free-living human subjects. The net effect of this could be an undermining of the reliability of epidemiological studies for setting future guidelines for optimal n-3 PUFA intake. Animal-based and in vitro experimental approaches for investigating the health benefits of n-3 PUFA can make significant contributions to this field. However, modest changes in experimental design could substantially enhance the preclinical value of such studies relative to understanding how and when n-3 PUFA may affect human health (Table 3).

**Acknowledgments** The author is grateful to Dr. Jay Whelan (University of Tennessee) for his inspiration and advice regarding this manuscript.

**Abstract** Oxygenation of 1-docosahexaenoyl lysophosphatidylcholine (docosahexaenoyl-lysoPC) by soybean lipoxygenase-1 (LOX-1) or porcine leukocyte LOX was examined. The oxidized products were identified to be hydroperoxydocosahexaenoyl-lysoPC by UV and LC/MS spectrometric analyses. In SP-HPLC and chiral phase-HPLC analyses, the products from the oxygenation of docosahexaenoyl-lysoPC by soybean LOX-1 and porcine leukocyte LOX were found to contain hydroperoxide group mainly at C-17 and C-14, respectively with the *S* form as a major enantiomer. Next, the sequential exposure of docosahexaenoyl-lysoPC to soybean LOX-1 and porcine leukocyte LOX led to the formation of conjugated triene derivatives possessing a maximal absorption at 271 nm with shoulders at 262 and 281 nm. Based on MS-MS analysis, the conjugated triene derivatives were identified to be 10,17- or 16,17-dihydroxydocosahexaenoyl-lysoPC analogues, suggesting that the diols were produced mainly from hydrolysis of 16,17(*S*)-epoxide intermediate. In kinetic studies, docosahexaenoyl-lysoPC was more favorable than docosahexaenoic acid as substrate for soybean LOX-1 or leukocyte LOX. Taken together, it is proposed that docosahexaenoyl-lysoPC can be oxygenated as substrates for some lipoxygenases to form conjugated diene and/or triene derivatives.

**Keywords** Docosahexaenoyl-lysoPC · Leukocyte lipoxygenase · Soybean lipoxygenase-1 · Oxygenation · 17(*S*)-hydroperoxydocosahexaenoyl-lysoPC

## Abbreviations

lysoPC	Lysophosphatidylcholine
LOX	Lipoxygenase
HDHA	Hydroxydocosahexaenoic acid
HPDHA	Hydroperoxydocosahexaenoic acid
SP	Straight-phase
RP	Reverse phase

## Introduction

Lipoxygenase (linoleate:oxygen oxidoreductase, EC 1.13.11.12) belongs to a diverse family of nonheme ferroproteins that catalyze the regio- and stereospecific oxygenation of free polyunsaturated fatty acids [1–3]. Lipoxygenases (LOXs) are designated as 5-, 12-, and 15-LOX on the basis of their positional selectivity in lipoxygenation of arachidonic acid, are known to form various bioactive substances from polyunsaturated fatty acids [2–4]. Generally, free polyunsaturated fatty acids are preferred as substrates for LOXs [1, 2–4]. Nonetheless, there have been reports [5–14] that certain plant LOXs can oxidize phospholipids [5–7] or triglycerides [8]. Additionally, mammalian LOXs such as reticulocyte LOX (15-LOX) or leukocyte-type LOX (12-LOX) oxygenate complex substrates such as phospholipids or biomembranes [9–14]. Besides, endothelial cell lipoxygenase can oxidize phospholipids in low density lipoprotein [15]. Recently, linoleoyl-lysoPC and linoleoyl-lysoPA, water-soluble,

were found to be readily oxidized by C12- or C15- specific LOXs such as soybean LOX-1, reticulocyte LOX or leukocyte LOX [16, 17], although potato 5-LOX did not oxygenate lysophospholipids. From these, it is suggested that lysophospholipids, containing a polyunsaturated fatty acyl chain, may correspond to endogenous substrates for position-specific lipoxygenases.

Meanwhile, recent data [18–20] indicate that docosahexaenoic acid is oxygenated by soybean or leukocyte lipoxygenase to form various oxygenated docosahexaenoic acid derivatives, monohydroperoxy and dihydroxy acids, some of which are known to be anti-inflammatory mediators. In this regard, it is supposed that docosahexaenoyl-lysophosphatidylcholine, favorable in the membrane transport [21, 22], may be also oxygenated by certain lipoxygenases to produce oxidized docosahexaenoic acid derivatives.

Here, it is demonstrated that 1-docosahexaenoyl lysophosphatidylcholine is more favorable than docosahexaenoic acid as substrate of soybean LOX-1 or leukocyte-type LOX. In addition, leukocyte-type LOX converts 17(*S*)-hydroperoxydocosahexaenoyl-lysoPC to conjugated dihydroxytriene derivative.

## Experimental Procedures

### Materials

Didocosahexaenoyl phosphatidylcholine (DDPC, 99%) was obtained from Avanti Polar Lipid (Alabaster, AL, USA). Soybean lipoxygenase (lipoxidase Type I-B, 187,400 Sigma units/mg protein), phospholipase A<sub>2</sub> (honey bee venom), sodium borohydride and docosahexaenoic acid were purchased from Sigma-Aldrich Corp (St. Louis, MO, USA). Leukocyte 12-lipoxygenase (porcine leukocyte, 1625 units/ml), 17(*S*, *R*)-hydroxydocosahexaenoic acid and 14 (*S*, *R*)- hydroxydocosahexaenoic acid were from Cayman Chemical Co. (Ann Arbor, MI, USA). HPLC solvents were of HPLC grade, and other chemicals were of analytical grade. Separately, 14(*S*)-HDHA and 17(*S*)-HDHA were prepared by the incubation of DHA with soybean LOX and leukocyte LOX, respectively as reported previously [13, 18]. 10(*S*),17(*S*)-dihydroxydocosahexa-4*Z*,7*Z*,11*E*,13*Z*,15*E*,19*Z*-enoic acid was prepared by incubating soybean LOX-1 with DHA as described before [19]. 1-Docosahexaenoyl lysophosphatidylcholine (docosahexaenoyl-lysoPC) was prepared from PLA<sub>2</sub>-catalyzed hydrolysis of didocosahexaenoyl phosphatidylcholine as described previously with a slight modification [16, 23]; DDPC (2.5 mg), dissolved in chloroform, was dried under N<sub>2</sub>, and then rapidly dispersed in 15 ml of 10 mM borax buffer, pH 8.5 containing 100 mM CaCl<sub>2</sub>. The hydrolysis

was started by adding PLA<sub>2</sub> (200 units), and allowed to continue under N<sub>2</sub> for 1 h at room temperature.

### Assay of LOX Activities in Oxygenation of Docosahexaenoic Acid Derivatives

Activities of various LOXs were monitored by measuring the increase in absorbance at 234 nm due to the formation of hydroperoxide ( $\epsilon_{234} = 28,000 \text{ M}^{-1} \text{ cm}^{-1}$ ) at 25 °C as described before [1, 24, 25]. One unit is defined as the amount of LOXs that can produce one nanomole of conjugated diene per min. The reaction mixture (500  $\mu\text{l}$ ) includes porcine leukocyte LOX (1 unit/ml) in 100 mM phosphate buffer (pH 7.5) containing 5 mM EDTA and 0.03% Tween 20, and the reaction was started by including each docosahexaenoic acid derivative (100  $\mu\text{M}$ ) into the above mixture. Separately, soybean LOX-1 (2.5 units/ml) was incubated with each docosahexaenoic acid derivative (100  $\mu\text{M}$ ) in 50 mM borax buffer (pH 9.0) at 25 °C.

### Determination of Kinetic Values in LOX-Catalyzed Oxygenation of a Docosahexaenoic Acid Derivative

Leukocyte LOX (1 units/ml) or soybean LOX-1 (2.5 units/ml) was incubated with a docosahexaenoic acid derivative of various concentrations as described above. The values of kinetic parameters were obtained according to Lineweaver Burke plot analyses as described previously [17, 24]. The catalytic efficiency of the substrate is defined as the relative value of  $V_m/K_m$ .

### LC/ESI-MS Analysis for Identification of Hydroperoxydocosahexaenoyl-LysoPC

Oxygenation of docosahexaenoyl-lysoPC was started by adding soybean LOX-1 (10 units/ml) to 150  $\mu\text{l}$  of 50 mM borax buffer (pH 9.0) containing docosahexaenoyl-lysoPC (100  $\mu\text{M}$ ), or including leukocyte LOX (1.5 units/ml) in 150  $\mu\text{l}$  of 50 mM phosphate buffer (pH 7.4) containing docosahexaenoyl-lysoPC (100  $\mu\text{M}$ ). After 10 min incubation at room temperature, the reaction products were subjected to LC/ESI-MS analysis, which was performed using a MSDI spectrometer (HP 1100 series LC/MSD, Hewlett Packard, USA) equipped with ZORBAX Eclipse XDB C<sub>18</sub> column (5  $\mu\text{m}$ , 50  $\times$  4.6 mm, Agilent Technologies, USA). The oxidized docosahexaenoyl-lysoPC was eluted (1 ml/min) with an isocratic solvent system of 45% solvent B (formic acid/acetonitrile/H<sub>2</sub>O; 0.1:80:20) in solvent A (methanol/H<sub>2</sub>O; 10:90), and the eluate was monitored at 234 nm [16].

### Determination of Position Specificity in LOX-Catalyzed Oxygenation of Docosahexaenoyl-LysoPC

Docosahexaenoyl-lysoPC (400  $\mu\text{M}$ ) was incubated with soybean LOX-1 (10 units/ml) or leukocyte LOX (30 units/ml) in 6 ml of the respective incubation buffer as described above. After 30 min incubation, the reaction products were subjected to  $\text{NaBH}_4$  reduction, and then subjected to hydrolysis in alkaline solution (1 M NaOH) at room temperature for 1 h under  $\text{N}_2$ . Finally, the lipid was extracted as described previously [15], and analyzed by SP-HPLC system equipped with silica gel column (10  $\mu\text{m}$ , 300  $\times$  7.8 mm, Phenomenex, USA), which was eluted (1 ml/min) with *n*-hexane/isopropyl alcohol/acetic acid (100:3:0.1) for HDHA from soybean LOX-1 - induced oxidation of docosahexaenoyl-lysoPC, or with *n*-hexane/isopropyl alcohol/acetic acid (100:2:0.1) for HDHA from leukocyte LOX-induced oxidation of docosahexaenoyl-lysoPC. The identification of each HDHA was performed by coinjection with each standard, 17(*S,R*)-HDHA or 14(*S,R*)-HDHA [17].

### Determination of Stereo-Selectivity in LOX-Catalyzed Oxygenation of Docosahexaenoyl-LysoPC

17-HDHA or 14-HDHA, obtained by SP-HPLC as described above, was subjected to analysis by chiral phase HPLC with a Chiralcel OD-H column (250  $\times$  4.6 mm, 5  $\mu\text{m}$ , Daicel Chemical Industries, LTD, Japan), which was eluted with the solvent system of *n*-hexane / isopropyl alcohol / trifluoroacetic acid (950:50:1). Identification of *S* and *R* enantiomers of 17-HDHA or 14-HDHA was performed by coinjection with each (*S*) HDHE standard. Under the condition used, two enantiomers of 17(*S,R*)-HDHA or 14(*S,R*)-HDHA were completely separated from each other. The flow rate of was 0.5 ml per min, and the effluent was monitored at 234 nm [17].

### Identification of Docosatriene Derivatives Generated from Oxygenation of Docosahexaenoyl-LysoPC

Docosahexaenoyl-lysoPC (100  $\mu\text{M}$ ) was incubated with soybean LOX-1 (100 units/ml) in 40 ml of 5 mM borax buffer (pH 9.0) at 4  $^\circ\text{C}$  for 1 h. Then, the reaction mixture, after pH adjustment to pH 7.0, was further incubated with leukocyte LOX (30 units/ml) for 1 h at 4  $^\circ\text{C}$ . The mixture was partially purified using a  $\text{C}_{18}$  extraction column (1  $\times$  3 cm), which was eluted with methanol. The products from the eluate, after  $\text{NaBH}_4$  reduction and alkaline hydrolysis, were again partially purified using  $\text{C}_{18}$

extraction column (1  $\times$  3 cm). The sample was diluted in methanol, and loaded onto a  $\text{C}_{18}$  column (3  $\mu\text{m}$ , 100  $\times$  3 mm, Waters, Island) connected to  $\text{C}_{18}$  pre-column (3  $\mu\text{m}$ , 20  $\times$  3 mm, Waters, Island), which was eluted (0.3 ml/min) with a gradient solvent system of solvent B (methanol/acetate; 100:0.1) in solvent A ( $\text{H}_2\text{O}$ /acetate; 100:0.1); 40% to 95% from 0 to 30 min. ESI-MS/MS was carried out on a 4000 QTrap quadrupole tandem mass spectrometer equipped with a turbo electrospray ion source (Applied Biosystems, CA, USA). The heated nebulizer at 500  $^\circ\text{C}$  was used with a curtain gas 20 psi, nitrogen collision gas (CAD) set to medium, GS1 50 psi and GS2 50 psi. The entrance potential was set to 10 V for all transitions. The data were collected in the negative ion mode from 100 to 400  $m/z$ . Parent ions (selected parent ion,  $m/z$  359) were detected on full-scan mode on Q1 quadrupole, and selected parent/daughter ion pairs for 10,17-dihydroxydocosahexaenoic acid and 16,17-dihydroxydocosahexaenoic acid were  $m/z$  359/153 and  $m/z$  359/231, respectively [26–28].

## Results

### LOX-Catalyzed Conversion of Docosahexaenoyl-LysoPC to Hydroperoxydocosahexaenoyl-LysoPC

When soybean LOX-1 was incubated with docosahexaenoyl-lysoPC, a time-dependent increase of absorption at 236 nm was observed (data not shown), consistent with the formation of conjugated dienes. Likewise, a similar change in the UV spectrum was also observed in the incubation of docosahexaenoyl-lysoPC with leukocyte LOX. Thus, docosahexaenoyl-lysoPC was effectively oxygenated by soybean LOX-1 and leukocyte LOX. In an attempt to isolate the oxygenation product, the products from the exposure of docosahexaenoyl-lysoPC to soybean LOX-1 were partially purified using  $\text{C}_{18}$  extraction column, and then subjected to RP-HPLC, which was monitored at 234 nm. Figure 1a shows that a peak with a retention time of 8.2 min appeared as a predominant product. When the compound from the major peak was analyzed by LC/ESI-MS (Fig. 1b), it was found to possess the mass spectrum characteristic of hydroperoxydocosahexaenoyl-lysoPC; molecular ions at  $m/z$  600.2 ( $[\text{M} + \text{H}]^+$ ),  $m/z$  622.2 ( $[\text{M} + \text{Na}]^+$ ) and  $m/z$  638.2 ( $[\text{M} + \text{K}]^+$ ). Thus, hydroperoxydocosahexaenoyl-lysoPC appeared as a major oxygenation product during soybean LOX-1-catalyzed oxygenation of docosahexaenoyl-lysoPC. The same result was also obtained when the products from leukocyte LOX-catalyzed oxygenation of docosahexaenoyl-lysoPC were subjected to UV spectrometry and LC/ESI-MS analysis (data not shown).

**Fig. 1** LC/ESI-MS analysis of products from oxygenation of docosahexaenoyl-lysoPC by soybean LOX-1. **a** The product, obtained from 10 min incubation of docosahexaenoyl-lysoPC (100  $\mu$ M) with soybean LOX-1 (10 units/ml) in 150  $\mu$ l of borax buffer (50 mM, pH 9.0), was injected into ZORBAX Eclipse XDB C<sub>18</sub> column (5  $\mu$ m, 50  $\times$  4.6 mm), which was eluted (1 ml/min) with isocratic solvent system of 45% solvent A (acetate/acetonitrile/H<sub>2</sub>O; 0.5:80:20) in solvent B (methanol/H<sub>2</sub>O; 10:90) as described in Experimental Procedures. The products were monitored by UV detection at 234 nm. **b** Representative mass spectrum of peroxy derivative of docosahexaenoyl-lysoPC. The mass spectrum of the major peak (retention time, 8.2 min) in Fig. 2a was obtained by ESI-MS analysis system using positive-ion scan mode as described in Experimental Procedures

#### Determination of Position- and Stereo-Selectivity in Oxygenation of Docosahexaenoyl-LysoPC

To establish the oxygenation position in oxygenation of docosahexaenoyl-lysoPC, the product from soybean LOX-1-catalyzed oxygenation of docosahexaenoyl-lysoPC was subjected to NaBH<sub>4</sub> reduction, followed by alkaline hydrolysis, to afford hydroxydocosahexaenoic acid (HDHA), which was further purified by SP-HPLC. When the purified HDHA was coinjected with each standard HDHA, it was

found that the predominant peak (retention time, 18.6 min) migrated with 17-HDHA (Fig. 2a, solid line arrow). Next, when the oxygenation position in leukocyte LOX-catalyzed oxygenation of docosahexaenoyl-lysoPC was determined (Fig. 2b), the major product (elution time, 20.0 min) was found to migrate with 14-HDHA (dotted line). Taken together, docosahexaenoyl-lysoPC is oxygenated mainly at C-14 by leukocyte 12-lipoxygenase, and at C-17 by soybean 15-lipoxygenase. In related studies, the stereo-specificity in the oxygenation of docosahexaenoyl-lysoPC was analyzed by chiral phase HPLC. When 17-HDHA, obtained as described in Fig 2a, was subjected to chiral phase HPLC analysis, the major part of 17-HDHA (retention time, 15.5 min) was found to migrate with 17(*S*)-HDHA (Fig. 3a). Separately, most of 14-HDHA (retention time, 14.1 min), obtained as described in Fig 2b, was found to migrate with 14(*S*)-HDHA (Fig. 3b). Thus, it is commonly observed that both LOXs express a stereo-specificity toward the *S* form enantiomer in oxygenation of docosahexaenoyl-lysoPC.

#### Conversion of 17(*S*)-Hydroperoxydocosahexaenoyl-LysoPC to Dihydroxydocosahexaenoyl-LysoPC

Previously, 17(*S*)-hydroperoxydocosahexaenoic acid (HPDHA) was shown to be converted to 10,17(*S*)-dihydroxydocosahexaenoic acid isomers via 16,17(*S*)-epoxide intermediate in leukocytes [29, 30]. In this relation, docosahexaenoyl-lysoPC was first exposed to soybean LOX-1 in a borax buffer (pH 9.0) to maximally produce 17(*S*)-hydroperoxydocosahexaenoyl-lysoPC, and then the mixture was further incubated with porcine leukocyte LOX at pH 7. As exhibited in Fig. 4a, the sequential exposure of docosahexaenoyl-lysoPC to soybean LOX-1 and leukocyte LOX resulted in the appearance of a particular UV spectrum,

**Fig. 2** SP-HPLC determination of oxygenation position in lipoxygenase-catalyzed oxygenation of docosahexaenoyl-lysoPC. Docosahexaenoyl-lysoPC was incubated with each LOX for 30 min, and after NaBH<sub>4</sub> reduction and alkaline hydrolysis, the final products were analyzed by SP-HPLC, equipped with silica gel column (300  $\times$  7.6 mm), which was eluted (1 ml/min) with *n*-hexane/

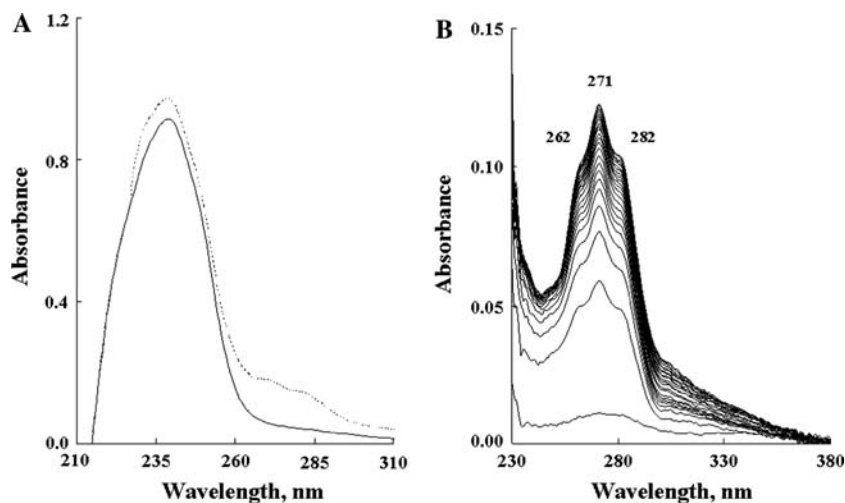

isopropyl alcohol/acetic acid (100:3:0.05) for 17-HDHA, and *n*-hexane/isopropyl alcohol/acetic acid (100:2:0.05) for 14-HDHA. **a** Incubation of docosahexaenoyl-lysoPC with soybean LOX-1 at pH 9.0. **b** Incubation of docosahexaenoyl-lysoPC with leukocyte LOX at pH 7.4. And the major products were co-injected with standard compounds, 17-HDHA (solid arrow) and 14-HDHA (dotted arrow)

**Fig. 3** Chiral-phase HPLC of HDHA derived from oxygenation of docosahexaenoyl-lysoPC by lipoxygenases. 17-HDHA and 14-HDHA, prepared as described in Fig. 3, were analyzed by chiral phase HPLC, equipped with chiralcel OD-H column, which was eluted with the solvent system of n-hexane/isopropyl alcohol/trifluoroacetic acid (950:50:1). The flow rate was 0.5 ml per min and the effluent was

monitored at 234 nm. **a** 17-HDHA derived from exposure of docosahexaenoyl-lysoPC to soybean LOX-1. **b** 14-HDHA derived from exposure of docosahexaenoyl-lysoPC to leukocyte LOX. Under condition used, (*S,R*) HDHA was separated into two peaks (*dotted and solid arrows*). The *arrow* indicates the coinjection with (*S*) isomer (*solid line*) or (*R*) isomer (*dotted line*) of 14-HDHA or 17-HDHA

**Fig. 4** Changes of UV spectra during sequential exposure of docosahexaenoyl-lysoPC to soybean LOX-1 and leukocyte LOX. **a** Docosahexaenoyl-lysoPC (100  $\mu$ M) was incubated with soybean LOX-1 (20 units/ml) in 5 mM borax buffer (pH 9) for 1 h at 4  $^{\circ}$ C, and then the mixture, after pH adjusted to pH 7.0, was further incubated with leukocyte LOX (30 units/ml) at r.t. for 30 min. **b** The UV spectral change in differential spectrometry was scanned with the cycle time of 1 min

characteristic of conjugated triene structure [31]. In the differential spectrophotometry (Fig. 4b), the compound was found to exhibit the UV spectrum with a maximum absorption at 271 nm and shoulders at 262 nm and 281 nm, quite similar to the observation after the incubation of DHA with leukocyte cells [30]. Thus, docosahexaenoyl-lysoPC is oxygenated by soybean LOX-1 to produce 17(*S*)-hydroperoxydocosahexaenoyl-lysoPC, which is in turn converted to conjugated triene derivatives by leukocyte LOX. Meanwhile, the further oxygenation of 17(*S*)-hydroperoxydocosahexaenoyl-lysoPC by soybean LOX-1 was negligible. In the next experiment to identify the products with conjugated triene structure, the oxidized products, after separation on a  $C_{18}$  extraction column, were subjected to  $\text{NaBH}_4$  reduction and alkaline hydrolysis to afford dihydroxydocosahexaenoic acids. Then, the final products, after partial purification on  $C_{18}$  column, were subjected to LC/MS-MS analyses employing selected parent ion

monitoring at  $m/z$  359, corresponding to  $[\text{M}-\text{H}]^-$  of dihydroxydocosahexaenoic acid, and selected parent/daughter ion pairs monitoring at  $m/z$  359/153. As demonstrated in Fig. 5a, b, it was found that three peaks, peak I (16.2 min), peak II (16.7 min) and peak III (17.0 min), showed the ions characteristic of the compound corresponding to 10,17(*S*)-dihydroxydocosahexaenoic acid [18, 19, 20]; a representative MS-MS spectrum (Fig 6a) showed several prominent fragment ions at  $m/z$  359.1 (M-H), 341.0 (M-H- $\text{H}_2\text{O}$ ), 323.4 (M-H- $2\text{H}_2\text{O}$ ), 315.0 (M-H- $\text{CO}_2$ ), and 297.2 (M-H- $\text{H}_2\text{O}-\text{CO}_2$ ). Supportive diagnostic ions demonstrating the presence of the 10 and 17 alcohol-containing carbon positions include the ions at  $m/z$  205.9, 261.0 and 289.0 (Fig 6a), in addition to the characteristic ion at  $m/z$  153.0 (Figs. 5b and 6a) as reported previously [18]. Separately, Fig. 5a, c demonstrated that two peaks, peak IV (17.8 min) and peak V (19.0 min), possessed the ions characteristic of 16,17(*S*)-dihydroxydocosahexaenoic acid [18]; its MS-MS (Fig. 6b) showed

**Fig. 5** LC-MS/MS chromatography of products with conjugated triene structure. Docosahexaenoyl-lysoPC was sequentially exposed to soybean LOX-1 and leukocyte LOX as described in Fig. 4, and the final products, after  $\text{NaBH}_4$  reduction and alkaline hydrolysis, were subjected to analysis of LC-MS/MS system as described in Materials and Methods. **a** Selected ion monitoring at  $m/z$  359 (parent ion) for dihydroxydocosahexaenoic acid derivative-containing products. **b** Selected ion monitoring at  $m/z$  153 in  $\text{MS}^2$  359 for 10,17-dihydroxydocosahexaenoic acid isomers: peak I, 16.2 min; peak II, 16.7 min; peak III, 17.0 min. **c** Selected ion monitoring at  $m/z$  231 in  $\text{MS}^2$  359 for 16,17-dihydroxydocosahexaenoic acid isomers: peak IV, 17.8 min; peak V, 19.0 min

several prominent fragment ions at  $m/z$  359.2 (M-H), 341.2 (M-H- $\text{H}_2\text{O}$ ), 323.4 (M-H- $2\text{H}_2\text{O}$ ), 315.1 (M-H- $\text{CO}_2$ ), 297.1 (M-H- $\text{H}_2\text{O}-\text{CO}_2$ ) and 279.3 (M-H- $2\text{H}_2\text{O}-\text{CO}_2$ ). Supportive diagnostic ions demonstrating the presence of the 16 and 17 alcohol-containing carbon positions include ions at  $m/z$  261.2 and 289.3 (Fig. 6b), in addition to the characteristic ion at  $m/z$  231.1 (Figs. 5c and 6b). Taken together, at least three isomers of 10,17(*S*)-dihydroxydocosahexaenoic acid derivative and two isomers of 16,17(*S*)-dihydroxydocosahexaenoic acid derivative were generated from the sequential exposure of docosahexaenoyl-lysoPC to soybean LOX-1 and leukocyte LOX. Noteworthy, peaks I and III appeared reproducibly as isomers of a similar amount in repeated experiments, where the rapid hydrolysis of the oxidized products was performed. However, the amount of peak II (retention time, 16.7 min), comigrating with 10(*S*),17(*S*)-dihydroxydocosahexa-4*Z*,7*Z*,11*E*,13*Z*,15*E*,19*Z*-enoic acid in RP- HPLC, decreased greatly when the partial purification of oxidized lipids on C18 column was omitted (data not shown), excluding the possibility that peak II was produced during the sequential exposure of docosahexaenoyl-lysoPC to lipoxygenases.

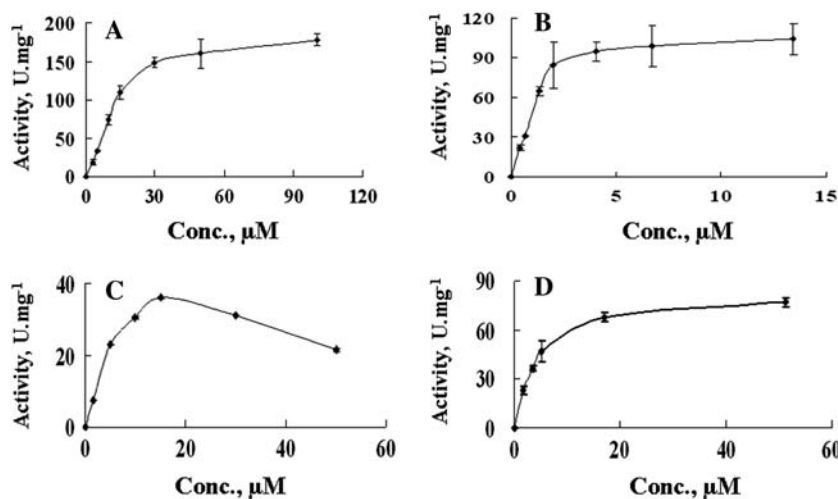

**Fig. 6** MS/MS spectrum of products with conjugated triene structure **a**, Representative MS/MS spectrum of the product from peak I, II or III in Fig. 5a. **b**, Representative MS/MS spectrum of the product from peak IV or V in Fig. 5a

#### Determination of Kinetic Values in LOX-Catalyzed Oxygenation of DHA Derivatives

Subsequently, LOX-catalyzed oxygenation of DHA derivatives was examined kinetically. As demonstrated in Fig. 7, the oxygenation of DHA derivative by each LOX followed classical Michaelis–Menten kinetics. From Lineweaver Burk plot analysis, the  $K_m$  and  $V_m$  values were estimated to be 2.2  $\mu\text{M}$  and 104.2 units/ $\mu\text{g}$  protein, respectively in oxygenation of docosahexaenoyl-lysoPC by soybean LOX-1, and 16.8  $\mu\text{M}$  and 178.0 units/ $\mu\text{g}$  protein, respectively in oxygenation of DHA by the enzyme (Table 1). Thus, the catalytic efficiency ( $V_m/K_m$ ) of docosahexaenoyl-lysoPC as substrate of soybean LOX-1 was about 4-fold greater than that of DHA. Next, in the oxygenation by leukocyte LOX (Table 2), the  $K_m$  and  $V_m$  values were estimated to be 3.4  $\mu\text{M}$  and 77.2 units/mg protein, respectively for docosahexaenoyl-lysoPC, and 17.6  $\mu\text{M}$  and 35.9 units/mg protein, respectively for DHA. Thus, the catalytic efficiency of docosahexaenoyl-lysoPC for leukocyte LOX was approximately 10-fold greater than that of docosahexaenoic acid. Nonetheless, docosahexaenoyl-lysoPC was not significantly oxygenated by potato LOX.

#### Discussion

Recently, lysophospholipids such as linoleoyl-lysoPC or linoleoyl-lysoPA were observed to be efficient substrates for lipoxygenases such as soybean LOX-1, leukocyte LOX or reticulocyte LOX [16, 17]. The present study

**Fig. 7** Effect of substrate concentration on LOX-catalyzed oxygenation of docosahexaenoyl-lysoPC and docosahexaenoic acid. Soybean LOX-1 (2.5 units/ml) was incubated with docosahexaenoic acid (A) or docosahexaenoyl-lysoPC (B) of various concentrations in borax buffer (50 mM, pH 9.0). Separately, leukocyte LOX (1 unit/ml) was

incubated with docosahexaenoic acid (C) or docosahexaenoyl-lysoPC (D) of various concentrations in 100 mM phosphate buffer (pH 7.5) containing 5 mM EDTA and 0.03% Tween 20. Data were expressed as mean  $\pm$  SD of results from at least three independent experiments

**Table 1** Kinetic values in oxygenation of docosahexaenoic acid derivatives by soybean LOX-1

	Km ( $\mu$ M)	Vm (units/ $\mu$ g)	Vm/Km (units/ $\mu$ g/ $\mu$ M)
Docosahexaenoic acid	16.8 $\pm$ 1.4	178.0 $\pm$ 7.4	10.3 $\pm$ 1.3
Docosahexaenoyl-lysoPC	2.2 $\pm$ 0.6	104.2 $\pm$ 5.2	42.4 $\pm$ 7.2
Didocosahexaenoyl-PC	1072 $\pm$ 184	7.8 $\pm$ 0.3	0.007 $\pm$ 0.001

Soybean LOX-1 (2.5 units/ml) was incubated with docosahexaenoyl-lysoPC, didocosahexaenoyl-lysoPC or docosahexaenoic acid of various concentrations in 500  $\mu$ l of 50 mM borax buffer (pH 9.0) at 25  $^{\circ}$ C. Kinetic values were obtained from Lineweaver Burke plot. Values were expressed as mean  $\pm$  SD of results from at least three independent experiments

**Table 2** Kinetic values in oxygenation of docosahexaenoyl-lysoPC or docosahexaenoic acid by leukocyte LOX

	Km ( $\mu$ M)	Vm (units/mg)	Vm/Km (units/mg/ $\mu$ M)
Docosahexaenoic acid	17.6 $\pm$ 1.7	35.9 $\pm$ 0.5	2.1 $\pm$ 0.9
Docosahexaenoyl-lysoPC	3.4 $\pm$ 1.8	77.2 $\pm$ 2.8	22.7 $\pm$ 0.8

Porcine leukocyte LOX (2 units/ml) was incubated with each substrate (docosahexaenoyl-lysoPC or docosahexaenoic acid) of various concentrations in 500  $\mu$ l of 100 mM phosphate buffer (pH 7.4) containing 5 mM EDTA and 0.03% Tween 20 at 25  $^{\circ}$ C

demonstrates that docosahexaenoyl-lysoPC is also oxygenated efficiently by soybean LOX-1 or leukocyte LOX. The higher catalytic efficiency of docosahexaenoyl-lysoPC, compared to DHA, may suggest that carboxyl group is not required for the interaction of substrates with lipooxygenases such as soybean LOX-1 or leukocyte LOX. Meanwhile, the lower catalytic efficiency (Vm/Km) of DHA, compared to docosahexaenoyl-lysoPC, may be ascribed to the negative charge property adopted by the free fatty acid, as suggested from its higher Km value. Alternatively, the difference of catalytic efficiency between

DHA and docosahexaenoyl-lysoPC may be accounted for by the difference of the micellar concentration [31, 32]. However, this possibility is not supported by present findings that the Km values of docosahexaenoyl-lysoPC and DHA are much below their critical micellar concentrations (>50  $\mu$ M). In this context, it is suggested that monomeric form of docosahexaenoyl-lysoPC is directly recognized by LOX as substrate, consistent with previous reports [15, 33]. It is well known that DHA is oxygenated by porcine leukocyte 12-LOX and soybean 15-LOX to produce 14(S)-HPDHA and 17(S)-HPDHA, respectively

[13, 28]. Such a stereo- and positional specificity was also reproduced in oxygenation of docosahexaenoyl-lysoPC. Thus, the stereo- and positional specificity of soybean LOX or leukocyte LOX was not altered by the esterification of docosahexaenoic acid [34, 35].

Recent studies have shown that 17(*S*)-HPDHA, which is generated from lipoxygenation of DHA, is further converted to 10,17(*S*)-dihydroxydocosahexaenoic acid isomers via 16,17(*S*)-epoxide intermediate in cellular systems [29, 30, 36]. The same pathway may apply to leukocyte LOX-catalyzed conversion of 17(*S*)-hydroperoxydocosahexaenoyl-lysoPC to dihydroxydocosahexaenoyl-lysoPC as suggested from gradual UV spectral change indicative of the conversion of conjugated diene to conjugated triene structure. Moreover, LC/MS-MS analysis indicates that the final oxidized products with conjugated triene include at least three isomers of 10,17(*S*)-dihydroxydocosahexaenoic acid derivative and two isomers of 16,17(*S*)-dihydroxydocosahexaenoic acid derivative. Concerning the mechanism for the formation of dihydroxydocosahexaenoic acid derivatives, there can be two possibilities; one is the epoxide intermediate pathway, and the other dioxygenation pathway. According to the former, 17(*S*)-hydroperoxydocosahexaenoyl-lysoPC may be converted by leukocyte LOX to dihydroxydocosahexaenoyl-lysoPC via 16,17-epoxide intermediate, consistent with the mechanism established for the conversion of DHA to 10,17(*S*)- and 16,17(*S*)-dihydroxyhexaenoic acids in leukocytes [29, 30]. This is strongly supported by present findings that in

addition to two isomers (peaks I and III) of 10,17(*S*)-dihydroxydocosahexaenoic acid derivative, two isomers (peaks IV and V) of 16,17(*S*)-dihydroxydocosahexaenoic acid derivative appeared as isomeric products of a similar quantity (Fig. 5), resulting from non-enzymatic hydrolysis of 16,17(*S*) epoxide intermediate. In this regard, the compounds from peaks I and III are proposed to contain double bond geometry configuration of 11*E*,13*E*,15*E* as described in Fig. 8. Meanwhile, it is not likely that peak II, comigrating with 10(*S*),17(*S*)-dihydroxydocosahexa-4*Z*,7*Z*,11*E*,13*Z*,15*E*,19*Z*-enoic acid [19], was derived from double oxygenation of docosahexaenoyl-lysoPC by lipoxygenases, since dihydroperoxydocosahexaenoyl-lysoPC was not detected in LC/MS monitoring at *m/z* 632 (*M* + *H* + 2*O*) [data not shown]. Furthermore, a significant amount of conjugated triene product was not produced after the exposure of docosahexaenoyl-lysoPC to excess soybean LOX-1, in contrast to soybean LOX-catalyzed conversion of DHA to 10(*S*),17(*S*)-dihydroxydocosahexa-4*Z*,7*Z*,11*E*,13*Z*,15*E*,19*Z*-enoic acid [19, 37]. Although peak II appeared as a major product in the present condition used, the height of peak II decreased to a great extent when the isolation of lipids on C18 column was omitted, implying that the peak II might be caused by the delayed process of lipid isolation.

A previous report indicates that docosahexaenoyl-lysoPC exists in human plasma [38] to a low level ( $\sim 1 \mu\text{M}$ ). However, the plasma level of docosahexaenoyl-lysoPC is close to its *K<sub>m</sub>* value for leukocyte LOX. Moreover,

**Fig. 8** Proposed pathway for enzymatic formation of dihydroxydocosahexaenoyl-lysoPC isomers from docosahexaenoyl-lysoPC. R, glycerophosphorylcholine moiety

docosahexaenoyl-lysoPC is oxygenated more readily than docosahexaenoic acid as substrate for leukocyte LOX. In addition, lysophosphatidylcholine was proposed as being a preferred physiological transporter of polyunsaturated fatty acids such as docosahexaenoic acid [21, 22]. In this regard, docosahexaenoyl-lysoPC may be preferentially utilized by certain lipoxygenases *in vivo*, which needs further study.

Taken all together, the current data demonstrate that docosahexaenoyl-lysoPC can be efficiently oxygenated by soybean and leukocyte lipoxygenases. In addition, 17(*S*)-hydroperoxydocosahexaenoyl-lysoPC can be further metabolized to an epoxide of the leukotriene A type, which is hydrolyzed to produce lysoPC derivatives containing dihydroxydocosahexaenoic acid.

**Fig. 1** Oxidation of 1-*O*-hexadec-1'-enyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (GPC 16:0<sub>plasm</sub>/22:6) to 1-hydroxy-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (LPC 22:6) and formyl-LPC 22:6. For further mechanistic details concerning oxidation of the docosahexaenoyl residue see [5]

plasmalogens under the influence of Cu(II)/H<sub>2</sub>O<sub>2</sub> or the free radical initiator AAPH (2,2'-azobis-2-methyl-propanimidamide, dihydrochloride) [5, 6]. Whereas the first oxidant induced primarily oxidation at carbon-5 of the arachidonoyl residue [6], the second oxidant gave a more complex mixture of products [5].

In the present paper we investigated the organic extracts of spermatozoa from cattle and roe deer because they are known to possess large amounts of plasmalogens [3]. Matrix-assisted laser desorption and ionization time-of-flight mass spectrometry (MALDI-TOF MS) [7] with post source decay (PSD) fragmentation [8] was used for lipid analysis as a fast and reliable method. This method was already successfully used for the investigation of oxidation products from PCs [9] under the influence of HOCl as well as for the analysis of oxidatively modified human lipoproteins [10].

We will show that along with 1-hydroxy-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (LPC 22:6), formyl-LPC 22:6 is an additional important oxidation product of plasmalogens under conditions that promote lipid oxidation. Particularly formyl-LPC 22:6 may serve as a selective marker of plasmalogen oxidation.

In addition to lipids from animal spermatozoa, selected experiments were also performed with purified phospholipids in order to check whether the results obtained under both conditions agree with each other.

## Materials and Methods

### Chemicals

All phospholipid standards used as reference compounds were obtained from Avanti Polar Lipids (Alabama, USA) as solutions in CHCl<sub>3</sub> and used without further purification. All further chemicals for sample preparation, MALDI-TOF MS (2,5-dihydroxybenzoic acid, DHB) as well as all solvents (chloroform and methanol) were obtained in highest commercially available purity from Fluka Feinchemikalien

GmbH (part of Sigma-Aldrich Chemie GmbH, Taufkirchen, Germany) and used as supplied. Phospholipase A<sub>2</sub> from hog pancreas was also obtained from Fluka. Percoll (L 6143) was purchased from Biochrom (Berlin, Germany).

### Semen Samples and Processing

Bull semen was obtained from different fertile animals at a breeding station (Rinderbesamung Berlin-Brandenburg GmbH, Besamungsbullenstation Schmergow, Germany). One ml portions of each ejaculate were centrifuged at room temperature (12,000×g, 2 min) and the seminal plasma was removed by pipette. The sperm cell sediment was carefully re-suspended with 1 ml 0.9% NaCl and the supernatant discarded after centrifugation (12,000×g, 2 min).

After the second washing step in 0.9% NaCl the cell concentrations in the remaining pellets were adjusted with 0.9% NaCl to about 4 × 10<sup>8</sup> spermatozoa/ml. Those samples were stored for 24 h at 16 °C without further protective agents or frozen at -20 °C until use for lipid extraction. Lipid extraction (according to a modified Bligh and Dyer method [11]) was performed in the following way: 0.3 ml of the thawed cell suspension (i.e., about 1.2 × 10<sup>8</sup> spermatozoa) were diluted with 0.5 ml 0.9% NaCl solution. Afterwards, 3 ml of a CHCl<sub>3</sub>/CH<sub>3</sub>OH (1:2 v/v) mixture were added and the sample was vigorously vortexed for 1 min and incubated for 30 min at RT. One ml CHCl<sub>3</sub> was added and the sample again vortexed for 1 min. After addition of 1 ml acetic acid (40 mM) and vortexing, the sample was centrifuged (10 min, 1,000×g, 4 °C) and the organic layer was removed and used for all further experimental procedures. Roe deer spermatozoa were obtained by electroejaculation at the field station of the Leibniz Institute for Zoo and Wildlife Research, and washed and extracted in the same way. Unprotected storage of semen was performed at 5 °C. Spermatozoa from cattle and roe deer were cryopreserved by slow freezing in commercial media (Minitüb, Landshut, Germany)

containing egg yolk. After thawing sperm cells were centrifuged (20 min, 600×g, 25 °C) through a Percoll gradient [45, 70, 90% in Hepes-buffered NaCl solution (HBS)] to remove the cryoextender (particularly the egg yolk). The resulting sperm pellets were washed again with 5 ml HBS (10 min, 500×g, 25 °C) and the pellet was re-suspended in HBS with a sperm number of about  $1 \times 10^7$  cells in 800  $\mu$ l for lipid extraction.

#### Autoxidation of Phospholipids

Oxidation of 1-*O*-octadecyl-1'-enyl-2-docosa-hexaenoyl-*sn*-glycero-3-phosphocholine and 1-palmitoyl-2-docosa-hexaenoyl-*sn*-glycero-3-phosphocholine was performed as described [12]. Briefly, 0.1 mg of the corresponding phospholipid dissolved in 100  $\mu$ l of chloroform was transferred to a small glass test tube and evaporated under a stream of nitrogen. The lipid residue was allowed to autoxidize while being exposed to air for 24 h. This simple approach was considered to be sufficient as no quantitative data analysis was planned.

#### Artificial Modifications of Phospholipids Extracted From Spermatozoa

Commercially available PLs and PLs extracted from spermatozoa were digested by the enzyme phospholipase A<sub>2</sub> to obtain the corresponding lysophospholipids (LPLs) [13]. Briefly, aliquots of the organic extracts of spermatozoa (see above) were evaporated to dryness. Lipid vesicles were prepared by dissolving the resulting PL film in 50 mM phosphate buffer, pH 7.4 and vortexing vigorously for 30 s. Vesicles were treated with 0.5 mg/ml phospholipase A<sub>2</sub> (ca. 100 U/ml) for 2 h at 37 °C. No further efforts were made to determine the exact PLA<sub>2</sub> activity as the only aim was the complete digestion of the PLs of spermatozoa. PLs were subsequently extracted in the same way as described above.

In order to prove the sensitivity of alkenyl-acyl species to acid treatment, a flask with the dried lipids obtained from roe deer spermatozoa was exposed to HCl fumes for 10 min by keeping the inverted flask over an open bottle of concentrated HCl [14].

#### MALDI-TOF Mass Spectrometry

Total spermatozoa extracts and individual autoxidized PLs were investigated by MALDI-TOF MS using 0.5 mol/l 2,5-dihydroxybenzoic acid (DHB) in methanol as matrix [15]. A recent investigation has shown that this isomer of

dihydroxybenzoic acid is most suitable as MALDI matrix [16]. All MALDI-TOF mass spectra were acquired on a Bruker Autoflex mass spectrometer (Bruker Daltonics, Bremen, Germany). The system utilizes a pulsed nitrogen laser, emitting at 337 nm. The extraction voltage was 20 kV and gated matrix suppression was applied to prevent the saturation of the detector by matrix ions [17]. One hundred and twenty-eight single laser shots were averaged for each mass spectrum to minimize shot-to-shot deviations. The laser strength was kept about ten percent above threshold to obtain optimum signal-to-noise (S/N) ratio. In order to enhance the spectral resolution all spectra were acquired in the reflector mode using delayed extraction conditions. A more detailed methodological description of MALDI-TOF MS is given in [7, 18].

In the PSD (post source decay) experiments, the precursor ions of interest were isolated using a timed ion selector. The laser intensities for PSD spectra were maintained the same as in the (reference) reflector mode spectra for the first segment spectrum but were gradually enhanced for all further segment spectra. Further information how to record PSD spectra is available in [19]. The fragment ions were refocused onto the detector by stepping the voltage applied to the reflectron in appropriate increments. This was done automatically by using the "FAST" (fragment analysis and structural TOF) subroutine of the Flex Control Program delivered by Bruker Daltonics [20]. As peaks in PSD spectra are broadened in comparison to standard mass spectra, not even the first decimals are given in that case [19].

#### Results and Discussion

Although a MALDI-TOF mass spectrometric characterization of bull spermatozoa lipid extracts was already performed [21], corresponding data on the lipid composition of roe deer spermatozoa are not yet available. Therefore, the method how the PL analysis may be performed by MALDI-TOF MS in combination with chemical modifications of the organic spermatozoa extracts shall be shortly introduced.

In Fig. 2 selected positive ion MALDI-TOF mass spectra of an organic extract of roe deer (a–c) and of a selected reference plasmalogen (d–f) are shown. Trace (2a) represents the native roe deer extract, whereas (2b) was recorded subsequent to PLA<sub>2</sub> digestion and (2c) subsequent to exposition to HCl fumes. PLA<sub>2</sub> cleaves the fatty acyl residue in *sn*-2 position selectively and HCl affects the vinyl ether linkage in *sn*-1 position. Therefore, the combination of both modifications provides important structural information.

The peaks at  $m/z = 790.6$  and  $812.6$  (2a) can be assigned to the H<sup>+</sup> and Na<sup>+</sup> adducts of 1-*O*-hexadec-1'-en-

**Fig. 2** Positive ion MALDI-TOF mass spectra of an organic extract of roe deer (a–c) and one commercially available plasmalogen 1-*O*-1'-(*Z*)-octadecenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (d–f). Spectra were recorded from the native samples (a, d) and subsequent to phospholipase A<sub>2</sub> digestion (b, e) or exposition to HCl fumes (c, f). Peaks are labeled according to their *m/z* values and peaks stemming from the applied DHB matrix (0.5 mol/l in CH<sub>3</sub>OH) are marked with asterisks [16]. Please note that the contribution of matrix signals is more pronounced in the spermatozoa extracts because these are much less concentrated and contain higher amounts of salts than the commercially available plasmalogen sample

yl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (GPC 16:0<sub>plasm</sub>/22:6), whereas the peaks at *m/z* = 792.6 and 814.6 are stemming from 1-*O*-hexadec-1'-enyl-2-docosapentaenoyl-*sn*-glycero-3-phosphocholine (GPC 16:0<sub>plasm</sub>/22:5) and the corresponding alkyl ether, 1-*O*-palmityl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (GPC 16:0<sub>alkyl</sub>/22:6). The reasons leading to these assignments will be outlined below in more detail. This composition is similar to that of bull [21] and boar [22] spermatozoa. It is well known that the content of ether-linked PLs and particularly plasmalogens is characteristic of bull and boar spermatozoa [21]. In contrast, spermatozoa from man consist nearly exclusively of regular PCs but with high contents of highly unsaturated fatty acyl residues [13]. As the contribution of further PLs in spermatozoa is relatively low and PCs are most sensitively detected in mixtures under MALDI conditions [17], PCs will be exclusively discussed in this paper.

Of course, the peak assignment given above is based exclusively on the *m/z* value and, therefore, rather ambiguous. The most simple and traditional method of confirming peak assignments is to alter the compound of interest chemically in a defined way and to check whether the observed changes are in agreement with the putative compound [21]. Subsequent to the digestion of the roe deer spermatozoa lipid extract with the enzyme PLA<sub>2</sub> (2b) that cleaves the acyl residue in *sn*-2 position selectively, it is

evident that the peaks in the original extract are replaced completely by the corresponding lyso compounds at *m/z* = 480.3 and 482.3 (H<sup>+</sup> adducts) as well as 502.3 and 504.3 (Na<sup>+</sup> adducts). This is in agreement with the previous assumption of the alkenyl (about 75%) and the alkyl ether (about 25%) but does not allow clear conclusions about the acyl residues in *sn*-2 position. However, this information can also be easily obtained. Subsequent to HCl-induced hydrolysis (2c), there are significant amounts of LPC 22:6 (*m/z* = 568.3 and 590.3), but only relatively small amounts of LPC 22:5 (*m/z* = 570.3 and 592.3). Please note that there are still small peaks at *m/z* = 792.6 and 814.6. These signals represent the corresponding alkyl ether that is—in contrast to the plasmalogens—not affected by the HCl fumes. It was not the primary aim of this paper to investigate the lipid composition of roe deer spermatozoa in more detail but it is evident from these data that ether-linked PLs (1-*O*-hexadecyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (GPC 16:0<sub>alkyl</sub>/22:6) and particularly plasmalogens (1-*O*-hexadec-1'-enyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (GPC 16:0<sub>plasm</sub>/22:6) and 1-*O*-hexadec-1'-enyl-2-docosapentaenoyl-*sn*-glycero-3-phosphocholine (GPC 16:0<sub>plasm</sub>/22:5) are their most abundant constituents. Please also note that the peaks at *m/z* = 551.0, 545.0 and 511.0 are stemming from the applied DHB matrix [16].

The reliability of the applied method can be easily verified by using a commercially available plasmalogen species and treating this compound in the same way as the spermatozoa extract: 1-*O*-1'-(*Z*)-octadecenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine was used because the most relevant plasmalogen of spermatozoa (with a hexadecenyl instead a octadecenyl residue) is not commercially available. The only difference between this reference compound and the plasmalogen of spermatozoa is one bismethylene group and, therefore, all masses differ for 28 Da. Accordingly, the pure plasmalogen gives two peaks at  $m/z = 818.6$  and  $840.6$  (2d), after cleavage of the docosahexaenoyl residue by PLA<sub>2</sub> digestion at  $m/z = 508.3$  and  $530.3$  (2e) and after cleavage of the alkenyl ether by HCl treatment at  $m/z = 568.3$  and  $590.3$  (2f). This is in perfect agreement with the data obtained with the spermatozoa extract. Please note that the much higher contribution of matrix peaks [8] in the spermatozoa extracts (marked with asterisks) is a clear indication of the lower lipid concentration in the case of the spermatozoa. Finally, spermatozoa extracts also give signals at  $m/z = 469.3$  and  $535.3$  (2c). Unfortunately, the origin of these peaks could not be clarified so far. However, it is most likely that these compounds represent PLs as they disappear completely subsequent to digestion with PLA<sub>2</sub> (cf. 2b).

All MALDI-TOF mass spectrometers equipped with a reflector detector are basically capable of recording MS/MS spectra and this technique is called post source decay (PSD). PSD enables the identification of significant fragment ions that may help to confirm the identity of putative lipids, but has also the disadvantage that higher sample amounts in comparison to conventional MALDI-TOF MS are required [20].

The post source decay mass spectra of the most prominent peaks of spermatozoa extracts are shown in Fig. 3. The quality of the PSD spectra derived from the precursor ions with  $m/z = 812.6$  (3a) and  $814.6$  (3b) is rather poor. Nevertheless both spectra are, besides the mass shift of 2 Da, virtually identical and confirm the proposed structures. The only difference is one fragment ion at  $m/z = 279$  that is exclusively derived from the plasmalogen but not from the ether lipid.

Unfortunately, it is very difficult to obtain information on acyl compositions of PCs by PSD because PCs are under conditions of MALDI-TOF MS only detectable as positive but not as negative ions [7]. In contrast, the negative ion PSD mass spectra would be most useful to obtain information about the released fatty acids. Nevertheless, the PSD spectra clearly confirm the presence of PC species [23].

One aim of this paper is the evaluation of the lipid composition of spermatozoa and the generation of

characteristic lipid oxidation products in dependence of storage conditions. In Fig. 4 characteristic positive ion MALDI-TOF mass spectra of organic extracts of cattle (4a, c) and roe deer spermatozoa (4b, d) are shown. Fresh ejaculates were cryopreserved and lipids were extracted after thawing and washing (4a, 4b). Fresh ejaculates were washed and stored in physiological NaCl solution (without any preserving agent) for 24 h at 16 °C (c) or 5 °C (d) before lipid extraction. Both data sets (4a, b and 4c, d) differ significantly as the cryomedium contains a significant amount of egg yolk PC ( $m/z = 782.6$ , for instance, is attributable to the Na<sup>+</sup> adduct of PC 16:0/18:1) that—even after centrifugation through a Percoll gradient—sticks to the spermatozoa membrane [24] and cannot be simply removed from the spermatozoa extracts by the washing process. Although the egg yolk PC interferes with the spermatozoa membrane lipids, it is obvious that the preserved spermatozoa do not give significant signals in the low mass region (the peak at  $m/z = 551.0$  in trace 4a and 4b is a matrix peak [17]).

Compared to cryopreservation, unprotected storage of spermatozoa from both ruminants leads to plasmalogen oxidation (4c, 4d). The LPC content is most pronounced in the roe deer sample after storage at 5 °C (4d). In addition to LPC 22:6 at  $m/z = 568.4$  and  $590.4$  there are also intense signals of formyl-LPC 22:6 ( $m/z = 596.4$  and  $618.4$ ), but only very small signals indicating a cleavage of the double bonds along the docosahexaenoyl residue. Although a variety of such oxidation products was previously detected [5], their generation obviously does not play any major role in ruminantia spermatozoa. Additionally, the LPC 22:6 and formyl-LPC 22:6 ratio indicates that the generation of the latter species is slightly preferred under these conditions (cf. the intensities of the signals at  $m/z = 590.4$  and  $618.4$ ). Accompanying investigations of isolated plasmalogen and PC species gave very similar results and will be discussed below in more detail. Please note that the peaks at  $m/z = 531.4$  and  $553.4$  are not caused by oxidation but by the cleavage of the quaternary amine group of LPC 22:6 [23].

Further confirmation of peak assignments was obtained by PSD mass spectrometry. In Fig. 5 two typical PSD spectra of putative LPC 22:6 (5a) and formyl-LPC 22:6 (5b) are shown. The Na<sup>+</sup> adducts ( $m/z = 590.4$  and  $618.4$ ) were exclusively chosen as parent ions because Na<sup>+</sup> adducts give a more intense fragmentation pattern than the corresponding H<sup>+</sup> adducts [23]. The structural assignments of all observed fragments are also provided in Fig. 5. It is obvious that all detected fragment ions agree perfectly with the previous peak assignments and, accordingly, LPC 22:6 as well as formyl LPC 22:6 can be assumed as the prime products of plasmalogen oxidation.

Spermatozoa are known to contain different types of phospholipases [25] that might be released if the

**Fig. 3** Post source decay (PSD) MALDI-TOF fragment ion mass spectra of the spermatozoa lipids with  $m/z = 812.6$  (a) and  $814.6$  (b) as parent ions. The same sample as shown in trace 1a was used. The derived fragment ions were refocused onto the detector by stepping the applied reflector voltage in appropriate increments. This is done automatically by using the “FAST” (“fragment analysis and structural TOF”) subroutine of the Flex Analysis Program provided by

Bruker Daltonics. Please note that the reflector voltage was gradually increased from higher to lower masses. Therefore, in the same order the noise level increases. Structural assignments of the observed fragments are also provided (according to data given in [23]). Please note that under the applied PSD conditions no cleavage of C–C bonds occurs [20]

**Fig. 4** Positive ion MALDI-TOF mass spectra of organic extracts (obtained according to Bligh and Dyer) of spermatozoa from cattle (a, c) and roe deer (b, d). Samples shown in a and b were cryopreserved [21]. Samples in c and d were stored in NaCl solution for 24 h at 16 and 5 °C, respectively. All samples were mixed 1:1 (v/v) with a 0.5 mol/l DHB solution in CH<sub>3</sub>OH. Peaks marked with asterisks are caused by the DHB matrix. A more detailed methodological description of MALDI-TOF MS is available in [8] and typical matrix peak patterns are discussed in [16]

spermatozoa membrane gets damaged upon storage. We cannot rule out the contribution of phospholipases completely. However, formyl-LPC 22:6 may be only generated in the presence of oxygen. As the formyl-LPC 22:6 peaks possess a higher intensity than the LPC 22:6 peaks, we suggest the dominating role of oxidation processes but only a minor contribution of phospholipases.

In order to exclude that PCs (e.g., from the applied media or the spermatozoa) potentially interfere with the

observed oxidation products, one selected PC (1-palmitoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine, PDPC) was also investigated by positive ion MALDI-TOF MS prior (6a) and subsequent to air oxidation (6b). These results were compared with 1-*O*-1'-(*Z*)-octadecenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine prior (6c) and subsequent to air oxidation (6d). It is obvious from (6a) that pure PDPC does not provide any other peaks than the H<sup>+</sup> and the Na<sup>+</sup> adducts at  $m/z = 806.6$  and  $828.6$ , respectively.

**Fig. 5** PSD MALDI-TOF mass spectra of  $m/z = 590.4$  (a) and 618.4 (b) as parent ions. Structural assignments of the observed fragments are also provided. Please note that it was not the aim of this paper to assign details of fragment ion structures. Therefore, the positions of charges and ions were only made by comparison with reference data [23]

**Fig. 6** Positive ion MALDI-TOF mass spectra of 1-palmitoyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (PDPC) (a) and subsequent to air oxidation (b). Traces (c) and (d) correspond to pure 1-*O*-1'-(*Z*)-octadecenyl-2-docosahexaenoyl-*sn*-glycero-3-phosphocholine (c) and after exposition to air (d). 2,5-dihydroxybenzoic acid (DHB) was used as matrix and all samples (1 mg/ml) were mixed 1:1

(v/v) with a 0.5 mol/l DHB solution in CH<sub>3</sub>OH. Details on methodology and phospholipid oxidation are provided in “Materials and Methods”. The given structures correspond to intact PDPC and the corresponding oxidation product. For means of clarity the corresponding Na<sup>+</sup> adducts (but not the H<sup>+</sup> adducts) are exclusively shown

However, subsequent to air oxidation (6b), many peaks with lower masses are obvious. These peaks can be assigned to LPC 16:0 ( $m/z = 496.3$  and 518.3) that indicates the cleavage of the complete docosahexaenoyl residue and an oxidation product that corresponds to the cleavage of the double bond next to the ester linkage under generation of an aldehyde (cf. structure in the Fig) [7]. The two peaks with highest intensities ( $m/z = 580.4$  and 602.4)

can be easily assigned to the corresponding aldehyde, whereas the minor peaks at  $m/z = 596.4$  and 618.4 are assumed to correspond to the organic acid resulting from the oxidation of the initially generated aldehyde. There are no products indicating an oxidative cleavage along the docosahexaenoyl residue in other positions than the position next to the ester linkage. In contrast, the artificial oxidation of the plasmalogen (6d) gives nearly exclusively

LPC 22:6 and formyl-LPC 22:6. Therefore, in both cases the preferred oxidation site is the double bond next to the glycerol backbone and the number of the remaining olefinic residues along the acyl chain is less important.

From these results we conclude that (a) formyl-LPC 22:6 is an intrinsic marker of spermatozoa lipid oxidation and (b) this compound as well as LPC 22:6 can be easily determined by MALDI-TOF MS without the need of major sample workup. Both markers may be of high relevance for the determination of oxidative damages induced by the storage of spermatozoa (Fig. 6).

targets can be achieved using effective statins or combination therapy [11]. However, the net benefit in CVD risk reduction is around 50%. If we aspire to a better result we may also need to address other lipid risk factors, such as HDL-C [12] or TAGs.

To assess whether baseline fasting TAG levels independently predict subsequent CVD events in patients with established coronary heart disease (CHD) we carried out a post hoc analysis of the GREek Atorvastatin and coronary-heart-disease evaluation (GREACE) study [13]. We also investigated whether the extent of statin-induced reduction in TAG levels is related to a decrease in CVD events both in the entire study population and in the subgroup of patients with CHD and metabolic syndrome (MetS).

## Study Population: Methods

### Study Design, Patients and Methods

The entire duration of the GREACE study, including the recruitment period, was 4 years (January 1998–February 2002); the mean follow-up period was 3 years. The design of the GREACE study and its main findings has been previously reported [13–19]. Briefly, GREACE included 1,600 men (78%) and women (22%) with established CHD, aged <75 years (mean 58.3 years). Their serum LDL-C concentration was >100 mg/dL (2.6 mmol/L) and serum TAG levels <400 mg/dL (4.5 mmol/L). Patients with recent acute coronary syndromes were not excluded. All patients attended the Atherosclerosis or the Metabolic Syndrome Units of the University Hospital, Thessaloniki, and if eligible were randomized either into the structured care group, followed up by the University Clinic, or into the usual care group followed up by heart specialists or general practitioners of the patient's choice outside the hospital. In the structured care group, the starting dose of atorvastatin was 10 mg/day. With evaluations every 6 weeks the dose of atorvastatin was titrated up to 80 mg/day for patients not reaching the National Cholesterol Education Program Adult Treatment Panel III (NCEP ATP III) LDL-C goal (<100 mg/dL; 2.6 mmol/L) at lower dosages. Those in the structure care ( $n = 800$ ) received a mean dose of 24 mg of atorvastatin a day, and 95% of them reached the LDL-C target [13]. In the usual care group ( $n = 800$ ) only 12% of subjects were on statin treatment and only 3% were at LDL-C target [13]. Usual care consisted of lifestyle changes plus necessary drug treatment, including lipid lowering agents; atorvastatin was not excluded. All patients were followed for a mean of 3 years. Other secondary prevention treatments were similar in both treatment groups [13].

All recorded endpoints were based on hospital records. Two independent committees, one for each initial

GREACE patient group, recorded and validated endpoints. Each committee was blinded to the results of the other group. The analyses include all CVD events (excluding non-cardiac mortality), vascular events [excluding congestive heart failure (CHF)], and hard vascular endpoints [CVD death, non-fatal myocardial infarction (MI), and stroke]. Standardized criteria for endpoints were used in all treatment groups.

In the present post hoc analysis we performed three different analyses:

1. using the initial study design (structured vs. usual care-intention to treat analysis),
2. statin treated ( $n = 869$ ) vs. not statin treated subjects ( $n = 731$ ), irrespective of their initial allocation to structured or usual care groups (treatment based analysis),
3. dividing subjects into those with ( $n = 365$ ) or without MetS ( $n = 504$ ) on a statin vs. those with ( $n = 347$ ) or without MetS ( $n = 384$ ) not treated with a statin, irrespective of their initial allocation to structured or usual care groups (subgroup analysis).

The aim of this post hoc analysis was to evaluate the effect of statin-related TAG reduction on overall and vascular events both in the whole study population and in those with/without MetS. We also assessed whether baseline TAG levels predicted the risk of an event. CVD events included CVD death, cardiac morbidity (non-fatal MI, revascularisation, UA, and CHF) and stroke. Vascular events included non-fatal MI, revascularisation, UA and stroke. Hard vascular endpoints included CVD death, non-fatal MI, and stroke.

### Definition of MetS

Participants having three or more of the following criteria (according to the American Heart Association/National Heart, Lung, and Blood Institute statement [20]), were defined as having MetS:

1. Abdominal obesity: waist circumference (WC)  $\geq 102$  cm in men and  $\geq 88$  cm in women.
2. Hypertriglyceridaemia: fasting TAGs  $\geq 150$  mg/dL (1.7 mmol/L).
3. Low HDL-C <40 mg/dL (1.0 mmol/L) in men and <50 mg/dL (1.3 mmol/L) in women.
4. Raised blood pressure:  $\geq 130/\geq 85$  mmHg or use of antihypertensive medication.
5. Raised fasting plasma venous glucose:  $\geq 100$  mg/dL (5.6 mmol/L) or treatment for diabetes.

This definition is practically identical with that of the NCEP ATP III [8] but with a lower fasting glucose

threshold [100 mg/dL (5.6 mmol/L) instead of 110 mg/dL (6.1 mmol/L)].

## Assessments

After fasting overnight, total cholesterol, HDL-C and TAG were assessed using an Olympus AU 560 autoanalyser (Olympus Diagnostica GmbH, Clare, Ireland). LDL-C was calculated by the Friedewald formula [LDL-C mg/dL = total cholesterol in mg/dL – (TAG mg/dL/5 + HDL-C mg/dL)]. The non-HDL-C value was obtained by subtracting the HDL-C value from that of total cholesterol. Biochemical parameters in all patients were assessed at baseline, at the sixth treatment week and every 6 months thereafter.

## Statistical Analyses

On-study lipid values were compared with those at baseline, using analysis of variance (ANOVA) to assess differences over time within and between treatment groups. A univariate analysis was initially performed, including 25 predictors of CHD-related events. Then, after the removal of 6 predictors with a  $P > 0.10$ , the remaining 19 were used. To calculate the hazards ratio (HR) and 95% confidence interval (CI) for all vascular events during the entire duration of the study we used a multivariate Cox Predictive Model. This involved a time-dependent backward stepwise logistic regression using the mean TAG levels during the entire duration of the study as a continuous variable and 18 more predictors of vascular events as categorical variables (0–1). All univariate or multivariate analyses were performed at each 20% stepwise reduction in TAG levels. The SPSS 11.01 software package (SPSS, Inc., Chicago, IL) was used for all statistical analyses. A two-tailed  $P < 0.05$  was considered significant. We tested another possible model of stepwise regression. We calculated the change in variables (including TAGs) up to the 6th treatment month and then correlated this change with the time-dependent event rate in the two groups thereafter (two and a half year period). This analysis showed that correlations were similar with the method finally used (mean values and changes during the entire duration of the study; described above). The six-month method was not considered appropriate, because it would not include sharp changes in variables (during the remaining two and a half year period) due to drug discontinuation or drug addition. The benefit with every 20% reduction in TAGs (which are the last predictor used in the backward stepwise logistic regression analysis) was calculated after the extraction of the harm

or benefit induced by the rest of the CVD risk factors used in the multivariate model.

## Results (Tables 1, 2, 3)

### Overall GREACE Population

#### *Structured vs. Usual Care (Intention to Treat Analysis)*

TAG levels at baseline, after adjustment for body mass index (BMI) had a positive correlation with plasma glucose levels ( $r = 0.55$ ,  $P < 0.0001$ ) and smoking ( $r = 0.31$ ,  $P = 0.01$ ) and a negative one with HDL-C levels ( $r = -0.52$ ,  $P = 0.0002$ ). In the usual care group, baseline TAG levels were an independent predictor of overall vascular events (HR 1.20, 95% CI 1.06–1.59,  $P = 0.04$ ), after adjusting for LDL-C, HDL-C as well as the use of beta-blockers and angiotensin-converting enzyme inhibitors (ACE-I). The effect of atorvastatin treatment on plasma TAGs was dose-related. In subjects receiving 10–20 mg/d ( $n = 688$ ) the mean reduction in TAG levels was 29% and for those on 40–80 mg/d ( $n = 112$ ) the mean reduction was 35% ( $P < 0.0001$ ). The response to atorvastatin treatment was also related to the TAG baseline value (the higher the baseline value, the greater the reduction). In the structured care group subjects ( $n = 448$ ) with baseline TAG value  $> 150$  mg/dL (1.7 mmol/L) the mean reduction was 35%, while in those ( $n = 352$ ) with TAGs  $< 150$  mg/dL (1.7 mmol/L) at baseline the mean reduction was 24% ( $P < 0.0001$ ). The relationship of TAG level change during the study with clinical outcome (CVD events, vascular events, hard vascular endpoints) after stepwise regression analysis is shown in Table 2.

#### *Statin vs. No Statin Treatment (Treatment Based Analysis)*

We separated patients into those on a statin ( $n = 869$ ) and to those not on a statin ( $n = 731$ ) regardless of their initial allocation to structured or usual care. In those not on a statin, baseline TAG levels were an independent predictor of overall vascular events (HR 1.26, 95% CI 1.04–1.62,  $P = 0.03$ ), after adjusting for LDL-C, HDL-C as well as the use of beta-blockers and ACE-I. In the statin treated patients baseline TAG levels were not predictive of vascular events. The low percentage of women included in the study (22%) did not allow separate calculations of risk and relative risk reductions by gender. Stepwise regression analysis showed an association of TAG level change during the study with clinical outcome (CVD events, vascular events, hard vascular endpoints) (Table 3).

### Statin vs. No Statin Treatment in CHD Subjects with MetS [MetS (+)] or without Mets [MetS (–)] (Subgroup Analysis)

#### Treatment Groups and Predictive Value of Baseline TAGs

Group A consisted of 365 CHD patients MetS (+) who were on statins (mainly atorvastatin,  $n = 323$ ), Group B included 347 patients with CHD MetS (+) not on statin treatment, Group C included 504 CHD patients MetS (–) on a statin (mainly atorvastatin,  $n = 457$ ) and Group D included 384 CHD patients MetS (–) not on statins. In

groups A and C (all patients were on statin treatment), baseline TAG levels were not predictive of subsequent vascular events. In Group B (statin untreated), TAG levels were an independent predictor of overall vascular events (HR 1.32, 95% CI 1.06–1.59,  $P = 0.02$ ), after adjusting for LDL-C, HDL-C as well as the use of beta-blockers and ACE-I. After adjusting for glucose levels the predictive value of TAG levels for recurrent vascular events remained significant (HR 1.21, 95% CI 1.02–1.74,  $P = 0.04$ ). In Group D (statin untreated) high TAG levels ( $> 150$  mg/dL, 1.7 mmol/L) were predictive of CVD risk to a similar degree as in group B, but after adjusting for glucose levels

this predictive value was no longer significant (HR 1.17, 95% CI 0.89–1.86,  $P = 0.09$ ). The patient characteristics at the end of the study and their change from baseline are shown in Table 1.

### Effect of Statins on Lipid Profile

All patients in groups A [CHD MetS (+)] and C [CHD MetS (–)] were on statins. Of them, 90% were on atorvastatin (mean dose 23 mg/day), and the rest on different statins at various doses. Statin-treated patients experienced a reduction in LDL-C levels by 43% ( $P < 0.0001$ ). They had lower LDL-C levels than patients not receiving statin treatment in Groups B [CHD MetS (+)] and D [CHD MetS (–)] ( $P < 0.0001$ ) (Table 1), and most of them (92%) were at the NCEP ATP III LDL-C target ( $<100$  mg/dL; 2.6 mmol/L). In Groups A and C, TAGs were reduced by 32 and 30%, respectively,  $P < 0.0001$  vs. baseline and vs. Groups B and D for both comparisons, Table 1). Non-HDL-C was reduced by 44% in both Groups A and C ( $P < 0.0001$  vs. baseline and Groups B and D, for both comparisons, Table 1). The mean increase in HDL-C levels in Groups A and C was 8 and 7%, respectively ( $P < 0.005$  vs. baseline and vs. Groups B and D, for both comparisons, Table 1).

### Vascular Events in the Overall Population and MetS Patient Subgroups

During the (mean) 3-year follow-up there were 287 CVD events (including the fatal ones but excluding non-cardiac mortality). These were related to CVD mortality, non-fatal MI, UA, revascularisation, CHF and stroke. Of those there were 254 vascular events (excluding CHF), and after excluding revascularisation and UA (considered to be softer vascular endpoints) there were 156 hard vascular endpoints (CVD death, non-fatal MI and stroke). Five patients died from non-CVD causes.

### Overall Population According to Statin Treatment

In the untreated group ( $n = 731$ ) there were 180 (24.6%) CVD events (CVD mortality, non-fatal MI, UA, revascularisation, CHF, and stroke), while those on a statin ( $n = 869$ ) had 107 CVD events (12.3%,  $RR = 0.51$ , 95% CI 0.30–0.73,  $P < 0.0001$ ). In regard to vascular events (cardiac mortality, non-fatal MI, UA, revascularisation and stroke) in the respective groups there were 167 (22.8%) events vs. 94 (10.8%,  $RR = 0.48$ , 95% CI 0.26–0.75,  $P < 0.0001$ ). Finally, in regard to hard vascular endpoints

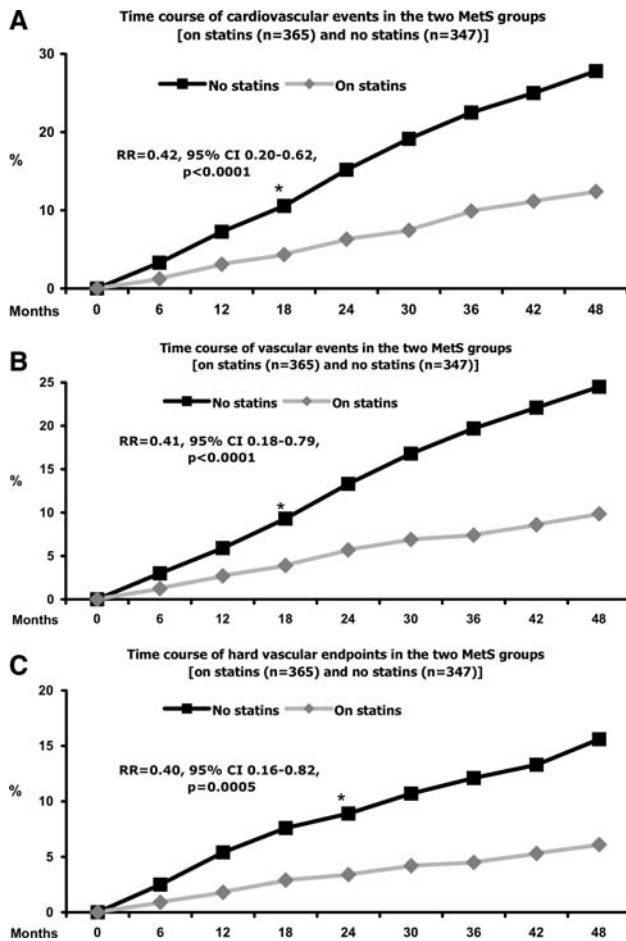

**Fig. 1** Number of patients with a recurrent cardiovascular disease (CVD) event (CVD deaths, non-fatal myocardial infarction (MI), unstable angina, revascularisation, congestive heart failure, and stroke panel A), vascular event (CVD deaths, non-fatal MI, unstable angina, revascularisation, and stroke panel B), and hard vascular endpoint (CVD deaths, non-fatal MI, and stroke panel C) in the treatment groups with or without the metabolic syndrome (MetS) on statin or without statin treatment

(cardiac mortality, non-fatal MI, and stroke) in the respective groups there were 99 (13.5) events vs. 56 (6.4%,  $RR = 0.47$ , 95% CI 0.24–0.78,  $P < 0.0001$ ) (Fig. 1).

### Subgroup Analysis According to Presence of MetS and Statin Treatment

In the subgroup analysis (Fig. 1) there were 42 (11.5%) CVD events in 365 patients with CHD + MetS on statins (Group A) and 96 (27.7%) in 347 patients with CHD + MetS but not on statin treatment (Group B); [risk ratio ( $RR$ ) = 0.42, 95% CI 0.20–0.62,  $P < 0.0001$ ]. In Group C ( $n = 504$ ), 65 CVD events were recorded (12.9%), while in Group D ( $n = 384$ ), 84 CVD related events (21.8%) occurred; ( $RR = 0.58$ , 95% CI 0.37–0.82,  $P < 0.0001$ ). The difference in vascular event rate between Groups A and C was not significant (11.5 vs. 12.9%,  $P = 0.1$ ), whereas the difference between Groups B and D was significant (27.7 vs. 21.8%,  $P = 0.002$ ). In regard to vascular events there was also a significant difference between groups A and B (36 vs. 54 events,  $RR = 0.41$ , 95% CI 0.18–0.79,  $P < 0.0001$ ). When only hard vascular endpoints were taken into consideration differences were very significant (22 vs. 54 events,  $RR = 0.40$ , 95% CI 0.18–0.88,  $P = 0.0005$ ). The time course of CVD events, vascular events, and hard vascular endpoints in the two MetS groups is shown in Fig. 2. Differences in CVD events ( $RR = 0.52$ , 95% CI 0.38–0.89,  $P = 0.001$ ), vascular events ( $RR = 0.53$ , 95% CI 0.36–0.91,  $P = 0.0016$ ) and hard vascular endpoints ( $RR = 0.54$ , 95% CI 0.41–0.92,  $P = 0.014$ ) were also significant between Groups C and D (Fig. 1), but at a lower level. The age ( $\pm$ SD) of subjects in

**Fig. 2** Change over time (up to 48 months) in cardiovascular disease (CVD) events (CVD deaths, non-fatal myocardial infarction (MI), unstable angina, revascularisation, congestive heart failure, and stroke panel A), vascular events (CVD deaths, non-fatal MI, unstable angina, revascularisation, and stroke panel B), and in hard vascular endpoints (CVD deaths, non-fatal MI, and stroke panel C) in the treatment groups with the metabolic syndrome on statin or without statin treatment. *MetS*, metabolic syndrome; *RR*, relative risk; *CI*, confidence interval. Asterisk time at which difference became statistically significant ( $P < 0.05$ )

Groups A, B, C, and D were  $59 \pm 8$ ,  $58 \pm 7$ ,  $59 \pm 6$ ,  $58 \pm 9$ , respectively ( $P = \text{NS}$ ). Percentage of smokers was very low (approximately 4%) and these were similarly distributed in the four treatment groups ( $P = \text{NS}$ ).

#### Relation Between TAG Levels Changes and Clinical Outcome in the Overall Population and MetS Patient Subgroups

The contribution of TAG level reduction (with each 20% decrease) to CVD risk reduction in the entire study population and subgroups in univariate and multivariate analysis is reported below. In the structured vs. usual care groups, univariate analysis of CVD events showed a HR of 0.74,

95% CI 0.52–0.86,  $P < 0.0001$ , while in multivariate analysis the HR was 0.88, 95% CI 0.75–0.95,  $P = 0.007$  (Table 2). In the patients treated with a statin vs. untreated patients univariate analysis of CVD events showed a HR of 0.76, 95% CI 0.55–0.88,  $P < 0.0001$ , while in multivariate analysis the HR was 0.92, 95% CI 0.81–0.97,  $P = 0.02$  (Table 3). In MetS patients on a statin vs. those with MetS not on a statin, univariate analysis of CVD events showed a HR of 0.71, 95% CI 0.53–0.87,  $P < 0.0001$ , while in multivariate analysis the HR was 0.85, 95% CI 0.65–0.94,  $P = 0.005$  (Table 4, part A). When only vascular events were taken into consideration univariate analysis of CVD events showed a HR of 0.74, 95% CI 0.48–0.86,  $P < 0.0001$ , while in multivariate analysis the HR was 0.82, 95% CI 0.57–0.96,  $P = 0.03$  (Table 4, part B), and when only hard vascular endpoints were considered univariate analysis of CVD events showed a HR of 0.78, 95% CI 0.51–0.95,  $P = 0.002$ , while in multivariate analysis the HR was 0.84, 95% CI 0.53–1.07,  $P = 0.08$  (Table 4, part C)

#### Discussion

This post hoc analysis of the GREACE study showed that fasting TAG levels predict vascular events among statin untreated patients with CHD. Patients who also had MetS were at a greater risk. Statin treatment (mainly with atorvastatin) resulted in a significant reduction in TAG levels and was related to a decrease in subsequent vascular events. This effect was independent of established risk factors, LDL-C, HDL-C or secondary prevention treatments. Patients with MetS experienced an even greater benefit from statin-induced TAG level reduction. In the present analysis of GREACE, all three pairs of patient groups compared [structured vs. usual care, treated with a statin vs. untreated, MetS (+) on a statin vs. MetS (+) not on a statin] received similar lifestyle advice and drug treatment for other CVD risk factors (e.g. diabetes, hypertension). Thus, the fall in TAG levels should mainly be attributed to statin treatment.

Our findings are in agreement with those of a study involving patients with premature CHD and controls, where fasting plasma TAG levels  $\geq 200$  mg/dL (2.3 mmol/L) were significantly associated with CHD even after adjusting for HDL-C and other risk factors [21]. Furthermore, the investigators found that the risk of premature CHD increased with high TAGs at all levels of HDL-C, even when HDL levels exceeded 40 mg/dL (1.0 mmol/L) [21].

In the present study the extent of TAG reduction after statin treatment was greater at higher the baseline TAG levels and the greater the statin-induced LDL-C reduction (or the higher the dose of the statin used), the greater was

<sup>a</sup> Eighteen univariate predictors of all vascular events all with  $P < 0.10$  (the above plus: gender male, gender female, current smoking, family history of premature coronary artery disease, arterial hypertension, diabetes mellitus, prior revascularisation, acute coronary syndrome, and prior myocardial infarction) were initially entered

<sup>b</sup> On treatment values were considered as the mean values of LDL-C and HDL-C during the entire study

CHD coronary artery disease, HR hazards ratio, CI confidence interval, LDL-C low density lipoprotein cholesterol, HDL-C high density lipoprotein cholesterol, ACE angiotensin converting enzyme inhibitors, TAGs triacylglycerols

the reduction in TAG levels. A similar relationship has been previously reported [22].

The statin-related TAG level reduction and associated decline in subsequent vascular events, independently of established CHD risk factors (including LDL-C and HDL-C) is reported for the first time. Endpoint trials focused on LDL-C reduction and in post hoc analyses investigated the joint effect of high LDL-C and TAGs as well as low HDL-C [23–26]. Investigators proposed that the higher CVD risk associated with elevated TAGs is due to the concomitant low HDL-C, a more established risk factor. For example, in two previous studies, the risk associated with TAGs  $\geq 200$  mg/dL (2.3 mmol/L) was dependent on low HDL-C levels or on an elevated LDL-C/HDL-C ratio [2, 26]. Nevertheless, a recent prospective study in a population with prevalent MetS showed that plasma TAGs is an independent predictor of CVD in men, but the risk increment did not reach significance in women [27].

Furthermore, in a meta-analysis of 17 population-based prospective studies of 46,413 men and 10,864 women, adjusting for HDL-C and other risk factors, there were increases of 16 and 42% in CVD endpoints in men and women, respectively, for every 100 mg/dL (1.1 mmol/L) increase in TAG level [4].

The Scandinavian Simvastatin Survival Study (4S) meta-analyses [23, 24], the joint meta-analysis of 4S and Air Force/Texas Coronary Atherosclerosis Prevention study (AFCAPS) [25], and the meta-analysis of Helsinki Heart Study (a fibrate trial) [26] showed that subjects with the lipid triad (elevated LDL-C, low HDL-C and increased TAGs) benefitted, both in primary and secondary CHD prevention, more than those with an isolated LDL-C increase. Nevertheless, 4S and AFCAPS did not assess the effect of statin-induced TAG reduction, after adjusting for LDL-C and HDL-C, on clinical outcome. The relatively “normal” baseline TAG levels and small reductions

achieved with the statins and doses used might be the reason for a lack of positive findings. In contrast, GREACE [13] had both higher baseline TAG levels and substantial reductions during treatment in most patients.

TAG-rich remnant-like lipoprotein (RLP) particles are atherogenic and predictive of CHD, [28]. However, RLP levels do not provide additional information about CHD incidence over and above TAG levels [28]. Therefore, their measurement may not provide valuable information if fasting TAGs are available [28]. The exact prognostic value of postprandial hypertriglyceridaemia remains to be established [29].

Atorvastatin lowers cholesterol content in all LDL subfractions (including small dense LDL particles), non-HDL particles, RLP lipoproteins, fasting and postprandial TAGs and TAGs in different very low-density lipoprotein (VLDL) classes [28–33]. Moreover, atorvastatin increases cholesterol in large HDL particles and significantly decreases the density of LDL particles resulting in a shift from small, dense LDL to more buoyant and less atherogenic particles [33–35]. This shift was mainly attributed to the significant (>30%, similar to that in our analysis) decrease in TAG levels in patients after atorvastatin treatment [34, 36]. Thus, the significant LDL-C reduction as well as a shift of LDL particles to a less atherogenic pattern might have contributed to the significant risk reduction we observed in statin-treated patients (mainly on atorvastatin). The NCEP ATP III [8] accepted small dense LDL as an emerging CVD risk factor [37]. However, the contribution of increasing LDL particle diameter in reducing CHD events is not yet widely acknowledged despite some supporting evidence from fibrate studies [26, 38]. After the Fenofibrate Intervention and Endpoint Lowering in Diabetes (FIELD) trial [39], it seems that targeting TAGs with a fibrate without a simultaneous substantial reduction in LDL-C and no increase in HDL-C does not result in clinical benefit. The contribution of other non-lipid effects of statins remains to be established [40, 41].

We also investigated MetS (+)/(-) subjects with elevated TAG levels because these patients are at a greater risk for recurrent CVD events even after adjusting for traditional risk factors [42]. Moreover, CHD MetS (+) patients are categorised by the NCEP ATP III 2004 update [43], as a very high risk group that need an even lower LDL-C target that those with stable CHD without MetS or diabetes.

### Study Limitations

The relatively small number of patients included in GREACE ( $n = 1,600$ ) and the small number of hard vascular

endpoints (CVD death, non-fatal MI, and stroke) does not allow a clear cut definition of the effect of TAG level reduction on the incidence of these events although there was a strong trend in this direction. The low percentage of women included in the study (22%) did not allow separate calculations of risk and risk reductions by gender but all analyses were adjusted for gender. The present study incurs all the limitations of a post hoc analysis.

### Conclusions

Fasting TAG levels predict CVD events in statin untreated CHD patients, especially in those MetS (+). The statin-induced reduction in TAG levels resulted in a significant decrease in risk of CVD and vascular events, which was independent of traditional risk factors, LDL-C, HDL-C or secondary prevention treatments. MetS (+) patients experienced an even greater benefit from statin-induced TAG level reduction. These findings suggest that statins that achieve a substantial reduction in TAG levels might provide an additional clinical benefit, especially in MetS (+) subjects.

Despite the growing body of evidence that DHA is important to health, the American diet is generally low in this nutrient. On average, Americans consume less than 100 mg of DHA per day [10, 11] despite recommendations for intakes of 200–300 mg DHA per day for pregnant and nursing women and 0.65–2 g per day of total long-chain omega-3 fatty acids DHA + eicosapentaenoic acid (EPA) for cardiovascular health [4, 12, 13]. The primary sources of dietary DHA are fish and marine foods. However, with recent concerns over oceanic contamination in some fish species and fish oils, and with US government warnings to reduce intake of some predatory species of fish, other, more sustainable sources of DHA are helping to meet a growing demand for this nutrient [14, 15]. Algae are the primary producers of DHA in the food chain, and two algal oil sources of DHA are available for fortification of infant formulas and foods, and for dietary supplements for adults including pregnant women.

One such algal DHA source, DHASCO<sup>1</sup>-T oil, is a triglyceride produced in a controlled, closed fermentation process by the microalga *Cryptocodinium cohnii*. This oil contains approximately 40% DHA by weight and no appreciable amount of any other polyunsaturated fatty acids (PUFA). This oil has been studied extensively in clinical trials in adults, children, and infants [16–35] and is now used commercially as a source of DHA for infant formula in the US and around the world. These studies consistently show increases in plasma and erythrocyte levels of DHA when infants receive formulas fortified with DHASCO-T oil and when adults and children were supplemented with DHASCO-T oil capsules. This algal oil has been widely tested for safety [36–41], and the US FDA has affirmed DHASCO-T as Generally Recognized As Safe (GRAS) for use in infant formula when combined with a fungal-derived arachidonic acid, ARASCO<sup>2</sup> (20:4n-6, ARA) oil [42].

Another algal DHA product, DHASCO-S, is a triglyceride produced by the microalga *Schizochytrium* sp. This oil also contains approximately 40% DHA as well as other PUFA including about 15% of the omega-6 fatty acid, docosapentaenoic acid (22:5n-6, DPAn-6) and 2.5% eicosapentaenoic acid (20:5n-3, EPA). The algae producing this oil have been used as an animal feed supplement in applications to enhance the level of DHA in eggs [43]. DHASCO-S oil has been used in a number of clinical studies [44–46], and the safety of the oil and the originating

algae have been confirmed [47–50]. This oil is affirmed as GRAS by US FDA for use in food fortification at levels up to 1.5 g DHA per day [51]. Both DHASCO-T and DHASCO-S oils have excellent organoleptic qualities, making them useful for food fortification applications.

Comparison of DHA levels following supplementation across clinical trials suggests that the DHASCO-T and DHASCO-S capsules deliver similar amounts of DHA to plasma, but different dosages and dosing schedules employed in these studies have made direct comparison between studies difficult. Moreover, previous studies suggested that DHASCO-T and DHASCO-S may have different effects on ARA and DPAn-6 levels in plasma, and others have suggested that DPAn-6 may interfere with DHA accretion. The present paper reports results from a clinical study undertaken to assess the bioequivalence, as well as the accretion kinetics and dose response, of DHA from the two algal-oil sources discussed above. The study directly compares DHASCO-T and DHASCO-S capsules at several DHA doses to each other as well as to an algal-oil fortified food, thus addressing the efficacy of fortified foods as vehicles for delivering dietary algal DHA. Bioequivalence of the algal DHA oils were assessed by comparing levels of the active ingredient, DHA, in plasma following 2- and 4-week supplementation of healthy adults.

## Subjects and Methods

### Experimental Procedures

#### Design

This study was an 8-arm, parallel group, randomized, clinical study designed to compare plasma phospholipid (PL) and erythrocyte DHA accretion after supplementation with either DHASCO-T or DHASCO-S algal DHA oil capsules over a range of DHA doses in a placebo-controlled, double-masked fashion, and to compare the capsules with an algal fortified snack bar (not masked). The study population included men and women in stable good health between the ages of 18 and 70 who resided in the greater Baltimore region. Pregnant women or adults consuming long-chain omega-3 supplements or whose intake of DHA exceeded 200 mg per day from their regular diet were excluded from the study. Dietary evaluation employed a validated seven-item food frequency questionnaire [52], which queried for intake of DHA/EPA-containing foods and calculated intakes based upon EPA and DHA contents reported in the USDA Nutrient Database for Standard Reference (release 14, 2002). One hundred and eleven subjects were screened for the study. The first 96 subjects who met the entrance criteria were

<sup>1</sup> DHASCO (DHA Single Cell Oil) is a registered trademark of Martek Biosciences Corporation of Columbia, MD, USA. DHASCO is contained in products marketed under the Martek trademarks of Neuromins, DHA Gold, Gold Circle Farms, Martek DHA, *life'sDHA* and in products sold by licensees under other trademarks.

<sup>2</sup> ARASCO (ARA Single Cell Oil) is a registered trademark of Martek Biosciences Corporation of Columbia, MD, USA.

randomly assigned to one of the eight treatment groups and received study supplements daily for 28 days. The treatments, outlined in Table 1, included placebo oil, and 200, 600, or 1,000 mg DHA doses from DHASCO-T or DHASCO-S algal oil capsules, or DHASCO-S-fortified snack bars. Study subjects were asked to maintain their normal diets, alcohol, and exercise levels throughout the study. Long-chain omega-3 intake from the subjects' background diet was monitored pre- and post-study by a validated food-frequency questionnaire. All adverse experiences were recorded and evaluated medically throughout the study period. Fasting blood samples for fatty acid analyses were collected by venipuncture at baseline, and after 14 and 28 days of supplementation. This study was conducted in compliance with Good Clinical Practices and conformed to the tenets of the Declaration of Helsinki. The protocol was approved by The New England Institutional Review Board (40 Washington Street, Suite 130, Wellesley, MA 02481, USA).

### Supplements

The study supplements were gelatin capsules containing 500 mg of DHASCO-T or DHASCO-S algal oil (Martek Biosciences Corporation, Columbia, MD, USA) or corn/soy placebo oil. The DHASCO-T and DHASCO-S capsules contained 201.5 and 194.2 mg DHA per capsule, respectively, and, as required for a bioequivalence study, were within 5% of each other for DHA content. The fatty acid composition of the algal oils and placebo oil are shown in Table 2. Subjects consumed 1, 3 or 5 capsules per day to achieve the desired doses of 200, 600, or 1,000 mg

**Table 1** Treatments administered

Group	DHA dose (mg per day)	Oil	Product form	# Capsules or bars per day
1	200	DHASCO-T	Capsules	1
2	200	DHASCO-S	Capsules	1
3	600	DHASCO-T	Capsules	3
4	600	DHASCO-S	Capsules	3
5	465	DHASCO-S	Snack bars	1
6	1,000	DHASCO-T	Capsules	5
7	1,000	DHASCO-S	Capsules	5
8	0	Corn/soy placebo	Capsules	1, 3, or 5

Subjects were instructed to consume 1, 3, or 5 capsules per day to achieve the desired DHA dose in the algal oil capsule groups. Within the placebo group, one third of the subjects were randomly assigned to receive one capsule per day, another one third to receive three capsules per day, and the remaining subjects to receive five capsules per day, to facilitate blinding and to ensure comparable fat intake with each of the DHA capsule treatment groups. Placebo subgroups were combined within a single placebo group for all analyses

DHA (Table 1). Since subjects in the placebo group were also randomly assigned to 1, 3, or 5 placebo capsules per day and all capsules were identical in appearance, the study was double masked, and placebo controlled for all capsule groups. A final supplementation group was assigned to receive 50 g chocolate-coated coconut snack bars containing 465 mg DHA from DHASCO-S oil. Bars were composed of 33 g carbohydrate, 2 g protein, 12 g fat, and 5 g water per bar.

### Fatty Acid Analyses

Blood for fatty acid analyses was collected into Vacutainer tubes containing EDTA and separated into plasma and erythrocytes by centrifugation. Erythrocytes were washed twice with isotonic saline. Both the plasma and erythrocytes were purged with N<sub>2</sub> and stored at -80°C until analysis. Plasma and erythrocyte lipids were extracted using the method of Folch [53] or the method of Bligh and

Dyer [54], respectively. The phospholipid fraction as well as the other lipid subfractions (sterol esters, triglycerides, unesterified fatty acids) of plasma were isolated by thin-layer chromatography (TLC) on silica gel plates developed in a 60:40:3 ratio solution (v/v/v) of hexane:ether:acetic acid. Internal standard (23:0 fatty acid) was added to each of the plasma lipid subfractions and total erythrocyte lipids. Lipids were saponified with 0.5 mol L<sup>-1</sup> NaOH in methanol, and the resulting fatty acids were methylated using 14% BF<sub>3</sub> in methanol and then extracted with hexane. The fatty acid methyl esters were separated by capillary column gas chromatography on an Agilent Series 6890 System equipped with a 30 m FAMEWAX (Restek, State College, PA, USA) column using a 48:1 split flow ratio with helium as a carrier gas and a programmed temperature gradient (130–250°C). Fatty acid methyl esters were identified by flame ionization detection and comparison of retention times to a mixed fatty acid methyl ester standard from NuChek Prep (Elysian, MN, USA). Fatty acids were quantified by comparison to the 23:0 internal standard. Individual fatty acid levels are reported as grams per 100 g total fatty acids or as an estimated concentration (μg mL<sup>-1</sup>).

#### Statistical Methods

The primary objective of this study was to establish the bioequivalence of DHA from DHASCO-T and DHASCO-S oil by comparing levels of the active ingredient DHA in plasma PL following dosing over a range of 200–1,000 mg DHA per day over a period of 4-week. A secondary objective was to assess the bioavailability of DHA from DHASCO-S in nutritional bars and its bioequivalence compared to soft gelatin capsules. The bioequivalence analysis was conducted in compliance with FDA standards for the statistical analysis of bioequivalence studies as described in the 1992 guidance [55]. Per this guidance, bioequivalence is established if the 90% confidence intervals for the geometric mean ratios of plasma levels of the active ingredient fall within the limits of 80–125%. Since baseline DHA and possibly subject weight was expected to be a significant covariate of interest, the geometric mean ratio was computed by fitting the following model:

$$\log \left( \frac{\text{week 4 DHA}}{\text{baseline DHA}} \right) = \text{treatment} \log(\text{baseline DHA}) \log(\text{weight})$$

where treatment is a class variable with levels designating each of the treatment groups.

Geometric mean percent changes and their standard errors were calculated for each treatment level by back

transforming the log scale LSMeans. Back transformations were done as follows:

$$\text{Geometric mean percent change} = 100 \times (e^{\log \text{ scale LSMean}} - 1)$$

$$\text{SE} = 100 \times (\log \text{ scale SE}) \times e^{\log \text{ scale LSMean}}$$

Geometric mean ratios were calculated between DHASCO-T and DHASCO-S treatments at each dose level (200, 600, and 1,000 mg). The geometric mean ratio and its confidence interval were calculated as follows:

$$\text{Geometric mean ratio} = 100 \times e^{(\log \text{ scale DHASCO-S LSMean} - \log \text{ scale DHASCO-T LSMean})}$$

$$\text{Lower bound} = 100 \times e^{\log \text{ lower bound}}$$

$$\text{Upper bound} = 100 \times e^{\log \text{ upper bound}}$$

where log lower bound and log upper bound are the respective boundaries for the 90% confidence interval for: log scale DHASCO-S LSMean – log scale DHASCO-T LSMean.

A step-down dose response testing scheme using a linear contrast in ANCOVA was implemented in order to assess the dose response relationship of DHASCO-T and DHASCO-S supplementation groups on plasma PL DHA levels. For this analysis, subjects were grouped together according to their dosage. Subjects receiving snack bars were not included in the analysis. The ANCOVA was performed on the change from baseline in plasma PL DHA levels and included main effect of dose and covariates baseline DHA and weight. The step-down trend testing scheme begins with testing a linear contrast up to and including the 1,000 mg dose group. If this contrast was found to be statistically significant, another linear contrast was tested with all dose groups up to and including the 600 mg dose. Testing continued in this same manner until a linear contrast had found to be non-significant or all linear contrasts had been tested. Since this was a closed testing scheme, no adjustments for multiplicity were used. All tests were performed to a 0.05 level of significance.

All analyses were performed on an intent-to-treat basis and included all subjects. As was contemplated in both the protocol and the statistical analysis plan, placebo subgroups receiving 1, 3, or 5 placebo capsules daily were combined into a single placebo group for analyses since there were no differences between the subgroups in DHA levels or in the main fatty acids found in placebo oil (LA or oleic acid) in either plasma PL or erythrocytes before or after supplementation. Statistics were performed using

SAS Version 8.2 (Cary, NC, USA) or MiniTab Software, version 13.32 (MiniTab, State College, PA, USA).

## Results

### Compliance and Baseline Demographics

This study compared DHA bioequivalence between two different algal DHA oil capsules, containing DHASCO-T or DHASCO-S oils, and also compared the bioavailability of these algal oil capsules to an algal-oil fortified snack bar. All 96 subjects completed the study along with all assessments. Mean compliance with study supplements over the 4-week study period, based on returned capsule or bar counts, was greater than 95% in all groups. All individuals, with one exception in the placebo group, consumed greater than 80% of their study supplements, the a priori lower limit for compliance as defined in the protocol. Subject weights and DHA intake from the background diet were stable throughout the study, and there were only minor changes in alcohol intake and exercise recorded in a few subjects. No subjects were excluded from the analyses based on these lifestyle changes. All analyses included all subjects on an intent-to-treat basis. The baseline demographic characteristics of the study groups are shown in Table 3. There were no statistically significant differences in weight, height, BMI, age, gender, race, or DHA intake at baseline between the study groups. Mean baseline dietary DHA intakes were less than 100 mg per day in each group, which is typical for American adults [10].

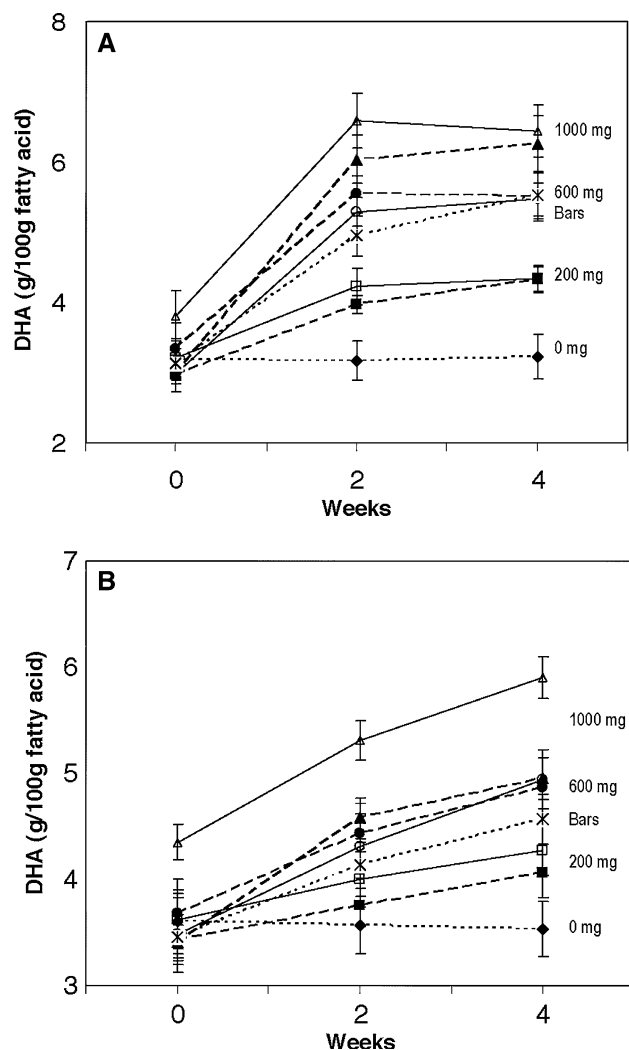

### Changes in DHA Fatty Acid Levels

Mean DHA levels in plasma PLs and erythrocytes at baseline and following supplementation for 2- or 4-week with DHASCO-T or DHASCO-S capsules, placebo capsules or DHASCO-S nutrition bars are shown in Fig. 1. Supplementation with both the DHASCO-T and DHASCO-S capsules resulted in similar rapid, dose-dependent increases in plasma PL DHA levels, with the majority of the increase occurring within the first 2 weeks of supplementation (Fig. 1a). Post-supplementation plasma DHA levels in the DHASCO-T and DHASCO-S capsule groups at each dose level were nearly identical. The DHA levels in the DHASCO-T and DHASCO-S capsule supplementation groups were compared at each dose level using the Student's *t* test. There were no differences between the groups at any time point at any dose level. Post-supplementation plasma DHA levels in the DHASCO-S bar group receiving 465 mg DHA per day were similar to those in the

**Table 3** Baseline demographics means ( $\pm$ SD) or counts were compared by ANOVA or Chi square analyses

There were no significant differences in baseline demographic characteristics between any of the study groups

**Fig. 1** DHA levels in plasma phospholipids. Mean ( $\pm$ SEM) DHA levels (g per 100g fatty acid) in plasma phospholipids (a) and erythrocytes (b) following supplementation with placebo (diamonds) or 200 mg (squares), 600 mg (circles), or 1,000 mg (triangles) of DHA per day from DHASCO-T oil (solid lines, solid symbols) or DHASCO-S oil (dashed lines, open symbols) or with snack bars (asterisks) for 2- and 4-week in plasma PL (a) and erythrocyte lipids (b). The DHA levels and concentrations in plasma PL and erythrocytes in the DHASCO-T and DHASCO-S capsule supplementation groups were compared at each dose level using the Student's *t* test. There were no differences between the groups at any time point at any dose level

DHASCO-T or DHASCO-S capsule groups receiving 600 mg DHA per day. There were no changes in plasma DHA levels in the placebo group over the 4-week supplementation period.

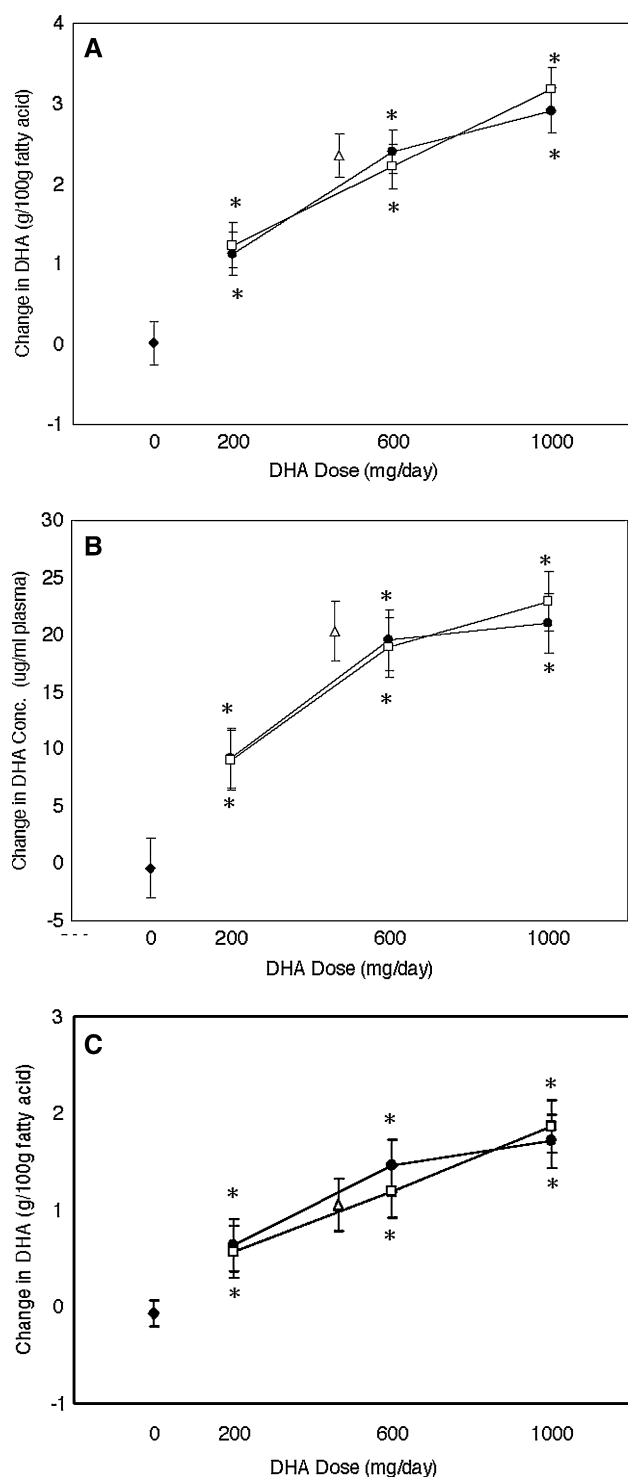

DHA levels also increased in a dose-dependent manner in erythrocyte lipids in all of the DHASCO-T and DHASCO-S capsule groups, as well as in the DHASCO-S bar group (Fig. 1b). In contrast to the plasma, the erythrocyte DHA levels rose more slowly and steadily throughout the 4-week treatment period in both the

DHASCO-T and DHASCO-S treatment groups. The erythrocyte DHA levels in the placebo group remained constant with time. The 1,000 mg DHASCO-T group had relatively high baseline erythrocyte DHA levels, but this was not statistically higher than the other groups. Nonetheless, the DHA levels in both the DHASCO-T and DHASCO-S 1,000 mg DHA treatment groups appeared to increase in a parallel fashion.

The mean change from baseline DHA levels as proportions of fatty acids and absolute DHA concentrations in plasma PLs and erythrocytes at the 4-week timepoint are shown in Fig. 2. The DHASCO-T and DHASCO-S oils resulted in very similar increases in DHA levels and concentrations with each of the DHASCO-T and DHASCO-S dose groups with no effect of the placebo. By visual inspection of Fig. 2, the nutritional bars (450 mg DHA per bar) resulted in increases in the DHA levels and concentrations in plasma PLs and erythrocytes similar to the 600-mg DHA doses from DHASCO-T and DHASCO-S capsules, suggesting similar or somewhat elevated DHA accretion with the bars. The DHA response in plasma PLs was highly dependent on baseline DHA levels ( $p < 0.001$ ), but there was no effect of age, race, weight, or gender on the DHA response (data not shown).

#### DHA Bioequivalence Assessments

Because DHASCO-T has been studied more extensively in clinical settings, it served as the reference compound and DHASCO-S as the comparator in this bioequivalence study. To assess bioequivalence of the two oils, the geometric LS mean ratio of the DHASCO-S to DHASCO-T 4-week change in DHA levels was calculated at each dose level. This ratio is expressed as a percent (100% represents unity). The 90% confidence intervals of the ratios must fall within 20% of unity (80–125% on a geometric scale) for the oils to be considered bioequivalent [55]. Figure 3 shows that the confidence intervals of the ratios of the DHASCO-S to DHASCO-T products at each DHA dose for both DHA levels and absolute concentrations in plasma PLs and erythrocytes fell within the 80–125% limits, thus establishing bioequivalence per FDA standards between the two products at all dose levels. A formal bioequivalence assessment was not conducted on the bar group because the doses were not within 5% of the capsule mid-dose level. However, the nutritional bars appeared to result in similar increases in the DHA levels in plasma PLs and erythrocytes as the 600 mg DHA doses from DHASCO-T and DHASCO-S capsules (Fig. 2), and therefore, DHASCO-S oil formulated into snack bars appears to deliver equivalent amounts of DHA on a per DHA consumed basis as DHASCO-S gelatin capsules.

**Fig. 2** Change in DHA levels and concentrations. LS Mean change ( $\pm$ SEM) in plasma PL DHA levels (a), in plasma PL DHA absolute concentrations (b) and in erythrocyte DHA levels (c) following 4-week of supplementation with placebo (filled diamonds), DHASCO-T (filled circles) or DHASCO-S (open squares) oil capsules or DHASCO-S fortified snack bars (open triangles). Capsule groups were compared to the placebo group using the step down trend test. \* $p < 0.05$  compared to placebo. Bar groups were not included in this analysis

### DHA Dose–Response Assessment

The DHA dose–response relationship of the two oils was explored using a step down trend test. Since the two oils resulted in equivalent DHA responses, the results from both oils at each dose level were initially combined for this dose response assessment. Mean DHA levels (95% CIs) in plasma PLs for the combined 200, 600, and 1,000 mg DHA doses increased by 1.17 (0.52, 1.82), 2.28 (1.63, 2.93) and 3.03 (2.38, 3.67) g per 100 g fatty acid, respectively ( $p < 0.001$  for each dose in comparison with placebo), indicating a dose–response relationship. Similar statistically significant dose-dependent increases in plasma PL and erythrocyte DHA levels and concentrations were observed when analyzed by the step down trend test for individual supplementation groups of DHASCO-T and DHASCO-S (Fig. 2). A general linear model analyzing the two oils separately further indicated that there was an effect of dose, confirming a dose response, and no interactions between dose and compound or dose by dose, indicating that the dose responses are linear and parallel for each compound for plasma PL DHA levels. In a regression model, with baseline DHA levels used as a covariate, the equation for the 4-week change in plasma PL DHA levels for the combined DHASCO-T and DHASCO-S oils group was:

$$\Delta \text{DHA levels} = 2.171 + 0.003 (\text{DHA dose}) - 0.535 (\text{baseline DHA level})$$

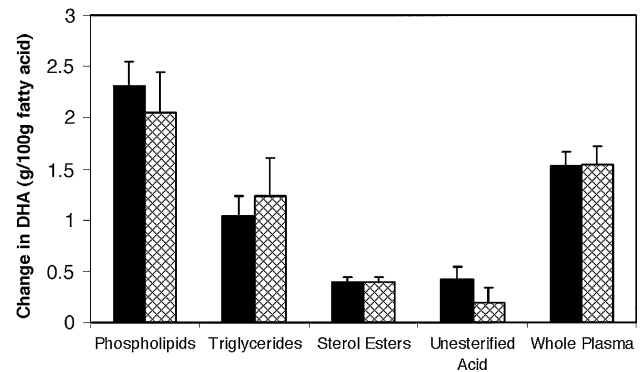

where DHA levels are expressed in g per 100 g fatty acids and DHA dose in mg per day ( $n = 72$ ,  $R^2 = 0.586$ ,  $p < 0.001$ ). This regression equation indicates that for every 100 mg of dietary DHA from either DHASCO-T or DHASCO-S oil supplements, plasma PL DHA levels increase by 0.3 g per 100 g fatty acid in the dose range studied.

### Effects on DHA Levels in Other Plasma Lipid Subfractions

We chose the mid-dose level to explore the effects of supplementation on the various lipid subfractions. Figure 4 shows the change from baseline in DHA levels in the various lipid subfractions of plasma after 4-week of supplementation with either DHASCO-T or DHASCO-S oil capsules at the 600 mg DHA dose level. Baseline DHA levels were 2.78 and 2.84 g per 100 g fatty acids in phospholipids, 0.40 and 0.51 g per 100 g in triglycerides, 0.45 and 0.46 g per 100 g in sterol esters, 0.62 and 0.58 g per 100 g as unesterified fatty acids, and 1.52 and 1.66 g per 100 g in whole plasma for DHASCO-T and DHASCO-S supplementation groups, respectively. Both oil supplements

**Fig. 3** DHA bioequivalence assessment. Graphs show ratios in percent of the LSmean change in DHA levels or concentrations of DHASCO-S to DHASCO-T ( $\pm 90\%$  confidence intervals). Ratios of plasma PL DHA levels measured in g per 100g fatty acids (a), of plasma PL absolute DHA concentrations as measured in  $\mu\text{g mL}^{-1}$  (b) and of erythrocyte levels as measured in g per 100 g fatty acids (c). Dotted lines show the limits of bioequivalence. The 90% confidence intervals of all the ratios fell within the 80–125% limits to establish bioequivalence

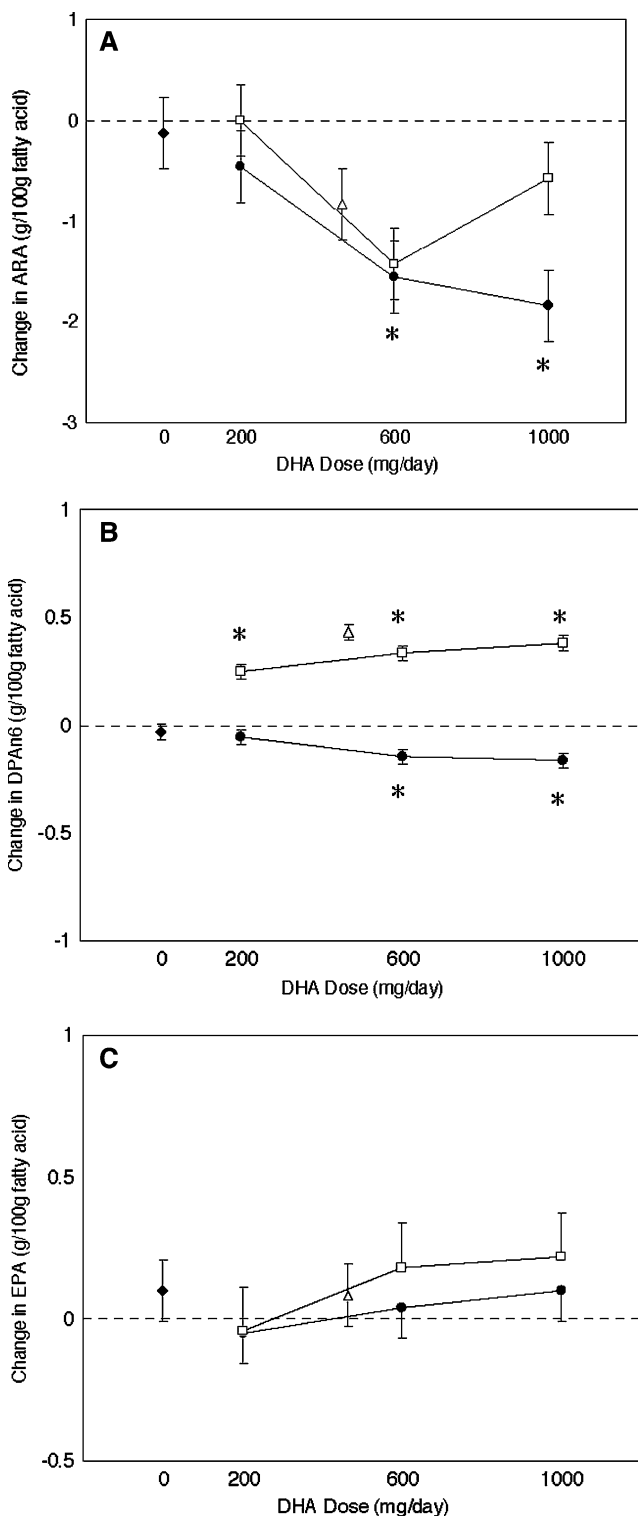

**Fig. 4** Changes in DHA Levels in plasma. Mean  $\pm$  SEM of the 4-week change in DHA levels in the various lipid subfractions of plasma following supplementation with DHASCO-T (solid bars) or DHASCO-S (hatched bars) at the 600 mg DHA dose level. There were no differences in the DHA responses between the supplementation groups when compared by Student's *t* tests

resulted in increases at the 4-week timepoint in DHA levels in each plasma fraction. There were no differences between the DHA responses of the DHASCO-T or DHASCO-S groups for any of the lipid fractions, indicating that the two oils resulted in the same magnitude of increase and the same distribution of DHA among the lipid fractions in plasma. Since unesterified fatty acids may be the bioactive form of fatty acids in plasma, we measured actual concentrations of unesterified DHA in whole plasma. The mean unesterified DHA concentration in plasma following supplementation with either oil ( $n = 24$ ) increased from 0.85 to 1.35  $\mu\text{mol L}^{-1}$  at this 600 mg DHA dose level.

#### Effects on ARA Levels

Baseline mean ARA levels in all groups ranged between 11.8 and 13.2 g per 100 g fatty acid in plasma PLs. The effects of DHASCO-T and DHASCO-S capsule and snack bar supplementation on the change in plasma PL ARA levels at the 4-week timepoint are presented in Fig. 5a. This figure shows a typical smooth dose-dependent reduction in ARA levels following DHASCO-T supplementation, with significant reductions in ARA at both the 600 and 1,000 mg doses relative to placebo (stepdown trend test). However, DHASCO-S supplementation resulted in a nonlinear ARA response with no significant reductions in ARA levels at any dose. The ARA levels between the oils deviated most at the 1,000 mg dose where the DHASCO-S nearly maintained ARA levels, whereas the DHASCO-T oil resulted in a significant reduction in ARA levels. This finding was corroborated by regression analysis showing a significant inverse correlation ( $r = -0.20$ ,  $p = 0.036$ ) between change in DHA levels and change in ARA levels when the DHA was provided by

**Fig. 5** Changes in other fatty acids. Four-week change in plasma PL ARA (a), DPAn-6 (b) and EPA (c) levels following supplementation with placebo (filled diamonds), DHASCO-T (filled circles) or DHASCO-S (open squares) oil capsules or DHASCO-S fortified snack bars (open triangles). Mean  $\pm$  SEM. Capsule groups were compared to the placebo group using the step down trend test. \* $p < 0.05$  compared to control. Bar groups were not included in this analysis

DHASCO-T capsules, but no such relationship ( $r = 0.11$ ,  $p = 0.187$ ) when DHA was provided by DHASCO-S capsules. The dose–response relationships between the oils and the resulting plasma ARA levels were further explored in post hoc analyses with general linear regression models using dose as a continuous variable. This analysis indicated a significant main effect of compound, i.e., differences between the DHASCO-T and DHASCO-S effect on plasma PLs ARA levels. Therefore, the dose response was further explored for each compound separately. These analyses confirmed a significant linear dose effect for DHASCO-T and a curvilinear (quadratic) dose effect for DHASCO-S<sup>3</sup>. Regression equations describing the dose effect of DHA supplementation from DHASCO-T on 4-week change in plasma PL ARA levels indicate that ARA levels decrease approximately 0.20 g per 100 g fatty acid for each 100 mg DHA dose from DHASCO-T.

#### Effects on DPAn-6 Levels

Baseline DPAn-6 levels in all groups ranged between 0.3 and 0.4 g per 100 g fatty acid in plasma PLs. The effects of DHASCO-T and DHASCO-S capsule and snack bar supplementation on the change in plasma PL DPAn-6 levels at the 4-week timepoint are presented in Fig. 5b. DHASCO-T oil led to a modest decrease in DPAn-6 levels, which was statistically significant at both the 600 and 1,000 mg dose groups (step down trend test) whereas DHASCO-S oil led to an increase in DPAn-6 levels at all three dose levels compared to placebo. The DHASCO-S nutritional bars led to an increase in plasma PL DPAn-6 levels of a similar magnitude to the mid-dose DHASCO-S capsules. These results are corroborated by regression analysis showing a highly significant reduction in DPAn-6 with DHASCO-T supplementation ( $r = -0.53$ ,  $p < 0.001$ ) and a highly significant increase in DPAn-6 ( $r = 0.62$ ,  $p < 0.001$ ) following supplementation with DHASCO-S, after adjustment for dose.

The efficiencies of DPAn-6 and DHA accretion following dietary administration of the respective fatty acids were evaluated by comparing actual concentrations in whole plasma following supplementation with the mid-dose of DHASCO-S oil capsules, which contains both fatty acids. The mid-dose DHASCO-S capsule group received 600 mg of DHA and 240 mg of DPAn-6 daily, which resulted in increases of 46.4 and 7.6  $\mu$ g of DHA and

<sup>3</sup> DHASCO-T ARA regression equation is: change in plasma PL ARA levels =  $4.087 - 0.002$  (DHA dose in mg per day)  $- 0.333$  (baseline ARA levels).  $n = 84$ ,  $R^2 = 0.420$ ,  $p < 0.001$ . The DHASCO-S ARA regression equation is: change in plasma PL ARA levels =  $3.971 - 0.005$  (DHA Dose) +  $0.000004$  (DHA Dose) (DHA Dose)  $- 0.296$  (Baseline ARA levels).  $n = 84$ ,  $R^2 = 0.224$ ,  $p = 0.01$ .

DPAn-6, respectively, per mL whole plasma. This suggests that DHA accumulates more efficiently in plasma ( $7.7 \mu\text{g mL}^{-1}$  plasma per 100 mg in the diet) than does dietary DPAn-6, which accumulates at  $3.2 \mu\text{g mL}^{-1}$  plasma per 100 mg dietary DPAn-6.

#### Effects on EPA and other Fatty Acids

Baseline mean EPA levels in plasma PLs ranged between 0.6 and 0.8% of fatty acids. The change in the plasma PL DHA levels are shown in Fig. 5c. EPA levels tended to modestly increase in a dose-dependent manner in both the DHASCO-T and DHASCO-S groups, with the DHASCO-S oil tending to have larger increases, but none of the differences was statistically different from placebo. Tables 4 and 5 available on line (Supplementary Material; doi: [10.1007/s11745-007-3098-5](https://doi.org/10.1007/s11745-007-3098-5)) show all fatty acid levels in plasma PLs and erythrocytes in each group at the 4-week timepoint. In addition to the aforementioned effects on PUFA, DHASCO-T and DHASCO-S oils result in significant dose-dependent reductions in DPAn-3 in plasma PLs and erythrocytes and in 22:4n-6 levels in plasma PLs. There was no effect of either algal oil on total saturated or monounsaturated fatty acid levels in either plasma PLs or erythrocytes (Tables 4 and 5, available through the journal online; doi: [10.1007/s11745-007-3098-5](https://doi.org/10.1007/s11745-007-3098-5)).

#### Safety

In compliance with good clinical practices, safety was assessed in this study by monitoring adverse events throughout the study. There were no deaths or serious or clinically significant adverse events (AEs) reported for any subject during the supplementation period. No subject discontinued supplementation due to an AE. All AEs were evaluated by the Investigator as being “Mild” to “Moderate” in severity. Only eructation was significantly associated with supplementation. Eructation was reported mainly by subjects receiving DHASCO-T 200 mg (50%), 600 mg (58%), and 1,000 mg (33%). Only one subject (1,000 mg) in the DHASCO-S groups reported eructation. A statistically significant difference was observed in the incidence of eructation between DHASCO-T 200 and 600 mg groups when compared to placebo. No other significant differences were noted.

#### Discussion

Previous studies have shown that both the DHASCO-T and DHASCO-S oils result in increases in plasma levels of DHA in humans. However, this was the first study to

compare the bioequivalence of these two different algal DHA sources. Bioequivalence was determined by assessing the levels as well the concentrations of the bioactive ingredient DHA in plasma and erythrocytes following 4-week of supplementation. The results of this study clearly establish that DHASCO-T and DHASCO-S oils are bioequivalent sources of DHA, per FDA standards, whether reported as proportions of fatty acids or as absolute concentrations of DHA in plasma or erythrocytes. This is also the first study to demonstrate that a DHA-rich oil, specifically DHASCO-S oil, incorporated into a fortified food, results in similar or somewhat enhanced amounts of DHA in blood as does supplementation with the encapsulated oil, indicating that DHASCO-S fortified foods are an appropriate vehicle for DHA supplementation. The observed trend toward enhanced bioavailability of DHA from food bars is consistent with previously reported greater bioavailability of LCPUFA from food rather than from capsules [56]. Those authors posited that the larger lipid bolus associated with food versus capsules activated lipid absorption. On the other hand, we conducted a clinical study demonstrating that the DHA in DHASCO-T oil capsules is equally bioavailable as the DHA in cooked salmon, a natural food source of this nutrient (Arterburn L manuscript submitted). Together, our results demonstrate that algal oil capsules, algal oil fortified foods or natural food sources of DHA are all equivalent sources of DHA with respect to raising blood levels of this nutrient. These sources all represent predominantly triglyceride forms of DHA. Others have found that DHA presented in capsules as an ethyl ester fish oil extract is not as bioavailable as DHA derived from fish, suggesting that triglycerides are the preferred DHA form with respect to bioavailability [56]. In this study, plasma PL levels of DHA increase at a rate of approximately 0.3 g per 100 g fatty acids for every 100 mg DHA administered over the daily dose range of 200–1,000 mg DHA. DHA accretion in plasma is highly inversely dependent on baseline DHA levels but is independent of age, weight, gender, or race.

The standard format for bioequivalence studies with pharmaceuticals is a pharmacokinetic crossover design following acute administration [57]. However, DHA washout times are on the order of weeks, so a crossover study is not appropriate [58]. Moreover, a more relevant measure for a nutrient such as DHA is to assess equilibrium plasma levels of DHA following subchronic rather than acute administration of the supplement, thus more closely mimicking a natural intake pattern. This type of assessment will not detect small differences in rate of uptake post-prandially, but rather assesses the more relevant measure of total accretion over time, which would reflect differences, if they exist, in the overall bioavailability, metabolism, and disposition of the DHA in the body. Plasma DHA levels are

known to equilibrate within approximately 2–3 weeks of daily supplementation [59]. Subjects in this study were supplemented for 4-week, ensuring measurement at an equilibrium state. The study therefore indicates that over time, these two algal oils result in equivalent plasma PL and erythrocyte equilibrium levels of DHA. Moreover, the study indicates that the DHA from DHASCO-T and DHASCO-S oils in plasma accumulates in and is distributed equivalently among the other plasma lipid subclasses, including sterol esters, triglycerides and unesterified fatty acid fractions, as well as in whole plasma. DHA as an unesterified fatty acid increased from 0.85 to 1.35  $\mu\text{mol L}^{-1}$  in whole plasma at the 600 mg DHA dose level. These concentrations may help determine physiologically relevant concentrations of DHA for designing and interpreting cell culture experiments.

The study included 2 weeks and 4-week assessments of blood DHA levels after supplementation, allowing assessment of the kinetics of uptake in blood. The results confirm earlier assessments that DHA levels in plasma PLs rapidly increase and reach new equilibrium levels after about 2 weeks of supplementation, irrespective of dose, and then remain at the new equilibrium level during the remaining course of supplementation [59]. Erythrocytes levels on the other hand continued to rise during the entire 4-week supplementation period, indicating that they had not yet reached an equilibrium status. Others have also reported slower equilibration of erythrocytes DHA levels in blood, which is not unexpected given their 120 days lifespan in the blood [59].

The DHA dose response was linear over the dose range studied. At higher doses of DHA, however, blood levels of this nutrient begin to saturate [59]. The range of doses used in this study (200–1,000 mg DHA per day, equivalent to approximately 3–14 mg  $\text{kg}^{-1}$  body weight per day for a 70-kg adult) encompasses doses to reflect levels in fortified foods, supplements and infant formulas. The high dose (1,000 mg DHA per day) is similar to DHA doses obtained by infants receiving fortified infant formulas in which DHA levels typically range between 0.1 and 0.35% of fat. This study therefore establishes bioequivalence of the DHASCO-T and DHASCO-S oils over a range of doses typical of intakes for infants and adults, and suggests that the oils may be interchangeable on a DHA basis for these applications.

The DHA contents of these two algal triglyceride oils are similar at ~40% of fatty acids. However, the overall fatty acid profiles of the DHASCO-S and DHASCO-T oils differ markedly. In particular, DHASCO-S contains a number of other long-chain PUFAs, including EPA at ~2.5% and DPAn-6 at ~15% of total fatty acids, whereas DHASCO-T oil has no appreciable amounts of any LC-PUFA other than DHA. It was unclear how other PUFA might affect the accretion of DHA from these oils. Both

DPAn-6 and DHA are 22-carbon PUFA that differ by one double bond at the omega-3 position, and it was possible that DPAn-6 may be accreted at the expense of DHA. However, this study clearly demonstrated that DPAn-6 had no effect on DHA accretion in either plasma or erythrocytes. Since plasma PLs are the primary carrier of lipids to tissues, tissue DHA levels are unlikely to be affected by the DPAn-6 present in the DHASCO-S oil either. Indeed, Lim et al. [60] have shown that co-administration of DPAn-6 with DHA does not interfere with DHA incorporation into brain tissue. To confirm this, a preclinical study to specifically address the question of whether accretion of DHA into multiple tissues is equivalent between both oils is being conducted in a piglet model.

An interesting and novel finding in this study is that while the oils were equivalent with respect to DHA bio-availability and accretion, they had markedly different effects on ARA levels. DHA supplementation, possibly through down regulation of  $\Delta 6$  desaturase and/or direct competition for acyl-CoA-mediated incorporation in phospholipids [61, 62], typically reduces ARA levels in plasma and tissues in a dose-dependent fashion, as was observed with the DHASCO-T supplementation in this study [59]. However, while the DHASCO-S oil at the low and mid-dose level resulted in the expected reduction in ARA levels, similar in magnitude to that observed with DHASCO-T oil, at the high dose it nearly maintained ARA levels in plasma, resulting in a curvilinear response on ARA levels in plasma. We hypothesize that the DPAn-6 contributes to maintaining ARA levels through a retro-conversion process of DPAn-6 to ARA, analogous to the DHA retroconversion to EPA [19, 59]. The curvilinear response represents a balance between the effect of DHA on reducing ARA levels, which predominates at the lower doses, and the DPAn-6 retroconversion to ARA, which predominates at the high dose, resulting in what appears to be a threshold effect of DPAn-6 occurring at the mid-dose level, which delivered 600 mg DHA + 240 mg DPAn-6. Since conducting this study, we have observed other ARA curvilinear responses of DHASCO-S oil in both animals and humans (L. Arterburn and A. Ryan, unpublished results).

The two algal oils also had differential effects on DPAn-6 plasma levels. As expected, DHASCO-T resulted in reduced levels of DPAn-6, whereas DHASCO-S resulted in elevated levels of DPAn-6 in plasma PLs. DPAn-6 levels increased at all doses of the DHASCO-S oil, but there was no apparent dose-response effect, suggesting that at higher doses of dietary DPAn-6, the fatty acid is converted to other fats, such as ARA, or simply  $\beta$ -oxidized for energy. Our study further indicated that the DHA accretion rate in whole plasma (approximately 8  $\mu\text{g}$  per 100 mg dietary DHA) was over twice the accretion rate of DPAn-6

(approximately 3  $\mu\text{g}$  per 100 mg DPAn-6) when the two fatty acids are administered in combination in the DHASCO-S oil. DPAn-6 accretion would be the net result of the DHA pressure to reduce this n-6 fatty acid and the tendency of the dietary DPAn-6 to accumulate as DPAn-6 or to be converted to other fatty acids, including ARA. The net result is that there is real but less pronounced accumulation of DPAn-6 following administration of DHASCO-S oil, whereas typically DHA oils significantly reduce the accumulation of DPAn-6.

The DHASCO-T and DHASCO-S oils had similar but small effects on EPA levels in plasma PLs, with a modest tendency to increase EPA levels, but not significantly so at the doses tested. The small increases in EPA levels are likely caused by the EPA present in the DHASCO-S, as well as retroconversion from DHA from the two oils.

Algal oils are produced in closed, tightly controlled fermentation facilities under Good Manufacturing Practices for foods, and unlike marine food sources, these oils are never in contact with oceanic contaminants. These oils, therefore, represent excellent and sustainable sources of bioavailable DHA.

## Conclusions

The algal oil sources of DHA, DHASCO-S, and DHASCO-T, provided in capsules or a fortified food, represent safe and equally bioavailable sources of DHA for humans. The DHASCO-S oil, at the highest dose is associated with maintenance of long-chain n-6 fatty acids in plasma, and therefore may be suitable for applications in which maintenance of ARA is beneficial.

methods to reduce body fat within their breeding programs. Considerable research efforts have been expended to study the factors that are associated with fat deposition and the methods needed to reduce it, and several beneficial solutions to address this complex problem have been identified [3–5].

Dehydroepiandrosterone (DHEA, 3 $\beta$ -hydroxy-5-androsterone-17-one) is a steroidal compound that is secreted by the mammalian adrenal cortex gland [6, 7]. It is known to be associated with various physiological actions, including antiobesity, antidiabetic and anticarcinogenic effects, when administered to rats and mice [8]. Many reports [9, 10] have described its effect on lipid metabolism. It has been shown to decrease serum TG levels in hyperlipidemic rats, and it also affects the peroxisomal  $\beta$ -oxidation pathway directly in mice hepatocytes [10–12]. Even though some research has been conducted on the regulation of DHEA on lipid metabolism in rats and mice, there has been a paucity of data generated on the effects of DHEA on lipid metabolism in broiler chickens. Our previous study (unpublished results) demonstrated that DHEA decreased abdominal lipid deposition and increased the rate of lipid catabolism by regulating serum metabolic hormones and parameters in broiler chickens.

The liver is the primary site of fatty acid synthesis in poultry [4]. Most of the body's endogenous lipids are of hepatic origin [13]. The liver shows a marked total fat content change, and TG, HL, and NEFA are primarily involved in hepatic lipid metabolism procedures [14, 15]. Many studies have shown that, among the different lipid metabolic pathway steps that can give rise to variations in the relative degree of obesity, liver fatty acid metabolism has been evidenced as the main source of variability [16, 17]. These results have prompted a focus on gene expression in the liver, particularly those genes that are involved in fatty acid synthesis and secretion [18, 19], including SREBP-1c, ACC, PPAR $\alpha$ , CPTI and ACOX1. In contrast to the large number of studies on these liver metabolic parameters and lipogenic gene mRNA expression variances induced by DHEA in mice, rats and humans [20, 21], little is known about the effect of DHEA on hepatic lipid metabolism in poultry, and especially in broiler chickens.

Therefore, the aim of the current study was to elucidate the effects of DHEA on abdominal lipid deposition, hepatic lipid metabolism parameters, and lipogenic gene mRNA expression in broiler chickens

## Experimental Procedures

### Animals and Housing

Seventy-two commercial broiler chickens (1-day age, 38 g, Nanjing Jiachang commercial broiler chicken company)

were housed from day 1 to 42 and included starter (day 1–21) and finishing (day 21–42) phases. Starter phase broiler chickens were housed in lighted coops (24-h day), with constant temperature ( $20 \pm 3$  °C) and humidity ( $50 \pm 3\%$ ); finishing phase broilers were kept on the ground with natural lighting. Nutrient levels of the diets (Table 1) were based on NRC (1994) recommendations [22]. Animal care and use above was approved by the Institutional Animal Care and Use Committee of Nanjing Agricultural University.

### Treatment and Diets

All broiler chickens were randomly divided into three equal groups (24 per group), and each group was assigned

**Table 1** Ingredients and nutrient composition of diets

Ingredient (%)	Starter (0–21 days)	Finisher (21–42 days)
Corn	52.6	57.4
Soybean meal	31.1	27

Nutrient level of the diets was based on NRC recommendations

<sup>a</sup> Crude protein content is 62.5% and ME is 2.79 Mcal/kg

<sup>b</sup> Metabolizable energy is 8.8 Mcal/kg

<sup>c</sup> Supplied per kilogram of diet: vitamin A (retinyl acetate) 1,500 IU, cholecalciferol 200 IU, vitamin E (DL- $\alpha$ -tocopheryl acetate) 10 IU, riboflavin 3.5 mg, pantothenic acid 10 mg, niacin 30 mg, cobalamin 10  $\mu$ g, choline chloride 1,000 mg, biotin 0.15 mg, folic acid 0.5 mg, thiamine 1.5 mg, pyridoxine 3.0 mg, Fe 80 mg, Zn 40 mg, Mn 60 mg, I 0.18 mg, Cu 8 mg, Se 0.15 mg

to 1 of 3 treatments. Birds in each group were kept in three pens (8 broilers each). All birds were offered a similar basal diet, with the addition of DHEA (Changzhou Jiaerke Pharmaceuticals Group Corp) at levels of 0 (control), 5 or 20 mg/kg. All birds had free access to feed and drinking water. Chickens were weighed individually at 42 days to determine final body weight. At the end of the experiment, food was withheld for 12 h before slaughter. After the birds were slaughtered, gender was identified, abdominal fat and liver were collected, blotted dry and weighed. The same part of the liver was cut into slices and rapidly frozen in liquid nitrogen, and stored at  $-80\text{ }^{\circ}\text{C}$  until RNA isolation. The liver blocks were isolated immediately for electron micrograph and the rest of them were stored at  $-40\text{ }^{\circ}\text{C}$  for the subsequent analysis of hepatic lipid parameters.

#### Determination of Hepatic Lipid Parameters Assay

A portion of the liver was homogenized, and the lipids were extracted with a mixture of chloroform-methanol (2:1 v/v) according to the method of Folch et al. [23]. TG content in the supernatant was determined by enzymatic/colorimetric GPO-PAP kit (Dongou, China) following the manufacturer's protocols. The optic density of the samples was measured using spectrophotometer in triplicate at a wavelength of 546 nm. Hepatic lipase (HL) and non-esterified fatty acid (NEFA) content was determined by using commercial kits from Nanjing Jianchen Biotechnology Institution. Approximately 100 mg of liver was homogenized on ice with 1 mL of physiological saline. An aliquot of these homogenates was used for protein determination according to the method described by Markwell et al. [24] and the remainder was centrifuged at  $1,000\times g$  for 10 min at  $4\text{ }^{\circ}\text{C}$ . Clear supernatants were used for the assay. HL and NEFA concentrations were directly proportional to the colour intensity and were determined by measurement of absorbance at 550 and 440 nm, respectively. One unit of HL enzyme activity represents 1 mg tissue protein releasing 1  $\mu\text{mol}$  of fatty acid per hour.

#### Electron Micrograph Preparations

Electron microscopy was conducted as described by Ikeda et al. [25]. Liver blocks were fixed in 2% glutaraldehyde in 0.1 M sodium phosphate (pH 7.4), post-fixed in 2%  $\text{OsO}_4$  in the same buffer, dehydrated and embedded in epoxy resin. Ultrathin sections were double stained with uranyl acetate followed by lead citrate and observed with a H-7650 transmission electron microscope (HITACHI Company, Japan).

#### Total RNA Isolation

Total RNAs were extracted from the liver by TRIZOL Reagent Kit (Sigma). The RNA concentration was then quantified by measuring the absorbance at 260 nm in a photometer (Eppendorf Biophotometer). Ratios of absorption (260/280 nm) of all preparations were between 1.8 and 2.0. Aliquots of RNA samples were subjected to electrophoresis through a 1.4% agarose-formaldehyde gel to verify their integrity. The RNA concentrations were adjusted to 1  $\mu\text{g}/\mu\text{l}$  by measuring the OD value, and stored at  $-80\text{ }^{\circ}\text{C}$ .

#### Oligonucleotide Primers Sequences

These primers were designed by premier 5.0 software (Premier Biosoft International, Palo Alto, CA, USA) and the positions are referred to chicken for SREBP-1c, ACC, PPAR $\alpha$ , CPTI, ACOX1 and 18s (Table 2). The primers synthesized by Shanghai Saibaisheng Biological Company were designed to flank known or putative introns, preventing amplification of any contaminating genomic DNA.

#### Semi-Quantitative RT-PCR

Two microgram of total RNA was reverse transcribed by incubation at  $37\text{ }^{\circ}\text{C}$  for 1 h in a 25  $\mu\text{l}$  mixture consisting of 100 U M-MLV reverse transcriptase (Promega, USA), 8 U RNase inhibitor (Promega, USA), 21  $\mu\text{mol/L}$  random primers (6 bp), 50 mmol/L Tris-HCl (pH 8.3), 3 mmol/L  $\text{MgCl}_2$ , 75 mmol/L KCl, 10 mmol/L DDT and 0.8 mmol/L each dNTP (Promega, USA). The reaction was terminated by heating at  $95\text{ }^{\circ}\text{C}$  for 5 min and quickly cooling on ice. Two microlitre of RT reaction mix was used for PCR in a final volume of 25  $\mu\text{l}$  containing 2.5  $\mu\text{l}$  of  $10\times$  PCR buffer, 2  $\mu\text{l}$  of each 2.5 mM dNTP mixture, 1 unit of Ex Taq DNA polymerase (Takara, Japan), 10 pmol of each forward and reverse primer. The condition of PCR amplification was as follows: one cycle at  $97\text{ }^{\circ}\text{C}$  for 5 min, 25–30 cycles at  $95\text{ }^{\circ}\text{C}$  for 30 s,  $50\text{--}60\text{ }^{\circ}\text{C}$  for 30 s and  $72\text{ }^{\circ}\text{C}$  for 1 min, and a final extension cycle at  $72\text{ }^{\circ}\text{C}$  for 10 min. The PCR products from each reaction were sent to Haojia Biotech, Ltd China for sequencing to verify the specificity. The reported sequences exactly matched those published in GenBank. PCR-amplified fragments were run beside molecular weight markers on 2% agarose gels stained with ethidium bromide. Gels were photographed with a digital camera and the net intensities of individual bands were measured using Kodak Digital Science 1D software (Eastman Kodak Company Rochester, NY, USA). The semi-quantitative measurement of gene expression was normalized to 18s.

### Statistical Analysis

The results were analyzed using GLM procedure of SAS software 9.0 (SAS Institute Inc., 2006). Independent variables included treatment, gender, and treatment  $\times$  gender interactions. Means and standard deviations were calculated and the mean differences were separated with the least significant difference procedure at the significance level of 95%.

## Results

### Body Weight and Liver Weight with Body Conversion Ratio

As shown in Table 3, body weight was significantly lower in female broiler chickens fed 5 and 20 mg DHEA/kg, and the same result was apparent in male broiler chickens fed 20 mg DHEA/kg, as compared to the control groups. During the experimental period, male broiler chickens fed 5 or 20 mg DHEA/kg and female broiler chickens fed 20 mg DHEA/kg had a significantly lower abdominal fat content when expressed as a percentage of body weight than did the control groups. In contrast, the relative liver weight was significantly higher than the control liver weight for both male and female broiler chickens.

### Hepatic Lipid Metabolic Parameters

The level of TG was significantly lower in female broiler chickens fed 5 or 20 mg DHEA/kg than those fed 0 (control), while in male broiler chickens, only those fed 20 mg DHEA/kg were lower. In contrast, male broiler chickens fed with 20 mg DHEA/kg resulted in a

pronounced higher level of HL as compared to the control group. However, no significant difference in HL was observed among female birds administered 0, 5, or 20 mg DHEA/kg. The concentration of NEFA was significantly higher in males and females at 20 mg DHEA/kg than at the control level (Table 4).

### Hepatic Lipid Metabolic Gene mRNA Expression

No significant differences were observed in both SREBP-1c (Fig. 1) and ACC (Fig. 2) mRNA expression in broiler livers treated with DHEA, except for a decline in the expression of ACC in females fed 5 mg DHEA/kg. As shown in Figs. 3 and 4, PPAR $\alpha$  and CPTI mRNA expression showed a trend toward enhancement as the treatment concentration of DHEA increased, in the absence of a gender difference, and the mRNA expression of both genes was higher in female as compared to male broilers. Similarly, this tendency toward increased mRNA expression was also indicated for ACOX1 gene (Fig. 5) in both male and female broilers. However, the peak expression of ACOX1 in male broilers was found at a treatment level of 5 mg DHEA/kg.

### Morphological Observations

The induction of hepatic peroxisome proliferation was examined by electron microscopy (Fig. 6). Normal broiler liver morphology (a limited number of peroxisomes with a visible core) is illustrated for male and female broiler chickens, respectively, in Fig. 6a, c (control groups). In contrast, numerous peroxisomes without a prominent core were evident in broilers fed 5 or 20 DHEA/kg (Fig. 6b, d,

respectively). The increase in the number of peroxisomes was the same in male and female birds.

## Discussion

The present study reports the effect of 5 and 20 mg/kg DHEA on body weight, abdominal fat weight, and the

**Fig. 2** Effect of DHEA on ACC mRNA expression in broiler livers

relative weight of livers in poultry. The results demonstrated that broiler chickens fed a DHEA-containing diet for 42 days had reduced body weight and abdominal fat weight as compared to a non-DHEA control group, regardless of gender difference. In contrast, liver weight as a percentage of body weight was significantly increased in these same birds treated with DHEA. The above results are in agreement with the results of Gansler et al [26], who reported that DHEA given chronically to lean or obese Zucker rats resulted in decreased body weight. The results

**Fig. 3** Effect of DHEA on PPAR $\alpha$  mRNA expression in broiler livers

**Fig. 5** Effect of DHEA on ACOXI mRNA expression in broiler livers

**Fig. 4** Effect of DHEA on CPTI mRNA expression in broiler livers

obtained here are also similar to a report [9], which showed that relative liver weight was enhanced in growing rats fed with DHEA. According to recent research [8], it is possible that DHEA activates hepatic mitochondria through the action of liver proteins, which enhance RNA transcription and subsequent protein synthesis, resulting in a higher relative liver weight than is evident in control-fed birds. However, the results of this study are in disagreement with those of Bobyleva et al. [27], which showed that DHEA did not significantly decrease body and liver weight in chickens. This discrepancy may be explained by the different breed and age of chickens used in the two studies. Furthermore, other results from our laboratory (unpublished data) have shown that supplementation of DHEA decreases

body weight and weight gain without having any adverse effect on feed intake. All chickens fed DHEA exhibited decreased abdominal fat weight with only a slight difference in breast and leg muscle weight, in accordance with previous studies that have found that DHEA administration reduces abdominal fat accumulation in both rats [28] and elderly women and men [29]. It is important to note that DHEA may decrease overall abdominal fat content without influencing feed intake or carcass composition.

The liver is the primary site of fatty acid synthesis in poultry [4]. Previous studies [30] have demonstrated that DHEA can induce a classic peroxisome proliferator-activated response via a procedure involving characteristic variances in hepatic peroxisome morphology and activation of gene transcription involving several PPAR $\alpha$  target genes, such as LPL, ACS and ACO [20]. Our morphological observations of hepatic peroxisomes illustrate that the liver from broilers fed with 5 or 20 mg DHEA/kg have some proliferation of hepatic peroxisomes without core and an increased number of peroxisomes, both in male and female birds. These findings were in accordance with previous reports [9] that state that rats treated with DHEA demonstrate a characteristic peroxisome multiplication. It is reasonable to suggest that DHEA, as a typical peroxisome proliferator, elicits all of these characteristic responses in broiler chickens. In the present study, supplementation of 5 or 20 mg DHEA/kg in male and female broilers improved the liver NEFA level. In contrast, the liver TG level declined in both male and female broilers. From the above findings, it is reasonable to speculate that DHEA directly stimulated the  $\beta$ -oxidation pathway in hepatocytes, catalyzed the conversion of TG to glycerol and fatty acids, and increased the hepatic uptake of the released

**Fig. 6** Electron micrographs of the liver peroxisome proliferation induced by DHEA from broilers. Ultrathin sections observed with magnification  $\times 10,000$ . **a, c** male and female control, **b, d** male and female DHEA-treated. *P* denote peroxisomes

NEFF [14, 15]. Another possible mechanism of action is that the dramatic activation of peroxisomal  $\beta$ -oxidation, which is associated with a more moderate induction of mitochondrial  $\beta$ -oxidation, results in less acyl-CoA esters being available to be utilized for triglyceride synthesis in birds treated with DHEA, leading to a decreased concentration of liver TG [20]. In addition to the above liver lipid metabolic parameters, HL is another important lipid metabolic enzyme produced primarily by the liver [31]. This study demonstrated a pronounced increase in HL activity after administration of 20 mg DHEA/kg in male broilers. In association with the increased HL activity, there were decreases in HDL-C in our previous study (results unpublished), consistent with the function of HL activity to catalyze the hydrolysis of triacylglycerols and phospholipids, mediate the removal of lipoproteins from plasma, and result in decreased lipid synthesis [31, 32].

As shown in Fig. 3, DHEA treatment caused a significant up-regulation of PPAR $\alpha$  expression in broilers liver tissue, which is in keeping with a recent study in Wistar rats [20], where significantly increased expression of PPAR $\alpha$  in liver tissue was observed. Together with the decreased abdominal fat effect caused by DHEA, one

possible explanation for this is that DHEA improved the activity of peroxisome proliferators activated receptor  $\alpha$  (PPAR $\alpha$ ). Activation of PPAR $\alpha$  induces transcriptional up-regulation of fatty acid transport proteins that facilitate fatty acid entry into cells and the enzymes involved in the  $\beta$ -oxidation of fatty acids, resulting in decreased expression of fatty acid synthesis [20]. Furthermore, although no obvious variance difference in SREBP-1c expression was found across treatments, a down-regulation tendency in gene expression was indicated for broilers treated with 20 mg DHEA/kg. A recent study [33] demonstrated that SREBP-1c activity and lipid synthesis in the liver was controlled by PPAR $\alpha$  through an increase in stearoyl-CoA desaturase activity. Our result, demonstrating enhanced SREBP-1c expression, in some way, was in agreement with that conclusion [33]. Moreover, different studies have shown that SREBP-1c can directly stimulate the transcription of genes encoding ACC [34, 35], making it a good candidate as a common regulator of the lipogenic genes expressed in the fat chicken lines. However, no significant variance in ACC expression was observed in the male broilers. Therefore, the non-significance of the expression analysis results for the SREBP-1c and ACC

genes indicates that neither of these two genes was directly responsible for the effect of DHEA on lipid synthesis at the DNA level. However, a weak expression of ACC was found in female broilers fed 5 mg DHEA/kg, which may have been the result of a combined effect of estrogen and DHEA. However, elucidation of the precise mechanism involved in the modification of ACC needs further investigation.

Similarly to the results for PPAR $\alpha$ , an increased tendency toward mRNA expression was also indicated for the ACOX1 gene in both male and female broilers, which is the first-step enzyme in peroxisomal  $\beta$ -oxidation [36]. Although its peak expression in females was shown at the treatment level of 5 mg DHEA/kg, the results are in accordance with a study conducted with turkeys, whereby the ACOX1 mRNA was highly expressed in the abdominal fat pad and in the liver [37], suggesting a strong peroxisomal FA  $\beta$ -oxidation capacity. The ACOX1 enzyme is the rate-limiting enzyme for peroxisomal FA  $\beta$ -oxidation. Its expression is regulated by PPAR $\alpha$  [38]. In the current study, it was demonstrated that a higher expression of ACOX1 was evident at a higher concentration of PPAR $\alpha$ , which verified the early reports that PPAR $\alpha$  increased the expression of ACOX1 in poultry livers [39, 40]. Our observation in broilers is similar to that seen in turkeys [37], mice [41], and humans [42], indicating that a considerable capacity for peroxisomal FA  $\beta$ -oxidation in liver is available in broiler chickens treated with DHEA.

Another interesting observation in this study was that the expression of CPTI was increased by DHEA, and that this was accompanied by an increased expression of PPAR $\alpha$ . CPTI catalyzes the formation of long-chain acyl-carnitine from activated fatty acids and free carnitine, thus committing fatty acids to oxidation [37]. By virtue of its inhibition by malonyl-coenzyme (CoA), CPTI controls the rate of  $\beta$ -oxidation and regulates the deposition or oxidation of fatty acids [43]. An increase in DHEA resulted in increased PPAR $\alpha$  expression in liver, which increased the rate of  $\beta$ -oxidation in liver cells and decelerated the transportation of acetyl-CoA from the mitochondria to the cytosol [44]. The rate of synthesis of malonyl-CoA decreases with a decline in the concentration of cytosolic acetyl-CoA [45]. By virtue of the decreased cellular synthesis of malonyl-CoA, the activity of CPTI in liver increases [46] and results in a higher rate of  $\beta$ -oxidation of fatty acids [47, 48], thus decreasing the abdominal fat content.

In conclusion, the present study confirms that the administration of DHEA in poultry accelerates liver catabolic processes through the regulation of the hepatic lipid metabolic pathways and the expression of the relevant genes involved.

physiological processes in these animals therefore changes in the lipid composition reflect changes in the ecology, nutrition, and health of corals. For example, coral bleaching is accompanied by significant variations in total lipid content and proportions of the main lipid classes in coral colonies [5–7]. The composition of lipids depends both on the currently prevailing food source of corals and the light regimes [8, 9] and varies during the annual cycle [10]. Also the lipid content of tumorous coral tissue is characterized by a reduced level of stored lipids [11].

The composition of fatty acids (FAs) is the primary common characteristic of lipids; therefore important aspects of coral life, with lipids involved, can be investigated by the analysis of coral FAs. FAs can serve as markers for a type of symbiotic zooxanthellae [12]; and they indicate the lipid exchange between symbionts and their coral host [13]. FA is most probably indicative of external food sources such as zoo- and phytoplankton in polytrophic feeding of corals [14].

FAs have been used for the biochemical classification of several groups of marine biota, such as bacteria, fungi, microalgae, plankton, macrophytic algae, and sea grasses [15–18]. Some combinations of FAs were supposed to be the distinguishing features of several taxonomic groups of reef-building corals [19, 20]; however, some investigators are inclined to conclude that FAs are not really useful for the biochemical classification of these cnidarians [3, 19]. On the one hand, this negative conclusion was due to a close resemblance of FA qualitative profiles of different coral species and the perceptible intraspecific variations of some FA contents exceeding the interspecific variations [21], on the other hand, a shortage of comparable FA data on numerous allied coral species was an obstacle to the fruitful advance of chemotaxonomy of corals. Recently, a principal components analysis (PCA) of FA composition was successfully applied to the chemotaxonomy of 32 soft coral species, and a clear division of soft coral specimens according to their orders (Gorgonacea, Alcyonacea, Antipatharia) was consequently attained [22]. Therefore, the application of PCA (or similar statistical methods) for the FA composition of sufficiently large species groups can be useful for the chemotaxonomic studies of another vast coral group—that of reef-building corals.

Studies of lipids in reef-building corals have not so far been systematic and data on FA contents of total lipids of the corals is limited [2, 3, 20, 23]. In the current study we both determined and compared the FA composition of 16 species of reef-building corals from Vietnam. We then supplemented this new data with the results of our earlier research on the subject [20] and sought to determine from this: (1) what taxonomic groups of reef-building corals can be distinguished through the use of FA data statistical processing; (2) what FAs are essential for this process; and

(3) what are the possible reasons of the differences in FA composition of the distinguished coral groups.

## Experimental Procedures

Sixteen species of scleractinian corals were collected by SCUBA divers in the South China Sea (Vietnam), firstly in the Nha Trang Bay in March–June 2004 at 2–4 m depths and, secondly, by the Mun Island (8°45'N, 106°38'E) in May 2005 at 1.5–2 m depths. The colonies were carefully cleaned of all non-coral debris. Three different colonies were used for a FA analysis. The corals were identified by the use of the taxonomic scheme of Wells [24].

The corals collected were placed into tanks under water at the site of collection and transported to the laboratory within half an hour. The coral samples were crushed into 1–3 mm pieces and total lipids were extracted by intensive homogenization in a chloroform/methanol (1:2, by vol.) mixture (30 ml for 10 g of coral weight). The obtained homogenate was filtered and the residue was repeatedly extracted (6 h, 4 °C) in a chloroform/methanol (2:1, by vol.) mixture (2 × 30 ml). The extracts were then mixed and separated into layers by adding 35 ml of water and 30 ml of chloroform. The lower layer was evaporated and the total lipids obtained were redissolved in chloroform and stored at –18 °C.

Fatty acid methyl esters (FAMES) were obtained by a sequential treatment of the total lipids with 1% sodium methylate/methanol and 5% HCl/methanol according to Carreau and Dubacq [25] and purified by preparative silica gel thin-layer chromatography (TLC) using the precoated silica gel plates Sorbfil PTLC-AF-V (Sorbfil, Krasnodar, Russia) developed in benzene. *N*-acylpyrrolidide derivatives of FAs were prepared according to Andersson [26] by direct treatment of the FAMES with pyrrolidine/acetic acid (10:1, by vol.) in a capped vial (1 h, 100 °C) followed by ethereal extraction from the acidified solution and purification by preparative TLC developed in ethyl acetate.

A gas chromatography (GC) analysis of FAMES was carried out on a Shimadzu GC-17A chromatograph (Shimadzu, Kyoto, Japan) with a flame ionization detector on a SUPELCOWAX 10 (Supelco, Bellefonte, PA) capillary column (bonded polyethylene glycol 20 M; 30 m × 0.25 mm i.d.) at 210 °C. Helium was used as the carrier gas at a linear velocity 30 cm/s (split ratio was 1:30). FAMES were identified by a comparison with authentic standards (a mixture of PUFA methyl esters No. 3 from menhaden oil was purchased from Supelco, Bellefonte, PA) and with the use of a table of equivalent chain-lengths (ECL) [27]. The structures of FAs were confirmed by gas chromatography–mass spectrometry (GC–MS) of their methyl esters and *N*-acylpyrrolidide derivatives. GC–MS of

FAMES was performed with a Shimadzu GCMS-QP5050A instrument (Shimadzu, Kyoto, Japan). The ionization of samples was undertaken by electron impact at 70 eV. Helium was used as the carrier gas at a linear velocity 30 cm/s (split ratio was 1:10) A Supelco MDN-5S (Bellefonte, PA) capillary column (bonded and crosslinked (5% phenyl)methylpolysiloxane; 30 m × 0.25 mm i.d.) was used at 160 °C with a 2 °C/min ramp to 240 °C held for 20 min. The injector and detector temperatures were 250 °C. GC–MS of *N*-acylpyrrolidides was performed on the same instrument, the injector and detector temperatures being 300 °C and 270 °C, respectively, the column temperature was 210 °C with a 3 °C/min ramp to 270 °C that was held for 40 min. GCSolution and GCMSSolution software (Shimadzu, Kyoto, Japan) were used for GC and GC–MS analysis. The percentage compositions of FAs were estimated by use of the GCSolution program, which integrated the GC chromatogram. All the data were the mean values of the results of the analyses of the FA composition of the three different colonies.

All variables (square root of ten PUFA contents) measured for the 35 specimens studied were included in multidimensional scale analyses (two dimensions used). The analyses were performed using the software STATISTICA 5.1 (StatSoft, Inc., USA).

## Results

Tables 1, 2, 3 show the data on distribution of fatty acids (FAs) in total lipids of 16 scleractinian species belonging to six families (Acroporidae, Pocilloporidae, Poritidae, Faviidae, Pectiniidae, and Fungiidae). Saturated 16:0 and 18:0 acids were predominant in all species. Other principal FAs were 14:0, 16:1(n-7), 18:1(n-9), 18:3(n-6), 18:4(n-3), 20:3(n-6), 20:4(n-6), 20:4(n-3), 20:5(n-3), 22:4(n-6), 22:5(n-3), and 22:6(n-3). The content of some ordinary even-chain acids, such as 18:1(n-7), 18:2(n-6), 20:1(n-7), 20:2(n-6), and 22:2(n-6), did not exceed the value of 2%. Except for *Sandalolitha robusta* (Fungiidae), odd-chain and methyl-branched FAs were detected in small amounts (0.2–1.4% of the total).

Saturated, mono-, di-, tri-, and tetraenoic very-long-chain FAs with 24 carbon atoms were identified in the Poritidae species. The mass spectra of methyl esters of 24:0, 24:1, two 24:2 isomers, 24:3, and 24:4 acids gave molecular ion peaks ( $M^+$ ) at  $m/z$  382,  $m/z$  380,  $m/z$  378,  $m/z$  376, and  $m/z$  374, respectively, confirming the presence of a corresponding number of double bonds and a  $C_{24}$  chain in the original FAs. Additionally, a strong characteristic peak at  $m/z$  348 ( $[M-MeOH]^+$ ) in mass spectra of 24:1 and a base peak at  $m/z$  79 with a peak at  $m/z$  108 characteristic of (n-3) polyunsaturated FAMES in mass-spectra of 24:4 were

observed. The first isomer of 24:2 was identified as methylene-interrupted 24:2(n-6) acid and a strong peak at  $m/z$  150 was particularly abundant in the mass spectra of its methyl ester [28]. The second isomer was nonmethylene-interrupted 24:2(5,9) acid. A combination of abundant ions at  $m/z$  81, 109, and 141 in its mass spectra was very characteristic of the 5,9-dienoic FAMES. The same characteristic peaks observed in the mass spectra of tetracosatrienoic acid methyl ester (24:3) indicated the presence of 5,9-dienoic fragment in the fatty chain.

The mass spectrum of the *N*-acylpyrrolidide derivative of 24:1(n-9) gave a molecular ion peak at  $m/z$  419 ( $M^+$ ) and diagnostic fragments at  $m/z$  280 and  $m/z$  292. Molecular ion peaks at  $m/z$  417 ( $M^+$ ), fragments at  $m/z$  140, 152, 194, 206, and at  $m/z$  280, 292, 320, 332 were found in the mass spectra of the *N*-acylpyrrolidide derivative of 24:2(5,9) and 24:2(n-6), respectively. The mass spectrum of the derivative of 24:3(5,9,17) gave a molecular ion peak at  $m/z$  415 ( $M^+$ ) and fragment peaks at  $m/z$  140, 152, 194, 206, 304, and 316. Also, the spectra from 5,9-unsaturated FA derivatives exhibited an intensive peak at  $m/z$  180. The mass spectrum of the *N*-acylpyrrolidide derivative of 24:4(n-3) showed a molecular ion peak at  $m/z$  413 ( $M^+$ ) and fragments at  $m/z$  238, 250, 278, 290, 318, 330, 358, and 370, indicating that the double bonds were localized at 12, 15, 18, and 21 carbon atoms of the original FA [26].

The ECL values on a SUPELCOWAX 10 column were 24.17, 24.42, 24.60, 25.03, and 25.36 for 24:1(n-9), 24:2(5,9), 24:2(n-6), 24:3(5,9,17), and 24:4(n-3), respectively. Each of these  $C_{24}$  acids amounted to no more than 0.3% of total FAs but they were absent in the other families investigated.

Unsaturated acids were about 50% of total FAs for all coral families studied. The highest levels of 18:1(n-7) and 16:1(n-7) were found in *S. robusta*. The contents of 20:4(n-6) and 20:5(n-3) ranged from 1.7 to 16.5% for the Acroporidae species, but the highest concentrations of 20:4(n-6) and 20:5(n-3) among all species studied were registered for *Acropora formosa* (14.7%) and *Acropora cerealis* (16.5%), respectively. The Pocilloporidae species were characterized by the highest average level of 20:3(n-6), 20:4(n-3), and 22:6(n-3), especially in comparison to the family Acroporidae. The average contents of principal PU-FAs in the Poritidae species were similar to that in the Pocilloporidae species, except for oleic acid (18:1(n-9)) and dihomo- $\gamma$ -linolenic acid (20:3(n-6)) whose highest concentration were 19.0% for *Porites lobata* and 3.1% for *Seriatopora hystrix*, respectively. Among all the species investigated, the most noticeable amount of 18:1(n-9) was recorded in *Echinophyllia orpheensis* (Pectiniidae). The average content of octadecatetraenoic acid (18:4(n-3)) was similar for all coral species investigated, but this acid was absent in *S. robusta*.

**Table 1** Fatty acid composition (% of total FAs) of Acroporidae

Values are mean ± SD ( $n = 3$ )

In general, the qualitative FA composition of the sixteen coral species investigated was similar enough and typical for other Scleractinia [3, 20]. To uncover differences in a quantitative FA composition, our data on PUFA content for the 16 specimens investigated were supplemented with that on the 19 reef-building coral specimens (the Acroporidae, Pocilloporidae, Poritidae, Dendrophylliidae, and Milleporidae families) studied previously by the same analytical protocol [20] (Table 4).

Figure 1 illustrates a comparison of the average contents of ten principal PUFAs for six reef-building coral families. Each family may be associated with characteristic FAs such as 18:3(n-6), 20:5(n-3), 22:4(n-6), and 22:5(n-3) for Acroporidae; 20:3(n-6), 20:4(n-3), and 22:6(n-3) for Pocilloporidae; 20:4(n-6) and 22:6(n-3) for Poritidae. The Faviidae species showed an enlarged percentage of 18:3(n-6) and 22:5(n-3) acids. The Dendrophylliidae, represented by *Tubastrea*, are mostly azooxanthellate corals [29]. Dominant among the fatty acids of the (n-3) series in the Dendrophylliidae were 20:5(n-3) and 22:5(n-3), while the proportion of DHA, the main PUFA in hermatypic corals, did not exceed 1%. The major PUFAs for Milleporidae (class Hydrozoa) were DHA and 22:5(n-6) (the sum was about 48% of total FAs) [20], though scleractinian corals have this last acid only in traces.

Five of the (n-6) series principal C<sub>18–22</sub> PUFAs (18:3(n-6), 20:3(n-6), 20:4(n-6), 22:4(n-6), 22:5(n-6)) and five of (n-3) series ones (18:4(n-3), 20:4(n-3), 20:5(n-3), 22:5(n-3), 22:6(n-3)) were selected as marker variables for further chemotaxonomic investigation of reef-building corals and subjected to multidimensional scale analysis (MSA).

Figure 2 shows the results of the MSA performed on data for the 35 specimens of 26 reef-building coral species belong to eight families. Curved lines were manually drawn to determine the boundaries of the regions for each family. Three coral families (Milleporidae, Dendrophylliidae, and Faviidae) were clearly separated in the non-overlapping regions of the two-dimensional space formed by axis 1 and axis 2. The central domain consisted of slightly-overlapping regions of the next three coral families (Acroporidae, Poritidae, and Pocilloporidae) (Fig. 2). Single species of Pectiniidae, as well Fungiidae, fell into the central domain. The separation of each family

is generated in both axis 1 and axis 2. At the family level, Milleporidae, Pocilloporidae and Dendrophylliidae separated from Acroporidae and Poritidae in axis 1. The families Milleporidae and Faviidae separated from other families in axis 2. Axis 1 serves as a discriminant between Acroporidae species, and axis 2 as that for Pocilloporidae species. The Acroporidae region was quite diffusive, and it could be conveniently divided into two groups whose separation was mainly caused by variations in 20:5(n-3) and 20:4(n-6) contents. Application of factor analysis to the same variables lead to a result (plots not shown) similar to that obtained by MSA (but with a longer distance between the non-scleractinian Milleporidae and other scleractinian corals). Axis 1 was most influenced by the main variable 22:4(n-6) followed by 20:3(n-6), 20:5(n-3), and 20:4(n-3). Axis 2 was mainly defined by 22:5(n-6) and 22:6(n-3) acids; 18:4(n-3), 22:5(n-3), 20:4(n-6); while the 20:5(n-3) acids were significant but had lower loading factors. Together both axes explained 68% of the total data variance.

## Discussion

Current data available on the FA composition of reef-building corals are very limited. Lipids and FAs of several wide-distributed species of the families Acroporidae, Pocilloporidae, and Poritidae have been described [3, 20] but the FA profiles of Faviidae, Fungiidae, and Pectiniidae species are practically unknown. The FA compositions of *Acropora cerealis*, *A. formosa*, *A. gemmifera*, *A. palifera*, *A. nobilis*, *S. hystrix*, *Porites nigrescens*, *P. lobata*, *Favia* spp., *E. orpheensis*, and *S. robusta* from Vietnam were determined in the present study for the first time, but the FAs of *Stylophora pistillata* and *Pocillopora damicornis* from the Seychelles and Vietnam had previously been investigated in our laboratory [20], and the lipid composition was described for *Porites cylindrica* from Okinawa [3].

In *S. pistillata* and *P. damicornis*, the concentrations of the main PUFAs determined earlier [20] were very close to that obtained in this present study (Table 2) except for 18:3(n-6) and 20:3(n-6) acids (the latter is biosynthesized

**Table 4** Reef-building coral specimens, which were used for comparison and multidimensional scaling analysis (MSA) of their fatty acid composition

by a C<sub>2</sub>-elongation of 18:3(n-6)). Previously, the abrupt depth-dependent increase of 18:3(n-6) level in *S. pistillata* was interpreted as being due to an increase in the number of zooxanthellae in deep-water corals [20]. Then, Zhukova and Titlyanov [12] confirmed that 18:3(n-6) acids are the main (n-6) series PUFAs in pure zooxanthellae isolated from *S. pistillata* and *P. damicornis*. It may therefore be presumed that one of the possible reasons for the variations in 18:3(n-6) content in *S. pistillata* and *P. damicornis* could be due to seasonal changes in the symbiotic algal population.

In the case of *P. cylindrica*, any direct comparison of our data with previous results was not possible because

analytical protocols were different, but the total FA profiles obtained in both studies were similar, except for docosahexaenoic acid (22:6(n-3), DHA). The concentrations of DHA in *P. cylindrica* from Okinawa were 0.8 and 0.9% for neutral and polar lipid fractions, respectively [3], contrary to the value of 8.7% that was detected for total lipids of *P. cylindrica* from Vietnam (Table 3). The reason for this difference is not clear but the last value conforms to the high levels of DHA (5.3–15.7% of total FAs) in five other Poritidae species from Vietnam, which were examined in our present and previous [20] studies.

The detection of a number of C<sub>24</sub> FAs, found only in the *Porites* species, seems very interesting, because the total

FA profiles (except for 18:1(n-9)) of the Poritidae and Pocilloporidae species investigated were quite similar. If C<sub>24</sub> FAs mentioned could be identified in other species of the family Poritidae, it may be an important chemotaxonomic sign of this family or the genus *Porites*. It has been shown that the subclass Hexacorallia, including the order Scleractinia, lacks marker tetracosapolyenoic 24:5(n-6) and 24:6(n-3) acids [30]. Our investigation confirmed the absence of the marker group of C<sub>24</sub> PUFAs with 5 and 6 double bonds in the scleractinian species, but another group of 24:0–24:4 acids was found in the genus *Porites*. It is clear that these two FA groups have completely different biosynthetic and biological origins. A biosynthetic sequence, including elongation and desaturation, from 20:4(n-6) and 20:5(n-3) acids to 24:5(n-6) and 24:6(n-3) acids, respectively, is supported by Vysotskii and Svetahev [31]. Contrary to this, most probably, the way for synthesis of the C<sub>24</sub> FAs in the genus *Porites* may be either a desaturation of 24:0 acids or an elongation of C<sub>22</sub> monoenoic (n-9) and polyunsaturated (n-6) acids. A Δ<sup>5,9</sup> non-methylene-interrupted double bond group presented in two of the five C<sub>24</sub> FAs from *Porites* is very typical of sponges [32]. It may be supposed that these FAs can originate from some sponges that infect corals but we did not find in the *Porites* samples the other main sponge markers, C<sub>26</sub> Δ<sup>5,9</sup> PUFAs (26:2Δ<sup>5,9</sup> and 26:3Δ<sup>5,9</sup>,19) that are very characteristic of Demospongia [32]. Whatever the case, we should consider the group of C<sub>24</sub> FAs as a signature of the *Porites* species if we are to precisely detect these FAs in all other Poritidae species collected at different times and places.

The highest level of *cis*-vaccenic acid 18:1(n-7) (3.6% of total FAs) and the sum of odd-chain and methyl-branched FAs (3.9% of total FAs) (Table 2) that are regarded as biomarkers of bacteria [33] were found in *S. robusta* (Fungiidae). It indicated the presence of an advanced bacterial community in this coral species compared to other species investigated.

To uncover differences in a quantitative FA composition of reef-building corals, we combined and compared our

data on the FA content for the 16 specimens obtained with those on the 19 reef-building specimens (belong to families Acroporidae, Pocilloporidae, Poritidae, Dendrophylliidae, and Milleporidae) studied previously [20]. The most interesting family-specific differences were observed in the content of polyunsaturated FAs (Fig. 1, ref. “Results”).

The availability of the family-specific sets of FAs (Fig. 1) pointed to a possibility of applying these FAs to the chemotaxonomy of reef-building coral based on an appropriate multivariate statistical method. In the example of soft corals, it has been recently shown that selected PUFAs are more suitable for the determination of significant distinctions between coral species than the total FA matrix [21, 22]. In the present study, the contents of five PUFAs of the (n-6) series and five PUFAs of (n-3) series mentioned above (Fig. 1) were used as the variables. According to general concept, PUFAs of (n-6) and (n-3) series are biosynthesized by chain-elongation and the desaturation of the corresponding (n-6) and (n-3) shorter-chain unsaturated FAs. Thus, in the case of reef-building corals, (n-6) series PUFAs that are selected for a statistical analysis may be presented as the links of the (n-6) pathway: 18:3(n-6)–20:3(n-6)–20:4(n-6)–22:4(n-6)–22:5(n-6). Correspondently, selected (n-3) series PUFAs form the (n-3) pathway: 18:4(n-3)–20:4(n-3)–20:5(n-3)–22:5(n-3)–22:6(n-3). These two parallel pathways were performed by the same sequential enzymatic actions: C<sub>2</sub>-elongation, Δ<sup>5</sup> desaturation, C<sub>2</sub>-elongation, and Δ<sup>4</sup> desaturation, but direct investigations of this process in coral hosts and zooxanthellae have not been published. There is strong evidence that the last enzymatic step is more complex and includes an elongation of PUFAs from C<sub>22</sub> to C<sub>24</sub> followed by Δ<sup>6</sup>-desaturation and degradation to Δ<sup>4</sup> C<sub>22</sub> PUFAs via β-oxidation [34]. However, the key tetracosapolyenoic acids 24:6(n-3) and 24:5(n-6) have not been found in Hexacorallia, and the absence of these acids are the central chemotaxonomic distinction between Hexacorallia (stony corals) and Octocorallia (soft corals) [31].

Multivariate analyses such as principal components analysis, factor analysis, and multidimensional scaling

**Fig. 1** Average content of principal fatty acids (% of total FAs) in families Acroporidae, Pocilloporidae, Poritidae, Faviidae, Dendrophylliidae, and Milleporidae, which are indicated in Table 4

analysis (MSA), were performed on the selected variables (data of coral PUFA contents). The most obvious plot was obtained by MSA (Fig. 2), furthermore, the using of other FA sets or total FA matrix have led to less clear plots. The MSA data plot shows (Fig. 2) that all representative reef-building coral families, which have essential phylogenetic and morphological distinctions [29] can be separated on the basis of their FA composition, and the select PUFAs may serve as chemotaxonomic markers of reef-building corals at the family level.

No significant differences were observed at species or genus level. In spite of the fact that *E. orpheensis* (Pectiniidae; point 22; Fig. 2) and *S. robusta* (Fungiidae; point 23; Fig. 2) fell into the Poritidae and Acroporidae regions, respectively (Fig. 2), the single species data is not enough to come to any conclusion about relationships between the families Pectiniidae and Poritidae, as well as Fungiidae and Acroporidae.

The established division (Fig. 2) was caused by the difference in content of individual PUFAs, mainly with 22 carbon atoms such as 22:4(n-6), 22:5(n-6), and 22:6(n-3) (Fig. 1). These marker PUFAs have not only different biosynthetic origins (mentioned above) but also different biological sources. Corals are polytrophic organisms, i.e., they simultaneously derive nutrients through a variety of mechanisms from different trophic sources, which include

**Fig. 2** Multidimensional scale analysis performed using the ten variables (square root of ten PUFA contents) measured in all the 35 reef-building coral specimens. Specimens are numbered as in Table 4. Curved lines were arbitrarily drawn to delimit regions for each family. the uptake of both particulate living and dead organic matter (POM) and the absorption of dissolved organic material. The POM supply is highly diverse in quantity and quality and comprises of different classes of plankton and organic detritus [35–37]. In zooxanthellate species, the phototrophic supply is delivered by endosymbiotic dinoflagellates [38]. All of these energy and food sources make a significant contribution to the total FAs of corals. Also, environmental conditions such as light intensity and water temperature induce seasonal changes in the coral lipids [10, 39]. The simultaneous influence of these factors leads inevitably to the dispersion of the FA content in coral samples [3], being the probable cause of the absence of chemotaxonomic differences at species and genus levels (Fig. 2).

The phototrophic supply is the most important carbon source for hermatypic corals. In some corals more than 90% of photosynthate may be released by the symbiont to its host cell [40]. Coral lipids and their FAs are mainly derived from carbon photosynthetically fixed by symbiotic dinoflagellates [2]. The active transport of saturated FAs from symbiotic dinoflagellates to the host is documented [2, 41]. As for unsaturated FAs, some studies suggest symbiotic dinoflagellates support only one PUFA [42], others suggest three PUFAs [39] or a diverse variety of PUFAs [13, 43]. The possibility of the translocation of total PUFAs of symbiotic dinoflagellates to the host is very probable, since hermatypic coral is able to digest up to 6% of its own symbiotic dinoflagellates per day and consume their lipids and proteins [44].

It is supposed that every coral taxonomic group contains dinoflagellates of its own type that is characterized by specific FA composition [12, 43]. The specific intracellular symbiotic dinoflagellates of “L” (large) type with a high content of exclusive 22:5(n-6) acid was found in hydrocoral species *Millepora intricata* [12, 45]. Other symbiotic dinoflagellates of “B” (brown) and “G” (green) types were found in scleractinian species *P. damicornis*, *S. hystrix*, and *S. pistillata* and characterized by the absence of 22:5(n-6) acid and a significant level of DHA [12].

Three coral groups examined such as hydroid coral Milleporidae, azooxanthellate Dendrophylliidae, and other zooxanthellate families have the most taxonomic and biological distinctions. The C<sub>22</sub> PUFA profiles of these three coral family groups were similar to the C<sub>22</sub> PUFA composition of their symbiotic dinoflagellates. Hydroid coral Milleporidae had extremely high levels of 22:5(n-6) acid (up to 10%) [20] but other hermatypic coral families (except of Dendrophylliidae) showed an absence of 22:5(n-6) acid and a noticeable concentration of DHA (about 10%) (Fig. 1). Correspondingly, the lowest level of DHA (1.4%) (Fig. 2) was found in Dendrophylliidae [20], which lack symbiotic dinoflagellates. Generally, corals without

zooxanthellae have low contents of polyenoic C<sub>18</sub> and 20:3(n-6) acids but high levels of characteristic 22:5(n-3) acid [20, 43].

Thus, the difference in FA composition of the symbiotic dinoflagellates may be one of the probable reasons for the difference in C<sub>22</sub> PUFA content of reef-building coral families; the latter mainly determine the chemotaxonomic separation of the coral families (Fig. 2).

In hermatypic corals, the algal population in a host should be viewed as a dynamic, and perhaps non-equilibrium, system [46]. The zooxanthellae community consists of several *Symbiodinium* phylotypes, which may have different FA compositions. The diversity of zooxanthellae in an individual coral taxonomic group depends on environment factors such as solar irradiance and water temperature [47]. In the coral host, the absorption and accumulation of zooxanthellate FAs are probably selective for some PUFAs. For example, there have been numerous unsuccessful attempts to detect in coral colonies any appreciable amount of 18:5(n-3) acid that is regarded as a marker for coral intracellular symbiotic [12] and free-living plankton [15] dinoflagellates. Therefore, additional studies of zooxanthellate FA diversity and transport will be useful for determining the limits and prospects of application of FAs for chemotaxonomic analysis of reef-building corals.

fatty acids are of pharmacological interest, since they are very good topoisomerase I inhibitors (IC<sub>50</sub> 0.9–1.3 μM) [11], display cytotoxicity, and more recently we have shown that they inhibit the enoyl-ACP reductase (Fab I) enzyme of *Plasmodium falciparum* (malarial parasite) with an IC<sub>50</sub> of 0.35 μM [12]. Therefore, fatty acids containing both an α-methoxy functionality and a Δ<sup>5,9</sup> double bond in a single acyl chain could be of considerable interest, not only as fatty acids with a unique and novel biosynthetic origin, but also as worthwhile marine natural products for pharmacological studies.

In this work is reported, for the first time, a novel series of α-methoxylated Δ<sup>5,9</sup> fatty acids with an interesting biosynthetic origin, and the complex phospholipid fatty acid composition of the Caribbean sponge *Erylus goffrilleri* (class Demospongiae, order Astrophorida, family Geodiidae) is also described.

## Materials and Methods

### General Experimental Procedures

Fatty acid methyl esters, pyrrolidides, and dimethyl disulfide derivatives were analyzed by direct ionization using GC–MS (Hewlett-Packard 5972A MS) at 70 eV equipped with a 30 m × 0.25 mm special performance capillary column (HP-5MS) of polymethylsiloxane cross-linked with a 5% phenyl methylpolysiloxane. The temperature program was as follows: 130 °C for 1 min, increased at a rate of 3 °C/min to 270 °C, and maintained for 30 min at 270 °C. IR spectra were recorded on a Nicolet 600 FT-IR spectrophotometer.

### Sponge Collection

The sponge *Erylus goffrilleri* (class Demospongiae, order Astrophorida, family Geodiidae, genus *Erylus*) (Weidenmayer 1977) was collected from Mona Island (near Cabo Norte), Puerto Rico in 13 July 2006 at 80 feet depth by scuba. The sponge was freeze-dried and stored at –20 °C until extraction. A voucher specimen (IM06-80) is stored at the Chemistry Department of the University of Puerto Rico, Río Piedras campus.

### Extraction and Isolation of Phospholipids

The sponge (17.7 g) was carefully cleaned and cut into small pieces. Extraction with 2 × 200 mL of CHCl<sub>3</sub>/MeOH (1:1) yielded the total lipids (5.4 g). The neutral

lipids, glycolipids, and phospholipids (3.1 g) were separated by column chromatography on Si gel (60–200 mesh) using the procedure of Privett et al. [13]. The phospholipid classes were qualitatively identified by thin-layer chromatography using Si gel H plates and CHCl<sub>3</sub>/MeOH/NH<sub>4</sub>OH (65:35:5) as developing solvent. The main phospholipids identified were phosphatidylethanolamine (PE), phosphatidylglycerol (PG), and phosphatidylserine (PS).

### Preparation and Isolation of Fatty Acid Derivatives

The fatty acyl components of the phospholipids (0.18 g) were obtained as their methyl esters by reaction of the phospholipids with methanolic HCl followed by column chromatography on Si gel eluting with hexane/ether (9:1). The methyl esters were hydrogenated in 10 mL methanol with catalytic amounts of Pd/C (10%). The double-bonds and methyl-branching positions in these compounds were determined by pyrrolidide and dimethyl disulfide derivatization following preparation procedures previously described [6, 9]. Mass spectral data for the novel methyl esters, and its derivatives, are presented below.

## Methyl (5Z,9Z)-2-methoxy-5,9-nonadecadienoate

ECL = 19.70, GC–MS  $m/z$  (relative intensity)  $[M-32]^+$  306 (1), 279 (2), 247 (3), 225 (1), 211 (1), 193 (1), 185 (1), 179 (2), 171 (2), 167 (1), 166 (3), 165 (3), 147 (2), 143 (3), 139 (13), 134 (2), 133 (3), 129 (3), 123 (6), 112 (5), 111 (21), 107 (10), 104 (37), 103 (3), 95 (23), 91 (9), 87 (17), 85 (29), 81 (40), 80 (14), 79 (34), 69 (46), 67 (46), 59 (16), 57 (83), 55 (100).

## Methyl (5Z,9Z)-2-methoxy-5,9-eicosadienoate

ECL = 20.70, GC–MS  $m/z$  (relative intensity)  $M^+$  352 (1), 320 (3), 293 (4), 261 (5), 254 (4), 234 (3), 225 (1), 193 (2), 181 (2), 171 (3), 166 (3), 147 (5), 139 (24), 135 (7), 134 (4), 133 (6), 129 (8), 123 (6), 112 (6), 111 (32), 107 (17), 104 (77), 103 (6), 97 (24), 95 (23), 91 (10), 87 (17), 85 (37), 81 (52), 80 (24), 79 (65), 69 (48), 67 (53), 59 (18), 57 (100).

## Methyl (5Z,9Z)-2-methoxy-15-methyl-5,9-hexadecadienoate

ECL = 17.32, GC–MS  $m/z$  (relative intensity)  $M^+$  310 (1), 278 (4), 251 (5), 219 (4), 197 (5), 193 (2), 192 (4), 185 (4), 179 (4), 171 (3), 166 (5), 165 (7), 153 (4), 147 (5), 143 (6), 139 (26), 135 (8), 134 (6), 133 (7), 129 (5), 123 (10), 112 (6), 111 (33), 107 (20), 104 (87), 103 (8), 95 (30), 91 (18), 87 (21), 81 (62), 80 (26), 79 (79), 69 (51), 67 (63), 59 (24), 57 (43), 55 (100).

## Methyl (9Z)-2-methoxy-15-methyl-9-hexadecenoate

ECL = 17.55, GC–MS  $m/z$  (relative intensity)  $M^+$  312 (1), 280 (5), 257 (1), 256 (1), 253 (24), 227 (0.1), 221 (3), 220 (4), 195 (1), 185 (1), 179 (2), 168 (1), 165 (3), 153 (2), 149 (4), 147 (2), 143 (5), 139 (4), 136 (7), 135 (11), 129 (4), 123 (14), 117 (5), 112 (3), 111 (16), 107 (10), 104 (31), 103 (3), 95 (55), 91 (12), 87 (17), 83 (46), 81 (64), 80 (21), 79 (34), 71 (61), 69 (66), 67 (75), 59 (17), 57 (44), 55 (100).

## Methyl 2-methoxy-15-methyl-9,10-bis(methylthio)hexadecanoate

GC–MS  $m/z$  (relative intensity)  $M^+$  406 (10), 359 (1), 247  $[C_{12}H_{23}SO_3]^+$  (73), 215 (2), 199 (3), 187 (5), 167 (12), 159  $[C_9H_{19}S]^+$  (29), 155 (20), 135 (5), 127 (16), 111 (17), 109 (14), 104 (9), 95 (24), 93 (15), 87 (46), 81 (30), 71 (94), 69 (89), 67 (40), 61 (40), 59 (15), 57 (88), 55 (100).

## Results and Discussion

The phospholipid composition of *E. goffrilleri* was typical of other sponges that have been previously analyzed [10]. It mainly consisted of phosphatidylethanolamine (PE), phosphatidylserine (PS), and phosphatidylglycerol (PG). The phospholipids were characterized by thin-layer chromatography (TLC) comparisons with authentic standards. Other minor phospholipids in the mixture were not characterized.

The fatty acids of the phospholipids were obtained by transesterification of the whole phospholipid mixture with HCl/MeOH as previously described [6]. *Erylus goffrilleri* presented a rather complex phospholipid fatty acid composition of around 70 identifiable fatty acids (Table 1). The presence of methyl-branched fatty acids was particularly noteworthy in the sponge suggesting the presence of a considerable number of bacterial symbionts. For example, the typical *isol anteiso*  $C_{15}$ – $C_{17}$  fatty acids of marine bacteria accounted for almost 21% of the total fatty acid composition. Other common bacterial fatty acids such as the 10-methylhexadecanoic acid (10-Me-16:0) and the 11-methyloctadecanoic acid (11-Me-18:0) were also particularly abundant in *E. goffrilleri* accounting for almost 13% of the total fatty acid composition. Another interesting characteristic of the fatty acids from *E. goffrilleri* was the presence of a considerable number of very-long chain  $\Delta 5,9$  fatty acids, but those between 26 and 29 carbons predominated. Most of the  $\Delta 5,9$  fatty acids were also *isol anteiso* methyl-branched, a not surprising fact since these so-called “demospongiac acids” are known to originate from bacterial *isol anteiso*  $C_{15}$ – $C_{17}$  fatty acids [10]. An *isol anteiso* pair of  $C_{21:2}$   $\Delta 5,9$  fatty acids was also present in *E. goffrilleri*, compounds which seem to be characteristic of the genus *Erylus* since these same fatty acids were characterized for the first time in the Caribbean sponge *Erylus formosus* [14]. Characterization of all of these fatty acids was possible by means of GC–MS of their corresponding methyl esters and pyrrolidide derivatives, which allowed the determination of the exact location of the methyl-branching in the acyl chain [15]. Monounsaturations in the acyl chains were best determined by preparing the corresponding dimethyl disulfide derivatives as previously described followed by mass spectrometry [16]. Catalytic hydrogenation ( $H_2/PtO_2$ ) of the whole fatty acid methyl ester mixture was also useful in elucidating the presence of unusual substitutions in the acyl chain as well as conversion of the unknowns to known standards. Comparison of GC retention times of the most interesting fatty acid methyl esters with our library of marine fatty acids also confirmed our mass spectral structural assignments [3].

The most interesting and novel series of fatty acids in *E. goffrilleri* were seven  $\alpha$ -methoxylated fatty acids present

<sup>a</sup> Unprecedented in nature

in less than 1.5% of the total fatty acid composition. Due to their presence in such small amounts in a complex fatty acid mixture, isolation of the individual fatty acids was practically impossible, and therefore, their characterization had to rely mainly in the GC-MS of the different derivatives. Four of these methoxylated fatty acids were a series of C<sub>16</sub>–C<sub>20</sub> normal-chain  $\alpha$ -methoxylated  $\Delta$ 5,9 fatty acids, identified as the acids (5*Z*,9*Z*)-2-methoxy-5,9-hexadecadienoic acid (**1**), (5*Z*,9*Z*)-2-methoxy-5,9-octadecadienoic

acid (**2**), (5*Z*,9*Z*)-2-methoxy-5,9-nonadecadienoic acid (**3**), and (5*Z*,9*Z*)-2-methoxy-5,9-eicosadienoic acid (**4**). The characterization of the methyl esters of **1–4** was complicated by the fact that, as we will see from the equivalent chain length (ECL) values, they co-eluted in GC with the corresponding one carbon longer non-methoxylated saturated *anteiso* fatty acid methyl esters. For example, methyl (5*Z*,9*Z*)-2-methoxy-5,9-octadecadienoate (ECL = 18.71) co-elutes in GC with methyl 16-methyloctadecanoate (*ai*-19:0), which presents the same ECL value. The methyl esters of **1–4** presented in their mass spectra a series of diagnostic peaks that allowed their full characterization (Fig. 1). All methyl esters presented a prominent and characteristic McLafferty rearrangement peak at  $m/z$  104 and a strong  $M^+$ -CO<sub>2</sub>CH<sub>3</sub> fragment due to  $\alpha$ -cleavage to the carbonyl. Revealing the presence of the  $\Delta$ 5,9 diunsaturation was a fragment at  $m/z$  171 (due to allylic cleavage between carbons 7 and 8) which readily loses a molecule of methanol to yield a more abundant and characteristic fragmentation at  $m/z$  139 (Scheme 1). The  $m/z$  139 fragment loses again another molecule of methanol (there are two methoxy substituents at this side of the molecule) to finally yield the fragmentation at  $m/z$  107. In addition, the  $\Delta$ 9 double bond in **1–4** was also confirmed by a second but less abundant allylic fragmentation between carbons 11 and 12 in the molecule, which resulted in a smaller fragment at  $m/z$  225. This fragment either loses the molecule of methanol to yield a  $m/z$  193 peak or a methoxy carbonyl fragment to afford another fragment at  $m/z$  166. Further loss of either a methoxy carbonyl fragment from the  $m/z$  193 peak or a methanol molecule from the  $m/z$  166 peak results in the same fragmentation observed at  $m/z$  134 (Scheme 1). Further confirmation of the  $\alpha$ -methoxy functionality and the linear chain present in **1–4** was obtained by catalytic hydrogenation of the whole fatty acid methyl ester mixture, which afforded the known methyl esters methyl 2-methoxyhexadecanoate, methyl 2-methoxyoctadecanoate, methyl 2-methoxynonadecanoate, and methyl 2-methoxyeicosanoate. The presence of the saturated analogs of **1–4** was confirmed by their mass spectra and comparison of their GC retention times with those of our library of saturated 2-methoxylated fatty acids previously isolated from other sponges. Fourier transform infrared (FT-IR) of the whole fatty acid mixture failed to yield an absorption between 900 and 1,000 cm<sup>-1</sup>, thus indicating the absence of *trans* double bonds in our fatty acid methyl ester mixture and favoring the *cis* assignment for all of the double bonds in the identified fatty acids.

Another set of interesting  $\alpha$ -methoxylated fatty acids in *E. goffrilleri* were three methyl-branched 2-methoxylated fatty acids. One of these, namely the 2-methoxy-14-methylhexadecanoic acid (2-OMe-*ai*-17:0) was previously described by us from an *Agelas* sponge [17]. However, two

of these  $\alpha$ -methoxylated methyl-branched fatty acids have not been described before in the literature. They were characterized as the (5*Z*,9*Z*)-2-methoxy-15-methyl-5,9-hexadecadienoic acid (**5**) and as the (9*Z*)-2-methoxy-15-methyl-9-hexadecenoic acid (**6**). The methyl ester of **5** ( $M^+$  = 310) presented the same mass spectral characteristics as the methyl esters of the acids **1–4** that we described above. However, its GC retention time was different from the other  $\alpha$ -methoxylated  $\Delta$ 5,9 methyl esters inasmuch as it displayed an ECL value of 17.32, thus implying methyl-branching in the acyl chain. A normal chain  $\alpha$ -methoxylated C<sub>17:2</sub> $\Delta$ 5,9 methyl ester would have been predicted to elute in GC with an ECL value of 17.70. Catalytic hydrogenation provided the means by which the *iso*-terminal methyl-branching was elucidated inasmuch as **5** was converted into the methyl 2-methoxy-15-methylhexadecanoate (2-OMe-*i*-17:0).

The second methyl-branched  $\alpha$ -methoxylated fatty acid in *E. goffrilleri* presented an ECL value of 17.55 and in its mass spectrum a molecular ion ( $M^+$ ) at  $m/z$  312, as well as a McLafferty rearrangement at  $m/z$  104; this indicates that **6** is a 2-methoxylated monounsaturated fatty acid. Upon catalytic hydrogenation the methyl ester of **6** was also converted into the 2-OMe-*i*-17:0, thus confirming the presence of the *iso* terminal methyl-branching. Dimethyl disulfide derivatization was key in elucidating the double bond position [16]. For example, methyl 2-methoxy-15-methyl-9,10-bis(methylthio)-hexadecanoate presented the key fragmentation ions at  $m/z$  247 [C<sub>12</sub>H<sub>23</sub>SO<sub>3</sub>]<sup>+</sup> and at  $m/z$  159 [C<sub>9</sub>H<sub>19</sub>S]<sup>+</sup>, which indicates a double bond at C-9. Therefore, the experimental data supports the (9*Z*)-2-methoxy-15-methyl-9-hexadecenoic acid (**6**) as the unknown in *E. goffrilleri*. Most of the previously identified 2-methoxylated monounsaturated fatty acids in sponges

**Fig. 1** Electron impact mass spectrum (70 eV) for methyl (5*Z*, 9*Z*)-2-methoxy-5,9-octadecadienoate

**Scheme 1** Characteristic allylic mass spectral fragmentations (70 eV) for the 2-methoxylated  $\Delta$ 5,9 fatty acid methyl esters

contained a  $\Delta$ 6 double bond [3], but the monounsaturated acid **6** in *E. goffrilleri* is different inasmuch as it has a  $\Delta$ 9 double bond. This indicates that  $\Delta$ 9 desaturases are important in the biosynthesis of fatty acids in *E. goffrilleri*.

The identified *iso*-methoxylated fatty acids **5** and **6** in *E. goffrilleri* are of interest since they could have originated from the acid *i*-17:1 $\Delta$ 9, which was also present in the sponge in a 4.8% relative abundance (Table 1). This tends to indicate that the fatty acid biosynthetic pathway *i*-17:1 $\Delta$ 9  $\rightarrow$  2-OMe-*i*-17:1 $\Delta$ 9  $\rightarrow$  2-OMe-*i*-17:2 $\Delta$ 5,9 might be operative in *E. goffrilleri*, or most likely, by a symbiotic microorganism within the sponge (Scheme 2). This is in contrast to the dual desaturation mechanism responsible for the biosynthesis of the very long-chain  $\Delta$ 5,9 fatty acids in sponges, i.e., sponge cells are capable of utilizing either a  $\Delta$ 5 desaturase or a  $\Delta$ 9 desaturase first, followed by the introduction of the other missing desaturations, either the  $\Delta$ 9 or  $\Delta$ 5 double bonds, respectively [10]. In animals the first double bond is normally introduced at C-9, with the second and subsequent ones inserted between the first bond and the carboxyl end [10]. Our proposed biosynthetic sequence for the 2-OMe-*i*-17:2 $\Delta$ 5,9 acid thus suggests that

**Scheme 2** Proposed biosynthetic origin for the (5*Z*,9*Z*)-2-methoxy-15-methyl-5,9-hexadecadienoic acid (**5**) in *E. goffrilleri*. The three fatty acids shown were identified in the sponge

the acid might be originating from a symbiotic microorganism within *E. goffrilleri* and not from a fatty acid biosynthesis within sponge cells. In fact, we have recently identified the 2-methoxypentadecanoic acid in a *Virgibacillus marismortui* isolated from Lake Pomorie in Bulgaria, which indicates that bacteria can be the primary source of this type of fatty acids (N. Carballeira and K. Stefanov, unpublished data).

In addition to the interesting biosynthetic proposals arising from our *E. goffrilleri* work, our results, besides presenting the complex phospholipid fatty acid composition of *E. goffrilleri* for the first time, also expand our present knowledge of possible 2-OMe- $\Delta$ 5,9 fatty acids to be found in sponges [3]. A few  $\alpha$ -methoxylated diunsaturated fatty acids were first reported from the sponge

*Higginsia tethyoides* [7], but the only reported example of a 2-OMe- $\Delta$ 5,9 fatty acid was the identification of the (5Z,9Z)-2-methoxy-5,9-hexacosadienoic acid in the sponge *Topsentia roquensis* [9]. The identification of the novel 2-OMe- $\Delta$ 5,9 fatty acids described in this work present new structural templates for further biological studies and the evaluation of these  $\alpha$ -methoxylated fatty acids as novel enzyme inhibitors.

## Introduction

Cholesterol is an essential class of lipids constituting bio-membranes. Cholesterol hydroperoxides (Chol-OOHs) are formed as primary products when cholesterol is peroxidized by reactive oxygen species. Chol-OOHs are known to be more resistant to glutathione peroxidase-dependent elimination than fatty acid hydroperoxides and their esterified form [1, 2]. Accordingly, Chol-OOHs seem to accumulate for a long time in biological fluid and tissues resulting in diverse effects on the body. It has been reported that exposure of experimental animals to chronic alcohol induces an imbalance of oxysterol metabolism by non-enzymatically produced cholesterol oxidation products including Chol-OOHs in skeletal muscle [3, 4] and liver [5]. Oxysterols derived from Chol-OOHs have been shown to participate in cell dysfunction as a result of oxidized plasma low-density lipoprotein (LDL) [6]. It has, on the other hand, been suggested Chol-OOH levels in rat skin increase with aging [7, 8]. Chol-OOHs are potential biomarkers of human oxidative stress, as indicated by the fact that Chol-OOHs have been clearly detected in the liver of alcoholic fatty liver patients [9], in human erythrocyte membranes [10], and in human skin after exposure to sunlight [11].

Chromatographic techniques such as HPLC combined with chemiluminescence (CL) detection are frequently applied to the quantitative analysis of Chol-OOHs in biological samples [4, 5, 7–11]. However, complicated and time-consuming pretreatment seems to be required for the preparation of Chol-OOHs from a variety of lipid classes. Furthermore, Adachi et al. [12] recently indicated that quantitative values of phosphatidylcholine hydroperoxide (PCOOH) obtained by HPLC with the CL detection technique are variable depending on the type of column used for the analysis. This implies that quantification of lipid hydroperoxides (LOOHs) using HPLC with CL should be performed carefully, with investigation of specificity. In contrast, gas chromatography–electron ionization–mass spectrometry (GC–EI–MS) with selected-ion monitoring (SIM) is a highly reliable method, because characteristic ions can be selected for monitoring specific compounds. In general, analysis of LOOHs by GC–EI–MS requires reduction of LOOHs to their hydroxyl derivatives as a pretreatment procedure, because LOOHs are thermally decomposed during GC–EI–MS analysis [13]. Thus

convenient pretreatment including separation and reduction procedures is desired for analysis of Chol-OOHs by GC–EI–MS/SIM.

We have already developed thin-layer chromatography (TLC) blotting with diphenyl-1-pyrenylphosphine (DPPP) reagent for simultaneous separation and reduction of LOOHs [14, 15]. We also succeeded in use of this technique for pretreatment in GC–MS/SIM analysis of cholesteryl ester hydroperoxide isomers in oxidized plasma LDL [16]. Here our objective was to develop a simple and sensitive method of analyzing peroxidized cholesterol, especially Chol-OOHs, using a combination of TLC blotting with DPPP reagent and GC–MS/SIM analysis.

## Experimental Procedures

### Chemicals and Reagents

Cholesterol was purchased from Kanto Chemical (Tokyo, Japan).  $\beta$ -Sitosterol was obtained from Tama Biochemical (Tokyo, Japan). Cholest-5-en-3 $\beta$ ,7 $\beta$ -diol (7 $\beta$ -hydroxycholesterol; Chol 7 $\beta$ -OH), cholest-5-en-3 $\beta$ ,25-diol (25-hydroxycholesterol), cholest-5-en-3 $\beta$ -ol-7-one (7-ketocholesterol), 5 $\alpha$ ,6 $\alpha$ -epoxycholestan-3 $\beta$ -ol (cholesterol 5 $\alpha$ ,6 $\alpha$ -epoxide), and 5 $\beta$ ,6 $\beta$ -epoxycholestan-3 $\beta$ -ol (cholesterol 5 $\beta$ ,6 $\beta$ -epoxide) were obtained from Sigma Chemical (St Louis, MO, USA). Cholestan-3 $\beta$ ,5 $\alpha$ ,6 $\beta$ -triol (cholestanetriol) and cholest-5-en-3 $\beta$ ,7 $\alpha$ -diol (7 $\alpha$ -hydroxycholesterol; Chol 7 $\alpha$ -OH) were purchased from Steraloids (Wilton, NH, USA). Trilinoleoylglycerol hydroperoxide (TLOOH) and linoleic acid hydroperoxide (LAOOH) were prepared from methylene blue-sensitized photooxidation products of trilinolein and linoleic acid, respectively, using preparative TLC, in accordance with a method described previously [17, 18]. PCOOH and phosphatidylethanolamine hydroperoxide (PEOOH) were prepared from methylene blue-sensitized photooxidation products of egg yolk PC and PE, respectively, and isolated using reversed phase-column chromatography [19]. All compounds were checked for purity by TLC. DPPP was purchased from Dojindo Laboratories (Kumamoto, Japan). Polyvinylidenedifluoride (PVDF) membranes, polytrifluoroethylene (PTFE) membranes, and glass fiber filters were obtained from ATTO (Tokyo, Japan). 2,4-Dimethylvaleronitrile (AMVN) and 2,2'-azobis(2-amidinopropane) dihydrochloride (AAPH) were products of Wako Pure Chemical Industries (Osaka, Japan). Hematoporphyrin was purchased from Sigma. *N,O*-Bis(trimethylsilyl)trifluoroacetamide in acetonitrile solution was obtained from Tokyo Kasei Kogyo (Tokyo, Japan). All other reagents and solvents were of guaranteed reagent grade from Kanto Chemical.

### Preparation of Peroxidized Cholesterol and Purification of Standard Chol-OOHs and $\beta$ -Sitosterol Hydroperoxide

Peroxidized cholesterol was prepared by azo radical-induced peroxidation of cholesterol or hematoporphyrin-sensitized photooxidation as follows. Cholesterol ( $0.1 \text{ mol L}^{-1}$ ; final concentration) was oxidized with AMVN ( $0.01 \text{ mol L}^{-1}$ ; final concentration) in 1:1 (*v/v*) hexane–isopropanol as solvent, at  $4^\circ\text{C}$  for 72 h. Photosensitized oxidation of cholesterol was based on the report by Kulig and Smith [20]. Briefly, cholesterol ( $8.3 \text{ mmol L}^{-1}$ , final concentration) was dissolved in 2:1 (*v/v*) chloroform–methanol containing *tert*-butyl hydroxytoluene ( $0.5 \text{ mmol L}^{-1}$ ). Hematoporphyrin ( $0.1 \text{ mmol L}^{-1}$ , final concentration) was then added and the solution was photo-irradiated with a tungsten projection lamp (300 W) at  $4^\circ\text{C}$  for 24 h. The hydroperoxide concentration of each solution was quantified using the potassium iodine method [21]. For preparation of  $\beta$ -sitosterol hydroperoxide (St-OOH),  $\beta$ -sitosterol was subjected to hematoporphyrin-sensitized photooxidation by the same procedure as used for cholesterol. St-OOH was purified from the photoirradiated solution using preparative TLC on silica gel F<sub>254</sub>, 0.25 mm thickness, 20 cm  $\times$  20 cm (Merck, Germany) with 93:7 (*v/v*) hexane–isopropanol as mobile phase. The band that newly emerged was scraped off and extracted. This extract was dissolved in 2:1 (*v/v*) chloroform–methanol. Chol-OOH for the TLC blot analysis of the standard LOOH mixture was separately prepared by methylene blue-sensitized photooxidation as follows. Cholesterol ( $65 \text{ mmol L}^{-1}$ ) was dissolved in 2:1 (*v/v*) chloroform–methanol containing methylene blue ( $0.1 \text{ mmol L}^{-1}$ ) and photoirradiated with a tungsten projection lamp (300 W) at  $4^\circ\text{C}$  for 6 h. Chol-OOH was isolated by preparative TLC using the same procedure as for St-OOH.

### Preparation of Peroxidized Human Low-Density Lipoprotein

Blood plasma was obtained from heparinized blood samples by centrifugation for 10 min at  $4^\circ\text{C}$ . Low-density lipoprotein (LDL) was obtained by density-gradient centrifugation, as described elsewhere [22]. Briefly, plasma obtained from male volunteers was adjusted to  $d = 1.21$  with KBr and overlaid with saline ( $d = 1.008$ ), and centrifugation was performed at 600,000 g for 40 min at  $4^\circ\text{C}$ . Then the LDL fraction was collected. Protein content was adjusted to  $1.2 \text{ mg protein mL}^{-1}$  phosphate-buffered saline (PBS). Oxidation of LDL was initiated by addition of AAPH ( $1 \text{ mmol L}^{-1}$ ) to 1 mL LDL solution. After incubation at  $37^\circ\text{C}$  for 6 h, total lipids were extracted according to the method of Bligh and Dyer [23]. Extracted lipids were dissolved in 20  $\mu\text{L}$  chloroform and subjected to DPPP-TLC blotting and GC–MS/SIM analysis.

### Cell Culture and UVA Treatment

A human keratinocyte cell line, HaCaT, kindly donated by Dr K. Takahata of Okayama University, was seeded in 60 mm dishes at a density of  $5 \times 10^5$  cells per dish and cultured for 2 days in Dulbecco's modified Eagle's medium (DMEM, SIGMA) with 10% fetal bovine serum (FBS; EQUITEC-BIO, TX, USA) at  $37^\circ\text{C}$  in a 5%  $\text{CO}_2$ /95% air mixed humidified incubator. Before irradiation the media were replaced with HBSS containing  $1 \mu\text{mol L}^{-1}$  hematoporphyrin; photo-irradiation was then performed with a UVA projection lamp (Black-light blue fluorescent lamp; Matsushita Electric Works, Osaka, Japan; 320–400 nm) at an intensity of  $2.5 \text{ J cm}^{-2}$  (700  $\mu\text{W}$ , 60 min) on an ice bath. Control cells were also kept in the dark for 60 min on an ice bath. After the UVA irradiation, cells were harvested by trypsinization. The suspension with exfoliated cells in DMEM was then centrifuged at 200g for 3 min at  $4^\circ\text{C}$  and the supernatant was removed. The pellet obtained was washed with HBSS three times and dispersed in HBSS. Total lipids in the pellet were extracted according to the method of Bligh and Dyer [23]. The lipid extract was dissolved in 20  $\mu\text{L}$  chloroform and subjected to DPPP-TLC blotting and GC–MS/SIM analysis.

### Animal Experiment

Male Hos; HR-1 hairless mice, 8 weeks old, were purchased from SLC Japan, (Hamamatsu, Japan) and maintained under standard experimental conditions ( $25^\circ\text{C}$ , 60% humidity; light and dark cycle every 12 h) according to the Guidelines for Animal Experimentation of Tokushima University. Mice were anesthetized with sodium pentobarbital ( $50 \text{ mg kg}^{-1}$ ) and exposed to irradiation with the UVA projection lamp for 8 h in a state where half of their back skin was covered with a cloth of UVA-fault permeability. The amount of UVA delivered to the skin was adjusted to  $47 \text{ J cm}^{-2}$ . After irradiation the mice were again anesthetized with sodium pentobarbital and part of dorsal skin, 1.0 cm  $\times$  3.0 cm, was obtained, avoiding contamination with hypodermic fats, and stored at  $-80^\circ\text{C}$  until analysis (no more than 5 days). Skin which had not been irradiated was also prepared and stored by the same procedure. Nine volumes of  $10 \text{ mmol L}^{-1}$  PBS was added to the dorsal skin preparation and the mixture was homogenized with a Polytron homogenizer (Kinematica AG, Littau/Luzern, Switzerland). The cholesterol content of the skin homogenate was quantified using a Cholesterol/Cholesteryl Ester Quantitation Kit (Bio Vision, CA, USA). The total lipids were extracted from the homogenates by the method of Bligh and Dyer [23] after addition of St-OOH as internal standard. Extracted lipids were dissolved in 20  $\mu\text{L}$  chloroform and subjected to DPPP-TLC blotting and GC–EI–MS/SIM analysis.

## DPPP-TLC Blotting for the Preparation of Chol-OOH Derivatives from Extracted Lipids

DPPP-TLC blotting was performed for extracted lipids to isolate Chol-OOHs as reduced hydroxyl derivatives from large amounts of non-oxidized lipids, in accordance with the method of Terao et al. [14]. First, peroxidized cholesterol solution or lipid extracted from a biological sample was applied to a TLC plate (silica gel F<sub>254</sub>, 0.25 mm thickness; Merck) and developed with 93:7 (v/v) hexane–isopropanol as mobile phase. The TLC plate was then blotted on to a PVDF membrane as follows. The plate was dried and then dipped in 0.01% (w/v) DPPP-containing blotting solvent (isopropanol–0.2% aqueous CaCl<sub>2</sub>–methanol, 40:20:7, v/v) for 30 s, after which it was placed on a glass fiber filter. Then the plate was covered with a PVDF membrane, a PTFE membrane, and finally a glass fiber filter, in layers. This TLC-blotting sandwich was pressed evenly for 90 s at 180°C using a TLC thermal blotter AC-5970 (ATTO, Tokyo, Japan) at a press level of 8. After blotting, the spot whose *R<sub>F</sub>* value corresponded to standard Chol-OOHs was cut out and immersed in 600 μL 1:1 (v/v) chloroform–methanol, with shaking for 1 min, to extract reduced Chol-OHs. The solvent was then removed with nitrogen gas. The residue was mixed with 50 μL *N,O*-bis(trimethylsilyl)trifluoroacetamide in acetonitrile solution and incubated at 60°C for 5 min for preparation of trimethylsilyloxy derivatives.

### GC–EI–MS/SIM Analysis

GC–EI–MS analysis was performed with an AQP5050 mass spectrometer (Shimadzu, Kyoto, Japan) equipped with an SPB-1 fused silica capillary column (30 m × 0.25 mm i.d., 10 μm film thickness; Supelco, Bellefonte, PA, USA). Splitless injection of 1 μL was performed with helium, flow rate 1.0 mL min<sup>-1</sup>, as carrier gas. The injection temperature was 260°C and the column oven was held at 150°C for 5 min before being elevated at 10° min<sup>-1</sup> to 280°C and then at 5° min<sup>-1</sup> to 300°C, which was held for 10 min. Full-scan mass spectra were obtained by electron-impact ionization, electron energy 70 eV, over the mass range *m/z* 50 to 600. SIM was performed with a dwell time of 200 ms.

## Results and Discussion

### GC–EI–MS Analysis of Oxysterol Standards

A mixture of Chol 7 $\alpha$ -OH, Chol 7 $\beta$ -OH, cholesterol 5 $\alpha$ ,6 $\alpha$ -epoxide, cholesterol 5 $\beta$ ,6 $\beta$ -epoxide, cholestanetriol, 7-ketocholesterol, and 25-hydroxycholesterol was analyzed by GC–EI–MS after derivatization to trimethylsilyloxy derivatives (Fig. 1). These oxysterol derivatives were

**Fig. 1** GC–EI–MS analysis of standard oxysterols. A total ion mass chromatogram of the standard mixture was obtained using the total ion current mode. The identities of the peaks were: 1, 7 $\alpha$ -hydroxycholesterol; 2, cholesterol 5 $\beta$ ,6 $\beta$ -epoxide; 3, 7 $\beta$ -hydroxycholesterol; 4, cholesterol 5 $\alpha$ ,6 $\alpha$ -epoxide; 5, cholestanetriol; 6, 7-ketocholesterol; 7, 25-hydroxycholesterol

separated incompletely from one another in the total-ion chromatogram. Therefore, SIM using a specific fragment ion for each oxysterol should be used for analysis of peroxidized cholesterol in biological samples. Table 1 shows the retention time of each oxysterol and its characteristic fragment ion in the chromatogram. The fragment ion derived from the elimination of trimethylsilyanol from the molecular ion,  $[M - \text{HOSi}(\text{CH}_3)_3]^+$ , was detected remarkably well for all the oxysterol derivatives except cholestanetriol. In addition, Table 1 shows the detection limit and response factor for each oxysterol derivative in the SIM chromatogram, using  $[M - \text{HOSi}(\text{CH}_3)_3]^+$ . The response factor is an area ratio of the fragment ion from each oxysterol derivative to that from the derivative of Chol 7 $\alpha$ -OH in the SIM chromatogram. The detection limit for each Chol-OH derivative was calculated from their response factors to be 20–60 fmol. Thus, analysis of peroxidized cholesterol using the GC–EI–MS/SIM technique seems to be either superior to or comparable with that with the HPLC–CL technique in sensitivity. Thus, we applied GC–EI–MS/SIM using  $[M - \text{HOSi}(\text{CH}_3)_3]^+$  as the selected ion as a method for analyzing peroxidized cholesterol in biological samples.

### Reduction of Chol-OOHs by DPPP-TLC Blotting and GC–EI–MS Analysis

Figure 2 illustrates results from DPPP-TLC blot analysis of LOOH standards including Chol-OOH in which each LOOH emerged as a fluorescent spot in two different solvent systems. The fluorescence derived from diphenyl-1-pyrenylphosphine oxide, which is formed by oxidation of DPPP with reduction of Chol-OOHs, could be visualized at

**Table 1** Characteristics of oxysterols in GC–EI–MS analysis

Compound number	Compound name	Major ion ( <i>m/z</i> )	[M – HOSi(CH <sub>3</sub> ) <sub>3</sub> ] <sup>+</sup> ( <i>m/z</i> )	Retention time (min)	Response factor	Detection limit (fmol)
	Cholesterol	368	368	15.95	–	–
1	7 $\alpha$ -Hydroxycholesterol	456	456	15.85	1.00	60
2	Cholesterol 5 $\beta$ ,6 $\beta$ -epoxide	384, 474	384	16.70	1.65	35
3	7 $\beta$ -Hydroxycholesterol	456	456	16.78	1.16	50
4	Cholesterol 5 $\alpha$ ,6 $\alpha$ -epoxide	384, 474	384	16.89	5.93	10
5	Cholestanetriol	456, 403	546	17.33	0.42	140
6	7-Ketcholesterol	382, 472	382	17.95	0.91	60
7	25-Hydroxycholesterol	456, 271	456	18.04	2.53	20

a concentration higher than 50 pmol and this spot migrated with an  $R_F$  value close to that of the spot of Chol-OHs (data not shown). Kriska and Girotti [24] indicated that Chol 7 $\alpha$ -OH was clearly separated from its hydroperoxide on the TLC plate. However, our TLC analysis is unlikely to distinguish Chol-OOH mixtures from respective Chol-OHs in biological samples. Thus, we decided to focus on the sum of Chol-OOH and Chol-OH, i.e. Chol-(O)OH, without distinguishing Chol-OOH from Chol-OH in peroxidized cholesterol, as heat-labile Chol-OOH should be reduced to its Chol-OH for GC–EI–MS analysis. Figure 3 shows the result of the GC–EI–MS analysis for the spot of Chol-OOH of peroxidized cholesterol after DPPP-TLC blotting and trimethylsilyloxylation. Peaks I and II, which originated from the spot of the blotting membrane, because of the

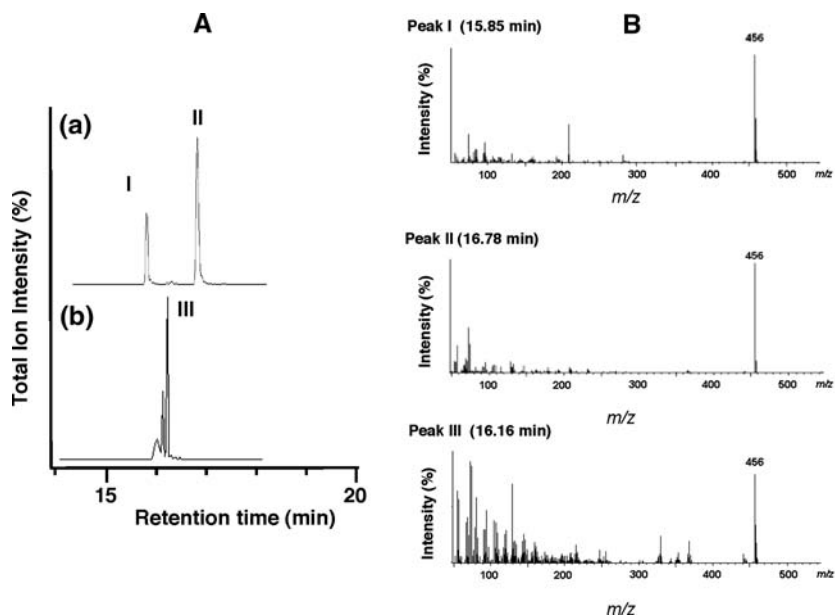

products of the azo radical-induced oxidation of cholesterol, appeared at the same retention times as the peaks for the Chol 7 $\alpha$ -OH and Chol 7 $\beta$ -OH standards in the chromatogram. In general, reducing agents such as NaBH<sub>4</sub> are used for reduction of hydroperoxyl groups in a GC–EI–MS analysis of lipid hydroperoxides. Here it was found that the hydroperoxyl group of peroxidized cholesterol was reduced effectively to its hydroxyl group by DPPP in the process of TLC blotting, as in previous reports for PCOOH [14, 15] and cholesteryl ester hydroperoxides [14, 16]. It was therefore concluded that peaks I and II are trimethylsilyloxy derivatives of  $\alpha$ -hydroperoxycholest-5-en-3 $\beta$ -ol (cholesterol 7 $\alpha$ -hydroperoxide; Chol 7 $\alpha$ -OOH) and 7 $\beta$ -hydroperoxycholest-5-en-3 $\beta$ -ol (cholesterol 7 $\beta$ -hydroperoxide; Chol 7 $\beta$ -OOH), respectively. Thus, we succeeded in reduction of Chol-OOHs to Chol-OHs and blotting of Chol-OHs to the membranes simultaneously. On the other hand, peak III appeared at a different retention time from Chol 7 $\alpha$ -OOH and Chol 7 $\beta$ -OOH in the case of peroxidized cholesterol prepared by hematoporphyrin-sensitized photooxidation. Photosensitized oxidation of cholesterol is known to yield Chol 5 $\alpha$ -hydroperoxycholest-6-en-3 $\beta$ -ol (Cholesterol 5 $\alpha$ -hydroperoxide; Chol 5 $\alpha$ -OOH) as a singlet molecular oxygen (<sup>1</sup>O<sub>2</sub>) oxygenation-specific product [25, 26]. It is therefore confirmed that peak III is derived from Chol 5 $\alpha$ -OOH. From these results, it can be concluded that DPPP-TLC blotting is a helpful pretreatment method in GC–EI–MS/SIM analysis of Chol-OOH isomers as trimethylsilyloxy derivatives. Taken together, we propose a method of GC–EI–MS with DPPP-TLC blotting for analysis of Chol-OOHs from biological samples, as shown in Scheme 1. First, cholesterol peroxidation products are separated from cholesterol and other lipids by the use of TLC analysis. Next, the TLC plate is blotted on to a PVDF membrane together with reduction of Chol-OOHs to Chol-OHs. The membrane corresponding to the region of Chol-OOHs is cut out and extracted with a mixture of chloroform and methanol. After trimethylsilylation, trimethylsilyloxy derivatives are

**Fig. 2** Results from DPPP-TLC blot analysis of a mixture of TLOOH, LAOOH, Chol-OOH, PCOOH, and PEOOH standards, 500 pmol each, on a TLC plate. The lanes show the results obtained by use of the mobile phases (a) hexane–diethyl ether–acetic acid, 70:30:1 (v/v) and (b) chloroform–methanol–water, 65:25:4 (v/v)

**Fig. 3** Results from GC–EI–MS analysis of peroxidized cholesterol after DPPP–TLC blotting. **A** Total-ion current mass chromatogram of the cholesterol peroxidation products, obtained using the total ion collection mode. (a) Cholesterol peroxidation products prepared by azo radical oxidation. (b) Cholesterol peroxidation products prepared by hematoporphyrin-sensitized photooxidation. **B** Mass spectrum of each peak shown in Fig. 3A. The peaks were identified as the trimethylsilyloxy derivative of Chol 7 $\alpha$ -OOH (I), Chol 7 $\beta$ -OOH (II), and Chol 5 $\alpha$ -OOH (III)

analyzed by GC–EI–MS/SIM. The recovery of standard Chol-OOHs by DPPP–TLC blotting was found to be 86%. It is likely that the combination of DPPP–TLC blotting and GC–EI–MS/SIM overcomes the problem of complicated and time-consuming pretreatment including reduction of hydroperoxyl groups and separation of cholesterol peroxidation products from extracted lipids. Furthermore, conversion of the reactive Chol-OOH to the stable Chol-OH during the blotting process is helpful in preventing the

formation of their decomposition products as artifacts during the analytical process.

#### Analysis and Quantification of Peroxidized Cholesterol in Biological Samples

We first used DPPP–TLC blotting as pretreatment for GC–EI–MS/SIM analysis of peroxidized cholesterol in human plasma LDL, because it has been suggested that

**Scheme 1** Flow chart for analysis of cholesterol hydroperoxides, as trimethylsilyloxy derivatives, by DPPP–TLC blotting and GC–EI–MS/SIM

peroxidation of LDL is involved in the initial stages of atherosclerosis. It has been already confirmed that peroxidized cholesterol was present in the oxidized LDL [6]. Trimethylsilyloxy derivatives of Chol 7 $\alpha$ -(O)OH and Chol 7 $\beta$ -(O)OH, radical mediated oxidation-specific products, were detected in the LDL after azo-radical oxidation, although no derivatives were found in intact human LDL (Fig. 4). Second, we applied this technique to analysis of peroxidized cholesterol from photoirradiated cultured cells. HaCaT cells were exposed to UVA irradiation in the presence of hematoporphyrin as photosensitizer and then peroxidized cholesterol in the lipid extract was detected using this technique. Compared with the non-irradiated cells, trimethylsilyloxy derivatives of Chol 5 $\alpha$ -(O)OH, in addition to those of Chol 7 $\alpha$ -(O)OH and Chol 7 $\beta$ -(O)OH, were readily detected in the UVA-exposed cells Fig. 5. Chol 5 $\alpha$ -OOH is a  $^1\text{O}_2$  oxygenation-specific oxidation product of cholesterol, as mentioned above, and detection of Chol 5 $\alpha$ -OOH has been used as evidence of the participation of  $^1\text{O}_2$  in the reaction mechanism of oxidative damage to biological samples [27]. That the peak corresponding to Chol 5 $\alpha$ -(O)OH was observed in the chromatogram of peroxidized cholesterol from the UVA-exposed cells implies that hematoporphyrin acts as a type II photosensitizer, which generates  $^1\text{O}_2$  by energy transfer from its excited state, in cultured cell systems.

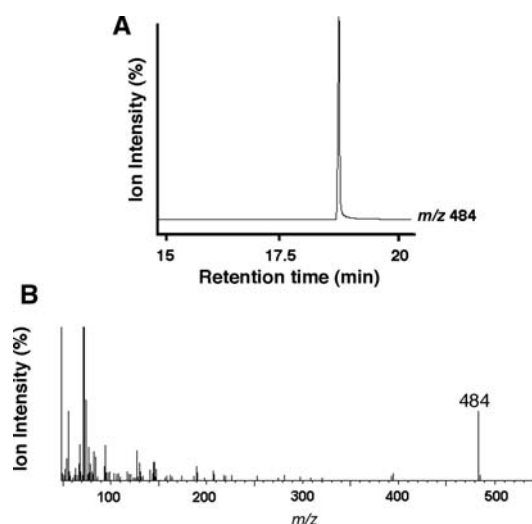

Finally, the technique was used for quantification of peroxidized cholesterol present in mouse skin by use of an internal standard. We selected  $\beta$ -sitosterol, a major plant sterol, and prepared its hydroperoxide (St-OOH) by the method of hematoporphyrin-sensitized photooxidation. Figure 6 shows the chromatogram and mass spectrum

**Fig. 4** Results from GC–EI–MS/SIM analysis of peroxidized cholesterol from human LDL after DPPP–TLC blotting. **Fig. 6** Results from GC–EI–MS/SIM analysis of peroxidized  $\beta$ -sitosterol after DPPP–TLC blotting.  $\beta$ -Sitosterol hydroperoxide was prepared by hematoporphyrin-sensitized photooxidation of  $\beta$ -sitosterol and subjected to GC–EI–MS/SIM analysis after DPPP–TLC blotting. (a) SIM chromatogram for specific fragment ion  $m/z$  484; (b) mass spectrum of the peak that appeared

obtained from the trimethylsilyloxy derivative of St-OOH isolated from the reaction mixture by DPPP–TLC blotting. A characteristic fragment ion for the derivative,  $[\text{M} - \text{HOSi}(\text{CH}_3)_3]^+$ , appeared at  $m/z$  484 in the GC peak corresponding to St-OOH. This ion was therefore used for SIM of the internal standard for the determination of Chol-(O)OHs. We tried to determine the amount of Chol-(O)OHs accumulated in hairless mouse skin as trimethylsilyloxy derivatives. The skin was removed from the

**Fig. 7** Results from GC–EI–MS/SIM analysis of peroxidized cholesterol obtained from the skin tissue of hairless mice after DPPP–TLC blotting. Total lipids were extracted from the skin tissue and subjected to GC–EI–MS/SIM after DPPP–TLC blotting. SIM chromatograms were obtained by use of the specific fragment ions  $m/z$  456 and  $m/z$  484 from peroxidized cholesterol and the internal standard, respectively

animal's back with or without irradiation of UVA and analyzed by DPPP–TLC blotting and GC–EI–MS/SIM after addition of St–OOH to the skin homogenate and extraction of total lipids. Figure 7 shows the SIM chromatogram of peroxidized cholesterol in mouse skin. The peaks were identified as the trimethylsilyloxy derivatives of Chol 7 $\alpha$ –(O)OH, Chol 5 $\alpha$ –(O)OH, and Chol 7 $\beta$ –(O)OH, respectively, by comparison with chromatograms obtained from the respective standards (Figs. 1 and 3). The amount of Chol 7 $\alpha$ –(O)OH and Chol 7 $\beta$ –(O)OH was determined from the standard calibration plots for Chol–OOHs obtained from cholesterol peroxidation products prepared by azo radical initiation (correlation coefficient = XX). The amount of Chol 5 $\alpha$ –(O)OH was indirectly measured by use of the response factor for Chol 5 $\alpha$ –OH (=1.2), which was obtained from the difference between the peak area of each Chol–OH from hematoporphyrin-sensitized photooxidation and that of Chol–7 $\alpha$ OH spiked Chol–OHs.

It was found that isomeric Chol–(O)OHs accumulated in considerable amounts in non-irradiated skin (Table 2). It is therefore likely that hairless mouse skin was subject to substantial oxidative stress under normal conditions, because Chol–(O)OHs, in particular Chol 7–(O)OH, are used as suitable oxidative stress markers in the skin [8, 11]. It was also clarified that  $^1\text{O}_2$  participated in the peroxidation of cholesterol in mouse skin even under normal conditions. Interestingly, *not* Chol 7 $\alpha/\beta$ –(O)OH *but* Chol 5 $\alpha$ –(O)OH level increased substantially after UVA-irradiation of the skin. Chol 5 $\alpha$ –OOH is capable of giving Chol 7 $\alpha$ –OOH by rearrangement of the hydroperoxyl group [20]. We confirmed this rearrangement was unlikely to occur during the sample processing, because the ratio of Chol 5 $\alpha$ –(O)OH in

**Table 2** Determination of peroxidized cholesterol in the skin of hairless mice with and without UVA irradiation

	Non-irradiation	UVA irradiation

$\mu\text{mol mol}^{-1}$ cholesterol	4.3 $\pm$ 3.0	6.1 $\pm$ 2.8*
$\text{nmol g}^{-1}$ wet tissue	0.14 $\pm$ 0.11	0.20 $\pm$ 0.11
Chol 7 $\beta$ –(O)OH		
$\mu\text{mol mol}^{-1}$ cholesterol	13.5 $\pm$ 9.7	17.7 $\pm$ 12.3
$\text{nmol g}^{-1}$ wet tissue	0.47 $\pm$ 0.38	0.62 $\pm$ 0.50

Total lipids were extracted from skin tissue and subjected to DPPP–TLC blotting and GC–EI–MS/SIM analysis with the specific fragment ion  $m/z$  456

Data are expressed as the average value  $\pm$  SD ( $n = 10$ )

Chol 5 $\alpha$ –(O)OH was determined by using its response factor (1.20)

\* Significantly different from the corresponding non-irradiated sample,  $P < 0.05$  (paired  $t$ -test)

the total Chol–OOHs was not changed by incubation of the skin homogenate for 1 h at 37°C after spiking with Chol–OOHs (data not shown). However, there is a possibility that some Chol 5 $\alpha$ –OOH was converted to Chol 7 $\alpha$ –OOH during UVA irradiation. In any case, the contribution of  $^1\text{O}_2$  to peroxidation of cholesterol was found to be enhanced when the skin was exposed to UVA irradiation. Coproporphyrin produced from *Propionibacterium acnes* has been implicated as a photosensitizer in human skin [29]. It was recently suggested that proteins of the extracellular matrix [28] and 3-hydroxypyridine chromophore [30] are endogenous photosensitizers present in human skin cells. Yamazaki et al. [31] have demonstrated that Chol 5 $\alpha$ –OOH accumulated in the skin when rats were administered pheophorbide, a type II photosensitizer, and exposed to visible light. Nevertheless, our results indicate that an unknown type II photosensitizer, which is capable of generating  $^1\text{O}_2$  on exposure to UVA, is located in mouse skin.

In conclusion, the combination of DPPP–TLC blotting and GC–EI–MS/SIM is effective for quantitative analysis of peroxidized cholesterol, particularly Chol–(O)OHs, with high sensitivity and simplicity. This technique is useful for detecting participation of  $^1\text{O}_2$  in oxidative damage occurring in tissues and fluids, although it is difficult to distinguish Chol–OOHs from their reduced Chol–OHs. We are now using this technique to evaluate the role of  $^1\text{O}_2$  in photoirradiation-induced oxidative stress in experimental animals.

the latest and simplest in vivo method that addresses the capability of an organism to produce highly unsaturated fatty acids (HUFA). In the present note on methodology, information and computations required to carry out the whole-body fatty acid balance method are presented.

## Description of the Method

For the execution of the whole-body fatty acid balance method a feeding trial is a fundamental necessity. The basic concept on which the method is based on is the quantification of the initial and final fatty acid composition of the whole-body and the quantification of the net intake of dietary fatty acids, based on a feeding trial.

The feeding trial must be of a sufficient duration to guarantee an adequate weight gain in order to enable an accurate quantification of fatty acid elongation and desaturation. Moreover, as the present method is fundamentally a mass balance analysis, by increasing the difference between the factors, it is possible to increase the sensitivity of the measurement. It is crucial that the feed intake is measured accurately. The total collection of faeces or a corresponding digestibility estimation using an appropriate dietary marker is essential for the quantification of the net intake of fatty acids.

The type of diet used for the whole-body fatty acid balance method is unimportant given that its proximate and fatty acid compositions are known. However, for the quantification of elongase and desaturase activities a diet containing minimal amounts of these enzyme products (i.e. HUFA) is desired. Considering the method is based mainly on a mass balance analysis of individual fatty acids, a high intake of HUFA can mask the appearance of newly elongated and/or desaturated fatty acids [5].

The analyses required for the subsequent computations of the whole-body fatty acid balance method are: the initial and final body weight, initial and final quantitative fatty acid composition of the whole body, the total feed intake, the quantitative fatty acid composition of the diet and the fatty acid digestibility or the quantitative fatty acid composition of the total faeces produced during the experiment.

The computation of the whole-body fatty acid balance method is best dealt with in four steps.

The first step is to determine the partitioning of the dietary fatty acids amongst excretion, accumulation, appearance or disappearance, as described previously by Cunnane and Anderson [4].

The individual fatty acid amounts in diet, faeces, initial and final carcass need to be expressed in mg per animal. After calculating the individual fatty acid (FA) intake ( $= \text{g of feed intake} \times \text{mg of FA per g of feed}$ ), excretion ( $= \text{mg of FA intake} \times \text{FA digestibility}$ ; or  $= \text{g of faeces} \times \text{mg of FA per g of faeces}$ ) and accumulation ( $= \text{mg of FA in final carcass} - \text{mg of FA in initial carcass}$ ) it is possible to estimate the fatty acid appearance or disappearance ( $= \text{FA accumulation} - \text{FA intake} - \text{FA excretion}$ ) (Fig. 1).

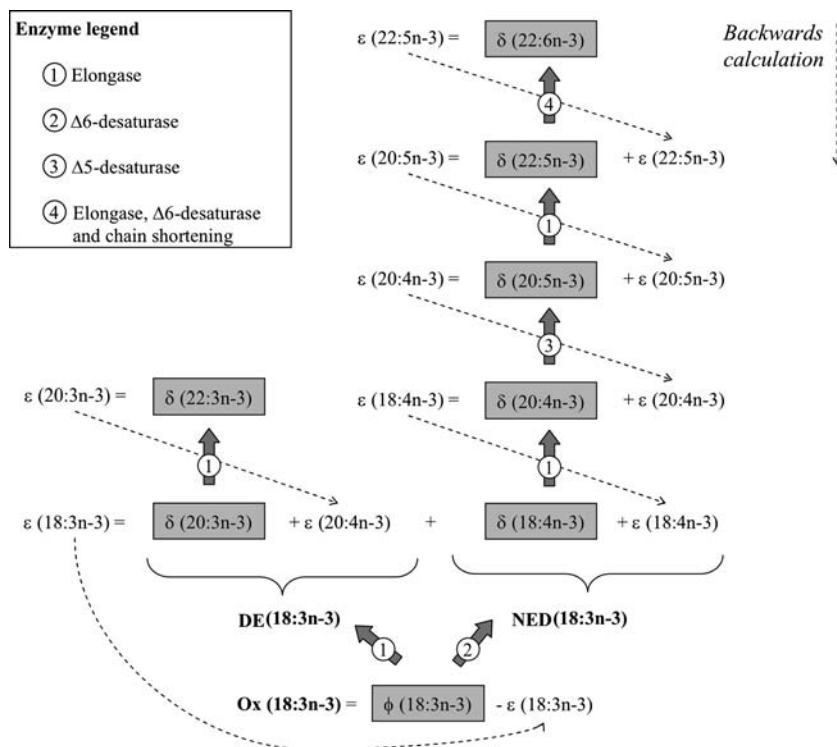

A disappearance of fatty acids may involve their elongation and desaturation to longer chain fatty acids or utilization of their carbon skeleton through  $\beta$ -oxidation for energy production. For purposes of this communication the metabolic pathway of  $\alpha$ -linolenic acid (18:3n-3) is presented. The metabolic pathways of other fatty acids are simpler and can therefore be deduced accordingly.

The common 18:3n-3 metabolic pathway can be subdivided into three categories: chain-shortening and oxidation (Ox), elongation towards dead end products (DE) and the normal elongation/desaturation pathway (NED). The fatty acids involved in the 18:3n-3 DE pathway are 20:3n-3 and 22:3n-3. While those involved in the 18:3n-3 NED pathway include 18:4n-3, 20:4n-3, 20:5n-3, 22:5n-3 and 22:6n-3. The production 22:6n-3 involves a further elongation of 22:5n-3 to 24:5n-3, a  $\Delta$ -6 desaturation of 24:5n-3 to 24:6n-3 and a chain-shortening reaction from 24:6n-3 to 22:6n-3 [2]. However, 24:5n-3 and 24:6n-3 are seldom present in detectable amounts and therefore, the passage from 22:5n-3 to 22:6n-3 is in the present computation considered as a sole elongase,  $\Delta$ -6 desaturase and chain-shortening reaction.

The second step of the method involves the computation of the 18:3n-3 balance. The amount of fatty acids represented in the 18:3n-3 metabolic pathway needs to be converted from mg to mmol of appeared/disappeared FA per animal.

**Fig. 1** Schematic representation of the mass balance analysis of the individual fatty acid intake and accumulation. The first step in the whole-body fatty acid balance method

<b>Final fatty acid body content</b> - <b>Initial fatty acid body content</b> = 		<b>Fatty acid intake</b> - <b>Fatty acid excretion</b> = 	
<b>Fatty acid accumulation</b>	-	<b>Fatty acid net intake</b>	= <b>Fatty acid appearance/disappearance</b>

**Fig. 2** Schematic representation of the computation involved in the whole-body fatty acid balance method. Shaded figures [ $\delta$  values i.e.  $\delta(22:6n-3)$ ,  $\delta(22:5n-3)$ , etc.] represent the results obtained following the first step of the method (mmol of the specified FA appeared/disappeared), while the  $\phi$  value (for 18:3n-3 only) represents the total number of mmol of 18:3n-3 disappeared (given that no appearance is possible in vertebrates). Via a backwards calculation, starting from the end of the two pathways it is possible to calculate the  $\epsilon$  values,

which represent the mmol of specified FA converted to longer or more unsaturated homologues. Successively, it is possible to quantify the fate of  $\alpha$ -linolenic acid (18:3n-3) as (i) chain shortening and oxidation (Ox), (ii) elongation towards a dead end product (DE) or (iii) elongation and desaturation along the normal pathway (NED). Ultimately, it is possible to estimate the elongase,  $\Delta$ -5 and  $\Delta$ -6 desaturase activities

The number of mmol of longer chain fatty acids that appeared is subtracted from the number of mmol of the previous fatty acid in the fatty acid elongation/desaturation pathway. A diagram depicting the backwards calculation along the fatty acid metabolic pathways is provided (Fig. 2). The mathematical model used for the whole-body fatty acid balance computation for n-3 fatty acids is described by the following equations (Eqs. 1, 2, 3, 4, 5, 6) [where:  $\epsilon$  = mmol of specified FA converted (elongated or desaturated);  $\delta$  = mmol of the specified FA appeared/disappeared per animal; if  $\delta$  is a negative number (FA disappeared = oxidized), then  $\delta = 0$  for the following computation]:

NED pathway:

$$\epsilon(22:5n-3) = \delta(22:6n-3) \tag{1}$$

$$\epsilon(20:5n-3) = \delta(22:5n-3) + \epsilon(22:5n-3) \tag{2}$$

$$\epsilon(20:4n-3) = \delta(20:5n-3) + \epsilon(20:5n-3) \tag{3}$$

$$\epsilon(18:4n-3) = \delta(20:4n-3) + \epsilon(20:4n-3) \tag{4}$$

DE pathway:

$$\epsilon(20:3n-3) = \delta(22:3n-3) \tag{5}$$

Total 18:3n-3 balance:

$$\epsilon(18:3n-3) = \delta(20:3n-3) + \epsilon(20:3n-3) + \delta(18:4n-3) + \epsilon(18:4n-3) \tag{6}$$

The estimation of the fate (elongation, desaturation or oxidation) of each fatty acid can therefore be computed accordingly to its specific metabolic pathway; for example 18:2n-6, 18:3n-6, 20:3n-6, 20:4n-6, 22:4n-6 or 18:1n-9, 18:2n-9, 20:2n-9, 20:3n-9, and pathways involving the  $\Delta$ -9 desaturase enzyme such as 16:0, 16:1n-7, 18:1n-7 can be evaluated as well.

At this point (the third step of the method) it is possible to quantify the amount of 18:3n-3 used in  $\beta$ -oxidation or elongated and desaturated (Fig. 2). The total 18:3n-3 balance can therefore be delineated by the following equations (Eqs. 7, 8, 9, 10, 11, 12) [where: DE(18:3n-3) = total 18:3n-3 elongated to dead end products; NED(18:3n-3) = total 18:3n-3 converted through the normal elongation/desaturation pathway; Ox(18:3n-3) = total 18:3n-3 oxidized;  $\phi$  (18:3n-3) = total number of mmol of 18:3n-3 disappeared]:

$$\text{DE}(18:3n-3) = \delta(20:3n-3) + \varepsilon(20:3n-3) \quad (7)$$

$$\text{NED}(18:3n-3) = \delta(18:4n-3) + \varepsilon(18:4n-3) \quad (8)$$

$$\text{Ox}(18:3n-3) = \phi(18:3n-3) - \text{DE}(18:3n-3) - \text{NED}(18:3n-3) \quad (9)$$

The fate of 18:3n-3 can be further reported as a percentage relative to its total net intake (NI; calculated from the first step of the method; NI = FA intake – FA excretion and converted into mmol)

$$\begin{aligned} \text{\% of 18:3n-3 elongated to dead end products} \\ = \text{DE}(18:3n-3) \times \text{NI}(18:3n-3)^{-1} \times 100 \end{aligned} \quad (10)$$

$$\begin{aligned} \text{\% of 18:3n-3 elongated and desaturated} \\ = \text{NED}(18:3n-3) \times \text{NI}(18:3n-3)^{-1} \times 100 \end{aligned} \quad (11)$$

$$\begin{aligned} \text{\% of 18:3n-3 oxidized} \\ = \text{Ox}(18:3n-3) \times \text{NI}(18:3n-3)^{-1} \times 100 \end{aligned} \quad (12)$$

Ultimately, it is possible to estimate the total elongase,  $\Delta$ -5 and  $\Delta$ -6 desaturase activities with the fourth and final step of the method. The enzyme activity is expressed as mmol of products per gram of body weight (average body weight) per day with the following equations (Eqs. 13–16):

$$\begin{aligned} \text{Gram of BW day}^{-1} \\ = (\text{initial body weight} + \text{final body weight}) \\ \times 2^{-1} \times \text{no. of days}^{-1} \end{aligned}$$

$$\begin{aligned} \Delta\text{-6 desaturase} = [\delta(18:4n-3) + \varepsilon(18:4n-3) + \delta(22:6n-3)] \\ (\text{gram of BW day}^{-1})^{-1} \end{aligned} \quad (14)$$

$$\begin{aligned} \Delta\text{-5 desaturase} = [\delta(20:5n-3) + \varepsilon(20:5n-3)] \\ (\text{gram of BW day}^{-1})^{-1} \end{aligned} \quad (15)$$

$$\begin{aligned} \text{Elongase} = [\delta(20:3n-3) + \varepsilon(20:3n-3) + \varepsilon(18:4n-3) \\ + \varepsilon(20:5n-3) + \varepsilon(22:5n-3)](\text{gram of BW day}^{-1})^{-1} \end{aligned} \quad (16)$$

## Computation example

The following example is reported to further clarify the steps in the calculations for the execution of the presented method. The example is based on data reported previously [5] on the freshwater fish Murray cod (*Maccullochella peelii peelii*) fed a semi purified diet containing linseed oil as the principal lipid source for 112 days. The sample preparation is of paramount importance for the proper functioning of the method. To properly quantify the fatty acid content of the whole body, the entire specimen (or pooled specimens) needs to be chopped and subsequently finely minced to obtain a representative and homogenous sample. Admittedly, this is a limit of the method and it can be difficult for large animals or animals with tough tissues. With fish samples, we find the repeated utilization of a heavy duty meat mincer, with a reduction of the die size after each pass, well suited for homogenization. Lipid extraction should then be performed on a relatively large sample, on as many replicates as possible to improve the accuracy of the quantification and accordingly to standardized reliable protocols [7]. A second, equally important aspect is to implement a proper chromatographic quantitative procedure, as the simple, commonly adopted evaluation of fatty acids as a percentage value is not informative enough and can not be utilised. The use of a suitable internal standard and the correction by theoretical relative FID response factors of the resulting peak areas are essential for accurate FA quantification [8].

In Table 1, the results obtained from the calculation of the first step of the whole-body fatty acid balance method are reported. Subsequently, following the second step of the whole-body fatty acid balance method it is possible to calculate the  $\varepsilon$  values (Fig. 2) along the NED and DE pathways:

(Eq. 1):

$$\varepsilon(22:5n-3) = \delta(22:6n-3) = 12.8(\text{mmol per fish})$$

(Eq. 2):

$$\begin{aligned} \varepsilon(20:5n-3) = \delta(22:5n-3) + \varepsilon(22:5n-3) \\ = 123.2 + 12.8 = 136.0(\text{mmol per fish}) \end{aligned}$$

(Eq. 3):

$$\begin{aligned} \varepsilon(20:4n-3) = \delta(20:5n-3) + \varepsilon(20:5n-3) = -111.4 + 136.0 \\ = 24.6(\text{mmol per fish}) \end{aligned}$$

**Table 1** The first step of the whole-body fatty acid balance method; data is relative to the n-3 fatty acid balance during a 112-day period on Murray cod fed a linseed oil based diet [5]

	18:3n-3	18:4n-3	20:3n-3	22:3n-3	20:4n-3	20:5n-3	22:5n-3	22:6n-3

	$\phi(18:3n-3)$	$\delta(18:4n-3)$	$\delta(20:3n-3)$	$\delta(20:3n-3)$	$\delta(20:4n-3)$	$\delta(20:5n-3)$	$\delta(22:5n-3)$	$\delta(22:6n-3)$
mmol FA per fish								
	7646.0	881.6	240.0	ND	409.3	-111.4	123.2	12.8

In the last row,  $\delta$  values represent the mmol of the specified FA appeared or disappeared (if value is positive or negative, respectively), while the  $\phi$  value (for 18:3n-3 only) represents the total number of mmol of 18:3n-3 disappeared

ND not detected

(Eq. 4):

$$\begin{aligned}\varepsilon(18:4n-3) &= \delta(20:4n-3) + \varepsilon(20:4n-3) = 409.3 + 24.6 \\ &= 433.9(\text{mmol per fish})\end{aligned}$$

(Eq. 5):

$$\varepsilon(20:3n-3) = \delta(22:3n-3) = 0(\text{mmol per fish})$$

Once the individual  $\varepsilon$  values which represent the mmol of specified FA converted to longer or more unsaturated homologues have been calculated, it is possible to calculate the total amount of 18:3n-3 elongated and desaturated through both of the pathways:

(Eq. 6):

$$\begin{aligned}\varepsilon(18:3n-3) &= \delta(20:3n-3) + \varepsilon(20:3n-3) + \delta(18:4n-3) \\ &+ \varepsilon(18:4n-3) = 240.0 + 0 + 881.6 + 433.9 \\ &= 1555.5(\text{mmol per fish})\end{aligned}$$

Through the third step of the method, it is possible to quantify the amount of 18:3n-3 used in  $\beta$ -oxidation or elongated and desaturated (Fig. 2).

(Eq. 7):

$$\begin{aligned}\text{DE}(18:3n-3) &= \delta(20:3n-3) + \varepsilon(20:3n-3) \\ &= 240 + 0 = 240(\text{mmol per fish})\end{aligned}$$

(Eq. 8):

$$\begin{aligned}\text{NED}(18:3n-3) &= \delta(18:4n-3) + \varepsilon(18:4n-3) \\ &= 881.6 + 433.9 = 1315.5(\text{mmol per fish})\end{aligned}$$

(Eq. 9):

$$\begin{aligned}\text{Ox}(18:3n-3) &= \phi(18:3n-3) - \text{DE}(18:3n-3) \\ &- \text{NED}(18:3n-3) = 7646.0 - 240 - 1315.5 \\ &= 6090.5(\text{mmol per fish})\end{aligned}$$

At this stage, with Eqs. 10, 11 and 12, the fate (DE, NED or Ox) of 18:3n-3 can be additionally reported as a percentage relative to its total net intake; in this example 1.5, 8.2 and 37.8%, respectively.

Ultimately, with the fourth and final step, through Eqs. 13, 14, 15, 16 it is possible to estimate the total elongase,  $\Delta$ -5 and  $\Delta$ -6 desaturase activities expressed as mmol of product per gram of body weight per day. In the example reported the initial fish weight was 21.3, final fish weight was 74.6 and the experimental period was 112 days, therefore (Eq. 13) the grams of BW day<sup>-1</sup> equates to 5,370.

(Eq. 14):

$$\begin{aligned}\Delta\text{-6 desaturase} &= [\delta(18:4n-3) + \varepsilon(18:4n-3) + \delta(22:6n-3)] \\ &(\text{gram of BW day}^{-1})^{-1} = (881.6 + 433.9 + 12.8) \\ &\times (5370)^{-1} = 0.24735(\text{mmol g}^{-1}\text{day}^{-1})\end{aligned}$$

(Eq. 15):

$$\begin{aligned}\Delta-5 \text{ desaturase} &= [\delta(20:5n-3) + \varepsilon(20:5n-3)] \\ (\text{gram of BW day}^{-1})^{-1} &= (-111.4 + 136.0) \times (5370)^{-1} \\ &= 0.00458(\text{mmol g}^{-1}\text{day}^{-1})\end{aligned}$$

(Eq. 16):

$$\begin{aligned}\text{Elongase} &= [\delta(20:3n-3) + \varepsilon(20:3n-3) + \varepsilon(18:4n-3) \\ &+ \varepsilon(20:5n-3) + \varepsilon(22:5n-3)](\text{gram of BW day}^{-1})^{-1} \\ &= (240.0 + 0 + 433.9 + 136.0 + 12.8) \times (5370)^{-1} \\ &= 0.15319(\text{mmol g}^{-1}\text{day}^{-1}).\end{aligned}$$

As previously reported [5], fish were housed in three replicate tanks (30 fish per tank) with four fish culled per tank and analyzed individually in duplicate. The analytical variability recorded was relatively low. For example, the average coefficient of variability ( $\text{st.dev} \times 100 \times \text{mean}^{-1}$ ) of DHA in the whole body within the replicates was 1.43%. However, the biological variability recorded between the four individuals was greater (8.43%), with the highest variability recorded in fish from the same tank ranging from 23 to 28 mg of DHA per g of lipid. Although this information is useful in understanding the analytical and biological variability within individual specimen, the actual replicate has to be considered the tank, hence  $N = 3$ , from a statistical viewpoint. If we were to focus our attention on the total  $\Delta$ -6 desaturase activity (Eq. 14) evidenced using the whole body fatty acid balance method, we recorded for the three tanks the values 0.20068, 0.26297 and 0.27840  $\text{mmol g}^{-1} \text{day}^{-1}$ . Clearly this is to be considered as a broad indication for the estimation of appropriate sample size when fish are used. Understandably, the specific variability of an individual sample would need to be taken into consideration if the method was to be applied to a different animal.

## Discussion

A variety of methods have been developed for measuring elongase and desaturase activity. The methodology presented here employs an in vivo approach which provides a reliable estimation of an organism's overall capacity to metabolize fatty acids. To date, to the best of the authors' knowledge, this method has been applied only twice [5, 6], but not presented in detail. With respect to the quantification of elongase and desaturase activity, the results obtained in these studies are highly consistent and in general agreement within the highly variable range of results obtained using ex vivo counterparts. For example,

the  $\Delta$ -6 desaturase activity reported on 18:3n-3 in the above mentioned separate studies and measured with the whole-body fatty acid balance method in juvenile fresh-water finfish Murray cod (*Maccullochella peelii peelii*) were  $0.147 \pm 0.006 \text{ mmol g}^{-1} \text{day}^{-1}$  and  $0.247 \pm 0.012 \text{ mmol g}^{-1} \text{day}^{-1}$  in fish fed semi purified diets containing only a blend of vegetable oils [6] and linseed oil [5] as the dietary lipid source. The differences in enzyme activity were ascribable to the difference in the percentage of 18:3n-3 in the diets, which were 25.7 and 55.4%, respectively.

Unfortunately, to date, it has not been possible to directly compare the results obtained by the utilization of the presented method with results from different ex vivo methods because they are generally reported as pmol per hour per gram of protein of the isolated cells, and not relative to the entire organism. Moreover, the two methods have not been implemented on a single species, and therefore a hypothetical comparison would be misleading.

Admittedly, there are certain limitations that can restrict accuracy and applicability of the proposed method. One variable that the whole-body fatty acid balance method does not take into consideration is the allowance of eicosanoid production. However, it is acceptable that the conversion of 20:4n-6 and 20:5n-3 is minimal, having little impact on the total balance of fatty acids [4]. A second variable not taken into consideration is the possible chain-shortening and oxidation of fatty acids previously elongated and desaturated [9]; for example if a given amount of 18:3n-3 is desaturated to 18:4n-3 and successively oxidized it will be considered as an oxidation process of 18:3n-3. However, although oxidation of longer and more unsaturated chain fatty acids is occurring to a lesser extent than their precursor [9], this is a possible occurrence, and hence a limit, also for other methods such as ex vivo approaches that employ whole cells and their incubation with labeled fatty acids. If for example [ $1\text{-}^{14}\text{C}$ ] labeled 18:3n-3 is utilised, the radioactive acid-soluble fatty acid oxidation products determined to quantify  $\beta$ -oxidation activity can derive from [ $1\text{-}^{14}\text{C}$ ] 18:3n-3 directly oxidized but also from [ $1\text{-}^{14}\text{C}$ ] 18:3n-3 previously desaturated to [ $1\text{-}^{14}\text{C}$ ] 18:4n-3 and successively oxidized.

In consideration that the method provides an accurate mass balance analysis it can quantify an animal's capability in depositing HUFA. We can therefore conclude that the whole-body fatty acid balance method is a simple, relatively inexpensive, routine laboratory technique and its utilization on different species will be instrumental in expanding our understanding of animal lipid metabolism.

4-methyl-1,2,4-triazoline-3,5-dione (MTAD) adducts for definitive identification of double bond positions. In addition, silver ion high-performance liquid chromatography (HPLC) has proved very useful for the separation of geometrical and positional isomers both on analytical and preparative scales.

In this review, we have been pragmatic and highly selective in describing those methods that appear to us to be most useful for isolation and analysis of CLA and CLA isomers, as opposed to an exhaustive discussion of the literature. There is inevitably an element of subjectivity in our approach. Most analysts will employ GC for routine analysis of CLA and this may be supplemented with mass spectrometry for definitive identifications. Silver ion high-performance liquid chromatography is an invaluable alternative or complementary procedure. However, CLA levels in tissues of foodstuffs may be too low to be directly amenable to such analyses. Then, pre-concentration methods may have to be applied. Detailed protocols for many of the methods described here are available in earlier reviews [3, 5].

### Preparation of Methyl Ester Derivatives of Lipids Containing CLA

The first step before chromatographic analysis of lipids containing CLA is preparation of the methyl ester derivatives. It is well established that acid-catalysed transesterification of lipids can bring about isomerization of *cis,trans*- to the *trans,trans*-forms with some loss of CLA, so that base-catalysed methods are most suitable for the purpose [6]. Sodium methoxide in anhydrous methanol is the preferred reagent for glycerolipids. Free fatty acids cannot be esterified by this means, and while trimethylsilyl-diazomethane is occasionally recommended, there is ample evidence that it can lead to artefact formation. However, free fatty acids can be methylated by acid-catalysed procedures if the reaction time is kept short. For example, boron trifluoride–methanol or sulfuric acid (1% v/v)–methanol reagents can be employed provided that scrupulous attention is paid to detail [5]; in particular, freshly prepared reagent should be used and the reaction time kept to the minimum. For example, free fatty acids are fully and safely methylated with boron trifluoride–methanol in 10 min at ambient temperature (or with sulfuric acid–methanol (1%) at 50 °C for up to 1 h). Methods of preparing methyl esters have been reviewed exhaustively elsewhere [7].

### Gas Chromatographic Analysis

Gas chromatography is by far the most widely used method for the analysis of the total CLA content of samples and for

the composition of individual isomers. Coupled to mass spectrometry for identification purposes, it is an extremely useful tool. It is recognized that long (50 or 100 m) polar columns coated with 100% cyanopropyl polysiloxane (e.g., CP-Sil 88<sup>TM</sup>, SP2380<sup>TM</sup> and SP 2560<sup>TM</sup>) give optimum resolution of CLA isomers. Under optimal conditions, methyl esters of CLA isomers elute just after 18:3(n-3) and 20:1 isomers and before 20:2(n-6), although under some conditions 20:1 isomers can interfere with the analysis of CLA. On a 100 m CP-Sil 88<sup>TM</sup> column, the following conditions have been used successfully for total cheese fatty acid methyl esters (FAMES); holding the temperature at 75 °C for 2 min, temperature programming at 5 °C/min to 180 °C, holding at 180 °C for 33 min, then at 4 °C/min to 225 °C and finally holding at 225 °C for 44 min [8]. Under these conditions the CLA isomers eluted between 49 and 53 min. The low starting temperature enabled short-chain fatty acids to be separated, but a higher starting temperature (150–175°C) can be used for most other tissue samples. If the total CLA content is all that is required, a column of medium polarity (CP-Wax 58<sup>TM</sup>) and moderate length (25 m) can be used, the CLA region emerging after 18:3(n-3), and before all C<sub>20</sub> and C<sub>21</sub> FAMES.

The distribution of CLA isomers in commercial preparations has been examined by GC of the methyl esters [with identification by GC–MS of the DMOX derivatives (see below)] [9]. Typical commercial CLA mixtures contain mainly *cis,trans/trans,cis* isomers and less *cis,cis* and *trans,trans* isomers (Fig. 1). The *trans,cis* CLA isomers elute before the *cis,cis* and finally the *trans,trans* isomers emerge. Usually only one of the *cis,trans/trans,cis* forms (e.g., 9*c*,11*t*-18:2 but not 9*t*,11*c*-18:2) of each positional isomer occurs. The main isomers are 9*c*11*t*- and 10*t*12*c*-18:2 in roughly equal amounts, and 8*t*10*c*- and 11*c*13*t*-18:2 may be either absent or present to varying degrees. The 8*t*10*c*-18:2 isomer is sometimes totally masked by the 9*c*11*t*-18:2 isomer but can be seen as a definite later-eluting shoulder or even as a split peak when the proportion of the two isomers is similar. The 11*c*13*t*-18:2 isomer emerges next and may not be totally resolved from the 10*t*12*c*-18:2 isomer. Trace amounts of 10*c*,12*t*- and 9*t*,11*c*-18:2 isomers are sometimes apparent, occurring between the 9*c*,11*t*-/8*t*,10*c*- and 11*c*,13*t*-18:2 peaks. Low levels of *cis,cis* isomers are reasonably well resolved (elution order 8,10- < 9,11- < 10,12- < 11,13-18:2) occurring just after the 10*t*,12*c*-18:2 peak. Within the *trans,trans* isomers the 11,13-18:2 isomer elutes ahead of the other (8,10-, 9,11- and 10,12-18:2) poorly resolved isomers.

Similarly, GC (and GC–MS of DMOX derivatives) has been utilized for characterizing CLA in a variety of natural samples. The materials may be analysed without pre-treatment or after concentration of total CLA by RP–HPLC (see below) or, for the most detailed examination as has

**Fig. 1** Partial gas chromatogram of a commercial CLA methyl ester mixture, separated on a CP-Sil 88 capillary column (100 m × 0.25 mm id × 0.2 μm film thickness; Chrompack UK Ltd, London, UK) with flame-ionization detection. The oven temperature was held at 160 °C for 3 min, then was programmed at 2 °C/min to 220 °C and held at 220 °C for 20 min. Hydrogen was the carrier gas at a constant flow rate of 1 ml/min and a split ratio of 50:1 was used

been applied to cheese, after fractionation of the CLA by silver-ion HPLC (discussed below). In the latter case it is interesting that a short non-polar (30 m HP5MS) column can be used for CLA analysis. It would appear that optimum resolution by GC may not be essential if pre-fractionation by silver ion HPLC is carried out.

Natural samples for CLA analysis often contain more isomers than commercial CLA and the proportion of isomers within each sample type is different, affecting peak resolution. Invariably the 9*c*,11*t*-18:2 isomer is the major peak representing 80–90% of total CLA isomers. The isomer distribution in cheese contains all the isomers found in other foods (Fig. 2) [10, 11]. The *cis,trans/trans,cis*, *cis,cis* and *trans,trans* groups all contain positional isomers ranging from 7,9- to 12,14-18:2. Within the *cis,trans/trans,cis* isomers, in contrast to most commercial CLA, all possible geometrical isomers have been detected with the exception of 8*c*,10*t*- and 12*t*,14*c*-18:2. Retention times increase with increasing distance of the *cis* double bond from the ester moiety, and for isomers that have the same *cis* double bond, with the exception of the 10*t*,12*c*-/12*c*,14*t*-18:2 pair, the isomer with the *trans* double bond nearest the ester moiety elutes first. In cheese, none of the *cis,trans/trans,cis* isomers elute as pure peaks; 7*t*,9*c*-, 8*t*,10*c*- and 9*c*,11*t*-18:2 overlap, as do 9*t*,11*c*- and 10*c*,12*t*-18:2, and 10*t*,12*c*- and 12*c*,14*t*-18:2, and 11*t*,13*c*-18:2 overlaps with the first *cis,cis* peak (Fig. 2). Within the *cis,cis* isomers, presumably due to the wide range in the relative amounts of the different positional isomers, only two peaks are apparent, the first comprising the 7,9- to 9,11-18:2 isomers, the second the 10,12- to 12,14-18:2 isomers. The 12*t*,14*t*-18:2 isomer elutes first followed by the 11*t*,13*t*-18:2 isomer and then the major *trans,trans* peak, comprising 7*t*,9*t*-10*t*,12*t*-18:2.

A CLA standard mixture for is essential for identifying CLA isomers in natural samples by GC. A commercial CLA mixture is useful but it does not contain all the

isomers found in natural samples. Other standard mixtures can be prepared. Preparations of mixtures containing all 16 possible isomers ranging from 8,10- to 11,13-18:2, obtained by isomerization of commercial CLA with either iodine or *p*-toluenesulfonic acid as catalyst [12], or with additional 7*t*,9*c*- and 12*c*,14*t*-18:2 isomers using a procedure involving sigmatropic rearrangements and selenium-catalysed geometrical isomerization [13], are useful as standards to assist identifications. All 32 possible isomers from 6,8- to 13,15-18:2 have been synthesised and the relative retention times determined on a 100 m CP-Sil 88™ [14] (Table 1).

Several peaks (e.g., 21:0) that are not CLA isomers may occur in the CLA region of the gas chromatogram of natural CLA samples, and in samples extracted from tissue derived from animals fed commercial CLA. The 21:0 is often at similar concentrations to the minor CLA isomers and can elute anywhere between 11*c*,13*t*- (as in Fig. 2) and 10*c*,12*c*-18:2 depending on the GC conditions [15]. Care has to be taken to avoid misidentifications, and use of columns differing in polarity can remove some dubiety. Mass spectrometry can eliminate all doubts [8].

### Silver Ion High-Performance Liquid Chromatography

Silver-ion high-performance liquid chromatography (Ag-HPLC) complements gas chromatographic analysis of samples containing CLA, and has the additional advantage of being a micro-preparative technique. Retention in Ag-HPLC is due primarily to the formation of transient complexes between the Ag<sup>+</sup> ions in the HPLC column and unsaturation (pi electrons) in the sample molecules. In general, the more unsaturation (double bonds), the more strongly the molecule is retained, though conjugated double bonds are an exception. Double bond configuration is

**Fig. 2** Comparison of partial gas chromatograms of the CLA methyl ester region from cheese total fatty acid methyl esters with flame-ionization detection (*top*) and the same region with high-resolution selected-ion recording (*SIR*) at  $m/z$  294.2559 (molecular weight of CLA methyl ester) (*bottom*). Separations were performed using a CP-Sil 88 capillary column (100 m  $\times$  0.25 mm id  $\times$  0.2  $\mu$ m film thickness; Chrompack Inc., Raritan, NJ) using hydrogen as carrier gas. For gas chromatography, the oven temperature was held at 75 °C for 2 min, programmed at 5 °C/min to 180 °C, held at 180 °C for 33 min, programmed at 4 °C/min to 225 °C, and finally held at 225 °C for 43.8 min. For GC–MS, the oven temperature was held at 75 °C for 2 min, programmed at 5 °C/min to 170 °C, held at 170 °C for 40 min, programmed at 5 °C/min to 220 °C, and finally held at 220 °C for 20 min. Peaks indicated by an asterisk were not found in the SIR chromatogram and are not CLA isomers. CLA isomers in brackets were detected at low levels. Redrawn from Roach et al. [8] with permission of the authors and *Lipids*. Some identities have been annotated using information from Delmonte et al. [14] and Sehat et al. [11]

RRT relative to  $\gamma$ -linolenic acid methyl ester (GLA) calculated using  $(RT_{\text{isomer}} - RT_{\text{solvent}}) / (RT_{\text{GLA}} - RT_{\text{solvent}})$ . Oven temperature programme: 75 °C for 2 min, then 5 °C/min to 175 °C, holding at 175 °C for 33 min, then at 5 °C/min to 225 °C and finally holding at 225 °C for 8 min. Adapted from Delmonte et al. [14]

also important, with *cis* double bonds retained more strongly than *trans*. Ag-HPLC utilizing columns packed with 5–10  $\mu$ m Nucleosil SA<sup>TM</sup> or a similar material, with phenylsulfonic acid groups bonded to a silica substrate, in which the sulfonic acid protons have been exchanged with Ag<sup>+</sup> ions, is an especially useful technique for the separation and isolation of *cis* and *trans* geometrical and

positional isomers of CLA as FAMES and, to a lesser extent, as free fatty acids (FFAs) and triacylglycerols (TAGs). The technique has been reviewed in relation to lipids in general [16, 17] and CLA specifically [18].

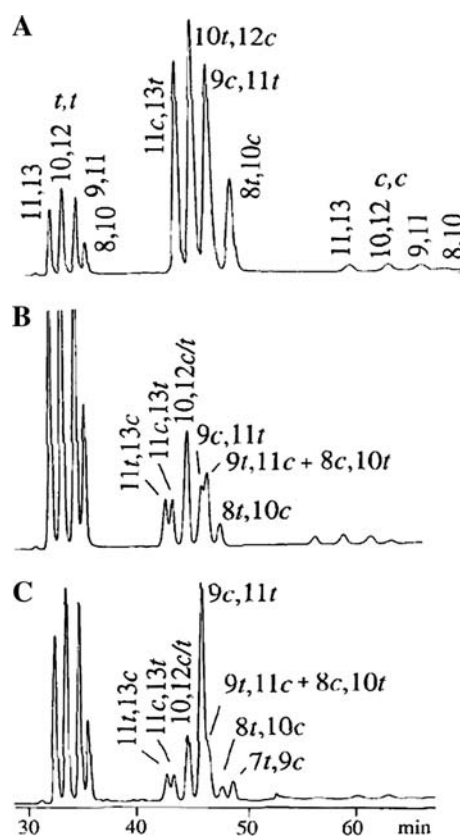

One of the most popular Ag-HPLC columns is the ChromSpher Lipids<sup>TM</sup> column (Cat. No. 28313; 4.6 mm ID  $\times$  250 mm stainless steel; 5  $\mu$ m particle size), which can be purchased from Varian-Chrompack International, Middelburg, The Netherlands. Many analysts recommend

the employment of two such columns connected in series to improve sample capacity and to provide the required peak-to-peak resolutions, but up to six columns in series have been used for enhanced separations [12]. Typical isocratic flow rates of 1.0–2.0 ml/min and compositions of 0.1–1.0% acetonitrile in hexane in the mobile phase, maintained at a constant temperature of  $\sim 23$  °C, are adjusted to maintain pump head pressures at  $\leq 2,500$  psi and to maintain total sample elution times of 35 min or less. Void volumes are approximately 1.0 ml per column.

In a solvent system of acetonitrile in hexane, the acetonitrile competes with the  $\text{Ag}^+$  ions for the unsaturated sites of the sample molecules. The more acetonitrile in the solvent, the faster the sample elutes from the column. With dioenoic fatty acids, the greater the distance between the double bonds (up to three methylene groups at least), the more strongly they are retained. Thus, fatty acids with conjugated double bonds elute before those with methylene-interrupted double bonds, and the expected elution order (*trans,trans*-, then *cis,trans/trans,cis*-, then *cis,cis*-) is observed. These arguments also apply to the three fatty acid molecules attached to a glycerol backbone of TAG (ABA, AAB, ABC, etc.), but the location is also important. Fatty acids on the 1(3)-positions of the TAG molecule (the “A” in ABA) shield that in the 2-position (the “B”) from the  $\text{Ag}^+$  ions. So, while oleic acid (O; 9*c*-18:1) is retained more strongly than stearic acid (S; 18:0), for TAGs composed of two O and one S fatty acids, the elution order is SOS before SSO.

### Separation as Methyl Esters

Ag-HPLC analysis of CLA isomers as methyl esters (or other ester derivatives [11, 19, 20]) continues to be the single largest application for this technology, an excellent example of which is illustrated in Fig. 3. Utilizing three Ag-HPLC columns connected in series and an isocratic solvent system of 0.1% acetonitrile in hexane, Eulitz and co-workers [12] were able to separate the very difficult 9*c*,11*t*- and 9*t*,11*c*-18:2 isomer pair as FAMES, and, by utilizing two elution systems, others were able to determine the relative retention orders of all 32 *cis/trans* 6,8- to 13,15-CLA isomers [21]. Two to six columns connected in series were required to separate such isomer pairs as 8*t*,10*c*- from 7*t*,9*c*- and 11*c*,13*t*- from 9*t*,13*c*-18:2. In comparison, analysis of this mixture by GC utilizing a 100 m, highly polar capillary column could separate the *cis/cis*, the *cis/trans* and *trans/cis* (incomplete separation) and *trans/trans* 11,13-18:2 isomers, but could not resolve *trans/trans* 8,10-, 9,11- or 10,12-18:2. Propionitrile or butyronitrile in heptane may give a more stable performance as mobile phases (although these solvents are more much toxic than acetonitrile) [22].

**Fig. 3** Partial Ag-HPLC profile of (A) the methyl esters of a commercial CLA isomer mixture, (B) of the  $\text{I}_2$ -isomerized product of (A) and (C) of the  $\text{I}_2$ -isomerized product of (A) co-injected with cheese total lipid FAME. Three Chromspher Lipids™ columns in series with a mobile phase of 0.1% acetonitrile in hexane (1 ml/min) and detection by UV spectroscopy at 234 nm (with the permission of the authors and AOCS Press, and redrawn from the original) [12]

In the analysis of CLA in tissue samples by such methods, especially at low concentrations, it has been recommended that the results should be confirmed by GC and/or GC-MS to eliminate errors due to false positives [22].

Ag-HPLC ( $4.6 \times 250$  mm columns) may also be used for the semi-preparative isolation of CLA esters. Two Ag-HPLC columns connected in series were also used to isolate milligram quantities of CLA isomers from a mixture of 78.8% 9*t*,11*t*-18:2/21.2% 9*c*,11*t*-18:2 (both 17,17,18,18- $d_4$ ) (Fig. 4) [23]. Resolution of the two CLA isomers, which decreased with increasing weights of samples injected, was maintained at  $>95\%$  of baseline by decreasing the percentage of acetonitrile in the isocratic hexane/acetonitrile solvent system. Purities of the isolated fractions were found to be  $>96\%$  by GC analysis. A 10 mg sample was fractionated within 35 min using a solvent system of 1.0 ml/min of 0.15% acetonitrile in hexane. One could continue to compensate for losses in peak-to-peak resolution with increased sample sizes by

**Fig. 4** Fractionation of a CLA sample by dual column Ag-HPLC. Sample sizes: 5 mg (A) and 10 mg (B). Flow rate: 1.0 ml/min 0.15% acetonitrile in hexane. UV detection at 215 and 212 nm, respectively. Peak #1 = 9-*trans*,11-*trans*-18:2; #2 = 9-*cis*,11-*trans*-18:2 (Published with the permission of Elsevier Ltd. and redrawn from the original) [23]

decreasing the percentage of acetonitrile in the solvent; but a 15 mg sample of the CLA isomer mixture (1.0 ml/min 0.1% acetonitrile in hexane) required some 80 min to elute. Two 10 mg samples could actually be fractionated within 70 min ( $2 \times 35$  min), less time than that required to separate one 15 mg sample.

#### Separation of Free Fatty Acids

More limited work has been done with the underivatized fatty acids. Using a single Chromspher Lipids™ Ag-HPLC column and isocratic solvent systems of hexane, acetonitrile (0.0–0.025%) and acetic acid (3.0–2.5%) and with UV detection at 234 nm, Cross and co-workers [24] fractionated a mixture of CLA isomers (8*t*,10*c*-, 9*c*,11*t*-, 10*t*,12*c*- and 11*c*-13*t*-18:2) in free fatty acid form. The resulting pattern was similar to that obtained with CLA FAME with acetonitrile in hexane as solvent (see Fig. 3). The FA composition of the isolated fractions, determined after conversion to FAME (BF<sub>3</sub>/methanol) and analysis by GC, were also identical to that obtained for CLA as FAME. The same group [25] utilized Ag-HPLC and a similar solvent system to fractionate mixtures of CLA isomers obtained from commercial mixtures and from biological samples. The most abundant isomers, *cis/trans* 10,12-18:2 and *cis/trans* 9,11-18:2, were separated better as free acids on a single column than in the methyl ester form. However, a diminution in retention over time of the Ag-HPLC columns was noted, possibly as a result of a loss of silver ions because of the acetic acid in the mobile phase [25].

#### Separation of Triacylglycerols

By utilizing Ag-HPLC, successful analysis of seed oils high in conjugated dienoic or trienoic fatty acids has been

achieved. Thus, Joh and co-workers [26] used a Nucleosil™ 5SA column (4.6 × 250 mm) saturated with silver ions and a complex gradient system of dichloromethane/dichloroethane/acetone/acetonitrile (1 ml/min) to separate TAGs from the Chinese melon [*Momordica charantia*; 57.1 mol% conjugated triene, primarily  $\alpha$ -eleostearic (9*c*,11*t*,13*t*-18:3)]. Ag-HPLC (1.5 ml/min of 1.0% acetonitrile in hexane) was also utilized to fractionate a commercially available CLA-enriched TAG formulation (G-80; Loders Crokiaan B.V., The Netherlands), as illustrated in Fig. 5 [27]. The elution patterns were achieved with either three (Fig. 5 Inset A) or four (Fig. 5 and Inset B) Ag-HPLC columns connected in series. A minimum of three columns in series were required to achieve ca. 50% separation (Fig. 5 Inset A) of peaks #3 and #4, but no fractionation of the major TAG peak (peak #4) was noted. Utilizing four Ag-HPLC columns connected in series resulted in a pattern of four distinct minor and one major peak (Fig. 5). The fractions were collected (the major peak was divided into three fractions, 2A1, 2A2 and 2A3), converted to FAMES and analysed by GC. Peak #1 = mono-CLA/2 misc FAs, peak #2 = di-CLA/mono-saturated FA, peak #3 = di-CLA/9*c*-18:1, peak #4 = Tri-CLA, and peak #5 = di-CLA/mono *cis/cis* CLA isomer. (In this instance, the term “CLA” is used for both the 9,11- and the 10,12-isomers, and *cis/cis*

**Fig. 5** Analysis of a commercial triacylglycerol formulation containing CLA by four-column Ag-HPLC [27]. Sample size: 100  $\mu$ g. Flow rate 1.5 ml/min, 1.0% acetonitrile in hexane. UV detection at 206 nm. Peak #1 = mono-CLA with two miscellaneous fatty acids, peak #2 = di-CLA/mono-saturated fatty acid, peak #3 = di-CLA/mono 9*c*-18:1 and peak #4 = Tri-CLA; peak #5 = Tri-CLA. Inset A three-column Ag-HPLC. Sample size, 50  $\mu$ g; flow rate 2.0 ml/min, 0.6% acetonitrile in hexane. Fraction 2A1 = 54/37%:10*t*,12*c*-18:2/9*c*,11*t*-18:2; fraction 2A2 = 36/56%:10*t*,12*c*-18:2/9*c*,11*t*-18:2; fraction 2A3 = 75/11%; di-9*c*,11*t*-18:2/mono-*cis/cis*-CLA (where *cis/cis* refers to 9*c*,11*c*- and 10*c*,12*c*-18:2). Inset B four-column Ag-HPLC. Sample size, 50  $\mu$ g; flow rate 1.5 ml/min, 0.7% acetonitrile in hexane. Note: The two major peaks in Insets A and B are peaks #3 and #4 of the main chromatogram and illustrate changes in separation due to changes in the number of columns used or in solvent composition. (Published with permission of Elsevier Ltd. and redrawn from the original)

refers to 9*c*,11*c*- and 10*c*,12*c*-18:2). At 0.6% acetonitrile (1.5 ml/min), the desired peak could not be eluted within 120 min. At 0.7% acetonitrile (1.5 ml/min), the peak #4 eluted at 55 min and was partially fractionated into three peaks (Fig. 5 Inset B; <10% resolution; 1:2:1 ratio). Fractionation of the individual TAG isomers was improved, but at a cost of increased elution time. Solvent flow rates and compositions could be adjusted to yield total TAG elution patterns within 30–35 min and to maintain a system pressure < 2,500 psi. Comparable methods could no doubt be used for other lipid classes after conversion to suitable non-polar derivatives.

### Concentration of Natural CLA Isomers for Further Analysis

In order to have sufficient material for analysis with tissue samples containing CLA at low levels, a pre-concentration step may be required. This can be accomplished either by subjecting the methyl esters to reversed-phase HPLC or Ag chromatography or at times by using the two techniques sequentially [28].

In reversed-phase chromatography, CLA isomers elute close to linoleate and can be collected preparatively by collecting a single broad C<sub>18</sub> diene fraction. Many analysts add water to the mobile phase or use acetonitrile–water gradients. However, acetonitrile alone is preferable either at a constant flow rate or with a flow gradient, as there is

no sacrifice of resolution and it is easier to recover the required esters by evaporation of the mobile phase. Most columns of the octadecylsilyl (ODS) type can be used for methyl esters of fatty acids [28], and base-stabilized ODS columns are of value for use with DMOX derivatives and picolinyl esters (but not free fatty acids) [29]. Evaporative light-scattering detection with a stream splitter can be used, or UV detection at 206 nm (isolated double bonds) or 230 nm (conjugated double bonds specifically), to collect appropriate fractions. Keeping the column at a constant temperature aids the reproducibility of the separation but is not essential for adequate resolution. On a standard analytical column (4.6 mm diameter), about 1 mg of sample can be separated in micro-preparative mode, but up to 20 mg can be chromatographed on a preparative column (10 mm diameter), as illustrated in Fig. 6 [5].

Ag thin-layer chromatography (TLC) and HPLC methods are available to obtain a concentrate of CLA as well as for analysis (see below), but they are needlessly complex for many purposes. A simple small-scale solid-phase extraction method adapted from a published procedure can be recommended in which an adsorbent with bonded phenylsulfonate groups is utilized in the silver ion form [30]. This can be applied to any methyl ester preparation, and to the C<sub>18</sub> diene fraction isolated by reversed-phase HPLC as above, as the CLA isomers tend to elute with the monoene fraction rather than with the methylene-interrupted dienes in this instance.

**Fig. 6** Reversed-phase HPLC separation of fatty acid methyl esters including CLA. A Nucleosil C<sub>18</sub> column (250 × 10 mm ID; 5 μm particles) was used with acetonitrile as mobile phase, and UV detection at 234 nm. Methyl esters (20 mg) in acetone were injected, with acetonitrile as mobile phase and a flow rate of 4 ml/min. The fraction corresponding to the C<sub>18</sub> dienes may also contain some 14:0, 16:1 and certain polyunsaturated fatty acids [28]

## Reversed-Phase HPLC With Second Derivative UV Detection

Conjugated dienes exhibit a distinct UV absorbance in the region of 230–235 nm, while isolated double bonds absorb at 206–210 nm. As the latter tend to be present in most tissues at relatively high levels, they can still interfere with the analysis of CLA isomers in tissues. Murru et al. [31] solved the problem by taking the differential of the first derivative spectrum and calculating a second derivative with two distinct peaks with minima at 234 and 242 nm. As the Beer–Lambert law is unaffected by differentiation, this technique enabled sensitive and accurate estimation of the conjugated diene content of fatty acids. In combination with reversed-phase HPLC, this is a powerful technique both for isolation and estimation of CLA and especially of CLA metabolites formed by elongation and desaturation of CLA in animal tissues, e.g., 9*c*,11*t*-18:2, 6*c*,9*c*,11*t*-18:3, 8*c*,11*c*,13*t*-20:3, and 5*c*,8*c*,11*c*,13*t*-20:4, together with the corresponding fatty acids formed by chain elongation and desaturation of 10*t*,12*c*-18:2. The 18:2 and 20:3 isomers tend to elute together, as do 18:3 and 20:4, but subsequent separation of these by GC is straightforward.

## Gas Chromatography–Mass Spectrometry

Although GC with appropriate standards will allow some tentative identification of CLA isomers to be made, GC–MS is essential for structural confirmation and for detecting overlapping isomers. The EI mass spectra of the methyl esters of CLA isomers are qualitatively indistinguishable from one another and from methyl linoleate. Although there may be some differences in the relative intensities of some ions, these are of limited value in the analysis of CLA mixtures. However, they are useful for distinguishing CLA peaks from other fatty acids that elute in the same region of the chromatogram. In order to distinguish between different CLA positional isomers, specific derivatives of either the carboxyl group or the conjugated diene system have been formed. The most useful derivatives of the carboxyl group for determining the structure of unsaturated fatty acids contain nitrogen atoms [29]. Following ionization, radical-site-induced cleavage occurs at every carbon in the chain, and by applying simple rules to the resultant mass spectrum, the structures of unknown fatty acids can usually be deduced from first principles without having to refer to the mass spectra of standard compounds. DMOX derivatives afford the most informative mass spectra for distinguishing CLA isomers and have the added advantage that the chromatographic resolution is comparable to methyl esters at only slightly higher column temperatures [29].

DMOX derivatives are easily prepared by reacting the free fatty acids or esters/intact lipids with an excess of 2-amino-2-methyl-1-propanol at 190°C for 6 and 18 h, respectively, followed by addition of water, extraction of the derivatives with diethyl ether/isohexane (1:1) and washing the extract with water [5]. The products should be dried and stored over anhydrous sodium sulfate to prevent ring opening. Although no adverse effects of using high temperatures for derivatizing CLA have been reported, other milder preparation procedures are available [32].

The mass spectra of DMOX derivatives of CLA contain an intense ion at  $m/z = 113$  corresponding to a McLafferty rearrangement ion and a molecular ion at  $m/z = 333$  (confirming a diunsaturated  $C_{18}$  structure) [33]. There is a series of ions between  $m/z = 318$  ( $[M-15]^+$  ion) and  $m/z = 126$ , each corresponding to chain fragments with one less carbon. In a saturated part of the chain, the difference between adjacent ions is 14 amu, corresponding to loss of a methylene group, but the pattern is altered when a double bond is encountered. If a double bond occurs between carbons at positions  $n$  and  $n + 1$  carbons (counting from the carboxyl end of the molecule) then there is a gap of 12 amu between ions containing  $n-1$  and  $n$  carbons. Thus in 10,12-18:2 the double bonds at  $\Delta 10$  and  $\Delta 12$  give rise to gaps of 12 amu between  $m/z$  values corresponding to C-9 ( $m/z = 210$ ) and C-10 ( $m/z = 222$ ), and C-11 ( $m/z = 236$ ) and C-12 ( $m/z = 248$ ) fragments, respectively (Fig. 7). Another characteristic feature is the presence of two intense ions (at  $m/z = 276$  and 290 for 10,12-18:2) containing  $m + 2$  (where  $m$  denotes the first carbon of the distal double bond, i.e., due to cleavage allylic to the distal double bond) and  $m + 3$  carbons. The allylic ion containing  $n-2$  carbons ( $m/z = 196$ ) (where  $n$  denotes the first carbon of the proximal double bond) is also often abundant. The same patterns hold for the published mass spectra of the DMOX derivatives of isomers from 6,8-18:2 to 13,15-18:2 except that the  $m + 2$  ion predominates over the  $m + 3$  ion as the diene system moves towards the extremities of the molecule, i.e., for 6,8-18:2 to 8,10-18:2 and 13,15-18:2.

Conjugated dienes react with  $\alpha,\beta$ -unsaturated carbonyl compounds to form six-membered ring adducts by a cycloaddition reaction known as the Diels–Alder reaction. CLA (as the methyl esters) readily react with the dienophile, MTAD thus fixing the position of the double bond, and the resultant adducts give informative mass spectra [34, 35]. The reaction is carried out by simply briefly mixing CLA with a solution of MTAD in dichloromethane at 0°C and stopping the reaction with 1,3-hexadiene. The adducts are analysed on a non-polar column (30 m DB5-MS<sup>TM</sup>) at high temperatures (160 °C for 3 min then programmed at 5 °C/min to 350 °C). There is a strong molecular ion at  $m/z = 407$  and an  $[M-CH_3O]^+$  ion at  $m/z = 376$ . Cleavages alpha to the ring give rise to two intense  $[M-R_1]^+$  and

**Fig. 7** Gas chromatography-electron-impact mass spectrum of the 4,4-dimethyloxazoline (DMOX) derivative of *trans*-10, *cis*-12-18:2 from a commercial CLA mixture

$[M-R_2]^+$  ions (where  $R_1$  corresponds to the alkyl moiety and  $R_2$  the methyl ester part of the chain), readily allowing the original position of the diene system to be deduced. Loss of methanol from  $[M-R_1]^+$  produces another prominent ion ( $[M-R_1-CH_3OH]^+$ ). Thus, for 9,11-18:2 and 10,12-18:2 the  $[M-R_1]^+$ ,  $[M-R_2]^+$  and  $[M-R_1-CH_3OH]^+$  ions occur at  $m/z = 322$ , 250 and 290 and  $m/z = 336$ , 236 and 304, respectively (Fig. 8).

MTAD adducts are especially useful for commercial CLA preparations, particularly for determining 8,10-18:2 which is difficult to separate from 9,11-18:2 by GC as methyl ester or DMOX derivatives [34]. Adducts of isomer mixtures occur as a single chromatographic peak (there is a small degree of separation within the peak) and individual isomers are identified by using reconstructed ion chromatograms (RICs) of the  $[M-R_1]^+$  and  $[M-R_2]^+$  ions. It is possible to estimate the different positional isomers semi-quantitatively using the summation of the areas of the  $[M-R_1]^+$  and  $[M-R_2]^+$  ions, although because of the lack of chromatographic resolution it can be difficult to be certain about the presence of isomers at very low levels. For isomers ranging from 7,9- to 11,13-18:2 good agreement with  $^{13}C$  NMR spectroscopy was obtained

for a highly isomerized CLA mixture, although NMR had the advantage that geometrical isomers could be distinguished [36]. In the GC-MS approach, geometrical isomers are not distinguished, the ions representing a particular positional isomer being derived from the sum of the geometrical isomers. However, it may be possible to utilize the claim that *cis,trans/trans,cis* and *trans,trans* isomers give MTAD adducts of different stereochemistry (*trans* and *cis* isomers of the chains about the ring, respectively) that can be resolved by GC-MS [35].

Tissue or food samples containing CLA at natural or slightly elevated levels do not appear to have been analysed as the MTAD adducts by GC-MS. Such an approach is likely to be problematic, partly because of the relatively low abundance of isomers compared to the major 9*c*11*t*-18:2 isomer and partly because it has been observed that MTAD may react with methylene-interrupted unsaturated fatty acids if conditions are too harsh [34].

Because CLA isomers in both commercial and natural CLA invariably overlap by GC there has been use of reconstructed ion chromatograms of specific ions to aid identification of CLA isomers in the form of DMOX derivatives. Roach and colleagues [37] have highlighted

**Fig. 8** Gas chromatography-electron-impact mass spectrum of the 4-methyl-1,2,4-triazoline-3,5-dione (MTAD) adduct of 10,12-18:2 methyl ester from a commercial CLA mixture

seven diagnostic ions per isomer, giving a total of 28 ions (56 ions were highlighted but some occurred more than once) for isomers ranging from 6,8- to 13,15-18:2, which are useful for identifying positional isomers (Table 2). The two pairs of ions (containing  $n-1$  and  $n$  and  $m-1$  and  $m$  carbons) each differing by 12 amu due to fragmentation around the double bonds can be used, but the allylic cleavage ion containing  $m+2$  carbons and that with  $m+3$  carbons are often more useful, especially for detecting isomers at trace levels, because of their greater intensity. However, the  $m/z$  values for the latter ions are not specific to any one positional isomer and therefore, some degree of chromatographic separation, which is often the case, is useful. Indeed, after locating an isomer using the latter ions, signal contributions from adjacent peaks can be subtracted so that a representative mass spectrum of the isomer can be obtained to confirm its identity. As an example, the RIC for the allylic cleavage ion ( $m/z = 234$ ) clearly showed the presence of two 7,9-18:2 *cis,trans/trans,cis* isomers at the leading edge of the major 9 $c$ ,11 $t$ -18:2 peak (allylic ion  $m/z = 262$ ) in a variety of materials [38]. The 7 $t$ ,9 $c$ -18:2 isomer, found to be the second major isomer at about 7% of the total CLA, had previously gone unnoticed because it was masked by the major 9 $c$ ,11 $t$ -18:2 peak. In addition, a rapid, specific and sensitive high-resolution GC-MS method using selected ion recording (SIR) of the molecular ion of CLA methyl ester ( $m/z$  294.2559) was developed to unambiguously differentiate CLA isomers from non-CLA peaks in total cheese FAMES [8] (Fig. 2).

DMOX derivatives, picolinyl esters and MTAD adducts have all been used, often in a complementary manner, to analyse the metabolites formed by elongation and desaturation of CLA following suitable fractionation by HPLC [4]. For example, the metabolites isolated from rats fed a commercial CLA containing a mixture of isomers were

examined as the DMOX derivatives. The structures of 8,11,13-20:3 (derived from 9,11-18:2), and 8,12,14-20:3 and 5,8,12,14-20:4 (derived from 10,12-18:2) acids were readily determined by using the “12 amu rule”. For example, the molecular ion for the DMOX derivative of 8,12,14-20:3 was at  $m/z = 359$  and gaps of 12 amu between  $m/z$  182 and 194, 236 and 248, and 262 and 274 located the double bonds at C-8, C-12 and C-14, respectively. The base peak at  $m/z = 222$  was due to cleavage between C-10 and C-11, i.e., at the centre of the *bis*-methylene-interrupted double bond system. However, the complete structure of a 5,8,11,13-20:4 acid (derived from 9,11-18:2) could not be elucidated from the mass spectrum of the DMOX derivative. The positions of all double bonds were determined from the mass spectrum of the picolinyl ester only after deuteration of the double bonds, gaps of 15 amu locating the positions of methylene groups containing a deuterium atom. Additionally, the position of the conjugated system was confirmed from the mass spectrum of the MTAD adduct of the methyl ester. The molecular ion was at  $m/z = 431$  and the  $[M-R_2]^+$  ion at  $m/z = 250$  corresponded to a hexyl chain attached to the ring, thus confirming an 11,13 conjugated double bond system. The intensity of the  $[M-R_1]^+$  ion ( $m/z = 346$ ) was particularly weak.

A powerful tandem mass spectrometry (MS/MS) technique using acetonitrile chemical ionization was developed for determining double bond position and geometry in CLA isomers from natural samples [39]. The acetonitrile generated a (1-methyleneimino)-1-ethenyl cation which reacted with the CLA isomers, as the methyl esters, to form a  $[M+54]^+$  ion which upon collisionally activated dissociation produced two ions as a result of carbon-carbon cleavage at positions vinylic to either side of the conjugated diene system. The two ions were characteristic of the

<sup>a</sup>  $m/z$  154 is weak and  $m/z = 220$  is more abundant than  $m/z = 234$

<sup>b</sup>  $m/z$  154 is weak and  $m/z = 234$  is more abundant than  $m/z = 248$

<sup>c</sup>  $m/z$  248 is more abundant than  $m/z = 262$

position of the double bonds, one ( $\alpha$ ) containing the ester group, the other ( $\omega$ ) the terminal methyl group. The ion resulting from vinylic cleavage to a *trans* double bond was more abundant than that from a *cis* double bond. Therefore, the ratio of the abundance of  $\alpha$  to that of  $\omega$  was highest ( $>4.8$ ) for a *cis,trans* arrangement, lowest ( $<0.5$ ) for *trans,cis* and intermediate (0.7–3.2) for *cis,cis* and *trans,trans*, thus allowing differentiation of the geometrical isomers (with pure standards at least). When used in conjunction with GC retention time data the majority of CLA isomers in milk samples were identified

### Distinguishing *cis* and *trans* Double Bonds

While infrared spectroscopy methods are especially useful for confirming the presence of *trans* double bonds in fatty acids, they do not help to locate the specific position in the fatty acid chain. For this purpose, there is no alternative to using chemical degradative techniques. The first step is to obtain a pure single component either by reversed-phase or silver ion chromatography (or by a combination of both). The CLA isomer must then be subjected to partial hydrogenation with hydrazine to yield a mixture of *cis* and *trans* monoenes, which can be easily separated by silver ion chromatography and identified either by chemical oxidative procedures or by GC–MS. Procedures of this kind have been used to identify natural CLA isomers [40] and for the elongation products of CLA [4]. Mass spectrometry with acetonitrile-covalent adduct chemical ionization can also be helpful though not necessarily definitive [39].

### Nuclear Magnetic Resonance Spectroscopy

$^{13}\text{C}$ -NMR spectroscopy has proven to be the single most comprehensive method for the identification and quantification of all the positional (7,9- to 11,13-18:2) and geometrical isomers (*cis,trans*-, *trans,cis*-, *cis,cis*- and *trans,trans*-) present in commercial CLA preparations [36]. This is arguably the most comprehensive analytical procedure for CLA, but unfortunately the methodology requires substantial amounts of sample and is not likely to be applicable to tissue extracts at natural levels.

in food from ruminants, milk and meat mainly, as a result of rumen biohydrogenation and endogenous conversion from vaccenic acid. To date, numerous animal studies indicate that CLA may influence diverse physiologic functions and promote health with regard to cancer, atherosclerosis, bone formation, growth modulation and immunity, and lately there is a growing focus on the physiological role of CLA in humans [1]. The major CLA isomers with known physiologic activities are 9-*cis*,11-*trans* linoleic acid, also called rumenic acid and 10-*trans*,12-*cis* linoleic acid, a predominant isomer in CLA commercial forms.

In the search for a possible anticarcinogenic mechanism, CLA has been tested for its antioxidant effects using model systems. In this context, antioxidative properties [2–6], no effect or even prooxidant activity [7, 8] has been reported. Likewise, studies on the oxidative stability of CLA and its non-conjugated counterpart, LA (linoleic acid), are also contradictory, showing either higher susceptibility of CLA [9–12], similar behavior of CLA and LA [13] or lower oxidative stability of CLA than that of LA [14] in model systems including free fatty acids, methyl esters, ethyl esters and triacylglycerols. The great variety of oxidation conditions (temperature, oxygen availability, light–dark, etc.) and, above all, the diversity of methods applied, normally evaluating only partial aspects of lipid oxidation, may have contributed to the differences in the results obtained.

The mechanism of autoxidation of methylene-interrupted fatty acid double bonds is well-established and involves a catalytic process which proceeds via a free radical mechanism [15]. The initiation step consists on alkyl radical formation ( $R^{\cdot}$ ) in the carbon adjacent to the double bond and the propagation step on addition of oxygen to form alkylperoxyl radicals ( $ROO^{\cdot}$ ), hence the oxygen consumed is primarily converted to hydroperoxides ( $ROOH$ ). However, Yurawecz, Eulitz and co-workers [13, 16] have suggested that the same mechanism is not likely to occur in CLA because high energy is a prior requirement for separating double bonds from conjugation, which could explain that formation of other compounds may be favored. On the basis of the reaction products detected by gas liquid chromatography–mass spectrometry (GLC–MS), these authors reported that CLA underwent 1,2 and 1,4 cycloadditions with oxygen, which gave rise to dioxetane structures, and endoperoxides leading to furan fatty acids, respectively. Other reactions such as dimerization and polymerization, although not evaluated, were not ruled out by those authors. In contrast to these assumptions, Hämäläinen et al. supported that hydroperoxides are one type of primary oxidation products formed during autoxidation of CLA [17, 18]. The controversy over this issue warrants further investigations on the oxidation mechanisms of CLA.

The objective of this study was to gain more insight into the oxidation kinetics of CLA. Samples of 9-*cis*,12-*cis*, 9-*cis*,11-*trans*, and 10-*trans*,12-*cis* linoleic acid methyl esters, oleic acid methyl ester,  $\alpha$ -linolenic acid methyl ester and selected mixtures were used. Experiments were conducted at 30 °C in the dark and loss of substrate was determined by gas liquid chromatography (GLC) along the oxidation process. Additionally, a different analytical approach was used here for the first time to monitor oxidation of conjugated fatty acid methyl esters throughout the entire process, which provided a good measurement of compounds formed during early and advanced oxidation stages concomitantly [19, 20]. It consisted on a simple and direct analysis by high-performance size-exclusion chromatography (HPSEC), run in just 15 min and without any previous treatment of the sample.

## Experimental Procedure

### Samples

Methyl esters of oleic acid (O), 9-*cis*,12-*cis*-linoleic acid (L) and  $\alpha$ -linolenic acid (Ln) (99% purity) and methyl esters of 9-*cis*,11-*trans*-linoleic acid (CL1) and 10-*trans*,12-*cis*-linoleic acid (CL2) (90% purity) were purchased from Nu-Chek Prep. Inc. (Elysian, MN, USA). Mixtures of CL1 and CL2 (CLM), of L and CL1 (LCL1), and of L and CL2 (LCL2) were prepared with a 1:1 ratio.

### Oxidation Conditions

One gram-samples were placed in glass tubes of 1.3-cm inner diameter (surface-to-volume ratio of  $1.33 \text{ cm}^{-1}$ ) and heated in an oven at 30 °C. Experiments were carried out in duplicate.

### Analytical Methods

- Determination of remaining substrate by GLC.* Fatty acid methyl esters were separated by GLC using a CP-Sil 88 fused-silica capillary column (100 m  $\times$  0.25 mm i.d.  $\times$  0.2  $\mu\text{m}$  film thickness, Chrompack, Middelburg, Netherlands) on a Perkin–Elmer chromatograph (Model Clarus, Beaconsfield, UK) equipped with a flame ionization detector. The column was held at 100 °C for 1 min after injection, temperature-programmed at 7 °C/min to 170 °C, held there for 55 min, then temperature programmed at 10 °C/min to 230 °C and held there for 23 min. Helium was the carrier gas with a column inlet pressure set at

214 KPa and a splitless injection system. Injection volume was 1.0  $\mu\text{L}$  (50 mg/mL). The areas of the O, L, Ln, CL1 and CL2 peaks were calculated as mg/g of sample using nonadecanoic acid (C19:0) methyl ester as internal standard.

- (b) *Quantitation of oxidized monomers, dimers and polymers by HPSEC.* Samples (20 mg) were dissolved in diisopropyl ether (50 mg/mL) for direct analysis by HPSEC, using a Rheodyne 7725i injector with 10- $\mu\text{L}$  sample loop, a Waters 510 pump and a Waters 2414 refractive index detector (Waters, Milford, MA, USA). The separation was performed on two 100- and 500- $\text{\AA}$  Ultrastaygel columns ( $25 \times 0.77$  cm i.d.) packed with porous, highly cross linked styrene-divinylbenzene copolymers (film thickness: 10  $\mu\text{m}$ ) (Hewlett-Packard, Avondale, PA, USA) connected in series, with tetrahydrofuran (1 mL/min) as the mobile phase [21]. The groups of compounds separated in methyl ester samples were unoxidized compounds (Unox) oxidized monomers (OxMon), dimers (Dim) and polymers (Pol). In certain samples, separation of Pol in trimers and higher oligomers could be achieved.

## Results

Figure 1 shows the time course of the remaining substrates during the oxidation period up to levels around 50% residual amounts. Results correspond to means from duplicate experiments and showed coefficients of variation lower than 8% for samples with substrate loss higher than 9%. As expected, O remained practically unchanged and Ln, the most unsaturated compound tested, degraded fastest (Fig. 1a). As to conjugated samples (CL1, CL2, CL1 in mixture CLM, CL2 in mixture CLM), no differences were observed between conjugated linoleic (CL) isomers, and their loss rate was slower than that of L samples. Results obtained in 1:1 mixtures of L and CL1 or CL2 (Fig. 1b) showed that the rate of substrate loss for L and CL samples was practically reversed in mixtures, that is, CL disappeared more rapidly than L in mixtures. As an illustrative example, about 50% unoxidized substrate was left at 33 days in the case of L versus 23 days in the case of CL in mixtures, while such a loss occurred at 22 days in the case of L and 34 days in the case of CL when assayed separately.

Data obtained were used to calculate oxidation rate constants for CL samples alone or in mixtures with L samples, following kinetic considerations applied by Minemoto and co-workers [22]. The entire autoxidation process can be expressed by the following autocatalytic-type equation:

$$dY/dt = -kY(1 - Y) \quad (1)$$

where  $Y$  is the fraction of unoxidized remaining substrate,  $t$  is the time and  $k$  is the rate constant. Integration of Eq. (1) under the condition of  $Y = Y_0$  at  $t = 0$  gives:

$$\ln[(1 - Y)/Y] = kt + \ln[(1 - Y_0)/Y_0] \quad (2)$$

Figure 2 shows the plots of  $\ln[(1 - Y)/Y]$  versus  $t$  for CL1 and CL2 alone and in mixtures with L, which lie on a straight line that allowed us to evaluate the rate constant  $k$ . Values of  $k$  for CL1 and CL2 alone were 1.24 and  $1.21 \times 10^4 \text{ s}^{-1}$ , respectively, while in mixtures with L (LCL1 And LC2),  $k$  increased to 2.01 and  $2.03 \times 10^4 \text{ s}^{-1}$ , respectively.

The time course of formation of OxMon, Dim and Pol quantitated by HPSEC for all compounds tested is shown in Fig. 3. Through this analytical approach, a complete picture of the oxidative state can be attained. The basis of the technique is separation by molecular weight or size, and groups of oxidation compounds elute in decreasing order of molecular weight, i.e., Pol, Dim and OxMon. Results are means from duplicate experiments and showed coefficients of variation lower than 4%. Presence of OxMon, Dim or Pol was not detected in starting samples. As in Fig. 1, no appreciable differences were found between CL isomers (CL1 and CL2) and the 1:1 mixture of both (CLM). Even though CL samples started to oxidize later than did L samples, in agreement with results obtained for remaining substrates (Fig. 1), the first group of compounds formed were polymerization products. Pol continued to increase throughout all the oxidation period without any significant parallel increase of OxMon, and up to levels markedly higher than those found in L samples. In the mixtures of non-conjugated and conjugated linoleic acid methyl esters, the most outstanding results were the marked decrease in formation of OxMon as compared to the level expected to come from L contribution, as well as the notable increase of Pol as compared to the level expected to come from CL contribution. These results are consistent and complementary with data on substrate loss.

Figure 4 illustrates the differences in the oxidation profiles obtained in HPSEC chromatograms corresponding to samples oxidized for 30 days. It is clearly observed that OxMon and Dim were the most abundant oxidation compounds in L and Ln. In contrast, an unusual profile is shown by CL samples, polymers being practically the only compounds present. This is also clearly shown by overlapping HPSEC chromatograms of L (dotted line) and CL (solid line) samples with the same level of total oxidation (Fig. 5). Between Dim and OxMon peaks in L and Ln samples (Fig. 4), some compounds with intermediate molecular weight often elute, coming from  $\beta$ -scission of

**Fig. 1** Remaining amounts of methyl esters during oxidation at 30 °C in the dark. **(a)** methyl oleate (*O*); methyl 9-*cis*,12-*cis* linoleate (*L*); methyl 9-*cis*,12-*cis*,15-*cis* linolenate (*Ln*); methyl 9-*cis*,11-*trans* linoleate (*CL1*); methyl 10-*trans*,12-*cis* linoleate (*CL2*); methyl 9-*cis*,11-*trans* linoleate in a 1:1 mixture of methyl 9-*cis*,11-*trans* and methyl 10-*trans*,12-*cis* linoleate (*CL1 in CLM*); methyl 10-*trans*,12-*cis* linoleate in a 1:1 mixture of methyl 9-*cis*,11-*trans* linoleate and methyl 10-*trans*,12-*cis* linoleate (*CL2 en CLM*). **(b)** methyl 9-*cis*,12-

*cis* linoleate in a 1:1 mixture of methyl 9-*cis*,12-*cis* linoleate and 9-*cis*,11-*trans* (*L in LCL1*); methyl 9-*cis*,11-*trans* linoleate in a 1:1 mixture of methyl 9-*cis*,12-*cis* linoleate and 9-*cis*,11-*trans* (*CL1 in LCL1*); methyl 9-*cis*,12-*cis* linoleate in a 1:1 mixture of methyl 9-*cis*,11-*trans* and methyl 10-*trans*,12-*cis* (*L in LCL2*) and methyl 10-*trans*,12-*cis* linoleate in a 1:1 mixture of methyl 9-*cis*,12-*cis* linoleate and 10-*trans*,12-*cis* (*CL2 in LCL2*)

the alkoxy radical derived from hydroperoxides, which is the main mechanism for volatile formation.

To illustrate the large degree of polymerization (DP) found in CL samples, Fig. 6 represents the contribution of polymers with DP higher than three in samples of CLM and Ln. Even though Ln possesses three double bonds and higher polymerization degree is therefore expected as compared to CL, the abundance of larger polymers was by

far higher in CLM, and even from the beginning of the oxidation process.

## Discussion

From the results obtained through evaluation of substrate loss (Fig. 1), it can be deduced that oxidation was more rapid in non-conjugated than in conjugated linoleic moieties. As to the similar loss substrate rate for CL isomers, results agree with those reported by Jiang and Kamal-Eldin in experiments under quite different oxidation conditions, i.e., photooxidation using methylene blue as a sensitizer [10]. Results obtained in 1:1 mixtures of L and CL1 or CL2 provided interesting information on the possible interaction between oxidative pathways of non-conjugated and conjugated linoleic acid moieties. The increase in oxidation rate for CL samples in mixtures with L (LCL1 and LC2) as compared to CL1 and CL2 alone (Fig. 2) could be due to the potential free radical scavenging properties of CL [5, 23, 24], and specifically to the reaction of furan fatty acids derived from CL oxidation with hydroperoxide radicals coming from L oxidation, thus producing a dioxoene compound which has been unequivocally detected by GLC-MS [13, 25, 26].

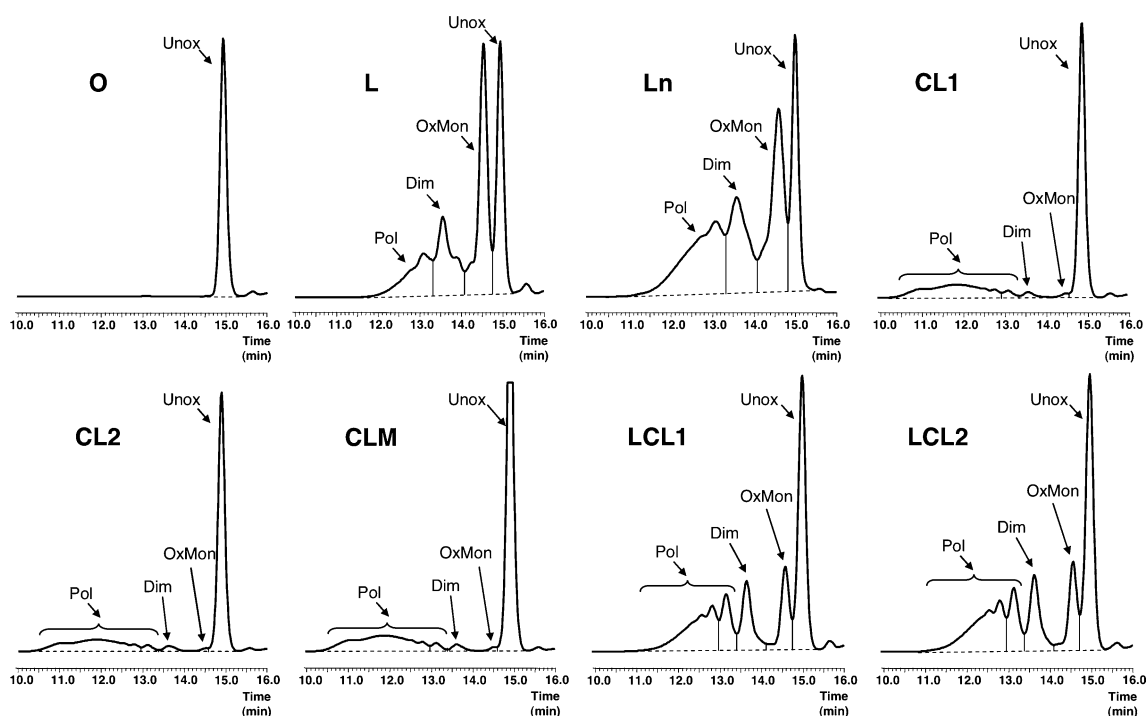

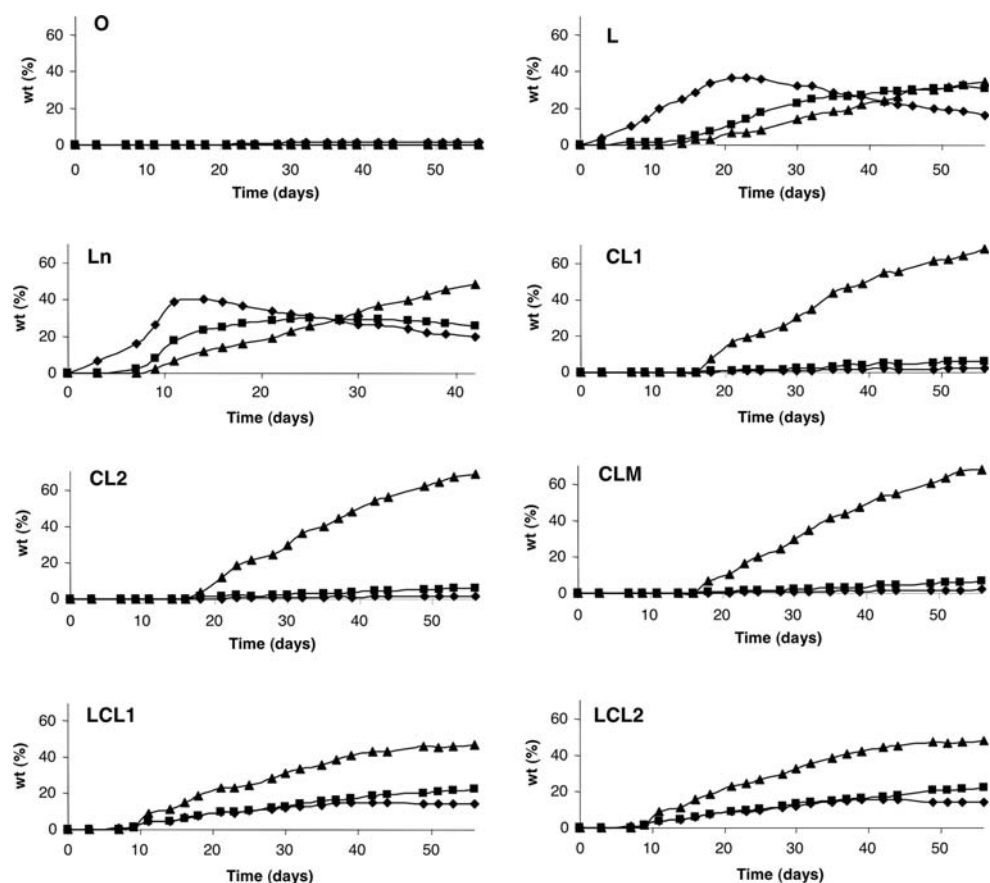

Application of HPSEC added essential information on oxidation kinetics since formation of different groups of

**Fig. 2** Applicability of equation  $\ln[(1 - Y)/Y] = kt + \ln[(1 - Y_0)/Y_0]$  to changes in the fraction of unoxidized, remaining methyl esters: CL1 (filled triangles), CL2 (filled squares), CL1 in LCL1 (void triangles), CL2 in LCL2 (void squares). *Y* fraction of remaining methyl esters; *t* time; *k* rate constant; *Y* = *Y*<sub>0</sub> at *t* = 0. oxidation compounds could be followed from the beginning and along the oxidation period. The method offers the advantage that differences in molecular weight between unoxidized and oxidized monomeric molecules of monoacid methyl esters are sufficient as to be eluted at distinct retention times [19, 20]. However, when analyzing triacylglycerols, fats or oils, a preliminary step to separate the non-oxidized fraction is essential, as described previously [21]. Oxidized monomers comprise the primary oxidation products, i.e., hydroperoxides, and once oxidation proceeds, include also secondary monomeric oxidation compounds, with oxygenated functions such as hydroxy-, keto- or epoxy-. In the same analysis, compounds typical of

advanced oxidation stages, i.e., dimers (two molecules) and polymers (more than two molecules), are concomitantly quantitated. Applications of methodologies based on HPSEC for quantitation of oxidation compounds have been reviewed recently [27, 28].

In Fig. 3, the typical oxidation profile can be observed for L and Ln, that is, initial formation of OxMon, mainly comprised of hydroperoxides during early oxidation, and further acceleration of oxidation denoted by a significant rise in Dim and Pol [19, 29]. As expected, the accumulation of sufficient amounts of OxMon led to the formation of Dim and, likewise, Pol did not build up until a notable increase of Dim had occurred. Also expected was the higher polymerization rate in Ln samples as compared to L samples as a result of increased degree of unsaturation. However, CL samples showed a very different oxidation pattern, not described so far in the literature. Thus, formation of typical primary oxidation products, i.e., hydroperoxides (included in the OxMon peak), seemed to be negligible in CL samples. Furthermore, Dim formation was rare and the starting point of oxidation for these samples was characterized by the appearance of polymers.

Interestingly, a study carried out back in the late 1940s reported that autoxidation of CLA methyl esters proceeded three times slower and eight to ten times the amount of peroxides was formed than in the autoxidation of methyl linoleate [30]. In addition, recent studies have indicated that peroxide values and TBARS did not increase in oxidized CLA at the levels expected from the increase in absorbed oxygen and loss of substrate found [31, 32].

Polymerization reactions in substrates with conjugated double bonds under conditions of oxidation at low temperatures are practically unknown. To our knowledge, only one recent study has published any results on polymer formation in relation to oxidative stability of CLA [31]. The authors found that the main oxidation products of bitter melon oil–triacylglycerols (61.6% conjugated linolenic acids) and CLA containing oil–triacylglycerols (69.5% conjugated linoleic acids) at 50 °C were dimers and polymers, whereas hydroperoxides were the main products in the oxidation of perilla oil–triacylglycerols (54.5% non-conjugated linolenic acid) and soybean oil–triacylglycerols (56.1% non-conjugated linoleic acid). In this context, Brimberg and Kamal-Eldin carried out a kinetic evaluation of rate data on CLA oxidation taken from literature and suggested that oligomeric peroxides can be formed in the very beginning of the oxidation in substrates with conjugated double bonds [33].

In this study, the early retention time at which polymers started to elute in CL samples, with unusually high molecular weight or size (Figs. 4, 5) in addition to the substantial contribution of such compounds to the total polymer fraction (Fig. 6) indicate that formation of very

complex molecules is favored even under the mild oxidation conditions used, i.e., 30 °C in the dark. This is of extraordinary importance since such structures are unknown and even the implication of high molecular size compounds due to steric configuration or cyclization should not be disregarded.

Overall, the results obtained in this study show that different oxidation pathways could be involved in conjugated and non-conjugated fatty acids, the latter showing an oxidation pattern where polymers were the main group of compounds formed. One of the most important conclusions of this work is that validity of a single index to evaluate partial aspects of oxidation needs to be questioned. Thus, a misleading picture of the development of oxidation of CLA can be obtained when the methods applied are based only on evaluation of hydroperoxides (peroxide value) or monomeric oxidation products (thio-barbituric acid reactive substances or carbonyl compounds). Otherwise, indirect methods such as loss of substrate and oxygen consumption provide useful information but, above all, from the results obtained in this study, it appears that polymer quantitation can be an appropriate measurement to follow-up oxidation of CLA. Finally, the results obtained support further studies aimed at examining the interaction of non-conjugated and conjugated fatty acids, and triacylglycerols containing them, in mixtures at compositions closer to those found in nutritional supplements and foods. Experiments are underway in our laboratory to determine differences in oxidative stability between linoleic acid-rich oils and conjugated linoleic acid-rich oils.

## Introduction

In recent years, conjugated linoleic acid isomers have received much attention due their potential beneficial properties to human health [1–3]. CLA has been implicated in the prevention of carcinogenesis, atherogenesis, obesity and enhancement of the immune function in animal models; however, in human studies inconsistent effects have been reported [4–7]. Of the two physiologically important isomers, *cis*-9,*trans*-11 CLA is the most prevalent accounting for up to 80–90% of total CLA in ruminant products, whereas *trans*-10,*cis*-12 CLA comprises 3–5% of total CLA [8]. The main dietary source of CLA in food is ruminant meat, milk and their products [9, 10].

It is well known that *cis*-9,*trans*-11 CLA is formed from two sources, one originates from ruminal biohydrogenation of linoleic acid to stearic acid in the rumen by *Butyrivibrio fibrisolvens* and other bacteria [11, 12]. The second source is the endogenous conversion of *trans*-11 18:1 by  $\Delta^9$ -desaturase in the mammary gland of dairy cows and ruminant adipose tissue [10, 13]. VA is a common intermediate produced during ruminal biohydrogenation of linolenic acid (18:3n-3) and linoleic acid (18:2n-6) [14, 15]. Griinari et al. [10] demonstrated that endogenous synthesis of *cis*-9,*trans*-11 CLA from VA represents the primary source in milk fat of lactating cows. More recently, Mosley et al. [16] confirmed using  $^{13}\text{C}$ -labeled VA that endogenous conversion of dietary VA to *cis*-9,*trans*-11 CLA in the mammary gland catalyzed by  $\Delta^9$ -desaturase occurred. The authors [16] found that approximately 80% of milk fat *cis*-9,*trans*-11 CLA originated from VA. In the course of endogenous synthesis of *cis*-9,*trans*-11 CLA, VA and  $\Delta^9$ -desaturase are the two primary prerequisites. Daniel et al. [17] demonstrated that the  $\Delta^9$ -desaturase is active in sheep adipose tissues, and its mRNA is well expressed. The genetic basis for the individual variation in milk fat content of *cis*-9,*trans*-11 CLA and the  $\Delta^9$ -desaturase index remains to be identified.

Furthermore, numerous investigations have demonstrated that diet has a substantial effect on the content of VA and *cis*-9,*trans*-11 CLA both in milk and intramuscular fat [1, 9, 13, 19]. When comparing pasture and concentrate diets there are several differences that relate to milk and intramuscular fat *cis*-9,*trans*-11 CLA [9]. Most research investigating the biohydrogenation of dietary fatty acids to VA, the desaturation of VA to *cis*-9,*trans*-11 CLA and the endogenous synthesis of *cis*-9,*trans*-11 CLA has focused on milk fat [1, 9]. However, there is a lack of information about the pathway of VA and *cis*-9,*trans*-11 CLA from the rumen, via duodenal digesta and blood transport into the muscle and subcutaneous fat.

A large study was carried out by Nuernberg et al. [19] to investigate the effect of feeding pasture versus concentrate

to two different cattle breeds (German Holstein and German Simmental bulls) on meat quality and fatty acid composition of intramuscular fat of bulls. The diet effects of pasture feeding on carcass- and meat quality, total fatty acid composition, fatty acid composition of polar and neutral lipids, CLA and *trans*-18:1 isomers in muscles and subcutaneous fat had been published previously [20–22]. However, the experiment results of diet effects on fatty acid concentrations in the rumen, duodenal digesta and blood have not been published until now. The objective of this paper was to compare the VA and *cis*-9,*trans*-11 CLA concentrations in the rumen and different tissues in beef cattle fed different diets, and to determine the relationships between VA and *cis*-9,*trans*-11 CLA concentrations in different tissues.

## Experimental Procedures

### Materials

Sixty-four bulls (5–6 months old) were randomly assigned to two dietary treatments (concentrate vs. grass-based) in the experiment. For indoor housing the concentrate group consisted of 16 German Simmental (GS) and 17 German Holstein (GH) bulls. The animals were fed semi ad libitum maize silage, concentrate, hay, straw and a mixture of minerals and vitamins up to 620 kg live weight. The pelleted concentrate for the indoor concentrate group was a mixture of winter barley, molasses, and soybean meal (Vollkraft-Mischfutterwerk, Güstrow, Germany). The other animals, (15 GS and 16 GH bulls) were kept on pasture during the summer period. During the following winter period and 3 months before finishing these bulls were kept in a stable and were fed wilted silage, hay, a pelleted concentrate diet and a mixture of minerals and vitamins up to 620 kg live weight. The pelleted concentrate for the pasture group was a mixture of 76% sugar beet pulp (molasses), 12% barley, and 10% coarsely cracked linseed (Vollkraft Mischfutterwerk, Güstrow, Germany). This is termed a grass based feeding. The details of chemical and fatty acid composition of the diet were previously described by Nuernberg et al. [19].

All bulls were slaughtered as they reached 620 kg live weight in the abattoir of the Research Institute for the Biology of Farm Animals in Dummerstorf, Germany. The slaughter and dressing procedures were in accordance with EU specifications. The carcasses were chilled (4 °C) before muscle samples were removed. The blood, rumen content, duodenal digesta (1 m after pylorus), heart and liver tissue samples were taken immediately after slaughter. Samples of longissimus muscle (at the sixth rib of the left carcass side), subcutaneous fat and semitendinosus muscles (left

carcass side) were taken 24 h after slaughter. Rumen content and digesta samples were prepared on the slaughter day. All tissue samples were stored frozen at  $-70\text{ }^{\circ}\text{C}$  until lipid extraction was carried out.

## Methods

### *Extraction and Methylation of Lipids*

**Plasma and Erythrocytes** For plasma and erythrocytes preparation EDTA blood was centrifuged at  $2,750\times g$  at  $4\text{ }^{\circ}\text{C}$  for 10 min into plasma and erythrocytes. Approximately 2 g plasma samples were taken for lipid extraction. Erythrocyte samples were washed two times by 0.9% sodium chloride solution, and then a 2 g sample was added to 5 ml methanol (cold, shaking by vortex). Waiting for 10 min, and then 10 ml chloroform was added to extract total lipids. After filtration the solution was dried under gentle nitrogen stream at room temperature. To obtain the phospholipid fraction (PL) of the isolated erythrocytes lipids were separated by thin layer chromatography on pre-coated silica gel 60 plates using the solvent mixture *n*-hexane/diethyl ether/acetic acid (70:30:2, vol/vol/vol). PL fraction was viewed under ultraviolet light after spraying with 2,7-dichlorofluoresceine (0.1% in ethanol, wt/vol). The PL bands were scraped off and eluted with chloroform/methanol (2:1, vol/vol), decanted after 1 h and eluted once more with chloroform/methanol (2:1, vol/vol). After combining both extracts, the solvent was removed under nitrogen at room temperature. The phospholipids were treated with 0.5 M methanolic sodium methylate for 20 min at room temperature. Methylation of fatty acids was performed with borontrifluoride/methanol (14% wt/vol) for 20 min at room temperature. The fatty acid methyl ester (FAME) formed was extracted with *n*-hexane, then evaporate using a rotary evaporator and dried under a gentle nitrogen stream at room temperature. The FAME was dissolved in *n*-heptane for gas chromatography analysis (GC).

**Tissue Samples** For tissue samples (muscle approximately 2g, subcutaneous fat 1 g, heart 2 g, liver 2 g), total lipids were extracted with chloroform/methanol (2:1, vol/vol) by homogenisation (Ultra Turrax,  $3 \times 15\text{ s}$ , 12,000 revolutions per minute) at room temperature according to Folch et al. [23]. The details of methylation were described previously [24].

**Rumen and Duodenal Digesta** Approximately 60 g of rumen content (representative mix of whole rumen content)

and 60 g duodenal digesta were freeze-dried, and then 1.2 g freeze-dried rumen or 1.2 g freeze-dried duodenal digesta content were taken for lipid extraction (duplicates). For extraction and direct fatty acid methylation of the rumen and digesta, a modified method from Sukhija and Palmquist [25] was used. The samples were treated with 3.5 ml toluene (containing 19:0 methyl ester as internal standard) and 4 ml of 5% methanolic HCl. The mixture was shaken in a water bath at  $60\text{ }^{\circ}\text{C}$  for 2 h. After cooling, methyl esters of total fatty acids were extracted with 3.5 ml toluene in the presence of 8.75 ml 6%  $\text{K}_2\text{CO}_3$  solution and stirred with a vortex stirrer. After centrifugation (1,200g for 5 min at  $4\text{ }^{\circ}\text{C}$ ) the toluene phase was separated and 1 g  $\text{Na}_2\text{SO}_4$  and activated charcoal were added and stored overnight until the organic phase was colourless. After filtration, an aliquot of the toluene extract was taken and analysed by GC.

### *Gas Chromatography (GC) Analysis*

An aliquot of this FAME extract was used for the gas chromatographic analyses of total fatty acids. The fatty acid composition of the samples was determined by GC on a CP SIL 88,  $100\text{ m} \times 0.25\text{ mm} \times 0.25\text{ }\mu\text{m}$  capillary column (Chrompack-Varian, USA) installed in a Perkin Elmer gas chromatograph Autosys XL with a flame ionisation detector and split injection. The initial oven temperature was  $120\text{ }^{\circ}\text{C}$ , held for 5 min, subsequently increased to  $170\text{ }^{\circ}\text{C}$  at a rate of  $2\text{ }^{\circ}\text{C min}^{-1}$ , held for 15 min, then to  $200\text{ }^{\circ}\text{C}$  at  $5\text{ }^{\circ}\text{C min}^{-1}$ , held for 5 min, then to  $235\text{ }^{\circ}\text{C}$  at  $2\text{ }^{\circ}\text{C min}^{-1}$  and held for 10 min. Hydrogen was used as the carrier gas at a flow rate of  $1\text{ ml min}^{-1}$ . The split ratio was 1:20; the injector was set at  $260\text{ }^{\circ}\text{C}$  and the detector at  $280\text{ }^{\circ}\text{C}$ . A reference standard mix added with *trans*-11 18:1 methyl ester, *cis*-9,*trans*-11 CLA methyl ester, 22:5n-3 methyl ester, *cis*-11 18:1 methyl ester, 18:4n-3 methyl ester and 22:4n-6 methyl ester was used for calibration and correction factors for individual fatty acids. The proportion and concentrations were calculated using the internal standard method of Turbochrom workstation software. 19:0 methyl ester was used as internal standard. The *cis*-9, *trans*-11 CLA concentrations includes the isomers *trans*-7,*cis*-9 CLA and *trans*-8,*cis*-10 CLA, because the separation of these CLA isomers is not possible by GC under these conditions [26]. The calculation for the index of  $\Delta^9$ -desaturase activity was calculated according to Malau-Aduli et al. [27]  $\Delta^9$ -Desaturase index =  $100 \times [(14:1 + 16:1 + 18:1)/(14:1 + 16:1 + 18:1 + 14:0 + 16:0 + 18:0)]$ .

**Reagents** FAMES were purchased from Sigma-Aldrich (Deisenhofen, Germany) and Matreya (Pleasant Gap, PA,

USA). The TLC plates coated with 0.25 mm silica gel (20 × 20 cm) were obtained from Merck (Darmstadt, Germany). FAMES were identified by means of purified standards (“Sigma-FAME mixture”, Sigma Aldrich Deisenhofen, Germany). Fatty acid methyl esters of *trans*-11 18:1, *cis*-11 18:1, 22:5n-3, 22:4n-6, *cis*-9,*trans*-11 18:2 were purchased from Matreya (Pleasant Gap, USA). All solvents used were HPLC grade from Lab-Scan (Dublin, Ireland). The 0.5 M methanolic sodium methylate were purchased from Fluka (Switzerland) and borontrifluoride/methanol (14% wt/vol) from Sigma-Aldrich (Deisenhofen, Germany).

**Statistical analysis.** All data were analysed by the least-squares method using the GLM procedures with fixed factors feeding and breed (SAS<sup>®</sup> Systems, Release 8.2, SAS Institute Inc., Cary, NC). All tables contain the least squares means (LSM) and the standard error (SE) of the LSM. All statistical tests of LSM were performed for a significance level of  $P \leq 0.05$ . Relationships between *cis*-9,*trans*-11 CLA and TVA in different tissues were examined by regression analysis using REG procedure (SAS<sup>®</sup> Systems).

## Results

The total fatty acid composition of longissimus and semitendinosus muscles, subcutaneous fat, liver and heart in German Holstein and German Simmental bulls fed different diets have been previously published [19–22].

Pasture-fed beef generally had lower intramuscular fat contents compared to concentrate-fed beef; therefore, when CLA proportions of the beef were calculated, the differences were less pronounced between pasture- and concentrate-fed beef [19]. Consequently, the results in the

present paper base on concentrations (mg/100 g fresh tissue or mg/100 g dry matter). The concentrations of *cis*-9,*trans*-11 CLA, VA and  $\Delta^9$ -desaturase index in rumen and duodenal digesta of German Holstein and German Simmental bulls are presented in Table 1. The diet had no effect on *cis*-9,*trans*-11 CLA concentration in both rumen and duodenal digesta. There was a significant interaction between diet and breed for the VA concentration in the rumen. Grazing of German Holstein bulls decreased the VA content but in grass-fed German Simmental bulls the VA concentration was higher compared with concentrate-fed bulls. However, compared with concentrate feeding, pasture feeding significantly increased the VA concentration in duodenal digesta (Table 1).

The *cis*-9,*trans*-11 CLA and VA concentration in plasma and erythrocyte phospholipids of German Holstein and German Simmental bulls is shown in Table 2. The results demonstrated that diet significantly affected the VA and *cis*-9,*trans*-11 CLA contents. The level of VA and *cis*-9,*trans*-11 CLA in plasma and erythrocyte PL was much lower ( $P < 0.05$ ) by concentrate feeding compared to pasture feeding of both breeds. The concentrations of *cis*-9,*trans*-11 CLA and VA in German Simmental bulls were more than two times higher with pasture feeding as compared with concentrate feeding. In contrast, the differences of *cis*-9,*trans*-11 CLA and VA contents in plasma and erythrocyte PL of German Holstein bulls were much smaller between both diets (Table 2).

The concentrations of *cis*-9,*trans*-11 CLA and VA (mg/100 g tissue) and  $\Delta^9$ -desaturase index in longissimus muscle, semitendinosus muscle and subcutaneous fat of German Holstein and German Simmental bulls are given in Table 3. There was a breed effect on the deposition of *cis*-9,*trans*-11 CLA in longissimus muscle, and the *cis*-9,*trans*-11 CLA concentration in muscle of German Holstein bulls

<sup>a</sup> For footnotes see Table 1

was significantly higher than that in German Simmental bulls. Furthermore, diet did not affect the deposition of *cis-9,trans-11* CLA in semitendinosus muscle and subcutaneous fat. Between the different tissues longissimus muscle, semitendinosus muscle and subcutaneous fat) *cis-9,trans-11* CLA accumulation in subcutaneous fat was the highest, up to 397.2 mg/100 g tissue in German Holstein bulls and 375.7 mg/100 g tissue in German Simmental bulls by pasture feeding (Table 3). The VA concentrations in subcutaneous fat were significantly higher with pasture compared to concentrate feeding.

The concentration of *cis-9,trans-11* CLA, VA (mg/100 g tissue) and  $\Delta^9$ -desaturase index (calculated) in

splanchnic tissue of liver and heart of German Holstein and German Simmental bulls is shown in Table 4. In contrast to the muscle and subcutaneous tissue, pasture feeding significantly increased CLA deposition in liver and heart tissue compared with concentrate feeding. The *cis-9,trans-11* CLA concentrations in heart tissue of German Simmental bulls was higher than that in German Holstein bulls, indicating breed difference. The accumulation of VA by pasture feeding was also enhanced significantly both in heart and liver tissue of German Holstein and German Simmental bulls. A diet effect on  $\Delta^9$ -desaturase index was detected, showing that the index was higher feeding concentrate relative to pasture, except in the heart of German

between *cis-9,trans-11* CLA and VA in rumen content, duodenal digesta content, plasma, erythrocyte phospholipids, *longissimus* muscle, *semitendinosus* muscle, subcutaneous fat, liver and in heart lipids were 0.43, 0.70, 0.59, 0.42, 0.78, 0.88, 0.29, 0.34 and 0.66, respectively (Fig. 1).

## Discussion

The majority of research examining the biohydrogenation of dietary fatty acids to VA, the desaturation of VA to *cis-9,trans-11* CLA, the absorption and the de novo synthesis

of *cis-9,trans-11* CLA has been focused on milk fat [1, 8, 10, 13–16]. Only a few papers reported the pathway of a *cis-9,trans-11* CLA and VA from the formation in the rumen, via duodenal digesta, and blood transport into the different muscle tissues [4, 8]. The present paper discusses the concentration of the two compounds VA and *cis-9,trans-11* CLA in the rumen, duodenal digesta, plasma, erythrocyte phospholipids and different tissues of beef at one sampling point (after slaughter) under two different feeding conditions. Increasing *cis-9,trans-11* CLA content in meat and milk from ruminants depends on the understanding of the sequential processes involved in the biohydrogenation of dietary unsaturated fatty acids in the

rumen. This process could be modified to increase *cis*-9,*trans*-11 CLA and VA output from the rumen by manipulating the ruminant diet [1, 4, 8]. In the rumen, *cis*-9,*trans*-11 CLA is formed from isomerization of dietary 18:2n-6 during the first step of the biohydrogenation process [28]. Once the *cis*-9,*trans*-11 CLA is formed, biohydrogenation of the *cis*-9 bond occurs by microbial reductase (group A microorganisms) to form VA. The extent, to which VA is hydrogenated to stearic acid (18:0; group B microorganisms) depends on the conditions in the rumen [28–30]. Dietary 18:3n-3 also undergoes biohydrogenation by being first isomerized to a conjugated triene (*cis*-9,*trans*-11,*cis*-15 18:3), followed by reductions of double bonds at carbons 9, 15, and 11 to yield *trans*-11, *cis*-15 18:2, VA, and 18:0, respectively [14, 30]. The lipids in the pasture diet are high in 18:3n-3, and the biohydrogenation by rumen micro-organisms does not include *cis*-9,*trans*-11 CLA as an intermediate [28]. VA is formed during the biohydrogenation of 18:3n-3 and 18:2n-6 to 18:0, and therefore VA is a common intermediate in the metabolic pathway of both PUFAs [28]. In the present study, feeding pasture-based diets to German Holstein and German Simmental bulls resulted in significantly higher VA concentrations in duodenal digesta, plasma, erythrocyte PL compared to concentrate-fed animals. Furthermore, these accumulations of VA by pasture feeding compared to concentrate feeding bulls were also measured in liver and heart tissues, and subcutaneous fat. The significantly higher VA concentrations in the rumen and duodenal digesta on a pasture diet indicates, that ruminal biohydrogenation of the predominant fatty acid in pasture diets, 18:3n-3, led to the production of high amounts of VA in the rumen and duodenal digesta. However, the *cis*-9,*trans*-11 CLA concentrations in the rumen and duodenal digesta were not affected by the diet. Very recently, Fukuda et al. [31, 32] found two new strains of *Butyrivibrio fibrosolvens*. One strain (MDT-10) does not have a great ability to hydrogenate 18:2n-6 to VA, and the other strain (MDT-5) rapidly isomerizes 18:2n-6 and 18:3n-3 to *cis*-9,*trans*-11 CLA and to *cis*-9,*trans*-11,*cis*-15 18:3. The authors assumed that the introduction of MDT-10 to the rumen might increase the amount of absorbed VA and therefore increase the conversion of VA to *cis*-9,*trans*-11 CLA in tissues [31, 32]. Harfoot and Hazlewood [28] have shown that *cis*-9,*trans*-11 CLA is rapidly metabolized, while VA accumulates during biohydrogenation of PUFA in the rumen. Piperova et al. [33] confirmed these results and demonstrated that the ratio of total *trans* 18:1 to *cis*-9,*trans*-11 CLA was high, approximately 60:1, in the duodenal flow of cows fed low and high levels of forage. It is known that pasture feeding resulted in significantly higher concentrations of *cis*-9,*trans*-11 CLA in milk and intramuscular fat [1, 13, 20, 34, 35]. With pasture feeding,

the duodenal flow of VA is higher, compared with low forage-containing diets, in which lipids are higher in linoleic acid [33, 36, 37]. Furthermore, Piperova et al. [33] and Sackmann et al. [37] demonstrated that the duodenal output of *trans* 18:1 fatty acids was high in *trans*-10 18:1 in diets with low forage contents. Under these conditions, shifts in the ruminal biohydrogenation pathway have occurred resulting in *trans*-10 18:1 replacing VA as predominant *trans* 18:1 fatty acids isomer leaving the rumen [33, 36, 38]. Finally, the amount of duodenal *trans*-10,*cis*-12 CLA isomer was significantly increased in cows fed diets with a low forage content [33].

Plasma is the transportation system of nutritional ingredients, and erythrocyte phospholipid fatty acids status reflects the overall long-term (erythrocytes 120 days half-time) lipid metabolism influenced by diet and rumen microbial activity. For blood lipids, phospholipids and cholesterol esters are the main components and account for over 95% of the total lipids in the plasma of ruminant animals. However, triglycerides and free fatty acids only represent < 5% and 1% of total plasma lipids, respectively [36]. PUFA that escape ruminal biohydrogenation are preferentially esterified to the plasma cholesterol esters and phospholipids [39]. The current study demonstrated that pasture feeding significantly increased the concentrations of *cis*-9,*trans*-11 CLA and VA both in the plasma and erythrocyte PL compared to concentrate feeding, with one exception *cis*-9,*trans*-11 CLA in erythrocyte PL of German Holstein bulls. The *cis*-9,*trans*-11 CLA and VA concentration was significantly higher (up to two times) on pasture in comparison with concentrate feeding, in German Simmental bulls. Loo et al. [40] investigated the rumen, blood and milk of Holstein cows fed diets with a high ratio of concentrate to forage (grass, hay) (65:35) supplemented with fish oil, linseed oil or sunflower oil. The authors also observed that significantly higher *cis*-9,*trans*-11 CLA contents in blood plasma with linseed oil supplements (high in 18:3n-3) compared with sunflower or fish oil supplements. However, the highest VA contents were detected in the blood plasma with fish oil compared with the other supplements. It is well known that a major proportion of the *cis*-9,*trans*-11 CLA found in ruminant tissues is formed through the activity of  $\Delta^9$ -desaturase on VA [12, 30]. Kinetic studies of rumen biohydrogenation of 18:2n-6 acid to 18:0 have shown that *cis*-9,*trans*-11 CLA is a transient intermediate in the rumen, whereas VA is the intermediate that accumulates under these certain dietary conditions [30, 41, 42]. Furthermore, dietary addition of plant oils containing 18:3n-3 also increases the *cis*-9,*trans*-11 CLA content of ruminant fat, and intermediates in its pathway of biohydrogenation include VA but not *cis*-9,*trans*-11 CLA [10, 41]. Griinari's results [10] demonstrated that an estimated 64% of the CLA in milk fat was of

endogenous origin, and endogenous synthesis of CLA from *trans*-11 18:1 represented the primary source of CLA in the milk fat of lactating cows [13]. Kay et al. [13] reported the first study to examine the importance of endogenous synthesis of *cis*-9,*trans*-11 CLA in the milk fat of pasture-fed cows. The authors confirmed these results and showed that approximately 90% of *cis*-9,*trans*-11 CLA was produced endogenously. Several investigations confirmed that pasture feeding to dairy cows doubles the *cis*-9,*trans*-11 CLA content of milk fat [41]. Kraft et al. [34] and Collomb et al. [35] showed differences between the individual CLA isomer distributions in milk lipids of cows fed diets with concentrates rations in PUFA indoors and grazing cows in the Alps (Switzerland). For intramuscular fat, Dannenberger et al. [21] concluded that pasture feeding affected the distribution of individual CLA isomers in the muscle lipids. No related investigations for milk fat have been reported to establish the importance of endogenous synthesis of *cis*-9,*trans*-11 CLA in the intramuscular fat of ruminant tissues. It could be assumed that the contribution from endogenous synthesis is similar to that reported for milk because VA and  $\Delta^9$ -desaturase are necessary requirements.

Martin et al. [43] and Ward et al. [44] showed that mammary gland and adipose tissue of ruminants have substantial  $\Delta^9$ -desaturase activity. A linear relationship between VA and *cis*-9,*trans*-11 CLA has been observed for milk fat in a number of studies and across a wide range of diets reviewed by Griinari and Bauman [41]. This relationship has also been observed over a wide range of TVA concentrations, indicating a high capacity for endogenous synthesis of *cis*-9,*trans*-11 CLA [41]. Madron et al. [45] and Enser et al. [46] observed a linear relationship between the concentration of *cis*-9,*trans*-11 CLA and VA in muscle adipose tissue in beef. The extent, to which  $\Delta^9$ -desaturase is responsible for *cis*-9,*trans*-11 CLA production in the muscle adipose tissue showed no differences in the index of  $\Delta^9$ -desaturase activity in muscle fat among diet treatments. Meanwhile, Ntambi [47] showed that there was a repressive effect of long-chain PUFA on the activity of the  $\Delta^9$ -desaturase. The results of our study confirmed that there was a correlation between *cis*-9,*trans*-11 CLA and VA concentrations in the rumen, duodenal digesta, blood and in the different tissues (Fig. 1). Piperova et al. [33] assumed that tissue level of *cis*-9,*trans*-11 CLA may not be a simple reflection of the proportions of these compound that escaped rumen biohydrogenation. The major source of tissue *cis*-9,*trans*-11 CLA should be the post absorptive synthesis via  $\Delta^9$ -desaturation of TVA produced during rumen biohydrogenation of dietary PUFA. However, in our experiment, pasture feeding led to different accumulation rates of *cis*-9,*trans*-11 CLA in the tissues. Although pasture feeding significantly increased the *cis*-9,*trans*-11 CLA concentrations in liver and heart, diet had no effect on the

*cis*-9,*trans*-11 CLA concentrations in the muscles and subcutaneous fat. The  $\Delta^9$ -desaturase index was significantly lower in all investigated tissues and gave no additional information about the cause for the different accumulation rates of *cis*-9,*trans*-11 CLA in the different tissues. Smith et al. [48] concluded that  $\Delta^9$ -desaturase index was not an indicator of absolute enzyme activity. Further research is needed to investigate the reasons of different accumulation of *cis*-9,*trans*-11 CLA in the beef tissues by pasture feeding and include the absolute enzyme activity measurement of  $\Delta^9$ -desaturase. Very recently J.M. Griinari and K. Shingfield (2006, private communication) established that the *cis*-9,*trans*-11 CLA accumulation in ruminant lipids can be increased up to ten fold by feeding diets that enhance the production of VA in the rumen. The focus should be on ruminal formation of VA rather than *cis*-9,*trans*-11 CLA. It suggests that the most effective methods to enhance *cis*-9,*trans*-11 CLA concentration in ruminant products is to feed supplements containing VA or manipulate rumen biohydrogenation to increase the formation of VA. So, understanding the mechanism involved in the biosynthesis of *cis*-9,*trans*-11 CLA and other CLA isomers will allow scientists to design feeding strategies for enhancing the CLA concentration in ruminant products.

**Acknowledgments** We thank B. Jentz and H. Rooch of the Department of Muscle Biology and Growth, who conducted the sample preparation and GC measurements. It is clear that bypassing the rumen increases n-3 FA in plasma and muscle, hence a key element to using feedstuffs containing n-3 FA is to protect it in the rumen from biohydrogenation. The concentration of 18:3n-3 increases in the blood when emulsions of flaxseed oil are infused into the abomasum, the true stomach of ruminants, [11, 12] or into the duodenum, [13]. There is evidence that the 18:3n-3 levels of neutral lipid in the muscle of cattle and sheep can be increased if more 18:3n-3 is made available for absorption from the small intestine [14–16]. Protecting n-3 FA by encapsulating them in a matrix of formaldehyde-treated protein increases n-3 FA levels in the muscle [17]. Although this method is believed to provide protection for polyunsaturated FA (PUFA) from microbial hydrogenation [12, 18], the use of formaldehyde lowers its consumer acceptance. In addition, there are conflicting results with respect to the effectiveness of this process [19, 20]. Several other approaches have been tested for protecting n-3 FA from microbial hydrogenation in the rumen that do not use formaldehyde, but these have had little success [20–24]. More recently, a method using a whey protein isolate gel appears promising [25, 26], but this approach may be impractical.

Therefore, the primary objective of this study was to find a practical, simple, and consumer-acceptable method to protect the 18:3n-3 in flaxseed from hydrogenation by rumen microbes. Condensed tannin has the ability to bind with plant proteins in the rumen, with enzymes secreted by rumen bacteria, and with rumen bacteria, but do this without altering absorption in the entire gastrointestinal tract [27, 28]. Hence, we rationalized that tannins might help protect 18:3n-3 in flaxseed from hydrogenation by rumen microbes. Furthermore, we rationalized that adding the protein casein to ground flaxseed before treating it with condensed tannin may help encase the 18:3n-3 in flaxseed in a protective coating. Therefore, the specific objectives were to: (1) determine if treating ground flaxseed with tannin with or without casein would result in less disappearance of 18:3n-3 during fermentations in vitro with cattle rumen fluid, and (2) determine if treating ground flaxseed with condensed tannin could increase the level of 18:3n-3 and other n-3 FA in the blood of cattle consuming forage or grain-based diets.

## Experimental Procedures

### Flaxseed Treatment with Tannin

Ground flaxseed was treated with condensed tannin (quebracho tannin), or condensed tannin plus either low (45 g/227 g flaxseed) or high (90.8 g/227 g flaxseed) amounts of casein. Ground flaxseed was treated with condensed tannin

by mixing 45.4 g of quebracho tannin syrup (34% DM; Tannin Corp., Peabody, MA) with 28.3 g of warm tap water then thoroughly mixing this solution with 227 g of ground flaxseed before drying in a forced air oven at 50 °C. For flaxseed containing casein, either 45.4 g of casein (Sigma-Aldrich, St. Louis, MO) or 90.8 g of casein was mixed with 227 g of ground flaxseed to which a solution containing 45.4 g of quebracho tannin syrup in 125 g of warm tap water was added and thoroughly mixed. The flaxseed-tannin-casein mixtures were dried as described above for the flaxseed-tannin mixture.

### Fermentation In Vitro

Fermentation of untreated and treated flaxseed with bovine rumen fluid was done at 39 °C and the reduction in 18:3n-3 assessed at 24 h. Each flask contained 250 mg of ground alfalfa-grass hay, 250 mg of untreated ground flaxseed or one of three treated flaxseeds, 40 ml of buffer solution, and 10 ml of strained rumen fluid. Rumen fluid was obtained from two ruminally fistulated beef cows and kept separate in pre-warmed insulated containers until it was used in the trial within 30 min after collection. The cows were fed alfalfa hay ad libitum for a month before ruminal digesta was collected for the trial. The rumen fluid was flooded with CO<sub>2</sub> while it was put into the flasks and again after the addition of the feedstuffs. Flasks were agitated at 1, 12 and 18 h. Microbial activity in the 0 time samples as well as 24 h fermentations was stopped by pouring the contents of each flask into a plastic bag then quickly freezing it as a thin (ca. 0.5 cm) layer. The buffer solution was distilled water and 0.68 mM CaCl<sub>2</sub>, 2 mM MgSO<sub>4</sub>, 73 mM KH<sub>2</sub>PO<sub>4</sub>, 142 mM Na<sub>2</sub>CO<sub>3</sub>, 8.6 mM NaCl, 7.9 mM Na<sub>2</sub>SO<sub>3</sub>, and 8.3 mM NH<sub>2</sub>CONH<sub>2</sub>. Each combination of flaxseed treatments was replicated twice with rumen fluid from one cow used in one replicate set and rumen fluid from the second cow used in the other.

### Calculations for the Fermentation Reaction

The percent change in the 18:3n-3 level at 24 h was determined relative to the initial levels at time 0. Percent change was used because initial amount of this FA varied somewhat as a function of whether or not the flaxseed was or was not treated with tannin. The Mixed Model Procedure of SAS [29] was used for data analysis, and tests were conducted to assure that data were normally distributed. The rumen-fluid donor cow was the random factor in all statistical analyses. The variance-covariance structure was examined and the variance components option was used. Means were considered different at an  $\alpha$  of 0.05.

## Assessment of Tannin-Treated Flaxseed In Vivo

Ten yearling Angus steers (castrated males) with a mean body weight of 392 kg (SD = 21 kg) were used in a trial with a factorial design with flaxseed treatment (none or tannin-treated) and time of blood collection (pre- or post-prandial) as the two factors. Separate analyses were conducted for each type of basal diet, which were either grain or forage. Five of the steers were given a grain-based diet during the whole trial and were given tannin-treated ground flaxseed for 15 days followed by collection of blood into heparinized tubes. These cattle were then fed non-treated ground flaxseed for 15 days before blood was collected. The other five steers on the forage-based diet followed the same treatment regimen as steers on the grain-based diet.

The steers were fed at 6 am and 6 pm, and on average had a daily intake of 7.8 or 8.8 kg of the grain or forage basal rations, respectively, plus 907 g of either ground flaxseed or 980 g of tannin-treated ground flaxseed (half of each fed per feeding). More tannin-treated flaxseed was fed to adjust for the additional weight of the tannin so that cattle received the same amount of flaxseed. Ground flaxseed was treated with quebracho tannin by mixing the flaxseed meal with tannin and water at a rate of 5:1:0.625 (w/w/w) then drying in a forced-air oven at 50 °C. Both grain and forage rations were formulated to meet or exceed the nutrient requirements of the growing steers [30].

The feed and nutritional composition of the two basal diets is described in Table 1 along with their composition of 18-carbon FA. Liquid molasses was added to the grain mixture to help maintain its integrity when fed, improve its palatability, and reduce feed dust. The alfalfa hay cubes in the forage-based diet were about 4 cm<sup>3</sup> in size and composed of coarsely chopped alfalfa hay. The same amount of liquid molasses and mineral-vitamin mixture was added to the forage ration.

Plasma neutral and phospholipid n-3 FA levels were evaluated with respect to flaxseed treatment and time of blood collection (post-prandial, 10-30 to 11 am or pre-prandial, 5-30 to 6 pm) using the Mixed Model Procedure of SAS [29]. Separate analyses were done for animals on the two basal diets since their daily intake of 18:3n-3 from the basal diets was 14 g for the forage-fed steers versus 8 g for the grain-fed steers. Animals were the random factor for both analyses. The variance-covariance structures were examined and the variance components option was used for both analyses. Means were considered different at an  $\alpha$  of 0.05.

## Plasma Total Lipid Extraction and Fatty Acid Analysis

Plasma lipids were then extracted by transferring a 200  $\mu$ l aliquot of plasma into a tube containing 5 ml of chloroform-

methanol (2:1, v/v) followed by mixing it by vortexing [31]. The addition of 1 ml of 0.9% KCl to these tubes resulted in two phases, which were thoroughly mixed and then separated overnight in a –20 °C freezer. The upper phase was removed, and the lipid-containing lower phase was rinsed with 1 ml of theoretical upper phase, consisting of chloroform-methanol-water (3:48:47, v/v), to remove any aqueous soluble contaminants [31]. The upper phase was discarded and the neutral lipids and phospholipids separated using solid-phase extraction with silicic acid [10]. The neutral lipids were eluted with chloroform and the phospholipids eluted with methanol. The respective solvents were removed via evaporation under a stream of nitrogen and the lipids redissolved in *n*-hexane:2-propanol (3:2 v/v). This lipid extract was stored at –80 °C until analysis.

A portion of each lipid fraction was used to determine fatty acid composition of the plasma neutral lipids and phospholipids. The *n*-hexane:2-propanol was removed by evaporation under a stream of nitrogen and 2 ml of 0.5 M KOH dissolved in anhydrous methanol was added to make fatty acid methyl esters (FAME) via a base-catalyzed transesterification [32]. The FAME were extracted from the methanol using 2 ml of *n*-hexane and the *n*-hexane phase containing the FAME was removed. The lower phase was reextracted two more times with 3 ml of *n*-hexane, and these washes were combined with the original aliquot. Individual FA were separated by GLC using an SP-2330 column (0.32 mm i.d.  $\times$  30 m length) and a Trace GLC (ThermoElectron, Austin, TX) equipped with dual auto-samplers and dual FID. FA were quantified using a

standard curve from commercially purchased standards (Nu-Chek-Prep, Elysian, MN) and 17:0 was used as the internal standard.

#### Fatty Acid Analysis of Feed for Cattle Trial and In Vitro Residue

Dietary ingredients were analyzed for fatty acids via direct transesterification with methanolic-HCl [33, 34]. In vitro fermentation samples were lyophilized (Freezemobile 25 SL, The Virtis Co., Gardiner, NY), ground with a mortar and pestle, and analyzed for fatty acids [35]. Briefly, 200 mg was subjected to direct saponification in 4.0 ml of ethanol containing 1 ml of 33% (w/v) KOH. Direct saponification was done in 16 × 25 mm tubes with Teflon-lined screw-caps at 85 °C for 1 h with vortex-mixing every 1 min. Tubes were cooled, and 1.0 ml of 12 M HCl and 3.0 ml of hexane were added to each tube and mixed by vortexing. The hexane layer was transferred to a clean tube and dried under a stream of N<sub>2</sub> gas. Fatty acid methyl esters were prepared by incubating the dried hexane layer with 4.0 ml of 0.5 M HCl in methanol that contained 1 mg of tridecanoic acid (Sigma, St. Louis, MO) as the internal standard for 1 h at 85 °C. Separation of fatty acid methyl esters was achieved by GLC (Model CP-3800, Varian Inc., Palo Alto, CA) equipped with a 100 m capillary column (SP-2560, Supelco, Bellefonte, PA). Identification of peaks was accomplished using purified standards (Sigma-Aldrich, St. Louis, MO; Nu-Chek Prep, Elysian, MN).

## Results

### In Vitro Fermentation Trial

The percent change in level of 18:3n-3 at 24 h were similar ( $P = 0.73$ ) among the three tannin treatments, indicating that adding either of the two amounts of casein to the flaxseed-tannin mixture did not reduce hydrogenation (Fig. 1). However, across the 24-h period, treating the ground flaxseed with condensed tannin reduced ( $P = 0.01$ ) hydrogenation of 18:3n-3 to only 13% compared to a loss of 43% in the untreated flaxseed.

### Assessment of Tannin-Treated Flaxseed In Vivo

With respect to neutral lipids in blood plasma, when the basal diet was either forage or grain, ingesting tannin-treated flaxseed did not raise plasma 18:3n-3 levels over those observed when the cattle consumed normal ground flaxseed ( $P \geq 0.10$ ; Fig. 2). Levels of 20:5n-3 were not

**Fig. 1** Least square means and standard errors (*T*-bars) for % change in 18:3n-3 during the 24 h period of fermentations in vitro of normal ground flaxseed (*Normal*), ground flaxseed mixed with a high amount of casein then treated with condensed tannin (*Tannin Hi C*), ground flaxseed mixed with a low amount of casein then treated with condensed tannin (*Tannin Lo C*), or ground flaxseed treated with only condensed tannin (*Tannin only*). The asterisk indicates significance from control  $P < 0.05$

raised by ingestion of treated flaxseed regardless of basal diet ( $P \geq 0.17$ ) nor were total n-3 levels (18:3n-3 and 20:5n-3) for either basal diet ( $P \geq 0.07$ ).

The level of plasma neutral lipid 18:3n-3 was similar at both blood collection times for forage-fed steers ( $P = 0.38$ ), but 18:3n-3 level was slightly higher (4.8%) at the pre-prandial collection time for the grain-fed steers ( $P = 0.04$ ). Neutral lipid 20:5n-3 level did not differ as a function of time of blood collection for either the forage- or grain-fed steers ( $P \geq 0.50$ ).

The ingestion of tannin-treated flaxseed increased blood plasma phospholipid 18:3n-3 by 11.2% ( $P = 0.03$ ) for the grain-fed steers but not for their forage-fed cohorts ( $P = 0.20$ ; Fig. 2). Levels of 22:5n-3 and 22:6n-3 were higher for the grain-fed steers when they ate the non-treated flaxseed ( $P \leq 0.02$ ), but levels of 22:5n-3 and 22:6n-3 were not affected by the type of flaxseed ingested for the forage-fed steers ( $P \geq 0.09$ ). Total plasma n-3 FA concentrations were not influenced by type of flaxseed ingested regardless of basal diet ( $P = 0.90$ ).

Forage-fed steers had slightly higher levels of phospholipid 22:5n-3 at the post-prandial time of blood collection ( $P = 0.02$ ), but levels of phospholipids 22:6n-3 were higher at the pre-prandial time of blood collection for both basal diets ( $P < 0.01$ ). Levels of phospholipids 18:3n-3 were not influenced by time of collection ( $P \geq 0.67$ ).

## Discussion

There are a number of treatment methods that have been used to treat flaxseed in order to reduce biohydrogenation.

**Fig. 2** Least square means and standard errors (*T*-bars) for mol% of 18:3n-3, 20:5n-3 and total n-3 (18:3n-3 and 20:5n-3 combined) in neutral (*N* or *NL*), and for mol% of 18:3n-3, 22:5n-3, 22:6n-3 and total n-3 (18:3n-3, 22:5n-3, and 22:6n-3 combined) in phospholipid (*P* or *PL*) in blood plasma of yearling Angus steers consuming either a grain-based diet (*G*) or a forage-based diet (*F*) and either tannin-treated ground flaxseed (*TF*) or non-treated ground flaxseed (*NF*). The three sets of four bars on the left side of the figure represent neutral lipid levels and the four sets of four bars on the right side of the figure represent phospholipid levels. The *asterisk* indicates significance from control  $P < 0.05$

For instance, in lactating cows consuming a complex of a 1:1 (w/w) mixture of soybean and flaxseed oils mixed with a whey protein isolate gel, their mean 18:3n-3 level (g/100 g lipid) in the plasma triacylglycerol fraction was 4.9-fold higher than the same lactating cows consuming a 1:1 (w/w) mixture of soybean and flaxseed oils with their basal diet [25]. However, the practicality of this method is questionable. Additional treatment regimens include protecting 18:3n-3 by encapsulation of the n-3 containing feed in a matrix of formaldehyde-treated proteins [17]. Although this is likely the only practical method that may provide some protection for polyunsaturated FA (PUFA) from rumen microbial hydrogenation [15, 18], using formaldehyde in a production setting would undoubtedly meet with limited consumer acceptance. Thus, it is important to derive a useful method for protecting n-3 FA containing oil seeds from the n-3 FA reducing effects of ruminal biohydrogenation.

Although we found a significant protection in our fermentation experiment, a similar positive effect was not seen in vivo. Tannin-treated flaxseed did not increase 18:3n-3 or total n-3 FA levels in plasma neutral lipids from forage-fed or grain-fed steers. Because the rumen pH of cattle on a diet dominated by grains is acidic ( $\text{pH} \leq 5.5$ ), this ruminal environment was expected to reduce the effectiveness of condensed tannin as a protection treatment [36], however we did not expect a similar result with forage-fed cattle.

It is important to note that the seed coat of flaxseed may also provide a small amount of protection for 18:3n-3 from rumen microbes. However, beef muscle had more phospholipid 18:3n-3, 20:5n-3, and 22:5n-3 and more neutral lipid 18:3n-3 when cattle were fed ground versus whole flaxseed [10], suggesting that the seed coat is not an important factor in protecting 18:3n-3 from hydrogenation. Yet, when whole flaxseeds were fed to yearling steers, plasma 18:3n-3 content (weight % of total fatty acid methyl esters) increased 2.6-fold compared to that for steers not consuming flaxseed [13]. However, in the same experiment when flaxseed oil was continuously infused into the proximal duodenum of yearling steers, thus bypassing the rumen microbes, plasma 18:3n-3 content increased 5.7-fold compared to that of control steers [13]. Thus, it is important to get more 18:3n-3 into the duodenum and this indicates the potential for increasing plasma 18:3n-3 if a highly rumen-protective treatment can be found for flaxseed.

We observed in our in vitro trial that treating flaxseed with condensed tannin significantly reduced hydrogenation, with a loss of only 13% of the 18:3n-3 over 24 h versus a 43% loss for the untreated flaxseed. Despite this significant reduction we observed no increase in 18:3n-3 in plasma neutral lipid when cattle were fed tannin-treated flaxseed. There are several explanations for this disparity.

First, that absorption of fatty acids is influenced by the intestinal wall. However, since both post-ruminal infusions of flaxseed oil and flaxseed oil in a gel with a whey protein isolate have raised blood plasma levels of 18:3n-3, we doubt that fatty acid absorption through the intestinal wall accounts for this disparity. Second, ingestion and rumination in the in vivo trial versus lack of this chewing action in the in vitro trial may have allowed for greater hydrogenation of 18:3n-3 in the treated flaxseed for the in vivo trial. Third, the ratio of n-3 fatty acids to ruminal fluid differed between the fermentations in vitro and the feeding regimen in vivo. When fish oil is incubated for 24-h in vitro with sheep rumen fluid, only 10–15% of the n-3 FA were hydrogenated (when the ratio of fish oil to rumen fluid exceeded 5 mg/ml) [37]. They concluded that sheep rumen microbes showed a great capacity to hydrogenate 20:5n-3 and 22:6n-3 in fish oil when the concentration of oil was less than 1 mg per ml of rumen fluid. The ratio of flaxseed oil to rumen fluid in our in vitro trial was about 9 mg per ml of rumen fluid. We expect that the ratio in vivo was much lower. Recently, others have argued that unrealistically high levels of oil should be avoided in fermentations in vitro relative to the amount of substrate used [38]. They suggested that FA in the tested oil or oilseed should be about 3% of substrate DM. Perhaps, the higher ratio of treated flaxseed (and condensed tannin) to rumen fluid in the fermentations in vitro permitted a much greater suppression of microbial hydrogenation than in vivo with its lower level of tannin in the total ruminal mix. However, greatly increasing the amount of tannin-treated flaxseed fed to cattle is probably not a viable option given the cost of flaxseed and tannin, but it may be useful to evaluate other types of condensed tannin since they affect rumen microbes differently [39].

In summary, results from our cattle trial indicate that treating ground flaxseed with quebracho tannin is probably not an effective method for reducing hydrogenation of 18:3n-3 by ruminal microbes in cattle. A method that protects most if not all of the 18:3n-3 in flaxseed must be identified before beef with much higher levels of 18:3n-3 and its long chain derivatives can be produced.

**Acknowledgments** We thank Clay Erickson and Curtis Klein for assistance with cattle management and feeding, and Faye Kroh and Becky Wald for feed nutritional analysis and assistance with fatty acid analysis of feed and fermentation residue. effects. Studies were conducted to investigate the growth inhibitory effects of low dose treatment of simvastatin, lovastatin, mevastatin and pravastatin alone or in combination with  $\gamma$ -tocotrienol on neoplastic +SA mouse mammary epithelial cells. Additional studies were also conducted to determine the intracellular signaling mechanisms involved in mediating the inhibitory effects of combined  $\gamma$ -tocotrienol and statin treatment on EGF-dependent mitogenesis.

## Experimental Procedures

### Reagents and Chemicals

All materials were purchased from Sigma Chemical Company (St Louis, MO, USA), unless otherwise stated. Simvastatin, lovastatin, mevastatin and pravastatin (sodium salt) were purchased from EMD Biosciences (La Jolla, CA, USA). Purified  $\gamma$ -tocotrienol was provided as a gift by Dr. Abdul Gapor (Malaysian Palm Oil Board, Kuala Lumpur, Malaysia). Antibodies for phospho-Akt (Ser473), phospho-p44/42 MAPK, phospho-p54/46 JNK, and phospho-p38 were purchased from Cell Signaling Technology (Beverly, MA, USA). Goat anti-rabbit secondary antibody was purchased from PerkinElmer Biosciences (Boston, MA, USA). Mouse anti-actin and peroxidase goat anti-mouse antibodies were purchased from Calbiochem (San Diego, CA, USA).

### Cell Line and Culture Conditions

Cell culture and experimental procedures have been previously described in detail [11, 13, 16–18]. Briefly, neoplastic mouse +SA mammary epithelial cells were grown and maintained in serum-free defined control media consisting of Dulbecco's modified Eagle's medium (DMEM)/F12 containing 5 mg/mL bovine serum albumin (BSA), 10  $\mu$ g/mL transferrin, 100 U/mL soybean trypsin inhibitor, 100 U/mL penicillin, 0.1 mg/mL streptomycin, 10 ng/mL EGF, and 10  $\mu$ g/mL insulin. Cells were maintained in a humidified incubator at 37 °C in an atmosphere of 95% air and 5% CO<sub>2</sub>.

### Experimental Treatments

In all experiments, the highly lipophilic  $\gamma$ -tocotrienol was first conjugated with bovine serum albumin (BSA) to form an aqueous stock solution as described previously [11, 19]. Simvastatin, lovastatin or mevastatin exist in their inactive lactone forms and must be activated prior to addition to

treatment media. To activate, these statins were first dissolved in a 70% ethanol solution containing 0.1 N NaOH and then incubated at 50 °C for 1 h. This process converts statins to their corresponding open-ring hydroxy-derivative (active form). This alkaline statin solution was then neutralized by the addition of an equal volume of 70% ethanol solution containing 0.1 N HCl to form a stock solution that was then used to prepare treatment media. Activated statins were freshly prepared daily. Pravastatin does not require activation because it contains an active open ring structure and was directly dissolved in 70% ethanol to form a stock solution. All media was adjusted so that the final ethanol concentration was same in all the groups within a given experiment and never exceeded 0.05%, and all cells were fed fresh control or treatment media everyday.

### Growth and Cytotoxicity Studies

Neoplastic +SA mammary epithelial cells were initially plated at a density of  $5 \times 10^4$  cells/well (6 wells/group) in serum-free defined control media in 24-well culture plates and allowed to attach overnight. Cells were then divided into different treatment groups and fed control or treatment media everyday. In growth studies, +SA cells were treated with individual statins (0–100  $\mu$ M) or  $\gamma$ -tocotrienol (0–4  $\mu$ M) for 4 days and then viable cell number was determined. In cytotoxicity studies, cells were plated in 24-well plates as described above, but maintained on serum-free defined control media for 3 days. Afterwards, cells were divided into different treatment groups, and fresh treatment media was added to their corresponding wells. After a 24 h treatment exposure period, viable cell number in each treatment groups was assayed.

### Measurement of Viable Cell Number

Viable +SA cell number was determined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) colorimetric assay as described previously [11, 18]. The optical density of each sample was measured at 570 nm on a microplate reader (SpectraCount, Packard BioScience Company, Meriden, CT, USA). The number of cells/well was calculated against a standard curve prepared by plating various concentrations of cells, as determined by hemocytometry, at the start of each experiment [11, 18].

### Electrophoresis and Western Blot Analysis

For Western blot analysis, +SA cells were plated at a density of  $1 \times 10^6$  cells/100 mm culture plate and grown in

serum-free defined control or treatment media. After a 4 day treatment period, cells were isolated with trypsin, washed, and whole cell lysates were then prepared as previously described [18, 19]. Protein concentration in each sample was determined using the Bio-Rad protein assay kit (Bio-Rad, Hercules, CA, USA). Equal amounts (30 µg/lane) of each sample were subjected to electrophoresis through 10% SDS-polyacrylamide minigels. Proteins were then transblotted (30 V for 12–16 h at 4 °C) to PVDF membranes (Dupont, Boston, MA, USA) according to the method of Towbin [20]. The membranes were then blocked with 2% BSA in 10 mM Tris-HCl containing 50 mM NaCl and 0.1% Tween 20, pH 7.4 (TBST) and then, incubated with specific primary antibodies against phospho-Akt, phospho-p44/42 MAPK, phospho-p54/46 JNK, and phospho-p38, diluted 1:5,000 in TBST/2% BSA for 2 h. Membranes were washed five times with TBST and then incubated with horseradish peroxidase-conjugated goat anti-rabbit antibody diluted 1:5,000 in TBST/2% BSA for 1 h followed by rinsing with TBST. Chemiluminescence (Pierce, Rockford, IL, USA) was used to visualize the antibody bound proteins. The visualization of actin was used to confirm that there was equal sample loading in each lane. Images of protein bands on the film were acquired and the densitometric analysis was performed with Metamorph Analysis software (Universal Imaging Corp.)

#### Treatment Synergism and Statistical Analysis

The level of interaction between individual statins and  $\gamma$ -tocotrienol was determined by isobologram and combination-index (CI) methods [21]. Data obtained from antiproliferative studies were used to perform these analyses. Isobologram is a graphical depiction of the pharmacological interaction of a two-drug combination and is constructed at a certain level of growth inhibition. In these studies,  $IC_{50}$  (dose resulting in 50% cell growth inhibition) values for  $\gamma$ -tocotrienol, statins and their combination were used.  $IC_{50}$  values were determined by non-linear regression curve fit analysis using GraphPad Prism 4. The straight line in each isobologram was formed by plotting  $IC_{50}$  doses of  $\gamma$ -tocotrienol and individual statins on the  $x$ - and  $y$ -axes, respectively. The data point in each isobologram corresponds to  $IC_{50}$  dose of  $\gamma$ -tocotrienol and individual statins given in combination. If a data point is on or near the line, this represents an additive treatment effect, whereas a data point that lies below or above the line indicates synergism or antagonism, respectively.

The combination index (CI) method is a quantitative representation of pharmacological interaction between two drugs. CI value of 1 indicates an additive effect, whereas a

CI < 1 or >1 indicates synergism or antagonism, respectively. The CI values were calculated at 50% cell growth inhibition, as:

$$CI = [S_C/S + T_C/T]$$

$S$  and  $T$  are the concentrations of statin and  $\gamma$ -tocotrienol, respectively, that induce a 50% cell growth inhibition;  $S_C$  and  $T_C$  are the concentrations of statin and  $\gamma$ -tocotrienol in combination that also inhibit cell growth by 50%.

The Dose Reduction Index (DRI) value represents the fold decrease in the dose of each individual agent possible if the two drugs are given in combination, as opposed to alone, to achieve a particular cell growth inhibition. DRI values for statins ( $DRI_S$ ) and  $\gamma$ -tocotrienol ( $DRI_T$ ) were calculated as:

$$DRI_S = S/S_C \text{ and } DRI_T = T/T_C$$

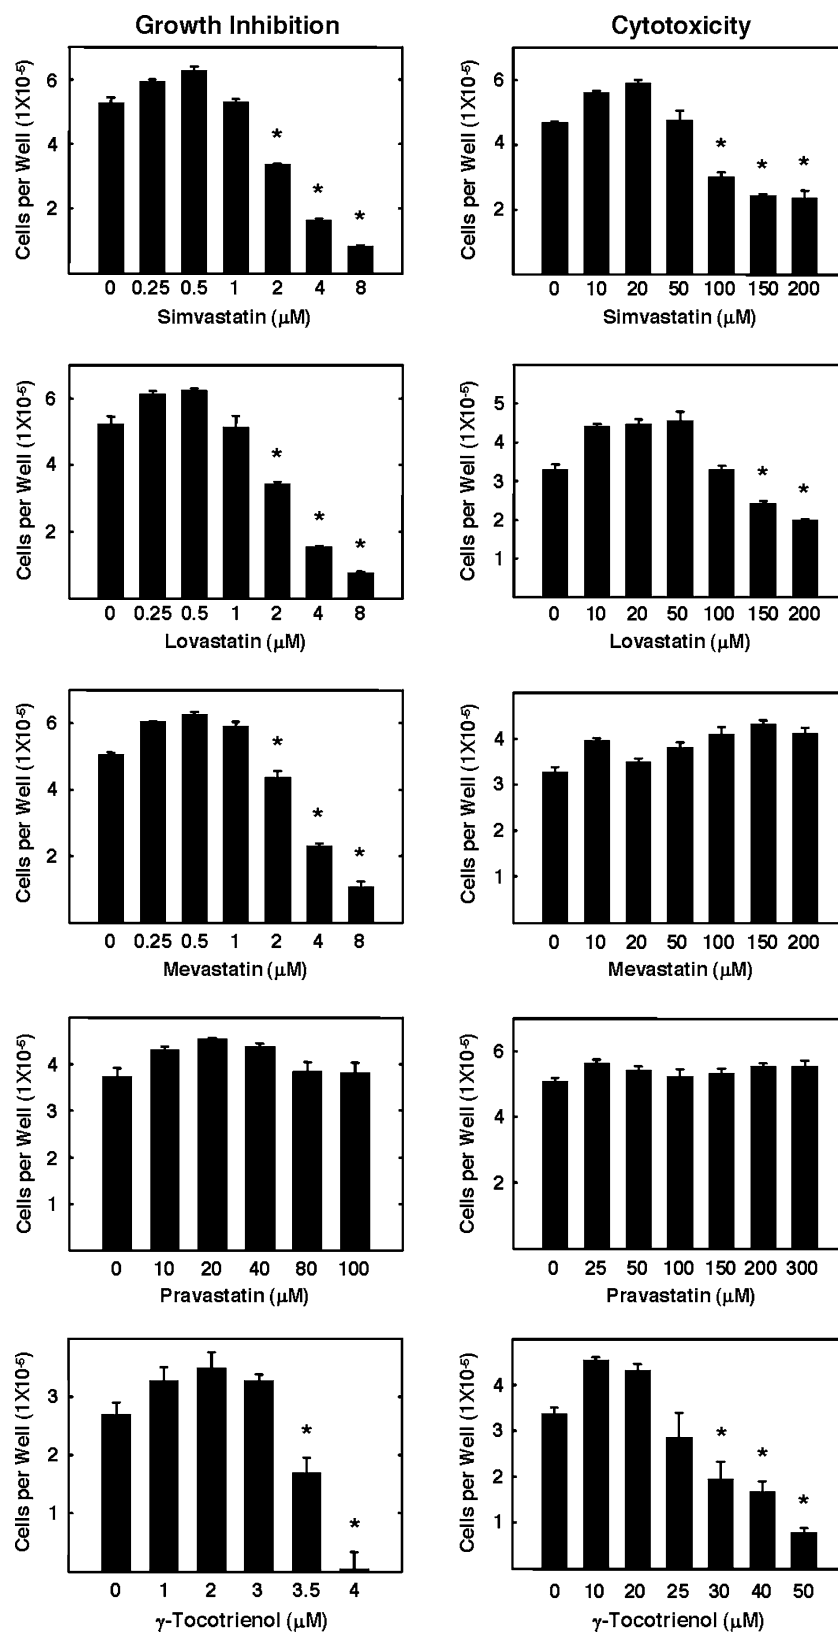

Differences among the various treatment groups in cell growth and viability studies were determined by analysis of variance (ANOVA) followed by Dunnett's  $t$ -test. A difference of  $P < 0.05$  was considered to be significant as compared to vehicle-treated controls.

## Results

### Growth and Cytotoxic Effects of $\gamma$ -Tocotrienol and Individual Statins

The effects of various doses of different statins and  $\gamma$ -tocotrienol on neoplastic +SA mammary epithelial cell proliferation over a 4 day culture period are shown in Fig. 1 (Left). Treatment with 0–8 µM simvastatin, lovastatin, mevastatin or 3–4 µM  $\gamma$ -tocotrienol significantly inhibited +SA cell growth in a dose-responsive manner, as compared to cells in the vehicle-treated control group (Fig. 1, Left). In contrast, similar treatment with 10–100 µM pravastatin had no inhibitory effect on +SA cell growth (Fig. 1, Left). The  $IC_{50}$  values for simvastatin, lovastatin, mevastatin and  $\gamma$ -tocotrienol were 1.97, 1.99, 2.7 and 3.52 µM, respectively. The cytotoxic effects of acute 24 h treatment exposure to various doses of  $\gamma$ -tocotrienol and individual statins and on +SA cell viability are shown in Fig. 1 (Right). Acute treatment with 0–50 µM of simvastatin, lovastatin, and mevastatin or 0–25 µM  $\gamma$ -tocotrienol had no effect on +SA viable cell number (Fig. 1, Right). However, similar treatment with 100–200 µM simvastatin, lovastatin or 30–50 µM  $\gamma$ -tocotrienol significantly reduced +SA viable cell number as compared to vehicle-treated controls (Fig. 1, Right). Acute 24 h treatment with 0–200 µM mevastatin or 0–300 µM pravastatin had no effect on neoplastic +SA mammary epithelial cell viability (Fig. 1, Right).

**Fig. 1** Antiproliferative (*Left*) and cytotoxic (*Right*) effects of individual statins and  $\gamma$ -tocotrienol on neoplastic +SA mammary epithelial cells in vitro. In growth studies (*Left*), cells were plated at a density of  $5 \times 10^4$  cells/well (6 wells/group) in 24-well culture plates and exposed to treatment media for a 4 day period. Afterwards, viable cell number was determined using MTT colorimetric assay. In cytotoxic studies (*Right*), cells were again plated at a density of  $5 \times 10^4$  cells/well and maintained on serum-free defined control media for 3 days. Afterwards, cells were divided into different treatment groups and media was replaced with their respective treatment media. After an acute 24 h treatment exposure, viable cell number was determined using the MTT assay. Vertical bars indicate the mean cell count  $\pm$  SEM in each treatment group. \* $P < 0.05$  as compared with vehicle-treated controls

## Growth and Cytotoxic Effects of Combined Treatment of Individual Statins with $\gamma$ -Tocotrienol

The effects of combined treatment of subeffective doses of  $\gamma$ -tocotrienol with subeffective doses of individual statins on neoplastic +SA mammary epithelial cell proliferation over a 4 day culture period are shown in Fig. 2. Treatment with 0.25–2.0  $\mu$ M  $\gamma$ -tocotrienol, 0.25  $\mu$ M simvastatin, lovastatin, mevastatin, or 10  $\mu$ M pravastatin had no effect on +SA cell growth (Fig. 2). However, combined treatment of 0.25  $\mu$ M simvastatin, lovastatin or mevastatin with 0.25–2.0  $\mu$ M  $\gamma$ -tocotrienol induced a significant inhibition of +SA cell growth in a dose-responsive manner, as compared to cells in the vehicle treated control group (Fig. 2). Similarly, combined treatment of 10  $\mu$ M pravastatin with 0.5–2.0  $\mu$ M  $\gamma$ -tocotrienol was also found to significantly inhibit +SA cell growth (Fig. 2).

In other studies, treatment with a subeffective dose of  $\gamma$ -tocotrienol (1.0  $\mu$ M) in combination with a range of subeffective doses of individual statins (0.25–1.0  $\mu$ M simvastatin, lovastatin, mevastatin or 5–15  $\mu$ M pravastatin) also resulted in a significant dose-responsive inhibition in +SA cell growth as compared to vehicle-treated controls (Fig. 3). Acute 24 h treatment of 0.25–2.0  $\mu$ M of  $\gamma$ -tocotrienol in combination with 0.25 or 10  $\mu$ M of individual statins had no effect on neoplastic +SA mammary epithelial cell viability (Fig. 4).

## Synergistic Antiproliferative Effects of Combined Treatment of $\gamma$ -Tocotrienol and Statins

Photomicrographs of treatment effects on the morphology of neoplastic +SA mammary epithelial cells grown in culture are shown in Fig. 5a. Exposure to 0.25  $\mu$ M simvastatin, 0.25  $\mu$ M or 1.0  $\mu$ M  $\gamma$ -tocotrienol alone had no effect on +SA cell growth or morphology throughout the 4 day treatment period. However, combined treatment of 0.25  $\mu$ M simvastatin with 0.25 or 1.0  $\mu$ M  $\gamma$ -tocotrienol resulted in a large suppression in +SA cell proliferation and a change from a flat squamosal morphology to a rounded metaplastic morphology (Fig. 5a). Isobologram analysis of combined treatment effects of  $\gamma$ -tocotrienol and individual statins are shown in Fig. 5b. Results showed that the growth inhibitory effect of combined treatment of subeffective doses of simvastatin, lovastatin, or mevastatin in combination with subeffective doses of  $\gamma$ -tocotrienol was synergistic because the data point in each isobologram was well below the line defining an additive effect (Fig. 5b). It was not possible to conduct isobologram analysis for the combined treatment of pravastatin and  $\gamma$ -tocotrienol because the  $IC_{50}$  value for pravastatin could not be determined with the doses tested in this study.

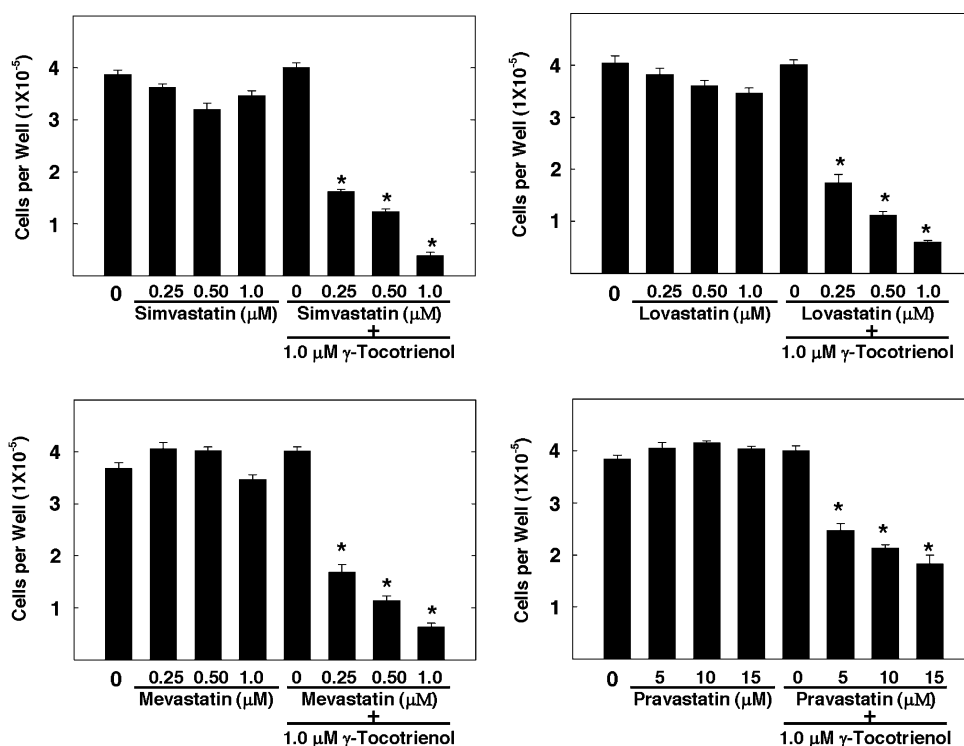

Table 1 shows a summary of isobologram analysis of combination treatment effects of  $\gamma$ -tocotrienol and individual statins. CI values for all the combinations tested were less than 1, indicating a high level of synergism that

**Fig. 2** Effects of range of subeffective doses of  $\gamma$ -tocotrienol when given alone or in combination with a subeffective dose of individual statins, on the growth of neoplastic +SA mammary epithelial cell growth. Cells were initially plated at a density of  $5 \times 10^4$  cells/well (6 wells/group) in 24-well culture plates and exposed to treatments for a 4 day period. Afterwards, viable cell number was determined using MTT colorimetric assay. Vertical bars indicate the mean cell count  $\pm$  SEM in each treatment group. \* $P < 0.05$  as compared with vehicle-treated controls

**Fig. 3** Effects of 1  $\mu\text{M}$  (subeffective dose)  $\gamma$ -tocotrienol when given alone or in combination with a range of subeffective doses of individual statins on the growth of neoplastic +SA mammary epithelial cell growth. Cells were plated at a density of  $5 \times 10^4$  cells/well (6 wells/group) in 24-well culture plates and treated for 4 days. Afterwards, viable cell number was determined by MTT assay. Vertical bars indicate the mean cell count  $\pm$  SEM in each treatment group.  $*P < 0.05$ , as compared with vehicle-treated controls

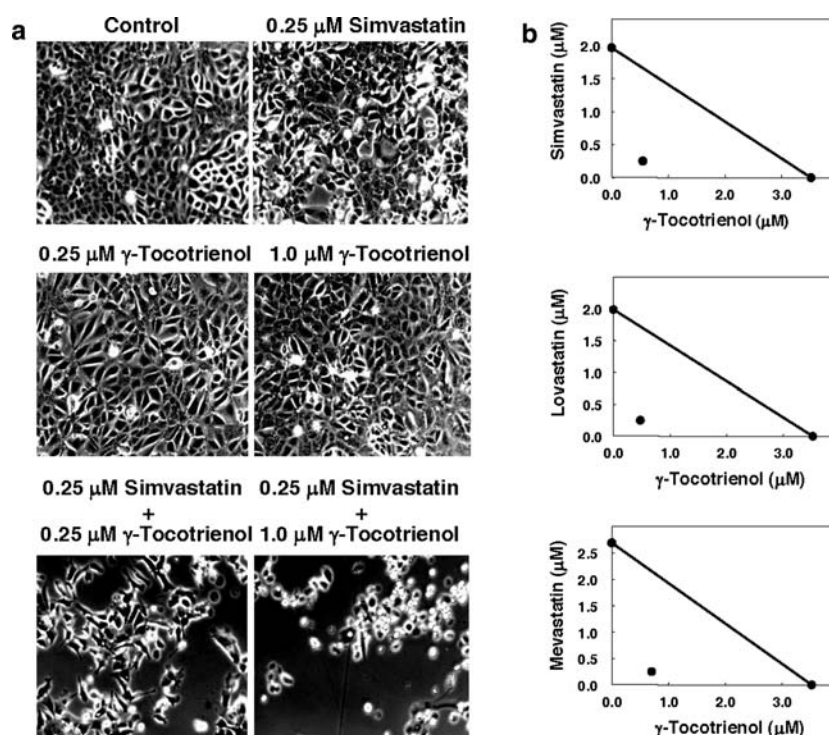

**Fig. 4** Effects of acute 24 h treatment exposure to low doses of  $\gamma$ -tocotrienol ( $\gamma$ -T<sup>3</sup>) and individual statins given alone and in combination on neoplastic +SA mammary epithelial cell viability. Cells were plated at a density of  $5 \times 10^4$  cells/well and maintained on serum-free defined control media for 3 days. Afterwards, control media in different treatment groups was replaced by their respective treatment media. After 24 h, viable cell count was determined using the MTT assay. Vertical bars indicate the mean cell count  $\pm$  SEM in each treatment group.  $*P < 0.05$ , as compared with vehicle-treated controls

resulted from combined treatment (Table 1). The dose reduction index (DRI) confirmed a high level of synergism that resulted from combined treatment. Specifically, the  $\text{IC}_{50}$  dose of simvastatin, lovastatin or mevastatin alone

could be reduced 8 to 11-fold and still produce the same antiproliferative effects if combined with  $\gamma$ -tocotrienol. Likewise, the  $\text{IC}_{50}$  dose of  $\gamma$ -tocotrienol given alone could be reduced 5 to 7-fold and still produce the same

**Fig. 5** **a** Photomicrographs of neoplastic +SA mammary epithelial cells in the different treatment groups after a 4 day incubation period. Magnification in each photomicrograph was 100 $\times$ . **b** Isobolograms of  $\gamma$ -tocotrienol and individual statin antiproliferative effects on neoplastic +SA mammary epithelial cells. Individual  $\text{IC}_{50}$  doses (dose that resulted in a 50% inhibition in cell growth over a 4 day period as compared to vehicle-treated controls) for  $\gamma$ -tocotrienol and individual statins were plotted on the  $x$ - and  $y$ -axes, respectively. The *solid line*

connecting these points represents the drug doses of each compound to induce the same relative growth inhibition when used in combination if the interaction between these compounds is additive. The *data point* on each isobologram represents the actual doses of  $\gamma$ -tocotrienol and individual statins which when used in combination result in 50% growth inhibition. Since all data points were positioned well below the line on each isobologram, these results indicate a strong synergistic antiproliferative effect

**Table 1** CI and DRI values for combined treatment of individual statins and  $\gamma$ -tocotrienol that resulted in a 50% inhibition of +SA cell growth

Combinations	Combination index (CI)	Dose reduction index (DRI)	
		Statin	$\gamma$ -tocotrienol
Simvastatin + $\gamma$ -tocotrienol	0.28	7.88	6.41
Lovastatin + $\gamma$ -tocotrienol	0.26	7.96	7.43
Mevastatin + $\gamma$ -tocotrienol	0.29	10.8	5.01

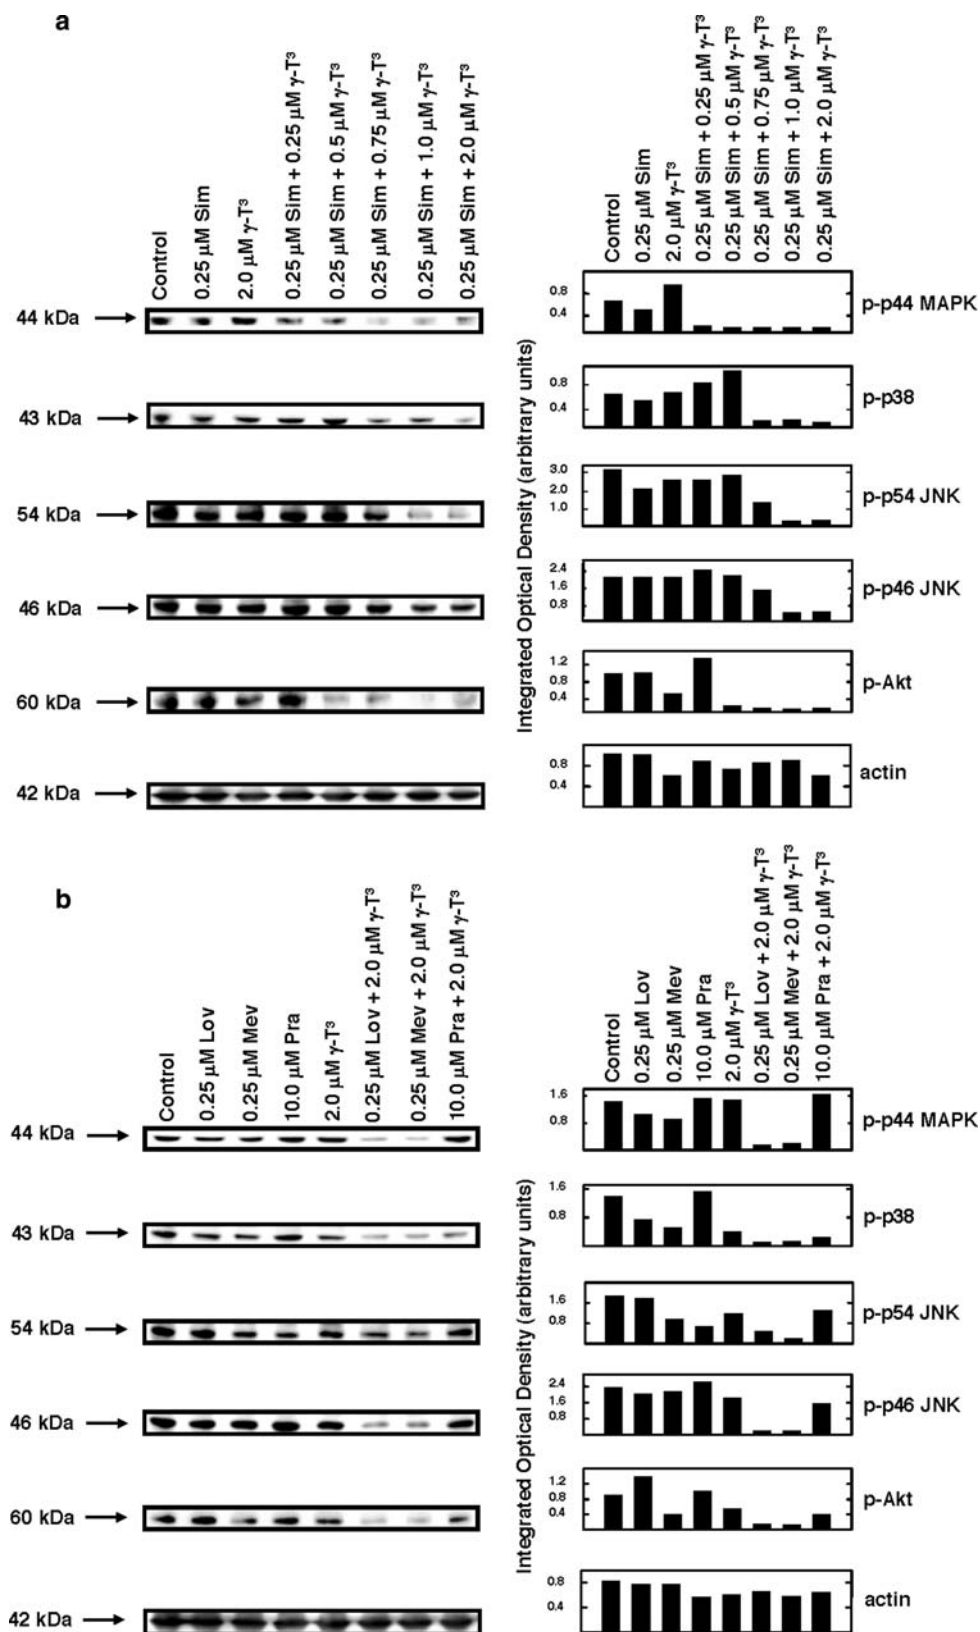

antiproliferative effect if combined with individual statins (Table 1). DRI values for the combination of pravastatin with  $\gamma$ -tocotrienol were not calculated because the  $\text{IC}_{50}$  value for pravastatin could not be determined with the doses tested in this study.

#### Treatment Effect on MAPK, JNK, p38 and Akt Activation

Figure 6 shows Western blot and scanning densitometric analysis of treatment effects on levels of phosphorylated

(activated) p44 MAPK, p38, p54/46 JNK and Akt, intracellular proteins involved in mediating EGF-dependent mitogenesis in neoplastic +SA mammary epithelial cells. Treatment with subeffective doses of simvastatin (0.25  $\mu\text{M}$ ) or  $\gamma$ -tocotrienol (2.0  $\mu\text{M}$ ) alone had little or no effect, whereas combined treatment of 0.25  $\mu\text{M}$  simvastatin with 0.25–2.0  $\mu\text{M}$   $\gamma$ -tocotrienol resulted in a large relative decrease in intracellular levels of these activated mitogenic signaling proteins as compared to vehicle-treated controls (Fig. 6a). In other studies, treatment with 0.25  $\mu\text{M}$  lovastatin, 0.25  $\mu\text{M}$  mevastatin or 10  $\mu\text{M}$  pravastatin alone had little or no effect on phosphorylated p44-MAPK, p38, p54/46 JNK or Akt, whereas combined treatment of 2.0  $\mu\text{M}$   $\gamma$ -tocotrienol with either 0.25  $\mu\text{M}$  lovastatin or mevastatin also caused in a relative large decrease in phosphorylated p44 MAPK, p38, p54/46 JNK and Akt, as compared to vehicle-treated controls (Fig. 6b). Combined treatment of 0.25  $\mu\text{M}$   $\gamma$ -tocotrienol with 10.0  $\mu\text{M}$  pravastatin had little or no effect on the relative levels of phosphorylated p44 MAPK, p54/46 JNK or Akt, while causing a relatively large decrease in intracellular levels of phospho-p38. (Fig. 6b). None of the treatments

**Fig. 6** Western blot and scanning densitometric analysis of  $\gamma$ -tocotrienol and statin treatment effects when given alone or in combination on the relative levels of phosphorylated intracellular signaling proteins (p-p44 MAPK, p-p38, p-p54/46 JNK and p-Akt) associated with EGF-dependent mitogenic signaling after a 4 day incubation period. **a** Neoplastic +SA mammary epithelial cells were initially plated at a density of  $1 \times 10^6$  cells/100 mm culture dish and treated with control or treatment media containing either 0.25  $\mu$ M simvastatin (Sim) alone or in combination with 0–2  $\mu$ M  $\gamma$ -tocotrienol ( $\gamma$ -T<sup>3</sup>). **b** +SA cells were plated in the same manner as described above in (a) and then exposed to control or treatment media containing 0.25  $\mu$ M lovastatin (Lov), 0.25  $\mu$ M mevastatin (Mev) or 10  $\mu$ M pravastatin (Pra) alone or in combination with 2  $\mu$ M  $\gamma$ -tocotrienol ( $\gamma$ -T<sup>3</sup>). Cells were fed fresh treatment media everyday throughout the 4 day incubation period. Afterwards, whole cell lysates were prepared for subsequent separation by polyacrylamide gel electrophoresis (30  $\mu$ g/lane), followed by Western blot analysis. Scanning densitometric analysis was performed for each blot and shown as bar graphs adjacent to corresponding Western blots. Vertical bars in the graphs indicate the integrated optical density of bands visualized in each lane

were found to induce any change in phospho-p42 MAPK levels as compared to vehicle-treated controls (data not shown).

## Discussion

These results demonstrate that  $\gamma$ -tocotrienol synergistically enhances the antiproliferative effects of statins on the highly malignant +SA mammary epithelial cells in vitro. Combined treatment of subeffective doses of simvastatin, lovastatin, mevastatin or pravastatin with subeffective doses (0.25–2.0  $\mu$ M) of  $\gamma$ -tocotrienol resulted in nearly an 2 to 11-fold reduction in the dose of statin required to obtain the same growth inhibitory effects as statin treatment alone. Furthermore, this synergistic growth inhibitory effect of combined treatment of  $\gamma$ -tocotrienol with individual statins was found to be cytostatic, not cytotoxic. Additional studies showed that the synergistic antiproliferative effects of combined treatment was associated with a suppression in multiple EGF-dependent mitogenic signaling pathways, including a relatively large reduction in the levels of phosphorylated (activated) p44MAPK, p38, p54/46JNK, and Akt.

Previous studies have shown that individual statins display growth inhibitory effects against different types of cancer cell lines [7, 22–26]. The present study confirms and extends these previous findings by demonstrating that treatment with 2–8  $\mu$ M simvastatin, lovastatin or mevastatin treatment alone significantly inhibited, whereas treatment with 10–100  $\mu$ M pravastatin had no effect neoplastic +SA mammary epithelial cell growth. Although the exact reason why pravastatin displays less potent anticancer activity [27, 28] than other statins is presently unknown, it may be related to the fact that pravastatin is much less lipophilic than the other statins and this physical characteristic may restrict drug uptake and/or accumulation into tumor cells. Additional studies are required to determine if this hypothesis is correct. It is also possible that the greater bioactivity of other statins may be due to actions independent of their HMGCoA reductase inhibition. The closed beta-lactone ring form of these statins has been shown to inhibit proteasome degradation of cyclin-dependent kinase inhibitors, p21 and p27, resulting in cell cycle arrest [29, 30]. Results also showed that treatment with growth inhibitory doses (2–8  $\mu$ M) of simvastatin, lovastatin, or mevastatin was not found to be cytotoxic to +SA mammary tumor cells. These statins were found to induce cytotoxicity and reduce viable +SA cell number only when used at very high, clinically irrelevant doses (100–200  $\mu$ M).

While treatment with 2–8  $\mu$ M simvastatin, lovastatin or mevastatin alone was found to significantly inhibit +SA

mammary tumor cell growth, it should be pointed out that an oral dose of 25 mg/kg or higher would be required to achieve the same levels of these statins in the blood of humans. However, use of treatment doses of 25 mg/kg or higher in humans is associated with severe adverse side effects, particularly myotoxicity [10]. As a result, the use of these statins as monotherapy in the prevention or treatment of cancer has been limited in order to avoid potential detrimental effects that would have a negative impact on the health and well-being of the patient.

In order to avoid unwanted adverse side effects associated with high dose statin use, several studies have taken the approach to combine low doses of statins with other anticancer agents [31–37]. Previous reports from this laboratory have demonstrated that low doses of  $\gamma$ -tocotrienol, a member of the vitamin E family of compounds, displays potent antiproliferative and apoptotic effects against the neoplastic +SA mammary epithelial cells [11, 13, 17]. Results showed that combined treatment with a subeffective dose (0.25  $\mu$ M) of simvastatin, lovastatin or mevastatin with subeffective doses (0.25–2.0  $\mu$ M) of  $\gamma$ -tocotrienol resulted in a synergistic inhibition of +SA cell growth. Furthermore, although treatment with high doses (10–100  $\mu$ M) of pravastatin alone had no growth inhibitory effects against +SA cells, combined treatment of 10  $\mu$ M pravastatin with subeffective doses of  $\gamma$ -tocotrienol resulted in a significant dose-responsive inhibition in +SA cell proliferation. However, these data again demonstrate that pravastatin is a much less potent anticancer agent either alone or in combination with  $\gamma$ -tocotrienol, as compared to the other statins tested. In addition, it is interesting to note that none of these low dose combinations of  $\gamma$ -tocotrienol and individual statins were found to be cytotoxic. These findings may have very important clinical implications in that combined low dose statin and  $\gamma$ -tocotrienol treatment may be effective in the treatment of breast cancer without the risk of severe myotoxicity that is associated with high dose statin use.

Additional studies showed that when given alone, subeffective doses of  $\gamma$ -tocotrienol and individual statins had no effect on EGF-dependent mitogenic signaling in neoplastic +SA mammary epithelial cells. However, when these subeffective doses of  $\gamma$ -tocotrienol and simvastatin, lovastatin or mevastatin were used in combination, a marked suppression in the relative intracellular levels of phosphorylated (activated) p44 MAPK, p54/46 JNK, p38 and Akt was observed. In contrast, combined treatment of  $\gamma$ -tocotrienol and pravastatin resulted only in a large suppression of phosphorylated p38 and had no significant effect on the relative intracellular levels of phosphorylated (activated) p44 MAPK, p54/46 JNK, and Akt. These results may explain, at least in part, why pravastatin is less potent than the other statins tested in combination with

$\gamma$ -tocotrienol in suppressing mammary tumor cell growth. These findings are consistent with previous findings that showed that tocotrienols inhibit MAPK and Akt activation in +SA mammary tumor cells [17, 38] and statin treatment inhibits the activation of MAPK, JNK, p38 and Akt in SKBr3 breast cancer cells [7]. However, other studies showed that statin treatment increased the activation of JNK, and induced apoptosis in MCF-7 and MD-MB 231 cells [24]. Differences between these results and those obtained in the present study may be due to the possibility that combined treatment with subeffective doses may modulate intracellular signaling pathway differently than high dose statin treatment alone. Additional studies are required to further characterize and differentiate the exact mechanisms involved in mediating the inhibitory effects of  $\gamma$ -tocotrienol and individual statins on specific intracellular signaling pathways, particularly the MAPK, PI3K/Akt, and JNK mitogenic cascades.

Studies have shown that statins and  $\gamma$ -tocotrienol both inhibit HMGCoA reductase activity and subsequent mevalonate synthesis through independent mechanisms. It has been established that  $\gamma$ -tocotrienol induces a down-regulation in HMGCoA reductase levels through a post-transcriptional acceleration in degradation [15], whereas statins act directly to inhibit HMGCoA reductase enzymatic activity [39]. Since cells treated with statins often display a compensatory up-regulation in HMGCoA reductase expression [40], it is possible that combined treatment with  $\gamma$ -tocotrienol counteracts this compensatory response and prevents the restoration of mevalonate synthesis. Since mevalonate is an upstream intermediate in the synthesis of reactive farnesyl residues, synergistic suppression of HMGCoA reductase activity by the combined treatment of statins and  $\gamma$ -tocotrienol might ultimately prevent the farnesylation and anchoring of Ras to the interior of the cell membrane [41, 42]. Once Ras is anchored to the cell membrane, it is able to interact with activated membrane bound receptors, such as the EGF-receptor, and initiate activation of the MAPK and Akt mitogenic signaling pathways [41–44]. Therefore, the synergistic antiproliferative effects of combined statin and  $\gamma$ -tocotrienol treatment may result from their independent actions to inhibit HMGCoA reductase activity, mevalonate synthesis, and subsequent farnesylation of second messengers involved in mediating EGF-dependent mitogenic signaling. Further studies are needed to determine if the synergistic anticancer effects of statins and  $\gamma$ -tocotrienol are due solely through the inhibition of mevalonate synthesis or also include other mechanisms. Studies have shown that  $\gamma$ -tocotrienol can directly inhibit EGF-receptor activation and mitogenic signaling [13].

In summary, these findings demonstrate the synergistic antiproliferative effects of combined low dose treatment of

$\gamma$ -tocotrienol and individual statins against mammary tumor cells. These findings strongly suggest that combined  $\gamma$ -tocotrienol and statin therapy may provide significant health benefits in the prevention and/or treatment of breast cancer in women, while at the same time avoiding myotoxicity that is associated with high dose statin treatment.

recommended daily intake of phytosterols to lower elevated LDL-cholesterol is 2 g/day, which results on average in a 10% reduction in LDL-cholesterol [2]. Higher intakes (>2.5 g/day) offer little additional benefit; intakes below 2 g/day result in a lower, although still significant LDL-cholesterol lowering effect [3].

In healthy individuals, 30–60% of the dietary cholesterol is absorbed, whereas, despite their almost identical structure, less than 2% of the phytosterols are absorbed. Consequently, the total phytosterol level in plasma of healthy individuals is less than 25  $\mu\text{mol/l}$  (<1 mg/dl) [4], representing less than 0.4% of the total plasma sterol level. Phytosterol concentrations in endothelial tissues of healthy subjects are mostly unknown, and hence in vitro studies are hampered by this lack in knowledge. However, it is plausible that the phytosterol concentrations in endothelial tissues should be considerably lower than recently reported in an atheromatous plaque study with patients undergoing carotid endarterectomy (1–4 mg/100 g of tissue) [5]. Despite the low absorption of phytosterols, elevated phytosterol levels have been associated with an increased risk for coronary artery disease (CAD) in hypercholesterolemic subjects and in families with a family history of CAD [6–8]. These studies have given rise to certain concerns whether an increased dietary intake of phytosterols results in an increased risk for CAD. Whether phytosterols are indeed a CAD risk factor is speculative and needs further clarification, since other studies do not show an association between elevated plasma phytosterol levels and an increased risk for CAD [9, 10].

Uncontrolled influx of oxLDL-cholesterol into macrophages via scavenger receptors is generally recognised as one of the hallmarks of the atherogenic process. Without proper defence cholesterol accumulates in macrophages, ultimately leading to atherogenic lipid-laden foam cells. Phytosterols are likewise taken up by macrophages [11, 12], and with increasing dietary intake may well accumulate in macrophages.

Kinetic data elucidating how phytosterols are handled by macrophages are still lacking. Isolating arterial macrophages from human tissue in sufficient amounts to study influx and efflux of phytosterols is technically challenging and as an alternative, an immortalised cell line may be used. The human THP-1 monocytic cell line is one of these established in vitro models frequently used for studying lipid metabolism. After phorbol-ester treatment THP-1 cells exhibit a more differentiated macrophage morphology and function, compared to other available monocytic cell lines [13]. Therefore, we studied whether phytosterols preferentially accumulate in human macrophages by monitoring the influx and efflux of sterols using differentiated THP-1 cells as a cellular model with lipoproteins as a carrier system.

## Materials and Methods

### Materials

THP-1 monocytes were obtained from the European Collection of Cell Cultures (Salisbury, UK). Amplex Red Cholesterol Assay Kit, foetal bovine serum (FBS) and RPMI 1640 medium were obtained from Invitrogen (Paisley, UK). 9-*cis*-retinoic acid, 22(*R*)-hydroxycholesterol, anti- $\beta$ -actin antibody, cholesterol, methyl- $\beta$ -cyclodextrin (M $\beta$ CD, average molecular weight 1,338 g/mol), phorbol-12-myristate-13-acetate (PMA), sitostanol and  $\beta$ -sitosterol were obtained from Sigma (Schnellendorf, Germany). Campesterol was obtained from Steraloids (Newport, RI, USA). ATPLite-M kit was obtained from Packard BioScience (Groningen, The Netherlands). Apolipoprotein (Apo) A-I, LDL and high-density lipoprotein (HDL) were obtained from Calbiochem (La Jolla, CA, USA). [ $1\alpha,2\alpha(n)^3\text{H}$ ]-cholesterol [specific activity (SA) 1.55 TBq/mmol, purity 99%] was obtained from Amersham International (Buckinghamshire, UK). [ $3\alpha\text{-}^3\text{H}$ ]-campesterol (SA 666 GBq/mmol, purity 97%), [ $22,23(n)^3\text{H}$ ]-sitosterol (SA 814 GBq/mmol, purity 93%) and [ $5,6(n)^3\text{H}$ ]-sitostanol (SA 1.63 TBq/mmol, purity 95%) were a kind gift of Dr. D. J. Sanders (Unilever, Bedfordshire, UK). A Bio-Rad Protein DC kit was obtained from Bio-Rad Laboratories (Richmond, CA, USA). 8-Bromo-cAMP (8-Br-cAMP) was obtained from Tocris (Ellisville, MO, USA). Complete protease inhibitors were obtained from Roche (Mannheim, Germany). Cy5-conjugated goat-anti-mouse antibody, ECL Kit, Hyperfilm ECL and Sepharose NAP-10 column were obtained from Amersham Biosciences (Uppsala, Sweden). Peroxidase-conjugated swine-anti-rabbit antibody was obtained from DAKO (Glostrup, Denmark). Anti-ABCA1 antibody was obtained from Novus Biologicals (Littleton, CO, USA). Immobilin-P nitrocellulose membranes were obtained from Millipore (Bedford, MA, USA).

### Cell Culture

THP-1 monocytes (passage 24–30) were grown in suspension in RPMI medium with 10% v/v FBS and antibiotics at 37 °C in 5% CO<sub>2</sub>. Monocyte-derived THP-1 macrophages were obtained by incubating cells for 48 h with 50 ng/ml PMA in a culture medium. PMA was absent during kinetic experiments.

### Incorporation of Sterols in M $\beta$ CD

Radiolabelled sterols (500 nM) were mixed with 2.5 mM unlabelled sterols, either campesterol, cholesterol, sitostanol

or  $\beta$ -sitosterol in chloroform. The organic solvent was evaporated under a gentle stream of nitrogen and 10 mM M $\beta$ CD in RPMI was added to the dry film of sterols. After 24 h of rotation at 37 °C, non-dissolved sterols were removed by 0.22  $\mu$ m filtration. The recovery of cholesterol, campesterol,  $\beta$ -sitosterol and sitostanol, either labelled or unlabelled, was on average 44, 18, 12 and 9.0%, respectively. The sterol containing M $\beta$ CD solution was diluted with RPMI to a final concentration of 2.5 mM M $\beta$ CD. Lower sterol concentrations were obtained by diluting in 2.5 mM sterol-free M $\beta$ CD.

### Incorporation of Sterols in oxLDL

Lipoproteins were commercially obtained or isolated from normolipemic human plasma by density ultracentrifugation. Isolated LDL ( $\rho$  1.006–1.063 g/ml) and HDL ( $\rho$  1.063–1.21 g/ml) were stored in PBS pH 7.2, 10  $\mu$ M EDTA and 10  $\mu$ M ascorbic acid at 4 °C. oxLDL was initially obtained by incubating LDL with 100  $\mu$ M CuSO<sub>4</sub> for 2 h at 37 °C, but in later experiments CuSO<sub>4</sub> was excluded, since the incorporation procedure also led to oxidation. The extent of oxidation was assessed by measuring thiobarbituric acid-reactive substances, mainly malondialdehyde (MDA). Organic solvent, containing radiolabelled sterol (400 pmol/mg LDL protein), was evaporated under a gentle stream of nitrogen and LDL (1 mg protein/ml) was added. After gentle rotation with glass beads for 24 h at 37 °C, non-incorporated radiolabelled sterols were removed by passage through a Sepharose NAP-10 column pre-equilibrated with RPMI, followed by filtration. Protein content of lipoproteins was determined and labelled oxLDL was diluted to 75  $\mu$ g protein/ml in RPMI.

### Influx Experiments

THP-1 cells were washed with serum-free RPMI and loaded with radiolabelled sterols using either M $\beta$ CD (in serum-free RPMI) or oxLDL (in RPMI with 1% FBS) as donor vehicle. At indicated time-points, cells were washed with PBS, lysed in 1% v/v Triton X-100 (TX-100) and total cell-associated radioactivity was measured on a TriCarb<sup>®</sup> 2300TR (Packard Bioscience, Groningen, The Netherlands). Total sterol influx was normalised for variation in protein content per well and in the case of oxLDL, for variation in radiolabelled sterol content.

### Efflux Experiments

THP-1 cells were incubated for 18–24 h with sterol-loaded oxLDL (75  $\mu$ g protein/ml) in the presence of 1% v/v FBS.

In some experiments, 100  $\mu$ M 8-Br-cAMP was present. THP-1 cells were washed with serum-free RPMI and either HDL (0–160  $\mu$ g protein/ml) or ApoA-I (100  $\mu$ g protein/ml) was added. At indicated time-points an aliquot of the efflux medium was removed, centrifuged (1,000g for 2 min) and radioactivity was determined. Total cell-associated radioactivity was measured after cell lysis in 1% v/v TX-100. Sterol efflux of radiolabelled sterols from cells to efflux medium or as cell-associated sterol was determined as a fraction of the total radioactivity in cells at time  $t = 0$  h. The presence of FBS in the medium improved cell viability, but caused some efflux to bovine HDL. Therefore, values were corrected for non-specific release to the medium alone. Total cellular cholesterol and cholesteryl ester were determined by the Amplex Red Cholesterol Assay Kit.

### ABCA1 Western Blotting

THP-1 cells were washed and scraped in PBS and lysed in 10 mM Tris-HCl, pH 7.3, 1 mM MgCl<sub>2</sub>, and 0.5% Nonidet P-40 containing protease inhibitors. Post-nuclear supernatants from cell lysates were prepared by centrifugation (3,000g for 10 min at 4 °C). Protein samples (40  $\mu$ g) were reduced with 2-mercaptoethanol in gel loading buffer, and separated by electrophoresis on a 4–12% Tris glycine polyacrylamide gel (Cambrex, Rockland, USA) and transferred to an Immobilon-P membrane using a semi-dry blotting apparatus (Ancos, Hojby, Denmark). Immunoblotting was performed using an anti-ABCA1 antibody (1:1,000) and a peroxidase-conjugated swine-anti-rabbit secondary antibody (1:1,000) and detection was done using an ECL kit followed by exposure to Hyperfilm ECL. Equal loading was confirmed after reprobing the membrane with an anti- $\beta$ -actin antibody (1:1,000) and Cy5-conjugated goat-anti-mouse secondary antibody (1:1,000) for detection. Induction of ABCA1 was verified by treating cells with 64  $\mu$ M 22(R)-hydroxycholesterol and 1  $\mu$ M 9-*cis*-retinoic acid. The relative intensities of the bands were determined by densitometry using TotalLab TL100 analysis software (Nonlinear Dynamics, Newcastle upon Tyne, UK).

### Data analysis

Retention of radiolabelled sterols in cells was described by Eq. 1:  $[\text{}^3\text{H}]_t/[\text{}^3\text{H}]_0 = C_1e^{-kt} + C_2$ . The release to medium of radiolabelled sterol was described by Eq. 2:  $1 - [\text{}^3\text{H}]_t/[\text{}^3\text{H}]_0$ , where  $t$  = incubation time (h);  $[\text{}^3\text{H}]_t$  = the amount of radioactivity in pmol/well after  $t$  hour and corrected for non-specific release of sterols to lipoprotein free

medium alone;  $[^3\text{H}]_0$  = the initial loading in pmol/well at time = 0 h and  $e$  = natural logarithm. Retention of radio-labelled sterols in cells starts at  $C_1$  (=span + plateau as fraction of  $[^3\text{H}]_0$ ) and decays to  $C_2$  (=plateau as fraction of  $[^3\text{H}]_0$ ) with a rate constant  $k$  (per h) [14].  $t_{1/2} = \ln 2/k$ . (Non-) linear regression and statistical analysis was performed using GraphPad Prism version 4.00 for Windows (GraphPad Software, San Diego, CA). Direct comparisons between two groups were performed using the Student's  $t$  test; data from more than two groups were analysed using one-way or two-way ANOVA. Data are presented as mean  $\pm$  SEM.

## Results

### Influx of Sterols into THP-1 Cells

$M\beta\text{CD}$  was used to deliver defined amounts of sterols in the micromolar range to THP-1 cells. Without cyclodextrin, the solubility of the sterols was less than 1 nM. With cyclodextrin, the solubility of the sterols increased, ranging from  $276 \pm 25 \mu\text{M}$  ( $n = 12$ ) for cholesterol to  $56 \pm 6 \mu\text{M}$  ( $n = 5$ ) for sitostanol. Intermediate values were obtained for campesterol ( $113 \pm 11 \mu\text{M}$ ,  $n = 5$ ) and  $\beta$ -sitosterol ( $75 \pm 6 \mu\text{M}$ ,  $n = 12$ ). The influx of sterols into THP-1 cells could not be saturated within the applied concentration range. So the initial influx rate of each sterol was determined when the rate approached first-order kinetics at  $t = 30$  min. No significant differences were observed in the initial influx rate between cholesterol, campesterol,  $\beta$ -sitosterol and sitostanol ( $4.0 \pm 0.2$ ,  $4.0 \pm 0.5$ ,  $3.7 \pm 0.3$  and  $3.6 \pm 0.3$  pmol/min per

**Fig. 1** Sterol influx of  $M\beta\text{CD}$  delivered sterols by THP-1 cells. Cells were incubated with increasing concentrations of sterols either, campesterol, cholesterol,  $\beta$ -sitosterol or sitostanol. After 30 min, cells were harvested and the influx rate in pmol/min per mg cellular protein was determined. The initial uptake rate is defined as the slope of the linear phase of sterol influx. Values are mean  $\pm$  SEM of a representative experiment ( $n = 2$  wells)

mg cellular protein, respectively,  $n = 3$  experiments) (Fig. 1).

To determine whether the influx of sterols via endocytosis of oxLDL displayed differences for the various sterols, sterol-loaded oxLDL ( $33 \pm 5$  nmol MDA equivalents/mg protein,  $n = 9$ ) was added to the THP-1 cells. The ranking of incorporation of sterols into oxLDL was comparable to that obtained with  $M\beta\text{CD}$ , but lower quantities were incorporated ( $88 \pm 27$ ,  $78 \pm 25$ ,  $78 \pm 18$  or  $44 \pm 14$  pmol/mg oxLDL protein for cholesterol, campesterol,  $\beta$ -sitosterol and sitostanol, respectively,  $n = 3$ ). As shown in Table 1, all sterols were taken up equally well at all time-points tested, when the sterol influx was normalised for the observed variations in incorporation in oxLDL.

The amount of cholesterol and cholesteryl ester in THP-1 cells after PMA stimulation was typically 20- $\mu\text{g}$  cholesterol/mg cellular protein with less than 2- $\mu\text{g}$  cholesteryl ester/mg cellular protein. Exposure to sterol-loaded cyclodextrin for 30 min decreased the cellular cholesterol and cholesteryl ester mass by approximately 25 and 40%, respectively. No significant differences in cellular ATP content, a marker for cell viability, was observed when THP-1 cells were incubated with sterol-loaded cyclodextrin compared to RPMI alone (data not shown). Exposure to sterol-loaded oxLDL for 18 h increased the cellular cholesterol mass by 150% and the cholesteryl ester mass by at least 500%.

### Efflux of Sterols from THP-1 Cells to HDL

In the next step towards mimicking the in vivo situation, THP-1 cells were preloaded with  $[^3\text{H}]$ -sterol-loaded oxLDL, washed and the efflux to HDL was monitored over time. The sterol efflux from THP-1 cells approached, but did not reach a steady state as observed in the efflux medium (Fig. 2a) or in cell extracts (Fig. 2b). As shown in Table 2, the rate constant of campesterol efflux did not significantly differ from that of cholesterol. However the rate constants of both  $\beta$ -sitosterol efflux ( $P < 0.05$ ) as well as sitostanol efflux ( $P < 0.001$ ) were significantly different from that of cholesterol. Comparable results were obtained when interpreting data from cell extracts ( $P < 0.01$  and  $P < 0.05$  for  $\beta$ -sitosterol and sitostanol, respectively). The sum of sterols in both fractions was approximately 1, indicating that all sterols were distributed over both compartments.

### $\beta$ -Sitosterol Efflux from THP-1 Cells to HDL or ApoA-I

To initiate elucidation of the underlying mechanism, the efflux to HDL versus ApoA-I alone was monitored in the

**Table 1** Total influx of oxLDL delivered sterols into THP-1 cells

Time (h)	Total sterol influx (corrected pmol/mg protein)			
	Cholesterol	Campesterol	$\beta$ -Sitosterol	Sitostanol
2	1.37 $\pm$ 0.02	1.18 $\pm$ 0.09	1.58 $\pm$ 0.41	1.55 $\pm$ 0.02
4	1.97 $\pm$ 0.13	1.72 $\pm$ 0.13	2.28 $\pm$ 0.28	2.16 $\pm$ 0.54
8	3.49 $\pm$ 0.32	3.21 $\pm$ 0.19	3.67 $\pm$ 0.29	3.51 $\pm$ 0.18

Total influx of oxLDL delivered sterols into THP-1 cells. Cells were incubated with sterol-loaded oxLDL as described in the methodology. At the indicated time-points, cells were harvested and the influx of [ $^3$ H]-sterols per milligram cellular protein was determined. The total sterol influx was normalised for variations in incorporation of sterols into oxLDL. Values are means  $\pm$  SEM of three experiments ( $n = 8$  wells, except at  $t = 8$  h,  $n = 5$  wells)

**Fig. 2** Sterol efflux from THP-1 cells to HDL. Cells were incubated with labelled oxLDL with either cholesterol, campesterol,  $\beta$ -sitosterol or sitostanol, washed and HDL was added. At indicated time-points radioactivity in the medium was determined (a) or cells were lysed and cell-associated [ $^3$ H]-sterols per milligram cellular protein was determined (b). Fractional sterol efflux was calculated relatively to the [ $^3$ H]-sterol content in cells at  $t = 0$  h. All values are mean  $\pm$  SEM of two experiments ( $n = 5$  wells)

presence of 8-Br-cAMP. THP-1 cells expressed ABCA1 protein, which was modestly increased after 8-Br-cAMP treatment (1.4-fold) and strongly increased after 9-*cis*-retinoic acid/22(*R*)-hydroxycholesterol treatment (2.4-fold, Fig. 3a). As depicted in Fig. 3b, the efflux of  $\beta$ -sitosterol and cholesterol to ApoA-I was significantly lower than efflux to HDL ( $P < 0.0001$ ). The efflux of cholesterol to

HDL could not be increased to levels observed for  $\beta$ -sitosterol when 8-Br-cAMP was added. The presence of 8-Br-cAMP resulted in a modest, but significant increase in  $\beta$ -sitosterol efflux to ApoA-I ( $P < 0.05$ ). The efflux of  $\beta$ -sitosterol to ApoA-I tended to be higher than that of cholesterol in the presence of 8-Br-cAMP ( $P = 0.086$ ). Fractional release of  $\beta$ -sitosterol and cholesterol to the medium alone was comparable (approximately 0.05), irrespective of the treatment.

## Discussion

Isolating macrophages in sufficient numbers from human arterial tissue to study the influx and efflux of phytosterols *ex vivo* is technically challenging and alternatively, immortalised cells, such as monocyte-derived THP-1 macrophages may be used. THP-1 cells are frequently used for studying macrophage specific processes and therefore this study was undertaken to examine for the first time the handling of phytosterols by macrophages with lipoproteins as the main carrier system. The rationale was to determine whether free phytosterols, which comprise approximately 30% of total phytosterol content in normal human LDL [15], preferentially accumulate in arterial macrophages and may thus affect atherogenesis.

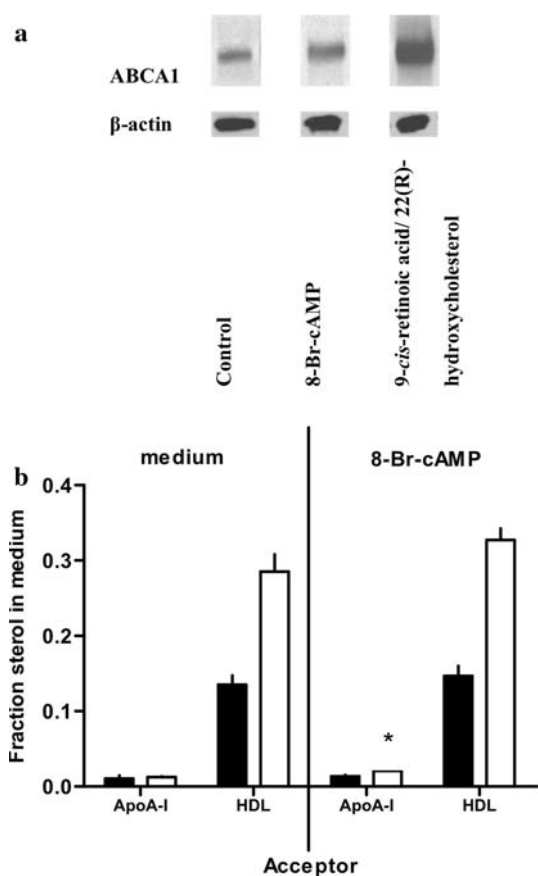

Miettinen et al. [5] observed that the concentration of  $\beta$ -sitosterol and campesterol in atherosclerotic plaque of patients undergoing carotid endarterectomy was 0.72–2.7 and 0.72–4.1 mg per 100 g of tissue, respectively, emphasizing the need for an *in vitro* carrier system capable of delivering high concentrations (in the micromolar range) of plant sterols. M $\beta$ CD, a cyclic oligosaccharide, was initially used as a carrier system because of its particle-like structure, but moreover, for its ability to deliver relative high concentrations of metabolic active sterols to cells [16]. Our data show that the initial influx rate of phytosterols from M $\beta$ CD to THP-1 cells did not differ significantly from that of cholesterol. The cyclodextrin molecules were, however, not saturated with phytosterols

**Table 2** Rate constants of sterol efflux by THP-1 cells

Sterol	$k$ (per h)	$t_{1/2}$ (h)	$C_1$ (fraction of total at $t = 0$ )	$C_2$ (fraction of total at $t = 0$ )
Cholesterol	$0.29 \pm 0.03$	$2.4 \pm 0.3$	$0.59 \pm 0.03$	$0.40 \pm 0.04$
Campesterol	$0.23 \pm 0.05$	$3.0 \pm 0.8$	$0.54 \pm 0.06$	$0.45 \pm 0.06$
$\beta$ -Sitosterol	$0.41 \pm 0.04^*$	$1.7 \pm 0.2$	$0.58 \pm 0.02$	$0.42 \pm 0.02$
Sitostanol	$0.62 \pm 0.08^{**}$	$1.1 \pm 0.2$	$0.49 \pm 0.02$	$0.51 \pm 0.02$

THP-1 cells were incubated with sterol-loaded oxLDL and the sterol transfer to HDL in the medium was monitored as described in “Materials and Methods” (Eq. 2). Retention of radiolabelled sterols in cells starts at  $C_1$  (=span + plateau as fraction of  $[^3\text{H}]_0$ ) and decays to  $C_2$  (=plateau as fraction of  $[^3\text{H}]_0$ ) with a rate constant  $k$  [14].  $t_{1/2} = \ln 2/k$ . All values are mean  $\pm$  SEM of two experiments ( $n = 5$  wells)

\* Statistically significant from cholesterol,  $P < 0.05$ ; \*\*  $P < 0.001$

**Fig. 3** Sterol efflux from THP-1 cells to HDL or ApoA-I. The presence of ABCA1 protein was verified in THP-1 cells after incubation with 8-Br-cAMP or 9-*cis*-retinoic acid/22(*R*)-hydroxycholesterol as described in “Materials and Methods” (a). Cells were incubated with labelled oxLDL with or without 8-Br-cAMP, washed and HDL or ApoA-I was added (b). At  $t = 3$  h fractional efflux to medium of  $[^3\text{H}]$ -cholesterol (closed bars) versus  $[^3\text{H}]$ - $\beta$ -sitosterol (open bars) was calculated relatively to the  $[^3\text{H}]$ -sterol content in cells at  $t = 0$  h. All values are mean  $\pm$  SEM of three experiments ( $n = 9$  wells), except for ApoA-I ( $n = 4$  wells). \* Statistically significant from efflux to ApoA-I in medium alone,  $P < 0.05$

due to low affinity. Consequently, the influx of phytosterols from cyclodextrin concomitantly occurred with the efflux of cellular cholesterol to cyclodextrin. As a result of this

efflux, the influx of sterols from cyclodextrin might be hampered and hence, a more physiological carrier system, like LDL is preferred.

Receptor-mediated endocytosis of modified LDL, like oxLDL, has been implicated in the pathogenesis of atherosclerosis, since it leads to the development of foam cells, an early step in atherogenesis. To determine whether sterol influx via receptor-mediated endocytosis of oxLDL was different for the various sterols, oxLDL was loaded with sterols and added to THP-1 cells. The observed ranking in affinity of oxLDL for sterols (cholesterol > campesterol >  $\beta$ -sitosterol > sitostanol) was interesting, since it correlates with the degree of similarity of phytosterols with cholesterol. Addition of one methyl group at C24 of the side chain (campesterol) was the smallest alteration and resulted in the highest affinity. Addition of an ethyl group at the same C24 position ( $\beta$ -sitosterol) resulted in an intermediate alteration and concomitantly a lower affinity. Addition of an ethyl group at C24 and saturation of the delta-5 double bond (sitostanol) was the biggest alteration and consequently resulted in the lowest affinity for oxLDL.

Several scavenger receptors mediate internalisation of the entire oxLDL particle, including scavenger receptors of class A and cluster determinant 36 (CD36) [17]. Whether these receptors exhibit sterol specificity during internalisation of the oxLDL particle is unknown, but our data do not indicate such a relationship, since no differences in cholesterol versus phytosterol influx were observed. The data are in line with results of an earlier mouse study [12]. It is possible that in our model, oxLDL simply facilitates diffusion of phytosterols from particle to cell, and that the particle itself is not internalised. If so, our data suggest that influx of phytosterols into cells, either mediated via passive diffusion or receptor-facilitated internalisation, does not differ from that of cholesterol.

In a next step towards mimicking the *in vivo* situation, THP-1 cells were incubated with oxLDL and then with HDL. HDL is considered to be the primary cholesterol carrier in reverse cholesterol transport; a process of

removing excess cholesterol from the periphery into the liver and bile, followed by excretion in stool. Our efflux data show that  $\beta$ -sitosterol and sitostanol were more efficiently transferred to HDL than campesterol and cholesterol, with the highest efficiency found for sitostanol. These data could indicate that the more a phytosterol differs structurally from cholesterol, the more efficiently it is removed from a peripheral cell and excreted from the body. It is again coincidental that the ranking in affinity of phytosterols for the applied carrier systems roughly correlates with their efflux efficiency to HDL, underscoring how physical properties of sterols can vary significantly, despite modest differences in molecular structure. A portion of the sterols was not exchanged (indicated by the plateau C2), presumably because they were excluded from efflux due to esterification by acyl-CoA:cholesterol *O*-acyltransferase (ACAT) type 1 and storage in lipid droplets during the pre-loading period with oxLDL. Nevertheless, for cholesterol the observed  $t_{1/2}$  was within the range of values found for other cell types (1–3 h) [14, 18]. Whether the differences in the sterol efflux were caused by different kinetics in tritium exchange due to different labelling positions is unknown and may be worth exploring in a subsequent study.

Since esterification and storage of esters in lipid droplets result in a decline of the intracellular sterol pool available for efflux, one could speculate that modest substrates for ACAT-1, like phytosterols, are more efficiently transferred to HDL than cholesterol. Although ACAT inhibition did decrease the fraction of cholesterol retained in THP-1 cells, levels as low as for  $\beta$ -sitosterol were not reached (data not shown). Another important step in sterol efflux is the hydrolysis of steryl esters by cellular cholesterol esterase. It might be that  $\beta$ -sitosterol and sitostanol, when esterified in the cell, are efficiently hydrolysed and thus rapidly available for efflux. However, a preferred hydrolysis of esterified  $\beta$ -sitosterol by cholesterol esterase is unlikely due to a reported twofold lower cholesterol esterase activity for  $\beta$ -sitosterol as compared to cholesterol [19]. A lower cholesterol esterase activity might also be expected for sitostanol, the hydrogenated form of  $\beta$ -sitosterol.

Several transporters, next to passive diffusion, may be responsible for the preferential efflux of  $\beta$ -sitosterol and sitostanol in our model, including ABCA1 [20]. ABCA1 was detected and inducible in our THP-1 model. In our experiments, the presence of 8-Br-cAMP modestly increased ABCA1 protein mass as reported earlier for human fibroblasts [21]. However, whether cAMP analogues indeed increase ABCA1 expression is still open for debate, since other groups did not observe any effect of cAMP analogues on human ABCA1 expression [22, 23].

Despite an excess of ApoA-I and the presence of ABCA1, the efflux to ApoA-I was relatively modest, even for cholesterol, indicating that the ABCA1–ApoA-I

pathway may not be responsible for the observed effects in our model. However, the small but statistically significant increase of  $\beta$ -sitosterol efflux to ApoA-I is noteworthy, since it might indicate that certain phytosterols are preferentially transported via this pathway. This observation is intriguing, since it might indicate a discriminatory role of ACAT1 in macrophages. Similarly to cholesterol, plant sterols are esterified by ACAT-1, but with lower efficiency [24], and secreted via chylomicrons into lymph. Since ABCA1 and ACAT-1 use the same pool of free sterols as substrate [25], a poor ACAT-1 substrate like  $\beta$ -sitosterol, might be more available for the alternative ABCA1–ApoA-I pathway than, e.g., cholesterol. Similarly to ABCA1, the CD36 and LIMPII analogous-1 receptor (CLA-1) may also not play an important role in our model. Results from earlier studies have shown that PMA stimulation reduces CLA-1 mRNA expression in THP-1 cells [26] and oxLDL incubation reduces expression of SR-BI, the mouse homologue of CLA-1, in mouse macrophages [27]. Therefore the role of another ABC protein, ABCG1, might be more relevant. ABCG1 is responsible for the transfer of cholesterol to HDL [28] and THP1 cells express ABCG1 mRNA [29]. Whether this transporter is indeed responsible for the observed preferential efflux of phytosterols requires further investigation.

Nguyen et al. [11] isolated monocytes from healthy individuals and determined their sterol concentration. A total of 3.8% was of phytosterol origin, including  $\beta$ -sitosterol (56%), campesterol (30%) and sitostanol (14%). Surprisingly, more  $\beta$ -sitosterol than campesterol was found in monocytes, despite a higher concentration of campesterol in plasma. Our data support the view that macrophages transfer  $\beta$ -sitosterol more efficiently than campesterol, and as a consequence might contain more of the latter. A possible explanation for this difference could be that phytosterol efflux in monocytes is different from that of macrophages. The preferential efflux of  $\beta$ -sitosterol and sitostanol to HDL is in agreement with the observation that phytosterols tend to accumulate in HDL of healthy individuals [15] and patients suffering from sitosterolemia [30], an autosomal recessive disorder characterised by an elevated plasma and tissue concentrations of phytosterols [4].

In conclusion, the present in vitro results indicate that (1) THP-1 cells absorb phytosterols at a level similar to that of cholesterol and (2)  $\beta$ -sitosterol and sitostanol are transferred to HDL more efficiently than cholesterol. Consequently, one could speculate that arterial macrophages in vivo also transfer phytosterols efficiently to HDL and that this transfer is increased as the molecular structure deviates more from cholesterol. Whether our in vitro results can be extrapolated to an in vivo situation requires more analysis. Suitable animal models or other

macrophage models should therefore be selected to test and study this hypothesis and the current results could be used as guideline for future work.

integrity of red blood cells which is affected in the hypercholesterolemic situation is effectively countered by dietary curcumin and capsaicin [5, 6]. The antioxidant potential of spice principles—curcumin and capsaicin has been experimentally documented in *in vitro* systems and in a few *in vivo* studies [1]. We have also recently reported the beneficial influences of dietary curcumin, capsaicin and their combination on the susceptibility of low-density lipoprotein (LDL) to oxidation and that the protective effect of the combination of curcumin and capsaicin on LDL oxidation was greater than that of the individual compounds [7]. We have also observed that while both dietary curcumin and capsaicin moderately lowered carrageenan-induced paw inflammation, these spice principles in combination were more effective [7].

The present animal study examined the hypolipidemic influence of dietary curcumin and capsaicin individually and in combination in induced hypercholesterolemic rats especially to verify if there is any additive or synergistic effect of these two bioactive compounds. Information on the possibility of an additive or synergistic effect of two hypolipidemic agents would be most relevant in the context of their possible use in the management of cardiovascular diseases. The study also examined their influence on antioxidant molecules and a few antioxidant enzymes in blood and liver in hypercholesterolemic condition.

## Experimental Procedures

### Chemicals and Reagents

The spice active principles—curcumin and capsaicin were procured from M/s Fluka Chemie, Switzerland. All other chemicals used were of analytical grade obtained from M/s Sigma Chemical Co., St Louis, USA and the solvents were distilled before use.

### Animal Treatment

Animal experiments were carried out taking appropriate measures to minimize pain or discomfort in accordance with the guidelines laid down by the NIH (USA) regarding the care and use of animals for experimental procedures and with due clearance from the Institute's Animal Ethics Committee. Female Wistar rats (eight per group) weighing 110–120 g and housed in individual stainless steel cages were maintained on various experimental diets *ad libitum* for 8 week. The basal diet consisted of: casein 21%, cane sugar 10%, corn starch 54%, NRC vitamin mixture 1%, Bernhardt–Tommarrelli modified NRC salt mixture 4%, and refined peanut oil 10%. The hypercholesterolemic diet

consisted of 0.5% cholesterol and 0.125% bile salts at the expense of an equivalent amount of corn starch in the basal diet, and also hydrogenated vegetable fat was used in place of refined peanut oil at 10% level in this diet. The spice principles were incorporated into the basal diet/hypercholesterolemic diet, replacing an equivalent amount of corn starch to give the various experimental diets containing: curcumin (0.2%), capsaicin (0.015%) and curcumin (0.2%) + capsaicin (0.015%). At the end of the experimental period, overnight fasted animals were sacrificed under light ether anesthesia. Blood was collected by heart puncture and serum separated by centrifugation. The liver was quickly excised, weighed and stored frozen till lipid extraction.

### Lipid Profile

Total lipids were extracted according to Folch et al. [8] and estimated gravimetrically. Cholesterol [9], triglycerides [10] and phospholipids [11] were determined in the lipid extracts of serum and liver by using standard procedures. Serum cholesterol and triglyceride associated with HDL fraction were determined after precipitation of apolipoprotein-B containing lipoproteins with heparin-manganese reagent according to the method of Warnick and Albers [12]. LDL–VLDL precipitate was extracted with chloroform:methanol (2:1, v/v) and used for cholesterol and triglyceride determination.

### Lipid Peroxides

Serum lipid peroxides were estimated by the fluorimetric measurement of the thiobarbituric acid complex by the method of Yagi [13]. The fluorimetric measurement was carried out at an excitation wavelength of 515 nm and an emission wavelength of 553 nm and compared with the standards prepared by reacting 0.5 nmol 1,1,3,3-tetraethoxy-propane with TBA reagent. Lipid peroxide in liver tissue was determined by the method described by Ohkawa et al. [14] involving photometric measurement of thiobarbituric acid complex extracted into butanol. Absorbance of the butanol extract was measured at 532 nm and compared with that of standard tetraethoxypropane, treated similarly.

### Antioxidant Molecules

Total thiols in serum and liver were measured spectrophotometrically by using Ellman's reagent according to Sedlock and Lindsay [15]. Glutathione in serum and liver was estimated by using Ellman's reagent according to

Beutler et al. [16]. Ascorbic acid was estimated spectrophotometrically by measuring the 2,4-dinitrophenylhydrazine derivative of dehydroascorbic acid according to Omaye et al. [17].  $\alpha$ -Tocopherol in liver and serum was determined by the HPLC method described by Zaspel and Csallany [18] using an ODS column (C-18) and an UV-visible detector (295 nm) and a solvent system acetonitrile–methanol (1:1).

#### Antioxidant Enzymes

Glutathione reductase activity was assayed in serum and liver homogenate by measuring the oxidation of NADPH at 340 nm by oxidized glutathione as described by Carlberg and Mannervik [19]. Glutathione-S-transferase activity was assayed by measuring the CDNB–GSH conjugate formed using 1-chloro-2,4-dinitrobenzene as the substrate as described by Warholm et al. [20]. Glutathione peroxidase activity in serum and liver homogenate was determined by following NADPH oxidation in a coupled reduction system consisting of hydrogen peroxide and oxidized glutathione as described by Flohe and Gunzler [21]. Catalase activity in serum and liver homogenate was assayed according to the method of Aebi [22] by following the decomposition of hydrogen peroxide at 240 nm.

#### Statistical Analysis

Results are expressed as means  $\pm$  SEM and comparisons between groups were made by means of one-way ANOVA for basal diet groups and another one-way ANOVA for high cholesterol diet groups [23]. Comparisons among

different groups were made applying the Dunnett test. Differences were considered significant when  $P < 0.05$ .

## Results

### Serum Lipid Profile

High cholesterol feeding for 8 weeks resulted in a significant increase in blood total cholesterol concentration and this increase was observed mainly in the LDL/VLDL-associated fraction (Table 1). The increase in total blood cholesterol was as much as sixfold. Dietary curcumin, capsaicin or their combination significantly countered the extent of hypercholesterolemia. Blood total cholesterol was 20, 22 and 21.5% lower in these respective animal groups compared to their corresponding control. The reduction in blood cholesterol brought about by dietary spice principles was predominantly in the LDL/VLDL-cholesterol fraction. The HDL-cholesterol fraction essentially remained unchanged as a result of treatment with spice principles. While the effect of curcumin and capsaicin on blood cholesterol was quantitatively almost equal at their dietary levels used here, the combination of the two spice principles—curcumin and capsaicin did not have any additive effect on blood cholesterol level. Neither of the two dietary spice principles had any effect on blood cholesterol level in normal rats.

Serum total triglyceride concentration was significantly lower in high cholesterol treatment when compared to the normal-control (Table 1). This decrease was about 33%, and was due to a specific decrease in the LDL/VLDL-associated fraction (38%). There was no change in the concentration of triglyceride associated with HDL as a

**Table 1** Influence of dietary curcumin and capsaicin on serum lipid profile

Animal group	Cholesterol			Triglycerides			Phospholipids
	Total	LDL + VLDL	HDL	Total	LDL + VLDL	HDL	
Control	55.6 $\pm$ 2.00	34.9 $\pm$ 1.42	20.7 $\pm$ 1.74	112.3 $\pm$ 2.76	96.4 $\pm$ 3.41	16.0 $\pm$ 1.06	118.5 $\pm$ 4.50

HCD control	398.0 $\pm$ 20.8	377.9 $\pm$ 22.0	20.1 $\pm$ 0.77	75.7 $\pm$ 3.46	59.5 $\pm$ 3.64	16.2 $\pm$ 0.85	159.6 $\pm$ 5.83
HCD curcumin	317.8 $\pm$ 13.7**	298.2 $\pm$ 14.7**	19.6 $\pm$ 0.49	71.4 $\pm$ 4.50	55.7 $\pm$ 3.84	15.8 $\pm$ 1.49	228.8 $\pm$ 5.54*
HCD capsaicin	309.2 $\pm$ 15.9**	289.0 $\pm$ 11.7**	20.2 $\pm$ 1.06	65.7 $\pm$ 5.23	52.1 $\pm$ 2.66	13.6 $\pm$ 0.96	185.4 $\pm$ 6.27*
HCD curcumin + capsaicin	312.6 $\pm$ 19.7**	291.7 $\pm$ 24.1**	20.9 $\pm$ 0.54	85.9 $\pm$ 2.70	69.0 $\pm$ 2.32	16.9 $\pm$ 0.63	201.6 $\pm$ 7.61*

Values expressed as mg/dl are the mean  $\pm$  SEM of eight rats in each group

LDL low-density lipoprotein, HDL high-density lipoprotein, VLDL very low-density lipoprotein, HCD high cholesterol diet

\* Significant increase compared to corresponding control ( $P < 0.05$ ), \*\* significant decrease compared to corresponding control ( $P < 0.05$ )

result of high cholesterol feeding. Dietary spice principles—curcumin, capsaicin or their combination did not alter the blood triglyceride concentration in these induced hypercholesterolemic animals. On the other hand, there was a statistically significant decrease in total triglycerides and LDL/VLDL-associated triglycerides in normal rats as a result of dietary capsaicin and dietary curcumin + capsaicin. The decreases in blood total triglyceride concentration brought about in the normal rats belonging to the two respective diet groups were 19 and 13%, which was mainly from the LDL/VLDL-associated fraction.

While the dietary spice principles did not affect the blood phospholipid concentration in normal rats, higher phospholipid content resulted in hypercholesterolemic rats by feeding these spice principles (Table 1). A hypercholesterolemic diet brought about a 32% increase in blood phospholipid concentration compared to normal control. The increases in phospholipid concentration seen in hypercholesterolemic rats in the diet groups—curcumin, capsaicin, and curcumin + capsaicin were 43, 16 and 26%, respectively, compared to HCD-control. No particular additive effect is seen when the two spice principles—curcumin and capsaicin were given in combination.

#### Liver Lipid Profile

The hepatic cholesterol concentration was significantly lowered as a result of dietary spice principles in normal rats (Table 2). This decrease was 20, 27 and 23% in curcumin fed, capsaicin fed and curcumin + capsaicin fed animals, respectively. Liver cholesterol was not influenced by the two spice compounds or their combination in hypercholesterolemic animals. The liver triglyceride level was significantly lowered in both normal and hypercholesterolemic rats maintained on a capsaicin diet, the decrease

brought about being 51 and 29%, respectively. Hepatic phospholipid concentration remained unaffected by dietary spice principles in both normal and hypercholesterolemic rats. The dietary capsaicin treatment lowered total lipids in the liver by 15% in hypercholesterolemic rats and by 26% in normal rats. Hepatic total lipid content was also lower in the normal—curcumin + capsaicin group, which was about 20%.

#### Antioxidant Molecules in Blood

Among the various antioxidant molecules, serum ascorbic acid concentration was not influenced by the dietary spice principles in normal rats, while it was significantly enhanced in hypercholesterolemic animals (Table 3). The extent of the increase in serum ascorbic acid produced by dietary curcumin, capsaicin and their combination was 64, 34 and 44%, respectively. Thus, the effect of curcumin seen on serum ascorbic acid was more than that produced by capsaicin, and there was no additive effect by their combination. On the other hand, serum  $\alpha$ -tocopherol concentration was significantly lowered in hypercholesterolemic animals by dietary curcumin, capsaicin, and their combination, the effect being 72, 71.5 and 35%, respectively (Table 3). Thus, the combination of the two spice principles produced a lower decrease in the concentration of this antioxidant vitamin than the two individual spice principles. Serum  $\alpha$ -tocopherol was not influenced by any of the spice principles in normal animals. Serum  $\alpha$ -tocopherol was about three times higher in the hypercholesterolemic animals (1.698 vs 0.57  $\mu$ g/dl).

Total thiol content in serum was lower as a result of treatment with spice principles in both normal and hypercholesterolemic animals, the effect being more in the latter (Table 3). The decreases in serum total thiol concentration

**Table 2** Influence of dietary curcumin and capsaicin on hepatic lipid profile

Animal group	Total lipids	Cholesterol	Triglycerides	Phospholipids
Control	65.6 $\pm$ 0.82	5.73 $\pm$ 0.19	27.8 $\pm$ 0.95	27.5 $\pm$ 0.30

were 20, 19 and 18% by dietary curcumin, capsaicin and curcumin + capsaicin, respectively, in normal rats. The decreases in serum total thiol concentration produced in hypercholesterolemic animals by these respective diet groups were 14, 38 and 33%. Significant decreases in serum glutathione concentration were also observed as a result of feeding animals with these spice principles, more so in hypercholesterolemic animals. The decreases in serum glutathione concentration seen in hypercholesterolemic rats maintained on curcumin, capsaicin, and their combination were 23, 56 and 41%, respectively. Blood lipid peroxide content was lower in the hypercholesterolemic rats as a result of feeding either curcumin and capsaicin or their combination (Table 3). The extent of reduction in lipid peroxide was 13, 17 and 41% in the respective diet groups. Dietary spice principles did not have any influence on the blood lipid peroxide value in the case of normal rats.

#### Antioxidant Molecules in the Liver

Ascorbic acid concentration in the liver was favourably influenced by dietary curcumin, capsaicin and their combination in normal rats (Table 4). The extent of the increase in hepatic ascorbic acid was 21, 14 and 11% in the respective diet groups. These dietary spice principles did not show any beneficial effect on liver ascorbic acid levels in hypercholesterolemic rats. On the other hand, there were marginal decreases in hepatic ascorbic acid of hypercholesterolemic rats in the dietary curcumin, capsaicin and curcumin + capsaicin groups. The decreases were of the order of 23, 16 and 27% in the respective diet groups.

Hepatic total thiols were higher as a result of dietary spice principles—curcumin, capsaicin or curcumin + capsaicin in normal rats (Table 4). The increase in total thiols was 11, 26 and 39% in the respective diet groups as compared to control. Thus, the combination of curcumin

and capsaicin produced an effect higher than the two individual compounds. Total thiols were 87% higher in high cholesterol treatment as compared to their normal counterpart. The spice principles did not have any influence on the same in hypercholesterolemic rats. Hepatic glutathione content was higher in normal rats under the influence of dietary curcumin, capsaicin or the combination of these two (Table 4). Dietary curcumin, capsaicin and curcumin + capsaicin produced an increase in hepatic glutathione of 29, 43 and 28%, respectively. Hypercholesterolemic rats displayed a higher hepatic glutathione content (0.528  $\mu\text{g}/\text{mg}$  protein in the HCD-control compared to 0.336  $\mu\text{g}/\text{mg}$  protein in the normal-control). Unlike in normal rats, only the combination of curcumin and capsaicin produced an enhancing effect on hepatic glutathione in hypercholesterolemic animals, the effect being 37%. Hepatic lipid peroxides were lowered by dietary spice compounds both in normal and hypercholesterolemic situation (Table 4), the decrease produced being 33, 13 and 17% by dietary curcumin, capsaicin and their combination, respectively, in normal rats, while in hypercholesterolemic rats, the decrease was by 20, 27 and 31% by the respective diet groups.

#### Antioxidant Enzymes in Serum

Activities of serum glutathione reductase and catalase were higher in hypercholesterolemic animals when compared to their normal counterparts (Table 5). Activity of glutathione reductase was significantly enhanced by dietary curcumin, capsaicin and curcumin + capsaicin in normal rats. The increase in the enzyme activity produced by these diet groups was 41, 82 and 44%, respectively. However, in the hypercholesterolemic animals, there was no similar

beneficial influence of these spice principles. Dietary curcumin, capsaicin and their combination produced beneficial increases in the activity of glutathione peroxidase in hypercholesterolemic rats (Table 5). The enzyme activity was 23, 23 and 18% higher in these diet groups. However, the same spice compounds negatively influenced the activity of glutathione peroxidase in normal rats, the extent of decrease being 15, 20 and 47% in the respective groups. This negative effect was much higher in the spice combination group compared to that of individual spice compounds.

Glutathione transferase activity was much higher as a result of dietary curcumin, capsaicin, and curcumin + capsaicin in normal rats (Table 5). The increase in the enzyme activity was 41, 35 and 32% in the respective groups. The enzyme activity was similarly higher (by 25%) as a result of curcumin feeding in hypercholesterolemic animals. Dietary capsaicin or the spice principles combination had no influence on the enzyme activity in hypercholesterolemic rats. Serum catalase activity was similarly beneficially influenced by dietary curcumin, capsaicin and curcumin + capsaicin in normal rats (Table 5). The increase in catalase activity was 43, 30 and 22% in the respective groups. Catalase activity was similarly higher (by 16%) only in the curcumin-fed group of hypercholesterolemic animals. Dietary capsaicin or the spice principles combination had no influence on this enzyme activity in hypercholesterolemic rats.

#### Antioxidant Enzymes in Liver

Activities of all the hepatic antioxidant enzymes examined here—glutathione reductase, glutathione peroxidase, glutathione transferase and catalase were lower in

\* Significant increase compared to the corresponding control ( $P < 0.05$ ), \*\* significant decrease compared to the corresponding control ( $P < 0.05$ )

hypercholesterolemic animals when compared to their normal counterparts (Table 6). Dietary curcumin, capsaicin and their combination significantly enhanced the activity of glutathione reductase in the liver of normal rats. The increases in this enzyme activity were 28, 24 and 34%, respectively, as a result of feeding curcumin, capsaicin or their combination. Dietary curcumin also enhanced hepatic glutathione reductase activity in hypercholesterolemic animals (by 24%). Hepatic glutathione peroxidase activity was unaffected by dietary spice principles in both normal and hypercholesterolemic animals. Whereas, dietary spice principles had no effect on hepatic glutathione transferase activity in normal rats, the same was increased by curcumin in hypercholesterolemic animals (by 17%). Hepatic catalase activity was unaffected by dietary spice principles in normal rats, which however was negatively influenced in all the three experimental groups of hypercholesterolemic rats (Table 6), the observed decreases being 32, 47 and 50%, respectively, in curcumin, capsaicin and curcumin + capsaicin groups.

## Discussion

In this study, spice compounds were fed to animals at levels corresponding to about ten times the average dietary intake of the corresponding spices among the Indian population [24]. The food intake was essentially similar in various spice principles fed groups and corresponding control group. Similarly, the gain in body weight during the 8-week spice treatment was comparable to corresponding controls [final weight (g) ranged from  $178.1 \pm 5.7$  to  $197.5 \pm 6.6$  in normal rats and from  $190.5 \pm 5.8$  to  $206.4 \pm 6.5$  in hypercholesterolemic animals] indicating

that dietary spices did not negatively affect the feed intake and body weight gain.

This animal study has shown that dietary curcumin, capsaicin and their combination significantly countered hypercholesterolemia brought about by high cholesterol feeding, and the effect was to a similar extent in all the three experimental groups and that the combination of the two spice compounds did not have any additive effect in this respect. The reduction in blood cholesterol brought about by dietary spice principles was mainly in the LDL–VLDL fraction.

Subba Rao et al. have reported lowering of serum and liver cholesterol levels in rats fed curcumin at 0.1–0.5% in the hypercholesterolemic diet, the anti-hypercholesterolemic effect being attended by an increase in the fecal excretion of bile acids and cholesterol [25]. The anti-hypercholesterolemic effect of curcumin has been evidenced at even a 0.05% dietary level and at as early as 4 week feeding [26]. The anti-hypercholesterolemic efficacy of dietary curcumin has been recently demonstrated in rats fed an atherogenic high cholesterol diet, which also resulted in countering the changes in the membrane lipid profile in the erythrocytes [5]. The hypocholesterolemic and hypotriglyceridemic action of dietary curcumin (0.5%) has also been demonstrated in streptozotocin-induced diabetic rats [27].

Reduction in serum cholesterol levels in rats on a normal 10% fat diet incorporated with 1.5, 3 and 15 mg% capsaicin [28], and lowered liver cholesterol in induced hypercholesterolemic rats by dietary 15 mg% capsaicin have been reported [29]. Fecal excretion of cholesterol and bile acids was enhanced in animals fed capsaicin in these studies. In a subchronic toxicity study in rats administered 50 mg/kg per day of capsaicin for 60 days, plasma

HCD high cholesterol diet

\* Significant increase compared to corresponding control ( $P < 0.05$ ), \*\* significant decrease compared to corresponding control ( $P < 0.05$ )

cholesterol levels were significantly reduced along with triglycerides and phospholipids [30]. Negulesco et al. [31] have observed that administration of 8 mg capsaicin/day for 35 days to rabbits on a 0.5% cholesterol diet produced a beneficial lowering of plasma cholesterol and triglycerides. Young turkeys on a 2–3 mg capsaicin/kg feed for 9 days along with 0.5% cholesterol had lower total serum cholesterol than controls [32]. Recently, the anti-hypercholesterolemic efficacy of dietary capsaicin has been shown in rats fed an atherogenic high cholesterol diet which resulted in countering of the changes in the membrane lipid profile in the erythrocytes [5].

Hepatic cholesterol concentration was significantly lowered in the present investigation as a result of dietary spice principles in normal rats, while the same was not influenced in hypercholesterolemic animals. Liver triglyceride levels were significantly lowered in both normal and hypercholesterolemic rats maintained on a capsaicin diet. Thus, no particular additive effect is seen when the two spice compounds—curcumin and capsaicin were given in combination with regard to blood and the liver lipid profile.

Among the various antioxidant molecules in serum, ascorbic acid and  $\alpha$ -tocopherol concentrations were significantly affected in hypercholesterolemic animals by dietary spice principles but not in normal rats. Serum ascorbic acid level was significantly enhanced by dietary spices in hypercholesterolemic animals while  $\alpha$ -tocopherol concentration was significantly lowered. The effect of curcumin on serum ascorbic acid was higher than that produced by capsaicin, and there was no additive effect in the case of their combination. Serum  $\alpha$ -tocopherol was about three times higher in the hypercholesterolemic animals, and this could probably explain the control of oxidative stress in the hypercholesterolemic situation where the lipid peroxide level in blood was essentially the same as found in normal animals.

Blood lipid peroxide content was lower in the hypercholesterolemic rats as a result of feeding curcumin, capsaicin or their combination; the lowering of blood lipid peroxides was cumulative when curcumin and capsaicin were fed in combination. The increase in blood ascorbic acid concentration in these three diet groups may have contributed to the observed reduced lipid peroxide level. Hepatic antioxidants—thiols, glutathione and ascorbic acid were elevated in hypercholesterolemic rats with concurrent low titres of lipid peroxides. All the three dietary spice principle groups brought about further depletion in hepatic lipid peroxides. Ascorbic acid concentration in liver was favourably influenced by dietary curcumin, capsaicin and their combination in normal rats while the increase in ascorbic acid was countered by dietary spice principles in hypercholesterolemic rats. With respect to hepatic glutathione content, only the combination of curcumin and

capsaicin produced an enhancing effect in hypercholesterolemic animals. Similarly, the combination of curcumin and capsaicin produced an effect higher than the two individual compounds in increasing the total thiol content in liver of normal rats.

There are several reports on the antioxidant effects of curcumin and capsaicin with regard to the modulation of lipid peroxide level and antioxidant status. Curcumin has been reported to exert a protective effect against nicotine-induced lung toxicity by modulating the extent of lipid peroxidation and augmenting the antioxidant defense system [33]. The enhanced circulatory lipid peroxides in nicotine-treated rats which was accompanied by a significant decrease in the levels of ascorbic acid, vitamin E, reduced glutathione, glutathione peroxidase, superoxide dismutase, and catalase was significantly countered by the administration of curcumin (80 mg/kg given simultaneously for 22 weeks) which significantly lowered the lipid peroxidation and enhanced the antioxidant status. Dietary supplementation of curcumin (2%) to mice for 30 days has been reported to have significantly increased the activities of glutathione peroxidase, glutathione reductase and catalase in liver [34]. Curcumin has been reported to have a protective role in alcohol and  $\delta$ -PUFA induced oxidative stress in Wistar rats [35]. The liver TBARS and antioxidants such as ascorbic acid,  $\alpha$ -tocopherol, reduced glutathione, and antioxidant enzymes were altered significantly in alcohol and  $\delta$ -PUFA groups, while administration of curcumin abrogated this effect by effectively modulating the antioxidant status. In vivo antioxidative effects of curcumin have been reported in trichloroethylene-induced oxidative stress in mouse liver [36]. Increases in the contents of peroxisome and TBARS and decreases in glutathione content of mouse liver by the trichloroethylene administration were suppressed by the pre-administration of curcumin. Iron-induced liver lipid peroxidation was 29% lower in turmeric-fed (1% in diet) Wistar rats [37]. The activities of antioxidant enzymes were higher in liver homogenates of rats fed the turmeric-containing diet in comparison with the controls, suggesting that dietary turmeric lowers lipid peroxidation by enhancing the activities of antioxidant enzymes. Wistar rats administered capsaicin (3 mg/kg) for three consecutive days showed a reduction in oxidative stress in the liver and other tissues suggesting that capsaicin can be a potent antioxidant [38].

In the present study, activities of glutathione reductase, glutathione transferase and catalase in the serum were significantly enhanced by dietary curcumin, capsaicin and curcumin + capsaicin in normal rats. Dietary curcumin, capsaicin and their combination produced beneficial increases in the activity of glutathione peroxidase in hypercholesterolemic rats. Glutathione transferase and catalase activities were higher as a result of curcumin

feeding in hypercholesterolemic animals. Dietary curcumin, capsaicin and their combination significantly enhanced the activity of glutathione reductase in the liver of normal rats. Dietary curcumin also enhanced hepatic glutathione reductase and glutathione transferase activities in hypercholesterolemic animals.

Activities of hepatic antioxidant enzymes—glutathione transferase, glutathione reductase and catalase were significantly depleted under hypercholesterolemia. Cholesterol feeding has been reported to decrease the level of TBARS, SOD and catalase [39]. The decrease in hepatic glutathione transferase activity in rats fed high cholesterol diet suggests a deficiency in defense against electrophilic compounds. Dietary spice principles were effective in reducing the oxidant stress, which was indicated by one or more of the following: (1) enhancing one or more of antioxidant molecules in the circulation, (2) enhancing one or more antioxidant molecules in the liver, (3) increasing the activities of antioxidant enzymes in blood, or (4) countering the depleted hepatic antioxidant enzymes—glutathione reductase, glutathione-*S*-transferase and catalase. Induction of glutathione transferase activity by curcumin has been reported in mice and rats [40, 41]. Similar to the observation in the current study, cholesterol feeding has been reported to decrease liver glutathione peroxidase in rats but controversial results exist in studies involving lipid peroxidation [42].

Dietary curcumin and capsaicin or their combination in the present study have demonstrated a significant stimulation of hepatic glutathione reductase activity in normal rats, while curcumin had a similar effect even in hypercholesterolemic animals. Earlier studies showed that curcumin causes an increase in glutathione transferase activity in rodent liver which may contribute to its anti-cancer and anti-inflammatory activities [43]. Glutathione peroxidase activity towards cumene hydroperoxide in liver homogenate was also found to be increased in a dose-dependent manner by curcumin. Induction of enzymes (glutathione transferase and glutathione peroxidase) involved in the detoxification of the electrophilic products of lipid peroxidation may contribute to the anti-inflammatory and anti-cancer activities of curcumin.

Thus, the present study has shown the absence of any additive effect of the combination of two hypocholesterolemic spice compounds—curcumin and capsaicin on blood cholesterol in experimentally induced hypercholesterolemic rats. The dietary spice compounds were effective in reducing the oxidant stress, which was indicated by countering of the changes in antioxidant molecules and activity of antioxidant enzymes in blood and liver. Although generally the beneficial effect of dietary curcumin and capsaicin was not additive when given in combination with respect to their hypolipidemic influence or antioxidant effect in hypercholesterolemic situation, the effect of the

combination of curcumin and capsaicin was certainly more pronounced than their individual effects in a few instances. We have also recently observed that the combination of dietary curcumin and capsaicin produced a higher protective effect on LDL oxidation and also lowered carrageenan-induced paw inflammation more effectively than their individual influences [7].

adaptations induced by hormonal changes and the production of inflammatory cytokines to fight the infection and/or facilitate tissue repair. The acute phase response is characterized by the hepatic synthesis of several acute phase proteins but also by profound alterations in plasma lipid and lipoprotein metabolism [1–3]. In man, plasma concentration of total cholesterol (TC), LDL-cholesterol and HDL-cholesterol decreases within the first 48 h following infectious or non-infectious insults with variable changes in plasma triglyceride (TG) levels [4, 5]. The extent of alterations in the concentration of plasma lipids notably depends on the type and severity of the insult [4]. The reduction of cholesterol-rich lipoproteins may result from reduced secretion, increased catabolism and from increased sequestration of lipoproteins in extra-vascular compartments. A negative correlation has been reported between TC as well as HDL-cholesterol levels and clinical outcome in critically ill and septic patients [4, 6, 7].

The composition of plasma lipoproteins has been mainly studied in conditions of sepsis with severe inflammation and substantial changes have been documented in LDL and HDL [8–11]. Alterations in lipoprotein lipid and apolipoprotein composition may enhance pro-inflammatory and pro-atherogenic properties of LDL and convert HDL from anti- into pro-inflammatory particles with reduced antioxidant functions [9, 12].

Major surgical injury also induces a severe acute phase response with postoperative decreases of plasma (as well as LDL and HDL) cholesterol concentration as reported after cardiac surgery [5, 7, 13, 14]. In contrast to sepsis, which is a very heterogeneous condition, cardiac surgery with cardiopulmonary bypass follows strict routine procedures and represents a fairly standardized insult. In addition to surgical trauma, contact of blood cells and plasma components with artificial membranes of the extracorporeal circuit, and ischemia–reperfusion are responsible for the severe systemic inflammation observed after cardiac surgery with cardiopulmonary bypass [15–17]. Since the composition of plasma lipoproteins has not been investigated in depth after surgery, we questioned whether the acute phase response induced by major cardiac surgery would affect plasma LDL and HDL composition differently as compared to previous observations in severely septic patients. Further, since such operations are associated to substantial oxidative stress and reduced plasma levels of vitamin E (alpha-tocopherol) [18], lipoprotein fractions were also used to determine whether decreased levels of vitamin E are due to a decreased number of lipoprotein carriers or to a reduced content of alpha-tocopherol. Improved knowledge on compositional changes occurring in plasma LDL and HDL after surgery may be important to better define strategies preventing pro-inflammatory changes.

## Materials and Methods

### Study Group Selection

The study group included 21 ASA 3 (American Society of Anesthesiologists class 3) patients undergoing elective cardiac surgery (coronary artery bypass or mitral valve replacement) with cardiopulmonary bypass. Clinical characteristics of the patients are shown in Table 1.

Major exclusion criteria were: patients on steroids or with body mass index  $>30 \text{ kg/m}^2$ , plasma creatinine concentration  $>1.5 \text{ mg/dl}$ , altered liver function tests, or diabetes mellitus. None of the patients received corticosteroids in the perioperative period. Patients were not on statin treatment before surgery, except for three of them in whose statins were not reinitiated during the immediate postoperative period of the study protocol. The patients were allowed nothing per os from the evening before the operation until day 1 post-surgery. The study was approved by the Ethical Committee of Erasme Hospital (Université Libre de Bruxelles, Brussels, Belgium) and all participating patients received complete information and signed a written consent form.

### Anesthesia and Cardiopulmonary Bypass

Anesthesia was induced and maintained with a target-controlled infusion of remifentanyl and propofol with cisatracurium. All patients received a full-dose of aprotinin ( $2 \times 10^6 \text{ KIU}$  at induction, followed by  $5 \times 10^5 \text{ KIU/h}$  until the end of surgery and  $1 \times 10^6 \text{ KIU}$  in the cardiopulmonary bypass). Cardiopulmonary bypass was performed under mild systemic hypothermia ( $>35^\circ\text{C}$ ). After cross-clamping of the ascending aorta, antegrade cold hyperkalemic cardioplegia was induced, followed by intermittent retrograde cold hyperkalemic cardioplegia whenever necessary. Mean aortic cross-clamp and cardiopulmonary bypass time as well as data on blood transfusion are shown in Table 1.

### Study Protocol

In order to ensure that measurements of lipoprotein composition are made during the acute phase response (and the resulting changes in plasma lipids), measurements of inflammatory proteins, of selected apolipoproteins, and of plasma lipid parameters were performed before surgery and on postoperative day 2 in the first six patients. Assessment of antioxidant status, of vitamin E and of PON was also performed in these patients. In addition, alpha-tocopherol content was analyzed in platelets, white blood

**Table 1** Patients clinical characteristics

Variable	Patients ( <i>n</i> = 21)
Mean age (range)	69 ± 3 (42–83)
Gender (M:F)	19:2

CPB (min)	108 ± 5
Aortic clamping (min)	83 ± 4
Patients requiring blood products	8
Number of patients transfused PRBC (mean units of PRBC transfused)	6 (3 ± 1)
Number of patients transfused FFP (mean units FFP transfused)	5 (4 ± 1)
Number of patients transfused platelets (mean units platelets transfused)	3 (2 ± 1)

CABG Coronary artery bypass graft, CPB cardiopulmonary bypass, PRBC packed red blood cells, FFP fresh frozen plasma

cells and red blood cells isolated from fresh blood samples [19]. In the 15 following patients, plasma lipoprotein fractions were isolated and analysed, before surgery and on postoperative day 2, for their content in lipid components, apolipoproteins, alpha-tocopherol as well as hydroperoxides. Preoperative concentrations of the different biological variables did not significantly differ from values recently measured in a control population from the same region of comparable age and gender with no known coronary heart disease [20, 21].

### Blood Sampling

Blood samples were drawn at the time of anesthesia induction (baseline) and again on day 2 post-surgery. Blood was collected in tubes with EDTA (1 mg/mL) for plasma separation and without EDTA for serum separation. Plasma and serum were immediately separated by low speed centrifugation at 3,500g (4 °C; 15 min) in a J2.21 centrifuge (Beckman Instruments, Fullerton, CA, USA).

### Separation of Lipoproteins

Plasma LDL and HDL fractions were isolated by sequential ultracentrifugation [22] in a L8–55 ultracentrifuge using a 50–4Ti rotor (Beckman, Palo Alto, CA, USA). Plasma density was adjusted by addition of solid KBr at density ranges 1.019–1.063 g/ml and 1.063–1.210 g/ml for separation of LDL and HDL, respectively. Plasma was centrifuged at 227,000g (5 °C) during 20 h for LDL and 40 h for HDL. LDL and HDL fractions were then either kept at 4°C for immediate lipid and protein measurements or at –70 °C for vitamin E analysis performed within

2 weeks. EDTA and salts present in the LDL and HDL fractions were removed by filtration on PD10 Sephadex columns (Amersham Pharmacia, Uppsala, Sweden) prior to hydroperoxide measurements by the FOX-2 method [23] or to evaluation of LDL resistance to *ex vivo* oxidation according to Esterbauer et al. [24].

### Analytical Measurements

TC and TG were measured in plasma, LDL and HDL fractions using enzymatic kits CHOD-PAP (Roche Diagnostics GmbH, Mannheim, Germany) and Triglycerides Glycerol blanked (Roche Diagnostics GmbH), respectively. Free Cholesterol (FC) and phospholipid concentrations were determined using enzymatic kits CHOD-PAP (Sopachem, Brussels, Belgium) and PAP 150 (Biomérieux, Lyon, France), respectively. Cholesteryl ester (CE) concentration was calculated by subtracting FC from TC.

Alpha-tocopherol was analysed in plasma and lipoprotein fractions by reverse-phase HPLC (Merck-Hitachi Ltd, Tokyo, Japan) using a Lichrospher column 100 RP 18 (5 µm; 125 × 4 mm, L × ID) with a mobile phase of methanol:water (95/5, w/w) at a flow rate of 1.5 ml/min; alpha-tocopherol was monitored by a UV detector at 292 nm [25]. In cells, alpha-tocopherol concentration was expressed relative to cell phospholipid content.

Plasma total antioxidant status (TAOS) was determined by the capacity to inhibit the peroxidase-mediated formation of the ATBS (2,2'-azinobis-3-ethylbenzothiazoline-6-sulfonic acid) radical [26]. In parallel, paraoxonase (PON) activity was determined spectrophotometrically at 270 nm by measuring the hydrolysis of phenyl acetate [27].

Total protein concentration was determined in plasma fractions using bovine serum/globulin solution as standard [28]. Apolipoproteins (apo) B and A1, as well as serum amyloid A (SAA) were measured in plasma and lipoprotein fractions by ELISA using rabbit polyclonal antibodies for apo A1, B or SAA, respectively [29].

CRP level was determined in plasma using high sensitive CRP immuno-turbidimetric method [30].

### Calculation of LDL and HDL Particle Size

Assuming a spherical configuration, LDL and HDL radii were determined by calculating both particle core volume and surface area. Calculations of core volume were based on the molar content of CE and TG per particle; values of 1.068 and 1.556 nm<sup>3</sup> were used for the molecular volume of CE and TG, respectively [31]. Total particle radius was obtained by adding surface monolayer thickness (2.02 nm) to core radius [32]. Calculations of surface area were based

on the molar content of phospholipids and FC per particle; values of 0.310 and 0.685 nm<sup>2</sup> were used for the molecular surface area of phospholipids and FC, respectively [31].

### Statistical Analysis

All results are expressed as mean values  $\pm$  SEM. Statistical significance of differences between pre- and postoperative values was assessed by the paired Student's *t*-test.

## Results

### Measurements of Selected Plasma Proteins, Apolipoproteins, Lipids and Antioxidants

Pre- and postoperative measurements of plasma parameters in the first six subjects are shown in Table 2 (statistical significance of tabulated results refers to the paired difference in pre- and postoperative absolute values, whilst in the text it often refers to the paired difference in percent changes relative to preoperative baseline values). Total protein concentration decreased by 15.7  $\pm$  3.4% on postoperative day 2 ( $P < 0.025$ ). In contrast, CRP concentration increased from 0.41  $\pm$  0.18 mg/dl (preoperative) to 13.90  $\pm$  3.90 mg/dl ( $P < 0.005$ ) and SAA concentration from 0.22  $\pm$  0.06 to 25.40  $\pm$  5.77 mg/dl ( $P < 0.005$ ) on postoperative day 2. Plasma concentration of apoB and apoA1 decreased by, respectively, 41.3  $\pm$  6.0% ( $P < 0.01$ ) and 31.2  $\pm$  1.1% ( $P < 0.0001$ ) post-surgery. This decrease of plasma apoB and apoA1 was

**Table 2** Plasma concentration of selected proteins, apolipoproteins, lipids and antioxidant measurements

TAOS (%)	19.0 $\pm$ 3.9	3.2 $\pm$ 2.8 <sup>a</sup>

CRP C-reactive protein, SAA serum amyloid A, apoB apolipoprotein B, apoA1 apolipoprotein A1, TC total cholesterol, TG triglycerides, PON paraoxonase, TAOS total antioxidant status

Values are expressed as mean  $\pm$  SEM. *P* values were calculated by paired Student *t* test. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ , <sup>c</sup> $P < 0.005$ , <sup>d</sup> $P < 0.001$ , <sup>e</sup> $P < 0.0001$  versus preoperative value

more marked than that of total plasma proteins. Indeed, apoB/total protein ratio decreased by 30.6  $\pm$  6.6% ( $P < 0.01$ ) on postoperative day 2 [from 14.5  $\pm$  2.8 to 9.8  $\pm$  1.7 mg/g ( $P < 0.05$ )]. Similarly, apoA1/total protein ratio decreased by 17.8  $\pm$  3.2% ( $P < 0.005$ ) post-surgery [from 28.0  $\pm$  2.7 to 22.9  $\pm$  2.2 mg/g ( $P < 0.05$ )].

Plasma concentration of TC and TG decreased by, respectively, 35.5  $\pm$  4.3% ( $P < 0.001$ ) and 23.7  $\pm$  9.5% ( $P < 0.06$ ) from initial values. Plasma alpha-tocopherol concentration decreased by 34.9  $\pm$  5.6% postoperatively ( $P < 0.005$ ). Of interest, alpha-tocopherol/TC ratio was not significantly modified after surgery ( $P > 0.25$ ). Postoperative alpha-tocopherol content in red blood cells and platelets (expressed in relation to phospholipid content) remained unchanged on postoperative day 2 ( $P > 0.4$ ). However, alpha-tocopherol content in white blood cells, (also expressed relative to phospholipid content), decreased by 20.5  $\pm$  6.1% ( $P < 0.03$ ) on postoperative day 2 (Table 3).

A dramatic fall in plasma TAOS was observed postoperatively, from 19.0  $\pm$  3.9 to 3.2  $\pm$  2.8% ( $P < 0.01$ ). Similarly, serum PON activity was decreased by 21.7  $\pm$  2.4% ( $P < 0.0001$ ) after surgery.

### Measurements of LDL and HDL Parameters

In 15 other subjects, plasma CRP concentrations increased from 0.41  $\pm$  0.14 mg/dl (preoperative) to a postoperative value of 12.04  $\pm$  1.95 mg/dl ( $P < 0.001$ ), these changes being comparable to those found in the first six patients ( $P > 0.6$ ). Results of pre- and postoperative measurements of LDL and HDL parameters are given in Tables 4 and 5.

### Apolipoproteins

LDL apoB concentration was decreased by 45.5  $\pm$  5.7% ( $P < 0.0001$ ) on postoperative day 2. This reflects a substantial reduction in the number of circulating LDL particles after cardiac surgery.

Likewise, HDL apoA1 concentration decreased by 21.8  $\pm$  6.5% ( $P < 0.005$ ) on postoperative day 2. This may

*apoB* Apolipoprotein B, *apoAI* apolipoprotein A1, *TC* total cholesterol, *FC* free cholesterol, *TG* triglycerides, *PL* phospholipids

correspond to a decrease in the number of HDL particles if an unchanged mean number of apoA1 molecules per HDL particle is assumed. The HDL apoSAA concentration increased markedly post-surgery, from 0.5 ± 0.2 to 39.2 ± 17.2 mg/dl (*P* < 0.05).

### Cholesterol

CE concentration in the LDL fraction decreased from 1.98 ± 0.11 to 1.09 ± 0.13 mmol/l (*P* < 0.0001), corresponding to a decrease of 45.9 ± 4.4% (*P* < 0.0001) from initial values. This fall in LDL-CE was comparable to the decrease in LDL-apoB. FC concentration in the LDL fraction decreased by 38.1 ± 4.5% (*P* < 0.0001) on postoperative day 2. The FC/CE and FC/apoB molar ratios in LDL increased by, respectively, 16.9 ± 4.4% (*P* < 0.002) and 21.6 ± 9.5% (*P* < 0.05) after cardiac surgery.

Comparable postoperative changes of CE and FC content were observed in the HDL fraction. HDL-CE decreased from 0.78 ± 0.08 to 0.60 ± 0.05 mmol/l (*P* < 0.005), i.e., by 18.9 ± 6.6% (*P* < 0.02) from preoperative values. In contrast, FC concentration in the HDL fraction remained unchanged after surgery (*P* > 0.8). Thus, the FC/CE ratio in the HDL fraction increased by 36.3 ± 8.3% (*P* < 0.001) post-surgery. HDL CE/apoA1

ratio was not significantly modified post-surgery (*P* > 0.31), while FC/apoA1 increased by 42.9 ± 7.1% compared to preoperative values (*P* < 0.0001).

### Triglycerides

In sharp contrast to cholesterol, TG concentration in the LDL fraction remained unchanged post-surgery (*P* > 0.6). Hence, the TG/CE ratio in LDL increased by 101.5 ± 18.9% (*P* < 0.0001) on postoperative day 2. Similarly, TG/apoB ratio in LDL increased by 112.9 ± 26.2% (*P* < 0.001) after surgery.

Likewise, TG concentration in the HDL fraction was not significantly modified after surgery (*P* > 0.5). TG/CE and TG/apoA1 ratios in the HDL fraction, however, increased by 31.3 ± 16.9% (*P* = 0.08) and 34.3 ± 15.2% (*P* < 0.05), respectively. Thus, TG content relative to either CE or apoA1 tended to be or increased in HDL but to a lesser extent than in LDL fraction.

### Phospholipids

Phospholipid concentration in the LDL fraction decreased by 37.6 ± 4.5% (*P* < 0.0001) on postoperative day 2. In contrast, phospholipid/apoB ratio in LDL increased by 22.5 ± 8.6% (*P* < 0.025) post-surgery.

Phospholipid concentration in the HDL fraction was not significantly modified after surgery (*P* > 0.9). Hence, phospholipid/apoA1 ratio increased by 30.2 ± 6.1% (*P* < 0.001) on postoperative day 2 compared to preoperative values.

In fair agreement with current knowledge [32], FC/phospholipid molar ratio was, before surgery, about four times higher in LDL (0.86 ± 0.02 mmol/mmol) than in HDL (0.23 ± 0.01 mmol/mmol). This ratio was unaffected by surgery in LDL but increased by 17.6 ± 7.4% (*P* < 0.05) in HDL.

### Calculation of LDL and HDL Particle Size

Before surgery, LDL particle radius calculated from the sum of core lipid molecule volumes averaged 9.98 ± 0.29 nm, in fair agreement with current knowledge [32] and also with LDL radius calculation from surface area molecules (including one apoB molecule), which averaged 9.60 ± 0.34 nm. After surgery, unchanged CE and increased TG content (+113%) per LDL particle imply an increase in the size of LDL particles. Consistently, FC/apoB and phospholipid/apoB ratios increased by 21.6 ± 9.5 and 22.5 ± 8.6%, respectively (*P* < 0.05) after surgery;

**Table 5** LDL and HDL ratios

Biological variables	Preoperative ( <i>n</i> = 15)	Postoperative ( <i>n</i> = 15)

Values are expressed as mean ± SEM. *P* values were calculated by the paired Student *t* test. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.025, <sup>c</sup>*P* < 0.01, <sup>d</sup>*P* < 0.001, <sup>e</sup>*P* < 0.0001 versus preoperative value  
*CE* Cholesteryl ester, *FC* free cholesterol, *TG* triglycerides, *PL* phospholipids, *apoB* apolipoprotein B, *apoA1* apolipoprotein A1

comparable changes were found for LDL-FC/CE (+16.9 ± 4.4%) and LDL phospholipid/CE ratios (+18.0 ± 3.9%) after surgery. These ratios suggest a postoperative increase of surface area and of particle radius by 14 ± 5% (*P* < 0.03) and 6 ± 2% (*P* < 0.03), respectively.

Before surgery, the HDL core volume corresponded to a core radius of 2.56 ± 0.09 nm and a total particle radius of 4.58 ± 0.09 nm, in fair agreement with current knowledge [32, 33]. Calculations from the sum of surface components (assuming a mean of 3 apoA1 molecules per HDL particle) correspond to a core radius of 3.02 ± 0.05 nm, in fair agreement with the HDL calculated core radius from core volume. The unchanged CE content and increased TG content in postoperative HDL particles imply an increase in core lipid molecules and volume. Accordingly, both FC/apoA1 and phospholipid/apoA1 ratios increased in HDL post-surgery, with a mean increase of, respectively, 42.9 ± 7.1% (*P* < 0.001) and 30.2 ± 6.1% (*P* < 0.001). Comparable percentages were obtained for HDL-FC/CE (36.3 ± 8.3%) and HDL-phospholipid/CE ratios (23.6 ± 6.7%). This suggests an increase of HDL area by 31 ± 6% (*P* < 0.001) and of HDL radius by 14 ± 3% (*P* < 0.001) after cardiac surgery. Note that calculations of

HDL size are underestimates since the molecular volume of apoSAA is not taken into account.

#### Hydroperoxides

The hydroperoxide concentration in the LDL fraction was not significantly modified after surgery (*P* > 0.3). However, hydroperoxide/apoB and hydroperoxide/TC ratios increased by, respectively, 189.1 ± 83.0 and 191.3 ± 89.2% on postoperative day 2 (*P* < 0.05).

Similarly, the hydroperoxide concentration in the HDL fraction was not significantly modified (*P* > 0.5) post-surgery but, when expressed relative to TC content, the hydroperoxide/TC ratio in HDL increased by 62.4 ± 29.3% (*P* < 0.03) after surgery.

#### Alpha-tocopherol

In the LDL fraction, alpha-tocopherol concentration decreased by 41.0 ± 3.9% (*P* < 0.0001) on postoperative day 2. However, alpha-tocopherol content relative to apoB

or TC content in the LDL fraction was not decreased by surgery. Similarly, the alpha-tocopherol/FC+phospholipid ratio was not modified after surgery.

In the HDL fraction, alpha-tocopherol concentration had decreased by  $21.6 \pm 4.4\%$  ( $P < 0.001$ ) on postoperative day 2. Alpha-tocopherol content relative to apoA1 or TC content was not or little affected after surgery. In contrast, the alpha-tocopherol/FC+phospholipid ratio had decreased by  $20.5 \pm 2.9\%$  ( $P < 0.001$ ) after surgery.

Notice that alpha-tocopherol/TC ratio was two times higher ( $P < 0.001$ ) in HDL versus LDL in pre- and post-operative conditions.

### LDL Peroxidation

LDL resistance towards oxidative stress, reflected by the lag phase preceding the generation of conjugated dienes from LDL exposed to  $\text{CuSO}_4$ , did not significantly decrease after surgery ( $73 \pm 3$  vs.  $71 \pm 3$  min; NS). The propagation slope decreased slightly after surgery (by  $10.4 \pm 4.0\%$ ;  $P < 0.025$ ). This coincided with a trend towards a lower maximal value for the generation of conjugated dienes, with a postoperative/preoperative ratio for dienes averaging  $91.8 \pm 4.5\%$  ( $P < 0.09$ ).

### Discussion

The present study was aimed at characterizing changes in plasma lipoprotein composition induced by cardiac surgery with cardiopulmonary bypass, notably in comparison to alterations reported in sepsis. Indeed, most current data on LDL and HDL alterations occurring in acute phase reactions comes from observations in patients with severe septic conditions [8, 9].

Analyses of plasma lipid parameters are in agreement with prior observations on the effect of surgical stress, i.e., decreased levels of TC, TG and alpha-tocopherol [5, 14, 34, 35]. An important decrease of apoB and apoA1 level was also observed in the present study that largely exceeded the reduction of total plasma protein concentration. The marked increase of SAA levels paralleled and even exceeded that of CRP. Reduced TAOS indicates decreased antioxidant defenses and/or consumption of antioxidant scavengers in response to oxidative stress as previously described after cardiac surgery with cardiopulmonary bypass [36]. Furthermore, the activity of the antioxidant enzyme PON, largely associated to HDL particles, was decreased post-surgery; this may substantially reduce protection against LDL oxidation [12]. Such alterations in antioxidant parameters have also been described in sepsis [37–39]. In this study, alpha-tocopherol content in blood

cells was analysed to evaluate whether the decreased antioxidant defenses and more specifically whether the marked reduction in circulating alpha-tocopherol level are associated to impaired alpha-tocopherol delivery to cells. Indeed, apart from one study reporting unchanged alpha-tocopherol content in erythrocytes after surgery [40], no data is currently available on alpha-tocopherol content in blood cells of surgical or septic patients. Since blood cell counts are modified after surgery, alpha-tocopherol content was expressed relative to cell phospholipid concentration, which to our knowledge, is not affected by the operative procedure. Alpha-tocopherol content was unchanged in erythrocytes and platelets on postoperative 2, but was decreased in leukocytes. This may reflect increased consumption by white blood cells or an impaired alpha-tocopherol uptake, or both; after surgery, another possibility is that, leukocytes released in great number in the circulation after surgery have a lower alpha-tocopherol content.

Analyses of lipoprotein fractions in 15 subjects characterize the effect of cardiac surgery on changes in the number, composition, and size of circulating particles.

LDL-cholesterol markedly decreased ( $-45\%$ ) after surgery. Such a decrease in LDL cholesterol is commonly observed after surgery [5, 14, 34] and in other types of acute phase reactions, including sepsis [11, 41, 42] and acute myocardial infarct [43]. In the later condition, however, cholesterol production and secretion appear not to be reduced but are rather augmented [44]. If this was also the case in the surgical acute phase, the lower LDL-cholesterol level would largely result from increased particle disposal (endocytosis via LDL B, E and scavenger receptors, and possible margination of LDL particles outside the plasma compartment).

ApoB concentration in the LDL fraction also substantially decreased ( $-46\%$ ) after cardiac surgery. Since LDL particles contain one single apoB molecule, this change reflects a proportional reduction of the number of circulating LDL particles. Lipid content per LDL particle was reflected by the concentration of each component relative to LDL-apoB (Fig. 1). CE content per LDL particle remained unchanged after cardiac surgery, while TG content was increased ( $+113\%$ ) together with surface components FC ( $+22\%$ ) and phospholipids ( $+23\%$ ). Such increase of both core and surface lipid components strongly suggests an increased LDL particle size postoperatively. This is in sharp contrast with changes observed during sepsis where the decrease in LDL number is associated with the appearance of small sized and denser LDL particles, in which an increased TG content is largely compensated for by a reduced CE content [45, 46]. Such small dense LDL particles are more sensitive to peroxidative damage, are more cytotoxic, and have an increased

**Fig. 1** Postoperative changes in LDL (A) and HDL (B) composition. LDL and HDL lipid components are expressed relative to LDL-apoB and HDL-apoA1, respectively. The figure shows an unchanged cholesteryl ester (CE) content in LDL and HDL particles, an increased triglyceride (TG) content (particularly in LDL) together with an increase in surface components [free cholesterol (FC) and

phospholipids (PL)]; in spite of unchanged alpha-tocopherol content, LDL and HDL showed increased hydroperoxide content. Values are expressed as mean  $\pm$  SEM. *P* values were calculated by paired Student *t* test. <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01, <sup>c</sup>*P* < 0.005, <sup>d</sup>*P* < 0.001, <sup>e</sup>*P* < 0.0001 versus preoperative value

atherogenic potential [47]. Of interest, alpha-tocopherol content per LDL particle remained unchanged after surgery and no difference of susceptibility to peroxidation was observed between pre- and postoperative circulating LDL particles when subjected *ex vivo* to copper oxidative stress. Still, as reported in sepsis [47], an increased hydroperoxide content was measured in circulating LDL particles after cardiac surgery, suggesting that the (unchanged) alpha-tocopherol content in postoperative LDL particles could not completely prevent the oxidative stress associated to cardiac surgery with cardiopulmonary bypass. From current data it is difficult to speculate whether these changes in LDL composition and size can modulate properties of LDL and influence (in one or another direction) the inflammatory response.

In contrast to LDL particles, which are characterized by the presence of one single apoB molecule, HDL particles contain 2 to 4 apoA1 molecules in physiological conditions [33]. In addition, HDL apolipoprotein composition is substantially modified during the acute phase reaction, notably by a massive increase of SAA [48, 49]. While high SAA concentrations had previously been suggested to displace apoA1 from HDL particles, apoA1 decrease during acute phase response seems to result mainly from an increased catabolic rate, which parallels that of HDL particles [50]. If one assumes that the mean number of apoA1 molecules in HDL is not appreciably modified by cardiac surgery, the number of circulating HDL particles would decrease by 20% on postoperative day 2. Such a decrease in HDL particles is lower than that observed for LDL and it is not as marked as in patients with sepsis [42, 51]. Of interest,

HDL-CE decreased by  $18.9 \pm 6.6\%$  (*P* < 0.02) postoperatively so that HDL-CE/apoA1 ratio remained virtually unchanged (Fig. 1). As indicated by the increased HDL-TG/apoA1 (+34%) and HDL-TG/CE (+31%) ratios, TG content in HDL particles increased after surgery, but to a lesser extent than in LDL particles. Such an increase in LDL- and HDL-TG content on postoperative day 2 contrasts with a lower plasma TG concentration. Lower plasma TG concentrations do not usually induce cholesteryl ester transfer protein-mediated exchanges of core lipids between TG-rich and CE-rich lipoproteins [52, 53]. Hence, TG enrichment in LDL and HDL may result from reduced hepatic lipase activity as reported in conditions of sepsis and inflammation [41]. The increase of core lipid molecules in postoperative HDL is associated to an increase of surface components, as indicated by increased FC/apoA1 and phospholipid/apoA1 ratios (Fig. 1). All together these changes and the presence of SAA molecules in HDL surface indicate an increased particle size after cardiac surgery. Changes in the balance between HDL surface lipid components were also observed after surgery with a higher FC relative to phospholipid content. This is in agreement with observations in septic patients where reduced lecithin:cholesterol acyltransferase activity is associated with an increased FC content in HDL particles [54, 55]. Finally, the alpha-tocopherol level decreased in the HDL fraction after cardiac surgery in close relation to the reduced number of circulating HDL particles. The hydroperoxide content in HDL increased after surgery but to a lesser extent than in LDL particles. The global reduction of alpha-tocopherol transport by LDL and

HDL may affect alpha-tocopherol delivery to cells and organs in a condition (ischemia–reperfusion) characterized by oxidative stress.

There are some limitations that need to be addressed regarding this study. First, it does not allow one to distinguish between the impact of surgical trauma, that of cardiopulmonary bypass and that of anesthesia on the inflammatory response and more particularly on the changes in plasma lipoproteins and oxidative stress. Second, measurements reflect changes in circulating LDL and HDL particles, but more profound alterations may occur in those lipoproteins that marginate outside the plasma compartment. Third, measurements were performed at two time points, i.e., before (=baseline) and at 48 h after surgery, the latter corresponding to the peak of the inflammatory response but not to the peak of systemic oxidative stress, which takes place during surgery (after reperfusion) and in the immediate postoperative period [56]. Finally, since the measured postoperative alterations of lipoprotein composition probably last over a limited period of time, their impact on the functional properties of circulating plasma lipoproteins remains to be determined.

In summary, the present study indicates that the acute phase response that occurs after major cardiac surgery induces profound alterations not only in the concentration but also in the composition of circulating LDL and HDL particles. Several of these surgery-induced alterations in the lipid composition of LDL and HDL particles differ from changes previously observed in sepsis. Thus acute phase reactions caused by different conditions may affect the properties of plasma lipoproteins differently and should be considered specifically. Although the increase in LDL and HDL particle size probably limits the pro-inflammatory risk, additional experiments are required to fully determine the impact of postoperative modifications on the roles and function of circulating lipoproteins. Reduced levels of circulating lipoproteins post-surgery may also affect the delivery to cells and tissues of substrates such as alpha-tocopherol.

[13]. The diet of the wild raccoon dog contains a large variety of FA and the FA composition of its WAT depots is homogeneous without significant vertical gradients [14]. As the raccoon dog is an omnivore [15], the obtained results can have biomedical value. Previously, the *in vivo* FA mobilization from regional WAT depots of captive raccoon dogs was shown to be selective [10]. Fasting stimulated the mobilization of shorter-chain saturated (SFA), monounsaturated (MUFA) and polyunsaturated FA (PUFA). There were also site-specific differences in fractional mobilization and the omental adipose tissue was the most divergent. The selectivity of FA accumulation remains uninvestigated in the species.

The FA composition of WAT, i.e., the FA signature, can be used to monitor the long-term dietary habits of humans and foraging ecology of predators. In humans, an important aspect is to estimate the supply and reserves of essential PUFA and the balance between n-3 and n-6 PUFA [16]. In ecophysiological studies, FA accumulated in the fat depots reflect the diet of predators [17]. It is important to understand the selective changes in the FA composition of WAT and plasma caused by seasonal weight regulation of wild mammals or by weight cycling of humans to interpret the obtained FA profiles correctly.

Selective mobilization of FA from WAT during energy depletion and selective incorporation of FA into WAT during energy storage have been scarcely examined in wild mammals. It can be hypothesized that the selectivity of FA release observed in captivity [4, 10] would be present also in wild animals. Using repeated sampling of free-ranging raccoon dogs the present study investigated (1) the effects of wintertime nutritional scarcity and summertime abundance on the WAT and plasma FA signatures and the selectivity of seasonal FA mobilization and incorporation, (2) the basis of this selectivity at the molecular level and (3) whether the molecular background of FA release and incorporation observed in laboratory animals and humans can be demonstrated in wild mammals living in their natural habitat. The present study significantly adds to our knowledge of lipid metabolism in the raccoon dog because it reflects the real world situation of seasonal FA metabolism in the wild.

## Experimental Procedures

The study area was located in Eastern Finland (62°33.094'N; 29°9.409'E). It has a boreal, continental climate with an average annual ambient temperature of +2.0°C and precipitation of 600 mm. The summers are relatively warm (mean and max in July +15.8 and +32.0°C) but the winters cold (mean and min in January -11.9 and -42.2°C). The permanent snow cover usually lasts from

mid-late November to late April with an average max snow depth of 63 cm. Potential food items for the raccoon dog include small mammals, frogs, insects, carcasses, fish, plant material, birds and eggs [18].

Seven wild raccoon dogs (four males and three females) were captured in autumn 2004 and fasted overnight before sampling. They were anaesthetized with intramuscular (im) ketamine (5 mg kg<sup>-1</sup>) and xylazine (2 mg kg<sup>-1</sup>). A blood sample was taken from a superficial vein of the hind leg with sterile needles and syringes with EDTA as an anti-coagulant. The complete blood count was determined with the Vet abc Animal Blood Counter (ABX Hematologie, Montpellier, France) calibrated to the canine hematologic profile. Plasma was removed after centrifugation of whole blood at 1,500g and stored at -80 °C. A 3-cm incision was cut caudal from the umbilicus and 1–2 g of ventral subcutaneous (sc) fat was removed. The WAT samples were immediately frozen in liquid nitrogen and stored at -80 °C. The skin was sutured with 3-0 resorbable madras knots. A single dose of im benzylpenicillin-procaine was used for antibiotic prophylaxis.

The animals were fitted with radio transmitter collars (Biotrack Ltd, Wareham, UK) to enable recapture. Body mass (BM) and body length were determined and body mass indices (BMI) correlating with the fat % calculated using the formula: BM (kg)/[body length<sup>3</sup> (m)] [19]. The animals were released at the capture sites, located with a portable radio receiver (AR8000, AOR Ltd, Tokyo, Japan) and a hand-held antenna in spring 2005, recaptured, sedated and sampled. Two raccoon dogs were shot by hunters and one lost its radio tag. Also two new females were captured, sampled and released. Four of these animals were recaptured in autumn 2005, two were shot by hunters. Also three new individuals (two males and one female) entered the study. Two of these animals were recaptured in spring 2006. One was killed by a dog, one was killed by a car, one died of scabies and one could not be located. The captured animals were sedated and sampled and the radio tags were removed. The sex, age, radio-tracking periods and sampling procedure of each individual are presented in Fig. 1. The Animal Care and Use Committee of the University of Joensuu approved all the procedures of the study.

For the FA analysis, subsamples of WAT and plasma were transmethylated [20] by heating with 1% (v/v) H<sub>2</sub>SO<sub>4</sub> in methanol under nitrogen atmosphere. The formed FA methyl esters (FAME) were extracted with hexane in two steps. The dried and concentrated FAME were analyzed with a gas-liquid chromatograph equipped with two injectors and flame ionization and mass detectors (GC-FID and GC-MS, 6890N network GC system with autosampler, FID detector and 5973 mass selective detector, Agilent Technologies Inc., Palo Alto, CA, USA) as described previously [10, 21]. The peak areas of the FID chromatograms were

**Fig. 1** The sex, age, sampling and periods of radio-tracking of the observed raccoon dogs between autumn 2004–spring 2006. *M* male, *F* female, *j* juvenile at first capture, *a* adult at first capture, *dagger* animal died from a natural cause or by human action, *asterisk* animal was lost, *1* white adipose tissue sampling, *2* blood sampling. *Dotted lines* indicate lost animals or dysfunctional radio collars

converted to mol% by using the theoretical response factors [22] and calibrations with quantitative authentic standards. The FA were marked by using the abbreviations: [carbon number]:[number of double bonds] n-[position of the first double bond calculated from the methyl end]. The double bond index (DBI) and the total average chain length (TACL) indicating the mean numbers of double bonds or carbon atoms per molecule were calculated according to standard formulae [23]. The  $\Delta 9$ -desaturation index ( $\Delta 9$ -DI), the ratio of the most important potentially endogenous  $\Delta 9$ -MUFA to the corresponding SFA, was calculated as  $[(\text{mol}\% \text{ 14:1n-5}) + (\text{mol}\% \text{ 16:1n-7}) + (\text{mol}\% \text{ 16:1n-9}) + (\text{mol}\% \text{ 18:1n-9}) + (\text{mol}\% \text{ 18:1n-7})] / [(\text{mol}\% \text{ 14:0}) + (\text{mol}\% \text{ 16:0}) + (\text{mol}\% \text{ 18:0})]$  [14]. Very-long-chain FA (VLCFA) were calculated as the sum of FA with a chain length of 24.

Relative changes in the proportions of FA in WAT during winter were calculated by the formula  $[\text{mol}\% \text{ in spring} - \text{mol}\% \text{ in autumn}] / [\text{mol}\% \text{ in autumn}] \times 100$  and during summer by the formula  $[\text{mol}\% \text{ in autumn} - \text{mol}\% \text{ in spring}] / [\text{mol}\% \text{ in spring}] \times 100$ . Relative changes were calculated only for the individuals that could be recaptured during two consecutive seasons (autumn–spring  $n = 7$ ; spring–autumn  $n = 6$ ), while the seasonal FA profiles of WAT and plasma consisted of all sampled individuals (WAT autumn  $n = 16$ , WAT spring  $n = 9$ , plasma autumn  $n = 14$ , plasma spring  $n = 8$ ). The numbers of WAT and plasma samples were dissimilar within a season, as some animals were killed and in some of these cases a WAT sample of good quality could still be obtained from a fresh carcass, while the blood had already clotted. The WAT FA

profile of one individual differed from the other raccoon dogs as this animal fed on freshwater fish discarded by fishermen on ice in winter 2005–2006 instead of fasting like the rest of the animals. For this reason, its vernal FA percentages were not included in the statistical analyses or in the means. The plasma total cholesterol (Chol), low-density lipoprotein (LDL) and high-density lipoprotein (HDL) Chol, triacylglycerols (TAG), glucose, creatinine, alanine aminotransferase (ALT), aspartate aminotransferase (AST), total protein, urea, ammonia, uric acid, bilirubin and creatine kinase were determined as described previously [10].

Differences in the BM and BMI in the time series were determined with the repeated measures analysis of variance using the SPSS program (SPSS Inc., Chicago, IL, USA). Comparisons between the two seasons were performed with the Student's *t*-test or the Mann–Whitney *U*-test for parametric and nonparametric data, respectively. Bivariate correlations were calculated with the Spearman correlation coefficient ( $r_s$ ). A *P* value less than 0.05 was considered statistically significant. The results are presented as mean  $\pm$  SE. To analyze the relationships in the FA composition of WAT and plasma during the two seasons, the data were also subjected to the multivariate principal component analysis (PCA) using the SIRIUS 6.5 software package (Pattern Recognition Systems AS, Bergen, Norway [24]). The data were standardized and the relative positions of the samples and variables were plotted using two new coordinates, the principal components PC1 and PC2, describing the largest and the second largest variance among the samples.

## Results

The raccoon dogs lost 3.4 kg (42%) of BM in winter and gained 5.1 kg (125%) in summer (Table 1). The seasonal changes in BMI for winter and summer were  $-35$  and  $+88\%$ , respectively. The hemoglobin, hematocrit, monocyte %, eosinophil %, plasma TAG, HDL-Chol, urea and ammonia concentrations and urea:creatinine ratios were higher in autumn than in spring. The percentages of 14:0, 16:0, total SFA, 16:1n-7, 18:3n-3 and total n-3 PUFA decreased in WAT in winter, while the proportions of 18:1n-9, 20:1n-11, 20:1n-9, total MUFA, 22:4n-6 and 22:5n-3 increased (Tables 2, 3, 4). In plasma, the proportions of *i*18:0, 18:2n-4 and 20:5n-3 decreased, while those of *i*15:0, 20:0, 20:1n-9, 24:1n-9 and 22:5n-6 increased. Opposite changes were observed in the FA profiles from spring to autumn. According to PCA, 16–18C SFA and MUFA were mostly responsible for the seasonal differences in the WAT FA composition. The differences between the autumnal and vernal plasma FA profiles were

minor and the FA that separated the seasons were 16–18C SFA, 18:1n-9 and n-6 PUFA.

The FA with the highest relative mobilization from WAT in winter included 20:5n-3, 18:3n-3, 16:1n-7, 15:1n-6, 14:1n-5, 20:4n-3 and 18:4n-3 (–47 to –80%), while preservation was the highest for 22:1n-11, 20:0, 22:4n-6, 20:1n-9, 22:1n-9, 22:1n-7, 22:0 and 20:1n-11 (201–607%; Fig. 2). In summer, 20:5n-3, 18:4n-3, 20:4n-3, 18:3n-3, 16:1n-7, 14:1n-5 and 22:6n-3 increased (139–734%) and 20:0, 22:4n-6, 22:0, 20:1n-11, 19:0, 20:1n-9 and 20:1n-7 decreased the most in proportion (–47 to –72%) in WAT. One female raccoon dog did not fast, unlike the rest of the animals in winter. In this individual, 20:5n-3, 20:4n-3, 18:4n-3, 16:1n-5, 18:3n-6 and 20:4n-6 increased in proportion in winter, while they were mobilized in the other animals. Moreover, this individual preserved more 22:5n-6, 20:1n-5, 22:1n-7, 20:1n-7, 20:1n-11, 17:1n-br, 22:5n-3 and 20:3n-6 than the other raccoon dogs.

Wintertime preservation of FA in WAT correlated positively with the FA chain length of SFA ( $r_s = 0.766$ ,  $P < 0.001$ ; Fig. 3) and n-5, n-7 and n-9 MUFA ( $r_s = 0.640$ – $0.824$ ,  $P < 0.001$ ; subset of data in Fig. 4). The influence of chain length on the preservation of PUFA was investigated by comparing PUFA with the same degree of unsaturation and position of the first double bond from the methyl end but with different chain lengths. In five out of eight pairs the PUFA with the longer chain length was more preserved during wintering (subset of data in Fig. 5). When SFA and the corresponding MUFA were compared, mobilization was higher in MUFA in five out of six cases (subset of data in Fig. 6). The influence of unsaturation on the mobilization of PUFA was investigated by comparing PUFA with the same chain length and position of the first double bond but with different double bond numbers. The difference was significant in six out of nine pairs in the way that the PUFA with the higher number of double bonds had a higher mobilization rate in five cases and a lower mobilization rate in one case (subset of data in Fig. 7). The influence of positional isomerism on the preservation of MUFA was investigated by comparing MUFA of the same chain length but of a different position of the double bond. The preservation of 14, 15, 16, 18 and 20C MUFA correlated positively with the position of the double bond ( $r_s = 0.525$ – $0.869$ ,  $P < 0.05$ ; subset of data in Fig. 8). When comparing PUFA with the same chain length and unsaturation but with a different position of the first double bond, the difference was significant in six out of eight pairs in the way that the PUFA with the first double bond closer to the methyl end had a lower (one case) or a higher mobilization rate (five cases; subset of data in Fig. 9).

less accumulated in summer (subset of data in Fig. 5). When SFA and the corresponding MUFA were compared, incorporation was higher in MUFA in four out of six cases (subset of data in Fig. 6). In seven out of nine PUFA pairs the PUFA with the higher number of double bonds had higher (six cases) or lower accumulation (one case; subset of data in Fig. 7). The incorporation of 15–16C MUFA correlated negatively with the position of the double bond from the methyl end ( $r_s = -0.564$  to  $-0.869$ ,  $P < 0.05$ ; Fig. 8). When comparing PUFA pairs the difference was significant in five out of eight cases in the way that the PUFA with the first double bond closer to the methyl end

had higher (four cases) or lower accumulation (one case; subset of data in Fig. 9).

## Discussion

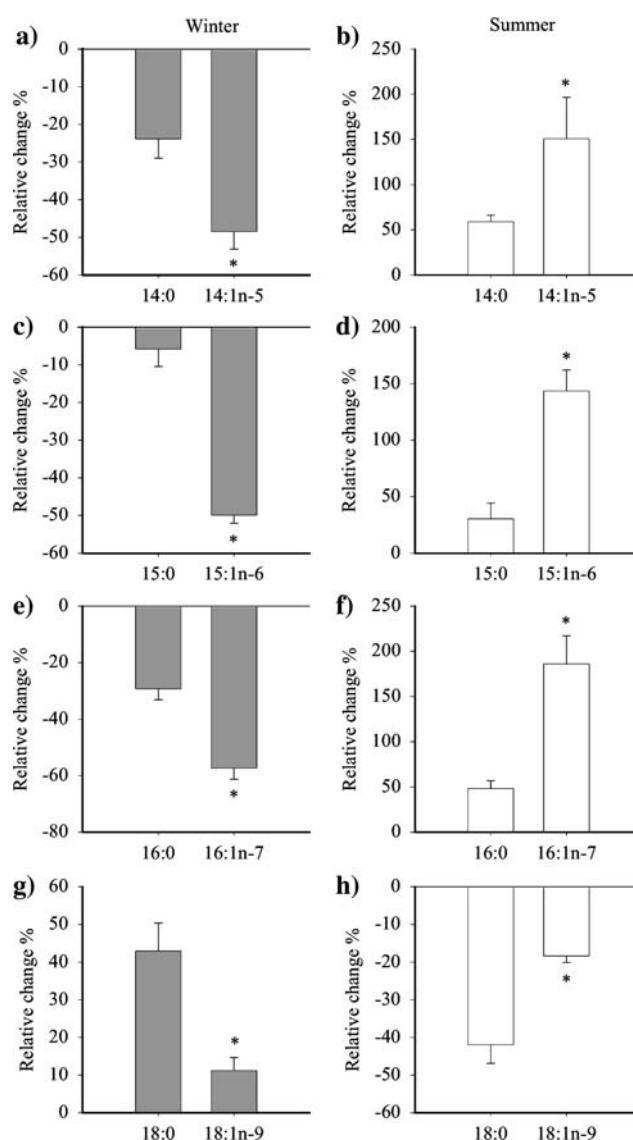

### Selective Mobilization of FA from the sc Adipose Tissue

Selective mobilization of FA from WAT was previously investigated, e.g., in humans fasted for 14–20 h [8] and in laboratory rodents fasted for 1–10 days [4]. Little data exist

**Fig. 5** The effect of chain length ( $C$ ) on the relative seasonal change (%) in the proportions of representative white adipose tissue polyunsaturated fatty acids ( $FA$ ) of the wild raccoon dogs during winter (**a, c, e, g**) and summer (**b, d, f, h**; mean  $\pm$  SE). + values indicate that a  $FA$  increased in proportion during winter or summer and – values signify a decrease in proportion. from wild animals with a long fast as a natural part of their seasonal weight cycling. The  $FA$  mobilization from the sc adipose tissue of the spontaneously fasting emperor penguin (*Aptenodytes forsteri*) was studied in this respect yielding results with high similarity to captive mammals [25]. The present study explored the selective  $FA$  mobilization in the wild raccoon dog. The sc adipose tissue samples were obtained from the same individuals before and after wintering and the results could be compared to previous data from the same species in captivity [10]. Although the average BM of the animals decreased by 42%, the fat stores

**Fig. 6** The effect of  $\Delta 9$ -desaturation on the relative seasonal change (%) in the proportions of representative white adipose tissue fatty acids ( $FA$ ) of the wild raccoon dogs during winter (**a, c, e, g**) and summer (**b, d, f, h**; mean  $\pm$  SE). + values indicate that a  $FA$  increased in proportion during winter or summer and – values signify a decrease in proportion. were large enough to provide metabolic energy during wintering without the need to stimulate proteolysis [13]. The negative energy balance did not cause deleterious health effects, such as liver or kidney dysfunction, in the animals.

The mobilization of  $FA$  decreases with the chain length for a given degree of unsaturation in laboratory rodents [4]. Similar to captive raccoon dogs [10], the wild raccoon dogs had an inverse correlation between the  $FA$  chain length and the mobilization of SFA, n-5, n-7 and n-9 MUFA and particular n-3 and n-6 PUFA. The observed low mobilization

**Fig. 7** The effect of double bond number on the relative seasonal change (%) in the proportions of representative white adipose tissue polyunsaturated fatty acids (FA) of the wild raccoon dogs during winter (a, c, e) and summer (b, d, f; mean + SE). + values indicate that a FA increased in proportion during winter or summer and – values signify a decrease in proportion. rate of 20–24C SFA and MUFA was previously documented in fasting rats [4] and emperor penguins [25]. 12–16C SFA and 14–16C MUFA were among the most mobilized FA in the farmed [10] and wild raccoon dogs, while 15:1n-8 and 16:1n-9 were less utilized. It is possible that the raccoon dogs had to prevent the solidification of the sc fat layer by chain-shortening of 18:1n-9 and 17:1n-8 leading to increased proportions of 16:1n-9 and 15:1n-8. In laboratory rats, rabbits and humans the mobilization of FA increases with unsaturation for a given chain length [4, 7, 8]. In the wild raccoon dogs, too, FA mobilization increased with  $\Delta 9$ -desaturation and with double bond number in n-3 and n-6 PUFA. The effect of unsaturation on mobilization efficiency was more prominent in the wild raccoon dogs than in captive animals [10].

It has been suggested that TAG are distributed in the lipid droplet according to their polarity. As the shorter and more

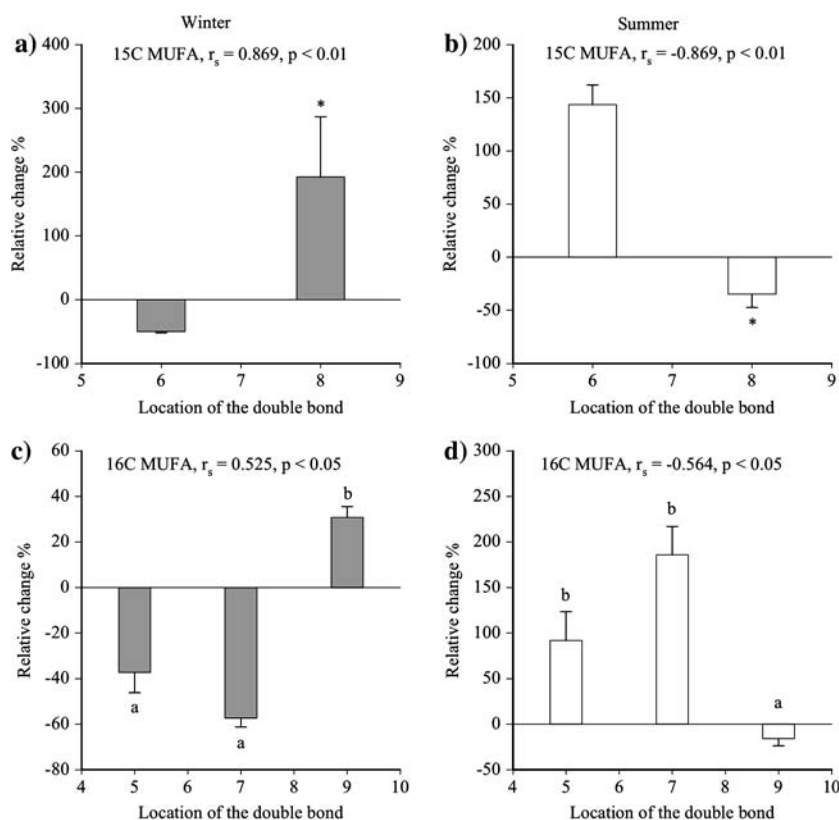

unsaturated FA are more polar, TAG containing them are located at the periphery of the lipid droplet. Thus they are more accessible to hydrolysis by hormone-sensitive lipase (HSL) at the lipid–water interface resulting in the preservation of the longer-chain FA [9, 26]. The preference of HSL to hydrolyze shorter-chain [27] and unsaturated FA (UFA) [28] could partly explain their depletion from WAT during wintering. Moreover, the reuptake of the more polar FA to WAT is weaker than that of the less polar FA during lipolysis [29], short SFA can be more readily oxidized than longer SFA [30] and peroxisomal  $\beta$ -oxidation increases with unsaturation [31]. On the other hand, the positional distribution of FA in TAG cannot explain the preferential mobilization of the more polar FA [32]. In the wild raccoon dogs, the highly unsaturated 22:4n-6, 22:5n-3, 22:5n-6 and 22:6n-3 were less mobilized than most other PUFA possibly as a result of their long carbon chains, resistance to HSL [33], their significance in membrane phospholipids and, in the case of 22:4n-6, in the synthesis of 4-series prostaglandins [2].

In laboratory rats, the mobilization of UFA increases when the double bonds are located closer to the methyl end of the FA chain [4]. The same was observed for most MUFA and for several n-3 and n-6 PUFA pairs in the wild raccoon dogs, while the effect was less pronounced in captive animals [10]. It has been demonstrated in several species that fasting decreases the proportions of particular n-3 PUFA in adipose tissue [4, 10, 21, 34]. In addition to the wild raccoon dog, the proportion of 18:3n-3 in the reindeer (*Rangifer tarandus tarandus*) adipose tissue also decreases during nutritional scarcity in winter [35]. This is in accordance with the principle of competitive inhibition, which states that in the rate-limiting steps of PUFA desaturation n-3 substrates are favored over n-6 ones [2]. In the scarcity of dietary n-3 PUFA the shorter-chain n-3 PUFA could be metabolized to produce the biologically most important member of the n-3 family, 22:6n-3, the WAT and plasma percentages of which were preserved during wintering.

In the rat, n-3 PUFA are mobilized in vitro in the following order: 20:5n-3 > 18:4n-3 > 22:6n-3 > 22:5n-3 [36], similar to the wild raccoon dog. 20:5n-3 is preferred over 22:5n-3 and 22:6n-3 by HSL [33] and it functions as the precursor for 3-series prostaglandins [2], which may be associated with its depletion during fasting. During lipolysis, the selective reuptake to WAT is weak for PUFA with 16–20C and 4–5 double bonds [37], i.e., the highly mobilized FA 20:5n-3, 20:4n-3 and 18:4n-3 in the present study. Moreover, the dietarily essential 18:3n-3 is a preferred substrate for  $\beta$ -oxidation and a precursor of longer-chain, more unsaturated n-3 PUFA [38]. The preferential mobilization of n-3 PUFA causes a decrease in the n-3/n-6 PUFA ratio, which affects the quality of eicosanoids produced. When 1-, 2- and 4-series prostaglandins (derived

**Fig. 8** The effect of the location of the double bond from the methyl end on the relative seasonal change (%) in the proportions of white adipose tissue 15–16C monounsaturated fatty acids (FA) of the wild raccoon dogs during winter (a, c) and summer (b, d; mean + SE). + values indicate that a FA increased in proportion during winter or summer and – values signify a decrease in proportion. Asterisks and dissimilar letters signify statistically significant differences between the means ( $P < 0.05$ )

from cyclooxygenated n-6 PUFA) increase their proportion at the expense of 3-series prostaglandins (derived from cyclooxygenated 20:5n-3) and comparable cascades occur in other eicosanoids; platelet aggregation, vascular tonus and blood pressure can change in an undesirable direction [2]. Therefore fasting or weight cycling may cause adverse health effects.

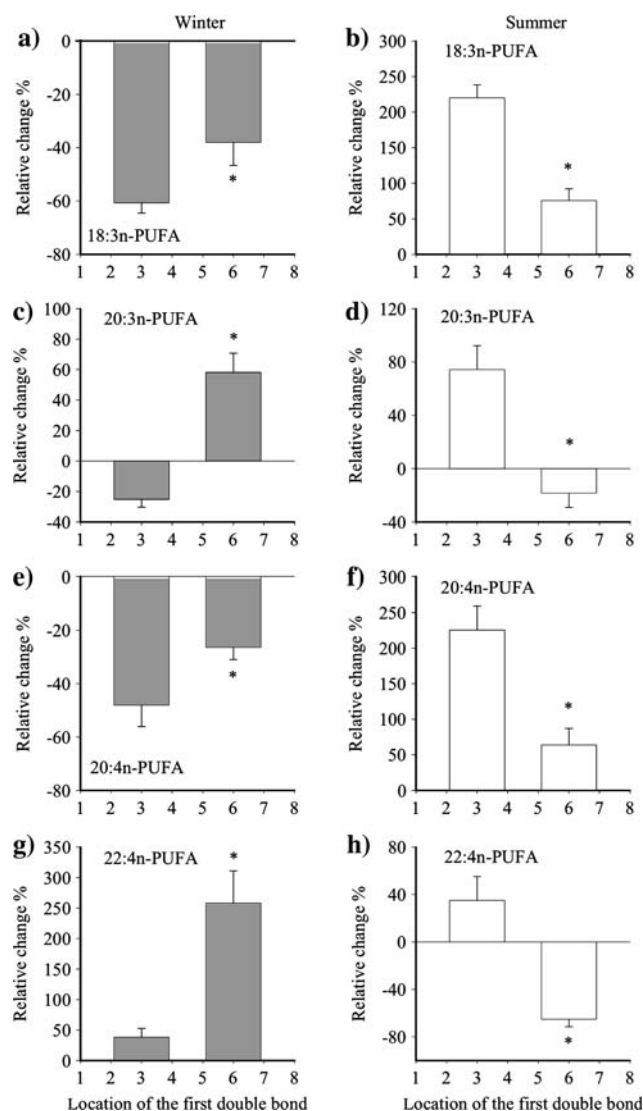

In contrast to the other raccoon dogs of the present study, one female was very active throughout the winter feeding on freshwater fish discarded by local fishermen on the ice in February–March. This individual had increased proportions of 16:1n-5 and particular n-3 and n-6 PUFA in WAT, unlike the other animals. Moreover, it preserved more 20–22C MUFA, 22:5n-3 and particular n-6 PUFA. The different FA composition was presumably caused by the intake of freshwater fish containing, e.g., high proportions of n-3 and n-6 PUFA [39, 40]. While the other raccoon dogs fasted in winter dens and utilized the most readily mobilizable FA, especially n-3 PUFA, this individual was able to restore these FA continuously from dietary sources.

#### Selective Incorporation of FA into the sc Adipose Tissue

The uptake of dietary FA into adipocytes occurs in several steps: (1) absorption, (2) incorporation into chylomicron

TAG, (3) hydrolysis of TAG by adipose tissue lipoprotein lipase (LPL), (4) uptake of FA into adipocytes and their esterification. The steps of FA accumulation have been previously investigated in laboratory animals and humans [36, 41–48] but rarely in seasonal mammals. In the captive alpine marmot (*Marmota marmota*) the FA composition of the sc and gonadal WAT did not change in spite of hibernation and the subsequent refeeding period with fat accumulation [49]. Wild Belding's ground squirrels (*Spermophilus beldingi*), on the other hand, accumulated 16:1n-7 and 18:1n-9 during the fattening period between summer and autumn with a simultaneous decrease in the proportion of 18:3n-3 in the sc and intraabdominal adipose tissues [50].

In contrast to studies on FA mobilization yielding similar results in diverse animal species and time periods of fasting [4, 8, 10, 25], data on FA incorporation into WAT have failed to provide comprehensive principles of FA storage in relation to their structure. It is known that while FA deposition depends on the composition of dietary FA, selectivity will influence the eventual profile of deposited FA in WAT [43, 44, 46–48]. Moreover, the in vivo accumulation of particular n-3 PUFA is inversely related to their in vitro mobilization in the rat [36]. Yet there is a lack of data on the selective accumulation of FA into WAT of wild mammals. The present study had certain advantages over previous work on laboratory rodents and humans: (1)

**Fig. 9** The effect of the location of the first double bond from the methyl end on the relative seasonal change (%) in the proportions of representative white adipose tissue polyunsaturated fatty acids (FA) of the wild raccoon dogs during winter (a, c, e, g) and summer (b, d, f, h; mean + SE). + values indicate that a FA increased in proportion during winter or summer and – values signify a decrease in proportion. Asterisks signify statistically significant differences between the means ( $P < 0.05$ )

it was conducted on free-ranging animals feeding on their natural diet, (2) the period of body fat accumulation lasted for 6–7 months with an 88% increase in the body fat content (BMI), (3) the vernal and autumnal FA profiles were determined from the same individuals and (4) 61 FA could be identified and their accumulation analyzed in relation to the FA structure.

The incorporation of FA into WAT was higher for shorter-chain SFA, n-5 and n-7 MUFA and PUFA in the wild raccoon dog, which may be due to a variety of factors, such as the preferential hydrolysis of shorter FA by LPL

[51, 52]. In contrast, longer FA were incorporated more efficiently than 10:0 and 12:0 in the rat [44]. According to Lin et al. [46], MUFA and PUFA accumulated more efficiently than SFA in the rabbit and the data from the wild raccoon dog support these findings. The incorporation into WAT was higher for several MUFA compared to the corresponding SFA and the accumulation of several PUFA increased with the insertion of an additional double bond. However, previous studies have shown decreased LPL hydrolysis with increased unsaturation [53]. For this reason, there may be also other mechanisms explaining the effect of the double bond number on the accumulation of FA into WAT of the wild raccoon dog.

15–16C MUFA accumulated more readily into WAT of the wild raccoon dogs when their double bond was located closer to the methyl end of the chain. Also particular n-3 PUFA had a higher accumulation efficiency than the corresponding n-6 PUFA. Our results are similar to those of Lin et al. [54] who showed in cattle (*Bos taurus*) that the in vitro incorporation of 18:3n-3 into adipocytes can be higher than that of 18:2n-6. In contrast, n-6 PUFA were stored more efficiently than n-3 PUFA in humans [48] and the deposition index of 18:2n-6 was higher than that of 18:3n-3 in rabbits [46]. According to previous studies [36, 45], n-3 PUFA are incorporated into WAT in the following order: 22:5n-3 > 22:6n-3 > 18:4n-3 > 20:5n-3, opposite to their relative mobilization. The wild raccoon dogs did not follow this rule during the summertime fat accumulation.

It is possible that the short-term storage of n-3 PUFA in WAT could have been weak [48] also in the raccoon dogs. Yet the animals were able to reverse the wintertime losses of the efficiently utilized n-3 PUFA in summer. In contrast, during short-term weight cycling of rats (24-h of fasting + 72-h of ad lib refeeding, four cycles), 18:3n-3 was selectively depleted from adipose tissue despite the adequate supply of this PUFA from the diet [55]. As the raccoon dogs mobilized 20:5n-3 and 18:4n-3 efficiently in winter, the relative increases in their proportions were high during the food abundance in summer. The long time period for fat accumulation could have masked the regulatory mechanisms responsible for the short-term control of fat storage. It is understandable that in a species with a lifespan often exceeding 1 year, the wintertime losses of particular FA have to be replenished in summer in order to return to the same physiological status as in the preceding autumn.

In conclusion, (1) the wild raccoon dog utilized preferentially 18–20C n-3 PUFA, 14–17C MUFA and 12–16C SFA as energy sources during wintertime nutritional scarcity. In summer, the same FA were selectively incorporated into WAT. (2) Mobilization was enhanced by short carbon chain length and unsaturation. In addition, n-3 PUFA were

preferred over n-6 PUFA. The same molecular determinants correlated with the incorporation of FA into WAT reversing the wintertime losses of the efficiently mobilized FA. (3) The molecular background for FA mobilization was the same in nature as observed previously in laboratory experiments, while the control of the long-term FA storage in wild mammals could be different from the short-term regulation of FA incorporation observed in laboratory animals and humans.

Nudibranch mollusks unprotected by a shell and named sea slugs are striking by beauty of their forms and colors and also by wide species diversity and a significant contribution into the ecology of southern seas [5]. The morphology, biology and ecology of the tropical nudibranch species have been purely described in details until now [5, 6]. Knowledge on their biochemistry is scrappy. The chemical ecology of nudibranchs is particularly appealing. Most nudibranchs contain the secondary metabolites that are active in chemical defenses against predators. Bioactive metabolites from opisthobranchs have been shown to possess feeding-deterrent, cytotoxic and ichthyotoxic properties, to have antibacterial, antifungal activity, and to act as sexual pheromones [7, 8]. These compounds exhibit a high variety of chemical structures including diterpene diacylglycerols [9]. Nudibranchs are capable of biosynthesizing the defensive compounds or accumulate them from their dietary sponge. No information is available on the lipid and FA composition of these invertebrates. To the best of our knowledge, only one paper concerning the fatty acid composition of the eggs of four nudibranchs from southwestern Spain exists; high concentration of n-3 PUFA, especially, 20:5n-3 and 22:6n-3 was reported [10].

The present study was carried out to examine lipid classes, phospholipids (PL) and FA compositions of the *Chromodoris* sp. and *Phyllidia coelestis*, representatives of the most common genera of tropical nudibranchs, in order to acquire data for lipid biochemistry of mollusks of the order Nudibranchia: Opisthobranchia: Mollusca that had not been studied earlier.

## Materials and Methods

Two species of nudibranchs, *Chromodoris* sp. and *P. coelestis* (Phylum: Mollusca, Class: Gastropoda, Subclass: Opisthobranchia, Order: Nudibranchia) were collected from the R.V. *Akademik Oparin* by SCUBA divers in the Nha Trang Bay of the South China Sea, Vietnam in January 2005 at 2–5 m depth.

Lipids were extracted according to method of Bligh and Dyer [11]. The total lipid content was determined gravimetrically. Lipid class separation was performed by one-dimensional TLC on silica-gel plates [12]. The primary solvent system was hexane/diethyl ether/acetic acid (80:20:1, by volume), a mobile phase resolving nonpolar compounds. After development, the TLC were dried under air flow. A second polar solvent system chloroform/methanol/acetone/acetic acid/water/benzene (70:30:5:4:1:10, by vol) was also used to partly resolve polar lipids. For this purpose, the TLC were developed on 20% of the plate

length. Lipids were detected on the TLC using 10% H<sub>2</sub>SO<sub>4</sub>/MeOH with subsequent heating to 180 °C. Lipid class concentrations were determined by analyzing a scanned image of the TLC plate using a Sorbfil TLC Videodensitometer DV program (Krasnodar, Russia). Preparative separation of lipid classes was performed by TLC on silica acid using a solvent system resolving nonpolar compounds mentioned above. After development, the zone of the polar lipids (this includes mainly PL) and the zone of neutral lipids (which include mainly TAG, DAGE, LCA and ES) were immediately scraped off and eluted with chloroform/methanol (1:1, by vol).

Polar lipids were separated by two-dimensional silica gel TLC in the solvent systems: chloroform/methanol/28% NH<sub>4</sub>OH/benzene (65:30:6:10, by volume) for the first direction, chloroform /methanol/acetone/acetic acid/water/benzene (70:30:5:4:1:10, by volume) for the second one. Lipids were detected on TLC plates using 10% H<sub>2</sub>SO<sub>4</sub>/MeOH with heating to 180 °C and by specific reagents for PL [13], amino-containing lipids (0.2% ninhydrin in acetone) and choline lipids (Dragendorff's reagent). PL were quantified by the method of Vaskovsky et al. [13].

FAME were prepared according to the method of Carreau and Dubacq [14] and purified by TLC in benzene. *N*-acylpyrrolidides of FA were prepared by heating FAME with 1 mL pyrrolidine and 0.1 mL of acetic acid at 100 °C for 30 min in capped vial followed by extraction with chloroform of the acidified solution and purification by TLC in chloroform/acetone (9:1, by vol) [15]. GC analysis was performed on a Shimadzu GC-17A gas chromatograph (Kyoto, Japan) equipped with a flame ionization detector and SUPELCOWAX 10 (Supelco, Bellefonte, PA, USA) capillary column (25 m × 0.25 mm i.d.), 210 °C and, additionally, SPB-5 (Supelco) capillary column (25 m × 0.25 mm i.d.), 230 °C was used. Helium was the carrier gas. Individual components of FAME were identified by comparing retention time data with those obtained for authentic standards and by using the ECL data, and confirmed by GC-MS of MEFA and their *N*-acylpyrrolidide derivatives. GC-MS analyses of FAME were performed on a Shimadzu GCMS-QP5050A instrument (Kyoto, Japan) fitted with a MDN-5S (Supelco) capillary column (30 m × 0.25 mm i.d.). Samples were injected at an oven temperature 160 °C. After 1 min, the oven temperature was raised at 3 °C min<sup>-1</sup> to 240 °C, which was held for 40 min. Injector and detector temperatures were 250 °C. GC-MS of *N*-acylpyrrolidides was performed on the same GC-mass spectrometer; the column temperature was 210 °C with a 3 °C min<sup>-1</sup> ramp to 270 °C, which was held for 60 min; injector and detector temperatures were 270 °C.

Mass spectral data are as follows:

*7,13-heneicosadienoic acid methyl ester*. MS  $m/z$  (relative intensity, %): 336 ( $M^+$ , 13), 318 (0.1), 305 (3), 287 (3), 276 (0.5), 262 (1), 252 (0.6), 238 (2), 224 (6), 210 (4), 194 (10), 178 (11), 164 (8), 150 (16), 135 (14), 123 (21), 109 (35), 95 (75), 81 (96), 67 (91), 55 (100).

*7,13-heneicosadienoic acid pyrrolidide*. MS  $m/z$  (relative intensity, %): 375 ( $M^+$ , 9.8), 363 (0.3), 346 (1), 332 (1.7), 318 (1), 304 (2), 290 (3.2), 276 (3), 262 (2.5), 250 (2.7), 236 (8), 222 (4.5), 208 (7.4), 194 (6), 180 (13.5), 168 (6.8), 154 (6.7), 140 (6), 126 (53), 113 (100).

## Results

The lipid content of the mollusks studied was high (14.7–19.5 mg g<sup>-1</sup> wet weight). PL was the major lipid class in both species (85.7 and 54.9% of the total lipids, Table 1). ST were also an abundant lipid class and constituted about 13% of the total lipids. FFA were the minor components. NL were distinguished between species with respect to the composition of TAG, DAGE, LCA and ES, which were present only in *P. coelestis*. The content of TAG was higher than that of DAGE (9.6 and 4.6%, respectively). Among PL classes, PC was predominant, accounting for nearly half of the total PL (Tables 2, 3). PE was also a major class. Other PL–PS and CAEP (sum of ceramide aminoethylphosphonate and ceramide methylaminoethylphosphonate)—were detected in almost equal concentrations. The proportions of individual PL classes were similar for both species.

In the case of *P. coelestis*, FA were analyzed separately for NL and PL. FA composition of PL and NL of *P. coelestis* was distinguished with higher concentrations of PUFA, NMID and VLC FA in PL (29.1, 9.5 and 9.4% in

**Table 1** Lipid classes (% of total lipids) of Nudibranchs *Chromodoris* sp. and *Phyllidia coelestis*

Lipid classes	Percentage composition			
	<i>Chromodoris</i> sp.		<i>Phyllidia coelestis</i>	
	Mean	SD	Mean	SD
Polar lipids	85.7 ± 1.5		54.9 ± 2.5	
Sterols	13.0 ± 1.0		12.5 ± 2.3	
Long-chain alcohols	–		10.2 ± 0.7	
Free fatty acids	1.4 ± 0.4		3.3 ± 0.4	
Triacylglycerols	–		9.6 ± 0.6	
Diacylglyceryl ethers	–		4.6 ± 0.4	
Sterol esters	–		5.1 ± 1.0	

Values are mean ± SD,  $n = 3$

**Table 2** Phospholipid composition (% of total PL) of Nudibranchs *Chromodoris* sp. and *Phyllidia coelestis*

Phospholipids	Percentage composition	
	<i>Chromodoris</i> sp.	<i>Phyllidia coelestis</i>
Phosphatidylcholine	45.3 ± 1.6	50.4 ± 2.0
Phosphatidylethanolamine	22.3 ± 2.1	23.4 ± 2.9
Phosphatidylserine	15.6 ± 2.1	12.5 ± 0.6
Ceramide aminoethylphosphonates	16.5 ± 3.5	14.2 ± 0.8

Values are mean ± SD,  $n = 3$

PL versus 11.5, 4.1 and 2.5% in NL). The saturated FA (SFA) was twice higher in NL than in PL (38.8 and 16.9% of the total FA, respectively). The enrichment of NL by 18:1n-9 was observed, whereas in PL the concentration of 7–21:1 was higher.

Considering that acyl-producing lipids of *Chromodoris* sp. consisted only of the PL with exception of minor amounts of FFA, it is more correctly to compare the FA composition of *Chromodoris* sp. with that of in particular PL of *P. coelestis*. The studied species had differences in their FA profiles. The dominant FA (more than 5%) of *Chromodoris* sp. were 17:0, 18:2n-6, 18:1n-7, 20:4n-6, 7–21:1, 22:4n-6 and 5,9–26:2; these seven components accounted for about 50% of the total FA. The main FA of *P. coelestis* were 15:0, 17:0, 18:1n-9, 20:4n-6, 7–21:1 and 22:4n-6, all together 41%.

In the sea slugs, the total SFA accounted, respectively, for 16.0 and 16.9% of the total FA. Among them, the common 16:0 and 18:0 as well as the odd chain 15:0 and 17:0 were found; the input of the last was especially noticeable in *P. coelestis*. The rare branched FA, 6-methyl-14:0, 10-methyl-16:0, 11-methyl-18:0 and *iso*-21:1n-5, were identified in *P. coelestis* lipids. The MUFA content was high in both species: 26.0 and 24.2% of the total FA, among them isomers of 18:1, 20:1 and 21:1 were the main. FA 7–21:1 was identified by MS–GC. A molecular ion peak  $m/z$  338 and major ion at  $m/z$  306 was obtained from the MS of MEFA indicating the presence of 21:1. A molecular ion peak of pyrrolidine derivative appeared at  $m/z$  377. Double bond at C7 was recognized from irregular interval of  $m/z$  12 between C6  $m/z$  168 and C7  $m/z$  180. These fragments offer further corroborating evidence for the structure of 7–21:1. The sea slugs contained a considerable content of this FA (about 6% of the total FA).

Both species had various NMID FA with C20, C21 and C22 chain (in sum 12.0 and 9.5% of the total FA). The most important NMI FA characteristic of the sea slugs were 5,11–20:2 and 5,13–20:2; as well as 7,13–22:2 and 7,15–22:2 and the novel FA 7,13–21:2. FA, which was tentatively identified according to retention time and ECL

Values are mean ± SD, n = 3. “Bacterial” refers to sum of odd and branched FA

Other FA identified include *iso*-13:0, 17:1n-6, 17:2, *iso*-18:0, 18:3n-6, 18:3n-3, 18:4n-3, *iso*-19:0, *anteiso*-19:0, 19:2, 20:0, 20:1n-9, 20:3n-6, 22:5n-6, 5,9–23:2, 24:4n-6, *iso*-25:0 and *iso*-26:0, which were present in trace amounts (<0.2%)

value as 21:2, reached 3.9% of the total FA in PL of *P. coelestis*. MS of the methyl ester of this FA gave a molecular ion at  $m/z$  336, indicating the presence of two double bonds in C21 FA. Neither a peak of  $m/z$  108, which is characteristic for the MS of n-3 PUFA nor a peak  $m/z$  150 characteristic for n-6 PUFA were present. Double bonds were located by GC–MS of pyrrolidine derivatives of FAME (Fig. 1). A molecular ion peak  $m/z$  375 was present. The presence of irregular interval of  $m/z$  12 between the most intensive peaks  $m/z$  168 and 180 and between  $m/z$  250 and 262 indicated the positions of double bonds at C7 and C13, respectively.

PUFA were presented mainly by 18:2n-6, 20:4n-6 and the most important 22:4n-6, which was 10.0–9.5% of the total FA. The common marine FA, 20:5n-3 and 22:6n-3, were minor components (0.6–0.8 and 1.0–1.5%, respectively).

Numerous VLC FA with straight and branched chain (*iso*-), saturated and dienes with  $\Delta$ 5,9 group were identified in both species (12.0 and 9.4% of the total FA). The major VLC FA were identified based on the MS. The molecular ions at  $m/z$  364, 378, 392 and 406 corresponded to the molecular weight of FAME of 23:2, 24:2, 25:2 and 26:2. Their MS of pyrrolidides had a diagnostic ion at  $m/z$  180 that is typical when two double bonds are located at the 5 and 9 positions. Hence, these proved that 5,9–23:2, 5,9–24:2; 5,9–25:2 and 5,9–26:2 were present. Additionally, the molecular ion of the pyrrolidine derivatives at  $m/z$  431 was consistent with 25:2 although the GC retention times were appreciably less than that of corresponding straight chain isomers. The gap of 28 amu between  $m/z$  388 and 416 was indicative of an *iso*-methyl branch, while the abundant ion

**Fig. 1** Mass spectra of the pyrrolidide derivatives of 7,13–21:2

at  $m/z$  180 is a characteristic marker for double bonds in the positions  $\Delta 5,9$ . Consequently, 5,9–25:2-*iso* was identified.

## Discussion

Although lipids and fatty acids of marine mollusks from different taxons have been extensively studied, it is the first report on the analysis for lipid composition of nudibranchs.

Our lipid analysis indicated that the nudibranchs comprised mainly PL, which are known to be major constituents of cell membranes. ST, another structural lipid, was also abundant. The concentrations of FFA reported here 1.4 and 3.3% of the total lipids is in agreement with results reported for other marine invertebrates [16, 17] and seemed unlikely to be due to enzymatic hydrolysis of the lipids. The proportion of the lipid classes varied according to the species mainly due to high values of NL in *P. coelestis*. In contrast to *Chromodoris* sp, lipids of *P. coelestis* comprised high concentrations of TAG, DAGE, LCA, and ES. This may be attributed to the differences in diet and biochemistry of the species, because lipids stored in the animals are likely to be of dietary origin. The level of the neutral storage lipids are known to be species specific and depends on mainly a life history strategy and food availability. For example, amounts of TAG are highly variable between different species of *Cnidaria* and *Ctenophora* [16]; its level in the sea butterfly *Limacina helicina* varies throughout the stages of the spawning cycle and seasons [17]. DAGE, which is also used as an energy store, have been previously mentioned for all classes of mollusks [4] and, indeed, some other marine invertebrates. Extraordinary large amounts (up to 40% of the total lipids) were reported for the pteropod *Clione limacine* [18]. PL were constituted of PC, PE, PS and CAEP. A similar distribution is reported for mollusks [4, 19]. Our PL data for nudibranchs are in a good agreement with the results published earlier. A high

concentration of CAEP was noticeable. Phosphonolipids are widely distributed in the phylum Mollusca and, in some cases, comprise the major PL class [4]. Phosphatidylinositol and diphosphatidylglycerol, the usual minor components of marine invertebrates [20], were not found in the species studied. Both species were similar in their PL distribution. The absence of a species-specific pattern in PL classes was suggested as an evidence for the similarity of the nature of biological membranes.

The species studied exhibited a wide diversity of FA, including common SFA, MUFA and PUFA, as well as NMID FA described firstly in mollusks [2, 21], and VLC FA specific for sponges [22, 23]. The FA profiles of the sea slugs distinguished in most respects from those described earlier for other gastropods and mollusks [4, 24].

Distribution of FA among PL and NL in *P. coelestis* reveal the known pattern, namely, NL were rich in SFA. Though the amount of MUFA was similar in the lipids, they differ in isomer ratio. Isomers of 16:1 and 18:1 were more abundant in NL whereas 20:1 isomers were prevalent in PL. It apparently indicates the structural role of the 20:1 along with NMID, PUFA and VLC FA which prevailed in PL in comparison with NL of *P. coelestis*. The acid 20:1(n-11) together with NMID were found to associate with aminophospholipid plasmalogens (PE and PS) in bivalve mollusks [20].

The FA composition of marine mollusks is considered to be characterized by predominance of n-3 PUFA, 20:5n-3 and 22:6n-3 [4, 24] which constitute usually near a half of total FA. In contrast, the sea slugs did not exhibit this specific feature; these two marine PUFA were minor components and in sum constituted 1.6 and 2.1% of the total FA. In the studied species, n-6 PUFA were dominant (26.0 and 25.3% of the total FA); their amounts were an order of magnitude higher than the concentration of n-3 PUFA. The content of the components decreased in the line of 22:4n-6, 20:4n-6 and 18:2n-6. High values of n-6 relative to n-3 PUFA are unusual in marine organisms. An

elevated level of 20:4n-6 was also found in two snails, *Littorina littorea* and *Lunatia triseriata*, (up to 8% of the total FA), but it was lower than that of 20:5n-3 [2, 21]. A prevalence of n-6 PUFA over n-3 was found in the asteroids [25] and in the PL of gorgonian corals [26], but the amounts of n-3 PUFA were also abundant.

The various NMI FA were found, their content reached 12.0% in *Chromodoris* sp. and 9.5% in PL of *P. coelestis*. Among them, 20:2 and 22:2 NMI FA, first found in the oyster *Crassostrea virginica* [2] and the clam *Arctica islandica* [3], were present also in the sea slugs. Their structures as shown by MS–GL analysis, were identical to those previously isolated from lipids of *C. virginica* and characterized as 5,11–20:2 and 5,13–20:2, as well as 7,13–22:2 and 7,15–22:2 [20]. Of particular interest was the finding of a novel NMI FA identified as 7,13–21:2. It amounted to 3.9% of the total FA in PL of *P. coelestis* and 1.5% in *Chromodoris* sp. This unusual NMI FA might be biosynthesized by the sea slugs rather than be of dietary origin, similar to that shown for 22:2 NMI in bivalves [27, 28]. The bivalve mollusks are able to synthesize the NMI FA 7,13–22:2 and 7,15–22:2 by a  $\Delta 5$  desaturation of corresponding precursors, 11–20:1 and 13–20:1, respectively, and a further elongation reaction [27]. Although isomer 7–21:1 was the main one (up to 6.2%) in the sea slugs, it is improbable that it might be the precursor of 7,13–21:2. An alternative pathway of this odd NMI FA production may be similar to that of NMI FA in bivalve mollusks. Probably, biosynthesis of 7,13–21:2 can occur via a  $\Delta 5$  desaturase acting upon the appropriate precursor 11–19:1 and further chain elongation of 5,11–19:2. It is possible that 11–19:1 might be derived from the diets of the sea slugs or arises from the chain elongation of 9–17:1. The potential precursors 9–17:1 and 11–19:1 were abundant in the sea slugs and, apparently, are of bacterial origin. FA 19:2 was also identified in both species at least in trace amounts. Unfortunately, too small quantity of 19:2 did not allow to establishing the position of double bonds in the isomer. Thus, biosynthesis of 7,13–21:2 in the nudibranchs entirely probable occurs in the following way: 9–17:1  $\rightarrow$  11–19:1– $\Delta 5$  desaturase  $\rightarrow$  5,11–19:2  $\rightarrow$  7,13–21:2.

The biological role and function of NMI FA are not clear. However, they were found in high concentrations in PL of the mollusks, and their amounts were in a reverse relation to common n-3 PUFA, 20:5n-3 and 22:6n-3 and therefore they are proposed as being important for membrane structure and function [20, 29].

The FA profile of *Chromodoris* sp. and *P. coelestis* differed from those for other gastropods and, indeed, for other mollusks by the presence of significant amounts of VLC FA specific of sponges [22, 23]. Distribution of the demospongiac FA was different for the species studied. VLC FA with double bonds at  $\Delta 5,9$ , among them 5,9–24:2,

5,9–25:2 and 5,9–26:2 and *iso*-5,9–25:2 were found in high concentrations; additionally, 5,9–23:2 and branched: *iso*-5,9–26:2, *iso*-25:0 and *iso*-26:0 were identified in *P. coelestis* in trace amounts. Their amounts were higher in PL in comparison with TAG, 9.4 and 2.5%, respectively, in *P. coelestis*. FA with  $\Delta 5,9$  pattern are typical for many sponges [22, 23]. Nudibranchs are carnivorous and majority of species are specialized feeders on sponges [5]. Utilization of this food source seems to be responsible for a high level of the VLC FA found in the nudibranchs.

Another unique feature of the FA composition of these two sea slugs concerned a high abundance (15.7 and 34.4% of the total FA) of the odd-chain and branched FA, predominantly *iso*- and *anteiso*-usually named bacterial FA. The dominant odd-chain FA were 15:0 and 17:0, which enriched especially in NL of *P. coelestis* (11.5 and 9.2% of the total). They are normal also as minor metabolites in most animals and can be derived from amino acid precursors which are freely available in marine mollusks. The presence of a high abundance of bacterial FA, especially in NL of *P. coelestis* (up to 41.7% of the total FA), is intriguing. It is obvious that different odd and branched FA were detected in many species of sponges [22, 23] which are a commonly part of nudibranchs diet. Therefore, the bacteria associated with sponges seem to be one of the suppliers of these FA for sea slugs. However, the contribution of these FA was so high that it seems unlikely that bacteria from the sponges are their only source in the sea slugs. The elevated levels of bacterial FA have been reported for some benthic invertebrates, for example, in tunicate [30] and asteroids [25]. The occurrence of odd-chain FA dominated by 17:1n-8 and 15:0, in exceptional amounts (up to 18 and 8.3%, respectively) have been found in the pteropode *Clione limacine* and assumed that 17:1n-8 could be synthesized via propionate de novo [18]. It is uncertain that the sea slugs can synthesize odd chain FA since the precursors of these compounds are accumulated from phytoplankton [18]. More probable they are of a dietary origin. It may suggest that odd-chain and branched FA may have come from bacteria in the food chain or from bacteria living in symbiosis with the sea slugs. More research has to be done to answer this question. The occurrence of odd and branched FA in PL in high level (15.7 and 21.6%) implies a possible structural requirement for them. In conclusion, the lipid and FA composition of the nudibranchs is determined by taxonomic relationships of the species, food supply and internal biosynthetic activities.
